In the above the last equality follows from Constraint (4). Unfixing the conditioning on $\pi$ by using the law of total probability concludes the proof. ◀

Our goal is to write an expression for the probability that an edge crosses between two different parts in the partition that Algorithm 1 outputs. Given a fixed pair of vertices $u, v \in V$ and $i = 1, 2, 3$, we denote by $t_i$ the inner product between $\mathbf{z}_u^i$ and $\mathbf{z}_v^i$. One should note that Constraint 3 in SDP 1 implies:

$$t_i = \frac{(\mathbf{y}_u^i - x_i \cdot \mathbf{y}_\emptyset) \cdot (\mathbf{y}_v^i - w_i \cdot \mathbf{y}_\emptyset)}{\sqrt{(x_i - x_i^2) \cdot (w_i - w_i^2)}} = \frac{\alpha_i - x_i w_i}{\sqrt{(x_i - x_i^2) \cdot (w_i - w_i^2)}}, \tag{9}$$

where $x_i \triangleq \|\mathbf{y}_u^i\|^2$ and $w_i \triangleq \|\mathbf{y}_v^i\|^2$ are the marginal values the SDP assigns to vertices $u$ and $v$, respectively, with respect to the $i^{\text{th}}$ cluster, and $\alpha_i \triangleq \mathbf{y}_u^i \cdot \mathbf{y}_v^i$ is the correlation the SDP assigns for both $u$ and $v$ being assigned to the $i^{\text{th}}$ cluster. The following lemma gives the desired expression. We require the following claim for its proof:

▷ Claim 10. Let $(X, Y)$ be a standard bi-variate Gaussian with correlation $t$. Then for every $q_1, q_2 \in [0, 1]$, we have $\Pr[X \geq \Phi^{-1}(1 - q_1), Y \geq \Phi^{-1}(1 - q_2)] = \Gamma_t(q_1, q_2)$.

▶ **Lemma 11.** *For every $u, v \in V$, let $\mathcal{A}_{u,v}$ be the event that Algorithm 1 separates $u$ and $v$:*

$$\Pr\left[\mathcal{A}_{u,v}\right] = 1 - \frac{1}{6} \sum_{\pi \in \mathcal{S}_3} \left[ \Gamma_{t_{\pi(1)}}\left(x_{\pi(1)}, w_{\pi(1)}\right) + \Gamma_{t_{\pi(1)}}\left(1 - x_{\pi(1)}, 1 - w_{\pi(1)}\right) \cdot \right.$$
$$\left. \cdot \left( \Gamma_{t_{\pi(2)}}\left(1 - \frac{x_{\pi(2)}}{1 - x_{\pi(1)}}, 1 - \frac{w_{\pi(2)}}{1 - w_{\pi(1)}}\right) + \Gamma_{t_{\pi(2)}}\left(\frac{x_{\pi(2)}}{1 - x_{\pi(1)}}, \frac{w_{\pi(2)}}{1 - w_{\pi(1)}}\right) \right) \right].$$

The proof of Lemma 11 appears in the full version of the paper.

Our goal now is to lower bound the expected value of the output of Algorithm 1, before it is re-balanced (with a negligible loss) to ensure the size of each cluster is exactly $n/3$. As our analysis is performed edge-by-edge, i.e., for every edge we lower bound the ratio of the probability Algorithm 1 separates the edge to the contribution of this edge to the objective of SDP (1), we introduce the notions of a configuration and a feasible configuration.

A *configuration* is a vector $\mathbf{c} = (x_1, x_2, x_3, w_1, w_2, w_3, \alpha_1, \alpha_2, \alpha_3, t_1, t_2, t_3) \in \mathbb{R}^{12}$, such that for every $i = 1, 2, 3$: $x_i, w_i, \alpha_i \in [0, 1]$ and $t_i \in [-1, 1]$. We say that a configuration $\mathbf{c}$ is a *feasible configuration* if it can be realized by vectors in a feasible solution to SDP (as the following definition states).

▶ **Definition 12.** *A configuration $\mathbf{c} = (x_1, x_2, x_3, w_1, w_2, w_3, \alpha_1, \alpha_2, \alpha_3, t_1, t_2, t_3) \in [0, 1]^9 \times [-1, 1]^3$ is called a* feasible configuration *if there are vectors $\mathbf{y}_u^1$, $\mathbf{y}_u^2$, $\mathbf{y}_u^3$, $\mathbf{y}_v^1$, $\mathbf{y}_v^2$, $\mathbf{y}_v^3$ and $\mathbf{y}_\emptyset$ satisfying:*

1. *The vectors $\mathbf{y}_u^1$, $\mathbf{y}_u^2$, $\mathbf{y}_u^3$, $\mathbf{y}_v^1$, $\mathbf{y}_v^2$, $\mathbf{y}_v^3$ and $\mathbf{y}_\emptyset$ satisfy Constraints (2) to (6) in* SDP.
2. *$x_i = \|\mathbf{y}_u^i\|^2$, $w_i = \|\mathbf{y}_v^i\|^2$ and $\alpha_i = \mathbf{y}_u^i \cdot \mathbf{y}_v^i$, $\forall i = 1, 2, 3$.*
3. *$t_i = (\alpha_i - x_i w_i)/((x_i - x_i^2)(w_i - w_i^2))^{1/2}$, $\forall i = 1, 2, 3$.*

*The vectors $\mathbf{y}_u^1$, $\mathbf{y}_u^2$, $\mathbf{y}_u^3$, $\mathbf{y}_v^1$, $\mathbf{y}_v^2$, $\mathbf{y}_v^3$ and $\mathbf{y}_\emptyset$ are called a* realization *of $\mathbf{c}$. The set of all feasible configuration is denoted by $\mathcal{C}$.*

We note that there is some redundancy in the above definition. First, we can reduce the dimension of the configuration by two simply by substituting $x_3$ with $1-x_1-x_2$ and $w_3$ with $1-w_1-w_2$. Second, we can remove $t_1$, $t_2$ and $t_3$ (or $\alpha_1$, $\alpha_2$ and $\alpha_3$) since each $t_i$ (or $\alpha_i$) can be derived from all the parameters excluding $t_1$, $t_2$, and $t_3$ (or excluding $\alpha_1$, $\alpha_2$, and $\alpha_3$). In Lemma 21, we give a characterization of $\mathcal{C}$ after projecting out $t_1, t_2, t_3$. This description consists of linear constraints and we utilize the description for our computer-assisted proof. For simplicity of the analysis, we will keep all the parameters.

Let us now define two functions over $\mathcal{C}$. The first function $f$, given a feasible configuration $\mathbf{c} \in \mathcal{C}$, returns the probability that Algorithm 1 cuts an edge whose associated vectors are a realization of $\mathbf{c}$. Formally, following Lemma 11:

$$f(\mathbf{c}) \triangleq 1 - \frac{1}{6}\sum_{\pi\in\mathcal{S}_3}\left[\Gamma_{t_{\pi(1)}}\left(x_{\pi(1)}, w_{\pi(1)}\right) + \Gamma_{t_{\pi(1)}}\left(1-x_{\pi(1)}, 1-w_{\pi(1)}\right)\cdot \right.$$
$$\left.\cdot\left(\Gamma_{t_{\pi(2)}}\left(1-\frac{x_{\pi(2)}}{1-x_{\pi(1)}}, 1-\frac{w_{\pi(2)}}{1-w_{\pi(1)}}\right) + \Gamma_{t_{\pi(2)}}\left(\frac{x_{\pi(2)}}{1-x_{\pi(1)}}, \frac{w_{\pi(2)}}{1-w_{\pi(1)}}\right)\right)\right].$$

The second function $g$, given a feasible configuration $\mathbf{c} \in \mathcal{C}$, returns the contribution to the objective of SDP of an edge whose associated vectors are a realization of $\mathbf{c}$. Formally, following (1):

$$g(\mathbf{c}) \triangleq 1 - \alpha_1 - \alpha_2 - \alpha_3.$$

It is important to note that both $f$ and $g$ can be evaluated for every configuration $\mathbf{c} \in [0,1]^9 \times [-1,1]^3$ which might not be necessarily feasible. However, for such a (non feasible) configuration $\mathbf{c}$, $f(\mathbf{c})$ and $g(\mathbf{c})$ lose their "meaning".

To lower bound the value of the solution $\{C_1, C_2, C_3\}$ Algorithm 1 outputs, we introduce the following:

$$\mu \triangleq \inf_{\mathbf{c}\in\mathcal{C}}\left\{\frac{f(\mathbf{c})}{g(\mathbf{c})}\right\}. \tag{10}$$

Clearly, from the above definition of $\mu$, the value of the output $\{C_1, C_2, C_3\}$ of Algorithm 1 is at least: $\mu \cdot \mathrm{OPT}_{\mathrm{SDP}} \geq \mu \cdot \mathrm{OPT}$ (where the inequality follows from Lemma 5 which states that SDP is a relaxation). Hence, if the output $\{C_1, C_2, C_3\}$ of Algorithm 1 was perfectly balanced, i.e., $|C_1| = |C_2| = |C_3| = n/3$, Algorithm 1 would achieve an approximation of $\mu$ to the Max-3-Section problem. In what follows we show that one can re-balance $\{C_1, C_2, C_3\}$ without a significant loss in the value of the solution. Thus, our goal is to lower bound $\mu$. For now, as formally proving the exact value of $\mu$ is a challenging task, we state the following conjecture that follows from numeric estimation of $\mu$.

▶ **Conjecture 13.** $\mu \geq 0.8192$.

Assuming the above conjecture regarding $\mu$ (Conjecture 13), there are two things that are left in order to conclude the analysis of our algorithm. First, we show that if the solution $Y$ to SDP is independent (as in Definition 7 and Lemma 8 ) then with a sufficiently high probability every cluster $C_i$ is close to the desired size of $n/3$. This gives rise to the following Definition 14 and Lemma 15. Second, we show that a solution $\{C_1, C_2, C_3\}$ that is close to being perfectly balanced can be efficiently re-balanced without a significant loss in its value. The latter is summarized in Lemma 16.

▶ **Definition 14.** *A partition* $\{C_1, C_2, C_3\}$ *of a graph on* $n$ *nodes is* $\varepsilon$-unbalanced *if for every* $i = 1, 2, 3$*:*

$$\frac{n}{3}(1-\varepsilon) \leq |C_i| \leq \frac{n}{3}(1+\varepsilon).$$

▶ **Lemma 15.** *Let* $Y$ *be a* $\frac{1}{t}$*-independent solution to* SDP *where* $t = \Omega(\varepsilon^{-18})$*, and* $\{C_1, C_2, C_3\}$ *be the partition that Algorithm 1 outputs on* $Y$*. Then for every* $i = 1, 2, 3$ *it holds that:*

$$Pr\left[||C_i| - n/3| \geq \frac{\varepsilon n}{3}\right] \leq \varepsilon.$$

Next, we show that such unbalanced partition can be balanced without a large loss in the objective. That is, we present an algorithm that given a $\epsilon$-unbalanced partition, finds in polynomial time a balanced partition with small loss in the objective, in expectation.

▶ **Lemma 16.** *There is a polynomial-time algorithm that given a* $\epsilon$*-unbalanced partition* $\{C_1, C_2, C_3\}$ *with value* $\Delta = |\delta(C_1, C_2)| + |\delta(C_2, C_3)| + |\delta(C_1, C_3)|$ *finds a balanced partition* $\{C_1', C_2', C_3'\}$ *with expected value* $\mathbb{E}[\Delta'] \geq (1 - 2\epsilon)\Delta$*.*

The proofs of Lemma 15 and Lemma 16 appear in the full version of the paper. We combine these lemmas and prove the following result.

▶ **Theorem 17.** *For every constant* $\varepsilon > 0$*, there exists a polynomial-time approximation algorithm for* Max-3-Section*, that runs in time* $n^{O(poly(\varepsilon^{-1}))}$*, achieving an approximation of* $(1 - 2\epsilon)(\mu - O(\varepsilon))$*.*

**Proof.** Let $\varepsilon > 0$ be a constant, and $t$ an integer satisfying $t = \Omega(\varepsilon^{-18})$. Lemma 8 shows that we can compute in polynomial time a solution $Y$ to SDP that is $\frac{1}{t}$-independent with only an additive loss of $1/t$ in the objective. We repeatedly apply Algorithm 1 to round the above $Y$ until we obtain a solution $\{C_1, C_2, C_3\}$ that is $\varepsilon$-unbalanced, and then apply Lemma 16 to re-balance it an obtain our final output.

Let us now analyze the approximation guarantee of the above algorithm. First, It follows form Lemma 15 and a simple union bound over the three clusters that with a probability of at least $1 - 3\varepsilon$, applying Algorithm 1 to round the above solution $Y$ yields a clustering $\{C_1, C_2, C_3\}$ that is $\varepsilon$-unbalanced (as in Definition 14). Let us denote by $\mathcal{A}$ the event that $\{C_1, C_2, C_3\}$ is $\varepsilon$-unbalanced. Hence, $\Pr[\mathcal{A}] \geq 1 - 3\varepsilon$ and $\Pr[\bar{\mathcal{A}}] \leq 3\varepsilon$. Moreover, as before, let us denote by $\Delta$ the value of the solution $\{C_1, C_2, C_3\}$. Thus, the expected value of this solution *conditioned* on it being $\varepsilon$-unbalanced is at least:

$$\mathbb{E}[\Delta|\mathcal{A}] = \frac{\mathbb{E}[\Delta] - \Pr[\bar{\mathcal{A}}] \cdot \mathbb{E}[\Delta|\bar{\mathcal{A}}]}{\Pr[\mathcal{A}]} \geq \mu \cdot \mathrm{OPT}_{\mathrm{SDP-H}} - \frac{9\varepsilon}{2}\mathrm{OPT}.$$

The inequality follows from the facts that: (1) $\mathbb{E}[\Delta|\bar{\mathcal{A}}] \leq (3/2) \cdot \mathrm{OPT}$ (since $\Delta \leq m$ and $\mathrm{OPT} \geq (2/3)m$); (2) $\mathbb{E}[\Delta] \geq \mu \cdot \mathrm{OPT}_{\mathrm{SDP-H}}$ (definition of $\mu$ (10)); and (3) $\Pr[\mathcal{A}] \leq 1, \Pr[\bar{\mathcal{A}}] \leq 3\varepsilon$. We note that $\mathrm{OPT}_{\mathrm{SDP-H}} \geq \mathrm{OPT}_{\mathrm{SDP}} - \varepsilon^{18} \geq \mathrm{OPT} - \varepsilon^{18}$. Hence,

$$\mathbb{E}[\Delta|\mathcal{A}] \geq \mathrm{OPT}(\mu - O(\varepsilon)).$$

Applying Lemma 16 concludes the proof. ◀

Moreover, in Observation 34 in the full version of the paper we present a configuration $\mathbf{c}$ that has a ratio of $\frac{f(\mathbf{c})}{g(\mathbf{c})} = 0.8192$, hence that is an upper bound on $\mu$.

## 4.1 Towards Estimating $\mu$ via a Computer Assisted Proof

For our computer assisted proof, we consider a slightly different version of $\mu$ which speeds up our code. Consider the following, for some fixed $\delta' > 0$:

$$\mu' \triangleq \inf_{\mathbf{c}\in\mathcal{C}, g(\mathbf{c})\geq\delta'} \left\{ \frac{f(\mathbf{c})}{g(\mathbf{c})} \right\}. \tag{11}$$

The following lemma shows the loss we incur when using $\mu'$ rather than $\mu$ is bounded.

▶ **Lemma 18.** *Let $\{C_1, C_2, C_3\}$ be the output of Algorithm 1 when run on a solution $Y$ to* SDP *1 with objective value* $\text{SDP}_{\text{VAL}}$. *Then we have that*

$$\mathbb{E}[|\delta(C_1, C_2)| + |\delta(C_1, C_3)| + |\delta(C_2, C_3)|] \geq \left(1 - \frac{\delta'}{2(1-\delta')}\right) \mu' \cdot \text{SDP}_{\text{VAL}}.$$

The following theorem summarizes the approximation guarantee when $\mu'$ is used instead of $\mu$.

▶ **Theorem 19.** *For any constant $\varepsilon > 0$, there is an algorithm that outputs a partition of the vertex set $\{C_1, C_2, C_3\}$ with $|C_1| = |C_2| = |C_3|$ satisfying,*

$$\mathbb{E}[|\delta(C_1, C_2)| + |\delta(C_1, C_3)| + |\delta(C_2, C_3)|] \geq (1-2\epsilon)\left(1 - \frac{\delta'}{2(1-\delta')}\right) \mu'(\text{OPT}_{\text{SDP}} - O(\epsilon^{3/2}))$$

*with an expected run-time of $n^{O(1/\varepsilon)}$.*

**Proof.** First we use Lemma 8 to get a $\frac{1}{t}$-independent solution $Y$ for $t = \Omega(\epsilon^{-18})$. Let $\text{OPT}_{\text{SDP}-\text{H}}$ denote the objective value of this solution. Next we run Algorithm 1 on $Y$ and repeat until it outputs sets $C_1', C_2', C_3'$ that are $\epsilon$-unbalanced. We note that by Lemma 15 $(C_1', C_2', C_3')$ is *not* $\epsilon$-unbalanced with probability at most $3\epsilon$, so we run Algorithm 1 at most $1/3\epsilon$ times in expectation. Since $C_1', C_2', C_3'$ are $\epsilon$-unbalanced, applying the random shifting of Lemma 16 to $C_1', C_2', C_3'$ we get $C_1, C_2, C_3$ satisfying

$$\mathbb{E}[|\delta(C_1, C_2)| + |\delta(C_1, C_3)| + |\delta(C_2, C_3)|] \geq (1-2\epsilon)\mathbb{E}[|\delta(C_1', C_2')| + |\delta(C_1', C_3')| + |\delta(C_2', C_3')|],$$

From Lemma 18 we have,

$$\mathbb{E}[|\delta(C_1, C_2)| + |\delta(C_1, C_3)| + |\delta(C_2, C_3)|] \geq (1-2\epsilon)\left(1 - \frac{\delta'}{2(1-\delta')}\right) \mu' \text{OPT}_{\text{SDP}-\text{H}}.$$

Then applying second item of Lemma 8 gives us that $\text{OPT}_{\text{SDP}-\text{H}} \geq \text{OPT}_{\text{SDP}} - O(\epsilon^{3/2})$ since we set $t = \Omega(\epsilon^{-18})$. ◀

# 5 Computer Assisted Proof

The goal of this section is to lower bound $\mu'$. We use a branch and bound procedure to lower $\mu'$ and which gives a guarantee for the approximation factor of our algorithm (Theorem 19) . We recall the definition of $\mu'$

$$\mu' \triangleq \inf_{\mathbf{c}\in\mathcal{C}, g(\mathbf{c})\geq\delta'} \left\{ \frac{f(\mathbf{c})}{g(\mathbf{c})} \right\}. \tag{12}$$

The following claim gives a simple, yet useful, bound on the probability that our rounding algorithm will separate two vertices in the graph.

▷ Claim 20. Let $u, v \in V$, let $x_i = \|\mathbf{y}_u^i\|^2$ and $w_i = \|\mathbf{y}_v^i\|^2$ for $i = 1, 2, 3$ and $\mathbf{c}$ be a configuration corresponding to this pair. Then it holds that

$$f(\mathbf{c}) \geq \frac{|x_1 - w_1| + |x_2 - w_2| + |x_3 - w_3|}{2}.$$

We characterize the configuration space $\mathcal{C}$ which we will consider in the computer assisted proof.

▶ **Lemma 21.** *Let* $\mathbf{c} = (x_1, x_2, x_3, w_1, w_2, w_3, \alpha_1, \alpha_2, \alpha_3, t_1, t_2, t_3) \in \mathcal{C}$. *Then* $\mathbf{c}$ *satisfies the following:*

1. $x_1 + x_2 + x_3 = w_1 + w_2 + w_3 = 1$.
2. $0 \leq \alpha_i \leq \min\{x_i, w_i\}$ *for all* $i = 1, 2, 3$.
3. $\max\{0, x_3 - \alpha_3 + \alpha_1 - w_1, w_2 - \alpha_2 + \alpha_1 - x_1\} \leq \min\{w_2 - \alpha_2, x_3 - \alpha_3, x_2 + x_3 - w_1 + \alpha_1 - \alpha_2 - \alpha_3\}$.
4. $t_i = \frac{\alpha_i - x_i w_i}{\sqrt{(x_i - x_i^2)(w_i - w_i^2)}}$ *for* $i \in [3]$.

We define the following two polytopes which we will consider when verifying bounding $\mu'$. These polytopes help us to speed up the branch and bound procedure.

1. $\mathcal{S} \triangleq \{(x_1, x_2, x_3, w_1, w_2, w_3, \alpha_1, \alpha_2, \alpha_3, t_1, t_2, t_3) | x_1 \leq \min(x_2, w_1, w_2, w_3, x_3), x_2 \leq x_3\}$.
2. $\mathcal{E} \triangleq \{\mathbf{c} = (x_1, x_2, x_3, w_1, w_2, w_3, \alpha_1, \alpha_2, \alpha_3, t_1, t_2, t_3)\}$ such that

$$\sum_{i=1}^{3} \frac{|x_i - w_i|}{2} \leq \rho g(\mathbf{c}), g(\mathbf{c}) \geq \delta'\}.$$

The following claim shows why we can restrict to configurations in $\mathcal{S}$ and follows from the symmetry of $f, g$.

▷ Claim 22. Let $\mathbf{c} \in \mathcal{C} - \mathcal{S}$. Then there exists $\mathbf{c}' \in \mathcal{C} \cap \mathcal{S}$ such that $f(\mathbf{c}) = f(\mathbf{c}')$ and $g(\mathbf{c}) = g(\mathbf{c}')$.

Then Claim 22 and Claim 20 imply the following.

▷ Claim 23. If $\inf_{\mathbf{c} \in \mathcal{C} \cap \mathcal{S} \cap \mathcal{E}} \frac{f(\mathbf{c})}{g(\mathbf{c})} \geq \rho$ then $\mu' \geq \rho$.

Proof. By Claim 22 we get the following: $\mu' = \inf_{\mathbf{c} \in \mathcal{C}, g(\mathbf{c}) \geq \delta'} \frac{f(\mathbf{c})}{g(\mathbf{c})} = \inf_{\mathbf{c} \in \mathcal{C} \cap \mathcal{S}, g(\mathbf{c}) \geq \delta'} \frac{f(\mathbf{c})}{g(\mathbf{c})}$. Assume for contradiction that $\mu' = \min_{\mathbf{c} \in \mathcal{C} \cap \mathcal{S}, g(\mathbf{c}) \geq \delta'} \frac{f(\mathbf{c})}{g(\mathbf{c})} < \rho$. Then $\exists \mathbf{c}' \in \mathcal{C} \cap \mathcal{S}$ with $g(\mathbf{c}') \geq \delta'$ and $\frac{f(\mathbf{c}')}{g(\mathbf{c}')} < \rho$. We have that $\mathbf{c}' \notin \mathcal{E}$ otherwise $g(\mathbf{c}') \geq \rho$ by the assumption of the lemma. Then by definition of $\mathcal{E}$, $\sum_{i=1}^{3} \frac{|x_i - w_i|}{2} > \rho g(\mathbf{c}')$, but this is a contradiction by Claim 20 since $f(\mathbf{c}') > \sum_{i=1}^{3} \frac{|x_i - w_i|}{2} > \rho g(\mathbf{c}')$. ◁

Thus our goal for the computed assisted proof is to show $\inf_{\mathbf{c} \in \mathcal{C} \cap \mathcal{S} \cap \mathcal{E}} \frac{f(\mathbf{c})}{g(\mathbf{c})} \geq \rho$ for some value of $\rho$. Given 12 intervals $(I_1, \ldots, I_{12})$ we define the following polytopes to divide our feasible region into hypercubes. Consider the following polytope,

$$\mathcal{P}(I_1, \ldots, I_{12}) = (I_1 \times I_2 \ldots \times I_{12}) \cap \mathcal{C}.$$

Note that intervals $I_j$ correspond to possible values of $x_j$ for $j \in [3]$, intervals $I_3, I_4, I_5$ correspond to values of $w_1, w_2, w_3$, intervals $I_7, I_8, I_9$ correspond to values of $\alpha_1, \alpha_2, \alpha_3$, and intervals $I_{10}, I_{11}, I_{12}$ correspond to $t_1, t_2, t_3$. Our computer assisted proof enumerates $I_1, \ldots, I_{12}$ so that the union of all $\mathcal{P}(I_1, \ldots, I_{12}) \cap \mathcal{S} \cap \mathcal{E}$ covers $\mathcal{C} \cap \mathcal{S} \cap \mathcal{E}$. For each $I_1, \ldots, I_{12}$ we show one of the following three:

1. $\mathcal{P}(I_1, \ldots, I_{12}) \cap \mathcal{S} \cap \mathcal{E} = \emptyset$.
2. $\inf_{\mathbf{c} \in \mathcal{P}(I_1,\ldots,I_{12}) \cap \mathcal{S} \cap \mathcal{E}} \frac{f(\mathbf{c})}{g(\mathbf{c})} \geq \rho$.
3. Divide $(I_1, \ldots, I_{12})$ into a collection $\mathcal{U}$ whose union equals $(I_1, \ldots, I_{12})$ so that each $(I'_1, \ldots, I'_{12}) \in \mathcal{U}$ satisfies one of the first two items.

which implies the hypothesis of Claim 23. The third item is the branching step and the first two items are how we eliminate branches. For our computer assisted proof we will only consider $x_1, x_2, w_1, w_2, t_1, t_2, t_3$ as independent variables. The remaining variables $w_3, x_3, \alpha_1, \alpha_2, \alpha_3$ will always take values $w_3 = 1 - w_1 - w_2, x_3 = 1 - x_1 - x_2, \alpha_i = x_i w_i + t_i \sqrt{(x_i - x_i^2)(w_i - w_i^2)}$ for $i \in [3]$. Our algorithm runs in stages. In the first stage we use an LP to eliminate hypercubes. The first stage works as follows,

1. Enumerate all $\mathcal{I} = (I_1, \ldots, I_{12})$ such that $|I_j| = \eta_1$ for $j \in \{1, 2, 4, 5\}$ and $|I_j| = \eta_2$ for $j = 10, 11, 12$ that the union of all $(I_1, I_2, I_3, I_4, I_{10}, I_{11}, I_{12})$ covers the region $[0, 1]^4 \times [-1, 1]^3$. Note that intervals $I_5, I_6, I_7$ can be determined by the bounds on the other intervals, $I_j$ such that $j \notin \{5, 6, 7\}$. This follows since bounds on $x_i, w_i, t_i$ imply bounds on $\alpha_i$ because $\alpha_i = t_i \sqrt{(x_i - x_i^2)(w_i - w_i^2)} + x_i w_i$. Similarly, $I_3, I_6$ are determined by $I_1, I_2$ and $I_4, I_5$ respectively since $x_3 = 1 - x_1 - x_2$ and $w_3 = 1 - w_1 - w_2$.
2. For each hypercube $\mathcal{I}$ enumerated in the previous step, check that $\mathcal{P}(\mathcal{I}) \cap \mathcal{E} \cap \mathcal{S}$ contains a feasible point by solving an LP. If yes, save $\mathcal{I}$ for further processing.

### Partial Derivatives

A crucial ingredient of the branch and bound procedure is to obtain a lower bound on the function $f(\mathbf{c})$ for any configuration $\mathbf{c} \in \mathcal{I}$ in any cube. This we do by computing $f(\mathbf{c}^*)$ for some well chosen $\mathbf{c}^* \in \mathcal{I}$ and then using bounds on the partial derivatives to infer a bound $f(\mathbf{c})$ for all other $\mathbf{c} \in \mathcal{I}$. A tight bound on partial derivatives ensures a smaller branch and bound tree. We detail the partial derivatives and bounds thus obtained now. Previously, we defined the notion of configuration and the function $f$ as a function of 12 variables. Since we only consider $(x_1, x_2, w_1, w_2, t_1, t_2, t_3)$ as variables we have $\frac{\partial f}{\partial x_3} = \frac{\partial f}{\partial w_3} = \frac{\partial f}{\partial \alpha_i} = 0$ and $f, g$ are functions of 7 independent variables. We recall the definition of $f$

$$f(x, w, \alpha, t) = 1 - \frac{1}{6} \sum_{\pi \in \mathcal{S}_3} \Bigg[ \Gamma_{t_{\pi(1)}} \left( x_{\pi(1)}, w_{\pi(1)} \right) + \Gamma_{t_{\pi(1)}} \left( 1 - x_{\pi(1)}, 1 - w_{\pi(1)} \right) \cdot \\ \cdot \left( \Gamma_{t_{\pi(2)}} \left( 1 - \frac{x_{\pi(2)}}{1 - x_{\pi(1)}}, 1 - \frac{w_{\pi(2)}}{1 - w_{\pi(1)}} \right) + \Gamma_{t_{\pi(2)}} \left( \frac{x_{\pi(2)}}{1 - x_{\pi(1)}}, \frac{w_{\pi(2)}}{1 - w_{\pi(1)}} \right) \right) \Bigg].$$

Moreover, for our use we can assume that the domain of $f$ is $0 \leq x_1 + x_2 \leq 1$, $0 \leq w_1 + w_2 \leq 1$, $\alpha_1, \alpha_2, \alpha_3 \in [0, 1]$ and $t_1, t_2, t_3 \in [-1, 1]$. In the following, we are going to prove bounds on the partial derivatives of $f(x, w, \alpha, t)$ with respect to $x_i$, $w_i$ and $t_i$.

▶ **Lemma 24.** *For each $(x, w, \alpha, t)$ in the domain of configuration, the following bounds on the partial derivatives of $f$ hold:*

1. $\frac{\partial}{\partial t_i} f(x, w, \alpha, t) < 0$, *for* $i = 1, 2, 3$.
2. $|\frac{\partial}{\partial x_i} f(x, w, \alpha, t)| \leq \frac{5}{3} - \frac{1}{3}(1 - x_{3-i})$, *for* $i = 1, 2$.
3. $|\frac{\partial}{\partial w_i} f(x, w, \alpha, t)| \leq \frac{5}{3} - \frac{1}{3}(1 - w_{3-i})$, *for* $i = 1, 2$.

The proof of the lemma is technical and appears in the full version of the paper. We now have the following claim that gives a lower bound on all configurations in the hypercube as compared to the point $\mathbf{m}$ in it.

▷ Claim 25. Let $\mathcal{I}$ be a hypercube and $\mathcal{Q} \triangleq \mathcal{P}(\mathcal{I}) \cap \mathcal{S} \cap \mathcal{E}$. Let $\mathbf{m} \in \mathbb{R}^{12}$ be a point where the coordinates corresponding to $x_1, x_2, w_1, w_2$ are the midpoints $I_1, I_2, I_4, I_5$ respectively and the last 3 coordinates corresponding are $\overline{t_1}, \overline{t_2}, \overline{t_3}$ which are the upper bounds of $I_{10}, I_{11}, I_{12}$. Then the following holds,

$$\min_{\mathbf{c}=(x_1,\ldots,t_1,t_2,t_3)\in\mathcal{Q}} f(x_1, x_2, \ldots, \overline{t_1}, \overline{t_2}, \overline{t_3}) \geq f(\mathbf{m}) - \frac{1}{6} \sum_{z\in\{x,w\}} \sum_{i=1}^{2} (5 - (1 - \overline{z_{3-i}}))(\overline{z_i} - \underline{z_i}).$$

▶ **Lemma 26.** *Let $\mathcal{I}, \mathbf{m}, \mathcal{Q}$ be defined as in Claim 25. Then $\min_{\mathbf{c}\in\mathcal{Q}} \frac{f(\mathbf{c})}{g(\mathbf{c})} \geq \rho$ if,*

$$f(\mathbf{m}) - \frac{1}{6} \sum_{z\in\{x,w\}} \sum_{i=1}^{2} (5 - (1 - \overline{z_{3-i}}))(\overline{z_i} - \underline{z_i}) \geq \rho \max_{\mathbf{c}\in\mathcal{Q}} g(\mathbf{c})$$

*where $\overline{z_i}, \underline{z_i}$ for $z \in \{w, x\}$ are the upper and lower bounds given by their corresponding interval in $\mathcal{I}$.*

**Proof.** We use the fact that $f$ is non-increasing in $t_i$ and Claim 25 to get,

$$\begin{aligned}\min_{\mathbf{c}\in\mathcal{Q}} f(\mathbf{c}) &\geq \min_{\mathbf{c}=(x_1,x_2,\ldots,t_1,t_2,t_3)\in\mathcal{Q}} f(x_1, x_2, \ldots, \overline{t_1}, \overline{t_2}, \overline{t_3}) \\ &\geq f(\mathbf{m}) - \frac{1}{6} \sum_{z\in\{x,w\}} \sum_{i=1}^{2} (5 - (1 - \overline{z_{3-i}}))(\overline{z_i} - \underline{z_i})\end{aligned}$$

The first inequality follows since $f$ is non-increasing in $t, \alpha$ by Lemma 24. The third inequality follows by Claim 25. Thus by the inequality in the lemma and the relation above, we have shown: $\min_{\mathbf{c}\in\mathcal{Q}} f(\mathbf{c}) \geq \rho \max_{\mathbf{c}\in\mathcal{Q}} g(\mathbf{c})$. ◀

Now we describe the final stage of the experiment which eliminates all remaining cubes from the first stage.

1. For all remaining hyper cubes $\mathcal{I}$ from stage 1 run the following steps until all cubes are eliminated.
2. Split the intervals $I_1, I_2, I_4, I_5$ corresponding to $x_1, x_2, w_1, w_2$ into halves to get 16 smaller sub-hypercubes $(I'_1, \ldots, I'_9, I_{10}, I_{11}, I_{12})$. We note that this also tightens the intervals corresponding to $x_3, w_3, \alpha_1, \alpha_2, \alpha_3$. Check if each smaller hypercube has a feasible point in $\mathcal{P}(I'_1, \ldots, I'_9, I_{10}, I_{11}, I_{12}) \cap \mathcal{S} \cap \mathcal{E}$. If yes, then the sub-hypercube can be eliminated.
3. Otherwise, verify if the inequality in 26 holds. If yes, the sub-hypercube can be eliminated.
4. Otherwise, split the $t_1, t_2, t_3$ intervals into halves to get 8 sub-hypercubes $\mathcal{I}' = (I'_1, \ldots, I'_9, I''_{10}, I''_{11}, I''_{12})$. This also tightens the intervals for $\alpha_1, \alpha_2, \alpha_3$. Check if each smaller hypercube $\mathcal{I}'$ has a feasible point in $\mathcal{P}(\mathcal{I}') \cap \mathcal{S} \cap \mathcal{E}$. If yes, then the sub-hypercube can be eliminated.
5. Otherwise, split the sub-hyper cube into 16 smaller hyper-cubes using Step 2. Repeat Steps 2-5 until all sub cubes are eliminated.

We ran this branch and bound procedure with $\rho = 0.80, \delta' = 0.01$ giving a final approximation of 0.795.

## 6 Max-k-Section

Our algorithm for Max-3-Section can be generalized for larger number of sections in the following way. For a natural number $k \geq 4$, one can write a similar SDP formulation, where each node $v \in V$ has $k$ vectors $\mathbf{y}_v^1, \ldots, \mathbf{y}_v^k$, with similar constraints and objective for the SDP

for Max-3-Section: maximize $\sum_{\{u,v\}\in E}\cdot(1-\sum_{i=1}^{k}\mathbf{y}_u^i\cdot\mathbf{y}_v^i)$. The rounding algorithm will work in a similar way. For example, we consider $k=4$. We draw a random permutation $\pi$ in $\mathcal{S}^4$ and three random gaussian vectors $\mathbf{g}_1,\mathbf{g}_2,\mathbf{g}_3$ with coordinates independently distributed by $N(0,1)$. Then, we define $S_{\pi(1)}$ and $S_{\pi(2)}$ in the same way like in the algorithm for Max-3-Section. Next, we define

$$S_{\pi(3)}\triangleq\left\{u\in V:\mathbf{z}_u^{\pi(3)}\cdot\mathbf{g}_3\geq\Phi^{-1}\left(1-\frac{\|\mathbf{y}_u^{\pi(3)}\|^2}{1-\|\mathbf{y}_u^{\pi(1)}\|^2-\|\mathbf{y}_u^{\pi(2)}\|^2}\right)\right\}$$

and the four clusters in the output will be $C_{\pi(1)}=S_{\pi(1)}$, $C_{\pi(2)}=S_{\pi(2)}\setminus S_{\pi(1)}$, $C_{\pi(3)}=S_{\pi(3)}\setminus(S_{\pi(2)}\cup S_{\pi(1)})$ and $C_{\pi(4)}=V\setminus(S_{\pi(1)}\cup S_{\pi(2)}\cup S_{\pi(3)})$. Then, for any constant $k$, we can claim that with high probability the solution is concentrated and can be re-balanced, similarly to Lemma 15 and Lemma 16.

Our goal now is to bound the approximation factors that these algorithms achieve, for each $k$. As we discussed in the previous sections, computing the worst approximation guarantee, or even bounding it analytically is not an easy task. For $k=3$, we used the branch and bound algorithm and presented a lower bound on the approximation ratio. For larger values of $k$, the computer-assisted proof method becomes computationally harder. However, one possible approach is to try and give a numerical estimation for the approximation factor. We will do that in the following way: for each $k$, one can write an optimization problem over $k^2$ variables that represent the inner products $\mathbf{y}_u^i\cdot\mathbf{y}_v^j$, for each $i,j\in[k]$, or as we denoted before, a feasible configuration. Then, we wish to minimize the ratio of the probability that $u,v$ are separated and the contribution of the edge $\{u,v\}$ to the SDP, which is $1-\sum_{i=1}^{k}\mathbf{y}_u^i\cdot\mathbf{y}_v^i$. To solve that optimization problem, we use Matlab and the *fmincon* functionality which can find a local minimum for this optimization problem, but only a local minimum. Therefore, we repeat the experiment for numerous random starting points in the feasible region. The results of the numerical estimations of the approximation for $k=3,4,5$ are presented in Conjecture 3.

We note that given a configuration of vectors $\mathbf{y}_u^1,\mathbf{y}_u^2,\mathbf{y}_u^3,\mathbf{y}_v^1,\mathbf{y}_v^2,\mathbf{y}_v^3$ that has a ratio of $\rho$ between the separation probability and the contribution of the edge $(u,v)$ to the SDP solution for Max-3-section, one can construct a configuration for max-4-section by adding two zero vectors $\mathbf{y}_u^4,\mathbf{y}_v^4$. That configuration will have the same contribution for the SDP for max-4-section, and the separation probability will also be the same, even though the algorithm admits four sections. Therefore, in that way of analysis, the approximation ratio of our algorithm can only decrease as $k$ increases. However, our numerical estimations show that for $k\leq 5$, the approximation is not worse than 0.8192. In addition, we note that the simple algorithm that returns a random balanced $k$-partition achieves a $1-\frac{1}{k}$ approximation, hence for $k=3,4,5$ our algorithm surpasses it.

## Abstract

In the $L_0$ Fitting Tree Metrics problem, we are given all pairwise distances among the elements of a set $V$ and our output is a tree metric on $V$. The goal is to minimize the number of pairwise distance disagreements between the input and the output. We provide an $O(1)$ approximation for $L_0$ Fitting Tree Metrics, which is asymptotically optimal as the problem is APX-Hard.

For $p \geq 1$, solutions to the related $L_p$ Fitting Tree Metrics have typically used a reduction to $L_p$ Fitting Constrained Ultrametrics. Even though in FOCS '22 Cohen-Addad et al. solved $L_0$ Fitting (unconstrained) Ultrametrics within a constant approximation factor, their results did not extend to tree metrics.

We identify two possible reasons, and provide simple techniques to circumvent them. Our framework does not modify the algorithm from Cohen-Addad et al. It rather extends any $\rho$ approximation for $L_0$ Fitting Ultrametrics to a $6\rho$ approximation for $L_0$ Fitting Tree Metrics in a blackbox fashion.

## 1 Introduction

Trees are used by many disciplines to describe relationships between entities. For example, in biology, the universal tree of life describes evolutionary distances between organisms. In fact, trees are relevant for any historical science studying an evolutionary branching process (e.g. historical linguistics and sociocultural evolution).

In these cases, we are guaranteed that the underlying truth can be described by a tree. This underlying tree may even have a special structure. For example in machine learning and data analysis (see e.g.: [3]) it may be an ultrametric, that is a rooted tree with all leaves being at the same depth. In any case, our access to this tree is usually only through estimations of pairwise distances. A natural task is thus the reconstruction of the tree, given (noisy) measurements of pairwise distances.

As the noisy measurements may not describe a tree, we are interested in finding the "closest" tree to the input. In this work we study the problem of minimizing the number of pairwise distance disagreements between the measurements and the output tree. As noted in [6], this objective has a practical relevance; often the distances are obtained by different (human) classifiers. It is expected that most will do a good job, but if an error occurs, it may be by a large amount.

Other objectives have also been studied, e.g. minimizing the total error [2, 5, 8], or minimizing the maximum error [1]. In order to formally introduce a class of problems that captures all aforementioned objectives we first make some definitions.

## 1.1 Problem Definitions

Given a set $V$, we denote by $\binom{V}{2}$ the set of all (unordered) pairs of disjoint elements from set $V$. We use the term distance matrix to refer to a function from $\binom{V}{2}$ to the non-negative reals. Let $D$ be a distance matrix. We slightly abuse notation and say that for any $u \in V$, $D(u,u) = 0$. For $p \geq 1$, we say that $\|D\|_p = \sqrt[p]{\sum_{\{u,v\} \in \binom{V}{2}} |D(u,v)|^p}$ is the $L_p$ norm of $D$. We extend the notation for $p = 0$. In this case $\|D\|_0$ denotes the number of pairs $\{u,v\}$ such that $D(u,v) \neq 0$. We even say $\|D\|_0$ is the $L_0$ norm of $D$, despite $L_0$ not being a norm. For ease of notation, we use $0^0 = 0$, so that $x^0 = 0$ if $x = 0$, and 1 otherwise. As in [6] (and implicitly in [1]), we allow tree metrics and ultrametrics to have distances equal to 0.

▶ **Definition 1.** *In the $L_p$ Fitting Tree (Ultra) Metrics problem, we are given as input a set $V$ and a distance matrix $D$.*

*The output is a tree metric (or ultrametric) $T$ that spans $V$ and fits $D$ in the sense of minimizing the $L_p$-norm*

$$\|T - D\|_p = \sqrt[p]{\sum_{\{u,v\} \in \binom{V}{2}} |T(u,v) - D(u,v)|^p}.$$

We also define a similar problem, $L_p$ Fitting Constrained Ultrametrics. It was initially defined in [1], who proved that, for $p \geq 1$, a $\rho$ approximation for $L_p$ Fitting Constrained Ultrametrics translates to a $3\rho$ approximation for $L_p$ Fitting Tree Metrics.

▶ **Definition 2.** *In the $L_p$ Fitting Constrained Ultrametrics problem, we are given as input a set $V$, a distance matrix $D$, a distinguished element $\alpha \in V$, a positive number $h$ and a positive number $l_u$ for each $u \in V$. In particular it holds that $l_\alpha = h$.*

*The output is an ultrametric $U$ that spans $V$. It shall also hold that*

$$\max\{l_u, l_v\} \leq U(u,v) \leq h \qquad \forall \{u,v\} \in \binom{V}{2}.$$

*$U$ shall fit $D$ in the sense of minimizing the $L_p$-norm*

$$\|U - D\|_p = \sqrt[p]{\sum_{\{u,v\} \in \binom{V}{2}} |U(u,v) - D(u,v)|^p}.$$

## 1.2 Previous work

When the input is a tree metric, a corresponding tree can be found in $O(|V|^2)$ time (linear in the input size) [9]. As this is usually not the case, research focused on $L_p$ Fitting Tree Metrics.

The first $L_p$ Fitting Tree Metrics problem solved within an asymptotically optimal approximation factor is the $L_\infty$ Fitting Tree Metrics problem, by Agarwala et al. [1]. In order to solve it, the authors give a reduction to the $L_\infty$ Fitting Constrained Ultrametrics problem which increases the approximation by a factor 3. They then use the exact solution of this problem from [7]. In the same paper, they also show how to extend this reduction for any $L_p$ norm, $p \geq 1$.

This reduction turned out to be an essential tool for tackling $L_p$ Fitting Tree Metrics. Harp, Kannan and McGregor [8] developed an $O(\min\{n, k \log n\}^{1/p})$ approximation factor for $L_p$ Fitting Ultrametrics, $p \geq 1$, where $k$ is the number of distinct distances in the input. Using

the reduction from [1], they extend their result to the $L_p$ Fitting Tree Metrics case[1]. Similarly, Ailon and Charikar [2] get an $O(((\log n)(\log\log n))^{1/p})$ approximation for the ultrametrics case, which they then extend to the tree metrics case using the well established reduction. Finally, Cohen-Addad et al. [5] achieve an asymptotically optimal $O(1)$ approximation factor for $L_1$ Fitting Tree Metrics, again using an asymptotically optimal $O(1)$ approximation factor for the ultrametrics case.

In FOCS '22 Cohen-Addad et al. [6] solved the $L_0$ Fitting Ultrametrics problem within an asymptotically optimal $O(1)$ approximation factor. However, their result was not extended to the $L_0$ Fitting Tree Metrics problem. We identify two possible reasons for that:

- Most importantly, the reduction from [1] does not work for $L_0$. The reason is that a crucial step of it uses the convexity of all $L_p$-norms, $p \geq 1$. $L_0$ however is not convex (and in fact is not a norm).
- Even if the reduction worked for $L_0$, the algorithm for $L_0$ Fitting Ultrametrics should be extended to the $L_0$ Fitting Constrained Ultrametrics problem.

## 1.3 Our results

In this work we show how any $\rho$ approximation for $L_0$ Fitting Ultrametrics can be extended to a $6\rho$ approximation for $L_0$ Fitting Tree Metrics.

In particular, we extend the reduction from [1] to the $L_0$ case, despite $L_0$ not being convex. We do so by avoiding the averaging argument from [1] which required convexity, and was necessary to prove the existence of a node with certain properties. Our argument is of course only valid for $L_0$.

Furthermore, we show how one can use any algorithm for $L_0$ Fitting Ultrametrics to solve $L_0$ Fitting Constrained Ultrametrics, in a blackbox manner. In contrast [1, 2, 8] all needed to apply ad-hoc modifications to their $L_p$ Fitting Ultrametrics algorithms to also solve $L_p$ Fitting Constrained Ultrametrics.

An immediate corollary of these two results is that the ultrametrics algorithm from [6] can be used to get an asymptotically optimal $O(1)$ approximation factor for $L_0$ Fitting Tree Metrics. Even though this constant is large, any improved approximation factor for $L_0$ Fitting Ultrametrics would immediately yield an improved approximation for $L_0$ Fitting Tree Metrics, using this framework.

Finally, we prove that $L_0$ Fitting Tree Metrics is APX-Hard.

It is interesting to notice that apart from avoiding the averaging argument from [1], the rest follow existing techniques. However, due to the special structure of $L_0$, we significantly simplify them.

# 2 From tree metrics to ultrametrics

In this section we prove the following result:

▶ **Theorem 3.** *A factor $\rho \geq 1$ approximation for $L_0$ Fitting Ultrametrics implies a factor $6\rho$ approximation for $L_0$ Fitting Tree Metrics.*

[1] The authors erroneously claim that they get the same approximation for the closest tree metric problem. However, the known reduction may create $\omega(k)$ distinct distances. We believe that the dependence in $k$ is polynomial, which makes the approximation worse, but still non-trivial.

Let $D$ be a distance matrix, $\alpha \in V$ be a distinguished element and $T$ be a tree spanning $V$. In more details, there exists a function mapping elements from $V$ to nodes in $T$. If element $u \in V$ is mapped to node $u' \in T$, we say that $u$ is associated with $u'$. We even say "node $u$" to refer to the node associated with $u$. We note that $T$ may also have auxiliary nodes, without any element from $V$ being mapped to them.

We say $T$ is an $\alpha$-restricted tree if the distance from $\alpha$ to any other element $u$ is the same both in $T$ and in $D$.

Given a tree $T$ we can obtain an $\alpha$-restricted tree $T^{/\alpha}$ by modifying $T$ as in Figure 1. We say that $T^{/\alpha}$ is the $\alpha$-restricted tree of $T$.

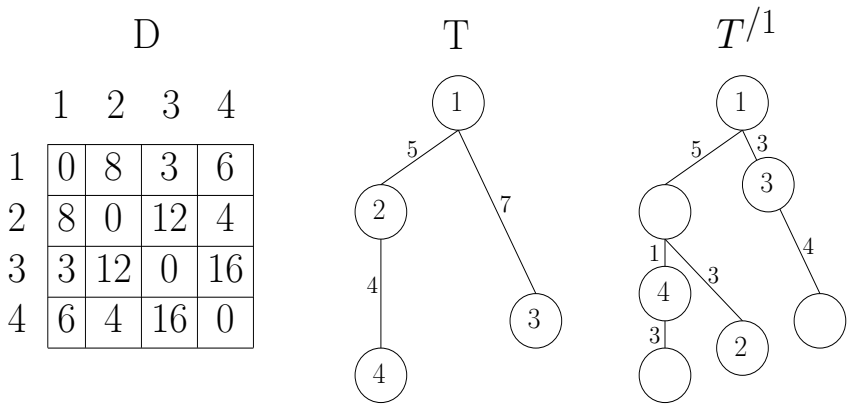

**Figure 1** $T$ is not $\alpha$-restricted, for any $\alpha \in \{1, 2, 3, 4\}$. By modifying $T$ we get $T^{/1}$ which is 1-restricted. Nodes 3 and 4 move towards 1, while 2 moves away from 1 (by creating a new leaf). Notice that some nodes of $T$ may be irrelevant for $T^{/1}$; however we do not need to explicitly delete them.

Intuitively, for any element $u$, if $T(\alpha, u) \neq D(\alpha, u)$, we move $u$ either closer to or further from $\alpha$. More specifically, if $T(\alpha, u) > D(\alpha, u)$, then:

- if there exists a node in the path from $u$ to $\alpha$ at distance $D(\alpha, u)$ from $\alpha$, we associate $u$ with this node,
- else there exists an edge in the path from $u$ to $\alpha$ such that one of its endpoints is at distance less than $D(\alpha, u)$ from $\alpha$, and the other endpoint is at distance larger than $D(\alpha, u)$ from $\alpha$. In this case we subdivide this edge in order to introduce a new node at distance exactly $D(\alpha, u)$ from $\alpha$. Then we associate $u$ with this new node.

Else if $D(\alpha, u) > T(\alpha, u)$ we create a new leaf under the node previously associated with $u$; the length of the edge connecting them is $D(\alpha, u) - T(\alpha, u)$. Then we associate $u$ with the newly created leaf, instead of its parent.

The proof strategy for our main result is the following:

- In order to approximate the optimal tree, it suffices to approximate the optimal $\alpha$-restricted tree, for some $\alpha \in V$. We prove this in Section 2.1.
- In order to approximate the optimal $\alpha$-restricted tree, it suffices to approximate $L_0$ Fitting Constrained Ultrametrics. The proof directly follows from [1]; we include it in the full version for completeness.
- In order to approximate $L_0$ Fitting Constrained Ultrametrics, it suffices to approximate $L_0$ Fitting Ultrametrics. We prove this in Section 2.2.

## 2.1 From tree metrics to restricted tree metrics

The main point where the reduction from [1] breaks for $L_0$ is the connection between optimal tree metrics and optimal $\alpha$-restricted tree metrics. The reason is that an averaging argument used to prove the result uses the convexity of $L_p$-norms, $p \geq 1$. In fact, this argument shows the existence of an element $\alpha$ such that the optimal $\alpha$ restricted tree is very close to the optimal tree. Then one can try all elements $\alpha$ and pick the best of them.

We show that even though $L_0$ is not convex, we can still select $\alpha$ in the same way as in [1]. In particular, we show that for any tree $T$, there exists an element $\alpha$ such that its $\alpha$-restricted tree metric $T^{/\alpha}$ does not increase the cost by more than a factor 3.

▶ **Lemma 4.** *Let $D$ be a distance matrix and $T$ be a tree. Then there exists an element $\alpha$ such that for the $\alpha$-restricted tree $T^{/a}$ of $T$ it holds that $\|D - T^{/a}\|_0 \leq 3\|D - T\|_0$.*

**Proof.** We simply let $\alpha$ be the element that minimizes disagreements, that is

$$\alpha = argmin_{u \in V} \|D(u) - T(u)\|_0$$

where $D(u)$ is the distance matrix $D$ restricted on the pairs containing $u$ (similarly for $T(u)$). We have that $\|D - T\|_0 = \frac{1}{2}\sum_{u \in V} \|D(u) - T(u)\|_0$, as the sum in the right hand side double counts every pair $u, v$ with $D(u, v) \neq T(u, v)$. By definition of $\alpha$, every term in the sum is lower bounded by $\|D(\alpha) - T(\alpha)\|_0$, meaning that

$$\|D - T\|_0 \geq \frac{n}{2}\|D(\alpha) - T(\alpha)\|_0.$$

We say that an element $u$ is good if $D(\alpha, u) = T(\alpha, u)$, and bad otherwise; notice that by definition, the number of bad elements is exactly $\|D(\alpha) - T(\alpha)\|_0$. As any element $u$ can have at most $n - 1$ disagreements in $T^{/\alpha}$ (that is $\|D(u) - T^{/\alpha}(u)\|_0 \leq n - 1$), it follows that the number of pairs $u, v$ with at least one of $u, v$ being bad and $D(u, v) \neq T^{/\alpha}(u, v)$ is at most $\|D(\alpha) - T(\alpha)\|_0 \cdot (n - 1) \leq 2\|D - T\|_0$.

On the other hand, notice that if both $u, v$ are good, then by construction $T^{/\alpha}(u, v) = T(u, v)$. Therefore, if $D(u, v) \neq T^{/\alpha}(u, v)$, it also holds that $D(u, v) \neq T(u, v)$. The number of such pairs is upper bounded by $\|D - T\|_0$. ◀

Letting $T$ be an optimal solution for $L_0$ Fitting Tree Metrics establishes that it suffices to approximate the optimal $\alpha$-restricted tree, only increasing the approximation by a factor 3.

Furthermore, we can directly use the techniques from [1] to show that any approximation for the constrained ultrametrics problem can give the exact same approximation for the optimal $\alpha$-restricted tree. We include this proof in the full version for completeness, as it is itself very brief. However we do not include it here, as it has been extensively used in the literature.

Notice that these results already show that a $\rho$ approximation for $L_0$ Fitting Constrained Ultrametrics translates to a $3\rho$ approximation for $L_0$ Fitting Tree Metrics. This is an extension of the result of [1] for the $L_0$ case.

## 2.2 From constrained ultrametrics to ultrametrics

In this section we show that it is sufficient to approximate $L_0$ Fitting Ultrametrics, which is more natural than $L_0$ Fitting Constrained Ultrametrics. The technique used follows the one used in [5] for $L_p$, $p \in \{1, 2, \ldots\} \cup \{\infty\}$. However, in the case of $L_0$ we can simplify.

The high-level view of the technique is the following: Instead of trying to find a constrained ultrametric close to a distance matrix $D$, we rather squeeze $D$ itself to obey the constraints. Let $S_D$ be the resulting distance matrix. Then we find an (unconstrained) ultrametric $U$

close to this matrix $S_D$; due to the extra structure we imposed on $S_D$, we can only improve $U$ if we again squeeze it to obey the constraints. The resulting ultrametric $S_U$ is a constrained ultrametric, but all we needed to obtain it was a black-box algorithm for general ultrametrics.

We now define the squeezing process more formally. In the $L_0$ Fitting Constrained Ultrametrics problem, for every element $u$ we are given a value $l_u$ which we call $u$'s lower-bound. Furthermore we are given an upper bound $h$.

A constrained ultrametric $U$ shall satisfy that

$$h \geq U(u,v) \geq \max\{l_u, l_v\} \qquad \forall \{u,v\} \in \binom{V}{2}.$$

Given a distance matrix $A$, we define the *squeezed* $A$ as the distance matrix $S_A$ for which $S_A(u,v) = \min\{h, \max\{D(u,v), l_u, l_v\}\}$, for all $\{u,v\} \in \binom{V}{2}$. Intuitively, $S_A$ is obtained by squeezing $A$ to fit the constraints.

We use the well-known characterization of ultrametrics, that $U$ is an ultrametric iff $\forall \{u,v,w\} \in \binom{V}{3} : U(u,v) \leq \max\{U(u,w), U(v,w)\}$.

▶ **Lemma 5.** *A factor $\rho \geq 1$ approximation for $L_0$ Fitting Ultrametrics implies a factor $2\rho$ approximation for $L_0$ Fitting Constrained Ultrametrics.*

**Proof.** Our approach starts with creating $S_D$, the squeezed $D$. Notice that if $U'$ is a constrained ultrametric, then $\|U' - S_D\|_0 \leq \|U' - D\|_0$. This follows because for any $u, v$ it holds that $\max\{l_u, l_v\} \leq U'(u,v) \leq h$, due to $U'$ being a constrained ultrametric. Therefore $D(u,v) = U'(u,v)$ only if $\max\{l_u, l_v\} \leq U'(u,v) \leq h$. But in this case $S_D(u,v) = D(u,v) = U'(u,v)$.

Similarly, suppose we have an ultrametric $U$, and we create the squeezed $S_U$.

With the exact same reasoning, we have

$$\|S_D - S_U\|_0 \leq \|S_D - U\|_0. \tag{1}$$

Our solution to $L_0$ Fitting Constrained Ultrametrics is to first create $S_D$ by squeezing $D$, then obtain ultrametric $U$ by a $\rho$ approximation to $L_0$ Fitting Ultrametrics on $S_D$, and finally obtain $S_U$ by squeezing $U$.

Let $OPT_{D,C}$ be the closest constrained ultrametric to $D$, and $OPT_{S_D}$ be the closest ultrametric to $S_D$. It suffices to show that $\|D - S_U\|_0 \leq 2\rho \|D - OPT_{D,C}\|_0$ and that $S_U$ is indeed an ultrametric.

By definition of $S_D$, and since $OPT_{D,C}$ is constrained, for any two elements $u, v$ it holds that

$$\min\{D(u,v), OPT_{D,C}(u,v)\} \leq S_D(u,v) \leq \max\{D(u,v), OPT_{D,C}(u,v)\}.$$

The proof follows by a straightforward case analysis of the 3 cases $D(u,v) \leq \max\{l_u, l_v\}$, $\max\{l_u, l_v\} < D(u,v) \leq h$, $h < D(u,v)$. Therefore:

- either $D(u,v) = OPT_{D,C}(u,v)$, in which case

$$|D(u,v) - OPT_{D,C}(u,v)|^0 = 0 = |D(u,v) - S_D(u,v)|^0 + |S_D(u,v) - OPT_{D,C}(u,v)|^0$$

- or $D(u,v) \neq OPT_{D,C}(u,v)$, in which case

$$|D(u,v) - OPT_{D,C}(u,v)|^0 = 1, |D(u,v) - S_D(u,v)|^0 + |S_D(u,v) - OPT_{D,C}(u,v)|^0 \leq 2.$$

We conclude that

$$|D(u,v) - S_D(u,v)|^0 + |S_D(u,v) - OPT_{D,C}(u,v)|^0 \leq 2|D(u,v) - OPT_{D,C}(u,v)|^0. \quad (2)$$

We now have

$$\begin{aligned}
\|D - S_U\|_0 &\leq \|D - S_D\|_0 + \|S_D - S_U\|_0 && \text{(triangle inequality)} \\
&\leq \|D - S_D\|_0 + \|S_D - U\|_0 && (1) \\
&\leq \|D - S_D\|_0 + \rho\|S_D - OPT_{D,C}\|_0. && \text{(definition of } U\text{)}
\end{aligned}$$

As $\rho \geq 1$, the latter is upper bounded by

$$\begin{aligned}
&\rho \sum_{\{u,v\} \in \binom{V}{2}} (|D(u,v) - S_D(u,v)|^0 + |S_D(u,v) - OPT_{D,C}(u,v)|^0) \\
&\leq 2\rho \sum_{\{u,v\} \in \binom{V}{2}} (|D(u,v) - OPT_{D,C}(u,v)|^0) && (2) \\
&= 2\rho\|D - OPT_{D,C}\|_0.
\end{aligned}$$

Finally, we need to prove that $S_U$ inherits that it is an ultrametric. This is clear if we proceed in rounds; each round we construct a new ultrametric, and the last one will coincide with $S_U$.

More formally, let $U_0 = U$. In the first $|V|$ rounds, we take out a different $u' \in V$ at a time, and let

$$U_r(u', v) = \max\{U_{r-1}(u', v), l_{u'}\} \qquad \forall v \neq u'.$$

Suppose $r > 0$ is the first round where $U_r$ is not an ultrametric. Then there exists a triplet $\{u, v, w\}$ such that $U_r(u, v) > \max\{U_r(u, w), U_r(v, w)\}$. As we only increase distances, this may only happen if $U_r(u, v) > U_{r-1}(u, v)$. But this means that at round $r$ we picked either $u$ or $v$ (w.l.o.g. assume it was $u$) and set $U_r(u, v) = l_u$. However, this would also give $U_r(u, w) \geq l_u = U_r(u, v)$, contradicting $U_r(u, v) > \max\{U_r(u, w), U_r(v, w)\}$.

Finally, for $S_U$ we simply have

$$S_U(u, v) = \min\{h, U_{|V|}(u, v)\}.$$

Suppose there exists a triplet $\{u, v, w\}$ that now violates the ultrametric property, then it holds that

$$S_U(u, v) > \max\{S_U(u, w), S_U(v, w)\}.$$

As we did not increase any distance of $U_{|V|}$, this means that $S_U(u, w) < U_{|V|}(u, w)$ or $S_U(v, w) < U_{|V|}(v, w)$; but distances can only reduce to $h$ which is an upper bound on $S_U(u, v)$ by construction. ◀

To prove our main theorem we use the following result from [1]. We only provide its proof in the full version, for completeness.

▶ **Lemma 6** (Implicit in the proof of Lemma 3.5 of [1]). *Let $D$ be a distance matrix, $\alpha$ be an element, and $T$ be an $\alpha$-restricted tree metric minimizing $\|T - D\|_0$. Assuming a $\gamma$-approximation to $L_0$ Fitting Constrained Ultrametrics, we can find an $\alpha$-restricted tree $T'$ such that $\|T' - D\|_0 \leq \gamma\|T - D\|_0$.*

We are now ready to prove our main theorem.

▶ **Theorem 3.** *A factor $\rho \geq 1$ approximation for $L_0$ Fitting Ultrametrics implies a factor $6\rho$ approximation for $L_0$ Fitting Tree Metrics.*

**Proof.** We iterate over all $u \in V$ nodes. In every iteration we use Lemma 6 along with a $2\rho$ approximation for $L_0$ Fitting Constrained Ultrametrics (obtained by Lemma 5) to obtain a tree $T_u$ with $\|T_u - D\|_0 \leq 2\rho\|T'_u - D\|_0$, where $T'_u$ is the optimal $u$-restricted tree metric. Out of all the trees $T_u$ that we obtain, we output $T$, the one that minimizes $\|T_u - D\|_0$.

Let $T_{OPT}$ be an optimal tree metric. By Lemma 4 there exists an element $\alpha$ such that for the $\alpha$-restricted tree $T_{OPT}^{/\alpha}$ of $T_{OPT}$ it holds that $\|T_{OPT}^{/\alpha} - D\|_0 \leq 3\|T_{OPT} - D\|_0$. Therefore there exists an element $\alpha$ for which we have $\|T'_\alpha - D\|_0 \leq 3\|T_{OPT} - D\|_0$.

It now holds that $\|T - D\|_0 \leq \|T_\alpha - D\|_0 \leq 2\rho\|T'_\alpha - D\|_0 \leq 6\rho\|T_{OPT} - D\|_0$. ◀

▶ **Corollary 7.** *There exists a polynomial time $O(1)$ approximation for $L_0$ Fitting Tree Metrics.*

**Proof.** Follows immediately, by using the polynomial time $O(1)$ approximation for $L_0$ Fitting Ultrametrics from [6]. ◀

## 3 APX-Hardness

In this section we show that $L_0$ Fitting Tree Metrics is APX-Hard. Assuming, for the sake of contradiction, that it is not the case, we show how to approximate Correlation Clustering (an APX-Hard problem [4]) within any constant factor.

This is a standard reduction used for $L_p$ Fitting Tree Metrics, $p \geq 1$. It is however further simplified for $L_0$. That is because once we decide to move a node, our cost does not depend on the distance we moved it.

In Correlation Clustering, we are given an unweighted undirected graph $G$, and the goal is to output a partition of the vertices[2] (clustering) such that we minimize the number of pairs of vertices connected by an edge in $G$ that are in different parts of the partition (clusters) plus the number of pairs of vertices not connected by an edge in $G$ that are in the same part of the partition.

The idea behind the reduction is the following: for every pair of vertices connected by an edge in $G = (V, E)$, we set their distance to 0, and for every pair of vertices not connected by an edge, we set their distance to something larger (2 in our case). Then we solve $L_0$ Fitting Tree Metrics. If the output tree has a good structure (every pair of nodes associated with elements of $V$ has equal distance), it would directly correspond to a clustering. Namely, each node associated with elements of $V$ corresponds to a cluster that contains all elements associated with it (may be more than one). Even though we can guarantee that an optimal solution has this structure, our approximation may not.

To fix this, we introduce many more elements at distance 0 from each other, and at distance 1 from every element in $V$. This has the effect of maintaining the structure of an optimal solution, while incuring a big error in every solution that does not have the desired structure.

We now formally prove our result.

[2] To avoid confusion, we use the term vertices when we refer to Correlation Clustering, and nodes when we refer to a tree.

▶ **Theorem 8.** *$L_0$ Fitting Tree Metrics is APX-Hard.*

**Proof.** Let $G = (V, E)$ be the input to Correlation Clustering, and $\epsilon > 0$ be a sufficiently small constant. For the sake of contradiction we assume that $L_0$ Fitting Tree Metrics can be approximated within an $1 + \epsilon$ factor. Then we show that using this approximation, we can approximate Correlation Clustering within the same factor.

Let $V'$ be a set, disjoint from $V$, of size $|V'| = 2\binom{|V|}{2}$. For any two elements $u', v' \in V'$ we have $D(u', v') = 0$. For $u, v \in V$ we have that $D(u, v) = 0$ if $\{u, v\} \in E$, and 2 otherwise. Finally, for $u \in V, u' \in V'$ we have $D(u, u') = 1$. Let $T$ be the tree output by $L_0$ Fitting Tree Metrics on $D$.

An upper bound for the optimal value is $\binom{|V|}{2}$. To see this, create the tree $T'$ consisting of two nodes $u_{T'}, v_{T'}$ at distance 1. All elements of $V'$ are associated with $u_{T'}$, and all elements of $V$ are associated with $v_{T'}$. As the only disagreements between $T'$ and $D$ are pairs of elements of $V$, the upper bound follows.

Furthermore, any solution that does not have all elements of $V'$ associated with the same node in $T$ has cost at least $|V'| - 1$. Therefore, for sufficiently small $\epsilon$, $T$ must have all elements of $V'$ associated with the same node $v'$. Similarly, all elements of $V$ must be associated with nodes at distance 1 from $v'$. In particular, this corresponds to an ultrametric, where the root node is $v'$, and all leaves are at depth 1. In what follows we consider this tree rooted at $v'$.

Finally, if any non-root node of $T$ is at distance less than 1 from $v'$, we remove it by connecting all its children with its parent node. Notice that this does not increase the number of disagreements, because the distance between elements of $V$ is either 0 or 2. After we can no longer remove any node, we are left with a tree $T$ with root $v'$, and children $v_1, \ldots, v_\ell$ at distance 1 from $v'$ (thus distance 2 from each other). Each $v_i$ is associated with some elements from $V$. Our solution to Correlation Clustering is the partition of $V$ induced by $v_1, \ldots, v_\ell$.

By construction of $D$, the cost of this Correlation Clustering solution is exactly equal to $\|T - D\|_0$. Furthermore, if $C_1, \ldots, C_{\ell'}$ is the optimal solution to Correlation Clustering, we can create a tree with a root $v'$ and children $v_1, \ldots, v_{\ell'}$ such that all elements of $V'$ are associated with $v'$ and all elements of $C_i$ are associated with $v_i$. This means that the optimal Correlation Clustering cost is an upper bound to the optimal $L_0$ Fitting Tree Metrics.

We conclude that we found an $1+\epsilon$ approximation for Correlation Clustering, contradicting its APX-Hardness. ◀

We note that the proof assumes some distances to be 0. If we want distances to be strictly positive, we can select a sufficiently small constant $\delta$ instead of 0. Then, we replace nodes that are associated with multiple elements with stars whose leaves all have distance $\delta$ to each other.

Laboratoire G-SCOP (CNRS, Univ. Grenoble Alpes), Grenoble, France

## Abstract

A *k-coloring* of a tournament is a partition of its vertices into $k$ acyclic sets. Deciding if a tournament is 2-colorable is NP-hard. A natural problem, akin to that of coloring a 3-colorable graph with few colors, is to color a 2-colorable tournament with few colors. This problem does not seem to have been addressed before, although it is a special case of coloring a 2-colorable 3-uniform hypergraph with few colors, which is a well-studied problem with super-constant lower bounds.

We present an efficient decomposition lemma for tournaments and show that it can be used to design polynomial-time algorithms to color various classes of tournaments with few colors, including an algorithm to color a 2-colorable tournament with ten colors. For the classes of tournaments considered, we complement our upper bounds with strengthened lower bounds, painting a comprehensive picture of the algorithmic and complexity aspects of coloring tournaments.

## 1 Introduction

A tournament $T = (V, A)$ is a complete, oriented graph: For each pair of vertices $i, j \in V$, there is either an arc from $i$ to $j$ or an arc from $j$ to $i$ (but not both). A subset of vertices $S \subseteq V$ induces the *subtournament* $T[S]$. If this subtournament contains no directed cycles, then it is said to be *acyclic*. The problem of *coloring a tournament* is that of partitioning the vertices into the minimum number of acyclic sets, sometimes referred to as the *dichromatic number* [32]. Since a tournament contains a directed cycle if and only if it contains a directed triangle, the problem of coloring a tournament is equivalent to partitioning the vertices into the minimum number of sets so that each set does not contain a directed triangle.

Coloring tournaments can be compared to the problem of coloring undirected graphs. For the latter, deciding if a graph is 2-colorable (i.e., bipartite) is easy, but it is NP-hard to decide if a graph is 3-colorable. A widely-studied promise problem is that we are given a graph promised to be 3-colorable and the goal is to color it (in polynomial time) with few colors [34, 5, 23, 24]. For tournaments, it is easy to decide whether or not a tournament is 1-colorable (i.e., transitive), since this is exactly when the tournament is acyclic. However, deciding if a tournament is 2-colorable is already NP-hard [8].

This suggests the following promise problem: Given a tournament promised to be 2-colorable, what is the fewest number of colors with which it can be colored in polynomial time? This question is the starting point for this paper and naturally leads to related problems of determining upper and lower bounds for coloring various classes of tournaments. For

**Table 1** Best known lower and upper bounds for various graph coloring problems. All inapproximability results are under the assumption P $\neq$ NP except those denoted by $^*$, which are under the $d$-To-1 Conjecture [26]. The lower bound should be read as, "It is hard to color a 3-colorable graph with 5 colors." The upper bound as, "A 3-colorable graph can be (efficiently) colored with $\tilde{O}(n^{0.19996})$ colors."

| Graph Type | Lower Bound | Upper Bound |
|---|---|---|
| 3-Colorable graphs | 5 [6], $O(1)^*$ [18] | $\tilde{O}(n^{0.19996})$[24] |
| $k$-Colorable graphs, $k \geq 3$ | $2k-1$ [6], $O(1)^*$[18] | $O(n^{1-\frac{3}{k+1}})$ [23] |
| General graphs | $n^{1-\epsilon}$ [22, 35] | $O(n(\log\log n)^2(\log n)^{-3})$ [19] |
| 3-Uniform 2-colorable hypergraphs | $O(1)$ [11] | $\tilde{O}(n^{\frac{1}{5}})$ [29] |

comparison, the complexity landscape of graph coloring is well studied and we have a general understanding of what it looks like. (See Table 1.) In contrast, the problem of coloring tournaments has been studied very little from the algorithmic or complexity perspective. This paper is an effort to address this disparity.

## 1.1 Previous Work

The problem of coloring a 2-colorable tournament with few colors is a special case of coloring a 2-colorable 3-uniform hypergraph with few colors. Deciding if a 3-uniform hypergraph is 2-colorable is NP-hard [31] and more recently it was proved to be NP-hard to color with any constant number of colors [11]. On the positive side, a 2-colorable 3-uniform hypergraph can be colored in polynomial time with $\tilde{O}(n^{1/5})$ colors [1, 7, 29], a result which uses tools from and is analogous to that of [23] for 3-colorable graphs. Thus, $\tilde{O}(n^{1/5})$ is the best-known upper bound on the number of colors needed to efficiently color a 2-colorable tournament. Deciding if a tournament is 2-colorable is NP-hard [8] and furthermore, deciding if a tournament is $k$-colorable for any $k \geq 2$ is NP-hard [15]. It is consistent with these results that we can, say, efficiently color a 2-colorable tournament with three colors.

From a structural graph theory perspective, the problem of coloring tournaments has been widely studied due to its connection to the famous Erdős-Hajnal Conjecture [12, 9], which has an equivalent formulation in terms of tournaments [2]. The latter posits that for any tournament $H$, there is a constant $\epsilon_H$ (where $0 < \epsilon_H \leq 1$) such that any $H$-free tournament on $n$ vertices has a transitive subtournament of size at least $O(n^{\epsilon_H})$. [4] exactly characterize the tournaments for which $\epsilon_H = 1$, which they call *heroes*. Forbidding a hero in a tournament $T$ actually results in $T$ being colorable with a constant number of colors [4], which yields a transitive induced subtournament of linear size. These results are existential and do not provide an efficient algorithm to color an $H$-free tournament with a constant number of colors, when $H$ is some fixed hero.

## 1.2 Our Results

We consider some basic algorithmic and computational complexity questions on the subject of coloring tournaments. Our main algorithmic tool, presented in Section 2, is a decomposition lemma which can be used to obtain efficient algorithms for coloring tournaments in various cases when certain conditions are met. On a high level, it bears some resemblance to decompositions previously used to prove bounded dichromatic number in tournaments and in dense digraphs with forbidden subgraphs [4, 20]. To apply our decomposition lemma to 2-colorable tournaments, we use an observation used by [1, 7, 29] which states that

**Table 2** Best known polynomial time inapproximability results and approximation algorithms for various tournament coloring problems. Previous results are indicated with a citation. All the results without a citation are established in this paper. Lower bounds are under the assumption $\mathsf{P} \neq \mathsf{NP}$ except those marked with a $^*$, which hold under the $d$-To-1 Conjecture [26]. The function $g(k)$ denotes the number of colors needed to efficiently color a $k$-colorable graph, while $f(k)$ is the number of colors needed to efficiently color a $k$-colorable tournament. The entry indicated by $^\dagger$ is a hardness of approximation result.

| Tournament Type | Lower Bound | Upper Bound |
|---|---|---|
| 2-Colorable tournaments | 2[8], 3 | 10 |
| 3-Colorable tournaments | 5, $O(1)$ $^*$ | $\tilde{O}(n^{0.19996})$ |
| $k$-Colorable tournaments, $k \geq 2$ | $2k-1$, $O(1)$ $^*$ | $5 \cdot f(k-1) \cdot g(k)$ |
| 2-Colorable light tournaments | in P? | 5 |
| Light tournaments | in P? | 9 |
| General tournaments | $n^{\frac{1}{2}-\epsilon}$ $^\dagger$ | $n/\log n$[13] |

there is an efficient algorithm to partition a 2-colorable tournament into two tournaments that are each light. A *light tournament* is one in which for each arc $uv$, the set of vertices $N(uv) = \{w \mid uvw$ forms a directed triangle$\}$ is transitive. (Let $C_3$ denote a directed triangle. A light tournament is $H$-free where $H$ is the hero $(C_3, 1, 1)$.)

In fact, due to this observation and the fact that [4] showed that light tournaments have constant dichromatic number, it cannot be NP-hard (unless NP= co-NP) to color a 2-colorable tournament with $O(1)$ colors. (This does not however immediately imply that there is an efficient algorithm, since there are many search problems that are believed to be intractable even though their decision variant is easy, e.g., those in the class TFNP.) Although [4] did not provide an efficient algorithm to color a light tournament with a constant number of colors, a careful modification of their techniques indeed results in a polynomial-time algorithm using around 35 colors to color a light tournament.

Like some other lemmas which show that the dichromatic number of a tournament is bounded (i.e., constant) if the out-neighborhoods of vertices have bounded dichromatic number [21], our decomposition lemma also has a local-to-global flavor: If the sets $N(uv)$ can be efficiently colored with few colors for all arcs $uv$ and if there are two vertices $s$ and $t$ such that the out-neighborhood of $s$ and the in-neighborhood of $t$ can be efficiently colored with few colors, then our decomposition lemma yields an efficient algorithm to color the whole tournament with few colors.

We give applications of our algorithmic decomposition lemma in Section 3. Specifically, we show that 2-colorable tournaments can be efficiently colored with ten colors and that light tournaments can be efficiently colored with nine colors. We then use our toolbox to study 3-colorable tournaments. Here we show that the problem of coloring a 3-colorable tournament has a constant-factor reduction to the problem of coloring 3-colorable graphs.

Next, we strengthen the lower bounds by showing in Section 4 that it is NP-hard to color a 2-colorable tournament with three colors. We then give a reduction from coloring graphs to coloring tournaments, which implies, for example, that it is hard to color 3-colorable tournaments with $O(1)$ colors under the $d$-To-1 Conjecture of Khot [26]. Finally, we show that it is NP-hard to approximate the number of colors required for a general tournament to within a factor of $O(n^{1/2-\epsilon})$ for any $\epsilon > 0$. Our results are summarized in Table 2.

## 1.3 Notation and Preliminaries

Let $T = (V, A)$ be a tournament with vertex set $V$ and arc set $A$. Sometimes, we use $V(T)$ to denote its vertex set and $A(T)$ to denote its arc set. For $S \subset V$, we use $T[S]$ to denote the subtournament induced on vertex set $S$, although we sometimes abuse notation and refer to the subtournament itself as $S$. We define $uv \in A$ to be an arc directed from $u$ to $v$. We define $N^+(v)$ to be all $w \in V$ such that arc $vw \in A$ and $N^-(v)$ to be all $w \in V$ such that arc $wv \in A$. We let $N^+[v] = N^+(v) \cup \{v\}$ and $N^-[v] = N^-(v) \cup \{v\}$. For $S \subset V$, we define $N^+(S) = \bigcup_{v \in S} N^+(v)$, and we define $N^-(S), N^+[S], N^-[S]$ analogously. We use $N^{\pm}(S)$ to denote vertices in $V \setminus S$ that have at least one in-neighbor and at least one out-neighbor in $S$. Sometimes we refer to $N^{\pm}(S)$ of a set as its *mixed neighborhood*.

For $S, U \subset V$ such that $S \cap U = \emptyset$, we use $S \Rightarrow U$ to indicate that all arcs between $S$ and $U$ are directed from $S$ to $U$. Let $C_3$ denote a directed triangle; usually, we refer to this simply as a triangle. Define $N(uv) \subset V$ to contain all vertices $w$ such that $uvw$ forms the directed triangle consisting of arcs $uv, vw$ and $wu$. In other words, $N(uv) = N^-(u) \cap N^+(v)$. For three tournaments $T_1, T_2$ and $T_3$, we use $\Delta(T_1, T_2, T_3)$ to denote the tournament resulting from adding all arcs from $T_1$ to $T_2$, all arcs from $T_2$ to $T_3$ and all arcs from $T_3$ to $T_1$.

A tournament $T = (V, A)$ is *$k$-colorable* if there is a partition of $V$ into $k$ vertex-disjoint sets, $V_1, V_2, \ldots, V_k$, such that $T[V_i]$ is transitive for all $i \in \{1, \ldots, k\}$. We use $\vec{\chi}(T)$ to denote the *dichromatic number* of $T$ (i.e., the minimum number of transitive subtournaments into which $V(T)$ can be partitioned). Computing the value $\vec{\chi}(T)$ is in general NP-hard [8]. We therefore use $\vec{\chi}_{\mathcal{C}}(T)$ to denote the number of colors by which $T$ can be efficiently colored. Our goal is to find upper and lower bounds on $\vec{\chi}_{\mathcal{C}}(T)$.

We remark that we will always assume that a tournament $T$ which we want to color is strongly connected; if this were not the case, we can color each strongly connected component separately. Therefore, each vertex has an out-neighborhood containing at least one vertex.

## 2 Efficient Tournament Decomposition for Coloring

We present a decomposition for a tournament that can be computed in polynomial time and yields an efficient method to color a tournament tournaments with few colors in certain cases.

▶ **Definition 1.** *We define a* $c$-vertex chain $(v_i)_{0 \le i \le k}$ *of a tournament* $T$ *the following way: Let* $v_0$ *and* $v_k$ *be a pair of vertices such that* $\vec{\chi}_{\mathcal{C}}(N^+(v_0) \cup N^-(v_k)) \le c$*, and let* $(v_i)_{0 \le i \le k}$ *be the vertices in the shortest directed path from* $v_0$ *to* $v_k$*.*

Additionally, we define an *arc chain* $(e_i)_{1 \le i \le k}$ corresponding to a vertex chain, where $e_i$ is the arc from $v_{i-1}$ to $v_i$. The main idea behind this decomposition is to build zones that can be efficiently colored, and such that all arcs between zones at distance more than four (i.e., *long* arcs) go backwards.

▶ **Definition 2.** *Given a* $c$*-vertex chain, a* path decomposition *of a tournament* $T$ *is defined as:*

- $D_0 = N^+(v_0)$.
- *For* $1 \le i \le k$, $D_i = N(e_i) \setminus (\cup_{0 \le j \le i-1} D_j)$.
- $D_{k+1} = N^-(v_k) \setminus (\cup_{0 \le j \le k} D_j)$.

First we prove that this is indeed a decomposition of $T$.

▶ **Lemma 3.** *Let* $T = (V, A)$ *be a tournament and let* $(D_0, \ldots, D_{k+1})$ *be a path decomposition of* $T$*. Then* $V = \cup_{0 \le i \le k+1} D_i$.

**Proof.** We will prove this lemma by contradiction: Suppose there is a vertex $w \in V$ that does not belong to any $D_i$. Assume that $w$ does not belong to the vertex chain. Since $w$ is neither in $D_0$ nor in $D_{k+1}$, then $w \in N^-(v_0)$ and $w \in N^+(v_k)$. Take the smallest integer $i$ such that $w \in N^+(v_i)$. There must be one since $w \in N^+(v_k)$. Notice that $i \geq 1$ since $w \notin N^+(v_0)$, so $e_i$ belongs to the arc chain and $w \in N(e_i)$. Therefore, $w \in D_i$, which is a contradiction.

Now consider the case in which $w$ is in the vertex chain. An arc with both endpoints in the vertex chain that is not in the arc chain is backwards. Thus, $v_i \in N(e_{i+2})$ for all $0 \leq i \leq k-2$. Notice that $v_{k-1}$ can belong to $D_{k+1}$ (if it does not belong to $D_j$ for some $j < k+1$). Finally, $v_k \in N(e_{k-1})$. ◀

We remark that, for the sake of simplicity and to more easily visualize the decomposition, it might be easier to not include the vertices in the vertex chain in the path decomposition. In this case, these vertices can be colored with two extra colors. Since all arcs not in the arc chain with both endpoints in the vertex chain go backwards (with respect to the arc chain; otherwise there would be an even shorter path), we can use two colors so that all forwards arcs (those in the arc chain) are bicolored.

▶ **Lemma 4.** *Let $0 \leq i, j \leq k+1$ and let $j \geq i+5$. For $u \in D_i$ and $w \in D_j$, we have $u \in N^+(w)$.*

**Proof.** We will prove this by contradiction. Suppose $j \geq i+5$ and $u \in N^-(w)$. Then there is a path of three arcs from $v_i$ to $v_{j-1}$, namely $(v_i, u, w, v_{j-1})$. (By definition of the decomposition, $u \in D_i$ implies $u \in N^+(v_i)$ and $w \in D_j$ implies $w \in N^-(v_{j-1})$.) This is not possible since by the definition of the vertex chain as the shortest path, there can be no path between $v_i$ and $v_{j-1}$ with fewer than four arcs (since $(j-1)-i \geq (i+5-1)-i = 4$). ◀

▶ **Lemma 5.** *If $T$ has a $c$-vertex chain that can be found in polynomial time and if $\vec{\chi}_{\mathcal{C}}(N(e)) \leq c$ for each arc $e$ in the corresponding arc chain, then $\vec{\chi}_{\mathcal{C}}(T) \leq 5c$.*

**Proof.** Given a $c$-vertex chain, we construct a path decomposition. We make five palettes of $c$ colors each with labels from 0 to 4. We color each $D_i$ using the color palette with label $i$ mod 5. Let us show that we can do this in polynomial time. First, note that the set of colors used is of size $c$ for every $D_i$. Then, let us consider $D_0$: $N^+(v_0)$ can be colored efficiently with $c$ colors by definition of a vertex chain. Similarly, $D_{k+1}$ is a subset of $N^-(v_k)$ and can thus also be efficiently colored with $c$ colors. Finally, for every $1 \leq i \leq k$, $D_i$ is a subset of $N(e_i)$, which can be colored efficiently with $c$ colors by the condition of the lemma.

Our goal is now to prove that this is a proper coloring of $T$. We will do this by showing that all forward arcs between different $D_i$ are bicolored. By Lemma 4, there are no forwards arcs between $D_i$ and $D_j$ when $j \geq i+5$. Furthermore, by the definition of the coloring, no vertex in $D_i$ and $D_j$ can share a color for $i+1 \leq j \leq i+4$. Thus all forward arcs from $D_i$ to $D_j$ will be bicolored. Since every $D_i$ is properly colored, and all forward arcs between different $D_i$ are bicolored, $T$ is properly colored. ◀

The next lemma has essentially the same proof as Lemma 5.

▶ **Lemma 6.** *If $T$ has a $c$-vertex chain that can be found in polynomial time and if $\vec{\chi}_{\mathcal{C}}(N(e)) \leq d$ for each arc $e$ in the arc chain and if $c > d$, then $\vec{\chi}_{\mathcal{C}}(T) \leq c + 4d$.*

**Proof.** We find the path decomposition using the $c$-vertex chain. We can color the set $S = D_0 \cup D_{k+1}$ with $c$ colors and the remaining sets $D_i$ for $1 \leq i \leq k$ with $d$ colors each. For the last $c-d$ of the colors used for $S$, we can remove these vertices from $S$ since these

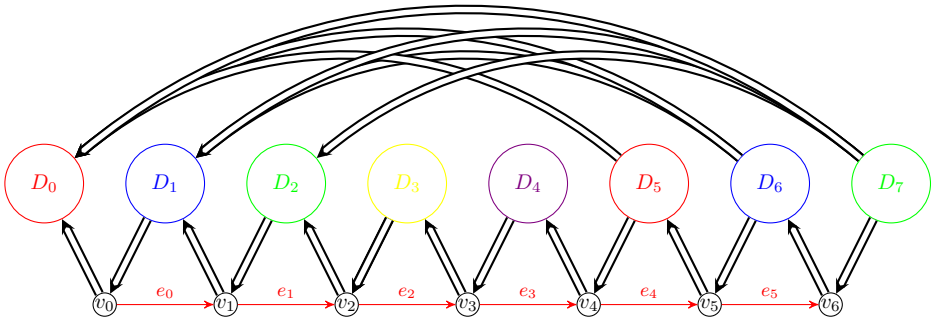

**Figure 1** A path decomposition of $T$. The red arcs $(e_i)$ form a shortest path from $v_0$ to $v_k$, thus all the arcs not depicted between the $v_i$'s go backward. All the vertices in a given $D_i$ are colored from the color palette indicated by the color of the $D_i$. Notice that because there are no long forward arcs between the $D_i$'s, all arcs between $D_i$'s that share a color palette are backwards.

colors will not be used again and call the remaining vertices in $S$ (colored with the first $d$ colors) $S'$. For the remaining vertices in $S$, we decompose them into $D_0 := D_0 \cap S'$ and $D_{k+1} := D_{k+1} \cap S'$ Now we have sets $D_0, D_1, \ldots, D_{k+1}$ each colored with $d$ colors. We color these sets using five color palettes of $d$ colors each and use the palette $i \bmod 5$ for set $D_i$. By Lemma 4, this does not create any monochromatic forward arcs. Thus, the total number of colors used is $(c-d)+5d = c+4d$. ◀

## 3 Algorithms for Coloring Tournaments

We consider various special cases of tournaments and show how to use our tools to color them with few colors.

### 3.1 2-Colorable Tournaments

A tournament $T = (V, A)$ is *2-colorable* if $\vec{\chi}(T) = 2$, and a 2-coloring of tournament $T$ is a partition of $V$ into two vertex sets, $V_1$ and $V_2$, such that $T[V_1]$ and $T[V_2]$ are each transitive. In this section, our goal is to prove Theorem 7.

▶ **Theorem 7.** *Let $T$ be a 2-colorable tournament. Then $\vec{\chi}_C(T) \leq 10$.*

We say an arc $uv$ in $A$ is *heavy* if there exist three vertices $a, b, c \in N(uv)$ which form a triangle $abc$. If a tournament contains no heavy arcs, then it is *light*. We will use the following observation.

▶ **Observation 8.** *Let $T$ be a 2-colorable tournament. Then $T$ can be partitioned into two light subtournaments $T_1$ and $T_2$ such that $\vec{\chi}_C(T) \leq \vec{\chi}_C(T_1) + \vec{\chi}_C(T_2)$.*

This observation appears in [1, 7, 29] where it is stated more generally for 2-colorable 3-uniform hypergraphs. We include a proof here for completeness.

▶ **Lemma 9.** *In a 2-coloring of a tournament $T$, each heavy arc must be 2-colored.*

**Proof.** If $u$ and $v$ are both, say, blue, then each vertex in $N(uv)$ would be red, forcing a triangle in $N(uv)$ to be all red (i.e., monochromatic), which is not possible in a 2-coloring. ◀

▶ **Corollary 10.** *In a 2-colorable tournament, the heavy arcs form a bipartite graph.*

Now we can prove Observation 8.

**Proof of Observation 8.** All heavy arcs can be easily detected. By Corollary 10, the set of heavy arcs forms a bipartite graph. The vertex set of this bipartite graph can be colored with two colors (red and blue), such that the tournament induced by each color does not contain a heavy arc. Then we partition the vertices into two sets one containing all the blue vertices and the other containing all the red vertices. The uncolored vertices can go in either set. Since neither of these sets contains any heavy arcs, we can partition the vertices of a 2-colorable tournament into two light subtournaments. ◀

Theorem 7 will follow from Observation 8 and the following theorem.

▶ **Theorem 11.** *Let $T$ be a 2-colorable light tournament. Then $\vec{\chi}_C(T) \leq 5$.*

Our goal it to use Lemma 5 to prove Theorem 11. In other words, we want to show that a 2-colorable light tournament has a 1-vertex chain. We first prove a useful claim.

▶ **Lemma 12.** *Let $T$ be a $k$-colorable tournament. Then there exist vertices $u$ and $w$ such that $N^+(u) \cup N^-(w)$ is $(k-1)$-colorable.*

**Proof.** Since $T = (V, A)$ is $k$-colorable, there exist $k$ transitive sets $X_1, \ldots, X_k$ such that $V = \cup_{i=1}^{k} X_i$. Then take $u$ to be the vertex in $X_1$ that has only incoming arcs from other vertices in $X_1$ (i.e., the sink vertex for $X_1$). Similarly, take $w$ to be the vertex in $X_1$ that has only outgoing arcs to other vertices in $X_1$ (i.e., the source vertex for $X_1$). The out-neighborhood of $u$ and the in-neighborhood of $w$ are both subsets of $V \setminus X_1$, and thus so is their union, which is therefore $(k-1)$-colorable. ◀

Now we are ready to prove that we can find a 1-vertex chain.

▶ **Lemma 13.** *Let $T$ be a 2-colorable, light tournament. Then $T$ contains a 1-vertex chain that can be found in polynomial time.*

**Proof.** By Lemma 12, there exist $u$ and $w$ such that $N^+(u) \cup N^-(w)$ is transitive. To find them, we can test the transitivity of $N^+(u) \cup N^-(w)$ for every pair of vertices in $T$. Then we simply need to find a shortest path from $u$ to $w$, which can be done in polynomial time. Let $k$ denote the length of the path, and define $v_0 = u$, $v_k = w$, and $(v_i)_{1 \leq i \leq k-1}$ the rest of the vertices in the path. ◀

The proof of Theorem 11 follows from Lemma 13, Lemma 5 and the fact that $\vec{\chi}_C(N(e)) \leq 1$ for every arc $e$ in a light tournament.

## Certificates of Non-2-Colorability

In Section 3.1, we presented an algorithm to color a 2-colorable tournament with ten colors. Suppose we run this algorithm on an arbitrary tournament $T$ (e.g., one that is *not* 2-colorable). Then our algorithm will either color $T$ with ten colors or it will produce at least one certificate that $T$ is not 2-colorable. A certificate will have the following form: either a) there is an odd cycle of heavy arcs in $T$, or b) for every ordered pair of vertices $(u, v)$, the subtournament $T[N^+(u) \cup N^-(v)]$ is not transitive. In particular, an 11-chromatic tournament must contain such a certificate.

## 3.2 3-Colorable Tournaments

Coloring 3-colorable tournaments turns out to be closely related to coloring 3-colorable graphs. This seems surprising since the techniques for 3-colorable graphs were applied to coloring 2-colorable 3-uniform hypergraphs, which are a generalization of 2-colorable tournaments.

We will first show that we can adapt ideas of [34] and [5] to the problem of coloring 3-colorable tournaments by using our algorithm for coloring 2-colorable tournaments with ten colors as a subroutine.

▶ **Lemma 14.** *A 3-colorable tournament can be colored with $O(\sqrt{n})$ colors in polynomial time.*

**Proof.** Let $T = (V, A)$ be a 3-colorable tournament. Notice that $T$ has at least three vertices each of whose out-neighborhoods is 2-colorable. To see this, consider any proper 3-coloring of $T$. Each color spans a transitive subtournament and each transitive subtournament has a sink vertex that has outgoing arcs only towards the other two colors.

For any vertex, if its out-neighborhood is 2-colorable, we can color its out-neighborhood with 10 colors by Theorem 7. So we can try to run the algorithm for the out-neighborhood of every vertex, and the algorithm will successfully produce a 10-coloring of the out-neighborhood of at least three vertices.

Therefore, if the minimum outdegree is at least $\sqrt{n}$, we find a transitive set of size at least $\sqrt{n}/10$. On the other hand, if the minimum outdegree is smaller than $\sqrt{n}$, we will make progress another way. In this case, let $u$ be a vertex with outdegree smaller than $\sqrt{n}$. Then, we add $u$ to a set $S$, and continue the algorithm on the subtournament of $T$ induced on $V \setminus N^+[u]$. We continue this until we find a transitive subtournament of size at least $\sqrt{n}/20$ or until we have removed half the vertices. In the first case, we will have found a transitive set of size $\Omega(\sqrt{n})$, and in the second case, the set $S$ will be transitive, and also of size $\Omega(\sqrt{n})$.

In conclusion, since we can find a transitive set of size $\Omega(\sqrt{n})$ in polynomial time, we can repeat the procedure recursively to find a coloring with $O(\sqrt{n})$ colors in polynomial time (see [5] for example). ◀

We can also use the decomposition of Section 2 to get a coloring with fewer colors based on a reduction to coloring 3-colorable graphs.

▶ **Theorem 15.** *If we can efficiently color a 3-colorable graph $G$ with $k$ colors, then we can efficiently color a 3-colorable tournament with $50k$ colors.*

**Proof.** Let $T = (V, A)$ be a 3-colorable tournament. For every arc $e \in A$, try coloring $N(e)$ with 10 colors using Theorem 7. If the algorithm fails, the neighborhood of the edge is not 2-colorable, and thus the edge is not monochromatic in any 3-coloring. Let $F \subset E$ denote the set of arcs whose neighborhoods cannot be colored with 10 colors using our algorithm. Ignore the direction of the arcs in $F$ and consider the graph $G = (V, F)$. This graph must be 3-colorable, since no arc in $F$ is monochromatic in any 3-coloring of $T$.

Now let us show that from a coloring of $G$ with $k$ colors, we can obtain a coloring of $T$ with $50k$ colors. Consider a coloring of the graph $G = (V, F)$ and let $V_i$ be the vertices colored with color $i$ in this coloring. Consider the induced subtournament $T' = T[V_i]$; it has no arc in $F$ and thus the neighborhood of every arc in this tournament can be colored efficiently with 10 colors. Furthermore, by Lemma 12 and Theorem 7, there are vertices $u$ and $v$ in $T'$ such that $N^+_{T'}(u) \cup N^-_{T'}(v)$ is efficiently 10-colorable. So by Lemma 5, we can efficiently color $T'$ with 50 colors. We can do this for the subtournament $T[V_i]$ for each of the $i$ colors used to color $G$. ◀

Combining this Lemma with approximation algorithm [24], which colors a 3-colorable graph with fewer than $n^{\frac{1}{5}}$ colors, we obtain the same asymptotic bound for 3-colorable tournaments.

▶ **Corollary 16.** *Let $T$ be a 3-colorable tournament on $n$ vertices. Then, $\vec{\chi}_{\mathcal{C}}(T) \leq O(n^{0.19996})$.*

We can extend Theorem 15 to a more general case.

▶ **Lemma 17.** *Let $f$ and $g$ be functions such that we can efficiently color $k$-colorable graphs (respectively, $k$-colorable tournaments) with $g(k)$ (respectively, $f(k)$) colors. Then $f(k) \leq 5 \cdot f(k-1) \cdot g(k)$.*

**Proof.** We use the same reduction as in the proof of Theorem 15, but now $F$ is the set of arcs whose neighborhoods cannot be efficiently $f(k-1)$-colored. Then each $V_i$ in $G$ is colored with $5 \cdot f(k-1)$ colors. So we need a total of $5 \cdot f(k-1) \cdot g(k)$ colors. ◀

## 3.3 Light Tournaments

Our goal in this section is to prove the following theorem.

▶ **Theorem 18.** *Let $T$ be a light tournament. Then $\vec{\chi}_{\mathcal{C}}(T) \leq 9$.*

We will prove Theorem 18 by showing that every light tournament has a $c$-vertex chain for some constant $c$. To do this, we will find one vertex whose in-neighborhood we can color efficiently with a constant number of colors, and another whose out-neighborhood we can color efficiently with a constant number of colors. We will start by establishing some structural claims about light tournaments which are adapted from [4].

Throughout this section $T = (V, A)$ will denote a light tournament. Note that we do not assume that $T$ is necessarily 2-colorable. Recall that a $C_3$ is a directed triangle.

▶ **Definition 19.** *Define a* $C_3$-chain *of length $\ell$ in $T$ to be a set of $\ell$ vertex disjoint $C_3$'s, $X = (X_1, X_2, X_3, \ldots, X_\ell)$, such that for each $i \in \{1, \ldots, \ell - 1\}$, $X_i \Rightarrow X_{i+1}$.*

A *backwards arc* in a $C_3$-chain is an arc $uv$ with $u \in X_i$ and $v \in X_j$ for $j < i$.

▶ **Lemma 20.** *A $C_3$-chain has no backwards arcs.*

This follows from the following claim.

▷ Claim 21. If $X = (X_1, X_2, \ldots, X_\ell)$ is a $C_3$-chain of length $\ell$, then $X_i \Rightarrow X_j$ for $i < j$, where $1 \leq i < j \leq \ell$.

Proof. Notice that there are no arcs from $X_{i+1}$ to $X_i$, since by definition of a $C_3$-chain, we have all arcs from $X_i$ to $X_{i+1}$. Moreover, there is no arc $uv$ from $X_{i+2}$ to $X_i$ since otherwise triangle $X_{i+1}$ would appear in the neighborhood $N(uv)$, meaning that $uv$ is heavy, which is a contradiction. This implies that all arcs go from $X_i$ to $X_{i+2}$ (since $T$ is a tournament). Now suppose $j > i + 2$. If there is a back arc $uv$ from $u \in X_j$ to $v \in X_i$, then $uv$ is a heavy arc, because $X_{j-1}$ would be in $N(uv)$ since by induction we have all arcs from $X_i$ to $X_{j-1}$ and from $X_{j-1}$ to $X_j$. ◁

Let us fix $X = (X_1, X_2, \ldots, X_\ell)$ to be a $C_3$-chain in $T$, and let $W = V(T) \setminus V(X)$. Initially, $X$ can be of any length $\ell \geq 1$.

▷ Claim 22. For $w \in W$:
1. If $w \Rightarrow X_i$, then $w \Rightarrow X_j$ for all $j \geq i$.
2. If $X_i \Rightarrow w$, then $X_j \Rightarrow w$ for all $j \leq i$.

Proof. Suppose $w \Rightarrow X_i$ and there is an arc $uw$ with $u \in X_j$ for $j > i$. Then $uw$ is a heavy arc. Similarly, suppose $X_i \Rightarrow w$ and there is an arc $wu$ with $u \in X_j$ for $j < i$, then $wu$ is a heavy arc. ◁

We partition the vertices in $W$ into zones $(Z_0, Z_1, \ldots, Z_\ell)$ using the following criteria. For $w \in W$, if $i$ is the highest index such that $X_i \Rightarrow w$, then $w$ is assigned to zone $Z_i$. If there is no such $X_i$, then $w$ is assigned to zone $Z_0$.

Say a vertex $w \in W$ is *clear* if $w \Rightarrow X_i$ or $X_i \Rightarrow w$ for all $X_i$ in $H$. Let $C \subseteq W$ be the set of clear vertices.

▷ Claim 23. If $C$ is not transitive, we can extend $X$.

Proof. If the set $Z_i \cap C$ contains a triangle, then we can extend $X$ by adding a new triangle to the chain between $X_i$ and $X_{i+1}$.

If there is no $i$ such that $Z_i \cap C$ contains a triangle, then we claim that $C$ is transitive. This follows from the observation that there are no backwards arcs from $Z_j \cap C$ to $Z_i \cap C$ for $i < j$. Indeed, should such an arc $uv$ from $Z_j \cap C$ to $Z_i \cap C$ exist, then $X_{i+1} \subset N(uv)$, so $uv$ would be heavy. ◁

We say that $X$ is a *maximal $C_3$-chain* if $C$ is transitive. Let us also now define the *unclear* vertices $U$, where $U = W \setminus C$. In a maximal $C_3$-chain $X = (X_1, \ldots, X_\ell)$, notice that for a vertex $a \in X_1$, we have $N^-(a) \cap U \subseteq N^\pm(X_1)$. (This is because if a vertex $u \in N^-(a)$ has $u \Rightarrow X_i$, then $u$ would be a clear vertex.)

▷ Claim 24. We can efficiently find two directed triangles $X_1 = abc$ and $X_\ell = xyz$ such that the set $S = \{v \mid v \Rightarrow X_1 \text{ or } X_\ell \Rightarrow v\}$ is transitive.

Proof. Find a maximal $C_3$-chain $X$ and let $\ell$ be the length of this chain. Let $abc = X_1$ and $xyz = X_\ell$. The set of vertices $\{v \mid v \Rightarrow X_1 \text{ or } X_\ell \Rightarrow v\}$ is a subset of $C$ and is therefore transitive. ◁

▷ Claim 25. Let $xyz$ be a directed triangle. Then $\vec{\chi}_{\mathcal{C}}(N^\pm(\{x, y, z\})) \leq 3$.

Proof. Each vertex $v \in N^\pm(\{x, y, z\})$ belongs to $N(xy), N(yz)$ or $N(zx)$. Since each of these sets is transitive, we conclude that $N^\pm(\{x, y, z\})$ can be colored with three colors. ◁

We can now easily prove Theorem 18, which is a corollary of Lemma 6 and the following lemma.

▶ **Lemma 26.** *Let $T$ be a light tournament. Then $T$ has a 5-vertex chain.*

**Proof.** Recall that for a vertex $a \in X_1$, we have $N^-(a) \cap U \subseteq N^\pm(X_1)$. If $X_1 = abc$, notice that for $v \in N^-(a) \cap U$, $v \notin N(ca)$. Thus, $N^-(a) \cap U \subseteq N(ab) \cup N(bc)$, which is efficiently 2-colorable. Making an analogous argument for $N^+(z) \cap U$, we conclude that $(N^+(z) \cup N^-(a)) \cap U$ is efficiently 4-colorable. The rest of the vertices in $N^+(z) \cup N^-(a)$ belong to the set $S$ defined in Claim 24 and can be colored with one color. Therefore $\vec{\chi}_{\mathcal{C}}(N^+(z) \cup N^-(a)) \leq 5$, so we can use $z$ and $a$ as the endpoints of a 5-vertex chain. ◀

The approach in this section can be extended to bound the chromatic number of a more general subclass of heroes. See the full version [28] for details.

# 4 Hardness of Approximate Coloring in Tournaments

In this section, we examine the hardness of approximate coloring of tournaments. [8] showed that deciding if a tournament can be 2-colored is NP-hard. Later, [15] proved that for any $k$, it is NP-hard to decide if a tournament is $k$-colorable.

We will first improve upon these NP-hardness results and then show hardness of coloring $k$-colorable tournaments for $k \geq 3$ with $O(1)$ colors under the $d$-To-1 conjecture. The $d$-To-1 conjecture was first introduced by Khot alongside the famous Unique Games conjecture [26], and has since been used to show hardness of coloring 3-colorable graphs with $O(1)$ colors [18].

First notice that the search problem must be at least as hard as its decisional equivalent.

▶ **Observation 27.** *Let $k < \ell$ be any two constants. If we can color $k$-colorable tournaments with $\ell$ colors, then we can distinguish $k$-colorable tournaments from tournaments with chromatic number at least $\ell + 1$.*

This comes immediately from the fact that if we could $\ell$-color all $k$-colorable tournaments, then we could see that they do not have chromatic number $\ell + 1$ or greater. The hardness of distinguishing between chromatic number $k$ and greater or equal to $\ell + 1$ is therefore commonly established as a way of implying the hardness of coloring $k$-colorable graphs with $\ell$ colors (see for example [6]).

All proofs of the theorems in this section are provided in the full version [28].

## 4.1 NP-Hardness of Approximate Coloring of $k$-Colorable Tournaments

It was shown previously that it is NP-hard to color a 2-colorable tournament with 2 colors [8, 15]. We prove a stronger theorem, that it is NP-hard to 3-color a 2-colorable tournament.

▶ **Theorem 28.** *It is NP-hard, given a tournament $T$, to distinguish whether $\vec{\chi}(T) = 2$ or $\vec{\chi}(T) \geq 4$.*

The proof of this Theorem relies on a reduction from the problem of coloring 2-colorable tournaments with three colors to the problem of coloring 2-colorable 3-uniform hypergraphs with six colors. This problem is NP-hard, since it was proven that coloring 2-colorable 3-uniform hypergraphs with any constant number of colors is NP-hard [11].

We then use a recursive construction that starts with the tournament obtained in the proof of Theorem 28 to generalize the hardness of approximation to $k$-colorable tournaments for any constant $k$.

▶ **Theorem 29.** *It is NP-hard, given a tournament $T$ and a constant $k$, to distinguish whether $\vec{\chi}(T) = k$ or $\vec{\chi}(T) \geq 2k$.*

## 4.2 Reduction from Coloring Graphs to Coloring Tournaments

In Section 3.2, we showed that if we can color a 3-colorable graph with $k$ colors, then we can color a 3-colorable tournament with $50k$ colors. We give a reduction in the other direction: We show that the problem of coloring a $k$-colorable graph with $\ell$ colors is reducible to the problem of coloring a $k$-colorable tournament with $\ell$ colors.

▶ **Theorem 30.** *Given any two constants $k, \ell \geq 3$, if we can efficiently distinguish $k$-colorable tournaments and tournaments with chromatic number at least $\ell$, then we can efficiently distinguish $k$-colorable graphs and graphs with chromatic number at least $\ell$.*

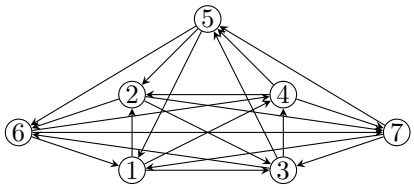

**Figure 2** 3-chromatic light tournament.

A corollary of this reduction is the hardness of coloring tournaments under the $d$-To-1 Conjecture of Khot [26]; [18] showed that assuming the $d$-To-1 Conjecture, it is hard to color 3-colorable graphs with $O(1)$ colors, and using our reduction, we can extend this hardness to tournaments.

▶ **Corollary 31.** *Let $3 \leq k < \ell$ be any two constants. Then if the $d$-To-1 conjecture is true, we cannot distinguish between tournaments with chromatic number $k$ and tournaments with chromatic number at least $\ell$.*

## 4.3 Hardness of Approximation for General Tournaments

Coloring digon-free digraphs has been shown to be NP-hard to approximate within a factor of $n^{1/2-\epsilon}$ [14]. This proof can easily be extended to the case of tournaments, which provides the following theorem.

▶ **Theorem 32.** *Given any arbitrarily small constant $\epsilon > 0$, it is NP-hard to approximate the chromatic number of tournaments within a factor of $n^{1/2-\epsilon}$.*

# 5 Conclusion

There are many open questions related to the theorems we have presented since all the rows in Table 2 present gaps between the upper and lower bounds. One example is light tournaments: What is the maximum number of colors required to color a light tournament? From Theorem 18, we know that light tournaments have dichromatic number at most 9. On the other hand, there exist light tournaments that are not 2-colorable. An example of such a tournament is the Paley tournament $P_7$, one of the four 3-chromatic tournaments on seven vertices [33]. This tournament is represented in Figure 2. We have not found any light tournament with chromatic number at least four. The Paley tournament $P_{11}$ is the unique 4-chromatic tournament on 11 vertices [33]. A light 4-chromatic tournament would have to have at least 13 vertices as [3] proved that any 4-chromatic tournament on 12 vertices must contain an induced copy of $P_{11}$ and $P_{11}$ is not light.

Moreover, notice that if we could show that it is hard to color a 2-colorable tournament with four colors (rather than three as per Theorem 28), this would imply hardness of coloring a 2-colorable light tournament with two colors by Observation 8. Indeed, we have no hardness results for coloring light tournaments. Any upper bound of $c$ on their dichromatic number would imply that it cannot be NP-hard to color them with $c$ colors, because the property of being light is checkable in polynomial time (unlike the property of being, say, 2-colorable).

Another observation is the relation of coloring tournaments and the feedback vertex set (FVS) problem on tournaments. There is an elegant 2-approximation for this problem [30]. Notice that Theorem 7 implies that in a 2-colorable tournament, we can efficiently find a FVS of size at most $9n/10$. In contrast, the algorithm in [30] could just return the whole vertex set

if the two transitive sets were of roughly equal size. Finally, we mention that, analogous to a well-studied question for general graphs [10, 27], one can ask what is the largest transitive induced subtournament that one can efficiently find in a 2-colorable tournament? Is it larger than $n/10$?

Finally, we remark that an implication of Theorem 15 is that proving any hardness of coloring 3-colorable tournaments would then provide hardness of coloring 3-colorable graphs with 50 times fewer colors. Since it has taken around 20 years to go from proving NP-hardness of coloring a 3-colorable graph with four colors [25, 16, 17] to NP-hardness of coloring a 3-colorable graph with five colors [6], it would be interesting to see if we can prove hardness of coloring 3-colorable tournaments for a constant larger than five (at least five is shown in Theorem 29), or perhaps show that the two problems are actually equivalent.

# Bellman–Ford Is Optimal for Shortest Hop-Bounded Paths

## Abstract

This paper is about the problem of finding a shortest $s$-$t$ path using at most $h$ edges in edge-weighted graphs. The Bellman–Ford algorithm solves this problem in $O(hm)$ time, where $m$ is the number of edges. We show that this running time is optimal, up to subpolynomial factors, under popular fine-grained complexity assumptions.

More specifically, we show that under the APSP Hypothesis the problem cannot be solved faster already in undirected graphs with nonnegative edge weights. This lower bound holds even restricted to graphs of arbitrary density and for arbitrary $h \in O(\sqrt{m})$. Moreover, under a stronger assumption, namely the Min-Plus Convolution Hypothesis, we can eliminate the restriction $h \in O(\sqrt{m})$. In other words, the $O(hm)$ bound is tight for the entire space of parameters $h$, $m$, and $n$, where $n$ is the number of nodes.

Our lower bounds can be contrasted with the recent near-linear time algorithm for the negative-weight Single-Source Shortest Paths problem, which is the textbook application of the Bellman–Ford algorithm.

## 1 Introduction

The Bellman–Ford algorithm [24, 14, 4] is the textbook solution for the Single-Source Shortest Paths (SSSP) problem in graphs with negative edge weights. It runs in $O(nm)$ time, where $n$ denotes the number of nodes and $m$ is the number of edges. If we limit the outer for-loop (see Algorithm 1) to only $h \leqslant n-1$ iterations, the algorithm computes single-source shortest paths that use at most $h$ edges (or *hops*) and runs in $O(hm)$ time.

**Algorithm 1** The Bellman–Ford algorithm.

$d^{(0)} \leftarrow [+\infty, +\infty, \ldots, +\infty]$;
$d^{(0)}[s] \leftarrow 0$;
**for** $i$ **from** 1 **to** $n-1$ **do**
  $d^{(i)} \leftarrow d^{(i-1)}$;
  **foreach** edge $(u, v) \in E$ **do**
    $d^{(i)}[v] \leftarrow \min\{d^{(i)}[v], d^{(i-1)}[u] + w(u, v)\}$;

Negative-weight SSSP has seen a lot of improvements over Bellman–Ford's running time: scaling algorithms [15, 16, 18], which eventually led to $O(n^{1/2}m \log W)$ running time, where $W$ denotes the maximum absolute value of a negative edge weight; interior-point methods for the more general Minimum-Cost Flow problem, which recently led to an almost-linear $O(m^{1+o(1)} \log W)$ time algorithm [8]; and finally, the recent combinatorial near-linear $O(m \log^8(n) \log W)$ time algorithm [5], subsequently improved to run in $O(m \log^2(n) \log(nW) \log \log n)$ time [7].

*Can we get similar improvements for the problem of finding shortest hop-bounded paths?*

This basic question stays embarrassingly open. Even in undirected graphs with only nonnegative edge weights, Bellman–Ford remains the fastest known algorithm for that problem. In this paper, we give a negative answer to the above question, up to subpolynomial factors, under popular fine-grained complexity assumptions.

## 1.1 Our results

Let us begin with formally stating the computational problem that we study: Given a graph $G = (V, E)$ with edge weights $w : E \to \mathbb{Z}$, two distinguished nodes $s, t \in V$, and a nonnegative integer $h \in \mathbb{Z}_{\geqslant 0}$, find (the length of) a shortest path from $s$ to $t$ that uses at most[1] $h$ edges. We call such paths *$h$-hop-bounded*, or simply *hop-bounded* when $h$ is implicit in the context.

In this paper, we give two fine-grained reductions, each proving that the $O(hm)$ running time of the Bellman–Ford algorithm is conditionally optimal for the problem, up to subpolynomial factors. Our two hardness results differ from each other in (1) how the parameters $n, m, h$ of the hard instances relate to each other, and (2) which hardness assumption is required. Table 1 summarizes these differences.

Our first result holds under the APSP Hypothesis.

▶ **Theorem 1.** *Unless the APSP Hypothesis fails, there is neither an $O(h^{1-\varepsilon}m)$ nor an $O(hm^{1-\varepsilon})$ time algorithm for finding the length of a shortest $h$-hop-bounded $s$-$t$ path in undirected graphs with nonnegative edge weights, for any constant $\varepsilon > 0$.*

*This holds even restricted to instances with density $n = \Theta(\sqrt{m})$ and hop bound $h = \Theta(m^\eta)$ for arbitrarily chosen $\eta \in (0, 1/2]$.*

Although the hard instances in Theorem 1 are dense, one can trivially obtain sparser instances by adding isolated nodes. Indeed, such nodes influence neither the length of a shortest $h$-hop-bounded $s$-$t$ path nor the running time bounds as functions of $h$ and $m$.

▶ **Corollary 2.** *The result of Theorem 1 holds even restricted to instances with density $n = \Theta(m^\nu)$ and hop bound $h = \Theta(m^\eta)$ for arbitrarily chosen $\nu \in [1/2, 1]$ and $\eta \in (0, 1/2]$.*

We remark that it is not very surprising that our reduction from APSP can only produce instances with $h \in O(\sqrt{m})$. The conjectured time complexity of APSP in $n$-node graphs is $n^{3-o(1)} = |\mathsf{input}|^{3/2-o(1)}$. For $h = \Theta(m^\eta)$, the $O(hm)$ time bound is actually $O(|\mathsf{input}|^{1+\eta})$. Fine-grained reductions from problems with smaller complexity to problems with larger complexity are possible (see, e.g., [22]) but rare, and to our best knowledge no such reduction from APSP is known. If Theorem 1 worked for $\eta > 1/2$, this would be the first such example.

[1] We could also consider a variant of the problem asking for a *walk* with *exactly* $h$ edges. It is the harder of the two variants (adding a length-0 self-loop to node $s$ reduces the "at most $h$" variant to the "exactly $h$" variant), and we prove the hardness of the easier one already.

**Table 1** Summary and comparison of our conditional hardness results for the problem of finding (the length of) a shortest hop-bounded path between two nodes.

| | Density | Hops | Hypothesis |
|---|---|---|---|
| Corollary 2 | $n = \Theta(m^\nu)$, $\nu \in [1/2, 1]$ | $h = \Theta(m^\eta)$, $\eta \in (0, 1/2]$ | APSP |
| Corollary 4 | $n = \Theta(m^\nu)$, $\nu \in [1/2, 1]$ | $h = \Theta(m^\eta)$, $\eta \in [1/2, \nu]$ | Min-Plus Convolution |

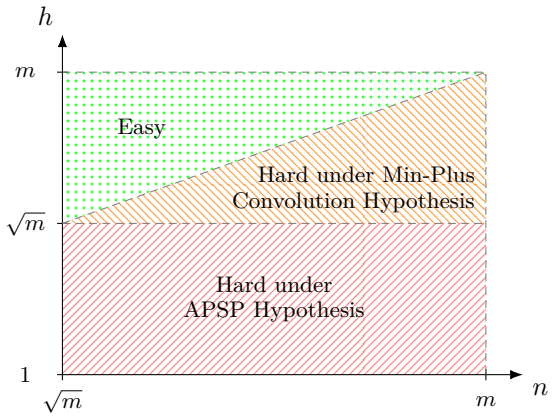

**Figure 1** Parameter space. The upper-left triangle represents the case of $h \geqslant n$, where the problem degenerates to the standard Shortest Path problem, without hop bound, which can be solved in $\tilde{O}(m)$ time.

In order to cover the remaining combinations of parameters, we use a stronger hypothesis, concerning a problem with conjectured quadratic time complexity, namely the Min-Plus Convolution Hypothesis. Since this hypothesis implies the APSP Hypothesis, it is also a sufficient condition for Theorem 1 and thus gives hardness for the entire parameter space.

▶ **Theorem 3.** *Unless the Min-Plus Convolution Hypothesis fails, there is neither an $O(h^{1-\varepsilon}m)$ nor an $O(hm^{1-\varepsilon})$ time algorithm for finding the length of a shortest $h$-hop-bounded $s$-$t$ path problem in undirected graphs with nonnegative edge weights, for any constant $\varepsilon > 0$.*

*This holds even restricted to instances with density $n = \Theta(m^\eta)$ and hop bound $h = \Theta(m^\eta)$ for arbitrarily chosen $\eta \in [1/2, 1]$.*

Just like before, we can sparsify the hard instances by adding isolated nodes.

▶ **Corollary 4.** *The result of Theorem 3 holds even restricted to instances with density $n = \Theta(m^\nu)$ and hop bound $h = \Theta(m^\eta)$ for arbitrarily chosen $\nu \in [1/2, 1]$ and $\eta \in [1/2, \nu]$.*

Combining Corollaries 2 and 4, we cover the entire range of parameters $\nu \in [1/2, 1]$ and $\eta \in (0, \nu]$ for which the $O(hm)$ running time is optimal; see Figure 1.

Let us point out that, even though the Bellman–Ford algorithm finds paths from a single source $s$ to all the nodes in the graph, the above two hardness results hold even for the easier problem of finding a single path between two distinguished nodes $s$ and $t$. Moreover, note that any (shortest path) algorithm for directed graphs could also be used for undirected graphs (but not necessarily vice versa). Bellman–Ford works in directed graphs with possibly negative edge weights, while our hardness results already hold for undirected graphs with nonnegative edge weights.

## 1.2 Hardness assumptions

In this section, we briefly recall the two hypotheses that we use in our theorems.

The APSP Hypothesis is the assertion that the All-Pairs Shortest Paths (APSP) problem in $n$-node graphs cannot be solved in truly subcubic $O(n^{3-\varepsilon})$ time for any constant $\varepsilon > 0$. It is one of the three main hypotheses in fine-grained complexity, the other two being the 3SUM Hypothesis and Strong Exponential Time Hypothesis (SETH) [26]. The APSP Hypothesis is strengthened by the existence of a large class of problems that are equivalent to the APSP problem under subcubic reductions [27, 26], and by the lack of a truly subcubic algorithm for any of these problems.

In the Min-Plus Convolution problem, we are given two sequences $(a[i])_{i=0}^{n-1}$, $(b[i])_{i=0}^{n-1}$, and the goal is to output sequence $(c[i])_{i=0}^{n-1}$ defined as $c[k] = \min_{i+j=k}(a[i] + b[j])$. So far, only subpolynomial $2^{O(\sqrt{\log n})}$-factor improvements [6, 28] over the naive quadratic running time are known. The Min-Plus Convolution Hypothesis [21, 11] states that the problem cannot be solved in truly subquadratic time, that is, $O(n^{2-\varepsilon})$ for any constant $\varepsilon > 0$. Similarly to APSP, there is also a class (albeit smaller) of problems equivalent to Min-Plus Convolution under subquadratic reductions [11].[2]

The two hypotheses are closely related because APSP is runtime-equivalent (up to constant factors) to the Min-Plus Product problem [13], which is the matrix product analogue of Min-Plus Convolution. There is a reduction from the convolution to the product problem [6], which entails that the Min-Plus Convolution Hypothesis implies the APSP Hypothesis, and the former is therefore a stronger assumption.

As is customary in fine-grained complexity, these hypotheses, as well as all the results in this paper, are stated in the word RAM model of computation with $O(\log n)$-bit machine words. We assume all input numbers fit into single machine words. Alternatively, the APSP Hypothesis is sometimes stated as follows [26]: For every $\varepsilon > 0$ there is a constant $c$ such that APSP cannot be solved in $O(N^{3-\varepsilon})$ time in $N$-node graphs with edge weights in $\{-N^c, \ldots, N^c\}$. Our results could also be stated this way because our reductions do not increase weights by more than polynomial factors.

## 1.3 Related work

Hop-bounded paths are studied in various areas related to graph algorithms, e.g., distributed algorithms [17], dynamic algorithms [25, 23], or even polyhedral combinatorics [12]. Problems of finding shortest hop-bounded paths appear, e.g., in the context of quality-of-service (QoS) routing in networks [2, 9].

Guérin and Orda [19] and Cheng and Ansari [10] studied the problem of finding shortest $h$-hop-bounded paths from single source $s$ to all nodes in the graph and for all hop bounds $h \leqslant H$. They proved an $\Omega(Hm)$ lower bound for that problem against so-called *path-comparison-based algorithms*, i.e., algorithms that only access the edge weights by comparing the lengths of two paths. Although Dijkstra and Bellman–Ford are known to be path-comparison-based, algebraic algorithms relying on fast matrix multiplication are not.

[2] One of the problems equivalent to Min-Plus Convolution is the Knapsack problem on instances with target value $t = \Theta(n)$. Recall that Knapsack can be solved in $O(nt)$ time by a dynamic programming algorithm due to Bellman [3]. Hence, we can half-jokingly rephrase Theorem 3 and say that if one Bellman's algorithm is optimal for Knapsack, then the other Bellman's algorithm is optimal for shortest hop-bounded paths.

**Bicriteria Path.** In the Bicriteria Path problem, we are given a graph $G = (V, E)$ with two types of nonnegative edge weights $l, c : E \to \mathbb{Z}$, called *lengths* and *costs*, respectively; two *budgets* $L, C \in \mathbb{Z}$; and two distinguished nodes $s, t \in V$. The goal is to find a path from $s$ to $t$ with the total length at most $L$ and the total cost at most $C$. Joksch's algorithm [20] solves the problem in pseudopolynomial $O(\min(L, C) \cdot m)$ time. For the special case of all edge costs equal to 1, the Bicriteria Path problem is equivalent to the problem we study in this paper and, moreover, Joksch's algorithm runs in the same time as the Bellman–Ford algorithm.

Abboud, Bringmann, Hermelin, and Shabtay [1] proved that, unless SETH fails, there is no algorithm solving the Bicriteria Path problem on sparse graphs (with $m = \Theta(n)$ edges) with budgets $L, C = \Theta(n^\gamma)$ in time $O(n^{1+\gamma-\varepsilon})$ for any $\varepsilon > 0$ and $\gamma > 0$. In other words, they proved that Joksch's algorithm is conditionally optimal, up to subpolynomial factors. Their reduction, however, heavily uses both types of edge weights, and hence it does not imply any lower bound for the special case with unit costs, i.e., for our problem of interest.

## 2 Hardness under APSP Hypothesis

**Preliminaries.** Given a complete tripartite graph $G = (A \cup B \cup C, E)$ with edge weights $w : E \to \mathbb{Z}$, the Negative Triangle problem asks to find three nodes $a \in A$, $b \in B$, and $c \in C$ with $w(a, b) + w(b, c) + w(c, a) < 0$. Vassilevska Williams and Williams [27] proved that APSP and Negative Triangle are equivalent under subcubic reductions. In particular, unless the APSP Hypothesis fails, there is no $O(N^{3-\varepsilon})$ time algorithm for Negative Triangle with $|A| = |B| = |C| = N$, for any $\varepsilon > 0$.

Via a by now standard argument, under the same assumption, for any $\varepsilon > 0$, there is no $O(N^{\alpha+2-\varepsilon})$ time algorithm for the problem restricted to instances with $|A| = \Theta(N^\alpha)$ and $|B| = |C| = N$ for arbitrarily chosen $\alpha \in (0, 1]$. Specifically, the reduction partitions the original set $A$ into $\Theta(N^{1-\alpha})$ subsets of size $\Theta(N^\alpha)$ each; the sets $B$ and $C$ are copied to all $\Theta(N^{1-\alpha})$ produced instances. A negative triangle exists in the original instance if and only if it exists in at least one of the produced instances. Thus, if each of the obtained instances could be solved in $O(N^{\alpha+2-\varepsilon})$ time, then the original instance could be solved in $O(N^{1-\alpha} \cdot (N^2 + N^{\alpha+2-\varepsilon})) = O(N^{3-\alpha} + N^{3-\varepsilon})$ time[3], violating the APSP Hypothesis.

**Reduction.** We show how to reduce an instance of Negative Triangle, with $|A| = \Theta(N^\alpha)$ and $|B| = |C| = N$, to finding the minimum length of an $h$-hop-bounded $s$-$t$ path in an undirected graph with $n = \Theta(N)$ nodes, $m = \Theta(N^2)$ edges, and the hop bound $h = \Theta(N^\alpha)$. In order to prove Theorem 1, we set $\alpha = 2\eta$ so that $n = \Theta(N) = \Theta(\sqrt{m})$ and $h = \Theta(N^\alpha) = \Theta(N^{2\eta}) = \Theta(m^\eta)$. An $O(h^{1-\varepsilon}m)$ time (or $O(hm^{1-\varepsilon})$ time) algorithm finding a shortest $h$-hop-bounded $s$-$t$ path would thus yield an $O(N^{\alpha(1-\varepsilon)+2}) = O(N^{\alpha+2-\alpha\varepsilon})$ time (respectively, $O(N^{\alpha+2-2\varepsilon})$ time) algorithm for the original instance of the Negative Triangle problem. As argued above, no such algorithm exists unless the APSP Hypothesis fails.

Let $P = |A|$. Suppose that $A = \{a_1, \ldots, a_P\}$, $B = \{b_1, \ldots, b_N\}$, and $C = \{c_1, \ldots, c_N\}$. Moreover, let $W$ denote the maximum absolute value of an edge weight. Create an undirected graph (see Figure 2) with node set $A \cup B \cup C \cup \bar{A}$, where $\bar{A} = \{\bar{a}_1, \ldots, \bar{a}_P\}$ is a disjoint copy of $A$.

[3] The $N^2$ term corresponds to the time it takes to construct each instance, which consists of $O(N^2)$ edges.

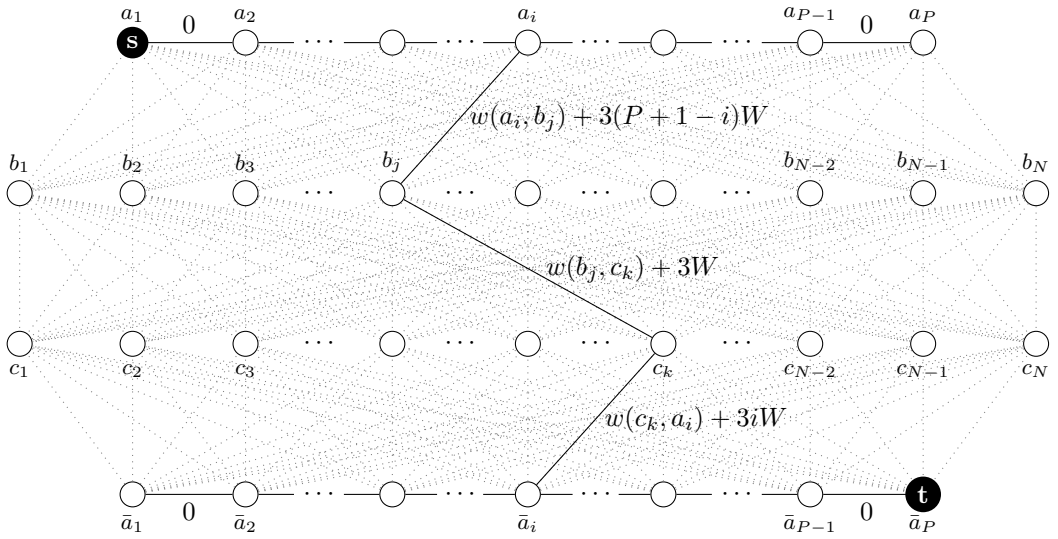

**Figure 2** The graph created in the reduction from Negative Triangle.

- For every $a_i \in A$ and $b_j \in B$, add edge $\{a_i, b_j\}$ with weight $w(a_i, b_j) + 3(P + 1 - i)W$.
- For every $b_j \in B$ and $c_k \in C$, add edge $\{b_j, c_k\}$ with weight $w(b_j, c_k) + 3W$.
- For every $c_k \in C$ and $a_i \in A$, add edge $\{c_k, \bar{a}_i\}$ with weight $w(c_k, a_i) + 3iW$.
- For every $i \in \{1, \ldots, P - 1\}$, add edges $\{a_i, a_{i+1}\}$ and $\{\bar{a}_i, \bar{a}_{i+1}\}$ with weights 0.

Consider a shortest path in this graph from $s \stackrel{\text{def}}{=} a_1$ to $t \stackrel{\text{def}}{=} \bar{a}_P$ using at most $h \stackrel{\text{def}}{=} P + 2$ hops. We claim that its total length is less than $(3P + 2)W$ if and only if there is a negative triangle in the initial graph. Indeed, each triple $(a_i, b_j, c_k) \in A \times B \times C$ corresponds to path $a_1 - a_2 - \cdots - a_i - b_j - c_k - \bar{a}_i - \bar{a}_{i+1} - \cdots - \bar{a}_P$, which uses exactly $P + 2$ hops and has total length

$$w(a_i, b_j) + 3(P + 1 - i)W + w(b_j, c_k) + 3W + w(c_k, a_i) + 3iW$$
$$= \big(w(a_i, b_j) + w(b_j, c_k) + w(c_k, a_i)\big) + (3P + 2)W.$$

Hence, the "if" direction follows. For the "only if" direction, fix an $s$-$t$ path with at most $P + 2$ hops and a total length strictly less than $(3P + 2)W$. The path must be of the form $a_1 - a_2 - \cdots - a_i - b_j - \cdots - c_k - \bar{a}_{i'} - \bar{a}_{i'+1} - \cdots - \bar{a}_P$, where $\{a_i, b_j\}$ is the first edge that leaves $A$ and $\{c_k, \bar{a}_{i'}\}$ is the last edge that enters $\bar{A}$. Every edge has weight at least 0, every edge incident to $b_j$ or $c_k$ has weight at least $-W + 3W = 2W$, and the direct edge between $b_j$ and $c_k$ has weight at most $W + 3W = 2 \cdot 2W$. Thus, the direct edge is the cheapest walk from $b_j$ to $c_k$ both in terms of the length and the number of hops. Consequently, we may assume without loss of generality that our $s$-$t$ path proceeds directly from $b_j$ to $c_k$. This means that the number of hops is $i + 3 + (P - 1 - i') = P + 2 + i - i'$, whereas the total length is

$$w(a_i, b_j) + 3(P + 1 - i)W + w(b_j, c_k) + 3W + w(c_k, a_{i'}) + 3i'W$$
$$= \big(w(a_i, b_j) + w(b_j, c_k) + w(c_k, a_{i'})\big) + (3P + 2)W + 3(i' - i)W.$$

If $i' < i$, then the number of hops is at least $P + 3$, which is larger than assumed. If $i' > i$, then the path length is at least $-3W + (3P + 2)W + 3W \geqslant (3P + 2)W$, a contradiction. Therefore, $i = i'$ holds. Since the path length is less than $(3P + 2)W$, we conclude that $w(a_i, b_j) + w(b_j, c_k) + w(c_k, a_i) < 0$, i.e., $(a_i, b_j, c_k)$ is a negative triangle in the initial graph.

## 3 Hardness under Min-Plus Convolution Hypothesis

**Preliminaries.** In the Max-Plus Convolution Upper Bound problem, we are given three sequences $(a[i])_{i=0}^{n-1}$, $(b[i])_{i=0}^{n-1}$, and $(c[i])_{i=0}^{n-1}$ of $n$ numbers each, and the goal is to decide whether $c[k] \geqslant \max_{i+j=k}(a[i]+b[j])$ holds for all $k$. In other words, we want to find $i, j, k$ such that $i + j = k$ and $c[k] < a[i] + b[j]$. The Max-Plus Convolution Upper Bound and Min-Plus Convolution problems are equivalent under subquadratic reductions [11, Theorem 3.1]; thus, in particular, unless the Min-Plus Convolution Hypothesis fails, there is no $O(n^{2-\varepsilon})$ time algorithm for Max-Plus Convolution Upper Bound, for any $\varepsilon > 0$.

Let us introduce an intermediate problem, which we call Common Max-Plus Convolution Upper Bound: Given $M$ pairs of sequences

$$\big((a_1[i])_{i=0}^{N-1}, (b_1[i])_{i=0}^{N-1}\big), \ldots, \big((a_M[i])_{i=0}^{N-1}, (b_M[i])_{i=0}^{N-1}\big),$$

and one sequence $(c[i])_{i=0}^{N-1}$, decide if there exist $i, j, k, \ell$ such that $i + j = k$ and $c[k] < a_\ell[i] + b_\ell[j]$. We call such $(i, j, k, \ell)$ a *violating quadruple*. First, we show that the naive running time of $O(MN^2)$ is conditionally optimal for this problem.

▶ **Lemma 5.** *Unless the Min-Plus Convolution Hypothesis fails, there is no $O(MN^{2-\varepsilon})$ time algorithm for Common Max-Plus Convolution Upper Bound, for any $\varepsilon > 0$, even when restricted to instances with $M = \Theta(N^\alpha)$ for an arbitrarily chosen constant $\alpha \geqslant 0$.*

**Proof.** The argument is based on a self-reduction of Min-Plus Convolution (see [11, proof of Theorem 5.5]). Let $\beta = \alpha/(1+\alpha) \in [0, 1)$. We start with an instance of Max-Plus Convolution Upper Bound with three sequences $a$, $b$, $c$, each of length $n$. We split $a$ and $b$ into $\Theta(n^\beta)$ blocks of consecutive elements, each block of length $\lceil n^{1-\beta} \rceil$ (the last block can be shorter). For every pair of blocks, one from $a$ and the other from $b$, we want to check if the corresponding fragment of $c$ is an upper bound of their max-plus convolution. Similarly to [11], we add suitable padding so that all three sequences are of the same length. This way, we end up with $\Theta(n^{2\beta})$ smaller instances of Max-Plus Convolution Upper Bound. The key step is to classify these instances according to the third sequence, which results in $\Theta(n^\beta)$ groups of size $\Theta(n^\beta)$ each (the instances in any single group share the same third sequence). Each such group becomes a single instance of Common Max-Plus Convolution Upper Bound, with $M = \Theta(n^\beta)$ and $N = \Theta(n^{1-\beta})$. If each of these instances can be solved in $O(MN^{2-\varepsilon}) = O(n^{\beta+(1-\beta)(2-\varepsilon)})$ time, then the original instance can be solved in $O(n^{2\beta+(1-\beta)(2-\varepsilon)}) = O(n^{2-(1-\beta)\varepsilon})$ time, and the Min-Plus Convolution Hypothesis fails. We conclude the proof by observing that $n^\beta = n^{\alpha/(1+\alpha)} = (n^{1/(1+\alpha)})^\alpha = (n^{1-\beta})^\alpha$, and thus $M = \Theta(N^\alpha)$ holds as desired. ◀

Cygan, Mucha, Węgrzycki, and Włodarczyk [11, proof of Theorem 5.4] showed that, without loss of generality, the input sequences to Max-Plus Convolution Upper Bound are nonnegative and strictly increasing. The same argument applies to Common Max-Plus Convolution Upper Bound. Using the additional structure, we can replace the condition $i+j = k$ with $i+j \leqslant k$. Indeed, suppose we find $(i, j, k, \ell)$ with $i+j \leqslant k$ and $c[k] < a_\ell[i]+b_\ell[j]$; then, by monotonicity, $c[i + j] \leqslant c[k]$, and hence $(i, j, i + j, \ell)$ is a quadruple satisfying the original condition.

▶ **Observation 6.** *The lower bound of Lemma 5 holds even restricted to instances with all the sequences nonnegative and strictly increasing. For such instances, the condition $i + j = k$ can be equivalently replaced by $i + j \leqslant k$.*

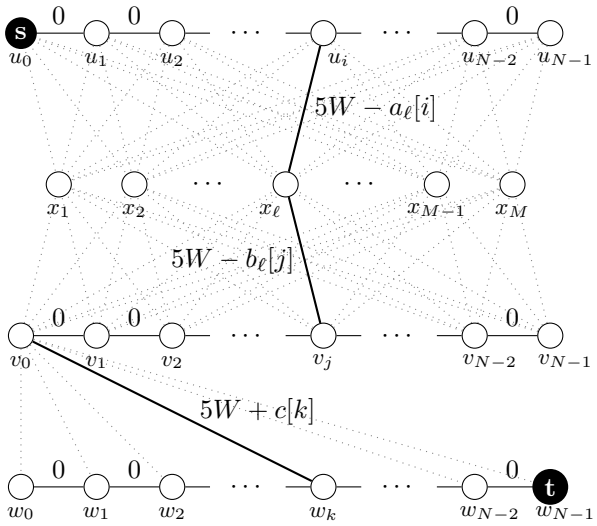

**Figure 3** The graph created in the reduction from Common Max-Plus Convolution Upper Bound.

**Reduction.** We show how to reduce an instance of Common Max-Plus Convolution Upper Bound, with $M$ pairs of length-$N$ sequences, to finding the length of a shortest hop-bounded $s$-$t$ path in an undirected graph with $n = \Theta(N + M)$ nodes, $m = \Theta(NM)$ edges, and the hop bound $h = \Theta(N)$. This will let us conclude that an $O(h^{1-\varepsilon}m)$ time (or $O(hm^{1-\varepsilon})$ time) shortest path algorithm would give an $O(MN^{2-\varepsilon})$ time (respectively, $O(M^{1-\varepsilon}N^{2-\varepsilon})$ time) algorithm for the Common Max-Plus Convolution Upper Bound problem and thus violate the Min-Plus Convolution Hypothesis.

Let $W$ denote the maximum value of any input sequence element. Create an undirected graph (see Figure 3) composed of three paths $u_0 - u_1 - \cdots - u_{N-1}$, $v_0 - v_1 - \cdots - v_{N-1}$, $w_0 - w_1 - \cdots - w_{N-1}$, and an independent set of $M$ nodes $x_1, x_2, \ldots, x_M$. Set the weights of all the path edges to 0. For every $i \in \{0, 1, \ldots, N-1\}$ and $\ell \in \{1, 2, \ldots, M\}$, add an edge between $u_i$ and $x_\ell$ with weight $5W - a_\ell[i]$. Then, for every $j \in \{0, 1, \ldots, N-1\}$ and $\ell \in \{1, 2, \ldots, M\}$, add an edge between $x_\ell$ and $v_j$ with weight $5W - b_\ell[j]$. Finally, for every $k \in \{0, 1, \ldots, N-1\}$, add an edge between $v_0$ and $w_k$ with weight $5W + c[k]$.

Consider a shortest path in this graph from $s \stackrel{\text{def}}{=} u_0$ to $t \stackrel{\text{def}}{=} w_{N-1}$ using at most $h \stackrel{\text{def}}{=} N + 2$ hops. We claim that its total length is less than $15W$ if and only if there is a quadruple $(i, j, k, \ell)$ with $i + j \leqslant k$ and $c[k] < a_\ell[i] + b_\ell[j]$. Indeed, each quadruple $(i, j, k, \ell)$ corresponds to path

$$u_0 - u_1 - \cdots - u_i - x_\ell - v_j - v_{j-1} - \cdots - v_0 - w_k - w_{k+1} - \cdots - w_{N-1}. \qquad (\star)$$

Such a path uses $i + 1 + 1 + j + 1 + (N - 1 - k) = (N + 2) + (i + j - k)$ hops and has total length $15W - a_\ell[i] - b_\ell[j] + c[k]$. Hence, the "if" direction follows. For the "only if" direction, since every non-zero edge weight is at least $4W$, an $s$–$t$ path of total length less than $15W$ can use at most three such edges, and therefore it must be of the form $(\star)$. The hop bound implies $i + j - k \leqslant 0$ and the total length bound implies $c[k] - a_\ell[i] - b_\ell[j] < 0$.

Recall that $n = \Theta(N + M)$, $m = \Theta(NM)$, and $h = \Theta(N)$. For $\eta \in [1/2, 1]$, in order to get hard shortest hop-bounded path instances with density $\Theta(m^\eta)$ and hop bound $h = \Theta(m^\eta)$, we start with the Common Max-Plus Convolution Upper Bound problem restricted to instances with $M = \Theta(N^{(1-\eta)/\eta})$. This implies $h = \Theta(N) = \Theta((NM)^\eta) = \Theta(m^\eta)$. Moreover, due to $\eta \geqslant 1/2$, we have $M \leqslant O(N)$, and thus $n = \Theta(N + M) = \Theta(N) = \Theta(m^\eta)$ holds as desired. This concludes the proof of Theorem 3.

# Towards Bypassing Lower Bounds for Graph Shortcuts

**Shimon Kogan**

## Abstract

For a given (possibly directed) graph $G$, a hopset (a.k.a. shortcut set) is a (small) set of edges whose addition reduces the graph diameter while preserving desired properties from the given graph $G$, such as, reachability and shortest-path distances. The key objective is in optimizing the tradeoff between the achieved diameter and the size of the shortcut set (possibly also, the distance distortion). Despite the centrality of these objects and their thorough study over the years, there are still significant gaps between the known upper and lower bound results.

A common property shared by almost all known shortcut lower bounds is that they hold for the seemingly simpler task of reducing the diameter of the given graph, $D_G$, by a constant additive term, in fact, even by just one! We denote such restricted structures by $(D_G-1)$-diameter hopsets. In this paper we show that this relaxation can be leveraged to narrow the current gaps, and in certain cases to also bypass the known lower bound results, when restricting to sparse graphs (with $O(n)$ edges):

- **Hopsets for Directed Weighted Sparse Graphs.** For every $n$-vertex directed and weighted sparse graph $G$ with $D_G \geq n^{1/4}$, one can compute an *exact* $(D_G-1)$-diameter *hopset* of linear size. Combining this with known lower bound results for *dense* graphs, we get a separation between dense and sparse graphs, hence *shortcutting sparse graphs is provably easier*. For reachability hopsets, we can provide $(D_G-1)$-diameter hopsets of linear size, for sparse DAGs, already for $D_G \geq n^{1/5}$. This should be compared with the diameter bound of $\widetilde{O}(n^{1/3})$ [Kogan and Parter, SODA 2022], and the lower bound of $D_G = n^{1/6}$ by [Huang and Pettie, SIAM J. Discret. Math. 2018].
- **Additive Hopsets for Undirected and Unweighted Graphs.** We show a construction of $+24$ *additive* $(D_G-1)$-diameter hopsets with linear number of edges for $D_G \geq n^{1/12}$ for sparse graphs. This bypasses the current lower bound of $D_G = n^{1/6}$ obtained for *exact* $(D_G-1)$-diameter hopset by [HP'18]. For general graphs, the bound becomes $D_G \geq n^{1/6}$ which matches the lower bound of exact $(D_G-1)$ hopsets implied by [HP'18]. We also provide new additive $D$-diameter hopsets with linear size, for any given diameter $D$.

Altogether, we show that the current lower bounds can be bypassed by restricting to sparse graphs (with $O(n)$ edges). Moreover, the gaps are narrowed significantly for any graph by allowing for a constant additive stretch.

## 1 Introduction

A shortcut set (a.k.a hopset) is a small collection of edges $H$ that when added to a given (possibly directed and weighted) graph $G$ reduces the diameter substantially, while preserving key properties from $G$, such as, reachability, shortest-path distances, etc. Since their

introduction by Ullman and Yannakakis [25] and Thorup [24], shortcut sets have been studied extensively due to their wide-range of applications for parallel, distributed, dynamic and streaming algorithms [16, 12, 10, 15, 9, 11, 3]. Their applicability is also demonstrated by recent algorithmic results, e.g., [15, 9, 11] that use shortcuts as their core component.

We focus on the fundamental notions of *reachability* $D$-diameter hopsets[1] and *exact* $D$-diameter hopsets. These are sets of edges that when added to $G$ reduce the directed diameter to at most $D$ while preserving reachability (resp., exact $D$-hop distances). For a graph on $n$ vertices and $m$ edges, the literature has mainly focused on how small the diameter $D$ can become after adding $\widetilde{O}(n)$ or $\widetilde{O}(m)$ edges to the graph. Recent years have witnessed a significant progress on the combinatorial and algorithmic aspects of these structures. Despite these efforts, there are still major gaps in our understanding. Thorup conjectured [24] that any $n$-vertex digraph with $m$ edges, has a $D$-diameter shortcut of size $\widetilde{O}(m)$ for[2] $D = \widetilde{O}(1)$. This has been shown to hold for a restricted class of graphs, such as planar [24]. Hesse [13] refuted this conjecture for general graphs by presenting a construction of an $n$-vertex digraph with $m = \Theta(n^{19/17})$ edges that requires $\Omega(mn^{1/17})$ shortcut edges to reduce its diameter to below $n^{1/17}$. Huang and Pettie [14] showed a diameter lower bound of $\Omega(n^{1/6})$ for $O(n)$-size shortcuts, and Lu, Vassilevska-Williams, Wein and Xu [21] have recently improved the lower bound for $D$-shortcuts with $O(m)$ edges to $D = \Omega(n^{1/8})$.

Up to very recently, the only known upper bound for reachability hopsets was given by a folklore randomized algorithm, attributed to Ullman and Yannakakis [25], that for every integer $D \geq 1$, provides a shortcut of size $\widetilde{O}((n/D)^2)$. Kogan and Parter [18] have improved the tradeoff to $\widetilde{O}(n^2/D^3 + (n/D)^{3/2})$. Hence, for reachability $D$-diameter hopsets of linear size, we have $D = \widetilde{O}(n^{1/3})$ and $D = \Omega(n^{1/6})$.

The gap becomes even more dramatic when insisting on preserving the *exact* distances. The only known upper bound for exact $D$-diameter hopsets are still given by the folklore algorithm of [25], even for the presumably simpler setting of *unweighted* and *undirected* graphs. Currently, exact $D$-diameter hopsets of linear size require $D = \Omega(n^{1/6})$ for unweighted and undirected graphs, while the upper bound is still $O(\sqrt{n})$. The lower bound for weighted graphs has been recently improved to $D = \Omega(n^{1/3})$ by [17].

In this paper we investigate this curious gap between upper and lower bound results for reachability and exact hopsets. We aim at understanding the limitations of the current lower bound constructions, and study whether they can be bypassed, algorithmically. Our viewpoint differs from the classical algorithmic approach in the sense that we aim to provide algorithms mainly for the purpose of understanding the key barriers for narrowing the observed gaps. In the following, for two given shortcutting tasks $\Pi, \Pi'$, we say that task $\Pi$ is *easier* than task $\Pi'$ if one can provide for task $\Pi$ an improved diameter vs. size tradeoff over the current tradeoff known for task $\Pi'$.

## 1.1 Our Contribution

Our starting observation is that almost all known lower bounds for hopsets, a partial list includes, [13, 14, 21, 17], in-fact hold for the seemingly easier task of reducing the diameter of the given graph by just 1. For example, the lower bound of Huang and Pettie [14] exhibits

[1] These structures are usually referred to as reachability shortcuts, and the notion of hopset is usually used in the context of preserving also the shortest-path distances. For clarity of presentation, we unify the notation and refer to all structures as variants of hopsets.

[2] The $\widetilde{O}(.)$ notation hides poly-log $n$ factors.

an $n$-vertex graph $G$ with diameter $D_G = \Theta(n^{1/6})$ for which any subset of linear number of shortcut edges cannot reduce the diameter to $D_G - 1$. As this property is shared by many of the lower bound results, we raise the following question:

▶ **Question 1.1** (Additive vs. Multiplicative Diameter Reduction). *Is reducing the graph diameter by a constant* ***additive*** *term easier than by a constant* ***multiplicative*** *factor?*

In this context, we say that task $\Pi$ is *easier* than task $\Pi'$, if one can provide a solution for $\Pi'$ which improves the state-of-the-art bounds known for $\Pi$. To answer this question, we focus on the notion of $(D_G - 1)$-diameter hopset: a subset of shortcut edges that reduces the diameter of $G$ from $D_G$ to $D_G - 1$. We provide new algorithmic results for $(D_G - 1)$-diameter hopsets that significantly *narrow* the current gap for these structures.

▶ **Theorem 1.1** (Reachability $(D_G - 1)$-Diameter Hopset). *Every $m$-edge $n$-vertex DAG $G$ admits a reachability $(D_G - 1)$-diameter hopset with $\widetilde{O}(m^{4/3}/D_G^{5/3})$ edges.*

By plugging $m = O(n)$, we get a reachability $(D_G - 1)$-hopset with linear number of edges for every $D_G \geq n^{1/5}$. This suggests that at least algorithmically and for the family of sparse graphs, the task of reducing the diameter additively is easier than reducing the diameter by a constant factor. Currently, for the latter task, linear reachability hopsets exist only for $D_G \geq n^{1/3}$, even for sparse DAGs [18, 19].

Another fundamental feature shared by most of the lower bound results [13, 14, 21, 17] is concerned with the density (i.e. number of edges) of the worst-case graph examples. In particular, all these lower bound graphs have a super-linear number of edges (referred to hereafter as *dense* graphs). E.g., the above-mentioned lower bound graph of [14] contains $\Omega(n^{7/6})$ edges. We therefore raise the following question:

▶ **Question 1.2** (Shortcutting Sparse vs. Dense Graphs). *Is reducing graph diameter easier for* ***sparse*** *graphs compared to* ***dense*** *graphs?*

We answer Question 1.2 in the affirmative by providing a *provable* gap between the sparse and dense settings, in the context of *exact* hopsets. We show:

▶ **Theorem 1.2** (Exact $(D_G - 1)$-Diameter Hopset, Directed and Weighted). *Every $m$-edge $n$-vertex directed (and possibly weighted) graph $G$ admits an exact $(D_G - 1)$-diameter hopset with $\widetilde{O}((m/D_G)^{4/3})$ edges.*

Taking $m = n$ yields $\widetilde{O}(n)$-size exact hopsets for diameter $D_G \geq n^{1/4}$. This should be compared with the lower bound for exact $(D_G - 1)$-diameter hopsets by [4] (one can adapt Theorem 5, therein to this setting) which requires a super-linear number of shortcut edges for dense graphs $G$ with $\Theta(n^{3/2})$ edges and diameter $D_G = n^{1/4}$.

Finally, we address the setting of exact $(D_G - 1)$-diameter hopsets for unweighted and undirected graphs, which currently admits the largest gap between the known upper and lower bound results. Recall that for exact $D$-diameter hopsets of linear size, we have $D = O(\sqrt{n})$. As no progress (at least for upper bounds) has been made for exact hopsets over the years, we consider the question of whether it is possible to narrow this gap by introducing an additive stretch:

▶ **Question 1.3** (Exact vs. Additive Stretch)**.** *Is reducing the graph diameter easier when allowing an* ***additive*** *stretch compared to* ***exact*** *distances?*

To address Question 1.3 we study the notion of additive hopsets, which to the best of our knowledge has not been considered before. For a given graph $G$, an $+\alpha$-additive $D$-diameter hopset is a subset of (weighted) shortcut edges $H$ whose addition guarantees the following: for every $u, v$ pair, the graph $G \cup H$ contains a $D$-hop $u$-$v$ path (that is the path contains at most $D$ edges) of total length[3] $\ell_{u,v}$ where $\text{dist}_G(u,v) \leq \ell_{u,v} \leq \text{dist}_G(u,v) + \alpha$. We show that the introduction of additive stretch can indeed achieve a lot in terms of improving the state-of-the-art bounds when compared to exact hopsets. We have:

▶ **Theorem 1.3** (Additive Hopsets Upper Bounds)**.** *Every $n$-vertex $m$-edge undirected unweighted graph $G$ admits a $+24$-additive $(D_G - 1)$-diameter hopset with $\widetilde{O}(\min\{(n/D_G)^{6/5}, (m/D_G)^{12/11}\})$ edges.*

Theorem 1.3 should be compared with the lower bound of [14]. The latter can be shown to imply that there exists an undirected and unweighted graph $G$ with $\omega(n^{7/6})$ edges for which any *exact* $(D_G - 1)$-diameter hopset requires $\Omega(n)$ edges. For $m = O(n)$, our construction in Theorem 1.3 provides $+24$-additive $(D_G - 1)$-hopset with linear number of edges, for any $D_G \geq n^{1/12}$. That is, by restricting to sparse graphs and introducing a small additive stretch we bypass the lower bound of [14]. Moreover, for any (possibly dense) graph $G$, we provide a linear-size *additive* $(D_G - 1)$-diameter hopset for $D_G \geq n^{1/6}$, hence matching the lower bound of $n^{1/6}$ implied by [14] for *exact* $(D_G - 1)$-diameter hopsets.

We also show a general construction of $\alpha$-additive $D$-hopsets for any given stretch parameter $\alpha$ and diameter bound $D$ (which is possibly much smaller than $D_G$):

▶ **Theorem 1.4.** *Every $n$-vertex undirected unweighted graph $G$ with input parameters $\alpha, D$, admits a $+\alpha$-additive $D$-diameter hopset with $\widetilde{O}((n/(\alpha \cdot D))^2 + (n/\alpha)^{4/3} + n)$ edges. Hence, of linear size for $D, \alpha = \Omega(n^{1/4})$.*

The construction of Theorem 1.4 is based on an interesting connection between hopsets and additive spanners for weighted graphs [1, 7].

**Remark.** In our upper bound results, we focus on $(D_G - 1)$-diameter hopsets since this is a recurrent feature of the state-of-the-art lower bounds. Our algorithms can indeed be easily extended to provide a $-c$ reduction for any given term $c$. In the context of exact hopsets and reachability preservers, the factor $c$ will appear in the final size bound (for constant $c$, the asymptotic size bound remains as is). For additive hopsets the factor $c$ will appear in the final size as well as in the final additive stretch (i.e., the $+24$ term in Theorem 1.3 might become $+24 \cdot c$).

**Recent Breakthrough Lower-Bound Results on Shortcuts and Hopsets.** Following the submission of this paper, Bodwin and Hoppenworth [5] provided new lower bound results for shortcuts and hopsets. In particular, they provide a lower bound of $D = \Omega(n^{1/4})$ for

[3] The length of a path is measured by the sum of its edge weights (note that in an unweighted graph the length is the number of edges in the path).

reachability $D$-diameter hopsets with linear number of edges. Hence, the current gap for these structures is $D = \widetilde{O}(n^{1/3})$ and $D = \Omega(n^{1/6})$. In addition, for exact $D$-hopsets of linear size, they show a lower bound of $D = \Omega(\sqrt{n})$, implying that the folklore algorithm for these structures is indeed tight.

## 1.2 Preliminaries

**Graph Notations.** For an $a$-$b$ dipath $P$ and a $b$-$c$ dipath $P'$ the concatenation of the paths is denoted by $P \circ P'$. Let $|P|$ denote the number of edges (hop) on $P$ and let $\text{len}(P)$ be the *length* of path $P$, measured by the sum of its (possibly) weighted edges. In the context of weighted graphs, we refer to number of edges on a path $P$ as the number of *hops*. For a collection of paths $\mathcal{P}$, let $V(\mathcal{P}) = \bigcup_{P \in \mathcal{P}} V(P)$. For an element set $X$ and $p \in [0,1]$, let $X[p]$ be the set obtained by taking each element of $X$ into $X[p]$ independently with probability $p$. For a subset $V' \subseteq V$, let $G[V']$ be the induced graph on $V'$. For a (possibly directed and weighted) graph $G$ and $u, v \in V(G)$, let $\text{dist}_G(u,v)$ be the shortest-path distance between $u, v$ in $G$. Let $N_{in}(u,G) = \{v \in V(G) \mid (v,u) \in E(G)\}$ and $N_{out}(u,G) = \{v \in V(G) \mid (u,v) \in E(G)\}$. Define $\deg_{in}(u,G) = |N_{in}(u,G)|$ and $\deg_{out}(u,G) = |N_{out}(u,G)|$. For an undirected graph $G$, a vertex $v \in V(G)$ and an integer $k$, let $N_k(v,G) = \{u \in V(G) \mid \text{dist}_G(u,v) \leq k\}$ and let $\deg_k(v,G) = |N_k(v)|$. When $G$ is clear from the context, we may omit it. Also, when $k = 1$, we may write $N(v,G)$, rather than $N_1(v,G)$. For a given path $P \subseteq G$ and $u \in P$, the $k$-hop $P$-neighbor of $u$ is some vertex in $P \cap N_k(u,G)$.

For an $n$-vertex digraph $G$, let $TC(G)$ denote its transitive closure. For $(u,v) \notin TC(G)$, $\text{dist}_G(u,v) = \infty$. A *shortcut* edge is an edge in $TC(G)$. These definitions are naturally extended to *undirected* graphs, by treating all edges as bidirectional, consequently, $TC(G)$ is an $n \times n$ clique for connected undirected graphs. For an integer weighted (possibly directed) graph $G = (V, E, \omega)$ where $\omega : E \to [1, W]$, the weighted transitive closure, denoted as $TC_W(G)$, has the same edge set as $TC(G)$ weighted by the $G$-distances between the edges' endpoints. For any vertices $u, v \in V$ and integer $\beta \leq n$, define $\text{dist}^{(\beta)}_G(u,v)$ to be the minimum length $u$-$v$ path with at most $\beta$ edges (hops). If there is no such path, then define $\text{dist}^{(\beta)}_G(u,v) = \infty$. Throughout, we define the *diameter* of the graph, $D_G$, by the smallest value $\beta$ satisfying that $\text{dist}^{(\beta)}_G(u,v) = \text{dist}_G(u,v)$ for every $u, v \in V$. In the context of weighted graphs $G$, $D_G$ as defined above is usually refereed to as the *hopbound*. For ease of readability, we slightly revise the notion of diameter in a way the captures weighted and unweighted hopsets as well as reachability shortcuts.

**Reachability, Exact and Additive Hopsets.** For a directed graph $G$, a reachability $d$-diameter hopset $H$ is a subset of edges from the transitive closure $TC(G)$ such that $D_{G \cup H} \leq d$. For a (possibly directed and weighted) graph $G$, an $\alpha$-additive $d$-diameter hopset $H$ is a subset of weighted edges in $TC_W(G)$ satisfying that for every $u, v \in V(G)$:

$$\text{dist}_G(u,v) \leq \text{dist}^{(d)}_{G \cup H}(u,v) \leq \text{dist}_G(u,v) + \alpha \ . \tag{1.1}$$

An *exact* $d$-diameter hopset satisfies Eq. (1.1) for $\alpha = 0$.

In this paper, we study the notion of $(D_G - 1)$-diameter hopsets which given a graph $G$ provide the desired hopbound guarantees for $d = D_G - 1$. Our algorithms can easily provide any constant additive reduction, i.e., a $(D_G - c)$-diameter hopsets, for any desired constant $c$. We use the notion of $(D_G - 1)$ as a reference to the special property of the current lower bounds. That is, $(D_G - 1)$-hopsets are precisely the structures for which we currently have lower bounds for. We note that our bounds also hold in the following alternative formulation:

Given an input parameter $D$, then the output hopset guarantees a hopbound reduction by 1 (or by a constant term) for any $u$-$v$ shortest path with hopbound at least $D$. That is, the reduction can be provided for all paths of length $\geq D$ and not only for $D = D_G$.

**Shortcutting Tools.** We use the basic shortcutting algorithm for dipaths from [23].

▶ **Lemma 1.5** (Restatement of Lemma 1.1 in [23]). *Any dipath $P$ admits a reachability 2-diameter hopset $H$ with $\widetilde{O}(|P|)$ edges.*

▶ **Lemma 1.6** ([25]). *For every $n$-vertex (possibly directed and weighted) graph $G$ and integer $D \leq n$, there is an algorithm* ExactHopset *that computes an exact $D$-diameter hopset $H$ with $\widetilde{O}((n/D)^2)$ edges.*

Our constructions employ a useful variant of reachability hopsets, in which it is required to provide the desired hopbound w.r.t to a given subset of vertices [19].

▶ **Definition 1.1** (Subset Reachability Hopset [19]). Given a graph $G = (V, E)$, a subset $S \subseteq V$ and an integer $D$, a set of edges $H \subseteq TC(G)$ is an $(S, D)$-reachability-hopset, if for every $u, v \in V$ such that $(u, v) \in TC(G)$, there is a $u$-$v$ path $P_{u,v}$ (not necessarily a shortest path) in $G \cup H$ with at most $D$ vertices from $S$.

For completeness we provide a complete proof for the following which also provides an additional property compared to the construction of [19]. See Appendix A for the proof.

▶ **Lemma 1.7.** *For every $n$-vertex DAG $G$, $S \subseteq V(G)$ and input parameter $D$, one can compute an $(S, D)$-reachability-hopset $H \subseteq TC(G)$ of size $\widetilde{O}(|S| + (|S|^2/D^3))$. In addition, the hopset $H$ satisfies the following for every $u, v \in V$: If there is a shortest path $P_{u,v} \subseteq G$ which contains $k$ vertices in $V \setminus S$, then in $G \cup H$, there is a $u$-$v$ path (which is not necessarily the shortest path) that contains at most $D$ vertices from $S$ and at most $k$ vertices from $V \setminus S$.*

**Spanners and Emulators.** Graph spanners introduced by Peleg and Schäffer [22] are sparse *subgraphs* that preserve shortest path distances up to a small stretch. In contrast to hopsets, these structures are defined only for *undirected* graphs, as no sparsificiation is possible in the worst-case for directed $n$-vertex graphs with $\Omega(n^2)$ edges.

▶ **Definition 1.2** ($(\alpha, \beta)$-Spanner). Given an undirected graph $G = (V, E)$, a subgraph $G^* \subseteq G$ is called an $(\alpha, \beta)$-*spanner* if $\text{dist}_{G^*}(u, v) \leq \alpha \cdot \text{dist}_G(u, v) + \beta$ for every $u, v \in V$.

An $(\alpha, \beta)$-*emulator* $E^*$ is a weighted set of edges in $V \times V$ (i.e., not necessarily a subgraph of $G$) that provides the same stretch guarantees as $(\alpha, \beta)$-spanners, where $\text{dist}_G(u, v) \leq \text{dist}_{E^*}(u, v) \leq \alpha \cdot \text{dist}_G(u, v) + \beta$ for every $u, v \in V$.

Our constructions also use recent algorithms for computing additive spanners for weighted graphs [1, 8]. For a weighted graph $G = (V, E, \omega)$ where $\omega : E \to \{1, \ldots, W\}$, these spanners provide a $+\beta \cdot W$ stretch guarantees. We use the following theorem for weighted additive spanners by [2] (recently improved by [7]).

▶ **Theorem 1.8** (Theorem 3 in [2]). *For any $n$-vertex weighted graph $G = (V, E, \omega)$ with maximum edge weight $W$, there is an algorithm* WeightedSpanner *that computes a $+8W$ additive spanner $H \subseteq G$ with $\widetilde{O}(n^{4/3})$ edges.*

## 2 Directed Shortcuts

In this section we observe that the existing lower bounds for directed hopsets hold for the relaxed task of $(D_G - 1)$-diameter hopsets. We then show that these lower bounds can be bypassed for sparse graphs. Our upper bounds yield a separation between sparse and dense graphs, implying that shortcutting *sparse* graphs might be *simpler* in terms of providing an improved diameter vs. size tradeoffs.

### 2.1 Exact $(D_G - 1)$-Hopsets

**Known Lower Bound.** The following lower-bound follows by plugging $\ell = n^{1/3}$ in Theorem 5 of [4]. See also Table 3 in [6]. We observe that this lower bound argument, as all prior lower bounds, holds even when it is required to reduce the diameter of the given graph by 1.

▶ **Theorem 2.1** (Exact Hopsets, Directed, Follows by Theorem 5 of [4]). *There exist an $n$-vertex (dense) directed graphs with $\Theta(n^{3/2})$ edges for which any exact $(D_G - 1)$-hopset must have $\Omega(n^{5/4})$ shortcut edges provided that $D_G \leq n^{1/4}$.*

**New Upper Bound (Proof of Theorem 1.2).** We show that the lower bound of Theorem 2.1 can be bypassed for sparse graphs while preserving the exact distances in a weighted digraph. Note that for $m = n$, Theorem 1.2 yields $O(n)$-size exact hopsets for diameter $D \geq n^{1/4}$ while the lower bound of Theorem 2.1 for exact $(D_G - 1)$-diameter requires a super-linear size for $D = n^{1/4}$.

**The Construction.** Set an integer threshold $k = \lceil (m/D_G)^{1/3} \rceil$ and define a vertex $u$ to be *low-deg* if $\deg_{in}(u) \leq k$ and $\deg_{out}(u) \leq k$. Otherwise, the vertex is *high-deg*. By a simple counting, there are $O(m/k)$ high-deg vertices in the given $m$-edge graph.

Let $L = V[p]$ for $p = \Theta(\log n/D_G)$ be a random sample of vertices, and let $L_h, L_\ell$ be the sets of high-deg (resp., low-deg) vertices in $L$ (hence, $L_h \cup L_\ell = L$). The algorithm adds *two* subsets of shortcut edges $H_h, H_\ell$ which handle the high-deg and low-deg, respectively:

- $H_h = (L_h \times L_h) \cap TC(G)$ .
- For every $u \in L_\ell$, $H_\ell(u) = \{(x, y) \mid x \in N_{in}(u), y \in N_{out}(u)\}$.
- $H_\ell = \bigcup_{u \in V} H_\ell(u)$.

All added shortcut edges in $H_h, H_\ell$ are weighted by their shortest-path distances in $G$. The output hopset is given by $H = H_h \cup H_\ell$. This completes the description of the construction.

**Proof of Theorem 1.2.**

**Size.** Since there are $O(m/k)$ high-deg vertices, w.h.p., $|L_h| = O(m \log n/(kD_G))$. Hence, $|H_h| = \widetilde{O}((m/(kD_G))^2)$. We next bound the size of $H_\ell$. Let $V_\ell$ be the set of all low-deg vertices in $G$. Then, $\sum_{u \in V_\ell} \deg_{in}(u) \cdot \deg_{out}(u) = O(km)$. Since $L_\ell$ is obtained by sampling each low-deg vertex with probability of $\Theta(\log n/D_G)$, we get that w.h.p., $|H_\ell| = \widetilde{O}(km/D_G)$. The size argument holds by setting $k = \lceil (m/D_G)^{1/3} \rceil$.

**Diameter and Distances.** Consider some $u$-$v$ shortest-path $P \subseteq G$ with $D_G$ edges. First assume that $P \cap L_\ell \neq \emptyset$. I.e., that $P$ contains at least one sampled low-deg vertex, say $z$. Let $z', z''$ be the vertex preceding (resp., subsequent to) $z$ on the path $P$. Since $z' \in N_{in}(z)$ and $z'' \in N_{out}(z)$, the shortcut edge $(z', z'')$ is in $H_\ell$. Consequently, the path $P$ can be shortcut into a path $P'$ obtained by replacing the 2-hop segment $P[z', z''] = (z', z) \circ (z, z'')$ by a weighted edge $(z', z'')$. Note that $\text{len}(P') = \text{len}(P)$ and that $|P'| = |P| - 1$.

From now on assume that $P$ has no sampled low-deg vertex. W.h.p., it then holds that $P$ contains at least two high-deg sampled vertices, i.e., $|P \cap L_h| \geq 2$. In addition, we can assume that those two sampled vertices, $x, y$ are at hop-distance at least $D/3$ from each other. Since the weighted edge $(x, y) \in H_h$, the $\Omega(D)$-hop segment $P[x, y]$ can be replaced by the single edge $(x, y)$. The distances are clearly preserved. Note that in this case, the hopbound can be reduced by an even a constant factor, and hence the additive reduction is bottle-necked by the low-deg vertices. ◀

## 2.2 Reachability $(D_G - 1)$-Hopsets

**Known Lower Bound.** We start by making the immediate observation that the well-known lower-bound by Huang and Pettie [14] also holds for $(D_G - 1)$-hopsets.

▶ **Theorem 2.2** (Reachability Hopsets, Slight Restatement of [14]). *There exists an $n$-vertex directed acyclic graph with $\Omega(n^{7/6})$ edges for which any reachability $(D_G - 1)$-hopset must have $\Omega(n)$ shortcut edges provided that $D_G \leq n^{1/6}$.*

**Reachability $(D_G - 1)$-Diameter Hopsets (Proof of Theorem 1.1).** When settling for reachability, rather than exact distances, one can provide improved bounds. In particular, Theorem 1.1 claims that sparse DAGs admit a reachability $(D_G - 1)$-diameter hopset of linear size for $D_G \geq n^{1/5}$ (compared to $D_G \geq n^{1/4}$ when preserving the exact distances).

Throughout, recall that $G$ is a DAG[4]. The algorithm for reachability $(D_G - 1)$-hopsets is similar to that of Theorem 1.2. The main distinction is that instead of connecting each pair of sampled high-deg vertices in the hopset, we add the subset reachability hopset of Lemma 1.7 w.r.t. to the set of high-degree vertices. In our context, this adds $|L_h|^2/D_G^3$ edges, rather than $|L_h|^2$ edges, where $L_h$ is the set of sampled high-degree vertices in the construction of Theorem 1.2.

**Proof of Theorem 1.1.** Set $k = \lceil m^{4/3}/D^{5/3} \rceil$. The definition of $H_\ell$ is the same, hence $|H_\ell| = \widetilde{O}(mk/D) = \widetilde{O}(m^{4/3}/D_G^{5/3})$. The subset $H_h$ is defined by applying the subset reachability hopset of Lemma 1.7 with $S = L_h$ and $D = D_G/2$. Since $|S| = \widetilde{O}(m/(kD))$, the size of $H_h$ can be bounded by $\widetilde{O}(|L_h| + (|L_h|^2/D_G^3)) = \widetilde{O}(m^{4/3}/D_G^{5/3})$.

It remains to consider the diameter argument. By the proof of Theorem 1.2 it is sufficient to consider a $u$-$v$ shortest path $P$ of hopbound $D_G$ that has at least $D_G/3$ high-deg vertices and at most $D_G/3$ low-deg vertices. By Lemma 1.7, we have that $H_h$ contains a $u$-$v$ path with at most $D_G/3$ low-deg vertices and at most $D_G/3$ high-deg vertices. Note that in this case, we get a constant reduction in the diameter. The theorem follows. ◀

# 3 Additive Shortcuts for Undirected Unweighted Graphs

We next consider the gap obtained for exact hopsets in undirected and unweighted graphs. Our goal is to narrow this gap by (i) restricting attention to $(D_G - 1)$-hopsets (for which the known lower bound results hold), and (ii) allow a constant additive stretch in the distances. We will show that for sparse graphs, one can even bypass the current lower bound obtained for exact hopsets, as the latter is based on a dense graph example.

[4] Note that the general DAG reduction introduces a factor of 2 in the diameter, and hence we cannot employ it. All lower-bound graphs for this problem are DAGs as well.

**Known Lower Bounds for Exact $(D_G-1)$-Hopsets.** We start by observing that the lower bounds for reachability hopsets by Huang and Pettie [14] also hold for exact hopsets for undirected and unweighted graphs. See Appendix A for a proof.

▶ **Theorem 3.1** (Lower Bound for Exact Hopsets, Undirected Unweighted, Immediate by [14]). *There exist $n$-vertex undirected and unweighted graphs $G$ with $m=\Omega(n^{7/6})$ edges and $D_G=\Theta(n^{1/6})$, such that any exact $(D_G-1)$-diameter hopset for $G$ has $\Omega(n)$ edges.*

We next show that the lower bound of Theorem 3.1 can be bypassed for sparse graphs when allowing additive stretch. In addition, for general graphs (possibly dense) we match the bound of $n^{1/6}$ obtained for exact hopsets.

**New Additive $(D_G-1)$-Hopsets (Proof of Theorem 1.3).** We start by presenting an algorithm that achieves a size bound of $\widetilde{O}((n/D_G)^{6/5})$ (hence, linear-size for $D_G\geq n^{1/6}$) and then explain how to modify the construction to yield the bound of $\widetilde{O}((m/D_G)^{12/11})$ (which provides the improved results for sparse graphs). For the sake of this extension, we show the following slightly stronger statement:

▶ **Lemma 3.2.** *Every $n$-vertex $m$-edge undirected unweighted graph $G$ and any input parameter $D$, one can compute a hopset $H$ with $\widetilde{O}((n/D)^{6/5})$ edges with the following guarantee: For any $u,v$ pair at distance at least $D$ in $G$, it holds that* $\mathrm{dist}_G(u,v)\leq \mathrm{dist}^{(D-1)}_{G\cup H}(u,v)\leq \mathrm{dist}_G(u,v)+24$.

Note that Lemma 3.2 in particular implies a $+24$-additive $(D_G-1)$-diameter hopsets with $\widetilde{O}((n/D)^{6/5})$ edges. The lemma is stronger in the sense that for any given $D$ (where possibly $D<D_G$), the $(-1)$ reduction in the hopbound holds for any shortest path of length at least $D$. In contrast, $(D_G-1)$-hopsets provides the $(-1)$ reduction only for shortest-paths of length *exactly* $D_G$.

**The Construction.** Let $\deg_2(u)$ be the number of 2-hop neighbors of $u$ in the given graph $G$. Set $k=(n/D)^{1/5}$ as a parameter that serves as our 2-degree threshold, as follows. A vertex $u$ is *low-deg* if $\deg_2(u)\leq k$ and it is *high-deg* otherwise. The algorithm has two phases. The first phase handles the low-deg vertices by adding $\widetilde{O}(nk/D)$ shortcut edges. At the end of that phase, the algorithm outputs also a subgraph $G'$ in which each vertex is high-deg. The second phase handles these high-deg vertices by adding an additional subset of $\widetilde{O}(nk/D+(n/(Dk^2))^2)$ shortcut edges. The size bound of $(n/D)^{6/5}$ is obtained by balancing these two size terms, which is achieved for $k=(n/D)^{1/5}$. Throughout, all added shortcut edges are weighted by the corresponding shortest-path distances between the edge endpoints.

**Step (1): Handling Low-Degree Vertices.** The algorithm iterates over the low-deg vertices in the graph, as long as such exists. Initially, set $G_0=G$ and $H_0=\emptyset$. In every iteration $i\geq 1$, it gets as input a subgraph $G_{i-1}$ and $H_{i-1}$ and considers an arbitrary low-deg vertex $u$. (If no such exists, then $G'=G_{i-1}$, $H'=H_{i-1}$ and the step terminates). First, the algorithm removes $u$ by letting $G_i=G_{i-1}\setminus\{u\}$. Then, with probability of $p=\Theta(\log n/D)$, the algorithm connects $u$ to each of its (current) 2-hop neighbors in $G_{i-1}$ by letting $H_i=H_{i-1}\cup\{(u,v)\ \mid\ v\in N_2(u,G_{i-1})\}$. This completes the description of the $i^{th}$ iteration. Denoting the number of iterations by $\ell$, then the output of the step is given by $G'=G_\ell$ and $H'=H_\ell$.

**Step (2): Handling the Remaining High-Degree Vertices.** We now restrict attention only to the graph $G'$. Letting $V' = V(G')$, the algorithm computes *three* random samples of $V'$-vertices: $S = V'[p]$, $Q = V'[q]$ and $R = V'[r]$ where $p = \Theta(\log n/D)$, $q = \Theta(\log n/k)$ and $r = \Theta(\log n/(Dk^2))$. Also, initially set $H'' = (R \times R)$, and add to $H''$ a subset of shortcut edges by applying the following shortcutting procedure for every vertex $u \in S$:

- Build a depth-6 BFS tree $T_6(u, G') \subseteq G'$ rooted at $u$ (i.e., a BFS which spans only $N_6(u, G')$).
- If $|T_6(u, G')| = O(k^2)$, add the edges $E'(u) = \{(u, v) \mid v \in T_6(u, G') \cap Q\}$ to $H''$.

The output hopset is given by $H' \cup H''$. We next turn to analyze the construction and prove Lemma 3.2.

**Size.** In the first step, for every low-deg vertex $u$, with probability of $p = \Theta(\log n/D)$, the algorithm adds $\deg_2(u) \leq k$ shortcut edges. Hence this adds $|H'| = \widetilde{O}(nk/D)$ edges, w.h.p. Consider the second step. W.h.p., $|S| = O(n \log n/D)$ and $|R| = O(n \log n/(Dk^2))$. For every $u \in S$ with $|T_6(u, G')| = O(k^2)$, we have that w.h.p. $|T_6(u, G') \cap Q| \leq k \log n$, and therefore, we have $O(|S| \cdot k \log n)$ edges, due to this step. Overall, we added to $H''$ a total of $O(|R|^2 + |S| \cdot k \log n)$ edges. The size bound follows by plugging $k = (n/D)^{1/5}$.

**Diameter and Stretch Analysis.** Throughout, we override notation and redefine a vertex $v$ to be low-deg if $v \notin V(G')$. That is, a vertex is low-deg if there exists an iteration $i$ in the Step (1) in which $N_2(v, G_{i-1}) \leq k$. A vertex $v$ is then high-deg if $v \in V(G')$ (i.e., it is a high-deg in each subgraph $G_{i-1}$ considered in each iteration $i$ of Step (1)). We also need the following classification of the high-deg vertices. A vertex $u \in V(G')$ is *large* if its 6-depth BFS tree has size $|T_6(u, G')| = \omega(k^2)$, and it is *small* otherwise. Let $V_\ell = V \setminus V(G')$ be the low-deg vertices, $V_h^{small}$ (resp., $V_h^{large}$) denote the small (resp., large) high-deg vertices. It then holds that $V_\ell \cup V_h^{small} \cup V_h^{large} = V(G)$.

Consider now a $u$-$v$ shortest-path $P$ with $D$ edges (hops). The analysis breaks into three cases depending on the number of vertices in $V(P)$ that belong to each of the three subsets of vertices $V_\ell, V_h^{small}$ and $V_h^{large}$.

**Case 1: $|P \cap V_\ell| = \Omega(D)$.** For every low-deg vertex $z$, let $i_z$ be the iteration in which $z$ is removed in Step (1). I.e., $z$ is the (unique) selected low-deg vertex in $G_{i_z-1}$. We then say that the low-deg vertex $z \in P \cap V_\ell$ is *bad* if both of its 2-hop $P$-neighbors $z_1, z_2$ are not in $G_{i_z-1}$. This can happen if these two 2-hop neighbors were removed in prior iterations. Otherwise, the vertex is *good*.

▶ **Lemma 3.3.** *The path $P$ can contain at most* two *consecutive bad vertices.*

**Proof.** The claim follows by noting that a 2-hop $P$-neighbor of a bad vertex $x \in P$ must be good. To see this, let $z$ be a 2-hop $P$-neighbor of $x$. Since $x$ is bad, it implies that $i_x \geq i_z + 1$, i.e., $z$ is removed *before* $x$ in Step (1). This implies that $x \in G_{i_z-1}$ and hence $z$ must be good. ◀

By Lemma 3.3, we get that in this case $P$ contains $\Omega(D)$ good vertices. Since the algorithm add shortcut edges to each good vertex w.p. $p = \Theta(\log n/D)$, we get that w.h.p., the coin flip is successful for at least one good vertex, say $x$, on $P$. By the definition of the good vertex, at least one of its 2-hop $P$-neighbors, say $x'$, is in $G_{i_x-1}$ and therefore the shortcut edge $(x', x)$ is in $H'$. Let $P'$ be the path obtained by replacing the 2-hop segment $P[x, x']$ with an edge $(x, x')$. Then, $\text{len}(P) = \text{len}(P')$ but $|P'| \leq |P| - 1$, as required.

**Case 2.1: $|P \cap V_h^{large}| = \Omega(D)$.** Note that for any for any two vertices $u', u''$ on $P$ at distance at least 13 from each other, it holds that their 6-hop neighborhoods are disjoint. Also note that since $N_6(u', G') \subseteq N_6(u', G)$, we have that $|N_6(u', G)| = \omega(k^2)$ for every $u' \in V_h^{large}$. As $P$ contains $\Omega(D)$ vertices from $V_h^{large}$, we get that the size of the 6-hop neighborhood of the path $P$ is $\Omega(Dk^2)$. Since we sample each vertex in $V$ into $R$ independently with probability of $r = \Theta(\log n/(Dk^2))$, we get that w.h.p., the following holds: There are two vertices $u', u'' \in S \cap P \cap V_h^{large}$ at distance $\Omega(D)$ from each other such that there exists $w \in N_6(u', G) \cap R$ and $w' \in N_6(u'', G) \cap R$. Since the algorithm adds to $H''$ the shortcut edge $(w, w')$, the hopbound between $u$ and $u'$ is reduced from $\Omega(D)$ to at most 13. By the triangle inequality, this introduces an additive stretch of at most $+24$. See Fig. 1 (Left) for an illustration.

**Case 2.2: $|P \cap V_h^{small}| = \Omega(D)$.** Since $P$ has $\Omega(D)$ vertices from $V_h^{small}$, we can also assume the following. The path $P$ contains $\ell = \Omega(D)$ segments $P_1, \ldots, P_\ell$ such that: (i) each $P_i \subseteq G'$, (ii) $|P_i| = 40$ and (iii) the internal 20-length segment of $P_i$ contains a vertex in $V_h^{small}$. We then get that w.h.p. there exists a vertex $u' \in S \cap P \cap V_h^{small}$ that belongs to the internal 20-length segment of some $P_i \subseteq G'$. Let $w$ be a vertex at distance 4 from $u'$ on $P_i$. Since each vertex in $G'$ has 2-deg at least $k$, we get (i) $|N_2(w, G')| \geq k$ and (ii) $N_2(w, G') \subset T_6(u', G')$. Therefore, w.h.p., it holds that there exists some $z \in N_2(w, G') \cap Q$ (where $Q = V'[\Theta(\log n/k)]$) and consequently, $(u', z) \in E'(u)$. The 4-hop path segment $P[u', w]$ can then be replaced by a 3-hop segment $P' = (u', z) \circ (z, z') \circ (z', w)$ for some $z' \in N(w, G') \cap N(z, G')$. It is easy to see that the additive stretch is at most $+4$, as we replace a 4-hop segment by a 3-hop segment of length at most 8. See Fig. 1 (Right) for an illustra

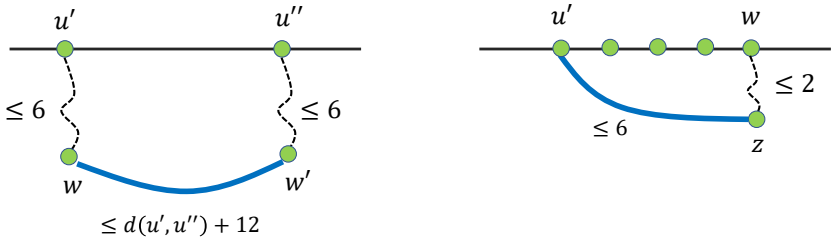

**Figure 1** An illustration for stretch and diameter argument of Theorem 1.3. Left: The path $P$ contains $\Omega(D)$ vertices which are high-deg and an in addition with large 6-depth BFS trees. The shortcut edge is shown in blue. Right: The path $P$ has $\Omega(D)$ vertices which are high-deg and with small 6-depth BFS trees.

We are now ready to complete the proof of Theorem 1.3.

**Theorem 1.3.** It remains to modify the construction to obtain a size bound of $\widetilde{O}((m/D_G)^{12/11})$ edges. We start with a preliminary sparsification step that handles vertices with 1-degree (that is simply the degree) at most $k' = (m/D_G)^{1/11}$. Let $V_{\ell,1}$ be the subset of all low-degree vertices (i.e., with 1-deg at most $k'$) and let $V_{h,1} = V \setminus V_{\ell,1}$. Let $H_1$ be a subset of shortcut edges that handles the low-degree vertices, as follows. Let $V'_{\ell,1} = V_{\ell,1}[p]$ for $p = \Theta(\log n/D_G)$. Then,

$$H_1 = \bigcup_{v \in V'_{\ell,1}} \{(x, y) \mid x, y \in N(v) \text{ and } x \neq y\} .$$

Next, we apply the construction of Lemma 3.2 on the graph $G_h = G[V_{h,1}]$ with $D = D_G$, which outputs a $+24$-additive $(D_G - 1)$-diameter hopset $H_2$ on the graph $G_h$. Observe that the diameter of $G_h$ might be considerably larger than $D$. This motivates the more dedicated guarantees of Lemma 3.2. The output hopset is given by $H_1 \cup H_2$.

**Size.** By the Chernoff bound, w.h.p., $|H_1| = \widetilde{O}(mk'/D_G)$. In addition, $|V_{h,1}| = O(m/k')$ by a simple counting argument. Letting $n' = |V_{h,1}| = O(m/k')$, by Lemma 3.2, $|H_2| = \widetilde{O}((n'/D_G)^{6/5})$. This size bound follows by plugging $k' = (m/D_G)^{1/11}$.

**Diameter and Stretch.** Consider a $u$-$v$ shortest-path $P$ with $D_G$ edges. If $P$ contains $\Omega(D_G)$ vertices of degree at most $k'$, then w.h.p., $P \cap V'_{\ell,1} \neq \emptyset$, and $P$ is shortcut by one hop, and the distances are preserved. It remains therefore to consider the case where $P$ contains $\ell = \Omega(D_G)$ segments $P_1, \ldots, P_\ell$, each of length 100, that are fully contained in the graph $G_h = G[V_h]$. For every $i \in \{1, \ldots, \ell\}$, letting $P_i = [u_{i1}, \ldots, u_{i100}]$ then define an internal segment $P'_i = [u_{i50}, \ldots, u_{i80}] \subset P_i$.

We next show that this suffices to recover the same argument as obtained in Lemma 3.2. Partition the vertices on $P \cap V_{h,1}$ into three subsets $V_\ell, V_h^{small}, V_h^{large}$ as in the argument of Lemma 3.2. We then consider the same cases as in Lemma 3.2 with minor modifications.

**Case 1: $V_\ell$ intersects with $\Omega(D_G)$ distinct segments of $P'_1, \ldots, P'_\ell$.** By Lemma 3.3, we get that w.h.p. the algorithm adds a shortcut edge between some vertex $V_\ell \cap P$ to its 2-hop neighbor on the path. Hence, the diameter (hopbound) is reduced by 1, and the distances are preserved.

**Case 2.1: $V_h^{large}$ intersects with $\Omega(D_G)$ distinct segments of $P'_1, \ldots, P'_\ell$.** Note that any for any two vertices $u, v$ on $P$ at distance at least 13 from each other, it holds that their 6-hop neighborhoods are disjoint. This implies that the 6-hop neighborhood of the path $P$ is $\Omega(Dk^2)$. By the exact same argument as obtained for Case 2.1 in Lemma 3.2, we get that there is at least one segment $P_j$ whose hopbound is reduced while introducing an additive stretch of at most $+24$. This holds as the argument in Lemma 3.2 is local in the sense that it shortcuts segments of constant length provided that there are sampled $u', u'' \in V_h^{large}$ that are sufficiently apart on $P$ and that each has a 4-hop $P$-neighbor on the segment.

**Case 2.2: $V_h^{small}$ intersects with $\Omega(D_G)$ distinct segments of $P'_1, \ldots, P'_\ell$.** The claim follows by noting that the argument for Case 2.2 of Lemma 3.2 shows that any segment $P_j$ gets shortcut (and while introducing an additive stretch of $+4$) with probability of $\Theta(\log n/D_G)$. The probabilities are independent for vertex-disjoint segments. Note that this holds since it is sufficient for the segment $P_j$ to include the 6-hop neighborhood of the vertex. Since $V_h^{small}$ intersects with $\Omega(D_G)$ disjoint segments, at least one of them is successful, w.h.p., and provides the desired $(-1)$ reduction in the hopbound (while introducing an additive stretch of $+4$). ◀

**New Additive $D$-Diameter Hopsets (for any $D$).** We now turn to proving Theorem 1.4. For simplicity we show a construction of $O(D)$-diameter hopsets with additive stretch $O(\alpha)$, but these constant factors can be easily omitted. The algorithm has two main steps. The first step computes a graph $G'$ on $O(n \log n/\alpha)$ vertices at the cost of introducing an additive stretch of $O(\alpha)$. The second step computes an exact $D$-diameter hopset on $G'$.

Specifically, the algorithm starts by computing a weighted *net* graph $G' = \mathsf{Net}(G, p)$ for the given (unweighted) graph $G$ where $p = \Theta(\log n/\alpha)$. The algorithm $\mathsf{Net}(G, p)$ outputs a graph $G' = (V', E', \omega')$ defined as follows. Let $V' = V[p]$ be a random sample of $V$, obtained by sampling each $v \in V$ independently with probability of $p$. Let $E' = \{(u, v) \in V' \times V' \mid \text{dist}_G(u, v) \leq \Theta(\log n/p) \cdot W\}$ and $\omega'((u, v)) = \text{dist}_G(u, v)$ for every $(u, v) \in E'$. We use the following observation in our constructions:

▶ **Observation 3.1** (Observation 3.4 in [20]). Let $G' = (V', E', \omega')$ be the output net graph of Alg. $\mathsf{Net}(G, p)$ where $G = (V, E, \omega)$ is an $n$-vertex graph with maximum edge weight $W$. Then w.h.p., the following holds: (i) $|V'| = O(np \log n)$, (ii) for every $u, v \in V'$, $\text{dist}_{G'}(u, v) = \text{dist}_G(u, v)$, and (iii) the maximum edge weight of $G'$ is bounded by $W' = \Theta(W \log n/p)$.

Denote $S_1 = V(G')$, hence $S_1 = V[p]$. By Obs. 3.1(iii), the maximum edge weight of $G'$ is $W = O(\alpha)$. Let $S_2 = S_1[q]$ for $q = \Theta(\log n/D)$. For a vertex $u$ and a set $S_1$, let $\mathit{Closest}(u, S_1)$ be the closest vertex to $u$ in $S_1$, breaking ties arbitrarily. The output hopset $H$ is the union of $H_0 \cup H_1 \cup H_2$ of weighted edges, where:

- $H_0 \leftarrow \{(u, \mathit{Closest}(u, S_1)) \mid u \in V\}$.
- $H_1 \leftarrow \mathsf{WeightedSpanner}(G')$ of Theorem 1.8.
- $H_2 \leftarrow \mathsf{ExactHopset}(H_1, D)$ of Lemma 1.6.

This completes the description of the hopset.

**Proof of Theorem 1.4.** Clearly, $|H_0| \leq n$. By the Chernoff bound, w.h.p., $|S_1| = O(n \log^2 n/\alpha)$, and therefore by Theorem 1.8, $|H_1| = \widetilde{O}((n/\alpha)^{4/3})$. The size of $H_2$ can bounded by $|S_2|^2 = \widetilde{O}((n/(\alpha \cdot D))^2)$, w.h.p. We next turn to consider the additive stretch and the hopbound.

Consider a $u, v$ pair and let $u' = \mathit{Closest}(u, S_1)$ and $v' = \mathit{Closest}(v, S_1)$. W.h.p., it holds that $\text{dist}_G(u, u'), \text{dist}_G(v, v') = O(\alpha)$. Since, $u', v' \in S_1$, by Obs. 3.1 we have that $\text{dist}_{G'}(u', v') = \text{dist}_G(u, v)$. Hence, $\text{dist}_{H_1}(u', v') \leq \text{dist}_{G'}(u', v') + O(\alpha)$. Since $H_2$ is an exact $D$-diameter hopset for $H_1$, we get:

$$\text{dist}^{(D)}_{H_1 \cup H_2}(u', v') = \text{dist}_{H_1}(u', v') \leq \text{dist}_G(u', v') + O(\alpha) \ .$$

Letting $P$ be the shortest $u'$-$v'$ path with at most $D$ hops in $H_1 \cup H_2$, we get that the $u$-$v$ path $P' = (u, u') \circ P \circ (v', v) \subseteq G \cup H$ has at most $O(D)$ hops and of total length $\text{dist}_G(u, v) + O(\alpha)$. The theorem follows. ◀

## A Missing Proofs

**Proof of Lemma 1.7.** Let $TC' = TC(G)[S]$ be the induced transitive closure on the subset $S$. Compute a collection of $O(|S|/D)$ vertex-disjoint paths $\mathcal{P}$ in $TC'$ such that $TC' \setminus V(\mathcal{P})$ has no directed path of length $D/10$. Let $H_1 = \bigcup_{P \in \mathcal{P}} H(P)$ where $H(P)$ is a 2-diameter hopset for $P$ that consists of $O(|P| \log |P|)$ edges, using Lemma 1.5. Let $S' = S[p]$ and $\mathcal{P}' = \mathcal{P}[p]$ for $p = \Theta(\log n/D)$. Let $H_2 = \{e(v, P) \mid v \in S', P \in \mathcal{P}'\}$ where $e(v, P)$ is an edge connecting $v$ to its first outgoing neighbor in $TC'$ on $P$. The size bound is immediate.

Consider the diameter argument. Let $Q$ be a $u$-$v$ shortest path in $G$ for $u, v \in S$ such that $|Q \cap S| \geq D$. By the properties of the paths $\mathcal{P}$, we can assume that $|Q \setminus V(\mathcal{P})| \leq D/10$. We next show that $Q$ can be transformed into a path $Q' \subseteq G \cup H_1$ such that the following holds: (i) for each $P \in \mathcal{P}$, $|P \cap Q'| \leq 3$ and $V(Q') \setminus V(\mathcal{P}) \subseteq V(Q)$. This can be obtained by traversing $Q$ and at each point of observing a vertex $z \in P \cap Q$, we add the shortcut edges $H(P)$ to connect $z$ with the far most vertex $z' \in P \cap Q$. It is easy to see that $V(Q') \subseteq V(Q)$ as by shortcutting $Q$ we can only omit vertices.

Finally, in the case where $|Q' \cap S| \geq D/2$, by property (i), we have that $Q'$ intersects with $\Omega(D)$ distinct paths from $\mathcal{P}$. Let $w \in S$ be the first sampled vertex in $Q' \cap S'$ (w.h.p., such exists among the first $D/10$ many $S$' vertices on $P$). Let $w' \in S$ be the last vertex on $Q'$ that belongs to a sampled path $P'$ in $\mathcal{P}'$ (w.h.p., such exists among that last $D/10$ many $S$' vertices on $P$). The diameter argument holds by noting that the shortcut edge $e(w, P')$ is in $H_2$. ◀

**Proof of Theorem 3.1.** The lower bound graph of [14] is a DAG with $D_G$ layers which contain $\Omega(n)$ critical pairs. For each critical pair $\langle u, v \rangle$, $u$ belongs to layer 1 and $v$ belongs to layer $D_G$. Furthermore, there is a unique directed path in $G$ between $u$ to $v$ and this path contains exactly one vertex from each layer. We now remove the directions of the edges in $G$ to get an undirected and unweighted graph $G'$. Notice that now for each critical pair $\langle u, v \rangle$ in $G'$, we have a unique shortest path of length $D_G - 1$ between $u$ and $v$, that is there might be other paths between $u$ and $v$ but the length of such path will be greater than $D_G - 1$ because such path will necessarily contain at least one vertex from each level, and for a certain level $i$ there will be two vertices from level $i$. In particular, the path will contain

vertices $u, w, v$ consecutively in the path, where $u$ is in level $i$, $w$ is in level $i-1$ and $v$ is in level $i$. We therefore have that the unique directed $u$-$v$ paths in $G$ are translated into unique undirected unweighted shortest paths in $G'$. Therefore, the claim holds in the exact same manner as in [14]. ◀

# Faster Block Tree Construction

## Abstract

The block tree [Belazzougui et al. J. Comput. Syst. Sci. '21] is a compressed text index that can answer access (extract a character at a position), rank (number of occurrences of a specified character in a prefix of the text), and select (size of smallest prefix such that a specified character has a specified rank) queries. It requires $O(z \log(n/z))$ words of space, where $z$ is the number of Lempel-Ziv factors of the text. For some highly repetitive inputs, a block tree can require as little as 0.015 bits per character of the text. Small values of $z$ make the block tree a space-efficient alternative to the wavelet tree, which is another index for these three types of queries. While wavelet trees can be constructed fast in practice, up so far compressed versions of the wavelet tree only leverage statistical compression, meaning that they are blind to spaced repetitions.

To make block trees usable in practice, a first step is to find ways in constructing them efficiently. We address this problem by presenting a practically efficient construction algorithm for block trees, which is up to an order of magnitude faster than previous implementations. Additionally, we parallelize our implementation, making it the first block tree construction implementation that works in parallel in shared memory.

## 1 Introduction

We experience an every-increasing amount of textual data produced in various domains. Examples include the exponentially increasing capability to sequence genetic data thanks to technical advances [63], code repositories such as GitHub, or natural text collections such as the English Wikipedia, which grows by around 2 million pages each year (currently there are over 58 million pages)[1]. Since there is no expectation that the production of such texts will decelerate, it seems that we start to drown in this sheer amount of data. Nevertheless, for the addressed examples, there is hope in that the produced textual data is usually highly

[1] See `https://en.wikipedia.org/wiki/Wikipedia:Size_of_Wikipedia`, last accessed 2023-07-04.

repetitive: When sequencing two human individuals, we can expect to find that they share more than 99.9 % of genetic data. In other domains such as code repositories or natural text collections, version control systems are used to track all versions of a document or source code to make it possible to revert changes or compare different versions. Since new versions often introduce only small changes, collections of all versions of the same document are often highly repetitive.

When stored or transmitted, texts are oftentimes compressed to save disk space or bandwidth, respectively. The most popular techniques for lossless text compression are based on the Lempel-Ziv 77 (LZ77) factorization [66]. Given $z$ is the number of factors of the LZ77 factorization of a given text, we can represent the text in $O(z)$ words of space. In many use cases, it does not suffice to only store or transmit textual data: the data also has to be processed. A naive way would be to decompress the data before processing it, which is, however, prohibitive for massive datasets. To avoid unnecessary decompression, we can use compressed text indices, which allow us to answer queries efficiently without decompression, while also guaranteeing us (asymptotically) the same space as the compressed text.

The *block tree* [6] is such a compressed text index that requires $O(z \log(n/z))$ words of space for a text $T$ of length $n$ with $z$ LZ77 factors. By default it can answer access queries. However, it can be augmented with additional information to also answer rank and select queries. The queries are defined as follows.

- $\mathrm{access}(T, i)$ returns the character at position $i$, i.e., $T[i]$ for $i \in [0, n)$,
- $\mathrm{rank}_\alpha(T, i)$ returns the number of occurrences of the character $\alpha$ in the $i$-th prefix of the text, i.e., $\mathrm{rank}_\alpha(T, i) = |\{j \leq i \colon T[j] = \alpha\}|$ for $\alpha \in \Sigma$ and $i \in [0, n)$, and
- $\mathrm{select}_\alpha(T, i)$ returns the position of the first character $\alpha$ that has rank $i$, i.e., $\mathrm{select}_\alpha(T, i) = \min\{j \colon \mathrm{rank}_\alpha(T, j) = i\}$ for $\alpha \in \Sigma$ and $i \leq \mathrm{rank}_\alpha(T, n-1)$.

One of the most popular data structures answering all three types of queries is the *wavelet tree* [35]. It is used in, among others, compressed full text indices based on the BWT [23,31,51] or on a grammar [15,16], lossless data compression [22,37,41], and computational geometry [14]. For more related work, see Section 3. Using the block tree, all these queries can be answered in $O(\log(n/z))$ time, with different space-time trade-offs available, see Section 4.

**Our Contribution.** In this paper, we present a block tree construction algorithm that leverages properties of the longest previous factor array, which is a common tool for computing the LZ77 factorization. We analyze our algorithm and show that it has the same asymptotic time complexity as previously presented construction algorithms. However, in our experimental evaluation, we observe that the implementation of our proposed algorithm is up to an order of magnitude faster than previous implementations. Finally, we show that our construction algorithm can also be parallelized.

## 2 Preliminaries

Let $T = T[0]T[1] \dots T[n-1]$ be a text of length $n$ over an alphabet $\Sigma = [0, \sigma)$. The substring $T[i..j] = T[i] \dots T[j]$ is called *prefix* if $i = 0$ and *suffix* if $j = n-1$.

The *Lempel-Ziv 77 (LZ77) factorization* [66] parses the text into $z$ factors $f_0, \dots, f_{z-1} \in \Sigma^+$ such that $T = f_0 \dots f_{z-1}$. For all $i \in [0, z)$, $f_i$ is either a single character not occurring in $f_0, \dots, f_{i-1}$ or the longest substring occurring at least twice in $f_0, \dots, f_i$. The LZ77 factorization can be computed in linear time and space (see Ref. [2] for a survey).

The *longest previous factor array* `LPF` stores at its $i$-th entry the length $\ell$ of the longest substring $T[i..i+\ell)$ having a previous occurrence in the text [17], i.e., $\mathtt{LPF}[i] = \max\{\ell \colon T[i..i+\ell) = T[j..j+\ell) \text{ for } j < i\}$ for $i \in [0, n)$. In particular, if $i$ is the starting position of an

LZ77 factor $f$, then $\texttt{LPF}[i] = |f|$, and thus we can compute the LZ77 factorization in linear time by scanning the LPF array, which can be constructed in linear time [17]. Later on, we also need the position of the occurrence of a longest previous factor, which we store in the *previous occurrence array* PrevOcc. The previous occurrence array is also called quasi suffix array [27]. Here, for all $i \in [0, n)$ we have $T[i..i + \texttt{LPF}[i]) = T[\texttt{PrevOcc}[i]..\texttt{PrevOcc}[i] + \texttt{LPF}[i])$ if $\texttt{LPF}[i] > 0$. We write $\texttt{PrevOcc}[i] = -1$ if $\texttt{LPF}[i] = 0$, i.e., when $T[i]$ is the leftmost occurrence of a single character in $T$.

## 3 Related Work

In this section, we give related work for compressed data structures answering our three types of queries (access, rank, and select) and work on block trees.

### Access, Rank, and Select Data Structures

Answering queries such as access, rank, select are profound problems that have been well addressed in literature. Starting with the case for binary alphabets, there are plenty of results for indexing compressed [10,31,54,55,60] and uncompressed [34,43,47,53,57,64,65] bit vectors. A recent compressed approach involves the linear approximation of the distributions of parts of the ranks in the bit vector [10]. Despite that block trees also work on general alphabets, a block tree variant over the gapped compressed integer array of the ranks of the bit vector can be used to answer rank and select queries [24].

For larger alphabets, we are aware of statistically compressed data structures, where space is expressed in relation to the $k$-th order of empirical entropy $H_k$ with $k = o(\log_\sigma n)$. Most prominent is the Huffman-shaped wavelet tree [35] using $n(H_0(T) + 1) + o(n(H_0(T) + 1)) + O(\sigma \log n)$ bits, and solving all three queries in $O(\log \sigma)$ time. This time could be reduced to $O(1 + \log \sigma / \log \log n)$ with multiary wavelet trees [25], and by a later work [33], the space got reduced to $nH_0(T) + o(n)$ bits. In practice, (Huffman-shaped) wavelet trees are also well-engineered [13, 18, 19, 20, 21, 26, 28, 45].

For faster queries on large alphabets, Golynski et al. [32] gave a data structure taking $n \lg \sigma + o(n \log \sigma)$ bits that answers all three types of queries in $O(\log \log \sigma)$ time. The space got improved by Barbay et al. [4] to $nH_0(T) + o(n(H_0(T) + 1))$ bits. Allowing slightly worse time complexities, Barbay et al. [5] achieved $nH_k(T) + o(n \log \sigma)$ bits, answering all queries in $o((\log \log \sigma)^{1+\epsilon})$ time, for any fixed constant $\epsilon > 0$. These time bounds were improved by Grossi et al. [36] to $O(\log \log \sigma)$ for rank and select, and constant time for access. Finally, Belazzougui and Navarro [9] presented a data structure achieving $nH_k(T) + o(n \log \sigma)$ bits of space, while answering rank in $O(\log \log_w \sigma)$ time. It further can answer access and select in $O(1)$ and any time in $\omega(1)$, respectively, or the other way around. There are also several results on lower bounds for data structures answering the three queries we address here.

Another line of research is to augment grammar compression with an index to support our queries. Here, Belazzougui et al. [7] and Pereira et al. [56] presented grammar indices answering rank and select queries in $O(\log n)$ time. Their indices use $O(g\sigma \log n)$ bits of space when built on a grammar of size $g$, where the latter reference requires that the grammar is balanced. This requirement can be dropped in the light that a grammar can be made balanced in linear time [29].

### Block Trees

Finally, we focus on block trees. Block trees have been proposed by Belazzougui et al. [8], who proposed a Monte Carlo construction algorithm using Karp-Rabin fingerprints in the external memory model. In the journal version [6], the authors provided two construction algorithms which we analyze in Section 4.1. Navarro [50, Section 4.2] recently surveyed block trees, who addresses also most of the references below for applications and variations.

A first application is pattern matching, where Navarro [49] uses block trees for locating pattern in the text. His index uses $O(z \log(n/z))$ words of space and finds all *occ* occurrences of a pattern of length $m$ in $O(m^2 \log n + occ \log^{\epsilon} n)$ time for any constant $\epsilon > 0$. Brisaboa et al. [11] presented an extension of block trees to a two-dimensional data structure simulating $k^2$-trees. Recently, Cáceres and Navarro [12] applied block trees for the compression of the suffix tree topology, the suffix array, and its inverse.

Despite the fact that the space of block trees is related to the size of the LZ77 factorization, the space can, if we vary the definition of a block tree, be made related to the size $\gamma$ of a string attractor [39] or the substring complexity $\delta$ [61].

For the former (string attractor size $\gamma$), we recall that a string attractor is a set of positions of the text such that each substring has an occurrence in the text that contains a position of the string attractor. Kempa and Prezza [39, Theorem 5.3] gave a variant of block trees whose blocks cover substrings of consecutive string attractor positions and thus partition $T$ irregularly. Their variant uses $O(\gamma \log(n/\gamma)) = O(z \log(n/z))$ space and extracts a length-$\ell$ substring in $O(\log(n/\gamma) \cdot (1 + \ell)/\log_\sigma n)$ time. For indexing, Prezza [58] (for rank and select queries) and Navarro and Prezza [52] (for pattern matching) could revert the property that blocks on the same level have equal length while retaining the space size.

For the latter (substring complexity $\delta$), let $\delta := \max\{d_k/k : k \in [1, n]\}$ denote the substring complexity of $T$, where $d_k$ is the number of distinct length-$k$ substrings of $T$. Then there is a block tree variant that can be represented in $O(\delta\tau \log_\tau \frac{n}{\delta})$ space supporting queries in $O(\log \frac{n}{\delta})$ time [40].

## 4 Block Trees

Let $T$ be a text of length $n$ over an alphabet of size $\sigma$, whose LZ77 factorization consists of $z$ factors. The *block tree* [6] is a compressed index requiring $O(z \log(n/z))$ words of space. It supports access, rank, and select queries in $O(\log(n/z))$ time. In the following, we describe a block tree with two integer parameters $s$ and $\tau$ that are greater than 1, which specify the out-degree of the root and all other internal nodes, respectively. For simplicity, we assume that $n = s \cdot \tau^h$ for some integer $h$. Now, the block tree is a tree of height $h = 1 + \log_\tau \frac{z \log n}{s \log n}$ with parameters $\tau$ and $s$ such that the root has $s$ children and every internal node is a leaf or has $\tau$ children.

Each node $u$ represents a substring of $T$ called *block* $B^u$. The root represents the whole text $T$ and has $s$ children representing $s$ consecutive blocks of length $n/s$. We refer to all blocks with the same depth as a *block tree level*. Two *blocks are consecutive* if they are in the same block tree level and if they are consecutive in $T$. Let $B_i \cdot B_{i+1}$ be the concatenated substring of two consecutive blocks. We *mark* the blocks $i$ and $i + 1$, if $B_i \cdot B_{i+1}$ is the leftmost occurrence of that substring in $T$. All non-root nodes that are not in the last level represent either marked or unmarked blocks.

All marked blocks $B^v$ are internal nodes with $\tau$ children. These children represent consecutive blocks of length $|B^v|/\tau$ whose concatenation is $B^v$. Unmarked blocks $B^u$, on the other hand, are leaves that only store a pointer towards the pair of consecutive blocks $B_i \cdot B_{i+1}$ containing the leftmost occurrence of $B^u$ and the offset of that occurrence in the blocks. The number of blocks per level of the block tree is bounded.

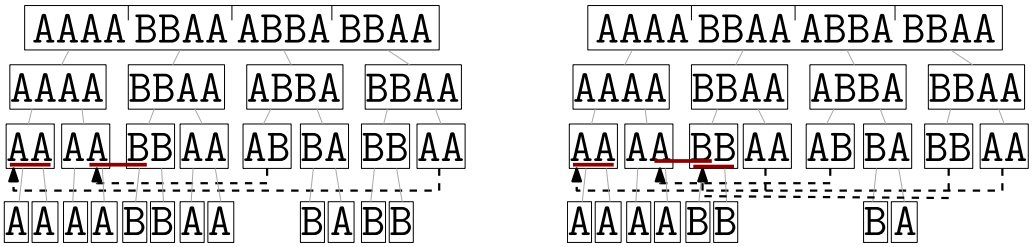

**Figure 1** The block tree (left) and its pruned version (right) for the text $T = \texttt{AAAABBAAABABBAA}$ with $\tau = 2$ and $s = 4$. Dashed arrows indicate pointers to the leftmost occurrence of the block the arrow starts at. The red line indicates the offset stored in addition to the pointer. Note that only characters in leaves are stored explicitly. For simplicity, our leaves contain only a single character. In the pruned block tree, we can replace an additional `AA` block. Note that we cannot prune the second `AA` block, as another block points into it.

▶ **Lemma 1** ([6, Lemma 1]). *Any level of a block tree (except the first) contains* $\leq 3z\tau$ *blocks.*

We have reached the last (or deepest) level of the block tree when explicitly storing the representing substring requires less space than storing the pointer for an unmarked block. At this level, we store the substring of each unmarked block explicitly. For example, if $|B^u| \in \Theta(\log_\sigma n)$, its encoding requires $O(1)$ words of space. Note that on each level, the block length decreases by a factor of $\tau$.

The block tree requires $O(s + z\tau \log_\tau \frac{n \log \sigma}{s \log n})$ words of space. Choosing $\tau$ as constant yields the minimum space requirement of the block tree mentioned above. Choosing $s = z$ results in block trees of size $O(z\tau \log_\tau \frac{n \log \sigma}{z \log n})$ words. Different values for $\tau$ can introduce other space-time trade-offs, as described by Belazzougui et al. [6].

## 4.1 Construction

Belazzougui et al. [6] give two construction algorithms, which we briefly review. Their first algorithm requires $O(n)$ words of working space, where the idea is to use an Aho-Corasick automaton [1] that can identify all consecutive pairs of blocks $B_0 \cdot B_1, B_1 \cdot B_2, \ldots, B_{s-2} \cdot B_{s-1}$ on the first level. This automaton is then used to identify the first occurrences of all pairs and to mark them accordingly. To set the leftwards pointers into unmarked blocks, the automaton is replaced by a new automaton that recognizes all unmarked blocks is created. The text is traversed using this automaton. Whenever an unmarked block is found for the first time, a pointer (and offset) is stored. For then on, the second automaton is no longer of use and can be removed. Subsequently, the algorithm continues with the next level, considering only the unmarked blocks from the previous level.

Their second algorithm uses $O(s + z\tau)$ words of working space and runs in $O(n)$ expected time. Here, the general idea is to replace the Aho-Corasick automaton with Karp-Rabin fingerprints [38], i.e., storing Karp-Rabin fingerprints of all consecutive pairs of blocks $B_i \cdot B_{i+1}$ in a hash table. Since there are at most $3z\tau$ blocks per level, this approach requires only $O(s + z\tau)$ words of working space. Both algorithms work in linear time if $s = \Theta(z)$.

The block tree as described here only supports access queries. For rank and select support, additional information has to be stored for each marked block. In the case of rank queries, the occurrence of all characters in the text up to the beginning of the block is necessary. For more details, we refer to the original block tree paper [6].

**Pruning.** When we construct block trees with one of the two aforementioned construction algorithms, we meet the asymptotic space bounds – but the block tree may contain more blocks than necessary, see Figure 1. Remember that we mark the first occurrence of each pair of consecutive blocks $B_i \cdot B_{i+1}$ to guarantee that any block $B^u$ to their right can point to them. However, there may be no rightwards block pointing to either (or both) $B_i, B_{i+1}$. In this case we would replace one of the blocks (or both) with leftward pointers, if one (or both) of them occurs previously. Since we do not modify this part of the algorithm, we refer to Belazzougui et al.'s [6, Section 6.1] description of the pruning step for more details.

# 5 Block Tree Construction using the LPF Array

We now describe our new block tree construction algorithm based on the LPF array.[2] First, in Section 5.1, we mark blocks using only the LPF array. Then, in Section 5.2, we find the leftmost occurrences of unmarked blocks, before, in Section 5.3, we combine all these ideas to our new algorithm.

## 5.1 Marking Blocks

The block tree is closely related to the LZ77 factorization of the text. Consecutive blocks $B_{i-1}$, $B_i$, and $B_{i+1}$ are only marked if an LZ77 factor starts in $B_i$, i.e., if they contain the leftmost occurrence of some substring. Similarly, LPF values witness the shortest substring starting at each text position that is a leftmost occurrence. Hence, we can make use of the LPF array to mark blocks. Let $\mathtt{s}(B^u)$ denote the starting *text* position of the substring represented by $B^u$.

▶ **Lemma 2.** *Given three consecutive blocks $B_{i-1}, B_i$, and $B_{i+1}$ of length $\ell$. We mark $B_i$ if $\mathtt{LPF}[\mathtt{s}(B_{i-1})] < 2 \cdot \ell$ or $\mathtt{LPF}[\mathtt{s}(B_i)] < 2 \cdot \ell$ is true.*

**Proof.** By the definition of the LPF array, a substring $T[i..i+\ell)$ has a preceding occurrence in the text if $\mathtt{LPF}[i] \geq \ell$. We only leave $B_i$ *un*marked if both $\mathtt{LPF}[\mathtt{s}(B_{i-1})]$ and $\mathtt{LPF}[\mathtt{s}(B_i)]$ are at least $2 \cdot |B_i|$ because this means that there is a previous occurrence of both $B_{i-1} \cdot B_i$, and $B_i \cdot B_{i+1}$. Otherwise, if there is no previous occurrence of one of the two pairs, we have to mark $B_i$. ◀

To determine whether the last block is marked, only its preceding block has to be considered. Otherwise, it is the same argument as used in Lemma 2. Since each level of the block tree contains $O(z\tau)$ blocks, we get the following result.

▶ **Lemma 3.** *Given the LPF array, we can mark all blocks of a level in the block tree in $O(z\tau)$ time.*

## 5.2 Identifying Leftmost Occurrences

Now, for each *unmarked* block, we have to identify the leftmost substring in the text that is equal to that block, as we need to add pointers (and offsets) from the unmarked blocks to these occurrences. Note that in all levels but the first one, the index of the block $B^u$ does not automatically translate to the block's starting position $\mathtt{s}(B^u)$, as we do not know how many blocks have been unmarked to its parent's left in the previous level. Therefore, we need to store additional information regarding a block's starting position for each block.

[2] The description is based on and has text overlaps with Daniel Meyer's Master's thesis [48].

### 5.2.1 Leftmost Occurrences as Text Positions

In this section, we describe how to identify the text position of the previous occurrence. Afterwards, in Section 5.2.2, we show how to identify the block that contains this text position on the current level. While the LPF array is sufficient to mark blocks, it does not contain information necessary to find the leftmost occurrences of blocks that we require for the leftward pointers. We now give a naive approach to compute the text positions in Section 5.2.1.1. Then, in Section 5.2.1.2, we improve the naive approach by using dynamic programming to obtain better asymptotic running times. The general idea in both cases is to follow the leftmost occurrences of previous occurrences for all blocks on a level.

▶ **Lemma 4.** *Let $i \in [0,n)$ be a text position, $j = \texttt{PrevOcc}[i]$, and $k = \texttt{PrevOcc}[j]$. If $0 < \texttt{LPF}[i] \leq \texttt{LPF}[j]$, then $T[i..i+\texttt{LPF}[i]) = T[j..j+\texttt{LPF}[i]) = T[k..k+\texttt{LPF}[i])$.*

**Proof.** $\texttt{LPF}[i] = \max\{k \colon T[i..i+k) = T[j..j+k) \text{ for } j < i\}$ and $\texttt{PrevOcc}[i]$ gives us the position $j$, where this longest factor occurs. Since $0 < \texttt{LPF}[i]$, we have $T[i..i+\texttt{LPF}[i]) = T[j..j+\texttt{LPF}[i])$ by definition. We also know that for text position $j$, there exists a previous factor of length at least $\texttt{LPF}[i]$ at position $k$. Hence $T[i..i+\texttt{LPF}[i]) = T[k..k+\texttt{LPF}[i])$. ◀

The same holds not only for length-$\texttt{LPF}[i]$ substrings, but for general length-$\ell$ substrings with $\ell \leq \texttt{LPF}[i]$, which is useful when processing a block tree level where blocks have all the same length $\ell$.

▶ **Observation 5.** *Let $i \in [0,n)$ be a text position and $j = \texttt{PrevOcc}[i]$. If $0 < \ell \leq \texttt{LPF}[i]$, then $T[i..i+\ell) = T[j..j+\ell)$.*

#### 5.2.1.1 Naive Approach

Using these properties, we can describe a *naive* algorithm to find the leftmost occurrence of a given unmarked block $B^u = T[i..i+\ell)$. Here, we simply follow the PrevOcc entries until the length of the longest previous factor of the previous occurrence is smaller than $\ell$. This leads us to the first occurrence of length $\ell$. Unfortunately, this naive approach requires $O(n)$ time for each block. For example, in an all-a text aa...a, for text position $i$ we would follow the longest previous occurrences $i-1, i-2, \ldots, 0$ in case that $\texttt{PrevOcc}(i) = i-1$ for all $i > 0$. Therefore, using the naive approach, we do not achieve the asymptotic running time of the original block tree construction algorithms by Belazzougui et al. [6]. However, in practice, this approach works very well, as we observed in our experimental evaluation in Section 6.

#### 5.2.1.2 Dynamic Programming

To retain the time complexities of the original block tree construction algorithms, we make use of dynamic programming to find the leftmost occurrences of a block in the text. We start with the definitions of $\ell$-factors and $\texttt{FirstOcc}_\ell$.

▶ **Definition 6** ($\ell$-factor and $\texttt{FirstOcc}_\ell$). *For $\ell > 0$, we denote $T[i..i+\ell)$ as $\ell$-factor$_i$. $\texttt{FirstOcc}_\ell[i]$ stores $\texttt{PrevOcc}[i]$, if no previous occurrence of $\ell$-factor$_i$ exists (remember that $\texttt{PrevOcc}[i] = -1$ if $T[i]$ is the leftmost occurrences of a character, i.e., $\texttt{LPF}[i] = 0$) and the leftmost occurrence of $\ell$-factor$_i$ otherwise.*

We can compute $\texttt{FirstOcc}_\ell$ using *dynamic programming* by iterating over PrevOcc from left to right. To start with, we set $\texttt{FirstOcc}_\ell[0] = -1$. Suppose that we have processed $\texttt{FirstOcc}_\ell[0..i-1]$ and are at text position $i$. For $j := \texttt{PrevOcc}[i]$, we consider two cases:

**Table 1** LPF, PrevOcc, $\texttt{FirstOcc}_2$, and the block tree (with parameters $s = 5, \tau = 2$) for the string AABAAAAAAA. The arrows above the first level of the block tree indicate the $\texttt{FirstOcc}_2$ values.

| $i$ | $T[i]$ | $T[i..n)$ | LPF$[i]$ | PrevOcc$[i]$ | $\texttt{FirstOcc}_2[i]$ | block tree |
|---|---|---|---|---|---|---|
| 0 | A | AABAAAAAAA | 0 | -1 | -1 |  |
| 1 | A | ABAAAAAAA | 1 | 0 | 0 | |
| 2 | B | BAAAAAAA | 0 | -1 | -1 | |
| 3 | A | AAAAAAA | 2 | 0 | 0 | |
| 4 | A | AAAAAA | 6 | 3 | 0 | |
| 5 | A | AAAAA | 5 | 4 | 0 | |
| 6 | A | AAAA | 4 | 5 | 0 | |
| 7 | A | AAA | 3 | 6 | 0 | |
| 8 | A | AA | 2 | 7 | 0 | |
| 9 | A | A | 1 | 8 | 8 | |

**Case 1** $\texttt{LPF}[i] \geq \ell$ and $\texttt{LPF}[j] \geq \ell$: From $\texttt{LPF}[j] \geq \ell$ follows that $\ell$-factor$_j$ has a previous occurrence. Combined with Observation 5 and $\texttt{LPF}[i] \geq \ell$, we can conclude that the previous occurrence of $\ell$-factor$_j$ is also an occurrence of $\ell$-factor$_i$. As we already calculated $\texttt{FirstOcc}_\ell[j]$, we can set $\texttt{FirstOcc}_\ell[i] = \texttt{FirstOcc}_\ell[j]$.

**Case 2** $\texttt{LPF}[i] < \ell$ or $\texttt{LPF}[j] < \ell$: We set $\texttt{FirstOcc}_\ell[i] = j$ since either $T[i..i+\ell)$ or $T[j..j+\ell)$ is the leftmost occurrence of $\ell$-factor$_i$.

See Table 1 for an example. Note that we still need the LPF array to correctly interpret any $\texttt{FirstOcc}_\ell[i]$. For $\texttt{LPF}[i] \geq \ell$ but $\texttt{LPF}[j] < \ell$ we know that $\ell$-factor$_i$ has an earlier occurrence at $j$ but no occurrence further left. This dynamic programming approach requires $O(n)$ time to compute $\texttt{FirstOcc}_\ell$. Such time is unfeasible if we need to calculate $\texttt{FirstOcc}_\ell$ for each level of the block tree.

However, it is possible to compute $\texttt{FirstOcc}_{\ell_0}$ using $\texttt{FirstOcc}_{\ell_1}$ for $\ell_1 \geq \ell_0$, as every occurrence of an $\ell_1$-factor contains an $\ell_0$-factor as a prefix. There might be an occurrence of the $\ell_0$-factor further left, but we store information about that in $\texttt{FirstOcc}_{\ell_1}$. Remember that we also store pointers to a previous occurrence of the longest previous factor if that factor is shorter than $\ell_1$.

We can now use this property to identify the leftmost occurrence for each block level-by-level in $\texttt{FirstOcc}_*$, where we store $\texttt{FirstOcc}_\ell$ for the current level and update it for each following level. Recall that by definition, each pair of marked blocks contains the leftmost occurrence of at least one substring of $T$. Therefore, each leftmost occurrence of any substring with length at most the current block level length $\ell$ is contained in a marked block. All blocks in the current level (except for the first level) are children of marked blocks in the level before. Hence, the leftmost occurrence of each substring of a length equal to the current block length is contained in a block in the current level. We still have to update all text positions contained in the previous block tree level. This is necessary as we need to consider cases where the values in the LPF array are smaller than the last level's block size $\ell_1$ but greater than the next level's block size $\ell_0$, i.e., the positions $i \in [0, n)$ where $\ell_0 \leq \texttt{LPF}[i] < \ell_1$.

In this case $\texttt{FirstOcc}_{\ell_1}[i]$ points to a previous occurrence of the longest previous factor of $i$. This occurrence can be in an unmarked block as it is not necessarily the first occurrence of said longest previous factor. Hence, we also have to update $\texttt{FirstOcc}_*$ for text positions $k \in [0, n)$ that fall into an unmarked block in the previous level. We do so from left to right. Suppose we have updated $\texttt{FirstOcc}_*[0..k-1]$ and are processing $\texttt{FirstOcc}_*[k]$. Let $p = \texttt{FirstOcc}_*[k]$. We will update $\texttt{FirstOcc}_*[k]$ if one of the two conditions is met.

**Condition 1** $\texttt{LPF}[k] \geq \ell_0$ and $\texttt{LPF}[p] \geq \ell_0$: We know that $p$ and $k$ share the same $\ell_0$-factor (Observation 5). Therefore, the first occurrence of $\ell_0$-factor$_p$ is also the first occurrence of $\ell$-factor$_k$, and we can set $\texttt{FirstOcc}_*[k] = \texttt{FirstOcc}_*[p]$.

**Condition 2** $0 < \texttt{LPF}[k] \leq \texttt{LPF}[p]$: If condition 2 is met but condition 1 is not, we still know that $\texttt{FirstOcc}_*[k] = \texttt{FirstOcc}_*[p]$, as there are just two cases:

**Case 2.1** $\texttt{LPF}[k] < \ell_0$ and $\texttt{LPF}[p] \geq \ell_0$: Due to condition 2 and Lemma 4 and Observation 5 we know that said longest previous factor is a prefix of $\ell_0$-factor$_p$. Due to $\texttt{LPF}[p] \geq \ell_0$, $\texttt{FirstOcc}_*[p]$ points to the leftmost occurrence of $\ell_0$-factor$_p$.

**Case 2.2** $\texttt{LPF}[k] < \ell_0$ and $\texttt{LPF}[p] < \ell_0$: Due to condition 2 and Lemma 4 we know that said longest previous factor has a previous occurrence at $\texttt{FirstOcc}_*[p]$.

If neither condition is met, i.e., $\texttt{LPF}[p] < \texttt{LPF}[k]$ and $\texttt{LPF}[p] < \ell_0$, $k$ is either the leftmost occurrence for all factors of size at least $\ell_0$ or $\texttt{FirstOcc}_*[k]$ points to a first occurrence of a substring smaller than $\ell_0$ and hence points into a marked block.

▶ **Lemma 7.** *Updating* $\texttt{FirstOcc}_*$ *for all levels during the block tree construction requires* $O(n(1 + \log_\tau \frac{z}{s}))$ *time in total.*

**Proof.** Initializing $\texttt{FirstOcc}_*$ takes $O(n)$ time. Every level but the first has at most $3z\tau$ blocks, and the size of blocks is decreasing by a factor $\tau$ for each further level. This reduces the number of string positions still contained inside of blocks geometrically with each level. The total sum of all block lengths is $O(n(1 + \log_\tau \frac{z}{s}))$ [6, Section 6.1]. Since we only have to update $\texttt{FirstOcc}_*$ for positions in unmarked blocks in the previous level, we obtain the required total time for all levels. ◀

### 5.2.2 Leftmost Occurrences as Blocks

After updating $\texttt{FirstOcc}_*$ to store the leftmost occurrence for each text position in the current block tree level $B_0, B_1, \ldots$, we still have to find the marked blocks covering the leftmost occurrence of each unmarked block $B^u$.

We can map the occurrences in the text to blocks in three parts. First, we store for each unmarked block $B_i$ a pair $\langle \texttt{FirstOcc}_*[\texttt{s}(B_i)], i\rangle$ containing its leftmost occurrence and its index in our block level in a set $U$. Second, we sort the set by each pair's first element using a radix sort, i.e., we sort our unmarked blocks by their leftmost occurrences in the text. Third, we sequentially scan our block tree level and our sorted set $U$ simultaneously in the following fashion. Let $\langle occ_j, j\rangle$ be the currently considered element in $U$ and $B_i$ be the current block of our block tree level. If $\ell$-factor$_{occ_j}$ starts inside $B_i$, we set a pointer from $B_j$ to $B_i$ with offset $occ_j - \texttt{s}(B_i)$ and continue with the next element in $U$. Otherwise, we continue with the next block in our block tree level.

▶ **Lemma 8.** *For block trees with* $z\tau = O(n)$*, finding the blocks containing the leftmost occurrences of unmarked blocks can be done in* $O(z\tau)$ *time and* $O(z\tau)$ *words of space.*

**Proof.** The first and third step require $O(z\tau)$ time, as we only scan over blocks in the current block tree level. Sorting $U$ with radix sort requires $O(z\tau)$ time and $O(z\tau)$ words of space. ◀

Alternatively, we can also identify the mapping between text positions and blocks by traversing the already built block tree. This mimics an access query on the block tree that stops as soon as it reaches the current level. Such a query requires $O(\log_\tau \frac{n \log \sigma}{s \log n})$ time, which is linear in the height of the tree. Overall, computing the mapping using this approach requires $O(z\tau \log_\tau \frac{n \log \sigma}{s \log n})$ time.

**Table 2** Input names, number of characters $n$, alphabet size $\sigma$, number of LZ77 factors $z$, measure of compressibility $\frac{z \log n}{n \log \sigma}$, and the compression achieved with `p7zip` (v. 16.02) expressed by the ratio of the compressed output size divided by the input size.

## 5.3 New Block Tree Construction Algorithm

Now, we can put all these building blocks together to form a practically efficient block tree construction algorithm. First, we calculate the `LPF` array and `PrevOcc` array. We then initialize $\texttt{FirstOcc}_*$ for $\ell = n/s$ and construct each block tree level top-down as described in this section, i.e., we identify all marked blocks and then compute all pointers (and offsets) for the unmarked blocks. Finally, we update $\texttt{FirstOcc}_*$ and repeat this process until we reach the deepest level, where the blocks are stored explicitly. While this algorithm does not introduce better asymptotic running times, it practically outpaces all other available construction implementations, as we will empirically evaluate in Section 6. Overall, combining all previous steps, we obtain the following result.

▶ **Theorem 9.** *Given a string $T$ of length $n$ over an alphabet of size $\sigma$, two integers $s$ and $\tau$ greater than 1, we can compute the block tree in $O(n(1 + \log_\tau \frac{z}{s}))$ time using $O(n)$ words of space.*

**Pruning.** The algorithm described in this section constructs the same block tree structure as the algorithms described by Belazzougui et al. [6], see Section 4.1. Thus, their pruning algorithm works without any changes of the block tree resulting from this construction.

# 6 Experimental Evaluation

We conducted our experiments on a server equipped with an AMD EPYC Rome 7702P (64 cores (128 hyperthreads), frequencies up to 3.35 GHz, and 256 MiB L3 cache) and 1024 GiB DDR4 ECC RAM. The server runs Ubuntu 20.04.2 LTS. We compiled all code with GCC 12.1 using the flags `-O3` and `-march=native`. For the evaluation of our parallel code written in OpenMP, we compiled the code with the additional flag `-fopenmp`.

**Table 3** Most space-efficient ($\tau_{\text{space}}$ and $b_{\text{space}}$) and fastest configurations ($\tau_{\text{time}}$ and $b_{\text{time}}$) of $\text{LPF}_1$ on the repetitive inputs (without rank and select support).

| Input | $\tau_{\text{space}}$ | $b_{\text{space}}$ | $\tau_{\text{time}}$ | $b_{\text{time}}$ |
|---|---|---|---|---|
| cere | 16 | 16 | 2 | 8 |
| coreutils | 8 | 8 | 2 | 2 |
| einstein.en.txt | 4 | 16 | 2 | 2 |
| Escherichia_Coli | 4 | 16 | 2 | 4 |
| influenza | 4 | 16 | 2 | 4 |
| kernel | 8 | 16 | 2 | 2 |
| para | 4 | 16 | 2 | 8 |
| world_leaders | 4 | 16 | 2 | 2 |

We compare our block tree construction algorithms [42,44] with the (to our best knowledge) only other block tree implementation by Belazzougui et al. [6].[3] Their implementation uses Karp-Rabin fingerprints (Section 4) with parameter $s = 1$. While $s = 1$ is not a feasible choice in the formal definition of block trees (see Section 4), in practice, all levels without any unmarked blocks are removed during the pruning phase, making this configuration possible.

There are two different variants of our block tree construction algorithm: $\text{LPF}_s^{\text{DP}}$ and $\text{LPF}_s$. The former uses the dynamic programming approach to identify the text position of the previous occurrence while the latter uses the naive approach, see Section 5.2. Since we need the `LPF` array for our construction algorithms, we can compute $z$ and also choose both $s = z$ and $s = 1$. To show that our improvements are not only based on engineering, we also include $\text{FP}_1$ which uses fingerprints instead of the `LPF` array while the rest of our code remains nearly unchanged, i.e., it is a reimplementation of the original algorithm.

For our implementation, we make use of `libsais`[4], the fastest suffix array construction algorithm implementation available to compute the suffix and longest common prefix arrays that we use for the `LPF` array construction. We also use the `int_vector` from the Succinct Data Structure Library [30] and the `pasta::bit_vector` [43] internally in the block tree.

We do not include fast wavelet tree construction algorithms [18, 30] in our plots as preliminary experiments show that they can be constructed at least an order of magnitude faster than block trees. For a detailed comparison of query speed of block trees and wavelet trees, we refer to the block tree article by Belazzougui et al. [6]. They show that block trees require around the same space but can answer queries an order of magnitude faster.

We conducted our sequential experiments with all combinations of $\tau \in \{2, 4, 8, 16\}$ and maximum leaf size $b = \{2, 4, 8, 16\}$, i.e., the threshold on the number of characters stored explicitly as a leaf. The timing starts when the input is loaded in main memory and stops as soon as the block tree has been constructed. All reported values are the average of three runs. We used the repetitive text corpus from the *Pizza&Chili* corpus[5], which was also used in the original block tree article [6]. Additionally, we used the non-repetitive *Pizza&Chili* corpus[6]. See Table 2 for details.

## 6.1 Sequential Block Tree Construction

In this section, we present the results of our experimental evaluation of block tree construction algorithms. For the evaluation, we used both, repetitive and non-repetitive inputs.

**Repetitive Inputs.** In Figures 2 and 3, we show the construction throughput (processed input in MiB per second) on the $y$-axis and the space requirements of the final block tree (without and with additional rank and select support) on the $x$-axis. Plotting the throughput helps normalizing the running times for different input sizes. Furthermore, it highlights that the construction time of the block tree without rank and select support does not depend on the compressibility of the input.

Surprisingly, on most inputs, smaller block trees are not that much slower to construct than larger block trees. Our fastest construction algorithm for the smallest block trees is always $\mathrm{LPF}_1$. Hence, we now only compare this algorithm with the original implementation. This also means that following the previous occurrence in the text naively is (for small block trees with fewer marked nodes) cheaper than explicitly computing the results. Furthermore, choosing $s = z$ provides no real benefit, as it does not result in a faster construction. For most inputs, the most space-efficient configuration of $\mathrm{LPF}_1$ uses $\tau = 4$ and $b = 16$ and the fastest configuration of $\mathrm{LPF}_1$ uses $\tau = 2$ and $b = 2$, see Table 3. Note that no two different configurations result in the same space requirements, even though, they can be very close.

When constructing only the block tree without rank and select support, $\mathrm{LPF}_1$ is between 6.48 and 11.52 times faster than the original implementation (average: 9.51, median: 9.86). Computing the additional data for the rank and select support is the same for our and the original implementation. Thus, here $\mathrm{LPF}_1$ is only between 3.61 and 11.23 times faster (average: 6.75, median: 6.24), despite the fact that the times for $\mathrm{LPF}_1$ include also the `LPF` array construction. We further want to mention that the `LPF` array construction also introduces higher memory requirements during the construction than the fingerprint-based approaches. Hence, there is a working-space-time trade-off for the construction.

**Non-Repetitive Inputs.** We now give additional experimental results on the non-repetitive inputs. We only use 32 MiB prefixes of the texts, as the block tree construction algorithm by Belazzougui et al. [6] requires more than 1 TiB of working space for larger non-repetitive inputs. This is due to the order in which their algorithm constructs the block tree. Instead of first compressing all data internally, many operations and auxiliary data is computed on the uncompressed data. The results of these experiments are depicted in Figure 5.

Overall, the results are similar to the results for the repetitive inputs: $\mathrm{LPF}_1$ is the fastest construction algorithm most of the time. However, on some inputs, the dynamic programming $\mathrm{LPF}_z^{\mathrm{DP}}$ is faster. This is due to the long chains of previous occurrences that have been marked. Since the texts are non-repetitive, there are fewer marked blocks overall, resulting in bigger block trees. Overall, for non-repetitive inputs, computing larger block trees is slightly faster than computing very space-efficient block trees. This becomes very apparent for block trees with rank and select support.

## 6.2 Parallel Block Tree Construction

While the total running time of our algorithm is fast compared to our competitor, on average 71.33 % of the running time is spent for the `LPF` array construction. Fortunately, `libsais` supports parallel computation. In addition, we use the LZ77 factorization algorithm by

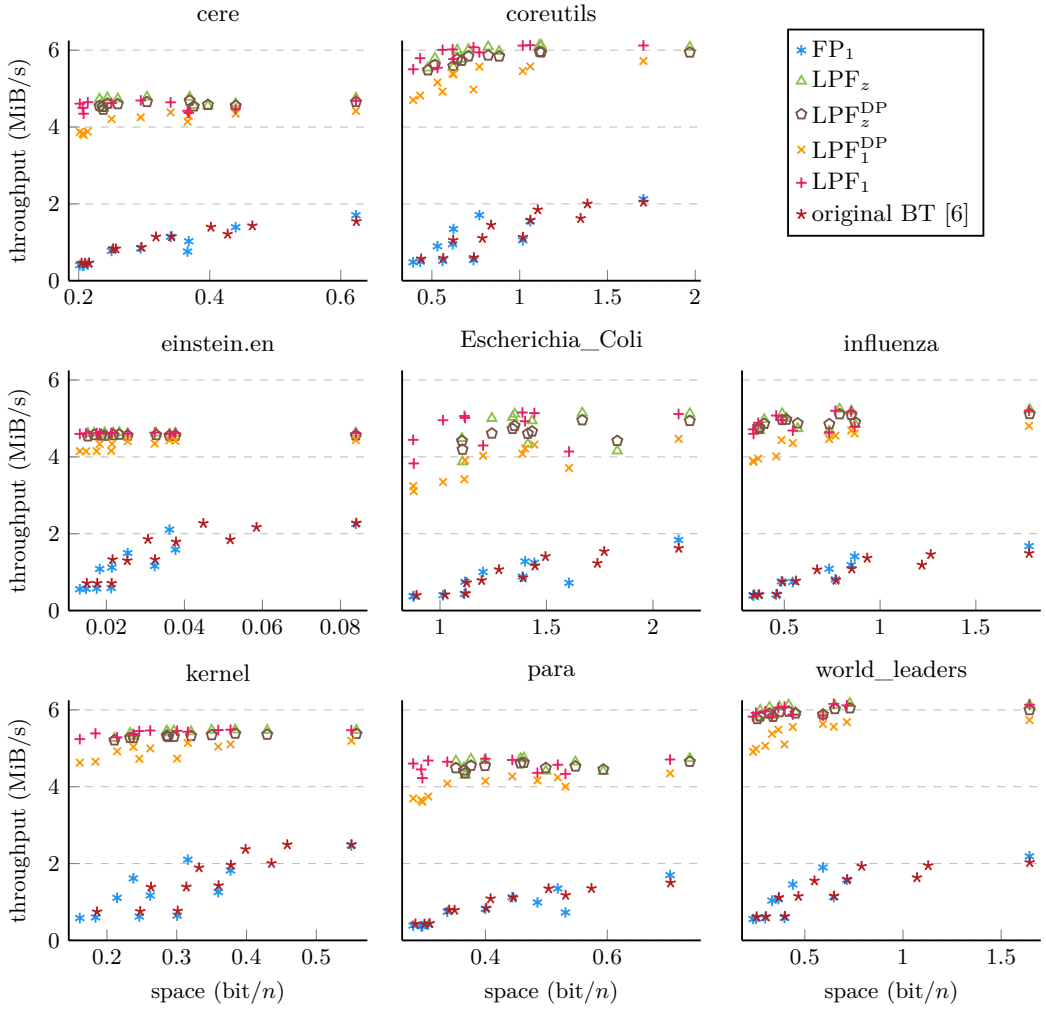

**Figure 2** Block tree construction *without* rank and select support, showing throughput (processed input in MiB per second) and space requirements of the final block tree (bits per character of the input) on repetitive inputs. The range of each $x$-axis depends on the compressibility of the input. Data points for each algorithm show different configurations of $\tau$ and $b$, see Table 3 for more details.

Shun and Zhao [62] that requires $O(n)$ work and $O(\log^2 n)$ time.[7] We also parallelized the construction of the rank and select support with a straight-forward implementation since the computed values are independent for each character.

We only achieve a speedup using up to 32 cores. This is most likely due to the fact that only eight memory controllers are available, which have to be shared by 16 groups of 4 cores. As soon as we use more than 32 cores, multiple groups have to share a controller. With 32 cores, we achieve a speedup of up to 6.64 (4.71 on average). This comes very close to the speedups of the parallel `libsais`, which achieves a speedup of at most 6 (5.2 on average). The additional speedup can be explained by the speedup thanks to the parallel construction of the rank and select support.

[7] See `https://github.com/zfy0701/Parallel-LZ77`, last accessed 2023-07-04.

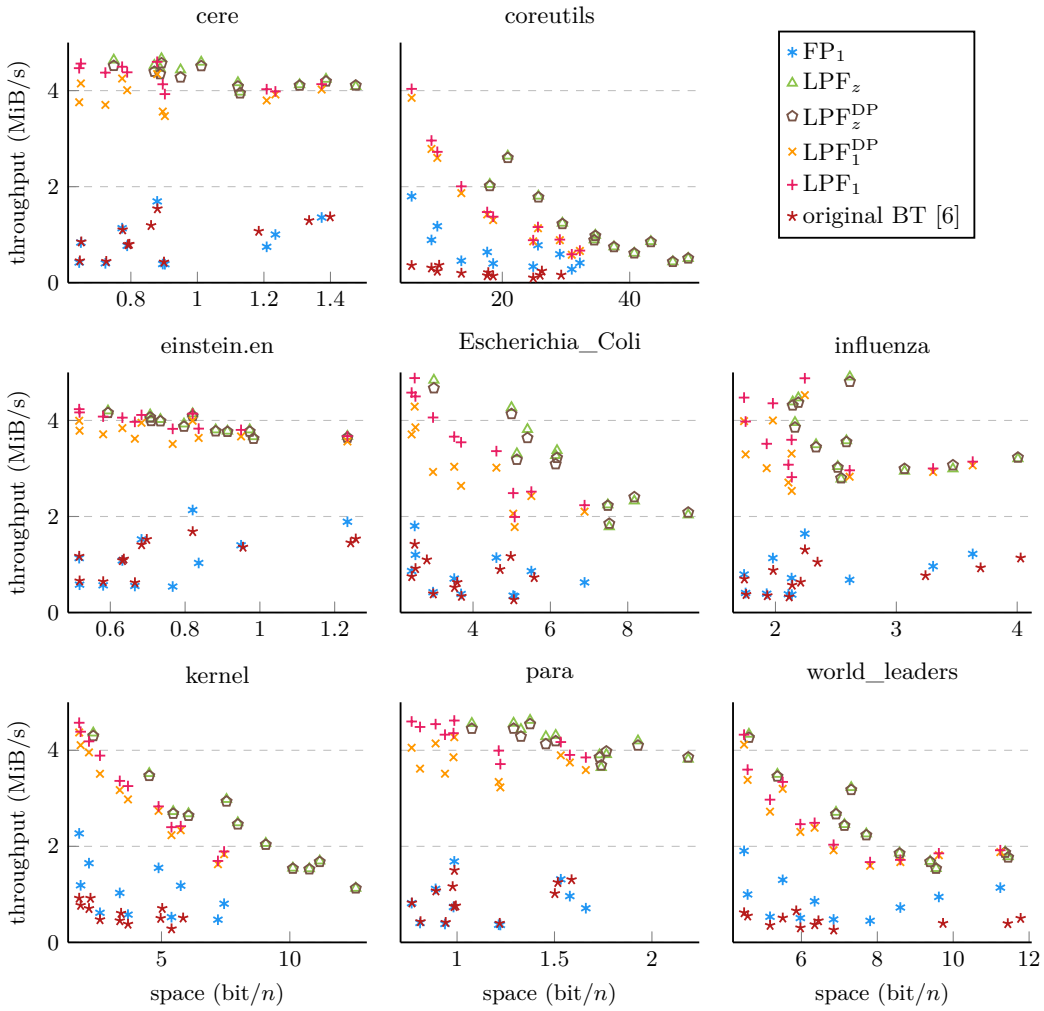

**Figure 3** Block tree *with* rank and select support construction throughput (processed input in MiB per second) and space requirements of the final block tree (bits per character of the input) on repetitive inputs. The range of each $x$-axis depends on the compressibility of the input. Data points for each algorithm show different configurations of $\tau$ and $b$, see Table 3 for more details.

## 7 Conclusion and Future Work

The LPF array allows us to construct the block tree up to an order of magnitude faster than using Karp-Rabin fingerprints. All tested algorithms produce the same block trees (when using the same parameters). A simple parallelization of our algorithm results in a speedup of up to 6.64 using 32 cores. However, the scalability of the current state of the algorithm is mostly limited by the LPF array computation. Here, it might be interesting to investigate a parallelization of the construction algorithm based on Karp-Rabin fingerprints using concurrent hash tables [46]. In general, better scalability is of great interest, as otherwise, construction speed similar to wavelet trees seems hard to achieve.

In the light that the LPF array can be represented in $2n + o(n)$ bits [3] with algorithms computing this representation in compact [3] or compressed space [59], future work includes engineering a more memory-efficient LPF array construction. Further improvements in

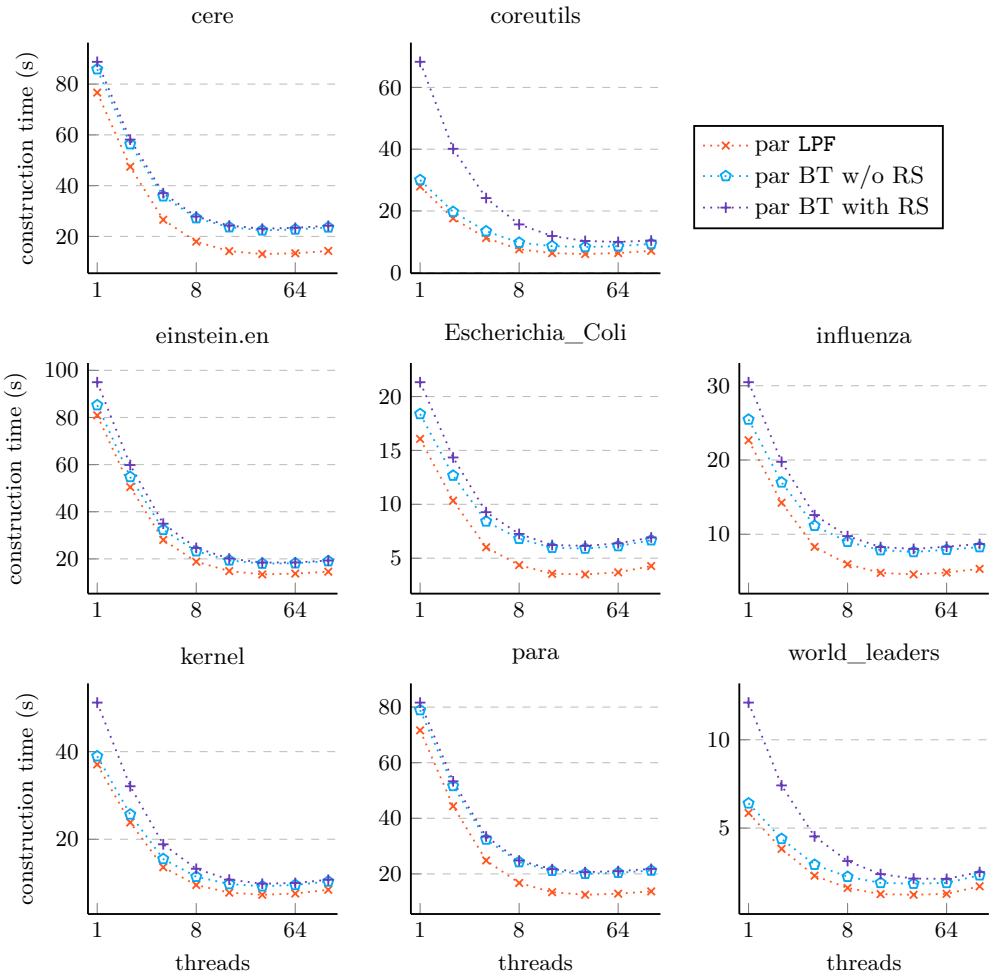

**Figure 4** Parallel (strong scaling) block tree construction using the configuration $\tau = 8$ and $b = 16$. Construction times of a block tree includes parallel LPF array construction time.

construction time can be obtained by introducing stricter rules for the marking of nodes in the block tree rendering the pruning phase unnecessary. Finally, we want to compress the block tree recursively by using block trees internally.

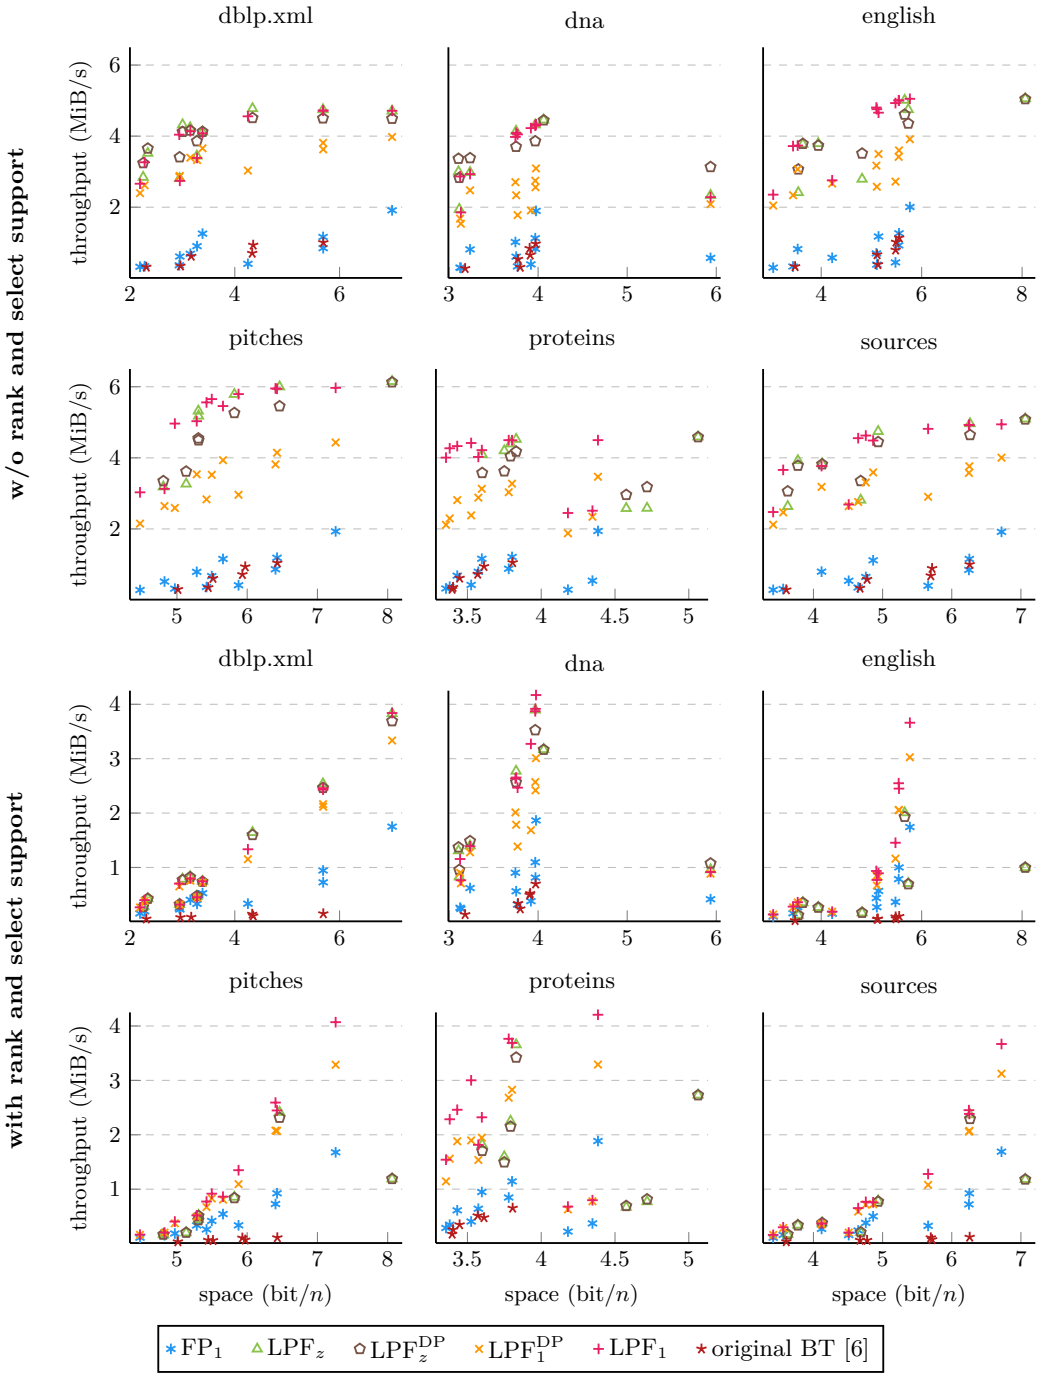

**Figure 5** Block tree construction throughput and space requirements per character of the input on 32 MiB prefixes of the non-repetitive inputs.

# Connectivity Queries Under Vertex Failures: Not Optimal, but Practical

**Evangelos Kosinas**
Department of Computer Science & Engineering, University of Ioannina, Greece

## Abstract

We revisit once more the problem of designing an oracle for answering connectivity queries in undirected graphs in the presence of vertex failures. Specifically, given an undirected graph $G$ with $n$ vertices and $m$ edges and an integer $d_\star \ll n$, the goal is to preprocess the graph in order to construct a data structure $\mathcal{D}$ such that, given a set of vertices $F$ with $|F| = d \leq d_\star$, we can derive an oracle from $\mathcal{D}$ that can efficiently answer queries of the form "is $x$ connected with $y$ in $G \setminus F$?". Very recently, Long and Saranurak (FOCS 2022) provided a solution to this problem that is almost optimal with respect to the preprocessing time, the space usage, the update time, and the query time. However, their solution is highly complicated, and it seems very difficult to be implemented efficiently. Furthermore, it does not settle the complexity of the problem in the regime where $d_\star$ is a constant. Here, we provide a much simpler solution to this problem, that uses only textbook data structures. Our algorithm is deterministic, it has preprocessing time and space complexity $O(d_\star m \log n)$, update time $O(d^4 \log n)$, and query time $O(d)$. These bounds compare very well with the previous best, especially considering the simplicity of our approach. In fact, if we assume that $d_\star$ is a constant ($d_\star \geq 4$), then our algorithm provides some trade-offs that improve the state of the art in some respects. Finally, the data structure that we provide is flexible with respect to $d_\star$: it can be adapted to increases and decreases, in time and space that are almost proportional to the change in $d_\star$ and the size of the graph.

## 1 Introduction

In this paper we deal with the following problem. Given an undirected graph $G$ with $n$ vertices and $m$ edges, and a fixed integer $d_\star$ ($d_\star \ll n$), the goal is to construct a data structure $\mathcal{D}$ that can be used in order to answer connectivity queries in the presence of at most $d_\star$ vertex-failures. More precisely, given a set of vertices $F$, with $|F| \leq d_\star$, we must be able to efficiently derive an oracle from $\mathcal{D}$, which can efficiently answer queries of the form "are the vertices $x$ and $y$ connected in $G \setminus F$?". In this problem, we want to simultaneously optimize the following parameters: (1) the construction time of $\mathcal{D}$ (preprocessing time), (2) the space usage of $\mathcal{D}$, (3) the time to derive the oracle from $\mathcal{D}$ given $F$ (update time), and (4) the time to answer a connectivity query in $G \setminus F$. This problem is very well motivated; it has attracted the attention of researchers for more than a decade now, and it has many interesting variations. The reader is referred to [5] or [7] for the details on its history and its variations.

## 1.1 Previous work

Despite being extensively studied, it is only very recently that an almost optimal solution was provided by Long and Saranurak [7]. Specifically, they provided a deterministic algorithm that has $\hat{O}(m) + \tilde{O}(d_\star m)$ preprocessing time, uses $O(m \log^* n)$ space, and has $\hat{O}(d^2)$ update time and $O(d)$ query time.[1] This improves on the previous best deterministic solution by Duan and Pettie [5], that has $O(mn \log n)$ preprocessing time, uses $O(d_\star m \log n)$ space, and has $O(d^3 \log^3 n)$ update time and $O(d)$ query time. We note that there are more solutions to this problem, that optimize some parameters while sacrifising others (e.g., in the solution of Pilipczuk et al. [9], there is no dependency on $n$ in the update time, but this is superexponential in $d_\star$, and the preprocessing time is $O(mn^2 2^{2^{O(d_\star)}})$). We refer to Table 1 in reference [7] for more details on the best known (upper) bounds for this problem. We also refer to Theorem 1.2 in [7] for a summary of known (conditional) lower bounds, that establish the optimality of [7].

## 1.2 Our contribution

The bounds that we mentioned are the best known for a deterministic solution. In practice, one would prefer the solution of Long and Saranurak [7], because that of Duan and Pettie [5] has preprocessing time $O(mn \log n)$, which can be prohibitively slow for large enough graphs. However, the solution in [7] is highly complicated, and it seems very difficult to be implemented efficiently. This is a huge gap between theory and practice. Furthermore, the (hidden) dependence on $n$ in the time-bounds of [7] is not necessarily optimal if we assume that $d_\star$ is a constant for our problem. We note that this is a problem with various parameters, and thus it is very difficult to optimize all of them simultaneously.

Considering that this is a fundamental connectivity problem, we believe that it is important to have a solution that is relatively simple to describe and analyze, compares very well with the best known bounds (even improves them in some respects), opens a new direction to settle the complexity of the problem, and can be readily implemented efficiently.

In this paper, we exhibit a solution that has precisely those characteristics. We present a deterministic algorithm that has preprocessing time $O(d_\star m \log n)$, uses space $O(d_\star m \log n)$, and has $O(d^4 \log n)$ update time and $O(d)$ query time.[2] Our approach is arguably the simplest that has been proposed for this problem. The previous solutions rely on sophisticated tree decompositions of the original graph. Here, instead, we basically rely on a single DFS-tree, and we simply analyze its connected components after the removal of a set of vertices. It turns out that there is enough structure to allow for an efficient solution (see Section 3.2).

The bounds that we provide compare very well with the previous best, especially considering the simplicity of our approach. (See Tables 1 and 2.) In fact, as we can see in Table 1, our solution is the best choice for implementations, considering that the algorithm of Long and Saranurak is very difficult to be implemented within the claimed time-bounds. Furthermore, if we assume that $d_\star$ is a constant ($d_\star \geq 4$), then, as we can see in Table 2, our algorithm provides some trade-offs, that improve the state of the art in some respects.

---

[1] The symbol $\hat{O}$ hides subpolynomial (i.e. $n^{o(1)}$) factors, and $\tilde{O}$ hides polylogarithmic factors. The hidden expressions in the time-bounds are not specified by the authors in their overview. Also, the description for the $\log^* n$ function that appears in the space complexity is that it "can be substituted with any slowly growing function". One thing that is explicitly stated, however, is that the hidden subpolynomial factors are worse than polylogarithmic. We must emphasize that the difficulty in stating the precise bounds is partly due to there being various trade-offs in the functions involved, and is partly indicative of the complexity of the techniques that are used.

[2] The log factors in the space usage and the time for the updates can be improved with the use of more sophisticated 2D-range-emptiness data structures, such as those in [2].

**Table 1** Comparison of the best-known deterministic bounds. We note that $m$ can be replaced with $\bar{m} = min\{m, d_\star n\}$, using the sparsification of Nagamochi and Ibaraki [8]. The data structure of Pilipczuk et al. does not support an update phase, but answers queries directly, given a set of (at most $d_\star$) failed vertices and two query vertices.

| | Preprocessing | Space | Update | Query |
|---|---|---|---|---|
| Pilipczuk et al. [9] | $O(2^{2^{O(d_\star)}} mn^2)$ | $O(2^{2^{O(d_\star)}} m)$ | – | $O(2^{2^{O(d_\star)}})$ |
| Duan and Pettie [5] | $O(mn \log n)$ | $O(d_\star m \log n)$ | $O(d^3 \log^3 n)$ | $O(d)$ |
| Long and Saranurak [7] | $\hat{O}(m) + \tilde{O}(d_\star m)$ | $O(m \log^* n)$ | $\hat{O}(d^2)$ | $O(d)$ |
| **This paper** | $O(d_\star m \log n)$ | $O(d_\star m \log n)$ | $O(d^4 \log n)$ | $O(d)$ |

**Table 2** Comparison of the best-known deterministic bounds, when $d_\star$ is a fixed (small) constant. Although the algorithm of Pilipczuk et al. has the best space and query-time bounds, it has very large preprocessing time. Our solution has the best preprocessing time, and also better update time compared to the solutions of [5] and [7]. Furthermore, our space usage is almost linear.

| | Preprocessing | Space | Update | Query |
|---|---|---|---|---|
| Pilipczuk et al. [9] | $O(mn^2)$ | $O(m)$ | – | $O(1)$ |
| Duan and Pettie [5] | $O(mn \log n)$ | $O(m \log n)$ | $O(\log^3 n)$ | $O(1)$ |
| Long and Saranurak [7] | $\hat{O}(m) + \tilde{O}(m)$ | $O(m \log^* n)$ | $\hat{O}(1)$ | $O(1)$ |
| **This paper** | $O(m \log n)$ | $O(m \log n)$ | $O(\log n)$ | $O(1)$ |

Finally, the data structure that we provide is flexible with respect to $d_\star$: it can be adapted to increases and decreases, in time and space that are almost proportional to the change in $d_\star$ and the size of the graph (see Corollary 3). We do not know if any of the previous solutions has this property. It is a natural question whether we can efficiently update the data structure so that it can handle more failures (or less, and thereby free some space). As far as we know, we are the first to take notice of this aspect of the problem.

## 2 Preliminaries

We assume that the reader is familiar with standard graph-theoretical terminology (see, e.g., [4]). The notation that we use is also standard. Since we deal with connectivity under *vertex* failures, it is sufficient to consider simple graphs as input to our problem (because the existence of parallel edges does not affect the connectivity relation). However, during the update phase, we construct a multigraph that represents the connectivity relationship between some connected components after removing the failed vertices (Definition 9). The parallel edges in this graph are redundant, but they may be introduced by the algorithm that we use to construct it, and it would be costly to check for redundancy throughout.

It is also sufficient to assume that the input graph $G$ is connected. Because, otherwise, we can initialize a data structure on every connected component of $G$; the updates, for a given set of failures, are distributed to the data structures on the connected components, and the queries for pairs of vertices that lie in different connected components of $G$ are always *false*. We use $G$ to denote the input graph throughout; $n$ and $m$ denote its number of vertices and edges, respectively. For any two integers $x, y$, we use the interval notation $[x, y]$ to denote the set $\{x, x+1, \ldots, y\}$. (If $x > y$, then $[x, y] = \emptyset$.)

## 2.1 DFS-based concepts

Let $T$ be a DFS-tree of $G$, with start vertex $r$ [10]. We use $p(v)$ to denote the parent of every vertex $v \neq r$ in $T$ ($v$ is a child of $p(v)$). For any two vertices $u, v$, we let $T[u, v]$ denote the simple tree path from $u$ to $v$ on $T$. For every two vertices $u$ and $v$, if the tree path $T[r, u]$ uses $v$, then we say that $v$ is an ancestor of $u$ (equivalently, $u$ is a descendant of $v$). In particular, a vertex is considered to be an ancestor (and also a descendant) of itself. It is very useful to identify the vertices with their order of visit during the DFS, starting with $r \leftarrow 1$. Thus, if $v$ is an ancestor of $u$, we have $v < u$. For any vertex $v$, we let $T(v)$ denote the subtree rooted at $v$, and we let $ND(v)$ denote the number of descendants of $v$ (i.e., $ND(v) = |T(v)|$). Thus, we have that $T(v) = [v, v + ND(v) - 1]$, and therefore we can check the ancestry relation in constant time. Two children $c$ and $c'$ of a vertex $v$ are called *consecutive children* of $v$ (in this order), if $c'$ is the minimum child of $v$ with $c' > c$. Notice that, in this case, we have $T(c) \cup T(c') = [c, c' + ND(c') - 1]$.

A DFS-tree has the following extremely convenient property: the endpoints of every non-tree edge of $G$ are related as ancestor and descendant [10], and so we call those edges *back-edges*. Our whole approach is basically an exploitation of this property, which does not hold in general rooted spanning trees of $G$ (unless they are derived from a DFS traversal, and only then [10]). To see why this is relevant for our purposes, consider what happens when we remove a vertex $f \neq r$ from $T$. Let $c_1, \ldots, c_k$ be the children of $f$ in $T$. Then, the connected components of $T \setminus f$ are given by $T(c_1), \ldots, T(c_k)$ and $T(r) \setminus T(f)$. A subtree $T(c_i)$, $i \in \{1, \ldots, k\}$, is connected with the rest of the graph in $G \setminus f$ if and only if there is a back-edge that stems from $T(c_i)$ and ends in a proper ancestor of $f$. Now, this problem has an algorithmically elegant solution. Suppose that we have computed, for every vertex $v \neq r$, the *lowest* proper ancestor of $v$ that is connected with $T(v)$ through a back-edge. We denote this vertex as $low(v)$. Then, we may simply check whether $low(c_i) < f$, in order to determine whether $T(c_i)$ is connected with $T(r) \setminus T(f)$ in $G \setminus f$.

We extend the concept of the $low$ points, by introducing the $low_k$ points, for any $k \in \mathbb{N}$. These are defined recursively, for any vertex $v \neq r$, as follows. $low_1(v)$ coincides with $low(v)$. Then, supposing that we have defined $low_k(v)$ for some $k \in \mathbb{N}$, we define $low_{k+1}(v)$ as $min(\{y \mid \exists \text{ a back-edge } (x, y) \text{ such that } x \in T(v) \text{ and } y < v\} \setminus \{low_1(v), \ldots, low_k(v)\})$. Notice that $low_k(v)$ may not exist for some $k \in \mathbb{N}$ (and this implies that $low_{k'}(v)$ does not exist, for any $k' > k$). If, however, $low_k(v)$ exists, then $low_{k'}(v)$, for any $k' < k$, also exists, and we have $low_1(v) < low_2(v) < \cdots < low_k(v)$. Notice that the existence of $low_k(v)$ implies that there is a back-edge $(x, low_k(v))$, where $x$ is a descendant of $v$.

▶ **Proposition 1** ([6]). *Let $T$ be a DFS-tree of a simple graph $G$, and assume that the adjacency list of every vertex of $G$ is sorted in increasing order w.r.t. the DFS numbering. Suppose also that, for some $k \in \{0, \ldots, n-1\}$, we have computed the $low_1, \ldots, low_k$ points of all vertices (w.r.t. $T$), and the set $\{low_1(v), \ldots, low_k(v)\}$ is stored in an increasingly sorted array for every $v \neq r$. Then we can compute the $low_{k+1}$ points of all vertices in $O(n \log(k+1))$ time.*[3]

▶ **Corollary 2** ([6]). *For any $k \in \{1, \ldots, n-1\}$, the $low_1, \ldots, low_k$ points of all vertices can be computed in $O(m + kn \log k)$ time.*

[3] We make the convention that $\log(1) = 1$, so that the time to compute the $low_1$ points is $O(n)$.

# 3 The algorithm for vertex failures

## 3.1 Initializing the data structure

We will need the following ingredients in order to be able to handle at most $d_\star$ failed vertices.

- **(i)** A DFS-tree $T$ of $G$ rooted at a vertex $r$. The values $ND$ and $depth$ (w.r.t. $T$) must be computed for all vertices. We identify the vertices of $G$ with the DFS numbering of $T$.
- **(ii)** A level-ancestor data structure on $T$.
- **(iii)** A 2D-range-emptiness data structure on the set of the back-edges of $G$ w.r.t. $T$.
- **(iv)** The $low_i$ points of all vertices, for every $i \in \{1, \ldots, d_\star\}$.
- **(v)** For every $i \in \{1, \ldots, d_\star\}$, a DFS-tree $T_i$ of $T$ rooted at $r$, where the adjacency lists of the vertices are given by their children lists sorted in increasing order w.r.t. the $low_i$ point.
- **(vi)** For every $i \in \{1, \ldots, d_\star\}$, a 2D-range-emptiness data structure on the set of the back-edges of $G$ w.r.t. $T_i$.

The $depth$ value in $(i)$ refers to the depths of the vertices in $T$. This is defined for every vertex $v$ as the size of the tree path $T[r, v]$. (Thus, e.g., $depth(r) = 1$.) It takes $O(n)$ additional time to compute the $depth$ values during the DFS.

The level-ancestor data structure in $(ii)$ is used in order to answer queries of the form $\texttt{QueryLA}(v, \delta) \equiv$ "return the ancestor of $v$ that lies at depth $\delta$". We use those queries in order to find the children of vertices that are ancestors of other vertices. (I.e., given that $u$ is a descendant of $v$, we want to know the child of $v$ that is an ancestor of $u$.) For our purposes, it is sufficient to use the solution in Section 3 of [1], that preprocesses $T$ in $O(n \log n)$ time so that it can answer level-ancestor queries in (worst-case) $O(1)$ time.

The 2D-range-emptiness data structure in $(iii)$ is used in order to answer queries of the form $\texttt{2D\_range}([X_1, X_2] \times [Y_1, Y_2]) \equiv$ "is there a back-edge $(x, y)$ with $x \in [X_1, X_2]$ and $y \in [Y_1, Y_2]$?".[4] We can use a standard implementation for this data structure, that has $O(m \log n)$ space and preprocessing time complexity, and can answer a query in (worst-case) $O(\log n)$ time (see, e.g., Section 5.6 in [3]). The $m$ factor here is unavoidable, because the number of back-edges can be as large as $m - n + 1$. However, we note that we can improve the $\log n$ factor in the space and the query time if we use a more sophisticated solution, such as [2].

The $low_1, \ldots, low_{d_\star}$ points of all vertices can be computed in $O(m + d_\star n \log d_\star) = O(m + d_\star n \log n)$ time (Corollary 2). We obviously need $O(d_\star n)$ space to store them.

For $(v)$, we just perform $d_\star$ DFS's on $T$, starting from $r$, where each time we use a different arrangement of the children lists of $T$ as adjacency lists. This takes $O(d_\star n)$ time in total, but we do not need to actually store the trees. (In fact, the parent pointer is the same for all of them.) What we actually need here is the DFS numbering of the $i$-th DFS traversal, for every $i \in \{1, \ldots, d_\star\}$, which we denote as $DFS_i$. We keep those DFS numberings stored, and so we need $O(d_\star n)$ additional space. The usefulness of performing all those DFS's will become clear in Section 3.4. Right now, we only need to mention that, for every $i \in \{1, \ldots, d_\star\}$, the ancestry relation in $T_i$ is the same as that in $T$. Thus, the $low_1, \ldots, low_{d_\star}$ points for all vertices w.r.t. $T_i$ are the same as those w.r.t. $T$.

The 2D-range-emptiness data structures in $(vi)$ are used in order to answer queries of the form $\texttt{2D\_range\_i}([X_1, X_2] \times [Y_1, Y_2]) \equiv$ "is there a back-edge $(x, y)$ with $x \in [X_1, X_2]$ and $y \in [Y_1, Y_2]$?", where the endpoints of the query rectangle refer to the $DFS_i$ numbering,

[4] The input to `2D_range` is just the endpoints $X_1, X_2, Y_1, Y_2$ of the query rectangle; we use brackets around them, and the symbol $\times$, just for readability.

for $i \in \{1, \ldots, d_\star\}$. Since the ancestry relation is the same for $T_i$ and $T$, we have that the queries `2D_range`$([X_1, X_2] \times [Y_1, Y_2])$ and `2D_range_i`$([X_1, X_2]_i \times [Y_1, Y_2]_i)$ are equivalent, where the $i$ index below the brackets means that we have translated the endpoints in the $DFS_i$ numbering.

The construction of the 2D-range-emptiness data structures w.r.t. the DFS-trees $T_1, \ldots, T_{d_\star}$ takes $O(d_\star m \log n)$ time in total. In order to keed those data structures stored, we need $O(d_\star m \log n)$ space. Thus, the construction and the storage of the 2D-range-emptiness data structures dominate the space-time complexity overall.

It is easy to see that the list of data structures from $(i)$ to $(vi)$ is flexible w.r.t. $d_\star$. Thus, if $d_\star$ increases by 1, then we need to additionally compute the $low_{d_\star+1}$ points of all vertices, the $T_{d_\star+1}$ DFS-tree, and the corresponding 2D-range-emptiness data structure. Computing the $low_{d_\star+1}$ points takes $O(n \log(d_\star + 1)) = O(n \log n)$ time, and demands an additional $O(n)$ space, assuming that we have sorted the adjacency lists of $G$ in increasing order, and that we have stored the $low_1, \ldots, low_{d_\star}$ points, for every vertex, in an increasingly sorted array (see Proposition 1).

▶ **Corollary 3.** *Suppose that we have initialized our data structure for some $d_\star$, and we want to get a data structure for $d_\star + k$. Then we can achieve this in $O(km \log n)$ time, using extra $O(km \log n)$ space.*

If $d_\star$ decreases by $k$, then we just have to discard the $low_{d_\star-k+1}, \ldots, low_{d_\star}$ points, the $T_{d_\star-k+1}, \ldots, T_{d_\star}$ DFS-trees, and the corresponding 2D-range-emptiness data structures. This will free $O(km \log n)$ space.

## 3.2 The general idea

Let $F$ be a set of failed vertices. Then $T \setminus F$ may consist of several connected components, all of which are subtrees of $T$. It will be necessary to distinguish two types of connected components of $T \setminus F$. Let $C$ be a connected component of $T \setminus F$. If no vertex in $F$ is a descendant of $C$, then $C$ is called a *hanging subtree* of $T \setminus F$. Otherwise, $C$ is called an *internal component* of $T \setminus F$. (See Figure 1 for an illustration.) Observe that, while the number of connected components of $T \setminus F$ may be as large as $n - 1$ (even if $|F| = 1$), the number of internal components of $T \setminus F$ is at most $|F|$. This is an important observation, that allows us to reduce the connectivity of $G \setminus F$ to the connectivity of the internal components.

More precisely, we can already provide a high level description of our strategy for answering connectivity queries between pairs of vertices. Let $x, y$ be two vertices of $G \setminus F$. Suppose first that $x$ belongs to an internal component $C_1$ and $y$ belongs to an internal component $C_2$. Then it is sufficient to know whether $C_1$ and $C_2$ are connected in $G \setminus F$. Otherwise, if either $x$ or $y$ lies in a hanging subtree $C$, then we can substitute $C$ with any internal component that is connected with $C$ in $G \setminus F$. If no such internal component exists, then $x$ and $y$ are connected in $G \setminus F$ if and only if they lie in the same hanging subtree.

Thus, after the deletion of $F$ from $G$, it is sufficient to make provisions so as to be able to efficiently answer the following:

**(1)** Given a vertex $x$, determine the connected component of $T \setminus F$ that contains $x$.

**(2)** Given two internal components $C_1$ and $C_2$ of $T \setminus F$, determine whether $C_1$ and $C_2$ are connected in $G \setminus F$.

**(3)** Given a hanging subtree $C$ of $T \setminus F$, find an internal component of $T \setminus F$ that is connected with $C$ in $G \setminus F$, or report that no such internal component exists.

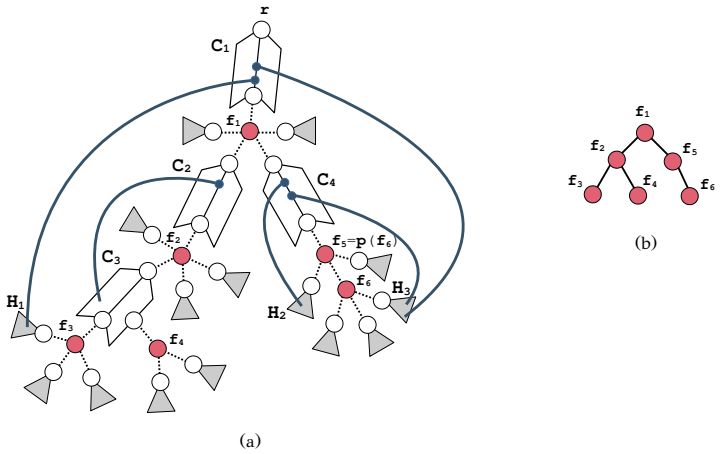

**Figure 1** (a) A set of failed vertices $F = \{f_1, \ldots, f_6\}$ on a DFS-tree $T$, and (b) the corresponding F-forest, which shows the $parent_F$ relation between failed vertices. Notice that $T \setminus F$ is split into several connected components, but there are only four internal components, $C_1$, $C_2$, $C_3$ and $C_4$. The hanging subtrees of $T \setminus F$ are shown with gray color (e.g., $H_1$, $H_2$ and $H_3$). The internal components $C_2$ and $C_3$ remain connected in $G \setminus F$ through a back-edge that connects them directly. $C_1$ and $C_4$ remain connected through the hanging subtree $H_3$ of $f_6$. We have $\partial(C_1) = \{f_1\}$, $\partial(C_2) = \{f_2\}$, $\partial(C_3) = \{f_3, f_4\}$ and $\partial(C_4) = \{f_5\}$. Notice that $f_6$ is the only failed vertex that is not a boundary vertex of an internal component, and it has $parent_F(f_6) = p(f_6)$.

Actually, the most difficult task, and the only one that we provide a preprocessing for (during the update phase), is (2). We explain how to perform (1) and (3) during the process of answering a query, in Section 3.5. An efficient solution for (2) is provided in Section 3.4.

The general idea is that, since there are at most $d = |F|$ internal components of $T \setminus F$, we can construct a graph with $O(d)$ nodes, representing the internal components of $T \setminus F$, that captures the connectivity relation among them in $G \setminus F$ (see Lemma 10). This is basically done with the introduction of some artificial edges between the (representatives of the) internal components. In the following subsection, we state some lemmas concerning the structure of the internal components, and their connectivity relationship in $G \setminus F$. All omitted proofs are contained in the full version of our paper [6].

## 3.3 The structure of the internal components

We will use the roots of the connected components of $T \setminus F$ (viewed as rooted subtrees of $T$) as representantives of them. Now we introduce some terminology and notation. If $C$ is a connected component of $T \setminus F$, we denote its root as $r_C$. If $C$ is a hanging subtree of $T \setminus F$, then $p(r_C) = f$ is a failed vertex, and we say that $C$ is *a hanging subtree of* $f$. If $C, C'$ are two distinct connected components of $T \setminus F$ such that $r_{C'}$ is an ancestor of $r_C$, then we say that $C'$ is an ancestor of $C$. Furthermore, if $v$ is a vertex not in $C$ such that $v$ is an ancestor (resp., a descendant) of $r_C$, then we say that $v$ is an ancestor (resp., a descendant) of $C$. If $C$ is an internal component of $T \setminus F$ and $f$ is a failed vertex such that $p(f) \in C$, then we say that $f$ is a boundary vertex of $C$. The collection of all boundary vertices of $C$ is denoted as $\partial(C)$. Notice that any vertex $b \in \partial(C)$ has the property that there is no failed vertex on the tree path $T[p(b), r_C]$. Conversely, a failed vertex $b$ such that there is no failed vertex on the tree path $T[p(b), r_C]$ is a boundary vertex of $C$. Thus, if $b_1, \ldots, b_k$ is the collection of the boundary vertices of $C$, then $C = T(r_C) \setminus (T(b_1) \cup \cdots \cup T(b_k))$.

The following lemma is a set of properties that are satisfied by the internal components.

▶ **Lemma 4** ([6]). *Let $C$ be an internal component of $T \setminus F$. Then:*

**(1)** *Either $r_C = r$, or $p(r_C) \in F$.*

**(2)** *For every vertex $v$ that is a descendant of $C$, there is a unique boundary vertex of $C$ that is an ancestor of $v$.*

**(3)** *Let $f_1, \ldots, f_k$ be the boundary vertices of $C$, sorted in increasing order. Then $C$ is the union of the following subsets of consecutive vertices: $[r_C, f_1 - 1], [f_1 + ND(f_1), f_2 - 1], \ldots, [f_{k-1} + ND(f_{k-1}), f_k - 1], [f_k + ND(f_k), r_C + ND(r_C) - 1]$. (We note that some of those sets may be empty.)*

We represent the ancestry relation between failed vertices using a forest which we call the *failed vertex forest* (*F-forest*, for short). The F-forest consists of the following two elements. First, for every failed vertex $f$, there is a pointer $parent_F(f)$ to the nearest ancestor of $f$ (in $T$) that is also a failed vertex. If there is no ancestor of $f$ that is a failed vertex, then we let $parent_F(f) = \perp$. And second, every failed vertex $f$ has a pointer to its list of children in the F-forest.

The F-forest can be easily constructed in $O(d^2)$ time: we just have to find, for every failed vertex $f$, the maximum failed vertex $f'$ that is a proper ancestor of $f$; then we set $parent_F(f) = f'$, and we append $f$ to the list of the children of $f'$ in the F-forest.

The next lemma shows how we can check in constant time whether a failed vertex belongs to the boundary of an internal component, and how to retrieve the root of this component.

▶ **Lemma 5** ([6]). *A failed vertex $f$ is a boundary vertex of an internal component if and only if $parent_F(f) \neq p(f)$. Now let $f$ be a boundary vertex of an internal component $C$. Then, if $parent_F(f)$ exists, we have that the root of $C$ is the child of $parent_F(f)$ that is an ancestor of $f$. Otherwise, the root of $C$ is $r$.*

Thus, according to Lemma 5, if $f$ is a boundary vertex of an internal component $C$ with $r_C \neq r$, we can retrieve $r_C$ in constant time using a level-ancestor query: i.e., we ask for the ancestor of $f$ (in $T$) whose depth equals that of $parent_F(f) + 1$. We may use this fact throughout without mention.

The following lemma shows that there are two types of edges that determine the connectivity relation in $G \setminus F$ between the connected components of $T \setminus F$.

▶ **Lemma 6** ([6]). *Let $e$ be an edge of $G \setminus F$ whose endpoints lie in different connected components of $T \setminus F$. Then $e$ is a back-edge and either $(i)$ both endpoints of $e$ lie in internal components, or $(ii)$ one endpoint of $e$ lies in a hanging subtree $H$, and the other endpoint lies in an internal component $C$ that is an ancestor of $H$.*

▶ **Corollary 7** ([6]). *Let $C, C'$ be two distinct connected components of $T \setminus F$ that are connected with an edge $e$ of $G \setminus F$. Assume w.l.o.g. that $r_{C'} < r_C$. Then $C'$ is an ancestor of $C$.*

The following lemma provides an algorithmically useful criterion to determine whether a connected component of $T \setminus F$ – a hanging subtree or an internal component – is connected with an internal component of $T \setminus F$ through a back-edge.

▶ **Lemma 8** ([6]). *Let $C, C'$ be two connected components of $T \setminus F$ such that $C'$ is an internal component that is an ancestor of $C$, and let $b$ be the boundary vertex of $C'$ that is an ancestor of $C$. Then there is a back-edge from $C$ to $C'$ if and only if there is a back-edge from $C$ whose lower end lies in $[r_{C'}, p(b)]$.*

▶ **Definition 9** (Connectivity graph). *Let $\mathcal{R}$ be a multigraph where $V(\mathcal{R})$ is the set of the roots of the internal components of $T \setminus F$, and $E(\mathcal{R})$ satisfies the following three properties:*

**(1)** *For every back-edge connecting two internal components $C$ and $C'$, there is an edge $(r_C, r_{C'})$ in $\mathcal{R}$.*
**(2)** *Let $H$ be a hanging subtree of a failed vertex $f$, and let $C_1, \ldots, C_k$ be the internal components that are connected with $H$ through a back-edge. (By Lemma 6, all of $C_1, \ldots, C_k$ are ancestors of $H$.) Assume w.l.o.g. that $C_k$ is an ancestor of all $C_1, \ldots, C_{k-1}$. Then $\mathcal{R}$ contains the edges $(r_{C_1}, r_{C_k}), (r_{C_2}, r_{C_k}), \ldots, (r_{C_{k-1}}, r_{C_k})$.*
**(3)** *Every edge of $\mathcal{R}$ is given by either (1) or (2), or it is an edge of the form $(r_C, r_{C'})$, where $C, C'$ are two internal components that are connected in $G \setminus F$.*

*Then $\mathcal{R}$ is called a* connectivity graph of the internal components *of $T \setminus F$. The edges of (1) and (2) are called Type-1 and Type-2, respectively.*

The following lemma shows that a connectivity graph captures the connectivity relationship of the internal components of $T \setminus F$ in $G \setminus F$.

▶ **Lemma 10** ([6]). *Let $\mathcal{R}$ be a connectivity graph of the internal components of $T \setminus F$. Then, two internal components $C, C'$ of $T \setminus F$ are connected in $G \setminus F$ if and only if $r_C, r_{C'}$ are connected in $\mathcal{R}$.*

## 3.4 Handling the updates: construction of a connectivity graph for the internal components of $T \setminus F$

Given a set of failed vertices $F$, with $|F| = d \leq d_\star$, we will show how we can construct a connectivity graph $\mathcal{R}$ for the internal components of $T \setminus F$, using $O(d^4)$ calls to 2D-range-emptiness queries. Recall that $V(\mathcal{R})$ is the set of the roots of the internal components of $T \setminus F$.

Algorithm 1 shows how we can find all Type-1 edges of $\mathcal{R}$. The idea is basically to perform 2D-range-emptiness queries for every pair of internal components, in order to determine the existence of a back-edge that connects them. More precisely, we work as follows. Let $C$ be an internal component of $T \setminus F$. Then it is sufficient to check every ancestor component $C'$ of $C$, in order to determine whether there is a back-edge from $C$ to $C'$ (see Corollary 7). Let $f_1, \ldots, f_k$ be the boundary vertices of $C$, sorted in increasing order. Let also $f'$ be the boundary vertex of $C'$ that is an ancestor of $C$, and let $I = [r_{C'}, p(f')]$. Then we perform 2D-range-emptiness queries for the existence of a back-edge on the rectangles $[r_C, f_1 - 1] \times I, [f_1 + ND(f_1), f_2 - 1] \times I, \ldots, [f_k + ND(f_k), r_C + ND(r_C) - 1] \times I$. We know that there is a back-edge connecting $C$ and $C'$ if and only if at least one of those queries is positive (see Lemma 4(3) and Lemma 8). If that is the case, then we add the edge $(r_C, r_{C'})$ to $\mathcal{R}$.

Observe that the total number of 2D-range-emptiness queries that we perform is $O(d^2)$, because every one of them corresponds to a triple $(C, f, C')$, where $C, C'$ are internal components, $C'$ is an ancestor of $C$, and $f$ is a boundary vertex of $C$, or $r_C$. And if $C_1, \ldots, C_k$ are all the internal components of $T \setminus F$, then the number of those triples is bounded by $(|\partial(C_1)| + 1) \cdot d + \cdots + (|\partial(C_k)| + 1) \cdot d = (|\partial(C_1)| + \cdots + |\partial(C_k)| + k) \cdot d \leq (d + k) \cdot d \leq (d + d) \cdot d = O(d^2)$.

▶ **Proposition 11** ([6]). *Algorithm 1 correctly computes all Type-1 edges to construct a connectivity graph for the internal components of $T \setminus F$. The running time of this algorithm is $O(d^2 \log n)$.*

**Algorithm 1** Compute all Type-1 edges to construct a connectivity graph $\mathcal{R}$ for the internal components of $T \setminus F$.

```
1  foreach internal component C of T \ F do
2      let f_1, ..., f_k be the boundary vertices of C, sorted in increasing order
3      // process every internal component C' that is an ancestor of C
4      set f' ← p(r_C)
5      while f' ≠ ⊥ do
6          if p(f') ≠ parent_F(f') then
7              let C' be the internal component of T \ F with f' ∈ ∂(C')
8              set I ← [r_{C'}, p(f')]
9              if at least one of the following queries is positive:
10             2D_range([r_C, f_1 − 1] × I)
11             2D_range([f_1 + ND(f_1), f_2 − 1] × I)
12             ...
13             2D_range([f_{k−1} + ND(f_{k−1}), f_k − 1] × I)
14             2D_range([f_k + ND(f_k), r_C + ND(r_C) − 1] × I) then
15                 add the Type-1 edge (r_C, r_{C'}) to R
16             end
17         end
18         f' ← parent_F(f')
19     end
20 end
```

The construction of Type-2 edges is not so straightforward. For every failed vertex $f$, and every two internal components $C$ and $C'$, such that $C$ is an ancestor of $f$ and $C'$ is an ancestor of $C$, we would like to know whether there is a hanging subtree of $f$, from which stem a back-edge $e$ with an endpoint in $C$ and a back-edge $e'$ with an endpoint in $C'$. The straightforward way to determine this is the following. Let $b$ (resp., $b'$) be the boundary vertex of $C$ (resp., $C'$) that is an ancestor of $f$. Then, for every hanging subtree of $f$ with root $c$, we perform 2D-range-emptiness queries on the rectangles $[c, c + ND(c) - 1] \times [r_C, p(b)]$ and $[c, c + ND(c) - 1] \times [r_{C'}, p(b')]$. If both queries are positive, then we know that $C$ and $C'$ are connected in $G \setminus F$ through the hanging subtree with root $c$.

Obviously, this method is not efficient in general, because the number of hanging subtrees of $f$ can be very close to $n$. However, it is the basis for our more efficient method. The idea is to perform a lot of those queries at once, for large batches of hanging subtrees. More specifically, we perform the queries on *consecutive* hanging subtrees of $f$ (i.e., their roots are consecutive children of $f$), for which we know that the answer is positive on $C'$ (i.e., for every one of those subtrees, there certainly exists a back-edge that connects it with $C'$). In order for this idea to work, we have to rearrange properly the lists of children of all vertices. (Otherwise, the hanging subtrees of $f$ that are connected with $C'$ through a back-edge may not be consecutive in the list of children of $f$.) In effect, we maintain several DFS trees (specifically: $d_\star$), and several 2D-range-emptiness data structures, one for every different arrangement of the children lists.

Let us elaborate on this idea. Let $H$ be a hanging subtree of $f$ that connects some internal components, and let $C'$ be the lowest one among them (i.e., the one that is an ancestor of all the others). Then we have that the lower ends of all back-edges that stem from $H$ and end in ancestors of $C'$ are failed vertices that are ancestors of $C'$. Thus, since there are at

most $d$ failed vertices in total, we have that at least one among $low_1(r_H), \ldots, low_d(r_H)$ is in $C'$. In other words, $r_H$ is one of the children of $f$ whose $low_i$ point is in $C'$, for some $i \in \{1, \ldots, d\}$. Now, assume that for every $i \in \{1, \ldots, d_\star\}$, we have a copy of the list of the children of $f$ sorted in increasing order w.r.t. the $low_i$ point; let us call this list $L_i(f)$, and let it be stored in way that allows for binary search w.r.t. the $low_i$ point. Then, for every internal component $C$ that is an ancestor of $f$, we can find the segment $S_i(C)$ of $L_i(f)$ that consists of the children of $f$ whose $low_i$ point lies in $C$, by searching for the leftmost and the rightmost child in $L_i(f)$ whose $low_i$ point lies in $[r_C, p(b)]$, where $b$ is the boundary vertex of $C$ that is an ancestor of $f$.

Now let $i \in \{1, \ldots, d\}$ be such that $low_i(r_H) \in C'$. Then we have that $r_H \in S_i(C')$. Furthermore, we have that every child of $f$ that lies in $S_i(C')$ and is the root of a hanging subtree $H'$ of $f$ has the property that $H'$ is also connected with $C'$ through a back-edge. Thus, we would like to be able to perform 2D-range-emptiness queries as above on the subset $S$ of $S_i(C')$ that consists of roots of hanging subtrees, in order to determine the connectivity (in $G \setminus F$) of $C'$ with all internal components $C$ that are ancestors of $f$ and descendants of $C'$. We could do this efficiently if we had the guarantee that $S$ consists of large segments of consecutive children of $f$. We can accommodate for that during the preprocessing phase: for every $i \in \{1, \ldots, d_\star\}$, we perform a DFS of $T$, starting from $r$, where the adjacency list of every vertex $v$ is given by $L_i(v)$.[5] Let $T_i$ be the resulting DFS tree, and let $DFS_i$ be the corresponding DFS numbering. Then, with the DFS numbering of $T_i$, we initialize a data structure *2D_range_i*, for answering 2D-range-emptiness queries for back-edges w.r.t. $T_i$ in subrectangles of $[1, n] \times [1, n]$.

Now let us see how everything is put together. Let $H$ be a hanging subtree of $f$ that connects two internal components $C_1$ and $C_2$, and let $b_1$ and $b_2$ be the boundary vertices of $C_1$ and $C_2$, respectively, that are ancestors of $f$. Let $C'$ be the lowest internal component that is connected through a back-edge with $H$. Then there is an $i \in \{1, \ldots, d\}$ such that $low_i(r_H) \in C'$. Let $S$ be the maximal segment of $S_i(C')$ that contains $r_H$ and consists of roots of hanging subtrees, let $L$ be the minimum of $S$ and let $R$ be the maximum of $S$.[6] Then the 2D-range-emptiness queries on $[L, R + ND(R) - 1]_i \times [r_{C_1}, p(b_1)]_i$ and $[L, R + ND(R) - 1]_i \times [r_{C_2}, p(b_2)]_i$ with *2D_range_i* are both positive, and so we will add the edges $(r_{C_1}, r_{C'})$ and $(r_{C_2}, r_{C'})$ to $\mathcal{R}$. This will maintain in $\mathcal{R}$ the information that $C'$, $C_1$ and $C_2$, are connected with the same hanging subtree of $f$.

The algorithm that constructs enough Type-2 edges to make $\mathcal{R}$ a connectivity graph of the internal components of $T \setminus F$ is given in Algorithm 2. Our result is stated in Proposition 12.

▶ **Proposition 12** ([6]). *Algorithm 2 computes enough Type-2 edges to construct a connectivity graph $\mathcal{R}$ for the internal components of $T \setminus F$ (supposing that $\mathcal{R}$ contains all Type-1 edges). The running time of this algorithm is $O(d^4 \log n)$.*

## 3.5 Answering the queries

Assume that we have constructed a connectivity graph $\mathcal{R}$ for the internal components of $T \setminus F$, and that we have computed its connected components. Thus, given two internal components $C$ and $C'$, we can determine in constant time whether $C$ and $C'$ are connected in $G \setminus F$, by simply checking whether $r_C$ and $r_{C'}$ are in the same connected component of $\mathcal{R}$ (see Lemma 10).

[5] I.e., it is necessary that the vertices in the adjacency list of $v$ appear in the same order as in $L_i(v)$.
[6] Notice that, due to the construction of $T_i$, we have that $DFS_i(L)$ and $DFS_i(R)$ are also the minimum and the maximum, respectively, of $DFS_i(S)$.

**Algorithm 2** Compute enough Type-2 edges to construct a connectivity graph for the internal components of $T \setminus F$.

```
1  foreach failed vertex f do
2      // process all pairs of internal components that are ancestors of f
3      set f' ← parent_F(f)
4      while f' ≠ ⊥ do
5          let C' be the internal component with f' ∈ ∂(C')
6          // skip the following if C' does not exist, and go immediately
               to Line 26
7          foreach i ∈ {1, ..., d} do
8              let S_i be the collection of all maximal segments of L_i(f) that consist of
                roots of hanging subtrees with their low_i point in C'
9          end
10         // process all internal components C that are ancestors of f
               and descendants of C'
11         set f'' ← f
12         while f'' ≠ f' do
13             let C be the internal component with f'' ∈ ∂(C)
14             // skip the following if C does not exist, and go
                   immediately to Line 24
15             // check if C is connected with C' through at least one
                   hanging subtree of f
16             foreach i ∈ {1, ..., d} do
17                 foreach S ∈ S_i do
18                     let L ← min(S) and R ← max(S)
19                     if 2D_range_i([L, R + ND(R) − 1]_i × [r_C, p(f'')]_i) = true then
20                         add the Type-2 edge (r_C, r_C') to R
21                     end
22                 end
23             end
24             f'' ← parent_F(f'')
25         end
26         f' ← parent_F(f')
27     end
28 end
```

Now let $x, y$ be two vertices in $V(G) \setminus F$. In order to determine whether $x, y$ are connected in $G \setminus F$, we try to substitute $x, y$ with roots of internal components of $T \setminus F$, and then we reduce the query to those roots. Specifically, if $x$ (resp., $y$) belongs to an internal component $C$ of $T \setminus F$, then the connectivity between $x$ and $y$ is the same as that between $r_C$ and $y$ (resp., $x$ and $r_C$). Otherwise, if $x$ (resp., $y$) belongs to a hanging subtree $H$ of $T \setminus F$, then we try to find an internal component that is connected with $H$ through a back-edge. If such an internal component $C$ exists, then we can substitute $x$ (resp., $y$) with $r_C$. Otherwise, $x, y$ are connected in $G \setminus F$ if and only if they belong to the same hanging subtree of $T \setminus F$. This idea is shown in Algorithm 3.

▶ **Proposition 13** ([6]). *Given two vertices $x, y$ in $V(G) \setminus F$, Algorithm 3 correctly determines whether $x, y$ are connected in $G \setminus F$. The running time of Algorithm 3 is $O(d)$.*

**Algorithm 3** query$(x, y)$.

```
1  if x lies in an internal component C and y lies in an internal component C' then
2      if r_C is connected with r_C' in R then return true
3      return false
4  end
5  // at least one of x, y lies in a hanging subtree
6  if x lies in a hanging subtree H then
7      // check whether H is connected with an internal component through
           a back-edge
8      for i ∈ {1, ..., d} do
9          if low_i(r_H) ≠ ⊥ and low_i(r_H) ∉ F then
10             return query(low_i(r_H), y)
11         end
12     end
13     // there is no internal component that is connected with H in G \ F
14     if y lies in H then return true
15     return false
16 end
17 return query(y, x)
```

## Abstract

Optimal packing of objects in containers is a critical problem in various real-life and industrial applications. This paper investigates the two-dimensional packing of convex polygons without rotations, where only translations are allowed. We study different settings depending on the type of containers used, including minimizing the number of containers or the size of the container based on an objective function.

Building on prior research in the field, we develop polynomial-time algorithms with improved approximation guarantees upon the best-known results by Alt, de Berg and Knauer, as well as Aamand, Abrahamsen, Beretta and Kleist, for problems such as Polygon Area Minimization, Polygon Perimeter Minimization, Polygon Strip Packing, and Polygon Bin Packing. Our approach utilizes a sequence of object transformations that allows sorting by height and orientation, thus enhancing the effectiveness of shelf packing algorithms for polygon packing problems. In addition, we present efficient approximation algorithms for special cases of the Polygon Bin Packing problem, progressing toward solving an open question concerning an $\mathcal{O}(1)$-approximation algorithm for arbitrary polygons.

## 1 Introduction

Many real-life situations require us to make decisions about optimally packing a collection of objects into a specific container. One particular category of these packing problems is two-dimensional packing, which is encountered in everyday scenarios like arranging items on a shelf and in industrial applications such as cutting cookies from rolled-out dough or manufacturing sets of tiles from standard-sized panels made of wood, glass, or metal. Another intriguing example involves cutting fabric pieces for clothing production. In this case, the pieces often cannot be rotated freely, as they must adhere to a desired pattern in the final product, which is tailored of multiple elements. The widespread applicability of two-dimensional packing problems has led to a surge of interest in designing efficient algorithms to address them. In this paper, we follow the line of research and study the problem of packing convex polygons without rotations in various settings depending on the type of containers used.

Past research focusing on theoretical considerations of two-dimensional packings mainly concentrates on the scenario when all objects are axis-parallel rectangles. In this paper, we will discuss packing without rotations, in which only translations are permitted. There are two main classes of the problem depending on whether the size of the container is fixed and we want to minimize the number of containers used or whether we want to minimize the container's size with respect to some objective function.

A seminal example of the first class is the Geometric Bin Packing problem in which a number of unit size squared bins to pack is to be minimized. The problem is arguably the most natural generalization of the regular $(1D)$ Bin Packing to two dimensions, and its absolute approximability has been fully understood. Unless $\mathcal{P} = \mathcal{NP}$, the best possible efficient constant factor approximation is 2 [15], and such an algorithm is known [10].

In the second class, there are several variants to be considered. An example is the Strip Packing Problem which is concerned with packing objects into a strip of width 1 and infinite height in such a way that the maximum of all the heights of the placed objects is minimized. Like Geometric Bin Packing, Strip Packing generalizes $(1D)$ Bin Packing. The best known efficient constant factor approximation for Strip Packing has approximation factor $(5/3 + \epsilon)$ [9]. It is known that there can not exist a polynomial time algorithm with an approximation ratio of $(3/2 - \epsilon)$ for any $\epsilon > 0$ unless $\mathcal{P} = \mathcal{NP}$, which follows directly from the approximation hardness of $(1D)$ Bin Packing. Both classes of problems have been also considered in the asymptotic setting, see e.g. [11, 5, 12].

In younger time, there was also an increase of interest in cases where the objects in question are general convex polygons. Alt, de Berg and Knauer [2, 3] considered the problem of packing an instance consisting of a number of convex polygons of the form $p \subset [0, 1]^2$ into a minimum area axis-parallel rectangular container. We refer to this problem as Polygon Area Minimization throughout this paper. In the special case where the instance consists of rectangles only, the problem is known to admit a PTAS [4]. They proved the existence of the following efficient algorithm:

- A 23.78-approximation for Polygon Area Minimization.

Recently, Aamand, Abrahamsen, Beretta and Kleist [1] showed that the algorithm of Alt, de Berg and Knauer can be leveraged to obtain also efficient approximation algorithms of further problems:

- A 7-approximation for Polygon Perimeter Minimization.
- A 51-approximation for Polygon Strip Packing.
- An 11-approximation for Polygon Bin Packing for polygons with diameter at most $\frac{1}{10}$.

## 1.1 Our results

The results of Alt, de Berg and Knauer [2, 3] and Aamand et al. [1] are heavily based on so-called shelf packing algorithms. In shelf packing algorithms, the objects are first placed on the shelves, possibly ordered by height, which are later stacked on one another to build a final solution. Compared to axis-parallel rectangles, the main challenge in designing an approximation algorithm for polygon packing problems is that objects cannot be sorted by height and orientation simultaneously. As a result, the algorithm and its analysis in [2, 3] have such a large approximation guarantee. In this paper, we provide new insight into how shelf packing algorithms should be applied to polygon packing problems. We introduce a sequence of transformations of the objects that allow us first to sort them by height and later by orientation to build a solution of a much better approximation guarantee. More precisely, we design polynomial-time algorithms with the following factors:

- A 9.45-approximation for Polygon Area Minimization.

Using this algorithm as a subroutine, we build upon the methods from Aamand et al. [1] to obtain the following efficient approximation algorithms:

- A $(3.75 + \epsilon)$-approximation for Polygon Perimeter Minimization.
- A 21.89-approximation for Polygon Strip Packing.
- A 5.09-approximation for Polygon Bin Packing for polygons which have their diameter bounded by $\frac{1}{10}$.

The results are proved in Sections 4, 5, 6, and 7 respectively. Furthermore, concerning Polygon Bin Packing, in the full version of this paper we show the following results, which make progress towards solving an open question of a $\mathcal{O}(1)$-approximation algorithm for Polygon Bin Packing for arbitrary polygons.

- There is an efficient $\mathcal{O}(\frac{1}{\delta})$-approximation algorithm for Polygon Bin Packing for instances where each polygon has width or height at most $1-\delta$.
- There is an efficient $\mathcal{O}(1)$-approximation algorithm for Polygon Bin Packing for instances with the property that all polygons share a spine (up to translation) with height at least $\frac{3}{4}$.

## 2 Preliminaries

We start out considerations by recalling a classical and well-known problem in theoretical computer science, the Bin Packing problem: Given a list of numbers $s_1, \ldots, s_n \in (0,1] \cap \mathbb{Q}$, representing the sizes of $n$ objects, the goal is to find the minimum number of bins of size 1, so that we can pack all objects into them. Bin Packing can be seen as the task of packing (1-dimensional) intervals into as few intervals of length 1 as possible. This definition can be extended to the two dimensional case. To do so we introduce several definitions.

Throughout the paper, for a set subset $A$ of the domain of a function $f$, $f(A)$ is a shorthand notation for $\sum_{a\in A} f(a)$. A **packing instance** is defined by a finite set $I$ containing objects to pack, a countable set $\mathcal{R}$ containing bins to pack the objects into and a set $\Phi$ of allowed transformations. A **shape** is a compact connected set $s \subset \mathbb{R}^2_{\geq 0}$. We denote a rectangular shape $r \subset \mathbb{R}^2_{\geq 0}$ by a tuple $r = (w,h) \in \mathbb{R}^2_{>0}$, which has width $w$ and height $h$. An **object** $o$ is an element of $I$ and has a shape $s \subset [0,1]^2$. Furthermore, we define $\mathcal{I}_{\square}$ and $\mathcal{I}_{\diamond}$ to be the sets which contain all finite sets $I$ with objects consisting of axis-parallel rectangles and convex polygons, respectively. We will usually denote $|I|$ by $n$. In order to ensure computability, we assume that each object in $\mathcal{I}_{\square}$ and $\mathcal{I}_{\diamond}$ is defined by finitely many vertices.

A **bin** $R \in \mathcal{R}$ is also characterized by having a shape. In this paper, we always assume that the shape of a bin $R$ is an axis-parallel rectangle. That is, it is a rectangle with each of its sides being parallel to one of the primal axes in $\mathbb{R}^2$, and normally, its lower left corner is at the origin $(0,0) \in \mathbb{R}^2$. We write $\texttt{width}(R)$ and $\texttt{height}(R)$ for the width and the height of a bin $R \in \mathcal{R}$. If $R = [0,1]^2$, we say that $R$ is a **unit bin**. In this study, the set of **allowed transformations** $\Phi$ is the set of all translations, i.e. $\Phi = \{\phi : R^2 \to \mathbb{R}^2 \mid \exists x_0 \in \mathbb{R}^2\ \forall x \in \mathbb{R}^2 : \phi(x) = x + x_0\}$. Note that we consider the setting where rotations or reflections of objects are not allowed. We denote the width and the height of an object $o$ (the length of the projection on the $x$-axis or $y$-axis respectively) by $\texttt{width}(o)$ and $\texttt{height}(o)$. The maximum width and height of a shape of an object in $I$, we denote by $w_{\max}(I)$ and $h_{\max}(I)$ respectively. We will also use the notation $\texttt{width}(S)$ and $\texttt{height}(S)$ for arbitrary subsets $S \subset \mathbb{R}^2$

A **packing** $P$ of $I$ is defined as a set of pairwise disjoint placements of all $o \in I$ with respect to the set of translations $\Phi$. Given a bin $R \in \mathcal{R}$, we say that we can **pack $I$ into $R$** if there is a packing $P$ of $I$ so that $P \subset R$. In this case, we also say that $P$ is a **packing of $I$ into $R$**. If we can pack the objects $I$ into the bin $R$, we call $R$ a **bounding box** of $I$. If we have an at most countable collection of bins $\mathcal{R} := \{R_j\}_{j\in J}$, we say that we can **pack $I$ into $\mathcal{R}$**, if there is a partition $I = \bigsqcup_{j\in J} I_j$ so that we can pack the objects $I_j$ into $R_j$ for all $j \in J$. In such case, if for all $j \in J$, $P_j$ is a packing of $I_j$ into $R_j$, we refer to $\mathcal{P} := \{P_j\}_j$ as a **multi-packing**. For any $j \in J$, we say that **$o$ is in the packing $P_j$**, if $o \in I_j$. We define the $\texttt{area}(P)$ to be the area of the smallest axis-parallel rectangle containing $P$.

The definition already demonstrates the more difficult nature of multi-dimensional packings compared to one dimensional packings. Even if the objects to pack are axis-parallel rectangles, it is no longer sufficient to consider in which bin to pack which rectangle, but the exact position in the bin also matters.

In this paper we consider problems consisting in packing convex polygonal shapes into axis-parallel rectangular bins under translational transformations. More precisely we consider the following problems.

▶ **Problem 1** (Polygon Packing).
***Input:*** *Convex polygons* $I \in \mathcal{I}_{\diamond}$.
***Goals:***

- *Bin Packing: Find the minimum number* $B \in \mathbb{N}$ *so that we can pack* $I$ *into* $B$ *unit bins.*
- *Strip Packing: Find the minimum height* $H \in \mathbb{Q}_{>0}$ *so that we can pack* $I$ *into a bin of width* 1 *and height* $H$*.*
- *Area Minimization: Find a bounding box* $R \in \mathbb{R}^2_{>0}$ *of* $I$ *so that* $f(R) = \texttt{width}(R) \cdot \texttt{height}(R)$ *is minimal.*
- *Perimeter Minimization: Find a bounding box* $R \in \mathbb{R}^2_{>0}$ *of* $I$ *so that* $f(R) = 2(\texttt{width}(R) + \texttt{height}(R))$ *is minimal.*
- *Minimum Square: Find a bounding box* $R \in \mathbb{R}^2_{>0}$ *so that* $f(R) = \max\{\texttt{width}(R), \texttt{height}(R)\}$ *is minimal.*

*Throughout the paper for the problems under consideration, we denote the optimal value of an instance* $I \in \mathcal{I}_{\diamond}$ *by* $\mathrm{opt}(I)$.

## 3 Shelf Packing Algorithms

Introducing well-known shelf-packing algorithms involves basic $(1D)$-Bin Packing algorithms, such as NextFit (NF), FirstFit (FF), and BestFit (BF). These place items $s_1, \ldots, s_n$ into bins sequentially, with $s_{i+1}$ placed according to specific rules. If no placement adheres to the rule, a new bin is opened. The rules differ for each algorithm.

- NF, places $s_{i+1}$ into the most recently opened bin, if it has enough space.
- FF, places $s_{i+1}$ in the earliest opened bin in which it fits.
- BF, places $s_{i+1}$ in the bin with least free space among bins in which $s_{i+1}$ fits.

NF and FF are often preprocessed by sorting the items in non-increasing size, which are called NextFitDecreasing (NFD) and FirstFitDecreasing (FFD). It is not hard to show that NF is a 2-approximation for the Bin Packing problem [14]. Moreover, NF packs it into at most $1 + 2\sum_{i=1}^{n} s_i$ bins. BF and FF both have an approximation ratio of 1.7 [7, 8], which are tight. Furthermore, as shown in [13], if $s_i \leq \frac{1}{m}$ for all $i \in [n]$ and some $m \geq 2$, FF packs this instance into at most $1 + (1 + \frac{1}{m})\sum_{i=1}^{n} s_i$ bins. [1]

Variants of NF, FF and BF exist for 2D rectangle packing problems, called NextFitDecreasingHeight (NFDH), FirstFitDecreasingHeight (FFDH), and BestFitDecreasingHeight (BFDH). These shelf-packing algorithms were introduced for Strip Packing, placing rectangles $r_1, \ldots, r_n \in \mathcal{I}_{\square}$ into a bin $R = [0, 1] \times [0, \infty)$ with infinite height. The three algorithms order rectangles $r_1, \ldots, r_n$ in non-increasing height and place them sequentially

[1] In fact they show that FF packs such instance in $2 + (1 + \frac{1}{m})\sum_{i=1}^{n} s_i$ bins. With a strategy analogous to the one from the proof of Theorem 3 in [6] in the two-dimensional case, however, one can show that an additive factor of 1 is sufficient.

into shelves in $R$. A shelf is a horizontal strip, and rectangles can open new shelves. A shelf-packing algorithm places $r_{i+1}$ in an existing shelf according to a rule or opens a new shelf. The placement is bottom-left without intersecting other rectangles.

- NFDH places $r_{i+1}$ in the most recently opened shelf, if it fits.
- FFDH places $r_{i+1}$ in the lowest possible shelf which has enough space.
- BFDH, as FFDH, allows for placing rectangles in a lower shelf than the most recently opened one. Here, $r_{i+1}$ is placed in the one which has minimal free horizontal space at the right end of the shelf among all shelves, while still having at least $\texttt{width}(r_{i+1})$ of it.

Since NFDH and FFDH are of particular interest in our paper, we present the following two absolute approximability results for axis-parallel rectangle Strip Packing problem.

▶ **Theorem 2** (Theorem 1 [6]). *Let $I \in \mathcal{I}_{\square}$. The packing $P$ obtained by* NFDH satisfies

$$\texttt{height}(P) \leq h_{\max}(I) + 2\,\texttt{area}(I) \leq 3\,\mathrm{opt}(I).$$

▶ **Theorem 3** (Theorem 3 [6]). *Let $m \in \mathbb{N}$ and $I \in \mathcal{I}_{\square}$ be satisfying that $w_{\max}(I) \leq \frac{1}{m}$. The packing $P$ of $I$ obtained by* FFDH satisfies

$$\texttt{height}(P) \leq h_{\max}(I) + \left(1 + \frac{1}{m}\right)\texttt{area}(I) \leq \left(2 + \frac{1}{m}\right)\mathrm{opt}(I).$$

## 4 An Efficient 9.45-Approximation for Polygon Area Minimization and 7-Approximation when all Polygons are $x$-Parallelograms

In this section, we prove that there is an efficient $9.\overline{4}$-approximation algorithm for Polygon Area Minimization, which improves the previous best approximation factor for polynomial time algorithms of 23.78 by Alt et al. [2, 3]. Based on that result, we also show a 7-approximation in the special case when all polygons are $x$-parallelograms, a special type of parallelograms we will introduce in Definition 5.

### 4.1 An Efficient 9.45-Approximation for Polygon Area Minimization

To start the discussions, we introduce the following definition.

▶ **Definition 4.** *Let $p \subset [0,1]^2$ be a polygon. A* ***spine*** *$s$ of $p$ is a (straight) line segment connecting a point in $\operatorname{argmin}_{(x,y)\in p} y$ with a point in $\operatorname{argmax}_{(x,y)\in p} y$. We call the angle between the $x$-axis in increasing direction and $s$ the* ***angle of $s$****. We say that $s$* ***is tilted to the right*** *or* ***leans to the right****, if this angle is in $(0, \frac{\pi}{2}]$ and* ***is tilted to the left*** *or* ***leans to the left****, if it is in $[\frac{\pi}{2}, \pi)$.*

Sometimes we also talk about "the" spine of a polygon, implicitly assuming that one has been fixed. The algorithm of Alt et al. is a shelf-packing algorithm and ordering polygons by the angle of their spines is a crucial step. Our algorithm shares these two characteristics. A key difference is that our algorithm first packs the polygons into parallelograms that have two of their sides parallel to the $x$-axis. We give such parallelograms their own definition:

▶ **Definition 5.** *An* ***$x$-parallelogram*** *is a parallelogram $q \subset \mathbb{R}^2$ that has two of its sides parallel to the $x$-axis. Of those two sides, we call the one with lower $y$-coordinate the* ***base*** *of $q$. We write $\texttt{base}(q)$ for the length of the base of $q$ and $\texttt{wside}(q)$ for the width of one of the sides of $q$ which is not parallel to the $x$-axis. Similar as to the definition for spines of*

*polygons, we say that $q$* ***is tilted to the right*** *or* ***leans to the right****, if the angle between its right side and the increasing direction of the $x$-axis is in $(0, \frac{\pi}{2}]$ and* ***is tilted to the left*** *or* ***leans to the left****, if it is in $[\frac{\pi}{2}, \pi)$. We refer to this angle simply as* ***angle of $q$****.*

For packing polygons into $x$-parallelograms, we prove the following result, which is a refined version of the discussions of Aamand et al. [1] in Subsection 5.2.4 of their paper.

▶ **Lemma 6.** *Let $p$ be a convex polygon. Then there exists an $x$-parallelogram $q$ that contains $p$ and satisfies*

**(i)** $\texttt{height}(q) = \texttt{height}(p)$
**(ii)** $\texttt{base}(q) \leq \texttt{width}(p)$
**(iii)** $\texttt{wside}(q) \leq \texttt{width}(p)$
**(iv)** $\texttt{area}(q) \leq 2\,\texttt{area}(p)$.

**Proof.** First, we construct a bounding $x$-parallelogram as the one that can be seen in Figure 1. Let $l_b$ and $l_t$ be lines parallel to the $x$-axis and tangent to $p$, touching the bottom of $p$ and the top of $p$ respectively. Choose $p_b \in p \cap l_b$ and $p_t \in p \cap l_t$ and define $s$ to be the line connecting $p_b$ and $p_t$. Note that $s$ is a spine of $p$. Let $s_l$ and $s_r$ be tangent to $p$ and parallel to $s$, lying on the left and on the right of $p$. Let $p_l \in p \cap s_l$ and $p_r \in p \cap s_r$. We now define $q$ to be the set bounded by $l_b, l_t, s_l$ and $s_r$. Note that $q$ is an $x$-parallelogram that satisfies $(i)$. As the left and right sides of $q$ are just translations of $s$, it also satisfies $(iii)$, because of course $s \subset p$ by convexity of $p$.

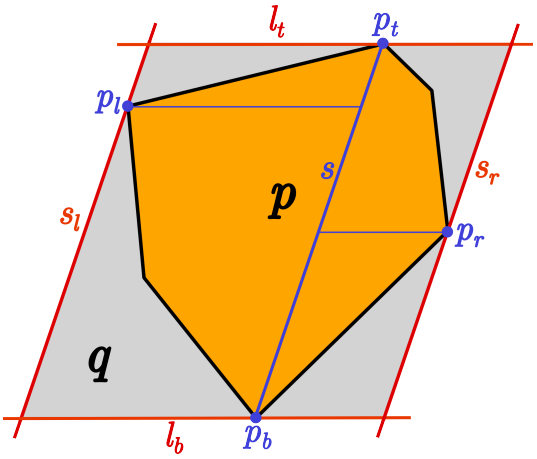

**Figure 1** The construction of a bounding parallelogram $q$ from the proof of Lemma 6 on an example polygon $p$. Note that here, it holds that $\texttt{base}(q) > \texttt{width}(p)$.

To see that $q$ also satisfies $(iv)$, we consider the triangle with vertices $p_t, p_b$ and $p_l$. We note that it is contained in $p$ due to convexity and contains exactly half the area of the part of $q$ that lies on the left of $s$. Analogously, the triangle with vertices $p_t, p_b$ and $p_r$ has half the area of the part of $q$ that lies on the right of $s$. So $q$ does indeed also satisfy $(iv)$.

However, $q$ does not necessarily satisfy $(ii)$ (see the polygon in Figure 1). If it does, then $q$ satisfies all assumptions of the lemma and we are done.

So we consider now the case when $\texttt{base}(q) > \texttt{width}(p)$. Consider the axis-parallel rectangle $r$ bounding $p$. That is, $r$ contains $p$ and each of its sides has non-empty intersection with $p$. Surely $r$ satisfies $(i), (ii)$ and $(iii)$. To see that it also satisfies $(iv)$, note that

$$\begin{aligned}\texttt{area}(r) &= \texttt{width}(r)\,\texttt{height}(r)\\ &= \texttt{width}(p)\,\texttt{height}(p)\\ &< \texttt{base}(q)\,\texttt{height}(q)\\ &= \texttt{area}(q)\\ &\leq 2\,\texttt{area}(p).\end{aligned}$$

So whenever $\texttt{base}(q) > \texttt{base}(p)$, we showed that $r$ satisfies all requirements $(i) - (iv)$ of the lemma instead. Since $r$ is also an $x$-parallelogram, we conclude. ◀

With the help of Lemma 6, we can now present the main result of this chapter.

▶ **Theorem 7.** *There is a polynomial time $9.\overline{4}$-approximation algorithm for Polygon Area Minimization. Moreover, there is such algorithm with running time $\mathcal{O}(n^2 + N)$, where $n$ is the number of polygons and $N$ the total number of vertices in a given input $I \in \mathcal{I}_{\diamondsuit}$, assuming that each polygon $p \in I$ is given as a list of its vertices.*

**Proof.** Let $I \in \mathcal{I}_{\diamondsuit}$. We construct a packing $P$ as the one depicted in Figure 2.

Pack each polygon $p \in I$ into an $x$-parallelogram $q$ as in Lemma 6. Call the instance of all so-obtained $x$-parallelograms $I_Q$. The idea of our algorithm is to use FFDH to pack straightened, axis-parallel versions of the $x$-parallelograms $I_Q$ and to then use this packing to obtain one for $I_Q$ and hence also $I$ which is not much bigger.

So, define yet another instance $I_R$ which, for each $q \in I_Q$, contains a rectangle $r = (\texttt{base}(q), \texttt{height}(q))$. With FFDH, we now pack $I_R$ into a strip of width $cw_{\max}(I)$, where $c \geq 1$ is to be determined later. Call the so-obtained packing $P_R$. By Theorem 3 it follows

$$\texttt{height}(P_R)(cw_{\max}(I)) \leq \left(1 + \frac{1}{m}\right)\texttt{area}(I_R) + ch_{\max}(I_R)w_{\max}(I), \tag{1}$$

where $m = \lfloor c \rfloor$, as $w_{\max}(I_R) = \max_{q \in I_Q} \texttt{base}(q) \leq w_{\max}(I)$ by Lemma 6.

Let $S \subset I_Q$ be the parallelograms corresponding to the rectangles in a certain shelf in the packing $P_R$. We can pack $S$ into a new shelf of width $(c+2)w_{\max}(I)$ by first ordering the parallelograms $S$ by decreasing angle. Indeed, if we, after this ordering, place them all next to each other in the shelf, we note that now all bases of the parallelograms are connected to each other and hence the overlap on either side is at most $\max_{q \in S} \texttt{wside}(q) \leq w_{\max}(I)$ by Lemma 6. Put all such shelves on top of each other and call the so-obtained packing $P_Q$. Note that $P_Q$ has the same height as $P_R$, but $\frac{c+2}{c}$ times its width. Finally, we pack each polygon into its respective parallelogram in the packing $P_Q$. Call this packing $P$. Then

$$\begin{aligned}\texttt{area}(P) &\leq \texttt{area}(P_Q)\\ &\leq \frac{c+2}{c}\,\texttt{height}(P_R)(cw_{\max}(I))\\ &\leq \frac{c+2}{c}\left(1 + \frac{1}{m}\right)\texttt{area}(I_R) + (c+2)h_{\max}(I_R)w_{\max}(I)\\ &= \frac{c+2}{c}\frac{m+1}{m}\,\texttt{area}(I_Q) + (c+2)h_{\max}(I_Q)w_{\max}(I)\\ &\leq 2\frac{c+2}{c}\frac{m+1}{m}\,\texttt{area}(I) + (c+2)h_{\max}(I)w_{\max}(I)\\ &\leq \left(2\frac{c+2}{c}\frac{m+1}{m} + (c+2)\right)\mathrm{opt}(I).\end{aligned}$$

One can check that the minimum is attained at $c = 3$, in which case we get a $9.\overline{4}$-approximation.

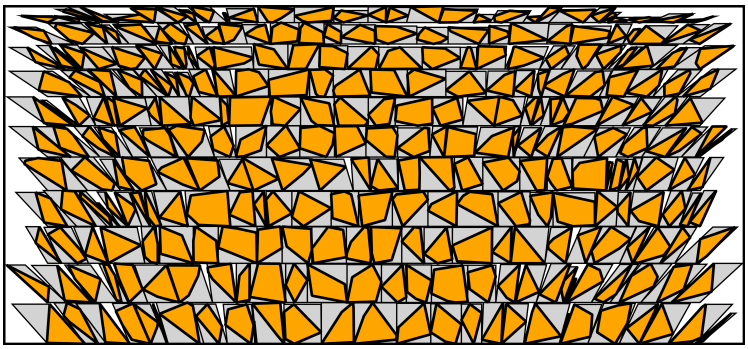

**Figure 2** A packing computed with the algorithm from the proof of Theorem 7, here with parameter $c = 15$. For each polygon, also its computed bounding $x$-parallelogram is drawn.

We now note that the claimed running times of the above algorithm follows by observing that: Constructing $I_Q$ from $I$ can be done in $\mathcal{O}(N)$ time, constructing $I_R$ from $I_Q$ can be done in $\mathcal{O}(n)$ time, constructing $P_R$ can be done in $\mathcal{O}(n^2)$ time, constructing $P_Q$ from $P_R$ can be done by sorting in $\mathcal{O}(n \log(n))$ time, and finally, constructing $P$ from $P_Q$ can be done in $\mathcal{O}(N)$ time. ◀

The algorithm of Alt et al. runs in time $\mathcal{O}(N \log(N))$ and thus for certain instances faster than our algorithm. If, in our algorithm, the use of FFDH for packing $I_R$ is replaced by NFDH, one can show using Theorem 2 that for an optimal choice of $c = 2\sqrt{2}$, the algorithm has an approximation guarantee of 11.66 while having a running time of $\mathcal{O}(n \log(n) + N)$, thus obtaining an algorithm that runs faster than the algorithm of Alt et al., while still having a greatly improved approximation ratio.

## 4.2 An Efficient 7-Approximation for Polygon Area Minimization when all Polygons are $x$-Parallelograms

In the algorithm presented in the previous subsection, we first pack general polygons into $x$-parallelograms and afterwards pack these $x$-parallelograms. One would expect that if one wants to pack $x$-parallelograms from the start, one should be able to obtain a better approximation factor. Showing that this is indeed the case is the content of this brief section.

▶ **Theorem 8.** *There is a polynomial time* 7*-approximation algorithm for* Polygon Area Minimization*, when all input polygons are $x$-parallelograms.*

The proof follows along the lines of the proof of Theorem 7.

**Proof.** Let $I \in \mathcal{I}_{\diamond}$ be so that every $p \in I$ is an $x$-parallelogram. As in the proof of Theorem 7, we define the set $I_R \in \mathcal{I}_{\square}$ that for every $p \in I$ contains some $r \in I_R$ with $\texttt{width}(r) = \texttt{base}(p)$ and $\texttt{height}(r) = \texttt{height}(p)$. Again, we pack $I_R$ with FFDH into a strip of width $cw_{\max}(I)$ and call the so-obtained packing $P_R$.

After ordering them by angle, we can pack the parallelograms $S \subset I$ corresponding to the rectangles in some shelf in $P_R$ into a new shelf of width $(c+2)w_{\max}(I)$, because of course $\texttt{wside}(p) \leq w_{\max}(I)$. Therefore, calling the so-obtained packing $P$,

$$\begin{aligned}\texttt{area}(P) &\leq \frac{c+2}{c}\,\texttt{area}(P_R)\\ &\leq \frac{c+2}{c}\frac{m+1}{m}\,\texttt{area}(I) + (c+2)h_{\max}(I)w_{\max}(I)\\ &\leq \left(\frac{c+2}{c}\frac{m+1}{m} + (c+2)\right)\operatorname{opt}(I),\end{aligned}$$

which, for $c = 2$, is minimized and equal to 7. ◀

## 5 An Efficient $(3.75+\epsilon)$-Approximation for Polygon Perimeter Minimization and $(3.56+\epsilon)$-Approximation for Polygon Minimum Square

In this section, we show how to leverage the algorithm from Theorem 7 to obtain an approximation-algorithm for Polygon Perimeter Minimization. We improve on the polynomial time 7.3-approximation algorithm obtained by Aamand et al. [1] and present an efficient $(3.75+\epsilon)$-approximation. Moreover, we show how to leverage that result to obtain an $(3.56+\epsilon)$-approximation-algorithm for Polygon Minimum Square.

### 5.1 An Efficient $(3.75+\epsilon)$-Approximation for Polygon Perimeter Minimization

▶ **Theorem 9.** *For every $\epsilon > 0$, there is an efficient $(3.75+\epsilon)$-approximation algorithm for Polygon Perimeter Minimization.*

**Proof.** Let $I \in \mathcal{I}_{\diamond}$. Note that for the perimeter objective, it surely holds that

$$\operatorname{opt}(I) \geq 2(w_{\max}(I) + h_{\max}(I)). \tag{2}$$

Furthermore, since a bounding box of $I$ has area at least $\texttt{area}(I)$ and the minimum perimeter rectangle having area $\texttt{area}(I)$ is a square, it also is true that

$$\operatorname{opt}(I) \geq 4\sqrt{\texttt{area}(I)}.$$

It follows from Inequality 2 that

$$\min\{h_{\max}(I), w_{\max}(I)\} \leq \frac{1}{4}\operatorname{opt}(I)$$

and without loss of generality, we assume that $w_{\max}(I) \leq \frac{1}{4}\operatorname{opt}(I)$. Otherwise we are making the following argument by packing into vertical shelves instead.

Let $P$ be the packing obtained from the algorithm in Theorem 7, leaving $c$ as a free parameter. Then $P$ satisfies

$$\texttt{width}(P) \leq (c+2)w_{\max}(I)$$

and by dividing the inequality (1) by the width of the strip used for the rectangle packing obtained by FFDH, $cw_{\max}(I)$, we see that

$$\texttt{height}(P) \leq 2\frac{m+1}{m}\frac{\texttt{area}(I)}{cw_{\max}(I)} + h_{\max}(I) \leq \frac{1}{8}\frac{m+1}{m}\frac{\operatorname{opt}(I)^2}{cw_{\max}(I)} + h_{\max}(I).$$

We restrict the domain of $c$ so that $c \geq \frac{\operatorname{opt}(I)}{4w_{\max}(I)} \geq 1$ and write $c = l\frac{\operatorname{opt}(I)}{4w_{\max}(I)}$ for some $l \geq 1$. Then

$$\texttt{width}(P) \leq \frac{l}{4}\operatorname{opt}(I) + 2w_{\max}(I), \quad \texttt{height}(P) \leq \frac{1}{2l}\frac{m+1}{m}\operatorname{opt}(I) + h_{\max}(I).$$

The perimeter of $P$ is hence bounded by

$$\begin{aligned}
2(\texttt{width}(P) + \texttt{height}(P)) &\leq 2\left(\left(\frac{l}{4} + \frac{m+1}{2lm}\right)\operatorname{opt}(I) + 2w_{\max}(I) + h_{\max}(I)\right) \\
&\leq 2\left(\frac{1}{4}\left(l + \frac{2(m+1)}{lm}\right) + 1\right)\operatorname{opt}(I) \\
&= \frac{1}{2}\left(l + \frac{2(m+1)}{lm} + 4\right)\operatorname{opt}(I),
\end{aligned}$$

which is minimized and equal to $3.75\operatorname{opt}(I)$ when $l$ is equal to $\bar{l} := 2$, where we used that $m = \lfloor c \rfloor \geq \lfloor l \rfloor$.

Now since the value of $\operatorname{opt}(I)$ is not known beforehand and since $\bar{l}$ depends on it, we need to guess an optimal value for $l$. This can be done as follows. Compute the packing from the algorithm in Theorem 7 for $c = 1, (1+\epsilon), \ldots, (1+\epsilon)^K$, where $K = \frac{\log(n)}{\log(1+\epsilon)}$ and denote the packing obtained for $c = (1+\epsilon)^k$ by $P_k$ for all $k \in \{0, 1, \ldots, n\}$. Over all those packings, choose the one that has minimum perimeter. Say this perimeter is $z > 0$. Let $k \in \{1, \ldots, K\}$ be so that

$$(1+\epsilon)^{k-1} \leq \bar{c} \leq (1+\epsilon)^k,$$

where $\bar{c} := \bar{l}\frac{\operatorname{opt}(I)}{4w_{\max}(I)}$. Then, for $l_k := (1+\epsilon)^k \frac{4w_{\max}(I)}{\operatorname{opt}(I)}$, it holds that

$$l_k = (1+\epsilon)^k \frac{4w_{\max}(I)}{\operatorname{opt}(I)} \leq (1+\epsilon)\bar{c}\frac{4w_{\max}(I)}{\operatorname{opt}(I)} = (1+\epsilon)\bar{l}.$$

In particular, as of course also $\bar{l} \leq l_k$, it holds that

$$\begin{aligned}
z &\leq 2(\texttt{width}(P_k) + \texttt{height}(P_k)) \\
&\leq \frac{1}{2}\left(l_k + \frac{2(m+1)}{l_k m} + 4\right)\operatorname{opt}(I) \\
&\leq (1+\epsilon)\frac{1}{2}\left(\bar{l} + \frac{2(m+1)}{\bar{l}m} + 4\right)\operatorname{opt}(I) \\
&\leq (1+\epsilon)3.75\operatorname{opt}(I),
\end{aligned}$$

which shows the statement. ◀

## 5.2 An Efficient $(3.56+\epsilon)$-Approximation for Polygon Minimum Square

In this section, we show how to leverage the algorithm from Theorem 7 to obtain an approximation-algorithm for Polygon Minimum Square.

▶ **Theorem 10.** *For every $\epsilon > 0$, there is an efficient $(3.56+\epsilon)$-approximation algorithm for Polygon Minimum Square.*

The proof is similar to the proof of Theorem 9.

**Proof.** Let $I \in \mathcal{I}_{\diamondsuit}$. Note that

$$\operatorname{opt}(I) \geq \max\{w_{\max}(I), h_{\max}(I)\}$$

and also

$$\operatorname{opt}(I) \geq \sqrt{\texttt{area}(I)}.$$

Analogously to the proof of Theorem 9, but substituting $c = l\frac{\operatorname{opt}(I)}{w_{\max}(I)}$ for some $l \geq 1$ instead, we can construct a packing $P$ with

$$\texttt{width}(P) \leq l \operatorname{opt}(I) + 2w_{\max}(I), \quad \texttt{height}(P) \leq \frac{2}{l}\frac{m+1}{m}\operatorname{opt}(I) + h_{\max}(I).$$

Then

$$\max\{\texttt{width}(P), \texttt{height}(P)\} \leq \max\left\{l+2, \frac{2(m+1)}{lm} + 1\right\}\operatorname{opt}(I).$$

The minimum is attained for $l = \bar{l} := \frac{1}{2}(\sqrt{17}-1)$ in which case $m = 1$ and the approximation factor is equal to to $\frac{1}{2}(\sqrt{17}+3) \approx 3.56$. As in the proof of Theorem 9, we can guess the value of $\bar{l}$ to obtain a $(3.56+\epsilon)$-approximation algorithm. ◀

## 6 An Efficient 21.89-Approximation for Polygon Strip Packing

In this section, we show how to obtain a polynomial time $21.\overline{8}$-approximation for Polygon Strip Packing, improving on the previous best known approximation factor for efficient algorithms of 51 by Aamand et al. [1]. The idea is to construct vertical shelves with the algorithm from Theorem 7 and then to stack such vertical shelves horizontally into the strip. This idea comes from [1]. We slightly improve their procedure using the following observation.

▶ **Lemma 11.** *Let $\overline{I} \in \mathcal{I}_{\diamondsuit}$ and let $\overline{P} \subset [0,(c+2)w_{\max}(\overline{I})] \times [0,\infty)$ be a shelf-packing obtained by the algorithm from Theorem 7 for some $c \geq 1$. Let $I \subset \overline{I}$ be the polygons in one of the shelves of $\overline{P}$ and define the packing $P := \{\overline{P}(p)\}_{p\in I}$. Then there is a shelf-packing $P'$ of $I$ into two shelves with $\texttt{width}(P') \leq \frac{1}{2}(c+3)w_{\max}(\overline{I})$ and $\texttt{height}(P') \leq 2\,\texttt{height}(P)$.*

**Proof.** The idea is to simply split the shelf in half in its middle as follows. Let $x_{\text{mid}} := \frac{(c+2)w_{\max}(\overline{I})}{2}$ and partition $I$ into the two sets

$$I_L := \left\{p \in I \mid \texttt{width}\left(P(p) \cap (\mathbb{R}_{\geq x_{\text{mid}}} \times \mathbb{R})\right) \leq \frac{\texttt{width}(p)}{2}\right\}$$

and $I_R = I \backslash I_L$. Note that

$$I_R \subset \left\{p \in I \mid \texttt{width}\left(P(p) \cap (\mathbb{R}_{\leq x_{\text{mid}}} \times \mathbb{R})\right) < \frac{\texttt{width}(p)}{2}\right\}.$$

We can now pack $I_L$ and $I_R$ into separate shelves while respecting the ordering of the polygons in $P$. We denote the packing where both of those shelves are stacked on each other by $P'$. Both shelves have width at most

$$x_{\text{mid}} + \frac{w_{\max}(I)}{2} \leq x_{\text{mid}} + \frac{w_{\max}(\overline{I})}{2} = \frac{1}{2}(c+3)w_{\max}(\overline{I}).$$

and hence $P'$ does as well. ◀

Making use of the lemma, we can show the following result.

▶ **Theorem 12.** *There is a polynomial time* $21.\overline{8}$*-approximation algorithm for* Polygon Strip Packing.

**Proof.** Let $I \in \mathcal{I}_{\diamond}$. We apply the algorithm from Theorem 7, for some $c$ which we will fix later, to construct vertical shelves. More precisely, we rotate each item by an angle of $\pi/2$, apply the algorithm to the rotated instance, and then rotate the whole packing back by $\pi/2$. Let $P$ be the so obtained packing and let $S_1, \dots, S_k$ be the vertical shelves of this packing.

We now stack $S_1, \dots, S_k$ horizontally into the (vertical) strip. That is, we pack the $\{S_i\}_{i\in[k]}$ into horizontal shelves $T_1, \dots, T_l$ themselves. Note that since each shelf $S_i$, where $i \in [k]$, has the same height, the problem reduces to $(1D)$-Bin Packing. In particular, stacking the $\{S_i\}_{i\in[k]}$ greedily, each except for possibly the last horizontal shelf is covered by at least half by the $S_i$. If the last shelf $T_l$ is covered by half, we need at most $l \leq \frac{2\,\mathtt{area}(P)}{(c+2)h_{\max}(I)}$ horizontal shelves to pack $S_1, \dots, S_k$. Otherwise, we need at most $l \leq \frac{2\,\mathtt{area}(P)}{(c+2)h_{\max}(I)} + 1$ shelves. However, in this case we can reduce the height of $T_l$, which is filled less than half by the $\{S_i\}_{i\in[k]}$, to $\frac{1}{2}(c+3)h_{\max}(I)$ by using Lemma 11 on every shelf $S$ in $T_l$.

In particular, for such packing $P'$ it holds that

$$\begin{aligned}
\mathtt{height}(P') &\leq \left(\frac{2\,\mathtt{area}(P)}{(c+2)h_{\max}(I)}\right)(c+2)h_{\max}(I) + \frac{1}{2}(c+3)h_{\max}(I) \\
&= 2\,\mathtt{area}(P) + \frac{1}{2}(c+3)h_{\max}(I) \\
&\leq \left(4\frac{c+2}{c}\frac{m+1}{m} + \frac{5}{2}c + \frac{11}{2}\right)\mathrm{opt}(I) \\
&= 21.\overline{8}\,\mathrm{opt}(I),
\end{aligned}$$

which is attained for $c = 3$. ◀

## 7 Efficient Approximation Algorithms for Polygon Bin Packing for Polygons of Width Upper Bounded by $1/M$

In this section, we present polynomial time approximation algorithms for Polygon Bin Packing for the case when polygons have their width bounded by a fraction of the form $\frac{1}{M}$ and also improved approximations if their height is bounded as well.

To the best of our knowledge, the only presently published polynomial time approximation algorithm for Polygon Bin Packing is an 11-approximation in the case when the diameter of the input polygons is bounded by $\frac{1}{10}$, see [1]. For this case, we obtain an efficient 5.09-approximation.

We prove the following theorem.

▶ **Theorem 13.** *Let* $I \in \mathcal{I}_{\diamond}$ *and assume that there is some* $M \in \mathbb{N}_{\geq 2}$ *with* $w_{\max}(I) \leq \frac{1}{M}$. *Then one can pack* $I$ *into*

$$\begin{cases} 32\,\mathrm{opt}(I) + 5 & \text{if } M = 2 \\ \frac{4M(M-1)}{(M-2)^2}\,\mathrm{opt}(I) + 3 & \text{if } M \geq 3 \end{cases}$$

*bins efficiently. If additionally* $h_{\max}(I) \leq \frac{1}{M}$, *then we can even efficiently pack* $I$ *into*

$$\begin{cases} 24\,\mathrm{opt}(I) + 3 & \text{if } M = 2 \\ \frac{2(M+1)(M-1)}{(M-2)^2}\,\mathrm{opt}(I) + 2 & \text{if } M \geq 3 \end{cases}$$

*bins.*

In particular, for inputs where both width and height of all polygons are upper bounded by $\frac{1}{10}$, we get a 5.09-approximation.

**Proof.** Assume first that $M \geq 3$. We use the algorithm from Theorem 7 for $c = \frac{1}{w_{\max}(I)} - 2 \geq M - 2$ to obtain a packing $P$ with shelves $S_1, \ldots, S_k$. The packing $P$ satisfies

$$\texttt{width}(P) \leq (c+2)w_{\max}(I) = 1,$$

and hence a shelf $S_i$, $i \in [k]$, fits into a unit bin. Note that $m = \lfloor c \rfloor \geq M - 2$, since $M - 2$ is an integer. Since $cw_{\max}(I) = 1 - 2w_{\max}(I) \geq \frac{M-2}{M}$, it holds that

$$\texttt{height}(P) \leq 2\left(1 + \frac{1}{m}\right)\frac{\texttt{area}(I)}{cw_{\max}(I)} + h_{\max}(I) \leq 2\left(1 + \frac{1}{M-2}\right)\frac{\texttt{area}(I)}{(M-2)/M} + h_{\max}(I).$$

We can now use NF to distribute the shelves into unit bins. Since $h_{max} = 1$, this uses at most $2\,\texttt{height}(P) + 1$ bins, see Section 3. But

$$2\,\texttt{height}(P) + 1 \leq 4\left(1 + \frac{1}{M-2}\right)\frac{\texttt{area}(I)}{(M-2)/M} + 2h_{\max}(I) + 1 \leq \frac{4M(M-1)}{(M-2)^2}\,\mathrm{opt}(I) + 3.$$

If $h_{\max}(I) \leq \frac{1}{M}$ as well, we can use FF instead of NF to distribute the shelves into bins, which needs at most $(1 + \frac{1}{M})\,\texttt{height}(P) + 1$ bins, see again Section 3. This way, the number of needed bins is bounded by

$$\left(1 + \frac{1}{M}\right)\texttt{height}(P) + 1 \leq \frac{2(M+1)(M-1)}{(M-2)^2}\,\mathrm{opt}(I) + 2,$$

as claimed.

Now we consider the case when $M = 2$. Partition $I$ into two sets $I_L$ and $I_R$, where a polygon $p \in I$ belongs to $I_L$ if its chosen $x$-parallelogram in the proof of Theorem 7 is tilted to the left and to $I_R$ if it is tilted to the right. We now proceed with the algorithm in the proof of Theorem 7 for $c = \frac{1}{w_{max}(I)} - 1 \geq 1$, but for $I_L$ and $I_R$ separately. Call the obtained packings $P_L$ and $P_R$, respectively. Note that since all are tilted to one side only,

$$\texttt{width}(P_L), \texttt{width}(P_R) \leq (c+1)w_{\max}(I) = 1$$

and, using $m = |c| \geq 1$ and $cw_{\max}(I) = 1 - w_{\max}(I) \geq \frac{1}{2}$,

$$\texttt{height}(P_L) \leq 2\left(1 + \frac{1}{m}\right)\frac{\texttt{area}(I_L)}{cw_{\max}(I_L)} + h_{\max}(I_L) \leq 8\,\texttt{area}(I_L) + h_{\max}(I),$$

as well as analogously $\texttt{height}(P_R) \leq 8\,\texttt{area}(I_R) + h_{\max}(I)$.

Hence, for the packing $P$, where $P_R$ is stacked on top of $P_L$, it holds that

$$\texttt{width}(P) \leq 1 \quad \text{and} \quad \texttt{height}(P) \leq 16\,\texttt{area}(I) + 2h_{\max}(I).$$

From here, with the same arguments as for $M \geq 3$, we obtain the desired bounds. ◀

## Abstract

We revisit two well-studied problems, Bounded Degree Vertex Deletion and Defective Coloring, where the input is a graph $G$ and a target degree $\Delta$ and we are asked either to edit or partition the graph so that the maximum degree becomes bounded by $\Delta$. Both problems are known to be parameterized intractable for the most well-known structural parameters, such as treewidth.

We revisit the parameterization by treewidth, as well as several related parameters and present a more fine-grained picture of the complexity of both problems. In particular:

- Both problems admit straightforward DP algorithms with table sizes $(\Delta+2)^{\mathrm{tw}}$ and $(\chi_{\mathrm{d}}(\Delta+1))^{\mathrm{tw}}$ respectively, where tw is the input graph's treewidth and $\chi_{\mathrm{d}}$ the number of available colors. We show that, under the SETH, both algorithms are essentially optimal, for any non-trivial fixed values of $\Delta, \chi_{\mathrm{d}}$, even if we replace treewidth by pathwidth. Along the way, we obtain an algorithm for Defective Coloring with complexity quasi-linear in the table size, thus settling the complexity of both problems for treewidth and pathwidth.
- Given that the standard DP algorithm is optimal for treewidth and pathwidth, we then go on to consider the more restricted parameter tree-depth. Here, previously known lower bounds imply that, under the ETH, Bounded Vertex Degree Deletion and Defective Coloring cannot be solved in time $n^{o(\sqrt[4]{\mathrm{td}})}$ and $n^{o(\sqrt{\mathrm{td}})}$ respectively, leaving some hope that a qualitatively faster algorithm than the one for treewidth may be possible. We close this gap by showing that neither problem can be solved in time $n^{o(\mathrm{td})}$, under the ETH, by employing a recursive low tree-depth construction that may be of independent interest.
- Finally, we consider a structural parameter that is known to be restrictive enough to render both problems FPT: vertex cover. For both problems the best known algorithm in this setting has a super-exponential dependence of the form $\mathrm{vc}^{\mathcal{O}(\mathrm{vc})}$. We show that this is optimal, as an algorithm with dependence of the form $\mathrm{vc}^{o(\mathrm{vc})}$ would violate the ETH. Our proof relies on a new application of the technique of $d$-detecting families introduced by Bonamy et al. [ToCT 2019].

Our results, although mostly negative in nature, paint a clear picture regarding the complexity of both problems in the landscape of parameterized complexity, since in all cases we provide essentially matching upper and lower bounds.

## 1 Introduction

Parameterized complexity and in particular the study of structural parameters such as treewidth is one of the most well-developed approaches for dealing with NP-hard problems on graphs. Treewidth is of course one of the major success stories of this field, as a plethora of hard problems become fixed-parameter tractable when parameterized by this parameter.

Naturally, this success has motivated the effort to trace the limits of the algorithmic power of treewidth by attempting to understand what are the problems for which treewidth-based techniques *cannot* work.

When could the treewidth toolbox fail? One common scenario that seems to be shared by a multitude of problems which are W[1]-hard[1] parameterized by treewidth is when a natural dynamic programming algorithm does exist, but the DP is forced to store for each vertex of a bag in the tree decomposition an arbitrarily large integer – for example a number related to the degree of the vertex. Our goal in this paper is to study situations of this type and pose the natural question of whether one can do better than the "obvious" DP, by obtaining an algorithm with better running time, even at the expense of looking at a parameter more restrictive than treewidth.

Given the above, we focus on two problems which are arguably among the most natural representatives of our scenario: Bounded Degree Vertex Deletion and Defective Coloring. In both problems the input is a graph $G$ and a target degree $\Delta$ and we are asked, in the case of Bounded Degree Vertex Deletion to delete a minimum number of vertices so that the remaining graph has degree at most $\Delta$, and in the case of Defective Coloring to partition $G$ into a minimum number of color classes such that each class induces a graph of degree at most $\Delta$. Both problems are well-studied, as they generalize classical problems (Vertex Cover and Coloring respectively) and we review some of the previous work below. However, the most relevant aspect of the two problems for our purposes is the following: (i) both problems admit DP algorithms with complexity of the form $n^{\mathcal{O}(\mathrm{tw})}$ and (ii) both problems are W[1]-hard parameterized by treewidth; in fact, for Defective Coloring, it is even known that assuming the ETH it cannot be solved in time $n^{o(\mathrm{tw})}$ [5].

Since the $n^{\mathcal{O}(\mathrm{tw})}$ algorithms follow from standard DP techniques, it becomes a natural question whether we can do better. Does a better algorithm exist? Realistically, one could hope for one of two things: either an algorithm which still handles the problem parameterized by treewidth and in view of the aforementioned lower bound only attempts a fine-grained improvement in the running time; or an algorithm which is qualitatively faster at the expense of using a more restricted parameter. The results of this paper give strong negative evidence for both questions: if we parameterize by treewidth (and even by pathwidth) the running time of the standard DP is optimal under the SETH even for all fixed values of the other relevant parameters ($\Delta$ and the number of colors $\chi_{\mathrm{d}}$); while if we parameterize by more restrictive parameters, such as tree-depth and vertex cover, we obtain lower bound results (under the ETH) which indicate that the best algorithm is still essentially to run a form of the standard treewidth DP, even in these much more restricted cases. Our results thus paint a complete picture of the structurally parameterized complexity of these two problems and indicate that the standard DP is optimal in a multitude of restricted cases.

**Our contribution in more detail.** Following standard techniques, the two problems admit DP algorithms with tables of sizes $(\Delta+2)^{\mathrm{tw}}$ and $(\chi_{\mathrm{d}}(\Delta+1))^{\mathrm{tw}}$ respectively. Our first result is a collection of reductions proving that, assuming the SETH, no algorithm can improve upon these dynamic programs, even for pathwidth. More precisely, we show that no algorithm can solve Bounded Degree Vertex Deletion and Defective Coloring in time $(\Delta+2-\varepsilon)^{\mathrm{pw}}n^{\mathcal{O}(1)}$ and $(\chi_{\mathrm{d}}(\Delta+1)-\varepsilon)^{\mathrm{pw}}n^{\mathcal{O}(1)}$ respectively, for any $\varepsilon>0$ and for

[1] We assume the reader is familiar with the basics of parameterized complexity theory, as given in standard textbooks [14].

any combination of fixed values of $\Delta, \chi_d$ (except the combination $\Delta = 0$ and $\chi_d = 2$, which trivially makes Defective Coloring polynomial-time solvable). Our reductions follow the general strategy pioneered by Lokshtanov, Marx, and Saurabh [37] and indeed generalize their results for Vertex Cover and Coloring (which already covered the case $\Delta = 0$). The main difficulty here is being able to cover all values of the secondary parameters and for technical reasons we are forced to give separate versions of our reductions to cover the case $\Delta = 1$ for both problems. Along the way we note that, even though an algorithm with complexity $(\chi_d\Delta)^{\mathcal{O}(\mathrm{tw})}n^{\mathcal{O}(1)}$ was given for Defective Coloring in [5], it was not known if an algorithm with complexity $(\chi_d(\Delta+1))^{\mathrm{tw}}n^{\mathcal{O}(1)}$ (that is, with a quasi-linear dependence on the table size) is possible. For completeness, we settle this by providing an algorithm of this running time, using the FFT technique proposed by Cygan and Pilipczuk [17]. Taking also into account the Bounded Degree Vertex Deletion algorithm of running time $(\Delta+2)^{\mathrm{tw}}n^{\mathcal{O}(1)}$ given by van Rooij [48], we have exactly matching upper and lower bounds for both problems, for both treewidth and pathwidth.

Given that the results above show rather conclusively that the standard DP is the best algorithm for parameters treewidth and pathwidth, we then move on to a more restricted case: tree-depth. We recall that graphs of tree-depth $k$ are a proper subclass of graphs of pathwidth $k$, therefore one could reasonably hope to obtain a better algorithm for this parameter. This hope may further be supported by the fact that known lower bounds do not match the complexity of the standard algorithm. More precisely, the W[1]-hardness reduction given for Bounded Degree Vertex Deletion parameterized by tree-depth by Ganian, Klute, and Ordyniak [27] has a quartic blow-up, thus only implying that no $n^{o(\sqrt[4]{\mathrm{td}})}$ algorithm is possible; while the reduction given for Defective Coloring in [5] has a quadratic blow-up, only implying that no $n^{o(\sqrt{\mathrm{td}})}$ algorithm is possible (in both cases under the ETH). Our contribution is to show that both reductions can be replaced by more efficient reductions which are *linear* in the parameter; we thus establish that neither problem can be solved in time $n^{o(\mathrm{td})}$, implying that the treewidth-based algorithm remains (qualitatively) optimal even in this restricted case. One interesting aspect of our reductions is that, rather than using a modulator to a low tree-depth graph, which is common in such reductions, we use a recursive construction that leverages the full power of the parameter and may be of further use in tightening other lower bounds for the parameter tree-depth.

Finally, we move on to a more special case, parameterizing both problems by vertex cover. Both problems are FPT for this parameter and, since vertex cover is very restrictive as a parameter, one would hope that, finally, we should be able to obtain an algorithm that is more clever than the treewidth-based DP. Somewhat disappointingly, the known FPT algorithms for both problems have complexity $\mathrm{vc}^{\mathcal{O}(\mathrm{vc})}n^{\mathcal{O}(1)}$ [5], and the super-exponential dependence on the parameter is due to the fact that both algorithms are simple win/win arguments which, in one case, just execute the standard treewidth DP. We show that this is justified, as neither problem can be solved in time $\mathrm{vc}^{o(\mathrm{vc})}n^{\mathcal{O}(1)}$ (under the ETH), meaning that the algorithm that blindly executes the treewidth-based DP in some cases is still (qualitatively) best possible. We obtain our result by applying the technique of $d$-detecting families, introduced by Bonamy et al. [10]. Our results indicate that parameterization by vertex cover is a domain where this promising, but currently under-used, technique may find more applications in parameterized complexity.

**Related work.** Both Bounded Degree Vertex Deletion and Defective Coloring are well-studied problems with a rich literature. Bounded Degree Vertex Deletion finds application in a multitude of areas, ranging from computational biology [21] to some related problems in voting theory [7, 9], and its dual problem, called $s$-Plex Detection,

has numerous applications in social network analysis [4, 39, 40]. Various approximation algorithms are known [24, 25, 43]. The problem has also been extensively studied under the scope of parameterized complexity. It is W[2]-hard for unbounded values of $\Delta$ and parameter $k$ (the value of the optimal) [21], while it admits a linear-size kernel parameterized by $k$ [21, 50], for any fixed $\Delta \geq 0$; numerous FPT algorithms have been presented in the latter setting [40, 41, 49]. FPT approximation algorithms were given for Bounded Degree Vertex Deletion in [34] and [38]. As for Defective Coloring, which also appears in the literature as Improper Coloring, it was introduced almost 40 years ago [1, 13]. The main motivation behind this problem comes from the field of telecommunications, where the colors correspond to available frequencies and the goal is to assign them to communication nodes; a small amount of interference between neighboring nodes may be tolerable, which is modeled by the parameter $\Delta$. There have been plenty of works on the problem (see [2, 3, 5, 6, 12, 30] and the references therein), especially on unit disk graphs and various classes of grids.

The previous work for both problems that is most relevant to us focuses on their parameterized complexity for structural parameters, such as treewidth. In this setting, Bounded Degree Vertex Deletion was one of the first problems to be discovered to be W[1]-hard parameterized by treewidth [8], though the problem does become FPT parameterized by $\mathrm{tw} + \Delta$ or $\mathrm{tw} + k$. This hardness result was more recently improved by Ganian et al. [27], who showed that Bounded Degree Vertex Deletion is W[1]-hard parameterized by tree-depth and feedback vertex set. Defective Coloring was shown to be W[1]-hard parameterized by tree-depth (and hence pathwidth and treewidth) in [5]. However, [5] gave a hardness reduction for pathwidth that is linear in the parameter, and hence implies a $n^{o(\mathrm{pw})}$ lower bound for Defective Coloring under the ETH, but a hardness reduction for tree-depth that is quadratic (implying only a $n^{o(\sqrt{\mathrm{td}})}$ lower bound). Similarly, the reduction given by [27] for Bounded Degree Vertex Deletion parameterized by tree-depth is quartic in the parameter, as it goes through an intermediate problem (a variant of Subset Sum), implying only a $n^{o(\sqrt[4]{\mathrm{td}})}$ lower bound. Defective Coloring is known to be FPT parameterized by vertex cover using a simple win/win argument which applies the treewidth-based DP in one case (if $\Delta > \mathrm{vc}$, then the graph is always 2-colorable; otherwise the standard DP algorithm runs in FPT time), and the same is true for Bounded Degree Vertex Deletion (if $\Delta \leq \mathrm{vc}$, we can use the aforementioned FPT algorithm for parameters $\mathrm{tw} + \Delta$, else assume that $k < \mathrm{vc}$, as otherwise the problem is trivial, follow the reduction of [8] to Vector Dominating Set [44] and notice that at most vc vertices have degree greater than $\Delta$). Hence, the best algorithms for both problems for this parameter have complexity $\mathrm{vc}^{\mathcal{O}(\mathrm{vc})}n^{\mathcal{O}(1)}$.

The fine-grained analysis of the complexity of structural parameterizations, such as by treewidth, is an active field of research. The technique of using the SETH to establish tight running time lower bounds was pioneered by Lokshtanov, Marx, and Saurabh [37]. Since then, tight upper and lower bounds are known for a multitude of problems for parameterizations by treewidth and related parameters, such as pathwidth and clique-width [15, 16, 19, 20, 23, 26, 28, 29, 31, 42, 47]. One difficulty of the results we present here is that we need to present a family of reductions: one for each fixed value of $\Delta$ and $\chi_{\mathrm{d}}$. There are a few other problems for which families of tight lower bounds are known, such as $k$-Coloring, for which the correct dependence is $k^{\mathrm{tw}}$ for treewidth [37] and $(2^k - 2)^{\mathrm{cw}}$ for clique-width [35] for all $k \geq 3$; distance $r$-Dominating Set, for which the correct dependence is $(2r+1)^{\mathrm{tw}}$ [11] and $(3r+1)^{\mathrm{cw}}$ [32], for all $r \geq 1$; and distance $d$-Independent Set, for which the correct dependence is $d^{\mathrm{tw}}$ [33]. In all these cases, the optimal algorithm is the "natural" DP, and our results for Bounded Degree Vertex Deletion and Defective Coloring fit this pattern.

**Table 1** Lower bounds established in the current work. The results of the first row are under SETH, while all the rest under ETH.

| Parameter | Bounded Degree Vertex Deletion | Defective Coloring |
|---|---|---|
| pathwidth + $\Delta$ | $\mathcal{O}^\star((\Delta+2-\varepsilon)^{\mathrm{pw}})$ | $\mathcal{O}^\star((\chi_{\mathrm{d}}\cdot(\Delta+1)-\varepsilon)^{\mathrm{pw}})$ |
| treedepth | $n^{o(\mathrm{td})}$ | $n^{o(\mathrm{td})}$ |
| vertex cover | $\mathrm{vc}^{o(\mathrm{vc})}n^{\mathcal{O}(1)}$ | $\mathrm{vc}^{o(\mathrm{vc})}n^{\mathcal{O}(1)}$ |

Even though the previous work mentioned above may make it seem that our SETH-based lower bounds are not surprising, it is important to stress that it is not a given that the naïve DP should be optimal for our problems. In particular, Bounded Degree Vertex Deletion falls into a general category of $(\sigma,\rho)$-domination problems, which were studied recently in [22] (we refer the reader there for the definition of $(\sigma,\rho)$-domination). One of the main results of that work was to show that significant improvements over the basic DP are indeed possible in some cases, and in particular when one of $\sigma,\rho$ is cofinite. Since Bounded Degree Vertex Deletion is the case where $\sigma=\{0,\ldots,\Delta\}$ and $\rho=\mathbb{N}$ (that is, $\rho$ is co-finite), our result falls exactly in the territory left uncharted by [22], where more efficient algorithms could still be found (and where indeed [22] did uncover such algorithms for some values of $\sigma,\rho$).

**Organization.** In Section 2 we discuss the general preliminaries, followed by the lower bounds for Bounded Degree Vertex Deletion in Sections 3–5, and the conclusion in Section 6. Proofs marked with $(\star)$, as well as all the results pertaining to Defective Coloring, can be found in the full version of the paper.

## 2 Preliminaries

Throughout the paper we use standard graph notation [18], and we assume familiarity with the basic notions of parameterized complexity [14]. All graphs considered are undirected without loops, unless explicitly stated otherwise. For a graph $G=(V,E)$ and two integers $\chi_{\mathrm{d}}\geq 1,\Delta\geq 0$, we say that $G$ admits a $(\chi_{\mathrm{d}},\Delta)$-coloring if one can partition $V$ into $\chi_{\mathrm{d}}$ sets such that the graph induced by each set has maximum degree at most $\Delta$. In that case, Defective Coloring is the problem of deciding, given $G,\chi_{\mathrm{d}},\Delta$, whether $G$ admits a $(\chi_{\mathrm{d}},\Delta)$-coloring. For $x,y\in\mathbb{Z}$, let $[x,y]=\{z\in\mathbb{Z}\mid x\leq z\leq y\}$, while $[x]=[1,x]$. Standard $\mathcal{O}^\star$ notation is used to suppress polynomial factors. For function $f:A\to B$, and $A'\subseteq A$, let $f(A')=\sum_{a\in A'}f(a)$. For the pathwidth bounds, we use the notion of *mixed search strategy* [45], where an edge is cleared by either placing a searcher on both of its endpoints or sliding one along the edge. We rely on a weaker form of the ETH, which states that 3-SAT on instances with $n$ variables and $m$ clauses cannot be solved in time $2^{o(n+m)}$.

In $k$-Multicolored Clique, we are given a graph $G=(V,E)$ and a partition of $V$ into $k$ independent sets $V_1,\ldots,V_k$, each of size $n$, and we are asked to determine whether $G$ contains a $k$-clique. It is well-known that this problem does not admit any $f(k)n^{o(k)}$ algorithm, where $f$ is any computable function, unless the ETH is false [14].

In $q$-CSP-$B$, we are given a Constraint Satisfaction (CSP) instance with $n$ variables and $m$ constraints. The variables take values in a set $Y$ of size $B$, i.e. $|Y|=B$. Each constraint involves at most $q$ variables and is given as a list of satisfying assignments for these variables, where a satisfying assignment is a $q$-tuple of values from the set $Y$ given to each of the $q$ variables. The following result was shown by Lampis [35] to be a natural consequence of the SETH, and has been used in the past for various hardness results [19, 20, 29].

▶ **Theorem 1** ([35]). *For any $B \geq 2$ it holds that, if the SETH is true, then for all $\varepsilon > 0$, there exists a $q$ such that $n$-variable $q$-CSP-$B$ cannot be solved in time $\mathcal{O}^\star((B-\varepsilon)^n)$.*

## 3 Treewidth and Maximum Degree Lower Bounds

In this section we present tight lower bounds on the complexity of solving both Bounded Degree Vertex Deletion and Defective Coloring parameterized by the treewidth of the input graph plus the target degree. The latter result can be found in the full version of the paper.

Both reductions are similar in nature: we start from an instance $\phi$ of $q$-CSP-$B$, and produce an equivalent instance on a graph of pathwidth $\mathrm{pw} = n + \mathcal{O}(1)$, where $n$ denotes the number of variables of $\phi$. An interesting observation however, is that for both problems, we have to distinguish between the case where $\Delta = 1$ and $\Delta \geq 2$; the whole construction becomes much more complicated in the second case.

### 3.1 Bounded Degree Vertex Deletion

In the following, we will present a reduction from $q$-CSP-$B$ to Bounded Degree Vertex Deletion, for any fixed $\Delta \geq 1$, where $\Delta = B - 2$. In that case, if there exists a $\mathcal{O}^\star((\Delta + 2 - \varepsilon)^{\mathrm{pw}})$ algorithm for Bounded Degree Vertex Deletion, where $\varepsilon > 0$, then there exists a $\mathcal{O}^\star((B-\varepsilon)^n)$ algorithm for $q$-CSP-$B$, for any constant $q$, which due to Theorem 1 results in SETH failing.

Our reduction is based on the construction of "long paths" of *Block gadgets*, that are serially connected in a path-like manner. Each such "path" corresponds to a variable of the given formula, while each column of this construction is associated with one of its constraints. Intuitively, our aim is to embed the $B^n$ possible variable assignments into the $(\Delta+2)^{\mathrm{tw}}$ states of some optimal dynamic program that would solve the problem on our constructed instance.

Below, we present a sequence of gadgets used in our reduction. The aforementioned block gadgets, which allow a solution to choose among $\Delta + 2$ reasonable choices, are the main ingredient. Notice that these gadgets will differ significantly depending on whether $\Delta$ is equal to 1 or not. We connect these gadgets in a path-like manner that ensures that choices remain consistent throughout the construction, and connect constraint gadgets in different "columns" of the constructed grid in a way that allows us to verify if the choice made represents a satisfying assignment, without increasing the graph's treewidth.

▶ **Theorem 2.** *For any constant $\varepsilon > 0$, there is no $\mathcal{O}^\star((3-\varepsilon)^{\mathrm{pw}})$ algorithm deciding Bounded Degree Vertex Deletion for $\Delta = 1$, where* pw *denotes the input graph's pathwidth, unless the SETH is false.*

**Proof.** Fix some positive $\varepsilon > 0$ for which we want to prove the theorem. We will reduce $q$-CSP-3, for some $q$ that is a constant that only depends on $\varepsilon$, to Bounded Degree Vertex Deletion for $\Delta = 1$ in a way that ensures that if the resulting Bounded Degree Vertex Deletion instance could be solved in time $\mathcal{O}^\star((3-\varepsilon)^{\mathrm{pw}})$, then we would obtain an algorithm for $q$-CSP-3 that would contradict the SETH. To this end, let $\phi$ be an instance of $q$-CSP-3 of $n$ variables $X = \{x_i \mid i \in [n]\}$ taking values over the set $Y = [3]$ and $m$ constraints $C = \{c_j \mid j \in [m]\}$. For each constraint we are given a set of at most $q$ variables which are involved in this constraint and a list of satisfying assignments for these variables, the size of which is denoted by $s : C \to [3^q]$, i.e. $s(c_j) \leq 3^q = \mathcal{O}(1)$ denotes the number of satisfying assignments for constraint $c_j$. We will construct in polynomial time an equivalent instance $\mathcal{I} = (G, k)$ of Bounded Degree Vertex Deletion for $\Delta = 1$, where $\mathrm{pw}(G) \leq n + \mathcal{O}(1)$.

**Block and Variable Gadgets.** For every variable $x_i$ and every constraint $c_j$, construct a path of 3 vertices $p^1_{i,j}, p^2_{i,j}$ and $p^3_{i,j}$, which comprises the *block gadget* $\hat{B}_{i,j}$. Intuitively, we will map the deletion of $p^y_{i,j}$ with an assignment where $x_i$ receives value $y$. Next, for $j \in [m-1]$, we add an edge between $p^3_{i,j}$ and $p^1_{i,j+1}$, thus resulting in $n$ paths $P_1, \ldots, P_n$ of length $3m$, called *variable gadgets*.

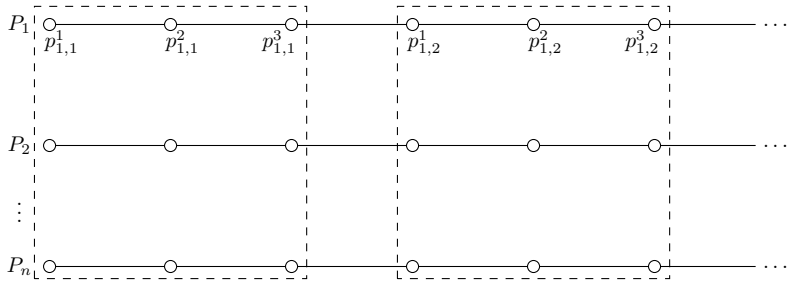

**Figure 1** Sequences of block gadgets comprise the variable gadgets.

**Constraint Gadget.** This gadget is responsible for determining constraint satisfaction, based on the choices made in the rest of the graph. For constraint $c_j$, construct the *constraint gadget* $\hat{C}_j$ as follows:

- construct a clique of $s(c_j)$ vertices $v^j_1, \ldots, v^j_{s(c_j)}$, and fix an arbitrary one-to-one mapping between those vertices and the satisfying assignments of $c_j$,
- attach to each vertex $v^j_\ell$ a leaf $l^j_\ell$,
- if variable $x_i$ is involved in the constraint $c_j$ and $v^j_\ell$ corresponds to an assignment where $x_i$ has value $y \in Y$, add an edge between $v^j_\ell$ and $p^y_{i,j}$.

Let graph $G_0$ be the graph containing all variable gadgets $P_i$ as well as all the constraint gadgets $\hat{C}_j$, for $i \in [n]$ and $j \in [m]$. To construct graph $G$, introduce $\kappa = 2n+1$ copies $G_1, \ldots, G_\kappa$ of $G_0$, such that they are connected sequentially as follows: for $i \in [n]$ and $j \in [\kappa - 1]$, add an edge between $p^3_{i,m}(G_j)$ and $p^1_{i,1}(G_{j+1})$, where $p^y_{i,j}(G_a)$ denotes the vertex $p^y_{i,j}$ of graph $G_a$. We refer to the block gadget $\hat{B}_{i,j}$, to the variable gadget $P_i$ and to the constraint gadget $\hat{C}_j$ of $G_a$ as $\hat{B}^{G_a}_{i,j}$, $P^{G_a}_i$ and $\hat{C}^{G_a}_j$ respectively. Let $\mathcal{P}^i$ denote the path resulting from $P^{G_1}_i, \ldots, P^{G_\kappa}_i$. Let $k' = \sum_{j=1}^{m}(s(c_j) - 1 + n) = m \cdot n + \sum_{j=1}^{m}(s(c_j) - 1)$, and set $k = \kappa \cdot k'$.

▶ **Lemma 3.** ($\star$) *If $\phi$ is satisfiable, then there exists $S \subseteq V(G)$ such that $G - S$ has maximum degree at most 1 and $|S| \leq k$.*

▶ **Lemma 4.** ($\star$) *If there exists $S \subseteq V(G)$ such that $G - S$ has maximum degree at most 1 and $|S| \leq k$, then $\phi$ is satisfiable.*

▶ **Lemma 5.** ($\star$) *It holds that $\mathrm{pw}(G) \leq n + \mathcal{O}(1)$.*

Therefore, in polynomial time, we can construct a graph $G$, of pathwidth $\mathrm{pw}(G) \leq n + \mathcal{O}(1)$ due to Lemma 5, such that, due to Lemmas 3 and 4, deciding whether there exists $S \subseteq V(G)$ of size $|S| \leq k$ and $G - S$ has maximum degree at most 1 is equivalent to deciding whether $\phi$ is satisfiable. In that case, assuming there exists a $\mathcal{O}^\star((3-\varepsilon)^{\mathrm{pw}(G)})$ algorithm for Bounded Degree Vertex Deletion for $\Delta = 1$, one could decide $q$-CSP-3 in time $\mathcal{O}^\star((3-\varepsilon)^{\mathrm{pw}(G)}) = \mathcal{O}^\star((3-\varepsilon)^{n+\mathcal{O}(1)}) = \mathcal{O}^\star((3-\varepsilon)^n)$ for any constant $q$, which contradicts the SETH due to Theorem 1. ◀

▶ **Theorem 6.** ($\star$) *For any constant $\varepsilon > 0$, there is no $\mathcal{O}^\star((\Delta + 2 - \varepsilon)^{\mathrm{pw}})$ algorithm deciding* Bounded Degree Vertex Deletion *for $\Delta \geq 2$, where* pw *denotes the input graph's pathwidth, unless the SETH is false.*

## 4 Tree-depth Lower Bounds

In this section we present lower bounds on the complexity of solving Bounded Degree Vertex Deletion and Defective Coloring, when parameterized by the tree-depth of the input graph. The latter result can be found in the full version of the paper.

The common starting point of both reductions is an instance of $k$-Multicolored Clique, where $k$ is a power of 2. Our main technical contribution is a recursive construction which allows us to keep the tree-depth of the constructed graph linear with respect to $k$, which we briefly sketch here. The main idea behind the construction is the following:

- First, we describe a *choice gadget* $\hat{C}_i$, which encodes, for every independent set $V_i$ of the graph, which vertex of $V_i$ is part of the clique.
- Afterwards, we describe how one can make a *copy* of such a choice gadget, by using only a constant number of vertices, while at the same time guaranteeing that the choices between the instances of the choice gadget remain the same.
- Lastly, we define an *adjacency gadget* $\hat{A}(i_1, i_2, i'_1, i'_2)$, whose purpose is to verify that, for the given choices of vertices, there exists an edge between $V_i$ and $V_{i'}$, for any $i \in [i_1, i_2]$ and $i' \in [i'_1, i'_2]$. Initially we deal with the case where $i_1 = i_2$ and $i'_1 = i'_2$, while ensuring that the tree-depth of the construction is constant. For the other case, the gadget is constructed in two steps. Firstly, it contains all the choice gadgets $\hat{C}_i$ and $\hat{C}_{i'}$. Secondly, it contains 4 instances of adjacency gadgets, due to the upper and lower half of $[i_1, i_2]$ and $[i'_1, i'_2]$, while the occurrences of the choice gadgets in those are copies of the choice gadgets introduced in the first step. The fact that $k$ is a power of 2 guarantees that the upper and lower half of both $[i_1, i_2]$ and $[i'_1, i'_2]$ are well defined.

Then, by removing the vertices used in the copy gadgets, it follows that all adjacency gadgets constructed in the second step become disconnected. Therefore, the tree-depth of the whole construction is given by a recursive formula of the form $T(k) = \mathcal{O}(k) + T(k/2)$.

### 4.1 Bounded Degree Vertex Deletion

▶ **Theorem 7.** *For any computable function $f$, if there exists an algorithm that solves* Bounded Degree Vertex Deletion *in time $f(\mathrm{td})n^{o(\mathrm{td})}$, where* td *denotes the tree-depth of the input graph, then the ETH is false.*

**Proof.** Let $(G, k)$ be an instance of $k$-Multicolored Clique, such that every vertex of $G$ has a self loop, i.e. $\{v, v\} \in E(G)$, for all $v \in V(G)$. Recall that we assume that $G$ is given to us partitioned into $k$ independent sets $V_1, \ldots, V_k$, where $V_i = \{v_1^i, \ldots, v_n^i\}$. Assume without loss of generality that $k = 2^z$, for some $z \in \mathbb{N}$ (one can do so by adding dummy independent sets connected to all the other vertices of the graph). Moreover, let $E^{i_1,i_2} \subseteq E(G)$ denote the edges of $G$ with one endpoint in $V_{i_1}$ and the other in $V_{i_2}$. Set $\Delta = n^3$. We will construct in polynomial time a graph $H$ of tree-depth $\mathrm{td}(H) = \mathcal{O}(k)$ and size $|V(H)| = k^{\mathcal{O}(1)} \cdot n^{\mathcal{O}(1)}$, such that there exists $S \subseteq V(H)$, $|S| \leq k'$ and $H - S$ has maximum degree at most $\Delta$, for some $k'$, if and only if $G$ has a $k$-clique.

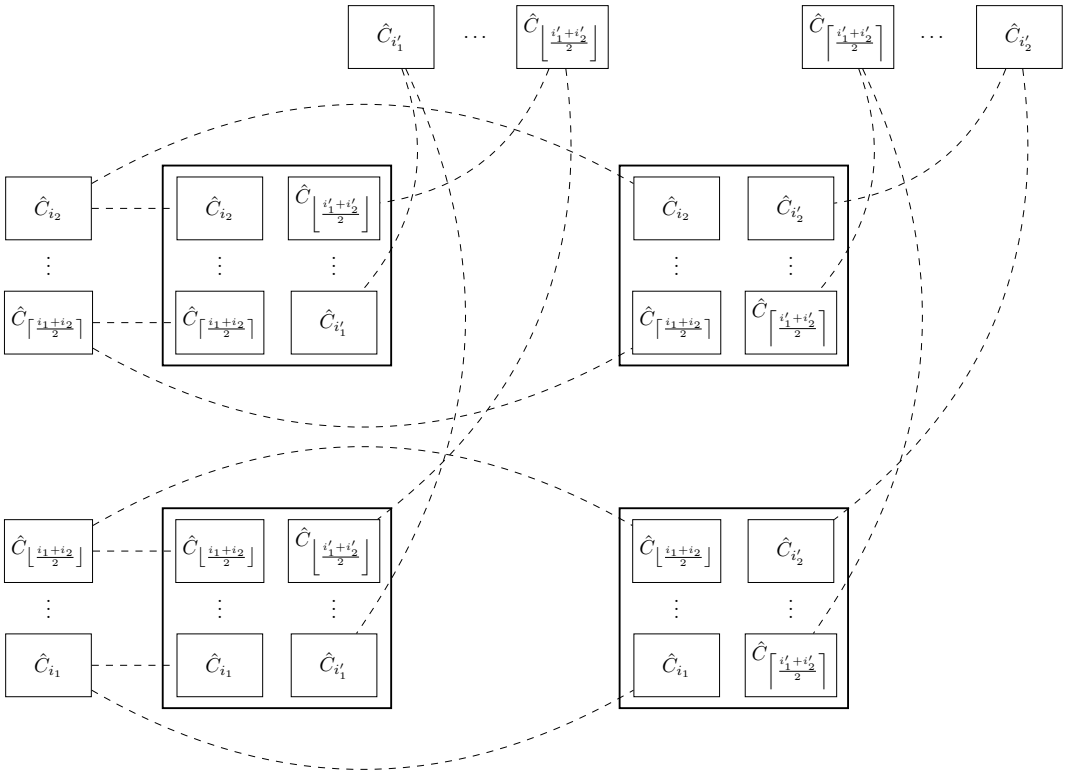

**Figure 2** Adjacency gadget $\hat{A}(i_1, i_2, i'_1, i'_2)$. Dashed lines denote copies.

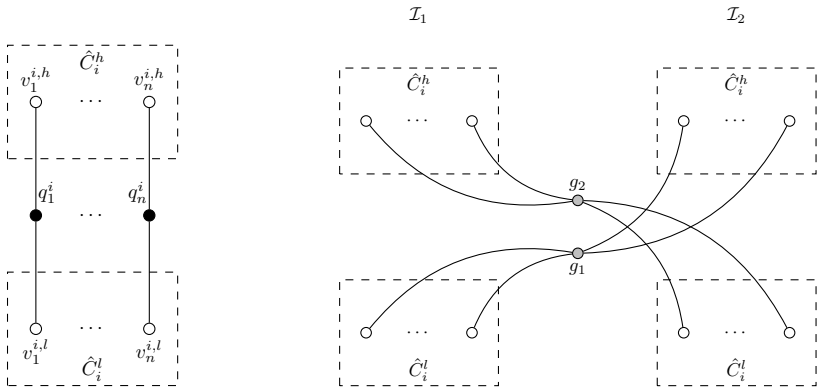
**Choice Gadget.** For an independent set $V_i$, we construct the *choice gadget* $\hat{C}_i$ as depicted in Figure 3a. We first construct independent sets $\hat{C}_i^p = \{v_1^{i,p}, \ldots, v_n^{i,p}\}$, where $p \in \{h, l\}$. Afterwards, we connect $v_j^{i,h}$ and $v_j^{i,l}$ with a vertex $q_j^i$, and add to the latter $\Delta - 1$ leaves. Intuitively, we will consider an one-to-one mapping between the vertex $v_j^i$ of $V_i$ belonging to a supposed $k$-clique of $G$ and the deletion of exactly $j$ vertices of $\hat{C}_i^l$ and $n - j$ from $\hat{C}_i^h$.

**Copy Gadget.** Given two instances $\mathcal{I}_1$, $\mathcal{I}_2$ of a choice gadget $\hat{C}_i$, when we say that we connect them with a *copy gadget*, we introduce two vertices $g_1$ and $g_2$, attach to each of those $\Delta - n$ leaves, and lastly add an edge between $g_1$ (respectively, $g_2$) with the vertices of $\hat{C}_i^l$ of instance $\mathcal{I}_1$ (respectively, $\mathcal{I}_2$), as well as the vertices of $\hat{C}_i^h$ of instance $\mathcal{I}_2$ (respectively, $\mathcal{I}_1$).

**Edge Gadget.** Let $e = \{v_{j_1}^{i_1}, v_{j_2}^{i_2}\} \in E^{i_1,i_2}$ be an edge of $G$. Construct the *edge gadget* $\hat{E}_e$ as depicted in Figure 4, where every vertex $c_j^i$ has $\Delta$ leaves attached.

**Adjacency Gadget.** For $i_1 \leq i_2$ and $i'_1 \leq i'_2$, we define the *adjacency gadget* $\hat{A}(i_1, i_2, i'_1, i'_2)$ as follows:

- Consider first the case when $i_1 = i_2$ and $i'_1 = i'_2$. Let the adjacency gadget contain instances of the edge gadgets $\hat{E}_e$, for $e \in E^{i_1,i'_1}$, the choice gadgets $\hat{C}_{i_1}$ and $\hat{C}_{i'_1}$, as well as vertices $\ell^l_{i_1,i'_1}$, $\ell^h_{i_1,i'_1}$, $r^l_{i_1,i'_1}$ and $r^h_{i_1,i'_1}$. Add edges between
  - $\ell^l_{i_1,i'_1}$ and $\hat{C}^l_{i_1}$,
  - $\ell^h_{i_1,i'_1}$ and $\hat{C}^h_{i_1}$,
  - $r^l_{i_1,i'_1}$ and $\hat{C}^l_{i'_1}$,
  - $r^h_{i_1,i'_1}$ and $\hat{C}^h_{i'_1}$.



**(a)** Choice gadget $\hat{C}_i$. **(b)** Making a copy of a choice gadget $\hat{C}_i$.

**Figure 3** Black vertices have $\Delta - 1$ and gray $\Delta - n$ leaves attached.

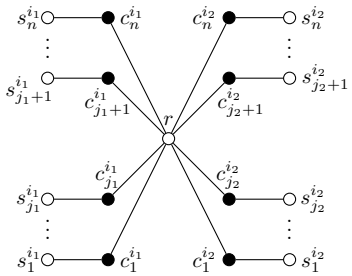


**Figure 4** Edge gadget $\hat{E}_e$ for $e = \{v_{j_1}^{i_1}, v_{j_2}^{i_2}\}$. Black vertices have $\Delta$ leaves attached.

If $e = \{v_{j_1}^{i_1}, v_{j_2}^{i'_1}\} \in E^{i_1,i'_1}$, then add the following edges adjacent to $\hat{E}_e$:

- $\ell^l_{i_1,i'_1}$ with $s^{i_1}_\kappa$, for $\kappa \in [j_1]$,
- $\ell^h_{i_1,i'_1}$ with $s^{i_1}_\kappa$, for $\kappa \in [j_1+1, n]$,
- $r^l_{i_1,i'_1}$ with $s^{i'_1}_\kappa$, for $\kappa \in [j_2]$,
- $r^h_{i_1,i'_1}$ with $s^{i'_1}_\kappa$, for $\kappa \in [j_2+1, n]$.

Let $\tau(x)$, where $x \in \{\ell^l_{i_1,i'_1}, \ell^h_{i_1,i'_1}, r^l_{i_1,i'_1}, r^h_{i_1,i'_1}\}$, denote the number of neighbors of $x$ belonging to some edge gadget. Attach $\Delta - \tau(x)$ leaves to vertex $x$.

- Now consider the case when $i_1 < i_2$ and $i'_1 < i'_2$. Then, let $\hat{A}(i_1, i_2, i'_1, i'_2)$ contain choice gadgets $\hat{C}_i$ and $\hat{C}_{i'}$, where $i \in [i_1, i_2]$ and $i' \in [i'_1, i'_2]$, which we will refer to as the *original choice gadgets* of $\hat{A}(i_1, i_2, i'_1, i'_2)$, as well as the adjacency gadgets

- $\hat{A}(i_1, \lfloor \frac{i_1+i_2}{2} \rfloor, i'_1, \lfloor \frac{i'_1+i'_2}{2} \rfloor)$,
- $\hat{A}(i_1, \lfloor \frac{i_1+i_2}{2} \rfloor, \lceil \frac{i'_1+i'_2}{2} \rceil, i'_2)$,
- $\hat{A}(\lceil \frac{i_1+i_2}{2} \rceil, i_2, i'_1, \lfloor \frac{i'_1+i'_2}{2} \rfloor)$,
- $\hat{A}(\lceil \frac{i_1+i_2}{2} \rceil, i_2, \lceil \frac{i'_1+i'_2}{2} \rceil, i'_2)$.

Lastly, we connect with a copy gadget any choice gadgets $\hat{C}_i$ and $\hat{C}_{i'}$ appearing in said adjacency gadgets, with the corresponding original choice gadget $\hat{C}_i$ and $\hat{C}_{i'}$. Notice that then, every original choice gadget is taking part in two copy gadgets.

Let graph $H$ be the adjacency gadget $\hat{A}(1, k, 1, k)$. Notice that it holds that $|V(H)| = (n \cdot k)^{\mathcal{O}(1)}$. Let $\beta = 2k(2k-1)$, and set $k' = 2(|E(G)| - kn) \cdot 2n + kn \cdot 2n + 2\binom{k}{2} + k + n \cdot \beta$.

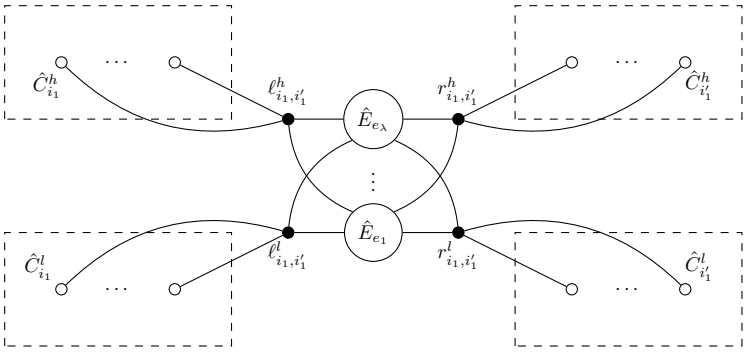

**Figure 5** Adjacency gadget $\hat{A}(i_1, i_1, i'_1, i'_1)$, where $E^{i_1,i'_1} = \{e_i \mid i \in [\lambda]\}$. Black vertices have leaves attached.

▶ **Lemma 8.** ($\star$) *$H$ has the following properties:*

- *The number of instances of choice gadgets present in $H$ is $\beta$,*
- *The number of instances of edge gadget $\hat{E}_e$ present in $H$, where $e = \{v^{i_1}_{j_1}, v^{i_2}_{j_2}\} \in E(G)$, is one if $i_1 = i_2$, and two otherwise.*

▶ **Lemma 9.** ($\star$) *It holds that* $\mathrm{td}(H) = \mathcal{O}(k)$.

▶ **Lemma 10.** ($\star$) *If $G$ contains a $k$-clique, then there exists $S \subseteq V(H)$, with $|S| \leq k'$, such that $H - S$ has maximum degree at most $\Delta$.*

▶ **Lemma 11.** ($\star$) *If there exists $S \subseteq V(H)$, with $|S| \leq k'$, such that $H - S$ has maximum degree at most $\Delta$, then $G$ contains a $k$-clique.*

Therefore, in polynomial time, we can construct a graph $H$, of tree-depth $\mathrm{td} = \mathcal{O}(k)$ due to Lemma 9, such that, due to Lemmas 10 and 11, deciding whether there exists $S \subseteq V(H)$ of size $|S| \leq k'$ and $H - S$ has maximum degree at most $\Delta = n^3$ is equivalent to deciding whether $G$ has a $k$-clique. In that case, assuming there exists a $f(\mathrm{td})|V(H)|^{o(\mathrm{td})}$ algorithm for Bounded Degree Vertex Deletion, where $f$ is any computable function, one could decide $k$-Multicolored Clique in time $f(\mathrm{td})|V(H)|^{o(\mathrm{td})} = g(k) \cdot n^{o(k)}$, for some computable function $g$, which contradicts the ETH. ◀

## 5 Vertex Cover Lower Bounds

In this section we present lower bounds on the complexity of solving Bounded Degree Vertex Deletion when parameterized by the vertex cover of the input graph. An analogous lower bound is shown for Defective Coloring, which has been deferred to the appendix due to space restrictions. In both cases, we start from a 3-SAT instance of $n$ variables, and produce an equivalent instance where the input graph has vertex cover $\mathcal{O}(n/\log n)$, hence any algorithm solving the latter problem in time $\mathrm{vc}^{o(\mathrm{vc})}n^{\mathcal{O}(1)}$ would refute the ETH. As a consequence of the above, already known algorithms for both of these problems are essentially optimal. We start by presenting some necessary tools used in both of these reductions, and then prove the stated results for Bounded Degree Vertex Deletion.

### 5.1 Preliminary Tools

We first define a constrained version of 3-SAT, called (3,4)-XSAT. This variant is closely related with the (3,4)-SAT problem [46] which asks whether a given formula $\phi$ is satisfiable, where $\phi$ is a 3-SAT formula each clause of which contains exactly 3 different variables and

each variable occurs in at most 4 clauses. As observed by Bonamy et al. [10], a corollary of Tovey's work [46] is that there is no $2^{o(n)}$ algorithm for (3,4)-SAT unless the ETH is false, where $n$ denotes the number of variables of the formula. Here we prove an analogous lower bound for (3,4)-XSAT. Subsequently, by closely following Lemma 3.2 from [10], we present a way to partition the formula's variables and clauses into groups such that variables appearing in clauses of the same clause group belong to different variable groups.

(3,4)-XSAT
**Input:** A 3-SAT formula $\phi$ every clause of which contains exactly 3 distinct variables and each variable appears in at most 4 clauses.
**Task:** Determine whether there exists an assignment to the variables of $\phi$ such that each clause has exactly one True literal.

▶ **Theorem 12.** ($\star$) *(3,4)-XSAT cannot be decided in time $2^{o(n)}$, where $n$ denotes the number of variables of the input formula, unless the ETH fails.*

We proceed by proving that, given a (3,4)-XSAT instance, we can partition the variables and clauses of the formula into groups such that variables appearing in clauses of the same clause group belong to different variable groups.

▶ **Lemma 13.** ($\star$) *Let $\phi$ be an instance of (3,4)-XSAT, where $V$ denotes the set of its $n$ variables and $C$ the set of its clauses. Moreover, let $b \leq \sqrt{n}$. One can produce in time $n^{\mathcal{O}(1)}$ a partition of $\phi$'s variables into $n_V$ disjoint sets $V_1, \ldots, V_{n_V}$ of size at most $b$ as well as a partition of its clauses into $n_C$ disjoint sets $C_1, \ldots, C_{n_C}$ of size at most $\sqrt{n}$, for some integers $n_V = \mathcal{O}(n/b)$ and $n_C = \mathcal{O}(\sqrt{n})$, such that, for any $i \in [n_C]$, any two variables appearing in clauses of $C_i$ belong to different variable subsets.*

▶ **Definition 14.** *A $d$-detecting family is a set of subsets of a finite set $U$ that can be used to distinguish between different functions $f, g : U \to \{0, \ldots, d-1\}$. Therefore, if $f \neq g$, there exists $U' \subseteq U$ such that $f(U') \neq g(U')$ and $U'$ belongs to said family.*

Lindström [36] has provided a deterministic construction of sublinear, $d$-detecting families, while Bonamy et al. [10] were the first to use them in the context of computational complexity, proving tight lower bounds for the Multicoloring problem under the ETH. The following theorem will be crucial towards proving the stated lower bounds.

▶ **Theorem 15** ([36]). *For every constant $d \in \mathbb{N}$ and finite set $U$, there is a $d$-detecting family $\mathcal{F}$ on $U$ of size $\frac{2|U|}{\log_d |U|} \cdot (1 + o(1))$. Moreover, $\mathcal{F}$ can be constructed in time polynomial in $|U|$.*

## 5.2 Bounded Degree Vertex Deletion

Let $\phi$ be an instance of (3,4)-XSAT of $n$ variables. Assume without loss of generality that $n$ is a power of 4 (this can be achieved by adding dummy variables to the instance if needed). Making use of Lemma 13, one can obtain in time $n^{\mathcal{O}(1)}$ the following:

- a partition of $\phi$'s variables into subsets $V_1, \ldots, V_{n_V}$, where $|V_i| \leq \log n$ and $n_V = \mathcal{O}(n/\log n)$,
- a partition of $\phi$'s clauses into subsets $C_1, \ldots, C_{n_C}$, where $|C_i| \leq \sqrt{n}$ and $n_C = \mathcal{O}(\sqrt{n})$,

where any two variables occurring in clauses of the same clause subset belong to different variable subsets. For $i \in [n_C]$, let $\{C_{i,1}, \ldots, C_{i,n^i_{\mathcal{F}}}\}$ be a 4-detecting family of subsets of $C_i$ for some $n^i_{\mathcal{F}} = \mathcal{O}(\sqrt{n}/\log n)$, produced in time $n^{\mathcal{O}(1)}$ due to Theorem 15. Moreover, let $n_{\mathcal{F}} = \max_{i=1}^{n_C} n^i_{\mathcal{F}}$. Define $\Delta = n^3$ and $k = n_V$. We will construct a graph $G = (V, E)$ such that there exists $S \subseteq V(G)$ of size $|S| \leq k$ and $G - S$ has maximum degree at most $\Delta$ if and only if there exists an assignment such that every clause of $\phi$ has exactly one True literal.

**Choice Gadget.** For each variable subset $V_i$, we define the choice gadget graph $G_i$ as follows:
- introduce vertices $\kappa_i$, $\lambda_i$ and $v_i^j$, where $j \in [n]$,
- add edges $\{\kappa_i, v_i^j\}$ and $\{\lambda_i, v_i^j\}$, for all $j \in [n]$,
- attach sufficiently many leaves to $\kappa_i$ and $\lambda_i$ such that their degree is $\Delta + 1$.

Let $\mathcal{V}_i = \{v_i^j \mid j \in [n]\}$, for $i = 1, \ldots, n_V$. We fix an arbitrary one-to-one mapping so that every vertex of $\mathcal{V}_i$ corresponds to a different assignment for the variables of $V_i$. Since $2^{|V_i|} \leq n$, there are sufficiently many vertices to uniquely encode all the different assignments of $V_i$. Let $\mathcal{V} = \mathcal{V}_1 \cup \ldots \cup \mathcal{V}_{n_V}$ denote the set of all such vertices.

**Clause Gadget.** For $i \in [n_C]$, let $C_i$ be a clause subset and $\{C_{i,1}, \ldots, C_{i,n_{\mathcal{F}}^i}\}$ its 4-detecting family. For every subset $C_{i,j}$ of the 4-detecting family, introduce vertices $c_{i,j}$ and $c'_{i,j}$. Add an edge between $c_{i,j}$ and $v_p^q$ if there exists variable $x \in V_p$ such that $x$ occurs in some clause $c \in C_{i,j}$, and $v_p^q$ corresponds to an assignment of $V_p$ that satisfies $c$. Due to Lemma 13, $c_{i,j}$ has exactly $|C_{i,j}| \cdot \frac{3n}{2}$ such edges: there are exactly $3|C_{i,j}|$ different variables appearing in clauses of $C_{i,j}$, each belonging to a different variable subset, and for each such variable, half the assignments of the corresponding variable subset result in the satisfaction of the corresponding clause of $C_{i,j}$. Attach to $c_{i,j}$ a sufficient number of leaves such that its total degree is $\Delta + |C_{i,j}|$. Moreover, for $v \in \mathcal{V}$, let $v \in N(c'_{i,j})$ if $v \notin N(c_{i,j})$. Notice that then, it holds that $N(c_{i,j}) \cup N(c'_{i,j}) \supseteq \mathcal{V}$, while $N(c_{i,j}) \cap N(c'_{i,j}) = \emptyset$. Lastly, attach to $c'_{i,j}$ a sufficient number of leaves such that its total degree is $\Delta + (k - |C_{i,j}|)$.

Let $\mathcal{I} = (G, \Delta, k)$ be an instance of Bounded Degree Vertex Deletion.

▶ **Lemma 16.** ($\star$) *It holds that* $\mathrm{vc}(G) = \mathcal{O}(n/\log n)$.

▶ **Lemma 17.** ($\star$) *If $\phi$ is a Yes instance of (3,4)-XSAT, then $\mathcal{I}$ is a Yes instance of Bounded Degree Vertex Deletion.*

▶ **Lemma 18.** ($\star$) *If $\mathcal{I}$ is a Yes instance of Bounded Degree Vertex Deletion, then $\phi$ is a Yes instance of (3,4)-XSAT.*

We can now prove the main theorem of this section.

▶ **Theorem 19.** ($\star$) *There is no* $\mathrm{vc}^{o(\mathrm{vc})} n^{\mathcal{O}(1)}$ *time algorithm for Bounded Degree Vertex Deletion, where* vc *denotes the size of the minimum vertex cover of the input graph, unless the ETH fails.*

## 6 Conclusion

In this work, we have examined in depth the complexity of Bounded Degree Vertex Deletion and Defective Coloring under the perspective of parameterized complexity. In particular, we have precisely determined the complexity of both problems parameterized by some of the most commonly used structural parameters. As a direction for future research, we consider the question of whether we could obtain a $n^{o(\mathrm{fvs})}$ lower bound for Bounded Degree Vertex Deletion as well as for Defective Coloring when $\chi_d = 2$, where fvs denotes the size of the minimum feedback vertex set of the input graph.

## Abstract

Learning the community structure of a large-scale graph is a fundamental problem in machine learning, computer science and statistics. Among others, the Stochastic Block Model (SBM) serves a canonical model for community detection and clustering, and the Massively Parallel Computation (MPC) model is a mathematical abstraction of real-world parallel computing systems, which provides a powerful computational framework for handling large-scale datasets. We study the problem of exactly recovering the communities in a graph generated from the SBM in the MPC model. Specifically, given $kn$ vertices that are partitioned into $k$ equal-sized clusters (i.e., each has size $n$), a graph on these $kn$ vertices is randomly generated such that each pair of vertices is connected with probability $p$ if they are in the same cluster and with probability $q$ if not, where $p > q > 0$.

We give MPC algorithms for the SBM in the (very general) *s-space MPC model*, where each machine is guaranteed to have memory $s = \Omega(\log n)$. Under the condition that[1] $\frac{p-q}{\sqrt{p}} \geq \tilde{\Omega}(k^{\frac{1}{2}} n^{-\frac{1}{2}+\frac{1}{2(r-1)}})$ for any integer $r \in [3, O(\log n)]$, our first algorithm exactly recovers all the $k$ clusters in $O(kr \log_s n)$ rounds using $\tilde{O}(m)$ total space, or in $O(r \log_s n)$ rounds using $\tilde{O}(km)$ total space. If $\frac{p-q}{\sqrt{p}} \geq \tilde{\Omega}(k^{\frac{3}{4}} n^{-\frac{1}{4}})$, our second algorithm achieves $O(\log_s n)$ rounds and $\tilde{O}(m)$ total space complexity. Both algorithms significantly improve upon a recent result of Cohen-Addad et al. [PODC'22], who gave algorithms that only work in the *sublinear space MPC model*, where each machine has local memory $s = O(n^\delta)$ for some constant $\delta > 0$, with a much stronger condition on $p, q, k$. Our algorithms are based on collecting the $r$-step neighborhood of each vertex and comparing the difference of some statistical information generated from the local neighborhoods for each pair of vertices. To implement the clustering algorithms in parallel, we present efficient approaches for implementing some basic graph operations in the $s$-space MPC model.

# 1 Introduction

Graph clustering is a fundamental task in machine learning, computer science and statistics. In this task, given a graph that may represent a social/information/biological network, the goal is to partition its vertex set into a few maximal subsets (called *clusters* or *communities*) of similar vertices. Depending on the context, a cluster may correspond to a social group of people with the same hobbies, a group of web-pages with similar contents or a set of proteins that interact very frequently. Intuitively, in a good clustering of a graph, there are few edges between different clusters while there are relatively many edges inside each cluster. There is no unified formalization on the notions of graph clustering and clusters. Here we focus on a natural and widely-used model for graph clustering, the *stochastic block model (SBM)*. In the SBM, we are given a set $V$ of $N = kn$ vertices such that there is a hidden partition of $V$ with $V = \bigcup_{i=1}^{k} V_i$, $V_i \cap V_j = \emptyset$ for any $1 \leq i < j \leq k$, where each set $V_i$ is called a *cluster* (or *community*). For simplicity, we assume that each cluster has an equal size, i.e., $|V_i| = n$. We say a graph $G = (V, E)$ is generated from the SBM with parameters $n, p, q, k$, abbreviated as $\mathrm{SBM}(n, p, q, k)$, if for any two vertices $u, v$ that belong to the same cluster, the edge $(u, v)$ appears in $G$ with probability $p$; for any two vertices $u, v$ that belong to two different clusters, the edge $(u, v)$ appears with probability $q$, where $0 < q < p < 1$.

Thanks to its simplicity and its ability in explaining the community structures in real world data, the SBM has been extensively studied in the computer science literature. Most previous work has been focusing on algorithms that work on a single machine, with the goal of extracting the communities with the optimal (computational and/or statistical) trade-offs between parameters $n, p, q, k$, for different types of recoveries (i.e., exact, weak, and partial recovery). Significant progress has been made on such algorithms (and their limitations) in the past decades (see the survey [1]). However, most of these algorithms are essentially sequential and cannot be adapted to the parallel or distributed environment, which is unsatisfactory as modern graphs are becoming massive and most of them cannot be fitted into the main memory of a single machine.

We study the problem of exactly recovering communities of a graph from the SBM in the massively parallel computation (MPC) model [24, 22, 5], which is a mathematical abstraction of modern frameworks of real-world parallel computing systems like MapReduce [19], Hadoop [28], Spark [29] and Dryad [23]. In this model, there are $M$ machines that communicate in synchronous rounds, where the local memory of each machine is limited to $s$ words, each of $O(\log n)$ bits. A word is enough to store a node or a machine identifier from a polynomial (in $n$) domain. Communication is the largest bottleneck in the MPC model. Take the graph problem as an example. The edges of the input graph are arbitrarily distributed across the $M$ machines initially. Ideally, we would like to use minimal number of rounds of computation while using small (say sublinear) space per machine and small total space (i.e., the sum of space used by all machines).

Recently, Cohen-Addad et al. [16] gave two algorithms Majority and Louvain that recover the communities in a graph generated from $\mathrm{SBM}(n, p, q, k)$ when $\frac{p-q}{\sqrt{p}} \geq \Omega(n^{-\frac{1}{4}+\varepsilon})$ and $k$ is constant. They work in $O(\frac{1}{\varepsilon \cdot \delta})$ rounds in the *sublinear space* MPC model, i.e., each machine has local memory $s = O(n^{\delta})$, for any constant $\delta > 0$. Their algorithms and analysis improve upon previous sequential versions of Majority and Louvain given by Cohen-Addad et al [12]. Note that for any sequential algorithm, it is known that $\frac{p-q}{\sqrt{p}} = \Omega(\sqrt{\frac{\log n}{n}})$ is necessary for exact recovery even for $k = 2$ [2]; there exist spectral algorithms and SDP-based algorithms that find all clusters and achieve this parameter threshold [1]. Therefore, it is natural to ask *if one can obtain a round-efficient MPC algorithm in the sublinear space model with roughly the same parameter threshold.*

In this paper, we consider a more general setting that we call *the s-space MPC model* in which the local memory $s$ is only guaranteed to satisfy that $s = \Omega(\log n)$. Nowadays, the growth rate of data volume far exceeds the growth rate of machine hardware storage and it is likely that we need much more machines to analyze large-scale data. Furthermore, the problem of clustering of data points from some metric space on such a model has recently received increasing interest [8, 20, 4, 14, 17, 18] (see also Section 1.3), partly due to the fact that in some scenarios, the number of clusters $k$ is too large such that even just storing $k$ representatives of all the clusters is not possible in a single machine. Note that this model is more difficult to handle than the sublinear space model, and we need to carefully partition the data across machines so that different machines work in different "regions of space" to get a good tradeoff between communication and the used space. Here, we are interested in the question *whether we can obtain an SBM clustering algorithm in the s-space MPC model with good tradeoffs between communication, space and SBM parameters.*

## 1.1 Our Results

We give clustering algorithms for the SBM that work in the $s$-space MPC model where the local memory $s$ of each machine is only guaranteed to satisfy that $s = \Omega(\log n)$. Let $m = \Theta(kn^2p + k^2n^2q)$ denote the total number of edges of the graph (our conditions always imply that $p \geq \Omega(\frac{\log n}{n})$ and $k \leq n$). We use "with high probability" to denote "with probability at least $1 - O(n^{-1})$".

Our first algorithm has the following performance guarantee.

▶ **Theorem 1.** *Let $r$ be any integer such that $3 \leq r \leq O(\log n)$. Let $p, q \leq 0.75$ be parameters such that $\max\{p(1-p), q(1-q)\} \geq C_0 \log n/n$ where $C_0 > 0$ is some constant. Suppose that $\frac{p-q}{\sqrt{p}} \geq \Omega\left(k^{\frac{1}{2}} n^{-\frac{1}{2}+\frac{1}{2(r-1)}} \log^7(kn)\right)$. Let $G$ be a random graph generated from SBM$(n, p, q, k)$. Then there exists an algorithm in the s-space MPC model that outputs $k$ clusters in $O(kr \log_s n)$ rounds with high probability where each machine has $s = \Omega(\log n)$ memory. The total space used by the algorithm is $\tilde{O}(m)$.*

We note that the round complexity can be improved to be $O(r \log_s n)$ at the cost of increasing the total space by a $k$ factor, which is formalized in the following theorem.

▶ **Theorem 2.** *Under the same condition in Theorem 1, there exists an algorithm that outputs $k$ clusters in $O(r \log_s n)$ rounds where each machine has $s = \Omega(\log n)$ memory with high probability and uses $\tilde{O}(km)$ total space.*

Note that for any integer constant $3 \leq r \leq o(\log n)$ and any $k \leq \text{poly}(\log n)$, the round complexity of the above algorithm is $O(\log_s n)$ while the total space is $\tilde{O}(m)$. When $r = \Theta(\log n)$, then the recovery condition becomes $\frac{p-q}{\sqrt{p}} \geq \tilde{\Omega}(\sqrt{\frac{k}{n}})$, which almost matches the statistical limit in the sequential setting up to logarithmic terms [2]. In this case, our algorithm has round complexity $O(\log n \log_s n)$ for any $k \leq \text{poly}(\log n)$ in the $s$-space MPC model.

When the gap between $p, q$ is sufficiently large, we can achieve $O(\log_s n)$ rounds using $\tilde{O}(m)$ total space, i.e., both the round complexity and the total space complexity are independent of the number $k$ of clusters. Formally, we have the following theorem.

▶ **Theorem 3.** *Given a random graph $G$ from SBM$(n, p, q, k)$ with $\frac{p-q}{\sqrt{p}} \geq \Omega\left(k^{\frac{3}{4}} n^{-\frac{1}{4}} (\log n)^{\frac{1}{4}}\right)$, there exists an algorithm in the s-space MPC model that can output $k$ hidden clusters within $O(\log_s n)$ rounds with high probability, where $s = \Omega(\log n)$, and uses $\tilde{O}(m)$ total space.*

We note that all the algorithms in Theorem 1, 2 and 3 significantly improve the results of [16], of which the algorithms only work in the sublinear space MPC model, i.e., $s = O(n^{\delta})$ for some constant $\delta > 0$, and finish in $O(\frac{1}{\delta\varepsilon})$ rounds, assuming that $\frac{p-q}{\sqrt{p}} \geq n^{-1/4+\varepsilon}$ and $k$ is a constant. In both sublinear space and $s$-space models, our algorithms work for a much wider class of SBM graphs (i.e., the requirement on the conditions of $p, q, k$ are much weaker) than those in [16]. Furthermore, even for the same regime of parameters, our algorithms have better round complexity. For example, in the sublinear space MPC model, our round complexity (from Theorem 3) is $O(1/\delta)$ under the condition that $\frac{p-q}{\sqrt{p}} \geq \Omega(n^{-\frac{1}{4}}(\log n)^{\frac{1}{4}})$ and $k$ is constant, while the algorithms in [16] have round complexity $O(\frac{\log n}{\delta \log\log n})$ under the same condition[2].

Our algorithms are quite different from those in [16], in which the algorithms are based on the local-search methods and proceed in rounds by updating the so-called *swap values* for each node to decide where to move the node. Our algorithms are based on collecting the $r$-step neighborhood of each vertex and comparing the difference of some statistical information generated from the local neighborhoods for each pair of vertices.

To implement the above MPC algorithms, we give new algorithms of some basic graphs operations in the $s$-space MPC model in Section 3, including **RandomSet** (for randomly sampling a set), **ReorganizeNBR** that is for organizing the neighborhood of any two nodes $u, v$ in a set so that they are "aligned", i.e., the $i$-th byte of $u$ (or $v$) indicates whether the $i$-th node is the neighbor of $u$ (or $v$ ). We believe these results will be useful as basic tools in designing algorithms for other problems in the $s$-space MPC model.

## 1.2 Our Techniques

Our MPC algorithms are based on two simple sequential algorithms. We first describe our first algorithm given in Theorem 3. It is based on the observation that if $\frac{p-q}{\sqrt{p}} \geq \tilde{\Omega}(k^{\frac{3}{4}} n^{-\frac{1}{4}})$, then the number of common neighbors of any two vertices can be used to distinguish if they belong to the same cluster or not. That is, if $u, v$ belong to the same cluster, then the number of their common neighbors is above some threshold $\Delta$; otherwise, the number of common neighbors is smaller than $\Delta$. Let $N(v)$ denote the set of all the neighbors of $v$. We further note that to get $k$ clusters of $V$, it is not necessary to compute $|N(u) \cap N(v)|$ for *all pairs* of $u, v$ in $V$, which may cause too much communication for MPC implementation. Instead, we first randomly sample a small set $S'$ with $|S'| = \Theta(k \log n)$. Then we find $k$ representatives of the hidden clusters from $S'$ by computing $|N(u) \cap N(v)|$ for all pairs of $u, v$ in $S'$ and update $S'$ to be the set of $k$ representatives. Then we sample independently another small set $S$ of vertices, and find $k$ sub-clusters from $S$ by computing $|N(u) \cap N(v)|$ for $u \in S$ and $v \in S'$. (A set $T \subseteq S$ is called a *sub-cluster* of some cluster $V_i$ if $T \subseteq V_i$.) Based on the $k$ sub-clusters obtained from $S$, we can find all the hidden clusters $V_1, \ldots, V_k$ putting any vertex $v \in V \setminus S$ to the sub-cluster that contains the most number of neighbors of $v$.

There are several challenges to implementing the above algorithm in the $s$-space MPC model in which the local memory only satisfies that $s = \Omega(\log n)$. Note that in this model, even just to compute the number of common neighbors $|N(u) \cap N(v)|$ for any *fixed pair* $u, v$ in a few parallel rounds (say $O(\log_s n)$ rounds) is non-trivial. The reason is that the neighborhoods $N(u), N(v)$ can be much larger than $s$ and some neighborhoods will be used too many times which leads to large round complexity. To efficiently compute $|N(u) \cap N(v)|$ for $u \in S$ and $v \in S'$, we first show how to reorganize $N(u)$ and $N(v)$ for $u \in S$ and $v \in S'$

[2] This can be seen by setting $\frac{1}{\varepsilon} = \Theta(\frac{\log n}{\log\log n})$ in [16].

so that each byte of $N(u)$ and $N(v)$ for any two nodes aligned; then we can show how to compute $|N(u) \cap N(v)|$ in parallel efficiently by appropriately making some copies of $N(u)$ and $N(v)$. For these tasks, we give detailed MPC implementations of some basic operations, e.g., a procedure for copying neighbors of some carefully chosen nodes and aligning their neighbors while using no more than $\tilde{O}(m)$ total space.

Our MPC algorithms from Theorem 1 and 2 are based on a recent sequential algorithm given in [25]. Roughly speaking, one can use the power iterations of some matrix $B = A - q \cdot J$ to find the corresponding clusters, where $A$ is the adjacency matrix of the graph and $J$ is the all-1 matrix. It is shown that with high probability, the $\ell_2$-norm of $B_u^r - B_v^r$ is relatively small, if $u, v$ belong to the same cluster; and is large, otherwise. Here $B_u^r$ is the row corresponding to vertex $u$ in the matrix $B^r$. We show that in order to compute $\|B_u^r - B_v^r\|_2$, it suffices to compute the expressions $\mathbf{1}_x^T (A - qJ)^{2r} \mathbf{1}_y$ for all $x, y \in \{u, v\}$. To do so, we expand the above expression so that we get a sum of terms, each being a vector-matrix-vector multiplication. Then we give a combinatorial explanation of each term, and then calculate it in parallel efficiently based on some basic graph operations in the $s$-space model.

## 1.3 Related Work

There is a line of research on metric clustering in the MPC model. In this setting, the input is a set of data points from some metric space (e.g., Euclidean space), and the goal is to find $k$ representative centers, such that some objective function (e.g. the cost functions of $k$-means, $k$-median and $k$-center) is minimized (e.g., [8]). Bhaskara and Wijewardena [8] developed an algorithm that outputs $O(k \log k \log n)$ centers whose cost is within a factor of $O((\log n \log\log n)^2)$ of the optimal $k$-means (or $k$-median) clustering, using a memory of $s \in \Omega(d \log n)$ per machine and $O(\log_s n)$ parallel rounds. Note that this does not require $\Omega(k)$ memory per machine. Coy et al. [18] recently improved the approximation ratio of the algorithm for $k$-center in [8] to $O(\log^* n)$. Cohen-Addad et al. [17] gave a fully scalable $(1+\varepsilon)$-approximate $k$-means clustering algorithm when the instance exhibits a "ground-truth" clustering structure, captured by a notion of "$O(\alpha)$-perturbation resilient", and it uses $O(1)$ rounds and $O_{\varepsilon,d}(n^{1+1/\alpha^2+o(1)})$ total space with arbitrary memory per machine, where each data point is from $\mathbb{R}^d$.

Regarding the power method for SBM, Wang et al. [27] proposed an iterative algorithm that first employs the power method with a random starting point and then turns to a generalized power method that can find the communities in a finite number of iterations. Their algorithm runs in nearly linear time and can exactly recover the underlying communities at the information-theoretic limit. Cohen-Addad et al. [15] further gave a linear-time algorithm that recovers exactly the communities at the asymptotic information-theoretic threshold. Their algorithm is based on similar ideas as in [16], that is, given a partition, moving a vertex from one part to the part where it has most neighbors should somewhat improve the quality of the partition.

Correlation clustering has been studied under the MPC model. In this problem, a signed graph $G = (V, E, \sigma)$ is given as input, and the goal is to partition the vertex set into arbitrarily many clusters so that the disagreement of the corresponding clustering is minimized, where the disagreement is the number of edges that cross different clusters plus the number of non-adjacent pairs inside the clusters [9, 11, 26, 21, 10, 13, 3]. The state-of-the-art is a $(3+\varepsilon)$-approximation algorithm in $O(1/\varepsilon)$ rounds in the massively parallel computation (MPC) with sublinear space [7].

## 2 Preliminaries

Consider an undirected graph $G = (V, E)$ where $V$ is the set of vertices, and $E$ is the set of edges. We use $n$ to denote the size of $|V|$ and $m$ to denote the size of $|E|$. Each node in $G$ has a unique ID from 1 to $n$. We use $\mathsf{ID}(u)$ to denote the ID for a node $u \in V$. We use $d(u)$ to denote the degree of $u \in V$. Let $N(u)$ denote the set of neighbors of a node $u \in V$. Given a vertex set $S \subset V$, we use $G[S]$ to denote the subgraph induced by vertices in $S$. In this paper, we abuse the use of node(s) and vertex(vertices). We use $[i]$ to denote $\{1, 2, \cdots i\}$. When nodes are active (inactive), they execute (do not execute) algorithms.

### Chernoff Bound

Let $X_1, ..., X_n$ be independent binary random variables, and $X = \Sigma_{i=1}^{n} X_i$, and $\mu = \mathbb{E}[X]$. Then it holds that for all $\delta > 0$ that $\mathbb{P}[X \geq (1+\delta)\mu] \leq (\frac{e^{-\delta}}{(1+\delta)^{1+\delta}})^{\mu} \leq e^{-\min[\delta^2, \delta]\mu/3}$; For all $\delta \in (0, 1)$, $\mathbb{P}[X \leq (1-\delta)\mu] \leq (\frac{e^{\delta}}{(1-\delta)^{1-\delta}})^{\mu} \leq e^{-\delta^2\mu/2}$.

### The MPC model

In this model, we assume that all data is arbitrarily distributed among some machines. Let $N$ denote the total amount of data. Each machine has local memory $s$. In our settings, $s = \Omega(\log n)$. The sum of all local memory is $N = O((m+n)\text{poly}(\log n))$. The communication between any pair of two machines is synchronous, and the bandwidth is $s$ words.

We ignore the cost of local communication and computation happening in each machine. As the description of the MPC model in the literature, we ignore some communication details among different machines and suppose that all machines are known to each other which means that any machine can send messages to another machine directly (even when the local memory is very small). For the problems in the MPC model, we aim to make the total number of communication rounds among machines as small as possible.

▶ **Definition 4** (separable function). *Let $f : 2^{\mathbb{R}} \to \mathbb{R}$ denote a set function. We say that $f$ is separable if and only if for any set of reals $A$ and for any $B \subseteq A$, we have $f(A) = f(f(B), f(A \setminus B))$* [3].

▶ **Lemma 5** ([6]). *Given an $n$-vertex graph, we have $x_u$ for each node $u \in V$. If the function $f$ is a separable function, then there exists an algorithm that computes $f(\{x_i \in N(u)\})$ for each $u \in V$ with high probability in the sublinear space MPC model in $O(1/\delta)$ rounds using $\tilde{O}(m)$ space where each machine has space $O(n^{\delta})$.*

In the $s$-space MPC model, we restate the following folklore lemma.

▶ **Lemma 6.** *Given an $n$-vertex graph, there exists an algorithm that makes each node $u \in V$ visit $N(u)$ in $O(\log_s n)$ rounds with high probability.*

The sorting algorithm is a very important black-box tool in the MPC model, which is stated as follows.

▶ **Theorem 7** ([22]). *Sorting can be solved in $O(\log_s n)$ rounds in the $s$-space MPC model.*

[3] For example, $f$ can be a sum function.

Furthermore, it has been shown that indexing and prefix-sum operation can be performed in $O(\log_s n)$ rounds [22]. We refer to the INDEX Algorithm for solving indexing problems in the $s$-space MPC model and the SORTING Algorithm for solving sorting problems in the same model. Throughout the context, we will rely on the fundamental properties associated with the aforementioned operations, as well as Lemma 5 and Lemma 6 by default.

## 3 Implementing Basic Graph Operations in the $s$-space MPC Model

In this section, we present algorithms for several fundamental graph operations in the $s$-space model, which will be utilized in our MPC algorithms. To the best of our knowledge, most of these operations have not been previously implemented in the $s$-space MPC model. We denote the machines holding node $x$ as $M_x$. (It is important to note that the MPC model follows an edge-partition model, which means that multiple machines may hold the same vertices). It is worth mentioning that in order to implement some of our proposed algorithms, we utilize previous algorithms for basic MPC operations, as demonstrated in the full version.

### RandomSet

In the RandomSet problem, given an input value $X = \Omega(\log n)$, our goal is to output a random set $S = \{x_1, x_2, \ldots, x_{|S|}\}$ where each element $x_i$ ($i \in [|S|]$) is selected uniformly and independently at random and $S' = \{(x, y)|x \in S \cap M_x, y = \mathrm{Ind}_S(x)\}$ where $|S| = \Theta(X)$, and $\mathrm{Ind}_S(x)$ is the index of of $x \in S$ in $S$. We use the algorithm RANDOMSET to solve the RandomSet problem.

▶ **Lemma 8.** *The RandomSet problem can be solved in the $s$-space MPC model in $O(\log_s n)$ rounds where $s = \Omega(\log n)$.*

### ReorganizeNBR

The ReorganizeNBR problem involves an input set $S$, where the objective is to reorganize $N(u)$ for all $u \in S$ in a manner that *aligns* the bytes of $N(u)$ and $N(v)$ for any two nodes $u, v \in S$. Specifically, the $i$-th byte of $N(u)$ indicates whether the $i$-th node is a neighbor of $u$. The motivation behind the ReorganizeNBR problem is to efficiently compute $|N(u) \cap N(v)|$ for any pair of nodes $u$ and $v$ in $S$ (refer to Figure 1 for illustration). We utilize the REORGANIZENBR algorithm to address this problem.

Now, we show how to reorganize a graph in MPC model where each machine has memory $s = \Omega(\log n)$. We say a subgraph $H$ is a randomly sampled subgraph if nodes in $V_H$ are randomly sampled, and $H$ is the set of edges and vertices constructed from picking $V_H$ with their incident edges. We use $H = (V_H, E_H)$ to denote such a random sampled graph.

▶ **Lemma 9.** *Given a graph $G = (V, E)$ with $m = \Theta(n^{c+1})$, where $m$ is the number of edges and $n$ is the number of vertices, and $c \in (0, 1]$ is some positive constant, for a given randomly sampled subgraph $H = (V_H, E_H)$ satisfying $|V_H| \leq \tilde{O}(m/n)$ where $V_H$ is constructed by RANDOMSET, there exists an algorithm that can reorganize $N(u)$ for each $u \in V_H$ in constant rounds, with total space complexity $\tilde{O}(m)$ in the MPC model where each machine has a memory of $s = \Omega(\log n)$.*

### CopyNBR($\mathcal{S}, t$)

Suppose we have $\mathcal{S} = \{N(v_1), \ldots, N(v_x)\}$ stored in machines where $v_i \in S$, $i \in [x]$ and $S$ is a random set created by RANDOMSET. We will create $N(v_i)_1, \ldots, N(v_i)_t$ for each $N(v_i)$ where $i \in [x]$. The goal is to make $t$ copies of $N(u)$ for each $u \in S$ such that we can execute

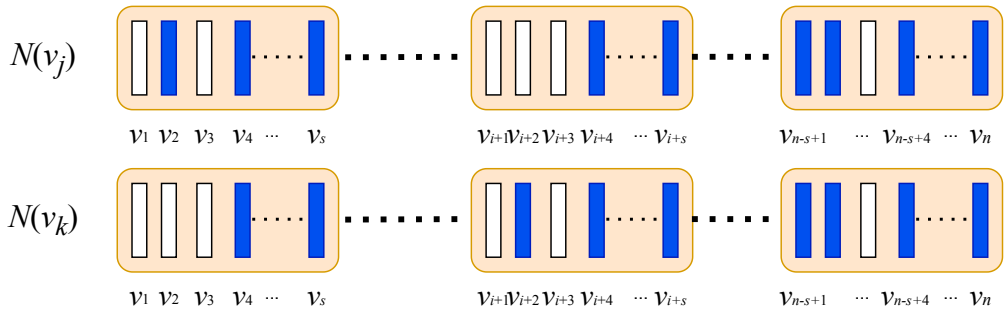

**Figure 1** Align Operation. The first row represents $N(v_j)$, the blue rectangle (treated as "1") indicates that the corresponding vertex $v_i \in N(v_j)$, and the white rectangle (treated as "0") indicates that the vertex $v_i \notin N(v_j)$. Once $N(v_j)$ and $N(v_k)$ are encoded as such bit strings, we can compare the strings simultaneously to compute their common neighbors.

other algorithms in parallel. In our setup, each $N(u)$ where $u \in S$ is organized in a collection of consecutive machines. To solve this problem, we employ the CopyNBR$(\mathcal{S}, t)$ algorithm. Upon executing CopyNBR$(\mathcal{S}, t)$, all $t$ copies of $\mathcal{S}$ are stored in consecutive machines.

▶ **Lemma 10.** *The CopyNBR$(\mathcal{S}, t)$ problem can be solved in $O(\log_s n)$ rounds in the $s$-space MPC model where $s = \Omega(\log n)$ and $t$ is a parameter satisying $n|S|t \leq \tilde{O}(m)$.*

### EvenCluster

Consider a set $S$ comprising nodes labeled from 1 to $k$. The objective is to ensure that the number of nodes with labels in $S$ is even. To achieve this, we employ the EvenCluster algorithm, designed specifically to solve this problem.

▶ **Lemma 11.** *In the MPC model with each machine's memory $s = \Omega(\log n)$, there exists an algorithm that can output $S' \subseteq S$ within $O(\log_s n)$ rounds, such that each label in $S'$ is associated with the same number of nodes with that label.*

### RepresentativeK($S$)

In the RepresentativeK$(S)$ problem, the input is a set $S = S_1 \cup \cdots \cup S_k$ of nodes with $|S|$ labels (each node in $S_i$ has $|S_i|$ labels) where $S_i \cap S_j = \emptyset$ for any $i \neq j$ and $|S_i| = \Theta(|S|/k) \geq \Omega(\log n)$. Our goal is to output $k$ nodes with $k$ representative labels. We use RepresentativeK$(S)$ to solve this problem.

▶ **Lemma 12.** *The RepresentativeK$(S)$ problem can be solved in $O(\log_s n)$ rounds where $S$ is created by RandomSet and $|S| \geq \Omega(k \log n)$ in the $s$-space MPC model ($s = \Omega(\log n)$).*

### CompareCut($S, V$)

In the CompareCut$(S, V)$ problem, the input is a set $S$ of $k$ sets, i.e., $\{S_1, S_2, \ldots, S_k\}$ and the vertex set $V$, the goal is to output the largest one among numbers $n(u, S_i)$ of edges between $u \in V$ and $S_i$ for each $S_i$, along with the label of $u$ (i.e., the label of the $S_i$), where $i \in [k]$. We use ComputeCut(S,V) to solve this problem.

▶ **Lemma 13.** *Given a graph $G = (V, E)$, let $S \subset V$ be a random set of nodes created by RandomSet. The CompareCut$(S, V)$ problem can be solved in $O(\log_s n)$ rounds in the $s$-space MPC model ($s = \Omega(\log n)$).*

# 4 The Algorithm Based on Neighbor Counting

Recall that a graph $G = (V, E)$ is generated from the SBM$(n, p, q, k)$ if there is a hidden partition $V = \cup_{i=1}^{k} V_k$ of the $nk$-vertex set $V$, and for any two vertices $u, v$ that belong to the same cluster, the edge $(u, v)$ appears in $E$ with probability $p$; for any two vertices $u, v$ that belong to two different clusters, the edge $(u, v)$ appears in $E$ with probability $q$, where $0 < q < p < 1$. In this section, we give the algorithm underlying Theorem 3.

We first give a simple sequential algorithm based on comparing common neighbors. Then we show how to implement it in the $s$-space model. To do so, we give implementations of a number of basic graph operations in the $s$-space model, which is deferred to Section 3.

## 4.1 A Sequential Algorithm Based on Counting Common Neighbors

▶ **Theorem 14.** *If* $\frac{p-q}{\sqrt{p}} \geq \Omega(\frac{(k+1)^{1/2}}{n^{1/4}})$*, the algorithm* CommNBR *can output* $k$ *clusters in* $O(\frac{k^2 n \log n}{p})$ *time with probability* $1 - O(\frac{1}{n})$.

In our sequential algorithm CommNBR, we first randomly sample a set $S$ of $\frac{21nk^2 \log n}{d}$ nodes from $V$ such that each cluster has more than $\Theta(\log n)$ nodes with high probability where $d$ is the number of neighbors of an arbitrary node $u \in V$. Then, for each pair $u, v$, we count the number of their common neighbors in $G$, i.e., those vertices that are connected to both $u$ and $v$. If the number of common neighbors is above some threshold $\Delta$, then we put them into the same cluster. In this way, we can obtain $k$ *sub-clusters* of $S$, $C_1, \ldots, C_k$. That is, each $C_i \subseteq S$ and is a subset of some cluster, i.e., $C_i = V_{\pi(i)} \cap S$ for some permutation $\pi : \{1, \ldots, k\} \to \{1, \ldots, k\}$. Let $L(v, C_i)$ denote the number of incident edges between a node $v$ and a cluster $C_i$. We can then cluster each remaining node $v \in V \setminus S$ by finding the index $j$ such that $L(v, C_j)$ is the greatest among all numbers $L(v, C_i), 1 \leq i \leq k$.

For the intuition of the existence of such a threshold $\Delta$, let us take the case $k = 2$ as an example. In this case, for any two vertices $u, v$ belonging to the same cluster, the expected number of common neighbors is $p^2 n + q^2 n$; for any two vertices $u, v$ belonging to two different clusters, the expected number of common neighbors is $2npq$. Since $\frac{p-q}{\sqrt{p}} \geq \Omega\left(\frac{(k+1)^{1/2}}{n^{1/4}}\right)$, there exists a sufficiently large gap between these two numbers so that we can define a suitable threshold. However, the values of $p$ and $q$ are not provided. To address this issue, we propose an algorithm called ComputeDEL, which can be described as follows. We first sample a set $\mathcal{S}_\Delta$ of $\Theta(k \log n)$ nodes, and for each pair $u, v \in \mathcal{S}_\Delta$, we compute a set $\mathcal{V}_\Delta$ of values of $|N(u) \cap N(v)|$. We let $\Delta' = \max\{value \in \mathcal{V}_\Delta\}$, and then we have $\Delta = \Delta' - 9\sqrt{\Delta' \log n}$.

## 4.2 Implementation in the $s$-space MPC model

Now we describe our MPC algorithm MPC-CommNBR, which is an implementation of CommNBR, where the local memory is $s = \Omega(\log n)$, and prove Theorem 3.

Recall that in CommNBR, there are two major steps. In the first step, we need to find $k$ clusters from a set $S$ of randomly sampled nodes. In the second step, based on the clustering on $S$, we cluster all nodes in $V$. The major challenge lies in the simulation (in MPC model) of the first step which is to compare common neighbors between two nodes $u$ and $v$. It is easy to see that computing $|N(u) \cap N(v)|$ for $u, v \in V$ is exactly the task of finding common elements in two sets. For convenience, we use a set $\mathsf{S}_u$ to denote $N(u)$ for a node $u \in V$. Then, we need to find the common elements between $\mathsf{S}_u$ and $\mathsf{S}_v$ by a method $\textsc{comm}(\mathsf{S}_u, \mathsf{S}_v)$. Note that we need to execute $\textsc{comm}(\mathsf{S}_u, \mathsf{S}_v)$ for different $u$ and $v$ for many times. Therefore, to compute $|N(u) \cap N(v)|$ for different $u, v \in V$ efficiently, we need to solve two problems.

The first one is to implement $\textsc{comm}(\mathsf{S}_u, \mathsf{S}_v)$ efficiently in MPC model where each machine's memory is $s = \Omega(\log n)$. The second one is to execute the first one in parallel. For the first one, we use a simple method to implement $\textsc{comm}(\mathsf{S}_u, \mathsf{S}_v)$ in MPC model. Let $V'$ be the set of nodes in which for each $u \in V'$, $\mathsf{S}_u$ will be compared. We make each byte of $\mathsf{S}_u (u \in V')$ aligned. Then, we can directly compute $|\mathsf{S}_u \cap \mathsf{S}_v|$. For the second one, we solve it by copying sets for enough times and then we let machines storing these copied sets execute the same algorithm in parallel. We use the MPC implementations of the basic graph operations in Section 3 to implement our clustering algorithm here.

**Algorithm 1** MPC-CommNBR: An MPC algorithm based on counting common neighbors.

**Input:** A SBM graph $G$;

1: Let $d = |N(u)|$ where $u$ is an arbitrary node in $V$
2: Apply RandomSet to obtain random node set $S'$ and $S$, where $|S'| = \Theta(k \log n)$ and $|S| = (21k^2 n \log n)/d$
3: Update $S'$ and obtain $\Delta$ by ComputeREP($S'$)
4: Obtain $k$ sub-clusters $S_1, \ldots, S_k$ by ComputeSubcluster($S, S', \Delta$)
5: Obtain $k$ clusters of $V$ by ComputeCluster($S_1, \ldots, S_k, V$).

**Algorithm 2** ComputeRep: Compute representative for each cluster by common neighbors and $\Delta$.

**Input:** Random vertex set $S'$;

1: Run CompareINIT($S'$);
2: Obtain $k$ nodes with $k$ representative lables by RepresentativeK($S'$);
3: Update $S'$ by only keeping $k$ nodes obtained from Step 2.
4: **return** $S'$ and $\Delta$

For the algorithm CompareINIT($S'$), we describe it as follows.

CompareINIT($S'$):
**1)** Reorganize neighbors of nodes in $S'$ by ReorganizeNBR($S'$).
**2)** Execute CopyNBR($S'$) to create $|S'|$ copies of $N(u)$ for each $u \in S'$.
**3)** Based on copies of $N(u)$ from 2), we directly compute $|N(u) \cap N(v)|$ in parallel where $u, v \in S'$.
**4)** Execute CompareGRP to obtain final results by summing all partial results obtained from 3).
**5)** Compute $\Delta'$, i.e., the maximum value of $|N(u) \cap N(v)|$ for all pairs of $u, v \in S'$ and output $\Delta = \Delta' - 9\sqrt{\Delta' \log n}$.

In ComputeSubcluster($S', S, \Delta$), the process is similar to ComputeREP($S'$). The major difference is that we only copy $N(u)$ for each $u \in S$ for $k$ times and copy $N(v)$ for each $v \in S'$ for $|S|$ times. By computing $|N(u) \cap N(v)|$ where $u \in$ copy-$S$, $v \in$ copy-$S'$, and copy-$S$, copy-$S'$ are the copies of $S$ and $S'$, we can obtain $k$ sub-clusters of $S$. The details of computing can refer to ComputeREP($S'$).

In ComputeCluster($S_1, \ldots, S_k, V$), we first apply EvenCluster($S$) to output $k$ sub-clusters from $S$ such that each cluster has the same number of nodes. Then, we use ComputeCut($S, V$) to cluster $V$.

Next, we show the details of CompareGRP used in the procedure of ComputeREP($S'$). In the CompareGRP problem, the input is a set of groups of machines and the goal is to output the results by comparing groups of machines. Take two groups $A$, $B$ of machines as

an example. Our goal is to output the common elements by comparing $A$ and $B$. We say that group $A$ compares to group $B$ which means that the $i$-th member machine of the group $A$ will compare to the $i$-th member machine of group $B$ ($i \in [n/s]$).

▶ **Lemma 15.** *Given a set of consecutive groups each of which has $n/s$ member machines, there exists an algorithm that takes $O(\log_s n)$ rounds to obtain the results of comparing data between groups correspondingly.*

Now we are ready to prove Theorem 3.

**Proof of Theorem 3.** The correctness of obtaining $k$ clusters based on counting common neighbors can be seen in Theorem 14. By Lemma 8, we can create randomly sampled sets $S$ and $S'$ such that each machine $M$ knows indexes of nodes in $M \cap S$ and $M \cap S'$ within $O(\log_s n)$ rounds.

Next, we first prove that by ComputeREP($S'$), we can obtain $k$ sub-clusters within $O(\log_s n)$ rounds. By Lemma 9, it takes $O(\log_s n)$ rounds for ReorganizeNBR($S'$). By Lemma 10, we use $O(\log_s n)$ rounds to finish CopyNBR($S'$) for each $N(u)$ where $u \in S'$. By Lemma 15, it takes $O(\log_s n)$ to first get partial results and then obtain the complete results of $|N(u) \cap N(v)|$ where $u, v \in S'$. We can use $O(\log_s n)$ rounds to obtain $\Delta$ by simulating ComputeDEL within $O(\log_s n)$ rounds. Then by Lemma 15 and Lemma 12, we can obtain $k$ sub-clusters from $S'$ in $O(\log_s n)$ rounds in the MPC model and the total space is $\tilde{O}(m)$. Similarly, by ComputeSubcluster($S', S, \Delta$), we can prove that within $O(\log_s n)$ rounds, we can obtain $k$ clusters from $S$ in the MPC model and the total space used is $\tilde{O}(m)$.

Now, let us see the last step of obtaining $k$ clusters of $V$. By Lemma 11 and setting $|S^*| = \frac{20k^2 n \log n}{d}$, we can output $S^* \subseteq S$ such that for any two labels $i, j \in [k]$, we have $\mathsf{N}_{S^*}(i) = \mathsf{N}_{S^*}(j)$ in $O(\log_s n)$ rounds, where $\mathsf{N}_{S^*}(i)$ is the number of nodes in $S^*$ with label $i$. Finally, by Lemma 13, we can decide all labels of $V$ within $O(\log_s n)$ rounds with high probability. The total space used in MPC model is $\tilde{O}(m)$. Thus, our proof is completed. ◀

## 5 The Algorithm Based on Power Iterations

In this section, we give another MPC algorithm for a general SBM graph in the $s$-space model and prove Theorem 1. The omitted proof of this section is deferred to the full version. Also, we first carefully design a sequential algorithm and then we implement it in the $s$-space MPC model. Our second sequential algorithm is based on power iterations which perform well in a recent algorithm in [25]. The algorithm makes use of the adjacency matrix $A$ of the graph $G$, from which we define a matrix $B = A - q \cdot J$, where $J$ is the $n \times n$ all-1 matrix. Then it decides if two vertices $u, v$ are in the same cluster or not by checking the $\ell_2$-norm of the difference between $B_u^r$ and $B_v^r$, which are the rows corresponding to vertices $u, v$, respectively, in the matrix $B^r$ (the $r$-th power of matrix $B$).

We note that the algorithm in [25] only considers the special case that $r = \log n$. Here, our sequential algorithm considers all possible $r \in \{1, \ldots, O(\log n)\}$ and for each $r$ we choose a different threshold $\Delta$, which depends on the value of $p, q$ and $k$. To implement our sequential algorithm in the MPC model, we divide the process of matrix computation into different components each of which can be implemented efficiently in the $s$-space model.

### 5.1 A Sequential Algorithm Based on Power Iterations

We now describe Algorithm PowerIteration. Let $A$ be an adjacency matrix of the input graph $G$ and $r$ where $r$ is a parameter. Let $\Delta = C\sqrt{k}\sqrt{p(1-q)}(\log kn)^7(p-q)^{r-1}n^{r-1}$, where $C > 0$ is some universal constant. We set $B = A - q \cdot J$ where $J = 1^{n \times n}$. Let $W = V$.

We choose an arbitrary vertex $v$ in $W$ and put $v$ into a sub-cluster $C_i$ where $i \in [k]$. For each node $u$ in $W$, if $\|B_u^r - B_v^r\| \leq \Delta$, then we add $u$ to $C_i$. Next, we remove $C_i$ from $W$. Repeat the above process until $W$ is empty. Then we return all the clusters $C_i$'s.

▶ **Theorem 16.** *Let $p, q \leq 0.75$ be parameters such that $\max\{p(1-p), q(1-q)\} \geq C_0 \log n/n$ where $C_0 > 0$ is some constant. Suppose that $\frac{p-q}{\sqrt{p}} \geq (C_0^2+1)k^{\frac{1}{2}} n^{-\frac{1}{2}+\frac{1}{2(r-1)}} (\log kn)^7$. Let $G$ be a random graph generated from SBM$(n, p, q, k)$ and $r \in [3, O(\log n)]$, then with probability at least $1 - O(n^{-1})$ the algorithm* PowerIteration *can output $k$ hidden clusters for suitable $\Delta$ and $r$.*

## 5.2 The MPC Algorithm

In this section, we show how to implement PowerIteration in the $s$-space MPC model. The pseudocode is found in Algorithm 3. Given a matrix $A$, we use $A_i^{2r}$ to denote the $i$-th row of $A^{2r}$. We use $A_{\cdot j}^{2r}$ to denote the $j$-th column of $A^{2r}$.

**Algorithm 3** MPC-PowerIteration.

**Input:** A SBM graph $G$, $\Delta$;

Let $A$ be an adjacent matrix of $G$, $r$ be the parameter
Let $\Delta = C\sqrt{k}\sqrt{p(1-q)}(\log kn)^7(p-q)^{r-1}n^{r-1}$, where $C \in \mathbb{R}_*^+$
$B = A - q \cdot J$ where $J = 1^{n\times n}$
Let $i = 1$ and $W = V$
Initially, all nodes in $W$ are active
**while** IsActive$(W)$ is true **do**
  Choose an arbitrary vertex $v \in W$ and send it to all machines
  Label $v$ with $i$, i.e., $C_i = \{v\}$
  **for** each machine holding active vertex $u \in W$, we execute the following procedure in parallel **do**
    ComputeNorm$(B, u, v, r)$
    **if** $\|B_u^r - B_v^r\| \leq \Delta$ **then**
      Label $u$ with $i$
  Set nodes in $C_i$ inactive
  $i = i + 1$
Return all the sub-clusters $C_i$'s.

We use IsActive$(W)$ to determine whether there are active nodes in $W$ or not, which can be done in $O(\log_s n)$ rounds. The details of IsActive$(W)$ is given in the full version.

We then use another subroutine ComputeNorm$(B, i, j, r)$ to compute $\|B_i^r - B_j^r\|$. Notice that we can't directly calculate matrix multiplication, which will take lots of rounds, we notice some good properties of $\|B_i^r - B_j^r\|$ and have the following theorem.

▶ **Theorem 17.** *For a fixed $i$ and $j \in [n]$ and any integer $r < O(\log n)$, the subrountine* ComputeNorm$(B, i, j, r)$ *for computing $\|B_i^r - B_j^r\|$ can be implemented in $O(r \log_s n)$ rounds where each machine has memory $s = \Omega(\log n)$.*

Now we give the ideas of ComputeNorm$(B, i, j, r)$. We find that the expansion of $\|B_i^r - B_j^r\|$ has good properties such that we only need to compute the key terms for these $O(r^2)$ terms and the coefficients have good combinatorial explanations. Then we can use graph algorithms to calculate the results. First we note that

$$||B_i^r - B_j^r||^2 = ||(\mathbf{1}_i^T - \mathbf{1}_j^T)(A - qJ)^r||^2 = (\mathbf{1}_i^T - \mathbf{1}_j^T)(A - qJ)^{2r}(\mathbf{1}_i - \mathbf{1}_j)$$
$$= \mathbf{1}_i^T(A - qJ)^{2r}\mathbf{1}_i - \mathbf{1}_i^T(A - qJ)^{2r}\mathbf{1}_j - \mathbf{1}_j^T(A - qJ)^{2r}\mathbf{1}_i + \mathbf{1}_j^T(A - qJ)^{2r}\mathbf{1}_j,$$

so we only need to calculate $\mathbf{1}_x^T(A - qJ)^{2r}\mathbf{1}_y$ where $x, y \in \{i, j\}$.

Now we have the following lemma about the expanded formula.

▶ **Lemma 18.** *We have*

$$\mathbf{1}_x^T(A - qJ)^{2r}\mathbf{1}_y = \mathbf{1}_x^T A^{2r}\mathbf{1}_y + \sum_{0 \le i_1 \le 2r-1} \sum_{0 \le i_t \le 2r-1} X_{i_1,i_t}(A_x^{i_1})J(A_{\cdot y}^{i_t})$$

*where $X_{i_1,i_t}$ is coefficient only related to $n, q$ and $C_i$ and $C_i$ is the total number of different walks with length $i$ from $n$ vertices.*

Since $r = O(\log n)$, there are $\text{poly}(\log n)$ terms in the right hand side. So we can store all coefficients in $\tilde{O}(n)$ space. Notice that $\mathbf{1}_x^T A^{2r}\mathbf{1}_y$ for all $y \in [n]$ is the $i^{th}$ row of $A^{2r}$, i.e., $A_x^{2r}$. To compute $\mathbf{1}_x^T(A - qJ)^{2r}\mathbf{1}_y$, we split it into computing $C_i$, $A_x^{i_1}JA_{\cdot y}^{i_t}$, and $A_x^{2r}$.

### Compute $C_i$ and $A_x^{i_1}JA_{\cdot y}^{i_t}$

We show how to compute the value of any $C_i$ and $A_x^{i_1}JA_{\cdot y}^{i_t}$. Let $\vec{\mathbf{j}}$ be all ones vector, which is a column of $J$. To compute $A_x^i\vec{\mathbf{j}}$, we propose a simple algorithm, i.e., Algorithm 4 that is described as follows.

**Algorithm 4** AixSum$(G(n), r)$: Calculating $A_x^i\vec{\mathbf{j}}$ for all $x \in [n], i \in [2r]$.

**Input:** A graph $G(n)$,$r$
1: **for** each node $u$ in $G$ **do**
2: $A_{u,0} = 1$
3: let $i = 1$
4: **while** $i \le 2r$ **do**
5: **for** each node $u$ in $G$ **do**
6: $sum_u = 0$
7: **for** each neighbor $v$ of $u$ **do**
8: $sum_u += A_{v,i-1}$
9: $A_{v,i} = sum_u$
10: $i = i + 1$
11: Return $A$, $A_{x,i}$ is $A_x^i\vec{\mathbf{j}}$

▶ **Lemma 19.** *For all $x \in [n], i \in [2r]$, Algorithm 4 outputs $A_x^i\vec{\mathbf{j}}$.*

To compute $C_i$ for any $i \in [n]$, we only need to sum up $A_x^i\vec{\mathbf{j}}$ for all $x, i \in [n]$.

Now, let us see how to implement Algorithm 4 in the $s$-space MPC model. Notice that in default, we use the fact that in the $s$-space MPC model, each vertex can visit its neighbors in $O(\log_s n)$ rounds where each machine has memory of $O(n^\delta)$ by Lemma 5.

▶ **Lemma 20.** *In $s$-space MPC model, for all $i \in [2r]$ and $x \in [n]$, there exists an algorithm that can compute all $A_x^i\vec{\mathbf{j}}$ in $O(r \log_s n)$ rounds,where each machine has memory $s = \Omega(\log_s n)$.*

Notice that $A_x^{i_1}JA_{\cdot y}^{i_t} = A_x^{i_1}\vec{\mathbf{j}}(A_y^{i_t}\vec{\mathbf{j}})$, $C_i = \sum_{x\in[n]} A_x^i\vec{\mathbf{j}}$ and we have computed $A_x^i\vec{\mathbf{j}}$ for all $i \in [2r]$ and $x \in [n]$, we can obtain $A_x^{i_1}JA_{\cdot y}^{i_t}$ in constant rounds. So the main round complexity is only about the calculation of $A_x^i\vec{\mathbf{j}}$ and we have the following corollary.

▶ **Corollary 21.** *In $s$-space MPC model, there exists an algorithm that can compute $A_x^{i_1}JA_{\cdot y}^{i_t}$ and $C_i$ in $O(r \log_s n)$ rounds, where each machine has memory $s = \Omega(\log n)$.*

### Compute $A_x^{2r}$

Note that each entry $a_{x,y}^{2r}$ in $A_x^{2r}$ is exactly the number of walks with step size $r$ from $v_x$ to $v_y$. The naive algorithm of computing $A^{2r}$ is to compute the matrix, but it is resources-consuming. Another idea is to compute $a_{x,y}^{2r}$ for any $x$ and $y$, respectively. If each machine can store all vertices within radius $r$, then we can directly compute all $a_{x,y}^{2r}$ $(x, y \in [n])$. Now, we consider the $s$-space MPC model, i.e., single machines cannot store vertices within radius $r$.

▶ **Lemma 22.** *Let $a_{x,y}^{2r}$ be the number of walks from the vertex $x$ to the vertex $y$ after walks with step size $2r$. There exists a procedure* ComputeArx *that can find $a_{x,y}^{2r}$ after $O(r \log_s n)$ rounds where each machine has memory $s = \Omega(\log n)$.*

By taking the union of different vertices, we can get the following corollary.

▶ **Corollary 23.** *Let $A_i^{2r}$ be set of the numbers of walks from the vertex $i$ to the vertex $j$ where $j \in [1, n]$ after walks with step size $r$. The procedure* ComputeArx *can find $A_i^{2r}$ after $O(r \log_s n)$ rounds where each machine has memory $s = \Omega(\log n)$.*

### Compute $\|B_i^r - B_j^r\|$

After obtaining $A_x^i$ and $A_{\cdot y}^i$, the value of $A_x^i J A_{\cdot y}^i$ is the multiplication of the sums of terms in each of two vectors. And the coefficient of each term is the multiplication of $C_i$, $n$ and $q$. Now, we can prove Theorem 17.

**Proof of Theorem 17.** By Lemma 18, $\mathbf{1}_x^T (A - qJ)^{2r} \mathbf{1}_y$ which consists of at most $O(r^2)$ terms with $C_i$, $A_x^{i_1} J A_{\cdot y}^{i_t}$, and $A_x^{2r}$. Let us see the round complexity of computing it. We take the round complexity of computing one key term as an example. We only need to look at the round complexity of computing $\left(\prod_{l=2}^{t-1} C_{i_l}\right) (A_x^{i_1}) J (A_{\cdot y}^{i_t})$. By Corollary 21, we need $O(i \log_s n)$ rounds to compute any $C_i$ where $i \in [2r]$. We can finish calculating $\left(\prod_{l=2}^{t-1} C_{i_l}\right)$ in $O(r \log_s n)$ rounds. By Lemma 20, we can obtain the result of $(A_x^{i_1}) J (A_{\cdot y}^{i_t})$ within $O(r \log_s n)$ rounds. Notice that there is a special term $\mathbf{1}_x^T A^{2r} \mathbf{1}_y^T$. By Corollary 23, we can find it within $O(r \log_s n)$ rounds. There are some other similar computations, which also take $O(r \log_s n)$ rounds. Recall that there are $O(r^2)$ terms, we deal with it by copying the whole graph for poly$(\log n)$ times and then put these results together. Therefore, it takes $O(r \log_s n)$ rounds to calculate $\mathbf{1}_x^T (A - qJ)^{2r} \mathbf{1}_y$. Therefore, we need $O(r \log_s n)$ rounds to finish the calculation of $\|B_i^r - B_j^r\|$. ◀

By Theorem 17, we can finish the proof of Theorem 1.

**Proof of Theorem 1.** The main idea of MPC-PowerIteration(Algorithm 3) is to fix a node $v_i$ first and calculate $\|B_i^r - B_j^r\|$ for any other node $v_j$ in the same cluster to obtain all nodes in the same cluster. We need to store all simplified coefficients in each round which uses $O(nr^2)$ space. For other operations in the algorithms, $O(m)$ space is enough. So the total space complexity is $\tilde{O}(m + nr^2) = \tilde{O}(m)$.

In the full version, we show how to implement IsActive$(W)$ in $O(\log_s n)$ rounds. By Theorem 17, we can finish $\|B_i^r - B_j^r\|$ within $O(r \log_s n)$ rounds. Therefore, we need $O(r \log_s n)$ rounds to find a cluster and all its nodes. There are $k$ hidden clusters and we execute the above procedure sequentially, so the round complexity is $O(kr \log_s n)$. ◀

Now we show how to use more space to trade off round complexity and give the proof of Theorem 2.

**Proof of Theorem 2.** Recall that in MPC-PowerIteration(Algorithm 3), we sequentially find $k$ clusters, that is the reason why there is a factor $k$ in the round complexity. Now, we execute the process in parallel. First, we randomly sample a set $S_k$ of $\Theta(k \log n)$ nodes. With high probability, for each hidden cluster, we sample $\Theta(\log n)$ nodes in $S_k$. Then, for each node $u \in S_k$, we execute ComputeMatrix$(B, u, v, r)$ for each $v \in V$. If $\|B_u^r - B_v^r\| \leq \Delta$, we put $u$ and $v$ in the same cluster. The space for this step is $\tilde{O}(km + knr^2 \log n)$. Then, we will have $k$ clusters with $\Theta(k \log n)$ labels. We remove duplicated labels by keeping the label with the minimum value among all received labels to get one label vertex for each cluster. Then by using these $k$ label vertices, we can use $\tilde{O}(km + knr^2 \log n) = \tilde{O}(km)$ space to cluster all vertices. So, we can find all $k$ clusters in $O(r \log_s n)$ rounds with high probability. ◀

## Abstract

The paper introduces two player connectivity games played on finite bipartite graphs. Algorithms that solve these connectivity games can be used as subroutines for solving Müller games. Müller games constitute a well established class of games in model checking and verification. In connectivity games, the objective of one of the players is to visit every node of the game graph infinitely often. The first contribution of this paper is our proof that solving connectivity games can be reduced to the incremental strongly connected component maintenance (ISCCM) problem, an important problem in graph algorithms and data structures. The second contribution is that we non-trivially adapt two known algorithms for the ISCCM problem to provide two efficient algorithms that solve the connectivity games problem. Finally, based on the techniques developed, we recast Horn's polynomial time algorithm that solves explicitly given Müller games and provide the first correctness proof of the algorithm. Our algorithms are more efficient than that of Horn's algorithm. Our solution for connectivity games is used as a subroutine in the algorithm.

## 1 Introduction

### 1.1 Müller games given explicitly

In the area of logic, model checking, and verification of reactive systems, studying games played on graphs is a key research topic [10]. This is mostly motivated through modelling reactive systems and reductions of model checking problems to games on graphs. Understanding the algorithmic content of determinacy results is also at the core of this research. Müller games constitute a well-established class of games for verification. Recall that a *Müller game* $\mathcal{G}$ is a tuple $(V_0, V_1, E, \Omega)$, where

- The tuple $G = (V_0 \cup V_1, E)$ is a finite directed bipartite graph so that $V_0$ and $V_1$ partition the set $V = V_0 \cup V_1$. Usually $G$ is called the arena of $\mathcal{G}$.
- The set $E \subseteq (V_0 \times V_1) \cup (V_1 \times V_0)$ of edges.

[1] Corresponding authors.

- $V_0$ and $V_1$ are sets from which player 0 and player 1, respectively, move. Positions in $V_\sigma$ are called player $\sigma$ positions, $\sigma \in \{0,1\}$.
- $\Omega \subseteq 2^V$ is a collection of winning sets.

Say that the *game* $\mathcal{G} = (V_0, V_1, E, \Omega)$ is *explicitly given* if $V$, $E$, and all sets in $\Omega$ are fully presented as input. The (input) size of explicitly given Müller game is thus bounded by $|V| + |E| + 2^{|V|} \cdot |V|$. Finally, the *game graph* of the Müller game $\mathcal{G}$ is the underlying bipartite graph $G = (V_0 \cup V_1, E)$.

For each $v \in V$, let $E(v) = \{u \mid E(v,u)\}$ be the set of successors of $v$. Let $X \subseteq V$. Call the set $E(X) = \bigcup_{v \in X} E(v)$ the successor of $X$. Similarly, for a $v \in V$, the predecessor of $v$ is the set $E^{-1}(v) = \{u \mid (u,v) \in E\}$. Call the set $E^{-1}(X) = \bigcup_{v \in X} E^{-1}(v)$ the predecessor of $X$.

Let $\mathcal{G} = (V_0, V_1, E, \Omega)$ be a Müller game. The players play the game by moving a given token along the edges of the graph. The token is initially placed on a node $v_0 \in V$. The play proceeds in rounds. At any round of the play, if the token is placed on a player $\sigma$'s node $v$, then player $\sigma$ chooses $u \in E(v)$, moves the token to $u$ and the play continues on to the next round. Formally, a play (starting from $v_0$) is a sequence $\rho = v_0, v_1, \ldots$ such that $v_{i+1} \in E(v_i)$ for all $i \in \mathbb{N}$. If a play reaches a position $v$ such that $E(v) = \emptyset$, then player 1 wins the play. For an infinite play $\rho$, set $\mathsf{Inf}(\rho) = \{v \in V \mid \exists^\omega i (v_i = v)\}$. We say player 0 wins the play $\rho$ if $\mathsf{Inf}(\rho) \in \Omega$; otherwise, player 1 wins the play.

A strategy for player $\sigma$ is a function that takes as inputs initial segments of plays $v_0, v_1, \ldots, v_k$ where $v_k \in V_\sigma$ and output some $v_{k+1} \in E(v_k)$. A strategy for player $\sigma$ is winning from $v_0$ if, assuming player $\sigma$ follows the strategy, all plays starting from $v_0$ generated by the players are winning for player $\sigma$. The game $\mathcal{G}$ is determined if one of the players has a winning strategy. Müller games are Borel games, and hence, by the result of Martin [18], they are determined. Since Müller games are determined we can partition the set $V$ onto two sets $Win_0$ and $Win_1$, where $v \in Win_\sigma$ iff player $\sigma$ wins the game starting at $v$, $\sigma \in \{0,1\}$. To solve a given Müller game $\mathcal{G} = (V_0, V_1, E, \Omega)$ means to find the sets $Win_0$ and $Win_1$. There are several known algorithms that solve Müller games. These algorithms provide the basis for analysis and synthesis of Müller games. In particular, these algorithms extract finite state winning strategies for the players [8, 12, 13, 19, 20, 22]. Also, efficiency of algorithms depend on the underlying structure of graphs [17] [9]. We stress that the algorithms that solve Müller games depend on the presentations of the games. The problem of solving Müller games is typically in PSPACE for many reasonable representations [19, 20]. However, if the winning condition is represented as a Zielonka tree [22] or as the well-known parity condition, then solving the games turns into a $NP \cap co\text{-}NP$ problem [5]. P. Hunter and A. Dawar [13] investigate five other representations: win-set, Muller, Zielonka DAGs, Emerson-Lei, and explicit Muller. They show that the problem of the winner is PSPACE-hard for the first four representations. F. Horn [12] provides a polynomial time algorithm that solves explicit Müller games. However, his proof of correctness has non-trivial flaws. So, we provide an alternative correctness proof based on ideas totally independent of Horn's. Designing new algorithms, improving and analysing the state of the art techniques in this area is a key research direction. This paper contributes to this.

## 1.2 Connectivity games

One motivation for defining connectivity games comes from solving Müller games. Many algorithms that solve Müller games or its variants are recursive. Given a Müller game $\mathcal{G}$, one constructs a set of smaller Müller games. The solution of the games $\mathcal{G}'$ from this set is then used to solve $\mathcal{G}$. Through an iteration process, these reductions produce sequences of the

form $\mathcal{G}_1, \mathcal{G}_2, \ldots, \mathcal{G}_r$, where $\mathcal{G}_{i+1} = \mathcal{G}'_i$ such that $\mathcal{G}'_r = \mathcal{G}_{r+1}$. The key point is that solving the game $\mathcal{G}_r$ at the base of this iteration boils down to investigating connectivity of the graph $G_r$ in the game-theoretic setting. Namely, to win the game $\mathcal{G}_r$, one of the players has to visit all the nodes of $\mathcal{G}_r$ infinitely often. This observation calls for deeper and refined analysis of those Müller games $\mathcal{G} = (V_0, V_1, E, \Omega)$ where the objective of player 0 is to visit all the nodes of the underlying graph $G$, that is, $\Omega = \{V\}$. We single out these games:

▶ **Definition 1.** *A Müller game $\mathcal{G} = (V_0, V_1, E, \Omega)$ is called a* **connectivity game** *if $\Omega$ is a singleton that consists of $V$.*

The second motivation to investigate the connectivity games comes from the concept of connectivity itself. The notion of (vertex) connectivity is fundamental in graph theory and its applications. There is a large amount of work ranging from complexity theoretic issues to designing efficient data structures and algorithms that aim to analyse connectivity in graphs. Connectivity in graphs and graph like structures is well-studied in almost all areas of computer science in various settings and motivations. For undirected graphs, connectivity of a graph $G$ is defined through existence of paths between all vertices of $G$. For directed graphs $G$ connectivity is defined through strong connectivity. The digraph $G$ is strongly connected if for any two vertices $x$ and $y$ there exist paths from $x$ to $y$ and from $y$ to $x$. One can extend these notions of (vertex) connectivity into a game-theoretic setting as follows. There are two players: player 0 and player 1. A token is placed on a vertex $v_0$ of a bipartite graph $G = (V_0 \cup V_1, E)$. Player 0 starts the play by moving the token along an outgoing edge $(v_0, v_1)$. Player 1 responds by moving the token along an outgoing edge from the vertex $v_1$, say $(v_1, v_2)$. This continues on and the players produce a path $v_0, v_1, \ldots, v_k$ called a play starting at $v_0$. Say that player 0 wins the play $v_0, v_1, \ldots, v_k$ if the play visits every node in $V$. Call thus described game *forced-connectivity game*. A posssible scenario for this situation is that player 0 wants to pass a message through all the nodes of a given network in the presense of an adversary. If player 0 has a winning strategy, then we say that the player wins the game starting at $v_0$. Winning this forced-connectivity game from $v_0$ does not always guarantee that the player wins the game starting at any other vertex. Therefore we can define game-theoretic connectivity as follows. A directed bipartite graph $G$ is *forced-connected* if player 0 wins the forced-connectivity game in $G$ starting at any vertex of $G$. Thus, finding out if $G$ is a forced-connected is equivalent to solving connectivity games as in Definition 1.

▶ **Definition 2.** *Let $\mathcal{G} = (V_0, V_1, E, \Omega)$ be a connectivity game. Call the bipartite graph $G = (V_0, V_1, E)$* **forced-connected** *if player 0 wins the game $\mathcal{G}$.*

The third motivation is related to generalised Büchi winning condition. The generalised Büchi winning condition is given by subsets $F_1$, ..., $F_k$ of the game graph $G$. Player 0 wins a play if the play meets each of these winning sets $F_1$, ..., $F_k$ infinitely often. Our connectivity games winning condition can be viewed as a specific generalised Büchi winning condition where the accepting sets are all singletons.

## 1.3 Our contributions

The focus of this paper is two-fold. On the one hand, we study connectivity games and provide the state-of-the-art algorithms for solving them. H. Bodlaender, M. Dinneen, and B. Khoussainov [3, 4] call connectivity games *update games*. Their motivation comes from modelling the scenario where messages should be passed to all the nodes of the network in the presence of adversary. On the other hand, using the connectivity game solution process as a subroutine, we recast Horn's polynomial time algorithm that solves explicitly given Müller games and provide a proof of its correctness. We detail these below.

1. Our first contribution is that given a connectivity game $\mathcal{G}$, we construct a sequence of directed graphs $\mathcal{G}_0, \mathcal{G}_1, \ldots, \mathcal{G}_s$ such that player 0 wins $\mathcal{G}$ if and only if $\mathcal{G}_s$ is strongly connected [See Theorem 8]. Due to this result, we reduce solving connectivity game problem to the incremental strongly connected component maintenance (ISCCM) problem, one of the key problems in graph algorithms and data structure analysis [1, 11].
2. A standard brute-force algorithm that solves the connectivity game $\mathcal{G}$ runs in time $\mathbf{O}(|V|^2(|V| + |E|))$. H. Bodlaender, M. Dinneen, and B. Khoussainov in [3, 4, 7, 16] provided algorithms that solve the connectivity games in $\mathbf{O}(|V||E|)$. Due to Theorem 8, we solve the connectivity game problem by adapting two known algorithms that solve the ISCCM problem. The first algorithm is by Haeupler et al. [11] who designed the *soft-threshold search algorithm* that handles sparse graphs. Their algorithm runs in time $\mathbf{O}(\sqrt{m}m)$, where $m$ is the number of edges. The second is the solution by Bender et al. [1, 2]. Their algorithm is best suited for the class of dense graphs and runs in time of $\mathbf{O}(n^2 \log n)$, where $n$ is the number of vertices. By adapting these algorithms, we design new algorithms to solve the connectivity games. The first algorithm, given a connectivity game $\mathcal{G}$, runs in time $\mathbf{O}((\sqrt{|V_1|}+1)|E| + |V_1|^2)$ [See Theorem 9]. The first feature of this algorithm is that the algorithm solves the problem in linear time in $|V_0|$ if $|V_1|$ is considered as a parameter. The parameter constant in this case is $|V_1|^{3/2}$. The second feature is that the algorithm runs in linear time if the underlying game graph is sparse. Our second algorithm solves the connectivity game in time $\mathbf{O}((|V_1| + |V_0|) \cdot |V_0| \log |V_0|)$ [See Theorem 10]. In contrast to the previous algorithm, this algorithm solves the connectivity game problem in linear time in $|V_1|$ if $|V_0|$ is considered as a parameter. The parameterised constant is $|V_0| \log |V_0|$. Furthermore, the second algorithm is more efficient than the first one on dense graphs. These two algorithms outperform the standard bound $O(|V||E|)$, mentioned above, for solving the connectivity games. As a framework, this is similar to the work of K. Chatterjee and M. Henzinger [6] who improved the standard $O(|V||E|)$ time bound for solving Büchi games to $O(|V|^2)$ bound through analysis of maximal end-component decomposition algorithms.
3. In [12] Horn provided a polynomial time algorithm that solves explicitly given Müller games. In his algorithm, Horn uses the standard procedure of solving connectivity games as a subroutine. Directly using our algorithms above, as a subroutine to Horn's algorithm, we obviously improve Horn's algorithm in an order of magnitude. Horn's proof of correctness uses three lemmas (see Lemmas 5, 6, and 7 in [12]). However, his Lemmas 6 and 7 contain non-trivial flaws. We provide our independent proof of correctness. In terms of ideas, our proof is completely different from Horn's proof ideas. We discuss these in Section 6. To the best of our knowledge, this is the first work that correctly and fully recasts Horn's polynomial time algorithm with the efficient sub-routine for solving the connectivity games. Furthermore, in terms of running time, our algorithms perform better than that of Horn's algorithm [See Theorem 20 and Theorem 21]. For instance, one of our algorithms decreases the degree of $|\Omega|$ from $|\Omega|^3$ in Horn's algorithm to $|\Omega|^2$ [See Theorem 21]. Since $|\Omega|$ is bounded by $2^{|V|}$, the improvement is significant.

## 2 A characterization theorem

A Müller game $\mathcal{G} = (V_0, V_1, E, \Omega)$ is a connectivity game if $\Omega = \{V\}$. In this section we focus on connectivity games $\mathcal{G}$. In the study of Müller games, often it is required that for each $v$ the successor set $E(v) = \{u \mid (v, u) \in E\}$ is not empty. We do not put this condition as it will be convenient for our analysis of connectivity games to consider cases

when $E(v) = \emptyset$. Recall that a strongly connected component of a directed graph is a maximal set $X$ such that there exists a path between any two vertices of $X$. Denote the collection of all strongly connected components of the game graph $G$ of game $\mathcal{G}$ by $SCC(\mathcal{G})$. For all distinct components $X, Y \in SCC(\mathcal{G})$, we have $X \cap Y = \emptyset$ and $\bigcup_{X \in SCC(\mathcal{G})} X = V$.

▶ **Definition 3.** *Let $\mathcal{G}$ be a connectivity game. Consider two sets $U \subseteq V_1$ and $S \subseteq V$. Define*

$$Force(U, S) = \{v \mid v \in (E^{-1}(S) \setminus S) \cap U \text{ and } E(v) \subseteq S\}.$$

▶ **Definition 4.** *We say that a set $X \subseteq V$ in game $\mathcal{G}$ is a* **forced trap (FT)** *if either $|X| = 1$ or if $|X| > 1$ then $E(X \cap V_1) \subseteq X$ and $X$ is strongly connected. Further $X$ is* **forced-connected component (FCC)** *if either $|X| = 1$ or if $|X| > 1$ then the sub-game $\mathcal{G}(X)$ of the game $\mathcal{G}$ played in $X$ is forced-connected.*

▶ **Lemma 5.** *Let $\mathcal{C} = \{C_1, C_2, \ldots, C_k\}$, where $k > 1$, be a collection of FTs that partition the game graph $G$. If $\mathcal{G}$ is forced-connected then for every $X \in \mathcal{C}$ there is a $Y \in \mathcal{C}$ distinct from $X$ such that either $Y$ is a singleton consisting of a player 1's node and $E(Y) \subseteq X$, or $Y$ has player 0's node $y$ with $E(y) \cap X \neq \emptyset$.*

We now define the sequence $\{\mathcal{G}_k\}_{k \geq 0}$ of graphs. Initially, in $G_0$, the edges are only those that start in the nodes of player 0. Then the inductive construction increases the set of edges as follows. Intuitive explanation of the process is the following. Throughout the sequence, the invariant that FTs coincide with strongly connected components is maintained. By Lemma 7, these FTs are FCCs. This is ensured at each iteration by only adding the edges of those Player 1 vertices from where Player 1 is forced onto an existing SCC in the graph constructed so far. When this iteration terminates, the FCCs of the original graph coincide with the FCCs of the resulting graph, which in turn coincides with the SCCs by the invariant.

Here is now a formal process. We will call each $\mathcal{G}_k$ the $k^{th}$-derivative of $\mathcal{G}$. We will also view each $\mathcal{G}_k$ as a connectivity game. Our construction is the following.

- Initially, for $k = 0$, set $F_0 = \emptyset$, $U_0 = V_1$ and $\mathcal{G}_0 = (V_0, V_1, E_0)$, where $E_0$ consists of all outgoing edges in $E$ of player 0.
- For $k > 0$, consider the set $F_k = \bigcup_{S \in SCC(\mathcal{G}_{k-1})} Force(U_{i-1}, S)$, and define $U_k = U_{k-1} \setminus F_k$, $\mathcal{G}_k = (V_0, V_1, E_k)$, where $E_k = E_{k-1} \cup \{(v, u) \mid v \in F_k \text{ and } (v, u) \in E\}$.

Note that the SCCs of $\mathcal{G}_0$ are all singletons. For $k = 1$ we have the following. The set $F_1$ consists of all player 1 nodes of out-degree 1. The set $E_1$ contains $E_0$ and all outgoing edges from the set $F_1$. We note that each SCC of $\mathcal{G}_1$ is also a FT in $\mathcal{G}_1$. Therefore each SCC $X$ in $\mathcal{G}_1$ is also a maximal FT. Observe that each $F_k \subseteq U_{k-1}$ consists of player 1's nodes $v$ such that all moves of player 1 from $v$ go to the same SCC in $\mathcal{G}_{k-1}$. Moreover, $U_k$ is the set of player 1's nodes whose outgoing edges aren't in $E_k$. Now we list some properties of the sequence $\{\mathcal{G}_k\}_{k \geq 0}$. A verification of these properties follows from the construction:

- For every player 1's node $v$ and $k > 0$, the outgoing edges of $v$ are in $E_k \setminus E_{k-1}$ iff all the outgoing edges of $v$ point to the same SCC in $\mathcal{G}_{k-1}$ and in $\mathcal{G}_{k-1}$ the out-degree of $v$ is 0.
- For each $k \geq 0$, every SCC in $\mathcal{G}_k$ is a FT in $\mathcal{G}_k$.
- For all $k \geq 0$ we have $F_{k+1} \subseteq U_k \subseteq U_{k-1} \subseteq \ldots \subseteq U_0 = V_1$.
- For all $k_1 \neq k_2$ we have $F_{k_1} \cap F_{k_2} = \emptyset$.
- If $F_k = \emptyset$ with $k > 0$ then for all $i \geq k$, $\mathcal{G}_i = \mathcal{G}_{k-1}$. We call the minimal such $k$ the **stabilization point** and denote it by $s$. Note that $s \leq |V_1|$.
- If for all $X \in SCC(\mathcal{G}_k)$, either $|X| > 1$ or $X$ is a singleton consisting of player 0's node only then $\mathcal{G}_k = \mathcal{G}$.
- For each $k \geq 0$ and player 1's node $v$, if $v$ is in a nontrivial SCC in $\mathcal{G}_k$ then all $v$'s outgoing edges from $v$ are in $E_k$.

▶ **Lemma 6.** *If $\mathcal{G}$ is forced-connected and $|SCC(\mathcal{G}_k)| > 1$, then $\mathcal{G}_k \neq \mathcal{G}_{k+1}$.*

Given a connectivity game $\mathcal{G}$, we now construct a sequence of forests $\{\Gamma_k(\mathcal{G})\}_{k\geq 0}$ by induction. The idea is to represent the interactions of the SCCs of the graphs $\mathcal{G}_k$ with SCCs of the $\mathcal{G}_{k-1}$, for $k = 1, 2, \ldots$. The sequence of forests $\Gamma_k(\mathcal{G}) = (N_k, Son_k)$, $k = 0, 1, \ldots$, is defined as follows:

- For $k = 0$, set $\Gamma_0(\mathcal{G}) = (N_0, Son_0)$, where $N_0 = \{\{v\} \mid v \in V\}$ and $Son_0(\{v\}) = \emptyset$ for all $v \in V$.
- For $k > 0$, let $C = SCC(\mathcal{G}_k) \setminus N_{k-1}$ be the set of new SCCs in $\mathcal{G}_k$. Define the forest $\Gamma_k(\mathcal{G}) = (N_k, Son_k)$, where
  1. $N_k = N_{k-1} \cup C$, and
  2. $Son_k = Son_{k-1} \cup \{(X, Y) \mid X \in C, Y \in SCC(\mathcal{G}_{k-1}) \text{ and } Y \subset X\}$.

  Thus the new SCCs $X$ that belong to $C$ have become the roots of the trees in the forest $\Gamma_k(\mathcal{G})$. The children of $X$ are now SCCs in $\mathcal{G}_{k-1}$ that are contained in $X$.

Note that if $s$ is the stabilization point of the sequence $\{\mathcal{G}_k\}_{k\geq 0}$, then for all $k \geq s$ we have $\Gamma_k(\mathcal{G}) = \Gamma_s(\mathcal{G})$. Therefore, we set $\Gamma(\mathcal{G}) = \Gamma_s(\mathcal{G})$. Thus, for the forest $\Gamma(\mathcal{G})$ we have $N = N_s$ and $Son = Son_s$. The following properties of the forest $\Gamma(\mathcal{G})$ can easily be verified:

- For all nodes $X \in N$, $X$'s sons partition $X = \bigcup_{Y \in Son(X)} Y$.
- For all nodes $X \in N$ with $|X| > 1$, $E(X \cap V_1) \subseteq X$.
- The roots of $\Gamma(\mathcal{G})$ are strongly connected components of $\mathcal{G}_s$.

▶ **Lemma 7.** *Consider $\Gamma(\mathcal{G}) = (N, Son)$. Let $X \in N$ be such that $|X| > 1$. Then the sub-game $\mathcal{G}(X)$ of the game $\mathcal{G}$ played in $X$ is forced-connected.*

Given the results above, we now relate solving forced connectivity problem to strong connectedness in directed graphs:

▶ **Theorem 8** (Characterization Theorem)**.** *The connectivity game $\mathcal{G}$ is forced-connected if and only if the directed graph $\mathcal{G}_s$ is strongly connected.*

## 3 Solving connectivity games efficiently

In a dynamic setting the increment strongly connected maintenance (ISCCM) problem is stated as follows. Initially, we are given $n$ vertices and the empty edge set. A sequence of edges $e_1, \ldots, e_m$ are added. No multiple edges and loops are allowed. The goal is to design a data structure that maintains the SCCs of the graphs after each addition of edges. By Theorem 8 the connectivity games problem is reduced to the incremental strongly connected component maintenance (ISCCM) problem. Note that Tarjan's algorithm solves the static version of the strongly connected component maintenance problem in time $\mathbf{O}(m)$ [21].

We mention two algorithms that solve the ISCCM problem. The first is the *soft-threshold search algorithm* by Haeupler et al. [11] that handles sparse graphs. Their algorithm runs in time $\mathbf{O}(\sqrt{m}m)$. The second is by Bender et al. [1, 2]. Their algorithm is best suited for the class of dense graphs and runs in time of $\mathbf{O}(n^2 \log n)$. We adapt these algorithms carefully in the proofs of our Theorems 9 and 10 below.

▶ **Theorem 9.** *The connectivity game $\mathcal{G}$ can be solved in time $\mathbf{O}((\sqrt{|V_1|}+1)|E| + |V_1|^2)$.*

We point out two features of this theorem. The first is that if the cardinality $|V_1|$ is considered as a parameter, then we can solve the problem in linear time in $|V_0|$. The parameter constant in this case is $|V_1|^{3/2}$. The second feature is that the algorithm runs in linear time if the underlying game graph is sparse. Our second theorem is the following:

▶ **Theorem 10.** *The connectivity game $\mathcal{G}$ can be solved in time* $\mathbf{O}((|V_1| + |V_0|) \cdot |V_0| \log |V_0|)$.

In comparison to the theorem above, this theorem implies that we can solve the problem in linear time in $|V_1|$. The parameterised constant is $|V_0| \log |V_0|$. Furthermore, the algorithm is more efficient than the first one on dense graphs.

Finally, both of the algorithms outperform the standard known bound $\mathbf{O}(|V||E|)$ that solves the connectivity games.

## 4 Solving explicitly given Müller games

We start with standard notions about games on graphs. Let $\mathcal{G}$ be a Müller game. A set $S \subseteq V$ determines a subgame in $\mathcal{G}$ if for all $v \in S$ we have $E(v) \cap S \neq \emptyset$. We call $\mathcal{G}(S)$, the subgame of $\mathcal{G}$ determined by $S$. The set $S \subseteq V$ is a $\sigma$-trap in $G$ if $S$ determines a subgame in $\mathcal{G}$ and $E(S \cap V_\sigma) \subseteq S$.

Let $Win_\sigma(\mathcal{G})$ be the set of all $v$ in $\mathcal{G}$ such that player $\sigma$ wins $\mathcal{G}$ starting from $v$. If $Win_\sigma(\mathcal{G}) = V$, we say that player $\sigma$ wins $\mathcal{G}$. Otherwise, we say that player $\sigma$ cannot win $\mathcal{G}$.

Let $Attr_\sigma(X, G(Y))$ be the set of all $v$ in $Y$ such that player $\sigma$ can force the token from $v$ to $X$ in game $\mathcal{G}(Y)$.

Let $\Omega$ be the set of all winning sets of the Müller game $\mathcal{G}$. We *topologically order* $<$ the set $\Omega$, that is, for all distinct $X, Y \in \Omega$, if $X \subsetneq Y$ then $X < Y$. Thus, if $W_1 < W_2 < \ldots < W_s$ is a topological linear order on $\Omega$ then we have this. If $i < j$ then $W_i \not\supseteq W_j$.

Below we provide several results that are interesting on their own. We will also use them in our analysis of Müller games.

▶ **Lemma 11.** *Let $\mathcal{G}$ be a game, $F_0 = \Omega$ and $F_1 = 2^V \setminus \Omega$. If $V \in F_\sigma$ and for all $v \in V$, either $Attr_\sigma(\{v\}, G) = V$ or player $\sigma$ wins $\mathcal{G}(V \setminus Attr_\sigma(\{v\}, G))$ then player $\sigma$ wins $\mathcal{G}$.*

The proof of the next lemma uses the lemma above:

▶ **Lemma 12.** *Let $\mathcal{S} = \{S_1, S_2, \ldots, S_k\} \subseteq 2^V \setminus \{V\}$ be the collection of all 0-traps in $\mathcal{G}$ and assume that $V \in \Omega$. If for all $S_i \in \mathcal{S}$, player 1 can't win $\mathcal{G}(S_i)$ then player 0 wins $\mathcal{G}$.*

The next lemma shows that we can reduce the size of the wining condition set $\Omega'$ if one of the sets $W \in \Omega'$ is minimal (with respect to $\subseteq$) and not forced-connected. The proof uses Lemmas 11 and 12.

▶ **Lemma 13.** *Let $W \subseteq V$ be a subgame. If $\mathcal{G}(W)$ isn't forced-connected and no winning set in $\Omega$ is contained in $W$, then $Win_1(\mathcal{G}) = Win_1(\mathcal{G}')$, where $\mathcal{G}'$ is the same as $\mathcal{G}$ but has the additional winning set: $\Omega' = \Omega \cup \{W\}$.*

Let $\mathcal{G}$ be Müller game with $\Omega = \{W_1, W_2, \ldots, W_s\}$. For the next two lemmas and the follow-up theorem we assume that there exists a $W \in \Omega$ such that $\mathcal{G}(W)$ is forced-connected and $W$ isn't a 1-trap. The following is a construction that occurs naturally if one wants to analyse Müller games. We attribute this to Horn [12]:

▶ **Definition 14** (Horn's construction). *Let $W \in \Omega$ such that $\mathcal{G}(W)$ is forced-connected and is not a 1-trap. The game $\mathcal{G}_W = (G_W, \Omega_W)$ determined by $W$ is defined as follows:*

1. $V_W = V_0 \cup V_1 \cup \{\mathbf{W}\}$, *where* $\mathbf{W}$ *is a player 1's new vertex.*
2. $E_W = E \cup (V_0 \cap W) \times \{\mathbf{W}\} \ \cup \ \{\mathbf{W}\} \times (E(V_1 \cap W) \setminus W)$.
3. $\Omega_W = (\Omega \cup \{W' \cup \{\mathbf{W}\} \mid W' \in R\}) \setminus (R \cup \{W\})$, *where the set $R$ is the following* $R = \{W' \mid W' \in \Omega$ *and* $W \subset W'\}$.

Note that $|\Omega_W| + 1 = |\Omega|$, and $\mathcal{G}_W(W)$ is forced-connected. Thus, similar to the lemma above, Horn's construction also reduces the size of $\Omega$. Now our goal is to show that Horn's construction preserves the winners of the original game. This is shown in the next two lemmas. Here we note that Horn's original proof of his correctness followed a different line of proof; this will be explained later.

▶ **Lemma 15.** *We have* $Win_0(\mathcal{G}_W) \setminus \{\mathbf{W}\} \subseteq Win_0(\mathcal{G})$.

**Proof.** Let $\sigma_W$ be a winning strategy for player 0 in game $\mathcal{G}_W$ starting at $s \in V$. We now describe a winning strategy for player 0 in $\mathcal{G}$ starting from $s$. Player 0 plays the game $\mathcal{G}$ by simulating plays $\rho$ consistent with $\sigma_W$ in $\mathcal{G}_W$. If a play $\rho$ stays out of $\mathbf{W}$, then the player 0 copies $\rho$ in $\mathcal{G}$. Once $\rho$ moves to $\mathbf{W}$, then player 0 in $\mathcal{G}$ moves to any node in $W \cap V_1$. Then player 0 stays in $W$ and uses its strategy to visit every node in $W$. If player 1 moves out of $W$ to a node $u$ in $\mathcal{G}$, this will correspond to a move by player 1 from $\mathbf{W}$ to $u$ in $\mathcal{G}_W$. Player 0 continues on simulating $\rho$.

Let $\rho'$ be the play in $\mathcal{G}$ consistent with the strategy. If $\rho$ meets $\mathbf{W}$ finitely often then $\mathsf{Inf}(\rho) = \mathsf{Inf}(\rho')$ and $\mathsf{Inf}(\rho') \in \Omega$. If $\rho$ never moves out of $\mathbf{W}$ from some point on, then $\mathsf{Inf}(\rho') = W$. In both cases player 0 wins. If the simulation leaves $\mathbf{W}$ infinitely often, then $\mathsf{Inf}(\rho) \in \{W' \cup \{\mathbf{W}\} \mid W' \in R\}$ and $W \subseteq \mathsf{Inf}(\rho)$. Therefore

$$\mathsf{Inf}(\rho') \subseteq \mathsf{Inf}(\rho) \setminus \{\mathbf{W}\} \cup W = \mathsf{Inf}(\rho) \setminus \{\mathbf{W}\} \subseteq \mathsf{Inf}(\rho'),$$

and hence $\mathsf{Inf}(\rho') = \mathsf{Inf}(\rho) \setminus \{\mathbf{W}\} \in R$, and player 0 wins. ◀

The next lemma is more involved. Assume that the set $W' \subseteq V$ determines a subgame in $\mathcal{G}$. Then $W'$ also determines a subgame of $\mathcal{G}_W$. We call the set $W'$ *extendible* if $W' \cup \{\mathbf{W}\}$ is a subgame of $\mathcal{G}_W$. Note that there could exist non-extendible $W'$. In particular, some winning sets in $\Omega$ could become non-extendible in $\mathcal{G}_W$. In the analysis of $Win_1(\mathcal{G}_W)$ extendible and non-extendible sets must be taken into account. The lemma below does extactly that.

▶ **Lemma 16.** *We have* $Win_1(\mathcal{G}_W) \setminus \{\mathbf{W}\} \subseteq Win_1(\mathcal{G})$.

**Proof.** We define the following two sets of subgames of the game $\mathcal{G}$. The first set $\mathcal{A}$ is the following set of subgames of $\mathcal{G}$:

$$\{W' \mid W' \text{ is extendible \& player 1 wins } \mathcal{G}_W(W' \cup \{\mathbf{W}\})\}.$$

Note that if $W' \in \mathcal{A}$ then player 1 wins the subgame $\mathcal{G}_W(W')$. The second set $\mathcal{B}$ is the following set of subgames of $\mathcal{G}$:

$$\{W' \mid W \not\subseteq W' \text{ and player 1 wins } \mathcal{G}_W(W')\}.$$

Now we define the set $\mathcal{S} = \mathcal{A} \cup \mathcal{B}$. The sets $\mathcal{A}$ and $\mathcal{B}$ are disjoint. The set $W$ does not belong to $\mathcal{S}$ because $W \cup \{\mathbf{W}\}$ is not a subgame in $\mathcal{G}_W$ and $W \notin \mathcal{B}$ by definition of $\mathcal{B}$. Note that the set $\mathcal{B}$ can contain sets $W'$ that are subsets of non-extendible (winning) sets.

Since player 1 wins $\mathcal{G}_W(Win_1(\mathcal{G}_W))$, $Win_1(\mathcal{G}_W)$ is a 0-trap in $\mathcal{G}_W$ and it's easy to see that $Win_1(\mathcal{G}_W) \setminus \{\mathbf{W}\}$ is also a 0-trap in $\mathcal{G}$. Then if $\mathbf{W} \in Win_1(\mathcal{G}_W)$ then $Win_1(\mathcal{G}_W) \setminus \{\mathbf{W}\} \in \mathcal{A}$, otherwise $Win_1(\mathcal{G}_W) \setminus \{\mathbf{W}\} \in \mathcal{B}$. Since $Win_1(\mathcal{G}_W) \setminus \{\mathbf{W}\} \in \mathcal{S}$, to prove the lemma it suffices to show that player 1 wins $\mathcal{G}(S)$ for all $S \in \mathcal{S}$.

Topologically order $\mathcal{S}$: $S_1 < S_2 < \ldots < S_s$. For each $\ell = 1, 2, \ldots, s$, we want to show that player 1 wins $\mathcal{G}(S_\ell)$. As player 1 wins $\mathcal{G}_W(S_\ell)$, for all 1-traps $S' \subset S_\ell$ player 1 wins $\mathcal{G}_W(S')$. Let $\mathcal{T} = \{T_1, T_2, \ldots T_t\} \subseteq 2^{S_\ell} \setminus \{S_\ell\}$ be all 1-traps in the game $\mathcal{G}(S_\ell)$. For each $T_i \in \mathcal{T}$ we reason as follows.

*Case 1*: $W \subseteq T_i$. Then $E_W(\mathbf{W}) \cap T_i = (E_W(V_1 \cap W) \setminus W) \cap T_i = (E_W(V_1 \cap W) \setminus W) \cap S_\ell = E_W(\mathbf{W}) \cap S_\ell$. Since $W \subseteq S_\ell$ implies player 1 wins $\mathcal{G}_W(S_\ell \cup \{\mathbf{W}\})$ and $E_W(\mathbf{W}) \cap S_\ell \neq \emptyset$, $T_i \cup \{\mathbf{W}\}$ is also a 1-trap in the game $\mathcal{G}_W(S_\ell \cup \{\mathbf{W}\})$ and player 1 wins $\mathcal{G}_W(T_i \cup \{\mathbf{W}\})$. Hence $T_i$ belongs to $\mathcal{A}$.

*Case 2*: $W \not\subseteq T_i$. Note that $T_i$ is also a 1-trap in the game $\mathcal{G}_W(S_\ell)$ and player 1 wins $\mathcal{G}_W(T_i)$. Hence $T_i$ belongs to $\mathcal{B}$.

Thus, $\mathcal{T} \subset \mathcal{S}$ and by hypothesis, player 1 wins all $\mathcal{G}(T_i)$.

If $S_\ell \in \mathcal{B}$ then player 1 wins $\mathcal{G}(S_\ell) = \mathcal{G}_W(S_\ell)$. Otherwise $S_\ell \in \mathcal{A}$ and player 1 wins $\mathcal{G}_W(S_\ell \cup \{\mathbf{W}\})$.

- If $S_\ell \notin \Omega$, then for all $v \in S_\ell$, $Attr_1(\{v\}, G(S_\ell)) = S_\ell$ or player 1 wins $\mathcal{G}(S_\ell \setminus Attr_1(\{v\}, G(S_\ell)))$ since $S_\ell \setminus Attr_1(\{v\}, G(S_\ell))$ is a 1-trap in the game $\mathcal{G}(S_\ell)$. By Lemma 11, player 1 wins $\mathcal{G}(S_\ell)$.
- Otherwise by Lemma 12, there is a 0-trap $Q \subset S_\ell \cup \{\mathbf{W}\}$ in $\mathcal{G}_W(S_\ell \cup \{\mathbf{W}\})$ such that player 1 wins $\mathcal{G}_W(Q)$.
  - If $\mathbf{W} \notin Q$ then $W \cap V_0 \cap Q = \emptyset$ and $Q$ also determines a 0-trap in the game $\mathcal{G}(S_\ell)$. Since $W \not\subseteq Q$, player 1 wins $\mathcal{G}(Q) = \mathcal{G}_W(Q)$ and let $Y = Q$.
  - If $\mathbf{W} \in Q$ then let $Y = Q \setminus \{\mathbf{W}\}$. Note that for all $v \in V_0 \cap W \cap Q$, $E_W(v) \cap Q = E_W(v) \cap (S_\ell \cup \{\mathbf{W}\})$ and $|E_W(v) \cap (S_\ell \cup \{\mathbf{W}\})| > 1$. Hence $Y$ determines a 0-trap in the game $\mathcal{G}(S_\ell)$. Since player 1 wins $\mathcal{G}_W(Y \cup \{\mathbf{W}\})$, $Y$ belongs to $\mathcal{A}$ and by hypothesis player 1 wins $\mathcal{G}(Y)$.

  Therefore there exists a 0-trap $Y$ in the game $\mathcal{G}(S_\ell)$ such that player 1 wins $\mathcal{G}(Y)$. Also $Attr_1(Y, G(S_\ell)) = S_\ell$ or player 1 wins $\mathcal{G}(S_\ell \setminus Attr_1(Y, G(S_\ell)))$ since $S_\ell \setminus Attr_1(Y, G(S_\ell))$ is a 1-trap in the game $\mathcal{G}(S_\ell)$. Then we construct a winning strategy for player 1 in the game $\mathcal{G}(S_\ell)$ as follows.
  - If the token is in $Y$ then player 1 forces the token in $Y$ forever and follows the winning strategy in $\mathcal{G}(Y)$.
  - If the token is in $Attr_1(Y, G(S_\ell))$ then player 1 forces the token to $Y$.
  - Otherwise, player 1 follows the winning strategy in $\mathcal{G}(S_\ell \setminus Attr_1(Y, G(S_\ell)))$.

By hypothesis, for all $S_i \in \mathcal{S}$, player 1 wins $\mathcal{G}(S_i)$. ◀

By Lemmas 15 and 16, we have the following theorem.

▶ **Theorem 17.** *$Win_0(\mathcal{G}) = Win_0(\mathcal{G}_W) \setminus \{\mathbf{W}\}$ and $Win_1(\mathcal{G}) = Win_1(\mathcal{G}_W) \setminus \{\mathbf{W}\}$.* ⌟

**Input**: An explicit Müller game $\mathcal{G} = (G, \Omega)$
**Output**: The winning regions of player 0 and player 1
topologically order $\Omega$;
$G' = (V_0', V_1', E') \leftarrow G = (V_0, V_1, E)$;
$\Omega' \leftarrow \Omega$;
$Win_0 \leftarrow \emptyset$;
**while** $\Omega' \neq \emptyset$ **do**
  $W_i' \leftarrow \text{pop}(\Omega')$

**Figure 1** Algorithm for explicit Müller games.

We briefly explain the algorithm, presented in Figure 1, that takes as input an explicit Müller game $\mathcal{G}$ and returns the winning regions of the players. Initially, the algorithm orders $\Omega$ topologically: $W_1 < W_2 < \ldots < W_s$. At each iteration, the algorithm modifies the arena and the winning conditions:

- If $W_i'$ doesn't determine a subgame in game $\mathcal{G}'$ or $\mathcal{G}'(W_i')$ isn't forced-connected, $W_i'$ is removed from $\Omega'$.
- Otherwise, $\mathcal{G}'(W_i')$ is forced-connected, then:
  - If $W_i'$ is a 1-trap in $\mathcal{G}'$ then $Attr_0(W_i', G')$ is removed from $\mathcal{G}'$ and added to the winning region of player 0. Note that all $W' \in \Omega'$ with $W' \cap Attr_0(W_i', G') \neq \emptyset$ are removed.
  - Otherwise, apply Horn's construction to $\mathcal{G}'$ by setting $\mathcal{G}' = \mathcal{G}'_{W_i'}$. In this construction, a new player 1's node $\mathbf{W}_i'$ is added to $G'$, $\mathbf{W}_i'$ is added to all supersets of $W_i'$ in $\Omega'$ and $W_i'$ itself is removed from $\Omega'$, which maintains the topological order of $\Omega'$.

Now our goal is to show that Horn's algorithm preserves the winner of the original games at each iteration so that the algorithm can compute the winning regions correctly. This is shown in the next lemma and theorem.

▶ **Lemma 18.** *At the end of each iteration, we have*

$$Win_0(\mathcal{G}) = (Win_0(\mathcal{G}') \cup Win_0) \cap V \text{ and } Win_1(\mathcal{G}) = Win_1(\mathcal{G}') \cap V.$$

**Proof.** Initially, $\mathcal{G}' = \mathcal{G}$ and $Win_0 = \emptyset$, which holds the lemma. Then for $i = 1, 2, \ldots, s$, we want to show that at the end of $i$th iteration, $Win_0(\mathcal{G}) = (Win_0(\mathcal{G}') \cup Win_0) \cap V$ and $Win_1(\mathcal{G}) = Win_1(\mathcal{G}') \cap V$. Let $\mathcal{G}''$ be $\mathcal{G}'$ and $Win_0'$ be $Win_0$ at the beginning of $i$th iteration. Let $\mathcal{G}'''$ be $\mathcal{G}'$ and $Win_0''$ be $Win_0$ at the end of $i$th iteration. By hypothesis, $Win_0(\mathcal{G}) = (Win_0(\mathcal{G}'') \cup Win_0') \cap V$ and $Win_1(\mathcal{G}) = Win_1(\mathcal{G}'') \cap V$. If $W_i'$ doesn't determine a subgame in game $\mathcal{G}'$ or $W_i'$ isn't forced-connected then by Lemma 13, $W_i'$ can be removed without affecting the winning regions of the players of the game. Otherwise, if $W_i'$ is a 1-trap in $\mathcal{G}'$ then player 0 wins $\mathcal{G}''(Attr_0(W_i', G''))$ by forcing the token to $W_i'$ and then to go through $W_i'$. Since $Attr_0(W_i', G'')$ is a 1-trap in $G''$, $Attr_0(W_i', G'') \subseteq Win_0(\mathcal{G}'')$. Since $\mathcal{G}''' = \mathcal{G}''(V'' \setminus Attr_0(W_i', G''))$, $Win_0(\mathcal{G}'') = Win_0(\mathcal{G}''') \cup Attr_0(W_i', G'')$ and $Win_1(\mathcal{G}'') = Win_1(\mathcal{G}''')$. Therefore, $Win_0(\mathcal{G}) = (Win_0(\mathcal{G}''') \cup Attr_0(W_i', G'') \cup Win_0') \cap V = (Win_0(\mathcal{G}''') \cup Win_0'') \cap V$ and $Win_1(\mathcal{G}) = Win_1(\mathcal{G}''') \cap V$. If $W_i'$ isn't a 1-trap in $\mathcal{G}'$ then by Theorem 17, $Win_0(\mathcal{G}'') = Win_0(\mathcal{G}''') \setminus \{\mathbf{W}_i'\}$ and $Win_1(\mathcal{G}'') = Win_1(\mathcal{G}''') \setminus \{\mathbf{W}_i'\}$. Therefore, $Win_0(\mathcal{G}) = (Win_0(\mathcal{G}''') \cup Win_0'') \cap V$ and $Win_1(\mathcal{G}) = Win_1(\mathcal{G}''') \cap V$. By hypothesis, at the end of each iteration, $\mathcal{G}'$ and $Win_0$ hold the lemma. ◀

By Lemma 18, we have the following theorem.

▶ **Theorem 19.** *At the end of the algorithm, we have*

$$Win_0(\mathcal{G}) = Win_0 \cap V \text{ and } Win_1(\mathcal{G}) = V \setminus Win_0.$$ ⌟

At each iteration, at most one player 1's vertex is added and at most $|V_0'|$ edges are added. Therefore, $|V_0'| = |V_0|$, $|V_1'|$ is bounded by $|V_1| + |\Omega|$ and $|E'|$ is bounded by $|E| + |V_0||\Omega|$. For time complexity of the algorithm, there are at most $|\Omega|$ iterations in a run and the most time-consuming operation is to determine if $\mathcal{G}'(W_i')$ is forced-connected. By Theorem 9 and Theorem 10, we have the following theorems.

▶ **Theorem 20.** *There exists an algorithm that solves the explicit Müller game $\mathcal{G}$ in time* $\mathbf{O}(|\Omega| \cdot ((\sqrt{|V_1| + |\Omega|} + 1)(|E| + |V_0||\Omega|) + (|V_1| + |\Omega|)^2))$. ⌟

▶ **Theorem 21.** *There exists an algorithm that solves the explicit Müller game $\mathcal{G}$ in time* $\mathbf{O}(|\Omega| \cdot (|V_0| + |V_1| + |\Omega|) \cdot |V_0| \log |V_0|)$. ⌟

Both of these algorithms beat the bound of Horn's algorithm. Importantly, Theorem 21 decreases the degree of $|\Omega|$ from $|\Omega|^3$ in Horn's algorithm to $|\Omega|^2$. Since $|\Omega|$ is bounded by $2^{|V|}$, the improvement is significant.

## 5 Applications

We now apply the results above to specific classes of games. Here we give three examples of such classes. The first such class is the class of fully separated Müller games. A Müller game $\mathcal{G}$ is *fully separated* if for each $W \in \Omega$ there is a $s_W$, called separator, such that all $s_W \in W$ but $s_W \notin W'$ for all $W' \in \Omega$ distinct from $W$. The second class of games is the class of linear games. A Müller game $\mathcal{G}$ is a *linear game* if the set $\Omega$ forms a linear order $W_1 \subset W_2 \subset \ldots \subset W_s$. These classes of games were studied in [15]. As the games are fully separated, when one constructs $\mathcal{G}'_{W'_i}$ there is no need to add a new vertex. Then applying Theorems 9 and 10 to Horn's algorithm, we get the following result:

▶ **Theorem 22.** *Each of the following is true:*
1. *Any fully separated Müller game $\mathcal{G}$ can be solved in time* $\mathbf{O}(|V| \cdot ((\sqrt{|V_1|}+1)|E| + |V_1|^2))$.
2. *Any fully separated Müller game $\mathcal{G}$ can be solved in time* $\mathbf{O}(|V|^2 \cdot |V_0| \log |V_0|)$. ⌟

Both of these algorithms beat the bound of [15] $\mathbf{O}(|V|^2|E|)$ that solves fully separated Müller game. Applying Theorem 20 and Theorem 21, we have the following theorems.

▶ **Theorem 23.** *Each of the following is true:*
1. *Any linear Müller game $\mathcal{G}$ can be solved in time* $\mathbf{O}(|V| \cdot ((\sqrt{|V|}+1) \cdot |V_0||V| + |V|^2))$.
2. *Any linear Müller game $\mathcal{G}$ can be solved in time* $\mathbf{O}(|V|^2 \cdot |V_0| \log |V_0|)$. ⌟

Both of these algorithms beat the bound $\mathbf{O}(|V|^{2\cdot|V|-1}|E|)$ from of [15] and the bound $\mathbf{O}(|V|^3 \cdot |V_0|)$ implied from Horn's algorithm.

The third class of Müller games was introduced by A. Dawar and P. Hunter in [14]. They investigated games with anti-chain winning condition. A winning condition $\Omega$ is an *anti-chain* if $X \not\subseteq Y$ for all $X, Y \in \Omega$. Applying Theorem 20 and Theorem 21, we have the following theorems. Note that, since the winning condition is an anti-chain, $|V'_1|$ is bounded by $|V_1|$, $|E'|$ is bounded by $|E|$ and no new player 1's vertex is added to $\Omega'$.

▶ **Theorem 24.** *Each of the following is true:*
1. *Any Müller game $\mathcal{G}$ with anti-chain winning condition can be solved in time* $\mathbf{O}(|\Omega| \cdot ((\sqrt{|V_1|}+1)|E| + |V_1|^2))$.
2. *Any Müller game $\mathcal{G}$ with anti-chain winning condition can be solved in time* $\mathbf{O}(|\Omega||V| \cdot |V_0| \log |V_0|)$. ⌟

Just as above, both of the algorithms beat the bound $\mathbf{O}(|\Omega||V|^2|E|)$ from [14] and the bound of Horn's algorithm $\mathbf{O}(|\Omega||V||E|)$ that solves the explicit Müller games with anti-chain winning conditions.

## 6 A note on Horn's proof

In [12], Horn considers sensible sets. A winning set $W \in \Omega$ is *sensible* if it determines a subgame. Initially, all non-sensible sets are removed (this is fine). Then Horn's assumption is that through the iteration process (in the algorithm in figure 1) sensibility is preserved.

When $\mathcal{G}_W$ is built (during iterations), a winning condition $W'$ that contains $W$ might become non-sensible. Hence, sensibility is not preserved during iterations. Horn's analysis doesn't take non-sensible sets into account. This is important. In Horn's defence, assume we remove all non-sensible winning sets in the current game $\mathcal{G}_W$ (Note that the algorithm removes non-sensible winning conditions). However, Horn does not prove that this is a correct action. Horn's proof does not analyse an intricate interplay between sensibility and maintenance of the winning sets at each iteration. Neglecting non-sensible sets makes the proofs of Lemmas 6 and 7 (in [12]) incorrect. Here is an example.

Let $\mathcal{G} = (G, \Omega)$ be a game where $G$ is shown in figure 2 and $\Omega = \{W_1, W_2, W_3\}$, where $W_1 = \{v_1, u_1\}$, $W_2 = \{v_1, u_1, u_2\}$, and $W_3 = \{v_1, v_2, u_1, u_2\}$. During the algorithm, player 0 wins the subgame determined by $W_1$. The set $W_1$ isn't a 1-trap. So the new player 1's node $\mathbf{W}_1$ is added. The sensible set $W_2$ now becomes non-sensible in $\mathcal{G}_{W_1}$. Let us assume that $W_2 \cup \{\mathbf{W}_1\}$ is removed from the winning set in $\mathcal{G}_{W_1}$. Then player 0 wins the subgame determined by $W_3 \cup \{\mathbf{W}_1\}$. Horn's Lemma 7 applied to the game in $\mathcal{G}_{W_1}$ that occurs on $W_3 \cup \{\mathbf{W}_1\}$ states the following.

*Player 1 wins the original game played on $W_3$, where $W_3$ is removed from $\Omega$.*

The proof uses induction that has the following important (in our view unrecoverable) flaw. The proof considers the maximal winning sets inside $W_3$. Clearly, the maximal winning set inside $W_3$ is $W_3$ itself. Horn refers to player 1 winning strategy on $W_3$. Such strategy does not exists as it needs to be built. This is a self-loop argument. Trying to save Horn's proof, lets assume that $W_2$ was considered by Horn to be the maximal set. Since $W_2 \cup \{\mathbf{W}_1\}$ is non-sensible in $\mathcal{G}_{W_1}$, it is removed during the algorithm. Horn claims that player 1 has a winning strategy by playing inside $W_2$ and uses it to build a winning strategy in $W_3$. However, player 0 wins $\mathcal{G}(W_1)$ and $W_1$ is a 1-trap in $\mathcal{G}(W_2)$. As a result, player 1 has no winning strategy in $\mathcal{G}(W_2)$ and Horn's proof fails. Since Horn reuses the proof of Lemma 7 in the proof of Lemma 6, Horn fails on the proofs of Lemmas 6 and 7. These show that Horn's inductive arguments fail.

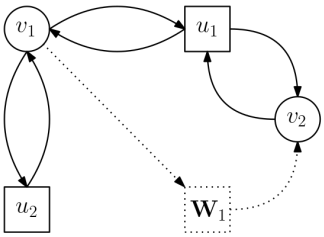

**Figure 2** The counter case to Horn's Lemmas 6 and 7.

Our section 4 develops new ideas and methods that are not present in Horn's arguments. As an example, we consider extendible and non-extendible sets in the proof of Lemma 16. The lemma takes winning regions that are subsets of non-sensible sets into account. These are placed in set $\mathcal{B}$ in the lemma. We also show that the players' winning nodes stay invariant with each iteration. This completely differs from Horn's arguments. Horn's Lemmas 5, 6, and 7 are aimed at proving that the original game restricted to $W$, given by the iteration, is won by one of the players. Our approach is obviously different.

## Abstract

Ranking and Balance are arguably the two most important algorithms in the online matching literature. They achieve the same optimal competitive ratio of $1 - 1/e$ for the integral version and fractional version of online bipartite matching by Karp, Vazirani, and Vazirani (STOC 1990) respectively. The two algorithms have been generalized to weighted online bipartite matching problems, including vertex-weighted online bipartite matching and AdWords, by utilizing a perturbation function. The canonical choice of the perturbation function is $f(x) = 1 - e^{x-1}$ as it leads to the optimal competitive ratio of $1 - 1/e$ in both settings.

We advance the understanding of the weighted generalizations of Ranking and Balance in this paper, with a focus on studying the effect of different perturbation functions. First, we prove that the canonical perturbation function is the *unique* optimal perturbation function for vertex-weighted online bipartite matching. In stark contrast, all perturbation functions achieve the optimal competitive ratio of $1 - 1/e$ in the unweighted setting. Second, we prove that the generalization of Ranking to AdWords with unknown budgets using the canonical perturbation function is at most 0.624 competitive, refuting a conjecture of Vazirani (2021). More generally, as an application of the first result, we prove that no perturbation function leads to the prominent competitive ratio of $1 - 1/e$ by establishing an upper bound of $1 - 1/e - 0.0003$. Finally, we propose the online budget-additive welfare maximization problem that is intermediate between AdWords and AdWords with unknown budgets, and we design an optimal $1 - 1/e$ competitive algorithm by generalizing Balance.

## 1 Introduction

Online bipartite matching has been extensively studied since the seminal work of Karp, Vazirani, and Vazirani [22]. Two remarkable algorithms, Ranking of Karp et al. [22] and Balance of Kalyanasundaram and Pruhs [19], achieve the same optimal competitive ratio of $1 - 1/e$ for the integral (randomized) and fractional (deterministic) version of the problem respectively.

**AdWords and Vertex-weighted.** Motivated by the display of advertising on the Internet, Mehta et al. [25] generalized the online bipartite matching problem so that it allows weighted graphs. Consider an underlying bipartite graph $G = (L \cup R, E)$ with $L, R$ being offline and online vertices. Each vertex $u \in L$ is associated with a budget $B_u$, and each edge $(u, v) \in E$ is associated with a bid $w_{uv}$. The offline vertices and their corresponding budgets are known in advance. The online vertices arrive one at a time, with their incident edges and associated bids, and have to be matched immediately and irrevocably to some $u \in L$. An offline vertex $u \in L$ can be matched to multiple online vertices. Let $S_u$ be the set of online vertices matched to $u$ and then, the revenue of $u$ equals $\min\{B_u, \sum_{v \in S_u} w_{uv}\}$, that is, the revenue cannot exceed the budget. The goal is to maximize the total revenue and to compete against the optimal revenue of an offline algorithm that knows the whole graph.

Mehta et al. [25] established an optimal $(1 - 1/e)$-competitive algorithm for the fractional version[1] of the problem by generalizing Balance to Perturbed-Balance. Later, Aggarwal et al. [1] considered a restricted setting of AdWords, called vertex-weighted online bipartite matching, in which all edges incident to $u$ have the same weight of $w_u = B_u$. They generalized Ranking to Perturbed-Ranking and obtained the same $1 - 1/e$ competitive ratio for the integral version of the problem.

The two generalizations are both greedy-based algorithms with a careful perturbation of the weights. Specifically, upon the arrival of each vertex $v$, the algorithm matches it with the offline vertex $u$ with the maximum perturbed weight $f(x_u) \cdot w_{uv}$, among those neighbors whose budgets have not yet been exhausted. Here, $x_u$ corresponds to the random rank of $u$ in Perturbed-Ranking and the fraction of budget spent so far in Perturbed-Balance. The canonical choice of the perturbation function is $f(x) = 1 - e^{x-1}$, applied by Mehta et al. [25] and Aggarwal et al. [1]. Notably, Devanur, Jain, and Kleinberg [7] provided a unified primal-dual analysis for Perturbed-Ranking and Perturbed-Balance, in which the perturbation function plays a critical role even for the unweighted online bipartite matching problem.

Despite the above successful generalizations of Ranking and Balance from unweighted to weighted graphs, we lack an understanding of the extra difficulty introduced by weighted graphs. In this paper, we revisit the two classic algorithms and focus on the perturbation function. Notice that for unweighted graphs, Perturbed-Ranking (resp. Perturbed-Balance) with an arbitrary perturbation function degenerates to the same Ranking (resp. Balance) algorithm and achieves the optimal competitive ratio of $1 - 1/e$. We examine the importance of perturbation functions by studying the performance of Perturbed-Ranking and Perturbed-Balance on weighted graphs with an arbitrary perturbation function.

Our first result confirms the importance of the perturbation function, proving that the canonical perturbation function $f(x) = 1 - e^{x-1}$ is the unique optimal perturbation function for vertex-weighted online bipartite matching.

[1] The paper states their result with the small-bid assumption, i.e., $\gamma = \max_{u,v} w_{uv}/B_u$ is small. We consider the fractional AdWords problem, corresponding to the case when $\gamma \to 0$. See our discussion in Section 2.

▶ **Theorem 1.** *The perturbation function* $f(x) = 1 - e^{x-1}$ *is unique (up to a scale factor) for* Perturbed-Ranking *and* Perturbed-Balance *to achieve the optimal competitive ratio of* $1 - 1/e$ *for vertex-weighted online bipartite matching.*

It is surprising that this question has been overlooked by the online matching community. We introduce a new family of hard instances that heavily exploits the power of weighted graphs. Noticeably, prior to our work, the only $1 - 1/e$ impossibility result by Karp et al. [22] is established for unweighted graphs. This advanced understanding is also the starting point for us to explore the limitation of Perturbed-Ranking in a more general model, i.e., AdWords with unknown budgets.

**AdWords with Unknown Budgets.** A major open question left by Mehta et al. [25] is the competitive ratio of Perturbed-Ranking for the fractional AdWords problem. In addition to obvious theoretical interests, the Perturbed-Ranking algorithm has a merit of budget-obliviousness, as pointed out by Vazirani [28] and Udwani [27]. I.e., the algorithm does not need to know the budget of each vertex, in contrast to the Perturbed-Balance algorithm. Formally, consider the setting of AdWords with unknown budgets: the algorithm has no prior knowledge of the budgets and only learns the budget of each vertex $u$ when the total revenue of $u$ first exceeds its budget. Observe that Perturbed-Balance is not applicable in this setting, since its decision at each step depends on the fraction of budget spent on each offline vertex.

Perturbed-Ranking is the only known algorithm for AdWords with unknown budgets so far. Using the canonical perturbation function $f(x) = 1 - e^{x-1}$, Vazirani [28] proved Perturbed-Ranking is $(1 - 1/e)$-competitive assuming a no-surpassing property. Udwani [27] proved that the algorithm is 0.508-competitive in the general case and is 0.522-competitive with a different perturbation function $f(x) = 1 - e^{1.15(x-1)}$.

It is natural to ask if other perturbation functions can lead to a better competitive ratio, or even $1 - 1/e$. In this paper, we give a limitation of *all* perturbation functions, showing a separation between vertex-weighted online bipartite matching and AdWords on the performance of Perturbed-Ranking.

We first show that Perturbed-Ranking with the canonical perturbation function can only achieve a competitive ratio of at most $0.624 < 1 - 1/e$. Then, together with the family of instances we constructed in the proof of Theorem 1, we manage to prove that any perturbation function cannot lead to the prominent competitive ratio of $1 - 1/e$:

▶ **Theorem 2.** *The competitive ratio of* Perturbed-Ranking *algorithm with any perturbation function* $f(x)$ *on fractional AdWords is at most* $1 - 1/e - 0.0003$. *In particular, using the canonical function* $f(x) = 1 - e^{x-1}$, *the competitive ratio is at most* 0.624.

Our result refutes the conjecture of Vazirani [28] that Perturbed-Ranking is $1 - 1/e$ competitive. Moreover, our construction is clean and simple, suggesting that the no-surpassing assumption might be too strong to hold in reality. Such result leads to the conjecture that there is no $1 - 1/e$ competitive algorithm for AdWords with unknown budgets.

**Remark.** Very recently, independently by our work, Udwani [27] updated his paper and proved that a specific perturbation function family $f(x) = 1 - e^{\beta(x-1)}$ is at most 0.624-competitive for any $\beta > 0$. Our result provides a stronger observation by another approach that shows *all* perturbation functions cannot achieve the competitive ratio of $1 - 1/e$.

**Online Budget-additive Welfare Maximization.** The above upper bound of the competitive ratio for Perturbed-Ranking suggests that AdWords with unknown budgets should be strictly harder than AdWords, in terms of the worse-case competitive ratio. Unfortunately, our current construction is specific to the Perturbed-Ranking algorithm and does not serve as a problem hardness.

Inspired by the online submodular welfare maximization problem (that we discuss below in the related work section), we consider a variant which we call online budget-additive welfare maximization problem, that lies in between the original AdWords and AdWords with unknown budgets. Specifically, we assume that 1) the algorithm has no information of the budgets at the beginning, 2) at each step, the algorithm can query for each vertex $u$, the value of $w_u(S) = \min\{B_u, \sum_{v \in S} w_{uv}\}$ for any subset $S$ of arrived vertices. Notice that AdWords with unknown budgets can be interpreted in a similar way, except that the algorithm can only query those sets $S$ that are subsets of $S(u) \cup \{v\}$ where $S(u)$ is the set of current matched vertices to $u$.

Our final result is an optimal algorithm for the fractional version of the problem. We hope it would shed some light on designing online algorithms beyond Perturbed-Ranking in the AdWords with unknown budgets setting and designing algorithms beyond greedy (with unrestricted computational power) in the online submodular welfare maximization setting.

▶ **Theorem 3.** *There exists a fractional algorithm that achieves the competitive ratio of* $(1 - 1/e)$ *for the Online Budget-Additive Welfare Maximization problem.*

**Roadmap.** Section 2 presents the formal definitions of the Perturbed-Ranking and Perturbed-Balance algorithms. We prove Theorem 1 in Section 3 and Theorem 2 in Section 4. Due to space limit, we provide the proof of Theorem 3 in the full version.

## 1.1 Related Work

The seminal work of Karp et al. [22] studied the unweighted and one-sided online bipartite matching model and proposed the optimal $(1 - 1/e)$-competitive algorithm: Ranking. The analysis of Ranking has been refined and simplified by a series of works [2, 7, 11, 8]. Kalyanasundaram and Pruhs studied the $b$-matching model and designed Balance (fractional) that also achieves the competitive ratio of $1 - 1/e$. The model has been generalized to many weighted variants, e.g., vertex-weighted [1, 14, 15, 18], edge-weighted [3, 9, 10], and AdWords [6, 25, 17]. Besides the aforementioned generalization of Ranking and Balance to the vertex-weighted and AdWords settings, Huang et al. [15] generalized Ranking to the vertex-weighted setting with random arrival order, by utilizing a two-dimensional perturbation function. They achieved a competitive ratio of 0.653 that is subsequently improved to 0.662 by Jin and Williamson [18]. Another line of work adapts Ranking and Balance to other matching problems, including online bipartite matching with random arrivals [21, 24], oblivious matching [5, 26] and fully online matching [12, 13, 16].

The most general extension of online bipartite matching is the online submodular welfare maximization problem. It captures most of the weighted variants of online bipartite matching discussed above. In this problem, a set of $n$ offline vertices are given, each associated with a

monotone submodular function $w_u$. Upon the arrival of an online vertex, it must be assigned to one of the offline vertices and the goal is to maximized the welfare $\sum_u w_u(S_u)$, where $S_u$ is the set of vertices received by $u$. The algorithm is assumed to have value oracles for the functions. I.e., an algorithm can query the value of $w_u(S)$ for an arbitrary subset $S$ of arrived online vertices. Kapralov et al. [20] proved that the 0.5-competitive greedy algorithm is optimal with restricted computational powers. For the unknown i.i.d. setting, they provided an optimal $(1-1/e)$-competitive algorithm. In the random arrival model, Korula et al. [23] proved that greedy is at least 0.5052-competitive, and the ratio is improved to 0.5096 by Buchbinder et al. [4]. Our budget-additive welfare maximization problem is a special case of the submodular welfare maximization problem where every $w_u$ is a budget-additive function and admits an $(1-1/e)$-competitive algorithm.

Moreover, the AdWords with unknown budgets problem suggests us to study a more restricted oracle access for online submodular welfare maximization. We call it *marginal oracle*, that on the arrival of an online vertex $v$, the algorithm can only query the value of $w_u(S)$ for $S \subseteq S_u(v) \cup \{v\}$, where $S_u(v)$ is the current matched vertex set to $u$. Based on our discoveries in this paper, we make the following three conjectures for future work:

- Online submodular welfare maximization with marginal oracles does *not* admit a $1-1/e$ competitive algorithm.
- AdWords with unknown budgets does *not* admit a $1-1/e$ competitive algorithm.
- Online submodular welfare maximization admits a $0.5+\Omega(1)$ competitive algorithm.

All the three conjectures assume unlimited computational powers so that the third conjecture does not violate the impossibility result of [20]. Observe that if the second conjecture holds, it automatically confirms the first conjecture, and implies a price of budget-obliviousness for AdWords.

## 2 Preliminaries

We first give the formal definitions of Perturbed-Ranking and Perturbed-Balance for the vertex-weighted online bipartite matching problem and then discuss their extensions to the fractional AdWords problem. Both algorithms depends on a perturbation function.

▶ **Definition 4** (Perturbation Function). *A perturbation function is a non-increasing and right continuous function* $f(x) : [0,1] \to [0,1]$.

### 2.1 Vertex-weighted

Given a perturbation function $f$, the two algorithms are defined as below. Observe that Perturbed-Ranking is a randomized algorithm and Perturbed-Balance is a deterministic algorithm.

▶ **Definition 5** (Perturbed-Ranking [1]). *Sample a rank $y_u$ for each offline vertex $u \in L$ independently from a uniform distribution on $[0,1]$. On the arrival of an online vertex $v$, we match $v$ to the unmatched neighbor $u$ with maximum perturbed weight $f(y_u) \cdot w_u$.*

▶ **Definition 6** (Perturbed-Balance). *On the arrival time of an online vertex $v$, we continuously match $v$ to the offline neighbor $u$ with maximum perturbed weight $f(x_u) \cdot w_u$, where $x_u$ is the current matched portion of $u$.*

We remark that in the context of Perturbed-Ranking, a perturbation function can be interpreted as an alternative representation of a $[0,1]$-bounded random variable, in which $f(x)$ corresponds to the value of a quantile $x$. Moreover, the right continuity is necessary for the Perturbed-Balance algorithm to be well-defined.

## 2.2 AdWords

In Section 4, we shall work on the fractional version of AdWords (and its variant) that is (slightly) more relaxed than the AdWords problem with small bid assumption. See e.g. Udwani [27] for a more detailed discussion.

**Fractional AdWords.** The fractional AdWords problem allows each edge $(u, v)$ to be fractionally matched by an amount of $x_{uv} \in [0, 1]$, as long as the total matched portion of each online vertex $v$ is no more than a unit, i.e., $\sum_u x_{uv} \leq 1$.

Consider the following generalizations of Perturbed-Ranking and Perturbed-Balance for the fractional AdWords problem:

▶ **Definition 7** (Perturbed-Ranking [28, 27]). *Sample a rank $y_u$ for each offline vertex $u \in L$ independently from a uniform distribution on $[0, 1]$. On the arrival of an online vertex $v$, we* continuously *match $v$ to the neighbor $u$ with maximum perturbed weight $f(y_u) \cdot w_{uv}$, among those neighbors whose budgets have not been exhausted yet.*

▶ **Definition 8** (Perturbed-Balance (a.k.a. MSVV [25])). *On the arrival time of an online vertex $v$, we continuously match $v$ to the offline neighbor $u$ with maximum perturbed weight $f(x_u/B_u) \cdot w_{uv}$, where $x_u$ is the current used budget of $u$.*

# 3 Vertex-Weighted

In this section, we consider vertex-weighted online bipartite matching. We prove that to achieve the optimal competitive ratio of $\Gamma = 1 - 1/e$, the canonical choice of the perturbation function $f(x) = 1 - e^{x-1}$ is unique (up to a scale factor).

Our result holds for both Perturbed-Ranking and Perturbed-Balance. Indeed, we establish a dominance of Perturbed-Balance over Perturbed-Ranking in terms of worst-case competitive ratio.

▶ **Lemma 9.** *For any perturbation function $f$, the competitive ratio of* Perturbed-Ranking *is at most the competitive ratio of* Perturbed-Balance *for vertex-weighted online bipartite matching.*

We sketch our proof below and provide the detailed proof in the full version.

**Proof Sketch.** Given an arbitrary instance $G = (L \cup R, E, w)$, we construct an instance $G'$ so that the competitive ratio of Perturbed-Balance for $G$ and the competitive ratio of Perturbed-Ranking for $G'$ are approximately the same.

- For each offline vertex $u \in L$, create $N$ duplicates $\{u^{(i)}\}_{i=1}^N$ in $G'$ and with weights $w_{u^{(i)}} = w_u$.
- For each online vertex $v \in R$, create $N$ duplicates $\{v^{(i)}\}_{i=1}^N$ in $G'$ that arrive in a sequence.
- For each $(u, v) \in E$, let there be a complete bipartite graph between $\{u^{(i)}\}$ and $\{v^{(i)}\}$ in $G'$.

Now, we consider the behavior of Perturbed-Ranking on $G'$. Intuitively, although the ranks are drawn independently for each offline vertex, the set of $N$ ranks of $\{u^{(i)}\}_{i=1}^N$ should be "close" to $\left\{\frac{1}{N}, \frac{2}{N}, \ldots, 1\right\}$ with high probability when $N$ is sufficiently large. Formally, we prove the following mathematical fact in the full version.

▶ **Lemma 10.** *Let $x_1, \ldots, x_n$ be i.i.d. random variables sampled from $[0, 1]$ uniformly. Let $y_i$ be the $i$-th order statistics of $\{x_1, \ldots, x_n\}$, for $i = 1, \ldots, n$. Then for any parameter $\varepsilon$ with $4n^{-1/4} < \varepsilon < 1$, we have*

$$\Pr_{x_1,\ldots,x_n}\left[\left|y_i - \frac{i}{n}\right| \leq \varepsilon,\ \forall i \in [n]\right] \geq 1 - 2ne^{-\sqrt{n}/6}. \tag{3.1}$$

For now, we assume the set of ranks of $\{u^{(i)}\}$ is $\{\frac{1}{N}, \frac{2}{N}, \ldots, 1\}$ for each vertex $u$. Then, upon the arrival of $\{v^{(i)}\}$, we are basically running a discretized version of the Perturbed-Balance algorithm, with a step size of $\frac{1}{N}$. To formalize this intuition, we can introduce a family of $\varepsilon$-approximate Perturbed-Balance algorithms that approaches the behavior of Perturbed-Balance when $\varepsilon \to 0$. Moreover, we prove that the Perturbed-Ranking algorithm can be interpreted as an $\varepsilon$-approximate Perturbed-Balance algorithm when the ranks of $\{u^{(i)}\}$ behave nicely (which is of high probability). Finally, we conclude the proof of the lemma by letting $N$ go to infinity. The detail is provided in the full version. ◀

Equipped with the above lemma, we hereafter focus on the easy-to-analyze Perturbed-Balance algorithm, since it is deterministic while Perturbed-Ranking is randomized.

Our main construction is a family of instances that strongly restricts the shape of the perturbation function. Naturally, our construction is built upon the classical upper triangle graph that gives the tight $1 - 1/e$ competitive ratio for unweighted online bipartite matching. On the other hand, our construction consists of a few novel gadgets that might be useful for other weighted online matching problems. The following lemma also serves as a stepping stone of our result for the AdWords with unknown budget problem in Section 4.

▶ **Lemma 11.** *If the* Perturbed-Balance *algorithm achieves a competitive ratio of* $\Gamma$ *for vertex-weighted online bipartite matching, then the perturbation function* $f$ *satisfies the following:*

$$\left(\beta + 1 - e^{\beta-1} - \Gamma\right) \cdot f(\alpha) \geq (1 - (1-\Gamma) \cdot e^{\alpha}) \cdot \int_0^{\beta} f(x)\mathrm{d}x, \quad \forall \alpha, \beta \in [0,1]. \tag{3.2}$$

We defer its proof till the end of the section and proceed by first proving our main theorem.

▶ **Theorem 1.** *The perturbation function* $f(x) = 1 - e^{x-1}$ *is unique (up to a scale factor) for* Perturbed-Ranking *and* Perturbed-Balance *to achieve the optimal competitive ratio of* $1 - 1/e$ *for vertex-weighted online bipartite matching.*

**Proof.** By Lemma 9, it suffices to prove the theorem for Perturbed-Balance. By Lemma 11 with $\Gamma = 1 - 1/e$, the perturbation function $f(x)$ satisfies the following:

$$\frac{f(\alpha)}{1 - e^{\alpha-1}} \geq \frac{\int_0^{\beta} f(x)\mathrm{d}x}{\beta - e^{\beta-1} + e^{-1}}, \quad \forall \alpha, \beta \in (0,1).$$

Let $M \overset{\text{def}}{=\!=} \inf_{\alpha \in (0,1)} \frac{f(\alpha)}{1-e^{\alpha-1}}$. We must then have

$$f(\alpha) \geq M(1 - e^{\alpha-1}), \quad \forall \alpha \in [0,1], \tag{3.3}$$

$$\int_0^{\beta} f(x)\mathrm{d}x \leq M(\beta - e^{\beta-1} + e^{-1}), \quad \forall \beta \in [0,1]. \tag{3.4}$$

Taking the integral of $f(x)$ and applying (3.3), we have

$$\int_0^{\beta} f(x)\mathrm{d}x \geq M \int_0^{\beta} (1 - e^{x-1})\mathrm{d}x = M(\beta - e^{\beta-1} + e^{-1}).$$

Together with (3.4), we conclude that $f(x) = M(1 - e^{x-1})$ for all $x \in [0,1]$ according to the right-continuity of function $f$. Specifically, if there exists an $x^* \in [0,1)$, that $f(x^*) = M(1 - e^{x^*-1}) + \varepsilon$ for some $\varepsilon > 0$, then there exists a sufficiently small $\delta > 0$ such that for any $x \in [x^*, x^* + \delta]$, $f(x) \geq M(1 - e^{x-1}) + \frac{\varepsilon}{2}$. Then we can see by (3.3) that

$$\int_0^1 f(x)\mathrm{d}x \geq \int_0^1 \Big(M(1-e^{x-1}) + \mathbb{1}[x^* \leq x \leq x^* + \delta] \cdot \frac{\varepsilon}{2}\Big)\mathrm{d}x = \frac{M}{e} + \frac{\varepsilon\delta}{2},$$

which violates the statement of (3.4), $\int_0^1 f(x)\mathrm{d}x \leq \frac{M}{e}$. Therefore, $\forall x \in [0,1)$, $f(x) = M(1-e^{x-1})$. Also, for $f(1)$, note that $f(x)$ is decreasing, so $f(1) \leq \lim_{x\to 1^-} f(x) = 0$. Then $f(1) = 0$.

This shows that $\forall x \in [0,1]$, $f(x) = M(1-e^{x-1})$, concluding the proof of the theorem. ◀

## 3.1 Proof of Lemma 11

Fix $\alpha, \beta \in [0,1]$. Let $n, m$ be sufficiently large numbers. Refer to Figure 3.1 for our instance.

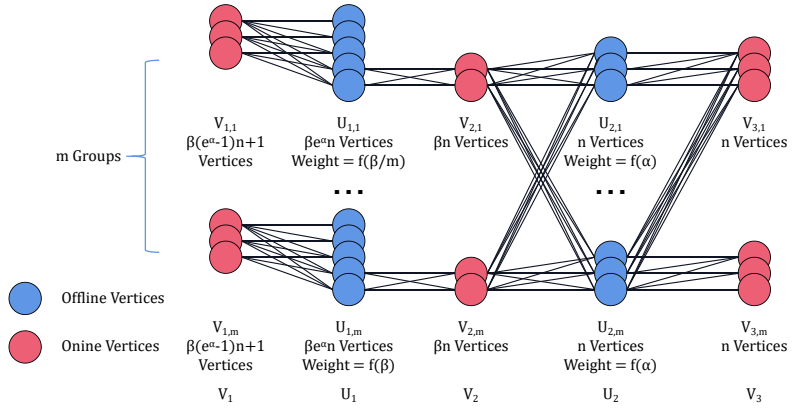

**Figure 3.1** Instance 1.

Our construction consists of $m$ groups of vertices, and each group consists of 5 parts. We use $V_{1,i}, V_{2,i}, V_{3,i}$ to denote the three online parts of group $i$ and $U_{1,i}, U_{2,i}$ to denote the two offline parts of group $i$. Let $V_j = \cup_{i\in m} V_{j,i}$ for $j \in \{1,2,3\}$ and $U_j = \cup_{i\in m} U_{j,i}$ for $j \in \{1,2\}$. We first define the vertices of the graph: for each $i \leq m$,

- $U_{1,i}$ consists of $(\beta e^\alpha n + 1)$ offline vertices[2] with the same weight of $f(\frac{i}{m} \cdot \beta)$.
- $U_{2,i}$ consists of $n$ offline vertices with the same weight of $f(\alpha)$.
- $V_{1,i}, V_{2,i}, V_{3,i}$ consist of $\beta(e^\alpha - 1)n, \beta n, n$ online vertices, respectively.

The arrival order of the vertices is the following:

$$V_{1,1} \to V_{1,2} \to \cdots \to V_{1,m} \to V_{2,1} \to V_{2,2} \to \cdots \to V_{2,m} \to V_{3,1} \to V_{3,2} \to \cdots \to V_{3,m}.$$

Next, we define the edges of the graph:

- $V_{1,i}$ and $U_{1,i}$ are connected as an *upper triangle*. I.e., the $j$-th vertex of $V_{1,i}$ is connected to the $k$-th vertex of $U_{1,i}$ if and only in $k \geq j$.
- $V_{2,i}$ and the last $\beta n$ vertices in $U_{1,i}$ are *fully connected*.
- $V_2$ and $U_2$ are *fully connected*.

[2] When $\beta e^\alpha n$ is a fraction, let there be $\lceil \beta e^\alpha n \rceil$ vertices. Since we are interested in the case when $n, m$ are sufficiently large, we safely omit the ceiling function for the simplicity of notation. We apply a similar treatment for fractions throughout the paper.

- $V_3$ and $U_2$ are connected as a *upper triangle*. I.e., the $j$-th vertex of $V_3$ is connected to the $k$-th vertex of $U_2$ if and only in $k \geq j$.

We first calculate the optimum matching of the graph. That is, matching together $(V_3, U_2)$ and $(V_1 \cup V_2, U_1)$. Therefore, we have

$$\mathrm{OPT} = \underbrace{nm \cdot f(\alpha)}_{(V_3,U_2)} + \underbrace{\sum_{i=1}^{m} \beta e^{\alpha} n \cdot f\left(\frac{i}{m} \cdot \beta\right)}_{(V_1 \cup V_2, U_1)} = nm \cdot \left(f(\alpha) + e^{\alpha} \int_0^{\beta} f(x)\mathrm{d}x + o(1)\right), \quad (3.5)$$

where the second equality holds when $m$ goes to infinity.

Next, we analyze the the performance of Perturbed-Balance. We split the whole instance into three stages, corresponding to the arrivals of $V_1, V_2, V_3$ respectively.

**First stage ($V_1$).** Upon the arrival of each vertex in $V_1$, it matches uniformly to its neighbours in $U_1$. The behavior of Perturbed-Balance is the same for different groups. We analyze the matched portion of the last $\beta n$ vertices of each group after the first stage:

$$x_u = \frac{1}{\beta e^{\alpha} n} + \frac{1}{\beta e^{\alpha} n - 1} + \cdots + \frac{1}{\beta n} = \ln\left(\frac{\beta e^{\alpha} n}{\beta n}\right) + o(1) = \alpha + o(1),$$

where the equality holds when $n$ goes to infinity.

**Second Stage ($V_2$).** Upon the arrival of each vertex $v$ of $V_{2,i}$, it will be weighing the perturbed weights from $U_{1,i}$ and $U_2$:

$$f(x_{u_1}) \cdot w_{u_1} = f(\alpha + o(1)) \cdot f\left(\frac{i}{m}\right), \qquad \text{for } u_1 \in U_{1,i} \cap N(v),$$

$$\text{and} \quad f(x_{u_2}) \cdot w_{u_2} \geq f\left(\frac{i}{m}\right) \cdot f(\alpha), \qquad \text{for } u_2 \in U_2.$$

Notice that the perturbed weights from $U_2$ is always larger than the perturbed weights from $U_{1,i}$. We claim that in the second stage, all vertices of $V_2$ would be fully matched to $U_2$ by Perturbed-Balance. Thus, at the end of the second stage, all vertices in $U_2$ have matched portion $\beta$.

**Third stage ($V_3$).** The behavior of the last stage is similar to the behavior of the first stage, except that all vertices in $U_2$ start with a matched portion of $\beta$. After the arrival of the $k$-th vertex in $V_3$, the matched portion of its neighbor equals

$$\beta + \frac{1}{nm} + \frac{1}{nm-1} + \cdots + \frac{1}{nm-k+1} \geq \beta + \ln\left(\frac{nm}{nm-k+1}\right).$$

Consequently, only the first $(1 - e^{\beta-1})nm + 1$ vertices from $V_3$ can be matched. For the rest of the online vertices, all their neighbors would be fully matched before their arrivals.

To sum up, we calculate the performance of Perturbed-Balance.

$$\begin{aligned}\mathrm{ALG} &\leq \underbrace{\sum_{i=1}^{m} (\beta(e^{\alpha}-1)n + 1) \cdot f\left(\frac{i}{m} \cdot \beta\right)}_{(V_1,U_1)} + \underbrace{\beta nm \cdot f(\alpha)}_{(V_2,U_2)} + \underbrace{\left((1-e^{\beta-1})nm + 1\right) \cdot f(\alpha)}_{(V_3,U_2)} \\ &= nm \cdot \left((e^{\alpha}-1)\int_0^{\beta} f(x)\mathrm{d}x + (\beta + 1 - e^{\beta-1}) \cdot f(\alpha) + o(1)\right). \quad (3.6)\end{aligned}$$

Together with (3.5) and the assumption that Perturbed-Balance is $\Gamma$-competitive, we conclude the proof by letting $n, m \to \infty$:

$$(e^{\alpha}-1)\int_0^{\beta} f(x)\mathrm{d}x + (\beta+1-e^{\beta-1})\cdot f(\alpha) \geq \Gamma\cdot\left(f(\alpha)+e^{\alpha}\int_0^{\beta} f(x)\mathrm{d}x\right)$$

$$\iff \left(\beta+1-e^{\beta-1}-\Gamma\right)\cdot f(\alpha) \geq (1-(1-\Gamma)\cdot e^{\alpha})\cdot\int_0^{\beta} f(x)\mathrm{d}x, \quad \forall \alpha,\beta\in[0,1].$$

# 4 AdWords with Unknown Budget

In this section, we prove Theorem 2.

▶ **Theorem 2.** *The competitive ratio of* Perturbed-Ranking *algorithm with any perturbation function $f(x)$ on fractional AdWords is at most $1-1/e-0.0003$. In particular, using the canonical function $f(x)=1-e^{x-1}$, the competitive ratio is at most* 0.624.

We first construct a hard instance for which Perturbed-Ranking with $f(x)=1-e^{x-1}$ only achieves a competitive ratio of 0.624. Recall that the vertex-weighted online bipartite matching problem is a special case of the AdWords problem. Together with Theorem 1, it should be convincing that Perturbed-Ranking (with any perturbation function) cannot achieve the prominent competitive ratio of $1-1/e$.

Our construction for general perturbation functions has a similar structure as the construction for the canonical perturbation function. On the other hand, general perturbation functions introduce extra technical difficulties to our argument that we shall discuss soon.

## 4.1 Canonical Perturbation Function $f(x)=1-e^{x-1}$

We prove the result by the following lemma.

▶ **Lemma 12.** *If* Perturbed-Ranking *with perturbation function $f(x)=1-e^{x-1}$ achieves a competitive ratio of $\Gamma$ on AdWords, then*

$$(1-\Gamma)\cdot f(\alpha) \geq (\Gamma-\alpha)\cdot\int_0^{\alpha} f(x)\mathrm{d}x + \Gamma\cdot\int_{\alpha}^{1} f(x)\mathrm{d}x, \quad \forall\alpha\in[0,1]. \tag{4.1}$$

**Proof.** Fix $\alpha\in[0,1]$. Let $n$ be a sufficiently large number. Refer to Figure 4.1 for our instance.

Our construction consists of $n+1$ offline vertices $u_0,u_1,\ldots,u_n$ and $2n$ online vertices $v_1,v_2,\ldots,v_{2n}$. The budgets of $u_1,u_2,\ldots,u_n$ are all 1 and the budget of $u_0$ is unlimited. The online vertices arrive in ascending order of their indices, i.e. $v_i$ is the $i$-th arriving online vertex. Next, we define the edges of the graph:

- $v_1,v_2,\ldots,v_n$ are connected to $u_0$, with edge weights $b_1,b_2,\ldots,b_n$ respectively.
- $v_1,v_2,\ldots,v_{2n}$ are fully connected to $u_1,u_2,\ldots,u_n$ with edge weights 1.

Before we define the weights, we make an extra assumption to simplify our analysis:

$$\forall 1\leq i\leq n, \text{the rank of } u_i \text{ is } y_i = i/n.$$

Indeed, by Lemma 10, we would have that the set of ranks $\{y_1,\ldots,y_n\}$ are "close" to $\{\frac{1}{n},\frac{2}{n},\cdots,1\}$. Moreover, all vertices $u_1,\ldots,u_n$ are symmetric in our graph. This assumption would significantly simplify our analysis and can be removed by a more conservative choice of the edge weights. We omit the tedious details for simplicity.

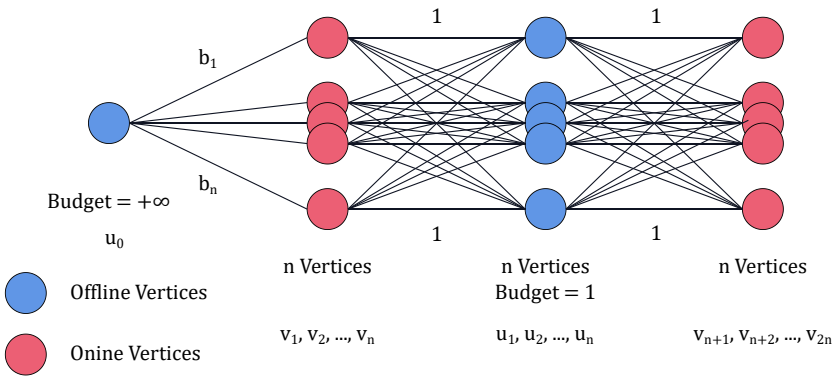

**Figure 4.1** Instance 2.

Let $b_i = \frac{f(i/n)}{f(\alpha)}$. The offline optimum is to match $v_1, v_2, \ldots, v_n$ to $u_0$ and to match $v_{n+1}, v_{n+2}, \ldots, v_{2n}$ to $u_1, u_2, \ldots, u_n$, respectively. Consequently,

$$\mathrm{OPT} = n + \sum_{i=1}^{n} b_i = n \cdot \left(1 + \frac{1}{f(\alpha)} \int_0^1 f(x)\mathrm{d}x + o(1)\right).$$

With the assumption, the only randomness of Perturbed-Ranking is the rank $y_0$ of $u_0$.

**Case 1.** $(y_0 \geq \alpha)$ For each online vertex $v_i$, the perturbed weight of $(u_0, v_i)$ is

$$b_i \cdot f(y_0) = \frac{f(y_0)}{f(\alpha)} \cdot f\left(\frac{i}{n}\right) \leq f\left(\frac{i}{n}\right),$$

while the perturbed weight of $(u_i, v_i)$ is $f(y_i) = f\left(\frac{i}{n}\right)$. Therefore, Perturbed-Ranking matches $(u_i, v_i)$ for all $1 \leq i \leq n$ and we have $\mathrm{ALG}(y_0) = n$.

**Case 2.** $(y_0 < \alpha)$ In this case, some of the $v_1, v_2, \ldots, v_n$ would be matched to $u_0$. However, the number of vertices matched to $u_0$ should be no more than $\alpha n$. The reason is as follows. For each online vertex $v_i$, suppose the number of previous vertices matched to $u_0$ is larger than $\alpha n$, then the perturbed weight of $(u_0, v_i)$ is $\frac{f(y_0)}{f(\alpha)} \cdot f\left(\frac{i}{n}\right)$, while the perturbed weight of $(u_{i-\alpha n}, v_i)$ is $f\left(\frac{i}{n} - \alpha\right)$. Notice that $f(x) = 1 - e^{x-1}$ is a log-concave function. Hence,

$$\frac{f(y_0)}{f(\alpha)} \cdot f\left(\frac{i}{n}\right) \leq \frac{f(0)}{f(\alpha)} \cdot f\left(\frac{i}{n}\right) \leq f\left(\frac{i}{n} - \alpha\right).$$

In other words, $v_i$ will not match $u_0$. This concludes the proof that the number of vertices matched to $u_0$ is no more than $\alpha n$. Notice that $b_i$'s are non-increasing, we have

$$\mathrm{ALG}(y_0) \leq \sum_{i=1}^{\alpha n} b_i + n = \sum_{i=1}^{\alpha n} \frac{f(i/n)}{f(\alpha)} + n = n \cdot \left(\frac{1}{f(\alpha)} \int_0^{\alpha} f(x)\mathrm{d}x + 1 + o(1)\right).$$

Putting the two cases together and assuming that Perturbed-Ranking algorithm is $\Gamma$-competitive, we conclude the proof of the lemma.

$$\Gamma \leq \frac{\mathbb{E}[\mathrm{ALG}]}{\mathrm{OPT}} = \frac{\alpha \cdot n \cdot \left(\frac{1}{f(\alpha)} \int_0^{\alpha} f(x)\mathrm{d}x + 1 + o(1)\right) + (1-\alpha) \cdot n}{n \cdot \left(1 + \frac{1}{f(\alpha)} \int_0^1 f(x)\mathrm{d}x + o(1)\right)} = \frac{\alpha \cdot \int_0^{\alpha} f(x)\mathrm{d}x + f(\alpha)}{\int_0^1 f(x)\mathrm{d}x + f(\alpha)}$$

$$\iff (1-\Gamma) \cdot f(\alpha) \geq (\Gamma - \alpha) \cdot \int_0^{\alpha} f(x)\mathrm{d}x + \Gamma \cdot \int_{\alpha}^1 f(x)\mathrm{d}x. \qquad \blacktriangleleft$$

▶ **Corollary 13.** Perturbed-Ranking *with* $f(x) = 1 - e^{x-1}$ *is at most* 0.624*-competitive for AdWords.*

**Proof.** Plugging in $\alpha = 0.1$ and $f(x) = 1 - e^{x-1}$ in equation (4.1), we have

$$\Gamma \le \frac{\alpha \cdot \int_0^\alpha f(x)\mathrm{d}x + f(\alpha)}{\int_0^1 f(x)\mathrm{d}x + f(\alpha)} = \frac{0.1 \cdot \left(0.1 - e^{-0.9} + e^{-1}\right) + 1 - e^{-0.9}}{e^{-1} + 1 - e^{-0.9}} < 0.624\ . \qquad \blacktriangleleft$$

## 4.2 General Perturbation Functions

Before we delve into the detailed proof, we explain the technical difficulty introduced by general perturbation functions. Our plan is to generalize Lemma 12: if we are able to prove equation (4.1) for an arbitrary function $f$, we would then conclude our theorem by combining it with equation (3.2).

However, our argument of the second case ($y_0 < \alpha$) of Lemma 12 crucially relies on the specific formula of $f(x)$. I.e., to upper bound the performance of Perturbed-Ranking, we use the fact that $f(0) \cdot f(x) \le f(\alpha) \cdot f(x - \alpha)$.

For a general perturbation function $f(x)$, if we stick to the same property that no more than $\alpha n$ vertices can be matched to $u_0$ when $y_0 < \alpha$, we could achieve it by setting the weights $b_i$ to be smaller. Indeed, if $f\left(\frac{i}{n} - \alpha\right) \ge f(0) \cdot b_i$ holds, the previous analysis can be easily generalized. Hence, a natural attempt is to modify the instance as the following.

$$b_i = \begin{cases} \frac{1}{f(\alpha)} \cdot f\left(\frac{i}{n}\right) & i < \alpha n, \\ \min\left\{\frac{1}{f(\alpha)} \cdot f\left(\frac{i}{n}\right), \frac{1}{f(0)} \cdot f\left(\frac{i}{n} - \alpha\right)\right\} & i \ge \alpha n. \end{cases}$$

Unfortunately, this modification is not strong enough to give a constant strictly smaller than $1 - 1/e$. The reason is that the function $f$ may have a steep drop in the neighborhood of 0, which leads to negligible $b_i$'s in the above construction.

On the other hand, the failure of the analysis comes from our coarse and brutal relaxation by establishing a single upper bound for all $y_0 < \alpha$. For instance, if the function steeply drops at some $\beta \in [0, \alpha]$, then we could resolve the issue by considering two cases of $y_0 < \beta$ or $y_0 \in [\beta, \alpha)$. Formally, we prove the following lemma that is slightly weaker than (4.1).

▶ **Lemma 14.** *If* Perturbed-Ranking *with perturbation function* $f(x)$ *achieves a competitive ratio of* $\Gamma$ *on AdWords, then*

$$(1 - \Gamma) \cdot f(\alpha) \ge (\Gamma - \alpha) \cdot \int_0^\alpha f(x)\mathrm{d}x + (\Gamma - \beta) \cdot \int_\alpha^1 \min\left\{f(x), \frac{f(\alpha)}{f(\beta)} f(x - \alpha)\right\}\mathrm{d}x, \quad \forall \alpha, \beta \in [0, 1], \alpha \ge \beta. \quad (4.2)$$

**Proof.** We apply the same construction as in Lemma 12 and make the same assumption that $y_i = \frac{i}{n}$ for the simplicity of presentation. We modify the instance by setting the weights $b_i$ differently:

$$\forall 1 \le i \le n, \quad b_i = \begin{cases} \frac{1}{f(\alpha)} \cdot f\left(\frac{i}{n}\right) & i < \alpha n, \\ \min\left\{\frac{1}{f(\alpha)} \cdot f\left(\frac{i}{n}\right), \frac{1}{f(\beta)} \cdot f\left(\frac{i}{n} - \alpha\right)\right\} & i \ge \alpha n. \end{cases}$$

The optimal solution equals

$$\mathrm{OPT} = n + \sum_{i=1}^{n} b_i = n \cdot \left(1 + \frac{1}{f(\alpha)} \int_0^\alpha f(x)\mathrm{d}x + \int_\alpha^1 \min\left\{\frac{f(x)}{f(\alpha)}, \frac{f(x - \alpha)}{f(\beta)}\right\}\mathrm{d}x + o(1)\right). \quad (4.3)$$

Next, we consider the performance of Perturbed-Ranking depending on the value of $y_0$.

**Case 1.** $(y_0 < \beta)$ We use OPT as a trivial upper bound of ALG, i.e., $\mathrm{ALG}(y_0) \le \mathrm{OPT}$.

**Case 2.** $(y_0 \ge \alpha)$ For each online vertex $v_i$, the perturbed weight of $(u_0, v_i)$ is

$$b_i \cdot f(y_0) \le \frac{f(y_0)}{f(\alpha)} \cdot f\left(\frac{i}{n}\right) \le f\left(\frac{i}{n}\right),$$

while the perturbed weight of $(u_i, v_i)$ is $f(y_i) = f\left(\frac{i}{n}\right)$. Therefore, Perturbed-Ranking matches $(u_i, v_i)$ for all $1 \le i \le n$ and we have $\mathrm{ALG}(y_0) = n$.

**Case 3.** $(y_0 \in [\beta, \alpha))$ We prove that the number of vertices matched to $u_0$ is no more than $\alpha n$. This can be similarly argued as follows. For each online vertex $i$ $(i > \alpha n)$, suppose the number of vertices matched to $u_0$ is already $\alpha n$, the perturbed weight for $u_0$ is $f(y_0) \cdot b_i \le \frac{f(y_0)}{f(\beta)} \cdot f\left(\frac{i}{n} - \alpha\right)$, while the perturbed weight for $u_{i-\alpha n}$ is $f\left(\frac{i}{n} - \alpha\right)$. So that $f\left(\frac{i}{n} - \alpha\right) \ge f(y_0) \cdot b_i$ and thus $v_i$ will not choose $u_0$ again. Therefore, as the number of vertices matched to $u_0$ is no more than $\alpha n$, we have

$$\mathrm{ALG} \le n + \sum_{i=1}^{\alpha n} b_i = n \cdot \left(1 + \frac{1}{f(\alpha)} \int_0^{\alpha} f(x)\mathrm{d}x + o(1)\right).$$

Taking expectation over the randomness of $y_0$, we conclude that

$$\mathbb{E}[\mathrm{ALG}] \le n \cdot \left(\frac{\alpha - \beta}{f(\alpha)} \int_0^{\alpha} f(x)\mathrm{d}x + 1 - \beta + o(1)\right) + \beta \cdot \mathrm{OPT}. \tag{4.4}$$

Finally, we conclude the proof by plugging in (4.3) and (4.4) to $\mathbb{E}[\mathrm{ALG}] \ge \Gamma \cdot \mathrm{OPT}$ and letting $n$ goes to infinity. ◀

Recall that the vertex-weighted online bipartite matching problem is a special case of AdWords. We conclude the proof of Theorem 2 by Lemma 11, 14 and the following mathematical fact. We provide the proof of the following lemma in the full version.

▶ **Lemma 15.** *If a perturbation function $f$ and $\Gamma > 0$ satisfy the following conditions:*

$$\left(\alpha + 1 - e^{\alpha - 1} - \Gamma\right) \cdot f(\beta) \ge \left(1 - (1 - \Gamma) \cdot e^{\beta}\right) \cdot \int_0^{\alpha} f(x)\mathrm{d}x, \quad \forall \alpha, \beta \in [0, 1], \tag{4.5}$$

$$(1 - \Gamma) f(\alpha) \ge (\Gamma - \alpha) \int_0^{\alpha} f(x)\mathrm{d}x + (\Gamma - \beta) \int_{\alpha}^{1} \min\left\{f(x), \frac{f(\alpha)}{f(\beta)} f(x - \alpha)\right\}\mathrm{d}x, \quad \forall \alpha, \beta \in [0, 1], \alpha \ge \beta, \tag{4.6}$$

*then* $\Gamma < 1 - 1/e - 0.0003$.

# Tight Bounds for Quantum Phase Estimation and Related Problems

**Nikhil S. Mande**

## Abstract

Phase estimation, due to Kitaev [arXiv'95], is one of the most fundamental subroutines in quantum computing, used in Shor's factoring algorithm, optimization algorithms, quantum chemistry algorithms, and many others. In the basic scenario, one is given black-box access to a unitary $U$, and an eigenstate $|\psi\rangle$ of $U$ with unknown eigenvalue $e^{i\theta}$, and the task is to estimate the eigenphase $\theta$ within $\pm\delta$, with high probability. The repeated application of $U$ and $U^{-1}$ is typically the most expensive part of phase estimation, so for us the *cost* of an algorithm will be that number of applications.

Motivated by the "guided Hamiltonian problem" in quantum chemistry, we tightly characterize the cost of several variants of phase estimation where we are no longer given an arbitrary eigenstate, but are required to estimate the *maximum* eigenphase of $U$, aided by *advice* in the form of states (or a unitary preparing those states) which are promised to have at least a certain overlap $\gamma$ with the top eigenspace. We give algorithms and matching lower bounds (up to logarithmic factors) for all ranges of parameters. We show a crossover point below which advice is not helpful: $o(1/\gamma^2)$ copies of the advice state (or $o(1/\gamma)$ applications of an advice-preparing unitary) are not significantly better than having no advice at all. We also show that having knowledge of the eigenbasis of $U$ does not significantly reduce cost. Our upper bounds use the subroutine of *generalized maximum-finding* of van Apeldoorn, Gilyén, Gribling, and de Wolf [Quantum'20], the state-based Hamiltonian simulation of Lloyd, Mohseni, and Rebentrost [Nature Physics'13], and several other techniques. Our lower bounds follow by reductions from a *fractional* version of the Boolean OR function *with advice*, which we lower bound by a simple modification of the adversary method of Ambainis [JCSS'02]. As an immediate consequence we also obtain a lower bound on the complexity of the Unitary recurrence time problem, matching an upper bound of She and Yuen [ITCS'23] and resolving an open question posed by them.

Lastly, we study how efficiently one can reduce the error probability in the basic phase-estimation scenario. We show that an algorithm solving phase estimation to precision $\delta$ with error probability at most $\varepsilon$ must have cost $\Omega\left(\frac{1}{\delta}\log\frac{1}{\epsilon}\right)$, matching the obvious way to error-reduce the basic constant-error-probability phase estimation algorithm. This contrasts with some other scenarios in quantum computing (e.g. search) where error-reduction costs only a factor $O(\sqrt{\log(1/\epsilon)})$. Our lower bound technique uses a variant of the polynomial method with trigonometric polynomials.

# 1 Introduction

## 1.1 Phase estimation

Kitaev [19] gave an elegant and efficient quantum algorithm for the task of *phase estimation* nearly 30 years ago. The task is easy to state: given black-box access to a unitary and an eigenstate, estimate the phase of the associated eigenvalue. Roughly speaking, the standard algorithm for this task sets up a superposition involving many different powers of the unitary to extract many different powers of the eigenvalue, and then uses a quantum Fourier transform to turn that into an estimate of the eigenphase.[1] Many of the most prominent quantum algorithms can either be phrased as phase estimation, or use phase estimation as a crucial subroutine. Some examples are Shor's period-finding algorithm [30] as presented in [10]; approximate counting [6] can be done using phase estimation on the unitary of one iteration of Grover's search algorithm [16], which also recovers the $O(\sqrt{N})$ complexity for searching an $N$-element unordered search space; the HHL algorithm for solving linear systems of equations estimates eigenvalues in order to invert them [17]. Applications of phase estimation in quantum chemistry are also very prominent, as discussed below.

More precisely, we are given black-box access to an $N$-dimensional unitary $U$ (and a controlled version thereof) and a state $|\psi\rangle$ that satisfies $U|\psi\rangle = e^{i\theta}|\psi\rangle$. Our goal is to output (with probability at least $2/3$) a $\tilde{\theta} \in [0, 2\pi)$ such that $|\tilde{\theta} - \theta|$ is at most $\delta$ in $\mathbb{R}$ mod $2\pi$. In the basic scenario we are given access to one copy of $|\psi\rangle$, and are allowed to apply $U$ and its inverse. Since the repeated applications of $U$ and $U^{-1}$ are typically the most expensive parts of algorithms for phase estimation, the *cost* we wish to minimize is the number of applications of $U$ and $U^{-1}$. We are additionally allowed arbitrary unitaries that do not depend on $U$, at no cost. Kitaev's algorithm has cost $O(1/\delta)$.

## 1.2 Phase estimation with advice

One of the core problems in quantum chemistry is the following: given a classical description of some Hamiltonian $H$ (for instance an "electronic structure" Hamiltonian in the form of a small number of local terms), estimate its *ground state energy*, which is its smallest eigenvalue. If $H$ is normalized such that its eigenvalues are all in $[0, 2\pi)$ and we define the unitary $U = e^{iH}$ (which has the same eigenvectors as $H$, with an eigenvalue $\lambda$ of $H$ becoming the eigenvalue $e^{i\lambda}$ for $U$), then finding the ground state energy of $H$ is equivalent to finding the smallest eigenphase of $U$. If we are additionally given a *ground state* $|\psi\rangle$ (i.e., an eigenstate corresponding to the smallest eigenphase), then phase estimation is tailor-made to estimate the ground state energy. However, in quantum chemistry it is typically hard to prepare the ground state of $H$, or even something close to it. What can sometimes be done is the preparation of some quantum state that has some non-negligible "overlap" $\gamma$ with the ground space, for instance the "Hartree-Fock state". We will call such a state an *advice state*. In the complexity-theoretic context, this problem of ground state estimation for a local Hamiltonian given an advice state, is known as the "guided local Hamiltonian problem", and has received quite some attention recently [13, 8, 12, 32] because of its connections with quantum chemistry as well as deep complexity questions such as the PCP conjecture. These complexity-theoretic results typically focus on the BQP-completeness of certain special cases

[1] An added advantage of the standard algorithm for phase estimation is that it can also work with a quantum Fourier transform that is correct on average rather than in the worst case [23]. However, there are also approaches to phase estimation that avoid the QFT altogether, see e.g. [28].

of the guided local Hamiltonian problem, and don't care about polynomial overheads of the cost in the number of qubits $\log N$ and in the parameters $\delta$ and $\gamma$. In contrast, we care here about getting essentially optimal bounds on the cost of phase estimation in various scenarios.

To be more precise, suppose our input unitary is $U = \sum_{j=0}^{N-1} e^{i\theta_j}|u_j\rangle\langle u_j|$ with each $\theta_j \in [0, 2\pi)$. Let $\theta_{\max} = \max_{j\in\{0,1,\ldots,N-1\}} \theta_j$ denote the maximum eigenphase, and let $S$ denote the space spanned by all eigenstates with eigenphase $\theta_{\max}$, i.e., the "top eigenspace". Advice is given in the form of a state $|\alpha\rangle$ whose projection on $S$ has squared norm at least $\gamma^2$: $\|P_S|\alpha\rangle\|^2 \geq \gamma^2$. Note that if $S$ is spanned by a single eigenstate $|u_{\max}\rangle$, then this condition is the same as $|\langle\alpha|u_{\max}\rangle| \geq \gamma$, which is why we call $\gamma$ the *overlap* of the advice state with the target eigenspace. The task $\mathsf{maxQPE}_{N,\delta}$ is to output, with probability at least 2/3, a $\delta$-precise (in $\mathbb{R}$ mod $2\pi$) estimate of $\theta_{\max}$.[2]

We will distinguish between the setting where the advice is given in the form of a number of copies of the advice state $|\alpha\rangle$, or the potentially more powerful setting where we can apply (multiple times) a *unitary* $A$ that prepares $|\alpha\rangle$ from some easy-to-prepare initial state, say $|0\rangle$. We would have such a unitary $A$ for instance if we have a procedure to prepare $|\alpha\rangle$ ourselves in the lab. We can also distinguish between the situation where the eigenbasis $|u_0\rangle, \ldots, |u_N\rangle$ of $U$ is known (say, the computational basis where $|u_j\rangle = |j\rangle$) and the potentially harder situation where the eigenbasis is unknown. These two binary distinctions give us four different settings. For each of these settings we determine essentially optimal bounds on the cost of phase estimation, summarized in Table 1.

**Table 1** Our results for the cost of $\mathsf{maxQPE}_{N,\delta}$. We assume $\gamma > 1/\sqrt{N}$ since a random state has overlap $1/\sqrt{N}$ with the target eigenspace with high probability, and such a state can be prepared at no cost. The "Basis" column indicates whether the eigenbasis of $U$ is known; "Access to advice" indicates whether we get copies of the advice state or a unitary to prepare it; "Number of accesses" refers to the number of accesses to advice that we have. The last two columns show our bounds with references to the lemmas where they are stated and proved. The $\widetilde{O}(\cdot)$ in the upper-bound column hides a factor $\log N$ for the odd-numbered rows, and $\log(1/\gamma)$ for the even-numbered rows.

| Row | Basis | Access to advice | Number of accesses | Upper bound | Lower bound |
|---|---|---|---|---|---|
| 1 | known | state | $o\left(\frac{1}{\gamma^2}\right)$ | $\widetilde{O}\left(\frac{\sqrt{N}}{\delta}\right)$, Lemma 20 | $\Omega\left(\frac{\sqrt{N}}{\delta}\right)$, Lemma 13 |
| 2 | known | state | $\Omega\left(\frac{1}{\gamma^2}\right)$ | $\widetilde{O}\left(\frac{1}{\gamma\delta}\right)$, Lemma 22 | $\Omega\left(\frac{1}{\gamma\delta}\right)$, Lemma 14 |
| 3 | unknown | state | $o\left(\frac{1}{\gamma^2}\right)$ | $\widetilde{O}\left(\frac{\sqrt{N}}{\delta}\right)$, Lemma 20 | $\Omega\left(\frac{\sqrt{N}}{\delta}\right)$, Lemma 13 |
| 4 | unknown | state | $\Omega\left(\frac{1}{\gamma^2}\right)$ | $\widetilde{O}\left(\frac{1}{\gamma\delta}\right)$, Lemma 22 | $\Omega\left(\frac{1}{\gamma\delta}\right)$, Lemma 14 |
| 5 | known | unitary | $o\left(\frac{1}{\gamma}\right)$ | $\widetilde{O}\left(\frac{\sqrt{N}}{\delta}\right)$, Lemma 20 | $\Omega\left(\frac{\sqrt{N}}{\delta}\right)$, Lemma 15 |
| 6 | known | unitary | $\Omega\left(\frac{1}{\gamma}\right)$ | $\widetilde{O}\left(\frac{1}{\gamma\delta}\right)$, Lemma 21 | $\Omega\left(\frac{1}{\gamma\delta}\right)$, Lemma 16 |
| 7 | unknown | unitary | $o\left(\frac{1}{\gamma}\right)$ | $\widetilde{O}\left(\frac{\sqrt{N}}{\delta}\right)$, Lemma 20 | $\Omega\left(\frac{\sqrt{N}}{\delta}\right)$, Lemma 15 |
| 8 | unknown | unitary | $\Omega\left(\frac{1}{\gamma}\right)$ | $\widetilde{O}\left(\frac{1}{\gamma\delta}\right)$, Lemma 21 | $\Omega\left(\frac{1}{\gamma\delta}\right)$, Lemma 16 |

Let us highlight some interesting consequences of our results. First, a little bit of advice is no better than no advice: the upper bounds in the odd-numbered rows of Table 1 are actually obtained by algorithms that don't use the given advice ($o(1/\gamma^2)$ copies of $|\alpha\rangle$ or $o(1/\gamma)$ applications of $A$ and $A^{-1}$) at all, yet their costs essentially match the lower bounds for algorithms that use advice.

[2] It doesn't really matter, but we focus on the *maximum* rather than minimum eigenphase of $U$ because eigenphase 0 (i.e., eigenvalue 1) is a natural baseline, and we are looking for the eigenphase furthest away from this baseline.

We remark here that the same proofs yield the same asymptotic lower bounds for algorithms with access to at most $c/\gamma^2$ advice states for Theorem 12, Rows 1 and 3 of Table 1, and for algorithms with access to at most $c/\gamma$ advice unitaries for Rows 5 and 7 of Table 1, where $c$ is a suitably small constant. We chose to use $o(\cdot)$ to avoid clutter.

A second interesting consequence is that too much advice is no better than a moderate amount of advice: the upper bounds in Rows 2 and 4 use $O(1/\gamma^2)$ advice states, and the upper bounds in Rows 6 and 8 use $O(1/\gamma)$ advice unitaries, and using more advice does not reduce the cost further. Thirdly, it turns out that knowledge of the eigenbasis of $U$ doesn't really help in reducing the cost: the costs in row 1 and row 3 are the same, and similarly for rows 2 vs. 4, 5 vs. 7 and 6 vs. 8.

Our upper bounds use the subroutine of *generalized maximum-finding* of van Apeldoorn, Gilyén, Gribling, and de Wolf [2] which allows us to find maximum values in the second register of a two-register superposition even when the first of these two registers has an unknown basis. We derive the upper bound of row 4 from the upper bound of row 8 by using roughly $1/\gamma$ copies of $|\alpha\rangle$ to simulate one reflection around the state $|\alpha\rangle = A|0\rangle$, using the techniques of Lloyd, Mohseni, and Rebentrost [24].[3] Our lower bounds follow from reductions from a fractional version of the Boolean OR function with advice. We show a lower bound for this by a simple modification of the adversary method [1] taking into account the input-dependent advice in the initial state.

### Comparison with related work

Some of the results in our table were already (partially) known. A cost-$\widetilde{O}(\sqrt{N}/\delta)$ algorithm for the adviceless setting with unknown eigenbasis (implying the upper bounds of rows 1, 3, 5, 7) was originally due to Poulin and Wocjan [27], and subsequently improved in the log-factors by van Apeldoorn et al. [2]; the latter algorithm is basically our proof of Lemma 20. Lin and Tong [21] (improving upon [11]) studied the situation with an advice-preparing unitary. Their setting is slightly different from ours, they focus on preparing the ground state[4] of a given Hamiltonian without a known bound on its spectrum, but [21, Theorem 8] implies a cost-$O(\log(1/\gamma)\log(1/\delta)\log\log(1/\delta)/\gamma\delta)$ algorithm for our row 8. Their follow-up paper [22] further reduces the number of auxiliary qubits with a view to near-term implementation, but does not reduce the cost further. Our cost-$O(\log(1/\gamma)/\gamma\delta)$ algorithm is slightly better in the log-factors than theirs, and uses quite different techniques ([21] uses quantum singular value transformation [15]).

On the lower-bound side, $\Omega(1/\delta)$ for the cost of phase estimation has long been known to hold when the success probability is required to be a constant, this follows for instance from the approximate counting lower bound of Nayak and Wu [26] (see also [4]). Lin and Tong [21, Theorem 10] proved lower bounds of $\Omega(1/\gamma)$ and $\Omega(1/\delta)$ on the cost for the setting with known eigenbasis and advice unitary (our row 6, and hence also row 8). This is subsumed by our stronger (and essentially optimal) $\Omega(1/\gamma\delta)$ lower bound in row 6. As far as we are aware, ours is the first paper to systematically tie together these different results and to complete the table with tight upper and lower bounds for the cost in all 8 cases.

---

[3] We only stated the cost (number of applications of $U$ and $U^{-1}$) of our algorithms here in the upper-bound column of Table 1. However, one can verify that the gate-complexities of our algorithms are only worse by log-factors: they use three main subroutines, all of which have only small overheads in gate-complexity. These subroutines are basic quantum phase estimation [19], generalized maximum-finding [2], and the simulation of a unitary reflecting about the state $|\alpha\rangle$ given a small number of copies of $|\alpha\rangle$.

[4] Because generalized maximum-finding (Lemma 17) actually outputs a state in addition to an estimate, our algorithms can be modified to also output a state that is close to the top eigenspace of $U$.

Let us also mention some recent work that is not directly covered by our results. First, lower bounds for the slightly unusual small-success-probability regime were recently studied by Lin [20]. Second, there has been work to make phase estimation more efficient in the important special case where the unitary $U = e^{iH}$ is induced by a Hamiltonian $H$ given classically as the sum of relatively simple terms, when the cost of phase estimation interacts with the cost of Hamiltonian simulation. See for instance the recent paper by Wan, Berta, and Campbell [31] and references therein.

#### Application

She and Yuen [29, Theorems 1.6 and 1.7] studied the $(t, \delta)$-*Unitary recurrence time problem*, which is to distinguish whether an input unitary $U$ satisfies $U^t = I$ or $\|U^t - I\| \geq \delta$, promised that one of these is the case (see Definition 7). They proved non-matching upper and lower bounds for the cost of quantum algorithms for this problem (see Theorem 8 in this paper). As an immediate application of our lower bound for fractional OR with advice, we also obtain improved lower bounds for the unitary recurrence time problem that match the upper bound of She and Yuen and answer one of their open problems [29, Section 2].

▶ **Theorem 1** (Lower bound for Unitary recurrence time). *Any quantum algorithm solving the $(t, \delta)$-recurrence time problem for $N$-dimensional unitaries has cost $\Omega(t\sqrt{N}/\delta)$.*

Interestingly, our lower bound uses the adversary method as opposed to their usage of the polynomial method.

### 1.3 Phase estimation with small error probability

For our results in this subsection we revert to the original scenario of phase estimation, where an algorithm is given the actual eigenstate $|\psi\rangle$ as input and the goal is to estimate its eigenphase $\theta$. However, we now consider the regime where we want small error probability $\varepsilon$ rather than constant error probability $1/3$. Let $\mathsf{QPE}_{N,\delta,\varepsilon}$ denote the task of computing, with error probability $\leq \varepsilon$, a $\delta$-approximation of $\theta$. By repeating Kitaev's $O(1/\delta)$-cost phase estimation algorithm $O(\log(1/\varepsilon))$ times and taking the median of the answers, we have the following $\varepsilon$-dependent upper bound.

▶ **Theorem 2** (Kitaev + standard error-reduction). *For all integers $N \geq 2$ and all $\varepsilon \in (0, 1/2), \delta \in [0, 2\pi)$, there exists an algorithm that solves $\mathsf{QPE}_{N,\delta,\varepsilon}$ with cost $O\left(\frac{1}{\delta}\log\frac{1}{\varepsilon}\right)$.*

Grover's algorithm [16] can compute the $\mathsf{OR}_N$ function with error probability $\leq 1/3$ using $O(\sqrt{N})$ queries to its $N$ input bits. Interestingly, there exists an $\varepsilon$-error quantum algorithm for $\mathsf{OR}_N$ with only $O(\sqrt{N\log(1/\varepsilon)})$ queries, which is asymptotically optimal [7], and similarly one can reduce error from $1/3$ to $\varepsilon$ for all symmetric Boolean functions at the expense of only a factor $\sqrt{\log(1/\varepsilon)}$ in the query complexity [33]. This is a speed-up over the naive $O(\log(1/\varepsilon))$ multiplicative overhead. Since optimal quantum algorithms with error probability $1/3$ for $\mathsf{OR}_N$ and for all symmetric functions can be derived from phase estimation, one may ask if one can achieve such an efficient error-reduction for quantum phase estimation as well: is there an algorithm for $\mathsf{QPE}_{N,\delta,\varepsilon}$ of cost $O\left(\frac{1}{\delta}\sqrt{\log(1/\varepsilon)}\right)$? We answer this in the negative, showing Theorem 2 is tight.

▶ **Theorem 3.** *For integers $N \geq 2$ and $\varepsilon, \delta \in (0, 1/2)$,*[5] *every algorithm that solves* $\mathsf{QPE}_{N,\delta,\varepsilon}$ *has cost* $\Omega\left(\frac{1}{\delta}\log\frac{1}{\varepsilon}\right)$.

In particular, this means that the optimal complexity of $\mathsf{OR}_N$ with small error probability $\varepsilon$ of [7] can*not* be derived from a phase estimation routine, in contrast to the case of $\mathsf{OR}_N$ (and search) with constant error probability. To show Theorem 3 we first argue that a cost-$C$ algorithm for $\mathsf{QPE}_{N,\delta,\varepsilon}$ gives us a cost-$C$ algorithm that distinguishes $U = I$ versus $U = I - (1 - e^{i\theta})|0\rangle\langle 0|$ where $\theta \notin [-3\delta, 3\delta] \bmod 2\pi$. We then note that the acceptance probability of such an algorithm can be written as a degree-$2C$ *trigonometric* polynomial in $\theta$, and invoke a known upper bound on the growth of such trigonometric polynomials in order to lower bound their degree.

## 2 Preliminaries

We state the required preliminaries in this section. All logarithms are taken base 2. For a positive integer $N$, $U(N)$ denotes the space of $N$-dimensional unitaries, and $I$ denote the $N$-dimensional Identity matrix (we drop the subscript if the dimension is clear from context).

For a positive integer $N \geq 2$ and a value $\theta \in [0, 2\pi)$, define the $N$-dimensional unitary $U_\theta$ as $U_\theta = I - (1 - e^{i\theta})|0\rangle\langle 0|$. In other words, $U_\theta$ is the diagonal matrix with all 1's except the first entry, which is $e^{i\theta}$. For an integer $j \in \{0, 1, \ldots, N-1\}$ and $\delta \in [0, 2\pi)$, define $M_{j,\delta} = I - (1 - e^{i\delta})|j\rangle\langle j|$.

### 2.1 Model of computation

Here we give a description of our model of computation for all tasks considered in this paper. All problems considered in this paper have the following properties:

- **Input:** An $N$-dimensional unitary $U$. We have access to the input as described below.
- **State space:** The state space of an algorithm comprises two registers: the first register is $N$-dimensional, and the second register is an arbitrarily large workspace.
- **Access to input and allowed operations:** An algorithm $\mathcal{A}$ may apply $U$ and $U^{-1}$ to the first register, and unitaries independent of $U$ to the whole space. It performs a POVM at the end to determine the classical output.
- **Cost of an algorithm:** Total number of applications of $U$ and $U^{-1}$.

Depending on the specific problem under consideration, the following properties are variable.

- **Initial state:** The initial state is assumed to be $|0\rangle|0\rangle$ unless mentioned otherwise.
- **Input promise:** The subset of $U(N)$ (possibly the full set) from which the input is taken.
- **Output:** The output requirement.
- **Advice:** We may be given access to a specific number of "advice states" $|\alpha\rangle$, or access to a specific number of applications of a unitary $A$ that prepares an advice state (e.g., $A|0\rangle = |\alpha\rangle$).

### 2.2 Problems of interest

We list our problems of interest here. All problems fit in the framework of the previous subsection, so we skip descriptions of the input, access to the input and allowed operations, and the workspace.

[5] We require $\delta < 2\pi/5$ for our proof of Claim 23 to work. This requirement can be strengthened a little to $\delta < 2\pi/3$, but we state our theorem with $\delta < 1/2$ for ease of notation.

▶ **Definition 4** (Phase Estimation). *Let $N \geq 2$ be an integer and $\varepsilon, \delta > 0$. The task* $\mathsf{QPE}_{N,\delta,\varepsilon}$ *is:*

- ***Advice:*** *We are given a single state $|\psi\rangle$ (in other words, our starting state is $|\psi\rangle|0\rangle$) with the promise that $U|\psi\rangle = e^{i\theta}|\psi\rangle$.*
- ***Output:*** *With probability at least $1-\varepsilon$, output $\tilde{\theta} \in [0, 2\pi)$ such that $|\tilde{\theta} - \theta| \leq \delta \mod 2\pi$.*

▶ **Definition 5.** *Let $N \geq 2$ be an integer and $\varepsilon, \delta \in (0,1)$. The task* $\mathsf{dist}_{N,\delta,\varepsilon}$ *is:*

- ***Input promise:*** *$U \in \{I, \{U_\theta : \theta \notin [\delta, \delta] \mod 2\pi\}\}$.*
- ***Output:*** *With probability at least $1-\varepsilon$, output 1 if $U = I$, and output 0 otherwise.*

We next define the natural variant of phase estimation that we consider when an algorithm need not be given a state from the target eigenspace.

▶ **Definition 6** (Maximum phase estimation). *Let $N \geq 2$ be an integer and $\delta > 0$. The task* $\mathsf{maxQPE}_{N,\delta}$ *is:*

- ***Input promise:*** *We consider two cases: one where the eigenbasis of $U$ is known, and the other where it is unknown. In the former case, we may assume $U = \sum_{j=0}^{N-1} e^{i\theta_j}|j\rangle\langle j|$. Define $\theta_{\max} = \max_{j \in \{0,1,\ldots,N-1\}} \theta_j \in [0, 2\pi)$.*
- ***Advice:*** *We consider two cases:*
  - *In one case we are given access to advice in the form of a state $|\alpha\rangle$ such that $\|P_S|\alpha\rangle\|^2 \geq \gamma^2$, where $P_S$ denotes the projection on $S$, the space of all eigenstates with eigenphase $\theta_{\max}$. If $S$ is spanned by one $|u_{\max}\rangle$, this requirement is the same as $|\langle\alpha|u_{\max}\rangle| \geq \gamma$.*
  - *In the other case, we have black-box access to a unitary $A$ that prepares such a state $|\alpha\rangle$. We can apply $A$ and $A^{-1}$. As before, $\gamma$ is the* overlap *of $|\alpha\rangle$ with the target eigenspace.*
- ***Number of accesses to advice:*** *We either have 'few' accesses to advice as defined above ($o(1/\gamma^2)$ advice states or $o(1/\gamma)$ advice unitaries), or 'many' accesses to advice ($\Omega(1/\gamma^2)$ advice states or $\Omega(1/\gamma)$ advice unitaries).*
- ***Output:*** *With probability at least $2/3$, output a value in $[\theta_{\max} - \delta, \theta_{\max} + \delta] \mod 2\pi$.*

▶ **Definition 7** (Unitary recurrence time, [29, Definition 1.5]). *For integers $N \geq 2, t \geq 1$ and $\delta \in (0,1)$, the $(t,\delta)$-recurrence time problem is:*

- ***Input promise:*** *Either $U = I$, or $\|U^t - I\| \geq \delta$ in spectral norm.*
- ***Output:*** *With probability at least $2/3$: output 1 if $U = I$, and 0 otherwise.*

The following are the non-matching upper and lower bounds for this problem of She and Yuen [29].

▶ **Theorem 8** ([29, Theorems 1.6 and 1.7]). *Let $\delta \leq \frac{1}{2\pi}$. Every quantum algorithm solving the $(t,\delta)$-recurrence time problem for $d$-dimensional unitaries has cost $\Omega\left(\max\left(t/\delta, \sqrt{d}\right)\right)$. The $(t,\delta)$-recurrence time problem can be solved with cost $O(t\sqrt{d}/\delta)$.*

## 2.3 Trigonometric polynomials and their growth

▶ **Definition 9** (Trigonometric Polynomials). *A function $p : \mathbb{R} \to$ is said to be a* trigonometric polynomial *of degree $d$ if there exist complex numbers $\{a_k : k \in \{-d, \ldots, d\}\}$ such that for all $\theta \in \mathbb{R}$,*

$$p(\theta) = \sum_{k=-d}^{d} a_k e^{ik\theta}.$$

▶ **Theorem 10** ([5, Theorem 5.1.2]). *Let $t$ be a degree-$n$ real-valued trigonometric polynomial and $s \in (0, \pi/2]$ be such that $\mu(\{\theta \in [-\pi, \pi) : |t(\theta)| \leq 1\}) \geq 2\pi - s$, where $\mu$ denotes the Lebesgue measure on $\mathbb{R}$. Then, $\sup_{x \in \mathbb{R}} |t(x)| \leq \exp(4ns)$.*

## 3 Lower bounds for maximum phase estimation and Unitary recurrence time

In this section we show lower bounds on the quantum complexity of maximum phase estimation obtained by varying all its parameters (see Section 2.1 and Definition 6). In this section and the next, we refer to the row numbers of Table 1 when stating and proving our bounds.

Recall that for an integer $j \in \{0, 1, \ldots, N-1\}$ and $\delta \in [0, 2\pi)$ we define $M_{j,\delta} = I - (1 - e^{i\delta})|j\rangle\langle j|$. Our lower bounds will be by reduction from the following "Fractional OR with advice" problem, which fits in the framework of the model described in Section 2.1.

▶ **Definition 11** (Fractional OR with advice). *Let $N \geq 2$ be integer, $\delta > 0$. The task $\mathsf{frOR}_{N,\delta,t}$ is:*

- ***Input promise:*** *$U \in \{I, \{M_{j,\delta} : j \in \{1, 2, \ldots, N-1\}\}\}$.*
- ***Advice:*** *When $U = I$ we are given $t$ copies of $|0\rangle$ as advice. When $U = M_{j,\delta}$, we are given $t$ copies of the state $\gamma|j\rangle + \sqrt{1-\gamma^2}|0\rangle$, i.e., part of our starting state is $(\gamma|j\rangle + \sqrt{1-\gamma^2}|0\rangle)^{\otimes t}$.*
- ***Output:*** *With probability at least $2/3$: output 1 if $U = I$, and 0 if $U \neq I$.*

We first show a lower bound on the cost of computing $\mathsf{frOR}_{N,\delta,t}$ when $t = o(1/\gamma^2)$. All of our lower bounds in Table 1 as well as our lower bound for the Unitary recurrence time problem will use this lower bound. We refer the reader to the full version of the paper [25, Appendix A] for the proof. The proof follows along the same lines as Ambainis' adversary lower bound [1, Theorem 4.1] of $\Omega(\sqrt{N})$ queries for the $N$-bit Search problem, but now we additionally take into account the initial advice states and the fact that our input unitaries are only *fractional* versions of phase queries.

▶ **Theorem 12.** *For an integer $N \geq 2$, real numbers $\gamma \geq 1/\sqrt{N}$, $\delta \in [0, \pi]$ and $t = o(1/\gamma^2)$, every algorithm solving $\mathsf{frOR}_{N,\delta,t}$ has cost $\Omega(\sqrt{N}/\delta)$.*

▶ **Lemma 13** (Lower bound for Rows 1,3). *Row 1 (and hence Row 3) has a lower bound of $\Omega(\sqrt{N}/\delta)$.*

**Proof.** A cost-$C$ algorithm $\mathcal{A}$ for $\mathsf{maxQPE}_{N,\delta}$ with $t$ advice states and known eigenbasis of $U$ immediately yields a cost-$C$ algorithm $\mathcal{A}'$ for $\mathsf{frOR}_{N,3\delta,t}$: run $\mathcal{A}$ on the input unitary, output 1 if the output phase is in $[-\delta, \delta]$ modulo $2\pi$, and output 0 otherwise. When $U = I$, the correctness of $\mathcal{A}$ guarantees that with probability at least $2/3$, the value output by $\mathcal{A}$ is in $[-\delta, \delta] \mod 2\pi$. When $U = M_{j,3\delta}$, the correctness of $\mathcal{A}$ guarantees that with probability at least $2/3$, the value output by $\mathcal{A}$ is in $[2\delta, 4\delta]$. For $\delta < 2\pi/5$, we have $[-\delta, \delta] \mod 2\pi \cap [2\delta, 4\delta] \mod 2\pi = \emptyset$. Thus, $\mathcal{A}'$ solves $\mathsf{frOR}_{N,3\delta,t}$ and has cost $C$. Theorem 12 yields the bound $C = \Omega\left(\sqrt{N}/\delta\right)$ when $t = o(1/\gamma^2)$, giving the desired result. ◀

▶ **Lemma 14** (Lower bound for Rows 2,4). *Row 2 (and hence Row 4) has a lower bound of $\Omega(1/\gamma\delta)$.*

**Proof.** We prove the required lower bound for $\mathsf{maxQPE}_{N,\delta}$ with inputs satisfying the promise that $U \in \left\{I_N, \left\{M_{j,3\delta} : j \in \left\{1, 2, \ldots, 1/\gamma^2 - 1\right\}\right\}\right\}$. Because of this assumption, we may take the uniform superposition over the first $1/\gamma^2$ computational basis states as our advice state:

the algorithm should work with such an advice state, since it has overlap $\gamma$ with the top eigenspace for each of the possible $U$. However, an algorithm can prepare such advice states at no cost, so we may assume that the algorithm has no access to advice at all. As in the previous proof, this gives an algorithm of the same cost for $\mathsf{frOR}_{1/\gamma^2,3\delta,0}$ (ignoring all other dimensions). Theorem 12 with $N = 1/\gamma^2$ and $t = 0$ yields the required lower bound of $\Omega(1/\gamma\delta)$. ◀

▶ **Lemma 15** (Lower bound for Rows 5,7). *Row 5 (and hence Row 7) has a lower bound of* $\Omega(\sqrt{N}/\delta)$.

**Proof.** Towards the required lower bound, consider a cost-$C$ algorithm $\mathcal{A}$ solving $\mathsf{maxQPE}_{N,\delta}$ with inputs satisfying the promise $U \in \{I_N, \{M_{j,3\delta} : j \in \{1,2,\ldots,N-1\}\}\}$, and with $t = o(1/\gamma)$ accesses to a unitary that prepares an advice state that has overlap at least $\gamma$ with the target eigenspace. We want to construct an algorithm $\mathcal{A}'$ for $\mathsf{maxQPE}_{N,\delta}$ with the same promised inputs that uses *no* advice, and with cost not much larger than that of $\mathcal{A}$. Note that we may assume $\gamma = o(1)$, since otherwise $t = 0$, so then $\mathcal{A}$ itself already uses no advice.

We first show how an algorithm can itself implement a good-enough advice unitary $A$ quite cheaply. Assuming without loss of generality that $1/3\delta$ is an integer, $U^{1/3\delta}$ is actually a "phase query": if $U = M_{j,3\delta}$, then we have $U^{1/3\delta} = I - 2|j\rangle\langle j|$, which is the diagonal matrix with 1's everywhere except a $-1$ in the $j$th entry; and if $U = I$ then $U^{1/3\delta} = I$. Thus $A$ can start by mapping $|0\rangle$ to a uniform superposition over all indices, and then use Grover's algorithm with $U^{1/3\delta}$ as our query operator to amplify the amplitude of $|j\rangle$ to $\geq \gamma$. We know that $O(\gamma\sqrt{N})$ "Grover iterations" suffice for this (see, for example, [34, Section 7.2] for details). Each Grover iteration would use one phase-query $U^{1/3\delta}$, so the overall cost (number of applications of $U$ and $U^{-1}$) of this advice unitary is $O(\gamma\sqrt{N}/\delta)$. If $U = I$, the state just remains the uniform superposition.

We now have all components to describe $\mathcal{A}'$: Run $\mathcal{A}$, and whenever $\mathcal{A}$ invokes an advice unitary, use the above $A$. Since $\mathcal{A}$ uses at most $t$ advice unitaries, the cost of $\mathcal{A}'$ is at most $C + t \cdot O(\gamma\sqrt{N}/\delta)$. Note that $\mathcal{A}'$ uses no advice at all anymore, and solves $\mathsf{maxQPE}_{N,\delta}$ under the promise that the input unitary satisfies $U \in \{I_N, \{M_{j,3\delta} : j \in \{1,2,\ldots,N-1\}\}\}$. Again, this immediately yields an algorithm of the same cost for $\mathsf{frOR}_{N,3\delta,0}$ as in the previous two proofs. Theorem 12 now implies

$$C + O(t\gamma\sqrt{N}/\delta) = \Omega(\sqrt{N}/\delta),$$

and hence $C = \Omega(\sqrt{N}/\delta)$ since $t = o(1/\gamma)$ ($t \leq c/\gamma$ for sufficiently small constant $c$ also suffices). ◀

▶ **Lemma 16** (Lower bound for Rows 6,8). *Row 6 (and hence Row 8) has a lower bound of* $\Omega\left(1/\gamma\delta\right)$.

**Proof.** Just as in the proof of Lemma 14, we may assume $N = 1/\gamma^2$ by only allowing input unitaries of the form $U \in \left\{I_N, \left\{M_{j,3\delta} : j \in \left\{1,2,\ldots,1/\gamma^2 - 1\right\}\right\}\right\}$. With this assumption, we may assume that we have no access to advice (i.e., $t = 0$) since an algorithm can prepare a good-enough advice state (namely the uniform superposition over all $1/\gamma^2$ basis states) at no cost. This yields the required lower bound of $\Omega(1/\gamma\delta)$ by Lemma 15. ◀

Finally we prove an optimal lower bound for the Unitary recurrence time problem, matching She and Yuen's upper bound (Theorem 8) and resolving one of their open problems [29, Section 2].

**Proof of Theorem 1.** Consider an algorithm $\mathcal{A}$ solving the $(t,\delta)$-recurrence time problem. Restrict to inputs of the form $U \in \{I_N, \{M_{j,3\delta/t} : j \in \{1,2,\ldots,N-1\}\}\}$. When $U = I$ we have $U^t = I$. When $U = M_{j,3\delta/t}$, we have $\|U^t - I\| = |1 - e^{3i\delta}| \geq \delta$ for all $\delta \in [0,1]$. Thus, $\mathcal{A}$ solves $\mathsf{frOR}_{N,3\delta/t,0}$. Theorem 12 yields the required lower bound of $\Omega(t\sqrt{N}/\delta)$. ◀

## 4 Upper bounds for maximum phase estimation

In this section we show upper bounds on the quantum complexity of our 8 variants of maximum phase estimation (see Section 2.1, Definition 6 and Table 1). We require the following generalized maximum-finding procedure, adapted from [2, Lemma 48]; we changed their wording a bit and modified it from minimum-finding to maximum-finding.

▶ **Lemma 17** ([2, Lemma 48]). *There exists a quantum algorithm $\mathcal{M}$ and constant $C > 0$ such that the following holds. Suppose we have a $q$-qubit unitary $V$ such that*

$$V|0\rangle = \sum_{k=0}^{K-1} |\psi_k\rangle|x_k\rangle,$$

*where $x_0 > x_1 > \cdots > x_{K-1}$ are distinct real numbers (written down in finite precision), and the $|\psi_k\rangle$ are unnormalized states. Let $X$ be the random variable obtained if we were to measure the last register, so $\Pr[X = x_k] = \||\psi_k\rangle\|^2$. Let $M \geq C/\sqrt{\Pr[X \geq x_j]}$ for some $j$. Then $\mathcal{M}$ uses at most $M$ applications of $V$ and $V^{-1}$, and $O(qM)$ other gates, and outputs an $x_i \geq x_j$ with probability at least $3/4$ (in particular, if $j = 0$ then $\mathcal{M}$ outputs the maximum).*

▶ Remark 18. It may be verified by going through [2, Lemma 48] that the only applications of $V$ and $V^{-1}$ used by $\mathcal{M}$ are to prepare $V|0\rangle$ starting from $|0\rangle$, and to reflect about $V|0\rangle$.

We can use generalized maximum-finding to approximate the largest eigenphase starting from the ability to prepare a superposition of eigenstates (possibly with some additional workspace qubits):

▶ **Lemma 19.** *There exists a quantum algorithm $\mathcal{B}$ such that the following holds. Suppose we have an $N$-dimensional unitary $U$ with (unknown) eigenstates $|u_0\rangle, \ldots, |u_{N-1}\rangle$ and associated eigenphases $\theta_0, \ldots, \theta_{N-1} \in [0, 2\pi)$. Suppose we also have a unitary $A$ such that*

$$A|0\rangle = \sum_{j=0}^{N-1} \alpha_j |u_j\rangle|\phi_j\rangle,$$

*where $\sum_{j:\theta_j=\theta_{\max}} |\alpha_j|^2 \geq \gamma^2$ and the $|\phi_j\rangle$ are arbitrary (normalized) states. Then $\mathcal{B}$ uses at most $O(1/\gamma)$ applications of $A$ and $A^{-1}$, and $O(\log(1/\gamma)/\gamma\delta)$ applications of $U$ and $U^{-1}$, and with probability at least $2/3$ outputs a number $\theta \in [\theta_{\max} - \delta, \theta_{\max} + \delta] \mod 2\pi$.*

**Proof.** Let $\tilde{V}$ be the unitary that applies phase estimation with unitary $U$, precision $\delta$, and small error probability $\eta$ (to be determined later), on the first register of the state $A|0\rangle$, writing the estimates of the phase in a third register. Then

$$\tilde{V}|0\rangle = \sum_{j=0}^{N-1} \alpha_j |u_j\rangle|\phi_j\rangle|\tilde{\theta}_j\rangle,$$

where, for each $j$, $|\tilde{\theta}_j\rangle$ is a superposition over estimates of $\theta_j$, most of which are $\delta$-close to $\theta_j$.

For the purposes of analysis, we would like to define a "cleaned up" unitary $V$ (very close to $\tilde{V}$) that doesn't have any estimates with error $> \delta$. Let $|\tilde{\theta_j}'\rangle$ be the state obtained from $|\tilde{\theta_j}\rangle$ by removing the estimates that are more than $\delta$-far from $\theta_j$, and renormalizing. Because we ran phase estimation with error probability $\leq \eta$, it is easy to show that $\left\||\tilde{\theta_j}'\rangle - |\tilde{\theta_j}\rangle\right\| = O(\sqrt{\eta})$. Then there exists[6] a unitary $V$ such that $\left\|\tilde{V} - V\right\| = O(\sqrt{\eta})$ and

$$V|0\rangle = \sum_{j=0}^{N-1} \alpha_j |u_j\rangle|\phi_j\rangle|\tilde{\theta_j}'\rangle = \sum_{k=0}^{K-1} |\psi_k\rangle|x_k\rangle,$$

where the $x_k$ are the distinct estimates that have support in the last register, and the $|\psi_k\rangle$ are (unnormalized) superpositions of the $|u_j\rangle|\phi_j\rangle$'s that are associated with those estimates.

The largest $x_k$'s are good estimates of $\theta_{\max}$. Algorithm $\mathcal{B}$ now applies the maximum-finding algorithm $\mathcal{M}$ of Lemma 17 with the unitary $\tilde{V}$. Let us first analyze what would happen if $\mathcal{B}$ used the cleaned-up $V$ instead of $\tilde{V}$. Let $X$ denote the random variable obtained if we measure the last register, and note that $\Pr[X \geq \theta_{\max} - \delta] \geq \sum_{j:\theta_j=\theta_{\max}} |\alpha_j|^2 \geq \gamma^2$ because all estimates in $V|0\rangle$ have error $\leq \delta$. Hence $\mathcal{B}$ would use $O(1/\gamma)$ applications of $V$ and $V^{-1}$ to find a $\theta \in [\theta_{\max} - \delta, \theta_{\max} + \delta]$ with success probability $\geq 3/4$. Algorithm $\mathcal{B}$ will actually use $\tilde{V}$ and $\tilde{V}^{-1}$ instead of $V$ and $V^{-1}$, which (because errors in quantum circuits add at most linearly) incurs an overall error in operator norm of $\leq O(\sqrt{\eta}) \cdot O(1/\gamma)$. Choosing $\eta \ll \gamma^2$, this overall error can be made an arbitrarily small constant. The success probability of the algorithm can drop slightly below $3/4$ now, but is still $\geq 2/3$.

It remains to analyze the cost of $\mathcal{B}$. Each $\tilde{V}$ uses 1 application of $A$, and $O(\log(1/\eta)/\delta) = O(\log(1/\gamma)/\delta)$ applications of $U$ and $U^{-1}$ for phase estimation (Theorem 2), so $\mathcal{B}$ uses $O(1/\gamma)$ applications of $A$ and $A^{-1}$, and $O(\log(1/\gamma)/\gamma\delta)$ applications of $U$ and $U^{-1}$ in total. ◀

The upper bounds for our 8 variants of phase estimation (see Table 1) will all follow from this. We start with the 4 odd-numbered rows, where it turns out the advice is not actually needed to meet our earlier lower bounds. The next proof is basically the same as [2, Lemma 50] about estimating the minimal eigenvalue of a Hamiltonian (this improved slightly upon [27]; see also [14, Lemma 3.A.4]).

▶ **Lemma 20** (Upper bound for Rows 1, 3, 5, 7)**.** *There is an algorithm that uses no advice and solves the case in Row 3 (and hence in Rows 1, 5, and 7 as well) with cost* $O(\sqrt{N}\log(N)/\delta)$.

**Proof.** Let $A$ be the unitary that maps $|0\rangle$ to the maximally entangled state in $N$ dimensions. This state can be written in any orthonormal basis, including the (unknown) eigenbasis of $U$:

$$A|0\rangle = \frac{1}{\sqrt{N}} \sum_{j=0}^{N-1} |j\rangle|j\rangle = \frac{1}{\sqrt{N}} \sum_{j=0}^{N-1} |u_j\rangle|\overline{u_j}\rangle,$$

where $|\overline{u_j}\rangle$ denotes the entry-wise conjugated version of $|u_j\rangle$. Applying Lemma 19 with this $A$, $|\phi_j\rangle = |\overline{u_j}\rangle$, and $\gamma = 1/\sqrt{N}$ gives the result. ◀

The next two lemmas cover the 4 cases where the advice states/unitaries *are* helpful.

▶ **Lemma 21** (Upper bound for Rows 6, 8)**.** *There is a quantum algorithm that uses* $O(1/\gamma)$ *applications of the advice unitary (and its inverse) and solves the case in Row 8 (and hence the case in Row 6 as well) with cost* $O(\log(1/\gamma)/\gamma\delta)$.

[6] This is fairly easy to show, see e.g. [9, proof of Theorem 2.4 in Appendix A].

**Proof.** Apply Lemma 19 with the unitary $A$ that maps $|0\rangle$ to $|\alpha\rangle$, with empty states $|\phi_j\rangle$. ◀

▶ **Lemma 22** (Upper bound for Rows 2, 4)**.** *There is a quantum algorithm that uses $O(1/\gamma^2)$ copies of the advice state and solves the case in Row 4 (and hence in Row 2) with cost $O(\log(1/\gamma)/\gamma\delta)$.*

**Proof.** We will build upon the algorithm for Row 8 of Lemma 21. By Remark 18 and the algorithm in Lemma 21, its $O(1/\gamma)$ applications of the advice unitary $A$ and its inverse $A^{-1}$ are only used there for two purposes: (1) to prepare a copy of the advice state $A|0\rangle = |\alpha\rangle$, and (2) to reflect about $|\alpha\rangle$. We now want to replace these applications of $A$ by using copies of the advice state. For (1) this is obvious. Assume the algorithm for Row 8 uses (2) at most $C/\gamma$ times, for some constant $C$. To implement these reflections, we will invoke the result of Lloyd, Mohseni, and Rebentrost [24] (see also [18]), who showed that given a number $t > 0$ and $O(t^2/\eta)$ copies of a mixed quantum state $\rho$, one can implement the unitary $e^{it\rho}$ up to error $\eta$ (in diamond-norm difference between the intended unitary and the actually-implemented channel). We will use this result with $\rho = |\alpha\rangle\langle\alpha|$, $t = \pi$, $\eta = \gamma/(100C)$, noting that the implemented unitary $e^{i\pi|\alpha\rangle\langle\alpha|} = I - 2|\alpha\rangle\langle\alpha|$ is a reflection about $|\alpha\rangle$ (up to a global minus sign that doesn't matter).

Accordingly, we can implement the $\leq C/\gamma$ reflections used by the algorithm for Row 8 using $O(1/\gamma^2)$ copies of $|\alpha\rangle$, each reflection implemented with error $\leq \eta$. Because errors in quantum circuits add at most linearly, the overall error between the algorithm of Row 8 and our simulation of it (using copies of $|\alpha\rangle$) is at most $\eta \cdot C/\gamma \leq 1/100$. Hence we obtain an algorithm for Row 4 that uses $O(1/\gamma^2)$ copies of $|\alpha\rangle$ and has the same cost $O(\log(1/\gamma)/\gamma\delta)$ as the algorithm of Row 8. ◀

## 5 Tight bounds for phase estimation with small error probability

Here we prove our lower bound for quantum algorithms solving phase estimation with precision $\delta$ and error probability at most $\varepsilon$, Theorem 3, which follows from Claims 23 and 24 below.

▷ Claim 23. For all integers $N \geq 2$ and all $\varepsilon, \delta \in (0, 1/2)$, if there is a cost-$d$ algorithm solving $\mathsf{QPE}_{N,\delta,\varepsilon}$, then there is a cost-$d$ algorithm solving $\mathsf{dist}_{N,\delta,\varepsilon}$.

Proof. Consider an algorithm $\mathcal{A}$ of cost $d$ that solves $\mathsf{QPE}_{N,\delta,\varepsilon}$. We construct below an algorithm $\mathcal{A}'$ of cost $d$ solving $\mathsf{dist}_{N,\delta,\varepsilon}$. Let $U \in U(N)$ be the input. The following is the description of $\mathcal{A}'$:

1. Run $\mathcal{A}$ with inputs $U$ and $|0\rangle$.
2. Output 1 if the output of $\mathcal{A}$ is in $[-\delta, \delta] \mod 2\pi$, and output 0 otherwise.

Clearly $\mathcal{A}'$ is a valid algorithm, as far as access to input and allowed operations are concerned, since its initial state is $|0\rangle$, it applies $U, U^{-1}$, some unitaries independent of $U$, and finally performs a two-outcome projective measurement to determine the output bit. The cost of $\mathcal{A}'$ is $d$.

The correctness follows along the same lines as the proofs in Section 3. We prove correctness here for completeness. First note that $|0\rangle$ is an eigenstate of all $U \in \{I\} \cup \{U_\theta : \theta \notin [-3\delta, 3\delta] \mod 2\pi\}$. When $U = I$, the correctness of $\mathcal{A}$ guarantees that with probability at least $1 - \varepsilon$, the value output by $\mathcal{A}$ is in $[-\delta, \delta] \mod 2\pi$. When $U = U_\theta$, the correctness of $\mathcal{A}$ guarantees that with probability at least $1 - \varepsilon$, the value output by $\mathcal{A}$ is in $[\theta - \delta, \theta + \delta] \mod 2\pi$. For $\theta \notin [-3\delta, 3\delta] \mod 2\pi$ we have $[-\delta, \delta] \mod 2\pi \cap [\theta - \delta, \theta + \delta] \mod 2\pi = \emptyset$ since $\delta < 1/2 < 2\pi/5$, and hence $\mathcal{A}'$ solves $\mathsf{dist}_{N,\delta,\varepsilon}$. ◁

We next show a lower bound for the cost of algorithms computing $\mathsf{dist}_{N,\delta,\varepsilon}$.

▷ Claim 24. For all integers $N \geq 2$, $\varepsilon, \delta \in (0, 1/2)$, every algorithm for $\mathsf{dist}_{N,\delta,\varepsilon}$ has cost $\Omega\left(\frac{1}{\delta}\log\frac{1}{\varepsilon}\right)$.

In order to prove Claim 24, we first show that amplitudes of basis states in low-cost algorithms that run on $U_\theta$ are low-degree trigonometric polynomials in $\theta$. This is analogous to the fact that amplitudes of basis states in query algorithms for Boolean functions are low-degree (algebraic) polynomials in the input variables [3, Lemma 4.1], and our proof is inspired by theirs.

▷ Claim 25. Let $t > 0$ be a positive integer and let $\theta \in [0, 2\pi]$. Consider a quantum circuit that has starting state $|0\rangle$, uses an arbitrary number of $\theta$-independent unitaries, uses $t$ applications of controlled-$U_\theta$ and controlled-$U_\theta^{-1}$ in total, and performs no intermediate measurements. Then the amplitudes of basis states before the final measurement are degree-$t$ trigonometric polynomials in $\theta$.

Proof. We prove this by induction on $t$. The claim is clearly true when $t = 0$ since all amplitudes are constants in this case. For the inductive step, suppose the claim is true for $t = d$. Let $|\psi_d\rangle$ denote the state of the circuit just before the application of the $(d+1)$th application of $U_\theta$ (the argument for $U_\theta^{-1}$ is similar, and we skip it). By the inductive hypothesis, we have

$$|\psi_d\rangle = \sum_w \sum_{b\in\{0,1\}} \sum_{j=0}^{N-1} p_{j,b,w}(\theta)|j\rangle|b\rangle|w\rangle,$$

where the first register is where $U_\theta$ and $U_\theta^{-1}$ act, the second register is the control qubit, and the last register represents the workspace (i.e., $U_\theta$ and $U_\theta^{-1}$ do not act on this register), and each $p_{j,b,w}$ is a trigonometric polynomial of degree at most $d$ in $\theta$. For a basis state $|j\rangle|b\rangle|w\rangle$, we have

$$U_\theta|j\rangle|b\rangle|w\rangle = \begin{cases} e^{i\theta}|0\rangle|b\rangle|w\rangle & \text{if } j = 0 \text{ and } b = 1 \\ |j\rangle|b\rangle|w\rangle & \text{otherwise.} \end{cases}$$

In both cases, the amplitudes of the basis states after the application of $U_\theta$ are degree-$(d+1)$ trigonometric polynomials in $\theta$. After the last application of $U_\theta$ the algorithm will apply an input-independent unitary. The amplitudes after that unitary are linear combinations of the amplitudes before, which won't increase degree. This concludes the inductive step, and hence the theorem. ◁

**Proof of Claim 24.** Consider a cost-$t$ algorithm $\mathcal{A}'$ solving $\mathsf{dist}_{N,\delta,\varepsilon}$. Claim 25 implies that on input $U_\theta$, the amplitudes of the basis states before the final measurement are degree-$t$ trigonometric polynomials in $\theta$. The acceptance-probability polynomial $p : \mathbb{R} \to \mathbb{R}$ given by $p(\theta) := \Pr[\mathcal{A}'(U_\theta) = 1]$ is a degree-$2t$ trigonometric polynomial, because it is the sum of squares of moduli of certain amplitudes, and each of these squares is a degree-$2t$ trigonometric polynomial. The correctness of the algorithm ensures that $p(0) \in [1-\varepsilon, 1]$ and $p(\theta) \in [0, \varepsilon]$ for all $\theta \notin [-3\delta, 3\delta] \mod 2\pi$. See Figure 1 for a visual depiction of the behaviour of $p$ for $\theta \in [-\pi, \pi)$.

Scaling by a global factor of $1/\varepsilon$, we obtain a trigonometric polynomial $q$ of degree $2t$ satisfying:

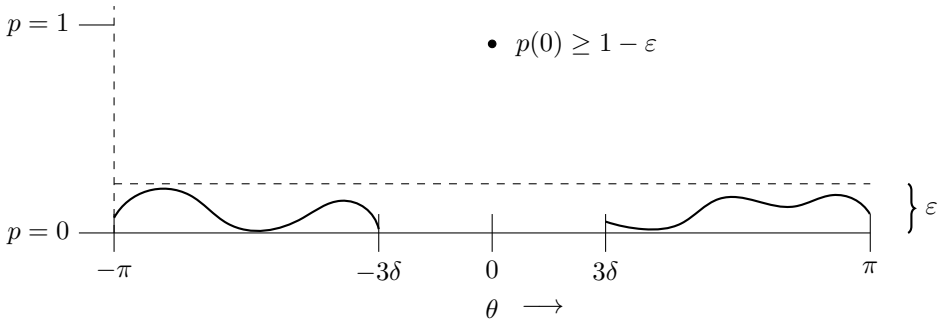

**Figure 1** Acceptance probability $p$ of $\mathcal{A}'$ as a function of $\theta$ in the proof of Claim 24.

- $q(0) \geq (1-\varepsilon)/\varepsilon > 1/(2\varepsilon)$, and
- $q(\theta) \in [0,1]$ for all $\theta \in [-\pi, \pi) \setminus [-3\delta, 3\delta]$.

Thus, Theorem 10 is applicable with $s = 6\delta$, which implies $1/(2\varepsilon) \leq \sup_{x\in\mathbb{R}} |q(x)| \leq \exp(24t\delta)$. By taking logarithms and rearranging we get $t = \Omega\left(\frac{1}{\delta}\log\frac{1}{\varepsilon}\right)$, proving the theorem. ◀

## 6 Conclusion

In this paper we considered several natural variants of the fundamental phase estimation problem in quantum computing, and proved essentially tight bounds on their cost in each setting. As an immediate application of one of our bounds, we resolved an open question of [29, Section 2].

We mention two interesting questions in the first variant of phase estimation we considered, where an algorithm is given a number of copies of advice states/unitaries instead of black-box access to a perfect eigenstate as in the basic phase estimation setup. First, are the logarithmic overheads in the input dimension $N$ and the inverse of the overlap $\gamma$ in our upper bounds (see Table 1) necessary, or can we give tighter upper bounds? Second, can we show the $\log(1/\varepsilon)$-dependence on the error probability also in the advice-guided case, like we did for basic phase estimation (Theorem 3)?

# A Fine-Grained Classification of the Complexity of Evaluating the Tutte Polynomial on Integer Points Parameterized by Treewidth and Cutwidth

**Isja Mannens**
Utrecht University, The Netherlands

**Jesper Nederlof**
Utrecht University, The Netherlands

## Abstract

We give a fine-grained classification of evaluating the Tutte polynomial $T(G; x, y)$ on all integer points on graphs with small treewidth and cutwidth. Specifically, we show for any point $(x, y) \in \mathbb{Z}^2$ that either

- $T(G; x, y)$ can be computed in polynomial time,
- $T(G; x, y)$ can be computed in $2^{O(tw)}n^{O(1)}$ time, but not in $2^{o(ctw)}n^{O(1)}$ time assuming the Exponential Time Hypothesis (ETH),
- $T(G; x, y)$ can be computed in $2^{O(tw \log tw)}n^{O(1)}$ time, but not in $2^{o(ctw \log ctw)}n^{O(1)}$ time assuming the ETH,

where we assume tree decompositions of treewidth $tw$ and cutwidth decompositions of cutwidth $ctw$ are given as input along with the input graph on $n$ vertices and point $(x, y)$.

To obtain these results, we refine the existing reductions that were instrumental for the seminal dichotomy by Jaeger, Welsh and Vertigan [Math. Proc. Cambridge Philos. Soc'90]. One of our technical contributions is a new rank bound of a matrix that indicates whether the union of two forests is a forest itself, which we use to show that the number of forests of a graph can be counted in $2^{O(tw)}n^{O(1)}$ time.

## 1 Introduction

We study the parameterized complexity of computing the Tutte Polynomial. The Tutte polynomial is a graph invariant that generalizes any graph invariant that satisfies a linear deletion-contraction recursion. Such invariants include the chromatic, flow and Jones polynomials, as well as invariants that count structures such as the number of forests or the number of spanning subgraphs. Due to its generality the Tutte polynomial is of great interest to a variety of fields, including knot theory, statistical physics and combinatorics.

For a number of these fields it is important to understand how difficult it is to compute the Tutte polynomial. A series of papers, culminating in the work by Jaeger, Vertigan, and Welsh [15] has given a complete dichotomy showing that the problem of evaluating the Tutte polynmial is #P-hard on all points except on the following *special points* on which it is known to be computable in polynomial time:

$$(1,1),(-1,-1),(0,-1),(-1,0),(i,-i),(-i,i),(j,j^2),(j^2,j),\ H_1 \tag{1}$$

where $j = e^{2\pi i/3}$ and $i = \sqrt{-1}$, and $H_\alpha$ denotes the hyperbola $\{(x,y) : (x-1)(y-1) = \alpha\}$. These hyperbolic curves turn out to be of great importance to understanding the complexity of the Tutte Polynomial, as the problem is generally equally hard on all points of the same curve, except for the *special points* listed in (1).

Further refinements of the result by [15] have since been made: Among others, a more fine-grained examination of the complexity was done by Brand et al. [5] (building on earlier work by Dell et. al. [12]): they showed that for almost all points the Tutte polynomial cannot be evaluated in $2^{o(n)}$ time on $n$-vertex graphs, assuming (a weaker counting version of) the Exponential Time Hypothesis. This is tight because, on the positive side, Björklund et al. [2] showed that the Tutte polynomial can be evaluated on any point in $2^n n^{O(1)}$ time.

Another perspective worth examining is that of the parameterized complexity of the problem, when parameterized by *width measures*. This is a rapidly evolving field within parameterized complexity.[1] Intuitively, it is concerned with the effects of structural properties of the given input graph on its complexity. This often generates results that have greater practical value and give a deeper understanding of the problem, in comparison with classical worst-case analysis. It is therefore natural to ask what a complexity classification for the Tutte Polynomial would look like in this parameterized context.

For the specific subject of evaluating the Tutte polynomial parameterized by width measures, research has already been done in this area over twenty years ago: Noble [21] has given a polynomial time algorithm for evaluation the Tutte Polynomial on bounded treewidth graphs. Noble mostly focused on the dependence on the number of vertices and edges, and showed each point of the Tutte polynomial can be evaluated in linear time, assuming the treewidth of the graph is constant. See also an independently discovered (but slower) algorithm by Andrzejak [1]. However, this glances over the *exponential* part of the runtime, i.e. the dependence on the treewidth. Since this is typically the bottleneck, recent work aims to refine our understanding of this exponential dependence with upper and lower bounds on complexity of the problem in terms of this parameter that match in a fine-grained sense.

In this work, we extend this research line and determine the fine-grained complexity for each integer point $(x,y)$ of the problem of evaluating the Tutte polynomial $(x,y)$. As was done in previous works, we base our lower bounds on the Exponential Time Hypothesis (ETH) and the Strong Exponential Time Hypothesis (SETH) formulated by Impagliazzo and Paturi [14]. For a given width parameter $k$, the former will be used to exclude run times of the form $k^{o(k)}n^{O(1)}$, while the latter will be used to exclude run times of the form $(c-\epsilon)^k n^{O(1)}$ for some constant $c$ and any $\epsilon > 0$.

Specifically we consider the *treewidth*, *pathwidth* and *cutwidth* of the graph. The first two, in some sense, measure how close the graph is to looking like a tree or path respectively. The cutwidth measures how many edges are layered on top of each other when the vertices are placed in any linear order. We will more precisely define these parameters in the preliminaries.

[1] For example, the biennial Workshop on Graph Classes, Optimization, and Width Parameters (GROW) already had its 10'th edition recently `https://conferences.famnit.upr.si/event/22/`.

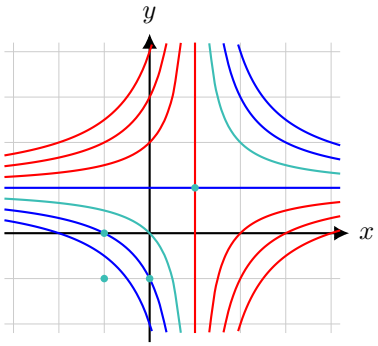

**Figure 1** The red points have time complexity of the form $k^{O(k)}$, the blue points have time complexity of the form $O(c^k)$ for some constant $c$ and the green points have polynomial time complexity.

Width measures in particular are interesting because instances where such structural parameters are small come up a lot in practice. For example, the curve $H_2$ corresponds to the partition function of the Ising model, which is widely studied in statistical physics, on graphs with particular topology such as lattice graphs or open/closed Cayley trees ([18]). In all such graphs with $n$ vertices, even the cutwidth (the largest parameter we study) is at most $O(\sqrt{n})$.

## 1.1 Our contributions

Our classification handles points $(x, y)$ differently based on whether $(x-1)(y-1)$ is negative, zero or positive, and reads as follows:

▶ **Theorem 1.1.** *Let $G$ be a graph with given tree, path and cut decompositions of width* tw, pw *and* ctw *respectively. Let $(x, y) \in \mathbb{Z}^2$ be a non-special point, then up to some polynomial factor in $|V(G)|$, the following holds.*

1. *If $(x-1)(y-1) < 0$ or $x = 1$, then $T(G; x, y)$ can be computed in time $\mathrm{tw}^{O(\mathrm{tw})}$ and cannot be computed in time $\mathrm{ctw}^{o(\mathrm{ctw})}$ under ETH.*
2. *If $y = 1$, then $T(G; x, y)$ can be computed in time $O(4^{\mathrm{pw}})$ or $O(64^{\mathrm{tw}})$ and cannot be computed in time $2^{o(\mathrm{ctw})}$ under ETH.*
3. *If $(x-1)(y-1) = q > 1$, then $T(G; x, y)$ can be computed in time $O(q^{\mathrm{tw}})$. Furthermore,*
   a. *if $x \neq 0$, then $T(G; x, y)$ cannot be computed in time $O((q-\epsilon)^{\mathrm{ctw}})$ under SETH.*
   b. *if $x = 0$, then $T(G; x, y)$ cannot be computed in time $O((q-\epsilon)^{\mathrm{pw}})$ and $O(q-\epsilon)^{\mathrm{ctw}/2})$ under SETH.*

This is a fine-grained classification for evaluating the Tutte polynomial at any given integer point, simultaneously for all the parameters treewidth, pathwidth and cutwidth. This is because if a graph has cutwidth ctw, pathwidth pw and treewidth tw, then $\mathrm{tw} \leq \mathrm{pw} \leq \mathrm{ctw}$. Our result implies that, for evaluating the Tutte polynomial at a given integer point, it does not give a substantial advantage to have small cutwidth instead of small treewidth. This is somewhat surprising since, for example, for computing the closely related chromatic number of a graph there exists a $2^{\mathrm{ctw}} n^{O(1)}$ time algorithm, but any $\mathrm{pw}^{o(\mathrm{pw})}\, n^{O(1)}$ time algorithm would contradict the ETH [19].

Of particular interest are the upper bounds in Case 2. for the points $\{(x, y) : y = 1\}$, which are closely related to the problem of computing the number of forests in the input graph. One reason why this results stands out in particular is that it indicates an inherent

asymmetry between the $x$- and $y$-axes, in this parameterized setting. In the general setting, problems related to the Tutte Polynomial often have a natural dual problem, which one can obtain by interchanging the $x$- and $y$-coordinates. For example the chromatic polynomial can be found (up to some computable term $f$) as $\chi_G(\lambda) = f(\lambda)T(1-\lambda, 0)$, while the flow polynomial can be found as $C_G(\lambda) = g(\lambda)T(0, 1-\lambda)$. These two problems are equivalent on planar graphs, in the sense that the chromatic number of a planar graph is equal to the flow number of its dual graph.

We note that for this curve we have an ETH bound, while for the other results of the form $c^{\mathrm{tw}}n^{O(1)}$ we have a stronger SETH bound. We suspect that a $(4-\epsilon)^{\mathrm{ctw}}n^{O(1)}$ lower bound for any $\epsilon > 0$, based on SETH, also holds for evaluating $T(G; 2, 1)$, but that it will take significant additional technical effort.

**Techniques.** In order to get the classification, our first step follows the method of [15] to reduce the evaluation of $T(G; x, y)$ for all points in hyperbola $H_\alpha = \{(x, y) : (x-1)(y-1) = \alpha\}$ to the evaluation to a *single* point in $H_\alpha$. This is achieved in [15] by some graph operations (*stretch* and *thickening*), but these may increase the involved width parameters. We refine these operations in Section 3 to avoid this.

With this step being made, several cases of Theorem 1.1 then follow from a combination of new short separate and non-trivial arguments and previous work (including some very recent work such as [8, 13]).

However, for the upper bound in Case **2.** of Theorem 1.1, our proof is more involved. To get our upper bound, we introduced the *forest compatibility matrix*. Its rows and columns are indexed with forests (encoded as partitions indicating their connected components). An entry in this matrix indicates whether the union of the two forests forms a forest itself. This matrix is closely related to matrices playing a crucial role in the Cut and Count method [11] and rank based method [4] to quickly solve connectivity problems on graphs with small tree-width. However, the previous rank upper bounds do not work for bounding the rank of the forest compatibility matrix over the reals since we check for *acyclicity* instead of *connectivity*. We nevertheless show that this the rank of this matrix is $4^n$; in fact the set of non-crossing partitions forms a basis of this matrix. We prove this via an inductive argument that is somewhat similar to the rank bound of $2^{n/2-1}$ of the matchings connectivity matrix over $GF(2)$ from [10]. Subsequently, we show how to use this insight to get a $2^{O(\mathrm{tw})}$ algorithm to evaluate $T(G; 1, 2)$ (i.e. counting the number of spanning forests).

## 1.2 Organization

The remainder of this paper supports Theorem 1.1, although some slightly less interesting cases (being the upper bound in Case **1.**) are deferred to the full version of the paper [20]. Proofs of Lemmas and Theorems indicated with † are also deferred to the full version [20].

In Section 2 we describe some preliminaries. In Section 3 we show how to reduce the task of computing all points along a hyperbola curve to a single point. We now describe where each part of Theorem 1.1 can be found in the paper. The lower bound in Case **1.** is given in Theorem 5.7 and 5.3. The lower bound in Case **2.** is by Dell et al. [12]. The upper bound in Case **2.** is given in Section 4 (specifically, Theorems 4.17 and 4.18). The lower bound in Case **3.** is given in Theorem 5.1 (for $q = 2$) and Theorem 5.4 (for $q > 2$). The upper bound bound in **3.** is given in Theorem 5.2 (for $q = 2$) and Theorem 5.5 (for $q > 2$).

## 2 Preliminaries

**Computational Model.** In this paper we frequently have real (and some inteormediate lemma's are even stated for even complex) numbers as intermediate results of computations. However, as is common in this area we work in the word RAM model in which all basic arithmetic operations with such numbers can be done in constant time, and therefore this does not influence our running time bounds.

**Interpolation.** Throughout this paper we will use interpolation to derive a polynomial, given a finite set of evaluations of said polynomial. For our purposes it suffices to note that this can be done in polynomial time, for example by solving the system of linear equations given by the Vandermonde matrix and the evaluations (see e.g. [7, Section 30.1]).

▶ **Lemma 2.1.** *Given pairs $(x_0, y_0), \ldots, (x_d, y_d)$, there exists an algorithm which computes the unique degree $d$ polynomial $p$ such that $p(x_i) = y_i$ for $i = 0, \ldots, d$ and runs in time $O(d^3)$.*

### 2.1 The Tutte polynomial

There are multiple ways of defining the Tutte polynomial. In this paper we will only need the following definition

$$T(G; x, y) = \sum_{A \subseteq E} (x-1)^{k(A)-k(E)}(y-1)^{k(A)+|A|-|V|},$$

where $k(A)$ denotes the number of connected components of the graph $(V, A)$. We will often use the following notation

$$H_\alpha = \{(x, y) : (x-1)(y-1) = \alpha\}.$$

Note that these curves form hyperbolas and that for $\alpha = 0$ the hyperbola collapses into two orthogonal, straight lines. We refer to these two lines as separate curves

$$H_0^x = \{(x, y) : x = 1\},$$
$$H_0^y = \{(x, y) : y = 1\}.$$

Throughout the paper we will refer to the problem of finding the value of $T(G; a, b)$ for an individual point as *computing the Tutte polynomial on* $(a, b)$. We will often restrict the Tutte polynomial to a one-dimensional curve $H_\alpha$. Note that in this case the polynomial can be expressed as a univariate polynomial[2]

$$T_\alpha(G; t) := T\left(G; \frac{\alpha}{t} + 1, t + 1\right).$$

We refer to the problem of finding the coefficients of $T_\alpha$ as *computing the Tutte polynomial along* $H_\alpha$.

As mentioned in the introduction, the Tutte polynomial is known to be computable in polynomial time on the points

$$(1,1), (-1,-1), (0,-1), (-1,0), (i,-i), (-i,i), (j,j^2), (j^2,j) \tag{2}$$

and along the curve $H_1$ and it is $\#P$ to evaluate it on any other point. We call the points listed in (2), along with the points on the curve $H_1$ *special points*. See [15] for more details.

[2] Note that one can get rid of the negative powers of $t$ in the following expression, by multiplying the whole polynomial by some power of $t$.

## 2.2 Width measures

We consider the width measures *treewidth*, *pathwidth* and *cutwidth* of a graph $G$ (denoted respectively with $tw(G)$, $pw(G)$ and $ctw(G)$). We use standard notation (such as introduced in [9]); see the appendix

## 2.3 Brylawski's tensor product formula

In Section 3 we will make use of Brylawski's tensor product formula [6] to reduce the computation of $T(G; x', y')$ to that of $T(G'; x, y)$ for some other point $(x', y')$ and some other graph $G'$. The original formula is formulated in terms of pointed matroids, however we will only need the formulation for (multi)graphs. Before we can state the formula, we first need to introduce some notation.

Given graphs $G$ and $H$, where an edge $e \in E(H)$ is labeled as a special edge, we define the *pointed tensor product*[3] $G \otimes_e H$ of $G$ and $H$ as the graph given by the following procedure. For every edge $f \in E(G)$ we first create a copy $H_f$ of $H$, then identify $f$ with the copy of the edge $e$ in $H_f$ and finally remove the edge f (and thus also the edge $e$) from the graph.

Intuitively it might be easier to think of this product as replacing every edge of $G$ with a copy $H \setminus e$, where two of the vertices in $H$ are designated as gluing points. For example one could replace every edge with a path of length $k$ by taking as $H$ the cycle $C_{k+1}$ on $k+1$ vertices, as seen in figure 2.

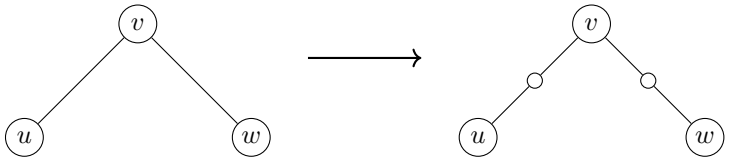

**Figure 2** The pointed tensor product of the left-hand graph with a 3-cycle is given by the right-hand graph.

Note that this is not always well-defined, as one can choose which endpoint is identified with which. It turns out that this choice does not affect the graphic matroid of $G \otimes_e H$ and thus it does not affect the resulting Tutte polynomial. In this paper we will only consider graphs $H$ that are symmetric over $e$ and thus the product is actually well-defined.

We are now ready to state Brylawski's tensor product formula. Let $T_C$ and $T_L$ be the unique polynomials that satisfy the following system of equations

$$(x-1)T_C(H; x, y) + T_L(H; x, y) = T(H \setminus e; x, y)$$
$$T_C(H; x, y) + (y-1)T_L(H; x, y) = T(H/e; x, y).$$

We define

$$x' = \frac{T(H \setminus e; x, y)}{T_L(H; x, y)} \qquad y' = \frac{T(H/e; x, y)}{T_C(H; x, y)}.$$

Let $n = |V(H)|$, $m = |E(H)|$ and $k = k(E(H))$. Brylawski's tensor product formula states that

$$T(G \otimes_e H; x, y) = T_C(H; x, y)^{m-n+k} T_L(H; x, y)^{n-k} T(G; x', y').$$

[3] Note that this is different from the standard tensor product for graphs.

## 3 Reducing along the curve $H_\alpha$

In this section we describe how we can lift hardness results from a single point $(a, b) \in H_\alpha$ to the whole curve $H_\alpha$. We summarize the results from this section in the following theorem.

▶ **Theorem 3.1.** *Let $(a, b) \in \mathbb{C}^2$. Also let $T(G; x, y)$ be the Tutte polynomial of $G$ and $\alpha := (a-1)(b-1)$. There exists a polynomial time reduction from computing $T$ on $(a, b)$ for graphs of given tree-, path- or cutwidth, to computing $T$ along $H_\alpha$ for graphs width the following with parameters.*

- *If $|a| \notin \{0, 1\}$ or if $|b| \notin \{0, 1\}$ and $a \neq 0$, then the treewidth remains $\mathrm{tw}(G)$. The cutwidth and pathwidth become at most $\mathrm{ctw}(G) + 2$ and $\mathrm{pw}(G) + 2$ respectively.*
- *If $|b| \notin \{0, 1\}$ and $a = 0$, then the treewidth remains $\mathrm{tw}(G)$. The pathwidth becomes at most $\mathrm{pw}(G) + 2$ and the cutwidth becomes at most $2\,\mathrm{ctw}(G)$.*
- *If $|a|, |b| \in \{0, 1\}$, then the treewidth remains $\mathrm{tw}(G)$. The pathwidth becomes at most $\mathrm{pw}(G) + 2$ and the cutwidth becomes at most $12\,\mathrm{ctw}(G)$.*

Theorem 3.1 lets us lift both algorithms and lower bounds from a point $(a, b)$ to the whole curve $H_\alpha$. While our main theorem only requires Theorem 3.1 to be stated for integer valued points, we will state it as the most general version we can prove. We note that for Case 1. of Theorem 1.1, we do not care too much about constant multiplicative factors in the cutwidth, since we have an ETH bound of the form $\mathrm{ctw}(G)^{o(\mathrm{ctw}(G))}$. For Case 2. we only need the bounds on the treewidth and pathwidth. Thus the blowup in the cutwidth is only relevant for Case 3.. In this case the only integer valued points that fall under the third item of Theorem 3.1 are $(-1, 0), (0, -1)$ and $(-1, -1)$. These are all special points, which means that this item is not relevant for Case 3..

In our proofs we will make use of the following transformations.

▶ **Definition 3.2** ([15])**.** *Let $G$ be a simple graph. We define the $k$-*stretch *${}^kG$ of $G$ as the graph obtained by replacing every edge by a path of length $k$. We define the $k$-*thickening *${}_kG$ of $G$ as the graph obtained by replacing every edge by $k$ parallel edges.*

A new variant we introduce to keep the cutwidth low is defined as follows:

▶ **Definition 3.3.** *We define the* insulated $k$-thickening *${}_{(k)}G$ as the graph obtained by replacing every edge by a path of length 3 and then replacing the middle edge in each of these paths by $k$ parallel edges.*

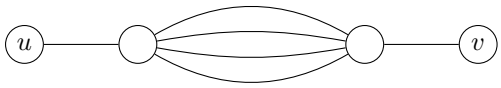

**Figure 3** The result of applying the insulated 4-thickening to an edge between $u$ and $v$.

### 3.1 Effect on width parameters

We give three lemmas that show how these transformations effect the parameters we use.

▶ **Lemma 3.4** (†)**.** *Let $G$ be a graph. Then we have that $\mathrm{tw}({}^kG) \leq \mathrm{tw}(G)$, $\mathrm{tw}({}_kG) \leq \mathrm{tw}(G)$ and $\mathrm{tw}({}_{(k)}G) \leq \mathrm{tw}(G)$.*

▶ **Lemma 3.5** (†)**.** *Let $G$ be a graph. Then we have that $\mathrm{pw}({}^kG) \leq \mathrm{pw}(G) + 2$, $\mathrm{pw}({}_kG) \leq \mathrm{pw}(G)$ and $\mathrm{pw}({}_{(k)}G) \leq \mathrm{pw}(G) + 2$.*

▶ **Lemma 3.6** (†). *Let $G$ be a graph. Then we have that* $\mathrm{ctw}({}^{k}G) \leq \mathrm{ctw}(G)$, $\mathrm{ctw}({}_{k}G) \leq k\,\mathrm{ctw}(G)$ *and* $\mathrm{ctw}({}_{(k)}G) \leq \mathrm{ctw}(G) + k - 1$.

We remark that the only significant blowup is that of the cutwidth, when applying the $k$-thickening. We will therefore limit our use of this transformation as much as possible.

## 3.2 Reductions

We now discuss the proof of Theorem 3.1. In the full version in the appendix we split the theorem into multiple separate cases. Here, we only give one case as a representative sample:

▶ **Lemma 3.7.** *Let $(a, b) \in \mathbb{C}^2$ be a point with $|a| \notin \{0, 1\}$. Also let $T(G; x, y)$ be the Tutte polynomial of $G$ and $\alpha := (a-1)(b-1)$. There exists a polynomial time reduction from computing $T$ on $(a, b)$ for graphs of given tree-, path- or cutwidth, to computing $T$ along $H_\alpha$ for graphs with the following with parameters. The treewidth and cutwidth remain* $\mathrm{tw}(G)$ *and* $\mathrm{ctw}(G)$ *respectively. The pathwidth becomes at most* $\mathrm{pw}(G) + 2$.

We prove this lemma using essentially the same proof as given in [15]. Note that in our setting we use Lemmas 3.4, 3.5 and 3.6 to ensure that relevant parameters are not increased by the operations we perform.

**Proof.** By Brylawski's tensor product formula [6], we find the following expression for the $k$-stretch of the graph G

$$(1 + a + \cdots + a^{k-1})^{k(E)} T\left(G; a^k, \frac{b + a + \cdots + a^{k-1}}{1 + a + \cdots + a^{k-1}}\right) = T({}^{k}G; a, b). \tag{3}$$

Note that

$$a^k - 1 = (1 + a + \cdots + a^{k-1})(a - 1)$$

and

$$\frac{b + a + \cdots + a^{k-1}}{1 + a + \cdots + a^{k-1}} - 1 = \frac{b - 1}{1 + a + \cdots + a^{k-1}}.$$

We find that the point on which we evaluate $T(G)$ in (3) also lies on $H_\alpha$.

By examining the formula for the Tutte polynomial, we find that for $n = |V(G)|$ the degree of the Tutte polynomial is at most $n^2 + n$. By choosing $k = 0, \ldots, n^2 + n$, since $|a| \notin \{0, 1\}$, we can find $T(G; x, y)$, for $n^2 + n + 1$ different values of $(x, y) \in H_\alpha$. By lemma 2.1, we can now interpolate the univariate restriction

$$T_\alpha(G; t) = T\left(G; \frac{\alpha}{t} + 1, t + 1\right).$$

of $T(G)$ along $H_\alpha$.

Note that by Lemmas 3.4 and 3.6 the $k$-stretch preserves both the cutwidth and the treewidth of the graph and by Lemma 3.5 the pathwidth increases by a constant additive factor. We find that any fine-grained parameterized lower bound for $H_\alpha$ extends to points $(a, b)$. ◀

# 4 Counting forests

In this section we consider the problem of counting the number of forests in a graph. This problem corresponds to the point $(2, 1)$ and thus by Theorem 3.1 any bounds found for this problem can be lifted to the whole curve $H_0^y$.

We trivially get the following lower bound from existing bounds on the non-parameterized version of the problem [12].

▶ **Theorem 4.1.** *Computing the Tutte polynomial along the curve $H_0^y$ cannot be done in time $2^{o(\mathrm{ctw}(G))}n^{O(1)}$, unless #ETH fails.*

To complement this lower bound, we give an algorithm to count the number of forests in a graph $G$ in $c^{\mathrm{tw}(G)}$ time. The algorithm uses a rank based approach, the runtime of which depends on the rank of the so called *forest compatibility matrix*. We start by introducing this matrix and examining its rank.

## 4.1 Notation

We will use the notation $[n] = \{1, \ldots, n\}$. Unless stated otherwise, we will assume the set $[n]$ to be ordered. We write $\pi \vdash S$ to indicate that $\pi$ is a partition of $S$.

We will consider matrices indexed by partitions. We will write $M[\pi, \rho]$ for the element in the row corresponding to $\pi$ and the column corresponding to $\rho$. We will write $M[\pi]$ for the vector containing all elements in the row corresponding to $\pi$.

## 4.2 Rank bound

In this section we prove the following theorem, for the so called *forest compatibility matrix* $F_n$.

▶ **Theorem 4.2.** *The rank of $F_n$ is at most $C_n$, the $n^{th}$ Catalan number. In particular* $\mathrm{rank}(F_n) = O(4^n n^{-3/2})$

Before we can define the forest compatibility matrix, we first need the following definitions.

▶ **Definition 4.3.** *We say that a boundaried graph $G = ([n] \cup V, E)$, with boundary $[n]$, is a* representative forest *for a partition $\pi \vdash [n]$, if for every $S \in \pi$ there is some connected component $C \subseteq V(G)$ such that $C \cap [n] = S$.*

*Given two boundaried graphs $G$ and $H$, both with boundary $B$, we define the* glue $G \oplus H$ *of $G$ and $H$ as follows. First take the disjoint union of $G$ and $H$. Then identify each $v \in B$ in $G$ with its analogue in $H$.*

This definition shows how one can relate forests and partitions. Throughout the section we will mostly consider partitions as they capture only the information we need. The following definition elaborates on this by lifting the concept of cycles in a clue of two trees to a cycle inducet by two partitions.

▶ **Definition 4.4.** *Let $\pi, \rho \vdash [n]$ and let $G_\pi$ and $G_\rho$ be representative forests of $\pi$ and $\rho$ respectively. We say that $\pi$ and $\rho$* induce a cycle *if $G_\pi \oplus G_\rho$ contains a cycle.*

It is not hard to see that it does not matter which representatives $G_\pi$ and $G_\rho$ we choose, since one only needs to know the connected components on $[n]$. This means that this definition is indeed well-defined. For this same reason, in the following definition, we only need a row and column for each partition of the separator.

▶ **Definition 4.5.** *We define the* forest compatibility matrix $F_S$ *of a set* $S$ *by*

$$F_S[\pi, \rho] := \begin{cases} 0 & \text{if } \pi \text{ and } \rho \text{ induce a cycle} \\ 1 & \text{otherwise} \end{cases}$$

*for any* $\pi, \rho \vdash S$*. We will write* $F_n := F_{[n]}$*.*

Finally we will need the following definition to bound the rank of the forest compatibility matrix.

▶ **Definition 4.6.** *We say that two sets* $A, B \in \pi$ *are* crossing *on an ordering* $<$*, if there are* $a_1, a_2 \in A$ *and* $b_1, b_2 \in B$ *such that* $a_1 < b_1 < a_2 < b_2$ *or* $b_1 < a_1 < b_2 < a_2$*. If a partition contains two crossing sets, we refer to it as a* crossing partition*.*

Throughout this section it will sometimes be convenient to think of the ordering as a permutation.

The general idea behind the proof of Theorem 4.2 is to show that any partition can be "uncrossed", i.e. its row in $F_n$ can be written as a linear combination of rows, corresponding to non-crossing partitions.

### 4.2.1 Manipulating partitions

For the proof of Theorem 4.2 we will need the following operations, which will allow us to manipulate partitions by contracting an expanding intervals and projecting down to subsets of the ground set.

▶ **Definition 4.7.** *An* interval *is a subset* $I \subseteq [n]$ *of consecutive numbers, i.e. there is no* $b \notin I$ *such that* $a_1 < b < a_2$ *for some* $a_1, a_2 \in I$*. Given an interval* $I$ *and a partition* $\pi$ *of* $[n]$*, we define the* contraction $\pi -_i I$ *of* $\pi$ *by* $I$ *as the partition of the set* $[n] -_i I := ([n] \cup \{i\}) \setminus I$ *given by we merging all sets that intersect* $I$ *and replacing* $I$ *by a single element* $i$*, i.e.*

$$\pi -_i I := \{S \in \pi : S \cap I = \emptyset\} \cup \left\{ \left( \bigcup \{S \in \pi : S \cap I \neq \emptyset\} \cup \{i\} \right) \setminus I \right\}.$$

*If we have an ordering on* $[n]$*, we place* $i$ *in the same place in the ordering as* $I$*, that is for any* $a \in [n] \setminus I$ *and* $b \in I$*, we have* $a < b$ *if and only if* $a < i$*.*

*We define the* blowup $\pi +_i I$ *of* $\pi$ *by* $I$ *as the partition of the set* $[n] +_i I := ([n] \cup I) \setminus \{i\}$*, given by adding all elements of* $I$ *to the set that contains* $i$ *and then removing* $i$*, i.e.*

$$\pi +_i I := \{S \in \pi : i \notin S\} \cup \{(S \setminus \{i\}) \cup I : i \in S\}.$$

*Again we place* $I$ *in the same place in the ordering as* $i$*.*

We will sometimes abuse notation and refer to $[n] -_i I$ as simply $[n']$ for $n' = n - |I| + 1$.

We now turn our attention to a number of useful lemmas. The first lemma intuitively says that if we contract an interval contained in some partition, then any decomposition of the resulting smaller partition gives the same decomposition of the larger partition.

▶ **Lemma 4.8.** *Let* $\pi$ *be a partition of* $[n]$ *and let* $I$ *be an interval such that* $I \subseteq S \in \pi$*. We set* $n' = n - |I| + 1$*. Suppose that for some set of partitions* $\mathcal{R}$ *of* $[n']$*, we have* $F_{n'}[\pi -_i I] = \sum_{\rho \in \mathcal{R}} a_\rho F_{n'}[\rho]$*. Then* $F_n[\pi] = \sum_{\rho \in \mathcal{R}} a_\rho F_n[\rho +_i I]$*.*

**Proof.** Let $\chi$ be some partition of $[n]$. Note that if $|S' \cap I| \geq 2$ for some $S' \in \chi$, we have that $F_n[\pi, \chi] = F_n[\rho +_i I, \chi] = 0$. Thus we may assume that $\chi$ contains no such sets. Also note that if there is some cycle that only requires $I$ and not the rest of $S$, then again we have that $F_n[\pi, \chi] = F_n[\rho +_i I, \chi] = 0$. Thus we may assume that any cycle induced by $\chi$ and $\pi$ that has a set that intersects $I$, also requires a set that intersects $S \setminus I$, but not $I$.

We now claim that for $\chi$ with the above assumptions we have $F_n[\rho +_i I, \chi] = F_n[\rho, \chi -_i I]$ for any $\rho$. This would immediately imply that for such $\chi$

$$F_n[\pi, \chi] = F_n[\pi -_i I, \chi -_i I] = \sum_{\rho \in R} a_\rho F_n[\rho, \chi -_i I] = \sum_{\rho \in R} a_\rho F_n[\rho +_i I, \chi],$$

which proves the lemma.

First note that if $\rho$ and $\chi -_i I$ induce a cycle, that does not involve $i$, then $\rho +_i I$ and $\chi$ also induce that same cycle and vice versa.

Now suppose that $\rho +_i I$ and $\chi$ induce a cycle involving $I$, then there is some $S'$ in the cycle that intersects $I$. By assumption there is also some set $S'' \in \chi$ in the cycle, that intersects $S \setminus I$, but not $I$. W.l.o.g. the cycle does not loop back on itself and thus these sets are the only two in the cycle that intersect $S$. Note that $S'$ gets merged into the set containing $i$, but $S''$ does not. Since the rest of the cycle does not involve $I$, it is unaffected and thus the cycle remains intact after contraction.

In the reverse direction we assume that $\rho$ and $\chi -_i I$ induce a cycle involving $i$, then it is clear to see that this cycle survives after blowing up $i$, using one of the sets in $\chi$ that intersect $I$. This proves the claim and thus the lemma. ◀

This next lemma intuitively says that if we project our partition to a subset of the ground set, then any decomposition of the resulting smaller partition gives the same decomposition of the larger partition.

▶ **Lemma 4.9.** *Let $\pi$ be a partition of $[n]$ and let $n' < n$. Suppose that for some set of partitions $\mathcal{R}$ of $[n']$, we have $F_{n'}[\pi|_{[n']}] = \sum_{\rho \in \mathcal{R}} a_\rho F_{n'}[\rho]$, then $F_n[\pi] = \sum_{\rho \in \mathcal{R}} a_\rho F_n[\rho \sqcup \pi|_{[n] \setminus [n']}]$.*

**Proof.** Let $\chi$ be some partition of $[n]$. If $\chi$ and $\pi|_{[n] \setminus [n']}$ induce a cycle, then the statement trivially holds. In the rest of the proof we will therefore assume that any cycle induced by $\chi$ and $\pi$ requires the use of $\pi|_{[n']}$.

We first define an equivalence relation $\sim$ on $[n]$ by defining two elements to be equivalent if they are either in the same set of $\chi$ or in the same set of $\pi|_{[n] \setminus [n']}$. We then complete this to a full equivalence relation. We now define the partition $\chi'$ of $[n']$ as the set of equivalence classes of $\sim$, restricted to $[n']$.

We claim that $F_n[\rho \sqcup \pi|_{[n] \setminus [n']}, \chi] = F_{n'}[\rho, \chi']$ for any $\rho$, which would immediately imply that

$$F_n[\pi, \chi] = F_{n'}[\pi|_{[n']}, \chi'] = \sum_{\rho \in \mathcal{R}} a_\rho F_{n'}[\rho, \chi'] = \sum_{\rho \in \mathcal{R}} a_\rho F_n[\rho \sqcup \pi|_{[n] \setminus [n']}, \chi]$$

which proves the lemma.

Suppose that $\rho \sqcup \pi|_{[n] \setminus [n']}$ and $\chi$ induce some cycle. Since the cycle must pass through $[n']$, there must be some path from one element of $[n']$ to another, induced by $\rho \sqcup \pi|_{[n] \setminus [n']}$ and $\chi$. Since all elements in this path are equivalent, this path must lie entirely inside of a set $S' \in \chi'$ and thus replacing such a path with $S'$ results in a cycle induced by $\rho$ and $\chi'$. Note that if a cycle only requires sets from $\pi|_{[n']}$, this operation results in a single set $S'$ from $\chi'$ in the new cycle. However, since any set involved in the old cycle must contain at least two elements in the path, that set together with $S'$ induces a cycle.

Similarly, in the reverse direction we take a cycle induced by $\rho$ and $\chi'$ and blow up any sets of $\chi'$ into a path in the corresponding connected component to find a cycle induced by $\rho \sqcup \pi|_{[n]\setminus[n']}$ and $\chi$. ◀

The following two lemmas help ensure that our operations do not introduce new crossings. The first of the two lemmas shows us that we can safely contract an interval, so long as it is contained in a set of the partition.

▶ **Lemma 4.10** (†). *Let $I \subseteq [n]$ be an interval of $[n]$. Let $\pi$ be a non-crossing partition of $[n] -_i I$. Then $\pi +_i I$ is also non-crossing.*

This next lemma shows us that, in our setting, projection is safe, as long as we do not forget any elements of sets that cross one another.

▶ **Lemma 4.11** (†). *Let $\pi \vdash [n]$ be a partition such that only $A, B \in \pi$ cross each other and all other pairs of sets in $\pi$ are non-crossing. Then for a non-crossing partition $\rho$ of $A \cup B$ we have that $\rho \cup \pi|_{[n]\setminus(A\cup B)}$ is non-crossing.*

### 4.2.2 Proof of the rank bound

With Lemmas 4.8, 4.9, 4.10 and 4.11 in hand, we are now ready to describe the main uncrossing operation.

▶ **Lemma 4.12.** *Let $\pi$ be a non-crossing partition on an ordering $p$. In time $O(n)$ we can find constants $c_\rho$, such that $F_n[\pi] = \sum_{\rho\in\mathcal{N}} c_\rho F_n[\rho]$, where $\mathcal{N}$ is the set of partitions that are non crossing on $p \circ (i, i+1)$.*

**Proof.** Throughout the proof, we will consider the partition $\pi$ on the ordering $p \circ (i, i+1)$. We first note that since $\pi$ is non-crossing on $p$, any crossing of $\pi$ must involve both $i$ and $i+1$. Let $i \in A \in \pi$ and $i+1 \in B \in \pi$. If $A = B$, then $\pi$ is non-crossing and thus we may assume that $A \neq B$. Note that $\pi|_{A\cup B}$, when viewed as a partition of $A \cup B$, consists of either 4 or 5 intervals which alternate between $A$ and $B$. Define $\pi'$ as the partition given by contracting these intervals. We find that $\pi'$ is a partition on $n'$ elements, where either $n' = 4$ or $n' = 5$ elements, with intervals of size 1 (see Figure 4).

We can explicitly construct the forest compatibility matrices for $n' \in \{4, 5\}$ and check that the non-crossing partitions give a basis. With this paper we provide a MATLAB script that verifies this. Thus we can write

$$F_{n'}[\pi'] = \sum_{\rho\in\mathcal{R}} c_\rho F_{n'}[\rho],$$

where $\mathcal{R}$ is the set of non-crossing partitions of $[n']$. By Lemma 4.8 we find that

$$F_{A\cup B}[\pi|_{A\cup B}] = \sum_{\rho\in\mathcal{R}} c_\rho F_{A\cup B}[\rho +_{i_1} I_1 + \cdots +_{i_{n'}} I_{n'}].$$

By Lemma 4.10 each $\rho +_{i_1} I_1 + \cdots +_{i_{n'}} I_{n'}$ is still non-crossing. By Lemma 4.9 we find

$$F_n[\pi] = \sum_{\rho\in\mathcal{R}} c_\rho F_{A\cup B}[(\rho +_{i_1} I_1 + \cdots +_{i_{n'}} I_{n'}) \cup \pi|_{[n]\setminus(A\cup B)}].$$

By Lemma 4.11 each $(\rho +_{i_1} I_1 + \cdots +_{i_{n'}} I_{n'}) \cup \pi|_{[n]\setminus(A\cup B)}$ is still non-crossing. We conclude that $F_n[\pi]$ can be written as a linear combination of rows corresponding to non-crossing partitions.

Note that we can construct $\pi'$ in $O(n)$ time. We then find the $c_\rho$ in $O(1)$ time and reconstruct the $(\rho +_{i_1} I_1 + \cdots +_{i_{n'}} I_{n'}) \cup \pi|_{[n]\setminus(A\cup B)}$ in $O(n)$ time. ◀

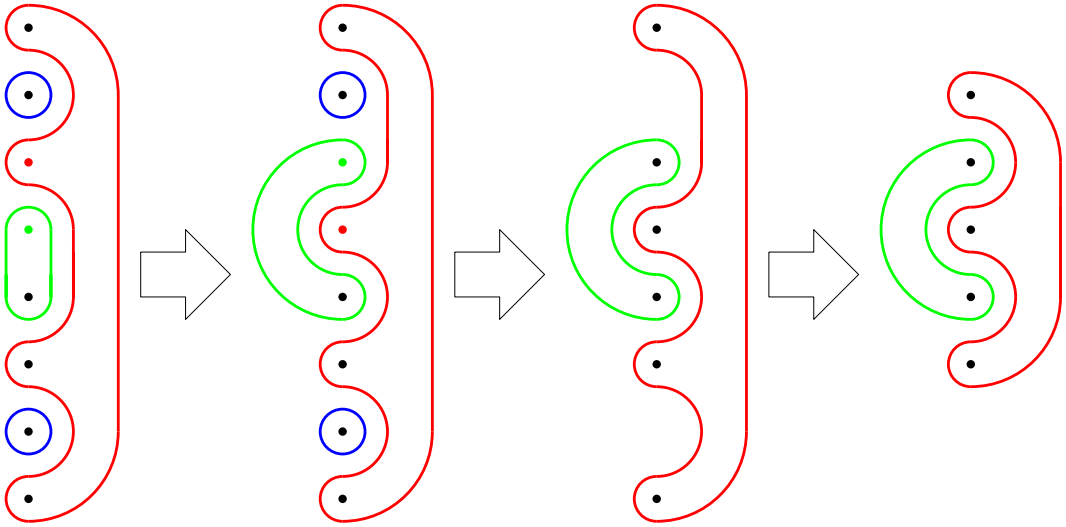

**Figure 4** From left to right, these are examples of $\pi$ before the swap, $\pi$ after the swap, $\pi|_{A\cup B}$ and $\pi'$.

By repeatedly applying Lemma 4.12, we can prove the following theorem.

▶ **Theorem 4.13.** *The rows corresponding to non-crossing partitions span a row basis of the forest compatibility matrix $F_n$.*

**Proof.** Let $\pi$ be a partition of $[n]$ such that we can turn it into a non-crossing partition by swapping two consecutive elements $i$ and $i+1$ in the order of $[n]$. By Lemma 4.12 we can write the row $F_n[\pi]$ corresponding to $\pi$ as a linear combination of rows corresponding to non-crossing partitions of $[n]$. This shows that, for $B_p$ the set of rows corresponding to non-crossing partitions on $p$, we have $B_{p\circ(i,i+1)} \subseteq \text{span}(B_p)$. Since every partition is non-crossing for some permutation and every permutation can be decomposed into 2-cycles on consecutive elements, this implies that every row can be written as a linear combination of rows corresponding to non-crossing partitions on some fixed ordering $p$. ◀

From this we immediately find a proof for Theorem 4.2.

**Proof of Theorem 4.2.** By Theorem 4.13 the non-crossing partitions form a basis of $F_n$. Since there are $C_n$ such partitions we find $\text{rank}(F_n) \leq C_n$. ◀

## 4.3 Algorithm

We will now describe the algorithm for counting forests. We first define the dynamic programming table and the notion of representation. For details on how to compute the table entries, see the full version [20].

▶ **Definition 4.14.** *Let $G$ be a graph and let $(\mathbb{T}, (B_x)_{x\in V(D)})$ be a tree/path decomposition of $G$. Recall that $G_x$ is defined as the graph induced by the union of all bags, whose nodes are descendants of $x$ in $\mathbb{T}$. We define the dynamic programming table $\tau$ by*

$$\tau_x[\pi] := |\{X \subseteq E(G_x) : (V, X) \text{ is acyclic},\\ \forall u, v \in B_x \text{ there is a path in } (V, X) \text{ from } u \text{ to } v \text{ iff } \exists S \in \pi \text{ s.t. } u, v \in S\}|$$

In other words, the table entry $\tau_x[\pi]$ counts the number of forests in $G_x$ whose connected components agree with $\pi$. In the rest of this section, we will refer to the number of nonzero entries $\tau_x[\pi]$ in a 'row' $\tau_x$ of the dynamic programming table as the support of $\tau_x$, written $\text{supp}(\tau_x)$. Our aim will be to ensure that the support of our rows remains contained in the entries corresponding to non-crossing partitions for some ordering on the bag $B_x$. This is captured in the following definition.

▶ **Definition 4.15.** *We say a vector $a$, indexed by partitions, is* reduced on an ordering $p$, *if $a_\pi = 0$ for any partition $\pi$ that is crossing for $p$.*

In order to ensure that we do not lose any relevant information we will reduce our rows, while retaining the following property for the matrix $F_{B_x}$.

▶ **Definition 4.16.** *Given a matrix $M$, we say that a vector $a$ $M$-*represents *a vector $b$ if $Ma = Mb$*

In the full version of the paper[20], we describe a dynamic programming algorithm that works with reduced rows, rather than the whole table. It does so by alternating between reducing the current row in the table and computing the next row. This allows us to work with a table where the rows effectively have size $\text{rank}(F_{\text{tw}})$ (or $\text{rank}(F_{\text{pw}})$). Doing so, we establish the following:

▶ **Theorem 4.17** (†). *There exists an algorithm that, given a graph $G$ with a path decomposition of width $\text{pw}(G)$, computes the number of forests in the graph in time $4^{\text{pw}(G)}n^{O(1)}$.*

▶ **Theorem 4.18** (†). *There exists an algorithm that, given a graph $G$ with a tree decomposition of width $\text{tw}(G)$, computes the number of forests in the graph in time $64^{\text{tw}(G)}n^{O(1)}$.*

# 5 Other cases

In this section we handle the remaining cases mentioned in Theorem 1.1.

## 5.1 The curve $H_2$

The curve $H_2$ is equivalent to the partition function of the Ising model. Both our proofs for the upper and lower bound on the complexity will make use of this fact.

▶ **Theorem 5.1.** *Computing the Tutte polynomial along the curve $H_2$ cannot be done in time $(2-\epsilon)^{\text{ctw}(G)}n^{O(1)}$, unless SETH fails.*

**Proof Sketch.** Using known equivalences we first reduce #MaximumClosedSubgraphs to the problem of computing the Tutte polynomial along the curve $H_2$. We then apply a simple transformation, based on a similar argument by [17] to ensure the graph only has odd degree vertices. It then suffices to note that on graphs with only odd degree vertices, the complement of a perfect matching is a maximum closed subgraph and thus #MaximumClosedSubgraphs is equivalent to #PerfectMatchings on such graphs. This allows us to lift an existing lower bound from [8] on #PerfectMatchings to #MaximumClosedSubgraphs. ◀

We also show in the full version that this lower bound can be matched with a tight upper bound. The proof uses dynamic programming combined with subset convolution [3, 9].

▶ **Theorem 5.2.** *Let $G$ be a graph with a given tree decomposition of width $\text{tw}(G)$. There exists an algorithm that computes $T(G;a,b)$, for $(a,b) \in H_2$, in time $2^{\text{tw}(G)}n^{O(1)}$.*

## 5.2 The curve $H_0^x$

The curve $H_0^x$ contains the point $(1, 2)$, which counts the number of connected edgesets of a connected graph. Using existing results this gives an ETH lower bound which matches the running time of the algorithm mentioned in theorem 1.1.

▶ **Theorem 5.3.** *Let $0 < \alpha < 1$. Computing the Tutte polynomial along the curve $H_0^x$ cannot be done in time $(\alpha \operatorname{ctw}(G) - \epsilon)^{(1-\alpha)\operatorname{ctw}(G)/2} n^{O(1)}$, unless SETH fails.*

**Proof.** In [13] a lower bound of $p^{\operatorname{ctw}(G)}$ is found for counting connected edgesets modulo $p$. In the reduction the authors reduce to counting essentially distinct $q$-coloring modulo $p$, with cutwidth $\operatorname{ctw}(G) + q^2$ and $p = q$. Thus we find a lower bound of $p^{\operatorname{ctw}(G)-p^2} = (\alpha \operatorname{ctw}(G))^{(1-\alpha)\operatorname{ctw}(G)/2}$ for $p = (\alpha \operatorname{ctw}(G))^{1/2}$. ◀

## 5.3 The curve $H_q$ for $q \in \mathbb{Z}_{\geq 3}$

These curves contain the points $(1 - q, 0)$, which count the number of $q$-colorings. Using previous results and a folklore algorithm, we find matching upper and lower bounds for these points and thus for the whole curves.

▶ **Theorem 5.4.** *Let $q \in \mathbb{Z}_{\geq 3}$. Computing the Tutte polynomial along the curve $H_q$ cannot be done in time $(q - \epsilon)^{\operatorname{ctw}(G)} n^{O(1)}$, unless SETH fails.*

**Proof.** Note that $H_q$ contains the point $(1 - q, 0)$. Computing the Tutte polynomial on this point is equivalent to counting the number of $q$-colorings of the graph $G$.

By choosing a modulus $p > q$ we can apply the results from [13] to find a lower bound of $q^{\operatorname{ctw}(G)}$ on the time complexity of counting $q$-colorings modulo $p$. This lower bound clearly extends to general counting. ◀

▶ **Theorem 5.5.** *Let $G$ be a graph with a given tree decomposition of width $\operatorname{tw}(G)$ and $q \in \mathbb{Z}_{\geq 3}$. There exists an algorithm that computes $T(G; a, b)$ for $(a, b) \in H_q$ in time $q^{\operatorname{tw}(G)} n^{O(1)}$.*

This theorem is a direct consequence of combining Theorem 3.1 with the following folklore result:

▶ **Theorem 5.6** (Folklore). *Let $G$ be a graph with a given tree decomposition of width $\operatorname{tw}(G)$ and $q \in \mathbb{Z}_{\geq 3}$. There exists an algorithm that computes the number of $q$-colorings of $G$ in time $q^{\operatorname{tw}(G)} n^{O(1)}$.*

## 5.4 The curve $H_{-q}$ for $q \in \mathbb{Z}_{>0}$

These curves contain the points $(1 + q, 0)$. Using the same results we used to prove theorem 5.4 and exploiting the fact these results hold for modular counting, we find an ETH lower bound which matches the running time of the algorithm mentioned in theorem 1.1.

▶ **Theorem 5.7.** *Let $q \in \mathbb{Z}_{>0}$. Computing the Tutte polynomial along the curve $H_{-q}$ cannot be done in $\operatorname{ctw}(G)^{o(\operatorname{ctw}(G))}$ time, unless ETH fails.*

**Proof.** Like mentioned earlier $H_{-q}$ contains the point $(1 + q, 0)$. For a prime $p > q$ we have that $T(G; 1 + q, 0) \equiv_p T(G; 1 + q - p, 0)$. This means that computing the Tutte polynomial modulo $p$ at the point $(1 + q, 0)$ is equivalent to counting the number of $p - q$-colorings of $G$ modulo $p$. Since $q > 0$ and $p > q$ we find that $0 < p - q < p$ and thus as before, by [13], we find a lower bound of $(p - q)^{\operatorname{ctw}(G)}$. Since the cutwidth of the construction in [13] is $O(n + rp^{r+2})$ for some $r$ dependant on $p - q$ and $\epsilon$. We find that there is no algorithm running in time $O((p - q - \epsilon)^{\operatorname{ctw}(G) - rp^{r+2}}) = O((\alpha \operatorname{ctw}(G) - \epsilon)^{\operatorname{ctw}(G)(1-\alpha)/(r+2)})$, where $p - q = (\alpha \operatorname{ctw}(G))^{1/(r+2)}$. ◀

## 6 Conclusion

In this paper we gave a classification of the complexity, parameterized by treewidth/pathwidth/cutwidth, of evaluating the Tutte polynomial at integer points into either computable

- in polynomial time,
- in $\mathrm{tw}^{O(\mathrm{tw})}\, n^{O(1)}$ time but not in $\mathrm{ctw}^{o(\mathrm{ctw})}\, n^{O(1)}$ time,
- in $q^{\mathrm{tw}} n^{O(1)}$ time but not in $2^{o(\mathrm{ctw})}$ (and for many points not even in $r^{\mathrm{ctw}} n^{O(1)}$ time for some constants $q > r$),

assuming the (Strong) Exponential Time Hypothesis.

This classification turned out to be somewhat surprising, especially considering the asymmetry between $H_0^x = \{(x, y) : x = 1\}$ and $H_0^y = \{(x, y) : y = 1\}$ that does not show up in other classifications such as the ones from [5, 12, 15].

Our paper leaves ample opportunities for further research. First, we believe that our rank upper bound should have more applications for counting forests with different properties. For example, it seems plausible that it can be used to count all Feedback Vertex Sets in time $2^{O(\mathrm{tw})} n^{O(1)}$ or the number of spanning trees with $k$ components in time $2^{O(\mathrm{tw})} n^{O(1)}$. The latter result would improve over a result by Peng and Fei Wan [22] that show how to count the number of spanning forests with $k$ components (or equivalently, $n - k - 1$ edges) in $\mathrm{tw}^{O(\mathrm{tw})}\, n^{O(1)}$ time. We decided to not initiate this study in this paper to retain the focus on the Tutte polynomial.

Second, it would be interesting to see if our classification of the complexity of all points on $\mathbb{Z}^2$ can be extended to a classification of the complexity of all points on $\mathbb{R}^2$ (or even $\mathbb{C}^2$). Typically, evaluation at non-integer points can be reduced to integers points (leading to hardness for non-integer points), but we were not able to establish such a reduction without considerably increasing the width parameters.

Third, it would be interesting to see if a similar classification can be made when parameterized by the vertex cover number instead of treewidth/pathwidth/cutwidth. We already know that the runtime of $2^n n^{O(1)}$ by Björklund et al. [2] for evaluating the Tutte polynomial cannot be strengthened to a general $2^{O(k)} n^{O(1)}$ time algorithm where $k$ is the minimum vertex cover size of the input graph due to a result by Jaffke and Jansen [16], but this still leaves the complexity of evaluating at many other points open.

# Matching Statistics Speed up BWT Construction

**Francesco Masillo**
Department of Computer Science, University of Verona, Italy

## Abstract

Due to the exponential growth of genomic data, constructing dedicated data structures has become the principal bottleneck in common bioinformatics applications. In particular, the Burrows-Wheeler Transform (BWT) is the basis of some of the most popular self-indexes for genomic data, due to its known favourable behaviour on repetitive data.

Some tools that exploit the intrinsic repetitiveness of biological data have risen in popularity, due to their speed and low space consumption. We introduce a new algorithm for computing the BWT, which takes advantage of the redundancy of the data through a compressed version of matching statistics, the *CMS* of [Lipták et al., WABI 2022]. We show that it suffices to sort a small subset of suffixes, lowering both computation time and space. Our result is due to a new insight which links the so-called insert-heads of [Lipták et al., WABI 2022] to the well-known run boundaries of the BWT.

We give two implementations of our algorithm, called `CMS-BWT`, both competitive in our experimental validation on highly repetitive real-life datasets. In most cases, they outperform other tools w.r.t. running time, trading off a higher memory footprint, which, however, is still considerably smaller than the total size of the input data.

## 1 Introduction

The Burrows-Wheeler Transform (BWT) [6] is a reversible permutation of the characters of the input text that can be computed in linear time and space. It is closely related to the suffix array, a permutation of the indices of $T$ which is based on the lexicographic order of the suffixes. It is known that the BWT, when applied to repetitive texts, results in an easier-to-compress string, especially when using simple run-length encoding.

Another virtue of the BWT is that it can be used as a self-index to replace the original text. It can support pattern matching queries, more specifically, it counts how many times a pattern $P$ occurs in $T$ using time proportional to $|P|$. It can be incorporated into more elaborate indexes [11, 13, 14, 27] to support locating queries (finding the positions in $T$ where $P$ occurs) and more complex queries such as finding Maximal Exact Matches (MEMs) and Maximal Unique Matches (MUMs). MEMs and MUMs are of key importance, especially in the field of bioinformatics, where they are used for read alignment (e.g. MUMmer [23]). Widely used tools such as BowTie2 [18] and BWA [20] are based on the BWT for aligning short reads to a reference genome.

Nowadays, the amount of biological data that is publicly available is too big for most BWT construction algorithms. A key observation is that, even though the size of these datasets is massive, the information contained within them is highly redundant. This is why

tools such as `big-BWT` [5], `r-pfBWT` [26] and `grlBWT` [10] have emerged. These tools exploit the intrinsic repetitiveness of the input data to build large BWTs fast and in compressed space.

Recently, Lipták et al. [22] devised a variant of matching statistics [8] called *compressed matching statistics* (*CMS*). This data structure has been proven to be effective in expressing the redundancy of sets of highly similar strings and being used in the process of suffix sorting. Cunial et al. [9] work with a *compact* representation of matching statistics, i.e. a bitvector of length $2|P|$ storing the differentially encoded lengths of the matches. They also present several ways of compressing the bitvector based on both lossless and lossy methods. This representation is fundamentally different from that of [22] due to the fact that the *CMS*, and more prominently its enhanced version, packs more information than just the length of the matches. This additional information can then be used for other applications such as suffix sorting.

In this paper, we are going to show that the *CMS* of [22] not only can be used to build the generalized suffix array of a collection of strings but can also be highly useful in building large BWTs, due to the fact that it uses considerably less space than the input data. Experimental results show that our implementation, `CMS-BWT`, is competitive, if not better, than the state-of-the-art tools for constructing the BWT, although heavier on the space consumption side.

Our algorithm is based on a new insight that allows us to find the run boundaries of the BWT within special buckets of suffixes, which are closely connected to the fundamental element of the compressed matching statistics, the so-called *insert-heads*.

The paper is organized as follows. In Section 2, we give definitions and notations used in the remainder of the paper. Section 3 contains an overview of the compressed matching statistics. In Section 4, we present our contribution, describing the algorithm used for constructing the BWT. In Section 5, we describe details of our implementation and then report experimental results in Section 6. Finally, in Section 7, conclusions and future work are discussed.

## 2 Basics

Let $\Sigma$ be an ordered alphabet of size $\sigma$. A string $T$ over $\Sigma$ is a finite sequence of characters from $\Sigma$. The $i$th character of $T$ is denoted $T[i]$, its length is $|T| = n$, and $T[i..j]$ denotes the substring $T[i] \cdots T[j]$. If $i > j$, then $T[i..j]$ is the empty string $\varepsilon$. The suffix $T[i..] = T[i..n]$ is referred to as the $i^{th}$ suffix $suf_i(T)$, and $T[..i] = T[1..i]$ is the $i^{th}$ prefix $pref_i(T)$. When T is clear from the context, we write $suf_i$ for $suf_i(T)$.

We assume that the last character of $T$ is the sentinel character \$. It is set to be smaller than any other character in $\Sigma$ and appears only once as the end-of-string character.

The *suffix array* $SA$ of a string $T$ is a permutation of the set $\{1, \ldots, n\}$ such that $SA[i] = j$ if $suf_j(T)$ is the $i$th in lexicographic order among all suffixes. Numerous suffix array construction algorithms (SACAs) exist in the literature [25, 24, 1, 21, 15]. SA-IS [25] is by far the most popular linear time SACA, being both simple and fast in practice.

The *inverse suffix array* $ISA$ is the inverse permutation of $SA$, namely $ISA[SA[i]] = i$.

The *longest common prefix* (*lcp*) of a pair of strings $T$ and $S$ is the longest string $U$ which is the prefix of both $T$ and $S$. The *longest-common-prefix array* $LCP$ is another array closely related to the $SA$. It is given by: $LCP[1] = 0$, and for $i > 1$, $LCP[i]$ is the length of the longest common prefix of the two suffixes $suf_{SA[i-1]}$ and $suf_{SA[i]}$. This array can be computed in linear time, too [17].

The Burrows-Wheeler Transform BWT [6] is a reversible permutation of the input text $T$. It is defined as $\text{BWT}[i] = \$$ if $SA[i] = 1$, and $\text{BWT}[i] = T[SA[i] - 1]$ otherwise.

Let $R$ and $S$ be two strings. The *matching statistics MS* of $S$ w.r.t. $R$ is an array of length $|S|$ in which every entry is a pair of integers defined as follows. Fix $i$, let $U_i$ be the longest prefix of suffix $suf_i(S)$ which occurs as a substring in $R$. Then, entry $MS[i] = (p_i, \ell_i)$, where $p_i$ is an occurrence of $U_i$ in $R$, or $-1$ if $U_i = \varepsilon$, and $\ell_i = |U_i|$. We will call $U_i$ *matching factor* and the character $c_i = S[i + \ell_i]$ will be referred to as *mismatch character* of position $i$. We set the end-of-string character of $R$ to be smaller than the one of $S$ ($\# < \$$).

For an integer array $A$ of length $n$ and an index $i$, the previous and next smaller values are defined as follows: $PSV(A, i) = \max\{i' < i \ : \ A[i'] < A[i]\}$, $NSV(A, i) = \min\{i' > i \ : \ A[i'] < A[i]\}$. The minimum of the empty set is $-\infty$ and the maximum is $+\infty$. There exists a data structure of size $n \log(3 + 2\sqrt{2}) + o(n)$ bits that can be built in $\mathcal{O}(n)$ time and answers both *PSV* and *NSV* queries in constant time [12].

Given a set of integers $X$ and an integer $x$, the predecessor of $x$ is the largest element in $X$ less than or equal to $x$. In other words, $pred_X(x) = \max\{y \in X \ : \ y \leq x\}$. Predecessor queries can be answered in $\mathcal{O}(\log \log |X|)$ time using the y-fast trie data structure of Willard [29] which uses $\mathcal{O}(|X|)$ space.

Let $\mathcal{C} = \{S_1, S_2, \ldots, S_m\}$ be a collection of strings not necessarily distinct, i.e. $\mathcal{C}$ is a multiset. The total length of $\mathcal{C}$ will be denoted by $N$, where we use end-of-string characters to delimit the strings, i.e. $N = \sum_{d=1}^{m} |S_d| + m$. From now on, we will treat $\mathcal{C}$ as this concatenated string, slightly abusing notation.

Our problem is defined as follows:

**Problem Statement:** Given a string collection $\mathcal{C} = \{S_1, \ldots, S_m\}$ and a reference string $R$, compute the Burrows-Wheeler Transform BWT of $\mathcal{C}$.

The end-of-string character # of $R$ is assumed to be smaller than any of $\mathcal{C}$. Moreover, in our setting, we assume that each $S_i \in \mathcal{C}$ is highly similar to $R$.

## 3 Compressed Matching Statistics

Recently, the authors of [22] introduced a new data structure called Compressed Matching Statistics (*CMS*). This data structure exploits the redundancy of plain *MS*, where we have the following property: if $\ell_i > 0$, then $\ell_{i+1} \geq \ell_i - 1$. We can identify sequences of the form $(x, x - 1, x - 2, \ldots)$ where $x = \ell_i$, called *decrement runs*. A decrement run ends when $\ell_j > \ell_{j-1} - 1$, and $j$ is the starting position of a head. For an example see Figure 1.

▶ **Definition 1** (Compressed matching statistics, [22]). *Let $R, S$ be two strings over $\Sigma$, and MS be the matching statistics of $S$ w.r.t. $R$. The* compressed matching statistics (*CMS*) of $S$ w.r.t. $R$ *is a data structure storing $(j, MS[j])$ for each head $j$, and a predecessor data structure on the set of heads $H$.*

It was shown in [22] that it is possible to recover each individual value $MS[i]$ for any $i$ using the following formula: $MS[i] = (p_i + k, \ell_i - k)$, where $j = pred_H(i)$ and $k = j - i$. This can be done in $\mathcal{O}(\log \log \chi)$ time and $\mathcal{O}(\chi)$ space, where $\chi = |H|$.

It was shown in [22] that storing the matching statistics information only for heads leads to a compression ratio of up to 100 times on real-life data.

## 3.1 Enhanced Compressed Matching Statistics

In [22], the *CMS* was refined with additional information to get the *enhanced compressed matching statistics* (*eCMS*). Assuming that all characters occurring in $S$ also occur in $R$ at least once, the information of $p_i$ can be made more specific, namely, one can compute the position that a suffix from $S$ would have if it was present in $SA_R$ the $SA$ of $R$. This position is called *insert point* of $i$:

$$ip(i) = \begin{cases} 1 & \text{if } U_i = \varepsilon, \\ \max\{j \mid U_i \text{ is a prefix of } R[SA_R[j]..] \text{ and } R[SA_R[j]..] < U_i c\} & \text{if this set is non-empty,} \\ \min\{j \mid U_i \text{ is a prefix of } R[SA_R[j]..]\} & \text{otherwise.} \end{cases}$$

The first case is satisfied only for the end-of-string characters of the collection $\mathcal{C}$, because the sentinel character of $R$ is smaller than any other character (# < \$). In the other two cases, the insert point is the lexicographic rank of suffix $i$ among all suffixes of $R$. Suffix $i$ ideally points to the next smaller occurrence of $U_i$ in $R$, if it exists (case 2). Otherwise, it coincides with the smallest occurrence of $U_i$ in $R$ (case 3).

For the *eCMS*, the positions for which the *MS* information is saved are called *insert-heads* and are defined as follows: $j$ is an insert-head if $SA_R[ip(j)] \neq SA_R[ip(j-1)] + 1$. Some additional information is also stored in each insert-head: $c_i$, the mismatching character, and $x_i$, a boolean value associated with $c_i$. This value is set to be smaller (S = 0) if $c_i < R[SA[ip(i)] + \ell_i]$ or larger (L = 1) otherwise. Referring to the definition of $ip$, $x_i = 1$ whenever we are in case 2, $x_i = 0$ when we are in case 3.

▶ **Definition 2** (Enhanced compressed matching statistics, [22]). *Let $R, S$ be two strings over $\Sigma$. Define the* enhanced matching statistics *of $S$ w.r.t. $R$ as follows: for $1 \leq i \leq |S|$, let $ems(i) = (q_i, \ell_i, x_i, c_i)$, where $q_i = SA_R[ip(i)]$, $\ell_i$ is the length of the matching factor $U$ of $i$, $c_i$ is the mismatch character, and $x_i \in \{S, L\}$ indicates whether $U_i c_i$ is smaller (S) or greater (L) than $R[q_i..]$. The* enhanced compressed matching statistics (*eCMS*) of $S$ w.r.t. $R$ *is a data structure storing $(j, ems(j))$ for each insert-head $j$, and a predecessor data structure on the set of insert-heads $K$.*

The size of $K$ is denoted by $|K| = \kappa$. The time for recovering $MS[i]$ becomes $\mathcal{O}(\log\log\kappa)$, while the space becomes $\mathcal{O}(\kappa)$ [22].

By definition, the number of insert-heads is larger than the number of heads. Although in [22] the difference in numbers is noticeable, the compression effect is still very strong. For actual numbers see Section 6.2, more specifically Table 1.

For an example of *eCMS* refer to Figure 1.

## 3.2 Comparing two suffixes using eCMS

The additional information of insert-heads helps bucketing suffixes with respect to the insert point. We will call these buckets *insert-buckets*. Assessing the order of any two suffixes having different insert point has been proven in the following lemma:

▶ **Lemma 3** ([22]). *Let $1 \leq i, j \leq N$. If $ip(i) < ip(j)$, then $suf_i < suf_j$.*

On the other hand, when two suffixes belonging to the same insert-bucket are compared the following lemma refines the order:

▶ **Lemma 4** ([22]). *Let $1 \leq i, j \leq N$, and $ip(i) = ip(j)$.*

| $i$ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| $R$ | C | A | T | T | A | G | A | T | T | A | G | # |
| $S$ | T | A | G | A | G | A | T | T | A | T | T | $ |
| $p_i$ | 4 | 5 | 6 | 5 | 6 | 7 | 8 | 9 | 2 | 3 | 4 | -1 |
| $\ell_i$ | 4 | 3 | 2 | 6 | 5 | 4 | 3 | 2 | 3 | 2 | 1 | 0 |
| head | ✓ | | | ✓ | | | | | ✓ | | | |
| $q_i$ | 4 | 5 | 6 | 5 | 6 | 2 | 3 | 4 | 7 | 8 | 9 | 12 |
| insert-head | ✓ | | | ✓ | | ✓ | | | ✓ | | | ✓ |
| $c_i$ | G | | | T | | T | | | $ | | | $ |
| $x_i$ | S | | | L | | L | | | S | | | L |

**Figure 1** An example for matching statistics and corresponding *CMS* and *eCMS*. In rows 1 and 2, we report $MS[i] = (p_i, \ell_i)$ of $S$ w.r.t. $R$. In row 3, we mark the starting positions of the heads (*CMS*). In row 4, for each index, we give the special position $q_i = SA_R[ip(i)]$, where $ip(i)$ is the insert point of $suf_i$ in $SA_R$. In row 5, we mark insert-heads (*eCMS*). In the last two rows, we complete the information stored in insert-heads, namely the mismatch character $c_i$ and $x_i$, the associated boolean value (S = smaller, L = larger).

1. *If* $\ell_i < \ell_j$ *and* $x_i = S$*, then* $suf_i < suf_j$.
2. *If* $\ell_i < \ell_j$ *and* $x_i = L$*, then* $suf_j < suf_i$.
3. *If* $\ell_i = \ell_j$ *and* $x_i = S$ *and* $x_j = L$*, then* $suf_i < suf_j$.
4. *If* $\ell_i = \ell_j$ *and* $x_i = x_j$ *and* $c_i < c_j$*, then* $suf_i < suf_j$.

To achieve the final correct order of two suffixes having the same insert-head information, in [22] it was suggested sorting only the insert-heads. Then, using the new rank for each head, the total order of two suffixes can be established.

If two arbitrary suffixes from $\mathcal{C}$ are being compared, one needs to perform two predecessor queries to get the insert-head of each suffix. This implies that the time spent for a single comparison is $\mathcal{O}(\log\log\kappa)$. As we will see in Section 4, we can avoid the predecessor queries when scanning the collection left to right, resulting in constant time comparisons. This is because we will only perform comparisons of suffixes of one insert-head at a time with other insert-heads of the same insert-bucket.

## 3.3 Computing the eCMS

We will use the procedure outlined in [22].

The data structures needed to compute the *eCMS* of $\mathcal{C}$ w.r.t. $R$ are the suffix array $SA_R$, the inverse suffix array $ISA_R$, the *LCP*-array $LCP_R$, and the *RMQ* data structure for *PSV-NSV* queries on $LCP_R$. Every data structure can be constructed in $\mathcal{O}(|R|)$ time and space.

This procedure takes $\mathcal{O}(N \log |R|)$ time and $\mathcal{O}(|R|)$ space and outputs the set of insert-heads of size $\mathcal{O}(\kappa)$.

To speed up the practical running time, we will use also the following proposed heuristic of [22]. Because we work with highly similar strings, it is common to have a singleton interval (an interval of size one) after the failure of a sequence of right extensions. A key insight is that also after the subsequent left contraction, the interval remains of size one. This means that the matching factor $U_i$ lies within a leaf branch in a hypothetical suffix tree of $R$. In order to detect these cases, we can compare $\ell_i$ to the maximum value in $LCP_R$. If $\ell_i - 1 > \max(LCP_R)$, then it means that there is no other suffix in $R$ with a prefix equal

to $U_i$. This means that we are in a leaf branch. Computing the left contraction is now equal to accessing $ISA[p_i + 1]$. This bypasses the $PSV$ and $NSV$ queries on $LCP_R$, avoiding the corresponding cache misses. Computing a single maximum can be too restricting for some datasets, so a refinement of this strategy is to divide $LCP_R$ into blocks and compute a maximum value for each of them.

The practical speedup can be of an order of magnitude when using this last strategy on sets of highly repetitive strings, as it was shown in [22].

## 4 Computing the BWT with enhanced Compressed Matching Statistics

In this section, we are going to outline the procedure used to compute the BWT of $\mathcal{C}$ using only data structures built on $R$ and the *eCMS* of $\mathcal{C}$ w.r.t. $R$.

We will use the following heuristic in order to speed up the computation of BWT($\mathcal{C}$): suffixes in text order between two insert-heads are preceded by the same character present in the reference. This can be intuitively explained by looking at the way *eCMS* is built: any position between two consecutive insert-heads is consecutive in text order both in $R$ and $\mathcal{C}$. Therefore, by knowing the insert point of each suffix we know what its position is in the previously computed $SA_R$, and consequently which is the preceding character stored in $\text{BWT}_R$. This insight tells us that we just have to "expand" $\text{BWT}_R$ based on the number of suffixes with the same insert-point while taking care of insert-heads. The suffixes corresponding to the starting positions of insert-heads are the only ones that need to be sorted inside each insert-bucket. See Figure 2 for an example.

▶ **Lemma 5.** *Let $suf_i$ and $suf_j$ be two suffixes of $\mathcal{C}$. If $ip(i) = ip(j)$ and the two suffixes are not the start of an insert-head, then $suf_i$ and $suf_j$ are preceded by the same character $c = R[SA[ip(i)] - 1]$, i.e. $\mathcal{C}[i-1] = \mathcal{C}[j-1] = c = R[SA[ip(i)] - 1]$.*

**Proof.** By assumption we know that $ip(i) = ip(j)$, therefore $SA[ip(i)] = SA[ip(j)]$. Because $suf_i$ and $suf_j$ are not the starting positions of any insert-head, it is true that $SA[ip(i-1)] = SA[ip(i)] - 1$ and $SA[ip(j-1)] = SA[ip(j)] - 1$. Therefore, $SA[ip(i-1)] = SA[ip(j-1)]$ and also $ip(i-1) = ip(j-1)$. Since $U_{i-1}, U_{j-1} \neq \varepsilon$ it follows that the first character of $U_{i-1}$ and $U_{j-1}$ is the same. ◀

While computing the *eCMS* of $\mathcal{C}$ w.r.t. $R$, we can simultaneously count how many suffixes fall in each insert-bucket. We recall that we can have at most $|R|$ insert-buckets, so the size of the array of counters called *bucket-counters* is $|R| \log N$ bits. By Lemma 5 we know that suffixes in the same insert-bucket have different preceding character only if one of them is an insert-head. By scanning again the collection, we just need to count how many suffixes belonging to the same insert-bucket come before each insert-head. In a sense, insert-heads work as run boundaries inside their insert-bucket, because they are preceded by a character that is different from the one preceding other non-insert-head suffixes. Therefore, we only need an additional counter for each insert-head to keep track of this quantity. We will store the counters in an array called *head-counters*. Inside a given insert-bucket we already know the total order of insert-heads, because we have sorted the whole set $K$ after the computation of *eCMS*, as mentioned in Section 3.2.

Since we are scanning $\mathcal{C}$ left-to-right, we know $MS[i]$ for every suffix, without the need of using predecessor queries as we explain next. By saving the *eCMS* in text order, we start from the first insert-head $k_1$. Every suffix $i$ before the starting position of $k_2$ have $MS[i] = (q_1 + (i - j_1), \ell_1 - (i - j_1))$, where $j_1 = 1$ is the starting position of $k_1$. Then, when

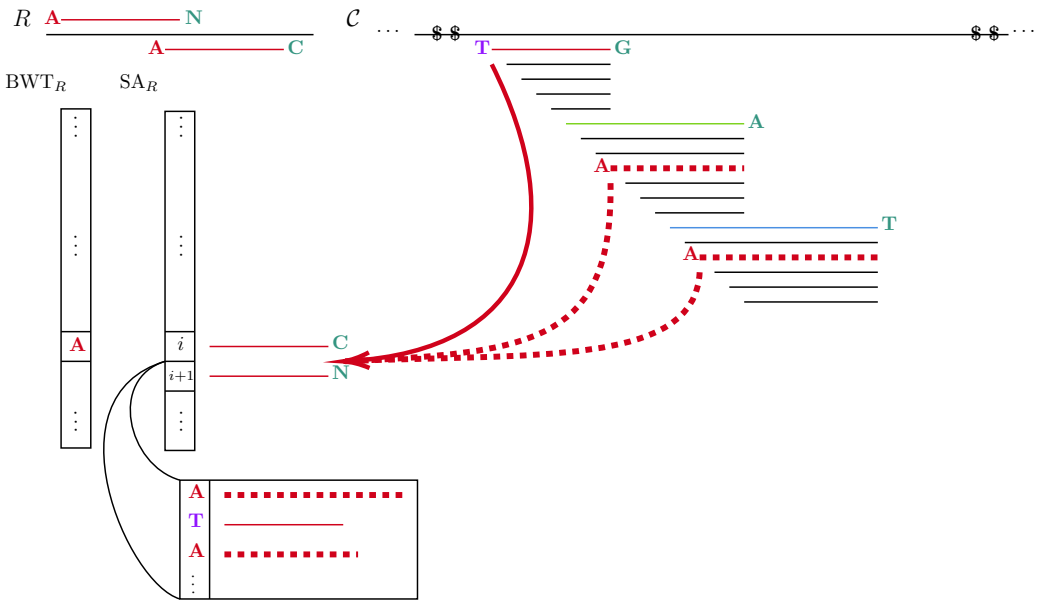

**Figure 2** Example showcasing the proposed heuristic. Solid coloured lines under $\mathcal{C}$ are matching factors for insert-heads, while solid black lines are matching factors for suffixes inbetween insert-heads. Dotted red lines are for suffixes inbetween insert-heads that share the same insert-point as the first solid red line (an insert-head). Suffixes inbetween insert-heads share the same preceding character (red A) with the reference $R$, while the red-coloured insert-head is preceded by a different character (purple T). Zooming in on the insert-bucket, we see that it can happen that the purple T goes between the red As, breaking what would have been a run of only red As.

we reach the starting position of $k_2$, we just have to repeat this procedure until every couple of insert-heads has been processed. We will compare suffix $i$ only with insert-heads stored in the corresponding insert-bucket, therefore we do not need to perform any predecessor query. Ultimately, the comparisons are made in constant time. Given $suf_i$, we can perform a binary search in the bucket corresponding to $ip(i)$ taking $\mathcal{O}(\log K_i)$ time, where $K_i$ is the set of insert-heads in the bucket with $ip(i)$. After finding the correct index using Lemma 4 and, if necessary, resorting to the rank of the sorted insert-heads, we increment the counter for that insert-head. The array of *head-counters* takes $\kappa \log N$ bits of space.

Building the BWT of $\mathcal{C}$ is then just a matter of interleaving bucket-counters and head-counters. For $1 \leq i \leq |R|$, let $x =$ bucket-counter$[i]$ be the number of suffixes in that bucket. If no insert-heads are present in the bucket, write $c = R[SA[i] - 1]$ in the output BWT$(\mathcal{C})$ $x$ times. Otherwise, if at least one insert-head is in the bucket, for each head-counter in the current insert-bucket write $c$ repeated as many times as indicated in the head-counter. Then, after the head-counter is processed, write the character that precedes the insert-head itself, namely $\mathcal{C}[j-1]$, where $j$ is the starting position of the insert-head. Each time we write a character from either the head-counter or the head itself, we subtract one from $x$. If at the end of this procedure, $x$ is not equal to 0, it means we still need to write that number of $c$ characters in the output BWT. This is because this amount of suffixes was bigger than any insert-head in their insert-bucket.

The main procedure is outlined in Algorithm 1 and the running time and space consumption are reported in Proposition 6. A full example can be found in Figure 3.

▶ **Proposition 6.** *Given $R$ and $\mathcal{C}$, we can compute BWT$(\mathcal{C})$ in $\mathcal{O}(N \log \kappa + N \log |R| + |R|)$ time and $\mathcal{O}(\kappa + |R|)$ space.*

**Figure 3** Example of the construction of BWT($\mathcal{C}$). The colour purple is used to indicate a relationship with insert-heads, whereas red is used to indicate a relationship with $R$ and BWT$_R$. On the left, under $\mathcal{C}$ we mark insert-heads with a purple circle and highlight with the same colour $q_j$ when $j$ is an insert-head. In the middle part of the figure, entries of bucket-counter highlighted in red contains a positive number, meaning that no insert-head is contained within that bucket. On the other hand, entries coloured in purple tell us that we have at least one insert-head in that bucket. On the right, we show the full BWT of $\mathcal{C}$, where we use the same colour code. We also show with horizontal lines insert-buckets, highlighting how we interleaved information from bucket-counters and head-counters.

**Proof.** Computing all data structures for $R$ can be done in linear time and space in $|R|$. Computing the $eCMS$ of $\mathcal{C}$ takes $\mathcal{O}(N \log |R|)$ time and $\mathcal{O}(|R|)$ space using the approach described in Section 3.3. The computation of BWT($\mathcal{C}$) is bounded by the time of counting how many suffixes are smaller than each insert-head in a bucket with the same $ip(i)$. More specifically, $\sum_{1 \leq i \leq |R|} B_i \log K_i \leq |C| \log \kappa$, where $B_i$ is the set of suffixes belonging to insert-bucket $i$ and $K_i$ the set of insert-heads within the same insert-bucket $i$. The space consumption is dominated by the number of insert-heads and the size of the data structures on $R$. ◀

Because we are working with highly similar strings, we expect to have few insert-heads, having long matches between any string of $\mathcal{C}$ and $R$. This makes the sorting part of insert-heads very fast in practice, due to $\kappa$ being small. Also, the process of binary searching is conducted bucket by bucket, so the number of heads in the same bucket is expected to be smaller than $\kappa$.

Moreover, if the insert-heads are concentrated in a few insert-buckets we can entirely skip the computation for each bucket without insert-heads. More information on real-life datasets related to this insight can be found in Section 6.2.

## 5 Implementation details

The algorithm starts by first augmenting the reference with characters that occur in $\mathcal{C}$ but not in $R$ so that we have a well-defined insert point for each suffix of the collection.

**Algorithm 1** CMS-BWT.

**Input:** reference $R$, collection $\mathcal{C}$
**Output:** BWT($\mathcal{C}$)

compute $SA_R$, $ISA_R$, $LCP_R$, $PSV - NSV(LCP_R)$
bucket-counters $\leftarrow [0] * N$
$eCMS \leftarrow [\,]$
$p_{\text{prev}} \leftarrow -\infty$
**for** $i \leftarrow 1$ ***to*** $N$ **do**
  $\langle i, p_i, \ell_i, c_i, x_i \rangle \leftarrow$ computeMS($R, \mathcal{C}, i$)
  **if** $p_i \neq p_{prev} + 1$ **then**
    $eCMS$.add($\langle i, p_i, \ell_i, c_i, x_i \rangle$)
    mark bucket-counter[$p_i$]  `// insert-bucket has an insert-head`
    bucket-counter[$p_i$] $++$
    $p_{\text{prev}} \leftarrow p_i$
  **else**
    bucket-counter[$p_i$] $++$
  **end**
**end**
sort $eCMS$
head-counters $\leftarrow [0] * K$
**for** $i \leftarrow 1$ ***to*** $N$ **do**
  **if** *bucket-counters*[$p_i$] *is marked* **then**
    $j \leftarrow$ binary-search correct position of $suf_i$ in $K_{p_i}$
    head-counters[$j$] $++$
  **end**
**end**
**for** $i \leftarrow 1$ ***to*** $|R|$ **do**
  $x \leftarrow$ bucket-counters[$i$]
  **if** $i > 1$ **then** $char \leftarrow R[SA_R[i-1]]$
  **else** $char \leftarrow R[|R|]$
  **if** *bucket-counter*[$i$] *is marked* **then**
    **for** $j \in indices(K_i)$ **do**  `// set of indices of` $K_i$
      write $char$ head-counters[$j$] times
      write character preceding $j$th head
      $x = x -$ head-counters[$j$] $- 1$
    **end**
    **if** $x > 0$ **then**
      write $char$ $x$ times
    **end**
  **else**
    write $char$ bucket-counter[$i$] times
  **end**
**end**

Then, we use `libsais` [16] to build $SA_R$ and $LCP_R$. We chose this tool because it has been experimentally proven to be one of the fastest tools for general-purpose suffix array construction. For the $LCP$ array it uses the $\Phi$ method [17]. The data structure for *PSV-NSV* queries on the $LCP_R$ is based on the work of Cánovas and Navarro [7].

For sorting the *eCMS*, we first rename each insert-head with a metacharacter based on the rank of the partial lexicographic order of the substrings associated with each insert-head. Then, by rearranging these metacharacters in text order we use again `libsais` to compute the suffix array of this metacharacter string.

When profiling the implementation, we found that the number of distinct insert-heads, i.e. the number of different tuples in $K$, grows even slower than the total set. For example, looking at the dataset consisting of 333 copies of Human Chromosome 19 described in Section 6.2, we have only 4,355,600 unique insert-heads versus $\kappa = 174,532,868$. Moreover, when performing binary search comparisons, more than 60% of the total number of comparisons were resolved by comparing the length plus $x_i$ information stored in the *eCMS*. Combining these two insights led us to another heuristic based on a two-layered binary search. First, we compare the length information $\ell_i = \ell_{k_i} - (i - j)$ along with $x_{k_i}$ of a suffix $i$ with insert-head $pred_K(i) = k_i$ starting at position $j$ with the set of unique insert-heads of its insert-bucket. Then, if the pair $\ell_i$ and $x_{k_i}$ is different from any other insert-head we increment the counter for the insert-head pointed to by this first binary search. Otherwise, we have to refine the search by comparing $suf_i$ with the whole set of insert-heads having $ip(i)$, $\ell = \ell_i$ and $x_{k_i}$. This technique led to a speedup in the binary search phase of between 10% and 20%.

To avoid continuous cache misses due to loading different subsets of insert-heads with different insert points during binary searching, we put a number of suffixes in a buffer divided into insert-buckets. After the buffer is at its full capacity, we proceed to process in bulk suffixes in the same insert-bucket, easing the loading in cache of subsets of insert-heads. For all of our experiments, we set this buffer to 2GB, but it can be arbitrarily chosen by the user.

Lastly, we also implemented a variant of `CMS-BWT` trading off space for running time. This was achieved by writing to disk some of the data structures involved in different phases of the algorithm. This version saves roughly a third of the space used by the non-memory-saving implementation.

## 6 Experiments

We implemented our algorithm for computing the BWT in C++. Our implementation, `CMS-BWT`, is available at `https://github.com/fmasillo/CMS-BWT`. The experiments were conducted on a desktop equipped with 64GB of RAM DDR4-3200MHz and an Intel(R) Core(R) i9-11900 @ 2.50GHz (with turbo speed @ 5GHz) with 16 MB of cache. The operating system was Ubuntu 22.04 LTS, the compiler used was `g++` version 11.3.0 with options `-std=c++20 -O3 -funroll-loops -march=native` enabled.

### 6.1 Tools compared

We compared two different implementations of `CMS-BWT` (simple and memory-saving) to the following four tools:

1. `big-BWT` [5], a tool which computes both the BWT and the suffix array. It is specifically made for highly repetitive data. We used the default parameters (`-w = 10`, `-p = 100`) and the `-f` flag to parse fasta files as input. We chose the default parameters in order to be consistent with the literature [5, 3, 4]. This tool outputs the entire BWT.

To double-check the choice of parameters, we performed further experiments on each combination of $w \in \{6, 8, 10\}$ and $p \in \{50, 100, 200, 400, 800\}$ as reported in [5]. On the basis of these experiments, we concluded that the default parameters $w = 10$ and $p = 100$ lead to the best combination of memory and time for the two datasets evaluated. It should be noted that the variation in memory and time between the different parameters is non-negligible, reaching a 7 times larger peak memory consumption and a 40% slowdown in running time for the `sars-cov2` dataset (data not shown).

2. `r-pfBWT` [26], is a tool improving on plain PFP. It has been shown to be both faster and to use less space than `big-BWT` for big enough dataset sizes. We run the experiments using `--bwt-only --w1 10 --w2 5` as flags. This tool outputs the run-length encoded BWT.
3. `grlBWT` [10], a tool computing the BCR BWT [2] again with a focus on highly repetitive data. We used the default parameters. This tool outputs the run-length encoded BWT.
4. `ropeBWT2` [19], a highly optimized tool to compute the BCR BWT on DNA data. We used the flag `-R` to skip the reverse complement. We also compare the effect of adding the `-P` flag, which limits the software to execute in single-threaded mode at all times. This tool outputs the entire BWT.

## 6.2 Datasets

In our experiments, we used two publicly available datasets. The first dataset, called `chr19` contains copies of the Human Chromosome 19 from the 1000 Genomes Project [28]. The second dataset, named `sars-cov2`, consists of copies of SARS-CoV2 genomes taken from COVID-19 Data Portal [1]. Some additional metadata can be found in Table 1.

The total size of both datasets is 60GB. We took increasing prefixes of size 1GB, 10GB, 20GB, 40GB, and 60GB. For the explicit number of sequences contained in each dataset see Table 2.

For example, looking at 20GB of `chr19` data, where we have around 333 copies of Human Chromosome 19, we have insert-heads only in 6% of the buckets. This means that around 94% of the suffixes will not be compared against any insert-head, speeding up the whole process.

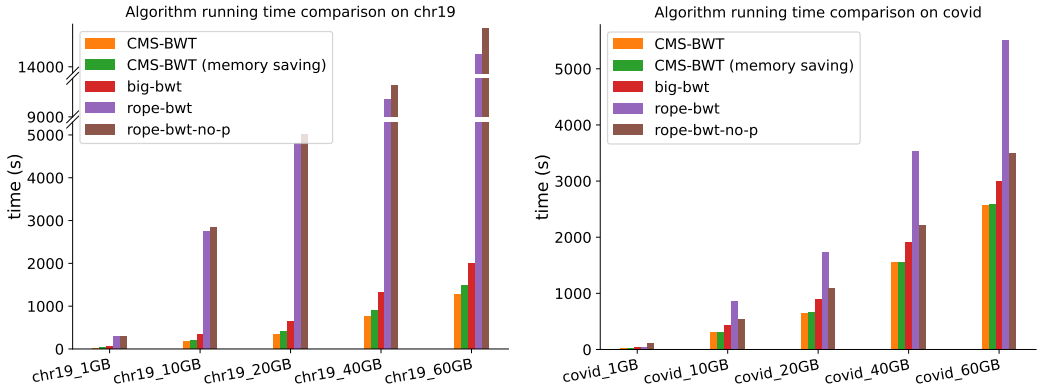
**Table 1** Datasets used in experiments. In column 3, we specify the alphabet size $\sigma$, in column 4 the number $r$ of runs of the BWT, in column 5 the number of insert-heads, and in column 6 the number of unique insert-heads. In our experiments, we use prefixes of each dataset up to 60GB. The last three columns refer to the 20GB prefix.

| Name | Description | $\sigma$ | $r$ (20 GB) | no. of i-heads (20 GB) | no. unique i-heads (20 GB) |
|---|---|---|---|---|---|
| `chr19` | Human Chromosome 19 | 5 | 36 723 404 | 174 532 868 | 4 355 600 |
| `sars-cov2` | SARS-CoV2 genome | 14 | 19 075 277 | 253 188 521 | 1 466 183 |

[1] We used the following command to download in bulk the data using the CDP File Downloader: `java -jar cdp-file-downloader.jar - -domain=VIRAL_SEQUENCES - -datatype=SEQUENCES - -format=FASTA - -location=/home/data/ - -email=xxx@xxx.xx - -protocol=FTP`

**Table 2** Number of sequences present in each dataset.

| Name | 1GB | 10GB | 20GB | 40GB | 60GB |
|---|---|---|---|---|---|
| `chr19` | 17 | 167 | 333 | 666 | 1 000 |
| `sars-cov2` | 36 204 | 332 209 | 659 441 | 1 312 058 | 1 966 237 |



**(a)** Running time comparison on different subsets of copies of Chromosome 19.

**(b)** Running time comparison on different subsets of copies of SARS-CoV2 genomes.

**Figure 4** Running time comparison of tools outputting the full BWT.

## 6.3 Results

As already pointed out in Section 6.1, the output of the tools can either be the full BWT or the run-length encoded BWT. This can be a non-negligible time overhead. Therefore, when comparing to tools that output the whole BWT we will also write this version of the BWT to disk. On the other hand, when comparing `CMS-BWT` to `r-pfBWT` and `grlBWT` we will write to disk the run-length encoded BWT.

In Figures 4a, 4b, 5a and 5b, we report the comparison of the running time of the five tools divided by dataset and output type.

On the `chr19` dataset, we are always the fastest tool compared to other tools that output the uncompressed BWT. More specifically, comparing the non-memory-saving implementation at 60GB of data, we are 57% faster than `big-BWT` and 10 times faster than `ropeBWT2` with and without `-P`. Compared to the tools that output the run-length encoded BWT, our fastest implementation is always the winner, while at 60GB, our memory-saving implementation takes 12% more time than `r-pfBWT`. Both implementations outperform `grlBWT`, e.g. at 60GB of data they take a fourth of the time.

On the `sars-cov2` dataset we are always the fastest tool in both settings. For example, at 60GB of data, we are faster than: `big-BWT` by 17%, `ropeBWT2` with `-P` by 114%, `ropeBWT2` with no `-P` by 35%, `r-pfBWT` by 445% and `grlBWT` by 53%.

In Figure 6a and 6b we show the memory footprint of the five tools. As one can notice, our tool has the highest memory requirement. However, it can be noted that the memory-saving variant of `CMS-BWT` on bigger sizes of both datasets requires always less than half of the input size in space. On the `sars-cov2` dataset we have a higher memory footprint than on `chr19` because for the same size of the datasets we have a significantly higher number of strings in the collection, leading to more insert-heads.

## 7 Conclusions

We presented a new algorithm for constructing the BWT of a collection of highly similar strings in compressed space. An experimental evaluation of two different implementations shows that our algorithm is competitive with state-of-the-art tools. Most of the time, both implementations outperform the other tools in terms of running time, but they are also the heaviest w.r.t. space consumption.

Future work will focus on parallelizing the implementation to allow taking advantage of multicore CPUs that are widespread nowadays. It is fairly straightforward to assign distinct sequences to a pool of multiple threads to compute the matching statistics. Another phase that would directly benefit from multi-threading is the for-loop at line 18 in Algorithm 1. With careful handling of locks for each head-counter, this is easily parallelizable, dividing the for-loop into equal parts. Moreover, we are going to investigate other ways of reducing memory consumption to close the gap between `CMS-BWT` and competing tools.

We are also working on extending our algorithm to incorporate the computation of $SA$-samples. This will allow us to build the $r$-index. With careful implementation, our tool can be extended to compute $SA$-samples along with bucket- and head-counters, without changing either the time or space bounds given in Proposition 6.

## Abstract

We consider the Min-Sum $k$-Clustering ($k$-MSC) problem. Given a set of points in a metric which is represented by an edge-weighted graph $G = (V, E)$ and a parameter $k$, the goal is to partition the points $V$ into $k$ clusters such that the sum of distances between all pairs of the points within the same cluster is minimized.

The $k$-MSC problem is known to be APX-hard on general metrics. The best known approximation algorithms for the problem obtained by Behsaz, Friggstad, Salavatipour and Sivakumar [Algorithmica 2019] achieve an approximation ratio of $O(\log |V|)$ in polynomial time for general metrics and an approximation ratio $2 + \epsilon$ in quasi-polynomial time for metrics with bounded doubling dimension. No approximation schemes for $k$-MSC (when $k$ is part of the input) is known for any non-trivial metrics prior to our work. In fact, most of the previous works rely on the simple fact that there is a 2-approximate reduction from $k$-MSC to the balanced $k$-median problem and design approximation algorithms for the latter to obtain an approximation for $k$-MSC.

In this paper, we obtain the first Quasi-Polynomial Time Approximation Schemes (QPTAS) for the problem on metrics induced by graphs of bounded treewidth, graphs of bounded highway dimension, graphs of bounded doubling dimensions (including fixed dimensional Euclidean metrics), and planar and minor-free graphs. We bypass the barrier of 2 for $k$-MSC by introducing a new clustering problem, which we call min-hub clustering, which is a generalization of balanced $k$-median and is a trade off between center-based clustering problems (such as balanced $k$-median) and pair-wise clustering (such as Min-Sum $k$-clustering). We then show how one can find approximation schemes for Min-hub clustering on certain classes of metrics.

## 1 Introduction

Clustering is a fundamental problem in many areas of data analysis and machine learning and has many applications across various fields. Given a set of points with a notion of similarity (distance) between every pair of points, in a typical $k$ clustering problem, the task is to partition the points into $k$ clusters to minimize dissimilarities of the points that fall into the same cluster.

In the well-known *center-based* $k$-clustering problems (such as $k$-*center*, $k$-*median*, $k$-*means*), the partition is obtained by selecting a set of $k$ *centers* and assigning each point to its nearest center. The clusters are then *evaluated* based on the distances between the points and their centers: in the case of $k$-center, the objective is to minimize the maximum distance of a point to its nearest center, while in the case of $k$-median ($k$-means), respectively, the

(a) (b)

**Figure 1** Clustering of a set of points: (a) a possible center-based clustering induced by a Voronoi diagram of two cluster centers , and (b) a min-sum $k$-clustering solution for $k = 2$. Observe that the min-sum $k$-clustering solution in (b) places all outliers into a separate cluster.

objective is to minimize the sum of distances (the sum of squared distances, respectively) between points and their centers. Compared to other clustering algorithms, center-based algorithms are efficient for clustering large datasets as the main task reduces to selecting $k$ centers; once we decided on the set of centers, points that are closest to a particular center are considered to be part of the cluster represented by that center. Center-based clustering algorithms are not always precise because they heavily rely on the assumption that each cluster has a *spherical* shape and hence can be represented by one center.

In *pair-wise* $k$-clustering, on the other hand, the goal of partitioning is to minimize the dissimilarity between pairs of points that are in the same cluster. For example, in the case of the *$k$-diameter* problem, the goal is to minimize the maximum distance between any two points in a cluster; or in the *min-sum $k$-clustering* problem, the goal is to minimize the sum of distances between all pairs of the points within the same cluster.

Unlike center-based clustering problems, min-sum $k$-clustering (which is the main focus of this paper) is less sensitive to the shape of clusters because it forms clusters based on the pair-wise distances between points rather than the distances of points to their cluster center. Also, as observed in [8], min-sum $k$-clustering can handle (detect) noises (outliers) in an effective way: in scenarios where data include well-defined clusters and a limited number of scattered noises (outliers), assigning an outlier to one of the clusters would be more costly than placing it in an outlier cluster that holds all the outliers. This results in a solution with a separate cluster specifically for outliers, avoiding the limitations of center-based clustering algorithms, which rely on Voronoi partitioning to divide the data space into clusters and are unable to handle overlapping cluster spaces. See Figure 1.

We now formally define the min-sum $k$-clustering problem. Given a metric space over a set of $n$ points $V$ with metric distances $d(u, v)$ between any two $u, v \in V$. We assume the metric is induced by an edge-weighted graph $G = (V, E)$. In the **Min-Sum $k$-Clustering** problem (**$k$-MSC**), the goal is to partition points $V$ into $k$ clusters $C_1, ..., C_k$ to minimize the sum of pairwise distances between points assigned to the same cluster: $\sum_{i=1}^{k} \sum_{\{u,v\} \subseteq C_i} d(u, v)$. This problem is closely related to the **Balanced $k$-Median** problem (**$k$-BM**), with the same input as in **$k$-MSC**. Here, the goal is to select $k$ points $c_1, ..., c_k \in V$ as the centers of the clusters and partition points $V$ into clusters $C_1, ..., C_k$ to minimize $\sum_{i=1}^{k} |C_i| \sum_{v \in C_i} d(v, c_i)$.

## Related Works

Sahni and Gonzalez introduced $k$-MSC in 1976 [13]. They showed the problem is $NP$-hard and provided a polynomial time $k$-approximation algorithm for the $k$-Max Cut problem, which is the dual of **$k$-MSC** and involves partitioning points into $k$ clusters to maximize the distance between points in different clusters. Kann et al. [12] showed it is $NP$-Hard

to approximate non-metric ***k*-MSC** within $O(n^{2-\epsilon})$ for any $\epsilon > 0$ and $k > 3$. Later, Cohen-Addad et al. [6] proved that it is $NP$-hard to approximate metric ***k*-MSC** within 1.415.

Guttman-Beck and Hassin [11] showed that ***k*-BM** and ***k*-MSC** are closely related. They showed an algorithm with $\rho$ approximation for one of these problems implies a $2\rho$ approximation for the other. In the literature, most of the previous work (with a guaranteed approximation factor) for ***k*-MSC** make use of this reduction. Guttman-Beck and Hassin [11] showed that **k-BM** can be solved in time $n^{O(k)}$ by guessing the cluster centers and sizes and finding the minimum-cost assignment from clients to these centers. This results in a 2-approximation solution for the min-sum $k$-clustering problem when $k$ is fixed. Bartal et al. [3] introduced the first polynomial time approximation algorithm for both ***k*-MSC** and ***k*-BM** in metric spaces. They devised an algorithm with an approximation factor of $O(\frac{1}{\epsilon}\log^{1+\epsilon} n)$ and running time of $n^{\frac{1}{\epsilon}}$ for ***k*-BM**. The algorithm is based on the embedding of metric spaces into hierarchically separated trees (HSTs). They also provided a bi-criteria approximation algorithm with a constant approximation factor with $O(k)$ clusters. Later, Behsaz et al. [4] improved the result by utilizing the properties of HSTs through a direct dynamic programming approach, leading to a $O(\log n)$ approximation algorithm for both ***k*-MSC** and ***k*-BM**. This is the current best result for general metrics. They also present a quasi-polynomial time approximation scheme for ***k*-BM** in metrics with constant doubling dimensions, leading to a $(2+\epsilon)$-approximation algorithm for the min-sum $k$-clustering problem that runs in quasi-polynomial time. More recently Banerjee et al. [2] gave a bicriteria approximation for ***k*-MSC** with outliers: for any $\epsilon > 0$, given an instance with $n$ points and any integer $n' \leq n$, their algorithm finds a solution that clusters at least $(1-\epsilon)n'$ points whose cost is poly$(1/\epsilon)$ times the optimum clustering of $n'$ points.

For small values of $k$, Vega et al. [9] introduced the first polynomial time approximation scheme for ***k*-MSC** in metric spaces. The running time of their algorithm is $O(n^{3k}2^{\epsilon^{-k^2}})$. Czumaj and Sohler [8], presented a $(4+\epsilon)$ approximation algorithm for ***k*-MSC** in metric spaces with a running time of linear for $k = o(\log n/\log\log n)$.

## Our Results and Techniques

As mentioned earlier, the previous methods for designing approximation for ***k*-MSC** attempt to approximate the cost using a center-based clustering objective (such as ***k*-BM** [3, 4] or a capacitated version of $k$-median [2]). Such methods have a barrier of 2 (even for tree metrics). A key challenge in extending the framework of [4] to work directly for ***k*-MSC** is to develop a compact representation of the cluster types in a near-optimal solution that can capture the essence of the cluster without relying on a center.

Here we introduce a new clustering objective that is in between the pair-wise distances objective of ***k*-MSC** and the center-based objective of ***k*-BM**, which we call min-hub clustering. We show that for metrics with a nice hierarchical decomposition (such as graphs of bounded treewidth, or bounded doubling dimension), the objective of min-hub clustering is a good (namely $(1+\epsilon)$) approximation of ***k*-MSC** and how one can obtain an approximation scheme for the new objective (and hence one for ***k*-MSC**).

In center-based clustering, a cluster is represented by a single center. However, as demonstrated in Figure 1 (see the outlier cluster in red), not all ***k*-MSC** clusters can be represented by a single center. To address this, we explore the possibility of using multiple centers to represent a cluster. Our results show that a cluster in the ***k*-MSC** solution can be represented by $O_\epsilon(1)$ centers, which we refer to as *hubs*, while incurring an error of $(1+\epsilon)$. Specifically, let $H$ be a set of hubs. The *hub-distance* between two points $u$ and $v$ in a cluster

$C$ is defined as the shortest path between the points that passes through hub points in $H$. Our results show that there exists a set of $H$ of constant size (depending on $\epsilon$) such that the sum of distances between all pairs of points within $C$ is "almost" equal to the sum of hub-distances between pairs of points in $C$. This suggests that the network interconnecting the hubs, called the *backbone structure*, carries the majority of the connection flow in the cluster. We represent a cluster by the type of its backbone structure and the distribution of points around its hubs.

In Section 2, we consider the special case of tree metrics. We construct a dynamic program for ***k*-MSC** on tree metrics that have a logarithmic height. In Section 3, we extend our approach to cover metrics with bounded treewidth, thereby covering general trees as well.

▶ **Theorem 1.** *There is a quasi-polynomial time algorithm that, given an instance of* ***k*-MSC** *on a metric of treewidth $f$, for any $\epsilon > 0$ finds a $(1+\epsilon)$-approximate solution in time $n^{O(f^2+(\frac{\log n}{\epsilon})^{\sigma+1})}$, where $\sigma$ depends on $\epsilon$.*

It is worth pointing out that, if one tries to extend the result from trees to graphs with treewidth $f$ in a natural way, the algorithm will have a run time of the form $n^{(\frac{\log n}{\epsilon})^{f^2+\sigma+1}}$ (instead of $n^{O(f^2+(\frac{\log n}{\epsilon})^{\sigma+1})}$), which is still quasi-polynomial for fixed $f$, but will not be quasi-polynomial if $f = \text{Polylog}(n)$. This is essential to obtain the next three theorems, as we use embeddings into graphs with treewidths $f = \text{Polylog}(n)$.

In Section 4, using frameworks from [14], [10], and [7], we expand our results to three additional metric classes: bounded doubling metrics, bounded highway dimension metrics, and minor-free metrics, respectively.

▶ **Theorem 2.** *There is a quasi-polynomial time algorithm that, given an instance of* ***k*-MSC** *on a metric of doubling dimension $D$, for any $\epsilon > 0$ finds a $(1+\epsilon)$ approximate solution in time $n^{O((\frac{D\log n}{\epsilon})^{2D}+(\frac{\log n}{\epsilon})^{\sigma+1})}$.*

▶ **Theorem 3.** *There is a quasi-polynomial time algorithm that, given an instance of* ***k*-MSC** *on a metric highway dimension $D$ and violation $\lambda$, for any $\epsilon > 0$ finds a $(1+\epsilon)$ approximate solution in time $n^{O((\log n)^{\alpha}+(\frac{\log n}{\epsilon})^{\sigma+1}))}$, where $\alpha = O(\log^2(\frac{D}{\epsilon\lambda})/\lambda)$.*

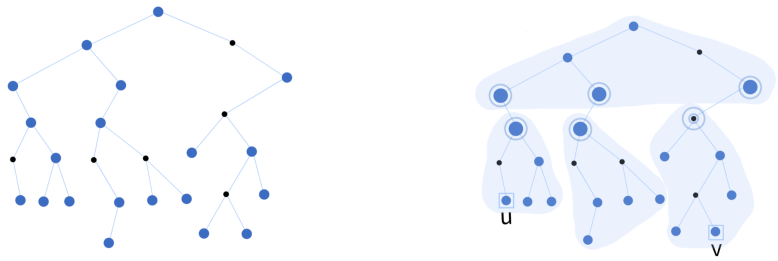
▶ **Theorem 4.** *There is a quasi-polynomial time algorithm that, given an instance of* ***k*-MSC** *in minor-free metrics, for any $1/2 > \epsilon > 0$ finds a $(1+\epsilon)$ approximate solution in time $n^{\epsilon^{-O(1)}\log^{O(1)} n}$.*

## 2 The $k$-MSC Problem in Tree Metrics

In this section, we construct a dynamic program for ***k*-MSC** on trees. Consider metric $(V, d)$ induced by an edge-weighted tree $T = (V, E)$. Let $w(e)$ denote the weight of edge $e$ in $E$.

We let $T$ be rooted at an arbitrary vertex $r \in V$. The parent of a vertex $v \in V \setminus \{r\}$ is the vertex adjacent to $v$ on the path from $v$ to $r$. If $u$ is the parent of $v$ then $v$ is a *child* of $u$. A tree vertex is called a *leaf* if it has no children and is called an *internal* vertex otherwise. The *level* of each node is the number of edges on the path from it to $r$. The *height* of the tree is the level of the leaf node with the highest level. We use $T_v$ to denote the *subtree* rooted at $v$, $V(T_v)$ and $E(T_v)$ to denote the vertex set and the edge set of $T_v$, respectively. By introducing zero-weight edges and nodes, we convert the tree into an equivalent binary tree. Note that the resulting binary tree has at most $2|V|$ nodes.

We use $C \subseteq V$ to denote a cluster and $D(C)$ to denote the total sum of the distances between all pairs of points in $C$; i.e., $D(C) = \sum_{\{u,v\}\subseteq C} d(u, v)$. We use $H \subseteq V$ to indicate a set of points referred to as *hubs*. The distance between any two points $u$ and $v$ in $C$, when



(a) (b)

**Figure 2** (a) A cluster on the tree, where the blue circles specify points of this cluster. (b) Shaded regions highlight the resulting groups by applying Lemma 5 on the cluster. Notice that the distance between any two points of the cluster that belong to different groups (such as $u$ and $v$) is equal to their hub-distance, $d_H(u,v)$, as long as $H$ contains the border nodes of the groups. The larger circles around the nodes depict the border nodes of the groups (so the proper hubs of the cluster).

**Algorithm 1** Tree Partitioning Algorithm.

$\mathbb{C}_\nu \leftarrow \emptyset$
$\eta \leftarrow \max\{\nu|C|, 1\}$
$L \leftarrow \{v \in V : \quad \frac{1}{2}\eta \le |V(T_v) \cap C| \le \eta\}$
**while** $L \neq \emptyset$ **do**
  $\hat{v} \leftarrow v \in L$ ▷ If multiple, select $v$ with the lowest level.
  $g \leftarrow V(T_{\hat{v}})$
  $\mathbb{C}_\nu \leftarrow \mathbb{C}_\nu \cup \{g\}$
  remove $T_{\hat{v}}$ from $T$
  $L \leftarrow \{v \in V(T) : \quad \frac{1}{2}\eta \le |V(T_v) \cap C| \le \eta\}$
**end**
$\mathbb{C}_\nu \leftarrow \mathbb{C}_\nu \cup \{V(T_r)\}$

measured through hubs in $H$, is called the *hub-distance* and is denoted by $d_H(u,v)$. This is the length of the shortest path between the two points that goes through hub points in $H$; i.e., $d_H(u,v) = \min_{h_1,h_2 \in H} \big(d(u,h_1) + d(h_1,h_2) + d(h_2,v)\big)$. Let $p_H(u,v)$ represent the path between points $u$ and $v$ that passes through hub points in $H$ and has the length of $d_H(u,v)$. The *sum of pairwise hub-distances* for the points in $C$ is represented by $D_H(C)$ and is equal to the total sum of the hub-distances between all pairs of points in $C$; i.e., $D_H(C) = \sum_{\{u,v\} \subseteq C} d_H(u,v)$. Note that $D_V(C)$=$D(C)$.

The following lemma shows how to find a (constant-size) set of hubs that represents a given cluster in metrics induced by a tree metric. See Figure 2. For a subset of nodes $g \subseteq V$, we use $\delta(g) = \{v \in g : \ uv \in E \ \& \ u \notin g\}$ to denote the *border nodes* of $g$.

▶ **Lemma 5.** *Let $C \subseteq V$ be a cluster and let $T = (V,E)$ be a given binary tree. For any $\nu > 0$, there exists a partition of $V$ into a set of groups $\mathbb{C}_\nu = \{g_1, \ldots, g_\sigma\}$ such that all of the following properties hold: (i) the subgraph induced by each group $g \in \mathbb{C}_\nu$ is connected. (ii) for each group $g \in \mathbb{C}_\nu$, $|g \cap C| \in [1, \max\{1, \nu|C|\}]$. (iii) $|\mathbb{C}_\nu| = O(1/\nu)$. (iv) $\forall g \in \mathbb{C}_\nu, \quad |\delta(g)| = O(1/\nu)$.*

**Proof.** We use Algorithm 1 to compute $\mathbb{C}_\nu$. The algorithm iteratively selects a subtree $T_{\hat{v}}$, with approximately $\frac{\nu}{2}$ of the total number of points $|C|$, adds the vertex set $V(T_{\hat{v}})$ to $\mathbb{C}_\nu$, and removes $T_{\hat{v}}$ from $T$. The number of iterations (i.e. the number of groups made by the algorithm) is at most $2/\nu$, and every vertex of $V$ belongs to one group.

Note that there is at most one edge between any two groups, so $|\delta(g)| = O(1/\nu)$, $\forall g \in \mathbb{C}_\nu$. The subgraphs induced by $g_i$'s are connected by construction. Thus, the algorithm has constructed a partition with the desired properties, as shown in Figure 2. ◀

Note that each cluster covers only a subset of points, however, the groups of the cluster always include all the nodes of $V$. Given a cluster $C \subseteq V$ and a constant $\nu > 0$, let $\mathbb{C}_\nu = \{g_1, \ldots, g_\sigma\}$ be the groups obtained by applying Lemma 5 on $C$ with the given value of $\nu$. We let $H_\nu(C) = \cup_{i=1}^{\sigma} \delta(g_i)$ denote the **$\nu$-proper hubs** of the cluster. Notice that the size of $|H_\nu(C)|$ is constant, depending on $\nu$.

Given a cluster $C \subseteq V$ and a constant $\nu > 0$, consider the $\nu$-proper hubs of the cluster, $H_\nu(C)$. We refer to $\text{cost}_{H_\nu}(C) = \sum_{i=1}^{\sigma} \sum_{j=i+1}^{\sigma} \sum_{u \in g_i \cap C, v \in g_j \cap C} d_{H_\nu(C)}(u, v)$ as the **$\nu$-approximate cost** of the cluster. This represents the sum of hub-distances between all pairs of points of $C$ belonging to different groups. The following lemma shows that $\text{cost}_{H_\nu}(C)$ is "almost" equal to $D(C)$, when the value of $\nu$ is sufficiently small.

▶ **Lemma 6.** *For each such cluster $C$ and any $\nu > 0$, $cost_{H_\nu}(C) \leq D(C) \leq (1 + O(\nu))cost_{H_\nu}(C)$.*

The proof is omitted due to page limitations.

To make the presentation of our dynamic programming algorithm simpler, we formulate a problem with the same input and objective as the min-sum $k$-clustering problem, but the cost of clusters is evaluated by $\text{cost}_{H\nu}(C)$ instead of $D(C)$: Given a constant $\nu > 0$ and an edge-weighted tree $T = (V, E)$. In the **Min-Hub $k$-Clustering** problem (**$k$-MHC**), we are asked to partition points $V$ into $k$ clusters $C_1, ..., C_k$ to minimize $\sum_{i=1}^{k} \text{cost}_{H_\nu}(C_i)$.

▶ **Theorem 7.** *Let $\epsilon > 0$. A $(1 + \epsilon)$-approximation for **$k$-MHC** will imply a $(1 + O(\epsilon))$-approximation for $k$-MSC on tree metrics.*

The proof is omitted due to page limitations.

## 2.1 QPTAS for $k$-MHC on Trees with Logarithmic Heights

Theorem 7 tells us that if we try to find a clustering which optimizes the objective of **$k$-MHC**, then the same clustering has a good value for the objective of **$k$-MSC**. Suppose we are given a tree $T = (V, E)$ that has a logarithmic height and a constant $\nu > 0$. Let $OPT$ be the minimum cost of partitioning $V$ into $k$ clusters $C_1, C_2, \cdots, C_k$ with the total cost being $\sum_{i=1}^{k} \text{cost}_{H_\nu}(C_i)$. Given $\epsilon > 0$, we will present a dynamic program that finds a $(1 + \epsilon)$-approximation of $OPT$. This, as a result of Theorem 7, leads to a $(1 + O(\epsilon))$ approximation solution for **$k$-MSC** on trees with logarithmic heights. Then, in the next section, we will extend the dynamic program to cover metrics with bounded treewidth, thereby covering general trees as well.

**Preprocessing.** We assume each node of the tree has a *token* on it and our goal is to cluster the tokens. We may modify the tree by adding dummy edges (with zero weight) and dummy nodes (that do not have tokens). Throughout this section, we refer to a node with a token as a *point* and a node without a token as a *vertex*. By introducing zero-weight edges and nodes, we convert the tree into an equivalent binary tree in which the points are only located on distinct leaves. We repeatedly remove leaves with no tokens until there is no such leaf in the tree. We also repeatedly remove internal vertices (with no token) of degree two by consolidating their incident edges into one edge of the total weight.

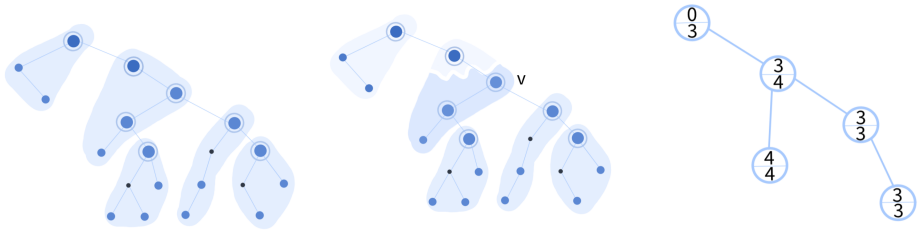


**Figure 3** (a) A cluster and its corresponding groups. (b) The partial cluster with respect to $T_v$. (c) The corresponding backbone tree whose nodes are labelled according to their sizes/weights.

**Cluster, Backbone Tree, and Partial Cluster Types.** Let $\nu > 0$ and consider a cluster $C \subseteq V$. Suppose $\mathbb{C}_\nu = \{g_1, \ldots, g_\sigma\}$ are the groups by Lemma 5. We define a tree called the **backbone tree** of $C$, with nodes corresponding to groups $g_1, \ldots, g_\sigma$. This tree has edges between nodes whose corresponding groups are connected by an edge. We use $g_i$ to refer to both the group and the corresponding node in the backbone tree. According to Cayley's formula [1], the number of different trees that can be formed by $\tilde{n}$ labeled nodes is $\tilde{n}^{\tilde{n}-2}$. Hence the cluster's backbone tree has one of the types $1, 2, \cdots, \sigma^{\sigma-2}$.

Each cluster $C$ is associated with a pair $(t_b, \vec{w})$ (referred to as the **cluster type** of $C$), where $t_b$ is an integer between 1 and $\sigma^{\sigma-2}$ and represents the type of the cluster's backbone tree, and $\vec{w}$ is a vector representing the weights of each node in the backbone tree, with $\vec{w}[i] = |g_i \cap C|$ being the number of points in the $i$-th group of the cluster; see Figure 3.

The maximum number of ways to assign weights to nodes of a backbone tree is $n^\sigma$, where $n = |V|$. To keep the number of different cluster types manageable, we store the group weights approximately by rounding them to the nearest *threshold value*. This reduces the number of possible ways to assign weights to nodes of a backbone tree to a poly-logarithmic number and so allows for a more compact representation of the cluster types.

▶ **Definition 8.** *Given $\epsilon > 0$, let $\epsilon'$ be $\frac{\epsilon}{c \log n}$. Let **logarithmic threshold values** be $\Phi_{\epsilon,n} = \{\phi_1, \cdots, \phi_\tau\}$ where $\phi_i = i$ for $1 \leq i \leq \lceil \frac{1}{\epsilon'} \rceil$, and for $i > \frac{1}{\epsilon'}$ we have $\phi_i = \lceil \phi_{i-1}(1+\epsilon') \rceil$, and $\phi_\tau = n$. So $\tau = O(\frac{\log n}{\epsilon})$. We define a **mapping** $\phi$ which associates with each value $1 \leq i \leq n$ the minimum threshold value $\phi_j$ for which $i \leq \phi_j$ holds.*

By rounding the weights of groups to the nearest threshold value, the number of different cluster types is reduced to $O(\sigma^{\sigma-2}(\frac{\log n}{\epsilon'})^\sigma))$, where $\sigma = O(1/\nu)$. We will show that, by choosing the number of thresholds appropriately large, the DP solution will have a multiplicative error of at most $1 + O(\epsilon)$ (provided that the tree has a logarithmic height).

For every cluster $C \subset V$ and every node $v \in V$, the part of cluster that falls into $T_v$ is referred to as the *partial cluster of $C$ with respect to $v$*. To represent such a partial cluster, we associate it with a triple $(t_c, \gamma_v, \vec{s}_v)$, where $t_c$ is an integer between 1 and $O(\sigma^{\sigma-2}(\frac{\log n}{\epsilon'})^\sigma))$ and represents the type of the cluster, $\gamma_v$ is the *split group* of the partial cluster and specifies the group that includes the node $v$, and $\vec{s}_v$ is a vector representing the sizes of each group of the partial cluster that intersects with the tree $T_v$, with $\vec{s}_v[i] = |(g_i \cap C) \cap V(T_v)|$ being the number of points in the $i$-th group that intersect with $V(T_v)$; see Figure 3. Similar to the group weights, the group sizes are stored approximately by rounding them to the nearest threshold value. This results in a reduction of the number of partial cluster types to $O(\sigma^{\sigma-2}(\frac{\log n}{\epsilon'})^\sigma))$. Observe that a partial cluster $C$ with respect to root $r$ is actually the full cluster $C$. This means that for every group $i$ in the cluster, the value $\vec{s}_r[i]$ is equal to $\vec{w}[i]$.

We let $\Gamma_v \subseteq \mathbb{C}_\nu$ indicate the groups, called the *inner groups*, of the partial cluster whose nodes are completely contained within the tree node $T_v$. For a specific partial cluster type $\ell$ at $v$, we use the notation $\gamma_v^\ell, \Gamma_v^\ell, \vec{s}_v^\ell$, and $\vec{w}^\ell$ to refer to its split group, inner groups, size, and weight vectors, respectively. It is important to note that both the weight vector $\vec{w}^\ell$ and the inner groups $\Gamma_v^\ell$ can be obtained from the triple $(t_c, \gamma_v, \vec{s}_v)$ that defines $\ell$.

A partial cluster type $\ell$ with respect to a node $v$ is considered **valid** if the following conditions are met: (i) the values of $\vec{s}_v^\ell[i]$ for each group $i$ of $\ell$ are between 0 and $\vec{w}^\ell[i]$, (ii) the value of $\vec{w}^\ell[i]$ for each group $i$ of $\ell$ is less than or equal to $\max\{\nu.\sum_{i'} \vec{w}^\ell[i'], 1\}$ (see Lemma 5), (iii) if $v$ is a leaf node of $T$, then $\gamma_v^\ell$ is a leaf node of the backbone tree of $\ell$ (from the definition of the backbone tree). A partial cluster type $\ell$ is considered a **leaf partial cluster type** at a node $v$ if $\gamma_v^\ell$ is a leaf node of the backbone tree of $\ell$ and $\vec{s}_v^\ell[\gamma_v^\ell] = 1$.

**Edge Load, Partial Cluster Cost, and Cluster Cost.** Consider a cluster $C$ together with its groups $\mathbb{C}_\nu = \{g_1, \ldots, g_\sigma\}$ and hubs $H_\nu(C)$ , and let $\ell$ be the type of this cluster with respect to $v$. Recall that, vectors $\vec{w}^\ell$ and $\vec{s}_v^\ell$ are used to show the weight and the size (with respect to the tree $T_v$) of the groups within the cluster $C$, and $\gamma_v$ is used to specify the group of the cluster that includes the node $v$. Here, we explain how to compute the $\nu$-approximate cost of the cluster, $\text{cost}_{H_\nu}(C)$, by utilizing the information provided by these vectors.

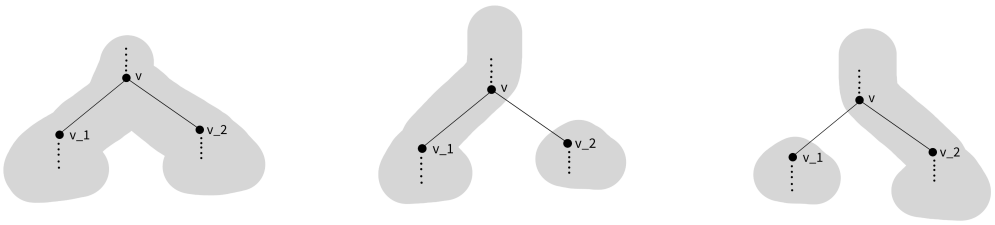
We define the load of edge $e$ with respect to the cluster $C$, its groups $\mathbb{C}_\nu$, and hubs $H_\nu(C)$ to be the number of paths $p_H(u,v)$ that include edge $e$ over all $(u,v) \in X$, where $X = \cup_{i=1}^{\hat{\sigma}} X_i$ and $X_i = \{(u,v) : u \in \hat{g}_i \;\; v \in C \setminus \hat{g}_i\}$. Let $e_v$ denote the edge connecting $v$ to its parent in $T$. The load of edge $e_v$ with respect to $\ell$ can be calculated using the following formula, represented as $load^\ell(e_v)$:

$$load^\ell(e_v) = \underbrace{\Big(\sum_{i=1, i\neq\gamma_v}^{\sigma} \vec{s}_v^\ell[i]\Big) \times \Big(\sum_{i=1}^{\sigma} (\vec{w}^\ell[i] - \vec{s}_v^\ell[i])\Big)}_{\#\text{paths crossing } e_v \text{ s.t. one of its ends is below } \gamma_v} + \underbrace{\vec{s}_v^\ell[\gamma_v] \times \Big(\sum_{i\notin\Gamma_v}^{\sigma} \vec{w}^\ell[i]\Big)}_{\#\text{paths crossing } e_v \text{ s.t. one of its ends is in } \gamma_v}$$

We define and compute the cost of a partial cluster type $\ell$ with respect to a node $v$ (we denote it by $cost_v^\ell$) recursively as follows. For the base case, $cost_v^\ell = 0$, if $v$ is a leaf node. For the recurrence, $cost_v^\ell = cost_{v_1}^\ell + cost_{v_2}^\ell + load^\ell(e_{v_1})w(e_{v_1}) + load^\ell(e_{v_2})w(e_{v_2})$, where $v_1, v_2$ are children of $v$. Note that the union of groups of each cluster always includes the root node $r$ (see Algorithm 1). One can verify that $cost_r^\ell = \text{cost}_{H_\nu}(C)$, if $\ell$ stores the exact weights and sizes of the groups of the cluster. However, here, $\ell$ stores weights and sizes approximately and therefore the edge load $load^\ell(e_v)$ might be overestimated by a factor of $(1+\epsilon')$ (by choosing the number of thresholds appropriately large). In the next section, we will see how this affects our approximation solution and results in a multiplicative error of at most $1 + O(\epsilon)$ (provided that the tree has a logarithmic height).

## Dynamic Program

The Dynamic Program (DP) starts at the leaves of $T$ and works its way up, exploring all possible ways to form clusters. For each node $v$ and each possible configuration $\mathbb{P}_v$ of partial clusters with respect to $v$, there is an entry in the DP table. A configuration $\mathbb{P}_v \in [k]^{O(\sigma^{\sigma-2}(\frac{\log n}{\epsilon'})^\sigma)\}}$ at node $v$ lists the number of each type of partial cluster covering points within subtree $T_v$. We let $A[v, \mathbb{P}_v]$ store the minimum cost to form a set of partial clusters, which match the configuration $\mathbb{P}_v$, and cover all points in $T_v$. Observe that the number of such subproblems is at most $n^{O(\sigma^{\sigma-2}(\frac{\log n}{\epsilon'})^\sigma)}$.



(a) (b) (c)

**Figure 4** Consider a node $v$ and its children $v_1$, $v_2$. There are three possible scenarios in which $v$, $v_1$, and $v_2$ may belong to one or two groups of a cluster. (a) is depicting the case where all three nodes are in the same group, (b) is depicting the case that $v$ and $v_1$ are in the same group, (c) is depicting the case that $v$ and $v_2$ are in the same group. Note that the case where all three nodes belong to different groups does not happen due to Algorithm 1.

Consider a node $v$ in the tree $T$. Assume for now that we have access to a table $\lambda[\mathbb{P}_v, \mathbb{P}_{v_1}, \mathbb{P}_{v_2}]$, where $\mathbb{P}_v$ is the configuration at node $v$, and $\mathbb{P}_{v_1}$ and $\mathbb{P}_{v_2}$ are the configurations at its children nodes $v_1$ and $v_2$, respectively. The table $\lambda$ indicates whether the configurations $\mathbb{P}_v$, $\mathbb{P}_{v_1}$, and $\mathbb{P}_{v_2}$ are *consistent*, meaning that there is a solution where the descriptions of partial clusters below nodes $v$, $v_1$, and $v_2$ match the configurations $\mathbb{P}_v$, $\mathbb{P}_{v_1}$, and $\mathbb{P}_{v_2}$, respectively. We shall describe how to compute $\lambda$. We will compute the subproblems $A[v, \mathbb{P}_v]$ in a bottom-up manner: We will compute $A[v, \mathbb{P}_v]$ after we have computed the subproblems $A[v_1, \mathbb{P}_{v_1}]$ and $A[v_2, \mathbb{P}_{v_2}]$ for the children of $v$. The subproblems are computed as follows:

**Base Case.** For every leaf node $v$ and every configuration $\mathbb{P}_v$, set: $A[v, \mathbb{P}_v] = 0$ if there exists a type $\ell$ such that $\mathbb{P}_v[\ell] = 1$ and $\ell$ is a leaf partial cluster at $v$. Otherwise, set $A[v, \mathbb{P}_v] = \infty$.

**Recurrence.** Let $load(v) = \sum_\ell \mathbb{P}_v[\ell] load^\ell(e_v)$. For each internal node $v$ and its children, $v_1, v_2$ and every combination of configurations of $\mathbb{P}_v$ on $v$ and $\mathbb{P}_{v_1}, \mathbb{P}_{v_2}$:

$$A[v, \mathbb{P}_v] = \min_{\mathbb{P}_v, \mathbb{P}_{v_1}, \mathbb{P}_{v_2} : \lambda[\mathbb{P}_v, \mathbb{P}_{v_1}, \mathbb{P}_{v_2}] = True} \sum_{i=1,2} \big( A[v_i, \mathbb{P}_{v_i}] + load(v_i) w(v v_i) \big)$$

The final solution is obtained by finding the minimum value of $A[r, \mathbb{P}_r]$ over all configurations $\mathbb{P}_r$ such that the sum of all $\mathbb{P}_r[\ell]$ values equals $k$; and $\vec{s}_r^{\,\ell}[i] = \vec{w}^{\ell}[i]$ holds, for each partial cluster type $\ell$ with $\mathbb{P}_r[\ell] > 0$, and for all $i$.

**Consistency Constraints.** Consider a node $v$ and its children $v_1, v_2$. Let $P_v = (t_c, \gamma_v, \vec{s}_v), P_{v_1} = (t_{c_1}, \gamma_{v_1}, \vec{s}_{v_1}), P_{v_2} = (t_{c_2}, \gamma_{v_2}, \vec{s}_{v_2})$ be some valid partial cluster types at $v, v_1, v_2$, respectively. We say $P_v$ is consistent with $P_{v_1}$ and $P_{v_2}$ if the following conditions are met:

- **Type Consistency**. The types of $P_v$, $P_{v_1}$, and $P_{v_2}$ must be the same, i.e. $t_c = t_{c_1} = t_{c_2}$.
- **Group Consistency**. The groups of $P_{v_1}$ and $P_{v_2}$ are consistent with those of $P_v$: Recall that $\gamma_v$ indicates the split group of a partial cluster $P_v$ and $\Gamma_v$ indicates the inner groups of $P_v$. Let $\delta_v^{in}$ be the inner groups adjacent to $\gamma_v$ in the backbone tree; $\delta_v^{in} = \delta(\{\gamma_v\}) \cap \Gamma_v$, where $\delta(\{\gamma_v\})$ indicates groups adjacent to $\gamma_v$ (in the backbone tree). Depending on the values of $\gamma_v, \gamma_{v_1}, \gamma_{v_2}$, one of the following cases holds:
  - If $\gamma_v = \gamma_{v_1} = \gamma_{v_2}$ (Figure 4a), then $\delta_{v_1}^{in} \cup \delta_{v_2}^{in} = \delta_v^{in}, \quad \delta_{v_1}^{in} \cap \delta_{v_2}^{in} = \emptyset$.
  - If $\gamma_v = \gamma_{v_1}$ and $\gamma_{v_2} \in \delta_v^{in}$ (Figure 4b), then $\delta_{v_1}^{in} = \delta_v^{in} \setminus \{\gamma_{v_2}\}, \quad \delta_{v_2}^{in} = \delta(\{\gamma_{v_2}\}) \setminus \{\gamma_v\}$.
  - If $\gamma_v = \gamma_{v_2}$ and $\gamma_{v_1} \in \delta_v^{in}$ (Figure 4c), then $\delta_{v_2}^{in} = \delta_v^{in} \setminus \{\gamma_{v_1}\}, \quad \delta_{v_1}^{in} = \delta(\{\gamma_{v_1}\}) \setminus \{\gamma_v\}$.

- **Size Consistency**. The group sizes of $P_1$ and $P_2$ are consistent with those of $P$. Depending on the values of $\gamma_v, \gamma_{v_1}, \gamma_{v_2}$, one of the following cases holds:
  - If $\gamma_v = \gamma_{v_1} = \gamma_{v_2}$, then we ensure that $\phi\big(\vec{s}_{v_1}[\gamma_{v_1}] + \vec{s}_{v_2}[\gamma_{v_2}]\big) = \vec{s}_v[\gamma_v]$.
  - If $\gamma_v = \gamma_{v_1}$ and $\gamma_{v_2} \in \delta_v^{in}$, then we ensure that $\vec{s}_{v_2}[\gamma_{v_2}] = w[\gamma_{v_2}]$ and $\vec{s}_{v_1}[\gamma_{v_1}] = \vec{s}_v[\gamma_v]$.
  - If $\gamma_v = \gamma_{v_2}$ and $\gamma_{v_1} \in \delta_v^{in}$, then we ensure that $\vec{s}_{v_1}[\gamma_{v_1}] = w[\gamma_{v_1}]$ and $\vec{s}_{v_2}[\gamma_{v_2}] = \vec{s}_v[\gamma_v]$.

Note that the case that $\gamma_{v_1} = \gamma_{v_2}, \gamma_v \neq \gamma_{v_1}$ is impossible since each group of the cluster covers a connected subtree. Furthermore, the case when $\gamma_{v_1} \in \delta_v^{in}$ & $\gamma_{v_2} \in \delta_v^{in}$ is impossible using the fact that there is no point on the internal node $v$ (see the preprocessing step).

The value of $\lambda[\mathbb{P}_v, \mathbb{P}_{v_1}, \mathbb{P}_{v_2}]$ is calculated recursively for every combination of configurations of $v$ and its children, $v_1, v_2$. For the base case $\lambda[\vec{0}, \vec{0}, \vec{0}] =$ True. Let $\mathbb{P}_v - P_v$ indicate the configuration of $\mathbb{P}_v$ with one less partial cluster of type $P_v$. For the recurrence, we consider all possible *consistent* valid partial cluster types $P_v$, $P_{v_1}$ and $P_{v_2}$

$$\lambda[\mathbb{P}_v, \mathbb{P}_{v_1}, \mathbb{P}_{v_2}] = \bigvee_{\forall \text{ consistent } P_v, P_{v_1}, P_{v_2}} \lambda[\mathbb{P}_v - P_v, \mathbb{P}_{v_1} - P_{v_1}, \mathbb{P}_{v_2} - P_{v_1}]$$

### Analysis

In our DP, configurations store the rounded sizes (and weights) of the partial clusters' groups. To ensure consistency between the sizes of the groups at node $v$ and its children $v_1$ and $v_2$, we allow the size of the group at $v$ to be a $(1+\epsilon')$ upper bound for the combined size of the groups at $v_1$ and $v_2$. This results in a multiplicative error of at most $(1+\epsilon')$ in the calculation of the edges' loads and so the cost of the partial clusters at each node of the tree when the sizes (weights) of merged partial clusters are rounded. Given that the height of the tree is $h$, it is not difficult to see that our dynamic programming approach finds a solution that is an $(1+\epsilon')^h$-approximation to the problem.

The number of possible configurations $\mathbb{P}_v$ for each node $v$ is at most $n^{O(\sigma^{\sigma-2}(\frac{\log n}{\epsilon'})^{\sigma}))}$, resulting in $n^{O(\sigma^{\sigma-2}(\frac{\log n}{\epsilon'})^{\sigma}))}$ dynamic program table entries. To compute each entry in the DP table, we iterate over all consistent configurations at $v$, $v_1$, and $v_2$, which takes $n^{O(\sigma^{\sigma-2}(\frac{\log n}{\epsilon'})^{\sigma}))}$ time. Hence, the overall running time of the algorithm is $n^{O(\sigma^{\sigma-2}(\frac{\log n}{\epsilon'})^{\sigma}))}$, which is still a quasi-polynomial time complexity in $n$. By setting $\epsilon' = \frac{\epsilon}{\log n}$ in the threshold mapping, the algorithm finds a $(1+\epsilon)$ approximation solution in time $n^{O(\sigma^{\sigma-2}(\frac{\log n}{\epsilon})^{\sigma+1}))}$.

▶ **Theorem 9.** *There is a QPTAS for the* ***k-MSC*** *problem on trees with logarithmic heights.*

## 3 The $k$-MSC Problem in Metrics of Bounded Treewidth

In this section, we extend our algorithm from Section 2 to metrics of bounded treewidth. A *tree decomposition* of a graph $G = (V, E)$ is a tree $T = (V', E')$ on a new set of nodes $V'$, where each $i \in V'$ corresponds to a subset $b_i$, called a *bag*, of vertices of $V$ with the following properties: (i) $\cup_{i \in V'} b_i = V$, (ii) for every edge $uv \in E$, there exists a bag $t$ of $T$ such that $b_t$ contains both $u$ and $v$, (iii) if $b_i, b_j$ contain vertex $v$ then every bag on the path between $i$ and $j$ in $T$ contains $v$. The *width* of a tree decomposition $T$ is the size of the largest bag of $T$ minus one; this is $\max_{i \in V'}(|b_i| - 1)$. The *treewidth* of a graph $G$ is the minimum width over all possible tree decompositions of G. The authors of [5] showed that any graph $G = (V, E)$ with treewidth $f$ has a tree decomposition $T$ of width at most $3f + 2$ that has the following two extra properties: (i) $T$ is binary, (ii) the height of $T$ is $O(\log |V|)$.

Given a graph $G = (V, E)$ with a treewidth of $f'$, we create a binary decomposition tree $T = (V', E')$ with a width of no more than $3f' + 2$ and a height of logarithmic in $|V|$ (see [5]). Let $f$ be the width of $T$. We will refer to $G$ as the graph and $T$ as the tree. We will refer to vertices in $V$ as *nodes* and vertices in $V'$ as *bags*. We will refer to edges in $G$ as *edges* and

edges in $T$ as *super-edges*. Let $T$ be rooted at an arbitrary bag $r \in V'$. We use $T_b$ to denote the *subtree* rooted at the bag $b$, $V'(T_b)$ to denote the bag set of $T_b$, and $E'(T_b)$ to denote the super-edge set of $T_b$. Each node $u \in V$ can appear in multiple bags of $V'$, and these bags form a subtree of $T$. To ensure that each point is covered only once, we consider the point as a *token* placed at the node. We place the token of a node at the bag closest to the root of $T$ that contains the node. This bag is marked as the one containing the point.

We further modify the tree to make sure that (i) only the leaf bags contain the tokens and (ii) each bag contains at most one token: for any bag A that violates these two rules, create two new bags B and C that are identical copies of A. Move one of the tokens from the original bag A to bag C and place any remaining tokens in bag B. Connect the children of the original bag A to the newly created bag B. Connect both bags B and C to A. Finally, we remove all leaf bags without any tokens. This process results in a binary tree decomposition with a height of $O(\log n)$. We call this tree decomposition with these properties the **proper tree decomposition** of the graph. For each point $u \in V$, we let $B_u \in V'$ denote the bag that contains point $u$. For each $C \subseteq V$, let $B_C = \{B_u : u \in C\}$.

Consider a mapping $p : V' \to V'$ that maps each bag to its parent bag and maps $r$ to itself. Let $e_b$ be the super-edge between $b$ and $p(b)$ in $T$. The edges $(s,t)$ where $s \in b$ and $t \in p(b)$ are referred to as the **bridge-edges** with respect to the super-edge $e_b$. We use the notation $e_b^{s,t}$ to refer to these edges. An edge between such vertices $s \in b$ and $t \in p(b)$ is added in $G$ with a weight of $d(s,t)$ if it does not already exist. For any pair of points $u$ and $v$ in $V$, one can verify that there exists a path between $u \in B_u$ and $v \in B_v$ in the tree $T$ consisting only of bridge-edges over the super-edges which is equivalent to the shortest path between $u$ and $v$ in the graph. This path connects the bags $B_u$ and $B_v$ in $T$ and only uses the bridge-edges over the super-edges of the unique path connecting these bags in the tree. The length of this path is equal to $d(u,v)$, the distance between $u$ and $v$ in the graph $G$. This path is referred to as $p_B(u,v)$.

For each bag $b \in V'$, let $V'_b = \cup_{i \in V'(T_b)} b_i$ denote the union of nodes in bags of $V'(T_b)$. For a tree decomposition $T = (V', E')$ and a subset of bags $\hat{V} \subseteq V'$, we use $\delta(\hat{V}) = \{b_i \in \hat{V} : b_i b_j \in E' \ \&\ b_j \notin \hat{V}\}$ to denote the *border bags* of $\hat{V}$. The proof of the following lemma is analogous to that of Lemma 5.

▶ **Lemma 10.** *Given a graph $G = (V, E)$ of bounded treewidth, a proper tree decomposition $T = (V', E')$ of $G$, a set of points $C \subseteq V$, for any $\nu > 0$, there exists a partition of $V'$ into a set of groups $\mathbb{C}_\nu = \{g_1, \ldots, g_\sigma\}$ such that all of the following properties hold: (i) The subgraph induced by each group $g \in \mathbb{C}_\nu$ is connected in $T$. (ii) For each group $g \in \mathbb{C}_\nu$, $|g \cap B_C| \in [1, \max\{1, \nu|C|\}]$. (iii) $\sigma = O(1/\nu)$. (iv) $\forall g \in \mathbb{C}_\nu, \quad |\delta(g)| = O(1/\nu)$.*

Let $\nu > 0$. Consider a cluster $C \subseteq V$. Let $\mathbb{C}_\nu = \{g_1, \ldots, g_\sigma\}$ be the groups obtained by Lemma 10. For each such cluster $C$ and any constant $\nu > 0$, we let $H_\nu(C) = \cup_{i=1}^{\sigma} \cup_{j \in \delta(g_i)} b_j$ denote the *border hubs* of the cluster and $\text{cost}_{H_\nu}(C) = \sum_{i=1}^{\sigma} \sum_{j=i+1}^{\sigma} \sum_{u \in V(g_i) \cap C, v \in V(g_j) \cap C} d_{H_\nu(C)}(u,v)$ be the *$\nu$-approximate cost* of the cluster. Notice that for any two points $u$ and $v$ in $C$ that belong to different groups of $\mathbb{C}_\nu$, the path $p_B(u,v)$ passes through the hubs $H_\nu(C)$, implying $d(u,v) = d_{H_\nu(C)}(u,v)$. The proof of the following is analogous to that of Theorem 7.

▶ **Theorem 11.** *Given $\epsilon > 0$, a $(1+\epsilon)$-approximation for **k-MHC**, will imply a $(1 + O(\epsilon))$-approximation for **k-MSC** on bounded treewidth graphs.*

## 3.1 QPTAS for $k$-MHC on Graphs of Bounded Treewidth

Given $\nu > 0$ and a graph $G(V, E)$ that has a *proper decomposition tree* $T = (V', E')$ with a logarithmic height and a treewidth of $f$. Let $OPT$ be the minimum cost of partitioning $V$ into $k$ clusters $C_1, C_2, \cdots, C_k$ with the total cost being $\sum_{i=1}^{k} \text{cost}_{H_\nu}(C_i)$. Given $\epsilon > 0$, we will present a dynamic program that finds a $(1+\epsilon)$ approximation of $OPT$. This, as a result of Theorem 11, leads to a $(1 + O(\epsilon))$ approximation solution for the ***k*-MSC** problem.

Consider a cluster $C \subseteq V$. Let $\mathbb{C}_\nu = \{g_1, \ldots, g_\sigma\}$ be the groups obtained by Lemma 10 on $C$. We define a *backbone tree* associated with the cluster $C$. This tree is made up of $O(1/\nu)$ nodes that correspond to the groups of $\mathbb{C}_\nu$ and there are edges between the nodes in the tree if the corresponding groups in $\mathbb{C}_\nu$ are connected by a super-edge in the tree $T$. A *cluster type* is defined as a node-weighted backbone tree where each node in the tree is assigned a weight from the threshold values $\Phi_{\epsilon,n}$ (see Definition 8) which represents the number of points in the corresponding group rounded up to the nearest threshold value.

For each cluster $C$ and bag $b$ in tree $T$, we associate a partial cluster type to it. This is represented by a triple $(t_c, \gamma_b, \vec{s}_b)$ and includes: the type of the cluster, $t_c$; the group of the cluster that has bag $b$, $\gamma_b$; and a vector $\vec{s}_b$, where $\vec{s}_b[i]$ denotes the number of points in the $i$th group located in tree $T_b$. It is not hard to verify that the number of possible partial clusters is $O(\sigma^{\sigma-2} \log^{\sigma}_{(1+\epsilon')} n) = O((\frac{\log n}{\epsilon})^{\sigma+1})$, where we fix $\sigma = O(1/\nu)$.

We use $\ell \in \{1, 2, \ldots, O((\frac{\log n}{\epsilon})^{\sigma+1})\}$ to refer to a specific partial cluster type. A partial cluster type $\ell$ with respect to a vertex $b$ is considered **valid** if: the values of $\vec{s}^{\ell}_v[i]$ for each group $i$ of $\ell$ are between 0 and $\vec{w}^{\ell}[i]$, the value of $\vec{w}^{\ell}[i]$ for each group $i$ of $\ell$ is less than or equal to $\max\{\nu. \sum_{i'} \vec{w}^{\ell}[i'], 1\}$, and if $v$ is a leaf vertex of $T$, then $\gamma^{\ell}_v$ is a leaf node of the backbone tree of $\ell$. A partial cluster type $\ell$ is considered a **leaf partial cluster type** at a vertex $b$ if $\gamma^{\ell}_b$ is a leaf node of the backbone tree of $\ell$ and $\vec{s}^{\ell}_b[\gamma^{\ell}_v] = 1$.

Consider a cluster $C$ together with its groups $\mathbb{C}_\nu = \{g_1, \ldots, g_\sigma\}$ and hubs $H_\nu(C)$, and let $\ell$ be the type of this cluster with respect to bag $b$. Here, we explain how to compute the $\nu$-approximate cost of the cluster, $\text{cost}_{H_\nu}(C)$. Let $X = \cup_{i=1}^{\sigma} X_i$ and $X_i = \{(u, v) : u \in V(g_i) \;\; v \in C \setminus V(g_i)\}$. Let $e_b$ denote the super edge connecting $b$ to its parent bag $p(b)$ in $T$. We define load of a bridge-edge $e^{s,t}_b$ with respect to the cluster $C$, its groups $\mathbb{C}_\nu$, and hubs $H_\nu(C)$ to be the number of paths $p_B(u, v)$ that contain this edge over all $\{u, v\} \in X$. We use $load^{\ell}(e^{s,t}_b)$ to represent the load of bridge-edge $e^{s,t}_b$ with respect to partial cluster type $\ell$ and bag $b$. Similarly, we use $load^{\ell}(e_b)$ to represent the load of super-edge $e_b$ with respect to partial cluster type $\ell$ and bag $b$.

Similarly to the case of the tree, the load of the super-edge $e_b$ with respect to $\ell$ can be calculated using the following formula: $load^{\ell}(e_b) = \big(\sum_{i=1, i\neq\gamma_b}^{\sigma} \vec{s}^{\ell}_b[i]\big) \times \big(\sum_{i=1}^{\sigma} (\vec{w}^{\ell}[i] - \vec{s}^{\ell}_b[i])\big) + \vec{s}^{\ell}_b[\gamma_b] \times \big(\sum_{i\notin\Gamma_b}^{\sigma} \vec{w}^{\ell}[i]\big)$. Note that $load^{\ell}(e_b)$ computes the number of paths $p_{H_\nu(C)}(u, v)$ in $G$ that cross the cut-set $(b, p(b))$ for all pairs of points $(u, v)$ in the set $X$.

When computing the cost of a cluster type, it is necessary to take into account the load among the bridge-edges. However, the load of a bridge-edge cannot be calculated simply from the sizes and weights of the groups within the cluster, unlike the load of the super-edges.

To address this issue, for each partial cluster type $\ell$ and each $b$, we have defined a vector $\psi^{\ell}_b$ with a dimension of $f^2$ (where $f$ is the treewidth of the graph), that $\psi^{\ell}_b[e^{s,t}_b]$ specifies the load of each bridge-edge $e^{s,t}_b$ with respect to $\ell$. One can now compute the cost of a partial cluster $\ell$ at bag $b$, denoted by $cost^{\ell}_b$, recursively as follows. For the base case, $cost^{\ell}_b = 0$, if $b$ is a leaf bag. For the recurrence, $cost^{\ell}_b = cost^{\ell}_{b_1} + cost^{\ell}_{b_2} + \sum_{\{s,t\}\in b_1\times b} \psi^{\ell}_{b_1}(e^{b_1}_{s,t}) w(e^{b_1}_{s,t}) + \sum_{\{s,t\}\in b_2\times b} \psi^{\ell}_{b_2}(e^{b_2}_{s,t}) w(e^{b_2}_{s,t})$, where $b_1, b_2$ are children of $b$.

We could attach $\psi_b^\ell$ (with a dimension of $f^2$ which approximately stores the flow of the bridge edges) to the vectores we store for each cluster type $\ell$ to obtain a QPTAS for the problem on graphs with bounded treewidth. However, this QPTAS cannot be extended to include graphs with bounded highway dimension or graphs with bounded doubling dimensions (as $f$ becomes logarithmic in these cases). To address this issue, in the next section we propose that at each bag $v$, it is sufficient to store information about the total flow of the partial clusters that passes through the bridge edges, in addition to the information about the type of partial cluster covering the points within the subtree. This eliminates the need to separately store the flow of each partial cluster.

### Dynamic program

The Dynamic Program (DP) traverses $T$ starting at the leaves and moving upward and considers all ways partial clusters can be made. At each bag $b$, a configuration $< b, \mathbb{P}_b, \psi_b >$ is defined. In this configuration, $\mathbb{P}_b$ specifies the number of partial clusters of each type covering points within $T_b$, and $\psi_b$ specifies the total load for each bridge-edge over all the partial cluster types $\ell$ specified in $\mathbb{P}_b$; namely, $\psi_b = \sum_\ell \mathbb{P}_b[\ell].\psi_b^\ell$.

**Valid Configuration.** The validity check of a configuration involves ensuring the feasibility of the load distributions among partial clusters. For a given bag $b$ and configuration $(\mathbb{P}_b, \psi_b)$, we can use the loads of super edges to get the total loads crossing $b$: $\Psi_b = \sum_\ell \mathbb{P}_b[\ell] load^\ell(e_b)$. We say the configuration $(\mathbb{P}_b, \psi_b)$ is *valid* if the following holds: $\phi(\Psi_b) = \phi\left(\sum_{e^b_{s,t} \in b \times p(b)} \psi[e^b_{s,t}]\right)$; this is, the total load of the partial clusters crossing super-edge $e_b$ (this can be obtained via $\mathbb{P}_b$ as described in the previous section) must be equal to the total load of the partial clusters crossing all the bridge-edges with respect to the super-edge $e_b$. Note that when $b$ is a leaf, this condition implies that, $\phi(\sum_{e^b_{s,t} \in b \times p(b)} \psi[e^b_{s,t}]) = \phi(\sum_i w[i] - 1)$.

Assume for now that we have access to an inner table $\varphi[(\mathbb{P}, \psi), (\mathbb{P}_1, \psi_1), (\mathbb{P}_2, \psi_2)]$ that for every combination of configurations of $(\mathbb{P}, \psi)$ on $b$ and $(\mathbb{P}_1, \psi_1), (\mathbb{P}_2, \psi_2)$ on its children, $b_1, b_2$, indicates whether they are *consistent* or not. The representation of $\perp$ is used to indicate the empty configurations for handling the cases when $b$ is a leaf or has one child.

Let $A[b, \mathbb{P}_b, \psi_b]$ be the minimum cost solution for subproblem $< b, \mathbb{P}_b, \psi_b >$ in which points in $V'_b$ are covered by a set of partial clusters whose types (and loads) are consistent with the configuration $\mathbb{P}_b, \psi_b$ (recall that $V'_b = \cup_{i \in T_b} b_i$).

We will compute the subproblems $A[b, \mathbb{P}_b, \psi_b]$ in a bottom-up manner:

**Base Case.** For each leaf vertex $b$: $A[b, \mathbb{P}_b, \psi_b] = 0$ if $\varphi[(\mathbb{P}_b, \psi_b), \perp, \perp] =$ True and otherwise it is $\infty$.

**Recurrence.** For each internal vertex $b$ and its children, $b_1, b_2$:

$$A[b, \mathbb{P}_b, \psi_b] = \min_{\varphi[(\mathbb{P}_b, \psi_b), (\mathbb{P}_{b_1}, \psi_{b_1}), (\mathbb{P}_{b_2}, \psi_{b_2})] = True} \left\{ \sum_{i=1,2} \left( A[b_i, \mathbb{P}_{b_i}, \psi_{b_i}] + \sum_{\{s,t\} \in b_i \times b} \psi_b[e^{b_i}_{s,t}] w(e^{b_i}_{s,t}) \right) \right\}$$

The case of $b$ having one child is similar. The final solution is obtained by finding the minimum value of $A[b, \mathbb{P}_b, \psi_b]$ over all valid configurations $< \mathbb{P}_b, \psi_b >$ such that the sum of all $\mathbb{P}_b[\ell]$ values equals $k$.

### Consistency Constraints

Consider a bag $b$ and its two children $b_1$ and $b_2$. Let $< \mathbb{P}_b, \psi_b >$, $< \mathbb{P}_{b_1}, \psi_{b_1} >, and < \mathbb{P}_{b_2}, \psi_{b_2} >$ be some configurations at $b$, $b_1$, and $b_2$, respectively. To check the consistency of them, there are two steps to follow: (1) verify the *feasibility of partial cluster types*; if the types of the partial clusters in $\mathbb{P}_b$ match those in $\mathbb{P}_{b_1}$ and $\mathbb{P}_{b_2}$. (2) ensure the *feasibility of load distributions*; if the load distribution of the clusters in $\psi_b$ aligns with the load distributions of the clusters in $\psi_{b_1}$ and $\psi_{b_2}$. If these two conditions are met, $\varphi[(\mathbb{P}_b, \psi_b), (\mathbb{P}_{b_1}, \psi_{b_1}), (\mathbb{P}_{b_2}, \psi_{b_2})]$ will be set to True. Otherwise, it will be set to False.

**Feasibility of Partial Cluster Types.** Here we check if there is a solution where the descriptions of partial clusters below nodes $b$, $b_1$, and $b_2$ match the configurations $\mathbb{P}_b$, $\mathbb{P}_{b_1}$, and $\mathbb{P}_{b_2}$, respectively. This step guarantees that the final clustering covers all the points and is therefore a valid solution. This check is very similar to the consistency verification we performed in the case of the tree. There are three cases, depending on whether $b$ is a *leaf*, a bag with *one child*, or a bag with *two children*:

- when $b$ is a leaf: $\mathbb{P}_b[\ell] = 1$ must hold for some $\ell$, where $\ell$ is a leaf partial cluster at b.
- when $b$ has one child, say bag $b_1$: since there is no point (token) on internal bags, $b$ and $b_1$ must belong to the same group. In this case, we must ensure the following: $t_b = t_{b_1}$ (*type consistency*); $\gamma_b = \gamma_{b_1}, \delta_b^{in} = \delta_{b_1}^{in}$ (*group consistency*); and $\vec{s}_b = \vec{s}_{b_1}$ (*size consistency*).
- when $b$ has two children, $b_1, b_2$. Let $P = (t_c, \gamma_b, \vec{s}_b), P_1 = (t_{c_1}, \gamma_{b_1}, \vec{s}_{b_1}), P_2 = (t_{c_2}, \gamma_{v_2}, \vec{s}_{b_2})$ be considered partial cluster types at $b, b_1, b_2$, respectively. Note that the type of a cluster is made up of backbone tree $t_b$ and weights $\vec{w}$. Recall that similar to trees, $\delta(\{\gamma_b\})$ stands for the adjacent bags of $\gamma_b$ and $\delta_b^{in}$ stands for the adjacent bags of $\gamma_b$ inside $T_b$. We say the partial cluster type $P$ (with respect to $T_b$) is consistent with the two partial clusters $P_1$ and $P_2$ (with respect to $T_{b_1}$ and $T_{b_2}$, respectively) if the following holds: (i) (*type consistency*) $t_c = t_{c_1} = t_{c_2}$. (ii)(*group consistency*) If $\gamma_b = \gamma_{b_1} = \gamma_{b_2}$, then we ensure that $\delta_{b_1}^{in} \cup \delta_{b_2}^{in} = \delta_b^{in}$ and $\delta_{b_1}^{in} \cap \delta_{b_2}^{in} = \emptyset$. If $\gamma_b = \gamma_{b_1}$ and $\gamma_{b_2} \in \delta_b^{in}$, then we ensure that $\delta_{b_1}^{in} = \delta_b^{in} \setminus \{\gamma_{b_2}\}$ and $\delta_{b_2}^{in} = \delta(\{\gamma_{b_2}\}) \setminus \{\gamma_b\}$. If $\gamma_b = \gamma_{b_2}$ and $\gamma_{b_1} \in \delta_b^{in}$, then we ensure that $\delta_{b_2}^{in} = \delta_b^{in} \setminus \{\gamma_{b_1}\}$ and $\delta_{b_1}^{in} = \delta(\{\gamma_{b_1}\}) \setminus \{\gamma_b\}$. (iii) (*size consistency*) If $\gamma_b = \gamma_{b_1} = \gamma_{b_2}$, then we ensure that $\phi\big(\vec{s}_{b_1}[\gamma_{b_1}] + \vec{s}_{b_2}[\gamma_{b_2}]\big) = \vec{s}_b[\gamma_b]$. If $\gamma_b = \gamma_{b_1}$ and $\gamma_{b_2} \in \delta_b^{in}$, then we ensure that $\vec{s}_{b_2}[\gamma_{b_2}] = w[\gamma_{b_2}]$ and $\vec{s}_{b_1}[\gamma_{b_1}] = \vec{s}_b[\gamma_b]$. If $\gamma_b = \gamma_{b_2}$ and $\gamma_{b_1} \in \delta_b^{in}$, then we ensure that $\vec{s}_{b_1}[\gamma_{b_1}] = w[\gamma_{b_1}]$ and $\vec{s}_{b_2}[\gamma_{b_2}] = \vec{s}_b[\gamma_b]$.

For every combination of configurations on $b$ and its children, $b_1, b_2$, $\lambda[\mathbb{P}_b, \mathbb{P}_{b_1}, \mathbb{P}_{b_2}]$ is computed recursively as below. For the base case $\lambda[\vec{0}, \vec{0}, \vec{0}] =$ True. For the recurrence, we consider all possible *consistent* partial cluster types $P_b$, $P_{b_1}$ and $P_{b_2}$

$$\lambda[\mathbb{P}_b, \mathbb{P}_{b_1}, \mathbb{P}_{b_2}] = \bigvee_{\forall \text{ consistent } P_b, P_{v_1}, P_{v_2}} \lambda[\mathbb{P}_b - P_b, \mathbb{P}_{b_1} - P_{b_1}, \mathbb{P}_{b_2} - P_{b_1}]$$

where $\mathbb{P}_b - P_b$ indicates the configuration of $\mathbb{P}_b$ with one less partial cluster of type $P_b$.

**Feasibility of Load Distributions.** This ensures that the sum of all flows through the bridge edges into bag $b$ and the sum of all flows out of it are consistent, and that the flow originates only from points that have tokens. This confirms the accuracy of the solution cost calculated using these bridge-edge load distributions. There are three cases, depending on whether $b$ is a leaf, a bag with one child, or a bag with two children:

- when $b$ is a leaf. Suppose $y \in b$ is the only point of bag $b$, we must ensure that: $\forall st : s \in b, t \in p(b), s \neq y, \psi[e_{s,t}^b] = 0$

- when $b$ has one child, say $b_1$. Loads of configurations $\psi_b, \psi_{b_1}$ are consistent if and only if, for each vertex of $b$, the load coming from $b_1$ into each vertex of $b$ is equal to the load going upwards, formulated as following: $\forall t \in b. \quad \sum_{s \in b_1} \psi[e^{b_1}_{s,t}] = \sum_{u \in p(b)} \psi[e^{b}_{t,u}]$
- when $b$ has two children, $b_1, b_2$. For each $t \in b$ let $L_t$ be $\sum_{s \in b_1} \psi[e^{b_1}_{s,t}]$, $R_t$ be $\sum_{s \in b_1} \psi[e^{b_2}_{s,t}]$, $U_t$ be $\sum_{s \in p(b)} \psi[e^{b}_{t,s}]$. Load vectors of configurations $\psi_b, \psi_{b_1}, \psi_{b_2}$ are consistent if and only if for each $u \in b_b$ one of the following constraints must hold: $L_b + R_b = U_b$ or $|L_b - R_b| = U_b$.

**Proof of Theorem 1.** There are $O((\frac{\log n}{\epsilon})^{\sigma+1})$ possible partial clusters, so the number of subproblem configurations, $\mathbb{P}_b$, at bag $b$ is $n^{O((\frac{\log n}{\epsilon})^{\sigma+1})}$. The number of the possible values for $\psi$, is $n^{f^2}$, resulting in a number of DP table entries of $n^{O(f^2+(\frac{\log n}{\epsilon})^{\sigma+1})}$.

Deciding configurations $(\mathbb{P}_b, \psi_b), (\mathbb{P}_{v_b}, \psi_{b_1}), (\mathbb{P}_{b_2}, \psi_{b_2})$ are consistent requires iterating over all consistent configurations which are at most equal $n^{O(f^2+(\frac{\log n}{\epsilon})^{\sigma+1})}$. Therefore the running time is $n^{O(f^2+(\frac{\log n}{\epsilon})^{\sigma+1})}$, which is quasi-polynomial in $n$. Notice that even if treewidth is poly-logarithmic, the running time stays quasi-polynomial.

We lose a factor of $(1+\epsilon/\log n)$ when computing $A[b, \mathbb{P}_b]$ at each level of recursion. Since the height of the tree is at most $c \log n$, the approximation factor of the solution is $1+\epsilon$. ◀

## 4 Bounded Doubling, Highway Dimension, and Minor-Free Metrics

We assume that the aspect ratio of a given metric in a $k$-MSC instance is polynomially bounded (the details are omitted). We use our QPTAS for $k$-MSC on graphs with bounded treewidth as a black box and combine it with embeddings into polylogarithmic-treewidth graphs [7, 10, 14] to develop QPTASs for $k$-MSC on metric spaces with bounded doubling dimension[1], bounded highway dimension, and minor-free metrics. The details are omitted in this version of the paper.

[1] To obtain a QPTAS for Euclidean Min-Sum clustering, we could adopt the approach we proposed for tree-like metrics. This involves using a $(1+\epsilon)$-reduction from Euclidean Min-Sum clustering to Euclidean Min-Hub clustering, achieved by placing hubs of constant size in suitable locations for each cluster. We could then apply Arora's scheme to get a QPTAS for Euclidean Min-Hub clustering, with cluster types determined by the backbone structure of the hubs. We skip the details since this can be derived from the reduction from doubling metrics to bounded treewidth metrics.

## Abstract

In this paper, we study the maximum clique problem on hyperbolic random graphs. A hyperbolic random graph is a mathematical model for analyzing scale-free networks since it effectively explains the power-law degree distribution of scale-free networks. We propose a simple algorithm for finding a maximum clique in hyperbolic random graph. We first analyze the running time of our algorithm theoretically. We can compute a maximum clique on a hyperbolic random graph $G$ in $O(m+n^{4.5(1-\alpha)})$ expected time if a geometric representation is given or in $O(m+n^{6(1-\alpha)})$ expected time if a geometric representation is not given, where $n$ and $m$ denote the numbers of vertices and edges of $G$, respectively, and $\alpha$ denotes a parameter controlling the power-law exponent of the degree distribution of $G$. Also, we implemented and evaluated our algorithm empirically. Our algorithm outperforms the previous algorithm [BFK18] practically and theoretically. Beyond the hyperbolic random graphs, we have experiment on real-world networks. For most of instances, we get large cliques close to the optimum solutions efficiently.

## 1 Introduction

Designing algorithms for analyzing large real-world networks such as social networks, World Wide Web, or biological networks is a fundamental problem in computer science that has attracted considerable attention in the last decades. To deal with this problem from the theoretical point of view, it is required to define a mathematical model for real-world networks. For this purpose, several models have been proposed. Those models are required to replicate the salient features of real-world networks. One of the most salient features of real-world networks is *scale-free*. In general, a graph is considered as a scale-free network if its diameter is small, one connected component has large size, it has subgraphs with large edge density, and most importantly, *its degree distribution follows a power law*. Here, for an integer $k \leq n$, let $P(k)$ be the fraction of nodes having degree exactly $k$. If $P(k) \sim k^{-\beta}$, we say that the degree distribution of the graph follows a power law. In this case, $\beta$ is called the *power-law exponent*.

One promising model for scale-free real-world networks is the hyperbolic random graph model. A hyperbolic random graph is constructed from two parameters. First, points in the hyperbolic plane are chosen from a certain distribution depending on the parameters. Then

we consider the points as the vertices of the constructed hyperbolic random graph. For two vertices whose distance is at most a certain threshold, we add an edge between them. For illustration, see Figure 1. It is known that the degree distribution of a hyperbolic random graph follows a power-law [15]. Moreover, its diameter is small with high probability [14, 16], and it has a giant connected component [10, 17]. Including these results, the structural properties of hyperbolic random graphs have been studied extensively [11]. However, only a few algorithmic results are known. In other words, the previous work focuses on *why* we can use hyperbolic random graphs as a promising model, but only a few work focuses on *how* to use this model for solving real-world problems. We focus on the latter type of problems.

In this paper, we focus on the maximum clique problem for hyperbolic random graphs from theoretical and practical point of view. The maximum clique problem asks for a maximum-cardinality set of pairwise adjacent vertices. For general graphs, this problem is NP-hard. Moreover, it is W[1]-hard when it is parameterized by the solution size, and it is APX-hard even for cubic graphs [2]. Therefore, the theoretical study on the clique problem focuses on special classes of graphs. In fact, this problem can be solved in polynomial time for special classes of graphs such as planar graphs, unit disk graphs and hyperbolic random graphs [7, 12, 13]. More specifically, the algorithm by Bläsius et al. [7] for computing a maximum clique of a hyperbolic random graph takes $O(mn^{2.5})$ *worst-case* time. The randomness in the choice of vertices is not considered in the analysis of the algorithm. One natural question here is to design an algorithm for this problem with improved *expected* time.

To analyze our algorithm, we use the *average-case analysis*. A traditional modeling choice in the analysis of algorithms is *worst-case analysis*, where the performance of an algorithm is measured by the worst performance over all possible inputs. Although it is a useful framework in the analysis of algorithms, it does not take into account the distribution of inputs that an algorithm is likely to encounter in practice. It is possible that an algorithm performs well on most inputs, but poorly on a small number of inputs that are rarely encountered in practice. In this case, the worst-case analysis can mislead the analysis of algorithms. The field of "beyond worst-case analysis" studies ways for overcoming these limitations [25]. One simple technique studied in this field is the average-case analysis. As the hyperbolic random graph model intrinsically defines an input distribution, the average-case analysis is a natural model for analyzing algorithms for hyperbolic random graphs.

**Previous Work.** While the structural properties of hyperbolic random graphs has been studied extensively, only a few algorithmic problems have been studied. The most extensively studied algorithmic problem on hyperbolic random graphs is the generation problem: Given parameters, the goal is to generate a hyperbolic random graph efficiently. The best-known algorithms run in expected linear time [5] and in worst-case subquadratic time [26]. Also, Bläsius et al. [8] studied the problem of embedding a scale-free network into the hyperbolic plane and presented heuristics for this problem.

Very recently, classical algorithmic problems such as shortest path problems, the maximum clique problem and the independent set problem have been studied. These problems can be solved significantly faster in hyperbolic random graphs. More specifically, given a hyperbolic random graph, the shortest path between any two vertices can be computed in sublinear expected time [4, 9]. A hyperbolic random graph admits a sublinear-sized balanced separator with high probability [6]. As applications, Bläsius et al. [6] showed that the independent set problem admits a PTAS for hyperbolic random graphs, and the maximum matching problem admits a subquadratic-time algorithm. Also, the clique problem can be solved in polynomial time for hyperbolic random graphs in the worst case [7].

The clique problem has been studied extensively because it has numerous applications in various field such as community search in social networks, team formation in expert networks, gene expression and motif discovery in bioinformatics and anomaly detection in complex networks [19]. From a theoretical perspective, the best-known exact algorithm runs in $2^{0.276n}$ time in [23]. However, it is not sufficiently fast for massive real-world networks, leading to the proposal of lots of exact algorithms and heuristics for this problem on real-world networks [1, 19, 21, 24]. While these algorithms and heuristics work efficiently in practice, there is no theoretical guarantee of their efficiency.

**Our results.** We present algorithms for computing a maximum clique in a hyperbolic random graph and analyze their performances theoretically and empirically.

Given a hyperbolic random graph with parameters $\alpha$ and $C$ together with its geometric representation, we can compute a maximum clique in $O(m+n^{4.5(1-\alpha)})$ expected time, where $n$ and $m$ denotes the numbers of vertices and edges of the given graph. Here, we have $1/2 < \alpha < 1$, and the O-notation hides a constant depending on $\alpha$ and $C$. With high probability, our algorithm outperforms the previously best-known algorithm by Bläsius et al. [7] running in $O(mn^{2.5})$ time. In the case that a geometric representation is not given, our algorithm runs in $O(m+n^{6(1-\alpha)})$ expected time. This is the first algorithms for the maximum clique problem on hyperbolic random graphs not using geometric representations.

Also, we implemented our algorithms and analyzed it empirically. We run our algorithms on both synthetic data (hyperbolic random graphs) and real-world data. For hyperbolic random graphs, since it is proved that our algorithm computes a maximum clique correctly, we focus on the efficiency of the algorithms. We observed that our algorithms perform efficiently; it takes about 100ms for $n = 10^6$. For real-world networks, our algorithm gives a lower bound on the optimal solution. We observed that our algorithm performs well especially for collaboration networks and web networks. These are typical scale-free real-world networks.

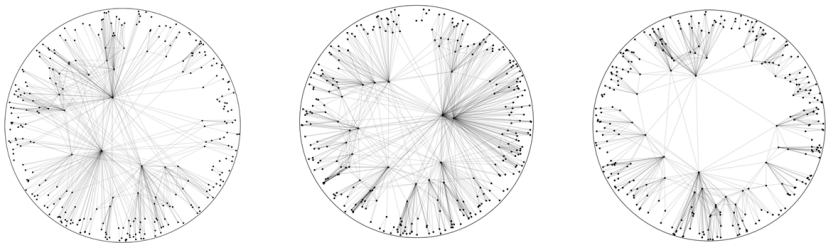
## 2 Preliminaries

Let $\mathbb{H}^2$ be the hyperbolic plane with curvature $-1$. We can handle hyperbolic planes with arbitrary (negative) curvatures by rescaling other model parameters which will be defined later. Thus it suffices to deal with the hyperbolic plane with curvature $-1$. Since the hyperbolic plane is isotropic, we choose an arbitrary point $o$ and consider it as the origin of $\mathbb{H}^2$. Also, we fix a half-line $\ell_o$ from $o$ going towards an arbitrary point, say $w$, as the *axis*. Then we can represent a point $v$ of $\mathbb{H}^2$ as $(r_v, \phi_v)$ where $r_v$ is the hyperbolic distance between $v$ and $o$, and $\phi_v$ is the angle from $\ell_o$ to the half-line from $o$ going towards $v$. We call $r_v$ and $\phi_v$ the *radial* and *angular coordinates* of $v$.

For any two points $x$ and $y$ in $\mathbb{H}^2$, we use $d(x, y)$ to denote the distance in $\mathbb{H}^2$ between $x$ and $y$. Then we have the following.

$$\begin{aligned} d(u,v) &= \cosh^{-1}(\cosh(r_u)\cosh(r_v) - \sinh(r_u)\sinh(r_v)\cos(\Delta\phi_{u,v}) \\ &\leq \cosh^{-1}(\cosh(r_u)\cosh(r_v) + \sinh(r_u)\sinh(r_v)), \end{aligned}$$

where $\Delta\phi_{u,v}$ denotes the small relative angle between $v$ and $u$ [3]. For a point $x \in \mathbb{H}^2$ and a value $r \geq 0$, we use $B_x(r)$ to denote the disk centered at $x$ with radius $r$. That is, $B_x(r) = \{v \in \mathbb{H}^2 \mid d(v, x) \leq r\}$.



(a) $\alpha = 0.75$ and $C = 3$ (b) $\alpha = 0.75$ and $C = 1$ (c) $\alpha = 0.85$ and $C = 1$

**Figure 1** HRGs with different parameters. As $C$ gets larger, the average degree gets larger (See (a–b)). As $\alpha$ gets larger, the points gets closer to the boundary of $D$ (See (b–c)).

## 2.1 Hyperbolic Random Graphs

A *hyperbolic unit disk graph (HRG)* is a graph whose vertices are placed on $\mathbb{H}^2$, and two vertices are connected by an edge if the distance between them on $\mathbb{H}^2$ is at most some threshold. This threshold is called the *radius threshold* of the graph. This is the same as the unit disk graph except that the hyperbolic unit disk graph is defined on $\mathbb{H}^2$ while the unit disk graph is defined on the Euclidean plane.

In this paper, we focus on the hyperbolic *random* graph model introduced by Papadopoulos et al. [20]. It is a family $\{\mathcal{G}_{n,\alpha,C}\}$ of distributions, indexed by the number $n$ of vertices, a parameter $C$ adjusting the average degree of a graph, and a parameter $\alpha$ determining the power-law exponent. A sample from $\{\mathcal{G}_{n,\alpha,C}\}$ is a hyperbolic unit disk graph on $n$ points (vertices) chosen independently as follows. Let $D$ be the disk centered at $o$ with radius $R = 2\ln n + C$. To pick a point $v$ in $D$, we first sample its radius $r_v$, and then sample its angular coordinate $\phi_v$. The probability density $\rho(r)$ for the radial coordinate $r_v$ is defined as

$$\rho(r) = \frac{\alpha \sinh(\alpha r)}{\cosh(\alpha R) - 1}. \tag{1}$$

Then the angular coordinate is sampled uniformly from $[0, 2\pi)$. In this way, we can sample one vertex with respect to parameters $\alpha$ and $C$, and by choosing $n$ vertices independently and by computing the hyperbolic unit disk graph with radius threshold $R$ on the $n$ vertices, we can obtain a sample from the distribution $\{\mathcal{G}_{n,\alpha,C}\}$.

An intuition behind the definition of $\rho(r)$ is as follows. To choose a point $v$ uniformly at random in $D$, we first choose its angular coordinate uniformly at random in $[0, 2\pi)$ as we did for $\mathcal{G}_{n,\alpha,C}$, and choose its radial coordinate according to the distribution with density function $\rho(r) = \frac{\sinh(r)}{\cosh(\alpha R)-1}$. But in this case, the power-law exponent of a graph is fixed. To add the flexibility to the model, the authors of [20] introduced a parameter $\alpha$ and defined the density function as in (1). Here, For $\alpha < 1$, this favors points closer to the center of $D$, while for $\alpha > 1$, this favors points closer to the boundary of $D$. For $\alpha = 1$, this corresponds to the uniform distribution [15]. For illustration, see Figure 1.

**Properties of HRGs.** Let $\mu(S)$ be the probability measure of a set $S \subseteq D$, that is,

$$\mu(S) = \int_{x \in S} \frac{\alpha \sinh(\alpha r_x)}{2\pi \cosh(\alpha R) - 1} dx.$$

For a vertex $v$ of a hyperbolic random graph $G$ with $n$ vertices, the expected degree of $v$ in $G$ is $n \cdot \mu(B_v(R) \cap D)$ by construction. Moreover, notice that $\mu(B_v(R) \cap D) = \mu(B_{v'}(R) \cap D)$ for any two vertices $v, v'$ with $r_v = r_{v'}$. Thus to make the description easier, we let $B_r(r')$ denote $B_{(r,0)}(r')$ if it is clear from the context. Note that $D = B_0(R)$.

Hyperbolic random graphs have all properties for being considered as scale-free networks mentioned above. In particular, hyperbolic random graphs with parameter $\alpha$ have power-law exponent $\beta$, where $\beta = 2\alpha + 1$ if $\alpha \geq 1/2$, and $\beta = 2$ otherwise. Most real-world networks have a power-law exponent larger than two. Thus we assume that $\alpha > 1/2$ in the paper.

## 2.2 Algorithms for the Maximum Clique Problem

In this section, we review the algorithm for this problem on hyperbolic random graphs described in [7], which is an extension of [12]. This algorithms requires geometric representations of hyperbolic random graphs. Let $G = (V, E)$ be a hyperbolic random graph.

For $\alpha \geq 1$, they showed that a hyperbolic random graph has $O(n)$ maximal cliques with high probability. Therefore, a maximum clique can be computed in linear time with high probability by just enumerating all the maximal cliques.

For $\frac{1}{2} < \alpha < 1$, they showed that the algorithm in [12] can be extended to hyperbolic random graphs. Assume first that, for a maximum clique $K$, we have two vertices $u$ and $v$ of $K$ with maximum $r = d(u, v)$. Then all vertices in $K$ are contained in the region $R_{uv} = B_u(r) \cap B_v(r)$. Then we can compute $K$ by considering the vertices in $R_{uv}$ as follows. We partition $R_{uv}$ into $R^1_{uv}$ and $R^2_{uv}$ with respect to the line through $u$ and $v$. They showed that the diameter of $R^1_{uv}$ (and $R^2_{uv}$) is at most one, and thus $V \cap R^1_{uv}$ (and $V \cap R^2_{uv}$)) forms a clique. Therefore, the subgraph $G_{uv}$ of $G$ induced by $V \cap R_{uv}$ is the complement of a bipartite graph with bipartition $(V \cap R^1_{uv}, V \cap R^2_{uv})$. Moreover, $K$ is an independent set of the complement of $G_{uv}$. Therefore, it suffices to compute an independent set of the complement of $G_{uv}$, and we can do this in in $O(n^{2.5})$ time using the Hopcroft-Karp algorithm. However, we are not given the edge $uv$ in advance. Thus we apply this procedure for every edge $uv$ of $G$, and then take the largest clique as a solution. This takes $\mathcal{O}(mn^{2.5})$ time in total.

Throughout this paper, we use $\mathbb{P}[A]$ to denote the probability that an event $A$ occurs. For a random variable $X$, we use $\mathbb{E}[X]$ to denote the expected value of $X$. Due to lack of space, some proofs and details are omitted. Missing proofs and details can be found in the full version of this paper.

# 3 Efficient Algorithm for the Maximum Clique Problem

In this section, we present an algorithm for the maximum clique problem on a hyperbolic random graph drawn from $\mathcal{R}_{n,\alpha,C}$ running in $\mathcal{O}\left(m + n^{4.5(1-\alpha)}\right)$ expected time. This algorithm correctly works for any hyperbolic unit disk graph, but its time bound is guaranteed only for hyperbolic random graphs. As we only deal with the case that $1/2 < \alpha < 1$, this algorithm is significantly faster than the algorithm in [7].

A main observation is the following. A clique of size $k$ consists of vertices of degree at least $k - 1$. That is, to find a clique of size at least $k$, removing vertices with degree less than $k - 1$ does not affect the solution. Thus once we have a lower bound, say $k$, on the size of a maximum clique, we can remove all vertices of degree less than $k$. Our strategy is to construct a sufficiently large clique (which is not necessarily maximum) as a preprocessing step so that we can remove a sufficiently large number of vertices of small degree. After applying a preprocessing step, we will see that the number of vertices we have decreases to $O(n^{1-\alpha})$ with high probability. Then we apply the algorithm in [7] to the resulting graph.

## 3.1 Computing a Sufficiently Large Clique Efficiently

In this section, we show how to compute a clique of size $\Omega(n^{1-\alpha})$ with probability $1-2^{-\Omega(n^{1-\alpha})}$. The algorithm is simple: Scan the vertices in the non-increasing order of their degrees, and maintain a clique $Q$, which is initially set as $\emptyset$. If the next vertex can be added to $Q$ to form a larger clique, then add it, otherwise exclude it. We can sort the vertices with respect to their degrees in $O(n+m)$ time using counting sort. Also, we can construct the clique $Q$ in $O(n+m)$ time. In the following, we call $Q$ the *initial clique*.

Now, we show that the size of the initial clique is $\Omega(n^{1-\alpha})$ with probability $1-2^{-\Omega(n^{1-\alpha})}$. First, we show that a sufficient large clique can be found by collecting all vertices in $B_0(R/2)$ with high probability. in Lemma 1. For its proof, see the full version.

▶ **Lemma 1.** *For any constant $c' > 0$, the vertices in $B_0(R/2-c')$ forms a clique of size $\Omega(n^{1-\alpha})$ with probability $1-2^{-\Omega(n^{1-\alpha})}$.*

Thus, we can get desired clique by choosing $\Omega(n^{1-\alpha})$ vertices in $B_0(R/2)$ with high probability. However, as we scan the vertices in the decreasing order of their degrees, this does not immediately imply that the size of the initial clique is $\Omega(n^{1-\alpha})$. In the following lemma, we show that the initial clique has the claimed size by showing that the $\Omega(n^{1-\alpha})$ vertices with highest degrees are contained in $B_0(R/2)$ with high probability.

▶ **Lemma 2.** *The initial clique has size $\Omega(n^{1-\alpha})$ with probability $1-2^{-\Omega(n^{1-\alpha})}$.*

**Proof.** Here, we give a brief sketch of the proof. For details, see the full version. First, we show that no vertex lying outside of $B_0(R/2)$ has degree greater than $2ec_1\sqrt{n}$ with high probability for some constant $c_1$ depending only on $C, \alpha$. Then we show that no vertex in $B_0(R/2-c_2)$ has degree smaller than $2ec_1\sqrt{n}$ with high probability for some constant $c_2$. To construct the initial solution, we scan the vertices in the decreasing order of their degrees. Therefore, with probability $1-2^{-\Omega(\sqrt{n})}$, we consider all vertices in $B_0(R/2-c_2)$ before considering any vertex lying outside of $B_0(R/2)$. Therefore, the initial clique contains all vertices in $B_0(R/2-c_2)$ with high probability. By Lemma 1, the initial clique has size at least $\Omega(n^{1-\alpha})$ with high probability. ◀

## 3.2 Removing All Vertices of Small Degree

In this section, we show how to remove a sufficiently large number of vertices, and show that the size of the remaining graph is $O(n^{1-\alpha})$ with high probability. This algorithm is also simple: given the initial clique of size $k$, we repeatedly delete all vertices of degree smaller than $k$. We call the resulting graph the *kernel*. Then no vertex in the kernel has degree smaller than $k$ at the end of the process. This process can be implemented in linear time as follows: maintain the queue of vertices of degree smaller than $k$, and maintain the degree of each vertex. Then remove the vertices in the queue in order. Whenever a vertex $v$ is removed, update the degree of each neighbor $w$ of $v$ and insert $w$ to the queue if its degree gets smaller than $k$.

We show that the kernel has size $O(n^{1-\alpha})$. Notice that we do not specify the order of vertices we consider during the deletion process. Fortunately, the kernel size remains the same regardless of the choice of deletion ordering. A proof of Lemma 3 can be found in the full version of this paper.

▶ **Lemma 3.** *In any order of deleting vertices, we can get a unique kernel.*

Because of the uniqueness of the kernel, for analysis, we may fix a specific deletion ordering and slightly modify the deletion process as follows. Imagine that we scan the vertices in the decreasing order of their radial coordinates. If the degree of a current vertex (in the remaining graph) is at least the size of the initial clique size, then we terminate the deletion process. Otherwise, we delete the current vertex, and consider the next vertex. By Lemma 3, the number of remaining vertices is at least the size of the kernel. In the following lemma, we analyze the number of remaining vertices.

▶ **Lemma 4.** *Given an initial solution of size $\Omega(n^{1-\alpha})$, then the size of the kernel is $O(n^{1-\alpha})$ with probability $1-2^{-\Omega(n^{1-\alpha})}$.*

**Proof.** Here, we give a sketch of the proof only. For details, see the full version.

Let $K$ be the initial solution, and let $r'$ be a value such that $n\mu(B_0(r')\cap B_{r'}(R))$ is $\frac{|K|}{2e}$. Then we show that all the vertices with radial coordinates larger than $r'$ are removed with probability $1-2^{-\Omega(n^{1-\alpha})}$. To do this, for a vertex $v$, we define the *inner degree* of $v$ as the number of its neighboring vertices whose radial coordinates are smaller than the radial coordinate of $v$. The expected inner degree of a vertex with radial coordinate $r \geq r'$ is at most $n\mu(B_0(r')\cap B_{r'}(R)) = \frac{|K|}{2e}$.

Chernoff bound implies that for a vertex with radial coordinate larger than $r'$, the probability that its inner degree is larger than the size of the initial clique is at most $2^{-|K|}$. By the union bound over at most $n$ vertices with radial coordinates larger than $r'$, the probability that no vertex with radial coordinate larger than $r'$ has inner degree larger than than the size of the initial clique is at most $n2^{-|K|} = 2^{-\Omega(n^{1-\alpha})}$. In other words, with probability $1-n2^{-c_3 n^{1-\alpha}} = 1-2^{-\Omega(n^{1-\alpha})}$, all vertices with radial coordinates larger than $r'$ have inner degree larger than the size of the initial clique.

If this event happens, we remove all vertices with coordinates larger than $r'$. We show that the number of vertices with coordinates at most $r'$ is at most $O(n^{1-\alpha})$ with probability $1-2^{-\Omega(n^{1-\alpha})}$. Therefore, the probability that the number of remaining vertices after applying the deletion process is at most $O(n^{1-\alpha})$ is at least $1-2^{-\Omega(n^{1-\alpha})}$. ◀

Although the deletion process we use for analysis requires the geometric representation of $G$, the original deletion process does not require the geometric representation of $G$. By combining the argument in Section 3.1 and Section 3.2, we have the following theorem.

▶ **Theorem 5.** *Given a graph drawn from $\mathcal{G}_{n,\alpha,C}$ with $\frac{1}{2} < \alpha < 1$ and its geometric representation, we can compute its maximum clique in $\mathcal{O}\left(m+n^{4.5(1-\alpha)}\right)$ expected time.*

## 4 Efficient Robust Algorithm for the Maximum Clique Problem

In this section, we present the first algorithm for the maximum clique problem on hyperbolic random graphs which does not require geometric representations. In many cases, a geometric representation of a graph is not given. In particular, real-world networks such as social and collaboration networks are not defined based on geometry although they share properties with HRGs. As we want to use hyperbolic random graphs as a model for such real-world networks, it is necessary to design algorithms not requiring geometric representations.

Our main key tool in this section is the notion of *co-bipartite neighborhood edge elimination ordering* (CNEEO) introduced by Raghavan and Spinrad [22]. It can be considered as a variant of a perfect elimination ordering. Let $G$ be an undirected graph. Let $L=(e_1,e_2,\dots e_m)$ be an edge ordering of all edges of $G$. Let $G_L[i]$ be the subgraph of $G$ with the edge set $\{e_i,e_{i+1}\dots e_m\}$. For a vertex $v\in V$, let $N_G(v)$ denote the set of neighbors of $v$ in $G$. Then

$L$ is called a *co-bipartite neighborhood edge elimination ordering* (CNEEO) if for each edge $e_i = (u_i, v_i)$, the subgraph of $G$ induced by $N_{G_L[i]}(u_i) \cap N_{G_L[i]}(v_i)$ is co-bipartite. Here, a *co-bipartite graph* is a graph whose complement is bipartite.

Raghavan and Spinrad [22] presented an algorithm for computing a CNEEO in polynomial time if it exists. It uses a simple greedy algorithm: compute the edges of a CNEEO one by one, and add an edge immediately if it does not violate the condition of a CNEEO. Moreover, they presented a polynomial-time algorithm for computing a maximum clique in polynomial time assuming a CNEEO is given. Since Raghavan and Spinrad [22] did not give an explicit time bound on their algorithm, we analyzed their algorithm and confirmed that their algorithm takes $O(m^3 + mn^{2.5})$ time in the full version. Note that this time bound holds for an arbitrary graph (not necessarily a hyperbolic unit disk graph) admitting a CNEEO.

We show that a hyperbolic unit disk graph admits a CNEEO. This immediately leads to an $O(m^3 + mn^{2.5})$-time algorithm for the maximum clique problem. Its proof can be found in the full version. In the case of hyperbolic *random* graphs, we can solve the problem even faster. As we did in Section 3, we compute an initial clique, remove vertices of small degrees, and then obtain a kernel of small size. Recall that these procedures do not require geometric representations. Note that the kernel is also a hyperbolic unit disk graph because we remove vertices only. The number of vertices of the kernel is $O(n^{1-\alpha})$ and the edges is $O(n^{2-2\alpha})$ in probability $1 - 2^{-\Omega(n^{1-\alpha})}$. Thus, we have the following theorem.

▶ **Corollary 6.** *Given a graph drawn from $\mathcal{G}_{n,\alpha,C}$ with $\frac{1}{2} < \alpha < 1$, we can compute a maximum clique in $\mathcal{O}\left(m + n^{6(1-\alpha)}\right)$ expected time without its geometric representation.*

**Heuristics for real-world networks.** A main motivation of the study of hyperbolic random graphs is to obtain heuristics for analyzing real-world networks. Many real-world networks share salient features with hyperbolic random graphs, but this does not mean that many real-world networks *are* hyperbolic random graphs. Because the algorithm in Corollary 6 is aborted for a graph not admitting a CNEEO, one cannot expect that this algorithm works correctly for many real-world networks. In fact, only a few real-world networks admit CNEEO as we will see in Section 6. That is, for most of real-world networks, the algorithm in Corollary 6 is aborted.

However, in this case, we can obtain a lower bound on the optimal clique sizes, and moreover, we can reduce the size of the graph. Although we do not have any theoretical bound here, our experiments showed that the size of the clique we can obtain is close to the optimal value for many instances. For details, see the full version.

## 5 Improving Performance through Additional Optimizations

For implementation, we introduce the following two minor techniques for improving the performance of the algorithms. Although these techniques do not improve the performance theoretically, they improve the performance empirically. Recall that our algorithms consist of two phases: Computing a kernel of size $O(n^{1-\alpha})$, and then computing a maximum clique of the kernel. As the first phase can be implemented efficiently, we focus on the second phase here. Again, the second phase has two steps. With geometric representations, we first compute a CNEEO, and then compute a maximum clique using the CNEEO. Without geometric representations, we consider every edge, and then compute a maximum clique in the subgraph induced by the common neighbors of the endpoint of the edge. The first technique applies to both of the two steps, and the second technique applies to the first step.

## 5.1 Skipping Vertices with Low Degree

The main observation of our kernelization algorithm is that, for any lower bound $k$ on the size of a maximum clique, a vertex of degree less than $k$ does not participate in a maximum clique. The first technique we use in the implementation is to make use of this observation also for computing a CNEEO, and for computing a maximum clique using the CNEEO.

While computing a CNEEO, the lower bound $k$ we have does not change; it is the size of the initial clique. Whenever we access a vertex, we check if its degree is less than $k$. If so, we remove this vertex from the kernel, and do not consider it any more. One can consider this as "lazy deletion." Then once we have a CNEEO, we scan the edges in the CNEEO, and for each edge, we compute a maximum clique of the subgraph defined by the edge. If it is larger than the lower bound $k$ we have, we update $k$ accordingly. In this process, whenever we find a vertex of degree less than $k$, we remove it immediately. Moreover, if the subgraph defined by each edge of CNEEO has vertices less than $k$, we skip this subgraph as it does not contain a clique of size larger than $k$.

## 5.2 Introducing the Priority of Edges

Recall that the second phases consists of two steps: computing a CNEEO, and computing a maximum clique using the CNEEO. In this section, we focus on the first step.

**With Geometric Representations.** In this case, we use the $O(m'n'^{2.5})$-time algorithm by [7] for computing a maximum clique of the kernel with $n'$ vertices and $m'$ edges. Although it is the theoretically best-known algorithm, we observed that computing a maximum clique using a CNEEO is more efficient practically. By the proof in the full version, the list of the edges sorted in the non-decreasing order of their lengths is a CNEEO. Without using a CNEEO, for each edge $uv$, we have to compute the subgraph of $G$ induced by the common neighbors of $u$ and $v$ in $G$. On the other hand, once we have a CNEEO, it suffices to consider the subgraph of $G$ induced by the common neighbors of $u$ and $v$ in $G_L$, where $G_L$ is the subgraph of $G$ with the edges coming after $uv$ in the CNEEO. If $uv$ lies close to the last edge in the CNEEO, the number of common neighbors of $u$ and $v$ in $G_L$ can be significantly smaller than the number of their common neighbors in $G$. This can lead to the performance improvement.

**Without Geometric Representations.** In this case, we compute a CNEEO in a greedy fashion. Starting from the empty sequence, we add the edges one by one in order. For each edge $e$ not added to the current ordering, we check if the common neighbors of the endpoints of $e$ in the kernel is co-bipartite. If an edge passes this test, we add it to the ordering. It is time-consuming especially when only a few edges can pass the test. To avoid considering the same edge repeatedly, we use the following observation. Once an edge $e$ fails this test, it cannot pass the test unless one of its incident edges are added to the ordering. Using this observation, we classify the edges into two sets: active edges and inactive edges. In each iteration, we consider the active edges only. Once an edge fails the test, then it becomes inactive. Once an edge passes the test, we make all its incident edges active. In this way, we can significantly improve the running time especially for graphs that do not accept CNEEO.

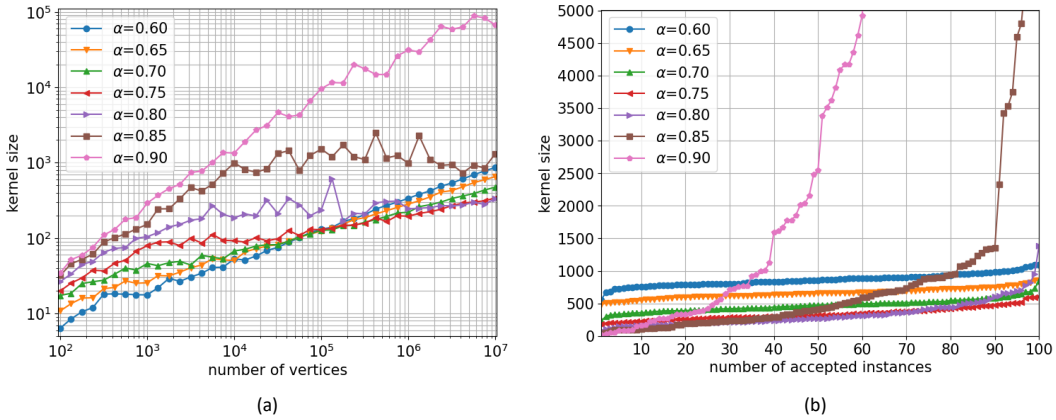


**Figure 2** (a) Comparison of the kernel sizes with varying $\alpha$. Here, $\delta = 10$. (b) Cactus plot of the kernel size versus the number of accepted instances for each value of $\alpha$ with fixed $n = 10^7$.

## 6 Experimental Evaluation

In this section, we evaluate the performance of our algorithm mainly on hyperbolic random graphs and real-world networks.

**Environment and data.** We implemented our algorithm using C++17. The code were compiled with GNU GCC version 11.3.0 with optimization flag "-O2". All tests were run on a desktop with Rygen 7 3800X CPU, 32GB memory, and Ubuntu 22.04LTS.

We evaluate the performance of our algorithm on hyperbolic random graphs and real-world networks. For hyperbolic random graphs, we generate graphs using the open source library GIRGs [5] by setting parameters differently. Recall that we have three parameters $n$, $C$ and $\alpha$. Here, instead of $C$, we use the average degree, denoted by $\delta$, as a parameter because $\delta$ can be represented as a function of $C$ and $\alpha$. As we consider the average performance of our algorithm, we sampled 100 random graphs for fixed parameters $n, \delta$ and $\alpha$, and then calculate the average results (the size of kernels or the running times).

For real-world networks, we use the SNAP dataset [18]. It contains directed graphs and non-simple graphs as well. In this case, we simply ignore the directions of the edges and interpret all directed graphs as undirected graphs. Also, we collapse all multiple edges into a single edge and remove all loops.

### 6.1 Experiment on Hyperbolic Random Graphs: Kernel Size

We showed that the size of the kernel of the hyperbolic random graph is $O(n^{1-\alpha})$ with probability $1 - 2^{\Omega(n^{1-\alpha})}$. In this section, we evaluated the tendency on the size of the kernel experimentally as $n$, $\alpha$ and $\delta$ change. Here, $\alpha$ controls the power-law exponent, and $\delta$ is the average degree of the graph. For experiments for $\delta$, see the full version.

Figure 2 shows the tendency on the size of the kernel as $\alpha$ changes. Here, we fix $\delta = 10$. Figure 2(a) shows a plot of the kernel size versus the number of vertices of a graph on a log–log scale for each value of $\alpha$. We generate 100 instances randomly and take the average of their results for each point in the plot. Figure 2(b) shows a cactus plot of the kernel size versus the number of accepted instances for each value of $\alpha$. Here, for a fixed kernel size $k$, an instance is said to *accepted* if our algorithm returns a kernel of size at most $k$ for this instance. Here, we fix $n = 10^7$ and $\delta = 10$.

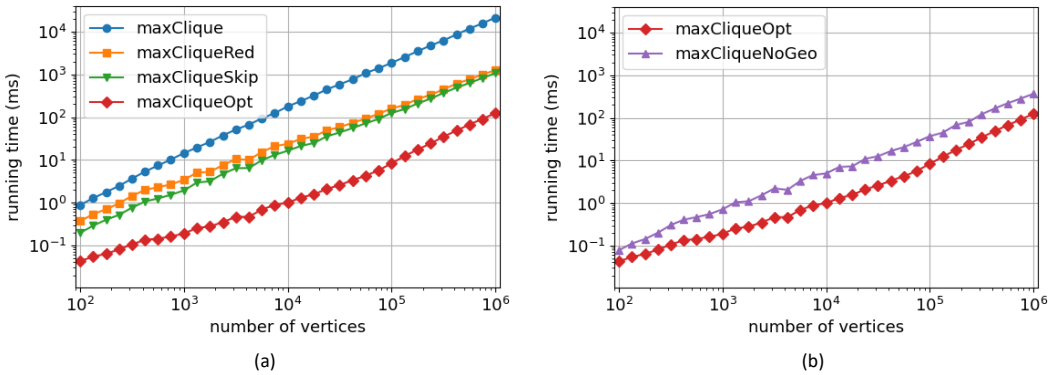

**Figure 3** (a) Comparison of running times of different versions of our algorithm. (b) Comparison of running times with and without geometric representations. Here, $\alpha = 0.75$ and $\delta = 10$.

**Table 1** Running time for each operation. The unit of time is a millisecond.

| | INIT | KERNEL | CNEEO | CONST | INDEP | OTHER | TOTAL |
|---|---|---|---|---|---|---|---|
| `MaxClique` | - | - | - | 21 516.34 | 4 470.38 | 8.18 | 25 994.90 |
| `MaxCliqueRed` | 15.67 | 89.27 | - | 1 126.95 | 37.92 | 2.88 | 1 272.70 |
| `MaxCliqueSkip` | 15.59 | 88.62 | - | 925.33 | 30.77 | 2.88 | 1 063.19 |
| `MaxCliqueOpt` | 15.64 | 88.61 | 1.07 | 12.55 | 1.19 | 2.88 | 121.94 |
| `MaxCliqueNoGeo` | 15.32 | 89.25 | 258.45 | 5.82 | 0.93 | 2.96 | 372.74 |

For $\alpha \leq 0.8$, the size of the average kernel decreases for sufficiently large $n$, say $n = 10^7$, as $\alpha$ increases in Figure 2(a). Also, the kernel sizes for all instances are concentrated on the average kernel size for each $\alpha \leq 0.8$ in Figure 2(b). This is consistent with Lemma 4 stating that the kernel size is $O(n^{1-\alpha})$ with high probability. However, this fact does not hold for $\alpha > 0.8$ in Figure 2(a), and the reason for this can be seen in Figure 2(b). At $\alpha = 0.85$, approximately 10% of instances did not have kernels of size at most 1500, and at $\alpha = 0.9$, over 60% of instances did not have such kernels. Notice that the plot sharply increases when the kernel size exceeds 1500. The success probability stated in Lemma 4 is $1 - 2^{\Omega(n^{1-\alpha})}$, which decreases as $\alpha$ increases. In other words, if $n$ is not sufficiently large, it is possible that the success probability $1 - 2^{\Omega(n^{1-\alpha})}$ is not sufficiently large for $\alpha > 0.8$. That is, if we increase the number of vertices on our experiments, we would get the desired tendency on the kernel size for all values $\alpha$. Nevertheless, at $n = 10^7$, our algorithm removes a significant number of vertices, leaving only 0.01% of vertices at $\alpha = 0.85$ and only 1% at $\alpha = 0.9$.

## 6.2 Experiment on Hyperbolic Random Graphs: Running Time

In this section, we conducted experiments for evaluating the running times of different versions of our algorithms. Figure 3 shows a plot of the number of vertices versus the running time of each version of our algorithm. Here, we fix $\alpha = 0.75$ and $\delta = 10$. Each point of the plot is averaged for 100 instances. Figure 3(a) shows a plot for the algorithm, denoted by `MaxClique`, by Bläsius et al. [7] and three different versions of the algorithm using geometric representations: `MaxCliqueRed`, `MaxCliqueSkip`, and `MaxCliqueOpt`. More specifically, `MaxCliqueRed` denotes the algorithm described in Section 4. `MaxCliqueSkip` denotes the algorithm described in Section 5.1 that skips low-degree vertices. `MaxCliqueOpt` denotes the algorithm described in Section 5.2 that introduces priorities of edges. As expected, `MaxCliqueOpt` outperforms all other versions of the algorithms in this experiment.

**Table 2** The performance of our algorithm on the real-world data.

| | $\|V\|$ | $\|E\|$ | $\|V_{\text{kernel}}\|$ | $\|V_{\text{left}}\|$ | $\|E_{\text{left}}\|$ | runtime | $\omega_{\text{kernel}}$ | $\omega_{\text{eval}}$ | $\omega$ |

For a precise analysis, we evaluated the running time of each task for our algorithms and reported them in in Table 1. More specifically, the algorithms conduct six tasks: INIT denotes the task of finding an initial solution. KERNEL denotes the task of finding the kernel. CNEEO denotes the task of computing a CNEEO. CONST denotes the task of constructing a co-bipartite graph by considering the common neighbors of the endpoints of each edge. INDEP denotes the task of computing a maximum independent set of the complement of a co-bipartite graph. OTHER denotes all the other tasks such as the initialization for variables and caches. TOTAL denotes the entire tasks of our algorithm.

As expected, `MaxCliqueRed` outperforms `MaxClique` significantly. However, CONST is still a time-consuming task for `MaxCliqueRed`. Thus we focus on optimization techniques for CONST and provides `MaxCliqueSkip` and `MaxCliqueOpt` in Section 5. Although `MaxCliqueSkip` gives a performance improvement, it still takes a significant amount of time in CONST and INDEP. `MaxCliqueOpt` computes a CNEEO by sorting the edges with respect to their lengths. This allows us to manage degree efficiently and apply low-degree skip technique to a larger number of vertices. This significantly improves the running time of `MaxCliqueSkip` for CONST and INDEP. This algorithm runs in about 100ms even at $n = 10^6$, exhibiting a performance improvement over 200 times compared to `MaxClique`.

Next, we compared the running times of two algorithms with and without geometrical representations. In the case that a geometric representation is given, we use `MaxCliqueOpt`. If a geometric representation is not given, we use the algorithm in Section 4 and denote it by `MaxCliqueNoGeo`. In `MaxCliqueOpt`, we can quickly compute a CNEEO by sorting the edges in non-decreasing order of length. However, `MaxCliqueNoGeo` computes a CNEEO in a greedy approach which incurs significant overhead. Despite this, the performance of `MaxCliqueNoGeo` in Figure 3(b) does not show a significant difference compared to `MaxCliqueOpt`, and it even outperforms `MaxCliqueSkip`.

## 6.3 Experiment on Real-World Dataset

Our algorithm can heuristically find large cliques for real-world data. We conducted experiments on several real-world datasets and recorded these results in Table 2. The unit of the running time is a second. $|V|$ and $|E|$ denote the numbers of vertices and edges of the input graph, respectively. $|V_{\text{kernel}}|$ denotes the number of vertices of the kernel. $|V_{\text{left}}|$ and $|E_{\text{left}}|$ denote the numbers of vertices and edges of the remaining graph. Also, $\omega_{\text{kernel}}$ denotes the size of the initial clique, $\omega_{\text{eval}}$ denotes the size of the clique computed from our algorithm, and $\omega$ denotes the size of the maximum clique of the graph. Here, $\omega$ is the correct answer given by the dataset. If a given graph accepts a CNEEO, it is theoretically guaranteed that $\omega_{\text{eval}}$ is the exact solution and $|V_{\text{left}}| = |E_{\text{left}}| = 0$. Otherwise, $\omega_{\text{eval}}$ is a lower bound on the exact solution, and $G_{\text{left}} = (V_{\text{left}}, E_{\text{left}})$ has a maximum clique if $\omega_{\text{eval}}$ is strictly smaller than the exact solution.

The collaboration networks such as ca-AstroPh, CondMat, HepPh, and com-dblp are one of the well-known scale-free networks. These networks accept a CNEEO, allowing us to find the exact maximum clique. Moreover, we were able to find a CNEEO considerably faster for these networks than for other graphs in our experiments. Web graphs such as web-BerkStan, web-Google, web-Notre Dame, and web-Stanford are also one of the well-known scale-free networks. Although these graphs do not accept a CNEEO, we were able to reduce the number of vertices and edges significantly, and we obtained maximum cliques. For the other graphs we tested, we were able to obtain lower bounds that were close to the maximum clique size in most cases, and we were able to significantly reduce the size of the graphs.

# 7 Conclusion

We presented improved algorithms for the maximum clique problem on hyperbolic random graphs. Our algorithms find a sufficiently large initial solution and find a sufficiently small kernel in linear time, which greatly improves the average time complexity and practical running time. Also we gave the first algorithm for the maximum clique problem on hyperbolic random graphs without geometrical representations. Beyond the hyperbolic random graph, we applied these algorithms to real-world dataset and obtained lower bounds close to the optimum solutions for most of instances.

There are two possible directions for further improvement on our algorithms. First, we compute a maximum clique of hyperbolic random graphs using the framework for computing a maximum clique of unit disk graphs in [12]. Recently, Espenant et al. [13] improved the algorithm [12] and presented an $O(n^{2.5} \log n)$-time algorithm for the maximum clique problem on unit disk graphs. It would be interesting if this technique can be applied to hyperbolic geometry. Second, the bottleneck of our algorithm lies in constructing a CNEEO. Especially, for most of real-world dataset, most of the running time is devoted to constructing a CNEEO. Thus to speed up the overall performance, this step must be improved.

# Parameterized Complexity of Equality MinCSP

**George Osipov**
Department of Computer and Information Science, Linköping University, Sweden

**Magnus Wahlström**
Department of Computer Science, Royal Holloway, University of London, UK

## Abstract

We study the parameterized complexity of MinCSP for so-called *equality languages*, i.e., for finite languages over an infinite domain such as $\mathbb{N}$, where the relations are defined via first-order formulas whose only predicate is $=$. This is an important class of languages that forms the starting point of all study of infinite-domain CSPs under the commonly used approach pioneered by Bodirsky, i.e., languages defined as reducts of finitely bounded homogeneous structures. Moreover, MinCSP over equality languages forms a natural class of optimisation problems in its own right, covering such problems as Edge Multicut, Steiner Multicut and (under singleton expansion) Edge Multiway Cut. We classify MinCSP($\Gamma$) for every finite equality language $\Gamma$, under the natural parameter, as either FPT, W[1]-hard but admitting a constant-factor FPT-approximation, or not admitting a constant-factor FPT-approximation unless FPT=W[2]. In particular, we describe an FPT case that slightly generalises Multicut, and show a constant-factor FPT-approximation for Disjunctive Multicut, the generalisation of Multicut where the "cut requests" come as disjunctions over $O(1)$ individual cut requests $s_i \neq t_i$. We also consider *singleton expansions* of equality languages, enriching an equality language with the capability for assignment constraints $(x = i)$ for either a finite or infinitely many constants $i$, and fully characterize the complexity of the resulting MinCSP.

## 1 Introduction

Let $D$ be a fixed domain, and let $\Gamma$ be a finite set of finitary relations over $D$. $\Gamma$ is referred to as a *constraint language*. A *constraint* over $\Gamma$ is a pair $(R, X)$, less formally written $R(X)$, where $R \in \Gamma$ is a relation of some arity $r$ and $X = (x_1, \ldots, x_r)$ is a tuple of variables. It is *satisfied* by an assignment $\alpha$ if $(\alpha(x_1), \ldots, \alpha(x_r)) \in R$. For a constraint language $\Gamma$, the *constraint satisfaction problem* over $\Gamma$, CSP($\Gamma$), is the problem where an instance $I$ is a collection of constraints over $\Gamma$, on some set of variables $V$, and the question is if there is an assignment satisfying all constraints in $I$. In the optimization variant MinCSP($\Gamma$), the input also contains an integer $k$ and the question is whether there is an assignment such that all but at most $k$ constraints are satisfied. Less formally, a constraint language $\Gamma$ determines the "type of constraints" allowed in an instance of CSP($\Gamma$) or MinCSP($\Gamma$), and varying the constraint language defines problems of varying complexity (such as $k$-SAT, $k$-Colouring, $st$-Min Cut, etc.). After decades-long investigations, *dichotomy theorems* have been established for these problems: for every constraint language over a finite domain, CSP($\Gamma$) and MinCSP($\Gamma$) is either in P or NP-complete, and the characterizations are

known [16, 40, 38, 31]. For fixed cases, such as the Boolean domain $D = \{0, 1\}$, *parameterized* dichotomies are also known, characterizing every problem MinCSP($\Gamma$) as either FPT or W[1]-hard [29], and similarly for approximate FPT algorithms [12]. This work represents significant advancements of our understanding of tractable and intractable computational problems (classical or parameterized).

But as highlighted by Bodirsky [3, 9], there are also many problems from a range of application domains that do not lend themselves to a formulation in the above CSP framework, yet which can be formulated via CSPs over structures with *infinite* domains. Unfortunately, CSPs with fixed templates over infinite domains are not as well-behaved as over finite domains; it is known that the problem CSP($\Gamma$) over an infinite domain can have any computational complexity (including being intermediate), making any dichotomy impossible [6, 9]. There are also questions of how an arbitrary infinite-domain relation would be represented. The approach used by Bodirsky, which is the standard approach for the study of infinite-domain CSPs, is to consider a language $\Gamma$ as a *reduct of a finitely bounded homogeneous structure*. Less technically, consider a structure, for example $(\mathbb{Q}, <)$ or $(\mathbb{Z}, <)$, and let $\Gamma$ be a finite language where every relation in $\Gamma$ has a quantifier-free first-order definition over the structure; i.e., $\Gamma$ is a *first-order reduct* of the structure. For such languages a dichotomy is plausible, and many cases have been settled, including *temporal* CSPs, i.e., first-order reducts of $(\mathbb{Q}, <)$ [8]; *discrete temporal* CSPs, i.e., first-order reducts of $(\mathbb{Z}, <)$ [10]; CSPs over the universal random graph [11]; and many more.

Our goal is to study the parameterized complexity of MinCSPs over such structures. Many important problems in parameterized complexity, which are not well handled by CSP optimization frameworks over finite-domain CSPs, can be expressed very simply in this setting. For example, the MinCSP with domain $\mathbb{Q}$ and the single relation $<$ is equivalent to the Directed Feedback Arc Set problem, i.e., given a digraph $D$ and an integer $k$, find a set $X$ of at most $k$ arcs from $D$ such that $D - X$ is acyclic. (Here, the vertices of $D$ become variables, the arcs constraints, and the topological order of $D - X$ becomes an assignment which violates at most $|X|$ constraints.) Other examples include Subset Directed Feedback Arc Set, which corresponds to MinCSP($<, \leq$), and Symmetric Directed Multicut which corresponds to MinCSP($\leq, \neq$). The former is another important FPT problem [18], while FPT status of the latter is open [23].

The structure we study in this paper is $(\mathbb{N}, =)$. The relations definable over this structure are called *equality constraint languages*. Here, $\mathbb{N}$ is an arbitrary, countably infinite domain; first-order reducts of $(\mathbb{N}, =)$ are simply relations definable by a quantifier-free first-order formula whose only predicate is $=$. Equivalently, relations in an equality language accept or reject an assignment to their arguments purely based on the partition that the assignment induces. Since every first-order formula is allowed to use equality in this framework, equality languages are contained in *every* other class of languages studied in the framework. Hence, characterizing the complexity of equality languages is a prerequisite for studying any other structure.

Moreover, the setting also covers problems that are important in their own right, as it captures undirected *graph separation* problems. In particular, (Vertex/Edge) Multicut is defined as follows. The input is a graph $G$, an integer $k$, and a set of *cut requests* $\mathcal{T} \subseteq \binom{V(G)}{2}$, and the task is to find a set $X$ of at most $k$ vertices, respectively edges, such that for every cut request $st \in \mathcal{T}$, vertices $s$ and $t$ are in different connected components in $G - X$. Multicut is FPT parameterized by $k$ – a breakthrough result, settling a long-open question [37, 14]. As with the above examples, there appears to be no natural way of capturing Multicut as a finite-domain CSP optimization problem. However, it naturally

corresponds to MinCSP$(=, \neq)$ over domain $\mathbb{N}$, where edges correspond to soft $=$-constraints and cut requests to crisp $\neq$-constraints. Another classic problem is Multiway Cut, which is the special case of Multicut where the cut requests are $\mathcal{T} = \binom{T}{2}$ for a set $T$ of *terminal vertices* in the graph. Multiway Cut was among the first graph separation problems shown to be FPT [36], and remains a relevant problem, e.g., for the question of *polynomial kernelization* [32, 39]. While Multiway Cut is not directly captured by an equality CSP, it is captured by the *singleton expansion* of the setting, i.e., allowing "assignment constraints" of the form $x = i$ for all $i \in \mathbb{N}$.

**Related work.** Bodirsky and Kara [7] characterized CSP($\Gamma$) as in P or NP-hard for every equality language $\Gamma$. Bodirsky, Chen and Pinsker [5] characterized the structure of equality languages up to pp-definitions (*primitive positive definitions*, see Section 2); these are too coarse to preserve the parameterized complexity of a problem, but their results are very useful as a guide to our search. For much more material on CSPs over infinite domains, see Bodirsky [4]. Singleton expansions (under different names) are discussed by Bodirsky [4] and Jonsson [25]. We have taken the term from Barto et al. [1].

Many variations on cut problems have been considered, and have been particularly important in parameterized complexity [20] (see also [19]). We cover Multicut, Multiway Cut and *Steiner cut*. Given a graph $G$ and a set of terminals $T \subseteq V(G)$, a Steiner cut is an edge cut in $G$ that separates $T$, i.e., a cut $Z$ such that some pair of vertices in $T$ is disconnected in $G - Z$. Steiner Cut is the problem of finding a minimum Steiner cut. This can clearly be solved in polynomial time; in fact, using advanced methods, it can even be computed in *near-linear* time [33, 17]. Steiner Multicut is the generalization where the input contains a set $\mathcal{T} = \{T_1, \ldots, T_t\}$ of terminal sets and the task is to find a smallest-possible cut that separates every set $T_i$. Since Multiway Cut with 3 terminals is NP-hard, Steiner Multicut is NP-hard if $t \geq 3$. Bringmann et al. [15] considered parameterized variations of this and showed, among other results, that Edge Steiner Multicut is FPT even for terminal sets $T_i$ of unbounded size, if the parameter includes both $t$ and the cut size $k$. On the other hand, parameterized by $k$ alone, Steiner Multicut is W[1]-hard for terminal sets of size $|T_i| = 3$.

Other parameterized CSP dichotomies directly relevant to our work are the dichotomies for Boolean MinCSP as having constant factor FPT-approximations or being W[1]-hard to approximate [12] (with additional results in a later preprint [13]) and the recent FPT/W[1]-hardness dichotomy [29].

The area of FPT approximations has seen significant activity in recent years, especially regarding lower bounds on FPT approximations [24, 26, 2, 34]. In particular, we will need that there is no constant-factor FPT-approximation for Nearest Codeword in Boolean codes unless FPT=W[1] [13, 2], or for Hitting Set unless FPT=W[2] [34]. Lokshtanov et al. [35] considered fast FPT-approximations for problems whose FPT algorithms are slow; in particular, our result for Steiner Multicut builds on their algorithm giving an $O^*(2^{O(k)})$-time 2-approximation.

## Our Results

We study the classical and parameterized complexity of MinCSP($\Gamma$) for every finite equality language $\Gamma$, as well as for singleton expansions over equality languages. We consider both exact FPT-algorithms and constant-factor FPT-approximations, and for every finite $\Gamma$ classify whether MinCSP($\Gamma$) is in FPT, MinCSP($\Gamma$) is W[1]-hard but admits constant-factor FPT-approximation, or MinCSP($\Gamma$) is W[1]-hard to approximate within any constant. To describe the cases in more detail, we need some definitions.

Unsurprisingly, MinCSP($\Gamma$) for an equality language $\Gamma$ is NP-hard except in trivial cases, since MinCSP($=, \neq$) already corresponds to Edge Multicut. Specifically, MinCSP($\Gamma$) is in P if $\Gamma$ is *constant*, in which case every relation in $\Gamma$ contains the tuple $(1, \ldots, 1)$, or *strictly negative*, in which case every relation in $\Gamma$ contains every tuple $(1, \ldots, r)$ where all values are distinct (proper definitions of the terms are found in Section 3). In all other cases, MinCSP($\Gamma$) is NP-hard by reduction from Edge Multicut. Moreover, under the Unique Games Conjecture [27], NP-hard MinCSP($\Gamma$) does not admit polynomial-time constant-factor approximation.

To describe constraint languages $\Gamma$ that give rise to fixed-parameter tractable MinCSP($\Gamma$), let $\mathsf{NEQ}_3$ be the ternary relation which contains all tuples with three distinct values, and let a *split* constraint be a constraint $R$ of some arity $p + q$ for $p, q \geq 0$, defined (up to argument order) by

$$R(x_1, \ldots, x_p, y_1, \ldots, y_q) \equiv \bigwedge_{i,j \in [p]} (x_i = x_j) \wedge \bigwedge_{i \in [p], j \in [q]} (x_i \neq y_j).$$

We note that MinCSP($\Gamma$) with split constraints reduces to Vertex Multicut. A split constraint $R(u_1, \ldots, u_p, v_1, \ldots, v_q)$ can be represented by introducing a new vertex $c$, adding edges $cu_i$ for every $i \in [p]$ and cut requests $cv_j$ for every $i \in [q]$. However, a constraint $\mathsf{NEQ}_3(u, v, w)$ cannot be handled by a gadget. Hence, we introduce the following auxiliary graph problem, and show that it is in FPT.

| Vertex Multicut with Deletable Triples (aka Triple Multicut) | |
|---|---|
| Instance: | A graph $G$, a collection $\mathcal{T} \subseteq \binom{V(G)}{3}$ of vertex triples, and integer $k$. |
| Parameter: | $k$. |
| Question: | Are there subsets $X_V \subseteq V(G)$ and $X_\mathcal{T} \subseteq \mathcal{T}$ such that $\lvert X_V \rvert + \lvert X_\mathcal{T} \rvert \leq k$ and every connected component of $G - X_V$ intersects every triple in $\mathcal{T} \setminus X_\mathcal{T}$ in at most one vertex? |

MinCSP($\Gamma$) for $\Gamma$ with only split relations and $\mathsf{NEQ}_3$ easily reduces to Triple Multicut. To complement this result with hardness, we prove the following.

▶ **Theorem 1.** *Let $\Gamma$ be an equality constraint language that is neither constant nor strictly negative. Then MinCSP($\Gamma$) is FPT if every relation in $\Gamma$ is either split or $\mathsf{NEQ}_3$, and W[1]-hard otherwise.*

Next, we describe the cases with constant-factor FPT-approximations. Consider relation

$$R_d = (x_1 \neq y_1 \vee \cdots \vee x_d \neq y_d)$$

and let $\Gamma$ be a constraint language where every relation is defined by conjunction of relations $R_d$ and $=$. We show that MinCSP($\Gamma$) for such $\Gamma$ is constant-factor fpt-approximable, with the factor depending on $d$. Again, we introduce a new graph problem to capture this case. Let $G$ be a graph; a subset $L \subseteq \binom{V(G)}{2}$ of pairs is a *request list*, and a set of vertices $X \subseteq V(G)$ *satisfies* $L$ if there is a pair $st \in L$ separated by $X$. For a graph $G$ and a collection of request lists $\mathcal{L}$, let $\mathrm{cost}(G, \mathcal{L})$ be the minimum size of a set $X \subseteq V(G)$ that satisfies all lists in $\mathcal{L}$.

| Disjunctive Multicut | |
|---|---|
| Instance: | A graph $G$, a collection $\mathcal{L}$ of request lists, each of size at most $d$, and an integer $k$. |
| Parameter: | $k$. |
| Question: | Is $\mathrm{cost}(G, \mathcal{L}) \leq k$? |

Our main algorithmic contribution is an FPT-approximation for Disjunctive Multicut. Note that Steiner Multicut is the special case of Disjunctive Multicut where each request list is $L = \binom{T_i}{2}$ for some terminal set $T_i$. Here we obtain an improved algorithm with approximation factor 2 and running time $O^*(2^{O(k)})$.

This precisely describes the FPT-approximable cases of MinCSP($\Gamma$): For every equality constraint language $\Gamma$ such that CSP($\Gamma$) is in P, either MinCSP($\Gamma$) reduces to Disjunctive Multicut in an immediate way (up to a constant-factor approximation loss), implying a constant-factor FPT-approximation, or there is a cost-preserving reduction from Hitting Set to MinCSP($\Gamma$). We refer to the latter as MinCSP($\Gamma$) being Hitting Set-hard.

▶ **Theorem 2.** *Let $\Gamma$ be an equality constraint language such that CSP($\Gamma$) is in P. Then either MinCSP($\Gamma$) reduces to Disjunctive Multicut and has a constant-factor FPT-approximation, or MinCSP($\Gamma$) is Hitting Set-hard.*

We can summarize the main result in the following way: for every finite equality constraint language $\Gamma$, either MinCSP($\Gamma$) is FPT by reduction to Triple Multicut, MinCSP($\Gamma$) is FPT-approximable by reduction to Disjunctive Multicut, or MinCSP($\Gamma$) is Hitting Set-hard. A more technical description in terms of the allowed relations can be found in Section 3.

**Singleton Expansion.** In addition to the above (main) results, we also investigate the effect of adding constants to an equality language motivated by the problem Multiway Cut. More precisely, for an equality language $\Gamma$, we investigate the effect of adding some number of unary singleton relations $\{(i)\}$ to $\Gamma$. This is equivalent to allowing "assignment constraints" $(x = i)$ in MinCSP($\Gamma$). We consider adding either a finite number of singletons, or every singleton relation. For an equality language $\Gamma$ and an integer $c \in \mathbb{N}$, $c \geq 1$, we define $\Gamma_c^+ = \Gamma \cup \{\{(i) \mid i \in [c]\}$ as the language $\Gamma$ with $c$ different singletons added, and let $\Gamma^+$ denote $\Gamma$ with every singleton $\{(i)\}$, $i \in \mathbb{N}$ added. Edge Multiway Cut corresponds to MinCSP($\Gamma^+$) over the language $\Gamma = \{=\}$, and $s$-Edge Multiway Cut, the special case with $s$ terminals, corresponds to MinCSP($\Gamma_s^+$). By a *singleton expansion of* $\Gamma$ we refer to either the language $\Gamma' = \Gamma^+$ or $\Gamma' = \Gamma_c^+$ for some $c \in \mathbb{N}$.

As the first step of the characterization, we observe that if $\Gamma$ can express $=$ and $\neq$, then the singleton expansion adds no power, i.e., MinCSP($\Gamma^+$) reduces back to MinCSP($\Gamma$) by introducing variables $c_1, \ldots, c_m$ for arbitrarily many constants, adding constraints $c_i \neq c_j$ whenever $i \neq j$, and using constraints $x = c_i$ in place of assignments $x = i$. For the rest of the characterization, we thus study the cases that either cannot express equality, or cannot express disequality. In the former case, MinCSP($\Gamma'$) is always FPT and constant-factor approximable; the latter case is more involved. We defer the full case description to the full paper, but in summary, for any singleton expansion $\Gamma'$ of a finite equality language $\Gamma$, we characterize MinCSP($\Gamma'$) as being in P or NP-hard, being FPT or W[1]-hard, and with respect to the existence of polynomial-time or FPT constant-factor approximations. Overall, the positive cases in the characterization follow without difficulty, but completing the picture with negative results requires significant additional work, building on the structural results of Bodirsky, Chen and Pinsker [5].

**Roadmap.** Section 2 contains technical preliminaries. Section 3 gives an overview of the classification proof. Section 4 shows the FPT algorithm for Triple Multicut. Section 5 gives the FPT approximation algorithms. This version omits several proofs, the approximation result for Steiner Multicut, and the classification of CSP and MinCSP for equality constraint languages under singleton expansion. These can be found in the full version.

## 2 Preliminaries

**Graph Separation.** Let $G$ be an undirected graph. Denote the vertex set of $G$ by $V(G)$ and the edge set by $E(G)$. For a subset of edges/vertices $X$ in $G$, let $G - X$ denote the graph obtained by removing the elements of $X$ from $G$, i.e. $G - X = (V(G), E(G) \setminus X)$ if $X \subseteq E(G)$ and $G - X = G[V(G) \setminus X]$ if $X \subseteq V(G)$. A *cut request* is a pair of vertices $st \in \binom{V(G)}{2}$, and an $st$-cut/$st$-separator is a subset of edges/vertices $X$ such that $G - X$ contains no path connecting $s$ and $t$. We write that $X$ *fulfills* $st$ if $X$ is an $st$-cut/$st$-separator. We implicitly allows the inputs to cut problems such as Multiway Cut and Multicut to contain undeletable edges/vertices: for edges, with a parameter of $k$, we can include $k+1$ parallel copies; for vertices, we can replace a vertex $v$ with a clique of size $k+1$, where every member of the clique has the same neighbourhood as $v$.

**Parameterized Deletion.** A *parameterized* problem is a subset of $\Sigma^* \times \mathbb{N}$, where $\Sigma$ is the input alphabet. The parameterized complexity class FPT contains problems decidable in $f(k) \cdot n^{O(1)}$ time, where $f$ is a computable function and $n$ is the bit-size of the instance. Let $L_1, L_2 \subseteq \Sigma^* \times \mathbb{N}$ be two parameterized problems. A mapping $F : \Sigma^* \times \mathbb{N} \to \Sigma^* \times \mathbb{N}$ is an *FPT-reduction* from $L_1$ to $L_2$ if

- $(x, k) \in L_1$ if and only if $F((x, k)) \in L_2$,
- the mapping can be computed in $f(k) \cdot n^{O(1)}$ time for some computable function $f$, and
- there is a computable function $g : \mathbb{N} \to \mathbb{N}$ such that for all $(x, k) \in \Sigma^* \times \mathbb{N}$, if $(x', k') = F((x, k))$, then $k' \leq g(k)$.

The classes W[1] and W[2] contains all problems that are FPT-reducible to Clique and Hitting Set, respectively, parameterized by the solution size. These problems are not in FPT under the standard assumptions FPT≠W[1] and FPT≠W[2]. For a thorough treatment of parameterized complexity we refer to [20].

**Constraint Satisfaction.** Fix a *domain* $D$. A relation $R$ of *arity* $r$ is a subset of tuples in $D^r$, i.e. $R \subseteq D^r$. We write $=$ and $\neq$ to denote the binary equality and disequality relations over $D$, i.e. $\{(a, b) \in D^2 : a = b\}$ and $\{(a, b) \in D^2 : a \neq b\}$, respectively. A *constraint language* $\Gamma$ is a set of relations over a domain $D$. A *constraint* is defined by a relation $R$ and a tuple of variables $\mathbf{x} = (x_1, \ldots, x_r)$, where $r$ is the arity of $R$. It is often written as $R(\mathbf{x})$ or $R(x_1, \ldots, x_r)$. An assignment $\alpha : \{x_1, \ldots, x_r\} \to D$ *satisfies* the constraint if $\alpha(\mathbf{x}) = (\alpha(x_1), \ldots, \alpha(x_r)) \in R$, and *violates* the constraint if $\alpha(\mathbf{x}) \notin R$.

| Constraint Satisfaction Problem for $\Gamma$ (CSP($\Gamma$)) | |
|---|---|
| Instance: | An instance $I$, where $V(I)$ is a set of variables and $C(I)$ is a multiset of constraints using relations from $\Gamma$. |
| Question: | Is there an assignment $\alpha : V(I) \to D$ that satisfies all constraints in $C(I)$? |

MinCSP is an optimization version of the problem seeking an assignment that minimizes the number of violated constraints. In this constraints are allowed to be *crisp* and *soft*. The *cost of assignment* $\alpha$ in an instance $I$ of CSP is infinite if it violates a crisp constraint, and equals the number of violated soft constraints otherwise. The *cost of an instance* $I$ denoted by $\text{cost}(I)$ is the minimum cost of any assignment to $I$.

| MinCSP($\Gamma$) | |
|---|---|
| Instance: | An instance $I$ of CSP($\Gamma$) and an integer $k$. |
| Question: | Is $\text{cost}(I) \leq k$? |

Next, we recall a useful notion that captures local reductions between CSPs.

▶ **Definition 3.** *Let $\Gamma$ be a constraint language over $D$ and $R \subseteq D^r$ be a relation. A* primitive positive definition (pp-definition) *of $R$ in $\Gamma$ is an instance $C_R$ of CSP$(\Gamma, =)$ with primary variables $\mathbf{x}$, auxiliary variables $\mathbf{y}$ and the following properties:*
**(1)** *if $\alpha$ satisfies $C_R$, then it satisfies $R(\mathbf{x})$,*
**(2)** *if $\alpha$ satisfies $R(\mathbf{x})$, then there exists an extension of $\alpha$ to $\mathbf{y}$ that satisfies $C_R$.*

Informally, pp-definitions can be used to simulate $R$ using the relations available in $\Gamma$ and equality: every constraint using $R$ can be replaced by a gadget based on the pp-definition, resulting in an equivalent instance. The type of reductions captured by pp-definitions is however incompatible with MinCSP because the reductions do not preserve assignment costs. This motivates the following definition.

▶ **Definition 4.** *Let $\Gamma$ be a constraint language over $D$ and $R \subseteq D^r$ be a relation. An* implementation *of $R$ in $\Gamma$ is a pp-definition of $R$ with primary variables $\mathbf{x}$, auxiliary variables $\mathbf{y}$ and an additional property: if $\alpha$ violates $R(\mathbf{x})$, there exists an extension of $\alpha$ to $\mathbf{y}$ of cost one.*

Although pp-definitions do not preserve costs, they can be used to simulate crisp constraints in MinCSP instances.

▶ **Proposition 5** (Proposition 5.2 in [30])**.** *Let $\Gamma$ be a constraint language over a domain $D$ and $R$ be a relation over $D$. Then the following hold.*
1. *If $\Gamma$ pp-defines $R$, then there is an FPT-reduction from MinCSP$(\Gamma, R)$ restricted to instances with only crisp $R$-constraints to MinCSP$(\Gamma, =)$.*
2. *If $\Gamma$ implements $R$, there is an FPT-reduction from MinCSP$(\Gamma, R)$ to MinCSP$(\Gamma, =)$.*

**Approximation.** A minimization problem over an alphabet $\Sigma$ is a triple $(\mathcal{I}, \mathrm{sol}, \mathrm{cost})$, where $\mathcal{I} \subseteq \Sigma^*$ is the set of instances, $\mathrm{sol} : \mathcal{I} \to \Sigma^*$ is a function such that maps instances $I \in \mathcal{I}$ to the sets of solutions $\mathrm{sol}(I)$, and $\mathrm{cost} : \mathcal{I} \times \Sigma^* \to \mathbb{Z}_{\geq 0}$ is a function that takes an instance $I \in \mathcal{I}$ and a solution $X \in \mathrm{sol}(I)$ as input, and returns a non-negative integer cost of the solution. Define $\mathrm{cost}(I) := \min\{\mathrm{cost}(I, X) : X \in \mathrm{cost}(I)\}$. A constant-factor approximation algorithm with factor $c \geq 1$ takes an instance $x \in \mathcal{I}$ and an integer $k \in \mathbb{N}$, and returns "yes" if $\mathrm{cost}(I) \leq k$ and "no" if $\mathrm{cost}(I) > c \cdot k$. A *cost-preserving reduction* from a problem $A = (\mathcal{I}_A, \mathrm{sol}_A, \mathrm{cost}_A)$ to $B = (\mathcal{I}_B, \mathrm{sol}_B, \mathrm{cost}_B)$ is a pair of polynomial-time computable functions $F$ and $G$ such that (1) for every $I \in \mathcal{I}_A$, we have $F(I) \in \mathcal{I}_B$ with $\mathrm{cost}_A(I) = \mathrm{cost}_B(F(I))$, and (2) for every $I \in \mathcal{I}_A$ and $Y \in \mathrm{sol}(F(I))$, we have $G(I, Y) \in \mathrm{sol}(I)$, and $\mathrm{cost}_A(I, G(I, Y)) \leq \mathrm{cost}_B(F(I), Y)$. If there is a cost-preserving reduction from $A$ to $B$, and $B$ admits a constant-factor polynomial-time/fpt approximation algorithm, then $A$ also admits a constant-factor polynomial-time/fpt approximation algorithm.

## 3 Classification Overview

We now give an overview of the complexity dichotomy. Details are deferred to the full paper. We begin with a definition of the relevant language classes. Recall that an *equality language* is a constraint language over $\mathbb{N}$ whose relations can be defined via Boolean formulas over the equality predicate. More precisely, for a set of variables $X = \{x_1, \ldots, x_n\}$, let a *positive literal* be a term $(x_i = x_j)$ and a *negative literal* a term $(x_i \neq x_j)$, $i, j \in [n]$. A *clause* is a disjunction of literals. Then every equality relation has a CNF definition as a conjunction of clauses. A relation (respectively language) is *Horn* if it (respectively every relation in the

**Table 1** Selected Horn relations $R$ and the complexity of MinCSP$(R, =, \neq)$. FPA refers to fixed-parameter approximation.

| Name | CNF Formula | Tuples | Complexity |
|---|---|---|---|
| $\mathsf{EQ}_3$ | $(x_1 = x_2) \wedge (x_2 = x_3) \wedge (x_1 = x_3)$ | $(1,1,1)$ | FPT |
| $\mathsf{NEQ}_3$ | $(x_1 \neq x_2) \wedge (x_2 \neq x_3) \wedge (x_1 \neq x_3)$ | $(1,2,3)$ | FPT |
| — | $(x_1 = x_2) \wedge (x_1 \neq x_3) \wedge (x_2 \neq x_3)$ | $(1,1,2)$ | FPT |
| $\mathsf{ODD}_3$ | $(x_1 = x_2 \vee x_1 \neq x_3) \wedge (x_1 = x_2 \vee x_2 \neq x_3) \wedge (x_1 \neq x_2 \vee x_2 \neq x_3)$ | $(1,1,1), (1,2,3)$ | Hitting Set-hard |
| $\mathsf{NAE}_3$ | $(x_1 \neq x_2 \vee x_2 \neq x_3)$ | excludes $(1,1,1)$ | W[1]-hard, FPA |
| $R^{\vee}_{\neq,\neq}$ | $(x_1 \neq x_2 \vee x_3 \neq x_4) \wedge (x_1 \neq x_3) \wedge (x_1 \neq x_4) \wedge (x_2 \neq x_3) \wedge (x_2 \neq x_4)$ | $(1,2,3,3)$, $(1,1,2,3)$, $(1,2,3,4)$ | W[1]-hard, FPA |

language) has a CNF definition where every clause has at most one positive literal, *negative* if positive literals only occur in singleton clauses $(x_i = x_j)$, *strictly negative* if there are no positive literals, and *conjunctive* if all clauses are singletons. Note that split relations and $\mathsf{NEQ}_3$ are both conjunctive.

Bodirsky and Kara [7] showed that for an equality language $\Gamma$, CSP$(\Gamma)$ is in P if $\Gamma$ is Horn or constant, and NP-hard otherwise. We note that MinCSP$(\Gamma)$ is trivial if $\Gamma$ is constant or strictly negative, and also show that if $\Gamma$ is Horn but not constant or strictly negative then $\Gamma$ implements the relations $=$ and $\neq$. Hence we focus on this case and assume that $\Gamma$ is Horn and $=, \neq \in \Gamma$. The polynomial-time complexity classification then follows since Edge Multicut reduces to MinCSP$(=, \neq)$. For the remaining steps, we show that

1. MinCSP$(\Gamma, =, \neq)$ admits a constant-factor FPT-approximation if $\Gamma$ is negative, otherwise it is Hitting Set-hard;
2. MinCSP$(R, =, \neq)$ is W[1]-hard if $R$ is negative but not conjunctive;
3. MinCSP$(R, =, \neq)$ is W[1]-hard if $R$ is conjunctive but neither split nor $\mathsf{NEQ}_3$;
4. MinCSP$(\Gamma, =, \neq)$ is in FPT if $\Gamma$ is conjunctive and all relations in $\Gamma$ are split or $\mathsf{NEQ}_3$.

Table 1 lists a number of Horn relations and the associated complexity of MinCSP.

Towards hardness of approximation, we recall a result of Bodirsky, Chen and Pinsker [5] that every equality language that is not negative can define $\mathsf{ODD}_3$ (see Table 1). We show that MinCSP$(\mathsf{ODD}_3, =, \neq)$ is Hitting Set-hard.

▶ **Lemma 6.** *There is a cost-preserving reduction from Hitting Set to MinCSP*$(\mathsf{ODD}_3, =, \neq)$ *where every* $\mathsf{ODD}_3$*-constraint is crisp.*

**Proof Sketch.** Let the input be $(V, \mathcal{E}, k)$, $V = \{1, \ldots, n\}$. Create an instance $(I, k)$ of MinCSP$(\mathsf{ODD}_3, =, \neq)$ starting from variables $x_1, \ldots, x_n$ and $z$, with soft constraints $x_i = z$ for all $i \in [n]$. For every set $e = \{a_1, \ldots, a_\ell\} \in \mathcal{E}$, add auxiliary variables $y_2, \ldots, y_\ell$ and crisp constraints $\mathsf{ODD}_3(x_{a_1}, x_{a_2}, y_2)$, $\mathsf{ODD}_3(y_{i-1}, x_{a_i}, y_i)$ for all $3 \leq i \leq \ell$, and $x_{a_1} \neq y_\ell$. These constraints are satisfiable if and only if not all variables $x_i$, $i \in e$ are equal, so to satisfy them it is sufficient to break a soft constraint $x_{a_i} = z$. Thus, $X \subseteq V$ is a hitting set if and only if $I - \{x_i = z : i \in X\}$ is consistent. ◀

As noted, this implies that MinCSP$(\Gamma)$ is W[1]-hard to even approximate in FPT time. Now assume that $\Gamma$ is negative. Then every relation $R \in \Gamma$ is defined by a conjunction of positive singleton clauses and strictly negative clauses. For a constant-factor approximation,

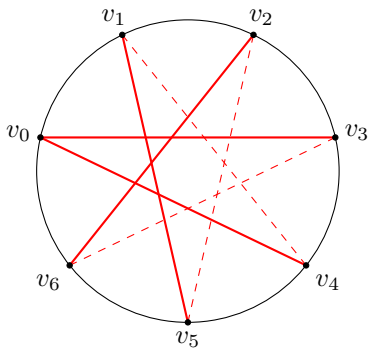

**Figure 1** An illustration of a choice gadget for $t = 3$. Black arcs correspond to equality constraints, dashed red edges to soft disequality constraints, and the bold red edge to a crisp disequality constraint.

by [12, Lemma 10] we may split these definitions into separate constraints, so we may assume that an instance of MinCSP($\Gamma$) uses constraint types $(x_i = x_j)$ and $(x_1 \neq y_1 \vee \ldots \vee x_r \neq y_r)$, of lengths $r \leq d$ for some constant $d$. Then MinCSP($\Gamma$) reduces to Disjunctive Multicut, and since $d = O(1)$ we get an FPT approximation. This settles the cases where MinCSP($\Gamma$) has a constant-factor FPT approximation.

Towards delineating FPT and W[1]-hard cases, assume that $\Gamma$ is negative but not conjunctive, and let $R \in \Gamma$ be a relation such that every CNF definition of $R$ contains a non-singleton clause. We show that in this case $\{R, =, \neq\}$ pp-defines $R^{\vee}_{\neq,\neq}$ or $\mathsf{NAE}_3$, and that MinCSP($R', =, \neq$) is W[1]-hard with crisp $R'$-constraints, where $R'$ is either $R^{\vee}_{\neq,\neq}$ or $\mathsf{NAE}_3$. The problem MinCSP($\mathsf{NAE}_3, =$) with crisp $\mathsf{NAE}_3$-constraints naturally corresponds to Steiner Multicut, which is W[1]-hard [15]. For the remaining proofs, we will need a *choice gadget*. Let $S = \{s_1, \ldots, s_t\}$ be a set. Define an instance $W(S)$ of CSP($=, \neq$) as follows. Introduce $2t + 1$ variables $v_0, \ldots, v_{2t}$ and identify indices modulo $2t + 1$, e.g. $v_0 = v_{2t+1}$. Connect variables in a cycle of equalities, i.e. add soft constraints $v_i = v_{i+1}$ for all $0 \leq i \leq 2t$. The *forward partner* of a variable $v_i$ is $f(v_i) := v_{i+t}$, i.e. the variable that is $t$ steps ahead of $v_i$ on the cycle. Add soft constraints $v_i \neq f(v_i)$ for all $0 \leq i \leq 2t$, and make the constraint $v_0 \neq v_t$ crisp. See Figure 1 for an illustration.

▶ **Lemma 7.** *Let $S$ be a set of size at least two and $W(S)$ be the choice gadget. Then* $\mathrm{cost}(W(S)) = 3$. *Moreover, if $X \subseteq W(S)$, $|X| = 3$, $W(S) - X$ is consistent and $X$ contains $v_i \neq f(v_i)$, then $X$ also contains $v_{i-1} = v_i$ and $f(v_i) = f(v_{i+1})$.*

**Proof Sketch.** Since $v_0 \neq v_t$ is a crisp constraint, we need to remove one link from the top and one from the the bottom chain of equality constraints connecting $v_0$ and $v_t$. After this deletion, at least one chain of length $\lceil \frac{2t+1-2}{2} \rceil = t$ remains, which connects a vertex $v_i$ with its forward partner $f(v_i)$. Thus, we either need to disconnect $v_i$ and $f(v_i)$, or remove the constraint $v_i \neq f(v_i)$. Observe that it is sufficient to delete $v_{i-1} = v_i$, $f(v_i) = f(v_{i+1})$ and $v_i \neq f(v_i)$ to satisfy $W(S)$. Moreover, if a deletion set $X$ of size 3 contains $v_i \neq f(v_i)$, the only pair of vertices $v_j$ and $f(v_j)$ that may remain connected in $W(S) - X$ is the pair with $j = i$. Out of the two compatible choices, only deleting $v_{i-1} = v_i$ and $f(v_i) = f(v_{i+1})$ leaves no constraint unsatisfied. ◀

Intuitively, deleting $v_{i-1} = v_i$, $f(v_i) = f(v_{i+1})$ and $v_i \neq f(v_i)$ from $W(S)$ corresponds to choosing element $s_i$ from the set $S$. We note a simple reduction from Multicoloured Independent Set to MinCSP($R^{\vee}_{\neq,\neq}, =$). Let the input be a graph $G$ with $k$ colour classes $V(G) = V_1 \cup \ldots V_k$. Create a choice gadget for every $V_i$ without soft $\neq$-constraints (but

keeping the crisp one), and set the budget to $2k$. For every pair $u \in V_i$, $v \in V_j$ for $i \neq j$ such that $uv \in E(G)$, add a crisp constraint $R^{\vee}_{\neq,\neq}(u, f(u), v, f(v))$. Due to the budget, $u = f(u)$ holds for at least one $u \in V_i$ for every $V_i$, corresponding to a selection, and the $R$-constraint prevents that $u = f(u)$ and $v = f(v)$, thereby blocking the combination of $u \in V_i$ and $v \in V_j$. We defer the details.

Having shown that MinCSP$(\Gamma, =, \neq)$ is W[1]-hard if $\Gamma$ is non-conjunctive, it remains to show hardness for languages which are conjunctive but not $\mathsf{NEQ}_3$ or split. We use the following W[1]-hard problem (see [22, Lemma 6.1]).

| Split Paired Cut | |
|---|---|
| Instance: | Graphs $G_1, G_2$, vertices $s_1, t_1 \in V(G_1)$, $s_2, t_2 \in V(G_2)$, a family of disjoint edge pairs $\mathcal{P} \subseteq E(G_1) \times E(G_2)$, and an integer $k$. |
| Parameter: | $k$. |
| Question: | Is there a subset $X \subseteq \mathcal{P}$ of size at most $k$ such that for both $i \in \{1, 2\}$, $\{e_i : \{e_1, e_2\} \in X\}$ is an $st$-cut in $G_i$? |

Assuming $\Gamma$ is conjunctive, associate with a relation $R(x_1, \ldots, x_r)$ a graph where for each pair $i, j \in [r]$ there is a blue edge $x_i x_j$ if $i \neq j$ and $R$ implies $x_i = x_j$, and a red edge $x_i x_j$ if $R$ implies $x_i \neq x_j$. Then the graph of a split relation $R(X, Y)$, $X = \{x_1, \ldots, x_p\}$ and $Y = \{y_1, \ldots, y_q\}$ is a blue clique on $X$ and a red biclique of $(X, Y)$, and the graph of $\mathsf{NEQ}_3$ is a red triangle. The remaining cases are precisely the cases when the graph contains two disjoint edges $x_1x_2$, $x_3x_4$ with no blue edges connecting their endpoints (such as $R^{\wedge}_{=,=}$, $R^{\wedge}_{=,\neq}$ or $R^{\wedge}_{\neq,\neq}$). There is a curious parallel to the characterization of FPT cases of Boolean MinCSP, in terms of 2CNF-definable relations whose *Gaifman graph* is $2K_2$-free [29]. We show hardness for all such cases. If both $x_1x_2$ and $x_3x_4$ are blue, a reduction is immediate from Split Paired Cut. We sketch the reduction for a more interesting case of MinCSP$(R^{\wedge}_{\neq,\neq}, =, \neq)$, and note that the reduction for MinCSP$(R^{\wedge}_{=,\neq}, =, \neq)$ is a variant of the above, and hence omitted in this version of the paper.

▶ **Lemma 8.** *MinCSP$(R^{\wedge}_{\neq,\neq}, =)$ is W[1]-hard.*

**Proof sketch.** Let $(G_1, G_2, s_1, t_1, s_2, t_2, \mathcal{P}, k)$ be an instance of Split Paired Cut. By the construction of [28, Lemma 5.7], assume $k = 2\ell$, and $\mathcal{F}_i$ for $i \in \{1, 2\}$ are $s_it_i$-maxflows in $G_i$ partitioning $E(G_i)$ into $k$ pairwise edge-disjoint paths. Construct an instance $(I, k')$ of MinCSP$(R, =, \neq)$ with $k' = 5\ell$ as follows. Start by creating a variable for every vertex in $V(G_1) \cup V(G_2)$ with the same name as the vertex. For each $i \in \{1, 2\}$, consider a path $P \in \mathcal{F}_i$, and let $p$ be the number of edges on $P$. Create a choice gadget $W(P)$ for every $P$ with variables $v^P_0, \ldots, v^P_p$ following the path, and fresh variables $v^P_j$ for $p < j \leq 2p$ added to the instance. Observe that variables may appear on several paths in $\mathcal{F}_i$. In particular, $v^P_0 = s_i$ and $v^P_p = t_i$ for every $P \in \mathcal{F}_i$, so we have crisp constraints $s_i \neq t_i$. Furthermore, since $\mathcal{F}_i$ partitions $E(G_i)$, the construction contains a copy of graphs $G_1$ and $G_2$ with equality constraints for edges. Now we pair up edges according to $\mathcal{P}$. For every pair $\{e_1, e_2\} \in \mathcal{P}$, let $P \in \mathcal{F}_1$ and $Q \in \mathcal{F}_2$ be the paths such that $e_1 \in P$ and $e_2 \in Q$, and suppose $e_1 = v^P_{i-1}v^P_i$ and $e_2 = v^Q_{j-1}v^Q_j$. Pair up soft constraints $v^P_i \neq f(v^P_i)$ and $v^Q_j \neq f(v^Q_j)$, i.e. replace individual constraints with one soft constraint $R(v^P_i, f(v^P), v^Q_j, f(v^Q_j))$. Finally, if an edge $uv \in E(G)$ does not appear in any pair of $\mathcal{P}$, make constraint $u = v$ crisp in $I$. This completes the construction.

The proof of correctness is deferred to the full paper. ◀

For all remaining cases, as noted, every $R \in \Gamma$ is either split or $\mathsf{NEQ}_3$, and there is a simple reduction from MinCSP($\Gamma$) to Triple Multicut. Since the latter is FPT (Theorem 10) the classification is complete.

We omit the details of the classification for singleton expansion cases. The proofs are somewhat more intricate, explicitly using the algebraic method as employed by Bodirsky, Chen and Pinsker [5], but ultimately both the hardness proofs and algorithmic cases are less interesting than for the above.

## 4 Triple Multicut

We show that Triple Multicut is in FPT, thus proving Theorem 10. The algorithm works by a reduction to Boolean MinCSP, i.e. MinCSP($\Delta$) for a constraint language $\Delta$ over the binary domain $\{0, 1\}$. Parameterized complexity of Boolean MinCSP was completely classified by [29]. As a result of our reduction, we obtain an instance where $\Delta$ is bijunctive, i.e. every relation in $\Delta$ can be defined by a Boolean formula in CNF with at most two literals in each clause. Define the *Gaifman graph* of a bijunctive relation $R$ with vertices $\{1, \ldots, r\}$, where $r$ is the arity of $R$, and edges $ij$ for every pair of indices such that $R(x_1, \ldots, x_r)$ implies a 2-clause involving $x_i$ and $x_j$. A graph is $2K_2$-free if no four vertices induce a subgraph with two independent edges.

▶ **Theorem 9** (Theorem 1.2 of [29]). *Let $\Delta$ be a finite bijunctive Boolean constraint language such that the Gaifman graphs of all relations in $\Delta$ are $2K_2$-free. Then MinCSP($\Delta$) is in FPT.*

We are ready to present the algorithm.

▶ **Theorem 10.** *Triple Multicut is fixed-parameter tractable.*

**Proof Sketch.** Let $(G, \mathcal{T}, k)$ be an instance of Triple Multicut. By iterative compression, we obtain $X_V \subseteq V(G)$ and $X_\mathcal{T} \subseteq \mathcal{T}$ such that $|X_V| + |X_\mathcal{T}| \leq k + 1$ and all components of $G - X_V$ intersect triples in $\mathcal{T} \setminus X_\mathcal{T}$ in at most one vertex. Moreover, by branching on the intersection, we can assume that a hypothetical optimal solution $(Z_V, Z_\mathcal{T})$ to $(G, \mathcal{T}, k)$ is disjoint from $(X_V, X_\mathcal{T})$. Let $X = X_V \cup \bigcup_{uvw \in X_\mathcal{T}} \{u, v, w\}$ and guess the partition of the vertices in $X$ into connected components of $G - Z_V$. Identify vertices that belong to the same component, and enumerate them via the bijective mapping $\alpha : X \to \{1, \ldots, d\}$. Observe that for every triple $uvw \in X_\mathcal{T}$, values $\alpha(u)$, $\alpha(v)$ and $\alpha(w)$ are distinct since $X_\mathcal{T} \cap Z_\mathcal{T} = \emptyset$. Create an instance $I_\alpha$ of Boolean MinCSP as follows.

1. Introduce variables $v_i$ and $\hat{v}_i$ for every $v \in V(G)$ and $i \in [d]$.
2. For every vertex $v \in V(G)$, add soft constraint $\bigwedge_{i<j}(\neg v_i \vee \neg v_j) \wedge \bigwedge_i (v_i \to \hat{v}_i)$.
3. For every vertex $v \in X$, add crisp constraints $v_{\alpha(v)}$, $\hat{v}_{\alpha(v)}$, and $\neg v_j$, $\neg \hat{v}_j$ for all $j \neq \alpha(v)$.
4. For every edge $uv \in E(G)$ and $i \in [d]$, add crisp constraints $\hat{u}_i \to v_i$ and $\hat{v}_i \to u_i$.
5. For every triple $uvw \in \mathcal{T}$ and $i \in [d]$, add soft constraints $(\neg \hat{u}_i \vee \neg \hat{v}_i) \wedge (\neg \hat{v}_i \vee \neg \hat{w}_i) \wedge (\neg \hat{u}_i \vee \neg \hat{w}_i)$.

This completes the reduction. We defer the correctness proof to the full version. ◀

## 5 Disjunctive Multicut

We show that Disjunctive Multicut is constant-factor fpt-approximable. Section 5 presents the main loop of the Disjunctive Multicut algorithm, while Section 5 is dedicated to the most technical subroutine of the algorithm that involves *randomized covering of shadow* [37].

## Main Loop of the Disjunctive Multicut Algorithm

Let $G$ be a graph with vertices $V(G) = V^{\infty}(G) \uplus V^1(G)$ partitioned into undeletable and deletable, respectively. A subset $L \subseteq \binom{V(G)}{2}$ of pairs is a *request list*, and a set of vertices $X \subseteq V(G)$ *satisfies* $L$ if there is a pair $st \in L$ separated by $X$. This includes the possibility that $s \in X$ or $t \in X$. For a graph $G$ and a collection of request lists $\mathcal{L}$, we let $\mathrm{cost}(G, \mathcal{L})$ be the minimum size of a set $X \subseteq V^1(G)$ that satisfies all lists in $\mathcal{L}$. Disjunctive Multicut asks, given an instance $(G, \mathcal{L})$, whether $\mathrm{cost}(G, \mathcal{L}) \leq k$.

Disjunctive Multicut problem generalizes not only Multicut (which is a special case with $d = 1$) but also $d$-Hitting Set. To see the latter, take an edgeless graph $G$ and make every request a *singleton*, i.e. a pair $ss$ for a vertex $s \in V(G)$. The only way to satisfy a singleton $ss$ is to delete the vertex $s$ itself, and the only way to satisfy a list of singletons is to delete one of the vertices in it.

The intuitive idea behind the approximation algorithm for Disjunctive Multicut is to iteratively simplify the instance $(G, \mathcal{L}, k)$, making it closer to Bounded Hitting Set after each iteration. Roughly, we make progress if the maximum number of non-singleton requests in a list decreases. In each iteration, the goal is to find a set of $O(k)$ vertices whose deletion, combined with some branching steps, simplifies every request list. This process can continue for $O(d)$ steps until we obtain an instance of Bounded Hitting Set, which can be solved in fpt time by branching. The instance may increase in the process, but finally we obtain a solution of cost $f(d) \cdot k$ for some function $f$. We do not optimize for $f$ in our proofs. Observe also that in the context of constant-factor fpt approximability, some dependence on $d$ is unavoidable since the problem with unbounded $d$ generalizes Hitting Set.

Formally, for a request list $L$, let $\mu_1(L)$ and $\mu_2(L)$ be the number of singleton and non-singleton cut requests in $L$, respectively. Define the measure for a list $L$ as $\mu(L) = \mu_1(L) + 3\mu_2(L) = |L| + 2\mu_2(L)$, and extend it to a collection of list requests $\mathcal{L}$ by taking the maximum, i.e. $\mu(\mathcal{L}) = \max_{L \in \mathcal{L}} \mu(L)$. Observe that $\mu(\mathcal{L}) \leq 3d$ for any instance of Disjunctive Multicut. Further, let $V(L) = \bigcup_{st \in L} \{s, t\}$ denote the set of vertices in a list $L$, and $\nu(\mathcal{L}) = \mu_1(L) + 2\mu_2(L)$ be an upper bound on the maximum number of variable occurrences in a list of $\mathcal{L}$. The workhorse of the approximation algorithm is the following lemma.

▶ **Lemma 11.** *There is a randomized algorithm* Simplify *that takes an instance $(G, \mathcal{L}, k)$ of Disjunctive Multicut as input, and in $O^*(2^{O(k)})$ time produces a graph $G'$ and a collection of requests $\mathcal{L}'$ such that $|V(G')| \leq |V(G)|$, $\nu(\mathcal{L}') \leq \nu(\mathcal{L})$, $|\mathcal{L}'| \leq k^2|\mathcal{L}|$, and $\mu(\mathcal{L}') \leq \mu(\mathcal{L}) - 1$. Moreover, the following holds.*

- *If $\mathrm{cost}(G, \mathcal{L}) \leq k$, then, with probability $2^{-O(k^2)}$, we have $\mathrm{cost}(G', \mathcal{L}') \leq 2k$.*
- *If $\mathrm{cost}(G, \mathcal{L}) > 3k$, then we have $\mathrm{cost}(G', \mathcal{L}') > 2k$.*

Randomization in Lemma 11 comes from the use of the *random covering of shadow* of [37, 18]. They also provide a derandomized version of this procedure, so our algorithm can be derandomized as well. We postpone the proof of Lemma 11 until Section 5 since it requires introduction of some technical machinery. For now, we show how to prove Theorem 12 using the result of the lemma.

▶ **Theorem 12.** *Disjunctive Multicut is fixed-parameter tractable.*

**Proof.** Let $(G, \mathcal{L}, k)$ be an instance of Disjunctive Multicut. Repeat the following steps until $\mu_2(\mathcal{L}) = 0$. Apply the algorithm of Lemma 11 to $(G, \mathcal{L}, k)$, obtaining a new graph $G$ and a new collection of lists $\mathcal{L}$, and let $(G, \mathcal{L}, k) := (G', \mathcal{L}', 2k)$. When $\mu_2(\mathcal{L}) = 0$, let

**Algorithm 1** Main Loop.

```
1: procedure SolveDJMC(G, L, k)
2:     while μ2(L) > 0 do
3:         (G, L) ← Simplify(G, L, k)
4:         if Simplify rejects then
5:             reject
6:         k ← 2k
7:     W ← {vv : v ∈ V(G)}
8:     if SolveHittingSet(W, L, k) accepts then
9:         accept
10:    else
11:        reject
```

$W = \{vv : v \in V(G)\}$ be the set of singleton cut requests for every vertex in $V(G)$. Check whether $(W, \mathcal{L}, k)$ is a yes-instance of Hitting Set – if yes, accept, otherwise reject. See Algorithm 1 for the pseudocode.

To argue correctness, let $(G, \mathcal{L}, k)$ be the input instance and $(G', \mathcal{L}', k')$ be the instance obtained after simplification. By induction and Lemma 11, we have $|V(G')| \leq |V(G)|$ and $\nu(\mathcal{L}') \leq \nu(\mathcal{L})$. Since $\nu(\mathcal{L}') \leq \nu(\mathcal{L}) \leq 2d$ and $\mu_2(\mathcal{L}) = 0$, every list in $\mathcal{L}$ has at most $2d$ requests. Let $r$ be the number of calls to Simplify performed by the algorithm. Note that $r \leq \mu(\mathcal{L}) \leq 3d$ since the measure decreases by at least one with each iteration, and define $k' = 2^r k$. The lists in $\mathcal{L}'$ only contain singletons, thus $(G', \mathcal{L}', k')$ is essentially an instance of Hitting Set with sets of size $2d$. Moreover, $|\mathcal{L}'| \leq k^{2r}|\mathcal{L}|$, so the number of lists is polynomial in $|\mathcal{L}|$. We can solve $(G', \mathcal{L}', k')$ in $O^*((2d)^{k'})$ time by branching (see, for example, Chapter 3 in [20]). For the other direction, suppose $\text{cost}(G, \mathcal{L}) \leq k$. By Lemma 11 and induction, we have $\text{cost}(G', \mathcal{L}') \leq 2^r k \leq k'$ with probability $2^{-O(rk^2)}$, and the algorithm accepts. If $\text{cost}(I) > 3k$, then $\text{cost}(G', \mathcal{L}') > k'$ and the algorithm rejects. ◀

## Simplification Procedure

In this section we prove Lemma 11. We start by iterative compression and guessing. Then we delete at most $k$ vertices from the graph and modify it, obtaining an instance amenable to the main technical tool of the section – the *shadow covering* technique.

### Initial Phase

Let $(G, \mathcal{L}, k)$ be an instance of Disjunctive Multicut. By iterative compression, assume we have a set $X \subseteq V(G)$ that satisfies all lists in $\mathcal{L}$ and $|X| = c \cdot k + 1$, where $c := c(d)$ is the approximation factor. Assume $Z$ is an optimal solution to $G$, i.e. $|Z| \leq k$ and $Z$ satisfies all lists in $\mathcal{L}$. Guess the intersection $W = X \cap Z$, and let $G' = G - W$, $X' = X \setminus W$, and $Z' = Z \setminus W$. Construct $\mathcal{L}'$ starting with $\mathcal{L}$ and removing all lists satisfied by $W$. Further, guess the partition $\mathcal{X} = (X_1, \ldots, X_\ell)$ of $X'$ into the connected components of $G' - Z'$, and identify the variables in each subset $X_i$ into a single vertex $x_i$, and redefine $X'$ accordingly. Note that the probability of our guesses being correct up to this point is $2^{-O(k \log k)}$. Also, these steps can be derandomized by creating $2^{O(k \log k)}$ branches.

Now compute a minimum $\mathcal{X}$-multiway cut in $G'$, i.e. a set $M \subseteq V^1(G')$ that separates every pair of vertices $x_i$ and $x_j$ in $X'$. Note that $Z'$ is a $\mathcal{X}$-multiway cut by the definition of $\mathcal{X}$, so $|M| \leq |Z'| \leq k$. Such a set $M$ can be computed in $O^*(2^k)$ time using the algorithm

of [21]. If no $\mathcal{X}$-multiway cut of size at most $k$ exists, then abort the branch and make another guess for $\mathcal{X}$. If an $\mathcal{X}$-multiway cut $M$ of size at most $k$ is obtained, remove the vertices in $M$ from $G$ and along with the lists in $\mathcal{L}'$ satisfied by $M$. This completes the initial phase of the algorithm. Properties of the resulting instance are summarized below.

▶ **Lemma 13** (Proof Omitted). *After the initial phase we obtain a graph $G'$, a family of list requests $\mathcal{L}'$, and subset of vertices $X' \subseteq V(G')$ such that $|V(G')| \leq |V(G)|$, $\nu(\mathcal{L}') \leq \nu(\mathcal{L})$, $\mu(\mathcal{L}') \leq \mu(\mathcal{L})$, and $|X'| \in O(k)$. The set $X'$ satisfies all lists in $\mathcal{L}'$ and intersects each connected component of $G'$ in at most one vertex. Moreover, the following hold.*

- $\mathrm{cost}(G, \mathcal{L}) \leq k + \mathrm{cost}(G', \mathcal{L}')$.
- *If* $\mathrm{cost}(G, \mathcal{L}) \leq k$, *then, with probability* $2^{-O(k \log k)}$, *we have* $\mathrm{cost}(G', \mathcal{L}') \leq k$. *Moreover, there is a set $Z' \subseteq V(G')$, $|Z'| \leq k$ that satisfies all lists in $\mathcal{L}'$ and is disjoint from $X'$.*

### Random Covering of Shadow

Random covering of shadow is a powerful tool introduced by [37] and sharpened by [18]. We use the latter work as our starting point. Although [18] present their theorems in terms of directed graphs, their results are applicable to our setting by considering undirected edges as bidirectional, i.e. replacing every edge $uv$ with a pair of antiparallel arcs $(u, v)$ and $(v, u)$. Consider a graph $G$ with vertices partitioned into deltable and undeletable subsets, i.e. $V(G) = V^1(G) \uplus V^\infty(G)$. Let $\mathcal{F} = (F_1, \ldots, F_q)$ be a family of connected subgraphs of $G$. An *$\mathcal{F}$-transversal* is a set of vertices $T$ that intersects every subgraph $F_i$ in $\mathcal{F}$. If $T$ is an $\mathcal{F}$-transversal, we say that $\mathcal{F}$ is *$T$-connected*. For every $W \subseteq V(G)$, the *shadow of $W$ (with respect to $T$)* is the subset of vertices disconnected from $T$ in $G - W$. We state it for the case $T \subseteq V^\infty(G)$ which suffices for our applications.

▶ **Theorem 14** (Random Covering of Shadow, Theorem 3.5 in [18]). *There is an algorithm* RandomCover *that takes a graph $G$, a subset $T \subseteq V^\infty(G)$ and an integer $k$ as input, and in $O^*(4^k)$ time outputs a set $S \subseteq V(G)$ such that the following holds. For any family $\mathcal{F}$ of $T$-connected subgraphs, if there is an $\mathcal{F}$-transversal of size at most $k$ in $V^1(G)$, then with probability $2^{-O(k^2)}$, there exists an $\mathcal{F}$-transversal $Y \subseteq V^1(G)$ of size at most $k$ such that*

1. *$Y \cap S = \emptyset$, and*
2. *$S$ covers the shadow of $Y$ with respect to $T$.*

The following consequence is convenient for our purposes.

▶ **Corollary 15** (Proof Omitted). *Let $S$ and $Y$ be the shadow-covering set and the $\mathcal{F}$-transversal from Theorem 14, respectively. Define $R = V(G) \setminus S$ to be the complement of $S$. Then $Y \subseteq R$ and, for every vertex $v \in R$, either $v \in Y$ or $v$ is connected to $T$ in $G - Y$.*

Note that if a vertex $v \in N(S)$ and $v$ is undeletable, then $v \in R$ and $v \notin Y$, hence $v$ is connected to $T$ in $G - Y$. Since $Y \cap S = \emptyset$, every vertex in $N(v) \cap S$ is also connected to $T$ in $G - Y$, so we can remove $N(v) \cap S$ from $S$ (and add it to $R$ instead). By applying this procedure to exhaustion, we may assume that no vertex in $N(S)$ is undeletable.

With the random covering of shadow at our disposal, we return to Disjunctive Multicut. By Lemma 13, we can start with an instance $(G, \mathcal{L}, k)$ and a set $X \subseteq V(G)$ such that $|X| \in O(k)$, $X$ satisfies all lists in $\mathcal{L}$, every connected component of $G$ intersects $X$ in at most one vertex, and there is an optimal solution $Z$ disjoint from $X$. Let $\mathcal{T} := \mathcal{T}(G, \mathcal{L}, X, Z)$ be the set of cut requests in $\bigcup \mathcal{L}$ satisfied by both $X$ and $Z$. Define $\mathcal{F}$ as the set of $st$-walks for all $st \in \mathcal{T}$. Observe that an $\mathcal{F}$-transversal is precisely a $\mathcal{T}$-multicut. Apply the algorithm from Theorem 14 to $(G, X, k)$. Since $X$ and $Z$ are $\mathcal{F}$-transversals and $|Z| \leq k$ by assumption,

Theorem 14 and Corollary 15 imply that we can obtain a set $R \subseteq V(G)$ in fpt time such that, with probability $2^{-O(k^2)}$, there is an $\mathcal{F}$-transversal $Y \subseteq R$ of size at most $k$, and every vertex in $R \setminus Y$ is connected to $X$ in $G - Y$.

For every vertex $v \in V^1(G) \setminus X$, define a set of vertices $R_v \subseteq R \setminus X$ as follows:

- if $v$ is disconnected from $X$, then let $R_v = \emptyset$;
- if $v \in N(X)$ or $v \in R$, then let $R_v = \{v\}$;
- otherwise, let $R_v = R \cap N(H)$, where $H$ is the component of $G[S]$ containing $v$.

Note that, by definition, the set $R_v$ is an $Xv$-separator in $G$. Moreover, we have ensured that $N(S)$ does not contain undeletable vertices, so $R_v$ does not contain undeletable vertices. In a certain sense, the sets $R_v$ are the only $Xv$-separators that $Y$ needs to use. This idea is made precise in the following lemma.

▶ **Lemma 16** (Proof Omitted). *Let $G$ be a graph. Let $X$ and $Y$ be disjoint subsets of $V(G)$ such that $X$ intersects every connected component of $G$ in at most one vertex. Suppose $R \subseteq V(G)$ is such that $Y \subseteq R$ and all vertices in $R \setminus Y$ are connected to $X$ in $G - Y$. If a vertex $s$ is disconnected from $X$ in $G - Y$, then $R_s \subseteq Y$.*

Now we compute a simplified collection of lists $\mathcal{L}'$. Start by adding all lists in $\mathcal{L}$ to $\mathcal{L}'$. Remove every singleton request $xx$ such that $x \in X$ from every list of $\mathcal{L}'$. For every list $L \in \mathcal{L}'$ not shortened this way, let $st \in L$ be a non-singleton cut request satisfied by $X$. Consider $R_s$ and $R_t$ and apply one of the following rules.

**(R1)** If $|R_s| > k$ and $|R_t| > k$, remove $st$ from $L$.
**(R2)** If $|R_s| \leq k$ and $|R_t| > k$, replace $L$ with sets $(L \setminus \{st\}) \cup \{aa\}$ for all $a \in R_s$.
**(R3)** If $|R_s| > k$ and $|R_t| \leq k$, replace $L$ with sets $(L \setminus \{st\}) \cup \{bb\}$ for all $b \in R_t$.
**(R4)** If $|R_s| \leq k$ and $|R_t| \leq k$, replace $L$ with sets $(L \setminus \{st\}) \cup \{aa, bb\}$ for all $a \in R_t$, $b \in R_t$.

Finally, make vertices in $X$ undeletable, obtaining a new graph $G'$. This completes the simplification step. Note that each list in $\mathcal{L}$ is processed once, so the running time of the last step is polynomial.

Now we prove some properties of $G'$ and $\mathcal{L}'$ obtained above. Note that $|V(G')| = |V(G)|$. Since every list in $\mathcal{L}$ is processed once and with at most $k^2$ new lists, the size of $|\mathcal{L}'|$ grows by a factor of at most $k^2$. To see that $\nu(\mathcal{L}') \leq \nu(\mathcal{L})$ and $\mu(\mathcal{L}') \leq \mu(\mathcal{L}) - 1$, observe that every reduction rule replaces a list $L$ with new lists with either one less non-singleton request (so $\mu_2$ decreases by at least 1), and adds up to two singleton requests (so $\mu_1$ increases by at most 2). Moreover, in every list of $\mathcal{L}$ there is a cut request satisfied by $X$, so no list of $\mathcal{L}$ remains unchanged in $\mathcal{L}'$. We state the remaining ingredients for proving correctness.

▶ **Lemma 17** (Proof Omitted). *If $\text{cost}(G, \mathcal{L}) \leq k$, then, with probability $2^{-O(k^2)}$, we have $\text{cost}(G', \mathcal{L}') \leq 2k$.*

▶ **Lemma 18** (Proof Omitted). *If $\text{cost}(G, \mathcal{L}) > 2k$, then we have $\text{cost}(G', \mathcal{L}') > 2k$.*

We are now ready to prove Lemma 11.

**Proof of Lemma 11.** Suppose $(G, \mathcal{L}, k)$ is a yes-instance of Disjunctive Multicut. By Lemma 13, after the initial phase we obtain $G'$, $\mathcal{L}'$ such that $|V(G')| \leq |V(G)|$, $\nu(\mathcal{L}') \leq \nu(\mathcal{L})$, $\mu(\mathcal{L}') \leq \mu(\mathcal{L})$, and $\text{cost}(G', \mathcal{L}') \leq k$. Moreover, we obtain a set $X' \subseteq V(G')$, $|X'| \in O(k)$, that satisfies all lists in $\mathcal{L}'$, intersects every component of $G'$ in at most one vertex, and is disjoint from an optimum solution $Z'$ to $(G', \mathcal{L}', k)$. Now we apply random covering of shadow and the list reduction rules to $G', \mathcal{L}', X'$, obtaining a new graph $G''$ and a new set of lists $\mathcal{L}''$. By Lemma 17, with probability $2^{O(-k^2)}$, we have $\text{cost}(G'', \mathcal{L}'') \leq 2k$. This proves one statement of Lemma 11. For the second statement of Lemma 11, suppose $\text{cost}(G'', \mathcal{L}'') \leq 2k$. By Lemma 18, we have $\text{cost}(G', \mathcal{L}') \leq 2k$. By Lemma 13, $\text{cost}(G'\mathcal{L}') \leq 2k$ implies that $\text{cost}(G, \mathcal{L}) \leq 2k + k \leq 3k$, and we are done. ◀

## Abstract

We investigate the maximum bottleneck matching problem in bipartite graphs. Given a bipartite graph with nonnegative edge weights, the problem is to find a maximum cardinality matching in which the minimum weight of an edge is the maximum. To the best of our knowledge, there are two widely used solvers for this problem based on two different approaches. There exists a third known approach in the literature, which seems inferior to those two which is presumably why there is no implementation of it. We take this third approach, make theoretical observations to improve its behavior, and implement the improved method. Experiments with the existing two solvers show that their run time can be too high to be useful in many interesting cases. Furthermore, their performance is not predictable, and slight perturbations of the input graph lead to considerable changes in the run time. On the other hand, the proposed solver's performance is much more stable; it is almost always faster than or comparable to the two existing solvers, and its run time always remains low.

## 1 Introduction

A matching in a graph is a set of edges without any common vertices. A maximum cardinality matching in a graph has the largest number of edges among all matchings. We investigate algorithms for finding a maximum cardinality matching whose minimum edge weight is the maximum on bipartite graphs with edge weights. This is called the bottleneck matching problem or linear bottleneck assignment problem when all vertices can be matched [3, Section 6.2]. Formally, the bottleneck matching problem is to find a maximum cardinality matching $\mathcal{M}$ which maximizes

$$\min_{(r_i,c_j)\in\mathcal{M}} w_{i,j}.$$

This problem can be solved in polynomial time.

The bottleneck matching problem arises in different contexts [3, Section 6.2.8]. We are motivated by the Birkhoff–von Neumann (BvN) decomposition of doubly stochastic matrices [2], which arises in practical applications [1, 4, 16, 21]. In this case, the bipartite graphs associated with matrices have equal number of vertices on both sides and contain perfect matchings. A known heuristic for the BvN decomposition [10] repeatedly calls a bottleneck matching algorithm on the bipartite graph of a dynamically changing matrix.

**Table 1** Run time, in seconds, of MC64J2 and MC64J3 on 12 problems. $\mathbf{A}$ is the original matrix, $\mathbf{AP}$ is the same matrix with a random column permutation; $\mathbf{S} = \mathbf{D}P(\mathbf{A})\mathbf{E}$, where $P(\mathbf{A})$ is the 0-1 matrix with 1s at the nonzero positions of $\mathbf{A}$; and $\mathbf{D}$ and $\mathbf{E}$ are positive diagonal matrices scaling $P(\mathbf{A})$ to be doubly stochastic.

| | **A** | | **AP** | | **S** | |
|---|---|---|---|---|---|---|
| matrix | J2 | J3 | J2 | J3 | J2 | J3 |
| atmosmodm | 0.05 | 0.26 | 0.13 | 0.40 | 684.87 | 6487.07 |

| vas_stokes_2M | 0.25 | 1.87 | 6310.44 | 727.57 | 1420.01 | 4571.14 |

The software MC64 [7, 8] is the state-of-the-art and implements two algorithms, denoted MC64J2 and MC64J3, for the bottleneck matching problem. To the best of our knowledge these are the only available codes that can handle bipartite graphs corresponding to large sparse matrices. Their worst-case run time are $O(n(m+n)\log_2 n)$ and $O(nm\log_2 n)$, on bipartite graphs with $n$ vertices on each side and $m$ edges [8]. MC64, especially the newer MC64J2 [8], is well engineered. It works very well for graphs corresponding to matrices from numerical applications. However, it does not have stable run time behavior in two senses. First, when run on the same bipartite graph twice with different edge weights the difference in run time can be in the order of hours. Second, on two equivalent problem instances, where one is obtained from the other by just reordering the vertices, the run time can change dramatically. We report the run time of MC64 on four matrices, from the SuiteSparse Matrix Collection [5], in Table 1 to explain this – more experiments of similar nature are in Section 4. Here, the set of rows and the set of columns of a matrix correspond to the two parts of the bipartite graph with an edge between two vertices if the corresponding entry in the matrix is nonzero, and the nonzero values are the edge weights. The table contains results for $\mathbf{A}$, for $\mathbf{AP}$ where $\mathbf{P}$ is a random permutation, and for the doubly stochastic matrix $\mathbf{S}$ which is obtained by scaling the pattern of $\mathbf{A}$ with Sinkhorn-Knopp algorithm [20].

The bipartite graphs of $\mathbf{A}$ and $\mathbf{AP}$ are the same apart from renumbering of the vertices in one part. While on $\mathbf{A}$ both MC64J2 and MC64J3 are fast, both methods suffer on $\mathbf{AP}$; the run time of MC64J2 is not acceptable for the last two instances, and that of MC64J3 is high for the last one in Table 1. The bottleneck matching problems on $\mathbf{A}$ and $\mathbf{AP}$ are essentially the same, as permuting the columns does not change the values, nor the bottleneck matching and its value. The bipartite graph of $\mathbf{S} = \mathbf{D}P(\mathbf{A})\mathbf{E}$ is the same as that of $\mathbf{A}$ with different edge weights, hence the problems are not equivalent. Now, the run time of both methods is too much for all instances. The wildly varying run time of both MC64 routines on $\mathbf{S}$ in comparison to those on $\mathbf{A}$ further highlight the instability in their performance.

Our aim in this paper is to develop an algorithm for the bottleneck matching problem which is better than the state-of-the-art codes in MC64. For this purpose, we study an overlooked alternative from the literature. We make observations that pave the way for an efficient algorithm, implement and compare it against the codes from MC64. We conduct a large set of experiments to show that our approach is usually much faster than MC64 and in addition exhibits stable and robust performance.

Section 2 gives a brief background and a summary of the known algorithms. Section 3 contains the proposed algorithm. Section 4 presents the experimental results, and Section 5 concludes the paper. Appendix of the related version, which is available at `https://inria.hal.science/hal-04146298`, contains detailed description of the experiments and further experiments.

## 2 Background and related work

A matrix $\mathbf{A}$ with $nnz(\mathbf{A})$ nonzero entries can be represented with a bipartite graph $G = (R \cup C, E)$ where each row of $\mathbf{A}$ corresponds to a unique vertex in $R$, each column of $\mathbf{A}$ corresponds to a unique vertex in $C$, and there is an edge $(r_i, c_j)$ whenever $a_{ij} \neq 0$. The number $m$ of edges in $G$ is thus equivalent to $nnz(\mathbf{A})$. When the edges are weighted, the weight of the edge $(r_i, c_j)$ is $|a_{ij}|$, that is the magnitude of the nonzeros of $\mathbf{A}$. For a vertex $v$, we use $\text{adj}(v)$ to denote the set of its neighbors.

A *matching* is a set of edges with no common vertices. A matching is of *maximum cardinality* if it has the largest number of edges. Given a matching $\mathcal{M}$, a vertex is *matched* if an edge from $\mathcal{M}$ is incident on it and *free* otherwise. A matching is *perfect* if it matches all vertices. The *deficiency* of a matching $\mathcal{M}$ is the difference between the maximum cardinality of a matching and $|\mathcal{M}|$. Given a matching $\mathcal{M}$ in the graph $G$, a path in $G$ is $\mathcal{M}$-*alternating* if its edges are alternately in $\mathcal{M}$. An $\mathcal{M}$-alternating path $\mathcal{P}$ is $\mathcal{M}$-*augmenting* if the start and end vertices of $\mathcal{P}$ are both free. A *vertex cover* is a set of vertices that includes at least one vertex from each edge. In a bipartite graph the maximum cardinality of a matching is equal to the minimum cardinality of a vertex cover [3, Th. 2.7].

Given a bipartite graph, any of its maximum cardinality matchings can be used to obtain a canonical decomposition called Dulmage-Mendelsohn (DM) decomposition [11]. Based on the DM decomposition, Pothen and Fan [18] describe algorithms to permute sparse matrices in a block upper triangular form (BTF):

$$\mathbf{A} = \begin{array}{c} \\ H_R \\ S_R \\ V_R \end{array} \begin{array}{c} \begin{array}{ccc} H_C & S_C & V_C \end{array} \\ \begin{pmatrix} \mathbf{A}_H & * & * \\ O & \mathbf{A}_S & * \\ O & O & \mathbf{A}_V \end{pmatrix} \end{array}. \tag{1}$$

In a BTF, the submatrix $\mathbf{A}_H$ has more columns than rows, and all rows in $H_R$ are matched to a column in $H_C$ in any maximum cardinality matching; the submatrix $\mathbf{A}_S$ is square with at least one perfect matching; the submatrix $\mathbf{A}_V$ has more rows than columns, and all columns in $V_C$ are matched to a row in $V_R$. The rows/columns in each block are defined as follows

$H_R = \{$row vertices reachable from free column vertices via alternating paths$\}$,
$H_C = \{$free column vertices or column vertices reachable from free column vertices via alternating paths$\}$,
$V_R = \{$free row vertices or row vertices reachable from free row vertices via alternating paths$\}$,
$V_C = \{$column vertices reachable from free row vertices via alternating paths$\}$,
$S_R = R \setminus (H_R \cup V_R)$, and
$S_C = C \setminus (H_C \cup V_C)$.

A standard BFS/DFS-based graph traversal algorithm will find these sets in linear time.

We make some observation on the BTF form of a matrix. First, the DM decomposition reveals a minimum cover [3, Alg. 3.1]. As all nonzeros in the BTF (1) are confined in the rows $H_R \cup S_R$ and the columns in $V_C$, the vertex set $\mathcal{C} = H_R \cup S_R \cup V_C$ is a cover. Since the cardinality of $\mathcal{C}$ is equal to the maximum cardinality of a matching, it is a minimum cover. Second, if one adds new nonzeros to the diagonal blocks, upper diagonal blocks, or to the blocks $(S_R, H_C)$ and $(V_R, S_C)$, the maximum cardinality of a matching does not change. This is so, as the new nonzeros cannot create augmenting paths.

Hall's theorem [13] states that for a bipartite graph $G$ to have a column-perfect matching, the relation $|S| \leq |\bigcup_{c \in S} \text{adj}(c)|$ must hold for any subset $S$ of columns. If a similar relation holds for all subsets of rows, then $G$ will have perfect matchings.

An $n \times n$ matrix $\mathbf{A} \neq 0$ is called *doubly stochastic* if every entry is nonnegative and the sum of entries in each row and each column is equal to 1. Any nonnegative square matrix, whose bipartite graph has perfect matchings, can be scaled with two diagonal matrices to be doubly stochastic [20]. A *permutation matrix* is a square matrix where each row/column contains exactly one nonzero value equal to 1. A perfect matching in the bipartite graph representation of $\mathbf{A}$ corresponds to a permutation matrix. The bipartite graphs of doubly stochastic matrices have perfect matchings.

Henceforth, we assume that the given bipartite graph contains perfect matchings. We comment on rectangular matrices and matrices without perfect matchings in Section 3.3.

## 2.1 Related work

We review three algorithms from the literature [3, 7, 8]. The first two are implemented in MC64, and to the best of our knowledge are currently the best practical algorithms. Burkard et al. [3, Section 6.2.4] describe two other algorithms [12, 19], which are more theoretical.

### 2.1.1 Shortest-augmenting path based algorithms

Algorithms based on shortest augmenting paths start with a matching which has the maximum bottleneck value for the currently matched vertices $C'$ in one part, say $C$. In order to augment the matching, a shortest augmenting path from a free vertex $c$ of $C$ is found with a variant of Dijkstra's shortest path algorithm. Augmenting along the shortest paths maintains the invariant that the current matching has the maximum bottleneck value for any matching that matches the vertices $C' \cup \{c\}$. The process continues until a perfect matching is obtained.

The state-of-the-art implementation in MC64 [8], MC64J2, starts by computing an upper bound $\omega$ on the bottleneck value, which is the minimum of maximum in each column and row. It then computes a maximal matching on the graph containing only edge weights no smaller than $\omega$, which is then improved by length-three augmenting paths in a preprocess step. Then, a shortest-augmenting path is sought from each free column vertex to solve the problem. MC64J2 implements an efficient adaptation of Dijkstra's algorithm to find these paths. Depending on the edge weights, the structure of the bipartite graph, or the visit order many edges and vertices may be visited while finding an augmenting path. As seen in Table 1, this can accumulate and result in very long run time.

### 2.1.2 Threshold-based algorithms

Let $G$ be a weighted bipartite graph. For a value $\omega$, let $G[\omega]$ contain only the edges of $G$ with weight at least $\omega$. Threshold-based algorithms find the largest $\omega$ for which $G[\omega]$ has a perfect matching. They do so by considering different values for $\omega$, testing whether $G[\omega]$

has a perfect matching or not and tuning the next $\omega$ to a higher or lower value accordingly. MC64's implementation, MC64J3, discusses initialization and algorithmic choices to reduce the number of tests [7]. However, MC64 uses a depth-first-search algorithm to find the augmenting paths for each test which can slow it down, as seen in Table 1.

### 2.1.3 An algorithm based on duality

This algorithm is also threshold-based and uses the duality of matchings and coverings to find the next threshold. We explain this algorithm in more detail as ours improves upon it. Let $\omega$ be a value where $G[\omega]$ does not contain a perfect matching. Let $\mathcal{M}$ be a maximum cardinality matching in $G[\omega]$. From $\mathcal{M}$ one can define a minimum vertex cover $\mathcal{C} = H_R \cup S_R \cup V_C$ of $G[\omega]$ with vertex sets $I = H_R \cup S_R$ and $J = V_C$ [3, Section 6.2.3]. Since $\mathcal{M}$ is not perfect, there must be an edge in $G$ from a vertex in $\bar{I} = R \setminus I$ to another vertex in $\bar{J} = C \setminus J$. The value $\max_{i \in \bar{I}, j \in \bar{J}} a_{ij}$ thus cannot be smaller than the bottleneck matching value of $G$ and can be used as the next threshold. This approach is shown in Algorithm 1 [3, Section 6.2.3].

**Algorithm 1** Duality-based algorithm.

**Input** : $G$, an edge weighted bipartite graph having perfect matchings
**Output** : $\mathcal{M}$, a bottleneck perfect matching

Let $\omega$ be an upper bound on the bottleneck matching value
$\mathcal{M} \leftarrow \emptyset$
**while** $|\mathcal{M}| < n$ **do**
  $\mathcal{M} \leftarrow$ a maximum cardinality matching in $G[\omega]$
  **if** $|\mathcal{M}| < n$ **then**
1  Let $I \subseteq R$ and $J \subseteq C$ be the vertex sets of the associated cover of $G[\omega]$
2  $\omega \leftarrow \max_{i \in R \setminus I, j \in C \setminus J} w_{i,j}$ `/* in G, not G[ω] */`

The maximum cardinality matching in $G[\omega]$ can be found in $O(\sqrt{n}\,\mathrm{nnz}(\mathbf{A}[\omega]))$ time in the worst case [14]. Once such a matching is found, the associated minimum cover and the maximum uncovered value at Line 2 can be obtained in linear time. Therefore, the worst case time complexity of Algorithm 1 is $O(\sqrt{n}\,\mathrm{nnz}(\mathbf{A}))$ times the number of iterations. The worst case run time for Algorithm 1 can hence be too high. This is so as a new edge, due to the reduced $\omega$, does not mean one more edge in the maximum matching, and hence the while loop can even run for more than $n$ iterations.

## 3 The proposed algorithm

Our algorithm is based on Algorithm 1 and integrates threshold techniques. Let $G = (R \cup C, E)$ be an edge weighted bipartite graph, with $w_{i,j}$ being the weight of the edge $(r_i, c_j)$. Let $\omega$ be a nonnegative value, $G[\omega]$ be as before, and the bottleneck matching value $b^\star$ be the largest $\omega$ for which $G[\omega]$ has a perfect matching. We call a value $\omega$ *safe*, when $\omega \geq b^\star$. Algorithm 1 produces decreasing safe values that converge to $b^\star$. We make a series of observations to find $b^\star$ faster. The first observation is that there are several minimum vertex covers associated with a given maximum cardinality matching. Using the BTF (1), let $\mathcal{C}' = H_R \cup S_C \cup V_C$. As all nonzeros are covered by $\mathcal{C}'$ and $|\mathcal{C}'| = |H_R \cup S_R \cup V_C|$, $\mathcal{C}'$ is also a minimum cover. If we choose this cover, the sets $I$ and $J$ at Line 1 of Algorithm 1 become $H_R$ and $S_C \cup V_C$, in which case, the maximum value can be different. This leads to the following proposition.

▶ **Proposition 1.** *Let $\mathcal{C}_1 = H_R \cup S_R \cup V_C$ and $\mathcal{C}_2 = H_R \cup S_C \cup V_C$ be two minimum covers of $G[\omega]$ revealed by the BTF (1). Let $\omega_1$ and $\omega_2$ be the maximum values defined in Line 2 of Algorithm 1 for $\mathcal{C}_1$ and $\mathcal{C}_2$, respectively. Then, $\min(\omega_1, \omega_2)$ is safe.*

**Proof.** Let $\omega$ be the current value, and $\omega_1 < \omega_2$ without loss of generality. This means that $\omega_2$ is in $\mathbf{A}(V_R, S_C)$ and all entries in $\mathbf{A}(V_R, H_C)$ are smaller than $\omega_2$. The maximum cardinality of a matching in $G[\omega_2]$ cannot be larger than that in $G[\omega]$, as the set $\mathcal{C}_1 = H_R \cup S_R \cup V_C$ still covers all edges of $G[\omega_2]$, including those that arise in $\mathbf{A}(S_R, H_C)$. Hence the cover $\mathcal{C}_1$ can be used to get the next $\omega$ in Line 2, which concludes the proof. ◀

Based on Proposition 1, one can use the smaller of the largest uncovered element in $(S_R \cup V_R, H_C)$ and that in $(V_R, H_C \cup S_C)$. We propose to exploit the two identified covers as much as possible for a faster convergence of $\omega$ to $b^\star$. As we reason in Lemma 2 below, one can find a tighter bound on $b^\star$, depending on the deficiency of the current matching as well as the (original) adjacencies of the vertices in the identified covers.

▶ **Lemma 2.** *Let $\mathcal{M}$ be a maximum cardinality matching in $G[\omega]$ with a deficiency of $k$ in $G$; $\mathbf{A}[\omega]$ and $\mathbf{A}$ be, respectively, the matrices associated with $G[\omega]$ and $G$; $\mathcal{C} = H_R \cup S_C \cup V_C$ be a minimum vertex cover of $G[\omega]$ associated with $\mathcal{M}$ when $\mathbf{A}[\omega]$ is permuted in a BTF (1); Let $\omega_k^r$ be the $k$th largest element in $\bigcup_{i \in S_R \cup V_R} \max\{w_{i,j} : j \in H_C\}$, and $\omega_k^c$ the $k$th largest element in $\bigcup_{j \in H_C} \max\{w_{i,j} : i \in S_R \cup V_R\}$. Then, $\omega_k = \min(\omega_k^r, \omega_k^c)$ is safe.*

**Proof.** Consider first the set $H_C$ of columns, and note that $|H_C| - |H_R| = k$ as all other columns are matched. By Hall's theorem, $|H_C| \leq |\bigcup_{c \in H_C} \text{adj}(c)|$ must hold in $\mathbf{A}$ as there is a perfect matching. Among all rows in $\bigcup_{c \in H_C} \text{adj}(c)$, we have $|H_R|$ in the set $H_R$. Therefore there must be at least $k$ other nonzero rows in $\mathbf{A}(S_R \cup V_R, H_C)$. The element $\omega_k^r$ from $\bigcup_{i \in S_R \cup V_R} \max\{w_{i,j} : j \in H_C\}$ is safe as any value greater than that will cover less than $k$ rows and Hall's conditions cannot be satisfied. A similar argument applies to $\omega_k^c$ by considering the set $S_R \cup V_R$ of rows. In $\mathbf{A}[\omega]$ we have $\text{adj}(S_R \cup V_R) = S_C \cup V_C$, and $|S_R \cup V_R| - |S_C \cup V_C| = k$. The element $\omega_k^c$ must be safe since we need at least $k$ nonzero columns in $\mathbf{A}(S_R \cup V_R, H_C)$. The value $\omega_k$ is thus safe as the minimum of two safe values. ◀

One can identify several minimum covers, collect the $k$th largest uncovered element with respect to each, and use the minimum of the collected elements as the next $\omega$. As finding these minimum covers can be expensive, we propose using the two which are readily revealed by the BTF. That is, we use $\omega = \min(\omega_1, \omega_2)$ where

$$\begin{aligned} \omega_1^r, \omega_1^c &= k\text{-th largest row and column maximum entries in } \mathbf{A}(S_R \cup V_R, H_C)\,, \\ \omega_1 &= \min(\omega_1^r, \omega_1^c)\,, \qquad (2) \\ \omega_2^r, \omega_2^c &= k\text{-th largest row and column maximum entries in } \mathbf{A}(V_R, H_C \cup S_C)\,, \\ \omega_2 &= \min(\omega_2^r, \omega_2^c)\,. \qquad (3) \end{aligned}$$

This corresponds to applying Hall's theorem to the sets $H_C$ and $H_C \cup S_C$ of columns and to the sets $V_R$ and $S_R \cup V_R$ of rows.

## 3.1 Putting it all together

The proposed algorithm BOTTLED is shown in Algorithm 2. The input is a sparse matrix represented in the compressed storage by columns (CSC) format. BOTTLED creates a compressed storage by rows (CSR) representation of the input matrix. It then sorts the nonzeros in each row and each column in non-increasing order of their values. Then the threshold $\omega$ is initialized as the minimum of the $2n$ nonzero values consisting of the maximum in each row and maximum in each column. The algorithm then updates the threshold $\omega$ in a while-loop as in Algorithm 1. In the while-loop there are three subroutines:

MaximumCardinalityMatching, SAP, and DM-dec. These subroutines correspond to a maximum cardinality matching algorithm, a shortest augmenting path-based method to match a column, and an algorithm obtaining the row and column blocks of the BTF (1).

**Algorithm 2** BOTTLED: The proposed bottleneck matching algorithm.

**Input** : $\mathbf{A}$, stored by columns
**Output**: $\mathcal{M}$, a bottleneck perfect matching

Create a CSR representation of $\mathbf{A}$
Sort the nonzeros in each row and in each column in non-increasing order of values
1 $\omega \leftarrow$ min of the maximum in each row, maximum in each column
$G[\omega] \leftarrow (R \cup C, \emptyset)$ and $\mathcal{M} \leftarrow \emptyset$
**while** $|\mathcal{M}| < n$ **do**
2 for each $i$, release new $a_{ij} \geq \omega$ and for each $j$ release new $a_{ij} \geq \omega$ into $G[\omega]$
**if** $|\mathcal{M}| = n - 1$ **then**
$\mathcal{M} \leftarrow \text{SAP}(G, \mathcal{M}, c)$ with the last free vertex $c$
**else**
3 $\mathcal{M}' \leftarrow \text{MaximumCardinalityMatching}(G[\omega], \mathcal{M})$
**if** $|\mathcal{M}'| = n$ **then** $\mathcal{M} \leftarrow \mathcal{M}'$; break
**if** $|\mathcal{M}'| = |\mathcal{M}|$ **then**
4 select a vertex $c$
$\mathcal{M} \leftarrow \text{SAP}(G, \mathcal{M}', c)$
**else**
$\mathcal{M} \leftarrow \mathcal{M}'$
$\langle H_R, S_R, V_R, H_C, S_C, V_C \rangle \leftarrow \text{DM-dec}(G[\omega], \mathcal{M})$
5 $\omega \leftarrow \min(\omega_1, \omega_2)$ with $\omega_1$ as in (2) and $\omega_2$ as in (3)

Algorithm 2 stores the edges of $G[\omega]$ over the storage of $\mathbf{A}$ in the CSC and CSR formats, without explicitly building adjacency lists. The start address of each row and column are the same as those of $\mathbf{A}$. For each row/column of $G[\omega]$, we keep an end-pointer which points to the smallest nonzero of $\mathbf{A}$ in that row/column that is no smaller than $\omega$. These end-pointers are initialized before the while-loop in $O(n)$ time, and incremented at Line 2 at each iteration of the while-loop. Therefore the total run time cost of building $G[\omega]$s is $O(\text{nnz}(\mathbf{A}))$.

In Algorithm 2, $\text{SAP}(G, \mathcal{M}, c)$ refers to the algorithm summarized in Section 2.1.1. As stated before, SAP needs the current matching to have the bottleneck value among all matchings covering the same set of column vertices. The approach outlined in Algorithm 1 produces such matchings, that is why, at any point, one can resort to SAP. We invoke SAP in two cases: (i) when the deficiency is one; (ii) when an update of $\omega$ did not yield an increase in the cardinality of the current matching. The first case is straightforward. For the second case, we apply a simple heuristic to help the algorithm converge faster. As any free column vertex can be the start of an augmenting path, we choose $c \in C$ whose largest edge weight not included in the current $G[\omega]$ is minimum. Matching $c$ will lead to a reduced $\omega$, and the reduction will hopefully be large with this choice of $c$ (some empirical results are in the appendix of the related version). The most common algorithms for the maximum cardinality matching problem take an initial matching as input and augment it. This is very suitable at Line 3 of Algorithm 2, as we have a maximum cardinality matching on a graph, we add new edges, and then ask for a maximum cardinality matching in the new graph. We have used the code-base of MatchMaker [6, 15] to implement this step in the implicit representation of $G[\omega]$.

At Line 5 of Algorithm 2, we use a binary heap with a limit $k$ on its size. For $\omega_1^r$, the nonzeros of each row in $S_R \cup V_R$ with value smaller than $\omega$ are visited, and the largest element is used as a key in the heap. When the heap is full, keys are added only if they are larger than the current minimum, which is then removed. The minimum of the heap is returned as

$\omega_1^r$. Other quantities of (2) and (3) are computed similarly. All nonzeros of $\mathbf{A} - \mathbf{A}[\omega]$ in the rows $S_R \cup V_R$ and columns $H_C$ can be visited and the heap operations can be performed in $O(\text{nnz}(\mathbf{A}(S_R \cup V_R, H_C)) + (|H_C| + |S_R \cup V_R|) \log k)$ time. A similar analysis holds for $\mathbf{A}(S_R \cup V_R, H_C)$. The run time of one iteration of the while loop is thus dominated by that of the maximum cardinality matching algorithm. We do not have an estimate on the number of iterations of the while-loop; in the empirical results in Section 4.3 the number is less than what a binary search approach would yield.

## 3.2 In the context of a BvN decomposition method

The Birkhoff–von Neumann (BvN) theorem [2] states that a doubly stochastic matrix $\mathbf{A}$ can be written as $\mathbf{A} = \sum_{i=1}^{\ell} \alpha_i \mathbf{P}_i$ where each $\mathbf{P}_i$ is a permutation matrix, and $\alpha_i$s are positive coefficients summing up to one. Such a decomposition is not unique, and the problem of finding a decomposition with the smallest $\ell$ value is NP-Complete [10].

One heuristic [10] for obtaining a BvN decomposition of a double stochastic matrix $\mathbf{A}$ works as follows. It finds the value $b$ of a bottleneck matching whose pattern is the permutation matrix $\mathbf{P}$, replaces $\mathbf{A}$ with $\mathbf{A} - b\mathbf{P}$, and continues until a zero matrix is obtained. A property of this heuristic is that the successive bottleneck values are in a non-increasing order [9]. Our bottleneck matching algorithm is very fitting in this case. One can create the CSR representation and sort each row and column once. Then, executing the while loop of Algorithm 2 will obtain a bottleneck matching for the current matrix. Once $b$ and $\mathbf{P}$ are obtained, replacing $\mathbf{A}$ with $\mathbf{A} - b\mathbf{P}$ can be done by subtracting $b$ from each matched entry and updating that entry's position in the sorted list of both rows and columns in overall $O(n + \text{nnz}(\mathbf{A}))$ time. While doing so, one can update the end-pointers used for $G[\omega]$, and avoid the preprocessing in Algorithm 2 at subsequent invocations.

## 3.3 Rectangular matrices or matrices without perfect matchings

The case in which there are perfect matchings in the given bipartite graph is common in applications where the bipartite graphs correspond to sparse matrices. This is especially so in the BvN decomposition, which was our motivation. Nonetheless MC64's J2 and J3 work for cases in which one part of the bipartite graph has more vertices than the other, where the smaller side can be perfectly matched. This corresponds to $n_R \times n$ matrices for $n_R > n$ that have column-perfect matchings. Our algorithm can handle this case either by initializing $\omega$ at Line 1 using only the column values, or by using those and only the $n$th maximum of the set of $n_R$ maximum entries, one from in each row.

Consider now the most general case corresponding to $n_R \times n$ matrices, with $n_R \geq n$ and without column perfect matchings. In this case, MC64J2 returns *a maximum cardinality matching*, without necessarily finding the correct bottleneck value. That is so because not all vertices from which the shortest-augmenting paths are sought can be matched in a bottleneck maximum cardinality matching. We do not know of a suitable fix for this. MC64J3 and its equivalent THRESH on the other hand work correctly. The presented algorithm BOTTLED needs four minor modifications to handle this general case: (i) the maximum size of a matching $n'$ should be computed at the beginning; (ii) the initialization should use the choose the smallest of the $n'$th maximum of $n$ maximum entries, one from each column, and the $n'$th maximum of the $n_R$ maximum entries, one from each row; (iii) at Line 5, the deficiency is $k = n' - |\mathcal{M}|$; and (iv) the shortest-augmenting path method should not be used.

# 4 Experiments

We observed in a preliminary set of experiments that MC64J2 is generally faster than MC64J3; the geometric mean of the ratios of the run time of the latter to that of the former was 4.6. As already highlighted in Table 1, the run time of MC64J3 can be too large to experiment (this happens more frequently than with MC64J2). That is why we have implemented a threshold-based approach, referred here as THRESH, using the same code base of BOTTLED, and use it in our experiments instead of MC64J3. THRESH uses the initialization procedure common to MC64J3 and BOTTLED to find a large initial matching and an upper bound $\omega$ on the bottleneck value. If this matching is not maximum, then the edge weights are sorted to find the bottleneck value by a binary search between the smallest edge weight and the initial value $\omega$. The binary search uses only the available edge weights and each time half of the edges are discarded. Our codes, written in C, are available at `https://gitlab.inria.fr/bora-ucar/bottled`; the codes used in the experiments are elsewhere [17].

The next subsection describes the data set, and Section 4.2 conducts a performance analysis of BOTTLED. Section 4.3 compares BOTTLED with MC64J2 and THRESH. Last, some experiments using BOTTLED within a BvN decomposition heuristic are discussed in Section 4.4. Appendix of the related version contains detailed information about experiments.

## 4.1 Data set and measurements

We have experimented with all square matrices with perfect matchings, at least 100,000 rows, less than 250,000,000 nonzeros, and with no explicit zeros from SuiteSparse [5]. There were 113 such matrices at the time of experimentation. From each matrix, we created six types of problem instances, which are denoted as $\mathbf{A}, \mathbf{DAE}, \mathbf{D}P(\mathbf{A})\mathbf{E}, \mathbf{AP}, \mathbf{DAPE}$, and $\mathbf{D}P(\mathbf{A})\mathbf{PE}$. The **A**-type instance corresponds to the bipartite graph of the original matrix with the magnitudes of the entries as edge weights. The **DAE**-type and $\mathbf{D}P(\mathbf{A})\mathbf{E}$-type instances correspond, respectively, to the scaled version of the matrices and their patterns with 20 iterations of the Sinkhorn–Knopp [20] algorithm, and the other three types of instances are obtained from the first three by random column permutations. We discarded the instances **A** and **AP** for 0-1 matrices; for the same set of matrices **DAE**-type and $\mathbf{D}P(\mathbf{A})\mathbf{E}$-type instances are identical, and hence we kept only one of them. We discarded the instances in which the initialization algorithm found the bottleneck value, in which case all three methods are equivalent. We report the experiments with 14 **A**-type, 18 **DAE**-type, 58 $\mathbf{D}P(\mathbf{A})\mathbf{E}$-type instances, and the same number of instances with column permutations. For each instance, each algorithm is run five times and the geometric mean of the run time is reported as that algorithm's performance on that instance; when column permutations are applied, these correspond to five different permutations. When comparing two algorithms' run time, we do not include cases where both algorithms run in less than one second (as both are very small and the difference between the algorithms is insignificant). Appendix of the related version contains all the results.

We carry out the experiments on a machine having Intel(R) Xeon(R) CPU E7-8890 v4 with a clock-speed of 2.20 GHz, and 1.5TB memory. The machine runs Debian GNU/Linux 11 (64 bit). All the codes are compiled with `GCC` version 10.2.1, with option `-O3`. We ran MatchMaker [6, 15] to verify that there were perfect matchings. We used MatchMaker with options "no cheap matching", "Push-Relabel + fairness" as the core algorithm. For the sake of completeness, we report that the maximum run time of MatchMaker for any matrix was 2.65 seconds for vas_stokes_4M and 28.19 for the column permuted version of the same matrix.

## 4.2 Performance analysis of BOTTLED

We first analyze the percentage of the total run time of BOTTLED spent in the preprocessing step – creating the CSR representation or sorting the entries. Table 2 summarizes the results for six different problem instances, where BOTTLED took more than one second for **A**-, **DAE**- and/or **D***P*(**A**)**E**-type instances. This table presents the geometric mean of the percentage of the time spent creating the CSR representation and sorting (with respect to the total time of BOTTLED). The row "tTime" contains the geometric mean of the run time of BOTTLED on the instances **A**, **DAE** and **D***P*(**A**)**E** in seconds, and for the instances **AP**, **DAPE** and **D***P*(**A**)**PE** it contains the geometric mean of the ratio of the run time of BOTTLED on the permuted instances to the original ones. For example, the run time under the column **D***P*(**A**)**PE** is obtained by taking the geometric mean of ratio of the run time of BOTTLED on the 33 **D***P*(**A**)**PE** instances to that on the 33 **D***P*(**A**)**E** instances.

As we can see from Table 2, the average run time of BOTTLED on any of the six problem instance types is below 10 seconds. A first observation is that for all instances, the two preprocessing steps account for a non-negligible part of the total run time. At two extremes, they take 7% and 37% of the total time in **D***P*(**A**)**E** and **DAPE** instances, respectively. We further observe that the absolute run time of CSR and sorting increases for the permuted instances. The percentage of the total time spent in CSR also increases for the permuted instances while that of sorting either increases or remains the same. If the CSR representation is available, its creation can be skipped and one can reduce the run time considerably. As discussed in Section 3.2, for the targeted BvN application BOTTLED can skip not only the CSR creation, but also the sorting phase across different runs of the algorithm.

**Table 2** Percentage of the total time spent in creating a CSR matrix and sorting the nonzeros in BOTTLED; "tTime": the geometric mean of the run time of BOTTLED on the instances **A**, **DAE** and **D***P*(**A**)**E** in seconds, and the ratios of the others to their counterparts.

| | **A** | **AP** | **DAE** | **DAPE** | **D***P*(**A**)**E** | **D***P*(**A**)**PE** |
|---|---|---|---|---|---|---|
| CSR | 5% | 13% | 7% | 25% | 4% | 17% |
| sort | 5% | 5% | 10% | 12% | 3% | 3% |
| tTime | 6.54(s) | 1.28 | 3.43(s) | 1.02 | 3.40(s) | 1.28 |

**Table 3** Breakdown of the total time (tTime) of BOTTLED in seconds.

| matrix | instance-type | tTime | CSR | sort |
|---|---|---|---|---|
| vas_stokes_4M | **A** | 14.81 | 6.70 | 3.17 |
| | **AP** | 32.36 | 20.13 | 5.51 |
| | **DAE** | 23.44 | 6.93 | 3.66 |
| | **DAPE** | 52.99 | 19.93 | 5.57 |
| vas_stokes_2M | **D***P*(**A**)**E** | 11.67 | 2.96 | 2.01 |
| | **D***P*(**A**)**PE** | 19.30 | 8.81 | 2.57 |

Another observation from Table 2 is that the run time of BOTTLED consistently increases for the permuted instances. To put this into perspective, we present the run time of BOTTLED on a few instances in Table 3. We see that the increase in run time for the permuted matrices can be attributed, in part, to the creation of the CSR. For example, for vas_stokes_4M, excluding CSR and sort times from the total time yields 4.94 and 6.72 seconds for the while loop for **A**- and **AP**-type respectively. A similar calculation for the pairs **D***P*(**A**)**E** and **D***P*(**A**)**PE** for vas_stokes_2M shows that the while loop takes 6.7 and 7.92 seconds, respectively. In the instance pairs **DAE** and **DAPE** for vas_stokes_4M, the increase in the CSR time is still a contributing factor. From these two tables, we conclude that BOTTLED's preprocessing takes up a significant portion of the total run time.

We have also investigated the number of iterations of the while-loop of BOTTLED in different types of instances to see how stable and robust it is with respect to random column permutations. The number of iterations of the while loop were almost always the same for all 90 instances; in a few cases there was a difference of one in the number of iterations. The small changes in the number of iterations confirm the robustness of BOTTLED.

**Table 4** The geometric mean and the maximum of the run time of the three methods on six different instance types.

| | | **A** | **AP** | **DAE** | **DAPE** | **D$P$(A)E** | **D$P$(A)PE** |
|---|---|---|---|---|---|---|---|
| geomean | MC64J2 | 0.49 | 6.23 | 0.16 | 0.74 | 12.47 | 20.16 |
| | THRESH | 2.58 | 3.80 | 1.09 | 1.54 | 2.24 | 3.16 |
| | BOTTLED | 1.23 | 2.38 | 0.44 | 0.81 | 1.23 | 2.07 |

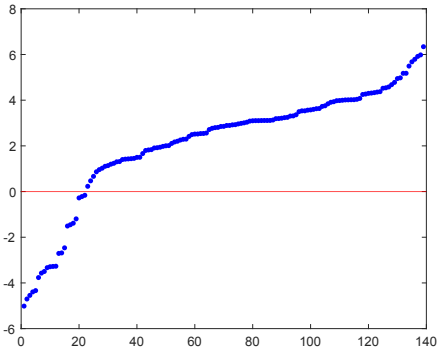
| | BOTTLED | 14.52 | 31.81 | 23.22 | 51.55 | 58.64 | 76.20 |

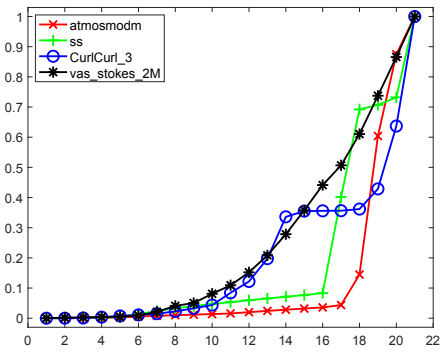
## 4.3 Comparison of different algorithms

We compared BOTTLED against MC64J2 and THRESH. We first provide a broad overview of the comparisons in Table 4, which lists the geometric mean of the run time of the three methods as well as their maximum run time in different problem instance types (all instances). As can be seen, BOTTLED exhibits the best performance overall, despite being slightly slower on average for **A**-, **DAE**-, **DAPE**- instance types than MC64J2– the margin is not large enough for MC64J2 to make up for the performance loss on the other instance types. Furthermore, BOTTLED's maximum run time is consistently smaller than those of both MC64J2 and THRESH. In contrast, the maximum run time of MC64J2 is prohibitive in all but the **A** and **DAE**-type instances. While THRESH avoids the prohibitive run time of its equivalent MC64J3 (see Table 1) by using a better cardinality matching algorithm [15], its maximum run time is still noticeably larger than that of BOTTLED in all but two cases.

We now look more into the performance of BOTTLED versus that of MC64J2. Figure 1a shows the natural logarithm (in the $y$-axis) of the ratio of the run time of MC64J2 to that of BOTTLED for the instances on which either method has a run time greater than 1 second. Here, MC64J2 is faster than BOTTLED on 22 instances, and BOTTLED is faster on the remaining 117 instances. In all 139 instances, the geometric mean of the ratio of the run time of MC64J2 to that of BOTTLED is 8.5, confirming that BOTTLED is faster than MC64J2 in average.



**(a)** The natural logarithm of the ratio of the run time of MC64J2 to that of BOTTLED in the $y$-axis in sorted order on 139 problem instances in the $x$-axis.



**(b)** The run time behavior of MC64J2 on four D$P$(A)E-type instances measured at 20 uniform steps ($x$-axis), normalized to the total time ($y$-axis).

**Figure 1** Performance comparison between MC64J2 and BOTTLED, and investigation on MC64J2.

In order to put these numbers into a perspective with the run time, we present Table 5. Table 5 lists six matrices in which the ratio of the run time of MC64J2 to that of BOTTLED was the smallest for certain instance types with or without permutation. It next lists six

**Table 5** The run time of MC64J2 and BOTTLED on selected instances, where their ratios were the lowest or the highest in different problem instance types or the permuted versions.

| matrix | type | MC64J2 | BOTTLED | type | MC64J2 | BOTTLED |
|---|---|---|---|---|---|---|
| c-73b | **A** | 0.09 | 13.55 | **AP** | 0.10 | 9.42 |
| c-73 | **A** | 0.19 | 14.52 | **AP** | 0.34 | 14.68 |

| dielFilterV3clx | **A** | 0.12 | 3.97 | **AP** | 0.49 | 7.19 |
| atmosmodd | **D**$P$(**A**)**E** | 555.76 | 7.01 | **D**$P$(**A**)**PE** | 1757.81 | 12.11 |
| vas_stokes_1M | **D**$P$(**A**)**E** | 452.36 | 4.20 | **D**$P$(**A**)**PE** | 2427.71 | 7.42 |
| vas_stokes_2M | **D**$P$(**A**)**E** | 1419.99 | 11.93 | **D**$P$(**A**)**PE** | 6813.20 | 18.37 |
| ss | **D**$P$(**A**)**E** | 824.91 | 4.66 | **D**$P$(**A**)**PE** | 2621.10 | 10.79 |
| CurlCurl_3 | **D**$P$(**A**)**E** | 610.16 | 1.54 | **D**$P$(**A**)**PE** | 211.56 | 3.80 |
| atmosmodj | **D**$P$(**A**)**E** | 565.60 | 7.27 | **D**$P$(**A**)**PE** | 1683.32 | 11.97 |
| vas_stokes_4M | **DAE** | 0.83 | 23.22 | **DAPE** | 9139.63 | 51.55 |
| ss | **A** | 2.25 | 2.65 | **AP** | 2532.09 | 8.65 |
| vas_stokes_4M | **A** | 0.53 | 14.23 | **AP** | 18054.00 | 31.81 |

matrices with different instance types in which the ratio of the run time of MC64J2 to that of BOTTLED was the largest for the original matrices and three for the permuted ones (three others were already in the list). Here we see that MC64J2 can have equivalently good performance on both the **A**- and **AP**-type instances (see the first block in Table 5). Still, there were some **AP** instances where MC64J2 ran prohibitively long (see the last two rows with ss and vas_stokes_4M). MC64J2 also struggled on several **D**$P$(**A**)**E** and **D**$P$(**A**)**PE** instances as seen in the second block. The prohibitively high run time of MC64J2 highlight the issue in the approaches based on the shortest augmenting paths: one may visit many edges and vertices to find augmenting paths at different stages during the execution. As such a behavior is also seen for DFS-based-cardinality matching algorithms [6], it cannot be attributed on the particular implementation of the shortest path algorithm in MC64J2.

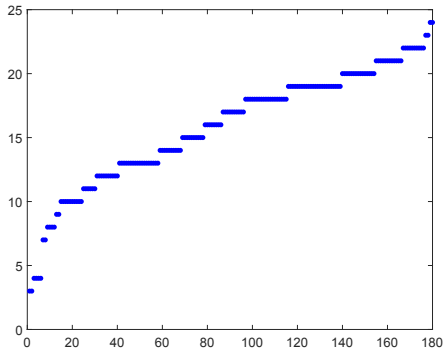
Figure 1b shows the run time behavior of MC64J2 on the four **D**$P$(**A**)**E**-type instances of Table 1. The total number of augmentations is divided by 20 to obtain a step size, the run time is measured after each step and normalized by the total time. As this figure shows, in some instances the augmentations took about the same time all throughout, whereas in others later augmentations took more time. As the greedy matching approach of MC64J2 does not always find a maximum matching, it can needlessly result in many additional augmentations. Those augmentations may lead to large run time, not solely because of their number. For example, in the **D**$P$(**A**)**E**-type instance of CurlCurl_3, a square matrix with $n = 1219574$ rows and nnz $= 13544618$ nonzeros, there are 20040 augmentations with a total run time of about 600 seconds, even though the maximum cardinality matching on $G[\omega_0]$ has a deficiency of one. Obviously, detecting this would lead to much better run time. On the other hand, for the **D**$P$(**A**)**E**-type instance of rajat31, a square martrix with $n = 4690002$ rows and nnz $= 20316253$ nonzeros, MC64J2 needs 1562500 augmentations (its greedy approach finds a maximum cardinality matching initially), and the whole run time is 48.39 seconds. As rajat31 is much bigger than CurlCurl_3 and needs more augmentations, its shorter run time attests that the process of augmenting one-by-one can take large time due to instance specific properties. It hence cannot constitute a reliable method for the bottleneck matching problem in general. In passing we note that MC64J2 is well-engineered and is faster than using our own SAP implementation for the augmentations.

We compare now BOTTLED and THRESH. In total, BOTTLED beat THRESH in 165 instances out of 180. The largest differences (in seconds) in favor of THRESH were in the **A**- and **AP**-type instances of c-73b and c-73. THRESH obtained a run time of 2.88 and 3.48 seconds

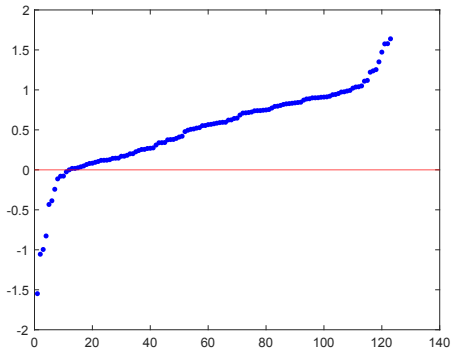
**Table 6** Run time, in seconds, of BOTTLED and the BvN decomposition heuristic, along with the number of permutation matrices in the decomposition.

| matrix | instance | BOTTLED initialization | longest run time of BOTTLED in an iteration | BvN num.perm | BvN time |
|---|---|---|---|---|---|
| atmosmodm | **DAE** | 0.22 | 58.73 | 46 | 452.14 |
| | **D**$P$(**A**)**E** | 0.21 | 14.43 | 50 | 200.80 |
| CurlCurl_3 | **DAE** | 0.35 | 17.30 | 50 | 183.43 |
| | **D**$P$(**A**)**E** | 0.34 | 4.33 | 50 | 68.45 |
| ss | **DAE** | 1.15 | 13.37 | 50 | 228.92 |
| | **D**$P$(**A**)**E** | 1.46 | 39.77 | 50 | 186.31 |
| vas_stokes_2M | **DAE** | 5.04 | 4.74 | 50 | 78.32 |
| | **D**$P$(**A**)**E** | 5.10 | 4.87 | 50 | 74.36 |

on c-73b, and 6.35 and 5.11 seconds on c-73. On these instances BOTTLED was relatively close to THRESH (see Table 5) – the largest difference is 10.67 seconds on the **A**-type instance of c-73b. Since both methods utilize the same core matching algorithm, the superiority of BOTTLED over THRESH should come from doing fewer iterations. Figure 2a supports this reasoning by plotting the difference between the number of iterations of THRESH and that of BOTTLED in nondecreasing order. As seen in this figure, THRESH's number of iterations is always larger than BOTTLED's; the theoretical observations of Section 3 translate to practical gains. We compute the ratio of the run time of THRESH to that of BOTTLED for the instances on which either THRESH or BOTTLED has a run time greater than 1 second (123 instances), and present the natural logarithm of this ratio in the $y$-axis in Figure 2b. As seen in this figure, BOTTLED fares better than THRESH in the majority of cases.



**(a)** The number of iterations of THRESH minus that of BOTTLED in the $y$-axis in sorted order on all 180 instances.



**(b)** The natural logarithm of the ratio of the run time of THRESH to that of BOTTLED in the $y$-axis in sorted order on 123 instances in the $x$-axis.

**Figure 2** Performance comparison between THRESH and BOTTLED.

## 4.4 Inside a BvN decomposition method

Table 6 presents the run time of the BvN decomposition method on the **DAE**- and **D**$P$(**A**)**E**-type instances of four matrices (obtained with 2500 scaling iterations). We run the BvN decomposition method until 50 permutation matrices or a coefficient of 0.92 are obtained. As each permutation matrix is obtained by a call to BOTTLED, we show their number in the column "num.perm". Further, the table also presents the time for the initial preprocessing of BOTTLED, and the maximum time taken in a call to BOTTLED subsequently for obtaining a

permutation matrix. We observe that the maximum run time of BOTTLED, in an iteration, multiplied by the number of calls is at least 2.92 (for **DAE** of ss) and up to 10.67 (for $\mathbf{D}P(\mathbf{A})\mathbf{E}$ of ss) times the total BvN time. This suggests that the run time of the subsequent bottleneck matching calls reduces appreciably, and BOTTLED works well inside the decomposition method by avoiding the preprocessing.

## 5 Conclusion

We have investigated the problem of finding a maximum bottleneck matching in bipartite graphs. Existing implementations for the problem suffer from unpredictable run time that can get prohibitively large, i.e., requiring thousands or even tens of thousands of seconds to complete. We have proposed a new algorithm called BOTTLED that converts an inefficient, duality-based approach into an efficient one through theoretical findings. Experimental results show that BOTTLED is almost always faster than the state-of-the-art methods. Furthermore, its run time is reliable and always remains within reasonable time limits. We have also explored its use inside a heuristic for the Birkhoff–von Neumann decomposition of doubly stochastic matrices and experimentally established the suitability of the proposed algorithm for this purpose.

Currently the proposed approach resorts to an augmenting-path-based method in few corner cases and only when there are perfect matchings. We plan to explore the possibility to use them more effectively, along with potential data reduction rules.

# Subcubic Algorithm for (Unweighted) Unrooted Tree Edit Distance

**Krzysztof Pióro** ✉
Jagiellonian University, Kraków, Poland

## Abstract

The tree edit distance problem is a natural generalization of the classic string edit distance problem. Given two ordered, edge-labeled trees $T_1$ and $T_2$, the edit distance between $T_1$ and $T_2$ is defined as the minimum total cost of operations that transform $T_1$ into $T_2$. In one operation, we can contract an edge, split a vertex into two or change the label of an edge.

For the weighted version of the problem, where the cost of each operation depends on the type of the operation and the label on the edge involved, $\mathcal{O}(n^3)$ time algorithms are known for both rooted and unrooted trees. The existence of a truly subcubic $\mathcal{O}(n^{3-\epsilon})$ time algorithm is unlikely, as it would imply a truly subcubic algorithm for the APSP problem. However, recently Mao (FOCS'21) showed that if we assume that each operation has a unit cost, then the tree edit distance between two rooted trees can be computed in truly subcubic time.

In this paper, we show how to adapt Mao's algorithm to make it work for unrooted trees and we show an $\widetilde{\mathcal{O}}(n^{(7\omega+15)/(2\omega+6)}) \leq \mathcal{O}(n^{2.9417})$ time algorithm for the unweighted tree edit distance between two unrooted trees, where $\omega \leq 2.373$ is the matrix multiplication exponent. It is the first known subcubic algorithm for unrooted trees.

The main idea behind our algorithm is the fact that to compute the tree edit distance between two unrooted trees, it is enough to compute the tree edit distance between an arbitrary rooting of the first tree and every rooting of the second tree.

## 1 Introduction

The tree edit distance problem is a natural generalization of the classic string edit distance problem. Given two trees $T_1$ and $T_2$, the edit distance between $T_1$ and $T_2$ is defined as the minimum total cost of operations that transform $T_1$ into $T_2$. The exact definition of the problem depends on whether we consider rooted or unrooted trees.

For the unrooted variant, which is the focus of this paper, the trees are edge-labeled and for each vertex its neighbors form a cyclic order. We can think of unrooted trees as if they were embedded in the plane. In one operation, we can contract an edge, split a vertex into two or change the label of any edge. The cost of each operation depends on the type of the operation and the label on the edge involved.

Computing the edit distance between two trees has found applications in many different areas, such as computational biology [18, 11], image processing [1, 12, 14, 17] and comparing XML data [3, 4, 10]. One of the most notable examples is comparing the secondary structures of RNA molecules, which can be represented as rooted trees [18].

The tree edit distance problem has been already studied for many years. In 1977, Tai [19] showed the first algorithm that computes the edit distance between two rooted trees of size $n$ in $\mathcal{O}(n^6)$ time. Next, Zhang and Shasha [21] used a dynamic programming approach to improve the complexity to $\mathcal{O}(n^4)$ time. Their dynamic programming scheme was used as a basis for later algorithms. Klein [13] showed how to optimize their algorithm to $\mathcal{O}(n^3 \log n)$ time by better choosing the direction of transitions in their dynamic programming scheme. Furthermore, he showed that his algorithm can be extended to also work for the unrooted trees in the same time complexity. Later, Demaine, Mozes, Rossman and Weimann [7] further improved the time complexity for the rooted case to $\mathcal{O}(n^3)$. Finally, Dudek and Gawrychowski [8] showed that the tree edit distance between unrooted trees can also be solved in $\mathcal{O}(n^3)$ time.

From the lower bound side, Bringmann, Gawrychowski, Mozes and Weimann [2] showed that the existence of a truly subcubic $\mathcal{O}(n^{3-\epsilon})$ time algorithm for the tree edit distance is unlikely. They proved that the existence of such an algorithm implies a truly subcubic algorithm for the All Pairs Shortest Paths problem (assuming an alphabet of size $\Theta(n)$) and $\mathcal{O}(n^{k(1-\epsilon)})$ time algorithm for finding a maximum weight $k$-clique (assuming a sufficiently large constant size alphabet).

However, all of these previous algorithms and lower bounds work when the costs of the operations are arbitrary. Recently, Mao [15] showed that if we assume that each operation has unit cost, then the tree edit distance between two rooted trees can be computed in $\mathcal{O}(n^{2.9546})$ time. Since in the weighted setting it was possible to obtain the same time complexity for unrooted trees as for rooted trees, Mao posed the following open problem:

*Is it possible to compute the unweighted tree edit distance between two unrooted trees in subcubic time?*

We answer this question affirmatively.

## 1.1 Our contribution

We build on ideas of Mao [15] and Klein [13] and obtain the first ever known subcubic algorithm for the tree edit distance between unrooted trees in the unweighted setting. Our main result is the following:

▶ **Theorem 1.** *There is an $\widetilde{\mathcal{O}}(mn^{(5\omega+9)/(2\omega+6)}) \leq \mathcal{O}(mn^{1.9417})$ time algorithm that computes the (unweighted) tree edit distance between two unrooted trees of sizes $n$ and $m$.*

We were not able to adapt one of the optimizations from Mao, thus our algorithm is slightly slower than the one for rooted trees. Note that, however the numerical value of the exponent in our result is actually better than in the original Mao's paper. It is only due to the fact that we replaced the algorithm for max-plus multiplication of two bounded-difference $n \times n$ matrices that Mao used (running in $\mathcal{O}(n^{2.8244})$ time) with a more recent result from Chi, Duan, Xie and Zhang ($\mathcal{O}(n^{2.687})$ time) [6]. Dürr [9] showed that with this new result, Mao's algorithm works in $\widetilde{\mathcal{O}}(mn^{1.915})$ time. Thus, our algorithm is in fact slower than Mao's algorithm.

## 1.2 Technical overview

**Sketch of Mao's algorithm for rooted trees.** First, let us note that in the unrooted tree edit distance, we consider edge-labeled trees, but Mao's algorithm works for node-labeled trees. However, the modification of Mao's algorithm to work for rooted edge-labeled trees is

simple. Indeed, for both trees we can introduce a virtual root that becomes a parent of the original root and then we can associate the label of every vertex with the label of edge to its parent.

Mao's algorithm is based on Chen's algorithm [5]. Chen showed a completely different approach than previous algorithms that were based on Zhang and Shasha's dynamic programming scheme. He reduced the problem to the $(\min, +)$ matrix multiplication and obtained an algorithm working in $\mathcal{O}(n^4)$ time[1].

Mao builds on Chen's approach but considers an equivalent maximization problem of the similarity of trees. Due to this, the matrices occurring in his algorithm satisfy additional properties: they are monotone and the difference between two adjacent cells is bounded by a constant. For such matrices, there exists a truly subcubic time algorithm that computes the $(\min, +)$ product [6], which is crucial for obtaining a subcubic complexity in the tree edit distance problem.

In summary, Mao's algorithm, given two trees $T_1$ and $T_2$, computes matrices $S(T_1')$ for some subtrees $T_1'$ of tree $T_1$. Every such matrix $S(T_1')$ encodes the similarity between tree $T_1'$ and all relevant fragments of tree $T_2$. These fragments are defined as segments of the Euler tour sequence[2] and are formally defined in Definition 8.

Mao first shows a dynamic programming scheme based on Chen's algorithm that computes $S(T_1)$ in $\mathcal{O}(n^4)$ time. Next, he optimizes it to $\mathcal{O}(n^3)$ time by exploiting the special properties of similarity matrices. Then, to achieve a subcubic complexity, he presents a special decomposition scheme, which allows him to skip some of the subproblems. For block size $\Delta = n^d$ for some $d$ slightly smaller than 0.5, he decomposes the computation of $S(T)$ into $\mathcal{O}(n/\Delta)$ transitions of one of two types.

The first type is a concatenation of two trees. For that, he shows an $\mathcal{O}(t^{1-\epsilon}n^2)$ time algorithm that computes the $(\max, +)$ product of two bounded-difference matrices such that the entries in one of them are bounded by $t$. The second transition type involves expanding a subtree by adding a path going up from its root along with some additional subtrees attached to this path. For these transitions, Mao presents a special three-part combinatorial method.

**Sketch of our algorithm for unrooted trees.** To generalize Mao's algorithm to unrooted trees, we use the idea that Klein [13] used in his $\mathcal{O}(n^3 \log n)$ time algorithm. Klein used the fact that to compute the tree edit distance between two unrooted trees, it is enough to consider arbitrary rooting of the first tree and try all possible rootings of the second tree.

Direct application of this fact requires solving $\mathcal{O}(n)$ particular instances of the rooted tree edit distance. However, Klein showed that his $\mathcal{O}(n^3 \log n)$ time algorithm for the rooted tree edit distance can be modified to solve all of these instances at once in the same time complexity. To achieve this, he used the fact that his algorithm for rooted trees computes the edit distance between some fragments of the first tree and all subtrees of the second tree that correspond to some segment of the Euler tour sequence of that tree. Since the different rootings of the second tree correspond to different cyclic shifts of the Euler tour sequence, Klein modified his algorithm so that it computes the edit distance between some fragments of the first tree and all cyclic segments of the Euler tour sequence of the second tree.

We notice that Mao's algorithm has properties similar to those of Klein's algorithm. For some of the subtrees $T_1'$ of the first tree, it computes a similarity matrix $S(T_1')$ that encodes the similarity between tree $T_1'$ and all subtrees of $T_2$ that correspond to some segment of the

[1] By reduction we mean that he used $(\min, +)$ matrix multiplication as a sub-procedure in his algorithm.
[2] Actually, Mao used the so-called bi-order traversal sequence, but Euler tour sequence is its equivalent for edge-labeled trees.

Euler tour sequence of that tree. Thus, we need to modify the algorithm to handle cyclic segments of the Euler tour sequence. To do this, we build our new similarity matrices on a doubled Euler tour sequence (see Definitions 7–9 in Section 2). Now every cyclic segment of the original Euler tour occurs as a normal segment in our sequence.

The introduction of a doubled Euler tour requires us to make a few modifications to Mao's algorithm. The key technical challenge is handling of multiplication of new similarity matrices which we describe in Section 4.1.

## 2 Preliminaries

In the tree edit distance problem we consider ordered trees with labels on edges. We consider both rooted and unrooted trees. For rooted trees, ordered means that for each vertex we are given a left-to-right order of its children. For unrooted trees, ordered means that for each vertex its neighbors form a cyclic order.

Note that we can transform an unrooted tree into a rooted tree by choosing a root and the first edge to its children. This choice carries over to the other vertices and defines the order of their children. It uniquely determines the rooting of the tree, thus there are $2(n-1)$ possible rootings for an unrooted tree with $n$ vertices.

For simplicity, we first assume that both input trees are of equal size $n$, but at the end we address the case when they have different sizes.

As we are interested in unrooted tree edit distance, we consider only trees that are edge labeled (for rooted tree edit distance it is more common to have labels on nodes). In this paper, we assume that every edge is labeled from some alphabet $\Sigma$ of size $\mathcal{O}(n)$.

▶ **Definition 2** ((Unweighted) Tree Edit Distance). *Let $T_1$ and $T_2$ be rooted, ordered trees with labels on edges. We consider two types of operations:*

- *Label change of a selected edge in tree $T_1$ or $T_2$.*
- *Contraction of a selected edge in tree $T_1$ or $T_2$. When contracting an edge $pu$ where $p$ is parent of $u$, children of $u$ become children of $p$, they replace $u$ in the children's list of $p$ and keep their order.*

*The tree edit distance between $T_1$ and $T_2$, denoted by $\mathrm{ed}(T_1, T_2)$, is the minimum number of operations we have to perform on $T_1$ and $T_2$ to transform both trees into an identical tree.*

▶ **Definition 3** ((Unweighted) Unrooted Tree Edit Distance). *Let $T_1$ and $T_2$ be unrooted, ordered trees with labels on edges. We define the tree edit distance between $T_1$ and $T_2$ as the minimum edit distance over all possible rootings of $T_1$ and $T_2$.*

Klein [13] mentioned, it is enough to consider arbitrary rooting of the first tree and try all possible rootings of the second tree to find an optimal solution for the unrooted tree edit distance.

▶ **Lemma 4.** *Let $T_1$ and $T_2$ be unrooted trees. For every rooting of tree $T_1$ there is at least one rooting of $T_2$ that admits minimum edit distance between $T_1$ and $T_2$.*

Same as Mao, we consider a maximization problem equivalent to the tree edit distance problem.

▶ **Definition 5** (Similarity). *The similarity between two rooted trees $T_1$ and $T_2$ is defined as* $\mathrm{sim}(T_1, T_2) = |E(T_1)| + |E(T_2)| - \mathrm{ed}(T_1, T_2)$.

Similarity can also be interpreted as the weight of the heaviest matching between the edges of the tree $T_1$ and $T_2$, where the cost of edge matching is 2 when edges have the same labels and 1 when they are different. In addition, the matching must respect the tree structure, which means:

- if edge $a \in T_1$ is matched to edge $b \in T_2$, then edges in the subtree of $a$ can be matched only to edges in the subtree of $b$,
- if edge $a \in T_1$ is matched to edge $b \in T_2$ and $c \in T_1$ is matched to $d \in T_2$, then $a$ is "to the left" of $c$ if and only if $b$ is "to the left" of $d$.

Note that $0 \leq \mathrm{sim}(T_1, T_2) \leq 2\min(|E(T_1)|, |E(T_2)|)$.

▶ **Definition 6.** *By $\eta(e, f)$ we denote the cost of matching edges $e$ and $f$, that means $\eta(e, f) = 2$ if labels of these edges are equal and $\eta(e, f) = 1$ otherwise.*

**Tree definitions.** For a rooted tree $T$, by $L_T$ we denote the subtree of the first (leftmost) child of the root of $T$ along with the edge to the root of $T$. Similarly, by $R_T$ we denote the subtree of the last (rightmost) child of the root of $T$ along with the edge to the root of $T$. Given an edge $e$ in a rooted tree, we use $sub(e)$ to represent the subtree rooted at edge $e$..

For two rooted trees $T_1$ and $T_2$, by $T_1 + T_2$ we denote the tree formed by merging the roots of tree $T_1$ and $T_2$ such that edges from the tree $T_1$ are "to the left" of the edges from the tree $T_2$.

For two trees (rooted/unrooted) $T_1$ and $T_2$ such that $T_1 \subseteq T_2$, by $T_2 - T_1$ we denote the tree formed from tree $T_2$ by contracting all edges that appear in tree $T_1$.

To describe the "fragments" of a tree that we will consider in our algorithm, we use segments of the Euler cycle of the tree. Due to technical reasons, instead of dealing with a cyclic sequence, we consider a doubled Euler tour sequence.

▶ **Definition 7.** *Let $T$ be an unrooted tree. Consider the walk on this tree that starts at an arbitrary edge and goes twice through the Euler Tour, which visits neighbors according to their order.*

**(a)** *For $i \in \{1, \ldots, 4|E(T)|\}$ by $T(i)$ we denote the $i$-th edge of this walk.*
**(b)** *By $I(e)_i$ we denote the index of the $i$-th occurrence of the edge $e$ in this walk.*
**(c)** *By $l_{i,j}(e)$ we denote the index of the first occurrence of the edge $e$ in $T(i), \ldots, T(j-1)$.*
**(d)** *By $r_{i,j}(e)$ we denote the index of the second occurrence of the edge $e$ in $T(i), \ldots, T(j-1)$.*

Note that each edge appears exactly 4 times in this walk.

▶ **Definition 8** (Segment). *Given an unrooted tree $T$ and integers $l$, $r$ such that $1 \leq l \leq r \leq 4|E(T)|$ and $r - l \leq 2|E(T)|$, by $T[l, r)$ we denote the tree formed from the tree $T$ by contracting every edge that occurs less than 2 times in $T(l), \ldots, T(r-1)$.*

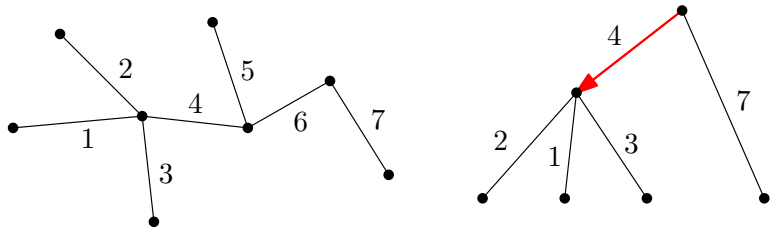
Let us note here that despite the fact that our input tree is unrooted, we can view the segments of this tree as rooted trees. Indeed, the first non-contracted edge that appears in the segment defines the rooting of this segment. Thus, the segments of length $2|E(T)|$ define all possible rootings of the tree $T$. See Figure 1.

**Matrix definitions.** Now we are ready to define similarity matrix – it encodes information about similarity of the whole rooted tree $T$ and all "relevant fragments" of unrooted tree $Q$.

▶ **Definition 9** (Similarity matrix). *Given a rooted tree $T$ and an unrooted tree $Q$ similarity matrix $S(T, Q)$ is a matrix of size $4|E(Q)| \times 4|E(Q)|$, where:*

$$S(T,Q)_{i,j} = \begin{cases} \mathrm{sim}(T, Q[i,j)) & \text{if } i \leq j \text{ and } j - i \leq 2|E(Q)| \\ -\infty & \text{if } i > j \text{ or } j - i > 2|E(Q)| \end{cases}$$

For simplicity, we also introduce additional notation for naming of similarity matrix cells. We divide them into three types:



1 3 3 4 6 7 7 6 5 5 4 2 2 1 1 3 3 4 6 7 7 6 5 5 4 2 2 1

**Figure 1** Example unrooted tree $T$ with its doubled Euler tour sequence and segment $T[11, 22)$ of this tree. The edge marked as red defines the rooting of this segment.

- *valid cells* – cells $S(T, Q)_{i,j}$ for which $i \leq j$ and $j - i \leq 2|E(Q)|$,
- *invalid cells* – cells $S(T, Q)_{i,j}$ for which $j - i > 2|E(Q)|$,
- *cells under diagonal*.

During our algorithm we will allow invalid cells to store values other than $-\infty$. Because of that, we introduce a special equality relation for similarity matrices:

▶ **Definition 10.** *By $=_{valid}$ we denote the relation on matrices which is true if and only if they are equal on the set of valid cells.*

▶ **Definition 11.** *Let $A$ and $B$ be $n \times n$ matrices. By $A \star B$ we denote their* $(\max, +)$ *product i.e.* $(A \star B)_{i,j} = max_{1 \leq k \leq n} A_{i,k} + B_{k,j}$.

Now, we define a few properties of matrices. Given an $n \times n$ matrix $A$ we call it:

**(a)** *finite-upper-triangular* matrix if all entries below diagonal are $-\infty$ and the rest are finite,
**(b)** *row-monotone* matrix if $A_{i,j} \leq A_{i,j+1}$ for all $i, j$,
**(c)** *column-monotone* matrix if $A_{i+1,j} \leq A_{i,j}$ for all $i, j$,
**(d)** *$W$-bounded-difference* matrix if for all $i, j$ we have:

$$|A_{i,j} - A_{i-1,j}| \leq W$$
$$|A_{i,j} - A_{i,j+1}| \leq W$$

**(e)** *bounded-difference* matrix if it is a $W$-bounded-difference matrix for some $W = \mathcal{O}(1)$,
**(f)** *finite-upper-triangular-$W$-bounded-difference* matrix if it is a finite-upper-triangular matrix and property d holds for all $i \leq j$,
**(g)** *$M$-bounded similarity matrix* if it is a similarity matrix and all finite entries are integers between 0 and $M$.

It is easy to see that for similarity matrices $S(T, Q)$ the properties row-monotone and column monotone hold for all cells except invalid cells. The following lemma, which is an analogy to Lemma 4.1 from Mao [15], tells that the finite-upper-triangular-2-bounded-difference property also holds for all cells except invalid cells.

▶ **Lemma 12.** *Given a rooted tree $T$ and an unrooted tree $Q$, we have:*

- $\text{sim}(T, Q[i, j + 1)) \leq \text{sim}(T, Q[i, j)) + 2$ *for all* $i \leq j, j - i + 1 \leq 2|E(Q)|$.
- $\text{sim}(T, Q[i - 1, j)) \leq \text{sim}(T, Q[i, j)) + 2$ *for all* $i \leq j, j - i + 1 \leq 2|E(Q)|$.

# 3 Cubic algorithm for Unrooted Tree Edit Distance

In this section, we introduce a basic dynamic programming scheme that computes the similarity of trees. It is the same scheme that Mao used, except that we use slightly different similarity matrices. We show how to efficiently compute this dynamic programming scheme in $\widetilde{\mathcal{O}}(n^3)$ time. This gives us a basic algorithm that will be later used in our subcubic algorithm.

As mentioned in Lemma 4, it is enough to consider an arbitrary rooting of the first tree and try all possible rootings of the second tree to find an optimal solution. Because of that, we can assume that we are given a rooted tree $T$, an unrooted tree $Q$ and we want to compute the edit distances between $T$ and every rooting of $Q$. To achieve that, we will compute the similarity matrix $S(T, Q)$. We will do this by computing recursively similarity matrices $S(T', Q)$ where $T'$ is some fragment of tree $T$. As the second argument of $S(T', Q)$ will always be $Q$ in our algorithm, we will use a shorthand $S(T') := S(T', Q)$. Additionally, we call $S(T')$ the similarity matrix of tree $T'$.

## 3.1 Dynamic programming scheme

To compute $S(T')$, we consider the following cases:

**(a)** $T'$ has no edges (it is a single vertex). Then the values in all valid cells are 0.

**(b)** The root of $T'$ has only one child. Let $r$ be the root and $u$ be its only child. We choose if we want to match $ru$ to some edge $e$ of $Q[i, j)$ or not:

$$S(T')_{i,j} = \max \begin{cases} S(T' - ru)_{i,j} \\ \max_{e \in Q[i;j)} \left\{ S(T' - ru)_{l_{i,j}(e)+1, r_{i,j}(e)} + \eta(ru, e) \right\} \end{cases}$$

**(c)** The root of $T'$ has more than one child. Let $R_{T'}$ be the subtree of the last child of the root of $T'$ along with the edge to the root of $T'$. Then:

$$S(T')_{i,j} = \max_{i \le k \le j} \{ S(T' - R_{T'})_{i,k} + S(R_{T'})_{k,j} \}$$

In other words: $S(T') = S(T' - R_{T'}) \star S(R_{T'})$.

Using this scheme, we can compute $S(T)$ in $O(n^4)$ time. Proof of the correctness of this algorithm is included in the full version of this paper [16].

## 3.2 Optimization to cubic

To optimize our algorithm to $\widetilde{\mathcal{O}}(n^3)$ time, we will exploit special properties of similarity matrices. We will rely on the fact that $S(T')$ is a $2|E(T')|$-bounded similarity matrix.

Furthermore, we will use the fact that these matrices are almost row-monotone and column-monotone. The only exception to this property are invalid cells, however their value is always $-\infty$. Because of that, we are able to use the same computation model that Mao used to store row-monotone, column-monotone matrices with slight modifications to handle invalid cells.

Let $l := 2n - 2$. We consider the following operations for $2l \times 2l$ matrices:

- create a new $2l \times 2l$ matrix $[-\infty]_{2l,2l}$,
- given a matrix $A$, create a copy of this matrix,

- given a matrix $A$, indexes $i', j'$ and a value $x$, create a new $2l \times 2l$ matrix $B := \text{rangemax}(A, i', j', x)$, such that:

$$B_{ij} = \begin{cases} \max(A_{ij}, x) & \text{if } i \leq i' \text{ and } j \geq j' \text{ and } j - i \leq l \\ A_{ij} & \text{otherwise} \end{cases}$$

Furthermore, given matrix $A$ we consider the following queries:

- get the value $A_{i,j}$,
- get the index $\text{mincol}(A, i, x) = \min\{j \mid A_{ij} \geq x\}$ or any index in $[1, 2l]$ if such an index does not exist,
- get the index $\text{maxrow}(A, j, x) = \max\{i \mid A_{ij} \geq x\}$ or any index in $[1, 2l]$ if such an index does not exist.

Note that the underlying data structure can keep a row-monotone, column-monotone matrix, and we can just modify queries to return $-\infty$ when reading invalid cells. This means we don't need to have the $j - i \leq l$ condition in the rangemax operation, thus we can use a simple 2D max operation (the same as Mao). All these operations can be performed with well-known data structures, such as persistent 2D segment trees in $\widetilde{\mathcal{O}}(1)$ time.

From now on, we assume that we store similarity matrices using the above computation model. We will go through all three cases of our dynamic programming scheme and we will show how to efficiently solve them using the above data structure:

**(a)** We can easily initialize all valid cells to 0 using $\mathcal{O}(n)$ rangemax queries. This gives us $\widetilde{\mathcal{O}}(n^2)$ time for the entire algorithm.

**(b)** Let us recall the equation for this case:

$$S(T')_{i,j} = \max \begin{cases} S(T' - ru)_{i,j} \\ \max_{e \in Q[i;j)} \left\{ S(T' - ru)_{l_{i,j}(e)+1, r_{i,j}(e)} + \eta(ru, e) \right\} \end{cases}$$

Naive computation of this equation relies on iterating through all cells we want to compute and for each $S(T')_{i,j}$ we iterate through each edge of $Q[i, j)$. Instead, we can do the opposite and iterate through each edge of $Q$ and update for each of them all relevant cells of $S(T')$. Thus, we first initialize $S(T')$ with $S(T' - ru)$ and then for each edge $e$ of $Q$ we make three rangemax operations. See Algorithm 1 for exact values of the parameters.

**Algorithm 1** Computation of case b.

**Input** $T, Q, S(T' - ru)$
**Output** $S(T')$

$S(T') \leftarrow S(T' - ru)$
**for all** $e \in E(Q)$ **do**
  $S(T') \leftarrow \text{rangemax}(S(T'), I(e)_1, I(e)_2 + 1, S(T' - ru)_{I(e)_1+1, I(e)_2} + \eta(ru, e))$
  $S(T') \leftarrow \text{rangemax}(S(T'), I(e)_2, I(e)_3 + 1, S(T' - ru)_{I(e)_2+1, I(e)_3} + \eta(ru, e))$
  $S(T') \leftarrow \text{rangemax}(S(T'), I(e)_3, I(e)_4 + 1, S(T' - ru)_{I(e)_3+1, I(e)_4} + \eta(ru, e))$
**return** $S(T')$

A single computation of this case takes $\widetilde{\mathcal{O}}(n)$ time, which gives us $\widetilde{\mathcal{O}}(n^2)$ time for the entire algorithm.

**(c)** This case is a matrix multiplication $S(T') = S(T' - R_{T'}) \star S(R_{T'})$. To speed up the computation, we will relay on the fact that $S(T')$ is a $2|E(T')|$ -bounded similarity matrix. The following lemma, which corresponds to Lemma 4.3 from Mao [15], shows that we can multiply similarity matrices in complexity dependent on the bounds of values of these matrices:

▶ **Lemma 13.** *Let $A, B$ be $l \times l$ matrices. If $A$ is a $t_A$-bounded similarity matrix and $B$ is a $t_B$-bounded similarity matrix, then we can compute $C = A \star B$ in $\widetilde{\mathcal{O}}(t_A t_B l)$ time.*

The algorithm that computes $C = A \star B$ is the same as Algorithm 1 from Mao [15] and can be found in the full version of this paper [16] together with the proof of correctness. Thus, every time we multiply similarity matrices of trees $T' - R_{T'}$ and $R_{T'}$, we contribute $\widetilde{\mathcal{O}}(|T' - R_{T'}||R_{T'}|n)$ time to the total time complexity of this case. To compute the sum of these components, we can correlate $|T' - R_{T'}||R_{T'}|$ with the number of pairs of edges $(e, f)$ where $e \in T' - R_{T'}$ and $f \in R_{T'}$. Let us sum these pairs over all multiplications. It is easy to see that each pair of edges from tree $T'$ appears at most once in such a sum. Thus, the total time complexity of this case is equal to $\widetilde{\mathcal{O}}(n^3)$.

After considering all three cases, we can see that the whole algorithm works in $\widetilde{\mathcal{O}}(n^3)$ time. Note here that if the input trees are of different sizes $n$ and $m$, then this algorithm works in $\widetilde{\mathcal{O}}(nm^2)$ time.

## 4 Subcubic algorithm for unrooted tree edit distance

In this section, we show how to get a subcubic algorithm for the unrooted tree edit distance problem. Our algorithm is based on the same decomposition scheme as Mao's algorithm. However, we will start by showing a different bottom-up view at $\widetilde{\mathcal{O}}(n^3)$ algorithm. This will give us a better intuition about Mao's decomposition scheme.

We can view the $\widetilde{\mathcal{O}}(n^3)$ algorithm as a decomposition scheme that computes $S(T)$ using the following two types of transitions:

- **Type I:** for trees $T_1, T_2$:
  compute $S(T_1 + T_2)$ from $S(T_1)$ and $S(T_2)$
- **Type II:** for trees $T_1, T_2$ such that $T_2$ is $T_1$ with one added edge going from the root up:
  compute $S(T_2)$ from $S(T_1)$

Note that the total time complexity of type I transitions is $\widetilde{\mathcal{O}}(n^3)$, while the total complexity of type II transitions is $\widetilde{\mathcal{O}}(n^2)$. This gives us an idea that to get a subcubic complexity we can try to balance these transitions. To reduce the number of type I transitions, we can generalize transitions of type II. Instead of adding a single edge going up from the root of $T_1$, we can add a "hat", that is, a path going up from the root along with some additional subtrees. This is the general idea of Mao's decomposition scheme, which we will now formally describe. See Figure 2 for an illustration of the "hat" structure.

First, we introduce additional definition that will help us define sub-problems occuring in the decomposition scheme. This definition corresponds to the synchronous subtree definition from Mao.

▶ **Definition 14** (Connected segment). *Given an unrooted tree $T$, segment $T[i, j)$ is called a connected segment if there is no edge that occurs in $T(i), \ldots, T(j-1)$ exactly once.*

A connected segment can be alternatively defined by a selection of a vertex $v \in T$ and a connected interval of children of the vertex $v$ (we call $v$ the root of the segment), so that subtrees of these children along with the edges from $v$ to these children belong to this segment. Thus, a connected segment forms a connected subtree of tree $T$.

Now let $\Delta$ be the block size – a parameter, that we will set later. We decompose the computation of $S(T)$ into $\mathcal{O}(n/\Delta)$ transitions of two types:

- **Type I:** for connected segments $T_1, T_2$ such that $|T_1| \geq \Delta$ and $|T_2| \geq \Delta$: compute $S(T_1 + T_2)$ from $S(T_1)$ and $S(T_2)$
- **Type II:** for connected segments $T_1, T_2$ such that $T_1 \subset T_2$ and $|T_2| - |T_1| = \mathcal{O}(\Delta)$: compute $S(T_2)$ from $S(T_1)$

To compute this decomposition, we will use the same algorithm as Mao did. This algorithm is included in the full version of this paper [16].

The following theorem, which corresponds to Theorem 4.5 from Mao [15], tells us how we can perform a type I transition efficiently. We prove this in Section 4.1.

▶ **Theorem 15.** *Let $A$, $B$ be $n \times n$ similarity matrices of unrooted trees. If $A$ is $t$-bounded, then $C = A \star B$ can be computed in $\mathrm{MUL}(t, n) := \widetilde{\mathcal{O}}(t^{0.8145} n^2)$ time.*

For type II transitions, in Section 4.2 we prove the following theorem, which corresponds to Theorem 4.6 from Mao [15].

▶ **Theorem 16.** *Let $T_1, T_2$ be the connected segments of tree $T$ such that $T_1 \subset T_2$ and $|T_2| - |T_1| = \mathcal{O}(\Delta)$. Given $S(T_1)$ we can compute $S(T_2)$ in $\widetilde{\mathcal{O}}(\mathrm{MUL}(\Delta, n) + n\Delta^4)$ time.*

Combining these two theorems, together with the decomposition scheme, gives us an algorithm from Theorem 1. Analysis of the time complexity of this algorithm can be found in the full version of this paper [16].

Note that in the Theorem 16 we have slightly worse time complexity for the type II transition than $\widetilde{\mathcal{O}}(\mathrm{MUL}(\Delta, n) + n\Delta^3)$ time from Mao's algorithm.

## 4.1 Type I transitions

In this section, we show how to efficiently multiply similarity matrices of unrooted trees and prove Theorem 15. Mao showed how to multiply similarity matrices of rooted trees in $\widetilde{\mathcal{O}}(t^{0.9038} n^2)$ time, where $t$ is a bound on the entries of one of the matrices. For unrooted trees, we will use his algorithm with a slight modification.

Mao's algorithm is a recursive procedure that uses the $(\max, +)$ matrix multiplication of bounded-difference matrices as a sub-procedure. Lately, Chi et al. [6] showed a better algorithm for the $(\max, +)$ product of bounded-difference matrices. This algorithm allows us to get a better exponent in Mao's matrix multiplication.

▶ **Theorem 17** ([6])**.** *There is an $\widetilde{\mathcal{O}}(n^{(3+\omega)/2}) \leq \widetilde{\mathcal{O}}(n^{2.687})$ time randomized algorithm that computes the $(\min, +)$ product of any two $n \times n$ bounded-difference matrices.*

To analyze the improvement in the exponent, we will use the following lemma implicitly proven by Mao:

▶ **Lemma 18** ([15, Section 4.4])**.** *Assume there is an $\widetilde{\mathcal{O}}(n^c)$ time algorithm that computes the $(\min, +)$ product of any two $n \times n$ bounded-difference matrices. Let $A$, $B$ be row-monotone, column-monotone and finite-upper-triangular-bounded-difference $n \times n$ matrices whose entries on the main diagonals are zero. If $A$ is $t$-bounded-upper-triangular and $\delta$ is a positive value, then $C = A \star B$ can be computed in $\widetilde{\mathcal{O}}(n^2 t^2/\delta + n^2 \delta^{c-2})$ time.*

The above complexity reaches the optimum when $n^2 t^2/\delta = n^2 \delta^{c-2}$. By setting $\delta = t^{2/(c-1)}$ we get that we can multiply the similarity matrices of rooted trees in $\widetilde{\mathcal{O}}(t^{(2c-4)/(c-1)} n^2)$ time, if one of the matrices has values bounded by $t$.

Now we want to use this algorithm also for unrooted trees. However, we need to make sure that the values from invalid cells do not affect the values of valid cells. To easily handle this, before calling the algorithm from Lemma 18 we fix the values of invalid cells based on the values of valid cells.

Let $A$, $B$ be similarity matrices of unrooted trees. We want to compute $C = A \star B$. For every invalid cell $A_{i,j}$ we set new value of $A_{i,j}$ as the maximum of valid cells $A_{i',j'}$, such that $i \leq i' \leq j' \leq j$. Let $A'$ be the resulting matrix. We can easily compute this transformation in $\mathcal{O}(n^2)$ time by using simple recursive equation $A'_{i,j} = \max(A'_{i+1,j}, A'_{i,j-1})$. Similarly, we convert matrix $B$ into matrix $B'$.

The obtained matrices $A'$ and $B'$ are obviously monotone and finite-upper-triangular. To prove that these new matrices are bounded-difference let us use induction on $i + j$. For a valid cell, our inductive thesis is satisfied. Now, take any invalid cell $A'_{i,j}$. Then, by inductive hypothesis we have that $A'_{i-1,j} \in [A'_{i-1,j-1}, A'_{i-1,j-1}+2]$ and $A'_{i,j-1} \in [A'_{i-1,j-1}, A'_{i-1,j-1}+2]$. Thus, $|A'_{i,j} - A'_{i-1,j}| \leq 2$ and $|A'_{i,j} - A'_{i,j-1}| \leq 2$, so matrices $A'$ and $B'$ are bounded-difference matrices.

Let $C' = A' \star B'$. It remains to show that $C' =_{valid} C$. Let us take any valid cell $C'_{i,j}$. There is a position $k$ such that $C'_{i,j} = A'_{i,k} + B'_{k,j}$. If one of $A'_{i,k}$, $B'_{k,j}$ is an invalid cell, then the other would be equal to $-\infty$ and we would have $C'_{i,j} < 0$. But $C'_{i,j} \geq A'_{i,i} + B'_{i,j} \geq 0$, which gives us a contradiction. Thus, invalid cells of $A'$ and $B'$ have no effect on valid cells of $C'$, so $C' =_{valid} C$.

This gives us that we can compute $C = A \star B$ in $\widetilde{\mathcal{O}}(t^{(2c-4)/(c-1)}n^2)$ time assuming we can compute the $(\min, +)$ product of any two $n \times n$ bounded-difference matrices in $\widetilde{\mathcal{O}}(n^c)$ time.

Combining this with Theorem 17 we get the proof of Theorem 15.

## 4.2 Type II transitions

In this section, we prove Theorem 16. Let $T_1$, $T_2$ be connected segments of tree $T$ such that $T_1 \subset T_2$ and $|T_2| - |T_1| = \mathcal{O}(\Delta)$. We want to compute $S(T_2)$ given $S(T_1)$.

Let us consider the path $p = e_1 e_2 \dots e_k$ in tree $T$ that goes from the root of $T_2$ to the root of $T_1$. For $1 \leq i \leq k$, let $L_i$ be the subtree of tree $T_2$ consisting of siblings of edge $e_i$ that are to the left of $e_i$ and all descendants of these edges. Additionally, let $L_{k+1}$ be a subtree of tree $T_2$ consisting of descendants of edge $e_k$ that are to the left of tree $T_1$. Similarly, we denote subtrees that are to the right of path $p$ by $R_i$ for $1 \leq i \leq k+1$. See Figure 2.

For $1 \leq i \leq j \leq k+1$, by $L_{i,j}$ we denote the tree $L_i + L_{i+1} + \ldots + L_j$ and by $R_{i,j}$ we denote the tree $R_j + R_{j-1} + \ldots + R_i$.

First, for all trees $L_{i,j}$, $R_{i,j}$, we compute the similarity matrices $S(L_{i,j})$, $S(R_{i,j})$ using the $\widetilde{\mathcal{O}}(nm^2)$ time algorithm from Section 3.2. We notice that in one run of this algorithm, we can compute $S(L_{i,j})$ for a fixed $i$ and all $j \geq i$. Thus, we only need to use that algorithm $\mathcal{O}(\Delta)$ times, which in total gives us $\widetilde{\mathcal{O}}(n\Delta^3)$ time for that step.

Now, we consider two cases:

**(a)** None of the edges $e_1, \dots, e_k$ is matched to some edge of tree $Q$.

**(b)** At least one of the edges $e_1, \dots, e_k$ is matched to some edge of tree $Q$.

For case (a), we can use Theorem 15 to compute $S(L_{1,k+1}) \star S(T_1) \star S(R_{1,k+1})$ in $\mathrm{MUL}(\Delta, n)$ time. For case (b), we define a restricted version of the similarity matrix for trees $T'$, such that the root of $T'$ has only one child.

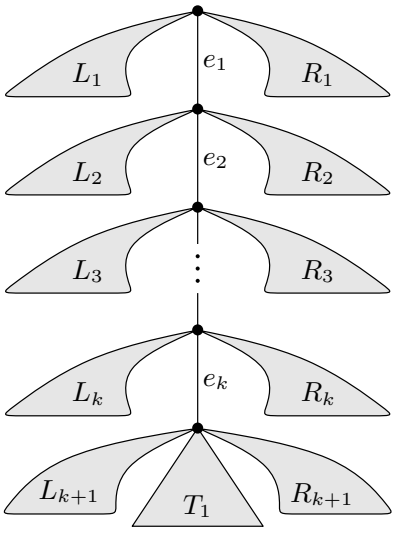


**Figure 2** Tree $T_2$. In the type II transition we compute $S(T_2)$ based on $S(T_1)$.

▶ **Definition 19** (Restricted similarity matrix). *Let $T'$ be a rooted tree such that the root $u$ of $T'$ has only one child $v$. The restricted similarity matrix $\hat{S}(T')$ is a $4|E(Q)| \times 4|E(Q)|$ matrix where:*

$$\hat{S}(T')_{i,j} = \begin{cases} \max_{e \in Q[i,j)} \{\mathrm{sim}(T' - uv, \mathrm{sub}(e) - e) + \eta(uv, e)\} & \text{if } i \leq j, j - i \leq 2|E(Q)| \\ -\infty & \text{otherwise} \end{cases}$$

We will compute $\hat{S}(\mathrm{sub}(e_i))$ for all edges $e_i$ on path $p$. But first, let us assume that we have already computed these restricted similarity matrices. We show how to compute $S(T_2)$ using these matrices.

As mentioned before we can first initialize $S(T_2)$ with $S(L_{1,k+1}) \star S(T_1) \star S(R_{1,k+1})$. Now, let us consider a single valid cell $S(T_2)_{i,j}$ that we want to compute. To cover case (b), we can iterate through:

- First edge $e_x$ from path $p$ that is matched.
- Edge $e \in Q[i,j)$ such that $e_x$ is matched to $e$.

Then, we have:

- Edges from $L_{1,x}$ are matched to edges from $Q[i, l_{i,j}(e))$ contributing $S(L_{1,x})_{i,l_{i,j}(e)}$.
- Edges from $\mathrm{sub}(e_x)$ are matched to edges from $Q[l_{i,j}(e), r_{i,j}(e)+1)$ contributing $\hat{S}(\mathrm{sub}(e_x))_{l_{i,j}(e), r_{i,j}(e)+1}$.
- Edges from $R_{1,x}$ are matched to edges from $Q[r_{i,j}(e)+1, j)$ contributing $S(R_{1,x})_{r_{i,j}(e)+1,j}$.

Note that we allow edge $e_x$ to be matched to some other edge than $e$ from $Q[l_{i,j}(e), r_{i,j}(e)+1)$. However, the cost of such matching will be at least as good as the cost of best matching that matches $e_x$ to $e$, thus it does not affect the correctness of our algorithm.

This gives us that we can compute $S(T_2)$ from all $\hat{S}(\mathrm{sub}(e_i))$ in $\widetilde{\mathcal{O}}(n^3\Delta)$. To optimize this, we can use a similar idea to the one from Algorithm 1. Instead of calculating all the cells from $S(T_2)$ separately, we can do it globally. We iterate through:

- First edge $e_x$ from path $p$ that is matched.
- Edge $e \in Q$ such that $e_x$ is matched to $e$.
- Occurrence $(I(e)_c, I(e)_{c+1})$ of the edge $e$ in the doubled Euler tour.
- Cost $a$ of matching edges from $L_{1,x}$.
- Cost $b$ of matching edges from $R_{1,x}$.

Now we can find the shortest segment $[i, j)$, such that it contains $(I(e)_c, I(e)_{c+1})$, the cost of matching $L_{1,x}$ to $Q[i, I(e)_c)$ is at least $a$ and the cost of matching $R_{1,x}$ to $Q[I(e)_{c+1} + 1, j)$ is at least $b$. Then we can use a single rangemax operation to update all valid cells $S(T_2)_{i',j'}$ for which $i' \leq i$ and $j \leq j'$. This gives us that we can compute $S(T_2)$ from $\hat{S}(\text{sub}(e_i))$'s in $\widetilde{\mathcal{O}}(n\Delta^3)$ time. The pseudocode for this part can be found in the full version of this paper [16].

Now, it remains to show how to compute all $\hat{S}(\text{sub}(e_i))$'s. We compute them starting with $e_k$ and going up to $e_1$. Thus, assume that we have already computed $\hat{S}(\text{sub}(e_i))$'s for all $i$ greater than some $x$. We want to compute $\hat{S}(\text{sub}(e_x))$. Let us consider two cases:

**(a)** None of the edges $e_{x+1}, \ldots, e_k$ is matched.

**(b)** At least one of the edges $e_{x+1}, \ldots, e_k$ is matched.

Both of these cases can be computed using similar ideas that we used to compute $S(T_2)$ from all $\hat{S}(\text{sub}(e_i))$. In the full version of this paper [16], we present how to compute case **(a)** in $\widetilde{\mathcal{O}}(n\Delta^2)$ time and case **(b)** in $\widetilde{\mathcal{O}}(n\Delta^3)$ time.

Thus, we can compute single $\hat{S}(\text{sub}(e_x))$ in $\widetilde{\mathcal{O}}(n\Delta^3)$ time and all of them in $\widetilde{\mathcal{O}}(n\Delta^4)$ time. Therefore, a whole single transition of type II can be computed in $\widetilde{\mathcal{O}}(\text{MUL}(\Delta, n) + n\Delta^4)$ time, which finishes the proof of Theorem 16.

## 5 Final remarks

We have presented the first truly subcubic algorithm for the unweighted variant of the unrooted tree edit distance. However, as mentioned before our algorithm has a slightly worse exponent than the best-known algorithm for rooted trees. The difference comes from Theorem 16 where we have time complexity $\widetilde{\mathcal{O}}(\text{MUL}(\Delta, n) + n\Delta^4)$, while Mao has $\widetilde{\mathcal{O}}(\text{MUL}(\Delta, n) + n\Delta^3)$ in corresponding theorem. It will be interesting to see if our algorithm could be optimized to match the time complexity of Mao's algorithm.

For the weighted tree edit distance probably the most interesting open problem is a question whether there exists a weakly subcubic algorithm for that version. One of the lower bounds [2] that claims this problem cannot be solved in a truly subcubic time is based on APSP conjecture. However, for APSP weakly subcubic time algorithms are already known. Williams [20] showed that the APSP problem can be solved in $\mathcal{O}(n^3/2^{\Omega(\sqrt{\log n})})$ time. Thus, we can try to obtain a weakly subcubic algorithm for the weighted tree edit distance by showing a reduction to the APSP problem.

# Linear Time Construction of Cover Suffix Tree and Applications

**Jakub Radoszewski**
University of Warsaw, Poland
Samsung R&D, Warsaw, Poland

## Abstract

The Cover Suffix Tree (CST) of a string $T$ is the suffix tree of $T$ with additional explicit nodes corresponding to halves of square substrings of $T$. In the CST an explicit node corresponding to a substring $C$ of $T$ is annotated with two numbers: the number of non-overlapping consecutive occurrences of $C$ and the total number of positions in $T$ that are covered by occurrences of $C$ in $T$. Kociumaka et al. (*Algorithmica*, 2015) have shown how to compute the CST of a length-$n$ string in $\mathcal{O}(n \log n)$ time. We give an algorithm that computes the same data structure in $\mathcal{O}(n)$ time assuming that $T$ is over an integer alphabet and discuss its implications.

A string $C$ is a cover of text $T$ if occurrences of $C$ in $T$ cover all positions of $T$; $C$ is a seed of $T$ if occurrences and overhangs (i.e., prefix-suffix occurrences) of $C$ in $T$ cover all positions of $T$. An $\alpha$-partial cover ($\alpha$-partial seed) of text $T$ is a string $C$ whose occurrences in $T$ (occurrences and overhangs in $T$, respectively) cover at least $\alpha$ positions of $T$. Kociumaka et al. (*Algorithmica*, 2015; *Theor. Comput. Sci.*, 2018) have shown that knowing the CST of a length-$n$ string $T$, one can compute a linear-sized representation of all seeds of $T$ as well as all shortest $\alpha$-partial covers and seeds in $T$ for a given $\alpha$ in $\mathcal{O}(n)$ time. Thus our result implies linear-time algorithms computing these notions of quasiperiodicity. The resulting algorithm computing seeds is substantially different from the previous one (Kociumaka et al., SODA 2012, *ACM Trans. Algorithms*, 2020); in particular, it is non-recursive. Kociumaka et al. (*Algorithmica*, 2015) proposed an $\mathcal{O}(n \log n)$-time algorithm for computing a shortest $\alpha$-partial cover for each $\alpha = 1, \ldots, n$; we improve this complexity to $\mathcal{O}(n)$.

Our results are based on a new combinatorial characterization of consecutive overlapping occurrences of a substring $S$ of $T$ in terms of the set of runs (see Kolpakov and Kucherov, FOCS 1999) in $T$. This new insight also leads to an $\mathcal{O}(n)$-sized index for reporting overlapping consecutive occurrences of a given pattern $P$ of length $m$ in the optimal $\mathcal{O}(m + \mathsf{output})$ time, where $\mathsf{output}$ is the number of occurrences reported. In comparison, a general index for reporting bounded-gap consecutive occurrences of Navarro and Thankachan (*Theor. Comput. Sci.*, 2016) uses $\mathcal{O}(n \log n)$ space.

## 1 Introduction

The Cover Suffix Tree (CST, in short) of a string $T$, denoted as $CST(T)$, is the suffix tree of $T$ ($ST(T)$) augmented with additional nodes and values. For every substring $C$ of $T$, $CST(T)$ allows to efficiently compute the number of positions in $T$ that are covered by occurrences of $C$, provided that the node representing $C$ in $CST(T)$ is known. Thus the CST

is a generalization of string covers [3]. The CST of a string was introduced by Kociumaka et al. [29] for computing so-called *partial covers* of a string (see below). Other applications of the CST to the field of quasiperiodicity (see [2]) were discussed in [29, 30].

Let $n$ denote the length of a string $T$. Kociumaka et al. [29] presented an algorithm computing $CST(T)$ in $\mathcal{O}(n \log n)$ time. Our main result is an algorithm that constructs $CST(T)$ in $\mathcal{O}(n)$ time. We assume that $T$ is over an *integer alphabet* $\{0, \ldots, n^{\mathcal{O}(1)}\}$. This assumption has become a standard in suffix tree construction algorithms since the linear-time suffix tree construction algorithm of Farach [18].

In Section 1.1 we provide more details on the CST. Then in Section 1.2 we discuss applications of our result to computing various notions of quasiperiodicity and in Section 1.3 we present an application of our approach to a variant of text indexing.

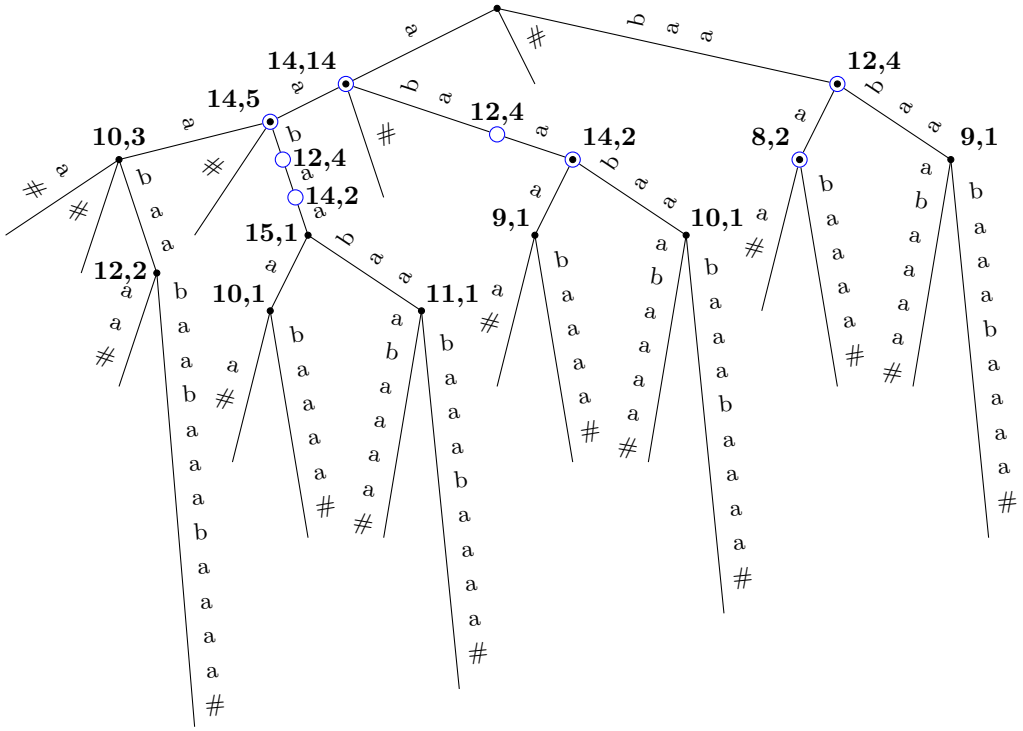

**Figure 1** $CST(T)$ for $T = \mathrm{aaabaabaabaaabaaaa\#}$. Black circles denote explicit nodes of $ST(T)$ and blue circles represent nodes corresponding to halves of square substrings in $T$. The numbers next to nodes denote $cv(v)$ and $nov(v)$.

## 1.1 Cover Suffix Tree

In the suffix tree $ST(T)$, there is a 1-to-1 correspondence between substrings of $T$ and (explicit and implicit) nodes. The same applies to $CST(T)$. The set of explicit nodes of the $CST(T)$ comprises of the explicit nodes of the suffix tree of $T$ and of nodes corresponding to halves of square substrings of $T$. Here a *square* is a string of the form $X^2 = XX$, for some string $X$ which is called the *square half*.

The CST has the same tree structure as the Maximal Augmented Suffix Tree (MAST) introduced by Apostolico and Preparata for the String Statistics Problem [4]. It was already observed by Brodal et al. [11] that the MAST of $T$ uses only $\mathcal{O}(n)$ space; this is because

the suffix tree has $\mathcal{O}(n)$ nodes [32] and the number of different square substrings of $T$ is $\mathcal{O}(n)$ [20]. By a recent result of Brlek and Li [9, 10] showing that a string of length $n$ contains at most $n$ different square substrings, it follows that the CST (and MAST) contains at most $3n$ explicit nodes.

For a node $v$ of $CST(T)$, by $\bar{v}$ we denote the substring of $T$ that corresponds to $v$. A *consecutive occurrence* of string $S$ in $T$ is a pair of indices $(i, j)$ in $T$ such that $j > i$, $S$ has occurrences starting at positions $i$ and $j$ in $T$ and $S$ does not occur at any of the positions $i + 1, \ldots, j - 1$. A consecutive occurrence $(i, j)$ of $S$ is called *overlapping* if $j < i + |S|$ and *non-overlapping* otherwise. In $CST(T)$, each node $v$ is annotated by two values (see Figure 1):

- $cv(v)$, equal to the total number of positions in $T$ covered by occurrences of $\bar{v}$, and
- $nov(v)$, equal to one plus the number of non-overlapping consecutive occurrences of $\bar{v}$ in $T$. (Intuitively, the one corresponds to the rightmost occurrence of $\bar{v}$ in $T$.)

The key property of values $cv(v)$ and $nov(v)$ is that if $u$ is an implicit node of $CST(T)$ that is located on an edge from an explicit node $v$ to its parent, then $cv(u)$ can be expressed in terms of $cv(v)$ and $nov(v)$ as follows: $cv(u) = cv(v) - (|\bar{v}| - |\bar{u}|)nov(v)$; see Figure 2.

**Figure 2** Left: the locus $v$ of $C = \text{abaabaa}$ in $CST(T)$ is an explicit node and we have $cv(v) = 10$, $nov(v) = 1$ (see Figure 1). Right: the locus $v'$ of the prefix $C' = \text{abaaba}$ of $C$ is an implicit node one character above $v$. We then have $cv(v') = cv(v) - nov(v) = 9$.

We obtain the following result.

▶ **Theorem 1.** *The Cover Suffix Tree (CST) of a string of length $n$ over an integer alphabet can be constructed in $\mathcal{O}(n)$ time.*

The $\mathcal{O}(n \log n)$-time algorithm from [29] for constructing $CST(T)$ processes the suffix tree of $T$ bottom-up, storing for each explicit node $v$ the set of occurrences of the corresponding substring of $T$ in an AVL tree. Its time complexity follows by using an efficient algorithm for merging AVL trees [13] (cf. [12]). We use a completely different approach, based on a new combinatorial observation that links overlapping consecutive occurrences of substrings of $T$ to runs in $T$ [31]. We show that the (multi)set of substrings whose overlapping consecutive occurrences are implied by a run has a simple, "triangular" structure. The values $ov(v)$ and $cv(v)$ for explicit nodes $v$ of $CST(v)$ are then computed in two bottom-up traversals, one in the tree of suffix links of $ST(T)$ and the other in the $CST(T)$.

## 1.2 Applications of CST to quasiperiodicity

Theorem 1 has several applications in the field of quasiperiodicity [2]. Basic notions of quasiperiodicity are covers [3], that were already mentioned before, and seeds [25]. A string $C$ is a cover of a string $T$ if each position of $T$ is inside at least one occurrence of $C$. A string $S$ is a seed of a string $T$ if it is a cover of a superstring of $T$. In other words, all positions of $T$ are covered by occurrences and overhangs of $S$, where an *overhang* is a prefix of $T$ being a suffix of $S$ or a suffix of $T$ being a prefix of $S$. A substring $C$ of $T$ is called an *$\alpha$-partial cover* of $T$ if the occurrences of $C$ in $T$ cover at least $\alpha$ positions in $T$. A substring $S$ of $T$ is called an *$\alpha$-partial seed* of $T$ if the occurrences and overhangs of $S$ in $T$ cover at least $\alpha$ positions in $T$. See Figure 3 for examples.

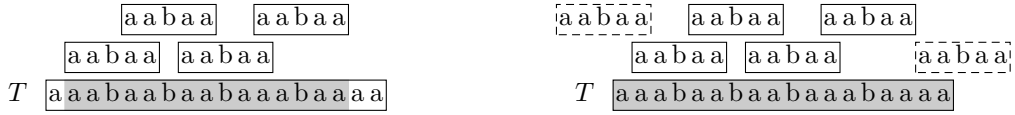

**Figure 3** $C = \mathrm{aabaa}$ is a 15-partial cover of $T$ (left). Indeed, the node $v$ of $CST(T)$ corresponding to $C$ has $cv(v) = 15$ (Figure 1). $C$ is also an 18-partial seed of $T$, hence, a seed of $T$ (right).

In [29, 30] it was noticed that given the $CST(T)$, all shortest $\alpha$-partial covers and $\alpha$-partial seeds of $T$ for a specified value of the parameter $\alpha$ can be computed in $\mathcal{O}(n)$ time. Thus our Theorem 1 implies the following result.

▶ **Corollary 2.** *Let $T$ be a string of length $n$ over an integer alphabet and $\alpha \in [1\,..\,n]$. All shortest $\alpha$-partial covers and seeds of $T$ can be computed in $\mathcal{O}(n)$ time.*

In [29] also the following problem was considered.

AllPartialCovers
**Input:** a string $T$ of length $n$
**Output:** for all $\alpha = 1, \ldots, n$, a shortest $\alpha$-partial cover of $T$

▶ **Example 3.** For $T$ from Figure 1, the solution to AllPartialCovers problem can be as follows: substring $C = \mathrm{a}$ for $\alpha \leq 14$, substring $C = \mathrm{aabaa}$ for $\alpha = 15$ (see Figure 3), and any length-$\alpha$ substring of $T$ for $\alpha \geq 16$.

An $\mathcal{O}(n \log n)$-time solution for AllPartialCovers based on $CST(T)$ and on computing the upper envelope [24] of $\mathcal{O}(n)$ line segments was presented in [29]. We obtain the following result.

▶ **Theorem 4.** *AllPartialCovers problem can be solved in $\mathcal{O}(n)$ time for a length-$n$ string over an integer alphabet.*

A linear-time algorithm computing all covers of a string was presented almost 30 years ago by Moore and Smyth [33, 34]. A rather involved linear-time algorithm computing a representation of all seeds in a string over an integer alphabet was given much more recently by Kociumaka et al. [27]. The representation (already introduced in the earlier, $\mathcal{O}(n \log n)$-time algorithm by Iliopoulos et al. [25]) consists of a set of paths in the suffix trees of $T$ and of $T$ reversed, at most one path on each edge of the suffix trees. Seeds of $T$ are exactly $|T|$-partial seeds of $T$, so Corollary 2 immediately implies an alternative linear-time algorithm computing all shortest seeds of $T$. Moreover, in [29, Theorem 3] it was observed that having $CST(T)$, the aforementioned representation of all seeds in $T$ can be computed in $\mathcal{O}(n)$ time. Thus Theorem 1 yields an alternative $\mathcal{O}(n)$-time algorithm computing the same representation of all seeds in $T$ as in [27]. The resulting algorithm is substantially different from the algorithm of [27]; in particular, it is non-recursive and arguably simpler.

Recently, Kociumaka et al. [28] showed that there exists a different representation of all seeds of a string, consisting of $\mathcal{O}(n)$ disjoint paths on just the suffix tree of $T$, and that this representation can be computed in $\mathcal{O}(n)$ time assuming an integer alphabet. This representation, however, no longer satisfies the convenient property that at most one path on each edge of the suffix tree is in the representation (see [28, Fig. 2] for an example).

## 1.3 Reporting overlapping occurrences

Data stored in the CST can be used to compute, for any substring $S$ of $T$, the number $ov(S)$ of overlapping consecutive occurrences of $S$ in $T$. We show that the technique behind Theorem 1 can be further exploited to obtain a linear-space index for reporting overlapping consecutive occurrences of a query pattern.

Navarro and Thankachan [35] proposed an index that, given a length-$m$ substring $S$ of $T$ and an interval $[\alpha, \beta]$, reports all consecutive occurrences $(i, j)$ of $S$ such that $\alpha \leq j - i \leq \beta$ in $\mathcal{O}(m + \mathsf{output})$ time, where $\mathsf{output}$ is the number of consecutive occurrences reported. The size of their index for a text $T$ of length $n$ is $\mathcal{O}(n \log n)$. We solve the following problem.

| Reporting bounded-gap overlapping consecutive occurrences |
|---|
| **Input:** A string $T$ of length $n$ |
| **Query input:** A substring $S$ of $T$, $\lvert S\rvert = m$, and a positive integer $\beta$ such that $\beta < m$ |
| **Query output:** All consecutive occurrences $(i, j)$ of $S$ in $T$ such that $j - i \leq \beta$ |

▶ **Theorem 5.** *There is an index of size $\mathcal{O}(n)$ that reports all bounded-gap overlapping consecutive occurrences of a length-$m$ pattern in $\mathcal{O}(m + \mathsf{output})$ time, where $\mathsf{output}$ is the number of consecutive occurrences reported. If $T$ is over a constant-sized alphabet, the index can be constructed in $\mathcal{O}(n)$ time. The construction time becomes expected if $T$ is over an integer alphabet.*

The data structure of Theorem 5 is superior to the data structure of [35] if $\alpha = 0$ and $\beta < m$.

In the data structure we use the same combinatorial observation as in Theorem 1. With it, a query for a pattern $S$ consists in finding the corresponding node $v$ in $CST(T)$ and reporting all "triangular" structures implied by runs that contain $v$. To this end, range minimum query data structures [8] are used to store the "bottom sides" of the triangles. Thanks to this, it is actually sufficient to store $ST(T)$ instead of the $CST(T)$. The expected time in the construction algorithm stems from using perfect hashing [21] to store children of a node of the suffix tree if $T$ is over a superconstant alphabet.

## 1.4 Structure of the paper

We start by recalling basic definitions related to strings and compact tries (including suffix trees). In Section 3 we present the proof of the main Theorem 1. Solution to AllPartialCovers (Theorem 4) is provided in Section 4. The data structure for reporting bounded-gap overlapping consecutive occurrences (proof of Theorem 5) is presented in the full version. We conclude in Section 5.

# 2 Preliminaries

## 2.1 Strings

By $\Sigma$ we denote the finite alphabet of all the considered strings. We assume that characters of a string $S$ are numbered 1 through $|S|$, with $S[i] \in \Sigma$ denoting the $i$th character. An integer $j \in [1\,..\,|S|]$ is called an index in $S$. A string $S[i]S[i+1]\cdots S[j]$ for any indices $i, j$ such that $i \leq j$ is called a *substring* of $S$. By $S[i\,..\,j]$ we denote a *fragment* of $S$ that can be viewed as a positioned substring $S[i]S[i+1]\cdots S[j]$ (formally, it is represented in $\mathcal{O}(1)$ space with a reference to $S$ and the interval $[i\,..\,j]$). We also denote $S[i\,..\,j-1]$ as $S[i\,..\,j)$. Two fragments

$S[i\,..\,j]$ and $S[i'\,..\,j']$ *match* (notation: $S[i\,..\,j] = S[i'\,..\,j']$) if the underlying substrings are the same. Similarly we define matching of a fragment and a substring. Two fragments $S[i\,..\,j]$ and $S[i'\,..\,j']$ are *equivalent* (notation: $S[i\,..\,j] \equiv S[i'\,..\,j']$) if $i = i'$ and $j = j'$. A string $U$ is called a prefix (suffix) of a string $S$ if $U = S[1\,..\,|U|]$ ($U = S[|S| - |U| + 1\,..\,|S|]$, respectively) and a *border* of $S$ if it is both a prefix and a suffix of $S$.

Henceforth by $T$ we denote the text string and by $n$ we denote $|T|$. We say that a string $S$ occurs in the text $T$ at position $i$ if $S = T[i\,..\,i + |S|)$. A pair of indices $(i, j)$ in $T$ is called a *consecutive occurrence of substring* $S$ if $i < j$, $T[i\,..\,i + |S|) = T[j\,..\,j + |S|)$ and $T[k\,..\,k + |S|) \neq S$ for all $k \in (i\,..\,j)$. A consecutive occurrence is called *overlapping* if $j < i + |S|$ and otherwise it is called *non-overlapping*. By $OvOcc(S)$ we denote the set of overlapping consecutive occurrences of $S$ in $T$.

For a string $U$ and $d \in \mathbb{Z}_{\geq 0}$, by $U^d$ we denote the $d$th power of $U$, equal to a concatenation of $d$ copies of $U$. A string $V$ is *primitive* if $V = U^d$ for $d \in \mathbb{Z}_+$ implies that $d = 1$. The following property of primitive strings is a known consequence of Fine and Wilf's lemma [19].

▶ **Lemma 6** (Synchronization property, see [14]). *A string $V$ is primitive if and only if $V$ has exactly two occurrences in $V^2$.*

A string of the form $U^2$ is called a *square*.

▶ **Theorem 7** ([20] and [15, 6]). *The number of distinct square substrings in a length-$n$ string is $\mathcal{O}(n)$ and they can all be computed in $\mathcal{O}(n)$ time assuming an integer alphabet.*

We say that a string $S$ has a period $p$ if $S[i] = S[i + p]$ holds for all $i \in [1\,..\,|S| - p]$; equivalently, if $S$ has a border of length $|S| - p$. By $per(S)$ we denote the smallest period of $S$.

A *run* in a string $T$ is a triad $(a, b, p)$ such that (1) $p$ is the smallest period of $T[a\,..\,b]$, (2) $2p \leq b - a + 1$, (3) $a = 1$ or $T[a-1] \neq T[a-1+p]$, and (4) $b = |T|$ or $T[b+1] \neq T[b+1-p]$. The *exponent* of a run $R = (a, b, p)$ is defined as $exp(R) = (b - a + 1)/p$. By $\mathcal{R}(T)$ we denote the set of all runs in $T$.

▶ **Theorem 8** ([5]). *A string $T$ of length $n$ has at most $n$ runs and they can be computed in $\mathcal{O}(n)$ time if $T$ is over an integer alphabet.*

An earlier bound $|\mathcal{R}(T)| = \mathcal{O}(n)$ together with an $\mathcal{O}(n)$-time algorithm for computing $\mathcal{R}(T)$ was proposed in [31]. All runs can be computed in $\mathcal{O}(n)$ time also for a string over a general ordered alphabet [17].

## 2.2 Compact tries

The *suffix trie* of a string $T$ contains a node for every distinct substring of $T\#$, where $\# \notin \Sigma$ is a special end marker. The root node is the empty string. For each pair of substrings $(S, Sc)$ of $T$, where $c \in \Sigma$, there is an edge from $S$ to $Sc$ labeled with the character $c$. Each suffix of $T\#$ corresponds to a leaf of the suffix trie.

A *compact suffix trie* of $T$ contains the root, the branching nodes, the leaf nodes, and possibly some other nodes of the suffix trie as *explicit nodes*. Maximal paths that do not contain explicit nodes are replaced by single compact edges, and a fragment of $T$ is used to represent the label of every such edge in $\mathcal{O}(1)$ space. The nodes that are dissolved due to compactification are called *implicit nodes*; an implicit node $u$ can be referred to as a pair $(v, d)$ where $v$ is the nearest explicit descendant of $u$ and $d$ is the distance (number of characters) between $u$ and $v$. The most common example of a compact suffix trie of $T$ is the *suffix tree* of $T$, denoted here as $ST(T)$, in which each maximal branchless path from the suffix trie is replaced by a single compact edge.

▶ **Theorem 9** ([18, 26]). *The suffix tree of a string of length $n$ over an integer alphabet can be constructed in $\mathcal{O}(n)$ time.*

For a node $v$ of a compact suffix trie $\mathcal{T}$ of $T$, the corresponding substring $\bar{v}$ of $T$ is called the *string label* of $v$. Conversely, for a substring (or fragment) $S$ of $T$, its locus in $\mathcal{T}$ is the (explicit or implicit) node $v$ of $\mathcal{T}$ such that $\bar{v} = S$.

The locus in $ST(T)$ of a substring $S$ is denoted as $locus(S)$. For a non-root explicit node $v$ of $ST(T)$, its *suffix link* leads from $v$ to the node $suf(v) = locus(X)$, where $\bar{v} = cX$, $c \in \Sigma$; it is known that $suf(v)$ is then an explicit node. By $ST'(T)$ we denote tree of suffix links in $ST(T)$. The nodes of $ST'(T)$ are the explicit nodes of $ST(T)$ and for each non-root explicit node $v$ of $ST(T)$, in $ST'(T)$ there is an edge connecting node $v$ with node $suf(v)$.

Let $Sq(T) = \{S : S^2 \text{ is a substring of } T\}$. Then the *tree structure* of $CST(T)$ is a compact suffix trie of $T$ that could be obtained from the suffix tree $ST(T)$ by making loci of substrings $Sq(T)$ explicit.

A *weighted ancestor query* on a compact suffix trie $\mathcal{T}$ is given a leaf $\ell$ of $\mathcal{T}$ and a non-negative integer $d$ and asks for the topmost (explicit) ancestor $w$ of $\ell$ such that $|\bar{w}| \geq d$. We denote such a query and its result as $w = WA(\ell, d)$. We use the following offline solution to the problem of answering $WA$ queries.

▶ **Theorem 10** ([28]). *Any $q$ weighted ancestor queries on a compact suffix trie with $\mathcal{O}(n)$ nodes of a length-$n$ string can be answered in $\mathcal{O}(n+q)$ time.*

Data structures for answering weighted ancestor queries with different complexities are known [1, 22], also in the special case of the compact suffix trie being the suffix tree [7, 23].

Let $v$ be a node of a compact suffix trie and $S = \bar{v}$. Then $cv(v)$ is formally defined as

$$cv(v) = \bigcup \{ [i \,..\, i + |S|) : T[i \,..\, i + |S|) = S \}.$$

Moreover, $nov(v)$ equals one plus the number of non-overlapping consecutive occurrences of $S$ in $T$. $CST(T)$ stores the values $cv(v)$ and $nov(v)$ for each explicit node $v$. By $occ(v)$ we further denote the total number of occurrences of $\bar{v}$ in $T$. The values $occ(v)$ for all explicit nodes of a compact suffix trie can be computed bottom-up in linear time, as $occ(v)$ is the number of leaves in the subtree of node $v$. By $ov(v)$ we denote the number of overlapping consecutive occurrences of $\bar{v}$ in $T$. We have $ov(v) + nov(v) = occ(v)$. We use the notations $cv()$, $nov()$, $ov()$ and $occ()$ also for substrings of $T$.

# 3 Construction of the CST

## 3.1 Computing the tree structure

▶ **Lemma 11.** *The tree structure of the CST of a string $T$ of length $n$ over an integer alphabet can be computed in $\mathcal{O}(n)$ time.*

**Proof.** The suffix tree of a string over an integer alphabet can be constructed in $\mathcal{O}(n)$ time (Theorem 9). By Theorem 7, the set $Sq(T)$ of square substring halves, each represented as a fragment of $T$, can be computed in $\mathcal{O}(n)$ time.

The final step is to make all implicit nodes of the suffix tree that correspond to elements of $Sq(T)$ explicit. Let $T[i \,..\, i + 2d)$ be a square substring and $\ell$ be the leaf of the suffix tree of $T$ corresponding to the suffix $T[i \,..\, n]$. Using a weighted ancestor query we can compute a pair $(v, p)$ where $v = WA(\ell, d)$ is the nearest explicit descendant of the locus $u$ of $T[i \,..\, i + d)$ and $p$ is the distance between $u$ and $v$. With Theorem 10 a batch of $\mathcal{O}(n)$ such queries

can be answered in $\mathcal{O}(n)$ time. Finally, we use Radix Sort to sort the pairs $(v, p)$ (under an arbitrary, fixed order on nodes of the suffix tree) in $\mathcal{O}(n)$ time. As a result, the loci of substrings in $Sq(T)$ are grouped by their nearest explicit descendants, and each group is sorted by decreasing depths. This allows to make all the desired implicit nodes explicit in $\mathcal{O}(n)$ time. ◀

## 3.2 Properties of overlapping consecutive occurrences

If a substring $S$ of $T$ does not have overlapping occurrences in $T$, i.e., $ov(S) = 0$, then $cv(S) = nov(S) \cdot |S| = occ(S) \cdot |S|$ is easy to compute. Hence, below we characterize overlapping consecutive occurrences of substrings. To this end, we use runs.

For indices $1 \le i \le j_1 \le j_2 \le n$, we denote the set of fragments corresponding to a path in the suffix tree of $T$:

$$\mathsf{Path}(i, j_1, j_2) = \{T[i\,..\,j] \,:\, j \in [j_1\,..\,j_2]\}.$$

For a run $R = (a, b, p)$ in $T$, we denote

$$\mathsf{Triangle}(R) = \mathsf{Triangle}(a, b, p) = \bigcup_{i=a}^{b-2p} \mathsf{Path}(i, i+p, b-p).$$

Figure 4 gives a graphical motivation for the name of this set of fragments, whereas Figure 5 shows that in some cases the triangle is "wrapped".

The following key combinatorial lemma shows that sets $\mathsf{Triangle}(R)$ for $R \in \mathcal{R}(T)$ are sufficient for counting overlapping consecutive occurrences.

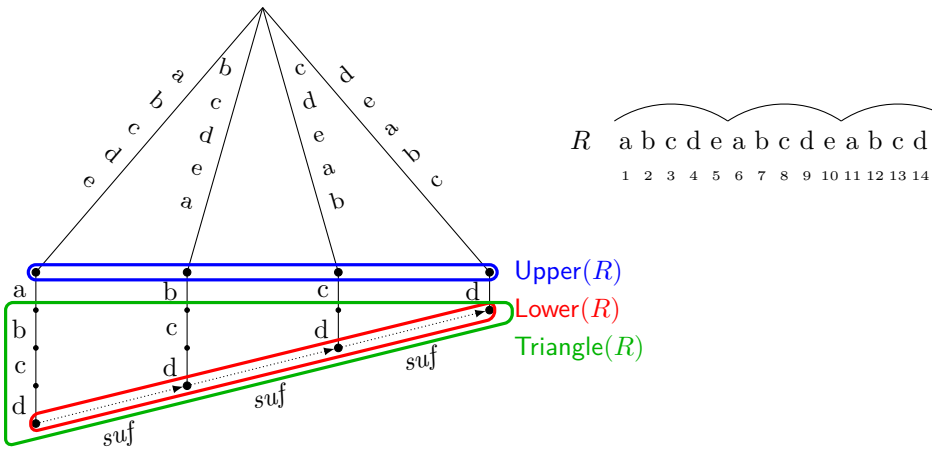

**Figure 4** Illustration of the sets $\mathsf{Triangle}(R)$, $\mathsf{Upper}(R)$ and $\mathsf{Lower}(R)$ on paths in $CST(T)$ for an example run $R = (1, 14, 5)$. All nodes representing fragments from $\mathsf{Triangle}(R)$ are distinct because $exp(R) = 2.8 \le 3$. The nodes in $\mathsf{Upper}(R)$ and $\mathsf{Lower}(R)$ are explicit in $CST(T)$ (see Observation 13).

▶ **Lemma 12.** *Let $S$ be a string of length $d$. Then $S$ has an overlapping consecutive occurrence $(i, j)$ in $T$ for some indices $i$, $j$ if and only if $S$ matches a fragment $T[i\,..\,i+d) \in \mathsf{Triangle}(R)$ for some run $R$ with period $j - i$ in $T$.*

**Proof.** ($\Rightarrow$) If $S$ has an overlapping consecutive occurrence $(i, j)$, then the substring $F = T[i\,..\,j+d)$ has a border $S$, so $F$ has a period $p = j - i < d$.

We further have $|F| = j + d - i > 2(j - i) = 2p$. Period $p$ is the smallest period of $F$; indeed, a period $q \in [1\,..\,p)$ would imply an occurrence $T[i + q\,..\,i + q + d)$ of $S$ at position $i + q$ such that $i < i + q < i + p = j - i$, so $(i, j)$ would not be a consecutive occurrence of $S$.

Finally, fragment $F$ extends to a unique maximal periodic fragment with smallest period $p$; it is a run $R = (a, b, p)$ in $T$. We have $T[i\,..\,i + d) \in \mathsf{Path}(i, i + p, b - p) \subseteq \mathsf{Triangle}(R)$ as $i \in [a\,..\,b - 2p]$.

($\Leftarrow$) Assume that $T[i\,..\,i + d) \in \mathsf{Triangle}(R)$ holds for some run $R = (a, b, p)$ and $S = T[i\,..\,i + d)$. Then $[i\,..\,i + d + p) \subseteq [a\,..\,b]$, so the period of the run implies that $T[i + p\,..\,i + p + d) = T[i\,..\,i + d) = S$. Moreover, $d > p$ by the definition of $\mathsf{Triangle}(R)$, so the two occurrences of $S$ overlap.

Finally, we need to show that $(i, j)$, for $j = i + p$, is a consecutive occurrence of $S$. If there was an occurrence $T[k\,..\,k + d) = S$ with $i < k < j$, then the string $X = T[i\,..\,i + p)$ would have an occurrence in $T[i\,..\,i + 2p) = X^2$ being neither a prefix nor a suffix of $X^2$. String $X$ is primitive, as otherwise the run $R$ would have a period smaller than $p$. Therefore this situation is impossible by the synchronization property (Lemma 6). ◀

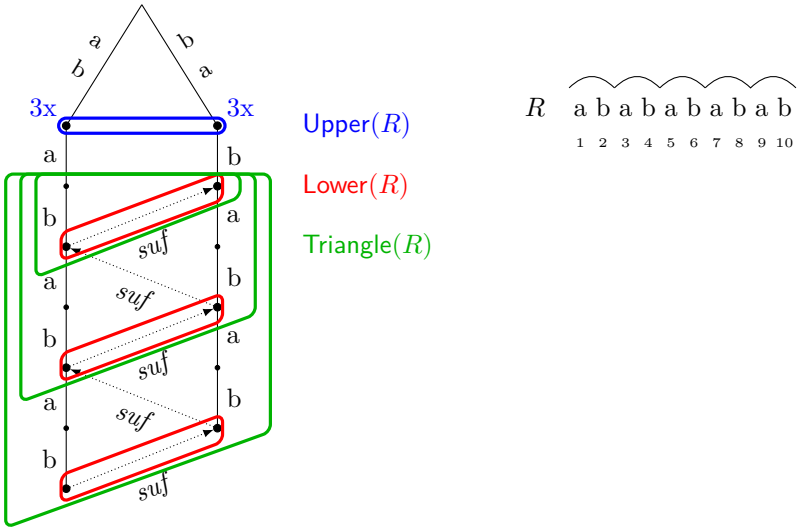

**Figure 5** Illustration of the sets $\mathsf{Triangle}(R)$, $\mathsf{Upper}(R)$ and $\mathsf{Lower}(R)$ on paths in $CST(T)$ for a run $R = (1, 10, 2)$ with exponent 5. The substrings in the set $\mathsf{Triangle}(R)$ form a multiset being the sum of the two trapezia and a triangle. The set $\mathsf{Upper}(R)$ contains six fragments; three of them match substring ab, and the remaining three match ba.

For a run $R = (a, b, p)$, we further denote:

$$\mathsf{Upper}(a, b, p) = \{T[i\,..\,i + p) \,:\, i \in [a\,..\,b - 2p]\}$$
$$\mathsf{Lower}(a, b, p) = \{T[i\,..\,b - p] \,:\, i \in [a\,..\,b - 2p]\}$$

Intuitively, $\mathsf{Lower}(R)$ consists of bottommost endpoints of paths $\mathsf{Path}$ from $\mathsf{Triangle}(R)$ and $\mathsf{Upper}(R)$ consists of parents of topmost endpoints of these paths. Informally, they are the "lower side" and the "excluded upper side" of the triangle; see also Figures 4 and 5. Below we show basic properties of these sets.

▶ **Observation 13.** *Let $R$ be a run in $T$.*

**(a)** *All fragments in $\mathsf{Upper}(R)$ are square halves in $T$.*

**(b)** *The loci of fragments in $\mathsf{Lower}(R)$ are explicit nodes in $ST(T)$.*

**Proof.** (a) By the periodicity of run $R$, each fragment $T[i\,..\,i+p) \in \mathsf{Upper}(R)$ is followed by a matching fragment $T[i+p\,..\,i+2p)$. This is because $i \le b-2p$. Hence, $T[i\,..\,i+2p)$ is indeed a square in $T$.

(b) Let $T[i\,..\,b-p] \in \mathsf{Lower}(R)$ and $c = T[b+1-p]$. The period of the run implies that $T[i\,..\,b-p] = T[i+p\,..\,b]$.

If $T[i\,..\,b-p]$ is a suffix of $T$, its locus in $ST(T)$ is explicit as the locus has children along the characters $c$ and $\#$.

Otherwise, character $c' = T[b+1]$ is different from $c$ by the right maximality of the run $R$. Hence, $T[i\,..\,b-p]c$ and $T[i\,..\,b-p]c'$ are different substrings of $T$, as claimed. ◀

Let us note that if $exp(R) > 3$, then each of the sets $\mathsf{Upper}(R)$, $\mathsf{Triangle}(R)$ may contain matching fragments; see Figure 5.

## 3.3 Counting overlapping consecutive occurrences

For each explicit node $v$ of $CST(T)$, instead of $nov(v)$, we will compute the number $ov(v)$ of overlapping consecutive occurrences of the substring $\bar{v}$ in $T$.

For a set $\mathcal{F}$ of fragments of $T$, we denote by $\#_v(\mathcal{F}) = |\{T[i\,..\,j] \in \mathcal{F} : \bar{v} = T[i\,..\,j]\}|$ the number of fragments in $\mathcal{F}$ that match $\bar{v}$. Lemma 12 implies the following formula for $ov(v)$.

▶ **Observation 14.** *For a node $v$ of $CST(T)$, $ov(v) = \sum_{R\in\mathcal{R}(T)} \#_v(\mathsf{Triangle}(R))$.*

We will show how to efficiently evaluate these formulas for all explicit nodes $v$ simultaneously.

For each explicit node $v$ of $CST(T)$ we will compute two counters:

$$C_{upper}[v] = \sum_{R\in\mathcal{R}(T)} \#_v(\mathsf{Upper}(R)), \quad C_{lower}[v] = \sum_{R\in\mathcal{R}(T)} \#_v(\mathsf{Lower}(R)).$$

That is, $C_{upper}[v]$ ($C_{lower}[v]$) stores the number of times fragments matching the substring $\bar{v}$ occur in $\mathsf{Upper}(R)$ ($\mathsf{Lower}(R)$, respectively) over all runs $R \in \mathcal{R}(T)$.

For an explicit node $v$ of $CST(T)$, by $subtree(v)$ we denote the set of explicit descendants of $v$ in the tree (including $v$). The following lemma shows how to compute $ov$ from the counters $C_{upper}$ and $C_{lower}$. The lemma follows by Observation 14.

▶ **Lemma 15.** *For an explicit node $v$ of the $CST(T)$, we have*

$$ov(v) = \sum_{w\in subtree(v)} (C_{lower}[w] - C_{upper}[w]).$$

**Proof.** If node $x$ is an ancestor of node $y$, by $x \rightsquigarrow y$ we denote the set of explicit nodes on the path from $x$ to $y$. By *root* we denote the root of $CST(T)$. By the definitions of $\mathsf{Triangle}(R)$, $\mathsf{Upper}(R)$ and $\mathsf{Lower}(R)$ and Observation 14, we have:

$$\begin{aligned} ov(v) &= \sum_{R\in\mathcal{R}(T)} \#_v(\mathsf{Triangle}(R)) \\ &= \sum_{(a,p,b)\in\mathcal{R}(T)} \sum_{i=a}^{b-2p} \#_v(\mathsf{Path}(i, i+p, b-p)) \\ &= \sum_{(a,p,b)\in\mathcal{R}(T)} |\{i \in [a\,..\,b-2p] : v \in (locus(T[i\,..\,i+p]) \rightsquigarrow locus(T[i\,..\,b-p]))\}| \end{aligned}$$

$$= \sum_{(a,p,b)\in\mathcal{R}(T)} |\{i \in [a\,..\,b-2p] \,:\, v \in (root \rightsquigarrow locus(T[i\,..\,b-p]))\}|$$
$$- \sum_{(a,p,b)\in\mathcal{R}(T)} |\{i \in [a\,..\,b-2p] \,:\, v \in (root \rightsquigarrow locus(T[i\,..\,i+p))\}|$$
$$= \sum_{R\in\mathcal{R}(T)} \sum_{w\in subtree(v)} \#_w(\mathsf{Lower}(R)) - \sum_{R\in\mathcal{R}(T)} \sum_{w\in subtree(v)} \#_w(\mathsf{Upper}(R))$$
$$= \sum_{w\in subtree(v)} (C_{lower}[w] - C_{upper}[w]).$$ ◀

### 3.3.1 Computing $C_{lower}$ and $C_{upper}$

Let us recall that $ST'(T)$ is the tree of suffix links of $ST(T)$.

▶ **Observation 16.** *For each run $R$ in $T$, $\mathsf{Lower}(R)$ forms a path in $ST'(T)$.*

▶ **Lemma 17.** *The counters $C_{lower}[v]$ for all explicit nodes $v$ of $CST(T)$ can be computed in $\mathcal{O}(n)$ time.*

**Proof.** By the observation, $C_{lower}[v]$ is simply the number of paths $\mathsf{Lower}(R)$ that cover node $v$ in $ST'(T)$ (in particular, no two fragments in a single set $\mathsf{Lower}(R)$ match).

To count paths covering each node in a rooted tree we apply a standard approach using $\pm1$ counters. Initially all counters $C_{lower}[v]$ are equal to 0. For each run $R = (a, b, p) \in \mathcal{R}(T)$, we increment $C_{lower}[v]$ for the bottom endpoint $v$ of the path $\mathsf{Lower}(R)$ ($v = locus(T[a\,..\,b-p])$) and decrement $C_{lower}[u]$ for the parent $u$ in $ST'(T)$ of the top endpoint of $\mathsf{Lower}(R)$ ($u = locus(T[b-2p+1\,..\,b-p])$). In the end for each node $u$ of $ST'(T)$ in a bottom-up order, we add $C_{lower}[v]$ to $C_{lower}[u]$ for all children $v$ of $u$ in $ST'(T)$.

Let us summarize and analyze the complexity of the algorithm. Tree $ST'(T)$ has $\mathcal{O}(n)$ nodes. By Theorem 8, there are at most $n$ paths $\mathsf{Lower}(R)$ and all runs $R$ can be computed in $\mathcal{O}(n)$ time. The endpoints of all paths $\mathsf{Lower}(R)$ can be located in $ST'(T)$ in $\mathcal{O}(n)$ time using weighted ancestor queries in $ST(T)$ (Theorem 10). Finally, the bottom-up traversal of the tree $ST'(T)$ takes $\mathcal{O}(n)$ time. ◀

We proceed to computing counters $C_{upper}$. Let us define an operation *rot* such that $rot(cX) = Xc$ for a string $X$ and character $c \in \Sigma$. For $k \in \mathbb{Z}_{\geq 0}$, by $rot^k(S)$ we denote the composition of *rot* $k$ times. If $S' = rot^k(S)$ for some strings $S, S'$ and $k \in \mathbb{Z}_{\geq 0}$, we say that $S'$ is a *cyclic rotation* of $S$. We also say that $S$ and $S'$ are *cyclically equivalent*.

For each run $R$ in $T$, the strings in $\mathsf{Upper}(R)$ are cyclic rotations of each other. This motivates introduction of the following directed graph $G = (V, E)$. The set of vertices is $V = Sq(T)$ and the arcs are defined as follows: $(S, S') \in E$ if and only if $S, S' \in V$ and $S' = rot(S)$. Instead of addressing vertices of $G$ by substrings of $T$, we will address them by their loci in $CST(T)$ which are explicit nodes of $CST(V)$.

▶ **Observation 18.** *For each run $R$ in $T$, $\mathsf{Upper}(R)$ corresponds to a (directed) walk in $G$.*

Let us note that the vertices (and arcs) on the walk $\mathsf{Upper}(R)$ may repeat if $exp(R) > 3$ (see Figure 5 again). In particular, in this case $\mathsf{Upper}(R)$ is contained in a cycle in $G$.

We proceed to the construction of graph $G$. More precisely, a sufficient subset of arcs of $G$ is constructed.

▶ **Lemma 19.** *A subset $E'$ of $E$ containing all arcs that belong to any walk $\mathsf{Upper}(R)$, for $R \in \mathcal{R}(T)$, can be constructed in $\mathcal{O}(n)$ time.*

**Proof.** For each distinct square substring $T[i\,..\,i+2d)$ of $T$, we insert into $E'$ an arc from $\mathit{locus}(T[i\,..\,i+d))$ to $\mathit{locus}(T[i+1\,..\,i+d])$ if $T[i+1\,..\,i+d] \in Sq(T)$; the latter condition can be checked from the construction of the tree structure of $CST(T)$ (Lemma 11). By Theorem 7, square substrings of $T$ can be enumerated in $\mathcal{O}(n)$ time. Then we use off-line weighted ancestor queries (Theorem 10) on $CST(T)$ to find the desired loci. This concludes that the time complexity is $\mathcal{O}(n)$. Now let us argue for the correctness of this algorithm in two steps.

Why $E' \subseteq E$: When adding an arc from $\mathit{locus}(T[i\,..\,i+d))$ to $\mathit{locus}(T[i+1\,..\,i+d])$, we know that $T[i\,..\,i+d) \in Sq(T)$ and we check if $T[i+1\,..\,i+d] \in Sq(T)$. Hence, an arc connects two vertices of $V = Sq(T)$. Finally, we have $\mathit{rot}(T[i\,..\,i+d)) = T[i+1\,..\,i+d]$ because $T[i\,..\,i+2d)$ is a square. Consequently, $E' \subseteq E$.

Why all arcs that belong to any walk $\mathsf{Upper}(R)$ are in $E'$: Let $T[i\,..\,i+p), T[i+1\,..\,i+p] \in \mathsf{Upper}(a,b,p)$ be two consecutive elements. Then $a \le i < b-2p$, so $T[i\,..\,i+2p)$ is a square. Therefore, $(\mathit{locus}(T[i\,..\,i+p)), \mathit{locus}(T[i+1\,..\,i+p])) \in E'$ by definition. ◀

In the lemma above, it can be the case that $E' \subsetneq E$ if there are two substrings $S, S' \in Sq(T)$ such that $S' = \mathit{rot}(S)$ but there are no two fragments $T[i\,..\,i+|S|)$, $T[i+1\,..\,i+1+|S|)$ matching $S$ and $S'$, respectively. Moreover, it can happen that $E'$ contains an arc that does not belong to any walk $\mathsf{Upper}(R)$. Indeed, when an arc from $\mathit{locus}(T[i\,..\,i+d))$ to $\mathit{locus}(T[i+1\,..\,i+d])$ is added to $E'$, we avoid the unnecessary check if $T[i\,..\,i+d), T[i+1\,..\,i+d]$ belong to a set $\mathsf{Upper}(R)$ for any run $R$.

▶ **Lemma 20.** *The counters $C_{upper}[v]$ for all explicit nodes $v$ of $CST(T)$ can be computed in $\mathcal{O}(n)$ time.*

**Proof.** By Observation 18, $C_{upper}[v]$ is the total number of times that walks $\mathsf{Upper}(R)$ visit the node $v \in V$. We will be able to compute these counters efficiently using the fact that graph $G$ has a particularly simple structure: it is a collection of disjoint cycles and paths. The same applies to the graph $G' = (V, E')$ that is computed in Lemma 19. For a node $u$, by $\mathit{next}(u)$ we denote the unique node $v$ such that $(u, v) \in E'$, and $\perp$ if no such node exists.

We can find all cycles in $G'$ using the DFS. Then we apply an algorithm using $\pm 1$ counters (as in the proof of Lemma 17) and additional counters $C'$ assigned to cycles. Initially all counters are equal to 0. For each cycle $Q$, let us order the nodes $v_1, \ldots, v_{|Q|} \in Q$ along the cycle (arbitrarily) and assign them consecutive id numbers $\mathit{id}(v_i) = i$.

For each walk $\mathsf{Upper}(R)$, $R = (a, b, p) \in \mathcal{R}(T)$, we check if its endpoints $v_1$ and $v_2$ ($v_1 = \mathit{locus}(T[a\,..\,a+p))$ and $v_2 = \mathit{locus}(T[b-2p\,..\,b-p))$) belong to a cycle. If not, we increment $C_{upper}[v_1]$; we also decrement $C_{upper}[\mathit{next}(v_2)]$ if $\mathit{next}(v_2) \neq \perp$. Otherwise, if $v_1, v_2$ belong to a cycle $Q$, we increase the cycle counter $C'[Q]$ by $\lfloor\, |\mathsf{Upper}(R)| \,/\, |Q| \,\rfloor$. Moreover (for $v_1, v_2 \in Q$), if $\mathit{id}(v_1) \le \mathit{id}(v_2)$, we increment $C_{upper}[v_1]$ and decrement $C_{upper}[\mathit{next}(v_2)]$ if $\mathit{id}(v_2) < |Q|$. If, however, $\mathit{id}(v_1) > \mathit{id}(v_2)$, we increment $C_{upper}[v_1]$ and $C_{upper}(u)$ for the node $u \in Q$ with $\mathit{id}(u) = 1$ and decrement $C_{upper}[\mathit{next}(v_2)]$, thus "breaking the cyclicity".

For each cycle $Q$, let us remove the arc $(v, \mathit{next}(v))$ for vertex $v \in Q$ such that $\mathit{id}(v) = |Q|$. This way $G'$ becomes acyclic; it can be viewed as a forest in which each tree is a path. For each node $v$ of the modified graph $G'$ in topological order, we add $C_{upper}[v]$ to $C_{upper}[\mathit{next}(v)]$ if $\mathit{next}(v) \neq \perp$. Finally, for each original cycle $Q$ in $G'$, we increase $C_{upper}[v]$ for all vertices $v \in Q$ by the counter $C'[Q]$. This way we have computed all the counters $C_{upper}$ as desired.

Let us analyze the complexity. By Lemma 19, graph $G' = (V, E')$ can be constructed in $\mathcal{O}(n)$ time. By Theorem 8, there are at most $n$ paths $\mathsf{Upper}(R)$ and all runs $R$ can be computed in $\mathcal{O}(n)$ time. The endpoints of walks $\mathsf{Upper}(R)$ can be located in $G'$ in $\mathcal{O}(n)$ time using weighted ancestor queries in $CST(T)$ (Theorem 10). Finally, the computation of counters via DFS and topological ordering takes $\mathcal{O}(n)$ time. ◀

This concludes efficient computation of the numbers of overlapping and non-overlapping consecutive occurrences.

▶ **Lemma 21.** *Values $ov(v)$ and $nov(v)$ for all explicit nodes $v$ of $CST(T)$ can be computed in $\mathcal{O}(n)$ time.*

**Proof.** We compute the counters $C_{lower}$ and $C_{upper}$ using Lemmas 17 and 20, respectively. By the formula from Lemma 15, for each node $v$ of $CST(T)$ in the bottom-up order, $ov(v)$ can be computed as a sum of $C_{lower}[v] - C_{upper}[v]$ and the sum of values $ov(w)$ for all explicit children $w$ of $v$. Such values can be computed via a bottom-up traversal in $\mathcal{O}(n)$ time.

Finally we recall that $nov(v) = occ(v) - ov(v)$ and that $occ(v)$ for all explicit nodes of $CST(T)$ can be easily computed in $\mathcal{O}(n)$ time bottom-up. ◀

## 3.4 Computing coverage

For a substring $S$ of $T$, we introduce the following notations:

$$cv\_ov(S) = \sum_{(i,j)\in OvOcc(S)} (j-i), \quad cv\_nov(S) = nov(S)\cdot|S|.$$

As before, we denote $cv\_ov(v) = cv\_ov(\bar{v})$ and $cv\_nov(v) = cv\_nov(\bar{v})$ for nodes $v$ of $CST(T)$. The proof of the following observation provides intuition on these definitions.

▶ **Observation 22.** *For every substring $S$ of $T$, $cv(S) = cv\_ov(S) + cv\_nov(S)$.*

**Proof.** Let us assign each position $k$ of $T$ that is covered by an occurrence of $S$ to the rightmost occurrence $T[i\,..\,i+|S|)$ of $S$ with $i < k$. Let $j$ be the next occurrence of $S$ to the right of position $i$ (then $j > k$), if any. If $j$ exists and $(i,j) \in OvOcc(S)$, then position $k$ is counted in $cv\_ov(S)$. Otherwise position $k$ is counted in $cv\_nov(S)$. ◀

Values $cv\_nov(v)$ for explicit nodes $v$ of $CST(T)$ can be easily computed using values $nov(v)$ computed in Lemma 21. Lemma 12 yields the following formula for $cv\_ov(v)$.

▶ **Observation 23.** *For a node $v$ of $CST(T)$, $cv\_ov(v) = \sum_{R\in\mathcal{R}(T)} \#_v(\mathsf{Triangle}(R))\cdot per(R)$.*

Now $cv\_ov$ values can be computed similarly as $ov$ values were computed in Section 3.3. We just need to multiply counter updates by periods of respective runs.

▶ **Lemma 24.** *The values $cv\_ov(v)$ for all explicit nodes $v$ of $CST(T)$ can be computed in $\mathcal{O}(n)$ time.*

**Proof.** Let

$$C'_{upper}[v] = \sum_{R\in\mathcal{R}(T)} \#_v(\mathsf{Upper}(R))\cdot per(R), \quad C'_{lower}[v] = \sum_{R\in\mathcal{R}(T)} \#_v(\mathsf{Lower}(R))\cdot per(R).$$

Following the proof of Lemma 15 it can be readily verified that for every explicit node $v$,

$$cv\_ov(v) = \sum_{w\in subtree(v)} (C'_{lower}[w] - C'_{upper}[w]).$$

The counters $C'_{lower}[v]$ ($C'_{upper}[v]$) for all explicit nodes can be computed as in Lemma 17 (Lemma 20, respectively), where instead of $\pm1$ counters, for each path $\mathsf{Lower}(R)$ (walk $\mathsf{Upper}(R)$, respectively), $R \in \mathcal{R}(T)$, we add and subtract $per(R)$ in the respective nodes (and increase cycle counters $C'[Q]$ by amounts $\lfloor\, |\mathsf{Upper}(R)|\,/\,|Q|\,\rfloor \cdot per(R)$). ◀

This concludes the construction of $CST(T)$.

▶ **Theorem 1.** *The Cover Suffix Tree (CST) of a string of length $n$ over an integer alphabet can be constructed in $\mathcal{O}(n)$ time.*

**Proof.** Lemma 11 can be used to construct the tree structure of $CST(T)$. We compute $occ(v)$ for all explicit nodes of $CST(T)$ in a bottom-up traversal and $ov(v)$ using Lemma 21, which lets us compute $nov(v) = occ(v) - ov(v)$ for all explicit nodes. Then for all explicit nodes we compute $cv\_ov(v)$ using Lemma 24, which lets us compute $cv(v)$ for all explicit nodes using values $cv\_nov(v)$ that, in turn, depend on $nov(v)$. Each of the lemmas, as well as the bottom-up processing, requires $\mathcal{O}(n)$ time. ◀

## 4 Solution to AllPartialCovers

An $\mathcal{O}(n \log n)$-time solution to AllPartialCovers from [29] is based on computing the upper envelope of $\mathcal{O}(n)$ line segments, each connecting points $(|v|, cv(v))$ and $(|v| - k, cv(v) - k \cdot nov(v))$ constructed for an edge of $CST(T)$ from $v$ to its parent $v'$ containing $k$ implicit nodes. An upper envelope of $\mathcal{O}(n)$ line segments can be computed in $\mathcal{O}(n \log n)$ time [24].

We show that the AllPartialCovers problem can be solved in $\mathcal{O}(n)$ time using the following observation. A substring $C$ of $T$ is called *branching* if the locus of $C$ in $ST(T)$ is a branching node.

▶ **Lemma 25.** *If $C$ is a substring of $T$, then there is a substring $C'$ of $T$ such that $|C'| = |C|$, $cv(C') \geq cv(C)$ and $C'$ is branching or a suffix of $T$.*

**Proof.** Let $C_0 = C$. If $C_0$ is branching or $C_0$ is a suffix of $T$, we are done. Otherwise, all occurrences of $C_0$ in $T$ are followed by the same character. Let $a$ be this character, $X$ be $C$ without its first character, and $C_1 = Xa$. We have $|C_1| = |C_0|$ and $cv(C_1) \geq cv(C_0)$. We use this construction to obtain substrings $C_1, C_2, \ldots$ The sequence ends at the first substring that is branching or a suffix of $T$; such a substring exists since the rightmost occurrence of $C_i$ in $T$, for $i \geq 1$, is located to the right of the rightmost occurrence of $C_{i-1}$ in $T$. Let $C_k$, for $k \geq 1$, be the last substring in this sequence. By the construction, $|C_k| = |C_0| = |C|$, $cv(C_k) \geq cv(C)$ and $C_k$ is branching or a suffix of $T$. We choose $C' = C_k$. ◀

By the lemma, in the solution to AllPartialCovers it suffices to iterate over all suffixes of $T$ and branching nodes of $ST(T)$. We obtain the following result that was already stated in Section 1.

**Algorithm 1** Solution to AllPartialCovers.

```
for i := 1 to n do shortest[n − i + 1] := T[i . . n];
foreach branching node v of ST(T) do
    if |v̄| < |shortest[cv(v)]| then
        shortest[cv(v)] := v̄;
for i := n − 1 down to 1 do
    if |shortest[i]| > |shortest[i + 1]| then
        shortest[i] := shortest[i + 1];
```

▶ **Theorem 4.** *AllPartialCovers problem can be solved in $\mathcal{O}(n)$ time for a length-$n$ string over an integer alphabet.*

**Proof.** We apply Algorithm 1. Clearly, the algorithm works in $\mathcal{O}(n)$ time. Let us argue for its correctness.

In the algorithm an auxiliary array *shortest* is used that stores fragments of $T$ represented in $\mathcal{O}(1)$ space each. By Lemma 25, after the foreach-loop, $shortest[\alpha] = C$ for $\alpha \in [1\,..\,n]$ if $C$ is a shortest substring of $T$ such that $cv(C) = \alpha$. At the end, $shortest[\alpha] = C$ if $C$ is a shortest substring of $T$ such that $cv(C) \geq \alpha$. Hence, $shortest[\alpha]$ is a shortest $\alpha$-partial cover of $T$ by definition. ◀

## 5 Conclusions

We have designed the first linear-time algorithm computing the Cover Suffix Tree. We have shown several applications of this result, some of which follow directly from previous work. Experimental comparison of our algorithms for computing the Cover Suffix Tree and the set of seeds in a string with implementations of existing methods from [16] is left as future work.

It remains an open problem if our approach can help to improve upon the $\mathcal{O}(n \log n)$-time algorithm of Brodal et al. [11] for constructing MAST.

# Simultaneous Representation of Interval Graphs in the Sunflower Case

**Ignaz Rutter**
Faculty of Computer Science and Mathematics, University of Passau, Germany

**Peter Stumpf**
Faculty of Computer Science and Mathematics, University of Passau, Germany

## Abstract

A simultaneous representation of (vertex-labeled) graphs $G_1, \ldots, G_k$ consists of a (geometric) intersection representation $R_i$ for each graph $G_i$ such that each vertex $v$ is represented by the same geometric object in each $R_i$ for which $G_i$ contains $v$. While Jampani and Lubiw showed that the existence of simultaneous interval representations for $k = 2$ can be tested efficiently (2010), testing it for graphs where $k$ is part of the input is NP-complete (Bok and Jedličková, 2018). An important special case of simultaneous representations is the *sunflower case*, where $G_i \cap G_j = (V(G_i) \cap V(G_j), E(G_i) \cap E(G_j))$ is the same graph for each $i \neq j$. We give an $O(\sum_{i=1}^{k}(|V(G_i)| + |E(G_i)|))$-time algorithm for deciding the existence of a simultaneous interval representation for the sunflower case, even when $k$ is part of the input. This answers an open question of Jampani and Lubiw.

## 1 Introduction

For a family of geometric objects, the *intersection graph* is a graph that has for each object a vertex such that two vertices are adjacent if and only if their objects intersect. Its *representation* is the assignment of the objects to the vertices. In this paper, we consider *interval representations*, which are assignments of intervals on the real line to the vertices of a graph $G$ such that two vertices of $G$ are adjacent if and only if their intervals intersect. Graph $G$ is an *interval graph* if it has such a representation; see Figure 1.

A fundamental problem in the area of intersection graphs is the *recognition* problem, where the task is to decide whether a given graph $G$ admits a particular type of (geometric) intersection representation. The simultaneous representation problem is a generalization of the recognition problem that asks for $k$ input graphs $G_1, \ldots, G_k$ (with vertex labels) whether there exist corresponding representations $R_1, \ldots, R_k$ such that each vertex $v$ that is shared by two graphs $G_i$ and $G_j$ is represented by the same geometric object in $R_i$ and in $R_j$. For ease of notation, we refer to $\mathcal{G} = (G_1, \ldots, G_k)$ as a *simultaneous graph*, and

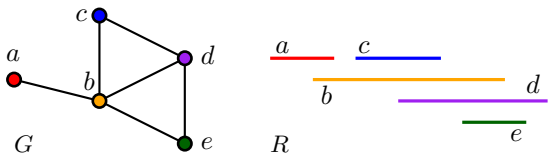

**Figure 1** An interval graph $G$, and an interval representation $R$ of $G$. A valid clique ordering is $\{a, b\}, \{c, b, d\}, \{b, d, e\}$.

to $\mathcal{R} = (R_1, \ldots, R_k)$ as a *simultaneous representation*. For two graphs $G$, $H$ we define the *intersection* $G \cap H = (V(G) \cap V(H), E(G) \cap E(H))$. A *sunflower* simultaneous graph is a simultaneous graph $\mathcal{G} = (G_1, \ldots, G_k)$ where $G_1, \ldots, G_k$ have pairwise the same intersection, i.e., there is a graph $S$ with $S = G_i \cap G_j$ for each $i \neq j$. We call $S$ the *shared graph* of $\mathcal{G}$.

Simultaneous representations have first been studied in the context of graph embeddings where also shared edges have to be represented by the same arc; see [3] for a survey. The notion of simultaneous representations of general intersection graph classes was introduced by Jampani and Lubiw, who gave an $O(n^3)$-algorithm for recognizing simultaneous sunflower permutation graphs (where $n$ is the number of vertices in $G_1 \cup \cdots \cup G_k$) [17], proved NP-completeness for sunflower chordal graphs (as intersection graphs of subtrees of a tree) [17], and gave an $O(n^2 \log n)$-time algorithm for simultaneous interval graphs with $k = 2$ [15]. They left the case $k > 2$ open. The running times of all these algorithms were subsequently reduced to optimal linear time (assuming each input graph is given separately, thus counting the shared graph $k$ times, and assuming that each input graph belongs to the corresponding class) [4, 19].

Since then, the simultaneous representation problem has also been studied for proper and unit interval graphs [20], circle graphs [8] and permutation graphs [17, 19] where $k$ is part of the input. Bok and Jedličková showed that recognizing simultaneous non-sunflower interval graphs is NP-complete [5] if $k$ is part of the input. Similar results hold for simultaneous proper and unit interval representations [20].

A problem closely related to the (sunflower) simultaneous representation problem is *partial representation extension*, where a representation $R$ of a subgraph $H$ of a single input graph $G$ is given, and the question is, whether $G$ has a representation whose restriction to $H$ coincides with $R$. It has been studied extensively for various graph classes, e.g. for interval graphs [18], circular-arc graphs [10], circle graphs [8, 19], as well as proper and unit interval graphs [18]. Bläsius and Rutter gave a linear-time reduction from the partial interval representation problem to the simultaneous interval representation problem on two graphs [4].

We characterize sunflower simultaneous interval graphs in terms of linear orderings of maximal cliques that satisfy certain consecutivity constrains. This allows us to work with an established data structure called *PQ-tree*, which represents linear orderings satisfying given consecutivity constraints. The algorithms of Jampani and Lubiw [15] and Bläsius and Rutter [4] for recognizing simultaneous interval graphs with $k = 2$ input graphs use a similar characterization and they also use PQ-trees. Jampani and Lubiw iteratively add non-maximal cliques to orders of maximal cliques and associate nodes of distinct PQ-trees to achieve necessary compatibilities. On the other hand, Bläsius and Rutter synchronize a PQ-tree $T$ that describes orderings of maximal cliques of both input graphs with two PQ-trees $T_1$, $T_2$ for the two individual input graphs. To this end, they construct PQ-trees for many nodes of $T$ and a 2-SAT formula which describes dependencies between decisions in these trees. While they establish a more general framework for *simultaneous PQ-orderings*, their approach does not work for more than two input graphs for sunflower simultaneous interval graph recognition.

**Our Result.** We show how to recognize sunflower simultaneous interval graphs in linear time (assuming the input graphs are given separately) even when the number of input graphs is part of the input, thereby answering the open question of Jampani and Lubiw [16]. We note that, similar to Bläsius and Rutter, we use a PQ-tree $T$ that describes orderings of the maximal cliques of the input graphs, synchronize it with PQ-trees for the individual

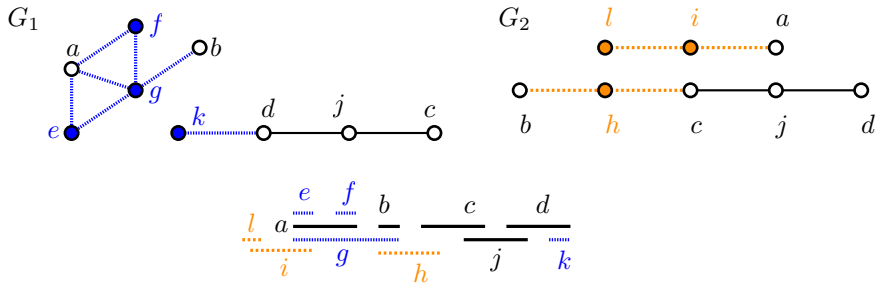

**Figure 2** A simultaneous graph $\mathcal{G} = (G_1, G_2)$ with a simultaneous interval representation of $\mathcal{G}$.

input graphs, and use a 2-SAT formula to describe dependencies between decisions in these PQ-trees. However, with each operation, they only synchronize pairs of PQ-trees while, in a sense, we synchronize multiple PQ-trees at once. Further, we essentially only construct a single PQ-tree for the synchronization, instead of one for potentially each node of $T$, which can be linear in the size of the input. For our construction, we exploit a close relation between consecutivity constraints and certain substructures in PQ-trees (Lemma 5) that provides a converse for a natural and widely used property of PQ-trees and may be of independent interest.

**Organization.** In Section 2, we characterize sunflower interval graphs in terms of linear orderings of maximal cliques and we describe PQ-trees. In Section 3, we describe operations on PQ-trees and dependencies between decisions in the original and resulting PQ-trees. In Section 4, we describe our construction, characterize sunflower interval graphs in terms of this construction, and give the linear-time algorithm for the sunflower interval representation problem. In Section 5 we conclude with open questions.

## 2 Preliminaries

For $n \in \mathbb{N}$ we set $[n] = \{j \in \mathbb{N} \mid 1 \leq j \leq n\}$. In this paper all graphs are simple.

**Simultaneous Interval Graphs.** An *interval representation* $R = \{I_v\}_{v \in V}$ of a graph $G = (V, E)$ associates with each vertex $v \in V$ an interval $I_v = [x, y] \subseteq \mathbb{R}$ such that for each pair of vertices $u, v \in V$ we have $I_u \cap I_v \neq \emptyset \Leftrightarrow uv \in E$; see Figure 1. A *simultaneous interval representation* of a simultaneous graph $\mathcal{G} = (G_1, \ldots, G_k)$ assigns each vertex $v \in \bigcup_{i=1}^{k} V(G_i)$ an interval $I_v$ such that the *induced* interval representation $\{I_v\}_{v \in V(G_i)}$ is an interval representation of $G_i$, for each $i \in [k]$; see Figure 2. In the following we only consider *sunflower simultaneous graphs* $\mathcal{G} = (G_1, \ldots, G_k)$ which are simultaneous graphs for which there is a graph $S$ such that $G_i \cap G_j = S$ for $i \neq j$. Note that it is necessary that $S$ is an induced subgraph of each input graph $G_i$ for $\mathcal{G}$ to be a simultaneous interval graph. We call $S$ the *shared graph* of $\mathcal{G}$.

It is well known that interval graphs can be characterized via orderings of maximal cliques. *A valid clique ordering* of $G$ is a linear ordering of the maximal cliques of $G$ such that for each $v \in V(G)$ the maximal cliques of $G$ that contain $v$ are consecutive.

▶ **Proposition 1** (Fulkerson and Gross [12]). *A graph is an interval graph if and only if it admits a valid clique ordering.*

Let $\mathcal{G} = (G_1, \dots, G_k)$ be a sunflower simultaneous graph with shared graph $S$. For $i \in [k]$, let $\mathcal{K}_i$ denote the set of maximal cliques of $G_i$ and let $\mathcal{K} = \dot{\bigcup}_{i=1}^{k} \mathcal{K}_i$. Note that we use the disjoint union since we want to treat the maximal cliques of the input graphs separately, even if they coincide with maximal cliques of other input graphs. I.e., each clique in $\mathcal{K}$ is tagged with the input graph $G_i$ it comes from. For a vertex $v \in V(G_i)$, we define $\mathcal{K}_i(v) = \{C \in \mathcal{K}_i \mid v \in C\}$ as the set of all maximal cliques of $G_i$ that contain $v$ and for $v \in V(S)$, we define $\mathcal{K}(v) = \{C \in \mathcal{K} \mid v \in C\}$ as the (multi)-set of all maximal cliques of $G_1, \dots, G_k$ that contain $v$. We further define $\mathcal{K}(S)$ as the set of maximal cliques in the shared graph $S$. A *simultaneous clique ordering* of $\mathcal{G}$ is a linear ordering $\sigma$ of $\mathcal{K}$ such that the following two properties hold:

▶ **Property 1.** *For each $v \in V(S)$ the set $\mathcal{K}(v)$ is consecutive.*

▶ **Property 2.** *The restriction of $\sigma$ to $\mathcal{K}_i$ is a valid clique ordering of $G_i$ for each $i \in [k]$.*

The following theorem provides a combinatorial description of sunflower interval graphs which we will use for our algorithm.

▶ **Theorem 2.** *A sunflower simultaneous graph $\mathcal{G}$ is a simultaneous interval graph if and only if it admits a simultaneous clique ordering.*

**Proof.** If $\mathcal{G} = (G_1, \dots, G_k)$ is a simultaneous interval graph, then it has a simultaneous interval representation. For $i \in [k]$, we choose a point $p_C$ for each clique $C \in \mathcal{K}_i$ such that all intervals for $C$ contain $p_C$ and no interval for vertices in $V(G_i) \setminus C$ contains $p_C$. Such a point must exist since intervals have the Helly property and $C$ is maximal in $G_i$. We call these points *clique points*. Then for each $v \in V(S)$ the clique points in the interval $R(v)$ of $v$ are consecutive and exactly the cliques in $\mathcal{K}(v)$. Note that Property 1 does not necessarily hold for non-shared vertices. However, for each input graph $G_i$ the clique points are placed according to the induced representation of $G_i$ and thus provide a clique ordering of $G_i$.

On the other hand, given a simultaneous clique ordering $\sigma$ for $\mathcal{G}$, we construct an interval representation of $\mathcal{G}$ as follows. We first place distinct (clique) points for the maximal cliques in $\mathcal{K}$ on the real line in the order of $\sigma$ from the left to the right. We then set for each vertex $v \in V$ its interval $R(v)$ to $[\ell(v), r(v)]$ where $\ell(v)$ and $r(v)$ are the leftmost point and the rightmost point for cliques containing $v$, respectively. We claim that the clique points and the consecutivity constraints then enforce correct adjacencies. Namely, two vertices $u$, $v$ of the same input graph $G_i$ have intersecting intervals $R(u)$, $R(v)$ if and only if those intervals share a clique point. It remains to show that $R(u)$, $R(v)$ share a clique point if and only if $u, v$ are adjacent. First observe that if $u$, $v$ are adjacent, then there is some maximal clique containing both and its clique point is contained in $R(u)$ and $R(v)$ by Properties 1, 2.

For the other direction, let $R(u), R(v)$ share a clique point. We aim to show that there is a clique containing $u$ and $v$, which implies that $u$ and $v$ are adjacent, concluding the proof. Since $R(u), R(v)$ share a clique point, one of the intervals, lets say $R(u)$, contains an endpoint of the other one. That endpoint $p$ is a clique point for a clique $C_p \in \mathcal{K}_i(v)$ by definition of $R(v)$. If $v \notin V(S)$, then $C_p$ is a clique in $G_i$ that also contains $u$ by Property 2. We can argue analogously if $R(v)$ contains an endpoint of $R(u)$ and $u \notin V(S)$. If both $u$ and $v$ lie in $V(S)$, then $C_p$ contains $u$ and $v$ by Property 1. Finally, consider the case where $u \notin V(S)$, $v \in V(S)$ and $R(v)$ contains no end of $R(u)$, meaning that $R(v) \subseteq R(u)$. Since $S$ has a maximal clique $C_v$ containing $v$ and $G_i$ has a maximal clique $C'_v$ containing $C_v, R(v)$ must contain a clique point for $C'_v$ and thus $u$ and $v$ are contained in clique $C'_v$. ◀

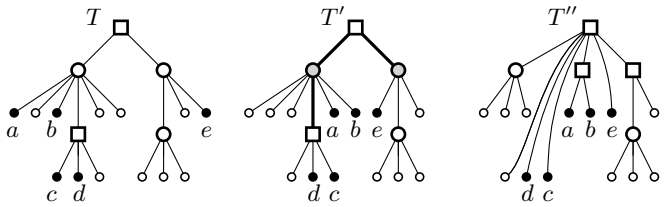

**Figure 3** A PQ-tree $T$, an equivalent PQ-tree $T'$ where the leaves $a, b, c, d, e$ are consecutive, and a reduction $T''$ of $T$ with $\{a, b, c, d, e\}$ (introduced in Section 3). We depict P-nodes as circles and squares as Q-nodes. $T''$ can be obtained from $T'$ by merging the nodes along the thick path after splitting the gray P-nodes. This results in nodes with only two children, which we consider as Q-nodes.

**PQ-Trees.** Let $L$ be a set and let $L' \subseteq L$. The ordering $\leq'$ of $L'$ is *induced* by a linear ordering $\leq$ of $L$, if we have $a \leq' b \Leftrightarrow a \leq b$ for all $a, b \in L'$. A *PQ-tree* is a data structure that represents linear orderings satisfying a set of consecutivity constraints [6]. Formally, a PQ-tree $T$ on a set $L$ of leaves is a rooted ordered tree where each inner node is either a *P-node* or a *Q-node*; see Figure 3. The order of its leaves is the order induced by a preorder traversal of the tree. A PQ-tree $T'$ is *equivalent* to $T$ if $T'$ can be obtained from $T$ by arbitrarily reordering the children of P-nodes and by reversing the order of the children of any subset of Q-nodes. Note that reversing the order of the children of a Q-node $\lambda$ does not change the order of the children of any child of $\lambda$. In this paper, we consider P-nodes with only two children as Q-nodes. Note that this does not affect which PQ-trees are equivalent. For each inner node $\mu$ we say we *flip* $\mu$, if we reverse the order of its children.

A PQ-tree *represents* a linear ordering $\leq$ of $L$ if $\leq$ is the order of the leaves of some equivalent PQ-tree. We write $R(T)$ for all linear orderings of $L$ represented by $T$. The *null-tree* is defined as a special PQ-tree $T_\emptyset$ with $R(T_\emptyset) = \emptyset$. For an inner node $\mu$ of a PQ-tree, let $L(\mu)$ denote the leaves of the subtree rooted at $\mu$. For a leaf $\mu$ let $L(\mu) = \{\mu\}$. We denote the lowest common ancestor of a set $N \subseteq V(T)$ by $\mathrm{lca}_T(N)$. We say that a node $\nu$ of $T$ is left of a node $\lambda$ in $t$ if $\nu$ comes before $\lambda$ in a preorder traversal. However, the order of a node and one of its ancestors will never be relevant in this paper.

## 3 Operations on PQ-Trees

By Theorem 2, we can recognize sunflower simultaneous interval graphs by testing the existence of a simultaneous clique ordering. We use PQ-trees to describe clique orderings that satisfy the properties of a simultaneous clique ordering. Namely, we use a PQ-tree $T$ with leaf set $\mathcal{K}$ to describe all linear orderings satisfying Property 1 and PQ-trees $T'_1, \ldots, T'_k$ where each $T'_i$ represents all valid clique orderings of $G_i$. A simultaneous clique ordering is then a linear ordering $\sigma \in R(T)$ that induces orderings in $R(T'_1), \ldots, R(T'_k)$.

To find such a linear ordering $\sigma$, we "synchronize" these PQ-trees. One step will be to construct a PQ-tree $T_S$ on $\mathcal{K}(S)$ that describes the maximal clique orderings of $S$ that are in some sense compatible with the linear orderings in $R(T'_1), \ldots, R(T'_k)$. Another aspect is to describe the dependencies between decisions at Q-nodes in all constructed PQ-trees.

**Consistency and Backward-Consistency.** We say that an ordered pair of leaves $(\lambda_1, \lambda_2)$ is *forward directed* if $\lambda_1$ comes before $\lambda_2$ in the leaf ordering of the PQ-tree. Otherwise, we call it *backward directed*. Hence, a pair of leaves is either forward directed or backward directed. Note that the corresponding children $\nu_1$, $\nu_2$ of $\mathrm{lca}(\lambda_1, \lambda_2)$ with $\lambda_1 \in L(\nu_1)$ and $\lambda_2 \in L(\nu_2)$

are ordered the same way as $\lambda_1$, $\lambda_2$. Hence, if $\mu$ is a Q-node, flipping $\mu$ changes the order of $\lambda_1$, $\lambda_2$. Let $T_1$, $T_2$ be two PQ-trees on sets $L_1$, $L_2$ with $L_1 \subseteq L_2$ and let $\mu_1$, $\mu_2$ be two Q-nodes in $T_1$, $T_2$ such that there are two leaves $\hat{\lambda}_1$, $\hat{\lambda}_2$ whose order is affected by flipping $\mu_1$ or $\mu_2$, respectively. More formally, let $\mu_1$ be a Q-node in $T_1$ with children $\nu_1^1$, $\nu_2^1$ and let $\mu_2$ be a Q-node in $T_2$ with children $\nu_1^2$, $\nu_2^2$, such that there exist two leaves $\hat{\lambda}_1 \in L(\nu_1^1) \cap L(\nu_1^2)$ and $\hat{\lambda}_2 \in L(\nu_2^1) \cap L(\nu_2^2)$.

We say $\mu_1$ and $\mu_2$ are *consistent*, if for each pair $(\lambda_1, \lambda_2)$ of leaves with $\mu_1 = \text{lca}_{T_1}(\lambda_1, \lambda_2)$, $\mu_2 = \text{lca}_{T_2}(\lambda_1, \lambda_2)$ we have that $(\lambda_1, \lambda_2)$ is forward directed in $T_1$ if and only if it is forward directed in $T_2$. We say $\mu_1$ and $\mu_2$ are *reverse consistent*, if for each pair $(\lambda_1, \lambda_2)$ of leaves with $\mu_1 = \text{lca}_{T_1}(\lambda_1, \lambda_2)$, $\mu_2 = \text{lca}_{T_2}(\lambda_1, \lambda_2)$ we have that $(\lambda_1, \lambda_2)$ is forward directed in $T_1$ if and only if $(\lambda_1, \lambda_2)$ is backward directed in $T_2$. Observe that $\mu_1$, $\mu_2$ cannot be both consistent and reverse consistent at the same time. Consider the case where $\mu_1$, $\mu_2$ are neither consistent nor reverse consistent. Then $\mu_1$, $\mu_2$ order at least one pair of leaves differently (one forward and one backward directed) and at least one pair of leaves the same way (forward or backward directed). This remains true even after flipping one or both of $\mu_1$, $\mu_2$. Hence, in that case no linear order in $R(T_1)$ can be extended to a linear order in $R(T_2)$, since at least one pair of leaves is ordered differently.

We use four operations on PQ-trees for the construction of the PQ-tree $T_S$ that orders the maximal cliques of the shared graph: *reduction*, *intersection*, *projection* and *pruning*. While the first three operations are frequently used for PQ-trees, pruning is less common, but was for example used in the context of level planarity [7] where the algorithm is attributed to Di Battista and Nardelli [2].

To achieve a linear running time for our algorithm, we track what happens to Q-nodes when applying these operations in a PQ-tree, similar as in [4].

**Reduction.** Let $T$ be a PQ-tree with leaf set $L$. The *reduction* of $R(T)$ with a set $L' \subseteq L$ is the set $R'(T, L')$ of linear orderings in $R(T)$ where $L'$ is consecutive. A PQ-tree $T'$ with $R(T') = R'(T, L')$ can be computed from $T$ in $O(|L'|)$ time [6]. This operation is the main operation for PQ-trees, since it allows to compute a PQ-tree $\hat{T}$ on $L$ where sets $S_1, \ldots, S_k \subseteq L$ are consecutive efficiently.

▶ **Proposition 3** (Booth and Lueker [6]). *Let $L$ be a finite set and let $S_1, \ldots, S_k \subseteq L$ be non-empty sets. A PQ-tree $\hat{T}$ on $L$ that represents the linear orderings of $L$ where $S_1, \ldots, S_k$ are consecutive can be computed in $O(|L| + \sum_{i=1}^{k} |S_i|)$ time.*

While the reduction for PQ-trees was originally described by applying a variety of templates, Hsu gave an alternative description [14]; see also [11]. Roughly speaking, we find a certain path $P$ in $T$ that separates $L'$ and $L \setminus L'$, split P-nodes on $P$ suitably and merge the resulting nodes on $P$ to a single P-node. Finally we remove some degeneracies (especially, if $P$ consists of a single P-node $\lambda$, the resulting Q-node is smoothed, effectively just splitting $\lambda$ into two P-nodes); see Figure 3. For more details, we refer to the papers of Booth and Lueker [6] or Hsu [14]. We only use the running time result for the construction of PQ-trees satisfying given consecutivity constraints mentioned above. Especially, we do not need to keep track of the consistencies between Q-nodes for the reduction.

**Intersection.** Let $T_1$, $T_2$ be PQ-trees with leaf set $L$. The *intersection* $T_1 \cap T_2$ is a PQ-tree on $L$ representing $R(T_1) \cap R(T_2)$. It can be computed from $T_1$, $T_2$ in $O(|L|)$ time together with the consistencies between the Q-nodes in $T_1 \cap T_2$ and the Q-nodes in $T_1$ and $T_2$ [19].

For any two cliques $A, B \in L$ where $\text{lca}_{T_1}(A, B)$ or $\text{lca}_{T_2}(A, B)$ is a Q-node, one can see that $\text{lca}_{T_1 \cap T_2}(A, B)$ is a Q-node as follows. Let $\text{lca}_{T_1}(A, B)$ be a Q-node. We can obtain $T_1 \cap T_2$ from $T_1$, by applying a reduction on $T_1$ for each consecutivity constraint of $T_2$. Since

the only possible change to Q-nodes in reductions is being merged with other nodes to a Q-node of higher degree, the lowest common ancestor of $A$, $B$ remains a Q-node (Note that the reduction of a PQ-tree for a given set is unique up to equivalence).

**Projection.** Let $T$ be a PQ-tree with leaf set $L$ and let $L' \subseteq L$. The *projection* $R^\star(T, L')$ from $R(T)$ to $L'$ is the set of linear orderings of $L'$ induced by the linear orderings in $R(T)$ on $L'$. The *projection* $T'$ of $T$ on $L'$ is a PQ-tree on $L'$ with $R(T') = R^\star(T, L')$. It can be computed in $O(|L|)$ time from $T$ by only keeping nodes $\mu$ with $L(\mu) \cap L' \neq \emptyset$ and smoothing all nodes with a single child (that is, removing the node and adding an arc connecting its parent with its child). Here all Q-nodes in $T'$ are *consistent* to their respective copy in $T$.

**Prune.** Let $T$ be a PQ-tree with leaf set $L$, let $\ell' \notin L$ and let $L' \subseteq L$ be consecutive in each $\sigma \in R(T)$. For any $\sigma \in R(T)$, the *prune* of $L'$ to $\ell'$ in $\sigma$ is the result of replacing $L'$ in $\sigma$ by $\ell'$. The *prune* of $L'$ to $\ell'$ in $R(T)$ is the set containing for each $\sigma \in R(T)$ the prune of $L'$ to $\ell'$ in $\sigma$. For pruning PQ-trees, we first observe that consecutive sets of leaves correspond to simple substructures of PQ-trees.

▶ **Lemma 4.** *Let $T$ be a PQ-tree with leaf set $L$ and let $L' \subseteq L$ be consecutive in each $\sigma \in R(T)$. Then, there is either a P-node $\lambda$ with $L(\lambda) = L'$ or a Q-node $\mu$ with a consecutive subset of children $\nu_1, \dots, \nu_l$ such that $\bigcup_{i=1}^{l} L(\nu_i) = L'$.*

**Proof.** We consider $\nu = \mathrm{lca}(L')$, i.e., $L' \subseteq L(\nu)$ and there are two distinct children $\mu_1$,$\mu_2$ of $\nu$ with $L' \cap L(\mu_1) \neq \emptyset$ and $L' \cap L(\mu_2) \neq \emptyset$.

First assume $\nu$ is a P-node. Then for any other child $\xi$ of $\nu$ we have $L(\xi) \subseteq L'$ since otherwise we could violate the consecutivity of $L'$ by placing $\xi$ between $\mu_1$ and $\mu_2$. We further have $L(\mu_1) \subseteq L'$ and $L(\mu_2) \subseteq L'$, since otherwise the consecutivity of $L'$ is violated after flipping $\mu_1$ and $\mu_2$. Hence, we have $L(\nu) = L'$.

Next let $\nu$ be a Q-node, and let $\mu_1, \mu_2$ be the leftmost and the rightmost child of $\nu$ with descendants in $L'$. Since $L'$ is consecutive, all children between $\mu_1$ and $\mu_2$ only have descendants in $L'$. If $\mu_1$ or $\mu_2$ had a descendant not in $L'$, then the consecutivity of $L'$ could be violated by flipping it. Hence, $\nu$ has the stated property. ◀

With this insight, the *prune* of $L'$ to $\ell'$ in $T$ is obtained as follows. By Lemma 4, either $\mathrm{lca}(L')$ is a P-node with $L(\mathrm{lca}(L')) = L'$ or $\mathrm{lca}(L')$ is a Q-node with consecutive children $\nu_1, \dots, \nu_l$ such that $L' = \bigcup_{i=1}^{l} L(\nu_i)$. If $\mathrm{lca}(L')$ is a P-node, the prune is obtained by replacing $\mathrm{lca}(L')$ and its subtree by leaf $\ell'$. Otherwise, the prune is obtained by replacing $\nu_1, \dots, \nu_l$ by $\ell'$ as a child of the Q-node $\mathrm{lca}(L')$. Clearly, given $L'$, the prune can be computed in $O(|L'|)$ time from $T$ with a bottom-up approach. We introduce additional consistencies. Namely, we consider each Q-node $\mu$ of $T$ consistent to its copy $\mu'$ in the prune of $L'$ to $\ell'$ in $T$, if that copy exists. These consistencies are trivial and not explicitly computed.

## 4 Recognition Algorithm

We use Theorem 2 to recognize sunflower simultaneous interval graphs by deciding whether a given sunflower simultaneous graph $\mathcal{G}$ has a simultaneous clique ordering. The rough idea is the following. For Property 1, we construct a PQ-tree $T$ on $\mathcal{K}$ where $\mathcal{K}(v)$ is consecutive for each $v \in V(S)$. For Property 2, we construct for each $i \in [k]$ a PQ-tree $T_i'$ on $\mathcal{K}_i$ where $\mathcal{K}_i(v)$ is consecutive for each $v \in V(G_i)$. I.e., each $T_i'$ represents the valid clique orderings of $G_i$; see Figure 4. By construction, a simultaneous clique ordering of $\mathcal{G}$ is then a linear ordering $\sigma \in R(T)$ that induces a linear ordering in each of $R(T_1'), \dots, R(T_k')$.

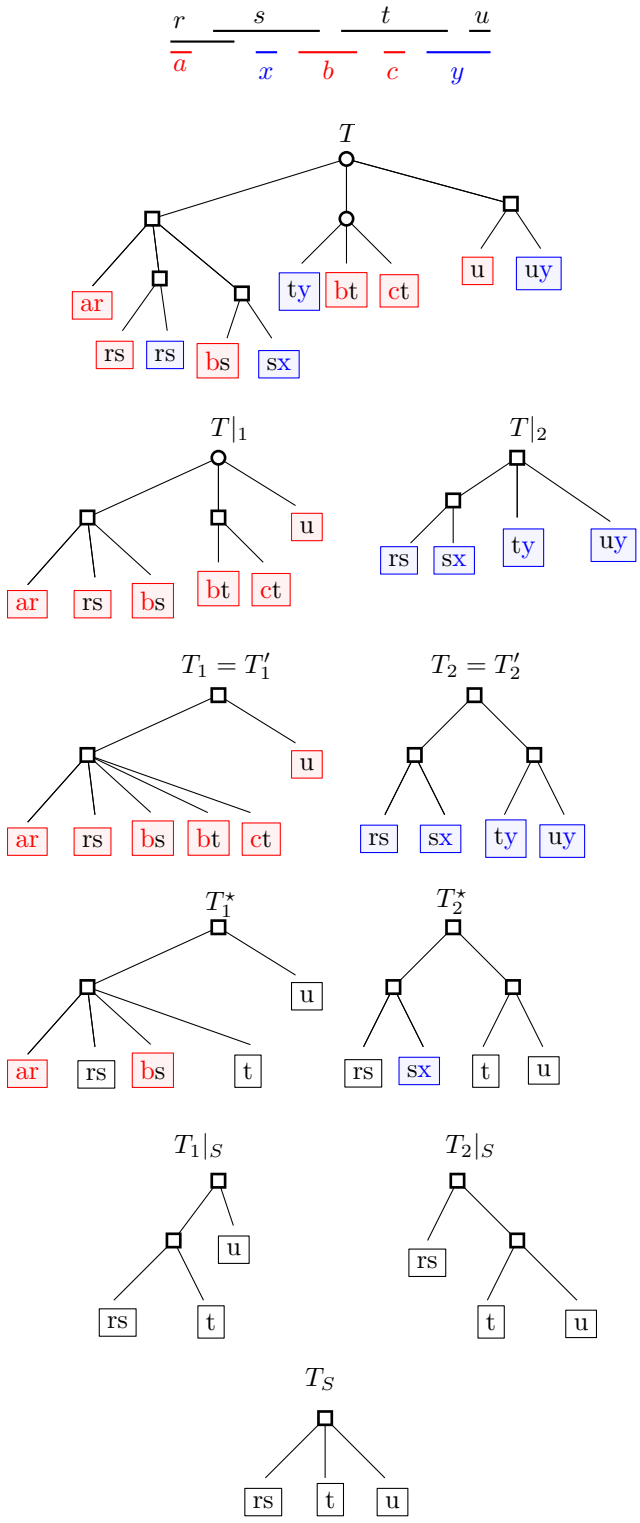

**Figure 4** Top: Simultaneous representation of a sunflower simultaneous graph $\mathcal{G} = (G_1, G_2)$ with $V(G_1) = \{a, b, c, r, s, t, u\}$ and $V(G_2) = \{x, y, r, s, t, u\}$. Below are the PQ-trees for $\mathcal{G}$ with circles for P-nodes and squares for Q-nodes, as defined in Section 4. The leaves are cliques described as strings of the contained vertices.

This means that we obtain $\sigma$ as the order of leaves of $T$, if for $i \in [k]$ any two cliques $A, B \in \mathcal{K}_i$ are ordered the same way in the order of leaves of $T$ and in the order of leaves of $T'_i$. We construct PQ-trees $T_1, \dots, T_k$ by restricting $T'_1, \dots, T'_k$ such that they are "compatible" with $T$ while only loosing linear orderings that do not match any simultaneous clique ordering. We will show that if $\mathrm{lca}_T(A, B)$ is a Q-node, then so is $\mathrm{lca}_{T_i}(A, B)$. This allows to ensure the same ordering of $A$, $B$ in $T$ and $T_i$ by making each pair of backward-consistent Q-nodes consistent. We achieve this with a 2-SAT formula $\Phi$. If $\mu = \mathrm{lca}_T(A, B)$ is a P-node, then we cannot just arrange the children of $\mu$ according to $T_i$, since this can also affect the order of maximal cliques for other input graphs. However, we can resolve this problem as follows. We will see that, if $A$ or $B$ is a child of $\mu$ directly, then its position can be chosen according to $T_i$ without affecting the order of the cliques for other input graphs. Otherwise, $\mu$ has two inner nodes $\nu_1$, $\nu_2$ with $A \in L(\nu_1)$, $B \in L(\nu_2)$ as children. The next lemma then shows that the order of $\nu_1$ and $\nu_2$ is in a sense decided by the order of two shared intervals ("below" $\nu_1$ and $\nu_2$, respectively). This allows us to synchronize $T$ and $T_1, \dots, T_k$ by considering corresponding valid clique orderings for $\mathcal{K}(S)$. Namely, we use the operations on PQ-trees from Section 3 to obtain a PQ-tree $T_S$ on $\mathcal{K}(S)$ that is in a sense compatible with $T_1, \dots, T_k$ and $T$. In $T$, we order the children of a P-node $\mu$ that are inner nodes according to the order of corresponding shared intervals whose order is given by the order of the leaves of $T_S$, and we apply corresponding orderings in each $T_i$. This ensures compatibility of the orders of $T_1, \dots, T_k$, since all children of $\mu$ that are leaves are private to some $T_i$ and can be arranged accordingly in $T$.

Note that each consecutivity constraint for $T$ is a set $\mathcal{K}(v)$ with $v \in V(S)$. In that sense, by the following lemma each child of a P-node in $T$ has a private shared vertex $v \in V(S)$ if it is an inner node.

▶ **Lemma 5.** *Let $L$ be a finite set and let $\{S_1, \dots, S_k\} \subseteq 2^L$ with $|S_i| \geq 2$ for $i \in [k]$. Let $T$ be the PQ-tree on $L$ obtained by making $S_1, \dots, S_k$ consecutive. Let $\mu$ be a P-node and let $\nu$ be a child of $\mu$ that is not a leaf. Then if $\nu$ is a P-node, there is an $S_i$ with $L(\nu) = S_i$. If $\nu$ is a Q-node, there is an $S_i$ with $\bigcup_{j=1}^{l} L(\nu_j) = S_i$ for a consecutive subset of children $\nu_1, \dots, \nu_l$ of $\nu$.*

**Proof.** Let $\nu$ be a P-node and suppose there is no $S_i$ with $L(\nu) = S_i$. First observe that by Lemma 4, for any $S_i$ with $S_i \cap L(\mu) \neq \emptyset$, we have either $L(\mu) \subseteq S_i$ or $S_i \subseteq L(\lambda)$ for some child $\lambda$ of $\mu$. This means that, after contracting the arc $\mu\nu$, no $S_i$ can be violated. However, the contraction allows to order other children of $\mu$ between the children of $\nu$. Thereby $L(\nu)$ is no longer consecutive in all represented linear orderings. This contradicts $T$ originally representing all linear orderings where $S_1, \dots, S_k$ are consecutive, since in each $\sigma \in R(T)$ for the original $T$, leaf set $L(\nu)$ is consecutive.

Next, let $\nu$ be a Q-node and suppose there is no $S_i$ with $\bigcup_{j=1}^{l} L(\nu_j) = S_i$ for any consecutive subset of children $\nu_1, \dots, \nu_l$ of $\nu$. If $\nu$ has precisely two children, we treat it as a P-node and argue as above that there is an $S_i$ with $L(\nu) = S_i$. Hence, assume that $\nu$ has at least three children. By Lemma 4, for any $S_i$ with $S_i \cap L(\mu) \neq \emptyset$, we then have either $L(\mu) \subseteq S_i$ or $S_i \subseteq L(\lambda)$ for some child $\lambda$ of $\mu$. This means that after switching the label of $\mu$ from Q-node to P-node, still all represented linear orderings have all $S_i$ consecutive. This contradicts the choice of $T$, since by making $\mu$ a P-node, $T$ represents additional linear orderings. ◀

Note that Lemma 5 is in a sense the converse of Lemma 4 for the children of P-nodes.

## 4.1 Polynomial-Time Algorithm

We now describe the construction of the 2-SAT formula $\Phi$ and all relevant PQ-trees. For $\Phi$, each Q-node $\lambda$ (of any constructed PQ-tree) is assigned a Boolean variable $x_\lambda$ that tells whether it should be flipped, and we add $(x_\lambda \leftrightarrow x_\mu)$ for consistent nodes $\mu$ and we add $(x_\lambda \not\leftrightarrow x_\nu)$ for backward-consistent nodes $\nu$ to $\Phi$. We describe for which PQ-trees we need to consider the consistencies after introducing all PQ-trees.

Let $\mathcal{G} = (G_1, \dots, G_k)$ be a sunflower simultaneous graph and let $T$ be the PQ-tree on $\mathcal{K}$ that enforces consecutivity of each set $\mathcal{K}(v)$ with $v \in V(S)$; see Figure 4. Note that if $T$ is the null-tree, then there exists no simultaneous clique ordering since Property 1 cannot be satisfied, and by Theorem 2 there is no simultaneous interval representation of $\mathcal{G}$. Hence, we assume in the following, that $T$ is not the null-tree.

For $i \in [k]$, let $T|_i$ be the projection of $T$ on $\mathcal{K}_i$, and let $T_i'$ be the PQ-tree on $\mathcal{K}_i$ that enforces consecutivity of each set $\mathcal{K}_i(v)$ with $v \in V(G_i)$. Note that $T_i'$ describes all valid clique orderings of $G_i$. We are interested in the PQ-tree $T_i = T|_i \cap T_i'$, which restricts the valid clique orderings of $G_i$ to those that are compatible with Property 1; see Figure 4. With Property 2 this means that, if any $T_i$ is the null-tree, then there is no simultaneous clique order. Hence, we assume in the following that no $T_i$ is the null-tree.

We would like to synchronize $T_1, \dots, T_k$ with $T$. However, they have distinct leaf sets. Thus, we cannot just intersect them. Instead, we aim to describe the clique orderings for $S$ that can be induced by $T_1, \dots, T_k$ with PQ-trees. This allows us to find a clique ordering for $S$ that is compatible with all $T_1, \dots, T_k$. With the Q-nodes flipped according to a solution of $\Phi$, this will be enough to synchronize $T_1, \dots, T_k$ with $T$.

We next aim to prune $T_1, \dots, T_k$ to maximal cliques of $S$. For any clique $A \in \mathcal{K}(S)$, we define $\mathcal{K}_i(A)$ as the set of maximal cliques of $G_i$ that contain $A$ as a subclique. It is $\mathcal{K}_i(A) = \{C \in \mathcal{K}_i \mid A \subseteq C\} = \bigcap_{v \in A} \{C \in \mathcal{K}_i \mid v \in C\} = \bigcap_{v \in A} (\mathcal{K}(v) \cap \mathcal{K}_i)$. The critical observation is that, since the intersection of consecutive sets is itself consecutive in a linear order, $\mathcal{K}_i(A)$ is consecutive in $T_i'$ and thus in $T_i$. Note that for distinct $A, B \in \mathcal{K}(S)$, the sets $\mathcal{K}_i(A)$ and $\mathcal{K}_i(B)$ are disjoint, since the set of shared vertices in a maximal clique $C \in \mathcal{K}_i(A) \cap \mathcal{K}_i(B)$ would otherwise be $A$ as well as $B$.

We can now construct for each $T_i$ a PQ-tree describing the corresponding orderings of $\mathcal{K}(S)$ as follows. For $i \in [k]$, let $T_i^\star$ be the PQ-tree obtained by starting with $T_i$ and pruning for each $A \in \mathcal{K}(S)$ the set $\mathcal{K}_i(A)$ to leaf $A$. Then, let $T_i|_S$ be the projection of $T_i^\star$ on $\mathcal{K}(S)$.

Finally, let $T_S = \bigcap_{i=1}^k T_i|_S$ be the intersection of all $T_i|_S$; see Figure 4. By construction, $R(T_S)$ contains all clique orderings of $S$ that can be induced by a simultaneous clique order. Hence, if it is the null-tree, there is no simultaneous clique order.

For each $1 \le i \le k$, we add clauses to $\Phi$ for the consistencies between $T$ and $T|_i$, between $T|_i$ and $T_i$, between $T_i$ and $T_i^\star$, between $T_i^\star$ and $T_i|_S$, and between $T_i|_S$ and $T_S$. If $\Phi$ is not satisfiable, then there is no simultaneous clique ordering. On the other hand, with this, the necessary conditions are also sufficient.

▶ **Theorem 6.** *$(G_1, \dots, G_k)$ is a sunflower interval graph if and only if $\Phi$ is satisfiable and neither $T$ nor $T_S$ is the null-tree.*

**Proof.** If $(G_1, \dots, G_k)$ is a sunflower interval graph the requirements are necessary as discussed above. Hence, assume that neither $T$ nor $T_S$ is the null-tree and that $\Phi$ has a satisfying assignment $\Gamma$. By Theorem 2, it suffices to find a simultaneous clique ordering. We aim to operate on $T$ and each $T_i$ such that the order $\sigma$ of $T$ induces the order of each $T_i$, thus ensuring that $\sigma$ is a simultaneous clique ordering. We first flip all Q-nodes according to $\Gamma$ (that is, flip each Q-node $\lambda$ where $x_\lambda$ is *true*). This ensures that any two cliques $A$, $B$

in $\mathcal{K}$ or $\mathcal{C}(S)$ are ordered the same way in each of $T, T_1, \ldots, T_k$ or $T_1|_S, \ldots, T_k|_S, T_S$ where $\text{lca}(A, B)$ is a Q-node and the sets $\mathcal{K}_i(A)$, $\mathcal{K}_i(B)$ are ordered in $T_i$ the same way as $A$, $B$ are ordered in $T_i|_S$, for $i \in [k]$.

We next order the children of the P-nodes of $T$. Let $\mu$ be a P-node of $T$. Then, by Lemma 5 for each child $\nu$ of $\mu$ that is an inner node, there is a vertex $v \in S$ such that $\mathcal{K}(v) \subseteq L(\nu)$: We choose an arbitrary clique $C_\nu \in \mathcal{K}(S)$ that contains $v$. We then order the children $\nu$ of $\mu$ that are inner nodes according to the order of the corresponding cliques $C_\nu$ given by $T_S$. For $i \in [k]$, we order the sets $\mathcal{K}_i(C_\nu)$ in $T_i$ accordingly. First note that these sets are not empty since each $G_i$ contains a clique containing $C_\nu$. Next note that this orders any two leaves $\lambda_1$,$\lambda_2 \in \mathcal{K}_i$ with $\mu = \text{lca}_T(\lambda_1, \lambda_2)$ that are not children of $\mu$ the same way in $T_i$ as in $T$ since for the corresponding children $\nu_1$, $\nu_2$ of $\mu$ we have that $L(\nu_1)$ and $L(\nu_2)$ are consecutive in $T$ and thus also in $T_i$. E.g., even if $\nu_1$ is a Q-node and $\mathcal{K}_i(C_{\nu_1})$ does not contain $\lambda_1$, this rearrangement still ensures the correct ordering of $\lambda_1$ and $\lambda_2$ in $T_i$. Finally note that this does not flip any Q-nodes of $T_i$ since projection and intersection preserve Q-nodes that order two leaves of the projection set [4]. I.e., for each pair of cliques $A, B \in \mathcal{K}(S)$ such that the order of $\mathcal{K}_i(A)$, $\mathcal{K}_i(B)$ is decided by a Q-node $\mu$ in $T_i$, there is a Q-node in $T_S$ deciding the order of $A$, $B$ the same way as $\mu$ orders $\mathcal{K}_i(A)$, $\mathcal{K}_i(B)$ (after flipping Q-nodes according to $\Gamma$).

With this, for any P-node $\mu$ of $T$ and any two children $\nu_1$, $\nu_2$ of $\mu$ that are inner nodes, each $T_i$ orders any pair of $A \in L(\nu_1) \cap \mathcal{K}_i$ and $B \in L(\nu_2) \cap \mathcal{K}_i$ the same way as $T$. This allows us to order the children of $\mu$ simultaneously according to $T_1, \ldots, T_k$ where each inner node $\nu$ is ordered as any leaf $C \in L(\nu) \cap \mathcal{K}_i$. Note that each child of $\mu$ that is a leaf is contained in a single $T_i$, i.e., it can be placed solely considering the order in $T_i$ (which ensures the correct order with regards to the children of $\mu$ that are inner nodes). Since $L(\nu) \cap \mathcal{K}_i$ is consecutive in $T_i$, the choice of $C(\nu)$ does not matter. I.e., we find an ordering of all children of $\mu$, which is compatible with the orderings given by $T_1, \ldots, T_k$. It remains to show that $T$ now actually provides a simultaneous clique ordering. Property 1 is satisfied by the definition of $T$. For Property 2 we verify that the order of $\mathcal{K}_i$ induced by $T$ is the same as the one given by $T_i$. Consider any two cliques $A, B \in \mathcal{K}_i$. If $\text{lca}_T(A, B)$ is a Q-node, then $A$, $B$ are ordered the same way in $T$ and $T_i$, since we flipped the Q-nodes according to $\Phi$. If $\text{lca}_T(A, B)$ is a P-node, then they are ordered the same way in $T$ and $T_i$ by the operations we just applied on the P-nodes of $T$. ◀

All three requirements in Theorem 6 are necessary; see Figure 5. Theorem 6 allows to recognize sunflower interval graphs in polynomial time by constructing $T, T_S$ and $\Phi$. If $\mathcal{G}$ is a simultaneous interval graph, we obtain a simultaneous clique ordering of $\mathcal{G}$ by following the construction in the proof of Theorem 6. With the construction in Theorem 2, we then obtain a simultaneous interval representation.

▶ **Corollary 7.** *Sunflower interval graphs can be recognized in polynomial time. For yes-instances a simultaneous interval representation can also be constructed in polynomial time.*

## 4.2 Linear-Time Algorithm

To achieve a linear running time, we use that the construction steps can be done efficiently, while also computing the consistencies between Q-nodes, as discussed in Section 3. However, we cannot afford to compute the projection from $T$ on $\mathcal{K}_i$ for each $i \in [k]$ separately, since this could result in an additional factor of $k$ for the running time. Instead, we use the next lemma to compute the projections simultaneously. A similar argumentation has been used by Münch et al. [19].

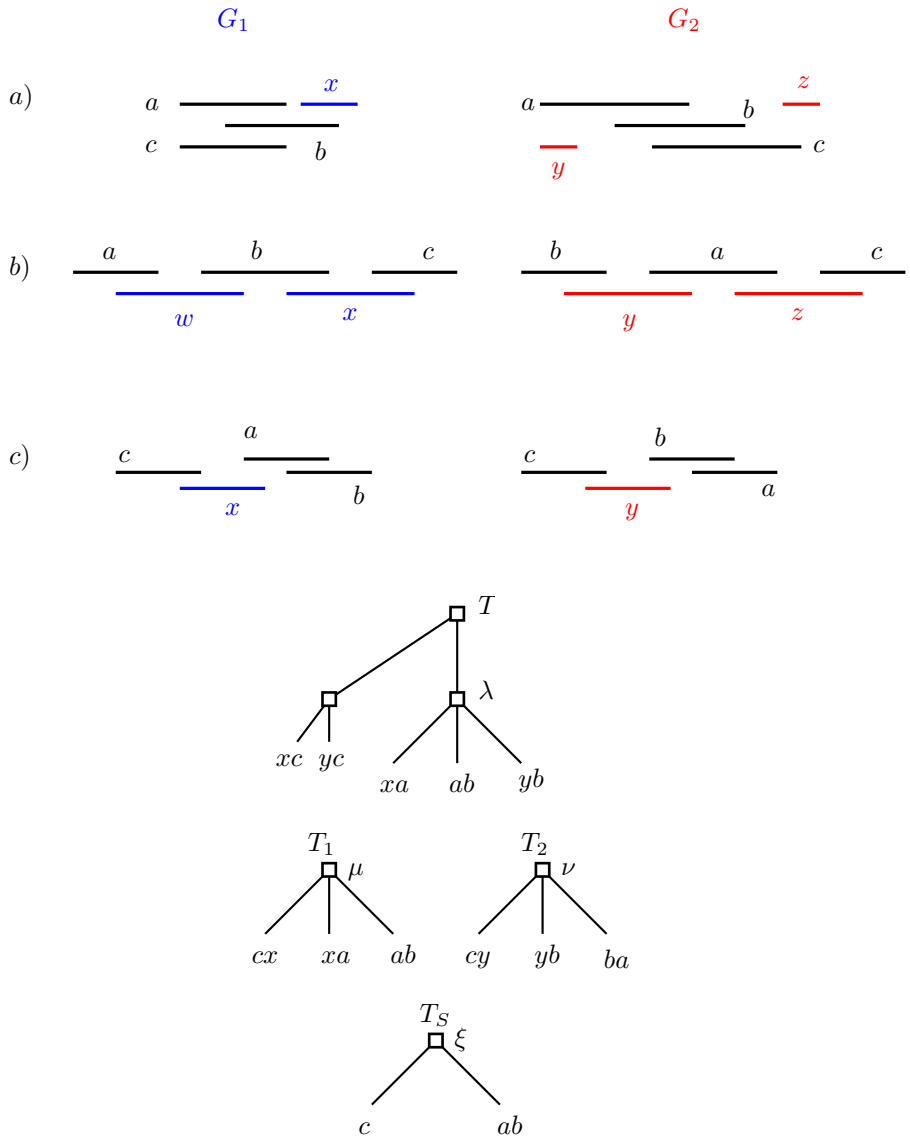

**Figure 5** Variants of a sunflower graph $\mathcal{G} = (G_1, G_2)$ where $G_1$ and $G_2$ are interval graphs, but $\mathcal{G}$ is not a simultaneous interval graph. a) $T$ is a null-tree since the sets $\{abc, bx\}$, $\{abc, ay\}$ and $\{abc, cz\}$ have to be consecutive, while $abc$ can only have two neighbors in the linear ordering. b) $T_S$ is a null-tree since $G_1$ forces $b$ to be in the middle of $a$ and $c$, while $G_2$ forces $a$ to be in the middle of $b$ and $c$. c) $\Phi$ cannot be satisfied since $\xi$ is consistent to $\mu$ and $\nu$ while $\lambda$ is consistent to $\mu$ and backward-consistent to $\nu$ (note that these consistencies are implied in $\Phi$ via the other constructed PQ-trees).

▶ **Lemma 8.** *Let $T$ be an ordered tree with leaf set $L$ and let $\mathcal{S} = \{S_1, \dots, S_l\} \subseteq 2^L$. Then, for each $S_i \in \mathcal{S}$ the projection $T_i^\star$ of $T$ on $S_i$ can be computed such that each node of $T_i^\star$ holds a reference to its original copy in $T$, with a total running time in $O(|L| + \sum_{i=1}^{l} |S_i|)$.*

**Proof.** Observe that a preorder traversal of a $T_i^\star$ is a subsequence of a preorder traversal of $T$. We create a list $U$ that contains a tuple $(S_i, \lambda.p)$ where $\lambda.p$ is the position of $\lambda$ in the preorder of $T$, for each $S_i \in \mathcal{S}$ and $\lambda \in S_i$. We then sort $U$ lexicographically in linear time using radix sort [9]. Then, for each set $S_i \in \mathcal{S}$, the tuples with $S_i$ are consecutive and provide the order of the leaves in $S_i$ in the preorder traversal. For any $S_i$, we find all nodes of $T_i^\star$ in $T$ with the following observation. Let $\mu$ be a node of $T_i^\star$ and let $\nu_1$, $\nu_2$ be two children of $\mu$ with $\nu_1 < \nu_2$ in the preorder. Then $\mu$ is the lowest common ancestor of the rightmost leaf in $L(\nu_1)$ and the leftmost leaf in $L(\nu_2)$. Hence, each inner node of $T_i^\star$ is the lowest common ancestor of two consecutive leaves. We use the lowest common ancestor data structure for static trees by Harel and Tarjan [13], to compute for every pair of nodes $\lambda_1$, $\lambda_2$ in $S_i$ that are consecutive in the preorder the least common ancestor $\mathrm{lca}_T(\lambda_1, \lambda_2)$ and place it between $\lambda_1$ and $\lambda_2$ in a copy $U_i$ of $S_i$ ordered as the preorder. This is already preparing the last step, which is to compute for each node of $T_i^\star$ its parent. Now every node $\lambda \in S_i$ is descendant of both its neighbors $\mu_1$, $\mu_2$ in $U_i$. If $\mu_1$, $\mu_2$ are distinct, the later one in the preorder is the parent of $\lambda$ (and descendant of the other one). By removing $S_i$ and then all duplicates from $U_i$, we get a list of all nodes of $S_i$ of height 1. Note that all duplicates of a node $\lambda$ are consecutive, when they are removed. By repeating the same for each height, we get the parents of all nodes. ◀

With that, the construction of the PQ-trees is straightforward.

▶ **Corollary 9.** *Sunflower interval graphs can be recognized in $O(\sum_{i=1}^{k}(|V(G_i)| + |E(G_i)|))$ time, where $(G_1, \dots, G_k)$ is the input sunflower graph. For yes-instances a simultaneous interval representation can be constructed in the same asymptotic running time.*

**Proof.** We follow the construction of $T$, $T_1, \dots, T_k$, $T_1|_S, \dots, T_k|_S$, $T_S$ for Theorem 6. For each constructed PQ-tree, we maintain the consistencies to the PQ-tree(s) it is constructed from (except for consistencies to unchanged copies of a Q-node, where we use the same variable). The trees $T$ and $T'_1, \dots, T'_k$, can be constructed in $O(\sum_{i=1}^{k}(|V(G_i)| + |E(G_i)|))$ time by Proposition 3. Then, $T|_1, \dots, T|_k$ can be constructed in $O(\sum_{i=1}^{k}(|V(G_i)| + |E(G_i)|))$ time by Lemma 8. The PQ-trees $T_1, \dots, T_k$ can be constructed in the same total time [19]. $T_1|_S, \dots, T_k|_S$ can then be constructed in $O(\sum_{i=1}^{k}(|V(G_i)| + |E(G_i)|))$ by computing the projection and prunes directly. However, we store the smoothed nodes and pruned subtrees (or sets of subtrees), such that we can compute easily a linear order in $R(T_i)$ whose prune is a given linear order in $R(T_i|_S)$ (after projection to $\mathcal{K}(S)$). Finally, $T_S$ can be computed in $O(k \cdot (|V(S)| + |E(S)|))$ time. The 2-SAT formula $\Phi$ can easily be computed from the maintained consistencies. A solution for $\Phi$ can be computed in linear time [1]. With Theorem 6 this suffices to decide whether there is a simultaneous interval representation.

To compute such a representation in linear time, we construct the simultaneous clique ordering a bit differently than in Theorem 6. We first operate on $T_1|_S, \dots, T_k|_S$ such that their leaves are ordered as in $T_S$. This can be done in $O(k \cdot (|V(S)| + |E(S)|))$ time. Then we reverse the smoothing and pruning from $T_1, \dots, T_k$ (using the stored nodes and subtrees) to obtain corresponding linear orderings in $R(T_1), \dots, R(T_k)$. This can be done in time linear in the size of $T_1, \dots, T_k$, i.e., in $O(\sum_{i=1}^{k}(|V(G_i)| + |E(G_i)|))$ time.

In the proof of Theorem 6 we established that the obtained linear orderings can now be merged to a simultaneous clique ordering. We only need to ensure the consecutivities for the shared vertices. Then, we compute for $i \in [k]$ the first and last position $s_i^v$, $t_i^v$ of each

shared vertex $v \in V(S)$ in the clique ordering of $T_i$ by iterating over the clique ordering once. For $i \in [k]$, we sort a list of all these positions in $O(|V(G_i)| + |E(G_i)|)$ time using counting sort [9]. After removing duplicates of positions appearing multiple times, we assign each shared vertex $v$ the positions $\hat{s}_i^v$, $\hat{t}_i^v$ of $s_i^v$, $t_i^v$ in that sorted list. We can then consider for each vertex $v \in V(S)$ two $k$-tuples $\hat{s}^v = (\hat{s}_1^v, \dots, \hat{s}_k^v)$ and $\hat{t}^v = (\hat{t}_1^v, \dots, \hat{t}_k^v)$. We sort a list $L_S$ of all these $k$-tuples lexicographically in $O(k \cdot |V(S)|)$ time using radix sort [9]. This provides us with an order of the start and endpoints of the intervals of the shared vertices in a simultaneous interval representation.

We get a simultaneous clique ordering $\sigma$ by simultaneously iterating over the sorted list $L_S$ and the clique orderings of $T_1, \dots, T_k$ as follows. At each entry $s^v$ (or $t^v$) of $L_S$, append to $\sigma$ for each $T_i$ all cliques between the last appended clique and position $s_i^v$ (or $t_i^v$). After the last entry of $L_S$, append the remaining cliques to $\sigma$. Since we followed the construction of the proof of Theorem 6 there is a simultaneous clique ordering inducing the clique orderings of $T_1, \dots, T_k$. Thus, we have for any two entries $r = (r_1, \dots, r_k)$, $r' = (r'_1, \dots, r'_k)$ that $r \leq r'$ in $L_S$ only if $r_i \leq r'_i$, for all $i \in [k]$. This ensures that each clique $C$ is appended when $C \cap V(S)$ are precisely the shared vertices $v$ for which $s^v$ is processed, but $t^v$ is not. Hence, Property 1 is satisfied and $\sigma$ actually is a simultaneous clique ordering. With that a simultaneous interval representation can be computed straightforwardly, by placing a point for each clique on the real line in that order and then assigning to each vertex $v$ the interval $[s_v, t_v]$ where $s_v$, $t_v$ are the points for the first and last clique containing $v$, as done for Theorem 2. ◀

## 5 Open Questions

While we solve the sunflower representation problem for interval graphs in linear time if each input graph is given separately, a more compact input description is possible, if the number of non-shared vertices is very small. In that case, the input can be given as the union $G = \bigcup_{i=1}^{k} G_i$ as a single graph with labels describing which input graph a non-shared vertex belongs to. Our approach would then have a running time in $O(k \cdot (|V(G)| + |E(G)|))$.

▶ **Question 1.** *Can the sunflower representation problem for interval graphs be solved in $o(k \cdot (|V(G)| + |E(G)|))$ time if the input is given as the union graph $G$?*

Note that it is not clear how to even verify that each input graph is an interval graph with less time.

While the general simultaneous representation problem is NP-complete for interval graphs if the number of input graphs is part of the input, and it is solvable in linear time for $k = 2$, we do not know the complexity for fixed $k > 2$.

▶ **Question 2.** *Can the simultaneous representation problem for interval graphs be solved in polynomial time for a fixed $k > 2$? In particular, considering $k$ as a parameter, is the problem in XP? Is it FPT?*

## Abstract

Streaming algorithms are typically analyzed in the *oblivious* setting, where we assume that the input stream is fixed in advance. Recently, there is a growing interest in designing *adversarially robust* streaming algorithms that must maintain utility even when the input stream is chosen *adaptively and adversarially* as the execution progresses. While several fascinating results are known for the adversarial setting, in general, it comes at a very high cost in terms of the required space. Motivated by this, in this work we set out to explore intermediate models that allow us to interpolate between the oblivious and the adversarial models. Specifically, we put forward the following two models:

- *The bounded interruptions model*, in which we assume that the adversary is only partially adaptive.
- *The advice model*, in which the streaming algorithm may occasionally ask for one bit of advice.

We present both positive and negative results for each of these two models. In particular, we present generic reductions from each of these models to the oblivious model. This allows us to design robust algorithms with significantly improved space complexity compared to what is known in the plain adversarial model.

## 1 Introduction

Streaming algorithms are algorithms for processing data streams in which the input is presented as a sequence of items. Generally speaking, these algorithms have access to limited memory, significantly smaller than what is needed to store the entire data stream. This field was formalized by Alon, Matias, and Szegedy [3], and has generated a large body of work that intersects many other fields in computer science. In this work, we focus on streaming algorithms that aim to track a certain function of the input stream, and to continuously report estimates of this function. Formally,

▶ **Definition 1.1** (Informal version of Definition 2.1). *Let $X$ be a finite domain and let $g : X^* \to \mathbb{R}$ be a function that maps every input $\vec{x} \in X^*$ to a real number $g(\vec{x}) \in \mathbb{R}$.*

*Let $\mathcal{A}$ be an algorithm that in every round $i \in [m]$ obtains an element $x_i \in X$ and outputs a response $z_i \in \mathbb{R}$. Algorithm $\mathcal{A}$ is said to be an* oblivious streaming algorithm *for $g$ with accuracy $\alpha$, failure probability $\beta$, and stream length $m$, if the following holds for every input sequence $\vec{x} = (x_1, x_2, \ldots, x_m) \in X^m$. Consider an execution of $\mathcal{A}$ on the input stream $\vec{x}$. Then,* $\Pr[\forall i \in [m]$ *we have* $z_i \in (1 \pm \alpha) \cdot g(x_1, \ldots, x_i)] \geq 1 - \beta$, *where the probability is taken over the coins of algorithm $\mathcal{A}$.*

Note that in Definition 1.1, the streaming algorithm is required to succeed (w.h.p.) for every *fixed* input stream. In particular, it is assumed that the choice for the elements in the stream is *independent* from the internal randomness of the streaming algorithm. This assumption, called the *oblivious setting*, is crucial for the correctness of most classical streaming algorithms. In this work, we are interested in a setting where this assumption does not hold, referred to as the *adversarial setting*.

## 1.1 The (Plain) Adversarial Model

The adversarial streaming model, in various forms, was considered by [20, 12, 13, 1, 2, 15, 8, 7, 16, 24, 6, 4]. The adversarial setting is modeled by a two-player game between a (randomized) `StreamingAlgorithm` and an `Adversary`. At the beginning, we fix a function $g : X^* \to \mathbb{R}$. Throughout the game, the adversary chooses the updates in the stream, and is allowed to *query* the streaming algorithm at $T$ time steps of its choice (referred to as "query times"). Formally, for round $i = 1, 2, \ldots, m$:

1. The `Adversary` chooses an update $x_i \in X$ and a query demand $q_i \in \{0, 1\}$, under the restriction that $\sum_{j=1}^{i} q_j \leq T$.
2. The `StreamingAlgorithm` processes the new update $x_i$. If $q_i = 1$ then, the `StreamingAlgorithm` outputs a response $z_i$, which is given to the `Adversary`.

The goal of the `Adversary` is to make the `StreamingAlgorithm` output an incorrect response $z_i$ at some query time $i$ in the stream. Let $g$ be a function defining a streaming problem, and suppose that there is an oblivious streaming algorithm $\mathcal{A}$ for $g$ that uses space $s$. It is easy to see that $g$ can be solved in the adversarial setting using space $\approx s \cdot T$, by running $T$ copies of $\mathcal{A}$ and using each copy for at most one query. The question is if we can do better. Indeed, Hassidim et al. [16] showed the following result.

▶ **Theorem 1.2** ([16], informal). *If there is an* oblivious *streaming algorithm for a function $g$ that uses space $s$, then there is an* adversarially robust *streaming algorithm for $g$ supporting $T$ queries using space $\approx \sqrt{T} \cdot s$.*

Note that when the number of queries $T$ is large, this construction incurs a large space blowup. One way for coping with this is to assume additional restrictions on the function $g$ or on the input stream. Indeed, starting with Ben-Eliezer et al. [7], most of the positive results on adversarial streaming assumed that the input stream is restricted to have a small *flip-number*, defined as follows.

▶ **Definition 1.3** (Flip number [7]). *The $(\alpha, m)$-flip number of an input stream $\vec{x}$ w.r.t. a function $g$, denoted as $\lambda_{\alpha,m}(\vec{x}, g)$, or simply $\lambda$, is the maximal number of times that the value of $g$ changes (increases or decreases) by a factor of $(1 + \alpha)$ during the stream $\vec{x}$.*

Starting from [7], the prior works of [7, 16, 24, 4] presented generic constructions that transform an oblivious streaming algorithm with space $s$ into an adversarially robust streaming algorithm with space $\approx s \cdot \text{poly}(\lambda)$. That is, under the assumption that the flip-number is bounded, these prior works can even support $T = m$ queries. This is useful since the

parameter $\lambda$ is known to be small for many interesting streaming problems in the *insertion-only* model (where there are no deletions in the stream). However, in general it can be as big as $\Theta(m)$, in which case the transformations of [7, 16, 24, 4] come at a very high cost in terms of space. To summarize this discussion, current reductions from the adversarial to the oblivious setting are useful either when the number of queries $T$ is small, or when the flip-number is small.

## 1.2 Our Results

One criticism of the adversarial model is that it is (perhaps) too pessimistic. Indeed, there could be many scenarios that do not fall into the oblivious model, but are still quite far from an "adversarial" setting. Motivated by this, in this work, we set out to explore intermediate models that allow us to interpolate between the oblivious model and the adversarial model. Specifically, we study two such models, which we call the *bounded interruptions model* and the *advice model*.

### 1.2.1 Adversarial Streaming with Bounded Interruptions (ASBI)

Recall that in the plain adversarial model, the adversary is fully adaptive in the sense that it does not commit to the $i$th update before time $i$. We consider a refinement of this setting in which the adversary is only *partially* adaptive. The game begins with the adversary specifying a complete input stream. Throughout the execution, the adversary (who sees the outputs of the streaming algorithm) can adaptively decide to *interrupt* and to replace the suffix of the stream (which has not yet been processed by the streaming algorithm). Formally, we define the following *ASBI game* between a `StreamingAlgorithm` and an `Adversary`.

**Parameters:** $m$ denotes the length of the stream, $T$ denotes the number of allowed queries, and $R$ denotes the number of allowed interruptions.

1. The `Adversary` chooses a stream $\vec{x} = (x_1, x_2, \ldots, x_m) \in X^m$.
2. For round $i = 1, 2, \ldots, m$
   a. The `Adversary` chooses a query demand $q_i \in \{0, 1\}$ and an interruption demand $d_i \in \{0, 1\}$, under the restriction that $\sum_{j=1}^{i} q_j \leq T$ and $\sum_{j=1}^{i} d_j \leq R$.
   b. If $d_i = 1$ then the adversary outputs a new stream suffix $(x'_i, \ldots, x'_m)$ and we override $(x_i, \ldots, x_m) \leftarrow (x'_i, \ldots, x'_m)$.
   c. The `StreamingAlgorithm` obtains the update $x_i$. If $q_i = 1$ then, the `StreamingAlgorithm` outputs a response $z_i$, which is given to the `Adversary`.

That is, the adversary sees all of the outputs given by the streaming algorithm (in query times), and adaptively decides on $R$ places in which it "interrupts" and arbitrarily modifies the rest of the stream. Importantly, the streaming algorithm "does not know" when interruptions occur. The ASBI model limits the adaptivity of the adversary in a natural way, capturing settings in which the number of "adaptivity rounds" can be bounded. It gives us an intuitive interpolation between the oblivious setting (in which $R = 0$) and the full adversarial setting (obtained by setting $R = T$).[1]

We show the following generic result.

[1] As described, the plain adversarial setting is obtained by setting $R = m$. However, an easy argument shows that setting $R > T$ does not give more power to the adversary over the case of $R = T$.

▶ **Theorem 1.4** (informal version of Theorem 3.1)**.** *If there exists an oblivious streaming algorithm for a function $g : X^* \to \mathbb{R}$ using space $s$ then for every $1 \leq R \leq T$ there exists an adversarially robust streaming algorithm for $g$ in the ASBI model that answers $T$ queries and resists $R$ interruptions using space $\approx \min\left\{R, \sqrt{T}\right\} \cdot s$.*

To obtain this result, we build on the *sketch switching* technique introduced by Ben-Eliezer et al. [7]. Intuitively, we maintain $2R$ copies of an oblivious streaming algorithm $\mathcal{A}$, where in every given moment exactly two of these copies are designated as "active". As long as the two active copies produce (roughly) the same estimates, they remain as the "active" copies, and we use their estimates as our response. Once they disagree, we discard them both (never to be used again) and designate two (fresh) copies as "active". In Section 3 we show that this construction can be formalized to obtain Theorem 1.4.

▶ **Remark 1.5.** *While our method resembles the sketch switching technique of [7], their technique is tailored to the setting where the flip-number is small (i.e., the value of the target function does not "jump" too many times throughout the stream), and is not directly applicable to the ASBI model. Specifically, in [7] there is only* one *active copy, which is "swithched" the moment its response differs significantly from* the previously released estimate*. This is useful under the assumption that the flip-number is small, because the flip-number bounds the number of switches. However, in the ASBI model we do not assume anything about the flip-number of the stream, and the value of the target function can be completely different at different query times.*

For example, the following is a direct application of Theorem 1.4 for $F_2$ estimation (i.e., estimating the second moment of the frequency vector of the input stream).

▶ **Theorem 1.6** ($F_2$ estimation in the ASBI model, informal)**.** *Let $1 \leq R \leq T$. There exists an adversarially robust $F_2$ estimation algorithm in the ASBI model that guarantees $\alpha$-accuracy (w.h.p.) for $T$ queries while resisting $R$ interruptions using space $\approx \min\left\{R, \sqrt{T}\right\}/\alpha^2$.*

This improves the state-of-the-art for turnstile streams in the plain adversarial model (from [16]) whenever $R \lesssim \sqrt{T}$.

**A negative result for the ASBI model.** Note that the space blowup of our construction from Theorem 1.4 grows linearly with the number of interruptions $R$. Recall that in the full adversarial model (where $R = T$ for $T$ queries) it is known that a space blowup of $\sqrt{T}$ suffices (see Theorem 1.2). Thus, one might guess that the correct dependence in $R$ in the ASBI model should be $\sqrt{R}$. However, we show that this is generally not the case. Specifically, we show that there exists a streaming problem that can easily be solved in the oblivious setting with small space, but necessitates space linear in $R$ in the ASBI model, provided that the number of queries is large enough (quadratic in $R$). This shows that our upper bound stated in Theorem 1.4 is (nearly) tight in general. Formally,

▶ **Theorem 1.7** (informal version of Corollary 3.8)**.** *For every $R \leq T$ there exists a streaming problem that requires at least $\Omega\left(\min\left\{R, \sqrt{T}\right\}\right)$ space to be solved in the ASBI model with $R$ interruptions and $T$ queries, but can be solved in the oblivious setting using space* $\mathrm{polylog}(T)$.

### 1.2.2 Adversarial Streaming with Advice (ASA)

We put forward another intermediate model, in which the streaming algorithm may occasionally ask for one bit of *advice* throughout the execution. Formally, we consider the following game, referred to as the ASA game, between the `StreamingAlgorithm` and an `Adversary`.

**Parameters:** $m$ denotes the length of the stream, $T \leq m$ denotes the number of allowed queries, and $\eta \in \mathbb{N}$ is a parameter controlling the query/advice rate.

For round $i = 1, 2, \ldots, m$ :

1. The `Adversary` chooses an update $x_i \in X$ and a query demand $q_i \in \{0, 1\}$, under the restriction that $\sum_{j=1}^{i} q_j \leq T$.
2. The `StreamingAlgorithm` processes the new update $x_i$.
3. If $q_i = 1$ then
   a. The `StreamingAlgorithm` outputs a response $z_i$, which is given to the `Adversary`.
   b. If $\left(\sum_{j=1}^{i} q_j\right) \bmod \eta = 0$ then the `StreamingAlgorithm` specifies a predicate $p_i : X^* \to \{0, 1\}$, and obtains $p_i(x_1, x_2, \ldots, x_i)$.

That is, in the ASA model the adversary is allowed a total of $T$ queries, and once every $\eta$ queries the streaming algorithm is allowed to obtain one bit of advice, computed as a predicate of the items in the stream so far.

Unlike our ASBI model, which (we believe) has a strong algorithmic motivation, the main motivation to study the ASA model is theoretical. It gives us an intuitive way to measure the amount of *additional information* that the streaming algorithm needs in order to maintain utility in the adversarial setting.

▶ **Remark 1.8.** *Even though the main motivation for the ASA model is theoretical, it could also be interesting from an algorithmic standpoint in the following context. Consider a streaming setting in which the input stream is fed into both a (low space) streaming algorithm $\mathcal{A}$ and to a server $\mathcal{S}$. The server has large space and can store all the input stream (and, therefore, can in principle solve the streaming problem itself). However, suppose that the server has some communication bottleneck and is busy serving many other tasks in parallel. Hence we would like to delegate as much of the communication as possible to the "cheap" (low space) streaming algorithm $\mathcal{A}$. The ASA model allows for such a delegation, in the sense that the streaming algorithm handles most of the queries itself, and only once every $\eta$ queries it asks for one bit of advice from the server.*

We show the following generic result.

▶ **Theorem 1.9** (informal version of Theorem 4.2)**.** *If there exists an oblivious* linear *streaming algorithm for a function $g : X^* \to \mathbb{R}$ with space $s$, then for every $\eta \in \mathbb{N}$ there exists an adversarially robust streaming algorithm for $g$ in the ASA model with query/advice rate $\eta$ using space $\approx \eta \cdot s^2$.*

To obtain this result, we rely on a technique introduced by Hassidim et al. [16] which uses *differential privacy* [11] to protect not the input data, but rather the internal randomness of the streaming algorithm. Intuitively, this allows us to make sure that the "robustness" of our algorithm deteriorates *slower* than the advice rate, which allows us to obtain an advice-robustness tradeoff.

Note that the space complexity of the algorithm from Theorem 1.9 does not depend polynomially on the number of queries $T$. For example, the following is a direct application of this theorem in the context of $F_2$ estimation.

▶ **Theorem 1.10** ($F_2$ estimation in the ASA model, informal)**.** *Let $\eta \in \mathbb{N}$. There exists an adversarially robust $F_2$ estimation algorithm in the ASA model with query/advice rate $\eta$ that guarantees $\alpha$-accuracy (w.h.p.) using space $\tilde{O}\left(\eta/\alpha^4\right)$.*

▶ **Remark 1.11.** *We stress that there is a formal sense in which the ASA model is "between" the oblivious and the (plain) adversarial models. Clearly, the ASA model is easier than the plain adversarial model, as we can simply ignore the advice bits. On the other hand, a simple argument shows that the ASA model (with any $\eta > 1$) is qualitatively harder than the oblivious setting. To see this, let $\mathcal{A}$ be an algorithm in the ASA model for a function $g$ with query/advice rate $\eta > 1$. Then $\mathcal{A}$ can be transformed into the following oblivious algorithm $\mathcal{A}_{\text{oblivious}}$ for $g$ (that returns an estimate in every time step without getting any advice):*

**An oblivious algorithm $\mathcal{A}_{\text{oblivious}}$**

1. *Instantiate algorithm $\mathcal{A}$ (which expects to operate in the ASA model).*
2. *In every time $i \in [m]$:*
   a. *Obtain an update $x_i \in X$.*
   b. *Duplicate $\mathcal{A}$ (with its internal state) into a shadow copy $\mathcal{A}^{\text{shadow}}$.*
   c. *Feed the update $(x_i, 0)$ to $\mathcal{A}$ and the update $(x_i, 1)$ to $\mathcal{A}^{\text{shadow}}$, and obtain an answer $z_i$ from the shadow copy. Here we use the notation that $(x, q)$ means an update $x$ with a query demand $q$. Note that we only query the shadow copy.*
   d. *Output $z_i$ and erase the shadow copy from memory.*

*As we "rewind" $\mathcal{A}$ after every query, it is never expected to issue an advice-request and so $\mathcal{A}_{\text{oblivious}}$ never issues an advice-request as well. Furthermore, a simple argument shows that $\mathcal{A}_{\text{oblivious}}$ maintains utility in the oblivious setting.*[2]

▶ **Remark 1.12.** *Our construction has the benefit that the predicates specified throughout the interaction are "simple" in the sense that every single one of them can be computed in a streaming fashion. That is, given the predicate $p_i$, the bit $p_i(x_1, x_2, \ldots, x_i)$ can be computed using small space with one pass over $x_1, x_2, \ldots, x_i$.*

**A negative result for the ASA model.** Theorem 1.9 shows a strong positive result in the ASA model for streaming problems that are defined by real valued functions, presenting space complexity that does not depend directly on the number of queries $T$. We compliment this result with a negative result for a simple streaming problem which is *not* defined by a real valued function. Specifically, we consider (a variant of) the well-studied $\ell_0$-sampling problem, where the streaming algorithm must return an (almost) uniformly random element from the set of non-deleted elements. It is known that the $\ell_0$-sampling problem is easy in the oblivious setting (see e.g. [17]) and hard in the plain adversarial setting (see e.g. [1]). Using a simple counting argument, we show that the $\ell_0$-sampling problem remains hard also in the ASA model *even if the query/advice rate is 1*, i.e., even if the streaming algorithm gets an advice bit for *every* query. Formally,

▶ **Theorem 1.13** (informal version of Theorem 4.5)**.** *Every algorithm for solving the $\ell_0$-sampling problem in the ASA model with $T$ queries must use space $\Omega(T)$. Furthermore, this holds even when $\eta = 1$, that is, even if the algorithm gets an advice bit after* every *query.*

[2] To see this, fix an input stream $\vec{x} = (x_1, x_2, \ldots, x_m)$, and fix $j \in [m]$. Note that the distribution of the output given by $\mathcal{A}_{\text{oblivious}}$ in time $j$ when running on $\vec{x}$ is identical to the outcome distribution of $\mathcal{A}$ when running on the stream $((x_1, 0), \ldots, (x_{j-1}, 0), (x_j, 1))$, which must be accurate w.h.p. by the utility guarantees of $\mathcal{A}$ (since there is only 1 query in this alternative stream, then $\mathcal{A}$ gets no advice when running on it). The claim now follows by a union bound over the query times.

## 1.3 Additional Related Works

The adversarial streaming model (in a setting similar to ours) dates back to at least [1], who studied it implicitly and showed an impossibility result for robust $\ell_0$ sampling in sublinear memory. The adversarial streaming model was then formalized explicitly by [15], who showed strong impossibility results for linear sketches. A recent line of work, starting with [7] and continuing with [16, 24, 4, 6] showed *positive* results (i.e., *robust algorithms*) for many problems of interest, under the assumption that the *flip-number* of the stream is bounded. On the negative side, [7] also presented an attack with $O(n)$ number of adaptive rounds on a variant of the AMS sketch, where $n$ is the size of the domain. Later, [19] presented a streaming problem that can be solved in the oblivious setting with polylogarithmic space, but requires polynomial space in the adversarial setting. Thus, the result of [19] separates the oblivious model from the (plain) adversarial model. More recently, [9] and [10] presented attacks on a concrete algorithm, namely `CountSketch`, with a number of queries that is *linear* in the space of the algorithm and while using only a single round of adaptivity. Following [16], the idea of using differential privacy to protect the internal randomness of interactive algorithms was used in additional settings, for example in the context of dynamic algorithms [5] and learning with experts [23].

# 2 Preliminaries

In this work we consider streaming problems which are defined by a real valued function (where the goal is to approximate the value of this function) as well as streaming problems that define a set of valid solutions and the goal is to return one of the valid solutions. The following definition unifies these two objectives for the oblivious setting.

▶ **Definition 2.1** (Oblivious streaming). *Let $X$ be a finite domain and let $g : X^* \to 2^W$ be a function that maps every input $\vec{x} \in X^*$ to a subset $g(\vec{x}) \subseteq W$ of valid solutions (from some range $W$).*

*Let $\mathcal{A}$ be an algorithm that, for $m$ rounds, obtains an element $x_i \in X$ and outputs a response $z_i \in W$. Algorithm $\mathcal{A}$ is said to be an* oblivious streaming algorithm *for $g$ with failure probability $\beta$, and stream length $m$, if the following holds for every input sequence $\vec{x} = (x_1, x_2, \ldots, x_m) \in X^m$. Consider an execution of $\mathcal{A}$ on the input stream $\vec{x}$. Then,*

$$\Pr\left[\forall i \in [m] \text{ we have } z_i \in g(x_1, \ldots, x_i)\right] \geq 1 - \beta,$$

*where the probability is taken over the coins of algorithm $\mathcal{A}$.*

For example, in the problem of estimating the number of distinct elements in the stream, the function $g$ in the above definition returns the interval $g(x_1, \ldots, x_i) = (1 \pm \alpha) \cdot |\{x_1, \ldots, x_i\}|$, where $\alpha$ is the desired approximation parameter.

# 3 Adversarial Streaming with Bounded Interruptions (ASBI)

In this section we present our results for the ASBI model, defined in Section 1.2.1. We begin with our generic transformation.

## 3.1 A Generic Construction for the ASBI Model

We present a generic construction whose space blowup depends only on the number of interruptions $R$ (and not on the number of queries $T$). We therefore assume in our construction that $T = m$, i.e., that the adversary queries the streaming algorithm on *every* time step. Our construction is given in algorithm `RobustInterruptions`. The following theorem specifies its properties.

**Algorithm 1** `RobustInterruptions`.

**Input:** Parameter $R \in \mathbb{N}^+$ bounding the number of possible interruptions.

**Algorithm used:** An oblivious streaming algorithm $\mathcal{A}$ with space $s$, accuracy $\alpha$, and confidence $\beta$.

1. Initialize $2R$ independent instances of algorithm $\mathcal{A}$, denoted as $\mathcal{A}_1^{\text{answer}}, \ldots, \mathcal{A}_R^{\text{answer}}$ and $\mathcal{A}_1^{\text{check}}, \ldots, \mathcal{A}_R^{\text{check}}$. Set $r = 1$.
2. For $i = 1, 2, \ldots, m$:
   a. Obtain the next item in the stream $x_i \in X$.
   b. Feed $x_i$ to *all* of the copies of algorithm $\mathcal{A}$.
   c. Let $z_{r,i}^{\text{answer}}$ and $z_{r,i}^{\text{check}}$ denote the answers returned by $\mathcal{A}_r^{\text{answer}}$ and $\mathcal{A}_r^{\text{check}}$, respectively.
   d. If $z_{r,i}^{\text{answer}} \in (1 \pm 2\alpha) \cdot z_{r,i}^{\text{check}}$ then output $z_{r,i}^{\text{answer}}$. Otherwise, output $z_{r,i}^{\text{check}}$ and set $r \leftarrow r + 1$.
   e. If $r > R$ then FAIL. Otherwise continue to the next iteration.

▶ **Theorem 3.1.** *Fix any function $g$ and fix $\alpha, \beta > 0$. Let $\mathcal{A}$ be an oblivious streaming algorithm for $g$ that uses space $s$ and guarantees accuracy $\alpha$ with failure probability $\beta$. Then for all $R \in \mathbb{N}^+$ there exists an adversarially robust streaming algorithm for $g$ that resists $R$ interruptions and guarantees accuracy $5\alpha$ with failure probability $O(R\beta)$ using space $O(Rs)$.*

▶ **Remark 3.2.** *Recall that Hassidim et al. [16] showed a generic transformation from an oblivious algorithm for a function $g : X^* \to \mathbb{R}$ with space $s$ to an adversarial algorithm (in the plain model) for $g$, answering $T$ queries with space $\approx \sqrt{T} \cdot s$ (see Theorem 1.2). Therefore, combined with the above theorem, we get that for every such function $g$ and every $1 \leq R \leq T$ there exists an adversarially robust streaming algorithm in the ASBI model that answers $T$ queries and resists $R$ interruptions using space $\approx \min\left\{R, \sqrt{T}\right\} \cdot s$.*

Fix an adversary $\mathcal{B}$ and consider the interaction between algorithm `RobustInterruptions` and the adversary $\mathcal{B}$. For $r \in [R]$, let $i_r$ denote the time step in which $z_{r,i_r}^{\text{check}}$ is returned.

▶ **Lemma 3.3.** *Fix $r^* \in [R]$. With probability at least $1 - \beta$, the answers returned by $\mathcal{A}_{r^*}^{\text{check}}$ in times $1, 2, \ldots, i_{r^*}$ are $\alpha$-accurate. That is, for every $1 \leq i \leq i_{r^*}$ it holds that $z_{r^*,i}^{\text{check}} \in (1 \pm \alpha) \cdot g(x_1, \ldots, x_i)$.*

**Proof.** For simplicity, we assume that the adversary $\mathcal{B}$ is deterministic (this is without loss of generality by a simple averaging argument). Fix the randomness of all copies of algorithm $\mathcal{A}$, except for $\mathcal{A}_{r^*}^{\text{check}}$. Let $\texttt{RI}_{r^*}$ be a variant of algorithm `RobustInterruptions` which is identical to `RobustInterruptions` until the time step $i^*$ in which $r$ becomes $r^*$. In times $i \geq i^*$, algorithm $\texttt{RI}_{r^*}$ simply outputs $z_{r^*,i}^{\text{answer}}$, i.e., the answer given by $\mathcal{A}_{r^*}^{\text{answer}}$. Note that $\mathcal{A}_{r^*}^{\text{check}}$ does not exist in algorithm $RI_{r^*}$.

As we fixed the coins of the copies of $\mathcal{A} \neq \mathcal{A}_{r^*}^{\text{check}}$, the interaction between $\mathcal{B}$ and $\texttt{RI}_{r^*}$ is deterministic. In particular, it generates a single stream $\vec{x}_{r^*}$. By the utility guarantees of algorithm $\mathcal{A}_{r^*}^{\text{check}}$, when run on this stream, then with probability at least $1 - \beta$ it maintains $\alpha$-accuracy throughout the stream.

The lemma now follows by observing that until time $i_{r^*}$ the stream generated by the interaction between $\mathcal{B}$ and algorithm `RobustInterruptions` is identical to the stream $\vec{x}_{r^*}$. ◀

▶ **Lemma 3.4.** *With probability at least $1 - R\beta$, all of the answers given by `RobustInterruptions` (before returning FAIL) are $5\alpha$-accurate.*

**Proof.** Follows from a union bound over Lemma 3.3, and by Step 2d of `RobustInterruptions`. ◀

▶ **Lemma 3.5.** *Algorithm* `RobustInterruptions` *returns FAIL with probability at most* $2R\beta$.

**Proof.** Let $j_1, j_2, \ldots, j_R$ denote the time steps in which the adversary conducts interruptions. That is, $j_1$ is the first time in which the adversary switches the suffix of the stream, $j_2$ is the second time this happens, and so on. Also let $p_1, p_2, \ldots, p_R$ denote the time steps in which the parameter $r$ increases during the execution of algorithm `RobustInterruptions`. Specifically, $p_\ell$ is the time $i$ in which $r$ becomes equal to $\ell + 1$. We show that for every $r \in [R]$, with probability at least $1 - 2r\beta$ it holds that $j_r \leq p_r$. (That is, interruptions happen "faster" then $r$ increases.)

The proof is by induction on $r$. For the base case, $r = 1$, let $\vec{x}_1$ denote the first stream chosen by the adversary. By the utility guarantees of $\mathcal{A}$, with probability at least $1 - 2\beta$ we have that both $\mathcal{A}_1^{\text{answer}}$ and $\mathcal{A}_1^{\text{check}}$ are $\alpha$-accurate w.r.t. this stream, in which case $r$ does not increase. Thus, with probability at least $1 - 2\beta$ we have $j_1 \leq p_1$.

The inductive step is similar: Fix $r \in [R]$, and suppose that $j_r \leq p_r$, which happens with probability at least $(1 - 2r\beta)$ by the inductive assumption. Let $\vec{x}_r$ denote the last stream specified by the adversary before time $p_r$. Note that the internal coins of $\mathcal{A}_{r+1}^{\text{answer}}$ and $\mathcal{A}_{r+1}^{\text{check}}$ are independent with this stream. Hence, by the utility guarantees of $\mathcal{A}$, with probability at least $1 - 2\beta$ we have that both $\mathcal{A}_{r+1}^{\text{answer}}$ and $\mathcal{A}_{r+1}^{\text{check}}$ are $\alpha$-accurate w.r.t. this stream, in which case $r$ does not increase. Overall, with probability at least $1 - 2(r+1)\beta$ we have $j_{r+1} \leq p_{r+1}$.

The lemma now follows by recalling that there are at most $R$ interruptions throughout the execution. Hence, with probability at least $1 - 2R\beta$ it holds that $r$ never increases beyond $R$, and the algorithm does not fail. ◀

Theorem 3.1 now follows by combining Lemmas 3.3, 3.4, 3.5.

## 3.2 A Negative Result for the ASBI Model

We show the following negative result.

▶ **Theorem 3.6.** *For every $R$, there exists a streaming problem over domain of size* $\text{poly}(R)$ *and stream length* $\text{poly}(R)$ *that requires at least* $\Omega(R)$ *space to be solved in the ASBI model with $R$ interruptions and $T = R^2$ queries to within constant accuracy (small enough), but can be solved in the oblivious setting using space* $\text{polylog}(R)$.

We next provide an overview for the proof of this theorem (see the full version of this work for more details). At a high level, Theorem 3.6 follows by strengthening the following negative result of Kaplan et al. [19] for the (plain) adversarial model.

▶ **Theorem 3.7** ([19])**.** *For every $T$, there exists a streaming problem over domain of size* $\text{poly}(T)$ *and stream length* $\text{poly}(T)$ *that requires at least* $\sqrt{T}$ *space to be solved in the (plain) adversarial setting with $T$ queries to within constant accuracy (small enough), but can be solved in the oblivious setting using space* $\text{polylog}(T)$.

To obtain their result, Kaplan et al. [19] presented a streaming problem, called the SADA problem, that is easy to solve in the oblivious setting but requires large space to be solved in the adversarial setting. Specifically, they showed a reduction from a hard problem in learning theory (called the *adaptive data analysis (ADA) problem*) to the task of solving the SADA problem in the adversarial setting with small space.

In the ADA problem, the goal is to design a mechanism $\mathcal{A}$ that initially obtains a dataset $D$ consisting of $n$ i.i.d. samples from some unknown distribution $\mathcal{P}$, and then answers $k$ *adaptively chosen queries* w.r.t. $\mathcal{P}$. Importantly, $\mathcal{A}$'s answers must be accurate w.r.t. the underlying distribution $\mathcal{P}$, and not just w.r.t. the empirical dataset $D$. Hardt, Ullman, and Steinke [14, 22] showed that the ADA problem requires a large sample complexity. Specifically, they showed that every efficient[3] mechanism for this problem must have sample complexity $n \geq \Omega(\sqrt{k})$.

Theorem 3.6 follows by the following two observations regarding the negative result of [19] for the SADA problem, and regarding the underlying hardness result of [14, 22] for the ADA problem:

1. In the hardness results of [14, 22] for the ADA problem, the adversary generates the queries using $O(n)$ rounds of adaptivity, where $n$ is the sample size. In more detail, the adversary poses $O(n^2)$ queries throughout the interaction, but these queries are generated in $O(n)$ bulks where queries in the $j$th bulk depend only on answers given to queries of *previous* bulks.
2. The reduction of Kaplan et al. [19] from the ADA problem to the SADA problem maintains the number of adaptivity rounds. That is, the reduction of Kaplan et al. [19] transforms an adversary for the ADA problem that generates the queries in $\ell$ bulks into an adversary for the SADA problem that uses $\ell$ interruptions.

The following is an immediate corollary of Theorem 3.6.

▶ **Corollary 3.8.** *For every $R \leq T$, there exists a streaming problem over domain of size* $\text{poly}(T)$ *and stream length* $\text{poly}(T)$ *that requires at least* $\Omega\left(\min\left\{R, \sqrt{T}\right\}\right)$ *space to be solved in the ASBI model with $R$ interruptions and $T$ queries to within constant accuracy (small enough), but can be solved in the oblivious setting using space* $\text{polylog}(T)$.

Observe that this (nearly) matches our upper bound stated in Theorem 1.4. We remark that Theorem 3.6 and Corollary 3.8 hold even in a model where the streaming algorithm is strengthen and gets an indication during each interruption round.

# 4 Adversarial Streaming with Advice (ASA)

In this section we present our results for the ASA model, defined in Section 1.2.2. We begin with our generic transformation.

## 4.1 A Generic Construction for the ASA Model

Our generic construction for the ASA model transforms an oblivious and *linear* streaming algorithm $\mathcal{A}$ into a robust streaming algorithm in the ASA model. The linearity property that we need is the following. Suppose that three copies of $\mathcal{A}$, call them $\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3$, are instantiated with the *same* internal randomness $r$, and suppose that $\mathcal{A}_1$ processes a stream $\vec{x}_1$ and that $\mathcal{A}_2$ processes a stream $\vec{x}_2$ and that $\mathcal{A}_3$ processes the stream $\vec{x}_1 \circ \vec{x}_2$ (where the operator $\circ$ stands for concatenation). Then there is an operation, denote it as "+", that allows us to obtain an internal state $(\mathcal{A}_1 + \mathcal{A}_2)$ that is identical to the internal state of $\mathcal{A}_3$. Many classical streaming algorithms have this property (for example, the classical AMS sketch for $F_2$ has this property [3]). Formally,

[3] The results of [14, 22] hold for all computationally efficient mechanisms, or alternatively, for a class of unbounded mechanisms which they call *natural* mechanisms.

**Algorithm 2** `RobustAdvice`$(\beta, m, \eta)$.

**Input:** Parameters: $\beta$ is the failure probability, $m$ is the length of input stream and $\eta$ is the advice query cycle.

**Algorithm used:** An oblivious linear streaming algorithm $\mathcal{A}$ with space $s$ for $\alpha$ accuracy.

**Constants calculation:**

1. $k = \Omega(\eta s \log(m/\beta) \log^2(m/(\beta\alpha)))$ is the number of instances of each of the sets "active", "next" and "shadow".
2. $\varepsilon_0 = \frac{\varepsilon}{\sqrt{8\eta k s \ln(1/\delta)}}$ is the privacy parameter of `PrivateMed` executions, where $\varepsilon = 1/100$, $\delta = O(\beta/m)$.

- - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - -

1. Initialize $k$ independent instances $\mathcal{A}_1^{\text{active}}, \ldots, \mathcal{A}_k^{\text{active}}$ of algorithm $\mathcal{A}$.
2. REPEAT (outer loop)
   a. Initialize $k$ independent instances $\mathcal{A}_1^{\text{next}}, \ldots, \mathcal{A}_k^{\text{next}}$ of algorithm $\mathcal{A}$.
   b. Let $\mathcal{A}_1^{\text{shadow}}, \ldots, \mathcal{A}_k^{\text{shadow}}$ be duplicated copies of $\mathcal{A}_1^{\text{next}}, \ldots, \mathcal{A}_k^{\text{next}}$, where each $\mathcal{A}_i^{\text{shadow}}$ is initiated with the same randomness as $\mathcal{A}_i^{\text{next}}$.
   c. Denote the current time step as $t$. (That is, so far we have seen $t$ updates in the stream.)
   d. REPEAT (inner loop)
      i. Receive next update $x_t$ and a query demand $q_t \in \{0, 1\}$.
      ii. Insert update $x_t$ into each of $\mathcal{A}_1^{\text{active}}, \mathcal{A}_1^{\text{next}}, \ldots, \mathcal{A}_k^{\text{active}}, \mathcal{A}_k^{\text{next}}$.
      iii. If $q_t = 1$ then:
         - Query $\mathcal{A}_1^{\text{active}}, \mathcal{A}_2^{\text{active}}, \ldots, \mathcal{A}_k^{\text{active}}$ and obtain answers $y_{t,1}, y_{t,2}, \ldots, y_{t,k}$
         - Output $z_t \leftarrow$ `PrivateMed`$(y_{t,1}, y_{t,2}, \ldots, y_{t,k})$ with privacy parameter $\varepsilon_0$.
         - If $\left(\sum_{\ell=1}^{t} q_\ell\right) \bmod \eta = 0$ then define the predicate $p_t$ that given a (prefix of a) stream $\vec{x}$ returns the next bit in the inner state of $(\mathcal{A}_1^{\text{shadow}}, \mathcal{A}_2^{\text{shadow}}, \ldots, \mathcal{A}_k^{\text{shadow}})$ after processing the first $t$ updates in $\vec{x}$. Update the corresponding bit in the state of the corresponding $\mathcal{A}_i^{\text{shadow}}$.
         - If $\left(\sum_{\ell=1}^{t} q_\ell\right) \bmod \eta k s = 0$ then EXIT inner loop. Otherwise, CONTINUE inner loop.
   e. For $i \in [k]$ let $\mathcal{A}_i^{\text{active}}.\mathcal{S}_v \leftarrow \mathcal{A}_i^{\text{next}}.\mathcal{S}_v + \mathcal{A}_i^{\text{shadow}}.\mathcal{S}_v$ and let $\mathcal{A}_i^{\text{active}}.\mathcal{S}_R \leftarrow \mathcal{A}_i^{\text{next}}.\mathcal{S}_R$.

▶ **Definition 4.1** (Linear state algorithm). *Let $\mathcal{A}$ be an algorithm with three segments of memory state. The first segment, denoted as $\mathcal{S}_R$, is randomized in the beginning of the execution and then remains fixed. The second segment, denoted as $\mathcal{S}_v$, is an encoding of a vector in $\mathbb{R}^d$. The third segment, denoted as $\mathcal{S}_c$, is the rest of its memory space and is used for other computations. Then, $\mathcal{A}$ is* linear state *w.r.t. its input stream if for any two streams $\vec{x}_1 = (x_1, \ldots, x_l) \in X^l$, $\vec{x}_2 = (x_1, \ldots, x_p) \in X^p$ with lengths of $l, p \in \mathbb{N}$ and three different executions of $\mathcal{A}$ with the same randomized state ($\mathcal{S}_R$) the following holds:*

$$\mathcal{A}(\vec{x}_1 \circ \vec{x}_2).\mathcal{S}_v = \mathcal{A}(\vec{x}_1).\mathcal{S}_v + \mathcal{A}(\vec{x}_2).\mathcal{S}_v$$

*Where $\mathcal{A}(\vec{x}).\mathcal{S}_v$ is the encoded vector $v \in \mathbb{R}^d$ resulting from the input stream $\vec{x}$ encoded in the corresponding memory state.*

Our construction is given in algorithm `RobustAdvice`, and its properties are stated in the following theorem.[4]. The analysis is deferred to the the full version of this work [21].

▶ **Theorem 4.2.** *Fix any real valued function $g$ and fix $\alpha, \beta > 0$ and $\eta \in \mathbb{N}$. Let $\mathcal{A}$ be an oblivious linear-state streaming algorithm for $g$ that uses space $s$ and guarantees accuracy $\alpha$ with failure probability $1/10$. Then there exists an adversarially robust streaming algorithm for $g$ in the ASA model with query/advice rate $\eta$, accuracy $\alpha$, and failure probability $\beta$ using space $O(\eta s^2 \log(m/\beta) \log^2(m/(\beta\alpha)))$.*

## 4.2 A Negative Result for the ASA Model

In this section we show that $\ell_0$-sampling, a classical streaming problem, cannot be solved with sublinear space in the adversarial setting with advice. Consider a turnstile stream $\vec{u} = (u_1, \ldots, u_m)$ where each $u_i = (a_i, \Delta_i) \in [n] \times \{\pm 1\}$. A $\beta$-error $\ell_0$-sampler returns with probability at least $1 - \beta$ an (almost) uniformly random element from

$$\text{support}(u_1, \ldots, u_m) = \left\{ a \in [n] : \sum_{i:a_i=a} \Delta_i \neq 0 \right\},$$

provided that this support is not empty. The next theorem, due to Jowhari et al. [18], shows that $\ell_0$-sampling is easy in the oblivious setting.

▶ **Theorem 4.3** ([18])**.** *There is a streaming algorithm with storage $O\left(\log^2(n) \log(\frac{1}{\beta})\right)$ bits, that with probability at most $\beta$ reports FAIL, with probability at most $1/n^2$ reports an arbitrary answer, and in all other cases produces a uniform sample from* $\text{support}(\vec{u})$.

Nevertheless, as we next show, this is a hard problem in the ASA setting. In fact, our negative result even holds for a simpler variant of the $\ell_0$-sampling problem, in which the algorithm is allowed to return an *arbitrary* element, rather than a random element. Formally,

▶ **Definition 4.4** (The $J_0$ problem)**.** *Let $X$ be a finite domain and let $\mathcal{A}$ be an algorithm that operates on a stream of updates $(u_1, \ldots, u_m) \in (X \times \{\pm 1\})$, given to $\mathcal{A}$ one by one. Algorithm $\mathcal{A}$ solves the $J_0$ problem with failure probability $\beta$ if, except with probability at most $\beta$, whenever $\mathcal{A}$ is queried it outputs an element with non-zero frequency w.r.t. the current stream. That is, if $\mathcal{A}$ is queried in time $i$ then it should output an element from* $\text{support}(u_1, \ldots, u_i)$.

▶ **Theorem 4.5.** *Let $X$ be a finite domain and let $T$ be such that $|X| = \Omega(T)$ (large enough). Let $\mathcal{A}$ be an algorithm for solving the $J_0$ problem over $X$ in the adversarial setting with advice with $T$ queries and with failure probability at most $3/4$. Then $\mathcal{A}$ uses space $\Omega(T)$. Furthermore, this holds also when $\eta = 1$, that is, even if algorithm $\mathcal{A}$ gets an advice after* every *query.*

**Proof.** Let $\mathcal{A}$ be an algorithm for the $J_0$ problem with $T$ queries over domain $X$ in the ASA setting with failure probability at most $3/4$. Consider the following thought experiment.

[4] We assume that the estimates given by the oblivious algorithm $\mathcal{A}$ are in the range $[-m^c, -1/m^c] \cup \{0\} \cup [1/m^c, m^c]$ for some constant $c$, and are rounded to the nearest power of $(1 + \alpha)$. See the full version of this work for more details [21].

**Input:** $Y \subseteq X$ of size $|Y| = T$
1. For every $x \in Y$, feed algorithm $\mathcal{A}$ the update $(x, 1)$.
2. Initiate $\hat{Y} = \emptyset$.
3. Repeat $T$ times:
   a. Query $\mathcal{A}$ and obtain an outcome $x \in X$
   b. If $\mathcal{A}$ requests an advice then give it a random bit $b$.
   c. Add $x$ to $\hat{Y}$
   d. Feed the update $(x, -1)$ to $\mathcal{A}$
4. Output $\hat{Y}$.

We say that the thought experiment *succeeds* if $\hat{Y} = Y$. By the assumption on $\mathcal{A}$, for every input $Y$, our thought experiment succeeds with probability at least $2^{-T}/4$. This is because if all of the bits of advice are correct then $\mathcal{A}$ succeeds with probability at least $1/4$, and the advice bits are all correct with probability at least $2^{-T}$. Hence, there must exist a fixture of $\mathcal{A}$'s coins and a fixture of an advice string $\vec{b}$ for which our thought experiments succeeds on at least $2^{-T}/4$ fraction of the possible inputs $Y$.[5]

That is, after fixing $\mathcal{A}$'s coins and the advice string $\vec{b}$ as above, there is a subset of inputs $\mathfrak{B}$ of size $|\mathfrak{B}| \geq \frac{2^{-T}}{4}\binom{|X|}{T}$ such that for every $Y \in \mathfrak{B}$, when executed on $Y$, our thought experiment outputs $\hat{Y} = Y$. Finally, note that the inner state of algorithm $\mathcal{A}$ at the end of Step 1 *determines* the outcome of our thought experiment. Hence, as there are at least $\frac{2^{-T}}{4}\binom{|X|}{T}$ different outputs, there must be at least $\frac{2^{-T}}{4}\binom{|X|}{T}$ possible different inner states for algorithm $\mathcal{A}$, meaning that its space complexity (in bits) is at least $\log\left(\frac{2^{-T}}{4}\binom{|X|}{T}\right)$, which is more than $T$ provided that $|X| = \Omega(T)$ (large enough). ◀

# Maximal $k$-Edge-Connected Subgraphs in Almost-Linear Time for Small $k$

**Thatchaphol Saranurak**
University of Michigan, Ann Arbor, MI, USA

**Wuwei Yuan**
Institute for Interdisciplinary Information Sciences, Tsinghua University, Beijing, China

## Abstract

We give the first almost-linear time algorithm for computing the *maximal $k$-edge-connected subgraphs* of an undirected unweighted graph for any constant $k$. More specifically, given an $n$-vertex $m$-edge graph $G = (V, E)$ and a number $k = \log^{o(1)} n$, we can deterministically compute in $O(m + n^{1+o(1)})$ time the unique vertex partition $\{V_1, \ldots, V_z\}$ such that, for every $i$, $V_i$ induces a $k$-edge-connected subgraph while every superset $V_i' \supset V_i$ does not. Previous algorithms with linear time work only when $k \leq 2$ [Tarjan SICOMP'72], otherwise they all require $\Omega(m + n\sqrt{n})$ time even when $k = 3$ [Chechik et al. SODA'17; Forster et al. SODA'20].

Our algorithm also extends to the decremental graph setting; we can deterministically maintain the maximal $k$-edge-connected subgraphs of a graph undergoing edge deletions in $m^{1+o(1)}$ total update time. Our key idea is a reduction to the dynamic algorithm supporting pairwise $k$-edge-connectivity queries [Jin and Sun FOCS'20].

## 1 Introduction

We study the problem of efficiently computing the *maximal $k$-edge-connected subgraphs*. Given an undirected unweighted graph $G = (V, E)$ with $n$ vertices and $m$ edges, we say that $G$ is *$k$-edge-connected* if one needs to delete at least $k$ edges to disconnect $G$. The maximal $k$-edge-connected subgraphs of $G$ is a unique vertex partition $\{V_1, \ldots, V_z\}$ of $V$ such that, for every $i$, the induced subgraph $G[V_i]$ is $k$-edge-connected and there is no strict superset $V_i' \supset V_i$ where $G[V_i']$ is $k$-edge-connected.

This fundamental graph problem has been intensively studied. Since the 70's, Tarjan [13] showed an optimal $O(m)$-time algorithm when $k = 2$. For larger $k$, the folklore recursive mincut algorithm takes $\tilde{O}(mn)$ time[1] and there have been significant efforts from the database community in devising faster heuristics [15, 17, 2, 12, 16] but they all require $\Omega(mn)$ time in the worst case. Eventually in 2017, Chechik et al. [3] broke the $O(mn)$ bound to $\tilde{O}(m\sqrt{n}k^{O(k)})$ using a novel approach based on *local* cut algorithms. Forster et al. [4] then improved the local cut algorithm and gave a faster Monte Carlo randomized algorithm with $\tilde{O}(mk + n^{3/2}k^3)$ running time. Very recently, Geogiadis et al. [5] showed a deterministic algorithm with

[1] The algorithm computes a global minimum cut $(A, B)$ (using e.g. Karger's algorithm [8]) and return $\{V\}$ if the cut size of $(A, B)$ is at least $k$. Otherwise, recurse on both $G[A]$ and $G[B]$ and return the union of the answers of the two recursions.

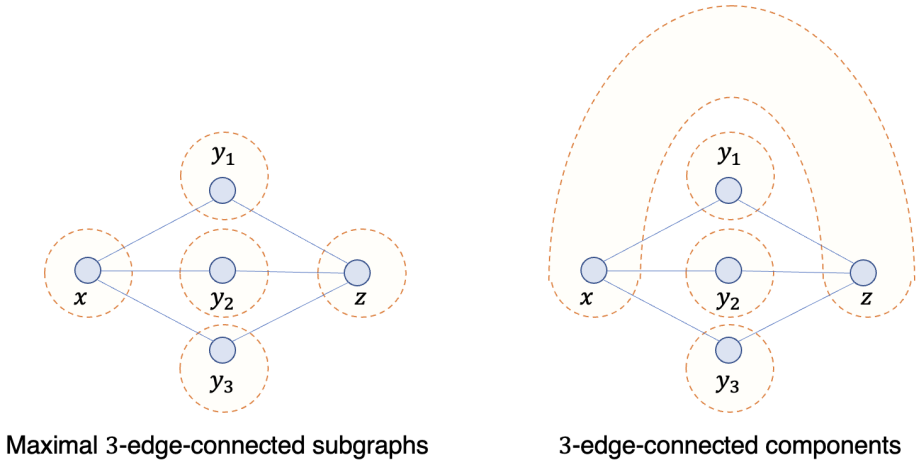

**Figure 1** A graph $G$ where its maximal 3-edge-connected subgraphs are different from its 3-edge-connected components.

$\tilde{O}(m + n^{3/2}k^8)$ time and also how to sparsify a graph to $O(nk \log n)$ edges while preserving maximal $k$-edge-connected subgraphs in $O(m)$ time. Thus, the factor $m$ in the running time of all algorithms can be improved to $O(nk \log n)$ while paying an $O(m)$ additive term. The $O(mn)$ bound has also been improved even in more general settings such as directed graphs and/or vertex connectivity [6, 3, 4] as well as weighted undirected graphs [10]. Nonetheless, in the simplest setting of undirected unweighted graphs where $m = O(n)$ and $k = O(1)$, the $\Omega(n\sqrt{n})$ bound remains the state of the art since 2017.

Let us discuss the closely related problem called *$k$-edge-connected components*. The goal of this problem is to compute the unique vertex partition $\{\hat{V}_1, \ldots, \hat{V}_{z'}\}$ of $V$ such that, each vertex pair $(s, t)$ is in the same part $\hat{V}_i$ iff the $(s, t)$-minimum cut in $G$ (not in $G[\hat{V}_i]$) is at least $k$. The partition of the maximal $k$-edge-connected subgraphs is always a refinement of the $k$-edge-connected components and the refinement can be strict. See Figure 1 for example. Very recently, the Gomory-Hu tree algorithm by Abboud et al. [1] implies that $k$-edge-connected components can be computed in $m^{1+o(1)}$ time in undirected unweighted graphs. This algorithm, however, does not solve nor imply anything to our problem. See Appendix A for a more detailed discussion.

It is an intriguing question whether one can also obtain an almost-linear time algorithm for maximal $k$-edge-connected subgraphs, or there is a separation between these two closely related problems.

## Our results

In this paper, we show the first almost-linear time algorithm when $k = \log^{o(1)} n$, answering the above question affirmatively at least for small $k$.

▶ **Theorem 1.** *There is a deterministic algorithm that, given an undirected unweighted graph $G$ with $n$ vertices and $m$ edges, computes the maximal $k$-edge-connected subgraphs of $G$ in $O(m + n^{1+o(1)})$ time for any $k = \log^{o(1)} n$.*

Our techniques naturally extend to the decremental graph setting.

▶ **Theorem 2.** *There is a deterministic algorithm that, given an undirected unweighted graph $G$ with $n$ vertices and $m$ edges undergoing a sequence of edge deletions, maintains the maximal $k$-edge-connected subgraphs of $G$ in $m^{1+o(1)}$ total update time for any $k = \log^{o(1)} n$.*

Dynamic algorithms for maximal $k$-edge-connected subgraphs were recently studied in [5]. For comparison, their algorithm can handle both edge insertions and deletions but require $O(n\sqrt{n}\log n)$ worst-case update time, which is significantly slower than our $m^{o(1)}$ amortized update time. When $k = 3$, they also gave an algorithm that handles edge insertions only using $\tilde{O}(n^2)$ total update time.

### Previous Approaches and Our Techniques

Our approach diverges significantly from the local-cut-based approach in [3, 4]. In these previous approaches, they call the local cut subroutine $\Omega(n)$ times and each call takes $\Omega(\sqrt{n})$ time. Hence, their running time is at least $\Omega(n\sqrt{n})$ and this seems inherent without significant modification. Recently, [5] took a different approach. Their $\tilde{O}(m + n^{3/2}k^8)$-time algorithm efficiently implements the folklore recursive mincut algorithm by feeding $O(nk)$ updates to the dynamic minimum cut algorithm by Thorup [14]. However, since Thorup's algorithm has $\Omega(\sqrt{n})$ update time, the final running time of [5] is at least $\Omega(n\sqrt{n})$ as well.

Our algorithm is similar to [5] in spirit but is much more efficient. We instead apply the dynamic $k$-edge connectivity algorithms by Jin and Sun [7] that takes only $n^{o(1)}$ update time when $k = \log^{o(1)} n$. Our reduction is more complicated than the reduction in [5] to dynamic minimum cut because the data structure by [7] only supports pairwise $k$-edge connectivity queries, not a global minimum cut. Nonetheless, we show that $\tilde{O}(nk)$ updates and queries to this "weaker" data structure also suffice.

Our approach is quite generic. Our algorithm is carefully designed without the need to check if the graph for which the recursive call is made is $k$-edge-connected. This allows us to extend our algorithm to the dynamic case.

### Organization

We give preliminaries in Section 2. Then, we prove Theorem 1 and Theorem 2 in Section 3 and Section 4, respectively.

## 2 Preliminaries

Let $G = (V, E)$ be an *unweighted undirected* graph. Let $n = |V|$ and $m = |E|$, and assume $m = \text{poly}(n)$ and $k = \log^{o(1)} n$. For any $S, T \subseteq V$, let $E(S, T) = \{(u, v) \in E \mid u \in S, v \in T\}$. For every vertex $u$, the degree of $u$ is $\deg(u) = |\{(u, v) \mid (u, v) \in E\}|$. For every subset of vertices $S \subseteq V$, the volume of $S$ is $\text{vol}(S) = \sum_{u \in S} \deg(u)$. Denote $G[S]$ as the induced graph of $G$ on a subset of vertices $S \subseteq V$.

Two vertices $s$ and $t$ are *$k$-edge-connected* in $G$ if one needs to delete at least $k$ edges to disconnect $s$ and $t$ in $G$. A vertex set $S$ is *$k$-edge-connected* if every pair of vertices in $S$ is $k$-edge-connected. We use the convention that $S$ is $k$-edge-connected when $|S| = 1$. We say that a graph $G = (V, E)$ is $k$-edge-connected if $V$ is $k$-edge-connected. A *$k$-edge-connected component* is an inclusion-maximal vertex set $S$ such that $S$ is $k$-edge-connected. A whole vertex set can always be partitioned into $k$-edge-connected components. We use $kECC(u)$ to denote the unique $k$-edge-connected component containing $u$. Note that a $k$-edge-connected component may not induce a connected graph when $k > 2$. A vertex set $S$ is a *$k$-cut* if $|E(S, V \setminus S)| < k$. Note, however, we also count the whole vertex set $V$ as a trivial $k$-cut.

We will crucially exploit the following dynamic algorithm in our paper.

▶ **Theorem 3** (Dynamic pairwise $k$-edge connectivity [7]). *There is a deterministic algorithm that maintains a graph $G$ with $n$ vertices undergoing edge insertions and deletions using $n^{o(1)}$ update time and, given any vertex pair $(s,t)$, reports whether $s$ and $t$ are $k$-edge-connected in the current graph $G$ in $n^{o(1)}$ time where $k = \log^{o(1)} n$.*

For the maximal $k$-edge-connected subgraph problem, we can assume that the graph is sparse using the *forest decomposition*.

▶ **Definition 4** (Forest decomposition [9]). *A $t$-forest decomposition of a graph $G$ is a collection of forests $F_1, \ldots, F_t$, such that $F_i$ is a spanning forest of $G \setminus \bigcup_{j=1}^{i-1} F_j$, for every $1 \leq i \leq t$.*

▶ **Theorem 5** (Lemma 8.3 of [5]). *Any $O(k \log n)$-forest decomposition of a graph has the same maximal $k$-edge-connected subgraphs as the original graph. Moreover, there is an algorithm for constructing such a $O(k \log n)$-forest decomposition in $O(m)$ time.*

## 3 The Static Algorithm

In this section, we prove our main result, Theorem 1. The key idea is the following reduction:

▶ **Lemma 6.** *Suppose there is a deterministic decremental algorithm supporting pairwise $k$-edge-connectivity that has $t_p \cdot m$ total preprocessing and update time on an initial graph with $n$ vertices and $m$ edges and query time $t_q$.*

*Then, there is a deterministic algorithm for computing the maximal $k$-edge-connected subgraphs in $O(m + (t_p + t_q) \cdot kn \log^2 n)$ time.*

By plugging in Theorem 3, we get Theorem 1. The rest of this section is for proving Lemma 6. Throughout this section, we let $t_q$ denote the query time of the decremental pairwise $k$-edge connectivity data structure that Lemma 6 assumes.

Recall again that, for any vertex $u$, $u$'s $k$-edge-connected component, $kECC(u)$, might not induce a connected graph. The first tool for proving Lemma 6 is a "local" algorithm for finding a connected component of $G[kECC(u)]$.

▶ **Lemma 7.** *Given a graph $G$ and a vertex $u$, there is a deterministic algorithm for finding the connected component $U$ containing $u$ of $G[kECC(u)]$ in $O(t_q \cdot \mathrm{vol}(U))$ time.*

**Proof.** We run BFS from $u$ to explore every vertex in the connected component $U$ containing $u$ of $kECC(u)$. During the BFS process, we only visit the vertices in $kECC(u)$ by checking if the newly found vertex is $k$-edge-connected to $u$. Since each edge incident to $U$ is visited at most twice, the total running time is $O(t_q \cdot \mathrm{vol}(U))$. ◀

Below, we describe the algorithm for Lemma 6 in Algorithm 1 and then give the analysis.

### Correctness

We start with the following structural lemma.

▶ **Lemma 8** (Lemma 5.6 of [3]). *Let $T$ be a $k$-cut in $G[C]$ for some vertex set $C$. Then, either*

- *$T$ is a $k$-cut in $G$ as well, or*
- *$T$ contains an endpoint of $E(C, V(G) \setminus C)$.*

Next, the crucial observation of our algorithm is captured by the following invariant.

**Algorithm 1** MAIN$(G, L)$: compute the maximal $k$-edge-connected subgraphs.

**Input:** An undirected connected graph $G = (V, E)$, and a list of vertices $L$ (initially $L = V$). Note that the parameters are passed by value.
**Output:** The maximal $k$-edge-connected subgraphs of $G$.

```
1  S ← ∅.
2  while |L| > 1 do
3      Choose an arbitrary pair (u, v) ∈ L.
4      if u and v are k-edge-connected in G then
5          L ← L \ {v}.
6      else
7          Simultaneously compute the u's connected component of G[kECC(u)] and
           the v's connected component of G[kECC(v)], until the one with the smaller
           volume (denoted by U) is found.
8          S ← S ∪ Main(G[U], U).
9          G ← G \ U.
10         L ← (L \ U) ∪ {w ∉ U | (x, w) ∈ E(U, V(G) \ U)}.
11     end
12 end
13 S ← S ∪ {V(G)}.
14 return S.
```

▶ **Lemma 9.** *At any step of Algorithm 1, every $k$-cut $T$ in $G$ is such that $T \cap L \neq \emptyset$.*

**Proof.** The base case is trivial because $L \leftarrow V$ initially. Next, we prove the inductive step. $L$ can change in Line 5 or Line 8.

In the first case, the algorithm finds that $u$ and $v$ are $k$-edge-connected and removes $v$ from $L$. For any $k$-cut $T$ where $v \in T$, an important observation is that $kECC(v) \subseteq T$ as well. But $kECC(u) = kECC(v)$ and so $u \in T$ too. So the invariant still holds even after removing $v$ from $L$.

In the second case, the algorithm removes $U$ from $G$. Let us denote $G' = G \setminus U$. Since the algorithm adds the endpoints of cut edges crossing $U$ to $L$, it suffices to consider a $k$-cut $T$ in $G'$ that is disjoint from the endpoints of the cut edges of $U$. By Lemma 8, $T$ was a $k$-cut in $G$. Since the changes in $L$ occur only at $U$ and neighbors of $U$, while $T$ is disjoint from both $U$ and all neighbors of $U$, we have $T \cap L \neq \emptyset$ by the induction hypothesis. ◀

▶ **Corollary 10.** *When $|L| = 1$, then $G$ is $k$-edge-connected.*

**Proof.** Otherwise, there is a partition $(A, B)$ of $V$ where $|E(A, B)| < k$. So both $A$ and $B$ are $k$-cuts in $G$. By Lemma 9, $A \cap L \neq \emptyset$ and $B \cap L \neq \emptyset$ which contradicts that $|L| = 1$. ◀

We are ready to conclude the correctness of Algorithm 1. At a high level, the algorithm finds the set $U$ and "cuts along" $U$ at Lines 7. Then, on one hand, recurse on $U$ at Line 8 and, on the other hand, continue on $V(G) \setminus U$. We say that the cut edges $E(U, V(G) \setminus U)$ are "deleted".

Now, since $U$ is the connected component of $G[kECC(u)]$ for some vertex $u$. We have that, for every edge $(x, y) \in E(U, V(G) \setminus U)$, the pair $x$ and $y$ are not $k$-edge-connected in $G$. In particular, $x$ and $y$ are not $k$-edge-connected in $G[V']$ for every $V' \subseteq V$.

**Algorithm 2** UPDATE(H, e).

**Input:** A $k$-edge-connected subgraph $H$ and an edge $e = (x, y) \in H$ to be deleted.
**Output:** The $k$-edge-connected subgraphs of $H$ after deletion.
1 $H \leftarrow H \setminus \{(x, y)\}$.
2 **return** MAIN$(H, \{x, y\})$.

Thus, the algorithm never deletes edges inside any maximal $k$-edge-connected subgraph $V_i$. Since the algorithm stops only when the remaining graph is $k$-edge-connected, the algorithm indeed returns the maximal $k$-edge-connected subgraphs of the whole graph.

### Running Time

Consider the time spent on each recursive call. Let $G'$ be the graph for which the recursive call is made and $m' = \mathrm{vol}(G')$. Every vertex is inserted to $L$ initially or as an endpoint of some removed edge, so the total number of vertices added to $L$ is $O(m')$. In each iteration, either we remove a vertex from $L$, or remove a subgraph from $G$. Hence we check pairwise $k$-edge-connectivity $O(m')$ times, so the running time of checking pairwise $k$-edge-connectivity is $O(t_q \cdot m')$. For the time of finding connected components of $k$-edge-connected components, since we spend $O(t_q \cdot \mathrm{vol}(U))$ time to find some $U$ and remove $U$ from $G$, the total cost is $O(t_q \cdot m')$. Plus, initializing the dynamic pairwise $k$-edge connectivity algorithm on $G'$ takes $O(t_p \cdot m')$ time. Thus the total running time of each recursive call is $O((t_p + t_q) \cdot m')$.

For the recursion depth, since each $U$ found has the smaller volume of the two, $\mathrm{vol}(U) \leq m'/2$. Hence the recursion depth is $O(\log m_0)$, where $n_0$ and $m_0$ are the numbers of vertices and edges of the initial graph. Thus the total running time of Algorithm 1 is $O((t_p + t_q) \cdot m_0 \log n_0)$.

By applying Theorem 5 to the initial graph $G$ and invoking Algorithm 1 on the resulting graph, the number of edges in the resulting graph is $O(kn_0 \log n_0)$, so the running time is improved to $O(m_0 + (t_p + t_q) \cdot kn_0 \log^2 n_0)$. This completes the proof of Lemma 6.

## 4 The Decremental Algorithm

Our static algorithm can be naturally extended to a decremental dynamic algorithm. To prove Theorem 2, we prove the following reduction. By combining Lemma 11 and Theorem 3, we are done.

▶ **Lemma 11.** *Suppose there is a deterministic decremental algorithm supporting pairwise $k$-edge-connectivity that has $t_p \cdot m$ total preprocessing and update time on an initial graph with $n$ vertices and $m$ edges and query time $t_q$.*

*Then there is a deterministic decremental dynamic algorithm for maintaining the maximal $k$-edge-connected subgraphs on an undirected graph of $n$ vertices and $m$ edges with $O((t_p + t_q) \cdot m \log n)$ total preprocessing and update time, and $O(1)$ query time.*

The algorithm for Lemma 11 as is follows. First, we preprocess the initial graph $G_0$ using Algorithm 1 and obtain the maximal $k$-edge-connected subgraphs $\{V_1, \ldots, V_z\}$ of $G_0$.

Next, given an edge $e$ to be deleted, if $e$ is in a maximal $k$-edge-connected subgraph $V_i$ of $G$, then we invoke UPDATE$(G[V_i], e)$ and update the set of the maximal $k$-edge-connected subgraphs of $G$; otherwise we ignore $e$. The subroutine UPDATE$(H, e)$ is described in Algorithm 2.

### Correctness

Let $H = (V', E')$ be the maximal $k$-edge-connected subgraph containing edge $(x, y)$ before deletion. It suffices to prove that Lemma 9 holds when we invoke Algorithm 1. Suppose there is a $k$-cut $C$ in $H \setminus \{(x, y)\}$ such that $C \cap \{x, y\} = \emptyset$, then $C$ is also a $k$-cut in $H$, a contradiction. Hence the correctness follows from the correctness of Algorithm 1.

### Running Time

In the case that $H \setminus \{(x, y)\}$ is still $k$-edge-connected, the running time is $t_q$. We charge this time $t_q$ to the deleted edge $(x, y)$.

Otherwise, consider the time spend on each recursive call of Main. Assume that the total volume of the subgraphs removed and passed to another recursive call in a recursive call is $\nu$. The total number of vertices added to $L$ is $O(\nu)$. In each iteration, we either remove a vertex from $L$ or remove a subgraph. Hence we check pairwise $k$-edge-connectivity $O(\nu)$ times, so the running time of checking pairwise $k$-edge-connectivity is $O(t_q \cdot \nu)$. Since we spend $O(t_q \cdot \mathrm{vol}(U))$ time to find $U$, the total cost is $O(t_q \cdot \nu)$. Plus, it takes $O((t_p + t_q) \cdot m')$ time to initialize the dynamic pairwise $k$-edge connectivity algorithm and check pairwise $k$-edge-connectivity on a graph $H'$ with $m'$ edges for the first time we invoke Main on $H'$. Also, removing all edges from $H'$ takes $t_p \cdot m'$ time. We charge $O(t_p + t_q)$ to each of the removed edges in each recursive call.

The recursion depth is $O(\log m_0)$ by Lemma 6, where $n_0$ and $m_0$ are the numbers of vertices and edges of the initial graph. Hence each edge will be charged $O(\log m_0)$ times, so the total preprocessing and update time is $O((t_p + t_q) \cdot m_0 \log n_0)$.

## A Relationship with $k$-Edge-Connected Components

The reason why a subroutine for computing $k$-edge-connected components is not useful for computing maximal $k$-edge-connected subgraphs is as follows. Given a graph $G = (V, E)$, we can artificially create a supergraph $G' = (V' \supseteq V, E' \supseteq E)$ where the whole set $V$ is $k$-edge-connected, but the maximal $k$-edge-connected subgraphs of $G'$ will reveal the maximal $k$-edge-connected subgraphs of $G$. So given a subroutine for computing the $k$-edge-connected components of $G'$, we know nothing about the maximal $k$-edge-connected subgraphs of $G$. The construction of $G'$ is as follows.

First, we set $G' \leftarrow G$. Assume $V = \{1, 2, \ldots, n\}$. For every $1 \leq i < n$, add $k$ parallel dummy length-2 paths $(i, d_{i,1}, i+1), \ldots, (i, d_{i,k}, i+1)$. Thus $i$ and $i+1$ are $k$-edge-connected, so $V$ is $k$-edge-connected at the end. When we compute the maximal $k$-edge-connected subgraphs of $G'$, we know that we will first remove all dummy vertices $d_{i,j}$ because they all have degree 2 (assuming that $k > 2$). We will obtain $G$ and so we will obtain the maximal $k$-edge-connected subgraphs of $G$ from this process.

## Abstract

The Connected Max Cut (CMC) problem takes in an undirected graph $G(V, E)$ and finds a subset $S \subseteq V$ such that the induced subgraph $G[S]$ is connected and the number of edges connecting vertices in $S$ to vertices in $V \setminus S$ is maximized. This problem is closely related to the Max Leaf Degree (MLD) problem. The input to the MLD problem is an undirected graph $G(V, E)$ and the goal is to find a subtree of $G$ that maximizes the degree (in $G$) of its leaves. [Gandhi et al. 2018] observed that an $\alpha$-approximation for the MLD problem induces an $\mathcal{O}(\alpha)$-approximation for the CMC problem.

We present an $\mathcal{O}(\log\log|V|)$-approximation algorithm for the MLD problem via local search. This implies an $\mathcal{O}(\log\log|V|)$-approximation algorithm for the CMC problem. Thus, improving (exponentially) the best known $\mathcal{O}(\log|V|)$ approximation of the Connected Max Cut problem [Hajiaghayi et al. 2015].

## 1 Introduction

The Connected Max Cut (CMC) problem takes in an undirected graph $G(V, E)$ and finds a subset $S \subseteq V$ such that the induced subgraph $G[S]$ is connected and the number of edges connecting vertices in $S$ to vertices in $V \setminus S$ is maximized. This problem is known to be NP-Hard [6]. We give an $\mathcal{O}(\log\log n)$-approximation algorithm for this problem, where $n = |V|$. This improves on the previously known $\mathcal{O}(\log n)$-approximation algorithm given in [6]. (We say that an approximation algorithm for a maximization problem achieves an $\alpha \geq 1$ approximation ratio if the value of its output is at least $\frac{1}{\alpha}$ of the maximum.)

A function $f\colon 2^V \to \mathbb{R}_+$ is *submodular* if for every $A, B \in V$, $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$. It is not difficult to verify that the cut function is submodular and non-monotone, and thus the CMC problem is a special case of non-monotone submodular function maximization subject to connectivity constraints. To the best of our knowledge there are no nontrivial approximation algorithms for the well motivated general non-monotone submodular function maximization subject to connectivity constraints.

The CMC problem is closely related to the Max Leaf Tree (MLT) and Max Leaf Spanning Tree (MLST) problems. The undirected version of the MLT problem takes in a vertex-weighted undirected graph $G(V, E, w)$ and finds a subtree with maximum weight on the leaves. The weighted version of the MLST problem requires the output tree of the MLT instance to be a spanning tree. We note that the MLT problem can also be posed as a non-monotone submodular function maximization problem subject to connectivity constraints.

In this case the submodular function $f: 2^V \to \mathbb{R}_+$ defined on subsets of vertices of $G$ is $f(U) = \sum_{x \in \mathcal{N}(U)} w(x)$, where $\mathcal{N}(U)$ is the set of neighbors of the vertices in $U$ that are not in $U$ (and $f(\emptyset) = 0$).

Gandhi et al. [4] observed that an $\alpha$-approximation algorithm for the MLT problem implies a $4\alpha$-approximation algorithm for the (edge) weighted CMC problem. Based on this observation we consider a special case of the MLT problem we call the MLD problem. In this problem we are given an undirected graph $G(V, E)$ and the goal is to find a subtree that maximizes the degree (in $G$) of its leaves, that is, the weight of vertices in this special case of the MLT problem is their degree in $G$. Applying the observation in Gandhi et al. [4] we get that an $\alpha$-approximation algorithm for the MLD problem gives a $4\alpha$-approximation algorithm for the *unweighted* CMC problem. We present an $\mathcal{O}(\log \log n)$-approximation algorithm for the MLD problem and thus an approximation algorithm with the same quality for the CMC problem.

Our algorithm is quite simple and involves successive local improvement steps. The proof that our algorithm indeed achieves an $\mathcal{O}(\log \log n)$ approximation ratio is somewhat involved and relies on the fact that the weights of the vertices in the MLD problem instance are the degrees of these vertices in an undirected graph with no parallel edges. To prove the $\mathcal{O}(\log \log n)$ approximation ratio we prove a stronger property of our solution: we prove that the total number of edges in the graph is $\mathcal{O}(\log \log n)$ times the sum of the degrees of the leaves of the computed subtree. This bound is tight as we can construct an instance that achieves this upper bound.

## 1.1 Motivation and Prior Art

We motivate both our CMC problem and the general non-monotone submodular function maximization subject to connectivity constraints. The Max Cut problem is a fundamental combinatorial optimization problem and is one of the problems listed in Karp's seminal paper on NP-Complete problems [9]. Extending the Max Cut problem to the CMC problem is natural. We note that a similar extension of the Min Cut problem is trivial since we can always find a minimum cut that separates a connected component.

The Max Cut problem has numerous applications, e.g., in circuit layout design, statistical physics [1], and image segmentation [3, 13]. Some of these applications can be extended to the connected max cut problem. For example, Hajiaghayi et al. [6] noted that the image segmentation application with the additional requirement that the pixels are connected can be modeled as a CMC problem.

There are quite a few applications of non-monotone submodular function maximization among them: maximum facility location and optimal sensor placement, segmentation problems [10], least core value of general supermodular cost games [15], optimal marketing over social networks [7], and revenue maximization for banner advertisement [2]. Some of these applications consider functions that are defined on a vertex set of a graph and thus it is natural to consider the maximization subject to graph constraints. For example, in sensor placement we may constrain the activated sensors to be connected to enable efficient communication, or sets targeted for marketing in a social network may be required to be in the same social community.

The CMC problem was introduced by Hajiaghayi et al. in [5] (see also [6]) who gave an $\mathcal{O}(\log n)$-approximation algorithm for this problem and obtained a polynomial time approximation scheme for the CMC problem on planar graphs and on bounded genus graphs.

Lee et al. [11] generalized the problem considered in [6] in two aspects: (i) they considered more general graph constraints and not just connectivity constraints, and (ii) they allowed the graph constraints to be on a separate graph from the one in which the max cut needs

to be computed (as long as both graphs are defined on the same set of vertices). The graph constraints considered in [11] include independent set, vertex cover, dominating set and connectivity. Lee et al. [11] showed a 2 approximation for this problem on graphs with bounded treewidth. Some of these results (for constraints such as independent set, dominating set, and connectivity) can be achieved also for planar graphs, bounded genus graphs, and graphs with a fixed excluded minor. The algorithm in [11] is not combinatorial but uses an LP relaxation based on the Sherali-Adams hierarchy.

As mentioned above, Gandhi et al. [4] showed that the weighted CMC problem and the MLT problem are closely related. They obtained a constant approximation algorithm for MLT problem in the special case of $\{0,1\}$ weights, and then used a "bucketing" technique to extend it to an $\mathcal{O}(\log n)$-approximation algorithm for the general case. This implies an $\mathcal{O}(\log n)$-approximation algorithm for the weighted CMC problem which improves the $\mathcal{O}\big(\log^2 n\big)$-approximation algorithm for this problem given in [6].

The unweighted MLT problem is simply the problem of finding a subtree with the maximum number of leaves. Note that there is always a spanning tree that maximizes the number of leaves, and thus the unweighted MLT problem and the unweighted MLST problem are equivalent and both can be approximated within a factor of 2 [16]. The weighted MLST problem admits no $n^{1-\varepsilon}$ approximation, for any constant $\varepsilon > 0$ as it is equivalent to the Maximum Independent Set problem, as observed in [8]. This is in contrast to the weighted MLT problem that admits an $\mathcal{O}(\log n)$ approximation [4], and to the MLD problem, which is a special case of the weighted MLT problem in which the weight of every vertex is equal to its degree, that admits an $\mathcal{O}(\log\log n)$ approximation, as shown in this paper.

The rest of the paper is organized as follows. Section 2 gives a formal definition of our problems. Section 3 describes the local search algorithm, and Section 4 proves its approximation ratio. Section 5 has some concluding remarks and open problems. Due to space constraints some of the proofs are omitted from this abridged version of the paper.

## 2 Preliminaries and Problem Definitions

In all our problems we consider undirected graphs with no parallel edges. Let $G(V,E)$ be such a graph, with $n = |V|$, and $m = |E|$. For a subset $S \subseteq V$, define $\mathcal{N}_G(S)$ to be the subset of the edges in $E$ with exactly one endpoint in $S$. For a vertex $v \in V$, let $d_G(v)$ denote the degree of $v$ in $G$; that is, $d_G(v) = |\mathcal{N}_G(\{v\})|$. For a subset $S \subseteq V$, define $G[S]$ to be the subgraph induced by $S$. Any subset $S \subseteq V$ such that $G[S]$ is connected, defines a connected cut of size $|\mathcal{N}_G(S)|$.

A tree $T(U,F)$ is a *subtree* of graph $G$ if $T$ is a tree, $U \subseteq V$, and $F \subseteq E$. We denote the "subtree" relation by the symbol $\sqsubseteq$, namely, $T \sqsubseteq G$ indicates that $T$ is a subtree of $G$. Let $V(T)$ be the set of vertices of $T$, $L(T)$ be the set of leaves of $T$, and $I(T)$ be the set of the internal vertices of $T$; that is, $L(T) = \{v \mid v \in U \wedge d_T(v) = 1\}$ and $I(T) = V(T) \setminus L(T)$. Obviously, $T(U,F)$ is a spanning tree of $G$ iff $U = V$.

For any given vertex $r \in U$, if $T$ is *rooted* at $r$, then all the edges in $F$ are oriented from $r$ outwards; namely, for $(x,y) \in F$, vertex $x$ precedes $y$ in the (unique) path from $r$ to $y$. In this case we say that $x$ is the *parent* of $y$ and $y$ is a *child* of $x$. Our convention is to specify the tree edge connecting $x$ to its child $y$ as $(x,y)$. If vertex $x$ is on the (unique) path from $r$ to $y$ then $x$ is an *ancestor* of $y$ and $y$ is a *descendant* of $x$. We denote this relation by $x \rightsquigarrow y$. A vertex $x$ is considered an ancestor and a descendant of itself (unless specified explicitly otherwise). For a subset $U' \subseteq U$, define $\mathsf{Desc}_T(U')$ to be the set of descendants of the vertices in $U'$, and $\mathsf{LDesc}_T(U')$ to be the set of *leaf* descendants of the vertices in

$U'$. Namely, $\mathsf{Desc}_T(U') = \{y \mid \exists x \in U' \colon\ x \rightsquigarrow y\}$, and $\mathsf{LDesc}_T(U') = \mathsf{Desc}_T(U') \cap L(T)$. To simplify notation for singleton sets, we define $\mathsf{Desc}_T(u) = \mathsf{Desc}_T(\{u\})$. We assume that $n > 2$ (since the problem is trivial when $n \leq 2$), and for convenience we always root $T$ at a vertex $r$ for which $d_T(r) > 1$.

For a vertex $x \in U$, let $C_T(x)$ be the set of its children in $T$, and $T_x$ be the subtree rooted at $x$; that is, the tree induced by the set of the descendants of $x$. For any two vertices $x, y \in U$, let $LCA(x, y)$ denote the lowest ancestor of $x$ and $y$; defined as the unique vertex $u \in U$ such that $u$ is an ancestor of both $x$ and $y$, and none of the children of $u$ is an ancestor of both $x$ and $y$.

For a graph $G(V, E)$ and a tree $T(U, F)$, where $U \subseteq V$, define the *leaf degree* of $T$ in $G$, denoted $\mathsf{LD}_G(T)$, as $\mathsf{LD}_G(T) = \sum_{v \in L(T)} d_G(v)$; in words, the leaf degree of $T$ is the sum of the degrees in $G$ of the leaves of $T$.

The input for both the Connected Max Cut (CMC) problem and the Max Leaf Degree (MLD) problem is a graph $G(V, E)$. The output of the CMC problem is a connected cut of maximum size. The output of the MLD problem is a subtree $T_{\mathsf{opt}} \sqsubseteq G$ with maximum leaf degree, i.e., $T_{\mathsf{opt}} = \arg\max_{T \sqsubseteq G} \{\mathsf{LD}_G(T)\}$.

Hajiaghayi et al. [6] proved that the CMC problem is NP-Hard even when the input is restricted to planar graphs. The MLD problem is NP-Hard as well. To see this note that when the graph $G(V, E)$ is regular the MLD problem is equivalent to the unweighted MLT problem (since all vertices have the same weight), which is equivalent to the unweighted MLST problem, as noted above. The unweighted MLST problem on regular graphs was shown to be NP-Hard in [12, 14] and thus the MLD problem is also NP-Hard even when the input is restricted to regular graphs. The MLD problem is APX-Hard as well since the unweighted MLST problem on 5-regular graphs is APX-Hard [14].

Both problems have a weighted version which is not considered in this paper. In the weighted CMC problem every edge $e \in E$ has a weight and the output of the weighted CMC problem is a connected cut of maximum weight. In the MLT problem, which is the weighted MLD problem, every vertex $v \in V$ has a weight $w(v)$ and the output of the MLT problem is a subtree $T_{\mathsf{opt}} \sqsubseteq G$ with maximum leaf weight, i.e., $T_{\mathsf{opt}} = \arg\max_{T \sqsubseteq G} \left\{\sum_{v \in L(T)} w(v)\right\}$. (Recall that the MLD problem is a special case of the weighted MLT problem in which the weight of the vertices is equal to their degree.)

Since both the CMC and the MLD problems are NP-Hard they call for approximation algorithms. Both are maximization problems. We say that an approximation algorithm for a maximization problem achieves an $\alpha \geq 1$ approximation ratio if the value of its output is at least $\frac{1}{\alpha}$ of the maximum. Gandhi et al. [4] proved a relation between the approximation of these problems.

▶ **Theorem 1** ([4]). *An $\alpha$-approximation algorithm for the MLD problem implies a $4\alpha$-approximation algorithm for the CMC problem.*

We note that [4] considered the weighted CMC and MLT problems. For an edge weighted CMC instance the weight of a vertex $v$ in the corresponding MLT instance is the sum of the weights of the edges in $\mathcal{N}_G(\{v\})$. It is easy to see that the MLD problem corresponds to the unweighted CMC problem since in the MLD problem the weight of every vertex equals its degree.

# 3 The Local Search Algorithm for MLD

Given a graph $G(V, E)$, we present a local search algorithm that finds a subtree $T^* \sqsubseteq G$ such that $\mathcal{O}(\mathsf{LD}_G(T^*) \log \log n) = \max_{T \sqsubseteq G} \{\mathsf{LD}_G(T)\}$. We start by computing any spanning tree $T(V, F)$ of $G$, and root it at an arbitrary vertex $r \in V$. The solution generated by our algorithm will be a subtree of $G$, also rooted at $r$. The algorithm proceeds iteratively by performing local search improvements. Each local search improvement considers an internal vertex $v \in I(T)$ and determines whether making $v$ a leaf, while potentially removing some of the current leaves in $T$, results in an improved tree. We call such an operation a *vertex improvement* defined below. The algorithm terminates when no local search improvements are available and the current tree $T$ at this point is returned as $T^*$.

## 3.1 Vertex improvement

To define the improvements we first introduce the notion of *dependent* children. Let $T \sqsubseteq G$ be a subtree of $G$. Consider a vertex $v \in I(T)$, and let $C_T(v) \subseteq V(T)$ be the set of children of $v$ in $T$. For a vertex $x \in C_T(v)$, consider $G[I(T) \cup \{x\} \setminus \{v\}]$ – the subgraph of $G$ induced by $x$, and the vertices in $I(T)$, except for $v$. We say that $x$ is a *dependent* child of $v$ if $x$ is disconnected from $r$ in this induced subgraph. Note that a *dependent* child of $v$ depends on $v$ for its connectivity to $r$ in the subgraph $G[I(T) \cup \{x\}]$ (implying that $v$ is a separating vertex in $G[I(T) \cup \{x\}]$). If a vertex $x \in C_T(v)$ is not a dependent child then it is an *independent* child of $v$. Let $D_T(v) \subseteq C_T(v)$ be the (possibly empty) set of dependent children of $v$ in $T$. (For the root $r$ of $T$, trivially $D_T(r) = C_T(r)$.) Figure 1 illustrates a vertex $v$ and its *independent* child $x$.

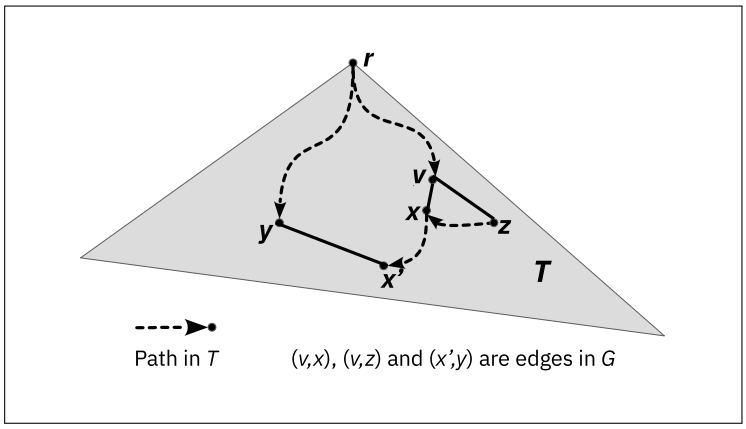

**Figure 1** Vertices $x$ and $z$ are independent children of $v$ since the paths from $z$ to $x$ and from $x$ to $r$ via $(x', y)$ use only internal vertices of $T$ and avoid $v$.

▶ **Lemma 2.** *For a subtree $T(U, F) \sqsubseteq G$ and a vertex $v \in I(T)$, if $v$ has any independent children, then there exists an independent child $x \in C_T(v) \setminus D_T(v)$ and a subtree $T'(U, F') \sqsubseteq G$, such that $C_{T'}(v) = C_T(v) \setminus \{x\}$, $L(T) \subseteq L(T') \subseteq L(T) \cup \{v, x\}$, and $\mathsf{LD}_G(T') \geq \mathsf{LD}_G(T)$.*

**Proof.** Consider an independent child $z \in C_T(v) \setminus D_T(v)$ (see Figure 1). By the definition of an independent child there exists a path in $G$ that connects $z$ to the root $r$ with the property that all the vertices along this path are in $I(T) \setminus \{v\}$. Follow such a path starting at $z$. It must include an edge $(x', y)$ such that $LCA(x', y)$ is an ancestor of $v$ other than $v$. (This is because $r$ is not a descendant of $v$.) Consider the first such edge along the path. For this

edge $x'$ is a descendant of $v$ (other than $v$) and $y$ is not a descendant of $v$. Adding the edge $(x', y)$ to the set $F$ of the edges of $T$ creates a cycle that consists of the tree paths from $LCA(x', y)$ to $x'$ and to $y$ and the edge $(x', y)$. Since $x'$ is a descendant of $v$ other than $v$, the path from $LCA(x', y)$ to $x'$ contains an edge that connects $v$ to one of its children. Let this child be $x \in C_T(v)$. Clearly, $x$ is also an independent child since the path from $x$ to $r$ that uses the tree path from $x$ to $x'$, the edge $(x', y)$ and the tree path from $y$ to $r$ avoids $v$.

Let $F' = F \cup \{(x', y)\} \setminus \{(v, x)\}$. (See also Figure 1.) All the vertices in $U$ are reachable from $r$ via edges of $F'$ as follows. The vertices that are not descendants of $x$ are reachable in the same way as before and the ones which are descendants of $x$ are reachable through the edge $(x', y)$ since $y$ (which is not a descendant of $x$ in $T$) is reachable from $r$ and all the descendants of $x$ are reachable from $y$ via edge $(x', y)$ and the edges in the subtree rooted at $x$ as all these edges are in $F'$. Since $|F'| = |F| = |U| - 1$ we have that $T'(U, F')$ is a tree that spans the vertex set $U$, and thus $T'(U, F') \sqsubseteq G$.

The path from $x$ to $r$ in $T'$ avoids $v$, and thus $x$ is not a descendent of $v$ in $T'$. This is the only change in the set of children of $v$, implying that $C_{T'}(v) = C_T \setminus \{x\}$. The only vertices in $U$ whose degree in $T'$ may be larger than their degree in $T$ are $y$ (always) and $x'$ (when $x' \neq x$). However, $y \in I(T)$ and when $x' \neq x$ also $x' \in I(T)$. Thus, none of the leaves of $T$ may become internal vertices in $T'$. On the other hand the degrees of $v$ and $x$ (when $x' \neq x$) in $T'$ are 1 less than their degrees in $T$ and thus they may become leaves in $T'$, implying that $L(T) \subseteq L(T') \subseteq L(T) \cup \{v, x\}$. Since $L(T) \subseteq L(T')$, we also have $\mathsf{LD}_G(T') \geq \mathsf{LD}_G(T)$. ◀

Given a subtree $T(U, F) \sqsubseteq G$ and a vertex $v \in I(T)$, Lemma 2 can be applied successively to obtain a tree $T'(U, F')$ in which $v$ has no independent children. This is done as follows. Start by initializing $T'$ to $T$. If $v$ has an independent child in $T'$, apply Lemma 2 to get a modified tree $T'$ that spans the same set of vertices $U$ and satisfies the conditions of the lemma. If vertex $v$ still has an independent child in the modified $T'$, then repeat the application of Lemma 2. The process is bound to terminate since the number of children of $v$ is decreased in each iteration. Note that when the process terminates $L(T) \subseteq L(T')$ and thus $\mathsf{LD}_G(T') \geq \mathsf{LD}_G(T)$.

The function VertexImprove$(G, T, v)$ described in Algorithm 1 gets a graph $G(V, E)$, a subtree $T(U, F) \sqsubseteq G$, and a vertex $v \in I(T)$ as parameters. It determines whether $\mathsf{LD}_G(T)$ can be improved by making $v$ a leaf. It returns a subtree $T'(U', F') \sqsubseteq G$ such that $\mathsf{LD}_G(T') \geq \mathsf{LD}_G(T)$. (In case of improvement $\mathsf{LD}_G(T') > \mathsf{LD}_G(T)$.)

**Algorithm 1** Check whether the leaf degree can be improved by making $v$ a leaf.

```
1:  function VertexImprove(G, T, v)
2:      Parameters: graph G(V, E), subtree T(U, F) ⊑ G, vertex v
3:      Returned value: subtree T' ⊑ G, s.t. LD_G(T') ≥ LD_G(T)
4:      T' ← T
5:      while ∃x ∈ C_{T'}(v) ∧ ∃(x', y) ∈ E such that x ⇝ x' and v ↛ y do
6:          Update tree T' by swapping the tree edge (v, x) with the nontree edge (x', y)
7:      if v is a leaf in T' then
8:          return T'
9:      else if d_G(v) ≤ 2LD_G(T'_v) then                ▷ no substantial improvement
10:         return T'
11:     else                          ▷ remove the subtrees rooted at the children of v
12:         return T' ← T'[(U \ Desc_{T'}(v)) ∪ {v}]
```

The function VertexImprove starts by modifying the tree $T$ to a tree $T'(U, F')$ in which $v$ has no independent children as described above. (Note that any independent child of $v$ before the modification becomes an independent child of another vertex in $I(T)$.) At this point $v$ may either be a leaf in $T'$ or an internal vertex with only dependent children. If $v$ is a leaf, then $L(T) \cup \{v\} \subseteq L(T')$ and $\mathsf{LD}_G(T') > \mathsf{LD}_G(T)$, resulting in an improvement of the leaf degree. In this case tree $T'(U, F')$ is returned by the function. If $v$ has only dependent children, then function VertexImprove checks whether removing the subtrees rooted at the children of $v$, and thus making $v$ a leaf improves the leaf degree (substantially). (See Figure 2.) Specifically, let $T'[\tilde{U}]$ be the subgraph of $T'$ induced by the vertex set $\tilde{U} = (U \setminus \mathsf{Desc}_{T'}(v)) \cup \{v\}$. Clearly, $T'[\tilde{U}]$ is connected and thus $T'[\tilde{U}] \sqsubseteq G$. Compare $\mathsf{LD}_G(T')$ and $\mathsf{LD}_G(T'[\tilde{U}])$: The only leaf in $T'[\tilde{U}]$ that is not a leaf in $T'$ is $v$. On the other hand the only leaves in $T'$ that are not in $T'[\tilde{U}]$ are the descendant leaves of $v$ in $T'$, namely, $\mathsf{LDesc}_{T'}(v)$. Let $T'_v$ be the subtree of $T'$ rooted at $v$. We get that $\mathsf{LD}_G(T'_v)$ is the sum of the degrees in $G$ of the leaves in $\mathsf{LDesc}_{T'}(v)$. Consequently, $\mathsf{LD}_G(T'[\tilde{U}]) - \mathsf{LD}_G(T') = d_G(v) - \mathsf{LD}_G(T'_v)$. It follows that if $d_G(v) > \mathsf{LD}_G(T'_v)$, then $\mathsf{LD}_G(T'[\tilde{U}]) > \mathsf{LD}_G(T')$. To achieve our approximation ratio we perform an improvement step in this case only if the resulting improvement is "substantial"; that is, only if $d_G(v) > 2\mathsf{LD}_G(T'_v)$ or equivalently $\mathsf{LD}_G(T'[\tilde{U}]) - \mathsf{LD}_G(T') > \mathsf{LD}_G(T'_v)$. In this case $T'[\tilde{U}]$ is returned by the function VertexImprove$(G, T, v)$.

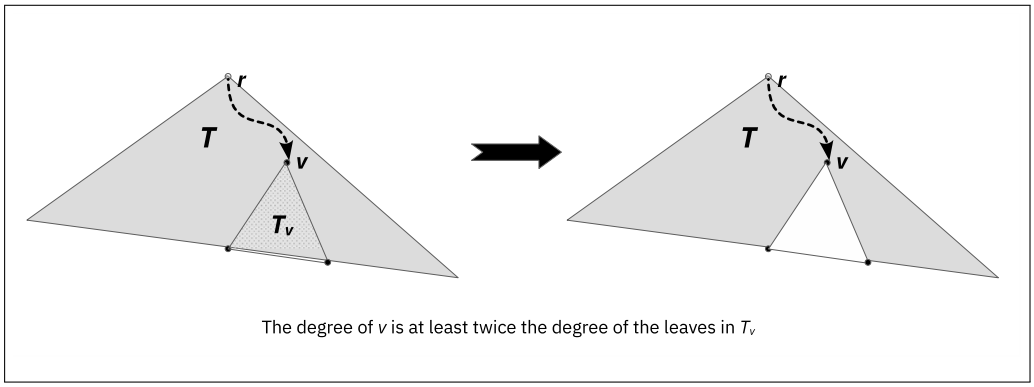

**Figure 2** Removing the children of $v$ and all their descendants.

It follows from the proof of Lemma 2 that as long as $v$ has any independent children, the condition of the While loop in Line 5 of Algorithm 1 must be satisfied. After the execution of this While loop all the vertices in $C_{T'}(v)$ must be dependent children of $v$. Note that Algorithm 1 can be implemented in polynomial time.

## 3.2 Sequencing the improvement steps

Algorithm 2 starts from an arbitrary spanning tree and calls the function VertexImprove successively, as long as tree $T$ has an internal vertex that was not considered as a candidate for improvement by this function. An internal vertex $v$ is considered as a candidate for improvement only after all its nonleaf children were considered as candidates for improvement. Such an internal vertex is guaranteed to exist whenever there are internal vertices that were not considered for improvement. The output of Algorithm 2 is the final tree, denoted $T^*$.

We prove the following properties of the tree $T^*$ that is the output of Algorithm 2.

▶ **Lemma 3.** *For every vertex $v \in I(T^*)$, $d_G(v) \leq 2\sum_{u \in D_{T^*}(v)} \mathsf{LD}_G(T^*_u) \leq 2\mathsf{LD}_G(T^*_v)$.*

**Algorithm 2** Local improvements.

**Input:** graph $G(V, E)$, and an arbitrary vertex $r \in V$
**Output:** a subtree $T^* \sqsubseteq G$ rooted at $r$
1: $T(V, F) \leftarrow$ a spanning tree rooted at $r$
2: $tested(v) \leftarrow$ false, $\forall v \in I(T)$
3: $tested(v) \leftarrow$ true, $\forall v \in L(T)$
4: **while** $\exists v \in I(T)$ s.t. $tested(v) =$ false **do**
5: find a vertex $v \in I(T)$ s.t. $tested(v) =$ false $\wedge$ $\forall u \in C_T(v)$ $tested(u) =$ true
6: $T \leftarrow$ VertexImprove$(G, T, v)$
7: $tested(v) \leftarrow$ true
8: **return** $T^* \leftarrow T$

**Proof.** Algorithm 2 starts with a spanning tree $T$ rooted at $r$. The tree $T$ is modified in every call to VertexImprove. Each such change may involve the removal of vertices from $T$ and conversion of some vertices from internal vertices to leaves. However, a leaf is never changed to an internal vertex, and a vertex that was removed from $T$ will never be brought back. Consider an internal vertex $v \in I(T^*)$ and the function call VertexImprove$(G, T, v)$. Fix $T$ to be the tree after this call. Vertex $v$ has to be an internal vertex of $T$ (as otherwise it would not be in $I(T^*)$). It follows that after this call $d_G(v) \leq 2\mathsf{LD}_G(T_v)$, and all the vertices in $C_T(v)$ are dependent children of $v$. Since all these vertices were children of $v$ also before the function call VertexImprove$(G, T, v)$, then by our algorithm they were considered for improvement before this call. It follows that removing any of these vertices in subsequent calls would imply also the removal of $v$, and since removed vertices are not brought back this did not happen. Thus, $D_T(v) = C_T(v) \subseteq C_{T^*}(v)$. Since $I(T^*) \subseteq I(T)$ all these vertices are also dependent children of $v$ in $T^*$ and thus $d_G(v) \leq 2\sum_{u \in D_{T^*}(v)} \mathsf{LD}_G(T^*_u)$. Clearly, $2\sum_{u \in D_{T^*}(v)} \mathsf{LD}_G(T^*_u) \leq 2\mathsf{LD}_G(T^*_v)$. ◀

▶ **Lemma 4.** *There are no edges connecting vertices in $I(T^*)$ to vertices outside $T^*$.*

**Proof.** We show that the following assertion holds throughout the computation of Algorithm 2: there are no edges connecting vertices in $I(T)$ to vertices outside $T$. The lemma follows since $T^*$ is the final value of $T$. The assertion holds at the start of Algorithm 2 since initially $T$ is a spanning tree and thus there are no vertices outside $T$. Suppose that the assertion holds for $T$ until the function call VertexImprove$(G, T, v)$. We need to show that it holds also after this call. This clearly holds in case the vertices of $T$ are not changed in this call. The only nontrivial case is when some vertices are removed from $T$ in this call; that is, Line 12 in Algorithm 1 is executed. Recall that the removed vertices are all the descendants of $v$ (other than $v$ itself) in the tree $T'$, and that in tree $T'$ all the children of $v$ are dependent children; i.e., $D_{T'}(v) = C_{T'}(v)$. This implies that none of the vertices in $desc_{T'}(v)$ are connected to an internal vertex of $T'[(U \setminus \mathsf{Desc}_{T'}(v)) \cup \{v\}]$ (which is the returned value of $T$) as this will imply that at least one of the vertices in $C_{T'}(v)$ is independent. Thus, the assertion holds for $T$ also after the call. ◀

It is not difficult to see that Algorithm 2 can be implemented in polynomial time. We remark that the efficiency of the algorithm can be improved by avoiding the search for a vertex $v$ for which $tested(v) =$ false $\wedge$ $\forall u \in C_T(v)$ $tested(u) =$ true (Line 5). This can be done by computing a postorder of the vertices of the initial tree $T$ (which is a spanning tree) and following this order when the vertices are considered for improvement. Recall that a vertex $v$ appears in a postorder after all its descendants. So, this is the case for the initial

tree. Now, suppose that Algorithm 2 follows the vertices in this order, and a vertex $v$ is considered for improvement. At this point all the descendants of $v$ in the initial tree were considered already. Any descendant of $v$ at this point that was not a descendant of $v$ in the original tree became a descendant as a result of a move of vertices in a function call to VertexImprove. The only vertices that are moved in this function call must have been considered for improvement already since they are the descendant of the vertex considered for improvement in the call to VertexImprove. Thus, when a vertex $v$ is considered for improvement all its descendants were already considered for improvement.

## 4 The Approximation Ratio of the Algorithm

Recall that $T^*$ is the tree computed by Algorithm 2. We start by proving that the number of edges with at least one endpoint in $V(T^*)$ is $\mathcal{O}(\mathsf{LD}_G(T^*)\log\log n)$. We prove this bound separately for tree edges and nontree edges. Next, we show that the total number of edges of $G$ outside $T^*$ is also $\mathcal{O}(\mathsf{LD}_G(T^*)\log\log n)$. It follows that $m = \mathcal{O}(\mathsf{LD}_G(T^*)\log\log n)$. Since for any subtree $S$ of $G$, $\mathsf{LD}_G(S) \leq 2m$, we get that for any subtree $S$ of $G$, $\mathsf{LD}_G(S) = \mathcal{O}(\mathsf{LD}_G(T^*)\log\log n)$. This implies that Algorithm 2 is an $\mathcal{O}(\log\log n)$-approximation algorithm for both the MLD and the respective CMC problems.

### 4.1 Bounding the number of tree edges in $T^*$

We show that the number of tree edges is $\mathcal{O}(\mathsf{LD}_G(T^*))$. For this we upper bound the number of vertices in $T^*$ which also bounds the number of tree edges in $T^*$. Clearly, the number of leaves is $|L(T^*)|$. Also, the number of vertices of degree at least 3 in $T^*$ is bounded by $|L(T^*)| - 1$. We still need to bound the number of vertices of degree 2 in $T^*$. To prove this bound we apply a lemma from [6] that states that WLOG it can be assumed that the input graph to the CMC problem and thus also to the respective MLD problem does not contain a path of three vertices of degree 2.

▶ **Lemma 5** ([6]). *WLOG it can be assumed that the input graph to the CMC problem and thus also to the respective MLD problem does not contain a path of three vertices of degree 2.*

We note that [6] considered the slightly more general $\{0,1\}$-weighted case rather than the unit weight case considered here.

For the remainder of our analysis we color the edges of $T^*$ in two colors *red* and *blue*. For $v \in I(T^*)$, a tree edge $(v,u)$ is colored red if $u$ is a dependent child of $v$ and colored blue otherwise. Trivially, all the edges outgoing from $r$ are red. By Lemma 3 every vertex $v \in I(T^*)$ has at least one outgoing red edge. We now bound the number of degree 2 vertices in $T^*$.

▶ **Lemma 6.** *The number of degree 2 vertices in $T^*$ is bounded by $8|L(T^*)| + 3\mathsf{LD}_G(T^*)$.*

**Proof.** Consider the subgraph of $T^*$ induced by its degree 2 vertices. This subgraph is a collection of paths. The endpoint of each such path is the parent of a distinct vertex of degree other than 2 in $T^*$. Hence, the number of these paths is bounded by the number of vertices with degree other than 2 in $T^*$. As stated above, the number of vertices of degree 1 in $T^*$ is $|L(T^*)|$, and the number of vertices of degree 3 or more is bounded by $|L(T^*)| - 1$. Thus, the total number of these paths is bounded by $2|L(T^*)| - 1$. Consider the paths of length (in edges) at most 3. Let $n_3$ be the number of these paths. The number of vertices of degree 2 on these paths is bounded by $4n_3$.

Consider the rest of the paths, and denote their number by $n_{\geq 4}$. Let $v_1, v_2, v_3, \ldots, v_\ell$, for $\ell \geq 5$, be such a path. Note that the edges $(v_i, v_{i+1})$, for $i \in [1..\ell-1]$, must be red since every internal vertex must have at least one dependent child and $v_{i+1}$ is the only child of $v_i$; namely, $C_{T^*}(v_i) = D_{T^*}(v_i) = \{v_{i+1}\}$. By Lemma 5 $G$ does not contain a path of three vertices of degree 2. Thus, at least one out of every three consecutive vertices on the path $v_2, \ldots, v_{\ell-1}$ must have degree at least 3 in $G$. Hence, at least $\lfloor \frac{\ell-2}{3} \rfloor$ vertices on the path $v_2, \ldots, v_{\ell-1}$ must have degree at least 3 in $G$. Let $v_i$ be one of these vertices, and let $y \notin \{v_{i-1}, v_{i+1}\}$ be a vertex connected to $v_i$ in $G$ ($y \notin \{v_{i-1}, v_{i+1}\}$ because $G$ has no parallel edges). By Lemma 4 vertex $v_i$ is not connected to vertices outside $T^*$, and hence $y \in V(T^*)$. We claim that $y$ must be a leaf. To obtain a contradiction assume that this is not the case and consider $LCA(v_i, y)$. If $LCA(v_i, y) \neq v_i$, then it must be an ancestor of $v_{i-1}$ but not $v_{i-1}$ itself (since $v_i$ is the only child of $v_{i-1}$). In this case $v_i$ cannot be a dependent child of $v_{i-1}$ because the path from $v_i$ to $y$ using edge $(v_i, y)$ and then up the tree to $LCA(v_i, y)$ avoids $v_{i-1}$. If $LCA(v_i, y) = v_i$, then $y$ must be a descendant of $v_{i+1}$ but not $v_{i+1}$ itself. In this case the only child of $v_{i+1}$ cannot be a dependent child because the path from this child down the tree to $y$ and then to $v_i$ using edge $(v_i, y)$ avoids $v_{i+1}$.

It follows that at least $\lfloor \frac{\ell-2}{3} \rfloor \geq \frac{\ell-4}{3}$ vertices on every path $v_1, v_1, v_2, \ldots, v_\ell$ of degree 2 vertices in $T^*$, where $\ell \geq 4$, are connected to leaves in $L(T^*)$. Thus, each one of the $n_{\geq 4}$ paths of length $\ell \geq 4$ of degree 2 vertices in $T^*$ contributes at least $\frac{\ell-4}{3}$ to the leaf degree of $T^*$, which equals $\mathsf{LD}_G(T^*)$. Summing this over all such paths implies that the total number of vertices of degree 2 on these paths is bounded by $3\mathsf{LD}_G(T^*) + 4n_{\geq 4}$. Since $n_3 + n_{\geq 4} < 2|L(T^*)|$ the number of degree 2 vertices is bounded by $8|L(T^*)| + 3\mathsf{LD}_G(T^*)$. ◀

We conclude the following theorem.

▶ **Theorem 7.** *The number of tree edges in $T^*$ is bounded by $10|L(T^*)| + 3\mathsf{LD}_G(T^*) = \mathcal{O}(\mathsf{LD}_G(T^*))$.*

## 4.2 Bounding the number of nontree edges with at least 1 endpoint in $V(T^*)$

The number of nontree edges with at least one endpoint in $L(T^*)$ is $\mathcal{O}(\mathsf{LD}_G(T^*))$. Thus, from now on we concentrate on bounding the number of nontree edges with at least one endpoint in $I(T^*)$, and the other not in $L(T^*)$. We have already established in Lemma 4 that a vertex in $I(T^*)$ cannot be connected to a vertex outside $T^*$. It follows that it suffices to bound the number of nontree edges with both endpoints in $I(T^*)$.

Recall that for $v \in I(T^*)$, a tree edge $(v, u)$ is colored red if $u$ is a dependent child of $v$ and colored blue otherwise. For a vertex $v \in I(T^*)$, let $B_{T^*}(v)$ be the subset of vertices of $T^*$ that can be reached from $v$ by paths that start at a red edge outgoing from $v$ and then use only blue edges. In other words, $B_{T^*}(v)$ consists of all the dependent children of $v$ and all the vertices that are reachable from these dependent children using only blue edges. (Notice that $v \notin B_{T^*}(v)$.) In the next lemma we prove that an internal vertex $x \in B_{T^*}(v)$ cannot be connected to an internal vertex of $T^*$ that is neither $v$ nor in $B_{T^*}(v) \cup B_{T^*}(x)$.

▶ **Lemma 8.** *If an internal vertex $x \in B_{T^*}(v)$ is connected by a nontree edge to a vertex $y \in I(T^*)$, then $y \in \{v\} \cup B_{T^*}(v) \cup B_{T^*}(x)$.*

**Proof.** To obtain a contradiction assume that $x$ is connected to a vertex $y \in I(T^*) \setminus (\{v\} \cup B_{T^*}(v) \cup B_{T^*}(x))$. We consider 4 cases.

**Case 1.** $y$ is a descendant of $x$. Follow the path from $x$ to $y$ in $T^*$. The vertex immediately after $x$ along this path must be in $B_{T^*}(v) \cup B_{T^*}(x)$. By our assumption $y \notin B_{T^*}(v) \cup B_{T^*}(x)$. Thus, the path from $x$ to $y$ in $T^*$ must leave either $B_{T^*}(v)$ or $B_{T^*}(x)$. Note that for any vertex $u \in I(T^*)$, any tree edge connecting a vertex in $B_{T^*}(u)$ to a vertex outside $B_{T^*}(u)$ must be red. It follows that the path from $x$ to $y$ in $T^*$ must include a red edge $(x', x'')$, where $x' \neq x$ is a descendant of $x$. Note that vertex $x''$ is a dependent child of $x'$ since $(x', x'')$ is red. This is a contradiction since the path from $x''$ down the tree to $y$, followed by the edge $(x, y)$, and the path from $x$ down the tree to the parent of $x'$ avoids $x'$, and thus $x''$ cannot be a dependent child of $x'$.

**Case 2.** vertex $y$ is a descendant of a vertex $z \in B_{T^*}(v)$, where $z \neq x$, and $y$ is not a descendant of $x$. Since $y \notin B_{T^*}(v)$ the path from $z$ to $y$ in $T^*$ must include a red edge $(z', z'')$, where $z' \in B_{T^*}(v)$. In this case $z''$ is an ancestor of $y$, and thus $z''$ is connected to $x$ through the edge $(x, y)$. To obtain a contradiction we show that there exists a path from $x$ to the parent of $z'$ that avoids the vertex $z'$. This implies that $z''$ cannot be a dependent child of $z'$ which is a contradiction. Consider $LCA(x, z')$. By our assumption in this case $x$ is not an ancestor of $y$ and thus it also cannot be an ancestor of $z'$. Thus, $LCA(x, z') \neq x$. In case $LCA(x, z') \neq z'$ the path from $x$ to the parent of $z'$ goes from $x$ to $LCA(x, z')$ and then down the tree to the parent of $z'$. In case is $LCA(x, z') = z'$ we must have that $z'$ is an ancestor of $x$. Since both $x$ and $z'$ are in $B_{T^*}(v)$, all the edges on the path in $T^*$ from $z'$ to $x$ are blue. But then the ancestor of $x$ which is the child of $z'$ is not a dependent child of $z'$, and thus there is a path from $x$ to the parent of $z'$ that goes through this child and avoids $z'$.

In the remaining two cases vertex $y$ is not a descendant of any vertex in $B_{T^*}(v)$.

**Case 3.** Vertex $y$ is not a descendant of $v$. In this case there is a path from $y$ to the parent of $v$ that avoids $v$. Let $x'$ be the child of $v$ that is an ancestor of $x$. Since $x \in B_{T^*}(v)$, the tree edge $(v, x')$ is colored red, and vertex $x'$ is a dependent child of $v$ but this is a contradiction since the path from $x'$ to $x$ and then through the edge $(x, y)$ to the parent of $v$ avoids $v$.

**Case 4.** Vertex $y$ is a descendant of $v$. Consider the first edge $(v, y')$ on the path from $v$ to $y$ in $T^*$. Since $y$ is not a descendant of any vertex in $B_{T^*}(v)$ this edge must be colored blue, and thus $y'$ is an independent child of $v$ and there exists a path from $y'$ to the parent of $v$ that avoids $v$. As in the previous case, let $x'$ be the child of $v$ that is an ancestor of $x$. The tree edge $(v, x')$ is colored red, and vertex $x'$ is a dependent child of $v$. This is a contradiction since the path from $x'$ that goes down the tree to $x$, then to $y$ through the edge $(x, y)$, then up the tree to $y'$, and then from $y'$ to the parent of $v$, avoids $v$. ◀

Consider a vertex $x \in V(T^*)$ that is not the root $r$. Since all the edges outgoing from $r$ are red, there must be at least one red edge $(v, v')$ on the path up the tree from $x$ to $r$. Thus there exists a vertex $v \in I(T^*)$ such that $x \in B_{T^*}(v)$. Note that $v$ is the unique ancestor of $x$ with the property that the (unique) path from $v$ to $x$ in $T^*$ starts in a red edge and then uses only blue edges. It follows that any two sets $B_{T^*}(v)$ and $B_{T^*}(u)$ are disjoint. Thus, the sets $B_{T^*}(v)$ form a partition of the vertices in $T^*$ (excluding $r$). This implies that the total number of edges of the form $(v, x)$, where $v \in I(T^*)$ and $x \in B_{T^*}(v) \cap I(T^*)$ is bounded by $|I(T^*)|$ (since there are no parallel edges). Clearly, $|I(T^*)|$ is bounded by the number of tree edges, and thus by Theorem 7 $|I(T^*)| = \mathcal{O}(\mathsf{LD}_G(T^*))$.

It follows from Lemma 8 that we are left with bounding the number of nontree edges $(x, y)$, where both $x$ and $y$ are in $B_{T^*}(v) \cap I(T^*)$, for some $v \in I(T^*)$. To bound the number of these edges we modify the tree $T^*$ to a tree $\tilde{T}$ that spans the same set of vertices as $T^*$ in which all the vertices in $B_{T^*}(v)$ become the children of $v$. Note that unlike the tree $T^*$, the tree $\tilde{T}$ is not a subtree of $G$.

### 4.2.1 The modification of $T^*$ to $\tilde{T}$

Tree $\tilde{T}$ is obtained from $T^*(U, F)$ by making all the vertices in $B_{T^*}(v)$ the children of $v$, for every $v \in I(T^*)$. Formally, for every $v \in I(T^*)$, edge $(v, x)$ is a tree edge of $\tilde{T}$ iff $x \in B_{T^*}(v)$. To illustrate the definition, consider a vertex $x \in B_{T^*}(v)$ that is not a child of $v$ in $T^*$, and let $y$ be the parent of $x$ in $T^*$. Note that the edge $(y, x)$ is a blue edge and $x$ is thus an independent child. We remove the edge $(y, x)$ and instead add the edge $(v, x)$, making $v$ the new parent of $x$. Let $\tilde{T}$ be the resulting tree. It is not difficult to see that $\tilde{T}$ is indeed a tree that spans the set $U$. This is because the parent of any vertex $v$ in $\tilde{T}$ is an ancestor of its parent in $T^*$.

▶ **Lemma 9.** *Any two vertices $\{x, y\} \subseteq B_{T^*}(v) \cap I(T^*)$, for some $v \in I(T^*)$ are siblings in $\tilde{T}$ and share $v$ as their parent.*

**Proof.** If both $x$ and $y$ are independent children in $T^*$ then after the modification both become children of $v$. The only other vertices in $B_{T^*}(v) \cap I(T^*)$ are the dependent children of $v$ and they remain children of $v$ also in $\tilde{T}$. ◀

Recall that we need to bound the number of nontree edges of the form $(x, y)$, where both $x$ and $y$ are in $B_{T^*}(v) \cap I(T^*)$, for some $v \in I(T^*)$. This is equivalent to bounding the number of the edges of $G$ that connect *siblings* in $I(\tilde{T})$.

▶ **Lemma 10.** *For any vertex $v \in I(T^*)$, if $x$ is a descendant of a dependent child of $v$ in $T^*$ then $x$ is a descendant of $v$ in $\tilde{T}$.*

By Lemma 3 for every vertex $v \in I(T^*)$, $d_G(v) \leq 2\sum_{u \in D_{T^*}(v)} \mathsf{LD}_G(T^*_u)$. By Lemma 10 any leaf descendant of a vertex $u \in D_{T^*}(v)$ is a descendant of $v$ in $\tilde{T}$ and thus we have $d_G(v) \leq 2\mathsf{LD}_G(\tilde{T}_v)$. As shown above, to bound the number of nontree edges with both endpoints in $B_{T^*}(v) \cap I(T^*)$, for some $v \in I(T^*)$, it suffices to bound the number of edges that connect siblings in $I(\tilde{T})$. For this we prove the following slightly more general theorem, where instead of considering the leaf degree, we assume general weights on the leaves of $\tilde{T}$. Associate a weight $w(\ell) \geq 1$ with every leaf $\ell \in L(\tilde{T})$. For a vertex $v \in I(\tilde{T})$, let $w(\tilde{T}_v)$ denote the total weight of the leaves of $\tilde{T}_v$, which is the subtree rooted at $v$. Also define $w(\tilde{T}) = w(\tilde{T}_r)$. The following theorem (proven below) may be interesting on its own.

▶ **Theorem 11.** *Let $\tilde{T}$ be a rooted tree with an integral weight $w(\ell) \geq 1$ associated with every leaf $\ell \in L(\tilde{T})$, and let $\tilde{G}(I(\tilde{T}), \tilde{E})$ be a graph with no parallel edges that all of its edges connect siblings in $I(\tilde{T})$. If for every $v \in I(\tilde{T})$, $d_{\tilde{G}}(v) \leq 2w(\tilde{T}_v)$, then $|\tilde{E}| = \mathcal{O}\big(w(\tilde{T}) \log\log w(\tilde{T})\big)$.*

To prove this theorem we further modify $\tilde{T}$ to $\hat{T}$ in which the degree of every internal vertex is lower and upper bounded by a constant times the weight of the leaves of its rooted subtree.

### 4.2.2 The modification of $\tilde{T}$ to $\hat{T}$

We obtain $\hat{T}$ from $\tilde{T}$ by removing some of the internal vertices of $\tilde{T}$. While doing so we maintain that the number of edges connecting siblings in $I(\hat{T})$ remains the same as the number of edges connecting siblings in $I(\tilde{T})$.

Initially, $\hat{T}$ is set to $\tilde{T}$ and $\hat{G}$ is set to $\tilde{G}$. Next, we traverse the vertices of $I(\hat{T}) \setminus \{r\}$ top down starting from the children of the root $r$. When a vertex $v$ is traversed we check whether $v$ has any children that are internal vertices, and if so whether $d_{\hat{G}}(v) < w(\hat{T}_v)$. (Recall that by the conditions of Theorem 11, initially, $d_{\hat{G}}(v) \leq 2w(\hat{T}_v)$.) If this is the case we execute the following modification steps.

**Step 1.** Remove $v$ from $\hat{T}$ and connect all the children of $v$ that are internal vertices to the parent of $v$. Denote the set of these children by $C$.

**Step 2.** Pick a vertex $x \in C$ and connect $x$ to all the leaves of $\hat{T}$ that were children of $v$ before its removal.

**Step 3.** For every edge $(v, y)$ in $\hat{G}$ that connected $v$ before its removal to a sibling in $\hat{T}$, find a vertex $z \in C$ such that $d_{\hat{G}}(z) < 3w(\hat{T}_z) - 1$, and add the edge $(z, y)$ to $\hat{G}$ in lieu of the edge $(v, y)$. Lemma 12 implies that such a vertex $z$ always exists.

▶ **Lemma 12.** *After Step 2 of the modification steps*

$$d_{\hat{G}}(v) + \sum_{z \in C} d_{\hat{G}}(z) < 3 \sum_{z \in C} w(\hat{T}_z). \tag{1}$$

Lemma 12 implies that for each of the $d_{\hat{G}}(v)$ edges that connected $v$ to its siblings we can find in Step 3 a vertex $z \in C$ such that $d_{\hat{G}}(z) < 3w(\hat{T}_z) - 1$. (Recall that the weights are integral.)

▶ **Lemma 13.** *After traversing all the vertices of $\hat{T}$ the following properties are satisfied.*

**Property 1.** *The graph $\hat{G}(I(\hat{T}), \hat{E})$ has no parallel edges and all of its edges connect siblings in $I(\hat{T})$.*

**Property 2.** *The number of edges of $\hat{G}$ is the same as the number of edges of $\tilde{G}$.*

**Property 3.** *For every internal vertex $v \in I(\hat{T}) \setminus \{r\}$ that is a parent of a nonleaf vertex in $\hat{T}$, $w(\hat{T}_v) \le d_{\hat{G}}(v)$.*

**Property 4.** *For every internal vertex $v \in I(\hat{T}) \setminus \{r\}$, $d_{\hat{G}}(v) \le 3w(\hat{T}_v)$.*

### 4.2.3 Bounding the number of edges connecting siblings in $\hat{T}$

To bound the number of edges connecting siblings in $\hat{T}$ we prove the following theorem.

▶ **Theorem 14.** *Let $\hat{T}$ be a rooted tree with an integral weight $w(\ell) \ge 1$ associated with every leaf $\ell \in L(\hat{T})$, and let $\hat{G}(I(\hat{T}), \hat{E})$ be a graph with no parallel edges that all of its edges connect siblings in $I(\hat{T})$. If for every $v \in I(\hat{T})$ that is a parent of a nonleaf vertex in $\hat{T}$, $w(\hat{T}_v) \le d_{\hat{G}}(v)$, and for every $v \in I(\hat{T})$, $d_{\hat{G}}(v) \le 3w(\hat{T}_v)$, then $|\hat{E}| = \mathcal{O}\Big(w(\hat{T}) \log\log w(\hat{T})\Big)$.*

To prove Theorem 14 we use the following simple inequality that holds for undirected graphs with no parallel edges.

▶ **Lemma 15.** *Let $H(V, E)$ be an undirected graph with no parallel edges and $m = |E|$. Let $U \subseteq V$ be the subset of vertices of degree at most $4\sqrt{m}$. Then, $\sum_{v \in U} d_H(v) > \frac{7}{8}m$.*

**Proof of Theorem 14.** To bound the number of edges of $\hat{G}$ we use a charging scheme. For a vertex $v \in I(\hat{T})$ that is a parent of at least 2 nonleaf vertices in $\hat{T}$, let $\hat{G}_v = \hat{G}[C_{\hat{T}}(v) \cap I(\hat{T})]$; that is, the subgraph of $\hat{G}$ induced by the children of $v$ that are internal vertices. Note that $\hat{G}$ is the union of all these subgraphs since $\hat{G}$ only contains edges that connect siblings in $I(\hat{T})$. Let $m_v$ be the number of edges in this subgraph. "Charge" these $m_v$ edges to the subset of children of $v$ whose degree in $\hat{G}_v$ and thus also in $\hat{G}$ is at most $4\sqrt{m_v}$. By Lemma 15 the sum of the degrees of all these children is greater than $\frac{7}{8}m_v$. Thus it suffices to charge each such child $x$ of $v$ the amount $\frac{8}{7} \cdot d_{\hat{G}}(x)$ to cover for all the $m_v$ edges.

To bound the total number of edges we need to sum the charges of all the vertices. We distinguish between charged vertices that are parents of a nonleaf vertex and those with only leaf children. There are 3 cases based on the characteristics of the charged vertex $x \in C_{\hat{T}}(v) \cap I(\hat{T})$.

**Case 1.** The charged vertex $x$ has only leaf children. By the conditions of the theorem $d_{\hat{G}}(x)$ is upper bounded by 3 times the weight of its leaf children. Since the leaf children of any two vertices are disjoint we get that the total amount charged to vertices with only leaf children is upper bounded by $\frac{8}{7} \cdot 3w(\hat{T})$.

**Case 2.** The charged vertex $x$ is a parent of a nonleaf vertex and $d_{\hat{G}}(x) \leq 48 \cdot 3 = 144$. The amount charged to all such vertices is upper bounded by $\frac{8}{7} \cdot 144$ times the number of vertices in $I(\hat{T})$ that have siblings. The number of internal vertices in $\hat{T}$ that have siblings (and thus are children of a vertex whose degree is at least 3 in $\hat{T}$) is bounded by the number of leaves of $\hat{T}$. Note that $\mathcal{O}\Big(L(\hat{T})\Big) = \mathcal{O}\Big(w(\hat{T})\Big)$ since for every leaf $\ell \in L(\hat{T})$, $w(\ell) \geq 1$. We conclude that the amount charged to all such vertices is $\mathcal{O}\Big(w(\hat{T})\Big)$.

**Case 3.** The charged vertex $x$ is a parent of a nonleaf vertex and $d_{\hat{G}}(x) > 144$. By our construction since $x$ is a parent of a nonleaf vertex we have $w(\hat{T}_x) \geq \frac{1}{3} d_{\hat{G}}(x) > 48$ and $d_{\hat{G}}(x) > w(\hat{T}_x)$. Recall that the number of edges in $\hat{G}_v$ is $m_v$. Since $d_{\hat{G}}(x) \leq 4\sqrt{m_v}$ we have also $w(\hat{T}_x) < 4\sqrt{m_v}$. On the other hand we claim that $w(\hat{T}_v) \geq \frac{2}{3} m_v$. This holds since for every child $y \in C_{\hat{T}}(v) \cap I(\hat{T})$ we have $d_{\hat{G}}(y) \leq 3w(\hat{T}_y)$ summing over all such children of $v$ we get that the sum of all degrees, which is $2m_v$, is bounded by 3 times the sum of the weights of the subtrees rooted at all these children. The sum of these weights is upper bounded by the weight of the subtree rooted at their parent $v$ and thus we have $2m_v \leq 3w(\hat{T}_v)$. Combining the two inequalities (i) $w(\hat{T}_x) < 4\sqrt{m_v}$ and (ii) $w(\hat{T}_v) \geq \frac{2}{3} m_v$, we get $w(\hat{T}_v) \geq \frac{2}{3} m_v = \frac{1}{24} \left(4\sqrt{m_v}\right)^2 > \frac{1}{24} \left(w(\hat{T}_x)\right)^2 > 2^2 \cdot 24$ (since $w(\hat{T}_x) > 48$), and thus for any ancestor $y$ of $v$ it also holds that $w(\hat{T}_y) > \frac{1}{24} \left(w(\hat{T}_x)\right)^2$. Note that $\frac{1}{24} \cdot \left(2^{2^{i-1}} \cdot 24\right)^2 = 2^{2^i} \cdot 24$. Thus, applying the inequality recursively on all the ancestors of $x$ that are also charged, implies that if $i$ ancestors of the charged vertex $x$ are also charged, then the weight of the subtree rooted at the highest such ancestor is at least $2^{2^i} \cdot 24$. This implies that the maximum number of such vertices that are charged along any path from the root to a leaf is $\mathcal{O}\Big(\log\log w(\hat{T})\Big)$.

To sum the total amount charged to vertices with a nonleaf child and degree in $\hat{G}$ greater than 144, we consider them in "layers". The first layer consists of all vertices $x$ such that (1) $x$ has a nonleaf child and $d_{\hat{G}}(x) > 144$, (2) $x$ was charged, and (3) none of the ancestors of $x$ (other than $x$) were charged. Similarly, layer $i > 1$ consists of all vertices $x$ such that (1) $x$ has a nonleaf child and $d_{\hat{G}}(x) > 144$, (2) $x$ was charged, and (3) $x$ has an ancestor (other than $x$) that belongs to layer $i - 1$. The number of layers is bounded by the maximum number of vertices that are charged along any path from the root to a leaf which is $\mathcal{O}\Big(\log\log w(\hat{T})\Big)$. By the construction of layers if vertices $x$ and $y$ are in the same layer then $\hat{T}_x$ and $\hat{T}_y$ are disjoint. Since the charge of a vertex $x$ that is a parent of a nonleaf vertex is $\frac{8}{7} \cdot d_{\hat{G}}(x) \leq \frac{8}{7} \cdot 3w(\hat{T}_x)$ the total amount charged to the vertices in the same layer is $\frac{8}{7} \cdot 3w(\hat{T})$. The proof follows since there are $\mathcal{O}\Big(\log\log w(\hat{T})\Big)$ layers. ◀

We note that the bound Theorem 14 is tight. We show a family of trees and associated graphs that achieve the upper bound in Theorem 14. Let $S_1$ be a tree of height 3 with 5 vertices: a root, 2 children of the root, and 2 leaves, each of which is a single child of a child of the root. Assign a weight of 1 to each of the 2 leaves. The graph $\hat{G}_1$ consists of a single edge connecting the 2 children of the root. For $i > 1$, the tree $S_i$ is given by taking $2^{2^{i-1}}$ copies of

$S_{i-1}$ and connecting them to a common root. The graph $\hat{G}_i$ includes $2^{2^{i-1}}$ copies of $\hat{G}_{i-1}$ associated with the copies of $S_{i-1}$. In addition, partition the $2^{2^{i-1}}$ children of the root of $S_i$ into two sets of size $2^{2^{i-1}-1}$ and add the edges of the complete bipartite graph connecting the vertices in these 2 sets. The number of these edges is $\left(2^{2^{i-1}-1}\right)^2 = 2^{2^i-2}$. Figure 3 shows the tree $S_2$ and the associated graph $\hat{G}_2$. It can be verified that the construction obeys the conditions in Theorem 14. It can be shown by a simple induction that the number of leaves in $S_i$ is $2^{2^i-1}$ and the number of edges in $\hat{G}_i$ is $i \cdot 2^{2^i-2}$ which achieves the bound tightly.

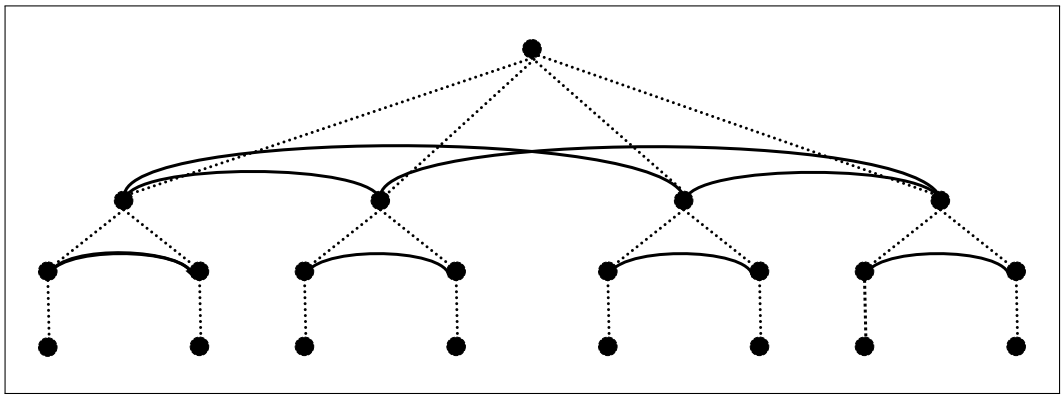

**Figure 3** The tree $S_2$ and the associated graph $\hat{G}_2$. Tree edges are dashed and graph edges are solid.

We use Theorem 14 to prove Theorem 11.

**Proof of Theorem 11.** The number of edges of $\tilde{G}$ connecting siblings in $I(\tilde{T})$ is the same as the number of edges of $\hat{G}$ connecting siblings in $I(\hat{T})$ (see Property 2 above). Also, by our modification process $w(\tilde{T}) = w(\hat{T})$. By Properties 3 and 4 above the tree $\hat{T}$ and the graph $\hat{G}$ satisfy the conditions of Theorem 14. It follows that the number of edges connecting siblings in $I(\hat{T})$ and thus also in $I(\tilde{T})$ is $\mathcal{O}\big(w(\tilde{T}) \log\log w(\tilde{T})\big)$. ◀

The analysis in Sections 4.1 and 4.2 implies the following theorem.

▶ **Theorem 16.** *The number of edges with at least one endpoint in $V(T^*)$ is $\mathcal{O}(\mathsf{LD}_G(T^*) \log\log n)$.*

**Proof.** Theorem 7 implies that the number of tree edges in $T^*$ is $\mathcal{O}(\mathsf{LD}_G(T^*))$. Clearly, the number of edges with one endpoint in $L(T^*)$ is $\mathcal{O}(\mathsf{LD}_G(T^*))$. As shown earlier the number of edges connecting a vertex $v$ to vertices in $B_{T^*}(v) \cap I(T^*)$ is also $\mathcal{O}(\mathsf{LD}_G(T^*))$. By Lemma 8 the only other edges with at least one endpoint in $V(T^*)$ are edges connecting 2 vertices in $B_{T^*}(v) \cap I(T^*)$, for some $v \in I(T^*)$. By Lemma 3 for every vertex $v \in I(T^*)$, $d_G(v) \leq 2 \sum_{u \in D_{T^*}(v)} \mathsf{LD}_G(T^*_u)$. This implies that after modifying $T^*$ to $\tilde{T}$ the conditions of Theorem 11 hold with $w(\ell) = d_G(\ell)$, for every leaf $\ell \in L(T^*)$. The theorem follows since $\log\log|E(G)| = \mathcal{O}(\log\log n)$. ◀

## 4.3 Bounding the number of edges outside $T^*$

The next theorem bounds the number of edges in $G[V \setminus V(T^*)]$.

▶ **Theorem 17.** *The number of edges in $G[V \setminus V(T^*)]$ is $\mathcal{O}(\mathsf{LD}_G(T^*) \log\log n)$.*

The proof of the theorem is omitted due to space constraints. It has two parts. First, we prove that there exists some constant $c$ such that the number of edges added to $G[V \setminus V(T^*)]$ when the subtrees rooted at the children of a vertex $v$ are removed from the tree is at most $c \cdot \mathsf{LD}_G(T'_v) \log\log n$. Second, we show that the total number of edges in $G[V \setminus V(T^*)]$ is bounded by $c \cdot \mathsf{LD}_G(T^*) \log\log n$ using the fact that that the subtrees rooted at the children of a vertex $v$ are removed only when the improvement is substantial; namely, $d_G(v) > 2\mathsf{LD}_G(T'_v)$.

We conclude with the main theorem.

▶ **Theorem 18.** *The total number of edges in $G(V, E)$ is $\mathcal{O}(\mathsf{LD}_G(T^*) \log\log n)$. Thus, Algorithm 2 is an $\mathcal{O}(\log\log n)$-approximation algorithm for both the MLD and the respective CMC problems.*

## 5 Conclusions and Future Research

We gave an $\mathcal{O}(\log\log n)$-approximation algorithm for the MLD problem that implies an approximation algorithm with the same quality to the CMC problem. The approximation algorithm consists of local improvement steps. While we have evidence that the *analysis of our algorithm* is tight, it is open whether *the approximation ratio* we achieved is tight or whether there exists a $o(\log\log n)$-approximation for the MLD and CMC problems.

Our algorithm uses the fact that the weights of the vertices in the MLD problem are the degrees of these vertices in an undirected graph with no parallel edges. It will be interesting to see if the same approach can be extended to other weights. It cannot be extended to general weights as there are examples of graphs with general edge weights in which the ratio of the total edge weight to the weighted connected cut is $\Omega(\log\log n)$.

To the best of our knowledge neither nontrivial approximation algorithms nor hardness of approximation results are known for non-monotone submodular function maximization subject to connectivity constraints. Any progress along these lines for either general or specific classes of graphs is bound to have numerous applications.

## Abstract

In this paper, we introduce the concept of *Density-Balanced Subset* in a matroid, in which independent sets can be sampled so as to guarantee that (i) each element has the same probability to be sampled, and (ii) those events are negatively correlated. These *Density-Balanced Subsets* are subsets in the ground set of a matroid in which the traditional notion of uniform random sampling can be extended.

We then provide an application of this concept to the *Matroid-Constrained Maximum Coverage* problem. In this problem, given a matroid $\mathcal{M} = (V, \mathcal{I})$ of rank $k$ on a ground set $V$ and a coverage function $f$ on $V$, the goal is to find an independent set $S \in \mathcal{I}$ maximizing $f(S)$. This problem is an important special case of the much-studied submodular function maximization problem subject to a matroid constraint; this is also a generalization of the maximum $k$-cover problem in a graph. In this paper, assuming that the coverage function has a bounded frequency $\mu$ (i.e., any element of the underlying universe of the coverage function appears in at most $\mu$ sets), we design a procedure, parameterized by some integer $\rho$, to extract in polynomial time an approximate kernel of size $\rho \cdot k$ that is guaranteed to contain a $1 - (\mu - 1)/\rho$ approximation of the optimal solution. This procedure can then be used to get a Fixed-Parameter Tractable Approximation Scheme (FPT-AS) providing a $1 - \varepsilon$ approximation in time $(\mu/\varepsilon)^{O(k)} \cdot |V|^{O(1)}$. This generalizes and improves the results of [Manurangsi, 2019] and [Huang and Sellier, 2022], providing the first FPT-AS working on an arbitrary matroid. Moreover, as the kernel has a very simple characterization, it can be constructed in the streaming setting.

## 1 Introduction

Matroids are fundamental combinatorial structures that generalize the notion of linear independence in a vector space as well as the notion of forest in a graph. In combinatorial optimization, the matroid constraints are an important generalization of the cardinality constraint. For instance, consider the problem of maximizing a submodular function under some constraint. If the constraint is that the feasible subsets are those of size bounded by some parameter $k$ (cardinality constraint), an approximation of $1 - 1/e$ can be obtained in polynomial time by a simple greedy algorithm [22] (this ratio is also the best possible in polynomial time unless $P = NP$, see [7]). Under the more general constraint that the feasible subsets are those that are independent in a given matroid $\mathcal{M}$ (matroid constraint), an approximation of $1 - 1/e$ can also be achieved in polynomial time [3], albeit by using

a more involved continuous greedy technique. Hence, somehow surprisingly, even though the matroid constraint is more complex than the cardinality constraint, some optimization problems are not really "harder" in the matroid context.

Following this perspective, in this paper we consider the problem of maximizing a coverage function of bounded frequency under some constraint. The starting point of our paper is the work of Manurangsi [18] in which, for cardinality constraints, a Fixed-Parameter Tractable Approximation Scheme (FPT-AS) is developed. Our main result here is a generalization of that FPT-AS to matroid constraints (Corollary 8), extending the approximate kernel construction of [18] to matroids (Theorem 6). A key idea in [18] is the use of uniform random sampling of subsets of given cardinality; unfortunately, in the matroid setting, near-uniform sampling of independent sets is in general impossible. Instead, here we introduce the concept of *Density-Balanced Subset* (DBS, Definition 2) in matroids. We show that in those particular subsets of the ground set we can generalize the traditional notion of uniform random sampling of a subset of a given cardinality, to that of sampling a maximum independent set, while guaranteeing that (i) every element of the DBS has the same probability of being sampled (i.e., the probabilities are "balanced") and that (ii) those events are negatively correlated (Proposition 3).

## Density-Balanced Subsets

We introduce here the concept of *Density-Balanced Subsets*. Let us first define the notion of density. (In the following we assume that readers already have some familiarity with matroids; an introduction to matroids is provided in the beginning of Section 2.)

▶ **Definition 1.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid. The* density *of a subset $U \subseteq V$ in $\mathcal{M}$ is defined as*

$$\rho_{\mathcal{M}}(U) = \frac{|U|}{\mathrm{rank}_{\mathcal{M}}(U)}.$$

*The density of an empty set is set to 0, and the density of a non-empty set of rank 0 is $+\infty$.*

From that we define a *Density-Balanced Subset* (DBS). Basically, in a DBS, no subset has a larger density than the DBS itself.

▶ **Definition 2.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid, and $\rho$ be a positive integer. A subset $V' \subseteq V$ is called a* $\rho$-DBS *in $\mathcal{M}$ if $\rho_{\mathcal{M}}(V') = \rho$ and for all $U \subseteq V'$, $\rho_{\mathcal{M}}(U) \leq \rho$.*

Density-Balanced Subsets appear naturally when extracting independent sets in matroid unions (as we will see in Section 3); in Figure 1 a simple example of DBS is given.

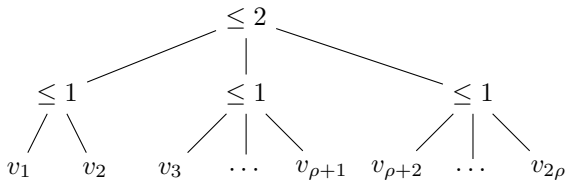

**Figure 1** Example of $\rho$-DBS of rank $k = 2$. The tree represents a laminar matroid $\mathcal{M} = (V, \mathcal{I})$ on the ground set $V = \{v_1, \ldots, v_{2\rho}\}$: the leaves represent elements of the ground set, and the inner nodes represent cardinality constraints on the elements in their associated subtree (e.g., if $S \in \mathcal{I}$, then $|S \cap \{v_3, \ldots, v_{\rho+1}\}| \leq 1$). Observe that $V' = V$ is a $\rho$-DBS.

In $\rho$-DBSes, it is possible to sample independent sets while having the desired balance and negative correlation properties. Moreover, the sampled independent sets are "maximal" (i.e., these sampled independent sets are bases in the restriction of the matroid to the DBS), hence, in this sense, this extends the notion of uniform random sampling. This result comes from a more general randomized rounding algorithm developed by Chekuri, Vondrák, and Zenklusen [4].

▶ **Proposition 3.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid, $V' \subseteq V$ be a $\rho$-DBS for some positive integer $\rho$, and $k = \operatorname{rank}_{\mathcal{M}}(V')$. There exists a procedure to sample randomly from $V'$ an independent set of $k$ elements $S = \{s_1, \ldots, s_k\} \in \mathcal{I}$ such that:*

**(i)** *for all $v \in V'$, $\mathbb{P}[v \in S] = 1/\rho$;*

**(ii)** *for all $T \subseteq V'$, $\mathbb{P}[T \subseteq S] \leq \prod_{v \in T} \mathbb{P}[v \in S] = 1/\rho^{|T|}$.*

## Matroid-Constrained Maximum Coverage

Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid of rank $k$ on a ground set $V$. Given a universe $U$, a weight function $w : U \to \mathbb{R}_+$, and a family $\{U_v\}_{v \in V}$ of subsets of $U$, the *matroid-constrained maximum coverage* problem is to select a subset $S \in \mathcal{I}$ maximizing the coverage function $f(S) = w(\bigcup_{s \in S} U_s) = \sum_{u \in \bigcup_{s \in S} U_s} w(u)$, namely, to find an element in $\arg\max_{S \in \mathcal{I}} f(S)$.

The *frequency* of an element of the universe $u \in U$ refers to the number of sets $U_v$ in which it appears. We say that $f$ has *bounded frequency* $\mu$ if every element of the underlying universe $U$ has a frequency bounded by $\mu$. In our paper, we will focus on the matroid-constrained maximum coverage problem for coverage functions having some bounded frequency $\mu$; this assumption is quite common and is used for instance in [2, 8, 13, 21, 24, 25]. An important special case is $\mu = 2$, where it corresponds to the coverage function over edges in a graph. Besides the frequency parameter, another parameter $z$, corresponding to the number of points covered in an optimal solution, has been used to design FTP algorithms in [15].

To put our problem in a larger picture, we can first observe that a coverage function is a special case of monotone submodular function. For the problem of maximizing a monotone submodular function under a matroid constraint, an approximation of $1 - 1/e$ can be achieved in polynomial time [3] using continuous greedy and pipage rounding techniques. Later, a combinatorial approach for maximizing coverage functions over matroids was developed to achieve the same ratio [9], and this approach was then generalized to monotone submodular functions [10].

A special case of our problem when the matroid constraint is simply a cardinality constraint (i.e., a uniform matroid) has been studied in [1, 7, 12, 26]. It has been shown in [12] that a simple greedy procedure (picking at each step the element maximizing the increase of the coverage function) guarantees a ratio of $1 - 1/e$. If a polynomial time algorithm could approximate maximum coverage within a ratio of $1 - 1/e + \varepsilon$ for some $\varepsilon > 0$, then it would imply that $P = NP$ [7]. Furthermore, one cannot obtain in FPT time (where the matroid rank $k$ is the parameter) an approximation ratio better than $1 - 1/e + \varepsilon$, assuming GAP-ETH [19]. However, when the coverage function has bounded frequency $\mu$, an approximation of $1 - (1 - 1/\mu)^{\mu}$ can be achieved [1].

The case where the coverage function has a frequency $\mu$ bounded by 2 is called the *matroid-constrained vertex cover* [13, 14], and is called MAX $k$-VERTEX-COVER when the matroid is uniform. The latter has also been studied through the lens of fixed-parameterized-tractability. The problem is $W[1]$-hard with $k$ being the parameter [11], thus getting an exact solution in FPT time is unlikely. Nonetheless, it is possible to get a near-optimal solution in FPT time [20]. Precisely, an FPT approximation scheme (FPT-AS) is given in [20], that delivers a $1 - \varepsilon$ approximate solution in $(k/\varepsilon)^{O(k^3/\varepsilon)} \cdot |V|^{O(1)}$ time, later improved to $(1/\varepsilon)^{O(k)} \cdot |V|^{O(1)}$ in [18, 25].

Here we recall the definition of an FPT-AS, introduced by Marx [20]:

▶ **Definition 4.** *Given a parameter function $\kappa$ associating a positive integer to each instance $x \in I$ of some problem, a* Fixed-Parameter Tractable Approximation Scheme (FPT-AS) *is an algorithm that provides a $(1-\varepsilon)$ approximate solution in time $g(\varepsilon, \kappa(x)) \cdot |x|^{O(1)}$ for some computable function $g$.*

In our case, each of the instances consists of a bounded-frequency coverage function and a matroid, and the parameter of an instance is the rank $k$ of its matroid.

For our problem, an FPT-AS has been designed for partition, laminar, and transversal matroids in [13], where the concept of *robust subset* is introduced to generalize the random sampling argument developed in [18]. In [13], an approximate kernel[1] is extracted, consisting of a maximum weight independent set in the union of several copies of the same matroid $\mathcal{M}$ (see below for a definition of the union of matroids), and then a brute-force enumeration is performed on that kernel of small size. The number of matroids in these unions depends on the type of matroid.

▶ **Definition 5.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid. Then we can define $\rho\mathcal{M} = (V, \mathcal{I}_\rho)$ as the* union of $\rho$ matroids $\mathcal{M}$*, as follows: $S \in \mathcal{I}_\rho$ if $S$ can be partitioned into $S_1 \cup \cdots \cup S_\rho$ so that for all $i$ we have $S_i \in \mathcal{I}$.*

It is known that the union of matroids is still a matroid and that an independence oracle for $\rho\mathcal{M}$ can be implemented in polynomial time given an independence oracle for $\mathcal{M}$, e.g., see [23]. Moreover, the rank of $\rho\mathcal{M}$ is at most $\rho$ times the rank of $\mathcal{M}$.

In this paper, we prove that a maximum weight independent set in $\rho\mathcal{M}$ contains an approximate solution of the problem, and that this ratio does not depend on the type of matroid (unlike [13]):

▶ **Theorem 6.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid and let $f$ be a coverage function on $V$ of frequency bounded by $\mu$. Let $V'$ be a maximum weight independent set in $\rho\mathcal{M}$, with respect to the weights $f(\{v\})$. Then $V'$ contains a $1 - (\mu - 1)/\rho$ approximate solution of the matroid-constrained maximum coverage problem.*

The proof of Theorem 6 relies on a reinterpretation of the greedy algorithm (extracting $V'$ in the matroid $\rho\mathcal{M}$, i.e., Algorithm 2) as the process of constructing $\rho$-DBSes in a series of contracted matroids of $\mathcal{M}$ (see Algorithm 1). These DBSes that appear during the construction of the kernel can then be used for random sampling purposes, allowing us to generalize the argument of [18] for uniform matroids to any matroid (details in Section 3).

▶ Remark 7. The simplicity of our characterization of the kernel implies that our kernelization process can be easily turned into a streaming algorithm, as in [13]. In fact, assuming that the matroid as well as the cover function is provided to the algorithm as oracles, maintaining a maximum weight independent set in $\rho\mathcal{M}$ with respect to the weights $f(\{v\})$ can be done in streaming using $O(\rho \cdot k)$ memory.

By taking the appropriate value $\rho = \lceil (\mu - 1)/\varepsilon \rceil$ and performing a bruteforce enumeration on the approximate kernel described in Theorem 6 (that kernel would be of size $\rho \cdot k = O(k \cdot \mu/\varepsilon)$ and could be extracted in polynomial time, assuming that an independence oracle for $\mathcal{M}$ and an oracle for $f$ are given), we obtain an FPT-AS, extending the result of [18]:

[1] An $\alpha$-approximate kernel [17, 18] for some parameterized optimization problem is a pair of polynomial time algorithms $\mathcal{A}$, the *reduction algorithm*, and $\mathcal{B}$, the *solution lifting algorithm*, such that (i) given an instance $(x, \kappa(x))$, $\mathcal{A}$ produces another instance $(x', \kappa(x'))$ such that $|x'|$, $\kappa(x')$ are bounded by $g(\kappa(x))$ and (ii) given a $\beta$ approximate solution $S'$ for $(x', \kappa(x'))$, $\mathcal{B}$ produces a solution $S$ of $(x, \kappa(x))$ such that $S$ is an $\alpha\beta$ approximate solution for $(x, \kappa(x))$. In the following we will use the terms "kernel" and "approximate kernel" interchangeably, dropping the adjective.

▶ **Corollary 8.** *There exists an algorithm that computes a $1-\varepsilon$ approximate solution of the matroid-constrained maximum coverage in $(\mu/\varepsilon)^{O(k)} \cdot |V|^{O(1)}$ time.*

To see the interest of this result, we note that if the only parameter is the rank $k$ of the matroid, one cannot obtain in FPT time an approximation ratio better than $1-1/e+\varepsilon$ (assuming GAP-ETH) for a general coverage function [19], even if the matroid is the simplest uniform matroid. In contrast, our result shows that it is possible to break through this lower bound and get arbitrarily close to 1 for an arbitrary matroid when the frequency of the coverage function is bounded. We also emphasize here that the randomization is only used in the analysis; our algorithm itself is deterministic.

An important special case of Theorem 6 is when $\mu = 2$, which corresponds to the matroid-constrained vertex cover problem, and for which we have:

▶ **Corollary 9.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid and let $G = (V, E)$ be a weighted graph. Let $V'$ be a maximum weight independent set in $\rho\mathcal{M}$, with respect to the weighted degrees $\deg_w(v)$. Then $V'$ contains a $1-1/\rho$ approximate solution of the matroid-constrained vertex cover problem.*

This extends and improves the previous kernelization results for this problem [13, 18]. In fact, in [18] the $1-1/\rho$ approximation is attained for the union of $\rho$ uniform matroids, and in [13] that ratio is attained either for the union of $\rho$ partition matroids, $2 \cdot \rho$ laminar matroids, or $\rho + k - 1$ (reduced later to $\rho$ in [16]) transversal matroids.

## 2 Density-Balanced Subsets

Let us start with some definitions. Given a finite set $V$, a matroid is a pair $\mathcal{M} = (V, \mathcal{I})$ where $\mathcal{I} \subseteq \mathcal{P}(V)$ is a family of subsets in $V$ that satisfies the following three conditions: (1) $\emptyset \in \mathcal{I}$, (2) if $X \subseteq Y \in \mathcal{I}$, then $X \in \mathcal{I}$, and (3) if $X, Y \in \mathcal{I}, |Y| > |X|$, then there exists an element $e \in Y \backslash X$ so that $X \cup \{e\} \in \mathcal{I}$.

The set $V$ is called the *ground set* of the matroid and the elements of $\mathcal{I}$ are called the *independent sets*. Matroids terminology borrows concepts from vector spaces as well as graph theory. The *rank* of a subset $X \subseteq V$ is defined as $\text{rank}_{\mathcal{M}}(X) = \max_{Y \subseteq X, Y \in \mathcal{I}} |Y|$; the rank of a matroid is defined as $\text{rank}_{\mathcal{M}}(V)$. The *span* of a subset $X \subseteq V$ in the matroid $\mathcal{M}$ is defined as $\text{span}_{\mathcal{M}}(X) = \{x \in V : \text{rank}_{\mathcal{M}}(X \cup \{x\}) = \text{rank}_{\mathcal{M}}(X)\}$, and these elements in the *span* are called *spanned by* $X$ in $\mathcal{M}$. A subset $C \subseteq V$ is a *circuit* if $C$ is a minimal non-independent set, i.e., for every $v \in C$, $C \backslash \{v\} \in \mathcal{I}$. An element in $V$ that is a circuit by itself is called a *loop*. For more details about matroids, we refer the reader to [23].

We recall the definition of a *restriction* and a *contraction* of a matroid. Performing such operation on a matroid results in another matroid.

▶ **Definition 10** (Restriction). *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid, and let $V' \subseteq V$ be a subset. Then we define the* restriction of $\mathcal{M}$ to $V'$ *as $\mathcal{M}|V' = (V', \mathcal{I}')$ where $\mathcal{I}' = \{S \subseteq V' : S \in \mathcal{I}\}$*

▶ **Definition 11** (Contraction). *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid, and let $U$ be a subset of $V$. Then we define the* contracted matroid *$\mathcal{M}/U = (V \backslash U, \mathcal{I}_U)$ so that, given a maximum independent subset $\mathcal{B}_U$ of $U$, $\mathcal{I}_U = \{S \subseteq V \backslash U : S \cup \mathcal{B}_U \in \mathcal{I}\}$.*

It is well-known that any choice of $\mathcal{B}_U$ produces the same $\mathcal{I}_U$, as a result the definition of contraction is unambiguous. The following proposition comes directly from the definition.

▶ **Proposition 12.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid and let $A \subseteq B \subseteq V$. Then we have $\text{rank}_{\mathcal{M}/A}(B \backslash A) = \text{rank}_{\mathcal{M}}(B) - \text{rank}_{\mathcal{M}}(A)$.*

In this paper, we use the notion of density of a subset in a matroid. We can observe from that definition that the density of a non-empty set is always larger or equal to one.

▶ **Definition 1.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid. The* density *of a subset $U \subseteq V$ in $\mathcal{M}$ is defined as*

$$\rho_{\mathcal{M}}(U) = \frac{|U|}{\mathrm{rank}_{\mathcal{M}}(U)}.$$

*The density of an empty set is set to 0, and the density of a non-empty set of rank 0 is $+\infty$.*

We now introduce the notion of *Density-Balanced Subset* (DBS).

▶ **Definition 2.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid, and $\rho$ be a positive integer. A subset $V' \subseteq V$ is called a* $\rho$-DBS *in $\mathcal{M}$ if $\rho_{\mathcal{M}}(V') = \rho$ and for all $U \subseteq V'$, $\rho_{\mathcal{M}}(U) \leq \rho$.*

Here is a theorem due to Edmonds [5] that will allow us to get another characterization of Density-Balanced Subsets.

▶ **Theorem 13** (Theorem 1 in [5])**.** *The elements of a matroid $\mathcal{M}$ can be partitioned into as few as $\rho$ sets, each of which is independent, if and only if there is no subset $A$ of elements of $\mathcal{M}$ for which $|A| > \rho \cdot \mathrm{rank}_{\mathcal{M}}(A)$.*

▶ **Proposition 14.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid. If $V'$ is a $\rho$-DBS for some positive integer $\rho$, then there exist $\rho$ independent sets $B_1, \ldots, B_\rho$ such that $V' = B_1 \cup \cdots \cup B_\rho$. Conversely, if a set $V'$ of density $\rho$ can be partitioned into $\rho$ independent sets $B_1, \ldots, B_\rho$, then $V'$ is a $\rho$-DBS.*

**Proof.** Consider the matroid $\mathcal{M}|V'$, i.e., the restriction of $\mathcal{M}$ to $V'$. By Theorem 13, as the density of any set $A \subseteq V'$ is bounded by $\rho$, $V'$ can be partitioned into $\rho$ independent sets $B_1, \ldots, B_\rho$. Conversely, if $V'$ can be partitioned into $\rho$ independent sets $B_1, \ldots, B_\rho$, then by Theorem 13 the density of any set $A \subseteq V'$ is bounded by $\rho$. As we assumed $\rho_{\mathcal{M}}(V') = \rho$, $V'$ is a $\rho$-DBS. ◀

In DBSes, the notion of uniform random sampling can be properly extended.

▶ **Proposition 3.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid, $V' \subseteq V$ be a $\rho$-DBS for some positive integer $\rho$, and $k = \mathrm{rank}_{\mathcal{M}}(V')$. There exists a procedure to sample randomly from $V'$ an independent set of $k$ elements $S = \{s_1, \ldots, s_k\} \in \mathcal{I}$ such that:*

**(i)** *for all $v \in V'$, $\mathbb{P}[v \in S] = 1/\rho$;*

**(ii)** *for all $T \subseteq V'$, $\mathbb{P}[T \subseteq S] \leq \prod_{v \in T} \mathbb{P}[v \in S] = 1/\rho^{|T|}$.*

**Proof.** By Proposition 14, we can write $V' = B_1 \cup \cdots \cup B_\rho$ for some disjoint independent sets. Hence we obtain (denoting $\mathbb{1}_U$ the indicator vector of the set $U$):

$$\frac{1}{\rho}\mathbb{1}_{V'} = \frac{1}{\rho}\sum_{i=1}^{\rho} \mathbb{1}_{B_i} \in P(\mathcal{M}),$$

where $P(\mathcal{M}) = \mathrm{conv}\{\mathbb{1}_S : S \in \mathcal{I}\} = \{x \in [0,1]^V : \forall\, S \subseteq V, \sum_{v \in S} x_v \leq \mathrm{rank}_{\mathcal{M}}(S)\}$ denotes the matroid polytope of $\mathcal{M}$. Therefore we can apply the randomized rounding algorithm developed in [4] to the vector $\frac{1}{\rho}\mathbb{1}_{V'}$ to get an integral vector $X = \mathbb{1}_S \in \{0,1\}^V$ such that $S \subseteq V'$ is a maximum independent set and

**(i)** for all $v \in V'$, $\mathbb{P}[v \in S] = \mathbb{E}[X_v] = 1/\rho$;

**(ii)** for all $T \subseteq V'$, $\mathbb{P}[T \subseteq S] = \mathbb{E}[\prod_{v \in T} X_v] \leq \prod_{v \in X} \mathbb{E}[X_v] = \prod_{v \in T} \mathbb{P}[v \in S] = 1/\rho^{|T|}$.

This concludes the proof. ◀

Conversely we also have the following proposition.

▶ **Proposition 15.** *Let $V'$ a set of integer density $\rho$ in which independent sets can be sampled randomly so that each element has probability $1/\rho$ of being sampled, then $V'$ is a $\rho$-DBS.*

**Proof.** In fact, if there exists $U \subseteq V'$ such that $\rho_{\mathcal{M}}(U) > \rho$, then an algorithm sampling each element in $V'$ with probability $1/\rho$ would take in expectation strictly more than $\mathrm{rank}_{\mathcal{M}}(U)$ elements in $U$, meaning that some of those sampled set violate the rank constraint on $U$. ◀

Another useful property of DBSes is that after a matroid contraction we can still recover in a $\rho$-DBS $V'$ a smaller $V''$ while preserving the rank of $V'$ in the contracted matroid:

▶ **Proposition 16.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid, and $V'$ be a $\rho$-DBS in $\mathcal{M}$ for some positive integer $\rho$. Let $A \subseteq V$ such that $V' \not\subseteq \mathrm{span}_{\mathcal{M}}(A)$. Then there exists a subset $V'' \subseteq V'$ such that:*

**(i)** *$V''$ is a $\rho$-DBS in $\mathcal{M}/A$;*

**(ii)** $\mathrm{rank}_{\mathcal{M}/A}(V'') = \mathrm{rank}_{\mathcal{M}/A}(V' \backslash A)$.

**Proof.** Using Proposition 14, we know that $V' = B_1 \cup \cdots \cup B_\rho$ for some disjoint independent sets $B_1, \ldots, B_\rho$, each of cardinality $\mathrm{rank}_{\mathcal{M}}(V')$ (because $V'$ has density $\rho$, so it contains $\rho \cdot \mathrm{rank}_{\mathcal{M}}(V')$ elements, and each independent set is made of at most $\mathrm{rank}_{\mathcal{M}}(V')$ elements), and each of them spanning $V'$ in $\mathcal{M}$. As a result, for all $i \in \{1, \ldots, \rho\}$ we also have $V' \backslash A \subseteq \mathrm{span}_{\mathcal{M}/A}(B_i \backslash A)$, hence $\mathrm{rank}_{\mathcal{M}/A}(B_i \backslash A) = \mathrm{rank}_{\mathcal{M}/A}(V' \backslash A)$ and thereby there exists $B'_i \subseteq B_i \backslash A$ such that $B'_i$ is independent in $\mathcal{M}/A$ and $|B'_i| = \mathrm{rank}_{\mathcal{M}/A}(V' \backslash A)$. Hence $V'' = B'_1 \cup \cdots \cup B'_\rho$ is a set of rank equal to $\mathrm{rank}_{\mathcal{M}/A}(V' \backslash A)$ in $\mathcal{M}/A$, contains $\rho \cdot \mathrm{rank}_{\mathcal{M}/A}(V' \backslash A)$ elements, and can be partitioned into $\rho$ independent sets, therefore, by Proposition 14, $V''$ is a $\rho$-DBS in $\mathcal{M}/A$ with $\mathrm{rank}_{\mathcal{M}/A}(V'') = |B'_1| = \cdots = |B'_\rho| = \mathrm{rank}_{\mathcal{M}/A}(V' \backslash A)$. ◀

The following propositions are about matroid contraction and densest subsets. The next proposition states how the density is changed after a matroid contraction.

▶ **Proposition 17.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid. If $A \subseteq B \subseteq V$ and $U \subseteq V \backslash B$ we have $\rho_{\mathcal{M}/A}(U) \leq \rho_{\mathcal{M}/B}(U)$, assuming that $\rho_{\mathcal{M}/A}(U) < +\infty$.*

**Proof.** We have $\mathrm{rank}_{\mathcal{M}/A}(U) \geq \mathrm{rank}_{\mathcal{M}/B}(U)$, while the cardinality $|U|$ remains the same. ◀

Now we give some results regarding densest subsets, which are closely related to *Density-Balanced Subsets*, as a densest subset in a matroid is automatically a DBS.

▶ **Proposition 18.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid, and $\rho$ be a positive integer. Let $V' \subseteq V$. If $\max_{U \subseteq V'} \rho_{\mathcal{M}}(U) < \rho$, then for any $v \in V \backslash V'$, $\max_{U \subseteq V' \cup \{v\}} \rho_{\mathcal{M}}(U) \leq \rho$.*

**Proof.** Consider $U \subseteq V'$, $U \neq \emptyset$. As $\rho_{\mathcal{M}}(U) < \rho$, we know that $|U| \leq \rho \cdot \mathrm{rank}_{\mathcal{M}}(U) - 1$ (because $\rho \cdot \mathrm{rank}_{\mathcal{M}}(U)$ is an integer). Therefore we have

$$\rho_{\mathcal{M}}(U \cup \{v\}) \leq \frac{|U| + 1}{\mathrm{rank}_{\mathcal{M}}(U)} \leq \frac{\rho \cdot \mathrm{rank}_{\mathcal{M}}(U) - 1 + 1}{\mathrm{rank}_{\mathcal{M}}(U)} = \rho,$$

which concludes the proof. ◀

▶ **Proposition 19.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid, $V'$ be a subset of $V$, and let $B$ be a subset that reaches the maximum density $\rho^* < +\infty$ in $V'$. Then given any $A \subsetneq B$, $\rho_{\mathcal{M}/A}(B \backslash A) \geq \rho^*$.*

**Proof.** If $\text{rank}_{\mathcal{M}/A}(B\backslash A) = 0$ then $\rho_{\mathcal{M}/A}(B\backslash A) = +\infty$ and we are done; otherwise, by Proposition 12:

$$\rho_{\mathcal{M}}(B) = \frac{\text{rank}_{\mathcal{M}}(A)\cdot\rho_{\mathcal{M}}(A) + \text{rank}_{\mathcal{M}/A}(B\backslash A)\cdot\rho_{\mathcal{M}/A}(B\backslash A)}{\text{rank}_{\mathcal{M}}(A) + \text{rank}_{\mathcal{M}/A}(B\backslash A)},$$

hence $\rho_{\mathcal{M}}(B)$ is a weighted average of $\rho_{\mathcal{M}}(A)$ and $\rho_{\mathcal{M}/A}(B\backslash A)$. As $\rho_{\mathcal{M}}(A) \leq \rho^*$ (by definition of $\rho^*$), it implies that $\rho_{\mathcal{M}/A}(B\backslash A) \geq \rho^*$. ◀

The following proposition states that the densest subsets are closed under union, thus proving the uniqueness of the maximum cardinality densest subset – that property will be useful in Algorithm 1 (Section 3).

▶ **Proposition 20.** *Let $\mathcal{M} = (V,\mathcal{I})$ be a matroid, and $V' \subseteq V$. Let $\rho^* = \max_{U\subseteq V'}\rho_{\mathcal{M}}(U) < +\infty$. Then given any two subsets $W_1$, $W_2$ in $V'$ of density $\rho^*$, $\rho_{\mathcal{M}}(W_1 \cup W_2) = \rho^*$.*

**Proof.** If $W_1 \subseteq W_2$, then the proposition is trivially true. So assume that $W_1\backslash W_2 \neq \emptyset$, and we can observe that

$$\rho^* \leq \rho_{\mathcal{M}/(W_1\cap W_2)}(W_1\backslash(W_1\cap W_2)) \leq \rho_{\mathcal{M}/W_2}(W_1\backslash(W_1\cap W_2)),$$

where the first inequality uses Proposition 19 and the second uses Proposition 17. As a result, by the facts that $\rho_{\mathcal{M}}(W_2) = \rho^*$ and that $\rho_{\mathcal{M}/W_2}(W_1\backslash(W_1\cap W_2)) \geq \rho^*$, we obtain $\rho_{\mathcal{M}}(W_1\cup W_2) \geq \rho^*$ (using a weighted average argument as in Proposition 19). Hence we have $\rho_{\mathcal{M}}(W_1\cup W_2) = \rho^*$. ◀

▶ **Proposition 21.** *Let $\mathcal{M} = (V,\mathcal{I})$ be a matroid, and $V' \subseteq V$ a non-empty set. Let $A$ be the largest densest subset in $V'$. Then for any $B \subseteq V'\backslash A$, we have $\rho_{\mathcal{M}/A}(B) < \rho_{\mathcal{M}}(A)$.*

**Proof.** We proceed by contradiction. Suppose that there exists $B \subseteq V'\backslash A$ such that $\rho_{\mathcal{M}/A}(B) \geq \rho_{\mathcal{M}}(A)$. Then it implies that

$$\rho_{\mathcal{M}}(A\cup B) = \frac{\rho_{\mathcal{M}}(A)\cdot\text{rank}_{\mathcal{M}}(A)}{\text{rank}_{\mathcal{M}}(A)+\text{rank}_{\mathcal{M}/A}(B)} + \frac{\rho_{\mathcal{M}/A}(B)\cdot\text{rank}_{\mathcal{M}/A}(B)}{\text{rank}_{\mathcal{M}}(A)+\text{rank}_{\mathcal{M}/A}(B)} \geq \rho_{\mathcal{M}}(A),$$

contradicting the hypothesis that $A$ was the largest densest set in $V'$. ◀

## 3 Matroid-Constrained Maximum Coverage

Here we will use a slightly different formalization of the coverage function, based on edge-weighted hypergraphs (compared to the one given in the introduction), but it is straightforward to see that these formalizations are equivalent. Let $G = (V,E)$ be a hypergraph, $V$ being a set of vertices and $E$ being a set of hyper-edges, i.e., an element $e \in E$ is a subset of $V$. We denote $n = |V|$. Let $w : E \to \mathbb{R}_+$ be a weight function on the hyper-edges. We extend this function to any set of hyper-edges by setting for any $A \subseteq E$, $w(A) = \sum_{e\in A} w(e)$. For a vertex $v \in V$, we denote $\delta(v)$ the set of its set of *incident* hyper-edges, namely, $\delta(v) = \{e \in E : v \in e\}$, and $\deg_w(v)$ its *weighted degree*, namely, $\deg_w(v) = w(\delta(v))$. The *frequency* of a hyper-edge $e$ is defined as the number of vertices for which $e$ appears in $\delta(v)$, namely, $|e|$. The hypergraph $G$ will be said of *bounded frequency* $\mu$ if all its hyper-edges have frequencies bounded by $\mu$. For two sets of vertices $S$, $T$ we denote by $E(S,T)$ the set of hyper-edges having at least one endpoint in each set $S$ and $T$, namely, $E(S,T) = \{e \in E : e\cap S \neq \emptyset, e\cap T \neq \emptyset\}$. For conciseness we will denote $E(S) = E(S,S)$.

Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid on the ground set $V$. In the matroid-constrained maximum coverage problem, we are asked to find a set of vertices $S \subseteq V$ that is independent in the matroid $\mathcal{M}$ (i.e., $S \in \mathcal{I}$) and that maximizes the total weight of the covered hyperedges, namely, an element of $\arg\max_{S \in \mathcal{I}} w(E(S))$. The problem can be solved exactly by the standard greedy algorithm if $\mu = 1$ [6], so in the following we will assume that our hypergraph has a bounded frequency of $\mu \geq 2$. Observe that the case $\mu = 2$ corresponds to the matroid-constrained vertex cover, studied in [13].

Here we want to construct a kernel that contains a good approximation of the optimal solution of the maximum coverage problem under a matroid constraint. We will start by describing a procedure to build the kernel that will be convenient for the analysis, and then we will show that this algorithm turn out to be equivalent to the one of Theorem 6. We build our kernel $V'$ as follows. Let $\rho$ be a fixed positive integer. Start with an empty set $V'$, and an auxiliary set $C$ that is also empty at the beginning. Process the elements $v_i \in V$ in the order of non-increasing weighted-degrees. If the element $v_i$ is not spanned by $V'$ at that time we add that element to $C$, we check whether $C$ contains a set of density larger or equal to $\rho$ with respect to the matroid $\mathcal{M}/V'$. If this is the case, then we consider that largest densest subset $X$ in $C$ with respect to $\mathcal{M}/V'$, we add that set into $V'$ and remove that set from $C$ (note that, because of Proposition 20, the largest densest set $X$ is well-defined). When the main loop terminates, the set $C$ is also added into $V'$. A formal description of this procedure is provided in Algorithm 1.

**Algorithm 1** Algorithm for building a maximum coverage approximate kernel.

```
1: V = {v_1, ..., v_n} where deg_w(v_1) ≥ ··· ≥ deg_w(v_n)
2: V' ← ∅, C ← ∅
3: for i = 1, ..., n do  ▷ vertices are processed in non-increasing order of weighted degree
4:     if v_i ∈ span_M(V') then
5:         continue                          ▷ v_i is ignored if already spanned by V'
6:     C ← C ∪ {v_i}
7:     let X be the largest densest subset in C with respect to the matroid M/V'
8:     if ρ_{M/V'}(X) ≥ ρ then
9:         C ← C\X
10:        V' ← V' ∪ X
11: V' ← V' ∪ C
12: return V'
```

▷ Claim 22. In Algorithm 1, at the end of each iteration of the loop, for all $U \subseteq C$, $\rho_{\mathcal{M}/V'}(U) < \rho$. Moreover, when the condition at Line 8 is true, we have $\rho_{\mathcal{M}/V'}(X) = \rho$.

Proof. We prove these two properties by induction. In the first iteration of the algorithm, both properties are clearly true. Suppose that during the $i$th iteration both properties are satisfied. It means that at the beginning of the $(i+1)$st iteration the densest subset in $C$ is of density strictly smaller than $\rho$, hence Proposition 18 implies that the densest subset after inserting $v_{i+1}$ in $C$ cannot be of density strictly larger than $\rho$. This implies the second property for the $(i+1)$st iteration. Regarding the first property,

- if condition at Line 8 is false, then the first property is clearly satisfied;
- if condition at Line 8 is true, then the preceding discussion implies that the largest densest subset $X$ removed from $C$ has density $\rho$, and therefore, by Proposition 21, the first property is satisfied.

This concludes the proof. ◁

The set $V'$ can be decomposed as follows:

$$V' = X_1 \cup \cdots \cup X_r \cup R \tag{1}$$

where the $X_i$s represent the largest densest subsets $X$ that were added through the execution of the algorithm (at Line 10), labeled in the order they were added, and $R$ represents the set of remaining elements coming from $C$ that were added after termination of the main loop (at Line 11). As each $X_i$ is a densest subset of density $\rho$ in $\mathcal{M}/(\bigcup_{j=1}^{i-1} X_j)$, each set $X_i$ is a $\rho$-DBS in the matroid $\mathcal{M}/(\bigcup_{j=1}^{i-1} X_j)$.

Now we can prove the following important lemma, which states that the set $V'$ built by Algorithm 1 is an approximate kernel, i.e., a small subset of $V$ containing a good approximation of the optimal solution:

▶ **Lemma 23.** *Let $V'$ be the kernel built in Algorithm 1, and let $O$ be an optimal solution. Then $V'$ contains an independent set $S$ such that $w(E(S)) \geq (1 - (\mu - 1)/\rho) \cdot w(E(O))$.*

**Proof.** Let $O \in \mathcal{I}$ be an optimal solution. We denote $O^{in} = O \cap V'$, $O^{out} = O \backslash O^{in}$. As in [13, 18], we want to sample randomly an independent set $S \subseteq V'$ so that we have an inequality *in expectation*, implying that some set satisfying that same inequality actually exists:

$$\mathbb{E}[w(E(S))] \geq (1 - (\mu - 1)/\rho) \cdot w(E(O)).$$

To sample $S$, we will do the following. For $i = 1, \ldots, r$, using Proposition 16, consider $X'_i \subseteq X_i$ a $\rho$-DBS in $\mathcal{M}/(O^{in} \cup \bigcup_{j=1}^{i-1} X_j)$ of rank $k_i = \operatorname{rank}_{\mathcal{M}/(O^{in} \cup \bigcup_{j=1}^{i-1} X_j)}(X_i)$ (if $X_i$ is spanned by $O^{in} \cup \bigcup_{j=1}^{i-1} X_j$ in $\mathcal{M}$, then we just set $X'_i = \emptyset$ and $k_i = 0$). From that set $X'_i$, using Proposition 3, we sample an independent set $S_i = \{s_{i,1}, \ldots, s_{i,k_i}\} \subseteq X'_i$ in $\mathcal{M}/(O^{in} \cup \bigcup_{j=1}^{i-1} X_j)$ such that:

**(i)** for all $v \in X'_i$, $\mathbb{P}[v \in S_i] = 1/\rho$;
**(ii)** for all $v, v' \in X'_i$ such that $v \neq v'$, $\mathbb{P}[v \in S_i \wedge v' \in S_i] \leq 1/\rho^2$.

Then we set $S = O^{in} \cup \bigcup_{i=1}^{r} S_i$. We denote $\tilde{S} = \bigcup_{i=1}^{r} S_i$ and $V'' = \bigcup_{i=1}^{r} X'_i$. The $S_i$s are sampled independently.

▷ Claim 24. The set $S$ sampled using the aforementioned method is always independent in $\mathcal{M}$. Moreover,

**(i)** for all $v \in V''$, $\mathbb{P}[v \in \tilde{S}] = 1/\rho$;
**(ii)** for all $v, v' \in V''$ such that $v \neq v'$, $\mathbb{P}[v \in \tilde{S} \wedge v' \in \tilde{S}] \leq 1/\rho^2$.

Proof. We prove by induction on $i$ that $O^{in} \cup \bigcup_{j=1}^{i} S_j$ is independent in $\mathcal{M}$. For $i = 0$ this is clearly true, as $O^{in}$ is a subset of $O$, which is an independent set in $\mathcal{M}$. Suppose that the property is true for some $i < r$. Then it means that $O^{in} \cup \bigcup_{j=1}^{i} S_j$ is an independent set in $\mathcal{M}$. We know that for any sampling in $X'_{i+1}$, the set $S_{i+1}$ is independent is $\mathcal{M}/(O^{in} \cup \bigcup_{j=1}^{i} X_j)$, so it is also independent in $\mathcal{M}/(O^{in} \cup \bigcup_{j=1}^{i} S_j)$ (as $O^{in} \cup \bigcup_{j=1}^{i} S_j \subseteq O^{in} \cup \bigcup_{j=1}^{i} X_j$) and therefore $O^{in} \cup \bigcup_{j=1}^{i+1} S_j$ is independent in $\mathcal{M}$.

Then, for property (i), consider some $v \in V''$. There exists a unique $i$ so that $v \in X_i$ (as the $X_i$s are disjoint). Hence from the properties of the sampling of $S_i$ we know that $\mathbb{P}[v \in S_i] = 1/\rho$, hence $\mathbb{P}[v \in \tilde{S}] = 1/\rho$. For property (ii), if $v$ and $v'$ are in the same $X_i$, then the way $S_i$ is sampled guarantees that $\mathbb{P}[v \in \tilde{S} \wedge v' \in \tilde{S}] \leq 1/\rho^2$. Otherwise, the choices of $v$ and $v'$ are independent, i.e., $\mathbb{P}[v \in \tilde{S} \wedge v' \in \tilde{S}] = 1/\rho^2$. ◁

For $i = 1, \ldots, r$, let $O_i^{out} = O^{out} \cap (\operatorname{span}_{\mathcal{M}}(\bigcup_{j=1}^{i} X_j) \backslash \operatorname{span}_{\mathcal{M}}(\bigcup_{j=1}^{i-1} X_j))$.

▷ Claim 25. We have $O^{out} = O^{out} \cap \text{span}_{\mathcal{M}}(\bigcup_{i=1}^{r} X_i) = \bigcup_{i=1}^{r} O_i^{out}$.

Proof. The second part of the equality is straightforward, so we focus on the first part. Consider $v \in O \backslash \text{span}_{\mathcal{M}}(\bigcup_{i=1}^{r} X_i)$. It means that when $v$ is processed in Algorithm 1, that element cannot be discarded by the condition in Line 4, because at that time $V' = \bigcup_{j=1}^{i} X_j$ for some $i$ and therefore $v$ is not spanned by $V'$: that element is thereby added to $C$. Hence $v$ is added to $V'$ in the end (Line 11) and $v \in O^{in}$ (more precisely, $v \in O \cap R$, using the notation of equation (1)). ◁

▷ Claim 26. For all $v \in O_i^{out}$, for all $v' \in X_j$ such that $j \leq i$, we have $\deg_w(v) \leq \deg_w(v')$.

Proof. The element $v \in O_i^{out}$ has been discarded after the sets $X_1, \ldots, X_i$ were built (otherwise it would not have been spanned by $V'$, see Line 4), therefore these sets only contain elements having larger or equal weighted degrees. ◁

▷ Claim 27. For all $1 \leq i \leq r$, we have $|\bigcup_{j=1}^{i} O_j^{out}| \leq \sum_{j=1}^{i} k_j$.

Proof. The set $\bigcup_{j=1}^{i} O_j^{out}$ is independent in $\mathcal{M}/O^{in}$ and as it is in $\text{span}_{\mathcal{M}}(\bigcup_{j=1}^{i} X_j)$, it is in $\text{span}_{\mathcal{M}/O^{in}}(\bigcup_{j=1}^{i} X_j)$. Then we obtain $|\bigcup_{j=1}^{i} O_j^{out}| \leq \text{rank}_{\mathcal{M}/O^{in}}(\bigcup_{j=1}^{i} X_j) = \sum_{j=1}^{i} \text{rank}_{\mathcal{M}/(O^{in} \cup \bigcup_{l=1}^{j-1} X_l)}(X_j) = \sum_{j=1}^{i} k_j$, where in the first equality we used Proposition 12 multiple times. ◁

Now we index the elements in $O^{out} = \{o_1, \ldots, o_{|O^{out}|}\}$ so that $O_1^{out} = \{o_1, \ldots, o_{|O_1^{out}|}\}$, $O_2^{out} = \{o_{|O_1^{out}|+1}, \ldots, o_{|O_1^{out}|+|O_2^{out}|}\}$, and so on. Similarly, we index the elements of $\tilde{S} = \{s_1, \ldots, s_{\sum_{i=1}^{r} k_i}\}$ so that $s_1 = s_{1,1}, \ldots, s_{k_1} = s_{1,k_1}$, $s_{k_1+1} = s_{2,1}, \ldots, s_{k_1+k_2} = s_{2,k_2}$, and so on.

In the following, we will say that the element $s_i$ "replaces" the element $o_i$.

▷ Claim 28. For all $1 \leq i \leq |O^{out}|$, we have $\deg_w(o_i) \leq \deg_w(s_i)$.

Proof. Because of Claim 27, an element $o_i \in O_j^{out}$ is replaced by $s_i \in X_{j'}$ for some $j' \leq j$. As a result, by Claim 26, we know that we always have $\deg_w(o_i) \leq \deg_w(v)$ for any $v \in X_{j'}$. As $s_i$ is drawn from $X_{j'}$ we obtain the desired result. ◁

Then, as $S = O^{in} \cup \tilde{S}$, we have:

$$w(E(S)) = w(E(O^{in})) + w(E(\tilde{S})) - w(E(O^{in}, \tilde{S})).$$

We bound $\mathbb{E}[w(E(O^{in}, \tilde{S}))]$ as follows. By construction, $\mathbb{P}[v' \in V''] = 1/\rho$ for all $v' \in V''$. Then we have

$$\begin{aligned}
\mathbb{E}[w(E(O^{in}, \tilde{S}))] &= \sum_{e \in E(O^{in})} w(e) \cdot \mathbb{P}[e \cap \tilde{S} \neq \emptyset] \\
&\leq \sum_{e \in E(O^{in})} \left[ w(e) \cdot \left( \sum_{v' \in e \cap V''} \mathbb{P}[v' \in \tilde{S}] \right) \right] && \text{by union-bound} \\
&= \sum_{e \in E(O^{in})} w(e) \cdot |e \cap V''| \cdot 1/\rho && \text{as } \mathbb{P}[v' \in \tilde{S}] = 1/\rho, \forall v' \in V'' \\
&\leq \sum_{e \in E(O^{in})} w(e) \cdot (\mu - 1) \cdot 1/\rho && \text{as } |e \cap V''| \leq \mu - 1 \\
&= (\mu - 1)/\rho \cdot w(E(O^{in})).
\end{aligned}$$

Furthermore, the value $w(E(\tilde{S}))$ can be rearranged as follows:

$$w(E(\tilde{S})) = \sum_{e\in E(\tilde{S})} \sum_{v\in e\cap\tilde{S}} \frac{w(e)}{|e\cap\tilde{S}|} = \sum_{v\in\tilde{S}} \sum_{e\in\delta(v)} \frac{w(e)}{|e\cap\tilde{S}|}$$
$$= \sum_{v\in\tilde{S}} \sum_{e\in\delta(v)} \left(\left(1 - \frac{|e\cap\tilde{S}|-1}{|e\cap\tilde{S}|}\right)\cdot w(e)\right) = \sum_{v\in\tilde{S}} \left(\deg_w(e) - \sum_{e\in\delta(v)} \frac{|e\cap\tilde{S}|-1}{|e\cap\tilde{S}|}\cdot w(e)\right).$$

Hence $\mathbb{E}[w(E(\tilde{S}))]$ can be written as

$$\mathbb{E}[w(E(\tilde{S}))] = \mathbb{E}\left[\sum_{v\in\tilde{S}} \deg_w(v)\right] - \mathbb{E}\left[\sum_{v\in\tilde{S}} \sum_{e\in\delta(v)} \frac{|e\cap\tilde{S}|-1}{|e\cap\tilde{S}|}\cdot w(e)\right]. \tag{2}$$

We will then focus on upper-bounding the second term, which captures the extent to which edges are counted multiple times in the first term of the sum. We have

$$\begin{aligned}
&\mathbb{E}\left[\sum_{v\in\tilde{S}} \sum_{e\in\delta(v)} \frac{|e\cap\tilde{S}|-1}{|e\cap\tilde{S}|}\cdot w(e)\right] \\
&\leq \mathbb{E}\left[\sum_{v\in V''} \sum_{e\in\delta(v)} w(e)\cdot \mathbb{1}[v\in\tilde{S}\wedge|e\cap\tilde{S}|\geq 2]\right] \\
&= \sum_{v\in V''} \sum_{e\in\delta(v)} w(e)\cdot\mathbb{P}[v\in\tilde{S}\wedge|e\cap\tilde{S}|\geq 2] \\
&\leq \sum_{v\in V''} \sum_{e\in\delta(v)} w(e)\cdot\left(\sum_{v'\in e\cap V''\setminus\{v\}} \mathbb{P}[v\in\tilde{S}\wedge v'\in\tilde{S}]\right) && \text{by union-bound} \\
&\leq \sum_{v\in V''} \sum_{e\in\delta(v)} w(e)\cdot\left(\sum_{v'\in e\cap V''\setminus\{v\}} 1/\rho^2\right) && \text{by Claim 24} \\
&\leq \sum_{v\in V''} \sum_{e\in\delta(v)} w(e)\cdot\left((\mu-1)\cdot 1/\rho^2\right) && \text{as } |e\cap V''\setminus\{v\}|\leq\mu-1 \\
&= (\mu-1)\sum_{v\in V''} 1/\rho^2\cdot\deg_w(v) \\
&= (\mu-1)/\rho\cdot\mathbb{E}\left[\sum_{v\in\tilde{S}}\deg_w(v)\right]. && \text{as } \mathbb{P}[v\in\tilde{S}]=1/\rho,\ \forall v\in V''
\end{aligned}$$

where for the first inequality we apply the worst possible coefficient (namely, $1\geq(\mu-1)/\mu$) each time $e$ is covered more than once by $\tilde{S}$, and for the second inequality we use a union bound, namely, $\mathbb{P}[v\in\tilde{S}\wedge|e\cap\tilde{S}|\geq 2]\leq\sum_{v'\in e\cap V''\setminus\{v\}}\mathbb{P}[v\in\tilde{S}\wedge v'\in\tilde{S}]$. As a result, combining with (2), we obtain

$$\mathbb{E}[w(E(\tilde{S}))]\geq(1-(\mu-1)/\rho)\cdot\mathbb{E}\left[\sum_{v\in\tilde{S}}\deg_w(v)\right].$$

Then this can be compared to $w(E(O^{out}))$ as we have

$$\mathbb{E}\left[\sum_{v\in\tilde{S}}\deg_w(v)\right] \geq \mathbb{E}\left[\sum_{i=1}^{|O^{out}|}\deg_w(s_i)\right] \geq \sum_{i=1}^{|O^{out}|}\deg_w(o_i)\geq w(E(O^{out})),$$

where we use Claim 27 for the first inequality (for $i = r$, i.e., $|\tilde{S}| \geq |O^{out}|$), Claim 28 in the second inequality, and then we use that the sum of the weighted degrees is always greater than the actual weight of covered hyper-edges (because the hype-edges may be counted multiple times in the sum of the weighted degrees) for the last one.

As a result, we finally get:

$$\mathbb{E}[w(E(S))] \geq w(E(O^{in})) + (1-(\mu-1)/\rho)\cdot w(E(O^{out})) - (\mu-1)/\rho \cdot w(E(O^{in})) \\ \geq (1-(\mu-1)/\rho)\cdot w(E(O)).$$

Therefore by averaging principle, there exists $S^* \subseteq V'$ such that $S^* \in \mathcal{I}$ and $w(E(S^*)) \geq (1-(\mu-1)/\rho)\cdot w(E(O))$. ◀

Now we give another interpretation of Algorithm 1 in terms of matroid union, which allows us to give a simpler description of the kernel $V'$. First recall the definition of matroid union:

▶ **Definition 5.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid. Then we can define $\rho\mathcal{M} = (V, \mathcal{I}_\rho)$ as the* union of $\rho$ matroids $\mathcal{M}$, *as follows: $S \in \mathcal{I}_\rho$ if $S$ can be partitioned into $S_1 \cup \cdots \cup S_\rho$ so that for all $i$ we have $S_i \in \mathcal{I}$.*

In Algorithm 2 we provide a simpler description of Algorithm 1 (the equivalence of the two algorithms is proved in Proposition 29).

**Algorithm 2** Algorithm for building a maximum coverage approximate kernel.

```
1: V = {v_1, ..., v_n} where deg_w(v_1) ≥ ··· ≥ deg_w(v_n)
2: V' ← ∅
3: for i = 1, ..., n do  ▷ vertices are processed in non-increasing order of weighted degree
4:     if V' ∪ {v_i} ∈ I_ρ then
5:         V' ← V' ∪ {v_i}
6: return V'
```

▶ **Proposition 29.** *Algorithm 1 and Algorithm 2 build the same kernel $V'$. Moreover, $V'$ is a maximum weight independent set in $\rho\mathcal{M}$ with respect to the weighted degrees.*

**Proof.** To prove the first part of the proposition, it suffices to prove that the condition in Line 4 of Algorithm 1 is equivalent to check whether $V' \cup C \cup \{v_i\}$ is or is not in $\mathcal{I}_\rho$ (if so, then $V' \cup C$ in Algorithm 1 plays the role of $V'$ in Algorithm 2).

Using the decomposition in equation (1), we know that when $v_i$ is processed and we check the condition in Line 4 of Algorithm 1, we have $V' = X_1 \cup \cdots \cup X_j$ for some $j \in \{0, \ldots, r\}$. We know that each $X_l$ is a $\rho$-DBS in $\mathcal{M}/(\bigcup_{l'=1}^{l-1} X_{l'})$, hence each one can be partitioned into $\rho$ independent sets $B_{l,1}, \ldots, B_{l,\rho}$ in $\mathcal{M}/(\bigcup_{l'=1}^{l-1} X_{l'})$, all of size $\mathrm{rank}_{\mathcal{M}/(\bigcup_{l'=1}^{l-1} X_{l'})}(X_l)$. Therefore,

$$V' = \underbrace{(B_{1,1} \cup \cdots \cup B_{j,1})}_{B_1} \cup \cdots \cup \underbrace{(B_{1,\rho} \cup \cdots \cup B_{j,\rho})}_{B_\rho}$$

can be partitioned into $\rho$ independent sets in $\mathcal{M}$, each of size $\mathrm{rank}_{\mathcal{M}}(V')$. Now, regarding condition in Line 4 of Algorithm 1:

- If $v_i \in \text{span}_{\mathcal{M}}(V')$, as $V'$ is a set containing $\rho \cdot \text{rank}_{\mathcal{M}}(X)$ elements, the set $V' \cup \{v_i\}$ will contain $\rho \cdot \text{rank}_{\mathcal{M}}(X) + 1$ elements while still being of rank equal to $\text{rank}_{\mathcal{M}}(V')$: hence it is not possible to partition $V' \cup \{v_i\}$ into $\rho$ independent sets (as each one can contain up to $\text{rank}_{\mathcal{M}}(V')$ elements), so $V' \cup C \cup \{v_i\} \notin \mathcal{I}_\rho$.
- Otherwise, by Claim 22, the densest subset in $C$ with respect to the matroid $\mathcal{M}/V'$ is of density strictly below $\rho$, hence, by Proposition 18, the densest subset in $C \cup \{v_i\}$ is of density at most $\rho$. We can therefore use Theorem 13 to partition $C \cup \{v_i\}$ into $\rho$ independent sets $C_1, \ldots, C_\rho$ in $\mathcal{M}/V'$, hence $V' \cup C \cup \{v_i\} = (B_1 \cup C_1) \cup \cdots \cup (B_\rho \cup C_\rho)$ can be partitioned into $\rho$ independent subsets, i.e., $V' \cup C \cup \{v_i\} \in \mathcal{I}_\rho$.

Therefore Algorithms 1 and 2 build the very same approximate kernel $V'$. As Algorithm 2 is simply the greedy algorithm to build a maximum weight independent set in the matroid $\rho\mathcal{M}$ with respect to the weighted degrees (see [6]), $V'$ is a maximum weight independent set in $\rho\mathcal{M}$. ◀

▶ **Theorem 6.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid and let $f$ be a coverage function on $V$ of frequency bounded by $\mu$. Let $V'$ be a maximum weight independent set in $\rho\mathcal{M}$, with respect to the weights $f(\{v\})$. Then $V'$ contains a $1 - (\mu - 1)/\rho$ approximate solution of the matroid-constrained maximum coverage problem.*

**Proof.** In fact, from the characterization of maximum weight independent sets in [6], any maximum weight independent set in $\rho\mathcal{M}$ can be obtained by choosing the right processing order in Algorithm 2 (i.e., for elements having the same weighted degrees, putting first the ones we want to pick in our kernel). Hence that kernel would have been built following the procedure of Algorithm 1, and therefore the result of Lemma 23 applies. ◀

## Abstract

In the committee selection problem, the goal is to choose a subset of size $k$ from a set of candidates $C$ that collectively gives the best representation to a set of voters. We consider this problem in Euclidean $d$-space where each voter/candidate is a point and voters' preferences are implicitly represented by Euclidean distances to candidates. We explore *fault-tolerance* in committee selection and study the following three variants: (1) given a committee and a set of $f$ failing candidates, find their optimal replacement; (2) compute the worst-case replacement score for a given committee under failure of $f$ candidates; and (3) design a committee with the best replacement score under worst-case failures. The score of a committee is determined using the well-known (min-max) Chamberlin-Courant rule: minimize the maximum distance between any voter and its closest candidate in the committee. Our main results include the following: (1) in one dimension, all three problems can be solved in polynomial time; (2) in dimension $d \geq 2$, all three problems are NP-hard; and (3) all three problems admit a constant-factor approximation in any fixed dimension, and the optimal committee problem has an FPT bicriterion approximation.

## 1 Introduction and Problem Statement

We consider the computational complexity of adding fault tolerance into spatial voting. In spatial voting [7, 1, 29], the voters and the candidates are both modeled as points in some $d$-dimensional space, where each dimension represents an independent *policy issue* that is important for the election, and each voter's preference among the candidates is implicitly encoded by a distance function. For example, in the simplest 1-dimensional setting, voters and candidates are points on a line indicating their real-valued preference on a single issue. The specific setting for our work is *multiwinner* spatial elections, also called *committee selection*, in $d$ dimensions where we have a set $V$ of $n$ voters, a set $C$ of $m$ candidates, and a committee size (integer) $k$. The goal is to choose a subset of $k$ candidates, called the *winning committee*, that collectively best represents the preferences of all the voters [9, 11, 12].

One aspect of committee selection that appears not to have been investigated is *fault tolerance*, that is, how robust a chosen committee is against the possibility that some of the winning members may default. Committee selection problems model a number of applications in the social sciences and in computer science where such defaults are not uncommon, such as democratic elections, staff hiring, choosing public projects, locations of public facilities, jury selection, cache management, etc. [21, 14, 26, 2, 4, 23, 13]. In this paper, we are particularly interested in designing algorithms to address questions of the following kind: If some of the winning members default, how badly does this affect the overall score of the committee? Or,

how much does the committee score suffer if a *worst-case* subset of size $f$ defaults? Finally, can we *proactively* choose a committee in such a way that it can tolerate up to $f$ faults with the minimum possible score degradation? We begin by formalizing these problems more precisely and then describing our results.

Suppose $V = \{v_1, \ldots, v_n\}$ is a set of $n$ voters and $C = \{c_1, \ldots, c_m\}$ is a set of $m$ candidates, modeled as points in $d$-dimensional Euclidean space. (We occasionally call the tuple $(V, C)$ an election $E$.) Given a positive integer $k$, we want to elect $k$ candidates, called the *committee*, using the well-known Chamberlin-Courant voting rule [5]. This rule assigns a score to each committee as follows. Let $T \subseteq C$ be a committee. For each voter $v$, the score of $T$ for $v$ is defined as $\sigma(v, T) = \min_{c \in T} d(v, c)$, namely, the distance from $v$ to its closest candidate in $T$.[1] The *score* of the committee $T$ is defined as $\sigma(T) = \max_{v \in V} \sigma(v, T)$, namely, the largest distance between any voter and its closest neighbor in $T$. (In facility location parlance, this is the well-known $k$-center problem.)

The fault tolerance of a committee is parameterized by a positive integer $f$, which is the upper bound on the number of candidates that can fail.[2] Throughout the paper, we use the notation $J$ to denote a failing set of candidates. We are allowed to replace the failing members of $J$ with any set of at most $|T \cap J|$ candidates from $C \setminus J$. We often denote this set of *replacement* candidates by $R$. However, *we must keep all the non-failing members of $T$ in the committee* – that is, the replacement committee is the set $(T \setminus J) \cup R$ – and throughout the paper our goal is to optimize this committee's score, namely $\sigma((T \setminus J) \cup R)$.

We consider the following three versions of fault-tolerant committee selection, presented in increasing order of complexity. The first problem is the simplest: given a committee and a failing set, find the best replacement committee.

**Optimal Replacement Problem** (ORP)
**Input:** An election $E = (V, C)$, a committee $T \subseteq C$ and a failing set $J \subseteq C$.
**Goal:** Find a replacement set $R \subseteq C \setminus J$ of size at most $|T \cap J|$ minimizing $\sigma((T \setminus J) \cup R)$.

Our second problem is to quantify the fault tolerance of a given committee $T$ over worst-case faults. That is, what is the largest score of $T$'s replacement when a worst-case subset of $f$ faults occur? We introduce the following notation as $T$'s measure of $j$-fault-tolerance, for any $0 \leq j \leq f$: $\sigma_j(T) = \max_{J \subseteq C \text{ s.t. } |J| \leq j} \sigma((T \setminus J) \cup R)$, where $R$ is an optimal replacement set with size at most $|T \cap J|$. We want to compute $\sigma_f(T)$. Occasionally, we also use the notation $\sigma_0(T)$ for the no-fault score of $T$, namely $\sigma(T)$.

**Fault-Tolerance Score** (FTS)
**Input:** An election $E = (V, C)$, a committee $T \subseteq C$ and a fault-tolerance parameter $f$.
**Goal:** Compute $\sigma_f(T)$.

Our third and final problem is to compute a committee with optimal fault-tolerance score.

**Optimal Fault-Tolerant Committee** (OFTC)
**Input:** An election $E = (V, C)$, a committee size $k$ and a fault-tolerance parameter $f$.
**Goal:** Find $T \subseteq C$ of size at most $k$ minimizing $\sigma_f(T)$.

[1] Originally, Chamberlin and Courant [5] defined a voting rule on Borda scores (also known as Borda-CC). In this paper, similarly to [2], we study a min-max version of this rule on a more general scoring function, which in our case is based on voter-candidate distances.

[2] In our work, we will allow any subset of size $f$ from $C$ to fail, so the faults can also include candidates not in the selected committee $T$. This only makes the problem harder because the adversary can always limit the faults to $T$, and elimination of candidates from $C \setminus T$ makes finding replacements for failing committee members more difficult.

## 1.1 Our Results

We first show that even in one dimension, fault-tolerant committee problems are nontrivial. In particular, while the Optimal Replacement Problem (ORP) is easily solved by a simple greedy algorithm, the other two problems, Fault-Tolerance Score (FTS) and Optimal Fault-Tolerant Committee (OFTC), do not appear to be easy. Our main result in one dimension is the design of efficient dynamic-programming-based algorithms for these two problems. Along the way, we solve a *fault-tolerant* Hitting Set problem for points and unit intervals, which may be of independent interest.

In two dimensions and higher, OFTC is NP-hard because of its close connection to the $k$-center problem. However, we show that even the seemingly simpler problem of optimal replacement (ORP) is also NP-hard. Our main results include a constant-factor approximation for all three problems in any fixed dimension (in fact, in any metric space), as well as a novel bicriterion FPT approximation via an EPTAS whose running time has the form $f(\epsilon)n^{\mathcal{O}(1)}$. For ease of reference, we show these results in the following table.

**Table 1** Summary of our results.

| | **One-dimensional instances** | **Dimension $d \geq 2$** | | |
|---|---|---|---|---|
| | | **Complexity** | **Approximation** | **Bounded $f$** |
| **ORP** | P (Theorem 1) | NP-hard (Theorem 11) | 3-approx. (Lemma 12) | P (full version) |
| **FTS** | P (Theorem 6) | NP-hard (Theorem 11) | 3-approx. (Lemma 13) | P (full version) |
| **OFTC** | P (Theorem 9) | NP-hard (Theorem 11) | 5-approx. (Lemma 17)<br>Bicriterion-EPTAS (Theorem 20) | NP-hard (full version)<br>3-approx. (Theorem 16) |

Due to limited space, proofs of some of the theorems/lemmas (marked with ($\star$)) are deferred to the full version of the paper.

## 1.2 Related Work

To the best of our knowledge, the issue of fault tolerance in committee selection has not been studied in voting literature – their primary focus is on protocols and algorithms for choosing candidates [11, 12, 25, 27, 28, 8, 3]. However, the following two lines of work consider some related issues. First, in the "unavailable candidate model" [22, 15] the goal is to choose a *single winner* with maximum expected score when candidates fail according to a given probability distribution; in contrast, we consider multiwinner elections under worst-case faults. In the second line of work, a set of election control problems are considered where candidates are added [10] or deleted [17] to change the outcome of the election. In this setting, the candidate set is modified to obtain a favorable election outcome, which is a rather different problem than ours.

In the facility-location research, there has been prior work on adding fault tolerance to $k$-center or $k$-median solutions [6, 20, 19, 30, 16], but the main approach there is to assign each user (voter) to multiple facilities (candidates). In particular, the "$p$-neighbor $k$-center" framework [6] minimizes the maximum distance between a user and its $p$th center as a way to protect against $p-1$ faults. This formulation, however, differs from our optimal fault-tolerant committee problem (OFTC) because in our setting the replacement candidates are chosen *after* failing candidates are announced. Therefore, in the OFTC problem, the

designer does not have to *simultaneously* allocate $p$ neighbors for all the voters. Furthermore, to the best of our knowledge, neither of our first two problems – Optimal Replacement (ORP) and Fault-Tolerance Score (FTS) – have been studied in the facility-location literature, and initiate a new research direction. We also formulate and solve a fault-tolerant hitting set problem in one dimension, which may be of independent interest.

## 2 Fault-Tolerant Committees in One Dimension

Even in one dimension, computing the fault-tolerance score of a given committee or finding a committee with minimum fault-tolerance score is nontrivial. The optimal replacement problem, however, is easy – a simple greedy algorithm works. Our main result in this section is to design efficient dynamic-programming algorithms for the former two problems. In doing so, we also solve the fault-tolerant version of Hitting Set for points and unit segments.

### 2.1 Optimal Replacement Problem

In the Optimal Replacement Problem (ORP), we are given a committee $T \subseteq C$ and a failing set $J \subseteq C$, and we must find a replacement set $R$ minimizing the score $\sigma((T \setminus J) \cup R)$, where $|R| \leq |T \cap J|$. Since this score is always the distance between some voter-candidate pair, it suffices to solve the following decision problem: Is there a replacement set with score at most $r$? We can then try all possible $O(nm)$ distances to find the smallest feasible replacement score.

This decision problem is equivalent to the following hitting set problem: for each voter $v \in V$, let $I_v$ be the interval of length $2r$ centered at $v$, and let $\mathcal{I} = \{I_v : v \in V\}$ be the set of these $n$ (voter) intervals. A subset of candidates is a hitting set for $\mathcal{I}$ if each interval contains at least one of the candidates. In our problem, we are given a hitting set $T$ and a failing subset of candidates $J$, and we must find the minimum-size replacement hitting set. Such a replacement is easily found using the standard greedy algorithm, as follows. We first remove all of the intervals from $\mathcal{I}$ that are already hit by a candidate in $T \setminus J$, and we also remove all the failing candidates $J$ from $C$. For the leftmost remaining interval, we then choose the rightmost candidate $c$ contained in it, add it to $R$, delete all intervals hit by $c$, and iterate until all remaining intervals are hit. If we ever encounter an interval containing no candidate, or if the size of the replacement set is larger than $|T \setminus J|$, the answer to the decision problem is no. Otherwise, the solution is $R$. The greedy algorithm is easily implemented to run in time $\mathcal{O}((m+n)\log(m+n))$. To find the optimal replacement set, we can do a binary search over $O(nm)$ values of $r$ and find the smallest $r$ for which $|(T \setminus J) \cup R| \leq k$.

▶ **Theorem 1.** *The Optimal Replacement Problem can be solved in time $\mathcal{O}((m+n)\log^2(m+n))$ for one-dimensional Euclidean elections.*

### 2.2 Computing the Fault-Tolerance Score (FTS) of a Committee

We now come to the more difficult problem of computing the fault-tolerance score $\sigma_f(T)$ of a committee $T$ in one dimension, which is the worst case over all possible failing sets of $T$. Once again it suffices to solve the following decision problem: given a size-$k$ committee $T$ and a real number $r$, can we find a replacement with score at most $r$ for *every* failing subset of size $f$? Using our hitting set formulation, $\sigma_f(T) \leq r$ if and only if $T$ is an *$f$-tolerant hitting set* of $\mathcal{I}$, that is, for any failing set $J \subseteq C$ of size at most $f$, there exists a replacement set $R \subseteq C \setminus J$ such that $|(T \setminus J) \cup R| \leq |T|$ and $(T \setminus J) \cup R$ hits $\mathcal{I}$. (Recall that each member of $\mathcal{I}$ is an interval of length $2r$ centered at one of the voter positions.) We can then compute the fault-tolerance score of $T$ by trying each of the $O(nm)$ voter-candidate distances to find the smallest $r$ for which this decision problem has a positive answer.

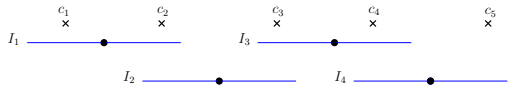

**Figure 1** The figure shows an interval hitting set instance with four intervals and five points. The set $\{c_2, c_4\}$ is a feasible hitting set. For $X = \{c_2, c_3, c_5\}$, the intervals $I_1, I_3, I_4$ are $X$-disjoint.

We solve this fault-tolerant hitting set decision problem by observing that the size of a *smallest* hitting set equals the size of a *maximum* independent set, defined with respect to candidate points and voter intervals in the following way. Suppose the intervals of $\mathcal{I} = \{I_1, \ldots, I_n\}$ are sorted left to right. First, we can assume without loss of generality that $|I_i \cap C| > f$ for all $i \in [n]$, since otherwise there is no $f$-tolerant hitting set for $\mathcal{I}$. Given a set of points $X$ in $\mathbb{R}$, we say that a set of intervals is *$X$-disjoint* if each point in $X$ is contained in at most one interval. (That is, $X$-disjoint intervals can be thought of as *independent* in that they contain disjoint sets of points in $X$). The following claim is easy to prove.

▶ **Lemma 2.** *Given a set of points $X$ and a set of intervals $\mathcal{J}$ on the real line, the size of a minimum hitting set $X' \subseteq X$ of $\mathcal{J}$ equals the maximum size of an $X$-disjoint subset of $\mathcal{J}$.*

Thus, if $T \subseteq C$ is an $f$-tolerant hitting set for $\mathcal{I}$, then for any failing set $J \subseteq C$, the size of any $(C \setminus J)$-disjoint subset of $\mathcal{I}$ is at most $|T|$. One should note that the size of the maximum $(C \setminus J)$-disjoint subset in $\mathcal{I}$ is a monotonically increasing function of $|J|$ – as more candidates fail, more intervals can become disjoint. Our goal is to find the maximum size of such a disjoint interval family over all possible failure sets $J$ of size at most $f$. We will do this using dynamic programming, by combining solutions of subproblems, where each subproblem corresponds to an index range $[i, j]$, over the set of candidate points $c_1, \ldots, c_m$. Assuming that the candidate points $C = \{c_1, \ldots, c_m\}$ are ordered from left to right, our subproblems are defined as follows, for $1 \leq i \leq j \leq m$:

- $C_{i,j} = \{c_i, \ldots, c_j\}$ is the set of candidates in the range $[c_i, c_j]$.
- $\mathcal{I}_{i,j} = \{I \in \mathcal{I} : I \cap C \subseteq C_{i,j}\}$ is the set of intervals that only contain points from $C_{i,j}$.
- For any $J \subseteq C_{i,j}$, $\delta_{i,j}(J)$ is the maximum size of a $(C_{i,j} \setminus J)$-disjoint subset of $\mathcal{I}_{i,j}$.
- The subproblems we want to solve are the values $\delta_{i,j}(f) = \max_{J \subseteq C_{i,j}, |J| \leq f} \delta_{i,j}(J)$.

The key technical lemma of this section is the following claim.

▶ **Lemma 3.** *$T \subseteq C$ is an $f$-tolerant hitting set of $\mathcal{I}$ if and only if $|T \cap C_{i,j}| \geq \delta_{i,j}(f)$, for all $1 \leq i \leq j \leq m$.*

**Proof.** We first show the "if" part of the lemma. Assume $|T \cap C_{i,j}| \geq \delta_{i,j}(f)$ for all $i, j \in [m]$ with $i \leq j$. To see that $T$ is an $f$-tolerant hitting set of $\mathcal{I}$, consider a failing set $J \subseteq C$ of size at most $f$. We have to show the existence of a replacement set $R \subseteq C \setminus J$ such that $|(T \setminus J) \cup R| \leq |T|$ and $(T \setminus J) \cup R$ is a hitting set of $\mathcal{I}$. We write $T \setminus J = \{c_{i_1}, \ldots, c_{i_p}\}$, where $i_1 < \cdots < i_p$. For convenience, set $i_0 = 0$ and $i_{p+1} = m + 1$. By our assumption, every interval $I \in \mathcal{I}$ is hit by some point in $C$. Thus, either $I$ is hit by $T \setminus J$ or $I$ belongs to $\mathcal{I}_{i,j}$ where $i = i_{t-1} + 1$ and $j = i_t - 1$ for some index $t \in [p + 1]$. Now consider an index $t \in [p + 1]$. We write $T_t = T \cap C_{i,j}$ and define $R_t \subseteq C_{i,j} \setminus J$ as a minimum hitting set of $\mathcal{I}_{i,j}$. By Lemma 2, the size of $R_t$ is equal to the maximum size of a $(C_{i,j} \setminus J)$-disjoint subset of $\mathcal{I}_{i,j}$, which is nothing but $\delta_{i,j}(J \cap C_{i,j})$. Also, by assumption, we have $|T_t| = |T \cap C_{i,j}| \geq \delta_{i,j}(f) \geq \delta_{i,j}(J \cap C_{i,j})$. Therefore, $|R_t| \leq |T_t|$. Finally, we define $R = \bigcup_{t=1}^{p+1} R_t$. Clearly, $(T \setminus J) \cup R$ hits $\mathcal{I}$. So it suffices to show that $|(T \setminus J) \cup R| \leq |T|$. Since $|R_t| \leq |T_t|$ for all $t \in [p + 1]$, we have

$$|(T\backslash J) \cup R| = |T\backslash J| + \sum_{t=1}^{p+1} |R_t| \leq |T\backslash J| + \sum_{t=1}^{p+1} |T_t| = |T|,$$

which completes the proof of the "if" part.

Next, we prove the "only if" part of the lemma. Assume $T \subseteq C$ is an $f$-tolerant hitting set of $\mathcal{I}$. Consider two indices $i, j \in [m]$ with $i \leq j$. To show $|T \cap C_{i,j}| \geq \delta_{i,j}(f)$, it suffices to show that $|T \cap C_{i,j}| \geq \delta_{i,j}(J)$ for all $J \subseteq C_{i,j}$ with $|J| \leq f$. Since $T$ is an $f$-tolerant hitting set of $\mathcal{I}$, there exists $R \subseteq C\backslash J$ such that $|(T\backslash J) \cup R| \leq |T|$ and $(T\backslash J) \cup R$ is a hitting set of $\mathcal{I}$. For brevity, let $T' = (T\backslash J) \cup R$. By definition, the intervals in $\mathcal{I}_{i,j}$ can only be hit by the points in $C_{i,j}$. Thus, $T' \cap C_{i,j}$ is a hitting set of $\mathcal{I}_{i,j}$. As $T' \cap C_{i,j} \subseteq C_{i,j}\backslash J$, by Lemma 2, the size of $T' \cap C_{i,j}$ is at least the maximum size of a $(C_{i,j}\backslash J)$-disjoint subset of $\mathcal{I}_{i,j}$, i.e., $|T' \cap C_{i,j}| \geq \delta_{i,j}(J)$. Furthermore, because $J \subseteq C_{i,j}$, we have $(T\backslash J)\backslash C_{i,j} = T\backslash C_{i,j}$. It follows that $T\backslash C_{i,j} \subseteq T'\backslash C_{i,j}$ and thus $|T\backslash C_{i,j}| \leq |T'\backslash C_{i,j}|$. For a committee $T$, we can partition $T$ into two parts: the part containing candidates in $C_{i,j}$ and the part containing candidates outside of $C_{i,j}$. Hence, $|T| = |T \cap C_{i,j}| + |T\backslash C_{i,j}|$ and $|T'| = |T' \cap C_{i,j}| + |T'\backslash C_{i,j}|$. Because $|T'| \leq |T|$ and $|T'\backslash C_{i,j}| \geq |T\backslash C_{i,j}|$, we have $|T' \cap C_{i,j}| \leq |T \cap C_{i,j}|$. Therefore, $|T \cap C_{i,j}| \geq \delta_{i,j}(J)$. This completes the proof of Lemma 3. ◀

In order to decide if $\sigma_f(T) \leq r$, therefore, we just have to compute $\delta_{i,j}(f)$, for all $i, j$, and check the condition $|T \cap C_{i,j}| \geq \delta_{i,j}(f)$. We now show how to do that efficiently.

### Efficiently Computing $\delta_{i,j}(f)$

For ease of presentation, we show how to compute $\delta_{1,m}(f)$; computing other $\delta_{i,j}(f)$ is similar. We have $C_{1,m} = C$, $\mathcal{I}_{1,m} = \mathcal{I}$, and $\delta_{1,m}(f)$ is size of the largest subset of $\mathcal{I}$ that is $(C\backslash J)$-disjoint for any failing set $J \subseteq C$ with $|J| \leq f$. The intervals of $\mathcal{I} = \{I_1, I_2, \ldots, I_n\}$ are in the left to right sorted order and, for each $i \in [n]$, let $C(I_i) = C \cap I_i$ be the set of points in $C$ that hits $I_i$. Define $\Gamma[i][j]$ as the maximum size of an $(C \setminus X)$-disjoint subset $\mathcal{J} \subseteq \{I_1, \ldots, I_i\}$ such that $X \subseteq C$ and $|X| \leq j$.

▶ **Lemma 4.** *We have the following recurrence*

$$\Gamma[i][j] \;=\; \max \left\{ \begin{array}{l} \Gamma[i-1][j], \\ \max\limits_{0 \leq i' \leq i} 1 + \Gamma[i'][j - |C(I_i) \cap C(I_{i'})|] \end{array} \right\}$$

Clearly, $\delta_{1,m}(f) = \Gamma[n][f]$. The base case for our dynamic program is $\Gamma[0, j] = 0$ for all $j \in [f]$ and $\Gamma[i][j] = -\infty$ for $j < 0$ and all $i \in [n]$. Our dynamic program runs in time $\mathcal{O}(n^2 m f)$. In the same way, we can compute the values of $\delta_{i,j}(f)$ for all $i, j \in [m]$ with $i \leq j$.

▶ **Lemma 5.** *$\delta_{i,j}(f)$, for all $1 \leq i \leq j \leq m$, can be computed in time $\mathcal{O}(n^2 m^3 f)$.*

Given a hitting set $T \subseteq C$ and the values $\delta_{i,j}(f)$, we can verify the condition in Lemma 3 in time $\mathcal{O}(m^3)$. We can then use binary search to find the smallest value of $r$ for which $T$ is an $f$-tolerant hitting set. This establishes the following result.

▶ **Theorem 6.** *The fault-tolerance score of a 1-dimensional committee $T$ can be computed in time $\mathcal{O}(n^2 m^3 f \log(nm))$.*

## 2.3 Optimal Fault-Tolerant Committee

We now address the problem of *designing* a fault-tolerant committee: select a committee $T$ of size $k$ whose fault-tolerance score $\sigma_f(T)$ is minimized. Thus, our goal is *not* to optimize the fault-free score of $T$, namely $\sigma_0(T)$, but rather the score that the best replacement will have after a worst-case set of $f$ faults in $T$, namely $\sigma_f(T)$. Following the earlier approach, we again focus on the decision question: given some $r \geq 0$, is there a committee of size $k$ with $\sigma_f(T) \leq r$? For a given value of $r$, we construct our hitting set instance with candidate-points and voter-intervals, and compute a minimum-sized $f$-tolerant hitting set $T \subseteq C$ as follows:

1. Compute the value of $\delta_{i,j}(f)$, for all $1 \leq i \leq j \leq m$.
2. Compute a minimum subset $T \subseteq C$ satisfying $|T \cap C_{i,j}| \geq \delta_{i,j}(f)$, for all $1 \leq i \leq j \leq m$.
3. If $|T| \leq k$, we have a solution; otherwise, the answer to the decision problem is no.

Step (1) is implemented using the dynamic program of the previous subsection, and so it suffices to explain how to implement step (2). We assume without loss of generality that $|C_{i,j}| \geq \delta_{i,j}(f)$ for all $i, j$, because otherwise there is no solution. We compute a set $T$ using the following greedy algorithm.

- Initialize $T = \emptyset$.
- For each $c_k$ for $k \in [m]$, if there exists $i, j \in [m]$ with $i \leq k \leq j \leq m$ such that $\delta_{i,j}(f) \geq |T \cap C_{i,j}| + (j - k + 1)$, then add $c_k$ to $T$.

The algorithm runs in time $\mathcal{O}(m^3)$. To prove correctness, we first claim the following.

▶ **Lemma 7.** *$|T \cap C_{i,j}| \geq \delta_{i,j}(f)$, for all $1 \leq i \leq j \leq m$.*

**Proof.** Suppose not, so we have $|T \cap C_{i,j}| < \delta_{i,j}(f)$, for some $i \leq j$. We recall that for any interval $I_i \in \mathcal{I}$, $|I_i \cap C| > f$. Therefore, for any failing set $J$, $C_{i,j} \setminus J$ is a hitting set of $\mathcal{I}_{i,j}$, and $|C_{i,j}| \geq \delta_{i,j}(f)$. This implies that there exists some point among $c_i, \ldots, c_j$ that is not in $T$. Let $k \in \{i, \ldots, j\}$ be the largest index such that $c_k \notin T$. For convenience, we use $T'$ to denote the set $T$ in the iteration of our algorithm that considers $c_k$. Note that $T \cap C_{i,j} = (T' \cap C_{i,j}) \cup \{c_{k+1}, \ldots, c_j\}$ and $(T' \cap C_{i,j}) \cap \{c_{k+1}, \ldots, c_j\} = \emptyset$. Therefore, $|T' \cap C_{i,j}| = |T \cap C_{i,j}| - (j-k) < \delta_{i,j}(f) - (j-k)$. This implies $|T' \cap C_{i,j}| + (j-k+1) \leq \delta_{i,j}(f)$. By our algorithm, in this case we should include $c_k$ in $T$, which contradicts the fact that $c_k \notin T$. ◀

We now argue that $T$ has the minimum size among all subsets of $C$ satisfying the property of Lemma 7. Let $\mathsf{opt}$ be the minimum size of a subset of $C$ satisfying the desired property. We write $T = \{c_{k_1}, \ldots, c_{k_r}\}$, where $k_1 < \cdots < k_r$.

▶ **Lemma 8 (⋆).** *For any $t \in [r]$, there exists a subset $T^* \subseteq C$ such that (1) $|T^* \cap C_{i,j}| \geq \delta_{i,j}(f)$ for all $i, j \in [m]$ with $i \leq j$, (2) $|T^*| = \mathsf{opt}$, and (3) $\{c_{k_1}, \ldots, c_{k_t}\} \subseteq T^*$.*

We use binary search to find the smallest $r$ such that the reduced instance has an $f$-tolerant hitting set of size at most $k$. Therefore, the following theorem holds.

▶ **Theorem 9.** *Optimal Fault-Tolerant Committee can be solved in time $\mathcal{O}(n^2 m^3 f \log(nm))$ for one-dimensional Euclidean elections.*

▶ Remark 10. Our dynamic programming algorithm works as long as either the set $V$ or the set $C$ is embedded in $\mathbb{R}$ (i.e., has a linear ordering), while the other set can have an arbitrary $d$-dimensional embedding. Moreover, we can also extend our algorithms to ordinal elections with (widely studied) single-peaked preferences [2, 24] to compute an optimal fault-tolerant Chamberlin-Courant committee.

# 3 Fault-Tolerant Committees in Multidimensional Space

We now consider fault tolerance in multidimensional elections. Unsurprisingly, the optimal committee design problem is intractable – it is similar to facility location – but it turns out that the seemingly simpler variants ORP and FTS are also intractable. In particular, we have the following (refer to the full version of the paper for details).

▶ **Theorem 11** (⋆). *All three problems (Optimal Replacement, Fault-Tolerance Score, and Optimal Fault-Tolerant Committee) are NP-hard, in any dimension $d \geq 2$ under the Euclidean norm, where size of the committee $k$ and the failure parameter $f$ are part of the input.*

## 3.1 Optimal Replacement Problem

A simple greedy algorithm achieves a 3-approximation for the Optimal Replacement Problem in any fixed dimension $d$ as well as in any metric space.

▶ **Lemma 12.** *We can find a 3-approximation for ORP in time $O(k(nk+m))$.*

**Proof.** Let $T \subseteq C$ be the given committee and let $J \subseteq T$ be the failing set. In order to find the replacement set $R$, we initialize $\hat{T} = T \setminus J$, and then repeat the following two steps $|T \cap J|$ times: (1) Choose the farthest voter from $\hat{T}$, namely, choose $\hat{v} = \arg\max_{v \in V} d(v, \hat{T})$, and (2) Add to $\hat{T}$ the candidate $\hat{c} \notin \hat{T}$ that is closest to $\hat{v}$. Upon termination, we clearly have $|\hat{T}| = |T|$. Due to limited space, the proof of the approximation ratio is deferred to the full version of our paper. ◀

## 3.2 Computing the Fault-Tolerance Score

We can also approximate the optimal fault-tolerance score of a committee within a factor of 3. Specifically, if the optimal fault-tolerance score of $T$ is $\sigma_f(T) = \sigma^*$, then our algorithm returns a real number $\sigma'$ such that $\sigma^* \leq \sigma' \leq 3\sigma^*$.

For each voter $v$, let $d_f(v)$ be $v$'s distance to its $(f+1)^{th}$ closest candidate, and let $d' = \max_{v \in V} d_f(v)$ be the maximum of these values over all voters. The basic idea behind our approximation is simple and uses the following two facts: (1) $\sigma^* \geq d'$, and (2) $\sigma^* \geq \sigma(T)$. The first one holds because $d'$ is the best score possible if some voter's $f$ nearest candidates fail, and the second one holds because a failure can only worsen the score (that is, $\sigma_f(T) \geq \sigma(T)$ for any $f > 0$). Therefore, the distance $\sigma' = d' + 2\sigma(T)$ is clearly within a factor of 3 of the optimal $\sigma^*$. We claim that for any failing set $J \subseteq C$, there exists a replacement $R \subseteq C \setminus J$ of size at most $|T \cap J|$ such that $\sigma((T \setminus J) \cup R) \leq \sigma'$. Due to limited space, we omit the proof from the extended abstract; it is included in the full version of our paper.

▶ **Lemma 13.** *The fault-tolerance score of a committee can be approximated within a factor of 3 in time $\mathcal{O}(nm \log(f))$.*

## 3.3 Optimal Fault-Tolerant Committee

We now discuss how to design approximately optimal fault-tolerant committees in multiwinner elections. Specifically, given a set of voters $V$ and a set of candidates $C$ in $d$-space, along with parameters $k$ (committee size) and $f$ (number of faults), we want to compute a size $k$ committee $T \subseteq C$ with the minimum fault-tolerance score $\sigma_f(T)$. We prove two approximation results for this problem: (1) We can solve this problem within an approximation factor of 3 in polynomial time if the parameter $f$ is treated as a constant (while $k$ remains possibly

unbounded). If $f$ is not assumed to be a constant, we can solve the problem within an approximation factor of 5. (2) We give an EPTAS with running time $(1/\varepsilon)^{O(1/\varepsilon^{2d})}(m+n)^{O(1)}$ which is a *bicriterion* approximation, where the output committee $T$ is fault-tolerant for at least $(1-\varepsilon)n$ voters with $\sigma_f(T) \leq (1+\varepsilon)\sigma^*$. The next two subsections discuss these results.

### 3.3.1 3-Approximation for Bounded $f$

Let $\sigma^*$ be the optimal $f$-tolerant score of a committee of size $k$. We compute the approximation solution via an approximate decision algorithm, which takes as input a number $\sigma \geq \sigma_f(C)$ and returns a committee $T \subseteq C$ of size at most $k$ with $\sigma_f(T) \leq 3\sigma$ if $\sigma \geq \sigma^*$. (We slightly abuse notation to introduce a convenient quantity $\sigma_f(C)$, which is the $f$-fault-tolerance score of a committee with all the input candidates. This is clearly a lower bound on any size $k$ committee's score.)

For a committee $T \subseteq C$ and a failing set $J \subseteq C$, let $\delta(T, J)$ denote the score obtained after finding an optimal replacement $K$. That is,

$$\delta(T, J) = \min_{K \in C \setminus J, |K| = |T \cap J|} \sigma_0((T \setminus J) \cup K).$$

Thus, $\sigma_f(T) = \max_{J \subseteq C, |J| \leq f} \delta(T, J)$. Our approximation algorithm is shown in Algorithm 1. It begins with an empty committee $T$ (line 1), and as long as there exists a failing set $J$ of size at most $f$ for which $\delta(T, J) > 3\sigma$, [3] we do the following.

First, we remove all candidates in $J$ from $T$ (line 3). Then, whenever there exists a voter $v \in V$ with $d(v, T) > 3\sigma$, we add to $T$ a candidate $c \in C \setminus J$ whose distance to $v$ is at most $\sigma$ (lines 5-6). Such a $c$ always exists because $\sigma$ is at least the distance to the $(f+1)^{th}$ closest neighbor to $v$.

We call this voter $v$ the *witness* of $c$, denoted by $\mathsf{wit}[c]$ (line 7). Adding $c$ to $T$ guarantees that $d(v, T) \leq \sigma$. We repeat this procedure (the inner while loop) until $d(v, T) \leq 3\sigma$ for all $v \in V$. Finally, the outer while loop terminates when $\delta(T, J) \leq 3\sigma$ for all $J \subseteq C$ of size at most $f$, i.e., $\sigma_f(T) \leq 3\sigma$. At this point, we return the committee $T$.

**Algorithm 1** Approximate decision algorithm.

**Input:** a set $V$ of voters, a set $C$ of candidates, the committee size $k$, the fault-tolerance parameter $f$, and a number $\sigma \geq \sigma_f(C)$

1: $T \leftarrow \emptyset$
2: **while** $\exists\ J \subseteq C$ such that $|J| \leq f$ and $\delta(T, J) > 3\sigma$ **do**
3: $\quad T \leftarrow T \setminus J$
4: $\quad$ **while** $\exists\ v \in V$ such that $d(v, T) > 3\sigma$ **do**
5: $\quad\quad c \leftarrow$ a candidate in $C \setminus J$ satisfying $d(v, c) \leq \sigma$
6: $\quad\quad T \leftarrow T \cup \{c\}$
7: $\quad\quad \mathsf{wit}[c] \leftarrow v$
8: **return** $T$

▶ **Lemma 14** (⋆). *Let $T$ be the committee computed by Algorithm 1. Then $d(\mathsf{wit}[c], \mathsf{wit}[c']) > 2\sigma$ for any two distinct $c, c' \in T$.*

▶ **Lemma 15.** *If $\sigma \geq \sigma^*$, then Algorithm 1 outputs a size $k$ committee $T$ with $\sigma_f(T) \leq 3\sigma$.*

[3] We can check this condition by iterating over all failing sets of size $f$ and computing an optimal replacement set in each case.

**Proof.** The condition of the outer while loop of Algorithm 1 guarantees that $\delta(T, J) \leq 3\sigma$ for all $J \subseteq C$ of size at most $f$, which implies $\sigma_f(T) \leq 3\sigma$. To prove $|T| \leq k$, suppose $T = \{c_1, \ldots, c_r\}$. By Lemma 14, the pairwise distances between the voters $\mathsf{wit}[c_1], \ldots, \mathsf{wit}[c_r]$ are all larger than $2\sigma$ and thus larger than $2\sigma^*$ (as $\sigma \geq \sigma^*$ by our assumption). Now consider a committee $T^* \subseteq C$ of size $k$ satisfying $\sigma_f(T^*) = \sigma^*$. For each $\mathsf{wit}[c_i]$, there exists $c_i^* \in T^*$ such that $d(\mathsf{wit}[c_i], c_i^*) \leq \sigma^*$. Observe that $c_1^*, \ldots, c_r^*$ are all distinct. Indeed, if $c_i^* = c_j^*$ and $i \neq j$, then by the triangle inequality,

$$d(\mathsf{wit}[c_i], \mathsf{wit}[c_j]) \leq d(\mathsf{wit}[c_i], c_i^*) + d(\mathsf{wit}[c_j], c_j^*) \leq 2\sigma^*,$$

contradicting the fact that $d(\mathsf{wit}[c_i], \mathsf{wit}[c_j]) > 2\sigma^*$. Since $|T^*| = k$ and $c_1^*, \ldots, c_r^* \in T^*$, we have $r \leq k$, which completes the proof. ◀

Using these two lemmas, we can compute a 3-approximate solution using Algorithm 1 as follows. First, we compute $\sigma_f(C)$ in $O(nm^{f+1})$ time by enumerating all failing sets $J \subseteq C$ of size at most $f$. For every voter $v \in V$ and every candidate $c \in C$ such that $d(v, c) \geq \sigma_f(C)$, we run Algorithm 1 with $\sigma = d(v, c)$. Among all the committees returned of size at most $k$, we pick the one, say $T^*$, that minimizes $\sigma_f(T^*)$. To see that $\sigma_f(T^*) \leq 3\sigma^*$, note that $\sigma^*$ must be the distance between a voter and a candidate. Thus, there is one call of Algorithm 1 with $\sigma = \sigma^*$, which returns a committee $T \subseteq C$ of size at most $k$ such that $\sigma_f(T) \leq 3\sigma = 3\sigma^*$, by Lemma 15. We have $\sigma_f(T^*) \leq \sigma_f(T)$ by construction, which implies $\sigma_f(T^*) \leq 3\sigma^*$. In the full version, we show that each call of Algorithm 1 takes $O(nm^{2f+1})$ time. We need to call the algorithm $O(nm)$ times. Thus, we have the following result.

▶ **Theorem 16.** *We can find a* 3*-approximation for Optimal Fault-tolerant Committee in time* $O(n^2m^{2f+2})$*, assuming the fault-tolerance parameter* $f$ *is a constant.*

If we do not assume $f$ to be a constant, then the well-known "farthest first" greedy rule for adding candidates achieves a factor 5 approximation. Due to limited space, we describe the algorithm and its analysis in the appendix.

▶ **Lemma 17** (⋆)**.** *We can find a* 5*-approximation for Optimal Fault-Tolerant Committee in time* $\mathcal{O}(mnk)$*.*

All of the above approximations hold not just for $d$-dimensional Euclidean space, for any fixed $d$, but also for any metric space.

### 3.3.2 A bicriterion EPTAS

Finally, we design a bicriterion FPT approximation scheme with running time $f(\varepsilon) \cdot n^{\mathcal{O}(1)}$, which finds a size-$k$ committee whose fault-tolerance score for at least a $(1 - \varepsilon)$ fraction of the voters is within a factor of $(1 + \varepsilon)$ of the optimum. Formally, we say a committee $T$ is $(r, \rho)$*-good* if there exists a subset $V' \subseteq V$ of size at least $\rho n$ such that the $f$-tolerant score of $T$ with respect to only the voters in $V'$ is at most $r$. Then our approximation scheme can output a size-$k$ committee which is $((1 + \varepsilon)\sigma^*, 1 - \varepsilon)$-good. The core of our approximation scheme is the following (approximation) decision algorithm. The decision algorithm takes the problem instance and an additional number $r > 0$ as input. The output of the algorithm has two possibilities: it either **(i)** returns YES and gives a size-$k$ committee that is $((1 + \varepsilon)r, 1 - \varepsilon)$-good or **(ii)** simply returns NO. Importantly, the algorithm is guaranteed to give output **(i)** as long as $r \geq \sigma^*$. Note that this decision algorithm directly gives us the desired approximation scheme. Indeed, we can apply it with $r = d(v, c)$ for all $v \in V$ and $c \in C$. Let $r^*$ be the smallest $r$ that makes the algorithm give output **(i)**. The size-$k$

committee $T^*$ obtained when applying the algorithm with $r^*$ is $((1+\varepsilon)r^*, 1-\varepsilon)$-good. We have $r^* \leq \sigma^*$ because the algorithm must be applied with $r = \sigma^*$ at some point and it is guaranteed to give output **(i)** at that time. Thus, $T^*$ is $((1+\varepsilon)\sigma^*, 1-\varepsilon)$-good, as desired.

For simplicity of exposition, we describe our decision algorithm in two dimensions. By scaling, we may assume that the given number is $r = 1$. To solve the decision problem, our algorithm uses the shifting technique [18]. Let $h$ be an integer parameter to be determined later. For a pair of integers $i, j \in \mathbb{Z}$, let $\square_{i,j}$ denote the $h \times h$ square $[i, i+h] \times [j, j+h]$. A square $\square_{i,j}$ is *nonempty* if it contains at least one voter or candidate. We first compute the index set $I = \{(i,j) : \square_{i,j} \text{ is nonempty}\}$. This can be easily done in time $\mathcal{O}((n+m)h^2)$.

Consider a pair $(x,y) \in \{0,\ldots,h-1\}^2$. Let $L_{x,y}$ be the set of all integer pairs $(i,j)$ such that $i \pmod h \equiv x$ and $j \pmod h \equiv y$. We write $\widetilde{I}_{x,y} = \widetilde{I} \cap L_{x,y}$. For a voter $v \in V$ and a square $\square_{i,j}$, we say $v$ is a *boundary voter* for $\square_{i,j}$ if $v \notin [i+2, i+h-2] \times [j+2, j+h-2]$. Furthermore, we say $v$ *conflicts* with $(x,y)$ if $v$ is a boundary voter in $\square_{i,j}$ for some $(i,j) \in \widetilde{I}_{x,y}$.

▶ **Lemma 18** (⋆). *There exists a pair $(x,y) \in \{0,\ldots,h-1\}^2$ such that at most $\frac{4h-4}{h^2} \cdot |V|$ voters conflict with $(x,y)$.*

We fix a pair $(x,y) \in \{0,\ldots,h-1\}^2$ that conflicts with the minimum number of voters. For $(i,j) \in \widetilde{I}_{x,y}$, we define the set of (non-boundary) voters $V_{i,j} = \{v \in \square_{i,j} : v \in [i+2, i+h-2] \times [j+2, j+h-2]\}$, and the set of candidates $C_{i,j} = \{c \in C : c \in \square_{i,j}\}$. Note that for $(i,j) \in \widetilde{I}_{x,y}$, the $C_{i,j}$'s are disjoint and form a partition of $C$. Next, we show an important lemma which allows our algorithm to divide our problem into smaller subproblems, solve them individually, and combine the solutions to solve the overall problem.

▶ **Lemma 19** (⋆). *Let $V_1, V_2, \ldots, V_s$ be subsets of $V$ and let $T_1, T_2, \ldots, T_s$ be pairwise disjoint subsets of $C$ such that $T_i$ is a fault-tolerant committee for $V_i$ with $\sigma_f(T_i) = \sigma$. Then, $T = \bigcup_{i=1}^{s} T_i$ is a fault-tolerant committee of $\bigcup_{i=1}^{s} V_i$ with $\sigma_f(T) = \sigma$.*

Consider a pair $(i,j) \in \widetilde{I}_{x,y}$. Let $\overline{T}_{i,j}$ be a smallest fault-tolerant committee for $V_{i,j}$ with $\sigma_f(\overline{T}_{i,j}) \leq 1$. We observe that any inclusion-minimal fault-tolerant committee $T_{i,j}$ for $V_{i,j}$ satisfies $T_{i,j} \subseteq C_{i,j}$. This is because any candidate outside $C_{i,j}$ has distance more than $1 + 6/h$ to any voter in $V_{i,j}$ (for a large enough value of $h$). In the next section we will show how to compute a fault-tolerant committee $T_{i,j} \subseteq C_{i,j}$ for $V_{i,j}$ such that $|T_{i,j}| \leq |\overline{T}_{i,j}|$ and $\sigma_f(T_{i,j}) \leq 1 + 6/h$ in $h^{O(h^4)} n^{O(1)}$ time. Assuming we can compute the above-mentioned committee $T_{i,j}$, our overall algorithm is as follows:

1. Fix a pair $(x,y) \in \{0,\ldots,h-1\}^2$ conflicting with the minimum number of voters, and set $h$ to be the smallest integer such that $(4h-4)/h^2 \leq \varepsilon$ and $6/h \leq \varepsilon$.
2. For each pair $(i,j) \in \widetilde{I}_{x,y}$, compute $T_{i,j} \subseteq C_{i,j}$.
3. Let $T = \bigcup_{(i,j) \in \widetilde{I}_{x,y}} T_{i,j}$. If $|T| \leq k$, return YES (along with $T$); otherwise, return NO.

Let $V' = \bigcup_{(i,j) \in \widetilde{I}_{x,y}} V_{i,j}$. Since the $C_{i,j}$'s are disjoint, using Lemma 19, we conclude that $T$ is a fault-tolerant committee for $V'$. Furthermore, from our choice of $(x,y)$, we have $|V'| \geq (1-\varepsilon)n$. It is easy to show that the $f$-tolerant score of $T$ with respect to the voters in $V'$ is at most $1+\varepsilon$, and in addition, if $\sigma^* \geq 1$, we have $|T| \leq k$; we give a formal argument in the full version of our paper. This proves correctness of our decision algorithm. The overall algorithm takes $(1/\varepsilon)^{O(1/\varepsilon^4)}(m+n)^{O(1)}$ time. We note that the algorithm can be directly generalized to the $d$-dimensional case with running time $(1/\varepsilon)^{O(1/\varepsilon^{2d})}(m+n)^{O(1)}$. Therefore, we have the following result.

▶ **Theorem 20.** *Given a $d$-dimensional Fault-Tolerant Committee Selection instance, we can compute a size-$k$ committee $T$ such that the $f$-tolerant score of $T$ with respect to at least $(1-\varepsilon)n$ voters is at most $(1+\varepsilon)\sigma^*$, where $\sigma^*$ is the optimal $f$-tolerant score of a size-$k$ committee (with respect to the entire set $V$). This algorithm runs in time $(1/\varepsilon)^{O(1/\varepsilon^{2d})}(m+n)^{O(1)}$.*

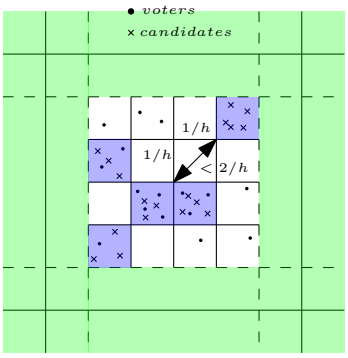

**Figure 2** The figure shows a cell in the shifted grid. The solid lines around the sides are the grid lines (and the region inside them is a cell). The shaded (green) region is the boundary region. Inside the boundary region, we divide the cell into $1/h \times 1/h$ smaller cells. The distance between any two points in a smaller cell is $< 2/h$. All candidates in smaller cells are identical (i.e., candidates in blue regions). In this example, since only five cells are nonempty, we have at most $2^5$ distinct failing sets.

### Algorithm to Compute $T_{i,j}$

We now present the most challenging piece of our algorithm: the computation of the $T_{i,j}$'s. Consider a box $\square_{i,j}$. Suppose there exists a fault-tolerant committee $T \subseteq C$ for $V_{i,j}$ with $\sigma_f(T) \leq 1$. Our task is to compute a fault-tolerant committee $T_{i,j} \subseteq C$ for $V_{i,j}$ such that $|T_{i,j}| \leq |T|$ and $\sigma_f(T_{i,j}) \leq 1 + 6/h$.

We divide $\square_{i,j}$ into $h^4$ smaller cells each with size $\frac{1}{h} \times \frac{1}{h}$, and we denote the set of these cells by $L = \{l_1, \ldots, l_{h^4}\}$. (See Figure 2.) Our algorithm is based on two key observations:
$(i)$ A committee with a candidate in every nonempty cell has $f$-tolerant score within a difference of at most $2/h$ from the optimum score. Since the number of cells is $h^4$, this implies that the size of a smallest approximately optimal committee is bounded by $h^4$ (formally shown in Lemma 21).
$(ii)$ All candidates in a cell can be treated as identical, causing only a loss of $2/h$ in the score. This implies that for any $T_{i,j}$, to approximately compute the $f$-tolerant score of $T_{i,j}$, we *only* need to consider the failing sets where either all or none of the candidates in a cell fail. Note that the number of such failing sets is at most $2^{O(h^4)}$ (formally shown in Lemma 22).

Using these two observations, at a high level, our algorithm goes through all committees of size at most $h^4$ (there are $h^{O(h^4)}$ of these as we can assume that each cell has at most $h^4$ candidates), approximately computes the $f$-tolerant score of each of these committees in time $2^{O(h^4)}$, and returns the smallest one with the desired score.

▶ **Lemma 21 (⋆).** *Let $T, T^* \subseteq C$ be fault-tolerant committees for $V_{i,j}$. If $|T^* \cap l_a| = 1$ for all $a \in [h^4]$ such that $C \cap l_a \neq \emptyset$, then $\sigma_f(T^*) - \sigma_f(T) \leq 2/h$.*

Based on the above observation, we solve the problem as follows. We enumerate all maps $\chi \colon L \to \{0, 1, \ldots, h^4\}$ where $\chi(l_a)$ is the number of candidates from $l_a$ in the committee. The total number of such maps is $h^{O(h^4)}$. For each feasible map, i.e., $\chi$ satisfying $\chi(l_a) \leq |C \cap l_a|$ for all $a \in [h^4]$, we construct a fault-tolerant committee $T^*_\chi$ for $V_{i,j}$ by picking (arbitrarily) $\chi(l_a)$ candidates in $C \cap l_a$ for all $a \in [h^4]$ and including them in $T^*_\chi$. For each constructed $T^*_\chi$, we compute a number $\widetilde{\sigma_f}(T^*_\chi)$ that approximates $\sigma_f(T^*_\chi)$ using the following lemma.

▶ **Lemma 22 (⋆).** *Given $T^*_\chi$, one can compute a number $\widetilde{\sigma_f}(T^*_\chi)$ in $2^{O(h^4)} n^{O(1)}$ time such that $|\widetilde{\sigma_f}(T^*_\chi) - \sigma_f(T^*_\chi)| \leq 2/h$.*

Finally, we let $T_{i,j}$ be the smallest among all committees $T^*_\chi$ satisfying $\widetilde{\sigma_f}(T^*_\chi) \leq 1 + 4/h$, and we return it as our solution. The running time of our algorithm is clearly $h^{O(h^4)}n^{O(1)}$. The following lemma shows that our algorithm is correct.

▶ **Lemma 23** (⋆). *We have $\sigma_f(T_{i,j}) \leq 1+6/h$. Furthermore, $|T_{i,j}| \leq |T|$ for any fault-tolerant committee $T$ for $V_{i,j}$ with $\sigma_f(T) \leq 1$.*

# Aggregating over Dominated Points by Sorting, Scanning, Zip and Flat Maps

**Jacek Sroka**
University of Warsaw, Poland

**Jerzy Tyszkiewicz**
University of Warsaw, Poland

## Abstract

Prefix aggregation operation (also called scan), and its particular case, prefix summation, is an important parallel primitive and enjoys a lot of attention in the research literature. It is also used in many algorithms as one of the steps.

Aggregation over dominated points in $\mathbb{R}^m$ is a multidimensional generalisation of prefix aggregation. It is also intensively researched, both as a parallel primitive and as a practical problem, encountered in computational geometry, spatial databases and data warehouses.

In this paper we show that, for a constant dimension $m$, aggregation over dominated points in $\mathbb{R}^m$ can be computed by $O(1)$ basic operations that include sorting the whole dataset, zipping sorted lists of elements, computing prefix aggregations of lists of elements and flat maps, which expand the data size from initial $n$ to $n \log^{m-1} n$.

Thereby we establish that prefix aggregation suffices to express aggregation over dominated points in more dimensions, even though the latter is a far-reaching generalisation of the former. Many problems known to be expressible by aggregation over dominated points become expressible by prefix aggregation, too.

We rely on a small set of primitive operations which guarantee an easy transfer to various distributed architectures and some desired properties of the implementation.

## 1 Introduction

In this paper we derive a tight relation between two computing problems: prefix aggregation and aggregation over dominated points. We first describe the problems alone, in a framework which covers them both.

The input data is assumed to be a collection of tuples composed of sortable atomic elements. We are interested in aggregation in general. We assume the data consists of two sets: a set $D$ of data points and a set $Q$ of queries where for each query there is a subset $\hat{q} \subseteq D$ of data points it matches.

A nonempty set $A$ is the domain of weights. We are also given an associative and commutative function $\oplus : A \times A \to A$ with unit $e$, i.e., neutral element of $\oplus$.

Data points have weights in $A$, defined by a function $w : D \to A$. We use notation $\bigoplus_{d \in S} w(d)$ and the like for the application of $\oplus$ to a multiset of weights of elements $S \subseteq D$, the same way as $\Sigma$ is used as a generalisation of $+$ to a multiset of numbers.

The goal is to compute $\bigoplus_{d \in \hat{q}} w(d)$ for all $q \in Q$. The two problems we consider in the paper are specific cases of the above schematic outline. We assume $D$ and $Q$ to be large.

## 1.1 Prefix aggregation and its role as a parallel primitive

Prefix aggregation (also called scan) arises when data and queries are linearly ordered, say are both elements of $\mathbb{R}$, and $\hat{q} = \{d \in D \mid d < q\}$. Then we wish to compute $\bigoplus_{d<q} w(d)$. The eponymous case is when $D = Q$, so the aggregations are applied to all prefixes of the whole sequence of data points.

Concerning the importance of prefix aggregation as a computing primitive, it is well-known that, no matter what practical or theoretical parallel computation model is considered, sorting and scan are among the very first algorithms to be developed. The importance of the latter has even led to patents around the idea of including a prefix sum in the instruction set of a microprocessor [27], attempts of hardware implementations [16, 17] or adapting the actual algorithm to the architecture of the processor, sequential [14] or parallel [9]. Attempts of formal verification have also been undertaken [20, 10].

Scans were also researched as a primitive to implement parallel variants of many algorithms, including radix sort, quicksort, lexical analysis, polynomial evaluation, stream compaction, histograms and string comparison [4, 5], and also geometric partitioning algorithms [13].

## 1.2 Aggregation over dominated points

In this problem, data and queries are points in the $m$-dimensional space $\mathbb{R}^m$. For two such points we write $(x_1, \ldots, x_m) < (y_1, \ldots, y_m)$ when inequalities hold coordinate-wise, i.e., $x_1 < y_1, \ldots, x_m < y_m$. Then let $\hat{q} = \{d \in D | d < q\}$.

The result of the algorithm should therefore consist of $\bigoplus_{d<q} w(d)$ for each query point $q$, which is the result of applying $\oplus$ to the set of all weights of points in $D$ which are *dominated* by $q$, i.e., coordinate-wise smaller than $q$.

Aggregation over dominated points can obviously be considered as a multidimensional generalisation of 1-dimensional prefix aggregation. Note however that typically prefix aggregation uses an associative operation $\oplus$ with unit, while in the multidimensional setting we also require it to be commutative. The reason is that prefix aggregation has a natural order in which the elements are aggregated. In multidimensional setting there is no such natural order and hence, for the sake of producing a deterministic result, we require commutativity.

Aggregation over dominated points, referred to as *general prefix computations*, has been shown to be a parallel primitive which allows expressing many computational problems [22]. This approach has been subsequently extended to a general parallel computation model called *Broadcast with Selective Reduction* PRAM (BSR for short). The multiple criteria variant of BSR, introduced by Akl and Stojmenović [2, 3] after a number of earlier papers about single criterion BSR, is the one whose only parallel primitive is aggregation over dominated points. Many computational problems have been then shown to have constant-round BSR algorithms including: counting intersections of isothetic line segments, vertical segment visibility, maximal elements in $m$ dimensions, ECDF searching, 2-set dominance counting and rectangle containment in $m$ dimensions, rectangle enclosure and intersection counting in $m$ dimensions [2], all nearest smaller values [28], all nearest neighbours and furthest pairs of points in a plane in $L_1$ metric, the all nearest foreign neighbours in $L_1$ metric and the all furthest foreign pairs of points in the plane in $L_1$ metric [18]. All of them therefore can be expressed by aggregation over dominated points.

Other applications of this primitive include calculating Empirical Cumulative Distribution Functions (ECDFs) in statistics, which are required in multivariate Kolmogorov-Smirnov, Cramér-von Mises and Anderson-Darling statistical tests [15]. The problem is also intensively studied, under the name range-aggregate queries by the spatial database community [1, 26, 21] and data warehouse community [11]. However, in this area one typically does not assume queries to be known in advance, so the focus is rather on storing data points in a data structure which allows efficient querying.

## 1.3 Our contribution

We prove the following.

▶ **Theorem 1.** *Aggregation over dominated points in $\mathbb{R}^m$, where $m$ is constant, can be computed in $O(1)$ basic operations: sorting of lists of tuples, zipping and computing prefix aggregations as well as flat maps over such lists. By using flat lists, our algorithm expands the initial size of the input data from $n$ to $O(n \log^{m-1} n)$ tuples.*

Our work thus creates a direct link between so far separate parallel primitives. In this respect, we follow the paradigm presented by Blelloch [4, 5], who has shown that many computational problems can be expressed by prefix aggregation. Our result does not add just one more such problem, but, by transitivity, all problems which have been previously shown to be expressible by aggregation over dominated points. An interesting theoretical conclusion can be drawn, that prefix aggregation suffices to express aggregation over dominated points, i.e., its own multidimensional generalisation.

Seen from another prespective, our work significantly simplifies the algorithm from our earlier paper Sroka et al. [23]. It presents a constant-rounds algorithms for solving the counting variant of the problem, written for MapReduce and designed to be *minimal* in the sense proposed by Tao et al. [25], which guarantees it evenly distributes computation among worker nodes. It distributes range trees explicitly, and we borrow the method to do so from that paper. However, it uses recursion to deal with consecutive dimensions and minimal group-by method from [25] to aggregate the counts. We regard it as a new contribution that all data processing tasks of this algorithm are replaced by invocations of a very few simple primitives of well-understood behaviours, and that this result neatly connects two computational tasks, each one with its own history of research of algorithms it can express.

This switch from a particular parallel model to high-level parallel primitives makes the algorithm simpler to understand, reducing the number and level of details which must be taken care of. Another benefit is the fact that the algorithm now avoids any direct references to the mechanisms of the parallel hardware it is running on, like processors, messages, shared resources, etc. It requires exactly those, which are used by the underlying implementations of of the primitives we rely on. Among them, prefix aggregation is the only one, which allows combining values from an unbounded number of data elements together. However, the role of flat maps is also crucial, because they distribute certain computations, the results of which prefix aggregation later reduces. Finally, scans allow distributing many algorithms which in the centralised setting are based on sorting and iterating over data. Such approach has many advantages similar to those pointed out in [25], e.g., the resulting algorithms have strong guarantees concerning the way they distribute work and load. The ideas we present this paper can be viewed as generalisation of such approach to multidimensional setting the same way as range tree generalises binary search tree.

There is also an algorithm by Yufei Tao [24][Theorem 5] that uses an entirely different idea. It is directly tailored for the MPC model and takes care of reducing the maximal amount of communication between processors. It is based on partitioning space into fragments,

recursively solving problem over them and finally aggregating partial results. It achieves the optimal load $m^{O(m)}N/p$ with $p$ processors. As far as we understand, neither of them can be adapted to use prefix aggregation as its main mechanism.

# 2 Primitives

## 2.1 Data model

We assume the data to be stored in immutable but ordered lists. We are going to transform lists into new lists. Such approach and immutability is typical for distributed architectures, while ordering can be achieved by imposing some order on nodes in the cluster and distributing values such that successive nodes have increasing elements. Initial ordering of the input data is arbitrary, but we assume that input values are equipped with some numerical IDs that define it and can be used to break ties if needed.

The initial list of data points (vectors in $\mathbb{R}^m$) is going to be referred to as $D$ and the list of queries as $Q$. The weights of data points are represented by weight function $w : D \to A$. To make the exposition simpler, we assume that weights are defined for queries, too, and $w(q) = e$ for $q \in Q$, so that they do not interfere with aggregation.

## 2.2 Primitives and macros

In this section we postulate primitive operations that are used to express our algorithms as well we define some convenient macros that combine them.

▶ **Definition 2** (Sort). *For $x = [x_0, \ldots, x_n]$ and some linear order relation $\preccurlyeq \subseteq X \times X$*

$$\mathbf{sort}(x, \preccurlyeq) = [x_{i_1}, \ldots, x_{i_n}],$$

*where the multisets $\{\!\{x_{i_1}, \ldots x_{i_n}\}\!\}$ and $\{\!\{x_1, \ldots x_n\}\!\}$ are equal, and $x_{i_j} \preccurlyeq x_{i_{j+1}}$ for all $j$.* ⌟

It is known that radix sort and quicksort are expressible by prefix aggregation [4, 5], hence we could theoretically eliminate sorting from the list of primitives we rely on.

▶ **Definition 3** (FlatMap). *For $x = [x_0, \ldots, x_n]$ and $f : X \to [Y]$, which applied to an element produces a list of elements as the result:*

$$\mathbf{flatmap}(x, f) = f(x_0) \,\&\, \ldots \,\&\, f(x_n),$$

*where $\&$ is list concatenation.* ⌟

For convenience we define map, which expects $f : X \to Y$ to produce single elements, by using FlatMap and composing $f$ with list constructor $list()$:

$$\mathbf{map}(x, f) := \mathbf{flatmap}(x, list() \circ f),$$

so that

$$\mathbf{map}([x_1, \ldots, x_n], f) = [f(x_1), \ldots, f(x_n)]$$

Zip is an operation which takes two (or more) lists of equal length and combines them into a single list of tuples, created from elements at the same positions.

▶ **Definition 4** (Zip). *For lists $x^1 = [x^1_1, \ldots, x^1_n], \ldots, x^k = [x^k_1, \ldots, x^k_n]$:*

$$\mathbf{zip}(x^1, \ldots, x^k) = [(x^1_1, \ldots, x^k_1), \ldots, (x^1_n, \ldots, x^k_n)].$$ ⌟

As usually immediately after zip we want to do something with those tuples, we define macros, which map or flatmap a provided function $f : X^k \to Y$ or $f : X^k \to [Y]$ on the tuples immediately:

$$\mathbf{mapzip}(x^1, \ldots, x^k, f) := \mathbf{map}(\mathbf{zip}(x^1, \ldots, x^k), f),$$

$$\mathbf{flatmapzip}(x^1, \ldots, x^k, f) := \mathbf{flatmap}(\mathbf{zip}(x^1, \ldots, x^k), f).$$

We define three variants of prefix aggregation of a list $[a_1, \ldots, a_n]$ of elements of $A$, known from literature.

▶ **Definition 5** (Scan). *For an aggregation operation $\oplus : A \times A \to A$, its natural element $e$ and a list $[a_1, \ldots, a_n]$ of elements of $A$:*

$$\mathbf{scan}([a_1, \ldots, a_n], \oplus) = [a_1, a_1 \oplus a_2, \ldots, a_1 \oplus \ldots \oplus a_n],$$

$$\mathbf{scan}^-([a_1, \ldots, a_n], \oplus) = [e, a_1, \ldots, a_1 \oplus \ldots \oplus a_{n-1}].$$ ⌟

As we need $\mathbf{scan}^-$ only for aggregating nondecreasing lists of numerical values with $\oplus = \max$ and $e = -\infty$ we define a macro: $\mathbf{shift}([x_1, \ldots, x_n]) := \mathbf{scan}^-([x_1, \ldots, x_n], \max) = [-\infty, x_1, \ldots, x_{n-1}]$, which is indeed a right-shift of its input if $[x_1, \ldots, x_n]$ is nondecreasing.

Another useful macro for lists of numerical values with $\oplus = \max$ and $e = -\infty$ is the following: $\mathbf{broadcastmax}([x_1, \ldots, x_n]) := \mathbf{scan}(\mathbf{sort}([x_1, \ldots, x_n], \geq), \max) = [x, \ldots, x]$ where $x = \max(x_1, \ldots, x_n)$. This macro indeed broadcasts the maximal value in a list to all positions. By zipping this list with another list we assure that the maximal value can be used for local processing of the latter, by **map**.

▶ **Definition 6** (Segmented scan). *For an aggregation operation $\oplus : A \times A \to A$ and two lists $[a_1, \ldots, a_n]$ of elements of $A$ and $[t_1, \ldots, t_n]$ of elements of some other set $T$, where the latter list is sorted:*

$$\mathbf{sscan}([a_1, \ldots, a_n], [t_1, \ldots, t_n], \oplus) = [\bigoplus_{\substack{i \leq 1 \\ t_i = t_1}} a_i, \bigoplus_{\substack{i \leq 2 \\ t_i = t_2}} a_i, \ldots, \bigoplus_{\substack{i \leq n \\ t_i = t_n}} a_i].$$

This means, that we essentially decompose the first argument list into maximal segments over which the corresponding elements of the second list remain identical, and then compute $\mathbf{scan}(s, \oplus)$ for each segment $s$ separately, e.g., $\mathbf{sscan}([1, 2, 3, 4, 5, 6], [0, 0, 1, 1, 1, 2], +) = [1, 3, 3, 7, 12, 6]$.

Segmented scan can be expressed by standard scan (see [4]), but is typically designed and implemented independently, which gives a chance for better performance, in particular on complex, constrained architectures, such as GPU [8]. It can also be implemented as a data oblivious algorithm, whose memory access pattern is independent of the actual data being processed [19]. Note that scan is our only operation for combining unbounded number of elements, here by aggregation into a single value.

The primitives described in this section essentially define our model of hardware the algorithm is running on.

## 3 Checking dominance by polylogarithmic data expansion

In this section we present an important tool we need in our algorithm. It allows us to distribute the process of checking dominance relations later on. It can be viewed as a method to distribute a range tree that allows to query multidimensional data. It derives from the paper [23].

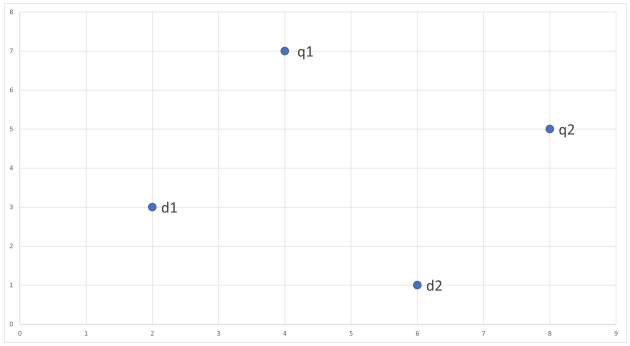

**Figure 1** Geometric visualization of the example data and queries. Note that the aggregation output in this case should be $w(d1)$ for $q1$ and $w(d1) \oplus w(d2)$ for $q2$.

We consider natural numbers written in binary notation, padded to some fixed length with leading 0's. Let $x$ be a bitstring. Then let $P0(x)$ be the set of all bitstrings $v$ such that $v0$ is a prefix of $x$, including the empty prefix, should $x$ start with a 0, e.g., $P0(01010) = \{0101, 01, \varepsilon\}$. Similarly, let $P1(x)$ be the set of all bitstrings $v$, such that $v1$ is a prefix of $x$.

▶ **Lemma 7.** *Suppose $x$ and $y$ are natural numbers represented as bitstrings of equal length, perhaps with leading 0's.*

*If $x < y$ then $P0(x) \cap P1(y)$ has exactly one element, and if $x \geq y$ then $P0(x) \cap P1(y) = \emptyset$.*

**Proof.** $x < y$ iff their longest common prefix is followed by 0 in $x$ and by 1 in $y$. Hence $P0(x) \cap P1(y)$ is nonempty iff $x < y$, which takes care of the $x \geq y$ part.

To rule out the possibility that $x < y$ and $P0(x) \cap P1(y)$ has more than 1 element, it is enough to observe that the longest element in $P0(x) \cap P1(y)$ is at the same time the shortest one because it has to be followed by different symbols in $x$ and $y$. ◀

Let $(x_1, \ldots, x_n)$ be a tuple of bitstrings. Define $P0((x_1, \ldots, x_n)) = P0(x_1) \times \ldots \times P0(x_n)$, and similarly $P1((x_1, \ldots, x_n)) = P1(x_1) \times \ldots \times P1(x_n)$.

▶ **Lemma 8.** *Let $\vec{x} = (x_1, \ldots, x_n)$ and $\vec{y} = (y_1, \ldots, y_n)$ be two tuples of natural numbers encoded as bitstrings, coordinate-wise of equal lengths.*

*If $\vec{x}$ is coordinate-wise smaller than $\vec{y}$ then $P0(\vec{x}) \cap P1(\vec{y})$ is a singleton, and otherwise it is empty.*

**Proof.** Follows from Lemma 7. ◀

## 4 Algorithm

We present the algorithm in several groups of numbered instructions and for each add explanations. Each such group is followed by an example of its action on a very small 2-dimensional dataset with $D = [(2,3)_{d1}, (6,1)_{d2}]$ and $Q = [(4,7)_{q1}, (8,5)_{q2}]$, which is intended to help with the explanation of the algorithm. Value subscripts indicate their IDs, whose order is $d1, q1, d2, q2$. See Figure 1 for a geometrical visualization.

The algorithm works on data and query points together, so first the union $DQ = D \cup Q$ of those two lists is created.

| | |
|---|---|
| 0 | $DQ = \textbf{flatmapzip}(D, Q, \lambda x, y.[x, y])$ |

| | |
|---|---|
| 0 | $DQ = [(2,3)_{d1}, (4,7)_{q1}, (6,1)_{d2}, (8,5)_{q2}]$ |

The next group of instructions is used to compute, for each dimension, the rank of each tuple's coordinate in that dimension and the total number of unique coordinates.

Let $less : \mathbb{R} \times \mathbb{R} \to \mathbb{R}$ be defined as

$$less(a,b) = \begin{cases} 1 & \text{if } a < b \\ 0 & \text{if } a \geq b \end{cases}.$$

For each dimension $i = 1, \ldots, m$ we add the following instructions.

| | |
|---|---|
| $5i-4$ | $S_i = \mathbf{map}(DQ, \lambda x.x[i])$ |
| $5i-3$ | $T_i = \mathbf{sort}(S_i, \leq)$ |
| $5i-2$ | $W_i = \mathbf{shift}(T_i)$ |
| $5i-1$ | $R_i = \mathbf{scan}(\mathbf{mapzip}(W_i, T_i, less), +)$ |
| $5i$ | $U_i = \mathbf{broadcastmax}(R_i)$ |

| | for $i = 1$: | | for $i = 2$: |
|---|---|---|---|
| 1 | $S_1 = [2_{d1}, 4_{q1}, 6_{d2}, 8_{q2}]$ | 6 | $S_2 = [3_{d1}, 7_{q1}, 1_{d2}, 5_{q2}]$ |
| 2 | $T_1 = [2_{d1}, 4_{q1}, 6_{d2}, 8_{q2}]$ | 7 | $T_2 = [1_{d2}, 3_{d1}, 5_{q2}, 7_{q1}]$ |
| 3 | $W_1 = [-\infty, 2_{d1}, 4_{q1}, 6_{d2}]$ | 8 | $W_2 = [-\infty, 1_{d2}, 3_{d1}, 5_{q2}]$ |
| 4 | $R_1 = [1,2,3,4]$ | 9 | $R_2 = [1,2,3,4]$ |
| 5 | $U_1 = [4,4,4,4]$ | 10 | $U_2 = [4,4,4,4]$ |

Line $5i-4$ extracts the sequence of $i$-th coordinates of vectors from $DQ$, which is then sorted in line $5i-3$, so that it can be shifted by one position to the right in line $5i-2$. Then $less$ in line $5i-1$ essentially compares each element of $T_i$ with its predecessor and produces a list of $1s$ and $0s$, with 1 on positions with a difference and 0 otherwise. Therefore prefix sum of that sequence computes ranks of the elements of $T_i$. In particular, on the last index there will be total number of unique elements. We need a list with this value present at every position. It is computed in line $5i$ with **broadcastmax**.

Now we transform each rank into its binary representation of fixed length which can be viewed as coordinates of that value in a binary search tree. Let $bin(n,k)$ for $n \leq k$ be defined as a binary expansion of $n-1$ using exactly $\lceil \log k \rceil$ binary digits, i.e., with leading zeros if necessary.

Again for each dimension $i = 1, \ldots, m$ we add the following instructions.

| | |
|---|---|
| $5m+i$ | $BR_i = \mathbf{sort}(\mathbf{mapzip}(R_i, U_i, bin), ID)$ |

| | for $i = 1$: | | for $i = 2$: |
|---|---|---|---|
| 11 | $BR_1 = [00_{d1}, 01_{q1}, 10_{d2}, 11_{q2}]$ | 12 | $BR_2 = [01_{d1}, 11_{q1}, 00_{d2}, 10_{q2}]$ |

The instructions in lines $5m+1, \ldots, 6m$ transform the original data in each dimension to the rank space, where values are replaced by their ranks within the whole dataset, written in binary. Ranks isomorphically preserve all inequalities of the original real values, and hence preserve the results of aggregations to be computed, too.

Let $P0(x)$ and $P1(x)$ be as in Lemma 8. Furthermore, let $P$ be a function from $m$-tuples of binary strings to sets of $m$-tuples of binary strings, defined as follows:

$$P(b_1, \ldots, b_m) = \begin{cases} P0(b_1, \ldots, b_m) & \text{if } (b_1, \ldots, b_m) \text{ is a data point;} \\ P1(b_1, \ldots, b_m) & \text{if } (b_1, \ldots, b_m) \text{ is a query point.} \end{cases}$$

| | |
|---|---|
| $6m+1$ | $EDQ = \mathbf{flatmapzip}(BR_1, \ldots, BR_m, P)$ |

| | |
|---|---|
| 13 | $EDQ = [(\varepsilon,\varepsilon)_{d1}, (0,\varepsilon)_{d1}, (0,\varepsilon)_{q1}, (0,1)_{q1}, (1,\varepsilon)_{d2}, (1,0)_{d2}, (\varepsilon,\varepsilon)_{q2}, (1,\varepsilon)_{q2}]$ |

This results in a new, expanded sequence $EDQ$ consisting of tuples of bitstrings. We assume they inherit ID and weights from their originating data and query points. This sequence will contain many duplicated tuples, but with different IDs. This operation increases the total size of data from $O(n)$ to $O(n \log^m n)$.

Let $\leq_{lex}$ be doubly lexicographic ordering relation on tuples from $EDQ$: lexicographic for bitstrings in each coordinate and lexicographic between coordinates, with the (crucial) additional requirement, that in case of a tie of two tuples data points precede queries.

| | |
|---|---|
| $6m+2$ | $SEDQ = \mathbf{sort}(EDQ, \leq_{lex})$ |

| | |
|---|---|
| 14 | $SEDQ = [(\varepsilon,\varepsilon)_{d1}, (\varepsilon,\varepsilon)_{q2}, (0,\varepsilon)_{d1}, (0,\varepsilon)_{q1}, (0,1)_{q1}, (1,\varepsilon)_{d2}, (1,\varepsilon)_{q2}, (1,0)_{d2}]$ |

$SEDQ$ is composed of segments consisting of duplicates, differing only by IDs and weights. Data points come before queries among each segment of equal values. At this point we have prepared all data we need, it remains to perform several steps of aggregations.

| | |
|---|---|
| $6m+3$ | $A_1 = \mathbf{sscan}(\mathbf{map}(SEDQ, \lambda x.w(x)), SEDQ, \oplus)$ |

| | |
|---|---|
| 15 | $A_1 = [w(d1)_{d1}, w(d1)_{q2}, w(d1)_{d1}, w(d_1)_{q1}, e_{q1}, w(d2)_{d2}, w(d2)_{q2}, w(d2)_{d2}]$ |

In line $6m+3$ we compute segmented prefix sums of the weights of the sorted data and queries. All bitstring coordinates serve as tags for segmentation. This way a list is created, where each query point $q$ corresponds (by position on the list) to the aggregation of all weights of data points which yielded the same tuple of bitstrings. By Lemma 8, each such identical tuple originates from a data point $d$ such that $d < q$, and, moreover, for each fixed tuple $t$ derived from $q$ there is one-to-one correspondence between such tuples and data points which also produced $t$ and are (therefore) dominated by $q$.

Queries have been assigned neutral weight, so they do not interfere with the scan. However, some aggregation happens at the positions of data points, too.

Let $\leq_{ID}$ be ordering relation on tuples which compares their associated $ID$ values.

| | |
|---|---|
| $6m+4$ | $A_2 = \mathbf{sort}(A_1, \geq_{ID})$ |
| $6m+5$ | $A_3 = \mathbf{sscan}(A_2, \mathbf{map}(A_1, \lambda x.ID(x)), \oplus)$ |

16 $A_2 = [w(d2)_{q2}, w(d1)_{q2}, w(d2)_{d2}, w(d2)_{d2}, e_{q1}, w(d1)_{q1}, w(d1)_{d1}, w(d1)_{d1}]$
17 $A_3 = [w(d2)_{q2}, (w(d2) \oplus w(d1))_{q2}, w(d2)_{d2}, (w(d2) \oplus w(d2))_{d2},$
$e_{q1}, w(d1)_{q1}, w(d1)_{d1}, (w(d1) \oplus w(d1))_{d1}]$

Line $6m + 4$ is a sort of partial aggregations by $ID$ in nonincreasing sequence, which creates a continuous segment of aggregation values corresponding to each query. There are also separate segments of data points, which are irrelevant now.

After that in line $6m + 5$ we compute segmented prefix sums of the already partially aggregated weights of the sorted data and queries, whereby their $ID$ values serve as tags for segmentation. This way partial aggregations for each query are further aggregated, so that the total aggregation of each query $q$ corresponds, by position, to the last tuple which originated from $q$. This total aggregation for $q$ comes from all $d$ such that $P(q) \times P(d) \neq \emptyset$ (those sets are created in line $6m + 1$). By Lemma 8, $\{d|P(q) \cap P(d) \neq \emptyset\} = \{d|d < q\}$, and each such $d$ in the r.h.s. is witnessed by exactly one element of $P(q) \cap P(d)$.

At this point the aggregation of each query is already computed, but the data contains many partial aggregations for the same query, too. Therefore the last task is to distribute the total aggregation of each query to all tuples with the same ID.

This can be significantly simplified if $A$ is linearly ordered and $a \oplus b \geq a$ for all $a, b \in A$. In this case for each query we need the maximum aggregation among all partial ones. Therefore a segmented variant of **broadcastmax** with ID defining segmentation would do that. Otherwise the method to achieve the goal is more complex and described below.

Let $neutral\_if\_eq(id_1, id_2, a) = \begin{cases} e & \text{if } id_1 = id_2 \\ a & \text{if } id_1 \neq id_2 \end{cases}$.

$6m + 6$ $A_4 = \mathbf{sort}(A_3, \leq_{ID})$
$6m + 7$ $H = \mathbf{shift}(\mathbf{map}(A_4, \lambda x.ID(x)))$
$6m + 8$ $A_5 = \mathbf{mapzip}(A_4, H, \mathbf{map}(A_4, \lambda x.ID(x)), neutral\_if\_eq)$
$6m + 9$ $Out = \mathbf{sscan}(A_5, \mathbf{map}(\lambda x.ID(x), A_5), \oplus)$

18 $A_4 = [(w(d1) \oplus w(d1))_{d1}, w(d1)_{d1}, w(d1)_{q1}, e_{q1}, (w(d2) \oplus w(d2))_{d2}, w(d2)_{d2},$
$(w(d2) \oplus w(d1))_{q2}, w(d2)_{q2}]$
19 $H = [-\infty, d1, d1, q1, q1, d2, d2, q2]$
20 $A_5 = [(w(d1) \oplus w(d1))_{d1}, e_{d1}, w(d1)_{q1}, e_{q1}, (w(d2) \oplus w(d2))_{d2}, e_{d2},$
$(w(d2) \oplus w(d1))_{q2}, e_{q2}]$
21 $Out = [(w(d1) \oplus w(d1))_{d1}, (w(d1) \oplus w(d1))_{d1}, w(d1)_{q1}, w(d1)_{q1}, (w(d2) \oplus w(d2))_{d2},$
$(w(d2) \oplus w(d2))_{d2}, (w(d2) \oplus w(d1))_{q2}, (w(d2) \oplus w(d1))_{q2}]$

In line $6m+6$ we reverse the sort order of $A_4$. Now the complete aggregations come at the beginning of each segment, and, moreover, the $ID$ values are nondecreasing, hence we can shift them in line $6m+7$. Line $6m+8$ resets all computed weights to the neutral $e$, except at the beginning of each segment, where the complete aggregation is present. Finally, segmented scan in line $6m + 9$ aggregates these values with neutral elements elsewhere, producing the desired output.

Now each query ID is accompanied by the aggregation of weights of its dominated points, which means that the desired output has been computed. In total it took $6m+9$ instructions and at most that many intermediate lists of data created. As it can be seen, the output of the example agrees with the output determined from the geometric presentation in Figure 1.

## 5 Improvement by one logarithm

It is possible to reduce the amount of data generated by a factor of $\log n$.

One of the coordinates (say: the last one) is chosen. It is not replaced by ranks and left in the form of real numbers. The remaining ones are replaced by ranks and prefixes are generated, exactly as in the basic algorithm, from both data points and queries. This results in a multiset of $\leq n \log^{m-1} n$ tuples with $m-1$ coordinates in the form of bitstrings and the last, $m$-th coordinate being real number. Identifiers are retained.

Now sort the data and queries $EDQ$ into $SEDQ$ (see line $6m+2$ and explanation thereof above) according to the doubly lexicographic order, with queries preceding data points in case of equality of all coordinates (including the $m$-th).

This results in segments of data elements with $m-1$ first coordinates equal, sorted according to the last coordinate within the segment. Then the remainder of the algorithm is executed exactly as in the basic version.

## 6 Relation to range trees and complexity

The algorithm we have presented above is derived from our earlier MapReduce algorithm Sroka et al. [23], and is indeed a parallelisation of the common sequential algorithm, based on range trees. The move to the rank space with ranks expressed as binary expansions is equivalent to speaking about elements in terms of their positions in a balanced binary tree, whose leaves hold the sorted data. The binary encodings then correspond to branches in the tree, and their prefixes to the positions where attached trees of smaller dimensions are located.

Our algorithm inherits its total data complexity of $O(n \log^{m-1} n)$ from the range tree algorithm. This distributed data structure is generated by flat maps, while the parallelisation is achieved by expressing operations on the tree in terms of sorting, zipping and prefix aggregation.

Time complexity of our algorithm depends very much on the underlying architecture and complexity of the primitive operations, but its analysis is pretty straightforward in each case, since it is a fixed length sequence of operations of very well known properties, applied to lists of data of sizes easy to determine. In particular, no matter what architecture it is executed on, if the implementations of primitives do the same total work as their sequential variants, then the whole algorithm will also have the total work of the sequential algorithm using range trees.

Indeed, in the sequential case the only nonlinear (and thus dominating) operation is sorting, and the size of the data is $O(n \log^{m-1} n)$. One linearithmic sort takes time $O(n \log^{m-1} n \cdot \log(n \log^{m-1} n)) = O(n \log^m n)$, which is equal to the worst case of the standard sequential implementation, calculated as creating the range tree with $n/2$ data points and then processing $n/2$ queries by this tree. There is a one logarithm better variant of Chazelle [6], which however works only for counting.

For the MPC model, it is known that for $\delta > 0$, sorting and scanning of $n$ values can be performed deterministically in a constant number of rounds using $n^\delta$ space per machine, $O(n)$ total space, and poly$(n)$ local computation, which follows directly from analogous bounds for MapReduce computation. The load can be made $O(N/p)$ [7]. This implies that our algorithm in dimension $m$ can be implemented deterministically in $O(m)$ rounds, with $n^\delta$ space per machine, $O(n \log^{m-1} n)$ total space and poly$(n)$ local computation, with load $O(N \log^{m-1} N/p)$.

By comparison, the algorithm by Hu et al. [12] achieves load $O(Np^{-1}\log^{m-1} p)$ with $p$ processors, which is better than what get in this paper. This is not surprising, since our reliance on high-level primitives gives us much less freedom in designing the computation mechanism and achieving low loads. In particular, the set of instructions we use does not permit shifting the computational effort into the local computation, which is the method to lower the loads. The algorithm of Tao [24] does it to an even higher extent, arriving at load $m^{O(m)}N/p$.

Our earlier algorithm from Sroka et al. [23] is quite similar, but at that time we did only tests of an implementation on MapReduce, for which it has been designed. The running times did not seem to scale linearly with the number of machines. Moreover, for its present form we can do complexity analysis, greatly simplified by known complxities of the primitives we use.

## 7 Summary and future research

In this paper we have presented algorithm for aggregating over dominated points in $\mathbb{R}^m$, where $m$ is constant. Our algorithm is based on a limited set of primitive operations: sorting, prefix aggregations, zip and flat maps. All those primitive operations are well studied and their efficient implementations exist for essentially all distributed architectures.

This proves that one-dimensional prefix aggregation allows expressing its own multidimensional generalisation. The latter problem has many practical applications, as well as it is known to be a parallel primitive, allowing to express in turn further problems. By transitivity, our result expresses all those problems in terms of the above mentioned primitive operations.

We consider our result to be primarily of theoretical interest at present, before experimental tests are conducted.

We believe that our algorithm may turn out to be quite practical. First of all, it is absolutely transparent and does not hide any significant computation steps. The local computation is on the level of individual tuples, only. No large collections of data need to be broadcasted to computation nodes and there is no limit on number of such nodes. Otherwise we use high-level primitives of very well understood algorithmic properties, and whose highly optimised implementations exist for virtually all hardware platforms. Also the organisation of the algorithm into a sequence of functional operations (without any branch) on immutable ordered lists is very convenient for implementation. Last but not least, the choice of primitives guarantees that the algorithm has several desired properties, e.g., it is minimal in the sense of [25].

On the other hand, the $\log^{m-1} n$ memory footprint will be a problem in larger dimensions.

Therefore an obvious item on the "further research" list is undertaking experiments with the algorithm on diverse parallel platforms.

## Abstract

We consider the Online Rent Minimization problem, where online jobs with release times, deadlines, and processing times must be scheduled on machines that can be rented for a fixed length period of $T$. The objective is to minimize the number of machine rents. This problem generalizes the Online Machine Minimization problem where machines can be rented for an infinite period, and both problems have an asymptotically optimal competitive ratio of $O(\log(p_{\max}/p_{\min}))$ for general processing times, where $p_{\max}$ and $p_{\min}$ are the maximum and minimum processing times respectively. However, for small values of $p_{\max}/p_{\min}$, a better competitive ratio can be achieved by assuming unit-size jobs. Under this assumption, Devanur et al. (2014) gave an optimal $e$-competitive algorithm for Online Machine Minimization, and Chen and Zhang (2022) gave a $(3e+7) \approx 15.16$-competitive algorithm for Online Rent Minimization. In this paper, we significantly improve the competitive ratio of the Online Rent Minimization problem under unit size to 6, by using a clean oracle-based online algorithm framework.

## 1 Introduction

*Machine Minimization* is a classical scheduling problem in combinatorial optimization. We are given $n$ jobs with release time and deadline to schedule. Each job $j$ has a length $p_j$ and must be assigned to a machine for $p_j$ units of time between its release time $r_j$ and its deadline $d_j$. However, in many practical scenarios, such as cloud computing, we may not need to buy the machines but only rent them for a fixed period of time. This motivates the *Rent Minimization* problem, introduced by Saha [12]. In this problem, we are given a constant $T$, which represents the duration of a machine rent. The goal is to minimize the number of rents we make to process all jobs within their deadlines.

Another related formulation, inspired by nuclear weapon testing, is the *Calibration* problem, proposed by Bender et al. [3]. In this problem, we are given $m$ machines and a set of jobs that must be completed feasibly. However, before using a machine, we need to *calibrate* it. Each calibration, similar to a rent, activates the machine for a time period of $T$. The goal is to minimize the number of calibrations to process all jobs on time. The main

difference between the Calibration and the Rent Minimization problems is that the former restricts us to have at most $m$ machines working in parallel at any given time, while the latter does not have such a constraint. Therefore, the Rent Minimization problem can be regarded as a special case of the Calibration problem when $m = \infty$.

On the other hand, in the cloud rental scenario and many other practical applications, the computing requests usually increase over time and can be modeled as online released jobs. Therefore, we investigate the problem in an online setting. We do not have any prior knowledge about the jobs before their release time, and need to schedule jobs and rent machines online and irrevocably over time. The goal is to minimize the total number of *rents* for scheduling all jobs. Note that the online generalization is also studied in the Calibration problem by Chen and Zhang [5]. To ensure that online algorithms can schedule all jobs, they also assume $m = \infty$ in their model, which coincides with the Online Rent Minimization model.

**Why consider unit-size jobs?** Saha [12] proposes an $O(\log(p_{\max}/p_{\min}))$-competitive algorithm for the Online Machine Minimization problem. By paying a constant factor, it can be extended to an $O(\log(p_{\max}/p_{\min}))$-competitive algorithm for the Online Rent Minimization problem. ($p_{\max}$ and $p_{\min}$ are the longest and shortest processing time among all jobs.), which was proved to be the best competitive ratio asymptotically. However, in many real-world applications, one company usually receives similar length requests, so the ratio between $p_{\max}$ and $p_{\min}$ may not be too large; and it is worthwhile to reduce the constant factor of the ratio when $p_{\max}/p_{\min}$ is small. To this end, we focus on the special case of unit-size jobs (i.e., all $p_j = 1$). Note that by partitioning jobs by their length into $\log(p_{\max}/p_{\min})$ groups, the $\alpha$-competitive unit-size algorithm can be extended to a roughly $(3\alpha \log(p_{\max}/p_{\min}))$-competitive algorithm in the general case.

The unit-size special case has also been considered in the Online Machine Minimization problem [5, 8, 10]. Devanur et al. [8] present an $e$-competitive algorithm for the Online Machine Minimization problem under unit-size jobs (though earlier work by Bansal et al. [2] implies the same result), and it is the optimal ratio among all deterministic algorithms. Current best lower bound of the online renting problem under unit-size jobs is also $e$ since it is a generalized model. On the positive side, Chen and Zhang [5] study the online renting problem under unit-size jobs. They improve the implicit constant ratio by Saha [12] to $3e + 7 \approx 15.16$. In their algorithm, jobs are distinguished by whether they are long or short based on the length of their time window (i.e., $d_j - r_j$) and are handled separately. Our paper significantly improves the competitive ratio to 6 with a cleaner oracle-based algorithm without identifying whether jobs are short or long.

▶ **Theorem 1.** *There exists an efficient* 6*-competitive algorithm for the online renting problems under unit-size jobs.*

**Our techniques.** In the work of Chen and Zhang [5], they rent machines for long and short jobs separately; as a result, their final competitive ratio is the sum of two cases, which makes the ratio large. The technical reason behind this result is that they use the $e$-competitive Online Machine Minimization algorithm by Devanur et al. [8] as a black box, which is only suitable for *short* jobs. (Roughly speaking, it is because we can view $T = \infty$ when jobs are short.) Therefore, they must use another approach to handle long jobs.

In our paper, we formalize and extend the Online Machine Minimization algorithm to an oracle-based framework, instead of using the algorithm as a black box. The oracle-based framework uses an offline algorithm to guide our online decision. Note that the Online

Machine Minimization algorithm also uses an efficient offline optimal algorithm as an oracle. However, we do not know a polynomial offline Rent Minimization algorithm for unit-size jobs. The main algorithmic novelty is that we find an efficient substitute for the optimal algorithm to act as a bridge between online decisions and the optimal offline solution. The oracle is a kind of optimal augmentation algorithm. It is allowed to use a rent length of $3T$, and the rent number is at most $\mathsf{OPT}$ with rent length $T$. It also satisfies some online monotone properties so that we can control the cost of the online algorithm. Finally, we prove that by following the offline oracle and paying a factor of 6 online, we can recover the same ability for scheduling jobs as the offline oracle. This concludes the competitive ratio of 6.

**Extension to the model with delay.** Chen and Zhang [5] also raise a perspective that the operation *rent* (a.k.a. *calibration* in their paper) needs a non-negative time $\lambda$ to finish. We call it *Online Rent Minimization with Delay*. They propose an $(3(e+1)\lambda+3e+7) \approx (11.15\lambda+15.16)$-competitive algorithm. We use a black box reduction to extend the algorithm in Theorem 1 and improve the ratio to $6(\lambda+1)$.

▶ **Theorem 2.** *As a corollary of Theorem 1, there exists an efficient $6(\lambda+1)$-competitive algorithm when we need $\lambda$ time to finish each rent.*

**Other related works.** Offline Machine Minimization is a well-studied and classic model. Garey and Johnson [9] shows that it is NP-hard. On the algorithm side, Raghavan and Thompson [11] propose an $O(\frac{\log n}{\log\log n})$-approximation algorithm. Later, the ratio has been improved to $O(\sqrt{\frac{\log n}{\log\log n}})$ by Chuzhoy et al. [6]. Whether there exists a constant approximation ratio is still open. Moreover, several special cases are also discussed. Cieliebak et al. [7] focus on the case that each job's active time $(d_j - r_j)$ is small. Yu and Zhang [13] achieve a ratio of 2 in the equal release time case and a ratio of 6 in the equal processing time case.

Scheduling to minimize the number of calibrations is proposed by Bender et al. [3]. The general case is NP-hard even for checking feasibility. Under unit-size jobs, Bender et al. give a 2-approximation algorithm; later, Chen et al. [4] give the first PTAS algorithm. However, it is worth noting that whether the unit-size special case is polynomially solvable is still open. Moreover, Angel et al. [1] introduce the concept of *delay*, which means that each calibration requires $\lambda$ time to finish. They study the delay setting on the one-machine special case of the offline calibration problem and show that it is polynomially solvable.

## 2 Preliminaries

We first define the models and introduce the basic notations.

**Rent Minimization.** We have a set of jobs $\mathcal{J} = \{1, \cdots, n\}$ and a fixed rent length $T$. For job $j \in \mathcal{J}$, it has a release time $r_j$, a deadline $d_j$, and a unit processing time $p_j = 1$. Each job should be assigned to one active machine at an integer time unit $[t, t+1)$, where $t$ is an integer such that $r_j \le t \le d_j - 1$. We can rent a machine at any integer time point $t$. Then we will have an active machine during $[t, t+T)$. The objective is to minimize the number of machine rents to process all jobs in $\mathcal{J}$.

**Online Rent Minimization.** In the online version, all jobs are released online, and they become *visible* at their release time. On the other hand, we need to make rent decisions and assign jobs online irrevocably. In particular, at an integer time point $t$, we have:

- Jobs with release time equal to $t$ become visible.
- We can decide to rent a machine at $t$ or any time after that.
- We can schedule jobs on active machines during the time unit $[t, t+1)$ irrevocably.

**Notations on Rent Set.** We use a multiset $I = \{[s_1, c_1), [s_2, c_2), \cdots [s_i, c_i), \cdots\}$ to denote a set of rents, where the $i$-th rent interval starts at $s_i$ and is active in $[s_i, c_i)$. Note that $c_i$ always equals $s_i + T$ when the rent length is $T$; however, we use the general notation for future reference.

Focusing on the time unit $[t, t+1)$, the number of *active units* $A_I(t)$ is defined as the number of active machines at time $t$, which means that we can schedule at most $A_I(t)$ jobs at time $t$. For a given rent set $I$, we have $A_I(t) = |\{[s_i, c_i) \in I \mid t \in [s_i, c_i)\}|$. We also extend the notation for intervals, such that $A_I(r^*, d^*) = \sum_{t=r^*}^{d^*-1} A_I(t)$ is the number of active units during the time interval $[r^*, d^*)$.

**Feasibility of Rent Set.** We call a rent set $I$ *feasible* for $J$, if we can schedule all jobs in $J$ on $I$. We introduce a lemma based on Hall's Theorem to check whether $I$ is feasible.

For a given jobs set $J$, we define $J(r^*, d^*) = \{j \in J | r^* \le r_j < d_j \le d^*\}$ to represent the jobs that must be assigned inside the interval $[r^*, d^*)$.

▶ **Lemma 3** (Feasibility). *$I$ is feasible for $J$ iff. $\forall r^* \le d^* \in \mathbb{N},\ A_I(r^*, d^*) \ge |J(r^*, d^*)|$ .*

**Proof.** For any fixed $r^*$ and $d^*$, the sum of active units provided by $I$ is $A_I(r^*, d^*)$. Each job released and due between this period must be scheduled on these time slots. If there exists a pair of $r^*$ and $d^*$ such that $A_I(r^*, d^*) < |J(r^*, d^*)|$, there is no feasible assignment because of the pigeonhole principle. On the other hand, if the inequality holds for all $r^*$ and $d^*$, we can view it as a bipartite matching between jobs and active units. There is a feasible assignment by Hall's Theorem. ◀

**An Efficient Checker and Scheduler: Earliest Deadline First (EDF).** **E**arliest **D**eadline **F**irst is a greedy algorithm that can find a feasible assignment for $J$ on $I$ if and only if $I$ is feasible for $J$. When we call $\mathsf{EDF}(J, I)$, we scan time units from early to late, and assign the released job with the earliest deadline to a free active machine at the current time unit. If a job with deadline $d$ cannot find a free active machine at the time unit $[d-1, d)$, $\mathsf{EDF}(J, I)$ fails, and we call $d$ the *fail time* of $\mathsf{EDF}(J, I)$. Otherwise, $\mathsf{EDF}(J, I)$ succeeds. Bender et al. [3] has already proved that EDF can check the feasibility. It is also worth noting that EDF can be efficiently implemented in $O(n \log n)$ by using a heap, instead of going through all integer time points directly.

▶ **Lemma 4** ([3]). *$\mathsf{EDF}(J, I)$ succeeds, i.e., it can find a feasible schedule for $J$ on $I$, if and only if $I$ is feasible for $J$.*

**Using EDF online.** Note that we only make comparisons between released jobs. Therefore, the EDF algorithm can be simulated online : we only need to find a feasible rent set $I$, and then EDF can automatically find a feasible assignment online.

## 3 Oracle-based Online Algorithm Framework

Moving towards online algorithms, one natural way is to use an offline algorithm as an *oracle* to suggest the actions of online algorithms. We keep track of this offline algorithm and make corresponding online decisions when the offline algorithm changes along with the online jobs

release. Whenever the offline algorithm increases by one at the moment $t$ because of the change of the job set, the online algorithm performs one Batch-Rent at this time $t$, which is a fixed rent scheme that contains $\Gamma$ machines. Intuitively, we use these $\Gamma$ machines to catch up with the one increment of the offline oracle. It is worth noting that the $e$-competitive algorithm for Online Machine Minimization follows this approach [8].

In our case, compared to Machine Minimization, we have two main differences in our oracle-based framework. The first difference is the job set we input to the oracle. Because of the online fashion, the most natural way is to input the set of all released jobs to the oracle. In Machine Minimization, it works because $T = \infty$ and earlier rents are always more powerful; however, this is not true in Rent Minimization. Indeed, too early rents may cause trouble in Rent Minimization. Intuitively, we are only allowed to make online rent when the offline oracle reports an increment if we want to bound the competitive ratio in the framework. Consider the case where $T = 10$ and two jobs will be due at 100 with release time 0 and 90. If we report the first job to the offline oracle at 0, the offline oracle will return one new rent interval. Following the oracle-based framework, we will make $\Gamma$ online rent intervals at 0. However, we still need to make more rent intervals at 90, while the offline oracle may not increase. To this end, we use the job set $J_t$ as the job set we input to the oracle at time $t$. A job $j$ is in $J_t$ if it satisfies the following two properties:

**1)** It is *visible* at $t$, i.e., $r_j \le t$.
**2)** It is *emergent* at (or before) $t$, i.e., $d_j \le t + T$.

Another difference is an augmentation factor $\alpha$. The oracle is allowed to have $\alpha T$ active time for each rent. Since the existence of a polynomial time optimal offline algorithm for Rent Minimization is still unknown, this factor allows us to find an efficient substitute. We use $\mathsf{Oracle}_\alpha(J, T)$ (instead of $\mathsf{Oracle}(J, \alpha T)$, since the target rent length is still $T$) to denote an oracle with augmentation factor $\alpha$. The framework is formalized in Algorithm 1.

**Algorithm 1** Oracle-based Online Algorithm Framework.

**procedure** OracleBasedOnline($t$: time, $J$: known jobs, $T$: length of rent)
  $\Delta_t = |\mathsf{Oracle}_\alpha(J_t, T)| - |\mathsf{Oracle}_\alpha(J_{t-1}, T)|$ ▷ $\alpha$ is a positive integer
  Perform $\Delta_t$(if $\Delta_t > 0$) Batch-Rent operations at $t$, consisting of $\Gamma$ machines that start at or after $t$.
  **schedule** jobs at $t$ following $\mathsf{EDF}(J, I)$, where $I$ is the current online rent set.
**end procedure**

Then, we discuss how this framework helps us control the number of rents made by the online algorithm. First, as a substitute for the optimal offline algorithm, $\mathsf{Oracle}_\alpha$ needs to maintain some properties similar to those of the optimal offline algorithm. Second, Batch-Rent should support the online algorithm to be as powerful as the offline oracle in scheduling all released jobs. We integrate and formalize these messages in the following lemma.

▶ **Lemma 5.** *Let* $\mathsf{OPT}(J, T)$ *be the number of rents used by the optimal offline algorithm to schedule the job set* $J$*, Algorithm 1 is* $\Gamma$*-competitive if these three properties are guaranteed:*

**1)** *For any job set* $J$*,* $|\mathsf{Oracle}_\alpha(J, T)| \le \mathsf{OPT}(J, T)$*;*
**2)** *The offline oracle is online monotone:* $|\mathsf{Oracle}_\alpha(J_{t_1}, T)| \le |\mathsf{Oracle}_\alpha(J_{t_2}, T)|$ *if* $t_1 \le t_2$*;*
**3)** *Algorithm 1 is feasible for scheduling all online released jobs.*

**Proof.** The online algorithm makes $\sum_{\Delta_t > 0} \Delta_t$ rent batches, which is exactly $|\mathsf{Oracle}_\alpha(\mathcal{J}, T)|$ by property 2) and is not greater than $|\mathsf{OPT}(\mathcal{J}, T)|$ by property 1). Also, the output satisfies the feasibility requirement by property 3). Therefore, Algorithm 1 is $\Gamma$-competitive. ◀

**The $e$-competitive algorithm for Online Machine Minimization.** We can use the framework to understand the $e$-competitive Online Machine Minimization algorithm.

- Oracle is the optimal offline algorithm, and we set $\alpha = 1$. The monotonicity directly comes from optimality.
- $J_t$ is the set of visible jobs at $t$ because all jobs are emergent.
- Each Batch-Rent contains $e$ new machines in average; for simplicity, we omit any rounding issues related to $e$.

**Choice of the oracle.** Recall that we do not have an efficient optimal algorithm for Rent Minimization currently. It remains to find a suitable substitute that also uses a small number of rents (property 1). One candidate algorithm may be the Lazy-Binning algorithm by Bender et al. [3], which requires an augmentation factor of 2 to satisfy property 1). However, Lazy-Binning algorithm, as well as other relatively simple 2 approximation algorithms we come up with, cannot guarantee monotonicity. This will make us fail to bound the competitive ratio of the online algorithm. In the next section, we introduce our oracle with an augmentation factor of 3, called the semi-online algorithm, which provides all the properties we need in Lemma 5.

## 4 The Semi-Online Algorithm

In this section, we introduce the semi-online algorithm shown as Algorithm 2, which uses an augmentation factor of 3 and acts as the $\mathsf{Oracle}_3$ in our framework.

**Algorithm 2** The Semi-Online Algorithm.

```
procedure SemiOnline(J: input job set, T: length of rent)
    J', I ← ∅                                   ▷ I is a multiset for rents.
    τ_j = max{r_j, d_j − T} for all j.
    for j ∈ J in non-decreasing order of τ_j do
        J' ← J' ∪ {j}
        if EDF(J', I) fails then
            I ← I ∪ {[τ_j − T, τ_j + 2T)}       ▷ A rent that starts at τ_j − T with length 3T.
        end if
    end for
    return I
end procedure
```

We call Algorithm 2 semi-online, because the enumerating order is exactly the same as how $J_t$ increases in the oracle-based framework. Thus, if we have some new jobs with $r_j = t$ or $d_j - T = t$ when the online time moves from $t-1$ to $t$, the only possible difference between $\mathsf{SemiOnline}(J_{t-1}, T)$ and $\mathsf{SemiOnline}(J_t, T)$ is some rent intervals of $[t-T, t+2T)$. This observation could be formalized into the following properties of the semi-online algorithm.

▶ **Lemma 6** (Strong Monotonicity). *We have the following two properties for Algorithm 2.*

1. *For any $J_{t_1}$ and $J_{t_2}$ where $t_1 \le t_2$, we have $\mathsf{SemiOnline}(J_{t_1}, T) \subseteq \mathsf{SemiOnline}(J_{t_2}, T)$.*
2. *$\mathsf{SemiOnline}(J_t, T) \setminus \mathsf{SemiOnline}(J_{t-1}, T)$ is a multiset of a fixed rent interval $[t-T, t+2T)$.*

**Proof.** Intuitively, the reason behind the lemma is that the order of $\tau_j$ is the same as the order in which we insert jobs into $J_t$ as $t$ increases. Formally speaking, compare $J_{t_1}$ and $J_{t_2}$ and consider a job $j \in J_{t_2} \setminus J_{t_1}$. By definition, we have that $\tau_j \ge \max_{j' \in J_{t_1}} \tau_{j'}$. Therefore,

Algorithm 2 first enumerates the jobs in $J_{t_1}$ and then the jobs in $J_{t_2} \setminus J_{t_1}$, which concludes the first property immediately. For the second property, the reason is that $J_t \setminus J_{t-1}$ is a set of jobs with $r_j = t$ or $d_j - T = t$. In other words, we enumerate them after jobs in $J_{t-1}$. Thus, if $I$ continues to grow when we enumerate them, the new interval must be $[t-T, t+2T)$. ◀

The strong monotonicity in Lemma 6 suffices to show the weak monotonicity in property 2) of Lemma 5. On the other hand, these two properties are also used in the proof of property 3) later. It remains to prove property 1) by bounding the cardinality of the semi-online algorithm's solution.

▶ **Lemma 7.** $|\mathsf{SemiOnline}(J,T)| \le \mathsf{OPT}(J,T)$, *and* $\mathsf{SemiOnline}(J,T)$ *is feasible for* $J$.

Before proving Lemma 7, we introduce coOPT so that we can better understand the solution structure.

▶ **Definition 8** (Optimal complement solution). *For a job set $J$, rent length $T$, and a given rent set $I$ (which may not be length $T$), the optimal complement solution of $I$, denoted as* $\mathsf{coOPT}(I)$, *is defined as a rent set of length $T$ with minimum cardinality such that $I \cup \mathsf{coOPT}(I)$ is feasible for $J$.*

▶ **Fact 9.** $\mathsf{coOPT}(\varnothing) = \mathsf{OPT}, \mathsf{coOPT}(\mathsf{OPT}) = \varnothing$.

Consider a rent set $I$ that is infeasible for $J$. Below, we state the main property of coOPT.

▶ **Lemma 10.** *Let $d$ be the fail time of* $\mathsf{EDF}(J,I)$. *There exists a* $\mathsf{coOPT}(I)$ *such that there is a rent interval $[s, s+T) \in \mathsf{coOPT}(I)$ that satisfies: $d - T \le s < d$.*

**Proof.** We use coOPT as a shorthand for $\mathsf{coOPT}(I)$ in this proof. Let $[s, s+T)$ be the earliest interval in coOPT.

First, we show that $s < d$. Suppose, for a contradiction, that $s \ge d$. Let $j$ be the job that fails in $\mathsf{EDF}(J,I)$, where $J$ is a fixed given job set. Then, $j$ has no more active units in coOPT, since all rent intervals start at or after $d$. But this contradicts the definition of coOPT, which is a feasible rent set for $J$.

Second, we show that $s \ge d - T$ can be true. If this is not true, we construct a new rent set $\mathsf{coOPT}' = \mathsf{coOPT} \setminus \{[s, s+T)\} \cup \{[d-T, d)\}$. That is, we replace the rent interval at $s$ with another one at $d - T$. We claim that $\mathsf{coOPT}' \cup I$ is also feasible for $J$. This means that coOPT′ is also a feasible coOPT, and $[s' = d - T, T)$ is a feasible rent interval that satisfies our desired condition.

To prove our claim, we fix an arbitrary choice of $r^* \le d^* \in \mathbb{N}$, and we verify the condition in Lemma 3, i.e., $A_{I \cup \mathsf{coOPT}'}(r^*, d^*) \ge |J(r^*, d^*)|$.

We consider two cases:

- Case 1: $d^* < d$. If the condition does not hold, we have $A_I(r^*, d^*) \le A_{I \cup \mathsf{coOPT}'}(r^*, d^*) < J'(r^*, d^*)$, which means that $\mathsf{EDF}(I, J')$ must fail no later than $d^*$ since the active units are not enough beforehand. This contradicts the definition of $d$.
- Case 2: $d^* \ge d$. The only difference between coOPT and coOPT′ is the contribution of active units by $[s, s+T)$ and $[d-T, d)$. We prove that $[d-T, d)$ must provide at least as many active units as $[s, s+T)$ does. Referring to Figure 1, we see that $[d-T, d)$ has more active units than $[s, s+T)$ in $[s+T, d)$, and vice versa in $[s, d-T)$. Since $d^* \ge d$, we need $r^* \le d - T$ to reach the advantage area of coOPT; however, $[r^*, d^*)$ then covers the whole part of $[d-T, d)$. This implies that the total contribution of coOPT never exceeds that of coOPT′.

The discussion concludes the claim. ◀

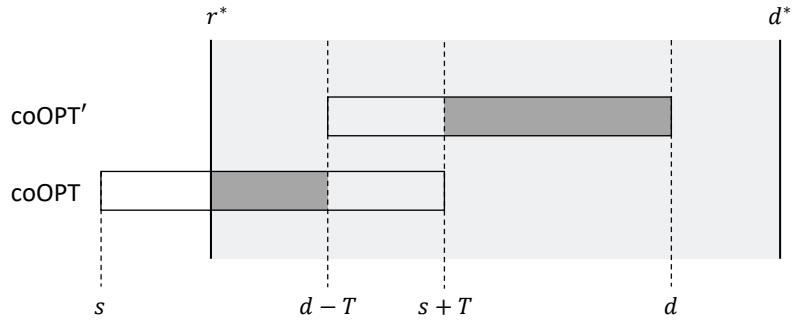

**Figure 1** coOPT' contributes at least as many active units as coOPT on $[r^*, d^*)$ when $d^* \geq d$.

▶ **Lemma 11.** *At the end of each iteration of $j$, $I$ is feasible for $J'$.*

**Proof.** We prove it by induction. In the base case, $I$ is feasible for $J'$ when they are $\varnothing$. Then, assume the lemma is true after the $(j-1)$-th iteration. At the $j$-th iteration, we add a job $j$ to $J'$. This means that $\forall r^* \leq r_j,\ d^* \geq d_j$, $|J'(r^*, d^*)|$ will increase by one. If $\mathsf{EDF}(J', I)$ is already feasible, we are done. Otherwise, the algorithm will employ a new $3T$ length rent interval $[\tau_j - T, \tau_j + 2T)$. Notice that $d^* \geq d_j \geq \tau_j$. Every $A_I(r^*, d^*)$ also increases by at least one. Thus, we still have $A_I(r^*, d^*) \geq |J'(r^*, d^*)|$ after we employ $[\tau_j - T, \tau_j + 2T)$ (at the end of the $j$-th iteration). ◀

▶ **Corollary 12.** $\mathsf{SemiOnline}(J, T)$ *is feasible for $J$.*

▶ **Lemma 13.** *In the $j$-th iteration, if $\mathsf{EDF}(J', I)$ is infeasible in Algorithm 2, before we rent $[t - T, t + 2T)$, we have*

$$|\mathsf{coOPT}(I \cup \{[t - T, t + 2T)\})| \leq |\mathsf{coOPT}(I)| - 1.$$

**Proof.** By the condition of the lemma and Lemma 11, we have $\mathsf{EDF}(J', I)$ is infeasible while $\mathsf{EDF}(J' \setminus \{j\}, I)$ is feasible. By the enumerating order, all the jobs $j'$ in $J'$ must satisfy $\max\{r_j, d_{j'} - T\} \leq \tau_j$. Therefore, $\mathsf{EDF}(J', I)$ must fail at a deadline $d \leq \tau_j + T$. On the other hand, for all $j' \in J$ such that $d_{j'} < \tau_j$, we must have $j' \in J' \setminus \{j\}$, also because of the enumerating order. Thus, we can show that $d \geq \tau_j$. Otherwise, $J' \setminus \{j\}$ would be infeasible for $I$, which is a contradiction. In conclusion, we show that the failure time $d$ of $\mathsf{EDF}(J', I)$ satisfies $\tau_j \leq d < \tau_j + T$.

Finally, by Lemma 10, there exists a coOPT with rent interval $[s, s + T]$ such that $d - T \leq s < d$. It implies that $\tau_j - T < s < \tau_j + T$. Therefore $[s, s + T)$ is always a subset of $[\tau_j - T, \tau_j + 2T)$. We have

$$|\mathsf{coOPT}(I \cup \{[t - T, t + 2T)\})| \leq |\mathsf{coOPT}(I \cup \{s\})| = |\mathsf{coOPT}(I)| - 1.$$ ◀

**Proof of Lemma 7.** Recall Fact 9 that $\mathsf{coOPT}(\varnothing) = \mathsf{OPT}$. It follows that SemiOnline rents at most OPT times as a corollary of Lemma 13. ◀

## 5 The 6-competitive Online Algorithm

It remains to define the rent scheme for each Batch-Rent in the framework. For completeness, we formally describe the algorithm in Algorithm 3.

**Algorithm 3** The Online algorithm.

**procedure** OnlineRent($t$: time, $J$: known jobs, $T$: length of rent)
  $\Delta = |\mathsf{SemiOnline}(J_t, T)| - |\mathsf{SemiOnline}(J_{t-1}, T)|$
  Perform $\Delta$ Batch-Rent at time $t$, each consists of 6 machines: 4 at $t$ and 2 at $t+T$.
  **schedule** jobs at $t$ following $\mathsf{EDF}(J, I)$, where $I$ is the current online rent set.
**end procedure**

Next, we prove the property 3) of Lemma 5 by our design of Batch-Rent, i.e., to show Algorithm 3 is feasible for the total job set $\mathcal{J}$. Combining with the property 1) and 2) by the semi-online algorithm, we can conclude our online algorithm is 6-compeititve as claimed in Theorem 1.

First, we introduce an obvious relationship between online and semi-online algorithms.

▶ **Fact 14.** *At every moment $t$, there always exists a bijection from one semi-online rent batch to one online rent batch, such that both batches are at the same time:* $4 \times [t, t+T) + 2 \times [t+T, t+2T)$ *in* Online $\mapsto [t-T, t+2T)$ *in* SemiOnline.

**Proof.** This fact is directly implied by the second property of Lemma 6. Whenever $\mathsf{SemiOnline}(J_t, T)$ increases from $\mathsf{SemiOnline}(J_{t-1}, T)$ by some rent intervals of $[t-T, t+2T)$, the new batches must be $4 \times [t, t+T) + 2 \times [t+T, t+2T)$. Each of them can correspond to one $[t-T, t+2T)$. ◀

We prove the feasibility by showing that the active units provided by the online algorithm are always enough for the possible jobs inside any possible interval $[r^*, d^*)$.

▶ **Lemma 15.** *Let $I$ be the rent sets made by our algorithm. We have $\forall r^* \le d^* \in \mathbb{N}$, $A(r^*, d^*) \ge |\mathcal{J}(r^*, d^*)|$, where we use $A$ to denote $A_I$ for simplicity.*

We remark that Lemma 15 provides the necessary information to prove the correctness via the feasibility lemma (Lemma 3). It only remains to complete the proof of Lemma 15.

## 5.1 Proof of Lemma 15

Let us fix an arbitrary range $r^* \le d^*$, and discuss $A(r^*, d^*)$ and $\mathcal{J}(r^*, d^*)$ separately. First, we discuss $A(r^*, d^*)$. The behavior of the online algorithm can be represented by a set of online rent batches. Note that only those rent batches that start in $(r^* - 2T, d^*)$ can provide active units inside $[r^*, d^*)$. Therefore, we only discuss a subset $B$ of all rent batches with a start time in $(r^* - 2T, d^*)$. Each $b$ means a Batch-Rent made by Algorithm 3. We use $t(b)$ to mean its decision time. That is, a batch $b$ contains 4 rent intervals of $[t(b), t(b)+T)$, and 2 of $[t(b)+T, t(b)+2T)$.

We partition the time interval $[r^*, d^*)$ by several critical time points. The first time point is $\theta_1 = \max\left\{\left(\frac{r^*+d^*}{2}\right), d^* - T\right\}$. It means that $\theta_1 = d^* - T$ when $d^* - r^* \ge 2T$ and $\theta_1 = \left(\frac{r^*+d^*}{2}\right)$ when $d^* - r^* < 2T$. Remark that in both cases, $\theta_1 \ge d^* - T$. Then we recursively define $\theta_{i+1} = \left(\frac{\theta_i + d^*}{2}\right)$ for every $i \ge 1$ until $\lfloor \theta_i \rfloor = d^* - 1$. Besides, we let $\theta_0 = r^* - 1$. For $i \ge 1$, we call $[\lfloor \theta_{i-1} \rfloor + 1, \lfloor \theta_i \rfloor]$ the $i$-th sub-interval, which is the minimal sub-interval of $(\theta_{i-1}, \theta_i]$ that contains all integers in it. We define $B_i \subseteq B$ as the set of rent batches starting in the $i$-th sub-interval. Moreover, we let $B_0$ be the set of rent batches starting in $(r^* - 2T, r^*]$.

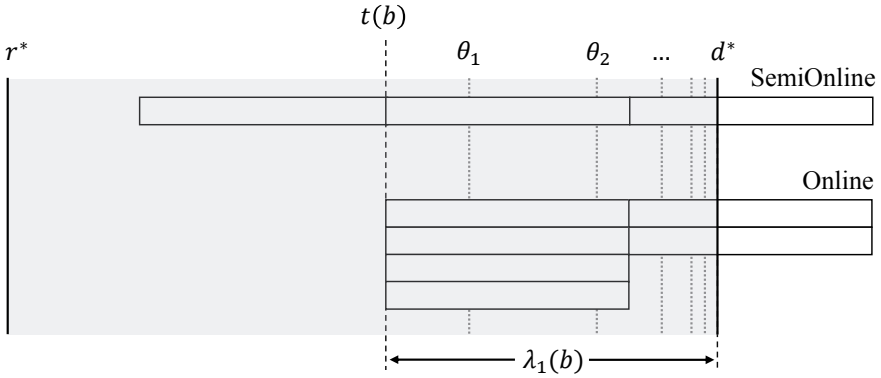

**Figure 2** An example for $b \in B_1$ when $d^* - r^* > 2T$. The shaded area is the considered $[r^*, d^*)$, and the online rent batch provides $2\lambda_1(b) + 2\min\{\lambda_1(b), T\}$ active units to it.

For each $b \in B$, recall that $t(b)$ is the time it was allocated, and we let $\lambda_i(b)$ be the length of the intersecting interval of $[t(b), t(b)+2T)$ and $[\lfloor\theta_{i-1}\rfloor + 1, d^*)$. Note that $\lambda_1(b)$ represents the intersecting interval with the whole $[r^*, d^*)$. Let $L = \min\{2T, d^* - r^*\} = 2(d^* - \theta_1)$ denote the maximum possible length in $\lambda_1$, and by our partition method. It follows the property of the length of sub-intervals by our partition.

▶ **Lemma 16** (Partition length property). *For any batch $b \in B_i$ where $i \geq 1$, the intersection of $[t(b), t(b)+2T)$ and $[\lfloor\theta_{i-1}\rfloor + 1, d^*)$ satisfies: $2^{-i} \cdot L \leq \lambda_i(b) \leq 2^{1-i} \cdot L$.*

**Proof.** For $i = 1$, $\lambda_1(b) = \min\{2T, d^* - t(b)\}$. By definition, $r^* \leq t(b) \leq \lfloor\theta_1\rfloor$, hence

$$L/2 = \min\{T, d^* - \theta_1\} \leq \min\{2T, d^* - t(b)\} \leq \min\{2T, d^* - r^*\} = L.$$

For $i \geq 2$, by definition $d^* - \theta_i = 2^{-i} \cdot L$. Because $t(b) \in [\lfloor\theta_{i-1}\rfloor + 1, \lfloor\theta_i\rfloor] \subseteq (\theta_{i-1}, \theta_i]$, we have $2^{-i} \cdot L \leq \lambda_i(b) \leq \min\{2T,\ 2^{1-i} \cdot L\}$. Since $2 \cdot L \leq 2T$, we conclude the lemma. ◀

Then, we present the lemmas for a lower bound of active units and an upper bound of job numbers.

▶ **Lemma 17** (Lower bound of active units).

$$\begin{aligned} A(r^*, d^*) \geq & \sum_{b \in B_0} (2\lambda_1(b) + 2\max\{\lambda_1(b) - T, 0\}) \\ & + \sum_{b \in B_1} (2\lambda_1(b) + 2\min\{\lambda_1(b), T\}) \\ & + \sum_{i \geq 2} 4 \cdot (2^{-i} \cdot L) \cdot |B_i|. \end{aligned}$$

**Proof.** Three terms on the RHS of the inequality are counting of $B_0, B_1$ and $B_{\geq 2}$, where the first two are straightforward counting as shown in Figure 2, and the last term was scaled down a bit by Lemma 16:

$$4 \sum_{i \geq 2} \sum_{b \in B_i} \lambda_1(b) = 4 \sum_{i \geq 2} \sum_{b \in B_i} \lambda_i(b) \geq \sum_{i \geq 2} 4 \cdot (2^{-i} \cdot L) \cdot |B_i|.$$ ◀

Let $\mathcal{J}_i$ be the job set with deadline at most $d^*$ and released in the $i$-th subinterval:

$$\mathcal{J}_i = \{j \in \mathcal{J} \mid \lfloor\theta_{i-1}\rfloor + 1 \le r_j \le \lfloor\theta_i\rfloor,\ d_j \le d^*\}.$$

We provide an upper bound of $\mathcal{J}_i$ by the performance of our algorithm.

▶ **Lemma 18.** *Let $I_t$ be the semi-online batches allocated at or before time $t$. We have that $\mathcal{J}_i$ is no more than the active units after $\lfloor\theta_{i-1}\rfloor + 1$ provided by* SemiOnline *at $\lfloor\theta_i\rfloor$. i.e.,*

$$\mathcal{J}_i \le A_{I_{\lfloor\theta_i\rfloor}}(\lfloor\theta_{i-1}\rfloor + 1, d^*).$$

**Proof.** Let us observe the time point $t = \lfloor\theta_i\rfloor$. SemiOnline$(J_t, T)$ reports $I_t$ at this time. By Lemma 11, $I_t$ is feasible for $J_t$. By the definition of $\theta_i$, we prove $t \ge d^* - T$ because $\theta_1 \ge d^* - T$. Thus, all jobs with deadlines at most $d^*$ are already in $J_t$, and combining with the feasibility of $I_t$, we have:

$$\mathcal{J}_i = J_t(\lfloor\theta_{i-1}\rfloor + 1, d^*) \le A_t(\lfloor\theta_{i-1}\rfloor + 1, d^*).$$

The lemma then concludes because we define $t = \lfloor\theta_i\rfloor$. ◀

▶ **Lemma 19** (Upper bound of job numbers)**.** *We have two different upper bounds for $\mathcal{J}_i$:*

- $i = 1$: $\quad |\mathcal{J}_1| \le \sum_{b\in B_0} \lambda_1(b) + \sum_{b\in B_1} (\lambda_1(b) + L/2)$.
- $i \ge 2$: $\quad |\mathcal{J}_i| \le \sum_{b\in B_0} \lambda_i(b) + 2\cdot(2^{-i}\cdot L)\cdot \sum_{j=1}^{i} |B_j|$.

**Proof.** In this proof, we apply Lemma 18 and count the number of active units after $\theta_{i-1}$ by $I_{\lfloor\theta_i\rfloor}$. Note that by Fact 14, each $3T$ length rent interval in $I_{\lfloor\theta_i\rfloor}$ corresponds to an online Batch-Rent.

First, let us consider the case $i = 1$. $I_{\lfloor\theta_i\rfloor}$ corresponds to the online batches with $t(b) \le I_{\lfloor\theta_i\rfloor}$. Note that the ending time of $b$ and its corresponding semi-online rent interval are both $t(b) + 2T$. Thus, $A_{I_{\lfloor\theta_i\rfloor}}(\lfloor\theta_{i-1}\rfloor + 1, d^*)$ corresponds to $B_0$ and $B_1$.

For $i = 1$, we keep the $B_0$ straightforward and calculate the upper bound of active units provided by the corresponding semi-online batch for each batch $b$ in $B_1$. Note that the semi-online rent set spans $[t(b) - T, t(b) + 2T)$. We split the $3T$ interval into first $T$ and last $2T$: the latter could be upper bounded by $\lambda_1(b)$ using Lemma 16, and we could find that the former is at most $L/2$:

- When $d^* - r^* < 2T$, $t(b) - r^* < (d^* - r^*)/2$, then $\min\{T, t(b) - r^*\} < L/2$.
- When $d^* - r^* \ge 2T$, $L = 2T$, and then $\min\{T, t(b) - r^*\} \le T = L/2$.

So we can conclude that

$$|\mathcal{J}_1| \le \sum_{b\in B_0} \lambda_1(b) + \sum_{b\in B_1} (\lambda_1(b) + L/2).$$

For the case $i \ge 2$, all jobs released in sub-interval $i$ can be allocated at most $[\theta_{i-1}+1, d^*)$, and by Lemma 16 each semi-online batch covers at most $2\cdot(2^{-i}\cdot L)$. Like $i = 1$, the inequality follows direct counting on $\cup_{j=0}^{i} B_j$. ◀

Thus far, we are ready to prove Lemma 15 by a charging argument.

**Proof of Lemma 15.** Recall that in Lemma 17 we have

$$A(r^*, d^*) \geq \sum_{b \in B_0} (2\max\{\lambda_1(b) - T, 0\} + 2\lambda_1(b)) + \sum_{b \in B_1} (2\lambda_1(b) + 2\min\{T, \lambda_1(b)\}) + \sum_{i \geq 2} 4 \cdot (2^{-i} \cdot L) \cdot |B_i|. \tag{1}$$

Also, by Lemma 19,

$$\mathcal{J}(r^*, d^*) \leq \sum_{b \in B_0} \lambda_1(b) + \sum_{b \in B_1} (\lambda_1(b) + L/2) + \sum_{i \geq 2} \left( \sum_{b \in B_0} \lambda_i(b) + 2 \cdot (2^{-i} \cdot L) \cdot \sum_{j=1}^{i} |B_j| \right). \tag{2}$$

Using these two inequalities, we charge the upper bound of $\mathcal{J}(r^*, d^*)$ and the lower bound of $A(r^*, d^*)$ to each $b \in B$. We prove that for each $b$, the charged amount of $\mathcal{J}(r^*, d^*)$'s upper bound is at most $A(r^*, d^*)$'s lower bound.

First, for $b \in B_0$, the contribution of $b$ to the lower bound of $A(r^*, d^*)$ (i.e., RHS of Equation (1)) is: $2\max\{\lambda_1(b) - T, 0\} + 2\lambda_1(b)$. The contribution to the upper bound of $\mathcal{J}(r^*, d^*)$ (i.e., RHS of Equation (2)) is: $\lambda_1(b) + \sum_{i \geq 2} \lambda_i(b)$. Note that $b \in B_0$ only contributes to a prefix of $[r, d)$, it is easy to see that $\lambda_i(b) \leq 2^{1-i}\lambda_1(b)$, and thus

$$\lambda_1(b) + \sum_{i \geq 2} \lambda_i(b) \leq \lambda_1(b) + \sum_{i \geq 2} 2^{1-i}\lambda_1(b) < 2\lambda_1(b).$$

We are done for $b \in B_0$.

Second, for $b \in B_1$, the contribution of $b$ to the lower bound of $A(r^*, d^*)$ (i.e., RHS of Equation (1)) is: $2\lambda_1(b) + 2\min\{T, \lambda_1(b)\}$. The contribution to the upper bound of $\mathcal{J}(r^*, d^*)$ (i.e., RHS of Equation (2)) is: $\lambda_1(b) + L/2 + \sum_{i \geq 2} 2 \cdot (2^{-i} \cdot L)$. Then, we have

$$\begin{aligned} \lambda_1(b) + L/2 + \sum_{i \geq 2} 2 \cdot (2^{-i} \cdot L) &< \lambda_1(b) + L/2 + 2 \cdot \left(2^{-1} \cdot L\right) \\ &\leq \lambda_1(b) + L/2 + 2 \cdot \min\{T, \lambda_1(b)\} \\ &\leq 2\lambda_1(b) + 2\min\{T, \lambda_1(b)\}. \end{aligned}$$

The last inequality holds by Lemma 16. Therefore, we are done for $b \in B_1$.

Finally, for $b \in B_{i \geq 2}$, the contribution of $b$ to the lower bound of $A(r^*, d^*)$ (i.e., RHS of Equation (1)) is: $4 \cdot (2^{-i} \cdot L)$. The contribution to the upper bound of $\mathcal{J}(r^*, d^*)$ (i.e., RHS of Equation (2)) is: $\sum_{i' \geq i} 2 \cdot (2^{-i'} \cdot L)$. We are done because $\sum_{i' \geq i} 2^{-i'} < 2^{1-i}$. Summing up three parts, we have proved that $A(r^*, d^*) \geq \mathcal{J}(r^*, d^*)$. ◀

## 5.2 A Remark on Running Time

We only need to recalculate SemiOnline if the job set gets updated, and the procedure of reconstructing the rent set in SemiOnline can be maintained incrementally. Thus, it is possible to implement the algorithm calling EDF at most $n + \mathsf{OPT} \leq 2n$ times, and hence achieve a worst case guarantee of $O(n^2 \log n)$. Also, note that a job can influence the calculation of SemiOnline for at most $O(T)$ time units, so the SemiOnline can also update in $O(nw \log w)$ if there are at most $O(w)$ jobs within any interval of length $O(T)$. Therefore, the online algorithm is efficient in terms of worst case guarantee and also average online updating.

## 6 Online Rent Minimization with Delay

In the version with delay, we are also given an online released job set $\mathcal{J}$ and a rent length $T$. We aim to minimize the number of rents needed to process all jobs. The notations are the same as in the Online Rent Minimization problem. Moreover, we are given a nonnegative integer $\lambda$ as the delay parameter. It means that if we rent a machine at time $t$, we will have an active machine at $[t+\lambda, t+\lambda+T)$. Note that it is impossible to serve an unknown emergency job with $d_j - r_j \leq \lambda$ online; following Chen and Zhang [5], we require that the active time $d_j - r_j$ is at least $\lambda + 1$.

We use the following reduction lemma and our 6-competitive no-delay algorithm as a black box to prove Theorem 2. Chen and Zhang [5] also mention this approach.

▶ **Lemma 20** (Reduction). *If* $\mathsf{ALG}(\mathcal{J}) \leq \Gamma \cdot \mathsf{OPT}(\mathcal{J})$ *for every job set* $\mathcal{J}$*, we have an algorithm* $\mathsf{ALG}_\lambda$ *that guarantees*

$$\mathsf{ALG}_\lambda(\mathcal{J}, \lambda) \leq \Gamma \cdot (\lambda + 1) \cdot \mathsf{OPT}(\mathcal{J}),$$

*if* $\forall j \in \mathcal{J}$, $d_j - r_j \geq \lambda + 1$.

After proving Lemma 20, Theorem 2 follows directly. See the full version for a complete proof.

▶ **Theorem 2.** *As a corollary of Theorem 1, there exists an efficient* $6(\lambda+1)$*-competitive algorithm when we need* $\lambda$ *time to finish each rent.*

## 7 Conclusion and Future Work

In conclusion, our main contribution is a 6-competitive algorithm for the Online Rent Minimization problem under unit-size jobs, which follows the oracle-based framework.

Since the Online Rent Minimization problem is a generalization of the Online Machine Minimization problem, where we have an optimal $e$-competitive algorithm, one major question is: Is the Rent Minimization problem strictly harder than the Machine Minimization problem?

On the other hand, we are also interested in the power of oracle-based algorithms. Note that the optimal $e$-competitive algorithm for Machine Minimization follows the oracle-based framework. It is interesting to ask: What is the best competitive ratio we can achieve for the Online Rent Minimization problem by using the oracle-based framework? The Semi-Online captures our current understanding of the possible range of optimal solutions, so replacing it with an optimal oracle cannot improve ratio directly by the same argument in the paper. Is it possible to obtain a better ratio with access to an optimal oracle?

## Abstract

Submodular maximization has been a central topic in theoretical computer science and combinatorial optimization over the last decades. Plenty of well-performed approximation algorithms have been designed for the problem over a variety of constraints. In this paper, we consider the submodular multiple knapsack problem (SMKP). In SMKP, the profits of each subset of elements are specified by a monotone submodular function. The goal is to find a feasible packing of elements over multiple bins (knapsacks) to maximize the profit. Recently, Fairstein et al. [ESA20] proposed a nearly optimal $(1 - e^{-1} - \epsilon)$-approximation algorithm for SMKP. Their algorithm is obtained by combining configuration LP, a grouping technique for bin packing, and the continuous greedy algorithm for submodular maximization. As a result, the algorithm is somewhat sophisticated and inherently randomized. In this paper, we present an arguably simple deterministic combinatorial algorithm for SMKP, which achieves a $(1 - e^{-1} - \epsilon)$-approximation ratio. Our algorithm is based on very different ideas compared with Fairstein et al. [ESA20].

## 1 Introduction

The *multiple knapsack problem* (MKP) is defined as follows. We are given a set $N$ of $n$ elements and a set $M$ of $m$ bins (knapsacks). Each element $u \in N$ has a positive cost $c(u) > 0$ and a positive profit $p(u) > 0$. The cost (profit) of a subset $S \subseteq N$ equals the sum of the costs (profits) of its elements. The $j$-th bin in $M$ has a positive budget $B_j > 0$ for $1 \leq j \leq m$. A subset $S \subseteq N$ is feasible if there is a disjoint partition $\{S_j\}_{j=1}^m$ of $S$ such that $c(S_j) \leq B_j$ for $1 \leq j \leq m$. The goal is to find a feasible set $S$ (and its partition $\{S_j\}_{j=1}^m$) whose profit is maximized. It is well-known that the problem admits a PTAS but no FPTAS assuming P $\neq$ NP [18, 5, 17].

In this paper, we consider the submodular generalization of the above problem, referred to as the *submodular multiple knapsack problem* (SMKP). In SMKP, the profit is in general non-additive and specified by a *monotone submodular* function $f : 2^N \to \mathbb{R}_+$. Here, a set function $f : 2^N \to \mathbb{R}$ is monotone if $f(S) \leq f(T)$ for any $S \subseteq T$ and submodular if

[1] Corresponding author

$f(S \cup \{u\}) - f(S) \geq f(T \cup \{u\}) - f(T)$ for any $S \subseteq T$ and $u \notin T$. The goal is again to find a feasible set $S$ which maximizes the profit $f(S)$. When $m = 1$, the problem reduces to submodular maximization under a knapsack constraint, which enjoys an optimal $(1 - e^{-1})$-approximation [18, 25].

Submodular functions capture the effect of diminishing returns in the economy and generalize many well-known functions such as coverage functions, cut functions, matroid rank functions, and log determinants. By introducing a submodular objective, SMKP falls in the field of submodular maximization, which studies maximization problems with submodular objectives, including maximum coverage problem, maximum cut problem, submodular welfare problem [26], influence maximization [19]. The study of submodular maximization has lasted for more than forty years. As early as 1978, it was shown that for monotone submodular maximization, a greedy algorithm achieves a $(1 - e^{-1})$-approximation under the cardinality constraint [24] and a $1/2$ approximation under the matroid constraint [15]. On the other hand, even for the cardinality constraint, the problem does not admit an approximation ratio better than $1 - e^{-1}$ [23]. It was a longstanding open question whether the problem admits a $(1 - e^{-1})$-approximation under the matroid constraint. In 2008, Vondrák [26] made a big breakthrough and answered this question affirmatively by proposing the so-called *continuous greedy* algorithm. Since then, plenty of optimal or well-performed approximation algorithms have been proposed for submodular maximization over a variety of constraints [2, 3, 4, 7, 12, 14, 16, 21, 22, 27].

For SMKP, a nearly optimal $(1-e^{-1}-\epsilon)$-approximation algorithm based on the continuous greedy technique was recently proposed in [9]. Their algorithm relies on two key ideas. First, they showed that by defining a configuration LP, an SMKP instance whose all bins have the same budget can be reduced to submodular maximization under 2-dimensional packing constraints (SMPC). Second, they developed a grouping technique inspired by [6] to convert a general SMKP instance to a leveled instance where bins are partitioned into blocks and bins in the same block have the same budget. In this way, they are able to reduce a general SMKP instance to an SMPC instance. They finally finished their work by a refined analysis of the continuous greedy algorithm for SMPC.

The techniques adopted by [9] and the way to combine them are somewhat sophisticated, which makes their algorithm not easy to understand and implement. Besides, the continuous greedy technique involves a sampling process and therefore their algorithm is inherently randomized. To the best of our knowledge, no deterministic algorithm was known for SMKP. In this paper, we present a simple deterministic combinatorial algorithm for SMKP, which achieves a $(1 - e^{-1} - \epsilon)$-approximation ratio.

▶ **Theorem 1.** *For any $\epsilon > 0$, there exists a deterministic combinatorial algorithm for SMKP that achieves a $(1 - e^{-1} - \epsilon)$-approximation ratio and runs in polynomial time.*

## 1.1 Technique Overview

We start with solving SMKP instances under the *identical case*, where all the bins have the same budget $B$. Such instances can be reduced to exponential-size instances of submodular maximization subject to a cardinality constraint. Inspired by this observation, we design an algorithm for the identical case by mimicking the greedy algorithm for the cardinality constraint. See Section 1.1.1 for details.

For any general SMKP instance, we use the grouping technique developed by [9] to convert it to the so-called leveled instance. While Fairstein et al. [9] resorts to the configuration LP to solve the leveled instance, we present a simple $(1 - e^{-1} - \epsilon)$-approximation algorithm for it by exploiting its structure and invoking our algorithm for the identical case as a subroutine. See Section 1.1.2 for details.

### 1.1.1 The Identical Case

Under the identical case, SMKP can be regarded as an exponential-size instance of submodular maximization subject to a cardinality constraint. Specifically, let $\mathcal{I} = \{S \subseteq N \mid c(S) \leq B\}$. For any $\mathcal{T} \subseteq \mathcal{I}$, define $g(\mathcal{T}) = f(\cup_{S \in \mathcal{T}} S)$. It is easy to verify that $g$ is a monotone submodular function. Then, $\max\{g(\mathcal{T}) \mid |\mathcal{T}| \leq m\}$ describes the SMKP instance under the identical case.

Inspired by the above observation, our algorithm packs bins one by one and manages to make each bin pack at least the average marginal value of the optimal solution over $m$ bins. In other words, for the $j$-th bin, it aims to find a set $S_j$ such that $f(S_j \mid \cup_{i=1}^{j-1} S_i) \geq \frac{1}{m} f(OPT \mid \cup_{i=1}^{j-1} S_i)$, where $OPT$ denotes the optimal solution. This naturally leads to $(1 - e^{-1})$ approximation.

We take the first bin as an example and explain that it is possible to find a set $S_1$ such that $f(S_1) \geq \frac{1}{m} f(OPT)$ when $m$ is large enough. If $S_1$ is obtained by packing elements in sequence greedily according to their marginal densities, then we can prove

$$f(S_1) \geq (1 - e^{-c(S_1)/c(OPT)}) \cdot f(OPT).$$

If we further allow $S_1$ to violate the budget constraint by adding one more element, then $c(S_1) \geq B$. Together with $c(OPT) \leq mB$, we have

$$f(S_1) \geq (1 - e^{-1/m}) \cdot f(OPT) \approx \frac{1}{m} f(OPT).$$

The story has not ended since the last element added to $S_1$ violates the budget constraint. To handle this issue, our algorithm divides elements into large and small elements according to their costs and then packs them in different ways. Specifically, an element $u \in N$ is large if $c(u) > \epsilon B$ and small otherwise. Our algorithm packs large elements by enumeration since there are polynomial ways to pack them in total. It packs small elements greedily as before. In this way, the last element added to $S_1$ has a cost less than $\epsilon B$ and there are at most $m$ such elements. Thus, all of them can be repacked using additional $\epsilon m$ bins and all $S_j$'s will then become feasible.

In Lemma 5, we show that $f(S_1) \geq \frac{1}{m} f(OPT)$ still holds although we introduce the enumeration step.

### 1.1.2 The General Case

Observe that a general SMKP instance can be reduced to an exponential-size instance of submodular maximization subject to a partition matroid constraint. Specifically, let $\mathcal{I}_j = \{S \subseteq N \mid c(S) \leq B_j\}$ be the feasible region for the $j$-th bin and $\mathcal{I} = \cup_{j=1}^{m} \mathcal{I}_j$. For any $\mathcal{T} \subseteq \mathcal{I}$, define $g(\mathcal{T}) = f(\cup_{S \in \mathcal{T}} S)$. Then, $\max\{g(\mathcal{T}) \mid |\mathcal{T} \cap \mathcal{I}_j| \leq 1, 1 \leq j \leq m\}$ describes the general SMKP instance. Recall that the optimal $(1 - e^{-1})$-approximation for the partition matroid constraint is obtained via the continuous greedy algorithm [26]. Thus, it is not a good idea to solve general SMKP instances directly.

The difficulty in solving general SMKP stems from that the budgets are distinct. Therefore, we first consider an "intermediate" instance where bins can be partitioned into $r$ blocks $\{M_k\}_{k=1}^{r}$ such that block $M_k$ contains sufficiently many bins and all of them have the same budget $B_k$. Clearly, this instance is slightly more general than the instance under the identical case. It can also be reduced to an exponential-size instance of submodular maximization subject to a partition matroid constraint. Specifically, let $\mathcal{I}_k = \{S \subseteq N \mid c(S) \leq B_k\}$ for $1 \leq k \leq r$ and $\mathcal{I} = \cup_{k=1}^{r} \mathcal{I}_k$. For any $\mathcal{T} \subseteq \mathcal{I}$, define $g(\mathcal{T}) = f(\cup_{S \in \mathcal{T}} S)$. Then, $\max\{g(\mathcal{T}) \mid |\mathcal{T} \cap \mathcal{I}_k| \leq |M_k|, 1 \leq k \leq r\}$ describes the above SMKP instance.

The above two reductions lead to different constraints $|\mathcal{T} \cap \mathcal{I}_j| \leq 1$ and $|\mathcal{T} \cap \mathcal{I}_k| \leq |M_k|$. For convenience, assume that $1/\epsilon$ is an integer, $|M_k| \geq 1/\epsilon$ and $\epsilon|M_k|$ is an integer for all $1 \leq k \leq r$. Our key observation is that for constraint $\{\mathcal{T} \subseteq \mathcal{I} \mid |\mathcal{T} \cap \mathcal{I}_k| \leq |M_k|, 1 \leq k \leq r\}$, there is a simple deterministic algorithm that can achieve $(1 - e^{-1} - \epsilon)$-approximation. The algorithm runs in $1/\epsilon$ iterations. In each iteration, block $M_k$ is visited in sequence and the algorithm will pack $\epsilon|M_k|$ bins in $M_k$. This forms an SMKP instance under the identical case. Thus, we can invoke our algorithm for the identical case to solve it.

Finally, we apply a grouping technique from [9] to convert a general instance to a $t$-leveled instance which has blocks $\{M_k\}_{k=1}^{r}$ and bins in the same block have the same budget. Besides, each of the first $t^2$ blocks contains a single bin, and each of the remaining blocks contains at least $t$. This is very similar to the intermediate instance before and it is not difficult to handle the first $t^2$ blocks.

## 1.2 Related Work

MKP has been fully studied previously. Kellerer [18] proposed the first PTAS for the identical case of the problem. Soon after, Chekuri and Khanna [5] proposed a PTAS for the general case. The result was later improved to an EPTAS by Jansen [17]. On the other hand, it is easy to see that the problem does not admit an FPTAS even for the case of $m = 2$ bins unless P = NP [5].

SMKP contains submodular maximization subject to a knapsack constraint as a special case. For this problem, there is an optimal $(1 - e^{-1})$-approximation algorithm that runs in $O(n^5)$ time [18, 25]. Later, a fast algorithm was proposed in [1] that achieves a $(1 - e^{-1} - \epsilon)$-approximation ratio and runs in $n^2(\log n/\epsilon)^{O(1/\epsilon^8)}$ time[2]. This was recently improved in [8] by a new algorithm that runs in $(1/\epsilon)^{O(1/\epsilon^4)} n \log^2 n$ time. The last two algorithms are impractical due to their high dependence on $1/\epsilon$. Very recently, a $(1 - e^{-1})$-approximation algorithm was proposed in [20, 13], which runs in $O(n^4)$ time. This algorithm can be further accelerated to achieve $(1 - e^{-1} - \epsilon)$-approximation in $\widetilde{O}(n^3/\epsilon)$ time.

To the best of our knowledge, SMKP was first considered in Feldman's Ph. D thesis [11]. Feldman proposed a polynomial time $(1/9 - o(1))$-approximation algorithm and a pseudo-polynomial time $1/4$ approximation algorithm for the general case of SMKP. For the identical case, he improved the results to a polynomial time $((e-1)/(3e-1) - o(1)) \approx 0.24$ approximation algorithm and a pseudo-polynomial time $(1 - e^{-1} - o(1))$-approximation algorithm. These algorithms are based on the *continuous greedy* technique and *contension resolution schemes* [27], and hence involve randomness inherently. Recently, Fairstein et al. [9] proposed a polynomial time randomized $(1 - e^{-1} - \epsilon)$-approximation algorithm for general SMKP.

## 1.3 Organization

In Section 2, we first formulate SMKP and introduce some notations. Then, we present a greedy algorithm that packs elements greedily according to their marginal densities. In Section 3, we present a $(1 - e^{-1} - \epsilon)$-approximation algorithm for SMKP under the identical case, assuming the number of bins $m \geq 1/(4\epsilon^3)$. In Section 4, we present a $(1 - e^{-1} - \epsilon)$-approximation algorithm for general SMKP. We conclude the paper and list some open problems in Section 5.

[2] As pointed out by [28, 8], the result in [1] has some issues.

**Algorithm 1** GREEDY.

**Input:** elements $N$, budgets $\{B_j\}_{j=1}^m$, profit $f$, cost $c$.
$S_j = \emptyset$ for $1 \le j \le m$ and $S = \cup_{j=1}^m S_j$.
**while** $N \setminus S \neq \emptyset$ *and there exists* $1 \le j \le m$ *such that* $c(S_j) < B_j$ **do**
  $u^* = \arg\max_{u \in N \setminus S} f(u \mid S)/c(u)$.
  $S_j = S_j + u^*$ and $S = S + u^*$.
**end**
**return** $S = \cup_{j=1}^m S_j$.

## 2 Preliminaries

An instance of the *submodular multiple knapsack problem* (SMKP) is defined as follows. We are given a set $N$ of $n$ elements and a set $M$ of $m$ bins (knapsacks). Each element $u \in N$ has a positive cost $c(u) > 0$. A subset $S \subseteq N$ of elements has a cost $c(S) = \sum_{u \in S} c(u)$. The $j$-th bin in $M$ has a positive budget $B_j > 0$ for $1 \le j \le m$. A subset $S \subseteq N$ is feasible for the problem if there is a disjoint partition $\{S_j\}_{j=1}^m$ of $S$ such that $c(S_j) \le B_j$ for $1 \le j \le m$. The profit of each subset $S \subseteq N$ of elements is specified by a *normalized*, *monotone* and *submodular* function $f : 2^N \to \mathbb{R}_+$. For a non-negative set function $f : 2^N \to \mathbb{R}_+$, it is called *normalized* if $f(\emptyset) = 0$, *monotone* if $f(S) \le f(T)$ for any $S \subseteq T$, and *submodular* if $f(S \cup \{u\}) - f(S) \ge f(T \cup \{u\}) - f(T)$ for any $S \subseteq T$ and $u \notin T$. The goal is to find a feasible set $S$ (and its partition $\{S_j\}_{j=1}^m$) such that the profit $f(S)$ (or $f(\cup_{j=1}^m S_j)$) is maximized.

An SMKP instance is specified by $(N, M, \{B_j\}_{j \in M}, f, c)$. Throughout this paper, we use $OPT$ to denote the optimal solution of an SMKP instance. Let $S + u$ be a shorthand for $S \cup \{u\}$. For the objective function $f$, we also use $f(u \mid S)$ and $f(T \mid S)$ to denote the marginal values $f(S + u) - f(S)$ and $f(S \cup T) - f(S)$, respectively. $f$ is accessed via a value oracle that returns $f(S)$ when set $S \subseteq N$ is queried. The query complexity of any algorithm for SMKP should be polynomial in the size of the problem.

### 2.1 The Greedy Algorithm

We first present a greedy algorithm, which is depicted as Algorithm 1. It serves as a cornerstone for other algorithms in this paper. It returns a (possibly infeasible) set with a $(1 - 1/e)$ approximation ratio. It packs elements one by one greedily, according to their *densities*, namely the ratios of their marginal values to their costs. The process continues provided there exists some bin whose budget has not been exhausted yet. As a side effect, each bin may pack one more element whose addition exceeds the budget of that bin. For convenience, we refer to this element as a *reserved element*. Nonetheless, we show that the set returned by Algorithm 1 has a large profit.

▶ **Lemma 2.** *Let $S$ be the set returned by Algorithm 1. For any set $X \subseteq N$, we have*

$$f(S) \ge \left(1 - e^{-c(S)/c(X)}\right) \cdot f(X).$$

**Proof.** If $c(S) < \sum_{j=1}^m B_j$, there is some $j$ such that $c(S_j) < B_j$. It means that Algorithm 1 ended with $S = N$. Thus, the lemma follows by monotonicity.

Now consider the case where $c(S) \ge \sum_{j=1}^m B_j$. Assume that $S = \{u_1, u_2, \ldots, u_\ell\}$, and for $0 \le i \le \ell$, $S^i = \{u_1, u_2, \ldots u_i\}$ denotes the first $i$ elements packed by Algorithm 1. Then, by the greedy rule,

$$\frac{f(u_i \mid S^{i-1})}{c(u_i)} \ge \frac{f(x \mid S^{i-1})}{c(x)}, \forall\, x \in X \setminus S^{i-1}.$$

By moving $c(x)$ to the left and summing over $x \in X \setminus S^{i-1}$,

$$c(X \setminus S^{i-1}) \cdot \frac{f(u_i \mid S^{i-1})}{c(u_i)} \geq \sum_{x \in X \setminus S^{i-1}} f(x \mid S^{i-1}) \geq f(X \setminus S^{i-1} \mid S^{i-1}).$$

The last inequality holds since $f$ is submodular. This gives us

$$\frac{f(S^i) - f(S^{i-1})}{c(u_i)} \geq \frac{f(X \setminus S^{i-1} \mid S^{i-1})}{c(X \setminus S^{i-1})} \geq \frac{f(X) - f(S^{i-1})}{c(X)}. \tag{1}$$

The last inequality holds since $f$ is monotone and $c(X \setminus S^{i-1}) \leq c(X)$.

Next, we assume that $f(X) > f(S^\ell)$, since otherwise the lemma already holds. Under this assumption, it must hold that $c(u_i) < c(X)$, since otherwise inequality (1) implies that $f(X) \leq f(S^i) \leq f(S^\ell)$. A contradiction! Now we can rearrange inequality (1) and obtain that

$$f(X) - f(S^i) \leq \left(1 - \frac{c(u_i)}{c(X)}\right)(f(X) - f(S^{i-1})).$$

By expanding the recurrence, we have

$$f(X) - f(S^i) \leq \prod_{j=1}^{i} \left(1 - \frac{c(u_j)}{c(X)}\right) \cdot f(X) \leq \prod_{j=1}^{i} e^{-\frac{c(u_j)}{c(X)}} \cdot f(X) = e^{-\frac{c(S^i)}{c(X)}} \cdot f(X).$$

The second inequality holds due to $e^x \geq 1 + x$. Hence we have

$$f(S^i) \geq \left(1 - e^{-c(S^i)/c(X)}\right) \cdot f(X).$$

The lemma follows by plugging $i = \ell$ into it. ◀

The above lemma immediately leads to the following corollary.

▶ **Corollary 3.** *The set $S$ returned by Algorithm 1 satisfies $f(S) \geq (1 - e^{-1}) \cdot f(OPT)$.*

**Proof.** If $c(S) < \sum_{j=1}^{m} B_j$, there is some $j$ such that $c(S_j) < B_j$. It means that Algorithm 1 ended with $S = N$. Thus, the corollary follows by monotonicity. If $c(S) \geq \sum_{j=1}^{m} B_j$, then $c(S) \geq c(OPT)$. The corollary follows from Lemma 2. ◀

## 3 The identical Case

In this section, we present a deterministic $(1 - e^{-1} - \epsilon)$ approximation algorithm for SMKP under the identical case, where all bins have the same budget. Our algorithm is depicted as Algorithm 2 and works when $m \geq 1/(4\epsilon^3)$. It packs bins one by one and manages to make each bin pack at least the average marginal value of the optimal solution over $m$ bins. In other words, for the $j$-th bin, it aims to find a set $S_j$ such that $f(S_j \mid \cup_{i=1}^{j-1} S_i) \geq \frac{1}{m} f(OPT \mid \cup_{i=1}^{j-1} S_i)$. This naturally leads to $(1 - e^{-1})$ approximation. For this purpose, Algorithm 2 divides elements into *large* and *small* elements according to their costs. Given input $\epsilon$, an element $u \in N$ is large if $c(u) > \epsilon B$ and small otherwise. Let $N_\ell = \{u \in N \mid c(u) > \epsilon B\}$ be the set of large elements and $N_s = N \setminus N_\ell$. For the $j$-th bin, Algorithm 2 first enumerates all feasible subsets of large elements. Then, for every such subset, Algorithm 1 is invoked over small elements to augment it. Finally, the one with the maximum marginal value is assigned to $S_j$.

Due to the call of Algorithm 1, $S_j$ might contain a reserved element, which is the last added into $S_j$ and violates the budget. To remedy this issue, Algorithm 2 divides the bins into two classes: the first $(1 - \epsilon)m$ bins are called *working bins* and the last $\epsilon m$ bins are

**Algorithm 2** IDENTICAL-CASE.

**Input:** elements $N$, budget $B$, number of bins $m$, profit $f$, cost $c$, constant $\epsilon > 0$.
1 Let the first $(1-\epsilon)m$ bins be *working bins* and the last $\epsilon m$ bins be *reserved bins*.
2 Define $N_\ell = \{u \in N \mid c(u) > \epsilon B\}$ and let $N_s = N \setminus N_\ell$.
3 $S_j = \emptyset$ for $1 \le j \le m$ and $T = \cup_{j=1}^{m} S_j$.
4 **for** $j = 1$ *to* $(1-\epsilon)m$ **do**
5  **foreach** *subset* $E \subseteq N_\ell$ *such that* $c(E) \le B$ **do**
6  $G_E = \text{GREEDY}(N_s, B - c(E), f(\cdot \mid T \cup E), c(\cdot))$.
7  **end**
8  $S_j = \arg\max_E f(E \cup G_E \mid T)$ and $T = \cup_{j=1}^{m} S_j$.
9 **end**
10 Repack the reserved elements in $T$ into the reserved bins.
11 **return** $T = \cup_{j=1}^{m} S_j$.

called *reserved bins*. The procedure described above only proceeds with the working bins. After that, Algorithm 2 repacks all reserved elements into the reserved bins. We will show that in this way, Algorithm 2 produces a feasible solution and the loss of the profit is little even if it does not use the reserved bins to pack new elements.

We now give an analysis of Algorithm 2. For $1 \le j \le (1-\epsilon)m$, let $S_j$ be defined as in line 8 of Algorithm 2 and $T_j = \cup_{i=1}^{j} S_i$. We first show that Algorithm 2 returns a feasible solution.

▶ **Lemma 4.** *Algorithm 2 produces a feasible solution.*

**Proof.** For $1 \le j \le (1-\epsilon)m$, observe that each $S_j$ contains at most one reserved element due to the call of Algorithm 1. By repacking those reserved elements into the reserved bins, each $S_j$ becomes feasible. Besides, the cost of each reserved element is at most $\epsilon B$ since it is a small element. Thus, a reserved bin can pack at least $1/\epsilon$ reserved elements. Then, $\epsilon m$ reserved bins can pack $m > (1-\epsilon)m$ reserved elements without exceeding their budgets. Therefore, Algorithm 2 produces a feasible solution. ◀

Next, we present Lemma 5 for Algorithm 2.

▶ **Lemma 5.** *Assume that* $m \ge 1/(4\epsilon^3)$. *For every* $1 \le j \le (1-\epsilon)m$,

$$f(S_j \mid T_{j-1}) \ge \frac{1-2\epsilon}{m} \cdot f(OPT \mid T_{j-1}).$$

**Proof.** For the sake of description, we define $g(\cdot) = f(\cdot \mid T_{j-1})$ and the lemma becomes $g(S_j) \ge \frac{1-2\epsilon}{m} \cdot g(OPT)$. Let $OPT_\ell = OPT \cap N_\ell$ and $OPT_s = OPT \setminus OPT_\ell$. We prove the lemma by case analysis, according to the cost and density of $OPT_s$.

**Case 1:** $c(OPT_s) \ge \epsilon m B$, namely $OPT_s$ has a large cost. Let $OPT_\ell = \cup_{j=1}^{m} OPT_{\ell,j}$ and $OPT_s = \cup_{j=1}^{m} OPT_{s,j}$, where $OPT_{\ell,j}$ and $OPT_{s,j}$ are the large and small elements packed in the $j$-th bin, respectively. For each $1 \le j \le m$, since $c(OPT_{\ell,j}) \le B$, $OPT_{\ell,j}$ will be enumerated during the **foreach** loop. Let $G_j$ be the output of GREEDY (Algorithm 1) starting from $OPT_{\ell,j}$. We will show that one of $OPT_{\ell,j} \cup G_j$ satisfies the lemma.
If $c(G_j) < B - c(OPT_{\ell,j})$, it means that Algorithm 1 ended with $G_j = OPT_s$ and therefore $g(G_j \mid OPT_{\ell,j}) = g(OPT_s \mid OPT_{\ell,j})$. If $c(G_j) \ge B - c(OPT_{\ell,j})$, then $c(G_j) \ge c(OPT_{s,j})$.

By Lemma 2,

$$\begin{aligned} g(G_j \mid OPT_{\ell,j}) &\geq \left(1 - e^{-c(G_j)/c(OPT_s)}\right) \cdot g(OPT_s \mid OPT_{\ell,j}) \\ &\geq \left(1 - e^{-c(OPT_{s,j})/c(OPT_s)}\right) \cdot g(OPT_s \mid OPT_{\ell,j}) \\ &\geq \left(\frac{c(OPT_{s,j})}{c(OPT_s)} - \frac{c(OPT_{s,j})^2}{2 \cdot c(OPT_s)^2}\right) \cdot g(OPT_s \mid OPT_{\ell,j}) \\ &\geq \left(\frac{c(OPT_{s,j})}{c(OPT_s)} - \frac{1}{2\epsilon^2 m^2}\right) \cdot g(OPT_s \mid OPT_{\ell,j}) \\ &\geq \left(\frac{c(OPT_{s,j})}{c(OPT_s)} - \frac{2\epsilon}{m}\right) \cdot g(OPT_s \mid OPT_{\ell,j}). \end{aligned}$$

The third inequality holds since $1 - e^{-x} \geq x - x^2/2$ for $x \geq 0$. The fourth inequality holds since $c(OPT_{s,j})/c(OPT_s) \leq 1/(\epsilon m)$. The last inequality holds since $m \geq 1/(4\epsilon^3)$. By adding $g(OPT_{\ell,j})$ on both sides of the last inequality and summing over $j$,

$$\begin{aligned} \sum_{j=1}^{m} g(OPT_{\ell,j} \cup G_j) &\geq \sum_{j=1}^{m} \left(\frac{c(OPT_{s,j})}{c(OPT_s)} - \frac{2\epsilon}{m}\right) \cdot g(OPT_s \mid OPT_{\ell,j}) + \sum_{j=1}^{m} g(OPT_{\ell,j}) \\ &\geq \sum_{j=1}^{m} \left(\frac{c(OPT_{s,j})}{c(OPT_s)} - \frac{2\epsilon}{m}\right) \cdot g(OPT_s \mid OPT_\ell) + g(OPT_\ell) \\ &= (1 - 2\epsilon) \cdot g(OPT_s \mid OPT_\ell) + g(OPT_\ell) \\ &\geq (1 - 2\epsilon) \cdot g(OPT). \end{aligned}$$

Hence, the maximum of $OPT_{\ell,j} \cup G_j$ satisfies the lemma and so does $S_j$.

**Case 2:** $g(OPT_s) \geq (1 - e^{-B/c(OPT_s)})^{-1} \cdot \frac{g(OPT)}{m}$, namely the density of $OPT_s$ is large. Consider one of the iterations of **foreach** loop where $E = \emptyset$. Note that it is augmented by $G_\emptyset$ via Greedy (Algorithm 1). If $c(G_\emptyset) < B$, it means that Algorithm 1 ended with $G_\emptyset = OPT_s$. Then,

$$g(G_\emptyset) = g(OPT_s) \geq (1 - e^{-B/c(OPT_s)})^{-1} \cdot \frac{g(OPT)}{m} \geq \frac{g(OPT)}{m}.$$

If $c(G_\emptyset) \geq B$, by Lemma 2,

$$g(G_\emptyset) \geq \left(1 - e^{-B/c(OPT_s)}\right) \cdot g(OPT_s) \geq \frac{g(OPT)}{m}.$$

This implies that $G_\emptyset$ satisfies the lemma and so does $S_j$.

**Case 3:** $c(OPT_s) < \epsilon m B$ and $g(OPT_s) < \left(1 - e^{-B/c(OPT_s)}\right)^{-1} \cdot \frac{g(OPT)}{m}$, namely both the cost and density of $OPT_s$ are small. We show that $OPT_s$ only contributes a negligible value in $OPT$:

$$\begin{aligned} g(OPT_s) &< (1 - e^{-1/\epsilon m})^{-1} \cdot \frac{g(OPT)}{m} \leq \left(\frac{1}{\epsilon m} - \frac{1}{2\epsilon^2 m^2}\right)^{-1} \frac{g(OPT)}{m} \\ &\leq \left(\frac{1}{2\epsilon m}\right)^{-1} \frac{g(OPT)}{m} = 2\epsilon \cdot g(OPT). \end{aligned}$$

The first inequality holds since $(1 - e^{-B/x})^{-1}$ is monotone increasing. The second holds since $1 - e^{-x} \geq x - x^2/2$ for $x \geq 0$. The third holds as long as $m \geq 1/\epsilon$. Hence, by submodularity,

$$g(OPT_\ell) \geq g(OPT) - g(OPT_s) \geq (1 - 2\epsilon) \cdot g(OPT),$$

and

$$\frac{1}{m}\sum_{j=1}^{m} g(OPT_{\ell,j}) \geq \frac{1}{m}\cdot g(OPT_\ell) \geq \frac{1-2\epsilon}{m}\cdot g(OPT).$$

This implies that the maximum of $OPT_{\ell,j}$ satisfies the lemma and so does $S_j$. ◀

By expanding the recurrence in Lemma 5, we have

▶ **Lemma 6.** *Assume that $m \geq 1/(4\epsilon^3)$. For every $1 \leq j \leq (1-\epsilon)m$,*

$$f(T_j) \geq (1 - e^{-j(1-2\epsilon)/m}) \cdot f(OPT).$$

**Proof.** By Lemma 5, for $1 \leq j \leq (1-\epsilon)m$,

$$f(S_j \mid T_{j-1}) \geq \frac{1-2\epsilon}{m}\cdot f(OPT \mid T_{j-1}).$$

By monotonicity of $f$,

$$f(T_j) - f(T_{j-1}) \geq \frac{1-2\epsilon}{m}\cdot (f(OPT) - f(T_{j-1})).$$

By rearranging the above inequality,

$$\left(1 - \frac{1-2\epsilon}{m}\right)(f(OPT) - f(T_{j-1})) \geq f(OPT) - f(T_j).$$

By expanding the recurrence,

$$f(OPT) - f(T_j) \leq \left(1 - \frac{1-2\epsilon}{m}\right)^j f(OPT) \leq e^{-j(1-2\epsilon)/m}\cdot f(OPT).$$

The last inequality holds since $e^{-x} \geq 1 - x$. Thus, we have

$$f(T_j) \geq (1 - e^{-j(1-2\epsilon)/m}) \cdot f(OPT).$$ ◀

We now provide a theoretical guarantee for Algorithm 2.

▶ **Theorem 7.** *When $m \geq 1/(4\epsilon^3)$, Algorithm 2 achieves a $(1 - e^{-1} - O(\epsilon))$ approximation ratio and uses $O(mn^{3+1/\epsilon})$ queries.*

**Proof.** For the approximation ratio, by plugging $j = (1-\epsilon)m$ into Lemma 6,

$$f(T_{(1-\epsilon)m}) \geq (1 - e^{-(1-\epsilon)(1-2\epsilon)}) \cdot f(OPT).$$

For the query complexity, observe that during the **foreach** loop, the number of subsets $E \subseteq N_\ell$ such that $c(E) \leq B$ is at most

$$\sum_{i=0}^{1/\epsilon} \binom{n}{i} = O(n^{1/\epsilon+1}).$$

Since each $E$ is augmented via Greedy, which uses $O(n^2)$ queries, the **foreach** loop uses $O(n^{1/\epsilon+3})$ in total. Then, Algorithm 2 overall uses $O(mn^{3+1/\epsilon})$ queries. ◀

# 4 The General Case

In this section, we present a deterministic $(1 - e^{-1} - \epsilon)$ approximation algorithm for solving general SMKP instances. A key difficulty is that the budgets of bins are distinct, which makes our technique for the identical case inapplicable. In Section 4.1, we introduce a grouping technique from [9], which reshapes any SMKP instance such that bins can be partitioned into *blocks* and almost every block contains sufficiently many bins with the same budget. Next, in Section 4.2, we show how one can design a nearly optimal algorithm for such instances.

## 4.1 Reshape the Instance

We first introduce a grouping technique from [9] to reshape any SMKP instance as follows.

▶ **Definition 8.** *A subset of bins $M' \subseteq M$ is called a block if for any $i, j \in M'$, $B_i = B_j$.*

▶ **Definition 9.** *For any $t \in \mathbb{N}_+$, a partition $\{M_k\}_{k=1}^r$ of bins $M$ is $t$-leveled if for every $1 \leq k \leq r$, $M_k$ is a block and $|M_k| = t^{\lfloor (k-1)/t^2 \rfloor}$.*

To gain some intuition, note that for every $1 \leq k \leq t^2$, block $M_k$ contains a single bin, and for every $t^2 < k \leq 2t^2$, block $M_k$ contains $t$ bins, etc. It follows that except for the first $t^2$ blocks, each of the remaining blocks contains at least $t$ bins with the same budget.

▶ **Lemma 10** ([9]). *There is a polynomial-time algorithm, referred to as* Block, *that takes a set of bins $M$, budgets $\{B_j\}_{j\in M}$ and a parameter $t \in \mathbb{N}_+$ as input, and returns a new set of bins $\widetilde{M} \subseteq M$, budgets $\{\widetilde{B}_j\}_{j\in\widetilde{M}}$ and a $t$-leveled partition $\{\widetilde{M}_k\}_{k=1}^r$ of bins $\widetilde{M}$ such that*

- *For every $j \in \widetilde{M}$, $\widetilde{B}_j \leq B_j$.*
- *For any SMKP instance $(N, M, \{B_j\}_{j\in M}, f, c)$ and a feasible solution $\{S_j\}_{j\in M}$ for it, there exists a feasible solution $\{\widetilde{S}_j\}_{j\in\widetilde{M}}$ for instance $(N, \widetilde{M}, \{\widetilde{B}_j\}_{j\in\widetilde{M}}, f, c)$ such that $f(\cup_{j\in\widetilde{M}} \widetilde{S}_j) \geq \left(1 - \frac{1}{t}\right) f(\cup_{j\in M} S_j)$ and $\cup_{j\in\widetilde{M}} \widetilde{S}_j \subseteq \cup_{j\in M} S_j$.*

The instance $(N, \widetilde{M}, \{\widetilde{B}_j\}_{j\in\widetilde{M}}, f, c)$ is called *$t$-leveled*. Lemma 10 tells us that any feasible solution for it is also feasible for the original instance $(N, M, \{B_j\}_{j\in M}, f, c)$, and an optimal solution for it causes a small loss in the profit.

## 4.2 The Final Algorithm

Now, we explain how one can design a nearly optimal algorithm for a $t$-leveled SMKP instance with bins $\widetilde{M}$, budgets $\{\widetilde{B}_j\}_{j\in\widetilde{M}}$ and a $t$-leveled partition $\{\widetilde{M}_k\}_{k=1}^r$ of $\widetilde{M}$.

For $t^2 < k \leq r$, block $\widetilde{M}_k$ contains $|\widetilde{M}_k| \geq t$ bins with the same budget $\widetilde{B}_k$. The problem restricted to each block $\widetilde{M}_k$ can be regarded as an SMKP instance under the identical case. Thus, a natural idea is to pack each block $\widetilde{M}_k$ in sequence by invoking Algorithm 2. However, we fail to get an optimal approximation via this procedure. Instead, we develop a technique that is inspired by [1]. We run $1/\epsilon$ iterations in total (assume that $1/\epsilon$ is an integer). In each iteration, we pack each block $\widetilde{M}_k$ in sequence but only pack $\epsilon|\widetilde{M}_k|$ bins (assume that $\epsilon|\widetilde{M}_k|$ is an integer). This forms an instance under the identical case with $\epsilon|\widetilde{M}_k|$ bins and therefore we can invoke Algorithm 2 to solve it.

For $1 \leq k \leq t^2$, block $\widetilde{M}_k$ contains a single bin with budget $\widetilde{B}_k$. Basically, we can use Greedy to pack elements. Likewise, we do not use the full budget at a time. Instead, we also run $1/\epsilon$ iterations. In each iteration, we pack elements using budget $(\epsilon - \epsilon^2)\widetilde{B}_k$. To avoid exceeding the budget, we only pack small elements $u$ satisfying $c(u) \leq \epsilon^2 \widetilde{B}_k$. To ensure this, we need to enumerate large-valued and large-cost elements in this bin. The overall procedure is depicted as Algorithm 3.

**Algorithm 3** The Final Algorithm for SMKP.

**Input:** elements $N$, bins $M$, budgets $\{B_j\}_{j\in M}$, profit $f$, cost $c$, constant $\epsilon > 0$.

Let $s = 1/(16\epsilon^9)$ and $t = 1/(4\epsilon^3)$.
Let $\mathcal{C} = \emptyset$.
$(\widetilde{M}, \{\widetilde{B}_j\}_{j\in\widetilde{M}}, \{\widetilde{M}_k\}_{k=0}^{r}) = \textsc{Block}(M, \{B_j\}_{j\in M}, t)$.
**foreach** *feasible solution* $\{E_j\}_{j=1}^{t^2}$ *such that* $|\cup_{j=1}^{m} E_j| \le s$ **do** \\ $E_j = \emptyset$ for $j > t^2$
  Let $E = \cup_{j=1}^{t^2} E_j$.
  Let $S_j = E_j$ for $1 \le j \le t^2$ and $S_j = \emptyset$ for $t^2 < j \le k$.
  **for** $i = 1$ *to* $1/\epsilon$ **do**
    **for** $k = 1$ *to* $r$ **do** \\ handle blocks one by one
      **if** $k \le t^2$ **then** \\ each block contains a single bin
        Let $D = \{u \in N \setminus E \mid f(u \mid E) > \frac{1}{s} \cdot f(E)\}$.
        Let $L_k = \{u \in N \setminus E \mid c(u) > \epsilon^2(\widetilde{B}_k - c(E_k))\}$.
        $R_k = \textsc{Greedy}(N \setminus (E \cup D \cup L_k), (\epsilon - \epsilon^2)(\widetilde{B}_k - c(E_k)), f(\cdot \mid \cup_{j=1}^{m} S_j), c(\cdot))$.
        $S_{k+1} = S_{k+1} \cup R_k$.
      **else** \\ each block contains $\ge t$ bins
        $\{R_j\}_{j\in\widetilde{M}_k} = \textsc{Identical-case}(N \setminus E, \widetilde{B}_k, \epsilon|\widetilde{M}_k|, f(\cdot \mid \cup_{j=1}^{m} S_j), c(\cdot), \epsilon)$.
        $S_j = S_j \cup R_j$ for $j \in \widetilde{M}_k$.
      **end**
    **end**
  **end**
  $\mathcal{C} = \mathcal{C} \cup \{\{S_j\}_{j=1}^{m}\}$.
**end**
**return** $\arg\max\{f(\cup_{j=1}^{m} S_j) \mid \{S_j\}_{j=1}^{m} \in \mathcal{C}\}$.

▶ **Theorem 11.** *Algorithm 3 achieves a* $1 - e^{-1} - O(\epsilon)$ *approximation ratio and uses a polynomial number of queries.*

**Proof.** Let $\widetilde{OPT} = \cup_{j=1}^{m} \widetilde{OPT}_j$ be the optimal solution of the SMKP instance with bins $\widetilde{M}$ and budgets $\{\widetilde{B}_j\}_{j\in\widetilde{M}}$. Let $OPT' = \cup_{j=1}^{t^2} \widetilde{OPT}_j$. Order elements in $OPT'$ greedily according to their marginal values such that $o_1 = \arg\max_{o\in OPT'} f(o)$, $o_2 = \arg\max_{o\in OPT'\setminus\{o_1\}} f(o \mid o_1)$, etc. Denote by $E$ the first $s$ elements in $OPT'$ (if $|OPT'| < s$, then $E = OPT'$). Let $E_j = E \cap \widetilde{OPT}_j$ for $1 \le j \le t^2$. Then, $\{E_j\}_{j=1}^{t^2}$ will be enumerated during the **foreach** loop. In the following, we focus on this particular set.

Let $D = \{u \in N \mid f(u \mid E) > \frac{1}{s} \cdot f(E)\}$. Since $E$ is the first $s$ elements in $OPT'$, we have $f(o \mid E) \le \frac{1}{s} \cdot f(E)$ for any $o \in OPT' \setminus E$. Thus, $D \cap (OPT' \setminus E) = \emptyset$ and therefore $OPT' \setminus E$ will not be excluded from the execution of $\textsc{Greedy}$ over $N \setminus (E \cup D)$. Besides, $\{\widetilde{OPT}_j \setminus E_j\}_{j=1}^{t^2}$ is a feasible solution given budgets $\{\widetilde{B}_j - c(E_j)\}_{j=1}^{t^2}$.

For $1 \le j \le t^2$, let $L_j = \{u \in N \setminus E \mid c(u) > \epsilon^2(\widetilde{B}_j - c(E_j))\}$. Define $OPT^*$ as follows. For $1 \le j \le t^2$, $OPT_j^* = \widetilde{OPT}_j \setminus L_j$. For $j > t^2$, $OPT_j^* = \widetilde{OPT}_j$. Then, $OPT^* = \cup_{j=1}^{m} OPT_j^*$. We have

$$\begin{aligned} f(OPT^* \mid E) &= f((\cup_{j=1}^{t^2} \widetilde{OPT}_j \setminus L_j) \cup (\cup_{j=t^2+1}^{m} \widetilde{OPT}_j) \mid E) \\ &\ge f(\cup_{j=1}^{m} \widetilde{OPT}_j \mid E) - f(\cup_{j=1}^{t^2} \widetilde{OPT}_j \cap L_j \mid E) \end{aligned}$$

$$\begin{aligned}
&\geq f(\widetilde{OPT} \mid E) - \sum_{j=1}^{t^2} \sum_{u \in (\widetilde{OPT}_j \setminus E) \cap L_j} f(u \mid E) \\
&\geq f(\widetilde{OPT} \mid E) - \frac{t^2}{\epsilon^2 s} \cdot f(E) \\
&= f(\widetilde{OPT} \mid E) - \epsilon \cdot f(E).
\end{aligned}$$

The first two inequalities are due to submodularity. The third inequality holds since by definition of $L_j$, $\widetilde{OPT}_j \setminus E$ contains at most $1/\epsilon^2$ elements in $L_j$, and $f(u \mid E) \leq \frac{1}{s} f(E)$ due to $D \cap (\widetilde{OPT}_j \setminus E) = \emptyset$. The last equality follows from the choices of $t$ and $s$. This implies that invoking Greedy over $N \setminus (E \cup D \cup L_j)$ for $1 \leq j \leq t^2$ only incurs little loss in the profit.

Now we are prepared to provide a theoretical bound for Algorithm 3. Let $g(\cdot) = f(\cdot \mid E)$. For $1 \leq i \leq 1/\epsilon$ and $1 \leq k \leq r$, let $R_{ik}$ be the set returned in line 12 if $k \leq t^2$ and $R_{ik} = \cup_{j \in \widetilde{M}_k} R_j$ otherwise, where $\{R_j\}_{j \in \widetilde{M}_k}$ is the set returned in line 15. Then, the $k$-th block $\widetilde{M}_k$ packs $\cup_{i=1}^{1/\epsilon} R_{ik}$ by the end of Algorithm 3. Define $T_0 = \emptyset$ and $T_i = T_{i-1} \cup (\cup_{k=1}^{r} R_{ik})$ for $1 \leq i \leq 1/\epsilon$.

For $1 \leq i \leq 1/\epsilon$ and $1 \leq k \leq t^2$, by Lemma 2,

$$\begin{aligned}
g(R_{ik} \mid T_{i-1} \cup (\cup_{k'=1}^{k-1} R_{ik'})) &\geq (1 - e^{-(\epsilon - \epsilon^2)}) \cdot g(OPT_k^* \mid T_{i-1} \cup (\cup_{k'=1}^{k-1} R_{ik'})) \\
&\geq (\epsilon - 2\epsilon^2) \cdot g(OPT_k^* \mid T_i).
\end{aligned}$$

The last inequality holds due to $1 - e^{-x} \geq x - x^2/2$ for $x \geq 0$ and submodularity.

For $1 \leq i \leq 1/\epsilon$ and $t^2 < k \leq r$, by Lemma 6,

$$\begin{aligned}
g(R_{ik} \mid T_{i-1} \cup (\cup_{k'=1}^{k-1} R_{ik'})) &\geq (1 - e^{-\epsilon(1-2\epsilon)}) \cdot g(OPT_k^* \mid T_{i-1} \cup (\cup_{k'=1}^{k-1} R_{ik'})) \\
&\geq (\epsilon - 3\epsilon^2) \cdot g(OPT_k^* \mid T_i).
\end{aligned}$$

Again, the last inequality holds due to $1 - e^{-x} \geq x - x^2/2$ for $x \geq 0$ and submodularity.

Summing up over $1 \leq k \leq r$, we have

$$\begin{aligned}
g(T_i) - g(T_{i-1}) &= \sum_{k=1}^{r} g(R_{ik} \mid T_{i-1} \cup (\cup_{k'=1}^{k-1} R_{ik'})) \\
&\geq \sum_{k=1}^{r} (\epsilon - 3\epsilon^2) \cdot g(OPT_k^* \mid T_i) \\
&\geq (\epsilon - 3\epsilon^2) \cdot g(OPT^* \mid T_i) \\
&\geq (\epsilon - 3\epsilon^2) \cdot (g(OPT^*) - g(T_i)).
\end{aligned}$$

The last two inequalities are due to submodularity and monotonicity, respectively. By adding $g(OPT^*)$ to both sides and move $g(T_i)$ to the right in the above inequality,

$$g(OPT^*) - g(T_{i-1}) \geq (1 + \epsilon - 3\epsilon^2)(g(OPT^*) - g(T_i)).$$

This leads to

$$g(OPT^*) - g(T_i) \leq \frac{1}{(1 + \epsilon - 3\epsilon^2)^i} \cdot g(OPT^*).$$

Hence, by plugging $i = 1/\epsilon$,

$$\begin{aligned}
g(T_{1/\epsilon}) &\geq \left(1 - \frac{1}{(1 + \epsilon - 3\epsilon^2)^{1/\epsilon}}\right) \cdot g(OPT^*) = \left(1 - e^{-\frac{1}{\epsilon} \ln(1 + \epsilon - 3\epsilon^2)}\right) \cdot g(OPT^*) \\
&\geq (1 - e^{-\frac{1}{\epsilon}(\epsilon - 3\epsilon^2 - (\epsilon - 3\epsilon^2)^2/2)}) \cdot g(OPT^*) \geq (1 - e^{-1} - O(\epsilon)) \cdot g(OPT^*).
\end{aligned}$$

The second inequality holds since $\ln(1+x) \geq x - x^2/2$ for $x > 0$. Finally, recall that $g(\cdot) = f(\cdot \mid E)$, we have

$$\begin{aligned} f(T_{1/\epsilon}) &= f(E) + f(T_{1/\epsilon} \mid E) \geq f(E) + (1 - e^{-1} - O(\epsilon)) \cdot f(OPT^* \mid E) \\ &\geq f(E) + (1 - e^{-1} - O(\epsilon)) \cdot (f(\widetilde{OPT} \mid E) - \epsilon f(E)) \\ &\geq (1 - e^{-1} - O(\epsilon)) \cdot f(OPT). \end{aligned}$$

◀

## 5 Conclusion

In this paper, we present a deterministic $(1 - e^{-1} - \epsilon)$-approximation algorithm for SMKP. Our algorithm is inspired by the viewpoint regarding SMKP instances as exponential-size instances of submodular maximization subject to a cardinality or partition matroid constraint. Thus our algorithm is conceptually much simpler than that of Fairstein et al. [9].

As pointed out by [9], it remains open to remove the loss of $\epsilon$ in the approximation ratio. As a first step, we present a $(1 - e^{-1})$-approximation algorithm for SMKP when the number of bins $m$ is constant in the full version of this paper. Recently, a randomized 0.385-approximation algorithm for *non-monotone* SMKP was proposed in [10]. It is an interesting question to design deterministic algorithms for this problem.

## Abstract

Spanner construction is a well-studied problem and Delaunay triangulations are among the most popular spanners. Tight bounds are known if the Delaunay triangulation is constructed using an equilateral triangle, a square, or a regular hexagon. However, all other shapes have remained elusive. In this paper we extend the restricted class of spanners for which tight bounds are known. We prove that Delaunay triangulations constructed using rectangles with aspect ratio $A$ have spanning ratio at most $\sqrt{2}\sqrt{1+A^2+A\sqrt{A^2+1}}$, which matches the known lower bound.

## 1 Introduction

A geometric graph is a weighted graph in the plane where every vertex $v$ has coordinates $(x_v, y_v)$ and the weight of an edge between any two vertices is the Euclidean distance between its endpoints. A *geometric spanner* is defined to be a class of subgraphs where the shortest path distance between any two vertices is at most the Euclidean distance between these two vertices multiplied by a constant $t$. The smallest constant $t$ for which this property holds is called the *spanning ratio* or *stretch factor* of the geometric spanner. A comprehensive overview on the topic of geometric spanners can be found in the book by Narasimhan and Smid [11] and the survey by Bose and Smid [5].

One way to construct a geometric spanner is by using a Delaunay triangulation. The Delaunay triangulation is defined as follows: for any two vertices $u$ and $v$, if there exists a circle with $u$ and $v$ on its boundary and no other vertex in its interior, then the edge between $u$ and $v$ is part of the Delaunay triangulation. Equivalently, this can be defined using three vertices $u$, $v$, and $w$, where the triangle connecting these three vertices is part of the Delaunay triangulation if and only if the unique circle through these three points does not contain any other vertices in its interior. For simplicity, it is usually assumed that no three points are collinear and no four points lie on the boundary of the circle.

The tight spanning ratio of the Delaunay triangulation is not known. Dobkin et al. [8] showed an upper bound of $\pi(1+\sqrt{5})/2 \approx 5.09$ for the spanning ratio, which Keil and Gutwin [9] improved to $4\pi/3\sqrt{3} \approx 2.42$. Currently, the best upper bound is 1.998, proven by Xia [14]. A lower bound on the spanning ratio was provided by Bose et al. [4], who showed that this is strictly larger than $\frac{\pi}{2}$. This was later improved to 1.59 by Xia and Zhang [15].

Usually, the distance between two points $u$ and $v$ in the plane is defined as $((x_u - x_v)^2 + (y_u - y_v)^2)^{\frac{1}{2}}$. This distance can be generalized to a family of metrics $L_p$ where the distance between $u$ and $v$ is defined as $((x_u - x_v)^p + (y_u - y_v)^p)^{\frac{1}{p}}$. The shape of a "circle" varies in different metrics, leading to different Delaunay triangulations in different metrics. For example, the shape of the "circle" would be a diamond or square in the $L_1$ and $L_\infty$ metrics.

In 1986, Lee and Lin [10] introduced the notion of generalized Delaunay triangulations. Instead of using a circle to construct the graph, generalized Delaunay triangulations can be constructed using arbitrary geometric shapes. It was proven that any generalized Delaunay triangulation constructed using a convex shape is a spanner [2].

Although generalized Delaunay triangulations using arbitrary convex shapes are known to be spanners, their spanning ratios are less well understood. Tight bounds on the spanning ratio are only known when an equilateral triangle, a square, or a regular hexagon is used in the construction. When using equilateral triangles, Chew [7] showed that the spanning ratio is 2. When using squares, Chew [6] showed an upper bound of $\sqrt{10} \approx 3.16$, and Bonichon et al. [1] showed a matching upper and lower bound of $\sqrt{4 + 2\sqrt{2}} \approx 2.61$. When using regular hexagons, Perković et al. [12] showed a tight bound of 2.

Bose et al. [3] studied generalized Delaunay triangulations using rectangles. For rectangles with aspect ratio $A$, they showed an upper bound of $\sqrt{2}(2A + 1)$ and a lower bound of $\sqrt{2}\sqrt{1 + A^2 + A\sqrt{A^2 + 1}}$. Inspired by the proof of Bonichon et al. [1], by significantly extending and generalizing their approach we obtain a tight bound of $\sqrt{2}\sqrt{1 + A^2 + A\sqrt{A^2 + 1}}$. This extends the class of shapes for which a tight bound is known for the spanning ratio of generalized Delaunay triangulations. We note that the proof of our result is not a straightforward extension of Bonichon et al. [1], as we cannot simply rotate our lemmas to get them to prove both the horizontal and vertical cases simultaneously.

## 2 Preliminaries

Let us first formally define the rectangle Delaunay triangulation of a set of points $P$. Given an arbitrary axis-aligned rectangle $R$, the rectangle Delaunay triangulation is constructed by considering scaled translates of $R$ (rotations are not allowed). Such scaled translates are also referred to as homothets. Given two vertices $u$ and $v$ in $P$, the rectangle Delaunay triangulation contains an edge between $u$ and $v$ if and only if there exists a scaled translate of $R$ with $u$ and $v$ on its boundary which contains no vertices of $P$ in the interior. Equivalently, the rectangle Delaunay triangulation contains a triangle $\triangle uvw$ if and only if there exists a scaled translate of $R$ with $u$, $v$, and $w$ on its boundary which contains no vertices of $P$ in the interior. We note that different rectangles can give different rectangle Delaunay triangulations.

For our proofs, we assume that $P$ is in general position. Specifically, we assume that no four vertices lie on the boundary of any scaled translate of $R$ and that no two vertices lie on a line parallel to any of the sides of $R$ (i.e., no two vertices lie on a vertical or horizontal line). These assumptions are common for Delaunay graphs and are required to guarantee their planarity.

Throughout this paper, we use $A$ to denote the aspect ratio of the rectangle $R$ used in the construction of the rectangle Delaunay triangulation, i.e., $A = l/s$ where $l$ and $s$ are the length of the long and short side of $R$ respectively. We also use $d_t(u, v)$ to denote the length of the shortest path in the rectangle Delaunay triangulation between $u$ and $v$, $d_x(u, v)$ to denote the difference in $x$-coordinate between $u$ and $v$, $d_y(u, v)$ to denote the difference in $y$-coordinate between $u$ and $v$, and $d_2(u, v)$ to denote the Euclidean distance between $u$ and $v$.

Due to space constraints, we have deferred proofs of several lemmas to the full version of this paper [13].

## 3 Bounding the Spanning Ratio

To show an upper bound on the spanning ratio between any two vertices $u$ and $v$, we consider the sequence of triangles $T_1, T_2, ..., T_k$ intersecting with line segment $uv$. The order of this sequence is determined by the order in which these triangles are encountered when following $uv$ from $u$ to $v$ (as shown in Figure 1). Each triangle except $T_1$ and $T_k$ intersects the interior of $uv$ twice. Hence, we can define the last line segment of $T_i$ $(1 \leq i < k)$ that intersects $uv$ as the line segment involved in the second intersection. We use $h_i$ and $l_i$ to denote the endpoints of the last line segment of $T_i$, where $h_i$ is the endpoint above $uv$ and $l_i$ is the endpoint below $uv$. Since all $T_i$ are triangles, we have that for every $T_i$ and $T_{i+1}$, either $l_i = l_{i+1}$ or $h_i = h_{i+1}$. We also define $h_0 = l_0 = u$, $l_k = h_k = v$.

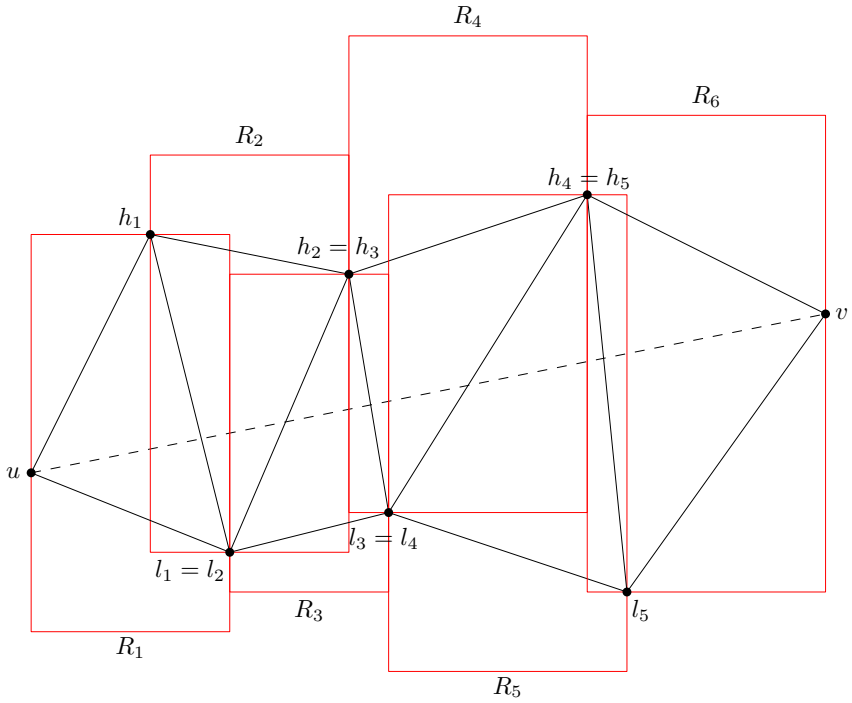

**Figure 1** The triangles intersecting $uv$ and their associated rectangles and $h_i$ and $l_i$.

Each triangle $T_i$ also has an associated rectangle $R_i$: the scaled translate of $R$ that has the three vertices of $T_i$ on its boundary. For ease of reference, we use W (west), N (north), E (east), and S (south) to refer to the four sides of a rectangle. We also use these sides to classify an edge, for example, if an endpoint of an edge lies on the W side of $R_i$ and the other endpoint lies on the N side of $R_i$, we call the edge a WN edge. We also define $u$ to be on the E side of $R_0$ (not associated with any triangle), as this will simplify some of the lemma statements.

Define $L$ to be the length of the vertical side of $R$ divided by the length of the horizontal size of $R$. Note that $L$ can be either $A$ or $1/A$. For our proofs, it is helpful to distinguish between edges of slope less than the slope of the diagonal of $R$ and those with larger slope.

▶ **Definition 1.** *An edge is gentle if it has a slope within [-L, L]. Otherwise it is steep.*

We let $u, v$ be any two vertices in the rectangle Delaunay triangulation. Fix the $(x, y)$-coordinate system so that we have $Ld_x(u, v) > d_y(u, v)$. Note that this is without loss of generality, since we can simply switch the $x$- and $y$-axes if needed. This implies that if we consider a scaled translate of $R$ with $u$ lying in the lower left corner and passing through $v$, then $v$ lies on the E side. Without loss of generality, we assume $u$ to be at the origin $(0, 0)$ and $v$ to be at $(x, y)$. We use $R(u, v)$ to denote the rectangle with $u$ and $v$ in opposite corners.

In order to bound the spanning ratio of the rectangle Delaunay triangulation, we first define what it means for a rectangle to have potential. This later helps us to bound the total length of the shortest path between $u$ and $v$ in the rectangle Delaunay triangulation.

▶ **Definition 2.** *The inductive point $c$ of a rectangle $R_i$ is the point with larger $x$-coordinate out of $h_i$ and $l_i$. Rectangle $R_i$ is inductive if edge $(l_i, h_i)$ is gentle.*

▶ **Definition 3.** *A rectangle $R_i$ has potential if $d_t(u, h_i) + d_t(u, l_i) + d_{R_i}(h_i, l_i) \leq (2 + 2L)x_i$ where $d_{R_i}(h_i, l_i)$ is the Euclidean distance when moving clockwise from $h_i$ to $l_i$ along the sides of $R_i$ and $x_i$ is the $x$-coordinate of the E side of $R_i$.*

We are now ready to prove that rectangles that are not inductive pass on their potential.

▶ **Lemma 4.** *If $R(u, v)$ is empty and $(u, v)$ is not an edge in the rectangle Delaunay triangulation, then $R_1$ has potential. Furthermore, for any $1 \leq i < k$, if $R_i$ has potential but is not inductive, then $R_{i+1}$ has potential.*

Next, we bound the distance from $u$ to the inductive point of a rectangle with potential when this inductive point lies on the E side of the rectangle.

▶ **Lemma 5.** *If rectangle $R_i$ has potential and its inductive point $c$ ($c = h_i$ or $c = l_i$) lies on the E side of $R_i$, then $d_t(u, c) \leq (1 + L)x_c$.*

Now we shift our focus to paths consisting of gentle edges (see Figure 2).

▶ **Definition 6.** *If $h_j$ is on the E side of $R_j$, the maximal high path ending at $h_j$ is $h_j$ itself; otherwise, it is the path $h_i, h_{i+1}, ..., h_j$ such that $h_m$ is not on the E side of $R_m$ (for $i < m \leq j$) and either $i = 0$ or $h_i$ is on the E side of $R_i$.*

*If $l_j$ is on the E side of $R_j$, the maximal low path ending at $l_j$ is $l_j$; otherwise, it is the path $l_i, l_{i+1}, ..., l_j$ such that $l_m$ is not on the E side of $R_m$ (for $i < m \leq j$) and either $i = 0$ or $l_i$ is on the E side of $R_i$.*

Next, we bound the length of these maximal high and maximal low paths.

▶ **Lemma 7.** *If the path $h_i, h_{i+1}, ..., h_j$ is a maximal high path then $d_t(h_i, h_j) \leq (x_{h_j} - x_{h_i}) + (y_{h_j} - y_{h_i})$. Similarly, if the path $l_i, l_{i+1}, ..., l_j$ is a maximal low path then $d_t(l_i, l_j) \leq (x_{l_j} - x_{l_i}) + (y_{l_i} - y_{l_j})$.*

We now use the above lemmas to prove bounds on the path length from $u$ to the inductive point on the first inductive rectangle (if one exists) when $R(u, v)$ does not contain any vertices. Note that in Property 2 of Lemma 8, we differentiate between $L = A$ and $L = 1/A$, which is crucial in proving Theorem 10.

▶ **Lemma 8.** *Let $R(u, v)$ not contain any vertices of $P$ and let $(u, v)$ not be an edge of the rectangle Delaunay triangulation. The following properties hold:*

**1.** *If no rectangle in $R_1, ..., R_k$ is inductive then*

$$d_t(u, v) \leq (L + \sqrt{L^2 + 1})x + y.$$

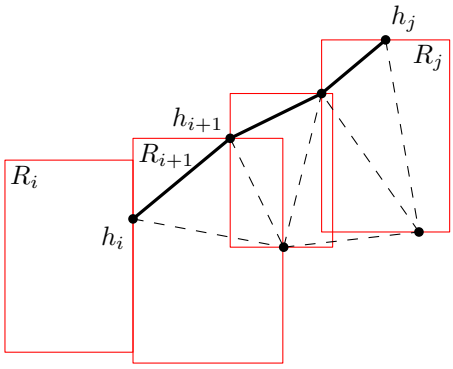

**Figure 2** An example of a maximal high path (thick edges). The other edges of the triangles are shown using dashed line segments.

2. *Otherwise, let $R_j$ be the first inductive rectangle in the sequence $R_1, ..., R_k$.*
   a. *If $h_j$ is the inductive point of $R_j$ and $L = A$, then*

$$d_t(u, h_j) + (y_{h_j} - y) \leq (A + \sqrt{A^2 + 1})x_{h_j}.$$

   b. *If $h_j$ is the inductive point of $R_j$ and $L = \frac{1}{A}$, then*

$$d_t(u, h_j) + A(y_{h_j} - y) \leq \left(1 + \sqrt{\tfrac{1}{A^2} + 1}\right) x_{h_j}.$$

   c. *If $l_j$ is the inductive point of $R_j$ and $L = A$, then*

$$d_t(u, l_j) - y_{l_j} \leq (A + \sqrt{A^2 + 1})x_{l_j}.$$

   d. *If $l_j$ is the inductive point of $R_j$ and $L = \frac{1}{A}$, then*

$$d_t(u, l_j) - Ay_{l_j} \leq \left(1 + \sqrt{\tfrac{1}{A^2} + 1}\right) x_{l_j}.$$

**Proof.** *Property 1:* By Lemma 4, if no rectangle in $R_1, ..., R_k$ is inductive then the last rectangle must have potential since $R_1$ has potential. Since no two vertices have the same $y$-coordinate, $v$ must lie on the E side of the last rectangle. Thus, we can use Lemma 5 to conclude that $d_t(u, v) \leq (1 + L)x \leq (L + \sqrt{L^2 + 1})x + y$.

*Property 2a:* We consider the situation where $R_j$ is the first inductive rectangle in the sequence $R_1, ..., R_k$. Let $l_i, ..., l_{j-1} = l_j$ be the maximal low path ending at $l_j$, and recall that $h_j$ is the inductive point of $R_j$. By Lemma 4 we know that $R_i$ has potential, since $R_1$ has potential and no rectangle before $R_i$ is inductive. Since $R_i$ has potential and $l_i$ is on the E side of $R_i$, by Lemma 5 we know $d_t(u, l_i) \leq (1 + L)x_{l_i}$. See Figure 3. Since $L = A$, we have

$$\begin{aligned} d_t(u, h_j) + (y_{h_j} - y) &\leq d_t(u, l_i) + d_t(l_i, l_j) + d_2(l_j, h_j) + (y_{h_j} - y) \\ &\leq (1 + A)x_{l_i} + d_t(l_i, l_j) + d_2(l_j, h_j) + y_{h_j}. \end{aligned}$$

Since $l_i, ..., l_{j-1} = l_j$ is a maximal low path, by Lemma 7 we know $d_t(l_i, l_j) \leq (x_{l_j} - x_{l_i}) + (y_{l_i} - y_{l_j})$. Hence, we obtain that:

$$\begin{aligned} d_t(u, h_j) + (y_{h_j} - y) &\leq (1 + A)x_{l_i} + (x_{l_j} - x_{l_i}) + (y_{l_i} - y_{l_j}) + d_2(l_j, h_j) + y_{h_j} \\ &= Ax_{l_i} + x_{l_j} + (y_{l_i} - y_{l_j}) + d_2(l_j, h_j) + y_{h_j}. \end{aligned}$$

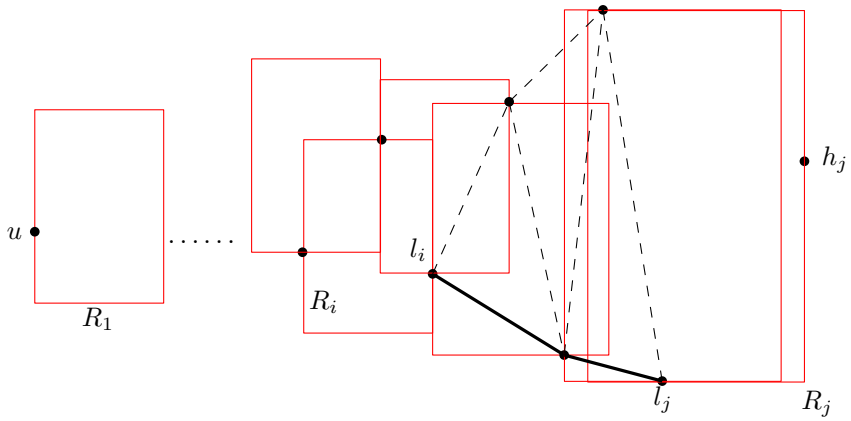

**Figure 3** In Property 2*a*, $R_j$ is the first inductive rectangle, $h_j$ is the inductive point of $R_j$, and $l_i, ..., l_{j-1} = l_j$ is the maximal low path ending at $l_j$. $R_i$ has potential and $l_i$ is on the E side of $R_i$.

Because $R_j$ is inductive, we know that edge $(l_j, h_j)$ is gentle. Therefore, $d_2(l_j, h_j) \leq \sqrt{1+A^2}(x_{h_j} - x_{l_j})$ and thus:

$$\begin{aligned} d_t(u, h_j) + (y_{h_j} - y) &\leq Ax_{l_i} + x_{l_j} + (y_{l_i} - y_{l_j}) + \sqrt{1+A^2}(x_{h_j} - x_{l_j}) + y_{h_j} \\ &\leq Ax_{l_i} + (y_{l_i} - y_{l_j}) + \sqrt{1+A^2}x_{h_j} + y_{h_j}. \end{aligned}$$

Furthermore, again because edge $(l_j, h_j)$ is gentle, we have that $y_{h_j} - y_{l_j} \leq A(x_{h_j} - x_{l_j})$ and therefore:

$$\begin{aligned} d_t(u, h_j) + (y_{h_j} - y) &\leq Ax_{l_i} + y_{l_i} + \sqrt{1+A^2}x_{h_j} + A(x_{h_j} - x_{l_j}) \\ &\leq y_{l_i} + \sqrt{1+A^2}x_{h_j} + Ax_{h_j}. \end{aligned}$$

Note that when $i \leq j$, then $x_{l_i} \leq x_{l_j}$. Finally, since $R(u, v)$ is empty, $l_i$ must lie below it and thus $y_{l_i} < 0$, which leads to: $d_t(u, h_j) + (y_{h_j} - y) \leq (A + \sqrt{A^2+1})x_{h_j}$.

*Property 2b:* Let $R_j$ be the first inductive rectangle in the sequence $R_1, ..., R_k$. Let $l_i, ..., l_{j-1} = l_j$ be the maximal low path ending at $l_j$, and recall that $h_j$ is the inductive point of $R_j$. By Lemma 4, $R_i$ has potential, and by Lemma 5, we have $d_t(u, l_i) \leq (1+L)x_{l_i}$. Since $L = \frac{1}{A}$, we have

$$\begin{aligned} d_t(u, h_j) + A(y_{h_j} - y) &\leq d_t(u, l_i) + d_t(l_i, l_j) + d_2(l_j, h_j) + A(y_{h_j} - y) \\ &\leq (1 + \tfrac{1}{A})x_{l_i} + d_t(l_i, l_j) + d_2(l_j, h_j) + Ay_{h_j}. \end{aligned}$$

Since $l_i, ..., l_{j-1} = l_j$ is a maximal low path, by Lemma 7 we know $d_t(l_i, l_j) \leq (x_{l_j} - x_{l_i}) + (y_{l_i} - y_{l_j})$. Because $R_j$ is inductive, we know that edge $(l_j, h_j)$ is gentle. Therefore, $d_2(l_j, h_j) \leq \sqrt{1 + \frac{1}{A^2}}(x_{h_j} - x_{l_j})$ and thus:

$$\begin{aligned} d_t(u, h_j) + A(y_{h_j} - y) &\leq (1 + \tfrac{1}{A})x_{l_i} + (x_{l_j} - x_{l_i}) + (y_{l_i} - y_{l_j}) + d_2(l_j, h_j) + Ay_{h_j} \\ &\leq (1 + \tfrac{1}{A})x_{l_i} + (x_{l_j} - x_{l_i}) + (y_{l_i} - y_{l_j}) + \sqrt{1 + \tfrac{1}{A^2}}(x_{h_j} - x_{l_j}) + Ay_{h_j} \\ &\leq \tfrac{1}{A}x_{l_i} + (y_{l_i} - y_{l_j}) + \sqrt{1 + \tfrac{1}{A^2}}x_{h_j} + Ay_{h_j}. \end{aligned}$$

Again because edge $(l_j, h_j)$ is gentle, we have that $y_{h_j} - y_{l_j} \leq \frac{1}{A}(x_{h_j} - x_{l_j})$. Therefore $A(y_{h_j} - y_{l_j}) \leq (x_{h_j} - x_{l_j})$. We have $A \geq 1$ and therefore:

$$\begin{aligned} d_t(u, h_j) + A(y_{h_j} - y) &\leq \tfrac{1}{A}x_{l_i} + A(y_{l_i} - y_{l_j}) + \sqrt{1 + \tfrac{1}{A^2}}x_{h_j} + Ay_{h_j} \\ &\leq \tfrac{1}{A}x_{l_i} + Ay_{l_i} + (x_{h_j} - x_{l_j}) + \sqrt{1 + \tfrac{1}{A^2}}x_{h_j}. \end{aligned}$$

Since $\frac{1}{A} \leq 1$ and $i \leq j$, we have $\frac{1}{A}x_{l_i} \leq x_{l_i} \leq x_{l_j}$. Therefore

$$d_t(u, h_j) + A(y_{h_j} - y) \leq Ay_{l_i} + x_{h_j} + \sqrt{1 + \tfrac{1}{A^2}}x_{h_j} \leq (1 + \sqrt{\tfrac{1}{A^2} + 1})x_{h_j}.$$

*Property 2c:* Let $R_j$ be the first inductive rectangle in the sequence $R_1, ..., R_k$. Now, let $h_i, ..., h_{j-1} = h_j$ be the maximal high path ending at $h_j$, and recall that $l_j$ is the inductive point of $R_j$. By Lemma 4, $R_i$ has potential, and by Lemma 5, we have $d_t(u, h_i) \leq (1 + L)x_{h_i}$. Since $L = A$,

$$\begin{aligned} d_t(u, l_j) - y_{l_j} &\leq d_t(u, h_i) + d_t(h_i, h_j) + d_2(h_j, l_j) - y_{l_j} \\ &\leq (1 + A)x_{h_i} + d_t(h_i, h_j) + d_2(h_j, l_j) - y_{l_j}. \end{aligned}$$

Since $h_i, ..., h_{j-1} = h_j$ is a maximal high path, by Lemma 7 we know $d_t(h_i, h_j) \leq (x_{h_j} - x_{h_i}) + (y_{h_j} - y_{h_i})$. It follows that:

$$\begin{aligned} d_t(u, l_j) - y_{l_j} &\leq (1 + A)x_{h_i} + (x_{h_j} - x_{h_i}) + (y_{h_j} - y_{h_i}) + d_2(h_j, l_j) - y_{l_j} \\ &= Ax_{h_i} + x_{h_j} + (y_{h_j} - y_{h_i}) + d_2(h_j, l_j) - y_{l_j}. \end{aligned}$$

Because $R_j$ is inductive, we know that edge $(l_j, h_j)$ is gentle. Therefore, $d_2(h_j, l_j) \leq \sqrt{1 + A^2}(x_{l_j} - x_{h_j})$ and thus:

$$\begin{aligned} d_t(u, l_j) - y_{l_j} &\leq Ax_{h_i} + x_{h_j} + (y_{h_j} - y_{h_i}) + \sqrt{1 + A^2}(x_{l_j} - x_{h_j}) - y_{l_j} \\ &\leq Ax_{h_i} + (y_{h_j} - y_{h_i}) + \sqrt{1 + A^2}x_{l_j} - y_{l_j}. \end{aligned}$$

Furthermore, again because edge $(l_j, h_j)$ is gentle, we have that $y_{h_j} - y_{l_j} \leq A(x_{l_j} - x_{h_j})$ and therefore:

$$\begin{aligned} d_t(u, l_j) - y_{l_j} &\leq Ax_{h_i} - y_{h_i} + \sqrt{1 + A^2}x_{l_j} + A(x_{l_j} - x_{h_j}) \\ &\leq -y_{h_i} + \sqrt{1 + A^2}x_{l_j} + Ax_{l_j}. \end{aligned}$$

Finally, since $R(u, v)$ is empty, $h_i$ must lie above it and thus $y_{h_i} > 0$, which leads to $d_t(u, l_j) - y_{l_j} \leq (A + \sqrt{A^2 + 1})x_{l_j}$.

*Property 2d:* Let $R_j$ be the first inductive rectangle in the sequence $R_1, ..., R_k$. Now, let $h_i, ..., h_{j-1} = h_j$ be the maximal high path ending at $h_j$, and recall that $l_j$ is the inductive point of $R_j$. By Lemma 4, $R_i$ has potential, and by Lemma 5, we have $d_t(u, h_i) \leq (1 + L)x_{h_i}$. Since $L = \frac{1}{A}$,

$$\begin{aligned} d_t(u, l_j) - Ay_{l_j} &\leq d_t(u, h_i) + d_t(h_i, h_j) + d_2(h_j, l_j) - Ay_{l_j} \\ &\leq (1 + \tfrac{1}{A})x_{h_i} + d_t(h_i, h_j) + d_2(h_j, l_j) - Ay_{l_j}. \end{aligned}$$

Since $h_i, ..., h_{j-1} = h_j$ is a maximal high path, by Lemma 7 we know $d_t(h_i, h_j) \leq (x_{h_j} - x_{h_i}) + (y_{h_j} - y_{h_i})$. Because edge $(l_j, h_j)$ is gentle, we have that $d_2(h_j, l_j) \leq \sqrt{1 + \frac{1}{A^2}}(x_{l_j} - x_{h_j})$. It follows that:

$$\begin{aligned} d_t(u,l_j) - Ay_{l_j} &\leq (1+\tfrac{1}{A})x_{h_i} + (x_{h_j} - x_{h_i}) + (y_{h_j} - y_{h_i}) + d_2(h_j,l_j) - Ay_{l_j} \\ &\leq (1+\tfrac{1}{A})x_{h_i} + (x_{h_j} - x_{h_i}) + (y_{h_j} - y_{h_i}) + \sqrt{1+\tfrac{1}{A^2}}(x_{l_j} - x_{h_j}) - Ay_{l_j} \\ &\leq \tfrac{1}{A}x_{h_i} + (y_{h_j} - y_{h_i}) + \sqrt{1+\tfrac{1}{A^2}}x_{l_j} - Ay_{l_j}. \end{aligned}$$

Again because edge $(l_j, h_j)$ is gentle, we have that $y_{h_j} - y_{l_j} \leq \frac{1}{A}(x_{l_j} - x_{h_j})$. Therefore $A(y_{h_j} - y_{l_j}) \leq (x_{l_j} - x_{h_j})$ and

$$\begin{aligned} d_t(u,l_j) - Ay_{l_j} &\leq \tfrac{1}{A}x_{h_i} + A(y_{h_j} - y_{h_i}) + \sqrt{1+\tfrac{1}{A^2}}x_{l_j} - Ay_{l_j} \\ &\leq \tfrac{1}{A}x_{h_i} + (x_{l_j} - x_{h_j}) - Ay_{h_i} + \sqrt{1+\tfrac{1}{A^2}}x_{l_j}. \end{aligned}$$

Since $\frac{1}{A} \leq 1$, we have $\frac{1}{A}x_{h_i} \leq x_{h_i} \leq x_{h_j}$. Thus

$$\begin{aligned} d_t(u,l_j) - Ay_{l_j} &\leq x_{l_j} - Ay_{h_i} + \sqrt{1+\tfrac{1}{A^2}}x_{l_j} \\ &\leq (1+\sqrt{\tfrac{1}{A^2}+1})x_{l_j}. \end{aligned}$$

as required, completing our proof of Property 1, 2*a*, 2*b*, 2*c* and 2*d*. ◀

Our final ingredient determines the types of edges we can encounter when the $y$-coordinate of a vertex differs significantly from that of $v$.

▶ **Lemma 9.** *Let $R(u,v)$ not contain any vertices of $P$ and let the coordinates of the inductive point $c$ of $R_i$ be such that it satisfies $0 < L(x - x_c) < |y - y_c|$.*

- *If $c = h_i$ and thus $0 < L(x - x_c) < y_c - y$, then let $j$ be the smallest index larger than $i$ such that $L(x - x_{h_j}) \geq y_c - y \geq 0$. All edges on the path $h_i, ..., h_j$ are NE edges.*
- *If $c = l_i$ and thus $0 < L(x - x_c) < y - y_c$, then let $j$ be the smallest index larger than $i$ such that $L(x - x_{l_j}) \geq y - y_c \geq 0$. All edges on the path $l_i, ..., l_j$ are SE edges.*

We now have all the ingredients needed to prove our main result. Recall that, up to Lemma 9, the $(x,y)$-coordinate system is fixed so that $Ld_x(u,v) > d_y(u,v)$, i.e. $Lx \geq y$. However, for ease of exposition, in Theorem 10 we instead fix the $(x,y)$-coordinate system so that all the homothet rectangles have their vertical sides being the long sides.

Note that in Lemma 8, we obtain different upper bounds depending on whether $L = A$ or $L = 1/A$. These two cases must be treated differently for the inductive proof of Theorem 10 to hold. In particular, in Theorem 10 the bound for $Ad_x(u,v) \geq d_y(u,v)$ does not coincide with the rotated version of the bound for $Ad_x(u,v) < d_y(u,v)$.

▶ **Theorem 10.** *Let $u, v$ be any two vertices in the rectangle Delaunay triangulation. If $Ad_x(u,v) \geq d_y(u,v)$, then*

$$d_t(u,v) \leq (A + \sqrt{A^2+1})x + y.$$

*Otherwise,*

$$d_t(u,v) \leq Ax + \left(1 + \sqrt{\tfrac{1}{A^2}+1}\right)y.$$

**Proof.** We consider all pairs of vertices $(u,v)$ and order them by the size of the smallest scaled translate of $R$ that has both $u$ and $v$ on its boundary. We perform induction based on the rank in this ordering.

The first pair $(u, v)$ in this ordering has the smallest overall scaled translate of $R$ and can thus contain no vertices of $P$, as any such vertex would imply the existence of a smaller rectangle with two vertices on its boundary, contradicting that we are considering the smallest one. Hence, by construction there exists an edge between $u$ and $v$ and thus $d_t(u, v) = d_2(u, v) \leq x + y$, satisfying the induction hypothesis, regardless of whether or not $Ad_x(u, v) \geq d_y(u, v)$.

Next, consider an arbitrary pair $(u, v)$ and assume the theorem holds for all pairs $(u, v)$ defining a smaller rectangle. We consider two cases: $R(u, v)$ does not contain any vertex of $P$, and $R(u, v)$ contains some vertices of $P$.

**Case 1:** There are no vertices inside $R(u, v)$. We distinguish two subcases, either $Ax \geq y$ or $Ax < y$.

**Subcase $Ax \geq y$:** Note that since the vertical side of the homothets is the longer side, for the $(x, y)$-coordinate system we have $L = A$, and $Lx \geq y$.

If $(u, v)$ is an edge in the rectangle Delaunay triangulation, then $d_t(u, v) \leq x + y \leq (A + \sqrt{A^2 + 1})x + y$. Otherwise, if no rectangle in $R_1, ..., R_k$ is inductive then by Property 1 of Lemma 8 we know $d_t(u, v) \leq (A + \sqrt{A^2 + 1})x + y$.

Hence, we focus on the case where there is an inductive rectangle. Let $R_i$ be the first inductive rectangle in the sequence $R_1, ..., R_k$. We distinguish the case where the inductive point is $h_i$ and where it is $l_i$. If $h_i$ is the inductive point of $R_i$ then by Property 2$a$ of Lemma 8 we know $d_t(u, h_i) + (y_{h_i} - y) \leq (A + \sqrt{A^2 + 1})x_{h_i}$ and thus $d_t(u, h_i) \leq (A + \sqrt{A^2 + 1})x_{h_i} - (y_{h_i} - y)$.

If $A(x - x_{h_i}) \geq y_{h_i} - y \geq 0$, we let $h_j = h_i$ in the remainder. Otherwise, we let $j$ be the smallest index larger than $i$ such that $A(x - x_{h_j}) \geq y_{h_j} - y \geq 0$. By Lemma 9, $h_j$ exists and all edges on the path $h_i, ..., h_j$ are NE edges. By triangle inequality, $d_t(h_m, h_{m+1}) \leq (x_{h_{m+1}} - x_{h_m}) + (y_{h_m} - y_{h_{m+1}})$ for any $h_m$ and $h_{m+1}$ on this path. This implies that $d_t(h_i, h_j) \leq (x_{h_j} - x_{h_i}) + (y_{h_i} - y_{h_j})$. Since $A(x - x_{h_j}) \geq y_{h_j} - y \geq 0$ and the smallest scaled translate of $R$ with $h_j$ and $v$ on its boundary is smaller than that of $u$ and $v$, we can use induction to get $d_t(h_j, v) \leq (A + \sqrt{A^2 + 1})d_x(h_j, v) + d_y(h_j, v)$. Putting everything together, we obtain that

$$\begin{aligned}
d_t(u, v) &\leq d_t(u, h_i) + d_t(h_i, h_j) + d_t(h_j, v) \\
&\leq (A + \sqrt{A^2 + 1})x_{h_i} - (y_{h_i} - y) + (x_{h_j} - x_{h_i}) + (y_{h_i} - y_{h_j}) \\
&\quad + (A + \sqrt{A^2 + 1})d_x(h_j, v) + d_y(h_j, v) \\
&= (A + \sqrt{A^2 + 1})x_{h_i} + (x_{h_j} - x_{h_i}) + (y - y_{h_j}) \\
&\quad + (A + \sqrt{A^2 + 1})d_x(h_j, v) + d_y(h_j, v) \\
&\leq (A + \sqrt{A^2 + 1})d_x(u, h_j) - d_y(h_j, v) + (A + \sqrt{A^2 + 1})d_x(h_j, v) + d_y(h_j, v) \\
&= (A + \sqrt{A^2 + 1})x.
\end{aligned}$$

proving the theorem when $h_i$ is the inductive point of $R_i$.

If $l_i$ is the inductive point of $R_i$ then by Property 2$c$ of Lemma 8 we know $d_t(u, l_i) - y_{l_i} \leq (A + \sqrt{A^2 + 1})x_{l_i}$ and thus $d_t(u, l_i) \leq (A + \sqrt{A^2 + 1})x_{l_i} + y_{l_i}$.

If $A(x - x_{l_i}) \geq y - y_{l_i}$, we let $l_j = l_i$ in the remainder. Otherwise, we let $j$ be the smallest index larger than $i$ such that $A(x - x_{l_j}) \geq y - y_c \geq 0$. By Lemma 9, $l_j$ exists and all edges on the path $l_i, ..., l_j$ are SE edges. By triangle inequality, $d_t(l_m, l_{m+1}) \leq (x_{l_{m+1}} - x_{l_m}) + (y_{l_{m+1}} - y_{h_m})$ for any $l_m$ and $l_{m+1}$ on this path. This implies that $d_t(l_i, l_j) \leq (x_{l_j} - x_{l_i}) + (y_{l_j} - y_{l_i})$. Since $A(x - x_{l_j}) \geq y - y_{l_j} \geq 0$ and the smallest scaled translate of $R$ with $l_j$ and $v$ on its boundary is smaller than that of $u$ and $v$, we can use induction to get $d_t(l_j, v) \leq (A + \sqrt{A^2 + 1})d_x(l_j, v) + d_y(l_j, v)$. Putting everything together, this implies that

$$\begin{aligned} d_t(u,v) &\leq d_t(u,l_i) + d_t(l_i,l_j) + d_t(l_j,v) \\ &\leq (A+\sqrt{A^2+1})x_{l_i} + y_{l_i} + (x_{l_j} - x_{l_i}) + (y_{l_j} - y_{l_i}) \\ &\quad + (A+\sqrt{A^2+1})d_x(l_j,v) + d_y(l_j,v) \\ &\leq (A+\sqrt{A^2+1})x_{l_i} + (x_{l_j} - x_{l_i}) + y_{l_j} + (A+\sqrt{A^2+1})d_x(l_j,v) + d_y(l_j,v) \\ &\leq (A+\sqrt{A^2+1})x + y. \end{aligned}$$

completing the proof of Case 1 when $Ax \geq y$.

**Subcase $Ax < y$:** Consider the $(x', y')$-coordinate system where the $x'$-axis equals the $y$-axis and the $y'$-axis equals the $x$-axis. See Figure 4. When we look at the homothet rectangles $R_1, \ldots, R_k$ intersecting the segment $uv$ in the $(x', y')$-coordinate system, the horizontal side of the homothets is the longer side and we have $L = 1/A$. Therefore, $Ax < y$ implies $Lx' > y'$.

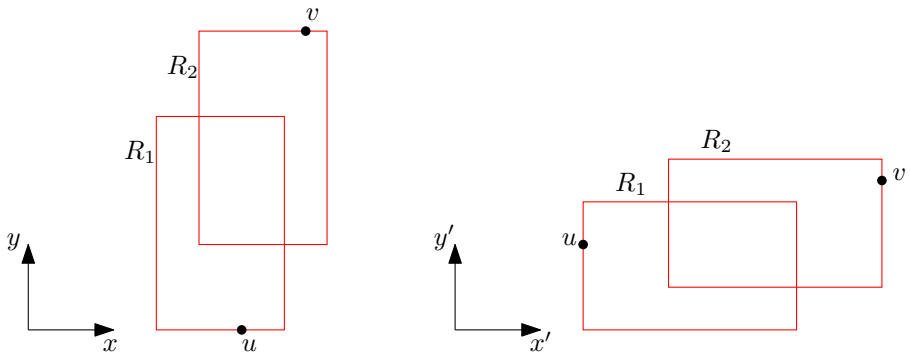

**Figure 4** Homothet rectangles $R_1, \ldots, R_k$ in the $(x', y')$-coordinate system, for $k = 2$.

If $(u, v)$ is an edge in the rectangle Delaunay triangulation, then $d_t(u,v) \leq x' + y' \leq (1+\sqrt{\frac{1}{A^2}+1})y + Ax$. If no rectangle in $R_1, ..., R_k$ is inductive then by Property 1 of Lemma 8 we know $d_t(u,v) \leq (\frac{1}{A}+\sqrt{\frac{1}{A^2}+1})x' + y' \leq (1+\sqrt{\frac{1}{A^2}+1})y + Ax$.

When there is an inductive rectangle, define $R_i$, $h_i$ and $l_i$ as above. If $h_i$ is the inductive point of $R_i$ then by Property 2$b$ of Lemma 8 we know $d_t(u,h_i) + A(y'_{h_i} - y') \leq (1+\sqrt{\frac{1}{A^2}+1})x'_{h_i}$.

If $\frac{1}{A}(x' - x'_{h_i}) \geq y'_{h_i} - y' \geq 0$, we let $h_j = h_i$ in the remainder. Otherwise, we let $j$ be the smallest index larger than $i$ such that $\frac{1}{A}(x' - x'_{h_j}) \geq y'_{h_j} - y' \geq 0$. By Lemma 9, $h_j$ exists and all edges on the path $h_i, ..., h_j$ are NE edges. By triangle inequality, $d_t(h_i,h_j) \leq (x'_{h_j} - x'_{h_i}) + (y'_{h_i} - y'_{h_j})$. Since $\frac{1}{A}(x' - x'_{h_j}) \geq y'_{h_j} - y' \geq 0$ and the smallest scaled translate of $R$ with $h_j$ and $v$ on its boundary is smaller than that of $u$ and $v$, we can use induction to get $d_t(h_j,v) \leq (1+\sqrt{\frac{1}{A^2}+1})d_y(h_j,v) + Ad_x(h_j,v)$. Putting everything together, we obtain

$$\begin{aligned}
d_t(u,v) &\leq d_t(u,h_i) + d_t(h_i,h_j) + d_t(h_j,v) \\
&\leq (1+\sqrt{\tfrac{1}{A^2}+1})x'_{h_i} - A(y'_{h_i} - y') + (x'_{h_j} - x'_{h_i}) + (y'_{h_i} - y'_{h_j}) \\
&\quad + (1+\sqrt{\tfrac{1}{A^2}+1})d_y(h_j,v) + Ad_x(h_j,v) \\
&\leq (1+\sqrt{\tfrac{1}{A^2}+1})x'_{h_i} - A(y'_{h_i} - y') + (x'_{h_j} - x'_{h_i}) + A(y'_{h_i} - y'_{h_j}) \\
&\quad + (1+\sqrt{\tfrac{1}{A^2}+1})d_y(h_j,v) + Ad_x(h_j,v) \\
&\leq (1+\sqrt{\tfrac{1}{A^2}+1})x'_{h_i} + (x'_{h_j} - x'_{h_i}) - Ad_{y'}(h_j,v) \\
&\quad + (1+\sqrt{\tfrac{1}{A^2}+1})d_y(h_j,v) + Ad_x(h_j,v).
\end{aligned}$$

Recall that the $y'$-axis in the $(x',y')$-coordinate system equals the $x$-axis in the $(x,y)$-coordinate system, so $Ad_{y'}(h_j,v) = Ad_x(h_j,v)$. Thus

$$\begin{aligned}
d_t(u,v) &\leq (1+\sqrt{\tfrac{1}{A^2}+1})x'_{h_j} + (1+\sqrt{\tfrac{1}{A^2}+1})d_y(h_j,v) \\
&= (1+\sqrt{\tfrac{1}{A^2}+1})y.
\end{aligned}$$

If $l_i$ is the inductive point of $R_i$ then by Property 2$d$ of Lemma 8 we know $d_t(u,l_i) - Ay'_{l_i} \leq (1+\sqrt{\tfrac{1}{A^2}+1})x'_{l_i}$. Thus $d_t(u,l_i) \leq (1+\sqrt{\tfrac{1}{A^2}+1})x'_{l_i} + Ay'_{l_i}$.
If $\frac{1}{A}(x' - x'_{l_i}) \geq y' - y'_{l_i} \geq 0$, we let $l_j = l_i$ in the remainder. Otherwise, we let $j$ be the smallest index larger than $i$ such that $\frac{1}{A}(x' - x'_{l_j}) \geq y' - y'_{l_j} \geq 0$. By Lemma 9, $l_j$ exists and all edges on the path $l_i, ..., l_j$ are SE edges. By triangle inequality, $d_t(l_i,l_j) \leq (x'_{l_j} - x'_{l_i}) + (y'_{l_j} - y'_{l_i})$. Since $\frac{1}{A}(x' - x'_{l_j}) \geq y' - y'_{l_j} \geq 0$ and the smallest scaled translate of $R$ with $l_j$ and $v$ on its boundary is smaller than that of $u$ and $v$, we can use induction to get $d_t(l_j,v) \leq (1+\sqrt{\tfrac{1}{A^2}+1})d_y(l_j,v) + Ad_x(l_j,v)$. Thus we obtain that

$$\begin{aligned}
d_t(u,v) &\leq d_t(u,l_i) + d_t(l_i,l_j) + d_t(l_j,v) \\
&\leq (1+\sqrt{\tfrac{1}{A^2}+1})x'_{l_i} + Ay'_{l_i} + (x'_{l_j} - x'_{l_i}) + (y'_{l_j} - y'_{l_i}) \\
&\quad + (1+\sqrt{\tfrac{1}{A^2}+1})d_y(l_j,v) + Ad_x(l_j,v) \\
&\leq (1+\sqrt{\tfrac{1}{A^2}+1})x'_{l_i} + Ay'_{l_i} + (x'_{l_j} - x'_{l_i}) + A(y'_{l_j} - y'_{l_i}) \\
&\quad + (1+\sqrt{\tfrac{1}{A^2}+1})d_y(l_j,v) + Ad_x(l_j,v) \\
&= (1+\sqrt{\tfrac{1}{A^2}+1})x'_{l_i} + (x'_{l_j} - x'_{l_i}) + Ay'_{l_j} \\
&\quad + (1+\sqrt{\tfrac{1}{A^2}+1})d_y(l_j,v) + Ad_x(l_j,v).
\end{aligned}$$

Using that $Ay'_{l_j} = Ax_{l_j}$, we obtain

$$\begin{aligned}
d_t(u,v) &\leq (1+\sqrt{\tfrac{1}{A^2}+1})y_{l_j} + (1+\sqrt{\tfrac{1}{A^2}+1})d_y(l_j,v) + Ax \\
&= (1+\sqrt{\tfrac{1}{A^2}+1})y + Ax.
\end{aligned}$$

completing the proof of Case 1.

**Case 2:** There are vertices of $P$ inside $R(u,v)$. We distinguish two subcases, either $Ax \geq y$ or $Ax < y$.

**Subcase $Ax \geq y$:** We split $R(u,v)$ into three regions formally defined as follows: $A = \{p \mid p \text{ is inside } R(u,v) \text{ such that } Ad_x(u,p) < d_y(u,p)\}$, $B = \{p \mid p \text{ is inside } R(u,v) \text{ such that } Ad_x(u,p) \geq d_y(u,p) \text{ and } Ad_x(p,v) \geq d_y(p,v)\}$, $C = \{p \mid p \text{ is inside } R(u,v) \text{ such that } Ad_x(p,v) < d_y(p,v)\}$. Informally, these three regions can be constructed by considering the line through $u$ and the line through $v$ parallel to the line through the diagonal of $R$ and labelling the resulting regions $A$, $B$, and $C$ from left to right (see Figure 5(a)).

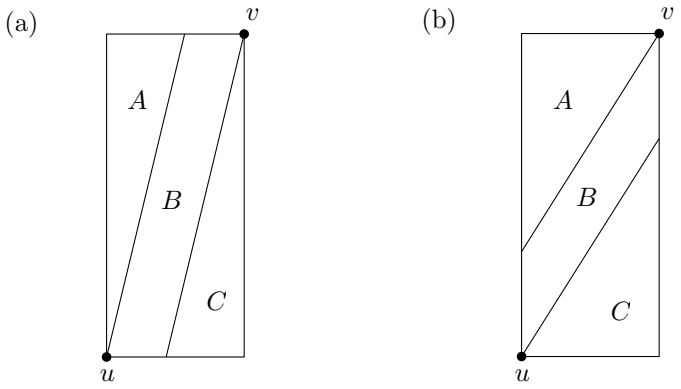

**Figure 5** (a) The three regions in $R(u,v)$ when $Ax \geq y$. (b) The three regions in $R(u,v)$ when $Ax < y$.

If there exists a vertex $p$ inside region $B$, then we can apply induction on the pairs $(u,p)$, which satisfies $Ad_x(u,p) \geq d_y(u,p)$, and $(p,v)$, which satisfies $Ad_x(p,v) \geq d_y(p,v)$:

$$\begin{aligned} d_t(u,v) &\leq d_t(u,p) + d_t(p,v) \\ &\leq (A + \sqrt{A^2+1})d_x(u,p) + d_y(u,p) + (A + \sqrt{A^2+1})d_x(p,v) + d_y(p,v) \\ &= (A + \sqrt{A^2+1})x + y. \end{aligned}$$

If there is no vertex inside region $B$, we define $R_u$ to be the smallest scaled translate of $R$ that has $u$ on its lower left corner and some vertex $p \in A$ in $R(u,v)$ on its boundary. Similarly, we define $R_v$ to be the smallest scaled translate of $R$ that has $v$ on its upper right corner and some vertex $q \in C$ in $R(u,v)$ on its boundary. Since $R(u,v)$ is not empty, at least one of $p$ and $q$ must exist. Assume without loss of generality that $p$ exists. In this case we have that $Ad_x(p,v) > d_y(p,v)$ and the smallest homothet with $p$ and $v$ on its boundary is smaller than that of $u$ and $v$. If $(u,p)$ is an edge in the rectangle Delaunay triangulation, then we obtain that:

$$\begin{aligned} d_t(u,v) &\leq d_t(u,p) + d_t(p,v) \\ &= d_2(u,p) + d_t(p,v) \\ &\leq d_x(u,p) + d_y(u,p) + (A + \sqrt{A^2+1})d_x(p,v) + d_y(p,v) \\ &\leq (A + \sqrt{A^2+1})x + y. \end{aligned}$$

An analogous argument can be used if $q$ exists and $(v,q)$ is an edge in the rectangle Delaunay triangulation.

Hence, it remains to consider the case where $(u, p)$ is not an edge, in which case $R_u$ is not empty. This implies that there exists a $p' \in C$ such that $(u, p')$ is an edge. We have that $Ad_x(p', v) < d_y(p', v)$ and the smallest scaled translate of $R$ with $p'$ and $v$ on its boundary is smaller than that of $u$ and $v$. By the induction hypothesis, we have:

$$\begin{aligned} d_t(u, v) &\leq d_t(u, p') + d_t(p', v) \\ &= d_2(u, p') + d_t(p', v) \\ &\leq d_x(u, p') + d_y(u, p') + Ad_x(p', v) + \left(1 + \sqrt{\tfrac{1}{A^2} + 1}\right) d_y(p', v) \\ &\leq Ax + \left(1 + \sqrt{\tfrac{1}{A^2} + 1}\right) y. \end{aligned}$$

Since $Ax \geq y$ and $\left(1 + \sqrt{\frac{1}{A^2} + 1}\right) > 1$, we have

$$\begin{aligned} d_t(u, v) &\leq 1Ax + \left(1 + \sqrt{\tfrac{1}{A^2} + 1}\right) y \\ &\leq \left(1 + \sqrt{\tfrac{1}{A^2} + 1}\right) Ax + 1y \\ &= \left(A + \sqrt{A^2 + 1}\right) x + y. \end{aligned}$$

**Subcase $Ax < y$:** We split $R(u, v)$ into three regions formally defined as follows: $A = \{p \mid p \text{ is inside } R(u, v) \text{ such that } Ad_x(v, p) \geq d_y(v, p)\}$, $B = \{p \mid p \text{ is inside } R(u, v) \text{ such that } Ad_x(v, p) < d_y(v, p) \text{ and } Ad_x(u, p) < d_y(u, p)\}$, $C = \{p \mid p \text{ is inside } R(u, v) \text{ such that } Ad_x(u, p) \geq d_y(u, p)\}$. See Figure 5(b).
If there exists a vertex $p$ inside region $B$, then we can apply induction on the pairs $(u, p)$, which satisfies $Ad_x(u, p) < d_y(u, p)$, and $(p, v)$, which satisfies $Ad_x(v, p) < d_y(v, p)$:

$$\begin{aligned} d_t(u, v) &\leq d_t(u, p) + d_t(p, v) \\ &\leq Ad_x(u, p) + (1 + \sqrt{\tfrac{1}{A^2} + 1}) d_y(u, p) + Ad_x(p, v) + (1 + \sqrt{\tfrac{1}{A^2} + 1}) d_y(p, v) \\ &= Ax + (1 + \sqrt{\tfrac{1}{A^2} + 1}) y. \end{aligned}$$

If there is no vertex inside region $B$, we define $R_u$ to be the smallest scaled translate of $R$ that has $u$ on its lower left corner and some vertex $p \in A$ in $R(u, v)$ on its boundary. Similarly, we define $R_v$ to be the smallest scaled translate of $R$ that has $v$ on its upper right corner and some vertex $q \in C$ in $R(u, v)$ on its boundary. Since $R(u, v)$ is not empty, at least one of $p$ and $q$ must exist. Assume without loss of generality that $p$ exists. In this case we have that $Ad_x(p, v) > d_y(p, v)$ and the smallest rectangle with $p$ and $v$ on its boundary is smaller than that of $u$ and $v$. If $(u, p)$ is an edge in the rectangle Delaunay triangulation, then we obtain that:

$$\begin{aligned} d_t(u, v) &\leq d_t(u, p) + d_t(p, v) \\ &= d_2(u, p) + d_t(p, v) \\ &\leq d_x(u, p) + d_y(u, p) + (A + \sqrt{A^2 + 1}) d_x(p, v) + d_y(p, v) \\ &\leq (A + \sqrt{A^2 + 1}) x + y. \end{aligned}$$

Since $Ax < y$, we have

$$\begin{aligned} d_t(u,v) &\leq (A+\sqrt{A^2+1})x + y \\ &= (1+\sqrt{1+\tfrac{1}{A^2}})Ax + 1y \\ &\leq Ax + (1+\sqrt{\tfrac{1}{A^2}+1})y. \end{aligned}$$

An analogous argument can be used if $q$ exists and $(v,q)$ is an edge in the rectangle Delaunay triangulation.
Hence, it remains to consider the case where $(u,p)$ is not an edge, in which case $R_u$ is not empty. This implies that there exists a $p' \in C$ such that $(u,p')$ is an edge. We have that $Ad_x(p',v) < d_y(p',v)$ and the smallest scaled translate of $R$ with $p'$ and $v$ on its boundary is smaller than that of $u$ and $v$. By the induction hypothesis, we have:

$$\begin{aligned} d_t(u,v) &\leq d_t(u,p') + d_t(p',v) \\ &= d_2(u,p') + d_t(p',v) \\ &\leq d_x(u,p') + d_y(u,p') + Ad_x(p',v) + \left(1+\sqrt{\tfrac{1}{A^2}+1}\right) d_y(p',v) \\ &\leq Ax + \left(1+\sqrt{\tfrac{1}{A^2}+1}\right) y. \end{aligned}$$

This completes the proof of Case 2 and the theorem. ◀

We can now use Theorem 10 to show an upper bound of the spanning ratio of the rectangle Delaunay triangulation. For any pair of vertices $u, v$ in the graph, if $Ad_x(u,v) \geq d_y(u,v)$ we have

$$\frac{d_t(u,v)}{d_2(u,v)} < \frac{(A+\sqrt{A^2+1})x + y}{\sqrt{x^2+y^2}}.$$

This function is maximized when $y/x = 1/(A+\sqrt{A^2+1})$, where the function is equal to

$$\sqrt{2}\sqrt{1+A^2+A\sqrt{1+A^2}}.$$

On the other hand, when $Ad_x(u,v) < d_y(u,v)$, we can get

$$\frac{d_t(u,v)}{d_2(u,v)} < \frac{Ax + (1+\sqrt{\frac{1}{A^2}+1})y}{\sqrt{x^2+y^2}}.$$

This function is maximized when $y/x = (1+\sqrt{\frac{1}{A^2}+1})/A$, where the function value equals

$$\sqrt{A^2+2+2\sqrt{1+\tfrac{1}{A^2}}+\tfrac{1}{A^2}},$$

which is at most $\sqrt{2}\sqrt{1+A^2+A\sqrt{1+A^2}}$. This implies the main result of the paper.

▶ **Theorem 11.** *The spanning ratio of the rectangle Delaunay triangulation is at most* $\sqrt{2}\sqrt{1+A^2+A\sqrt{1+A^2}}$*, where A is the aspect ratio of the rectangle used in its construction.*

Since it was already known that $\sqrt{2}\sqrt{1+A^2+A\sqrt{1+A^2}}$ is a lower bound on the spanning ratio [3], we obtain that the bound of $\sqrt{2}\sqrt{1+A^2+A\sqrt{1+A^2}}$ is tight.

# Canonization of a Random Graph by Two Matrix-Vector Multiplications

**Oleg Verbitsky**
Institut für Informatik, Humboldt-Universität zu Berlin, Germany

**Maksim Zhukovskii**
Department of Computer Science, University of Sheffield, UK

## Abstract

We show that a canonical labeling of a random $n$-vertex graph can be obtained by assigning to each vertex $x$ the triple $(w_1(x), w_2(x), w_3(x))$, where $w_k(x)$ is the number of walks of length $k$ starting from $x$. This takes time $\mathcal{O}(n^2)$, where $n^2$ is the input size, by using just two matrix-vector multiplications. The linear-time canonization of a random graph is the classical result of Babai, Erdős, and Selkow. For this purpose they use the well-known combinatorial color refinement procedure, and we make a comparative analysis of the two algorithmic approaches.

## 1 Introduction

A *walk* in a graph $G = (V, E)$ is a sequence of vertices $x_0x_1 \dots x_k$ such that $(x_i, x_{i+1}) \in E$ for every $0 \le i < k$. We say that $x_0x_1 \dots x_k$ is a walk of *length* $k$ *from* $x_0$ *to* $x_k$. For a vertex $x \in V$, let $w_k^G(x)$ denote the total number of walks of length $k$ in $G$ starting from $x$. Furthermore, we define $\mathbf{w}_k^G(x) = (w_1^G(x), \dots, w_k^G(x))$.

The Erdős-Rényi random graph $G(n, p)$ is a graph on the vertex set $[n] = \{1, \dots, n\}$ where each pair of distinct vertices $x$ and $y$ is adjacent with probability $p$ independently of the other pairs. In particular, $G(n, 1/2)$ is a random graph chosen equiprobably from among all graphs on $[n]$.

▶ **Theorem 1.** *Let $G = G(n, 1/2)$. Then*

$$\mathbf{w}_3^G(x) \neq \mathbf{w}_3^G(y) \text{ for all } x \neq y$$

*with probability at least $1 - O(\sqrt[4]{\ln n / n})$.*

If $\alpha$ is an isomorphism from a graph $G$ to a graph $H$, then clearly $\mathbf{w}_k^G(x) = \mathbf{w}_k^H(\alpha(x))$. Theorem 1, therefore, shows that the map $x \mapsto \mathbf{w}_3^G(x)$ is a canonical labeling of $G$ for almost all $n$-vertex graphs $G$. This labeling is easy to compute. Indeed, if $A$ is the adjacency matrix of $G$ and $\mathbb{1}$ is the all-ones vector-column of length $n$, then

$$(w_k^G(1), \dots, w_k^G(n))^\top = A^k \mathbb{1}.$$

After noting that $w_1^G(x) = d(x)$, where $d(x)$ denotes the degree of a vertex $x$, this yields the following simple canonical labeling algorithm.

**Algorithm A.** Canonical labeling of a random graph.

INPUT: a graph $G$ on $[n]$ with adjacency matrix $A$.

1. Form a vector $D_1 = (d(1), \dots, d(n))^\top$.
2. Compute $D_2 = AD_1$ and $D_3 = AD_2$.
3. Let $W$ be the matrix formed by the three columns $D_1, D_2, D_3$ and let $W_1, \dots, W_n$ be the rows of $W$.
4. If there are identical rows $W_x = W_y$ for some $x \neq y$, then give up. Otherwise,
5. to each vertex $x$, assign the label $W_x$.

▶ **Corollary 2.** *Algorithm A with high probability canonizes a random $n$-vertex graph, taking time $\mathcal{O}(n^2)$ on every input.*

The notation $\mathcal{O}(\cdot)$ in the time bound means a linear function up to the logarithmic factor $\log n \log\log n$ corresponding to the complexity of integer multiplication [7], that is, $\mathcal{O}(n^2) = O(n^2 \log n \log\log n)$. If the model of computation assumes that multiplication of two integers takes a constant time, then we just set $\mathcal{O}(n^2) = O(n^2)$. This time bound stems from the fact that the two matrix-vector multiplications in Step 2 are the most expensive operations performed by the algorithm. Note that this bound is essentially linear because a random graph is with high probability dense, having $(1/4 + o(1))n^2$ edges.

The linear-time canonization of almost all graphs is a classical result of Babai, Erdős, and Selkow [2], which was a basis for settling the average-case complexity of graph isomorphism in [3]. While our algorithm is based solely on basic linear-algebraic primitives, the method used in [2, 3] is purely combinatorial. Before comparing the two approaches, we put Theorem 1 in the context of the earlier work on walk counts and their applications to isomorphism testing.

Of course, Algorithm A can be enhanced by taking into account also longer walks, that is, by involving also other vector-columns $A^k\mathbb{1}$ for $k > 3$. Note that there is no gain in considering these vectors for $k \geq n$. Indeed, if $A^k\mathbb{1}$ is a linear combination of the vectors $\mathbb{1}, A\mathbb{1}, A^2\mathbb{1}, \dots, A^{k-1}\mathbb{1}$, the same is obviously true also for $A^{k+1}\mathbb{1}$ (cf. [11, Lemma 1] and see also [6] for a more detailed linear-algebraic analysis). Therefore, it suffices to start our matrix $W$ from the column $\mathbb{1}$ and add a subsequent column $A^k\mathbb{1}$ as long as this increases the rank of $W$, which is possible only up to $k = n - 1$. The $n \times n$ matrix $W = W^G$ formed by the columns $\mathbb{1}, A\mathbb{1}, \dots, A^{n-1}\mathbb{1}$ is called the *walk matrix* of the graph $G$ (*WM* for brevity). The entries of $W^G = (w_{x,k})_{1\leq x\leq n,\, 0\leq k<n}$ are nothing else as the walk counts $w_{x,k} = w_k^G(x)$. Note that $w_0^G(x) = 1$ as there is a single walk of length 0 from $x$.

We say that a graph $G$ is *WM-discrete* if the rows of the walk matrix $W^G$ are pairwise different, i.e., $W_x^G \neq W_y^G$ for all $x \neq y$. For a such $G$, the walk matrix yields a canonical labeling where each vertex $x$ is assigned the vector $W_x^G = (w_0^G(x), w_1^G(x), \dots, w_{n-1}^G(x))$. Note that if $W^G$ has identical rows, then this matrix is singular; cf. [5, Section 7]. O'Rourke and Touri [10] prove that the walk matrix of a random graph is non-singular with high probability. This implies that a random graph is WM-discrete with high probability and, hence, almost all graphs are canonizable by computing the $n \times n$ walk matrix similarly to Algorithm A. Note that this takes time $O(n^3)$, which is outperformed by our Corollary 2 due to using the truncated variant of WM of size $n \times 4$.

Remarkably, non-singular walk matrices can be used to test isomorphism of two given graphs directly rather than by computing their canonical forms. If graphs $G$ and $H$ are isomorphic, then their walk matrices $W^G$ and $W^H$ can be obtained from one another by

rearranging the rows. If the last condition is satisfied, we write $W^G \approx W^H$. This relation between matrices is efficiently checkable just by sorting the rows in the lexicographic order. We say that a graph $G$ is *WM-identifiable* if, conversely, for all $H$ we have $G \cong H$ whenever $W^G \approx W^H$. Liu and Siemons [8] prove that if the walk matrix of a graph is non-singular, then it uniquely determines the adjacency matrix. This implies by [10] that a random graph is WM-identifiable with high probability.

Note that, by a simple counting argument, almost all $n$-vertex graphs *cannot* be identified by the shorter version of the walk matrix of size $n \times k$ as long as $k = o(\sqrt{n/\log n})$. In particular, Theorem 1 cannot be extended to the identifiability concept.

The combinatorial approach of Babai, Erdős, and Selkow [2] is based on the *color refinement* procedure (*CR* for brevity) dating back to the sixties (e.g., [9]). CR begins with a uniform coloring of all vertices in an input graph and iteratively refines a current coloring according to the following principle: If two vertices are equally colored but have distinct color frequencies in their neighborhoods, then they get distinct colors in the next refinement step. The refinement steps are executed as long as the refinement is proper. As soon as the color classes stay the same, CR terminates and outputs the current coloring (a detailed description of the algorithm is given in Section 3.1). CR *distinguishes* graphs $G$ and $H$ if their color palettes are distinct. A graph $G$ is called *CR-identifiable* if it is distinguishable by CR from every non-isomorphic $H$. CR can also be used for computing a canonical labeling of a single input graph. We say that a graph $G$ is *CR-discrete* if CR assigns a unique color to each vertex of $G$. It is easy to prove that every CR-discrete graph is CR-identifiable. We do not know whether or not this is true also for the corresponding WM concepts.

Powers and Sulaiman [11] discuss examples when the CR-partition and the WM-partition are different, that is, CR and the WM-based vertex-classification algorithm give different results. In particular, [11, Fig. 3] shows a graph which is, in our terminology, CR-discrete but not WM-discrete. We give a finer information about the relationship between the two algorithmic approaches.

▶ **Theorem 3.**

1. *Every WM-discrete graph is also CR-discrete.*
2. *Every WM-identifiable graph is also CR-identifiable.*
3. *There is a graph that is*
   - **(a)** *CR-discrete (hence also CR-identifiable) and*
   - **(b)** *neither WM-discrete*
   - **(c)** *nor WM-identifiable.*

Theorem 3 shows that the WM approach is superseded by the CR algorithm with regard to canonization of a single input graph and testing isomorphism of two input graphs. Moreover, CR is sometimes more successful with respect to both algorithmic problems. Thus, WM can be regarded as a weaker algorithmic tool for canonical labeling and isomorphism testing, which is not so surprising as this approach is actually based on a single basic linear-algebraic primitive, namely matrix-vector multiplication. In this sense, Algorithm A is arguably simpler than the classical CR-based canonization of a random graph as it demonstrates that a random graph can be canonized in an essentially linear time even with less powerful computational means.

Theorems 1 and 3 are proved in Sections 2 and 3 respectively.

# 2 Canonization of a random graph

## 2.1 Probability preliminaries

Let $X$ be a binomial random variable with parameters $n$ and $p$, that is, $X = \sum_{i=1}^{n} X_i$ where $X_i$'s are mutually independent and, for each $i$, we have $X_i = 1$ with probability 1 and $X_i = 0$ with probability $1 - p$. We use the notation $X \sim \mathrm{Bin}(n, p)$ when $X$ has this distribution. As well known, $X$ is well-concentrated around its expectation $np$.

▶ **Lemma 4** (Chernoff's bound; see, e.g., [1, Corollary A.1.7]). *If $X \sim \mathrm{Bin}(n, p)$, then*

$$\mathsf{P}[|X - np| > t] \le 2e^{-2t^2/n}$$

*for every $t \ge 0$.*

▶ **Lemma 5.** *If $X$ and $Y$ are independent random variables, each having the probability distribution $\mathrm{Bin}(n, 1/2)$, then $\mathsf{P}[X = Y] < 1/\sqrt{\pi n}$.*

**Proof.** Using the well-known estimate

$$\binom{2n}{n} < \frac{2^{2n}}{\sqrt{\pi n}}, \tag{1}$$

we obtain

$$\mathsf{P}[X = Y] = \sum_{k=0}^{n} \left( \binom{n}{k} 2^{-n} \right)^2 = 2^{-2n} \sum_{k=0}^{n} \binom{n}{k}^2 = 2^{-2n} \binom{2n}{n} < \frac{1}{\sqrt{\pi n}},$$

where the last equality is a special case of Vandermonde's convolution. ◀

## 2.2 Proof of Theorem 1

For a vertex $i \in [n]$, recall that $\mathbf{w}_3(i) = (w_1^G(i), w_2^G(i), w_3^G(i))$. By the union bound,

$$\mathsf{P}[\mathbf{w}_3(i) = \mathbf{w}_3(j) \text{ for some } i, j] \le \sum_{i,j} \mathsf{P}[\mathbf{w}_3(i) = \mathbf{w}_3(j)] = \binom{n}{2} \mathsf{P}[\mathbf{w}_3(1) = \mathbf{w}_3(2)].$$

Therefore, it suffices to prove that

$$\mathsf{P}[\mathbf{w}_3(1) = \mathbf{w}_3(2)] = O(n^{-9/4} \ln^{1/4} n). \tag{2}$$

Let $N_H(v)$ denote the neighborhood of a vertex $v$ in a graph $H$. Given two sets $U_1 \subset [n] \setminus \{1\}$ and $U_2 \subset [n] \setminus \{2\}$, let $G' = G'(U_1, U_2)$ be the random graph $G$ subject to the conditions $N_G(1) = U_1$ and $N_G(2) = U_2$. In other terms, $G'$ is a random graph on $[n]$ chosen equiprobably among all graphs satisfying these conditions. Let $w'_k(i) = w_k^{G'}(i)$ denote the number of walks of length $k$ emanating from $i$ in $G'$ (the dependence of $w'_k(i)$ on the pair $U_1, U_2$ will be dropped for the sake of notational convenience). Define

$$p(U_1, U_2) = \mathsf{P}\left[ \sum_{i \in U_1} w'_1(i) = \sum_{i \in U_2} w'_1(i) \text{ and } \sum_{i \in U_1} w'_2(i) = \sum_{i \in U_2} w'_2(i) \right].$$

We have

$$\begin{aligned}&\mathsf{P}[\mathbf{w}_3(1)=\mathbf{w}_3(2)]\\&=\sum_{U_1,U_2\,:\,|U_1|=|U_2|}\mathsf{P}[\mathbf{w}_3(1)=\mathbf{w}_3(2)\mid N_G(1)=U_1,\ N_G(2)=U_2]\\&\qquad\times\mathsf{P}[N_G(1)=U_1,\,N_G(2)=U_2]\\&\qquad=\sum_{U_1,U_2\,:\,|U_1|=|U_2|}p(U_1,U_2)\times\mathsf{P}[N_G(1)=U_1,\,N_G(2)=U_2].\quad(3)\end{aligned}$$

Note first that

$$\begin{aligned}\sum_{|U_1|=|U_2|}\mathsf{P}\left[N_G(1)=U_1,\,N_G(2)=U_2\right]&=\mathsf{P}\left[|N_G(1)|=|N_G(2)|\right]\\&=\mathsf{P}\left[|N_G(1)\setminus\{2\}|=|N_G(2)\setminus\{1\}|\right]=O(n^{-1/2})\end{aligned}$$

by Lemma 5 because $|N_G(1)\setminus\{2\}|\sim\mathrm{Bin}(n-2,1/2)$ and $|N_G(2)\setminus\{1\}|\sim\mathrm{Bin}(n-2,1/2)$ are independent binomial random variables. This allows us to derive (2) from (3) if we prove that

$$p(U_1,U_2)=O(n^{-7/4}\ln^{1/4}n)\qquad(4)$$

for the neighborhood sets $U_1$ and $U_2$.

In fact, we do not need to prove (4) for all pairs $U_1,U_2$ because the contribution of some of them in (3) is negligible. Indeed, set $\varepsilon(n)=n^{-1/4}$. Note that $|N_G(j)|\sim\mathrm{Bin}(n-1,1/2)$ for $j=1,2$ and $|(N_G(1)\cap N_G(2))\setminus\{1,2\}|\sim\mathrm{Bin}(n-2,1/4)$. By the Chernoff bound (see Lemma 4), we have $(1/2-\varepsilon(n))n\le|N_G(j)|\le(1/2+\varepsilon(n))n$ for $j=1,2$ and $(1/4-\varepsilon(n))n\le|N_G(1)\cap N_G(2)|\le(1/4+\varepsilon(n))n$ with probability $1-e^{-\Omega(\sqrt{n})}$. Call a pair $U_1,U_2$ *standard* if $|U_j|$ for $j=1,2$ and $|U_1\cap U_2|$ are in the same ranges. Thus, all non-standard pairs make a negligible contribution in (3), and we only have to prove (4) for each standard pair $U_1,U_2$.

For a graph $H$ and a subset $U\subset V(H)$, let $E_H(U)$ denote the set of edges of $H$ with at least one vertex in $U$. Given two sets of edges $\mathcal{E}_1$ and $\mathcal{E}_2$ incident to the vertices in $U_1\setminus\{2\}$ and $U_2\setminus\{1\}$ respectively, let $G''=G''(U_1,U_2,\mathcal{E}_1,\mathcal{E}_2)$ be the random graph $G'$ subject to the conditions $E_{G'}(U_1\setminus\{2\})=\mathcal{E}_1$ and $E_{G'}(U_2\setminus\{1\})=\mathcal{E}_2$. Let $w''_k(i)=w_k^{G''}(i)$ denote the number of walks of length $k$ emanating from $i$ in $G''$ (the dependence of $w''_k(i)$ on $U_1,U_2,\mathcal{E}_1,\mathcal{E}_2$ is dropped for notational simplicity). Using this notation, we can write

$$\begin{aligned}p(U_1,U_2)=\sum_{\mathcal{E}_1,\mathcal{E}_2:\,\sum_{U_1}w'_1(i)=\sum_{U_2}w'_1(i)}&\mathsf{P}\left[E_{G'}(U_1\setminus\{2\})=\mathcal{E}_1,\,E_{G'}(U_2\setminus\{1\})=\mathcal{E}_2\right]\\&\times\mathsf{P}\left[\sum_{i\in U_1}w''_2(i)=\sum_{i\in U_2}w''_2(i)\right].\quad(5)\end{aligned}$$

We first show that

$$\sum_{\mathcal{E}_1,\mathcal{E}_2:\,\sum_{U_1}w'_1(i)=\sum_{U_2}w'_1(i)}\mathsf{P}\left[E_{G'}(U_1\setminus\{2\})=\mathcal{E}_1,\,E_{G'}(U_2\setminus\{1\})=\mathcal{E}_2\right]=O(1/n).\qquad(6)$$

Note that the sum in the left hand side of (6) is equal to the probability that $\sum_{i\in U_1}w'_1(i)=\sum_{i\in U_2}w'_1(i)$. This equality is equivalent to $\sum_{i\in U_1\setminus(U_2\cup\{2\})}w'_1(i)=\sum_{i\in U_2\setminus(U_1\cup\{1\})}w'_1(i)$, which in its turn is true if and only if $U_1\setminus(U_2\cup\{2\})$ and $U_2\setminus(U_1\cup\{1\})$ send the same number of edges to $[n]\setminus[(U_1\cup U_2\cup\{1,2\})\setminus(U_1\cap U_2)]$. Since the pair $U_1,U_2$ is standard, these numbers are independent binomial random variables with $\Theta(n^2)$ trials. Equality (6) now follows by Lemma 5.

We now can derive Equality (4) from Equality (6) by proving that

$$\mathsf{P}\left[\sum_{i\in U_1} w_2''(i) = \sum_{i\in U_2} w_2''(i)\right] = O(n^{-3/4}\ln^{1/4} n) \tag{7}$$

for each potential pair $\mathcal{E}_1, \mathcal{E}_2$. Again, it is enough to do this only for most probable pairs whose contribution in (5) is overwhelming. Specifically, let $w_2'(u,v)$ denote the number of all paths of length 2 between $u$ and $v$ in $G'$ and define

$$\Delta(i,j) = (w_2'(i,1) + w_2'(j,1)) - (w_2'(i,2) + w_2'(j,2)).$$

Note that the numbers $w_2'(i,1), w_2'(j,1), w_2'(i,2), w_2'(j,2)$ and, hence, the numbers $\Delta(i,j)$ are completely determined by specifying $E_{G'}(U_1 \setminus \{2\}) = \mathcal{E}_1$ and $E_{G'}(U_2 \setminus \{1\}) = \mathcal{E}_2$. We call a pair $\mathcal{E}_1, \mathcal{E}_2$ *standard* if $\Delta(i,j)$ takes on $O(\sqrt{n\ln n})$ different values for $i \neq j$ from $[n] \setminus (U_1 \cup U_2 \cup \{1,2\})$. The following fact shows that it is enough if we prove (7) for each standard pair $\mathcal{E}_1, \mathcal{E}_2$.

▷ Claim 6. If a pair $U_1, U_2$ is standard, then

$$|\{\Delta(i,j) \,:\, i,j \in [n] \setminus (U_1 \cup U_2 \cup \{1,2\}),\, i \neq j\}| = O(\sqrt{n\ln n})$$

with probability $1 - O(n^{-6})$.

Proof. Let $u_1 = |U_1|$, $u_2 = |U_2|$, and $u = |U_1 \cap U_2|$. Note that

$$\Delta(i,j) = |N_{G'}(i) \cap (U_1 \setminus U_2)| + |N_{G'}(j) \cap (U_1 \setminus U_2)| - |N_{G'}(i) \cap (U_2 \setminus U_1)| - |N_{G'}(j) \cap (U_2 \setminus U_1)|.$$

The four terms in the right hand side are independent random variables $\mathrm{Bin}(u_1 - u, 1/2)$, $\mathrm{Bin}(u_1 - u, 1/2)$, $\mathrm{Bin}(u_2 - u, 1/2)$, $\mathrm{Bin}(u_2 - u, 1/2)$ respectively. Since $N - \mathrm{Bin}(N,p) \sim \mathrm{Bin}(N, 1-p)$, we conclude that $\Delta(i,j) \sim 2u - 2u_2 + \mathrm{Bin}(2u_1 + 2u_2 - 4u, 1/2)$. The Chernoff bound (see Lemma 4) implies that, for each pair $i,j$, the inequalities

$$2u - 2u_2 + (u_1 + u_2 - 2u)\left(1 - \frac{\sqrt{2\ln n}}{\sqrt{u_1 + u_2 - 2u}}\right) \leq \Delta(i,j) \leq 2u - 2u_2 + (u_1 + u_2 - 2u)\left(1 + \frac{\sqrt{2\ln n}}{\sqrt{u_1 + u_2 - 2u}}\right)$$

are violated with probability at most $O(n^{-8})$. By the union bound, the probability that not all values $\Delta(i,j)$ fall in an integer interval of length at most

$$2\sqrt{2\ln n(u_1 + u_2 - 2u)} = O(\sqrt{n\ln n})$$

is bounded by $O(n^{-6})$. ◁

It remains to prove (7) for a fixed standard pair $\mathcal{E}_1, \mathcal{E}_2$. Note that all walks of length 3 starting from 1 and 2 and having at least 2 vertices inside $U_1 \cup U_2 \cup \{1,2\}$ are determined by $U_1, U_2, \mathcal{E}_1, \mathcal{E}_2$. Let $\gamma_j = \gamma_j(U_1, U_2, \mathcal{E}_1, \mathcal{E}_2)$ denote the number of such walks starting at $j$ for $j = 1, 2$. Let $e''_{i,j}$ be the indicator random variable of the presence of the edge $\{i,j\}$ in $G''$. The equality $\sum_{i\in U_1} w_2''(i) = \sum_{i\in U_2} w_2''(i)$ can be rewritten as

$$\gamma_1 + \sum_{i,j\notin U_1\cup U_2\cup\{1,2\}} e''_{ij}(w_2'(i,1) + w_2'(j,1)) = \gamma_2 + \sum_{i,j\notin U_1\cup U_2\cup\{1,2\}} e''_{ij}(w_2'(i,2) + w_2'(j,2)), \tag{8}$$

where the sums count the walks of length 3 from 1 and 2 whose last two vertices are outside $U_1 \cup U_2 \cup \{1,2\}$. Since $\mathcal{E}_1, \mathcal{E}_2$ is a standard pair, there exists an integer $x \neq 0$ such that $\Delta(i,j) = x$ for $\Omega(n^{3/2}/\sqrt{\ln n})$ pairs $i,j$. Let $S_x$ be the set of all such pairs. Let $G^* = G^*(U_1, U_2, \mathcal{E}_1, \mathcal{E}_2, \mathcal{E}^*)$ be obtained from $G''$ by exposing all edges except those between $i,j$ in $S_x$, where $\mathcal{E}^*$ is the set of exposed edges. Equality (8) is fulfilled if and only if

$$\sum_{\{i,j\} \in S_x} e''_{ij} x = \gamma(U_1, U_2, \mathcal{E}_1, \mathcal{E}_2, \mathcal{E}^*) \tag{9}$$

for some integer $\gamma(U_1, U_2, \mathcal{E}_1, \mathcal{E}_2, \mathcal{E}^*)$ which is completely determined by $U_1, U_2, \mathcal{E}_1, \mathcal{E}_2, \mathcal{E}^*$. It remains to note that the binomial random variable $\sum_{\{i,j\} \in S_x} e''_{ij} \sim \mathrm{Bin}(|S_x|, 1/2)$ takes on any fixed value with probability at most $\binom{|S_x|}{\lfloor |S_x|/2 \rfloor}/2^{|S_x|} = O(|S_x|^{-1/2}) = O(n^{-3/4} \ln^{1/4} n)$, where the first equality is due to (1). This completes the proof of Equality (7) and of the whole theorem.

▶ Remark 7. The probability bound in Theorem 1 cannot be significantly improved because $\mathsf{P}[\mathbf{w}_3^G(1) = \mathbf{w}_3^G(2)] = n^{-\Omega(1)}$. To see this, note first that $\mathsf{P}[w_1^G(1) = w_1^G(2)] = \Theta(n^{-1/2})$ (see the proof of Lemma 5). Assuming that a standard pair $U_1, U_2$ with $|U_1| = |U_2|$ is fixed, we can similarly show that $p(U_1, U_2) = \Theta(n^{-1})$, which implies that $\mathsf{P}[\big(w_1^G(1), w_2^G(1)\big) = \big(w_1^G(2), w_2^G(2)\big)] = \Theta(n^{-3/2})$. Showing a polynomial lower bound for $\mathsf{P}[\big(w_1^G(1), w_2^G(1), w_3^G(1)\big) = \big(w_1^G(2), w_2^G(2), w_3^G(2)\big)]$ is a slightly more delicate issue. Following the same proof strategy as for the upper bound, we have to ensure that the equation (9) has at least one integer solution $\sum_{\{i,j\} \in S_x} e''_{ij}$. We can do this because we have enough freedom in adjusting the right hand side of (9) by choosing an appropriate value of $\gamma_1 - \gamma_2$. Indeed, first of all, $|x|$ does not exceed $2n$ with probability 1. Second, we have an interval of length at least $100n$ for the values of $\gamma_1 - \gamma_2$ that are reachable with probability $\Omega(n^{-1})$. As easily seen, this is enough for obtaining a desired lower bound.

We leave as an open question whether Theorem 1 can be improved by excluding paths of length 3. Our conjecture is that this is impossible, that is, Theorem 1 is optimal in this respect, but proving this poses some technical challenges.

# 3 Comparing WM and CR

## 3.1 Color refinement

We begin with a formal description of the *color refinement* algorithm (*CR* for short). CR operates on vertex-colored graphs but applies also to uncolored graph by assuming that their vertices are colored uniformly. An input to the algorithm consists either of a single graph or a pair of graphs. Consider the former case first. For an input graph $G$ with initial coloring $C_0$, CR iteratively computes new colorings

$$C_i(x) = \Big(C_{i-1}(x), \{\!\{C_{i-1}(y)\}\!\}_{y \in N(x)}\Big), \tag{10}$$

where $\{\!\{\}\!\}$ denotes a multiset and $N(x)$ is the neighborhood of a vertex $x$. Denote the partition of $V(G)$ into the color classes of $C_i$ by $\mathcal{P}_i$. Note that each subsequent partition $\mathcal{P}_{i+1}$ is either finer than or equal to $\mathcal{P}_i$. If $\mathcal{P}_{i+1} = \mathcal{P}_i$, then $\mathcal{P}_j = \mathcal{P}_i$ for all $j \geq i$. Suppose that the color partition stabilizes in the $t$-th round, that is, $t$ is the minimum number such that $\mathcal{P}_t = \mathcal{P}_{t-1}$. CR terminates at this point and outputs the coloring $C = C_t$. Note that if the colors are computed exactly as defined by (10), they will require exponentially long color names. To prevent this, the algorithm renames the colors after each refinement step, using the same set of no more than $n$ color names.

We say that a graph $G$ is *CR-discrete* if $C(x) \neq C(x')$ for all $x \neq x'$.

If an input consists of two graphs $G$ and $H$, then it is convenient to assume that their vertex sets $V(G)$ and $V(H)$ are disjoint. The vertex colorings of $G$ and $H$ define an initial coloring $C_0$ of the union $V(G) \cup V(H)$, which is iteratively refined according to (10). The color partition $\mathcal{P}_i$ is defined exactly as above but now on the whole set $V(G) \cup V(H)$. As soon as the color partition of $V(G) \cup V(H)$ stabilizes[1], CR terminates and outputs the current coloring $C = C_t$ of $V(G) \cup V(H)$. The color names are renamed for both graphs synchronously.

We say that CR *distinguishes* $G$ and $H$ if $\{\!\{C(x)\}\!\}_{x \in V(G)} \neq \{\!\{C(x)\}\!\}_{x \in V(H)}$. A graph $G$ is called *CR-identifiable* if it is distinguishable by CR from every non-isomorphic $H$. Note that every CR-discrete graph is CR-identifiable.

## 3.2 Proof of Theorem 3

### 3.2.1 Parts 1 and 2

Parts 1 and 2 of Theorem 3 follow immediately from the lemma below. We prove this lemma by a direct combinatorial argument. Alternatively, one can use an algebraic approach in [11, Theorem 2] or the connection to finite variable logics exploited in [4, Lemma 4].

▶ **Lemma 8.** *Let $G$ and $H$ be uncolored $n$-vertex graphs (the case $G = H$ is not excluded). Let $x \in V(G)$, $x' \in V(H)$, and $k$ be an arbitrary non-negative integer. Then $C_k(x) \neq C_k(x')$ whenever $w_k^G(x) \neq w_k^H(x')$.*

**Proof.** Using the induction on $k$, we prove that $w_k^G(x) = w_k^H(x')$ whenever $C_k(x) = C_k(x')$. In the base case of $k = 0$, these equalities are equivalent just because they are both true by definition (recall that $w_0^G(x) = 0$). Assume that $C_k(y) = C_k(y')$ implies $w_k^G(y) = w_k^H(y')$ for all $y \in V(G)$ and $y' \in V(H)$. Let $C_{k+1}(x) = C_{k+1}(x')$. By the definition of the refinement step, we have $\{\!\{C_k(y)\}\!\}_{y \in N(x)} = \{\!\{C_k(y)\}\!\}_{y \in N(x')}$. Using the induction assumption, from here we derive the equality $\{\!\{w_k^G(y)\}\!\}_{y \in N(x)} = \{\!\{w_k^H(y)\}\!\}_{y \in N(x')}$. The equality $w_{k+1}^G(x) = w_{k+1}^H(x')$ now follows by noting that $w_{k+1}^G(x) = \sum_{y \in N(x)} w_k^G(y)$. ◀

### 3.2.2 Part 3

We now construct a graph $G$ with the three desired properties (a)–(c). Note that this graph can be used in an obvious way to produce infinitely many examples separating the strength of WM and CR.

Let $\mathbb{Z}_n$ denote the cyclic group with elements $0, 1, \ldots, n$ and operation being the addition modulo $n$. Our construction is based on the well-known Shrikhande graph; see, e.g., [12]. This is the Cayley graph of the group $\mathbb{Z}_4 \times \mathbb{Z}_4$ with connection set $\{\pm(1,0), \pm(0,1), \pm(1,1)\}$. A natural drawing of the Shrikhande graph on the torus can be seen in both parts of Fig. 1.

Recall that a graph $G$ is *strongly regular* with parameters $(n, d, \lambda, \mu)$ if it has $n$ vertices, every vertex in $G$ has $d$ neighbors (i.e., $G$ is *regular* of degree $d$), every two adjacent vertices of $G$ have $\lambda$ common neighbors, and every two non-adjacent vertices have $\mu$ common neighbors. We will use two properties of the Shrikhande graph:

- It is a strongly regular graph with parameters $(16, 6, 2, 2)$.
- The pairs $u, v$ of non-adjacent vertices in the graph are split into two categories depending on whether the two common neighbors of $u$ and $v$ are adjacent or not.

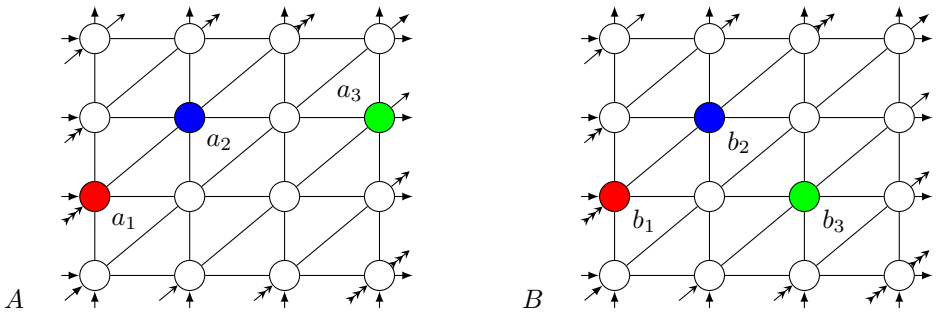

**Figure 1** Two colored versions of the Shrikhande graph.

Consider two copies $A$ and $B$ of the Shrikhande graph. In each of $A$ and $B$, let us individualize three vertices, $a_1, a_2, a_3$ in $A$ and $b_1, b_2, b_3$ in $B$, by assigning unique colors as shown in Fig. 1. The vertices $a_i$ and $b_i$ for each $i = 1, 2, 3$ are equally colored. All non-individualized vertices are considered also colored, all in the same color. Of the three vertices $a_1, a_2, a_3$, only $a_1$ and $a_2$ are adjacent, and the vertices $b_1, b_2, b_3$ have the same adjacency pattern. An important difference between $A$ and $B$ is that the two common neighbors of $b_2$ and $b_3$ are adjacent while the two common neighbors of $a_2$ and $a_3$ are not.[2] This implies that the vertex-colored graphs $A$ and $B$ are non-isomorphic.

Before presenting further details, we give a brief outline of the rest of the proof. We will begin with establishing some useful properties of $A$ and $B$. Though these graphs are non-isomorphic, it is useful to notice that they are still quite similar in the sense that they are indistinguishable by one round of CR (Claim 9). On the other hand, both $A$ and $B$ are CR-discrete (Claim 10) and are, therefore, distinguished after CR makes sufficiently many rounds (Claim 11). The desired graph $G$ will be constructed from $A$ and $B$ by connecting the equally colored vertices, i.e., $a_i$ and $b_i$, via new edges and vertices. While $a_1, a_2, a_3, b_1, b_2, b_3$ are not colored any more in $G$, their neighborhoods are modified so that their colors are actually simulated by iterated degrees. This allows us to derive from Claims 10 and 11 that $G$ is CR-discrete (Claim 12). On the other hand, $G$ is not WM-discrete (Claim 14). In order to show that some vertices in $G$ have the same numbers of outgoing walks of each length, we use some basic properties of strongly regular graphs (Claim 13) and the fact that a walk can leave $A$ or $B$ only via one of the vertices $a_1, a_2, a_3, b_1, b_2, b_3$ (and here an important role is played by Claim 9). Finally, we argue that $G$ is not WM-identifiable (Claim 15). Indeed, if we construct another graph $G'$ similarly to $G$ but using two copies of $A$, then $G$ and $G'$ will have the same walk matrix.

We now proceed with the detailed proof.

▷ Claim 9. After the first round of CR, the vertex-colored graphs $A$ and $B$ are still indistinguishable. That is, there is a bijection $f : V(A) \to V(B)$ such that $C_1(x) = C_1(f(x))$ for all $x \in V(A)$.

[1] Note that the stabilization on each of the sets $V(G)$ and $V(H)$ can occur earlier than on $V(G) \cup V(H)$.
[2] Using the fact that the Shrikhande graph is arc-transitive, it is easy to check that $A$ and $B$ are defined uniquely up to isomorphism of colored graphs.

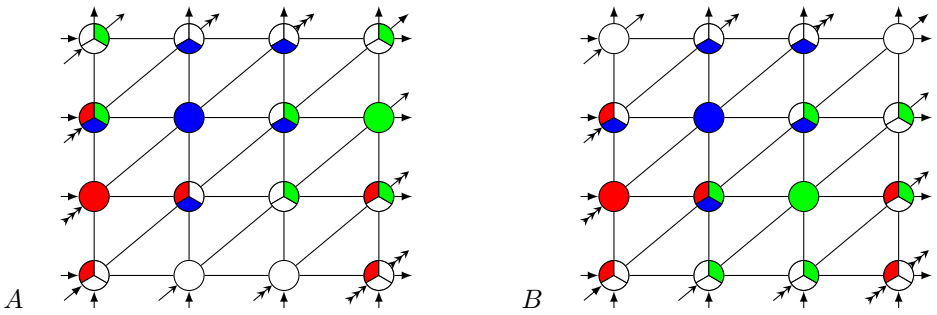

**Figure 2** The colorings of $A$ and $B$ after the first color refinement round. For each $i = 1, 2, 3$, the vertices $a_i$ and $b_i$ have the same unique color. The color of each non-individualized vertex is determined by its adjacency to the individualized vertices. For example, the color of a vertex in $A$ means that this vertex is adjacent to $a_1$ and $a_2$ but not to $a_3$.

Proof. Since $A$ and $B$ are regular graphs of the same degree, the equally colored vertices $x \in V(A)$ and $x' \in V(B)$ obtain distinct colors after the first color refinement round only when their neighborhoods contain different sets of individualized vertices (that is, $a_i \in N(x)$ while $b_i \notin N(x')$ or vice versa for some $i = 1, 2, 3$). This is not the case for the individualized vertices because the correspondence $a_i \mapsto b_i$ is a partial isomorphism of $A$ and $B$. As for the non-individualized vertices, both $A$ and $B$ have exactly one vertex adjacent to all the three individualized vertices, three vertices adjacent to exactly two of them, and two vertices adjacent to none of them. Moreover, in both $A$ and $B$ there are two non-individualized vertices adjacent to $a_i$ (resp. to $b_i$) for each $i = 1, 2$ and three non-individualized vertices adjacent to $a_3$ (resp. to $b_3$). The colorings of $A$ and $B$ after the first refinement round are shown in Fig. 2. ◁

▷ Claim 10. Both vertex-colored graphs $A$ and $B$ are CR-discrete.

Proof. Call a vertex *solitary* if CR colors it differently than the other vertices of the graphs. We prove that every vertex in $A$ is solitary. Virtually the same argument applies also to $B$. The individualized vertices $a_1, a_2, a_3$ are solitary from the very beginning. The single vertex $a$ adjacent to all of them is obviously also solitary. Thus, $A$ contains a triangle subgraph whose all vertices, namely $a, a_1, a_2$, are solitary. Let $a'$ be the common neighbor of $a_1$ and $a_2$ different from $a$ (recall that the Shrikhande graph is strongly regular with the third parameter $\lambda = 2$). The fact that $a_1$ and $a_2$ are solitary implies that the equality $C(a') = C(x)$ for $x \neq a'$ can be true only if $x = a$, which is actually impossible because $a$ is solitary. Therefore, $a'$ is solitary too. This argument applies to any triangle whose all vertices are solitary and to the other common neighbor of any two vertices of this triangle. Consider the graph whose vertices are the triangles of the Shrikhande graph, adjacent exactly when they share an edge. This graph (known as the *Dyck graph*) is obviously connected, which readily implies that all vertices of $A$ are solitary. ◁

▷ Claim 11. The vertex-colored graphs $A$ and $B$ are distinguishable by CR.

Proof. Recall that $A$ and $B$ are non-isomorphic because the two common neighbors of $b_2$ and $b_3$ are adjacent while the two common neighbors of $a_2$ and $a_3$ are not. By Claim 10, both $A$ and $B$ are CR-discrete. Assume that $A$ and $B$ are indistinguishable by CR. Let $f$ be

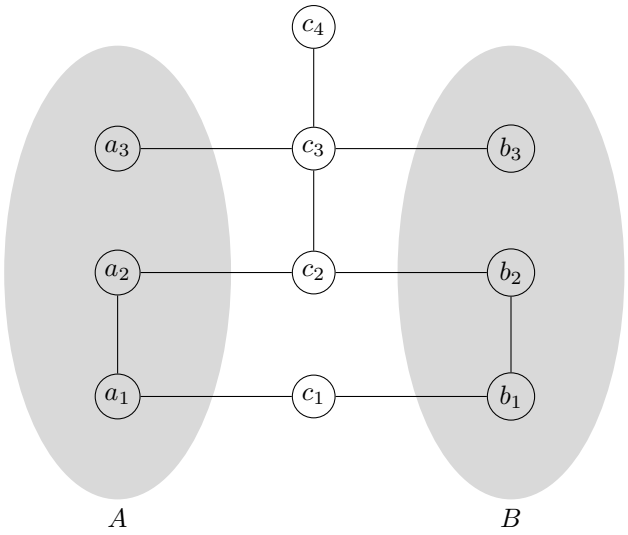

**Figure 3** Construction of $G$.

the bijection from $V(A)$ to $V(B)$ respecting the final CR-coloring, that is, $C(f(x)) = C(x)$ for all $x \in V(A)$. Since $f$ is not an isomorphism, there are vertices $u$ and $v$ in $A$ such that $u$ and $v$ are adjacent but $f(u)$ and $f(v)$ are not or vice versa. This shows, however, that the coloring $C$ is still unstable because, by the refinement rule, $u$ and $f(u)$ have to receive distinct colors in the next round. This contradiction proves the claim. ◁

We now construct a graph $G$ as the vertex-disjoint union of $A$ and $B$ where each pair $a_i, b_i$ is connected via new edges and new intermediate vertices as shown in Fig. 3. Thus, $V(G) = V(A) \cup V(B) \cup \{c_1, c_2, c_3, c_4\}$ where $c_1, c_2, c_3, c_4$ are new connector vertices of degree $2, 3, 4, 1$ respectively. The graph $G$ is uncolored, that is, the colors of the six individualized vertices $a_1, a_2, a_3, b_1, b_2, b_3$ are erased. The next claim proves Part 3(a) of the theorem.

▷ Claim 12. $G$ is CR-discrete.

Proof. The connector vertices $c_1, c_2, c_3, c_4$ have unique degrees $2, 3, 4, 1$ and become solitary after the first refinement round. The vertices $a_1, a_2, a_3$ have degree 7, while the other vertices in $A$ have degree 6. Each of the three vertices $a_1, a_2, a_3$ is distinguished from the other two by the adjacency to its own connector. It follows that after the second refinement round, the colors $C_2(a_1), C_2(a_2), C_2(a_3)$ become unique within $A$ (even when still $C_2(a_i) = C_2(b_i)$). Claim 10, therefore, implies that eventually $C(x) \neq C(x')$ for all $x \neq x'$ in $A$. The same argument applies to $B$. Using the same argument as in the proof of Claim 11, we also have $C(x) \neq C(x')$ for all $x \in V(A)$ and $x' \in V(B)$. ◁

Let $w_k^R(x, y)$ denote the number of walks of length $k$ from a vertex $x$ to a vertex $y$ in a graph $R$. We will need the following simple and well-known facts.[3]

[3] Let $P_{k+1}$ be a path of length $k$ with end vertices $s$ and $t$. Note that $w_k^R(x, y)$ is equal to the number of all homomorphisms from $P_{k+1}$ to $R$ taking $s$ to $x$ and $t$ to $y$. Part 2 of Claim 13 is a particular case of a much more general result about the invariance of homomorphism counts under the Weisfeiler-Leman equivalence for graphs with designated vertices [4, Lemma 4].

▷ Claim 13.

1. If $R$ is a regular graph of degree $d$, then $w_k^R(x) = d^k$ for every $x \in V(R)$.
2. Suppose now that $R$ is a strongly regular graph with parameters $(n, d, \lambda, \mu)$ and fix an arbitrary $k \geq 0$. Then the walk count $w_k^R(x, x)$ is the same for every $x \in V(R)$. If $x \neq y$, then the value of $w_k^R(x, y)$ depends only on the adjacency of $x$ and $y$ (and on the parameters $d, \lambda, \mu$).

Proof. Part 1 is obvious. Part 2 follows from an easy inductive argument. Indeed, it is trivially true for $k = 0$. Assume that $w_k^R(x, y) = a_k$ for all adjacent $x$ and $y$ and that $w_k^R(x, y) = n_k$ for all non-adjacent unequal $x$ and $y$. Then $w_{k+1}^R(x, x) = \sum_{z \in N(x)} w_k^R(z, x) = d\, a_k$. If $x$ and $y$ are adjacent, then

$$w_{k+1}^R(x, y) = \sum_{z \in N(x) \cap N(y)} w_k^R(z, y) + \sum_{z \in N(x) \setminus N(y)} w_k^R(z, y) = \lambda a_k + (d - \lambda) n_k.$$

If $x$ and $y$ are non-adjacent and unequal, then

$$w_{k+1}^R(x, y) = \sum_{z \in N(x) \cap N(y)} w_k^R(z, y) + \sum_{z \in N(x) \setminus N(y)} w_k^R(z, y) = \mu a_k + (d - \mu) n_k,$$

enabling the induction step. ◁

We are now prepared to prove Part 3(b) of the theorem.

▷ Claim 14. $G$ is not WM-discrete.

Proof. Define an equivalence relation $\equiv$ on $V(G)$ as follows. Each connector vertex is equivalent only to itself. Let $C_1$ be the coloring of $V(A) \cup V(B)$ obtained after the first round of the execution of CR on the vertex-colored graphs $A$ and $B$; see Claim 9. We set $x \equiv x'$ for $x, x' \in V(A) \cup V(B)$ if $C_1(x) = C_1(x')$. Recall that the largest equivalence class of $\equiv$ consists of six vertices (three uncolored vertices in $A$ adjacent to $a_3$ but neither to $a_1$ nor to $a_2$ and three uncolored vertices in $B$ adjacent to $b_3$ but neither to $b_1$ nor to $b_2$). We claim that $w_k^G(x) = w_k^G(x')$ for every $k$ whenever $x \equiv x'$. Indeed, if $x \in V(A)$, then

$$w_k^G(x) = w_k^A(x) + \sum_{i=1}^{3} \sum_{j=0}^{k-1} w_j^A(x, a_i) w_{k-j-1}^G(c_i). \tag{11}$$

Here, we separately consider the walks of length $k$ inside $A$ and the walks of length $k$ leaving $A$. A walk can leave $A$ only after visiting one of the vertices $a_1, a_2, a_3$. If such a walk leaves $A$ first after the $j$-th step via $a_i$, it arrives at the connector $c_i$ and, starting from it, makes the remaining $k - j - 1$ steps. The similar equality holds for $x \in V(B)$.

It remains to notice that the right hand side of (11) and its analog for $B$ yield the same value for all $x$ in the same $\equiv$-class. Indeed, let $x \equiv x'$ and suppose that $x \in A$ and $x' \in B$ (the cases $x, x' \in A$ and $x, x' \in B$ are completely similar). Then $w_k^A(x) = w_k^B(x') = 6^k$ by Part 1 of Claim 13. Finally, for each $j$ the equalities $w_j^A(x, a_i) = w_j^B(x, b_i)$ for $i = 1, 2, 3$ follow from Part 2 of Claim 13 by the definition of the relation $\equiv$ and the description of $C_1$ in the proof of Claim 9. ◁

It remains to prove Part 3(c) of the theorem.

▷ Claim 15. $G$ is not WM-identifiable.

Proof. Construct $G'$ in the same way as $G$ but using a copy $A'$ of $A$ instead of $B$. The graphs $G$ and $G'$ are non-isomorphic, basically because $A$ and $B$ are non-isomorphic as colored graphs. In particular, $G'$ has an automorphism fixing the connector vertices and transposing $A$ and $A'$, whereas $G$ has no non-trivial automorphism by Claim 12. Fix a colored-graph isomorphism $f'$ from $A'$ to $A$. Define a bijection $F$ from $V(G') = V(A) \cup V(A') \cup \{c_1, c_2, c_3, c_4\}$ onto $V(G) = V(A) \cup V(B) \cup \{c_1, c_2, c_3, c_4\}$ so that $F(c_i) = c_i$ for $i = 1, 2, 3, 4$, the restriction $f$ of $F$ to $V(A)$ is as in Claim 9, and the restriction of $F$ to $V(A')$ is the isomorphism $f'$. The proof of Claim 14 applies to the graph $G'$ virtually without changes. In particular, the analog of Equality (11) for $G'$ allows us to show by a simple induction that $w_k^{G'}(x) = w_k^G(f(x))$ for $x \in V(A)$ and $w_k^{G'}(x') = w_k^G(f'(x'))$ for $x' \in V(A')$, as well as that $w_k^{G'}(c_i) = w_k^G(c_i)$ for $i = 1, 2, 3, 4$. Thus, for every $x \in V(G')$ we have $w_k^{G'}(x) = w_k^G(F(x))$ for all $k$, implying that $G$ and $G'$ are WM-indistinguishable. ◁

The proof of Theorem 3 is complete.

## Abstract

In this paper, we propose new techniques for solving geometric optimization problems involving interpoint distances of a point set in the plane. Given a set $P$ of $n$ points in the plane and an integer $1 \leq k \leq \binom{n}{2}$, the distance selection problem is to find the $k$-th smallest interpoint distance among all pairs of points of $P$. The previously best deterministic algorithm solves the problem in $O(n^{4/3} \log^2 n)$ time [Katz and Sharir, 1997]. In this paper, we improve their algorithm to $O(n^{4/3} \log n)$ time. Using similar techniques, we also give improved algorithms on both the two-sided and the one-sided discrete Fréchet distance with shortcuts problem for two point sets in the plane. For the two-sided problem (resp., one-sided problem), we improve the previous work [Avraham, Filtser, Kaplan, Katz, and Sharir, 2015] by a factor of roughly $\log^2(m+n)$ (resp., $(m+n)^\epsilon$), where $m$ and $n$ are the sizes of the two input point sets, respectively. Other problems whose solutions can be improved by our techniques include the reverse shortest path problems for unit-disk graphs. Our techniques are quite general and we believe they will find many other applications in future.

## 1 Introduction

In this paper, we propose new techniques for solving geometric optimization problems involving interpoint distances in a point set in the plane. More specifically, the optimal objective value of these problems is equal to the (Euclidean) distance of two points in the set. Our techniques usually yield improvements over the previous work by at least a logarithmic factor (and sometimes a polynomial factor).

The first problem we consider is the *distance selection* problem: Given a set $P$ of $n$ points in the plane and an integer $1 \leq k \leq \binom{n}{2}$, the problem asks for the $k$-th smallest interpoint distance among all pairs of points of $P$. The problem can be easily solved in $O(n^2)$ time. The first subquadratic time algorithm was given by Chazelle [10]; the algorithm runs in $O(n^{9/5} \log^{4/5} n)$ time and is based on Yao's technique [21]. Later, Agarwal, Aronov, Sharir, and Suri [1] gave a better algorithm of $O(n^{3/2} \log^{5/2} n)$ time and subsequently Goodrich [13] solved the problem in $O(n^{4/3} \log^{8/3} n)$ time. Katz and Sharir [14] finally presented an $O(n^{4/3} \log^2 n)$ time algorithm. All above are deterministic algorithms. Several randomized algorithms have also been proposed for the problem. The randomized algorithm of [1] runs in $O(n^{4/3} \log^{8/3} n)$ expected time. Matousek [17] gave another randomized algorithm of

[1] Corresponding author.

$O(n^{4/3}\log^{2/3} n)$ expected time. Very recently, Chan and Zheng proposed a randomized algorithm of $O(n^{4/3})$ expected time (see the arXiv version of [9]). Also, the time complexity can be made as a function of $k$. In particular, Chan's randomized techniques [7] solved the problem in $O(n\log n + n^{2/3}k^{1/3}\log^{5/3} n)$ expected time and Wang [18] recently improved the algorithm to $O(n\log n + n^{2/3}k^{1/3}\log n)$ expected time; these algorithms are particularly interesting when $k$ is relatively small.

In this paper, we present a new deterministic algorithm that solves the distance selection problem in $O(n^{4/3}\log n)$ time. Albeit slower than the randomized algorithm of Chan and Zheng [9], our algorithm is the first progress on the deterministic solution since the work of Katz and Sharir [14] published 25 years ago (30 years if we consider their conference version in SoCG 1993). One technique we introduce is an algorithm for solving the following *partial batched range searching problem*.

▶ **Problem 1** (Partial batched range searching). *Given a set $A$ of $m$ points and a set $B$ of $n$ points in the plane and an interval $(\alpha,\beta]$, one needs to construct two collections of edge-disjoint complete bipartite graphs $\Gamma(A,B,\alpha,\beta) = \{A_t \times B_t \mid A_t \subseteq A, B_t \subseteq B\}$ and $\Pi(A,B,\alpha,\beta) = \{A'_s \times B'_s \mid A'_s \subseteq A, B'_s \subseteq B\}$ such that the following two conditions are satisfied.*

1. *For each pair $(a,b) \in A_t \times B_t \in \Gamma(A,B,\alpha,\beta)$, the (Euclidean) distance $\|ab\|$ between points $a \in A_t$ and $b \in B_t$ is in $(\alpha,\beta]$.*
2. *For any two points $a \in A$ and $b \in B$ with $\|ab\| \in (\alpha,\beta]$, either $\Gamma(A,B,\alpha,\beta)$ has a unique graph $A_t \times B_t$ that contains $(a,b)$ or $\Pi(A,B,\alpha,\beta)$ has a unique graph $A'_s \times B'_s$ that contains $(a,b)$.*

*In other words, the two collections $\Gamma$ and $\Pi$ together record all pairs $(a,b)$ of points $a \in A$ and $b \in B$ whose distances are in $(\alpha,\beta]$. While all pairs of points recorded in $\Gamma$ have their distances in $(\alpha,\beta]$, this may not be true for $\Pi$. For this reason, we sometimes call the point pairs recorded in $\Pi$* uncertain pairs.

Note that if context is clear, we sometimes use $\Gamma$ and $\Pi$ to refer to $\Gamma(A,B,\alpha,\beta)$ and $\Pi(A,B,\alpha,\beta)$, respectively. Also, for short, we use BRS to refer to batched range searching.

In the traditional BRS, which has been studied with many applications, e.g.,[20, 15, 4], the collection $\Pi$ is $\emptyset$ (and thus $\Gamma$ itself satisfies the two conditions in Problem 1); for differentiation, we refer to this case as the *complete BRS*. The advantage of the partial problem over the complete problem is that the partial problem can usually be solved faster, with a sacrifice that some uncertain pairs (i.e., those recorded in $\Pi$) are left unresolved. As will be seen later, in typical applications the number of those uncertain pairs can be made small enough so that they can be handled easily without affecting the overall runtime of the algorithm. More specifically, we derive an algorithm to compute a solution for the partial BRS, whose runtime is controlled by a parameter (roughly speaking, the runtime increases as the graph sizes of $\Pi$ decreases). Previously, Katz and Sharir [14] gave an algorithm for the complete problem. Our solution, albeit for the more general partial problem, even improves their algorithm by roughly a logarithmic factor when applied to the complete case.

On the one hand, our partial BRS solution helps achieve our new result for the distance selection problem. On the other hand, combining some techniques for the latter problem, we propose a general algorithmic framework that can be used to solve any geometric optimization problem that involves interpoint distances of a set of points in the plane. Consider such a problem whose optimal objective value (denoted by $\delta^*$) is equal to the distance of two points of a set $P$ of $n$ points in the plane. Assume that the decision problem (i.e., given $\delta$, decide whether $\delta \geq \delta^*$) can be solved in $T_D$ time. A straightforward algorithm for computing $\delta^*$ is to

use the distance selection algorithm and the decision algorithm to perform binary search on interpoint distances of all pairs of points of $P$; the algorithm runs in $O(\log n)$ iterations and each iteration takes $O(n^{4/3}\log n + T_D)$ time (if we use our new distance selection algorithm). As such, the total runtime is $O((n^{4/3}\log n + T_D)\log n)$. Using our new framework, the runtime can be bounded by $O((n^{4/3} + T_D)\log n)$, which is faster when $T_D = o(n^{4/3}\log n)$.

One application of this new framework is the *two-sided discrete Fréchet distance with shortcuts* problem, or *two-sided DFD* for short. Fréchet distance is used to measure the similarity between two curves and many of its variations have been studied, e.g., [2, 3, 4, 5, 6, 12]. To reduce the impact of outliers between two (sampled) curves, discrete Fréchet distance with shortcuts was proposed [4, 12]. If outliers of only one curve need to be taken care of, it is called *one-sided DFD*; otherwise it is *two-sided DFD*. Avraham, Filtser, Kaplan, Katz, and Sharir [4] solved the two-sided DFD in $O((m^{2/3}n^{2/3} + m + n)\log^3(m+n))$, where $m$ and $n$ are the numbers of vertices of the two input curves, respectively. Using our new framework, we improve their algorithm to $O((m^{2/3}n^{2/3}\cdot 2^{O(\log^*(m+n))} + m\log n + n\log m)\log(m+n))$ time, an improvement of roughly $O(\log^2(m+n))$.

For the one-sided DFD, the authors of [4] gave a randomized algorithm of $O((m+n)^{6/5+\epsilon})$ expected time, for any constant $\epsilon > 0$. Using our solution to the partial BRS, we improve their algorithm to $O((m+n)^{6/5}\log^{8/5}(m+n))$ expected time. Based on the techniques of [4], Katz and Sharir [15] proposed an algorithmic framework for solving geometric optimization problems that involve interpoint distances in a point set. Consider such a problem whose optimal objective value (denoted by $\delta^*$) is equal to the distance of two points of a set $P$ of $n$ points in the plane. The framework has two main procedures. The first procedure is to compute an interval that contains $\delta^*$ and with high probability at most $L$ interpoint distances of $P$. Using the interval and a *bifurcation tree* technique, the second main procedure finally computes $\delta^*$. Assuming that the decision problem can be solved in $T_D$ time, the first main procedure takes $O(n^{4/3+\epsilon}/L^{1/3} + T_D\cdot\log n\cdot\log\log n)$ expected time and the second one runs in $O(L^{1/2}\cdot T_D\cdot\log n)$ time, resulting in an algorithm of $O(n^{4/3+\epsilon}/L^{1/3} + T_D\cdot\log n\cdot\log\log n + L^{1/2}\cdot T_D\cdot\log n)$ expected time in total [4, 15]. Using our partial BRS solution, we improve the first main procedure to $O(n^{4/3}/L^{1/3}\cdot\log^2 n + T_D\cdot\log n\cdot\log\log n)$ expected time, which eliminates the $O(n^\epsilon)$ factor. Thus, the total expected time of the framework becomes $O(n^{4/3}/L^{1/3}\cdot\log^2 n + T_D\cdot\log n\cdot\log\log n + L^{1/2}\cdot T_D\cdot\log n)$. Our result for the one-sided DFD is a direct application of this framework. More specifically, since $T_D = O(m+n)$ [4], we set $L = (m+n)^{2/5}\log^{6/5}(m+n)$ and replace $n$ by $(m+n)$ in the above time complexity as there are two parameters $m$ and $n$ in the problem.

We demonstrate two more applications of the framework where our new techniques lead to improved results over the previous work: the *reverse shortest paths in unit-disk graphs* and its weighted case. Given a set $P$ of $n$ points in the plane and a parameter $\delta > 0$, the unit-disk graph $G_\delta(P)$ is an undirected graph whose vertex set is $P$ such that an edge connects two points $p, q \in P$ if the (Euclidean) distance between $p$ and $q$ is at most $\delta$. In the unweighted (resp., weighted) case, the weight of each edge is equal to 1 (resp., the distance between the two vertices). Given $P$, two points $s, t \in P$, and a parameter $\lambda$, the problem is to compute the smallest $\delta^*$ such that the shortest path length between $s$ and $t$ in $G_{\delta^*}(P)$ is at most $\lambda$.

Deterministic algorithms of $O(n^{5/4}\log^{7/4} n)$ and $O(n^{5/4}\log^{5/2} n)$ times are known for the unweighted and weighted problems, respectively [20]. The decision problem for the unweighted case can be solved in $O(n)$ time (after points of $P$ are sorted) [8] while the weighted case can be solved in $O(n\log^2 n)$ time [19]. As such, using their framework, Katz and Sharir [15] solved both problems in $O(n^{6/5+\epsilon})$ expected time (by setting $L = n^{2/5}$). With our improvement to the framework, we can now solve the unweighted problem in $O(n^{6/5}\log^{8/5} n)$ expected time (by setting $L = n^{2/5}\log^{6/5} n$) and solve the weighted case in $O(n^{6/5}\log^{12/5} n)$ expected time (by setting $L = n^{2/5}/\log^{6/5} n$).

In summary, we propose two algorithmic frameworks for geometric optimization problems that involve interpoint distances in a set of points in the plane. The first one is deterministic while the second one is randomized. The first framework is mainly useful when the decision algorithm time $T_D$ is relatively large (e.g., close to $O(n^{4/3})$) while the second one is more interesting when $T_D$ is small (e.g., near linear). Both frameworks rely on our solution to the partial BRS problem. As optimization problems involving interpoint distances are very common in computational geometry, we believe our techniques will find more applications.

**Outline.** The rest of the paper is organized as follows. Section 2 presents our algorithm for the partial BRS. The distance selection algorithm is described in Section 3. The two-sided DFD problem is solved in Section 4, where we also propose our first algorithmic framework. The one-sided DFD and our second algorithmic framework are discussed in Section 5. Due to the space limit, some details and proofs are omitted but can be found in the full paper.

## 2 Partial batched range searching

In this section, we present our solution to the partial BRS problem, i.e., Problem 1. We follow the notation in the statement of Problem 1. In particular, $m = |A|$ and $n = |B|$.

For any set $P$ of points and a compact region $R$ in the plane, let $P(R)$ denote the subset of points of $P$ in $R$, i.e., $P(R) = P \cap R$. For any point $p$ in the plane, with respect to the interval $(\alpha, \beta]$ in Problem 1, let $D_p$ denote the annulus centered at $p$ and having radii $\alpha$ and $\beta$ (e.g., see Fig. 1); so $D_p$ has an inner boundary circle of radius $\alpha$ and an outer boundary circle of radius $\beta$. We assume that $D_p$ includes its outer boundary circle but not its inner boundary circle. In this way, a point $q$ is in $D_p$ if and only if $\|pq\| \in (\alpha, \beta]$. Define $\mathcal{D}$ as the set of all annuli $D_p$ for all points $p \in A$. Define $\mathcal{C}$ to be the set of boundary circles of all annuli of $\mathcal{D}$. Hence, $\mathcal{C}$ consists of $2m$ circles. For any compact region $R$ in the plane, let $\mathcal{C}_R$ denote the subset of circles of $\mathcal{C}$ that intersect the relative interior of $R$.

An important tool we use is the cuttings [11]. For a parameter $1 \leq r \leq n$, a $(1/r)$-cutting $\Xi$ of size $O(r^2)$ for $\mathcal{C}$ is a collection of $O(r^2)$ constant-complexity cells whose union covers the plane such that the interior of each cell $\sigma \in \Xi$ is intersected by at most $m/r$ circles in $\mathcal{C}$, i.e., $|\mathcal{C}_\sigma| \leq m/r$. We actually use *hierarchical cuttings* [11]. We say that a cutting $\Xi'$ *c-refines* a cutting $\Xi$ if each cell of $\Xi'$ is contained in a single cell of $\Xi$ and every cell of $\Xi$ contains at most $c$ cells of $\Xi'$. Let $\Xi_0$ denote the cutting whose single cell is the whole plane. Then we define cuttings $\{\Xi_0, \Xi_1, ..., \Xi_k\}$, in which each $\Xi_i$, $1 \leq i \leq k$, is a $(1/\rho^i)$-cutting of size $O(\rho^{2i})$ that $c$-refines $\Xi_{i-1}$, for two constants $\rho$ and $c$. By setting $k = \lceil \log_\rho r \rceil$, the last cutting $\Xi_k$ is a $(1/r)$-cutting. The sequence $\{\Xi_0, \Xi_1, ..., \Xi_k\}$ of cuttings is called a hierarchical $(1/r)$-cutting of $\mathcal{C}$. For a cell $\sigma'$ of $\Xi_{i-1}$, $1 \leq i \leq k$, that fully contains cell $\sigma$ of $\Xi_i$, we say that $\sigma'$ is the *parent* of $\sigma$ and $\sigma$ is a *child* of $\sigma'$. Thus the hierarchical $(1/r)$-cutting can be viewed as a tree structure with $\Xi_0$ as the root.

A hierarchical $(1/r)$-cutting of $\mathcal{C}$ can be computed in $O(mr)$ time, e.g., by the algorithm in [18], which adapts Chazelle's algorithm [11] for hyperplanes. The algorithm also produces the subset $\mathcal{C}_\sigma$ for all cells $\sigma \in \Xi_i$ for all $i = 0, 1, \ldots, k$, implying that the total size of these subsets is $O(mr)$. In particular, each cell of the cutting produced by the algorithm of [18] is a *pseudo-trapezoid* that is bounded by two vertical line segments from left and right, an arc of a circle of $\mathcal{C}$ from top, and an arc of a circle of $\mathcal{C}$ from bottom (e.g., see Fig. 2).

Using cuttings, we obtain the following solution to the partial BRS problem.

▶ **Lemma 1.** *For any $r$ with $1 \leq r \leq \min\{m^{1/3}, n^{1/3}\}$, we can compute in $O(mr \log r + nr)$ time two collections $\Gamma(A, B, \alpha, \beta) = \{A_t \times B_t \mid A_t \subseteq A, B_t \subseteq B\}$ and $\Pi(A, B, \alpha, \beta) = \{A'_s \times B'_s \mid A'_s \subseteq A, B'_s \subseteq B\}$ of edge-disjoint complete bipartite graphs that satisfy the conditions*

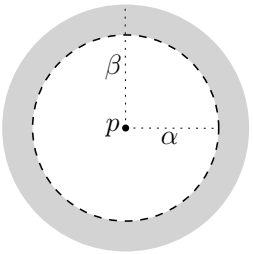

**Figure 1** An annulus $D_p$ (the grey region).

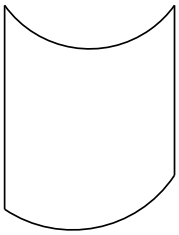

**Figure 2** Illustrating a pseudo-trapezoid.

*of Problem 1, with the following complexities: (1)* $|\Gamma| = O(r^4)$*; (2)* $\sum_t |A_t|, \sum_t |B_t| = O(mr \log r + nr)$*; (3)* $|\Pi| = O(r^4)$*; (4)* $|A'_s| = O(m/r^3)$ *and* $|B'_s| = O(n/r^3)$ *for each* $A'_s \times B'_s \in \Pi$*; (5) the number of pairs of points recorded in* $\Pi$ *is* $O(r^4 \cdot m/r^3 \cdot n/r^3) = O(mn/r^2)$.

**Proof.** We begin with constructing a hierarchical $(1/r)$-cutting $\{\Xi_0, \Xi_1, ..., \Xi_k\}$ for $\mathcal{C}$, which takes $O(mr)$ time as discussed above. We use $\Xi$ to refer to the set of all cells $\sigma$ in all cuttings $\Xi_i$, $0 \leq i \leq k$. Next we compute the set $B(\sigma)$ for each cell $\sigma$ in the cutting (recall that $B(\sigma)$ refers to the subset of points of $B$ inside $\sigma$; we call $B(\sigma)$ a *canonical subset*). This can be done in $O(n \log r)$ time in a top-down manner by processing each point of $B$ individually. Specifically, for each point $p \in B$, suppose we know that $p$ is in $\sigma'$ for a cell $\sigma'$ in $\Xi_{i-1}$ (which is true initially when $i = 1$ as $\Xi_0$ has a single cell that is the entire plane). By examining each child of $\sigma'$ we can find in $O(1)$ time the cell $\sigma$ of $\Xi_i$ that contains $p$ and then we add $p$ to $B(\sigma)$. Since $k = \Theta(\log r)$, each point of $B$ is stored in $O(\log r)$ canonical subsets and the total size of all canonical subsets $B(\sigma)$ for all cells $\sigma \in \Xi$ is $O(n \log r)$.

Next, for each cell $\sigma$ of $\Xi$, we compute another canonical subset $A_\sigma \subseteq A$. Specifically, a point $p \in A$ is in $A_\sigma$ if the annulus $D_p$ contains $\sigma$ but not $\sigma$'s parent. The subsets $A_\sigma$ for all cells $\sigma$ of $\Xi$ can be computed in $O(mr)$ time. Indeed, recall that the cutting algorithm already computes $\mathcal{C}_\sigma$ for all cells $\sigma \in \Xi$. For each $\Xi_{i-1}$, $1 \leq i \leq k$, for each cell $\sigma'$ of $\Xi_{i-1}$, we consider each circle $C \in \mathcal{C}_{\sigma'}$. Let $p$ be the point of $A$ such that $C$ is a bounding circle of the annulus $D_p$. For each child $\sigma$ of $\sigma'$, if $D_p$ fully contains $\sigma$, then we add $p$ to $A_\sigma$. In this way, $A_\sigma$ for all cells $\sigma$ of $\Xi$ can be computed in $O(mr)$ time since $\sum_{0 \leq i \leq k} \sum_{\sigma' \in \Xi_i} |\mathcal{C}_{\sigma'}| = O(mr)$ and each cell $\sigma'$ has $O(1)$ children. As such, the total size of $A_\sigma$ for all cells $\sigma \in \Xi$ is $O(mr)$.

By definition, for each cell $\sigma \in \Xi$, for any point $a \in A_\sigma$ and any point $b \in B(\sigma)$, we have $\|ab\| \in (\alpha, \beta]$. As such, we return $\{A_\sigma \times B(\sigma) \mid \sigma \in \Xi\}$ as a subcollection of $\Gamma(A, B, \alpha, \beta)$ to be computed for the lemma. Note that the complete bipartite graphs of $\{A_\sigma \times B(\sigma) \mid \sigma \in \Xi\}$ are edge-disjoint. The size of the subcollection is equal to the number of cells of the hierarchical cutting, which is $O(r^2)$. Also, we have shown above that $\sum_{\sigma \in \Xi} |A_\sigma| = O(mr)$ and $\sum_{\sigma \in \Xi} |B(\sigma)| = O(n \log r)$.

For each cell $\sigma$ of the last cutting $\Xi_k$, we have $|\mathcal{C}_\sigma| \leq m/r$. Let $\hat{A}_\sigma$ denote the subset of points $p \in A$ such that $D_p$ has a bounding circle in $\mathcal{C}_\sigma$. We do not know whether distances between points of $\hat{A}_\sigma$ and points of $B(\sigma)$ are in $(\alpha, \beta]$ or not. If $|B(\sigma)| > n/r^2$, then we arbitrarily partition $B(\sigma)$ into subsets of size between $n/(2r^2)$ and $n/r^2$. We call these subsets *standard subsets* of $B(\sigma)$. Since $|B| = n$ and we have $O(r^2)$ cells in cutting $\Xi_k$, the number of standard subsets of all cells of $\Xi_k$ is $O(r^2)$. For each standard subset $\hat{B}(\sigma) \subseteq B(\sigma)$, we form a pair $(\hat{A}_\sigma, \hat{B}(\sigma))$ as an "unsolved" *subproblem*. Then we have $O(r^2)$ subproblems. Note that $|\hat{A}_\sigma| \leq m/r$ and $|\hat{B}(\sigma)| \leq n/r^2$. If we apply the same algorithm recursively on each subproblem, then we have the following recurrence relation (which holds for any $1 \leq r \leq m$):

$$T(m, n) = O(mr + n \log r) + O(r^2) \cdot T(\frac{m}{r}, \frac{n}{r^2}). \tag{1}$$

Note that if we use $T(m,n)$ to represent the total size of $A_t$ and $B_t$ of all complete bipartite graphs $A_t \times B_t$ in the subcollection of $\Gamma(A,B,\alpha,\beta)$ that have been produced as above, then we have the same recurrence as above. If $N(m,n)$ denotes the number of these graphs, then we have the following recurrence:

$$N(m,n) = O(r^2) + O(r^2) \cdot N(\frac{m}{r}, \frac{n}{r^2}).$$

We now solve the problem in a "dual" setting by switching the roles of $A$ and $B$, i.e., define annuli centered at points of $B$ and compute the hierarchical cutting for their bounding circles. Then, symmetrically we have the following recurrences (which holds for any $1 \le r \le n$):

$$T(m,n) = O(nr + m\log r) + O(r^2) \cdot T(\frac{m}{r^2}, \frac{n}{r}), \tag{2}$$

$$N(m,n) = O(r^2) + O(r^2) \cdot N(\frac{m}{r^2}, \frac{n}{r}).$$

By applying (2) to each subproblem of (1) using the same parameter $r$ and we can obtain the following recurrence:

$$T(m,n) = O(mr\log r + nr) + O(r^4) \cdot T(\frac{m}{r^3}, \frac{n}{r^3}).$$

Similarly, we have

$$N(m,n) = O(r^4) + O(r^4) \cdot N(\frac{m}{r^3}, \frac{n}{r^3}).$$

The above recurrences tell us that in $O(mr\log r + nr)$ time we can compute a collection of $O(r^4)$ edge-disjoint complete bipartite graphs $A_t \times B_t$ with $A_t \subseteq A$ and $B_t \subseteq B$ such that for any two points $a \in A_t$ and $b \in B_t$ their distance $\|ab\|$ lies in $(\alpha,\beta]$. Further, the size of all such $A_t$'s and $B_t$'s is bounded by $O(mr\log r + nr)$. We return the above collection as $\Gamma(A,B,\alpha,\beta)$ for the lemma.

In addition, we have also $O(r^4)$ graphs $A'_s \times B'_s$ with $A'_s \subseteq A$ and $B'_s \subseteq B$ corresponding to the unsolved subproblems $T(m/r^3, n/r^3)$ and we do not know whether $\|ab\| \in (\alpha,\beta]$ for points $a \in A'_s$ and $b \in B'_s$. We return the collection of all such graphs as $\Pi(A,B,\alpha,\beta)$ for the lemma. Hence, $|\Pi(A,B,\alpha,\beta)| = O(r^4)$, and $|A'_s| \le m/r^3$ and $|B'_s| \le n/r^3$ for each graph $A'_s \times B'_s$ in the collection. The number of pairs of points recorded in $\Pi(A,B,\alpha,\beta)$ is $O(|\Pi(A,B,\alpha,\beta)| \cdot m/r^3 \cdot n/r^3)$, which is $O(mn/r^2)$. This proves the lemma. ◀

Theorem 2 solves the complete BRS by running the algorithm of Lemma 1 recursively.

▶ **Theorem 2.** *We can compute in $O(m^{2/3}n^{2/3} \cdot 2^{O(\log^*(m+n))} + m\log n + n\log m)$ time a collection $\Gamma(A,B,\alpha,\beta) = \{A_t \times B_t \mid A_t \subseteq A, B_t \subseteq B\}$ of edge-disjoint complete bipartite graphs that satisfy the conditions of Problem 1 (with $\Pi(A,B,\alpha,\beta) = \emptyset$), with the following complexities: (1) $|\Gamma| = O(m^{2/3}n^{2/3}\cdot\log^*(m+n)+m+n)$; (2) $\sum_t |A_t|, \sum_t |B_t| = O(m^{2/3}n^{2/3} \cdot 2^{O(\log^*(m+n))} + m\log n + n\log m)$.*

**Proof.** To solve the complete BRS problem, the main idea is to apply the recurrence (2) recursively until the size of each subproblem becomes $O(1)$. We first consider the symmetric case where $m = n$. By setting $r = n^{1/3}/\log n$ and applying (2) with $m = n$, we obtain the following

$$T(n,n) = O(n^{4/3}) + O(n^{4/3}/\log^4 n) \cdot T(\log^3 n, \log^3 n). \tag{3}$$

Similarly, we have

$$N(n,n) = O(n^{4/3}/\log^4 n) + O(n^{4/3}/\log^4 n) \cdot N(\log^3 n, \log^3 n). \tag{4}$$

The recurrences solve to $T(n,n) = n^{4/3} \cdot 2^{O(\log^* n)}$ and $N(n,n) = O(n^{4/3} \cdot \log^* n)$. This means that in $n^{4/3} \cdot 2^{O(\log^* n)}$ time we can compute a collection $\Gamma(A,B,\alpha,\beta) = \{A_t \times B_t \mid A_t \subseteq A, B_t \subseteq B\}$ of $O(n^{4/3}\log^* n)$ edge-disjoint complete bipartite graphs, with $\sum_t |A_t|, \sum_t |B_t| = n^{4/3} \cdot 2^{O(\log^* n)}$, and it satisfies the conditions of Problem 1 with $\Pi(A,B,\alpha,\beta) = \emptyset$.

For the asymmetric case, i.e., $m \neq n$, it is solved by utilizing the above symmetric case result; the details can be found in the full paper. ◀

For comparison, Katz and Sharir [14] solved the complete BRS problem in $O((m^{2/3}n^{2/3} + m + n)\log m)$ time by producing $O(m^{2/3}n^{2/3} + m + n)$ complete bipartite graphs whose total vertex set size is $O((m^{2/3}n^{2/3} + m + n)\log m))$. Our result improves their runtime and vertex set size by almost a logarithmic factor with slightly more graphs produced.

## 3 Distance selection

In this section, we present our algorithm for the distance selection problem. Let $P$ be a set of $n$ points in the plane. Define $\mathcal{E}(P)$ as the set of distances of all pairs of points of $P$. Given an integer $1 \leq k \leq \binom{n}{2}$, the problem is to find the $k$-th smallest value in $\mathcal{E}(P)$, denoted by $\delta^*$.

Given any $\delta$, the *decision problem* is to determine whether $\delta \geq \delta^*$. Wang [18] recently gave an $O(n^{4/3})$ time algorithm that can compute the number of values of $\mathcal{E}(P)$ at most $\delta$, denoted by $k_\delta$. Observe that $\delta \geq \delta^*$ if and only if $k_\delta \geq k$. Thus, using Wang's algorithm [18], the decision problem can be solved in $O(n^{4/3})$ time. We should point out that the $O(n^{4/3}\log^2 n)$ time algorithm of Katz and Sharir [14] for computing $\delta^*$ utilizes a decision algorithm of $O(n^{4/3}\log n)$ time. However, even if we replace their decision algorithm by Wang's $O(n^{4/3})$ time algorithm, the runtime of the overall algorithm for computing $\delta^*$ is still $O(n^{4/3}\log^2 n)$ because other parts of the algorithm dominate the total time. To reduce the overall time to $O(n^{4/3}\log n)$, new techniques are needed, in addition to using the faster $O(n^{4/3})$ time decision algorithm. These new techniques include, for instance, Lemma 1 for the partial BRS problem, as will be seen below.

Before presenting the details of our algorithm, we first give the following lemma, which is critical to our algorithm and is obtained by using Lemma 1.

▶ **Lemma 3.** *Given an interval $(\alpha,\beta]$, Problem 1 with $A = P$ and $B = P$ can be solved in $O(n^{4/3})$ time by computing two collections $\Gamma(P,P,\alpha,\beta) = \{A_t \times B_t \mid A_t, B_t \subseteq P\}$ and $\Pi(P,P,\alpha,\beta) = \{A'_s \times B'_s \mid A'_s, B'_s \subseteq P\}$ with the following complexities: (1) $|\Gamma| = O(n^{4/3}/\log^4 \log n)$; (2) $\sum_t |A_t|, \sum_t |B_t| = O(n^{4/3})$; (3) $|\Pi| = O(n^{4/3}/\log^4 \log n)$; (4) $|A'_s|, |B'_s| = O(\log^3 \log n)$, for each $A'_s \times B'_s \in \Pi$.*

**Proof.** We first apply Lemma 1 with $A = P$, $B = P$, and $r = n^{1/3}/\log n$. This constructs a collection $\Gamma_1 = \{A_t \times B_t \mid A_t, B_t \subseteq P\}$ of $O(n^{4/3}/\log^4 n)$ edge-disjoint complete bipartite graphs in $O(n^{4/3})$ time. The total size of vertex sets of these graphs is $O(n^{4/3})$, i.e., $\sum_t |A_t|, \sum_t |B_t| = O(n^{4/3})$. We also have a collection $\Pi_1 = \{A'_s \times B'_s \mid A'_s, B'_s \subseteq P\}$ of $O(n^{4/3}/\log^4 n)$ edge-disjoint complete bipartite graphs that record uncertain point pairs, with $|A'_s|, |B'_s| = O(\log^3 n)$.

Hence, the number of uncertain pairs of points of $P$ (i.e., we do not know whether their distances are in $(\alpha,\beta]$) is $\sum_s |A'_s| \cdot |B'_s| = O(n^{4/3}\log^2 n)$. To further reduce this number, we apply Lemma 1 on every pair $(A'_s, B'_s)$ of $\Pi_1$. More specifically, for each pair $(A'_s, B'_s)$

of $\Pi_1$, we apply Lemma 1 with $A = A'_s$, $B = B'_s$, and $r = \log n / \log\log n$. This computes a collection $\Gamma_s$ of $O(\log^4 n / \log^4 \log n)$ edge-disjoint complete bipartite graphs in $O(\log^4 n)$ time; the total size of vertex sets of all graphs in $\Gamma_s$ is $O(\log^4 n)$. We also have a collection $\Pi_s$ of $O(\log^4 n / \log^4 \log n)$ edge-disjoint complete bipartite graphs. The size of each vertex set of each graph of $\Pi_s$ is bounded by $O(\log^3 \log n)$. The total time for Lemma 1 on all pairs $(A'_s, B'_s)$ of $\Pi_1$ as above is $O(n^{4/3})$. We return $\Gamma_1 \cup \bigcup_s \Gamma_s$ as collection $\Gamma$, and $\bigcup_s \Pi_s$ as collection $\Pi$ in the lemma statement. As such, the complexities in the lemma hold. ◀

In what follows, we describe our algorithm for computing $\delta^*$. Like Katz and Sharir's algorithm [14], our algorithm proceeds in stages. Initially, we have $I_0 = (0, +\infty]$. In each $j$-th stage, an interval $I_j = (\alpha_i, \beta_j]$ is computed from $I_{j-1}$ such that $I_j$ must contain $\delta^*$ and the number of values of $\mathcal{E}(P)$ in $I_j$ is a constant fraction of that in $I_{j-1}$. Specifically, we will prove that $|\mathcal{E}(P) \cap I_j| = O(n^2 \rho^j)$ holds for each $j$, for some constant $\rho < 1$. Once $|\mathcal{E}(P) \cap I_j|$ is no more than a threshold (to be given later; as will be seen later, this threshold is not constant, which is a main difference between our algorithm and Katz and Sharir's algorithm [14]), we will compute $\delta^*$ directly. In the following we discuss the $j$-th stage of the algorithm. We assume that we have an interval $I_{j-1} = (\alpha_{j-1}, \beta_{j-1}]$ containing $\delta^*$.

We first apply Lemma 3 with $(\alpha, \beta] = (\alpha_{j-1}, \beta_{j-1}]$. This is another major difference between our algorithm and Katz and Sharir's algorithm [14], where they solved the complete BRS problem, while we only solve a partial problem (this saves time by a logarithmic factor). Applying Lemma 3 produces a collection $\Gamma_{j-1} = \{A_t \times B_t \mid A_t, B_t \subseteq P\}$ of $O(n^{4/3} / \log^4 \log n)$ edge-disjoint complete bipartite graphs, with $\sum_t |A_t|, \sum_t |B_t| = O(n^{4/3})$, as well as another collection $\Pi_{j-1}$ of $O(n^{4/3} / \log^4 \log n)$ graphs. By Lemma 3 (3) and (4), the number of pairs of points of $P$ in $\Pi_{j-1}$ is $O(n^{4/3} \log^2 \log n)$.

If $\sum_t |A_t| \cdot |B_t| \leq n^{4/3} \log n$, which is our threshold, then this is the last stage of the algorithm and we compute $\delta^*$ directly by Lemma 4. Each edge of the graph in $\Gamma_{j-1} \cup \Pi_{j-1}$ connects two points of $P$; we say that the distance of the two points is *induced* by the edge.

▶ **Lemma 4.** *If $\sum_t |A_t| \cdot |B_t| \leq n^{4/3} \log n$, then $\delta^*$ can be computed in $O(n^{4/3} \log n)$ time.*

**Proof.** We first explicitly compute the set $S$ of distances induced from edges of all graphs of $\Gamma_{j-1}$ and $\Pi_{j-1}$. Since $\sum_t |A_t| \cdot |B_t| \leq n^{4/3} \log n$ and the number of edges of all graphs of $\Pi_{j-1}$ is $O(n^{4/3} \log^2 \log n)$, we have $|S| = O(n^{4/3} \log n)$ and $S$ can be computed in $O(n^{4/3} \log n)$ time by brute force. Then, we compute the number $k_{\alpha_{j-1}}$ of values of $\mathcal{E}(P)$ that are at most $\alpha_{j-1}$, which can be done in $O(n^{4/3})$ time [18]. Observe that $\delta^*$ is the $(k - k_{\alpha_{j-1}})$-th smallest value in $S$. Hence, using the linear time selection algorithm, we can find $\delta^*$ in $O(|S|)$ time, which is $O(n^{4/3} \log n)$. ◀

We now assume $\sum_t |A_t| \cdot |B_t| > n^{4/3} \log n$. The rest of the algorithm for the $j$-th iteration takes $O(n^{4/3})$ time. For each graph $A_t \times B_t \in \Gamma_{j-1}$, if $|A_t| < |B_t|$, then we switch the name of $A_t$ and $B_t$, i.e., $A_t$ now refers to $B_t$ and $B_t$ refers to the original $A_t$. Note that this does not change the solution of the partial BRS produced by Lemma 3 and it does not change the complexities of Lemma 3 either. This name change is only for ease of the exposition. Now we have $|A_t| \geq |B_t|$ for each graph $A_t \times B_t \in \Gamma_{j-1}$. Let $m_t = |A_t|$ and $n_t = |B_t|$.

We partition each $A_t$ into $g = \lfloor m_t / n_t \rfloor$ subsets $A_{t1}, A_{t2}, \ldots, A_{tg}$ so that each subset contains $n_t$ elements except that the last subset $A_{tg}$ contains at least $n_t$ but at most $2n_t - 1$ elements. Each pair $(A_{ti}, B_t)$, $1 \leq i \leq g$, can be viewed as a complete bipartite graph. As in [14], we construct a *$d$-regular LPS-expander graph $G_{ti}$* on the vertex set $A_{ti} \cup B_t$, for a

constant $d$ to be fixed later.[2] The expander $G_{ti}$ has $O(|A_{ti}|+|B_t|)$ edges and can be computed in $O(|A_{ti}|+|B_t|)$ time [14, 16]. Let $G_t$ be the union of all these expander graphs $G_{ti}$ over all $i = 1, 2, \ldots, g$. The construction of $G_t$ takes $\sum_{i=1}^{g} O(|A_{ti}| + |B_t|) = O(|A_t| + \lfloor \frac{m_t}{n_t} \rfloor \cdot |B_t|) = O(|A_t|)$ time. Hence, computing all graphs $\{G_t\}_t$ for all $O(n^{4/3}/\log^4 \log n)$ pairs $A_t \times B_t$ in $\Gamma_{j-1}$ takes $\sum_t O(|A_t|) = O(n^{4/3})$ time. The number of edges in $G_t$ is $O(|A_t| + |B_t|)$, and thus the number of edges in all graphs $\{G_t\}_t$ is $\sum_t O(|A_t| + |B_t|) = O(n^{4/3})$.

For each edge $(a, b)$ in graph $G_t$ that connects a point $a \in A_t$ and a point $b \in B_t$, we associate it with the interpoint distance $\|ab\|$. We compute all these distances for all graphs $\{G_t\}_t$ to form a set $S$. The size of $S$ is bounded by the number of edges in all graphs $\{G_t\}_t$, which is $O(n^{4/3})$. Note that all values of $S$ are in the interval $I_{j-1}$.

One way we could proceed from here is to find the largest value $\delta_1$ of $S$ with $\delta_1 < \delta^*$ and the smallest value $\delta_2$ with $\delta^* \leq \delta_2$, and then return $(\delta_1, \delta_2]$ as the interval $I_j$ and finish the $j$-th stage of the algorithm. Finding $\delta_1$ and $\delta_2$ could be done by binary search on $S$ using the linear time selection algorithm and the $O(n^{4/3})$ time decision algorithm. Then the runtime of this step would be $O(n^{4/3} \log n)$, resulting in a total of $O(n^{4/3} \log^2 n)$ time for the overall algorithm for computing $\delta^*$ since there are $O(\log n)$ stages. To improve the time, as in [14], we use the "Cole-like" technique to reduce the number of calls to the decision algorithm to $O(1)$ in each stage, as follows.

We assign a *weight* to each value of $S$. Note that since each graph $G_{ti} \in G_t$ is a $d$-regular LPS-expander, the degree of $G_{ti}$ is $d$ [14]. Hence, $G_{ti}$ has at most $(|A_{ti}| + |B_t|) \cdot d/2$ edges and thus it contributes at most $(|A_{ti}| + |B_t|) \cdot d/2$ values to $S$. We assign each distance induced from $G_{ti}$ a weight equal to $|A_{ti}| \cdot |B_t|/(|A_{ti}| + |B_t|)$. As such, the total weight of the values of $S$ is at most

$$\sum_{t,i} (|A_{ti}| + |B_t|) \cdot \frac{d}{2} \cdot \frac{|A_{ti}| \cdot |B_t|}{|A_{ti}| + |B_t|} = \frac{d}{2} \cdot \sum_{t,i} |A_{ti}| \cdot |B_t| = \frac{d}{2} \cdot m_{j-1},$$

where $m_{j-1} = \sum_t |A_t| \cdot |B_t|$. Recall that $m_{j-1} > n^{4/3} \log n$ and $|B_t| \leq |A_{ti}|$ in each $G_{ti}$. We can assume $n \geq 16$ so that $m_{j-1} \geq 16$. As such, we have the following bound for the weight of each value in $S$: $|A_{ti}| \cdot |B_t|/(|A_{ti}| + |B_t|) \leq |B_t| \leq \sqrt{|B_t| \cdot |A_{ti}|} \leq \sqrt{m_{j-1}} \leq m_{j-1}/4$.

We partition the values of $S$ into at most $2d$ intervals $\{I'_1, I'_2, ..., I'_h\}$, $1 \leq h \leq 2d$, such that the total weight of values in every interval is at least $m_{j-1}/4$ and but at most $m_{j-1}/2$. The partition can be done in $O(|S|)$ time, which is $O(n^{4/3})$, using the linear time selection algorithm. Then, we invoke the decision algorithm $\log(2d) = O(1)$ times to find the interval $I'_l$ that contains $\delta^*$, for some $1 \leq l \leq h$. We set $I_j = I'_l$. Since the decision algorithm is called $O(1)$ times, this step takes $O(n^{4/3})$ time. This finishes the $j$-th stage of the algorithm.

The following Lemma 5 shows that the number of values of $\mathcal{E}(P)$ in $I_j$ is a constant portion of that in $I_{j-1}$. This guarantees that the algorithm will finish in $O(\log n)$ stages since $|\mathcal{E}(P)| = O(n^2)$. As each stage runs in $O(n^{4/3})$ time (except that the last stage takes $O(n^{4/3} \log n)$ time), the total time of the algorithm is $O(n^{4/3} \log n)$.

▶ **Lemma 5.** *There exists a constant $\rho$ with $0 < \rho < 1$ such that the number of values of $\mathcal{E}(P)$ in $I_j$ is at most $\rho$ times the number of values of $\mathcal{E}(P)$ in $I_{j-1}$.*

[2] A good summary of definitions and properties of expanders can be found in Section 2 of [14]. Here it suffices for the reader to know the following property (which is needed in the proof of Lemma 5): If $X$ and $Y$ are two vertex subsets of a $d$-regular expander graph of $M$ vertices and there are fewer than $3M$ edges connecting points of $X$ and points of $Y$, then $|X| \cdot |Y| \leq 9M^2/d$.

**Proof.** Define $n_j$ (resp., $n_{j-1}$) as the number of values of $\mathcal{E}(P)$ in $I_j$ (resp., $I_{j-1}$). Our goal is to find a constant $\rho \in (0,1)$ so that $n_j \leq \rho \cdot n_{j-1}$ holds.

Recall that $m_{j-1}$ is the number of distances induced from the graphs of $\Gamma_{j-1}$. Define $m'_{j-1}$ as the number of distances induced from the graphs of $\Pi_{j-1}$. Define $q_j$ (resp., $q'_j$) as the number of interpoint distances of $\mathcal{E}(P) \cap I_j$ whose point pairs are recorded in $\Gamma_{j-1}$ (resp., $\Pi_{j-1}$). Note that all interpoint distances induced from graphs of $\Gamma_{j-1}$ are in $I_{j-1}$. Hence, $m_{j-1} \leq n_{j-1}$. By definition, $n_j = q_j + q'_j$ and $q'_j \leq m'_{j-1}$. By Lemma 3 (3) and (4), we have $m'_{j-1} = O(n^{4/3} \log^2 \log n)$.

We first make the following **claim:** there exists a constant $\gamma \in (0, 1/3)$ such that $q_j \leq \gamma \cdot m_{j-1}$. The proof of this claim is similar to the analysis in [14] and can be found in the full paper. Next, we prove the lemma by using this claim.

As this is not the last stage of the algorithm (since otherwise $\delta^*$ would have already been computed without producing interval $I_j$), it holds that $m_{j-1} > n^{4/3} \log n$. Since $m'_{j-1} = O(n^{4/3} \log^2 \log n)$, there exists a constant $c' \in (0, 1/3)$ such that $\frac{m'_{j-1}}{m_{j-1}} \leq c'$ when $n$ is sufficiently large. As $n_j = q_j + q'_j$, $q'_j \leq m'_{j-1}$, and $m_{j-1} \leq n_{j-1}$, we can obtain the following using the above claim:

$$n_j = q_j + q'_j \leq q_j + m'_{j-1} \leq \gamma \cdot m_{j-1} + c' \cdot m_{j-1} \leq (\gamma + c') \cdot m_{j-1} \leq (\gamma + c') \cdot n_{j-1}.$$

Set $\rho = \gamma + c'$. Since both $\gamma$ and $c'$ are in $(0, 1/3)$, we have $\rho \in (0, 2/3)$ and $n_j \leq \rho \cdot n_{j-1}$. This proves the lemma. ◀

We conclude with the following result. Note that once $\delta^*$ is computed, one can find a pair of points of $P$ whose distance is equal to $\delta^*$ in additional $O(n^{4/3})$ time [18].

▶ **Theorem 6.** *Given a set $P$ of $n$ points in the plane and an integer $1 \leq k \leq \binom{n}{2}$, the $k$-th smallest interpoint distance of $P$ can be computed in $O(n^{4/3} \log n)$ time.*

**Remark.** Our algorithm can be easily extended to the following *bipartite version* of the distance selection problem: Given a set $A$ of $m$ points and a set $B$ of $n$ points in the plane, and an integer $1 \leq k \leq mn$, compute the $k$-th smallest interpoint distance $\delta^*$ in the set $\{\|ab\| \mid a \in A, b \in B\}$. This problem can be solved in $O((m^{2/3}n^{2/3} + m \log n + n \log m) \log(m+n))$ time by extending our algorithm. More detailed discussions can be found in the full paper.

## 4 Two-sided discrete Fréchet distance with shortcuts

In this section, we show that our techniques in Section 3 can be used to solve the two-sided DFD problem. Let $A = \{a_1, a_2, ..., a_m\}$ and $B = \{b_1, b_2, ..., b_n\}$ be two sequences of points in the plane. Consider two frogs connected by an inelastic leash, initially placed at $a_1$ and $b_1$, respectively. Each frog is allowed to jump forward at most one step in one move, i.e., if the first frog is currently at $a_i$, then in the next move it can either jump to $a_{i+1}$ or stay at $a_i$. Note that frogs are not allowed to go backwards. The *discrete Fréchet distance* (or DFD for short) is defined as the minimum length of the inelastic leash that allows two frogs to reach their destinations, i.e., $a_m$ and $b_n$, respectively.

Because the Fréchet distance is very sensitive to outliers, to reduce the sensitivity, DFD with outliers have been proposed [4]. Specifically, if we allow the $A$-frog to jump from its current point to any of its succeeding points in each move but $B$-frog has to traverse all points in $B$ in order plus one restriction that only one frog is allowed to jump in each move (i.e., in each move one of the frogs must stay still), then this problem is called *one-sided discrete Fréchet distance with shortcuts* (or *one-sided DFD* for short), where the goal is to compute

the minimum length of the inelastic leash that allows two frogs to reach their destinations. If we allow both frogs to skip points in their sequences (but again with the restriction that only one frog is allowed to jump in each move), then problem is called *two-sided DFD*.

We focus on the two-sided DFD in this section while the one-sided version will be treated in the next section. Let $\delta^*$ denote the optimal objective value, i.e., the minimum length of the leash. Avraham, Filtser, Kaplan, Katz, and Sharir [4] presented an algorithm that can compute $\delta^*$ in $O((m^{2/3}n^{2/3}+m+n)\log^3(m+n))$ time. In what follows, we show that our techniques in Section 3 can improve their algorithm to $O((m^{2/3}n^{2/3}\cdot 2^{O(\log^*(m+n))}+m\log n+n\log m)\log(m+n))$ time, roughly a factor of $O(\log^2(m+n))$ faster.

To solve the problem, the authors of [4] first proposed an algorithm to solve the decision problem, i.e., given any $\delta$, decide whether $\delta^* \le \delta$; the algorithm runs in $O((m^{2/3}n^{2/3}+m+n)\log^2(m+n))$ time. Then, to compute $\delta^*$, the authors of [4] used the bipartite version of the distance selection algorithm from Katz and Sharir [14] for point sets $A$ and $B$ together with their decision algorithm to do binary search on the interpoint distances between points in $A$ and those in $B$, i.e., in each iteration, using the distance selection algorithm to find the $k$-th smallest distance $\delta_k$ for an appropriate $k$ and then call the decision algorithm on $\delta_k$ to decide which way to search. As both the distance selection algorithm [14] and the decision algorithm run in $O((m^{2/3}n^{2/3}+m+n)\log^2(m+n))$ time, computing $\delta^*$ takes $O((m^{2/3}n^{2/3}+m+n)\log^3(m+n))$ time.

The following lemma (whose proof is in the full paper) shows that the runtime of their decision algorithm [4] can be improved by a factor of roughly $O(\log^2(m+n))$, by using our result in Theorem 2 for the complete BRS problem.

▶ **Lemma 7.** *Given any $\delta$, we can decide whether the two-sided DFD $\delta^* \le \delta$ in $O(m^{2/3}n^{2/3}\cdot 2^{O(\log^*(m+n))}+m\log n+n\log m)$ time.*

**Improving the optimization algorithm for computing $\delta^*$.** With our new $O((m^{2/3}n^{2/3}+m\log n+n\log m)\log(m+n))$ time bipartite distance selection algorithm in Section 3 and the above faster decision algorithm, following the same binary search scheme as discussed above, $\delta^*$ can be computed in $O((m^{2/3}n^{2/3}+m\log n+n\log m)\log^2(m+n))$ time, a logarithmic factor improvement over the result of [4]. Notice that the time is dominated by the calls to the bipartite distance selection algorithm.

To further improve the algorithm, an observation is that we do not have to call the distance selection algorithm as an oracle and instead we can use that algorithm as a framework and replace the decision algorithm of the distance selection problem by the decision algorithm of the two-sided DFD problem. This will roughly reduce another logarithmic factor. The proof of the following theorem provides the details about this idea.

▶ **Theorem 8.** *Given two sequences of points $A=(a_1,a_2,...,a_m)$ and $B=(b_1,b_2,...,b_n)$ in the plane, the two-sided DFD problem can be solved in $O((m^{2/3}n^{2/3}\cdot 2^{O(\log^*(m+n))}+m\log n+n\log m)\log(m+n))$ time.*

**Proof.** Following our distance selection algorithm, we run in stages and each $j$-th stage will compute an interval $I_j$ that contains $\delta^*$. In the $j$-th stage, we first perform the partial BRS on point sets $A$ and $B$ with respect to interval $I_{j-1}$, in the same way as before. This produces a collection $\Gamma$ of $(m^{2/3}n^{2/3}/\log^4\log(m^2/n)+m^{2/3}n^{2/3}/\log^4\log(n^2/m)+m+n)$ edge-disjoint complete bipartite graphs that record some pairs of $A\times B$ whose interpoint distances are in $I_{j-1}$. The total size of vertex sets of all graphs in $\Gamma$ is $O(m^{2/3}n^{2/3}+m\log n+n\log m)$. In addition, we also have a collection $\Pi$ of complete bipartite graphs representing $O(m^{2/3}n^{2/3}\log^2\log(m+n))$ uncertain pairs of $A\times B$. The total runtime is $O(m^{2/3}n^{2/3}+m\log n+n\log m)$.

We next compute the number $n_\Gamma$ of distances induced from the graphs of $\Gamma$. If $n_\Gamma$ is larger than the threshold $\tau = (m^{2/3}n^{2/3} + m\log n + n\log m)\log(m+n)$, then we use the "Cole-like" technique to perform a binary search on the interpoint distances induced from the expander graphs that are built on the vertex sets of the graphs in $\Gamma$, which calls the decision algorithm $O(1)$ times. The runtime for this stage is $O(m^{2/3}n^{2/3} \cdot 2^{O(\log^*(m+n))} + m\log n + n\log m)$. If $n_\Gamma \leq \tau$, then we reach the last stage of the algorithm and we can compute $\delta^*$ as follows. We compute the interpoint distances induced from the graphs in $\Gamma$ and $\Pi$. The total number of such distances is $O((m^{2/3}n^{2/3} + m\log n + n\log m)\log(m+n))$. Using the decision algorithm and the linear time selection algorithm, a binary search on these interpoint distances is performed to compute $\delta^*$, which takes $O((m^{2/3}n^{2/3} \cdot 2^{O(\log^*(m+n))} + m\log n + n\log m)\log(m+n))$ time as the decision algorithm is called $O(\log(m+n))$ times. The algorithm finishes within $O(\log(m+n))$ stages by an analysis similar to Lemma 5 (indeed, the proof of Lemma 5 does not rely on which decision algorithm is used).

In summary, the total runtime for computing $\delta^*$ is bounded by $O((m^{2/3}n^{2/3} \cdot 2^{O(\log^*(m+n))} + m\log n + n\log m)\log(m+n))$. ◀

**A general (deterministic) algorithmic framework.** The algorithm of Theorem 8 can be made into a general algorithmic framework for solving geometric optimization problems involving interpoint distances in the plane. Specifically, suppose we have an optimization problem $\mathcal{P}$ whose optimal objective value $\delta^*$ is equal to $\|ab\|$ for a point $a \in A$ and a point $b \in B$, with $A$ as a set of $m$ points and $B$ as a set of $n$ points in the plane. The goal is to compute $\delta^*$. Suppose that we have a decision algorithm that can determine whether $\delta \geq \delta^*$ in $T_D$ time for any $\delta$. Then, we can compute $\delta^*$ by applying exactly the same algorithm of Theorem 8 except that we use the decision algorithm for $\mathcal{P}$ instead. The total time of the algorithm is $O((m^{2/3}n^{2/3} + m\log n + n\log m + T_D) \cdot \log(m+n))$. Note that in the case $T_D = o((m^{2/3}n^{2/3} + m\log n + n\log m)\log(m+n))$ this is faster than the traditional binary search approach by repeatedly invoking the distance selection algorithm.

▶ **Theorem 9.** *Given two sets $A$ and $B$ of $m$ and $n$ points respectively in the plane, any geometric optimization problem whose optimal objective value is equal to the distance between a point of $a \in A$ and a point of $b \in B$ can be solved in $O((m^{2/3}n^{2/3} + m\log n + n\log m + T_D) \cdot \log(m+n))$ time, where $T_D$ is the time for solving the decision version of the problem.*

## 5 One-sided discrete Fréchet distance with shortcuts

We consider the one-sided DFD problem defined in Section 4. Let $\delta^*$ denote the optimal objective value. Avraham, Filtser, Kaplan, Katz, and Sharir [4] proposed an a randomized algorithm of $O((m+n)^{6/5+\epsilon})$ expected time. We show that using our result in Lemma 1 for the partial BRS the runtime of their algorithm can be reduced to $O((m+n)^{6/5}\log^{8/5}(m+n))$.

Define $\mathcal{E}(A,B) = \{\|ab\| \mid a \in A, b \in B\}$. It is known that $\delta^* \in \mathcal{E}(A,B)$ [4]. The decision problem is to decide whether $\delta \geq \delta^*$ for any $\delta$. The authors [4] solved the decision problem in $O(m+n)$ (deterministic) time. To compute $\delta^*$, their algorithm has two main procedures.

The first main procedure computes an interval $(\alpha, \beta]$ that is guaranteed to contain $\delta^*$, and in addition, with high probability the interval contains at most $L$ values of $\mathcal{E}(A,B)$, given any $1 \leq L \leq mn$; the algorithm runs in $O((m+n)^{4/3+\epsilon}/L^{1/3} + (m+n)\log(m+n)\log\log(m+n))$ time, for any $\epsilon > 0$. More specifically, during the course of the algorithm, an interval $(\alpha, \beta]$ containing $\delta^*$ is maintained; initially $\alpha = 0$ and $\beta = \infty$. In each iteration, the algorithm first determines, through random sampling, whether the number of values of $\mathcal{E}(A,B)$ in $(\alpha, \beta]$ is at most $L$ with high probability. If so, the algorithm stops by returning the current interval

$(\alpha, \beta]$. Otherwise, a subset $R$ of $O(\log(m+n))$ values of $\mathcal{E}(A, B)$ is sampled which contains with high probability an approximate median (in the middle three quarters) among the values of $\mathcal{E}(A, B)$ in $(\alpha, \beta]$. A binary search guided by the decision algorithm is performed to narrow down the interval $(\alpha, \beta]$; the algorithm then proceeds with the next iteration. As such, after $O(\log(m+n))$ iterations, the algorithm eventually returns an interval $(\alpha, \beta]$ with the property discussed above.

The second main procedure is to find $\delta^*$ from $\mathcal{E}(A, B) \cap (\alpha, \beta]$. This is done by using a *bifurcation tree* technique (Lemma 4.4 [4]), whose runtime relies on $L'$, the true number of values of $\mathcal{E}(A, B)$ in $(\alpha, \beta]$. As it is possible that $L' > L$, if the algorithm detects that case happens, then the first main procedure will run one more round from scratch. As $L' < L$ holds with high probability, the expected number of rounds is $O(1)$. If $L' \leq L$, the runtime of the second main procedure is bounded by $O((m+n)L^{1/2}\log(m+n))$.

As such, the expected time of the algorithm is $O((m+n)^{4/3+\epsilon}/L^{1/3} + (m+n)\log(m+n)\log\log(m+n) + (m+n)L^{1/2}\log(m+n))$. Setting $L$ to $O((m+n)^{2/5+\epsilon})$ for another small $\epsilon > 0$, the time can be bounded by $O((m+n)^{6/5+\epsilon})$.

**Our improvement.** We can improve the runtime of the first main procedure by a factor of $O((m+n)^{\epsilon})$, which leads to the improvement of overall algorithm by a similar factor. To this end, by applying Lemma 1 with $r = (\frac{m+n}{L})^{1/3}$, we first have the following corollary, which improves Lemma 4.1 in [4] (which is needed in the first main procedure).

▶ **Corollary 10.** *Given a set $A$ of $m$ points and a set $B$ of $n$ points in the plane, an interval $(\alpha, \beta]$, and a parameter $1 \leq L \leq mn$, we can compute in $O((m+n)^{4/3}/L^{1/3} \cdot \log(\frac{m+n}{L}))$ time two collections $\Gamma(A, B, \alpha, \beta) = \{A_t \times B_t \mid A_t \subseteq A, B_t \subseteq B\}$ and $\Pi(A, B, \alpha, \beta) = \{A'_s \times B'_s \mid A'_s \subseteq A, B'_s \subseteq B\}$ of edge-disjoint complete bipartite graphs that satisfy the conditions of Problem 1, with the following complexities: (1) $|\Gamma| = O((\frac{m+n}{L})^{4/3})$; (2) $\sum_t |A_t|, \sum_t |B_t| = O((m+n)^{4/3}/L^{1/3} \cdot \log(\frac{m+n}{L}))$; (3) $|\Pi| = O((\frac{m+n}{L})^{4/3})$; (4) $|A'_s| = O(\frac{mL}{m+n})$ and $|B'_s| = O(\frac{nL}{m+n})$ for each $A'_s \times B'_s \in \Pi$; (5) the number of pairs of points recorded in $\Pi$ is $O((m+n)^{4/3}L^{2/3})$.*

Replacing Lemma 4.1 in [4] by our results in Corollary 10 and following the rest of the algorithm in [4] leads to an algorithm to compute $\delta^*$ in $O((m+n)^{6/5}\log^2(m+n))$ time. More details can be found in the full paper, which makes the discussion in the context of a more general algorithmic framework (indeed, a recent result of Katz and Sharir [15] already gave such a framework; here we improve their result by a factor of $O((m+n)^{\epsilon})$ due to Corollary 10). As discussed in Section 1, another immediate application of the framework is the reverse shortest path problem in unit-disk graphs [20].

## Abstract

Given a collection of $m$ sets, each a subset of a universe $\{1, \ldots, n\}$, *maximum coverage* is the problem of choosing $k$ sets whose union has the largest cardinality. A simple greedy algorithm achieves an approximation factor of $1 - 1/e \approx 0.632$, which is the best possible polynomial-time approximation unless P = NP.

In the streaming setting, information about the input is revealed gradually, in an online fashion. In the set-streaming model, each set is listed contiguously in the stream. In the more general edge-streaming model, the stream is composed of set-element pairs, denoting membership. The overall goal in the streaming setting is to design algorithms that use sublinear space in the size of the input. An interesting line of research is to design algorithms with space complexity polylogarithmic in the size of the input (i.e., polylogarithmic in both $n$ and $m$); we call such algorithms low-space. In the set-streaming model, it is known that $1/2$ is the best possible low-space approximation. In the edge-streaming model, no low-space algorithm can achieve a nontrivial approximation factor.

We study the problem under the assumption that the order in which the stream arrives is chosen uniformly at random. Our main results are as follows.

- In the random-arrival set-streaming model, we give two new algorithms to show that low space is sufficient to break the $1/2$ barrier. The first achieves an approximation factor of $1/2 + c_1$ using $\tilde{O}(k^2)$ space, where $c_1 > 0$ is a small constant and $\tilde{O}(\cdot)$ notation suppresses polylogarithmic factors; the second achieves a factor of $1 - 1/e - \varepsilon - o(1)$ using $\tilde{O}(k^2\varepsilon^{-3})$ space, where the $o(1)$ term is a function of $k$. This is essentially the optimal bound, as breaking the $1 - 1/e$ barrier is known to require high space.
- In the random-arrival edge-streaming model, we show for all fixed $\alpha > 0$ and $\delta > 0$, any algorithm that $\alpha$-approximates maximum coverage with probability at least 0.9 in the random-arrival edge-streaming model requires $\Omega(m^{1-\delta})$ space (i.e., high space), even for the special case of $k = 1$.

## 1 Introduction

*Maximum coverage* is a classic NP-hard problem in computer science with a range of applications, including facility allocation [16], information retrieval [2], and content recommendation [18]. We are given a collection of $m$ sets, $\mathcal{F}$, each a subset of a universe $[n] \coloneqq \{1, \ldots, n\}$, and a positive integer, $k$. The goal is to choose $k$ sets from $\mathcal{F}$ such that the cardinality of the union of the chosen sets – known as their *coverage* – is maximised. A standard greedy algorithm achieves a $(1 - 1/e)$-approximation and unless P = NP, this is the best approximation possible in polynomial time [7].

The greedy algorithm performs well in practice, but requires access to the entire input during its operation, which scales poorly for massive data sets. In the last 15 years, there has been an increasing focus on *streaming algorithms* for maximum coverage [18, 15, 6, 11]. These algorithms process the input piece by piece and use substantially less space than would be required to simply read the entire input into memory and run a classical algorithm, which requires $O(mn)$ space in general. In the *set-streaming* model, each set arrives contiguously in the stream: all the elements in one set are listed, then all the elements in the next set, and so on. In the more general *edge-streaming* model, each entity in the stream is a set-element pair, so the full description of a set might be spread across the stream.

Most existing work on streaming algorithms for maximum coverage has focused on the *arbitrary-arrival* model, in which the stream may arrive in any order. In particular, the stream may arrive in a *worst-case* order, so any theoretical guarantees made about an algorithm in this model must be made for all possible stream orderings. In practice, however, it is often reasonable to assume that the data stream is randomly ordered;[1] in the *random-arrival* model, all possible stream orderings are considered equally likely, and theoretical guarantees about an algorithm in this model need only be made as an *average* over these orderings. The random-arrival model has been studied for many important problems, including quantile estimation [10], maximum matching [13, 4], and submodular maximisation [17, 1], often revealing improved space-accuracy trade-offs.

In this paper, we study maximum coverage in the random-arrival model. In the *random-arrival set-streaming* model,[2] the order in which the sets appear in the stream is uniformly random, but we assume nothing about the order in which the elements in each set arrive. By contrast, in the *random-arrival edge-streaming* model, the edges arrive in a uniformly random order, so large sets are more likely to be represented early in the stream. For each model, our goal is to determine whether the random-arrival assumption permits a better approximation factor than is possible in the corresponding arbitrary-arrival model, when very low space is available (i.e., polylogarithmic in both $n$ and $m$). We answer this question in the affirmative for random-arrival set-streaming: we present two low-space algorithms, each achieving an approximation factor better than $1/2$ (the best possible approximation in the arbitrary-arrival model). For random-arrival edge-streaming, we demonstrate a near-tight space lower bound, hence answering in the negative: nearly linear in $m$ space is required to achieve a nontrivial approximation.

## 1.1 Related work

Table 1 summarises relevant past work on streaming algorithms for maximum coverage. Note that any algorithm that guarantees an approximation factor in the arbitrary-arrival model trivially also guarantees this approximation factor in the random-arrival model.

The multi-pass variant of streaming maximum coverage has also been studied, in which a small number of passes over the stream are allowed [15, 12]. In this paper, however, we focus exclusively on single-pass algorithms.

Unless otherwise specified, the following results apply to the arbitrary-arrival model.

---

[1] See Guha and McGregor [10] §1.1 for a discussion on justifications for this assumption.

[2] Note that we consider both "random-arrival" and "set-streaming" to be part of the model specification. When we talk about *the* random-arrival model, we mean both the random-arrival set-streaming and random-arrival edge-streaming models.

**Set-streaming.** Saha and Getoor [18], who introduced the set-streaming model, gave a 1/4-approximation algorithm called SOPS,[3] which uses $\tilde{O}(nk)$ space and explicitly returns the $k$ chosen sets. Yu and Yuan [20] studied the problem under the more relaxed ID-reporting output specification, in which only the *IDs* of the $k$ chosen sets must be returned by the algorithm.[4] They gave an algorithm, GOPS, which achieves an approximation factor of approximately 0.3 and uses $\tilde{O}(n)$ space, where $\tilde{O}(\cdot)$ notation suppresses dependence on polylogarithmic factors. Further progress came indirectly from Badanidiyuru et al. [5], who gave a $(1/2-\varepsilon)$-approximation algorithm for the related submodular maximisation problem. A careful adaptation to maximum coverage uses $\tilde{O}(n\varepsilon^{-1})$ space [15].

More recently, McGregor and Vu [15] developed the first set-streaming maximum coverage algorithms that use sublinear-in-$n$ space. Using *subsampling*, which effectively discards much of the universe, $[n]$, they substantially reduce the space consumption of their algorithms with minimal loss in solution quality. Of the four new algorithms they developed, the fourth, which we call MV-4 after the authors, is the most relevant to our work, as it is both low-space and single-pass. MV-4 achieves an approximation factor of $1/2-\varepsilon$ using just $\tilde{O}(k\varepsilon^{-3})$ space. The algorithm is explained in detail in Section 2.1. The other two MV algorithms that are also single-pass are also included in Table 1 (although note that they are not low-space).

McGregor and Vu [15] also proved the first nontrivial space lower bound for set-streaming maximum coverage. They showed that achieving an approximation factor better than $1-1/e$ requires $\Omega(mk^{-2})$ space in the arbitrary-arrival model and $\Omega(mk^{-3})$ space in the random-arrival model. Feldman et al. [8] extended this result to approximation factors better than $1/2$ for the arbitrary-arrival model.[5] Note that all lower bounds discussed in this work apply to the problem of simply *estimating* the optimal coverage.

The results of McGregor and Vu [15] and Feldman et al. [8] imply that the best possible approximation factor that can be achieved using low space in the arbitrary-arrival model is $1/2$, where by "low space" we mean space polylogarithmic in both $n$ and $m$.[6] In the random-arrival model, however, there is a knowledge gap for approximation factors between $1/2$ and $1-1/e$: can some low-space algorithm achieve an approximation factor in this range, or is high space always required?

**Edge-streaming.** Bateni et al. [6] gave the first edge-streaming maximum coverage algorithm, which achieves an approximation factor of $1-1/e-\varepsilon$ using $\tilde{O}_\varepsilon(m)$ space, where the subscript suppresses dependence on $\varepsilon$ (which was not analysed by the authors). Indyk and Vakilian [11] improved this result by showing that the optimal space bound is $\tilde{\Theta}(\alpha^2 m)$, where $\alpha > 0$ is the approximation factor. This result implies that achieving a nontrivial (i.e., nonzero) approximation factor using low space is impossible in the arbitrary-arrival edge-streaming model.

[3] The algorithm was given this name in a later work [20].

[4] IDs appear explicitly in the edge-streaming model as part of the set-element pairs. In the set-streaming model, we assume for convenience that the ID of each set is listed directly before the elements in the set, but this is a largely unimportant implementation detail.

[5] The authors actually studied the more general submodular maximisation problem. However, the submodular function constructed for the hardness instance is also a coverage function, so the result applies to maximum coverage as well.

[6] Other reasonable definitions exist, but we choose to focus on $n$ and $m$ since these are the parameters that can cause a maximum coverage problem instance to require a huge amount of space to store, which is the motivation for using streaming algorithms in the first place.

**Table 1** A summary of known results and our new results for the space complexity of single-pass streaming approximation algorithms for maximum coverage. Each of the parameters $\alpha, \delta, \varepsilon$ is positive, and $c_1$ is a small positive constant.

| Stream | Name | Arrival | Approximation | Space | Ref. |
|---|---|---|---|---|---|
| Set | SOPS | Arbitrary | $1/4$ | $O(nk)$ | [18] |
| | GOPS | Arbitrary | $\sim 0.3$ | $\tilde{O}(n)$ | [20] |
| | MCSS | Arbitrary | $1/2 - \varepsilon$ | $\tilde{O}(n\varepsilon^{-1})$ | [5, 15] |
| | MV-1 | Arbitrary | $1 - 1/e - \varepsilon$ | $\tilde{O}(m\varepsilon^{-2})$ | [15] |
| | MV-3 | Arbitrary | $1 - \varepsilon$ | $\tilde{O}(m\varepsilon^{-2} \cdot \min(k, \varepsilon^{-1}))$ | [15] |
| | MV-4 | Arbitrary | $1/2 - \varepsilon$ | $\tilde{O}(k\varepsilon^{-3})$ | [15] |
| | – | Arbitrary | $> 1 - 1/e$ | $\Omega(mk^{-2})$ | [15] |
| | – | Arbitrary | $> 1/2$ | $\Omega(mk^{-3})$ | [8] |
| | – | Random | $> 1 - 1/e$ | $\Omega(mk^{-3})$ | [15] |
| | GS-SALSA | Random | $1/2 + c_1$ | $\tilde{O}(k^2)$ | **Here** |

| Edge | – | Arbitrary | $1 - 1/e - \varepsilon$ | $\tilde{O}_\varepsilon(m)$ | [6] |
| | – | Arbitrary | $\alpha > 0$ | $\tilde{\Theta}(\alpha^2 m)$ | [11] |
| | – | Random | Any fixed $\alpha > 0$ | $\Omega(m^{1-\delta})$ | **Here** |

## 1.2 Our contributions

The results of this paper are included in Table 1.

**Set-streaming.** In the arbitrary-arrival model, the best approximation factor that can be achieved using low space is $1/2$. We present two low-space algorithms that break the $1/2$ barrier in the random-arrival model.

- The first algorithm, GS-SALSA, uses $\tilde{O}(k^2)$ space and achieves an approximation factor of $1/2 + c_1$ in-expectation, where $c_1 > 0$ is a small absolute constant.
- The second algorithm, GS-SMC$^+$, uses $\tilde{O}(k^2\varepsilon^{-3})$ space and achieves an approximation factor of $1 - 1/e - \varepsilon - o(1)$ in-expectation, where the $o(1)$ term is a function of $k$. For large $k$, this is essentially the optimal low-space approximation.[7]

Both algorithms are based on existing state-of-the-art random-arrival algorithms for the related *submodular maximisation* problem [17, 1]. Our main contribution is a generalisation of the subsampling technique introduced by McGregor and Vu [15] in the design of MV-4, which we apply to these existing submodular maximisation algorithms to achieve our results.

**Edge-streaming.** Indyk and Vakilian [11] showed that $\tilde{\Theta}(\alpha^2 m)$ space is necessary and sufficient for $\alpha$-approximating maximum coverage in the arbitrary-arrival model. An immediate corollary is that for all *fixed* $\alpha > 0$, the problem requires $\Omega(m)$ space. We prove an almost matching hardness result for the random-arrival case.

[7] Throughout this work, we typically do *not* consider the approximation factor of an algorithm (or hardness result) as a function of $k$, and instead consider the *worst-case* value of $k$ (just as we take a worst-case collection of sets $\mathcal{F}$). We make an exception for GS-SMC$^+$ due to the quality of its approximation for large values of $k$. Note that the hardness results of McGregor and Vu [15] and Feldman et al. [8] apply as $k$ approaches infinity, so the algorithm really is near-optimal for large $k$.

▶ **Theorem 1.** *For all fixed $\alpha > 0$ and $\delta > 0$, any algorithm that $\alpha$-approximates maximum coverage with probability at least 0.9 in the random-arrival edge-streaming model requires $\Omega(m^{1-\delta})$ space, even for the special case of $k = 1$.*

Our result implies that unlike set-streaming, edge-streaming maximum coverage is *not* made easier by the random-arrival assumption, in the sense that the assumption does not increase the best possible low-space approximation. Our proof of Theorem 1 is a careful combination of ideas from the proof for the arbitrary-arrival case by Indyk and Vakilian [11] with ideas from Andoni et al. [3], who proved a random-arrival space lower bound for the *frequency moment estimation* problem.

## 2 Beating 1/2 for Set-Streaming

In this section, we show that the 1/2 barrier can be broken for random-arrival set-streaming maximum coverage using low space. Our main contribution is a generalised version of the subsampling technique introduced by McGregor and Vu [15], which allows us to replace the core subroutine of MV-4 with *any* set-streaming maximum coverage algorithm. In particular, replacing the subroutine with state-of-the-art streaming algorithms for the related *submodular maximisation* problem yields two new maximum coverage algorithms with approximation factors better than 1/2 in the random-arrival model. The first, GS-SALSA, achieves an approximation factor of $1/2 + c_1$ for a small constant $c_1 > 0$. The second, GS-SMC$^+$, achieves an approximation factor of $1 - 1/e - \varepsilon - o(1)$, where the $o(1)$ term is a function of $k$. For large $k$, this is essentially the optimal bound.

### 2.1 Preliminaries: Design of MV-4

We start by providing a high-level overview of the MV-4 algorithm designed by McGregor and Vu [15], which achieves an approximation factor of $1/2 - \varepsilon$ using $\tilde{O}(k\varepsilon^{-3})$ space in the arbitrary-arrival model, which is essentially the optimal low-space approximation.

At the heart of MV-4 is a subroutine, $\mathcal{A}$, which achieves an approximation factor of $1/2 - \varepsilon$ using high space. This seeming contradiction is avoided by only providing a small sample of the input to $\mathcal{A}$; MV-4 is equipped with a binary hash function $h : [n] \to \{0, 1\}$, and as each element $e$ arrives in the stream, it is passed to the subroutine $\mathcal{A}$ only if $h(e) = 1$. The subroutine is therefore run on a *subsampled* problem instance $\mathcal{I}'$ over a smaller universe $[n]' = \{e \in [n] : h(e) = 1\}$, with subsampled sets $S'_i = S_i \cap [n]'$ for each $S_i \in \mathcal{F}$. An optimal solution to $\mathcal{I}'$ may not correspond to an optimal solution to $\mathcal{I}$, but when the hash function is chosen appropriately, a good solution to $\mathcal{I}'$ corresponds to a nearly-as-good solution to $\mathcal{I}$ with high probability. The hash function $h$ is chosen such that $\mathbb{P}[h(e) = 1] = p$ for all $e \in [n]$. When the subsampling rate $p$ is small, the space consumption of $\mathcal{A}$ is substantially reduced, and the overall algorithm becomes low-space.

The subsampling rate $p$ is set in terms of the optimal coverage, OPT. Of course, we do not know OPT in advance! To get around this, MV-4 runs parallel instantiations of $\mathcal{A}$, each corresponding to a different guess $v$ for OPT. Each instantiation $\mathcal{A}_v$ therefore has its own subsampling rate $p_v$, hash function $h_v$, and is run on a separate subsampled instance $\mathcal{I}'_v$. This introduces two new problems. Firstly, at the end of the stream, how do we know which instantiation corresponds to the correct guess? Rather than solve this problem directly, MV-4 maintains an $F_0$-*sketch*[8] of the set of elements covered (in the *unsubsampled* universe, $[n]$)

[8] Given a stream of items, an $F_0$-sketch is a small data structure capable of closely estimating the number

by the solution found by each instantiation. At the end of the stream, the solution with the highest estimated coverage is taken. Jaud et al. [12] gave a simpler method, which uses the *subsampled* coverage achieved by each instantiation to decide which solution to return.

The second problem introduced by the use of parallel instantiations concerns the space consumption of instantiations corresponding to bad guesses for OPT. If a guess $v$ is much smaller than OPT, the subsampling rate $p_v$ is set too high, the subsampled universe is too large, and so $\mathcal{A}_v$ uses too much space. To address this, MV-4 keeps track of the space consumption of each instantiation and terminates the instantiation if it uses too much space.

## 2.2 Generalised subsampling

In this section, we present a generalised version of McGregor and Vu's [15] subsampling technique. This allows the subroutine $\mathcal{A}$ to be replaced by *any* set-streaming maximum coverage algorithm $\mathcal{B}$. In Section 2.3, we apply our generalised subsampling technique to maximum coverage algorithms derived from state-of-the-art algorithms for submodular maximisation. The space consumption of these algorithms is proportional to $d = \max_{S_i \in \mathcal{F}} |S_i|$, the maximum set size of the problem instance. Under this condition, generalised subsampling substantially reduces the space consumption of $\mathcal{B}$. Our main result is as follows.

▶ **Theorem 2** (Generalised subsampling). *Suppose $\mathcal{B}$ achieves an approximation factor of $\alpha$ in-expectation*[9] *for set-streaming maximum coverage using $O(ds)$ space, where $d$ is the maximum set size. There exists an algorithm, called GS($\mathcal{B}$), which, given $\varepsilon > 0$, achieves an approximation factor of $\alpha - \varepsilon$ in-expectation and uses $\tilde{O}(k\varepsilon^{-2}s)$ space.*

An important aspect of Theorem 2 is that no assumptions are made about the design of $\mathcal{B}$. This presents a challenge when we try to replace $\mathcal{A}$ with $\mathcal{B}$ in MV-4, as the operation of MV-4 relies on an important property of $\mathcal{A}$. In particular, $\mathcal{A}$ is *threshold-based*: as each set arrives in the stream, the algorithm decides irrevocably whether to include the set in the solution, and maintains a set $C$ of the elements covered by the chosen sets. The decision to include an incoming set is based on whether the additional coverage provided by the set exceeds some threshold. This property is important to the design of MV-4 for two reasons. Firstly, it allows MV-4 to maintain a sketch of the elements covered by each instantiation of $\mathcal{A}$ in the unsubsampled universe, since after each set arrives, $\mathcal{A}$ can inform MV-4 as to whether it chose the set.[10] Secondly, the space consumption of $\mathcal{A}$ is directly proportional to the size of $C$, so this value may be used to trigger the termination of instantiations that use too much space.

We do not want to assume that $\mathcal{B}$ is threshold-based – indeed, we want to assume nothing at all about the design $\mathcal{B}$ – so we use an alternative idea. We abandon guessing OPT, and instead guess $d$, the maximum set size.[11] Our approach requires that some guess $w$ satisfies $d/2 \leq w \leq d$, so we make guesses in powers of 2. The problem of choosing which

---

of distinct items in the stream. The details are unimportant for our purposes.

[9] There is nothing special about in-expectation guarantees, and the theorem could just as easily be proved for with-high-probability guarantees. We focus on in-expectation results since this is the type of guarantee made about the state-of-the-art submodular maximisation algorithms that we apply our results to in Section 2.3.

[10] The alternative approach used by Jaud et al. [12] works quite differently, but also exploits the threshold-based architecture of $\mathcal{A}$ by using the size of $C$ for each instantiation to decide which solution to return.

[11] This is similar to an idea appearing in Badanidiyuru et al. [5], who studied streaming algorithms for submodular maximisation. Their algorithm, SIEVE-STREAMING, runs parallel instantiations corresponding to guesses for the maximum value of the given submodular function over any one item from the stream.

**Algorithm 1** The generalised subsampling algorithm GS($\mathcal{B}$).

```
1:  W ← {2^i : i ∈ ℕ, 2^i ≤ n}                          ▷ Guesses for d
2:  λ ← ⌊2k log(emε^{-1})⌋                              ▷ Hash function independence parameter
3:  for w ∈ W do
4:      Initialise B_w, an instantiation of B
5:      p_w ← min{1, 3kε^{-2} log(emε^{-1}) w^{-1}}     ▷ Subsampling rate
6:      Sample h_w ∈ H_{p_w,λ} uniformly at random      ▷ Choose hash function
7:      active_w ← true                                 ▷ Kill switch indicator
8:  for i = 1, ..., m do                                ▷ Iterate over each set in the stream
9:      for e ∈ S_i do                                  ▷ Iterate over each element in the set
10:         for w ∈ W do
11:             if d*_w > 2p_w w(1 + ε) then
12:                 active_w ← false                    ▷ Terminate B_w
13:             if active_w and h_w(e) = 1 then
14:                 Supply e to the stream of B_w
15: Let I_w ⊂ [m] be the solution returned by B_w
16: w_c ← min{w ∈ W : d*/2 ≤ w ≤ d*}                     ▷ At this point, d* = d.
17: return I_{w_c}
```

solution to return becomes trivial, since we can easily keep track of the maximum observed set size and choose the appropriate instantiation at the end of the stream (Line 16). We also keep track of the maximum observed set size for each *subsampled* problem instance, and use this value to trigger the termination of bad instantiations (Line 11).

Our generalised subsampling algorithm GS($\mathcal{B}$) is formalised by Algorithm 1. The variable $d^*$ keeps track of the running maximum set size observed so far in the stream. For example, $d^* = 0$ at the start of the stream, and $d^* = d$ at the end of the stream. Similarly, $d^*_w$ keeps track of the maximum set size observed for the subsampled problem instance $\mathcal{I}'_w$ corresponding to the guess $w$ for $d$. We omit from Algorithm 1 the straightforward steps required to keep track of these variables. The set $\mathcal{H}_{p_w,\lambda}$ appearing on Line 6 represents a $\lambda$-wise independent family of hash functions with the property that for all $e \in [n]$, $\mathbb{P}[h(e) = 1] = p_w$. A hash function $h$ from this family may be sampled, stored, and evaluated using $O(\lambda)$ space [15]. In the remainder of this section, we show that GS($\mathcal{B}$) achieves the approximation factor and space consumption guaranteed by Theorem 2.

**Approximation factor.** GS($\mathcal{B}$) returns the solution found by $\mathcal{B}_{w_c}$, where $w_c$ is the smallest guess for $d$ satisfying $d/2 \leq w_c \leq d$ (see Line 16), so we focus on this instantiation of $\mathcal{B}$. In particular, $S'_i$ is taken to mean the version of $S_i$ subsampled using the hash function $h_{w_c}$, and the $w_c$ subscript is often suppressed (e.g., $p = p_{w_c}$ and $\mathcal{I}' = \mathcal{I}'_{w_c}$).

Since each element $e \in [n]$ is subsampled with probability $p$, we expect that for any given choice of sets $S_1, \ldots, S_l$, the subsampled coverage of these sets will be approximately $p$ times their unsubsampled coverage. The following result formalises this intuition.

▶ **Lemma 3.** *With probability at least $1 - \varepsilon$, for all collections of up to $k$ sets $S_1, \ldots, S_l \in \mathcal{F}$, $|S'_1 \cup \cdots \cup S'_l| = p \cdot |S_1 \cup \cdots \cup S_l| \pm p\varepsilon d$.*

This result is similar to Lemma 8 from McGregor and Vu [15], with a few minor changes. Most notably, the probability of success is changed from a term involving $m$ to one involving $\varepsilon$, which is important for the purpose of making an in-expectation guarantee.

Our proof more closely resembles the proof of Corollary 5 from Jaud et al. [12], who showed that the independence factor $\lambda$ can be decreased substantially from its original definition in McGregor and Vu [15]. As in Jaud et al. [12], we require the following concentration bound for our proof.

▶ **Theorem 4** (Schmidt et al. [19]). *Let $X_1, \ldots, X_n$ be $\lambda$-wise independent binary random variables. Let $X = \sum_{i=1}^{n} X_i$ and $\mu = \mathbb{E}[X]$. If $\lambda \leq \lfloor \min(\gamma, \gamma^2)\mu e^{-1/3} \rfloor$, then*

$$\mathbb{P}\left[|X - \mu| \geq \gamma\mu\right] \leq e^{-\lfloor \lambda/2 \rfloor}.$$

**Proof of Lemma 3.** Fix any collection of sets $S_1, \ldots, S_l \in \mathcal{F}$ with $1 \leq l \leq k$. Let $D = |S_1 \cup \cdots \cup S_l|$ be the unsubsampled coverage of the collection and let $D' = |S'_1 \cup \cdots \cup S'_l|$ be the subsampled coverage. Let $X_e = 1$ if $e \in S_1 \cup \cdots \cup S_l$ and $h(e) = 1$, and let $X_e = 0$ otherwise. Then $D' = \sum_{i=1}^{n} X_i$ and $\mu \coloneqq \mathbb{E}[D'] = pD$. The $X_i$ are $\lambda$-wise independent by the choice of $h$, where $\lambda = \lfloor 2k \log(em\varepsilon^{-1}) \rfloor$. Define $\gamma = \varepsilon d/D$ so that $\gamma\mu = p\varepsilon d$. Before applying Theorem 4, we verify the necessary condition on the independence factor:

$$\begin{aligned}\left\lfloor \min(\gamma, \gamma^2)\mu e^{-1/3} \right\rfloor &= \left\lfloor \min(1, \gamma)\gamma\mu e^{-1/3} \right\rfloor \geq \left\lfloor \varepsilon \cdot p\varepsilon d \cdot \frac{2}{3} \right\rfloor \\ &= \left\lfloor \varepsilon^2 \cdot 3k\varepsilon^{-2} \log(em\varepsilon^{-1}) w^{-1} \cdot d \cdot \frac{2}{3} \right\rfloor \geq \left\lfloor 2k \log(em\varepsilon^{-1}) \right\rfloor = \lambda,\end{aligned}$$

where we make use of the fact that $\gamma \geq \varepsilon$ (since $d \geq D$), $e^{-1/3} \geq 2/3$, and $w \leq d$. Therefore, we have

$$\begin{aligned}\mathbb{P}\left[|D' - \mu| \geq p\varepsilon d\right] = \mathbb{P}\left[|D' - \mu| \geq \gamma\mu\right] &\leq \exp\left(-\left\lfloor \frac{\lfloor 2k \log(em\varepsilon^{-1}) \rfloor}{2} \right\rfloor\right) \\ &\leq \exp\left(-\left\lfloor k \log(em\varepsilon^{-1}) \right\rfloor\right) \leq \exp\left(-k \log(em\varepsilon^{-1}) + 1\right) \\ &\leq (em\varepsilon^{-1})^{-k} \cdot e = e^{-k+1} m^{-k} \varepsilon^k \leq m^{-k}\varepsilon.\end{aligned}$$

The total number of collections is $\sum_{i=1}^{k} \binom{m}{i} \leq \sum_{i=1}^{k} \frac{m^k}{k} = m^k$, so taking a union bound, the probability that $|D' - \mu| \geq p\varepsilon d$ for some collection is at most $m^k m^{-k}\varepsilon = \varepsilon$. ◀

Using Lemma 3, we can show that a good solution to the subsampled instance $\mathcal{I}'$ corresponds to a nearly-as-good solution to $\mathcal{I}$. This result is analogous to Corollary 9 from McGregor and Vu [15].

▶ **Corollary 5.** *Let $\mathrm{OPT}'$ be the optimal coverage for the subsampled problem instance $\mathcal{I}'$. If a choice of $k$ sets $S_1, \ldots, S_k$ satisfies $|S'_1 \cup \cdots \cup S'_k| \geq \beta \cdot \mathrm{OPT}'$, then with probability at least $1 - \varepsilon$, $|S_1 \cup \cdots \cup S_k| \geq (\beta - 2\varepsilon) \cdot \mathrm{OPT}$.*

**Proof.** Let $O_1, \ldots, O_k$ be an optimal solution to the unsubsampled problem instance $\mathcal{I}$. We have

$$\mathrm{OPT}' \geq |O'_1 \cup \cdots \cup O'_k| \geq p \cdot |O_1 \cup \cdots \cup O_k| - p\varepsilon d \geq p(1 - \varepsilon) \cdot \mathrm{OPT},$$

where the second inequality follows from Lemma 3. Now let $S_1, \ldots, S_k$ be a collection of sets satisfying $|S'_1 \cup \cdots \cup S'_k| \geq \beta \cdot \mathrm{OPT}$. Applying Lemma 3 once again, we have

$$\begin{aligned}|S_1 \cup \ldots \cup S_k| &\geq \frac{1}{p} \cdot |S'_1 \cup \ldots \cup S'_k| - \varepsilon d \geq \frac{1}{p} \cdot \beta \cdot \mathrm{OPT}' - \varepsilon \cdot \mathrm{OPT} \\ &\geq \frac{\beta}{p} \cdot p(1 - \varepsilon) \cdot \mathrm{OPT} - \varepsilon \cdot \mathrm{OPT} \geq (\beta - 2\varepsilon) \cdot \mathrm{OPT}.\end{aligned}$$

◀

Now $\mathcal{B}$ achieves an approximation factor of $\alpha$ in-expectation on the subsampled instance $\mathcal{I}'$. Therefore, by Corollary 5, with probability at least $1-\varepsilon$, $\mathcal{B}$ achieves an approximation factor of $\alpha - 2\varepsilon$ in-expectation. The unconditional expected approximation factor is therefore at least $(1-\varepsilon)(\alpha-2\varepsilon) \geq (\alpha - 3\varepsilon)$. Dividing $\varepsilon$ by 3 at the start (omitted from Algorithm 1 for brevity) corrects this to $\alpha - \varepsilon$ without changing the asymptotic space complexity.

Of course, the above reasoning is only valid if, in the at-least-$(1-\varepsilon)$-probability event that all the approximations in Lemma 3 hold, the instantiation $\mathcal{B}_{w_c}$ is not terminated.[12] Let $i'_{\max} = \arg\max_i |S'_i|$ be the index of the largest set in the subsampled instance. We have

$$d^*_{w_c} \leq d_{w_c} = \left|S'_{i'_{\max}}\right| \overset{*}{\leq} p_{w_c} \left|S_{i'_{\max}}\right| + p_{w_c}\varepsilon d \leq p_{w_c} d(1+\varepsilon) \leq 2p_{w_c} w_c(1+\varepsilon),$$

where the starred inequality follows from an application of Lemma 3 on the singleton collection containing only $S_{i'_{\max}}$. Therefore, the instantiation $\mathcal{B}_{w_c}$ is not terminated.

**Space consumption.** We now consider an arbitrary instantiation $\mathcal{B}_w$, where $w$ is not necessarily the correct guess for $d$. Unlike $n$, $m$, and $k$, we do not assume that a maximum coverage streaming algorithm is provided with the maximum set size $d$ at the start of the stream. Furthermore, at any point during the stream, it could be that the largest set has already been observed (i.e., $d^* = d$). Therefore, since $\mathcal{B}_w$ uses $O(d_w s)$ space, it must also use $O(d^*_w s)$ space. Now as long as $\mathcal{B}_w$ is not terminated, by Line 11, we have $d^*_w \leq 2p_w w(1+\varepsilon)$, so the space consumption of $\mathcal{B}_w$ is

$$O(d^*_w s) = O(p_w w(1+\varepsilon)s) = O(k\varepsilon^{-2}\log(em\varepsilon^{-1})w^{-1}ws) = \tilde{O}(k\varepsilon^{-2}s).$$

Each instantiation also requires the storage of the hash function $h_w$, but this takes just $O(\lambda) = \tilde{O}(k)$ space. There are $|W| = O(\log n)$ instantiations, so the total space complexity of $\mathrm{GS}(\mathcal{B})$ is $\tilde{O}(k\varepsilon^{-2}s)$. This completes the proof of Theorem 2.

## 2.3 Beating 1/2 via submodular maximisation

Submodular maximisation is a heavily studied problem in combinatorial optimisation that may be viewed as a generalisation of maximum coverage. A function $f : 2^V \to \mathbb{R}$ over a ground set $V$ is said to be *submodular* if we have

$$f(e \mid X) \geq f(e \mid Y) \quad \text{for all } X \subseteq Y \subseteq V \text{ and } e \in V \setminus Y,$$

where $f(e \mid X) = f(X \cup \{e\}) - f(X)$ is the marginal gain of $e$ given $X$. Submodular maximisation is the problem of choosing $A \subseteq V$ such that $f(A)$ is maximised. We consider a popular variant of the problem in which a cardinality constraint $|A| \leq k$ is applied and $f$ is assumed to be non-negative and monotone.

Submodular maximisation has received a lot of attention in the streaming model [5, 17, 1]. In this model, the items of $V$ arrive one at a time in the stream, and we assume access to an oracle for $f$, which may be queried in $O(1)$ time. In the arbitrary-arrival model, it is known that $\Omega(mk^{-3})$ space is required to achieve an approximation factor above $1/2$, where $m = |V|$ is the length of the stream [8].[13] In the random-arrival model, however, the $1/2$ barrier has been broken. This was first achieved by Norouzi-Fard et al. [17], who gave a $\tilde{O}(k)$-space

[12] Note that the inequality in Corollary 5 always holds in this event.

[13] This is the same result that states that $\Omega(mk^{-3})$ space is required to achieve approximation factors better than $1/2$ for arbitrary-arrival set-streaming maximum coverage (cf. Table 1).

algorithm, called SALSA, which achieves an approximation factor of $1/2 + c_0$ in-expectation for a very small constant $c_0 > 0$. More recently, Agrawal et al. [1] gave an algorithm which achieves an approximation factor of $1 - 1/e - \varepsilon - o(1)$ in-expectation, where the $o(1)$ term is a function of $k$. The algorithm, which we call SMC after its authors, uses $\tilde{O}_\varepsilon(k)$ space, where a complicated exponential dependence on $\varepsilon$ is suppressed. Liu et al. [14] improved the space complexity to $\tilde{O}(k\varepsilon^{-1})$ while maintaining the approximation factor; we call this improved algorithm SMC$^+$.

Submodular maximisation generalises maximum coverage: given a maximum coverage instance $\mathcal{I} = (\mathcal{F}, k)$, we simply set $V = \mathcal{F}$ and define $f$ to be the coverage function $f(X) = |\cup_{S_i \in X} S_i|$. It is not hard to see that $f$ is non-negative, monotone, and submodular. In the study of maximum coverage, however, we do *not* assume oracle access for evaluating coverage, so it must be evaluated explicitly. Therefore, if we use a submodular maximisation streaming algorithm for set-streaming maximum coverage, entire sets must be retained in memory, leading to an increase in space consumption proportional to $d$, the size of the largest set. Applying Theorem 2, however, we have the following key result.

▶ **Corollary 6.** *Suppose $\mathcal{B}$ achieves an approximation factor of $\alpha$ in-expectation for streaming submodular maximisation using $O(s)$ space. There exists an algorithm for set-streaming maximum coverage which, given $\varepsilon > 0$, achieves an approximation factor of $\alpha - \varepsilon$ in-expectation and uses $\tilde{O}(k\varepsilon^{-2}s)$ space.*

Applying this result to SALSA with $\varepsilon = c_1 \coloneqq c_0/2$ yields GS-SALSA, which achieves an approximation factor of $1/2 + c_0 - \varepsilon = 1/2 + c_1$ in-expectation using $\tilde{O}(k\varepsilon^{-2} \cdot k\varepsilon^{-1}) = \tilde{O}(k^2)$ space (note that $\varepsilon$ in this case is constant). Applying the result to SMC$^+$ yields GS-SMC$^+$, which uses $\tilde{O}(k^2\varepsilon^{-3})$ space and achieves an approximation factor of $1 - 1/e - \varepsilon - o(1) - \varepsilon$ in-expectation. Dividing $\varepsilon$ by 2 returns the approximation factor to $1 - 1/e - \varepsilon - o(1)$ with no change to the space complexity. Recall that achieving an approximation factor above $1 - 1/e$ requires high space [15], so for large $k$, this is essentially the optimal approximation. The $o(1)$ term decreases quite slowly, however, so for small $k$, GS-SALSA may be preferable.

## 3 Hardness Result for Edge-Streaming

In this section, we prove Theorem 1, which essentially says that no low-space algorithm can achieve a nontrivial approximation in the random-arrival edge-streaming model.

Our proof is a reduction from the heavily studied *$t$-party set disjointness problem*, DISJ$_t$. In this problem, $t$ players are each given a set $S_i \subseteq [N]$, where the $i^{\text{th}}$ player knows only $S_i$. Either all sets are pairwise disjoint (a YES instance), or are pairwise disjoint except for an element that is common to all $t$ sets (a NO instance). Gronemeier [9] showed that any protocol that solves this problem with probability 2/3 requires $\Omega(N/t)$ bits of communication, even if the players may use public randomness. The hardness instance for this problem is such that we may assume that $|S_1| = \ldots = |S_t| = cN/t$ for an arbitrarily small constant $c > 0$.

Our proof combines ideas from two existing approaches, both of which are also reductions from DISJ$_t$. The first is a result due to Andoni et al. [3], who proved a near-tight space lower bound for the problem of *frequency moment estimation* on random-arrival streams. Given a stream $\langle a_1, \ldots, a_l \rangle$, where each $a_i \in [n]$, the $k^{\text{th}}$ frequency moment is defined as $F_k \coloneqq \sum_{i \in [n]} f_i^k$, where $f_i = |\{j : a_j = i\}|$ is the number of times $i$ appears in the stream. Andoni et al. [3] studied the problem of 0.5-estimating this quantity, which is known to require $\tilde{\Theta}(n^{1-2/k})$ space in the arbitrary-arrival model. They showed that $\Omega(n^{1-2.5/k}/\log n)$ space is necessary in the random-arrival model, almost matching the upper bound. In their

proof, a stream of integers is constructed such that we have $F_k = l$ for a YES instance and $F_k \geq 2l$ for a NO instance. Our proof is very similar, but we include all the details for completeness. The main difference in our proof is that we need to construct a stream of *edges*, rather than a stream of integers. We use an idea from Indyk and Vakilian [11], who proved that $\Omega(\alpha^2 m)$ space is required to $\alpha$-approximate maximum coverage in the arbitrary-arrival edge-streaming model. Their proof involves the construction of a stream of edges such that the maximum coverage is 1 for a YES instance and $1/\alpha$ for a NO instance. We make a small change to this construction to ensure that the stream is in random order.

We start with two slightly reparameterised preliminary results from Andoni et al. [3]. Throughout this section, we assume that $\alpha$ and $\delta$ have been fixed.

▶ **Lemma 7.** *Let $\mathcal{W} = \{I_1, \ldots, I_t\}$ be $t = l^{2\delta/5}$ random intervals from*

$$\text{Cycle}_{l,w} \coloneqq \{[i-1 \pmod l + 1, \ldots, w+i-2 \pmod l + 1] : i \in [l]\} ,$$

*where $w = c_1 l^{1-3\delta/5}$ and $c_1 > 0$ is a sufficiently small absolute constant. With probability at least 0.99,*

1. *$I_{i_1} \cap I_{i_2} \cap I_{i_3} = \emptyset$ for any $i_1 < i_2 < i_3$.*
2. *$|\{(i_1, i_2) : i_1 < i_2,\ I_{i_1} \cap I_{i_2} \neq \emptyset\}| \leq \sqrt{t}$.*

The set $\text{Cycle}_{l,w}$ is simply the set of size-$w$ intervals from $[l]$, including those that "wrap around" from $l$ to 1. For example, $\text{Cycle}_{4,3} = \{[1,2,3],[2,3,4],[3,4,1],[4,1,2]\}$.

▶ **Lemma 8.** *Consider a uniformly random subset $S \subseteq [l]$ of size $t = l^{2\delta/5}$. For some sufficiently small absolute constant $c_2 > 0$, with probability at least 0.99, for each $j_1, j_2 \in S$, $|j_2 - j_1| \geq c_2 l^{1-4\delta/5}$.*

We also require the following result.

▶ **Lemma 9.** *Let $X$ be the number of unique values produced by $\lceil t/4 \rceil$ independent, uniformly random draws from $[t]$ (with replacement). For sufficiently large $t$, $\mathbb{P}(X \geq t/6) \geq 0.99$.*

**Proof.** Let $X_i = \mathbf{1}(i \text{ is drawn at least once})$, then $X = \sum_{i=1}^{t} X_i$. We have

$$\mu \coloneqq \mathbb{E}[X] = t\mathbb{E}[X_1] = t\left(1 - (1-1/t)^{\lceil t/4 \rceil}\right) \geq t\left(1 - e^{-1/4}\right) \geq t/5.$$

By a Chernoff bound for negatively correlated Boolean random variables where we set $\beta = 6/5$, we have

$$\mathbb{P}\left(X < \frac{t}{6}\right) = \mathbb{P}\left(X < \frac{t/5}{\beta}\right) \leq \mathbb{P}\left(X < \frac{\mu}{\beta}\right) \leq \left(\frac{e^{1/\beta - 1}}{\beta^\beta}\right)^\mu = c_3^\mu \leq c_3^{t/5},$$

where $c_3$ is an absolute constant less than 1. By setting $t \geq 5 \log_{c_3}(0.01) \approx 11.9$, we get $\mathbb{P}(X < t/6) \leq 0.01$ and the result follows. ◀

We are now ready to prove Theorem 1. Let $\mathcal{S} = \{S_1, \ldots, S_t\}$ be an instance of $\text{DISJ}_t$ where $t = l^{2\delta/5}$, $N = l^{1-\delta/5}$, and for all $i \in [t]$, we have $|S_i| = c_1 N/t = c_1 l^{1-3\delta/5} =: w$, where $c_1$ is as in Lemma 7. Any protocol that solves $\mathcal{S}$ with probability at least 2/3 requires $\Omega(N/t) = \Omega(l^{1-3\delta/5})$ bits of communication.

Let $\mathcal{A}$ be an $s$-space algorithm for random-arrival edge-streaming maximum coverage that achieves an approximation factor of $\alpha$ with probability at least 0.9 on streams containing $l$ edges. We describe a protocol that uses $\mathcal{A}$ to solve $\mathcal{S}$ using $O(ts)$ bits of communication, and therefore deduce that $s = \Omega(l^{1-3\delta/5}/t) = \Omega(l^{1-\delta}) = \Omega(m^{1-\delta})$ (note that $m \leq l$, since $l$ edges cannot possibly specify the contents of more than $m$ non-empty sets).

Using public randomness, the players pick:

1. Intervals $\mathcal{W} = \{I_1 = [a_1, b_1], \ldots, I_t = [a_t, b_t]\}$ from $\text{Cycle}_{l,w}$, ordered such that $b_i \le b_j$ if $i \le j$. The intervals are chosen independently with replacement.
2. A permutation $\sigma$ of $[2l]$.
3. A binary string $r$ of length $t^2/c_2$, where $c_2$ is as in Lemma 8.

Each interval in $\mathcal{W}$ has size $|I_i| = w$. If $b_1 < w$, then at least one set "wraps around" from $l$ to 1. In this case, terminate with failure. Each interval has probability $(w-1)/l$ of wrapping around, so by a simple union bound, $\mathbb{P}[b_1 < w] \le t(w-1)/l \le c_1 l^{-\delta/5}$. For large enough $l$, this value is at most 0.01. Also, if any $j \in [n]$ appears in three or more distinct intervals in $\mathcal{W}$, or if more than $\sqrt{t}$ pairs of intervals intersect, the protocol terminates with failure. By Lemma 7, this too occurs with probability at most 0.01.

The players construct, as described below, a length-$l$ stream $U = \langle u_1, \ldots, u_l \rangle$ representing a maximum coverage problem instance $\mathcal{I} = (\mathcal{F} = \{H_1, \ldots, H_m\}, k = 1)$ in the edge-streaming model, where each $H_i \subseteq [t]$. Each edge is a set-element pair $u_j = (y_j, e_j)$ indicating that $e_j \in H_{y_j}$. The players take turns generating edges and feeding them to the stream of the algorithm $\mathcal{A}$. When it is no longer a player's turn to generate the next edge, the player sends the entire state of $\mathcal{A}$ to the appropriate player, which requires $O(s)$ bits of communication.

**Constructing the stream.** The construction is very similar to the one presented by Andoni et al. [3]. First, each player $i$ randomly orders their set $S_i$ to produce a string $s^i$ of length $w$. Now consider $u_j$, the $j^{\text{th}}$ element in the stream $U$. The player chosen to construct $u_j$ depends on the number of intervals in $\mathcal{W}$ that contain $j$.

0. If $j$ appears in none of the intervals, $u_j$ is determined by player $i$, where $I_i = [a_i, b_i]$ is the interval with the smallest $a_i$ such that $a_i > j$. If no such interval exists (which may occur towards the end of the stream) then $u_j$ is determined by player $t$.
1. If $j$ appears in just one interval $I_i$, $u_j$ is determined by player $i$.
2. If $j$ appears in two intervals $I_i$ and $I_{i+1}$, we have a "clash" between players $i$ and $i+1$. We partition $[l]$ into $t^2/c_2$ equally sized intervals, which we call *zones*. We say that zone $u$ is a *0-zone* if $r_u = 0$, and a *1-zone* otherwise. If $j$ is in a 0-zone, $u_j$ is determined by player $i$. Otherwise, $u_j$ is determined by player $i+1$. Each zone has length $w_2 \coloneqq c_2 l^{1-4\delta/5}$.

Note that $j$ never appears in more than two intervals, since this results in termination of the protocol. Figure 1 shows an example of how players might be chosen to construct the stream.

At the end of their interval, each player sends the state of $\mathcal{A}$ to the next player. Also, when two players' intervals overlap, they may need to send the state of $\mathcal{A}$ back and forth several times (e.g., in Figure 1, players 2 and 3 need to pass the state to each other three times). Assuming the protocol does not terminate, there are at most $\sqrt{t}$ clashes, and each clash results in at most $w/w_2 = O(\sqrt{t})$ messages being sent. The total number of messages is $O(t + \sqrt{t} \cdot \sqrt{t}) = O(t)$, so the communication complexity of the protocol is $O(ts)$.

Now suppose player $i$ has been chosen to construct the edge $u_j = (y_j, e_j)$. The set ID $y_j$ is chosen in exactly the same way as the integer $a_j$ in Andoni et al. [3]: set $y_j = \sigma(x_j)$, where the definition of $x_j$ differs for each of the three cases.

0. Set $x_j = l + j$ to be a *padding value*.
1. Set $x_j = s^i_q$ to be a *standard value* with probability 1/2, where $j$ is the $q^{\text{th}}$ element of $I_i$. Otherwise, set $x_j = l + j$ to be a padding value.
2. Set $x_j = s^i_q$ to be a standard value, where $j$ is the $q^{\text{th}}$ element of $I_i$.

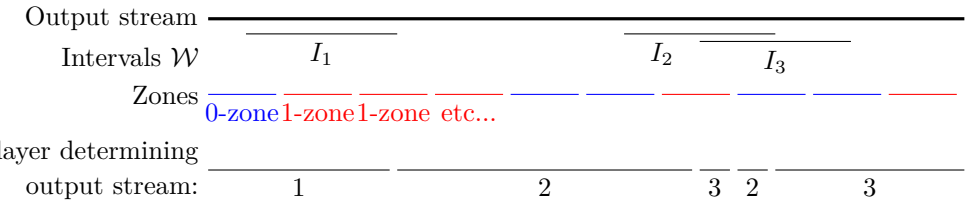

**Figure 1** An example allocation of stream construction responsibility for a simple $\text{DISJ}_3$ instance in which there is a single overlap between two intervals ($I_2$ and $I_3$). Note that this is a non-terminating instance.

**Table 2** A portion of an example reduction for a $\text{DISJ}_t$ NO instance with multiply occurring element 3. Column $j$ denotes the index of the stream, while the strings $s^2$ and $s^3$ (which contain the contents of the sets $S_2$ and $S_3$) have been positioned in place of the intervals $I_2 = \{11, \ldots, 14\}$ and $I_3 = \{13, \ldots, 16\}$ for clarity. The "Player" column denotes the player who determines the edge $u_j = (\sigma(x_j), p_j)$. In Case 1 (e.g., $j = 11$), there are two different equally likely values for $x_j$; both values are shown. We assume that $l = 20$.

| $j$ | $s^2$ | $s^3$ | Zone | Player | Case | $x_j$ |
|---|---|---|---|---|---|---|
| ⋮ | | | ⋮ | ⋮ | ⋮ | ⋮ |
| 10 | | | 0 | 2 | 0 | $l + j = 30$ |
| 11 | 4 | | 0 | 2 | 1 | $s^2_1 = 4$ or $l + j = 31$ |
| 12 | 5 | | 1 | 2 | 1 | $s^2_2 = 5$ or $l + j = 32$ |
| 13 | 3 | 8 | 1 | 3 | 2 | $s^3_1 = 8$ |
| 14 | 1 | 2 | 0 | 2 | 2 | $s^2_4 = 1$ |
| 15 | | 3 | 0 | 3 | 1 | $s^3_3 = 3$ or $l + j = 35$ |
| 16 | | 6 | 0 | 3 | 1 | $s^3_4 = 6$ or $l + j = 36$ |
| 17 | | | 0 | 4 | 0 | $l + j = 37$ |
| ⋮ | | | ⋮ | ⋮ | ⋮ | ⋮ |

Table 2 shows an example of how the $x_j$ are defined for a portion of the stream that includes two overlapping intervals. Observe that each occurrence of an element $e$ in a set $S_i$ has probability 1/2 of appearing as a standard value $x_j = e$ for some $j$.[14]

It remains to choose the element $e_j$. In their proof for the arbitrary-arrival case, Indyk and Vakilian [11] set $e_j = i$ and insert the edge $(x_j, e_j)$ into the stream, where $x_j$ is always a standard value (the intervals are contiguous sections of the stream). The result is that each $H_e \in \mathcal{F}$ contains the IDs of the players holding the element $e$, so the maximum coverage is either 1 (in a YES instance) or $t$ (in a NO instance). This idea does not work for our purposes, since if we set $e_j = i$, consecutive edges inserted by the same player will always have the same $e_j$. Instead, we set $e_j = p_j$, where $p_j \in [t]$ is a *randomly sampled* player ID.

By the same argument given by Andoni et al. [3], the stream is in (nearly[15]) random order. The only difference is the presence of $p_j$ in each of our edges. However, as the $p_j$ are randomly and independently sampled from $[t]$, they have no effect on whether the stream is randomly ordered.

[14] In Case 1, this probability comes from the random choice between a standard value and a padding value. In Case 2, this probability comes from the random choice of zone due to the binary string $r$.

[15] Certain orderings are impossible due to the termination with failure conditions. Since termination happens with probability at most 0.02, however, the biggest detrimental effect that this can possibly have on the performance of $\mathcal{A}$ is a decrease of 0.02 in the probability of successfully achieving the approximation factor.

**Using the output of $\mathcal{A}$.** What does the output of $\mathcal{A}$ tell us about the $\text{DISJ}_t$ instance $\mathcal{S}$? The following claims are made assuming that the protocol does not terminate with failure.

▷ Claim 10. If $\mathcal{S}$ is a YES instance, the optimal coverage of $\mathcal{I}$ is 1.

Proof. First, observe that the $x_j$ are all distinct, since all padding values are distinct from each other, all standard values are distinct from each other (as $\mathcal{S}$ is a YES instance), and no standard value can ever equal a padding value, as $s^i_q \leq N < l < l + j$. Therefore, since $\sigma$ is a permutation, the $y_j$ are also all distinct, so each edge in the stream specifies a different set ID. Every set is therefore singleton, so the optimal coverage is 1. ◁

▷ Claim 11. If $\mathcal{S}$ is a NO instance, then with probability at least 0.97, the optimal coverage of $\mathcal{I}$ is at least $t/6$.

Proof. There is some $e \in [N]$ such that $e \in S_i$ for all $i \in [t]$. For each occurrence of $e$ in a set $S_i$, there is some position in the stream where $e$ appears as an edge $(\sigma(e), p_j)$ with probability $1/2$. Let $V$ be this set of positions (e.g., in Table 2, the multiply occurring element is $e = 3$, and the set $V$ includes 13 and 15). Since the intervals $\mathcal{W}$ are chosen randomly and the strings $s^i$ are randomly ordered, $V$ is a uniformly random subset of $[l]$, so by Lemma 8, with probability at least 0.99, no two elements of $V$ fall within $c_2 l^{1-4\delta/5}$ of each other. This is precisely $w_2$, the size of each zone, so no two elements fall within the same zone. Each occurrence of $e$ therefore appears in the stream with probability $1/2$ *independently*, so the number of occurrences that appear has a Binomial distribution $q \sim B(t, 1/2)$. When $t$ is sufficiently large,[16] $q \geq t/4$ with probability at least 0.99.

Now consider these $q$ appearances, $(\sigma(e), p_1), \ldots, (\sigma(e), p_q)$. Assuming that we indeed have $q \geq t/4$, by Lemma 9, the number of distinct values among $p_1, \ldots, p_q$ is at least $t/6$, so choosing $H_{\sigma(e)}$ yields a coverage of at least $t/6$. By a union bound on the three sources of error (Lemma 8, variation in the Binomial distribution, and Lemma 9), this occurs with probability at least 0.97. ◁

By taking $l$ large enough, we can ensure that $t/6 \geq 1/\alpha$, in which case $\mathcal{A}$ is powerful enough to distinguish between YES and NO instances. Tallying up the various sources of error, $\mathcal{A}$ succeeds with probability at least 0.9, we avoid early termination with probability at least 0.98, and (in the case of a NO instance) Claim 11 holds with probability at least 0.97. Thus, by a union bound, the protocol succeeds with probability at least $1 - 0.1 - 0.02 - 0.03 = 0.85 \geq 2/3$. This completes the proof of Theorem 1.

## Abstract

Randomized matrix algorithms have had significant recent impact on numerical linear algebra. One especially powerful class of methods are algorithms for approximate matrix multiplication based on sampling. Such methods typically sample individual matrix rows and columns using carefully chosen importance sampling probabilities. However, due to practical considerations like memory locality and the preservation of matrix structure, it is often preferable to sample contiguous blocks of rows and columns all together. Recently, (Wu, 2018) addressed this setting by developing an approximate matrix multiplication method based on block sampling. However, the method is inefficient, as it requires knowledge of optimal importance sampling probabilities that are expensive to compute.

We address this issue by showing that the method of Wu can be accelerated through the use of a randomized implicit trace estimation method. Doing so allows us to provably reduce the cost of sampling to near-linear in the size of the matrices being multiplied, without impacting the accuracy of the final approximate matrix multiplication. Overall, this yields a fast practical algorithm, which we test on a number of synthetic and real-world data sets. We complement our algorithmic contribution with the first extensive empirical comparison of block algorithms for randomized matrix multiplication. Our method offers a significant runtime advantage over the method of (Wu, 2018) and also outperforms basic uniform sampling of blocks. However, we find another recent method of (Charalambides, 2021) which uses sub-optimal but efficiently computable sampling probabilities often (but not always) offers the best trade-off between speed and accuracy.

## 1 Introduction

Matrix computations are central across computing, with applications in optimization, scientific computing, data science, and more. In recent years, in an effort to tackle the challenge of scaling computations to larger and larger matrices, randomized methods have taken center stage [14, 27]. Collectively known as Randomized Numerical Linear Algebra or "RandNLA", the study of randomized matrix algorithms has led to faster algorithms for a number of central problems in linear algebra, including least squares regression [5, 24, 25], low-rank approximation [10, 13, 17, 23], trace estimation [18, 21], and more. Many of these algorithms are based on relatively simple sampling and sketching routines (like Johnson-Lindenstrauss random projection hashing-based methods) which are easily parallelized and adapted to modern computational environments, including distributed and streaming architectures [4].

## 1.1 Randomized Matrix Multiplication

Beyond the problems listed above, another topic of central interest in RandNLA is, of course, matrix multiplication. There has been significant work on developing randomized algorithms for matrix multiplication that return an approximate solution in a fraction of the time it would take to perform exact multiplication [6, 7]. Roughly, randomized matrix-multiplication methods can be split into two categories – random projection methods [25] and random sampling methods [12]. In both cases, the idea is to quickly compress given input matrices $\mathbf{A} \in \mathbb{R}^{m\times n}$ and $\mathbf{B} \in \mathbb{R}^{n\times p}$ to form matrix "sketches" $\mathbf{C} \in \mathbb{R}^{m\times c}$ and $\mathbf{D} \in \mathbb{R}^{c\times p}$, where $c \ll n$. We then return $\mathbf{CD}$ as an approximation to $\mathbf{AB}$. For many standard methods, including Johnson-Lindenstrauss random projection [25] and norm-based column and row sampling [12], a choice of $c = O(1/\epsilon^2)$ for $\epsilon \in (0, 1)$ ensures that with high probability:

$$\|\mathbf{AB} - \mathbf{CD}\|_F \leq \epsilon \|\mathbf{A}\|_F \|\mathbf{B}\|_F. \tag{1}$$

The approximation $\mathbf{CD}$ can be computed in $O(cmp) = O(mp/\epsilon^2)$ time, significantly improving on the naive cost of $O(nmp)$ when $n$ is large in comparison to $1/\epsilon^2$. So, we get an algorithmic speedup as long as $\mathbf{C}$ and $\mathbf{D}$ can be quickly obtained from $\mathbf{A}$ and $\mathbf{B}$.

### 1.1.1 The BasicMatrixMultiplication Method

In this paper, we are specifically interested in random sampling methods for computing $\mathbf{C}$ and $\mathbf{D}$. The most well-known method is the BasicMatrixMultiplication algorithm of Drineas, Kannan, and Mahoney [11, 12]. The idea behind the algorithm is elegant: the matrix multiplication $\mathbf{AB}$ can be cast as the sum of rank-one components, each an outer product of a column in $\mathbf{A}$ and the corresponding row in $\mathbf{B}$. In particular, $\mathbf{AB} = \sum_{i=1}^{n} \mathbf{A}^{(i)}\mathbf{B}_{(i)}$, where $\mathbf{A}^{(i)}$ denotes the $i^{\text{th}}$ column of $\mathbf{A}$ and $\mathbf{B}_{(i)}$ denotes the $i^{\text{th}}$ row of $\mathbf{B}$. BasicMatrixMultiplication approximates this sum by sampling the rank-one components using non-uniform sampling probabilities. To be more specific, we sample $\mathbf{A}^{(i)}\mathbf{B}_{(i)}$ with probability $p_i = \frac{\|\mathbf{A}^{(i)}\|_2\|\mathbf{B}_{(i)}\|_2}{\sum_{j=1}^{n}\|\mathbf{A}^{(j)}\|_2\|\mathbf{B}_{(j)}\|_2}$, so "heavy" columns and rows (which contribute more to the matrix product) are sampled with high probability. Equivalently, for the BasicMatrixMultiplication method, $\mathbf{C}$ and $\mathbf{D}$ consist of a subset of columns and rows from $\mathbf{A}$ and $\mathbf{B}$, sampled according to their $\ell_2$ norms. More details are provided in Section 2.

The BasicMatrixMultiplication algorithm is a powerful method with a number of desirable properties. First, the method achieves the strong bound of Equation (1), matching random projection methods in the worst case. However, on top of this:

1. When constructing $\mathbf{C}$ and $\mathbf{D}$, the BasicMatrixMultiplication method preserves sparsity and structure originally present in $\mathbf{A}$ and $\mathbf{B}$. This can lead to more compact sketches in practice. The same is not true of random projection based methods, which e.g. produce dense sketches $\mathbf{C}$ and $\mathbf{D}$, even if $\mathbf{A}$ and $\mathbf{B}$ are sparse.
2. The sampling probabilities $p_1, \ldots, p_n$, and thus the sketches $\mathbf{C}$ and $\mathbf{D}$ can be computed in just $O(mn + pn)$ time, which is linear in the size of the input. We simply need to compute the norm of all columns (resp., rows) in $\mathbf{A}$ (resp., $\mathbf{B}$).
3. The sampling probabilities used are *provably optimal* in the sense that they minimize the expected squared error $\mathbb{E}\left[\|\mathbf{AB} - \mathbf{CD}\|_F^2\right]$ amongst all choices of probabilities. As a result, BasicMatrixMultiplication often outperforms the worst-case bound of Equation (1).

Thanks to the advantages above, the BasicMatrixMultiplication algorithm has been widely adapted and applied to problems in information retrieval [15], image processing [20], and distributed computation [19].

## 1.2 Our Contributions

Despite its many virtues, an important practical issue with the BasicMatrixMultiplication method is that it samples columns and rows from $\mathbf{A}$ and $\mathbf{B}$ *independently at random.* In many applications, it would actually be preferable to sample contiguous *blocks* of columns from $\mathbf{A}$, and respective blocks of rows from $\mathbf{B}$, i.e., to sample every column $\mathbf{A}^{(i)}, \mathbf{A}^{(i+1)}, \ldots, \mathbf{A}^{(i+q-1)}$ for some starting index $i$ and block size $q$. The need for block sampling arises for a few reasons. First, in some settings it is desirable to keep nearby rows together to preserve structure in $\mathbf{A}$. As an example, [28] and [29] consider a problem where samples are obtained from block-structured finite element stiffness matrices. Moreover, even when $\mathbf{A}$ and $\mathbf{B}$ are unstructured, sampling multiple blocks of columns is typically more efficient on modern architectures where memory access costs are a major factor in determining final runtimes. When $\mathbf{A}$ and $\mathbf{B}$ are large enough that they must be stored in slow memory (e.g. on disk instead of in RAM) accessing a block of $q$ adjacent columns (which are stored adjacent on disk) will often be far cheaper than accessing a set of $q$ columns with non-adjacent indices.

### 1.2.1 The BlockBasicMatrixMultiplication Method

To address these concerns, recent work by Wu introduces a block-wise version of the BasicMatrixMultiplication method, which we call BlockBasicMatrixMultiplication [28]. The method maintains many of the nice properties of the BasicMatrixMultiplication method, and for any block size $q$, it can be shown that sampling $O(1/\epsilon^2)$ blocks results in the same error guarantee of Equation (1).[1] Moreover, it can be shown that the sampling probabilities used by Wu's method are *optimal for block sampling*, just as those used by BasicMatrixMultiplication were optimal for single column sampling. However, a major disadvantage of BlockBasicMatrixMultiplication is that these probabilities are no longer efficient to compute. Concretely, consider $\Theta_1, \ldots, \Theta_\ell$ which are disjoint subsets of adjacency indices that partition $\{1, \ldots, n\}$, i.e. for all $j$, $\Theta_i = \{k_i, k_i + 1, \ldots, k_i + q_i\}$ for some starting index $k_i$ and block size $q_i$, and $\Theta_1 \cup \ldots \cup \Theta_\ell = \{1, \ldots, n\}$. If we want to sample a subset of blocks from $\Theta_1, \ldots, \Theta_\ell$, [28] shows that the optimal probability to sample the $i^{\text{th}}$ block is equal to:

$$\hat{p}_i = \frac{\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F}{\sum_{j=1}^{\ell} \|\mathbf{A}^{(\Theta_j)}\mathbf{B}_{(\Theta_j)}\|_F} \tag{2}$$

This strictly generalizes the probabilities from BasicMatrixMultiplication, since for two vectors $\mathbf{A}^{(i)}$ and $\mathbf{B}_{(i)}$, $\|\mathbf{A}^{(i)}\mathbf{B}_{(i)}\|_F = \|\mathbf{A}^{(i)}\|_2 \|\mathbf{B}_{(i)}\|_2$. However, in the general block case, the probability is more expensive to compute. In particular, the naive cost of computing $\hat{p}_i$ equals $O(q_i mp)$ (the cost of multiplying $\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}$) so the total cost of sampling is $\sum_{i=1}^{\ell} O(q_i mp) = O(nmp)$. This is as slow as if we had computed $\mathbf{AB}$ exactly! Assuming for simplicity that $q_1 = \ldots = q_\ell = q$ (typically blocks have the same size), this runtime can be improved to $O(nmq + npq)$ when $q \leq p, m$ (see Equation (4) for more details). But nevertheless, the complexity is still greater than the linear run time of $O(nm + np)$ achieved by BasicMatrixMultiplication by a multiplicative factor of $q$. In practice, we might want $q$ in the 100s or 1000s to take sufficient advantage of memory locality.

[1] We might have hoped to obtain a *better* guarantee with block sampling. E.g. that when sampling blocks of size $q$, we would only need $O(\frac{1}{q\epsilon^2})$ block samples, which is a total of $O(1/\epsilon^2)$ columns. This is not possible, however, as can be seen by considering adversarial matrices with e.g. all but columns $1, q+1, 2q+1, \ldots$ set to zero. That said, in practice, sampling $c$ blocks from $\mathbf{A}$ and $\mathbf{B}$ often performs much better in terms of accuracy than sampling $c$ individual columns.

## 1.3 Faster Probabilities via Stochastic Trace Estimation

Our main contribution is to present a simple method for efficiently implementing the optimal sampling scheme of [28]. In particular, we show how to approximate the required sampling probabilities from Equation (2) up to a multiplicative constant factor using the classic Hutchinson's stochastic traces estimation method [18]. Another central technique in randomized numerical linear algebra, Hutchinson's traces estimator can approximate the $\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F$ term from Equation (2) with just a small number of matrix-vector multiplies with $\mathbf{A}^{(\Theta_i)}$ and $\mathbf{B}_{(\Theta_i)}$ involving randomly chosen vectors. The end result is a method running in $O((nm+np)\log(n))$ time for computing all probabilities, which is near linear in the size of the total size of the input matrices. At the same time, an analysis of our method shows that using approximate sampling probabilities yields the same theoretical guarantees as [28], up to constant factors. We call our method Hutchinson-estimated Block Approximate Matrix Multiplication (Hutch AMM for short).

### 1.3.1 Empirical Evaluation

We perform an extensive experimental evaluation of our Hutch AMM method, showing that, empirically, the probability computation can be performed to sufficient accuracy using just $5(nm + np)$ floating-point operations, even for very large values of $m$. The cost of then computing $\mathbf{CD}$ once the probabilities are computed and used for sampling is then a lower order computational. As a result, our method outperforms an efficient implementation of the approach from [28] in terms of runtime, without sacrificing accuracy in approximating $\mathbf{AB}$.

We also compare Hutch AMM to other baselines. For example, one natural approach is simply to uniformly sample from the rows and columns of $\mathbf{A}$ and $\mathbf{B}$ (either blocks or individual rows and columns). Uniform sampling typically requires more samples in comparison to using optimal importance sampling probabilities to obtain a given level of accuracy. The trade-off, however, is that uniform sampling has no computational overhead to compute probabilities – a sample of $c$ columns from $\mathbf{A}$ can be chosen in $O(c)$ time. The only major runtime cost is computing $\mathbf{CD}$. Nevertheless, we show that for block sampling, our method typically outperforms uniform sampling in terms of runtime to achieve a given level of approximation accuracy, showing the value of importance sampling.

Finally, we compare against a recent method of [3], which also studies block based sampling methods for approximate matrix multiplication. Their "Block CR Method" introduces an alternative approach that samples blocks with probabilities equal to:

$$\tilde{p}_i = \frac{\|\mathbf{A}^{(\Theta_i)}\|_F \|\mathbf{B}_{(\Theta_i)}\|_F}{\sum_{j=1}^{\ell} \|\mathbf{A}^{(\Theta_j)}\|_F \|\mathbf{B}_{(\Theta_j)}\|_F} \tag{3}$$

While not optimal for minimizing $\mathbb{E}\left[\|\mathbf{AB} - \mathbf{CD}\|_F^2\right]$, these probabilities minimize a natural upper bound[2] on the expected squared error, and can be shown to achieve the bound of Equation (1) with $q = O(1/\epsilon^2)$ samples [3]. So, they match the result of Wu in the worst case. At the same time, $\tilde{p}_1, \ldots, \tilde{p}_\ell$ can be computed in linear time, $O(nm + np)$, as they do not require multiplying the blocks $\mathbf{A}^{(\Theta_i)}$ and $\mathbf{B}_{(\Theta_i)}$.

[2] The text of [3] implies that the probabilities are optimal, but there is a small error in the derivation of the variance of the estimator considered, where an upper bound is mistakenly considered to be an equality. Nevertheless, the authors conclusion, that $O(1/\epsilon^2)$ block samples suffice to achieve error $\|\mathbf{AB} - \mathbf{CD}\|_F \leq \epsilon\|\mathbf{A}\|_F\|\mathbf{B}\|_F$, still holds.

Overall, we find the Block CR method of [3] extremely effective. While it does not yield as good an accuracy for a given number of samples as our method and that of Wu, the difference is relatively small. So, when comparing overall runtime to approximate the matrix product $\mathbf{AB}$, the method of [3] usually offers the best accuracy vs. runtime trade-off.

### 1.4 Paper Organization

The organization of this paper is as follows: In Section 2, we introduce the BlockBasicMatrixMultiplication and our proposed modification. Section 3 presents a detailed analysis and comparison of the expected squared error of the methods. In Section 4, we provide the experiment details, followed by a brief discussion of the results. Finally, we conclude the paper and discuss future research directions in Section 5.

## 2 Methodology

### 2.1 Notation

We denote matrices and vectors using bold Roman letters. For a vector $\mathbf{v} \in \mathbb{R}^n$, $\|\mathbf{v}\|_2 = \sqrt{\sum_{i=1}^n \mathbf{v}_i}$ denotes the standard Euclidean norm. For a matrix $\mathbf{A} \in \mathbb{R}^{m\times n}$, $\|\mathbf{A}\|_F = \sqrt{\sum_{i=1}^m \sum_{j=1}^n \mathbf{A}_{ij}}$ denotes the Frobenius norm. We use superscript $\mathbf{A}^{(i)}$ to denote the $i^{\text{th}}$ column of $\mathbf{A}$ and subscript $\mathbf{A}_{(j)}$ to denote the $j^{\text{th}}$ row. For a set of $c$ indices $S$, we let $\mathbf{A}^{(S)}$ denote the $m \times c$ matrix containing $\mathbf{A}^{(j)}$ for $j \in \mathcal{S}$. Similarly, $\mathbf{A}_{(S)}$ denote the $c \times n$ matrix containing $\mathbf{A}_{(j)}$ for $j \in \mathcal{S}$. For a square $\mathbf{M} \in \mathbb{R}^{n\times n}$, $\text{tr}(\mathbf{M}) = \sum_{i=1}^n \mathbf{M}_{ii}$ denotes the trace. We use $\Pr[B]$ to denote the probability of a random event $B$ and $\mathbb{E}[X]$ to denote the expectation of a random variable $X$.

### 2.2 Hutchinson-estimated block Approximate Matrix Multiplication

Given matrices $\mathbf{A} \in \mathbb{R}^{m\times n}$ and $\mathbf{B} \in \mathbb{R}^{n\times p}$, BasicMatrixMultiplication returns an unbiased estimator for the matrix product $\mathbf{AB}$ by sampling rank-one components (each is an outer product of a column from $\mathbf{A}$ and corresponding row from $\mathbf{B}$). Specifically, the algorithm selects and re-weights a subset of $c$ columns from $\mathbf{A}$ to form a matrix $\mathbf{C} \in \mathbb{R}^{m\times c}$ and the corresponding $c$ rows from $\mathbf{B}$ to form a matrix $\mathbf{D} \in \mathbb{R}^{c\times p}$ so that $\mathbf{CD} \approx \mathbf{AB}$. To reduce the approximation error, rows and columns are sampled with non-uniform probabilities, and appropriately scaled after sampling by the inverse probability to ensure the $\mathbb{E}[\mathbf{CD}] = \mathbf{AB}$. The algorithm is summarized in Algorithm 1:

**Algorithm 1** BasicMatrixMultiplication w/ Optimal Sampling Probability [12].

**Input:** $\mathbf{A} \in \mathbb{R}^{m\times n}, \mathbf{B} \in \mathbb{R}^{n\times p}$, number of samples $c$.
**Output:** Estimate of matrix product $\mathbf{AB}$.

For all $i \in 1, \ldots, n$, compute optimal sampling probability $p_i = \frac{\|\mathbf{A}^{(i)}\|_2 \|\mathbf{B}_{(i)}\|_2}{\sum_{j=1}^n \|\mathbf{A}^{(j)}\|_2 \|\mathbf{B}_{(j)}\|_2}$.
**for** $t = 1 \ldots, c$ **do**
  Pick $j \in \{1, \ldots, n\}$ with probability $\Pr(j = k) = p_k$.
  Set $\mathbf{C}^{(t)} = \frac{\mathbf{A}^{(j)}}{\sqrt{cp_j}}$ and $\mathbf{D}_{(t)} = \frac{\mathbf{B}_{(j)}}{\sqrt{cp_j}}$
**end**
Return $\mathbf{CD}$

As discussed in Section 1, the sampling probabilities $p_1, \ldots, p_n$ used in Algorithm 1 are optimal in that they minimize $\mathbb{E}\left[\|\mathbf{AB} - \mathbf{CD}\|_F^2\right]$ amongst all possible choices of probabilities [12] (when using an unbiased estimator of the same form as Algorithm 1).

It is possible to extend the BasicMatrixMultiplication method to sampling blocks of rows and columns. To do so, we consider a partition of the indices $\{1, \ldots, n\}$ into $\ell$ disjoint sets $\Theta_1, \ldots, \Theta_\ell$. [28] derived optimal probabilities $\hat{p}_1, \ldots, \hat{p}_\ell$ for sampling in the block setting, which are shown below in Algorithm 2. Again, these probabilities minimize $\mathbb{E}\left[\|\mathbf{AB} - \mathbf{CD}\|_F^2\right]$ amongst all possible choices of sampling probabilities.

**Algorithm 2** Block BasicMatrixMultiplication w/ Optimal Sampling Probability [28].

**Input:** $\mathbf{A} \in \mathbb{R}^{m\times n}, \mathbf{B} \in \mathbb{R}^{n\times p}$, number of samples $c$, disjoint set of column indices $\{\Theta_1, \ldots, \Theta_\ell\}$ with $\Theta_1 \cup \ldots \cup \Theta_\ell = \{1, \ldots, n\}$.

**Output:** Estimate of matrix product $\mathbf{AB}$.

For all $i \in 1, \ldots, \ell$, compute optimal sampling probability $\hat{p}_i = \frac{\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F}{\sum_{j=1}^{\ell} \|\mathbf{A}^{(\Theta_j)}.\mathbf{B}_{(\Theta_j)}\|_F}$

Initialize $\mathbf{C}$ and $\mathbf{D}$ as empty matrices.

**for** $t = 1, \ldots, c$ **do**

  Pick $j \in \{1, \ldots, \ell\}$ with probability $\Pr(j = k) = \hat{p}_k$.

  Append $\frac{\mathbf{A}^{(\Theta_j)}}{\sqrt{c\hat{p}_j}}$ onto $\mathbf{C}$'s columns and $\frac{\mathbf{B}_{(\Theta j)}}{\sqrt{c\hat{p}_j}}$ onto $\mathbf{D}$'s rows.

**end**

Return $\mathbf{CD}$

▷ Claim 1. Assume $\Theta_1, \ldots, \Theta_\ell$ are equally sized, so each contains $q = \frac{n}{l}$ indices. Then the BlockBasicMatrixMultiplication method of Algorithm 2 can be implemented in time $O(mnp)$, or in time $O(n(m+p)q + cqmp)$, which is faster when $q \leq m, p$.

Proof. Once sampling probabilities are computed and sampling performed, the cost of multiplying $\mathbf{CD}$ is equal to $O(cqmp)$. Specifically, $\mathbf{C}$ contains $c$ blocks of $q$ columns, so has dimension $m \times cq$ and $\mathbf{D}$ has dimension $cq \times p$. We focus on the cost of computing the optimal probabilities, $\hat{p}_1, \ldots, \hat{p}_\ell$. Doing so requires computing $\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F$ all $i$. Since $\mathbf{A}^{(\Theta_i)} \in \mathbb{R}^{m\times q}$ and $\mathbf{B}_{(\Theta_i)} \in \mathbb{R}^{q\times p}$, this can be done directly in $O(qmp)$ time. Summing over all $\ell$ blocks and using that $q = \frac{n}{\ell}$, the total runtime is $O(nmp)$ to compute $p_1, \ldots, p_\ell$. Alternatively, if $q \leq m + p$, we can use the cyclic property of the trace:

$$\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F^2 = \mathrm{tr}(\mathbf{B}_{(\Theta_i)}^T(\mathbf{A}^{(\Theta_i)})^T\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}) = \mathrm{tr}((\mathbf{A}^{(\Theta_i)})^T\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\mathbf{B}_{(\Theta_i)}^T). \quad (4)$$

If we first compute $(\mathbf{A}^{(\Theta_i)})^T\mathbf{A}^{(\Theta_i)}$ and $\mathbf{B}_{(\Theta_i)}\mathbf{B}_{(\Theta_i)}^T$ and then multiply the resulting $q \times q$ matrices, the above trace can be computed in time $O(q^2m + q^2p + q^3) = O((m+p)q^2)$. Again, summing over all $\ell$ blocks and using that $q = \frac{n}{\ell}$, the total runtime is $O(n(m+p)q)$. ◁

As illustrated by Claim 1, the computational cost of BlockBasicMatrixMultiplication can be prohibitively expensive. When $q$ is larger than either $m$ or $p$, the cost is as large as the cost of computing the product $\mathbf{AB}$ exactly.

Our proposed approach is to speed up the BlockBasicMatrixMultiplication method by using Hutchinson's stochastic trace estimator [16, 18] to efficiently approximate $\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F^2 = \mathrm{tr}(\mathbf{B}_{(\Theta_i)}^T(\mathbf{A}^{(\Theta_i)})^T\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)})$. Given an $p \times p$ matrix $\mathbf{M}$, this estimator estimates $\mathrm{tr}(\mathbf{M})$ via repeated multiplication of the matrix by random vectors. In particular, for a sampling parameter $h$ and vectors $\mathbf{g}_1, \ldots, \mathbf{g}_h$ each chosen to have independent random entries with mean 0 and variance 1, the estimator takes the form:

$$H_h(\mathbf{M}) = \frac{1}{h}\sum_{j=1}^{h} g_j^\intercal \mathbf{M} g_j. \tag{5}$$

Typically, random $\{-1, +1\}$ Rademacher random variables are chosen for the entries of each $\mathbf{g}_j$. It is easily checked that $\mathbb{E}\left[H_h(\mathbf{M})\right] = \mathrm{tr}(\mathbf{M})$ and for sufficiently large $h$, the estimator concentrates around its expectation [1, 8]. The value of the estimation in Equation (5) is that, for $\mathbf{M} = \mathbf{B}_{(\Theta_i)}^T(\mathbf{A}^{(\Theta_i)})^T\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}$, each term in the sum $\sum_{i=1}^{h} g_j^\intercal \mathbf{M} g_j$ can be computed in just $O(pq + mq + pq + mq) = O(q(m+p))$ time by multiplying $\mathbf{B}_{(\Theta_i)}^T(\mathbf{A}^{(\Theta_i)})^T\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\mathbf{g}_j$ from right to left. When $h$ is a small constant, the cost is thus linear in the total size of the blocks $\mathbf{A}^{(\Theta_i)}$ and $\mathbf{B}_{(\Theta_i)}$. Overall, our proposed algorithm is summarized in Algorithm 3:

**Algorithm 3** Hutchinson-estimated Block Approx. Matrix Multiplication (Hutch AMM).

**Input:** $\mathbf{A} \in \mathbb{R}^{m\times n}, \mathbf{B} \in \mathbb{R}^{n\times p}$, number of samples $c$, disjoint sets of column indices $\{\Theta_1, \ldots, \Theta_\ell\}$ with $\Theta_1 \cup \ldots \cup \Theta_\ell = \{1, \ldots, n\}$, number of Hutchinson's samples $h$.

**Output:** Estimate of matrix product $\mathbf{AB}$.

For all $i \in 1, \ldots, \ell$, compute approximate optimal sampling probability

$$\bar{p}_i = \frac{\sqrt{H_h(\mathbf{B}_{(\Theta_i)}^T(\mathbf{A}^{(\Theta_i)})^T\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)})}}{\sum_{j=1}^{\ell}\sqrt{H_h(\mathbf{B}_{(\Theta_j)}^T(\mathbf{A}^{(\Theta_j)})^T\mathbf{A}^{(\Theta_j)}\mathbf{B}_{(\Theta_j)})}}$$

Initialize $\mathbf{C}$ and $\mathbf{D}$ as empty matrices.

**for** $t = 1, \ldots, c$ **do**

  Pick $j \in \{1, \ldots, \ell\}$ with probability $\Pr(j = k) = \bar{p}_k$.

  Append $\frac{\mathbf{A}^{(\Theta_j)}}{\sqrt{c\bar{p}_j}}$ onto $\mathbf{C}$'s columns and $\frac{\mathbf{B}_{(\Theta_j)}}{\sqrt{c\bar{p}_j}}$ onto $\mathbf{D}$'s rows.

**end**

Return $\mathbf{CD}$

We can bound the runtime of Algorithm 3 as follows:

▷ Claim 2. Assume $\Theta_1, \ldots, \Theta_\ell$ are equally sized, so each contains $q = \frac{n}{l}$ indices. Then the Hutch AMM method of Algorithm 3 can be implemented in time $O(nh(m+p) + cqmp)$.

Proof. The proof follows from the discussion above. For each block, computing the Hutchinson's estimate $H_h(\mathbf{B}_{(\Theta_i)}^T(\mathbf{A}^{(\Theta_i)})^T\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)})$ takes time $O(qh(m+p))$ for a total runtime of $\ell \cdot O(qh(m+p)) = O(nh(m+p))$. We then have an additional cost of $O(cqmp)$ to compute $\mathbf{CD}$, which will typically be a lower order term when the number of samples $c$ is small. ◁

From Claim 1 and Claim 2, we can check that Hutch AMM improves on the BlockBasicMatrixMultiplication algorithm whenever the number of Hutchinson's iterations $h$ is less than the block size $q$. As we will prove in the next section, if suffices to set $h = O(\log n)$ to match the accuracy guarantees of BlockBasicMatrixMultiplication up to a multiplicative constant.

## 3 Error Analysis

In this section we provide an analysis of our Hutch AMM method. We start by stating the main result from [28], which bounds the expected squared error of the BlockBasicMatrixMultiplication method.

▶ **Proposition 3** (Proposition 2.2 [28]). *For input matrices* $\mathbf{A} \in \mathbb{R}^{m\times n}$ *and* $\mathbf{B} \in \mathbb{R}^{n\times p}$*, let* $\mathbf{CD}$ *be the approximate matrix product returned by Algorithm 2. We have that* $\mathbb{E}[\mathbf{CD}] = \mathbf{AB}$ *and the expected squared approximation error in Frobenius norm is:*

$$\mathbb{E}[\|\mathbf{AB} - \mathbf{CD}\|_F^2] = \frac{1}{c}\sum_{i=1}^{\ell}\frac{1}{\hat{p}_i}\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F^2 - \frac{\|\mathbf{AB}\|_F^2}{c}. \tag{6}$$

*Setting* $\hat{p}_i := \frac{\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F}{\sum_{i=1}^{l}\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F}$ *for* $i = 1, \ldots, \ell$*, we obtain minimum expected error, which can be upper bounded by:*

$$\mathbb{E}[\|\mathbf{AB} - \mathbf{CD}\|_F^2] \leq \frac{1}{c}\left(\sum_{i=1}^{\ell}\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F\right)^2 \tag{7}$$

Note that, applying submultiplicativity of the Frobenius norm and Cauchy-Schwarz inequality we can (loosely) bound:

$$\begin{aligned}\frac{1}{c}\left(\sum_{i=1}^{\ell}\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F\right)^2 &\leq \frac{1}{c}\left(\sum_{i=1}^{\ell}\|\mathbf{A}^{(\Theta_i)}\|_F\|\mathbf{B}_{(\Theta_i)}\|_F\right)^2 \\ &\leq \frac{1}{c}\left(\sum_{i=1}^{\ell}\|\mathbf{A}^{(\Theta_i)}\|_F^2\right)\left(\sum_{i=1}^{\ell}\|\mathbf{B}^{(\Theta_i)}\|_F^2\right) = \frac{1}{c}\|\mathbf{A}\|_F^2\|\mathbf{B}\|_F^2\end{aligned}$$

Using the resulting bound on $\mathbb{E}[\|\mathbf{AB} - \mathbf{CD}\|_F^2]$ we can apply Markov's inequality to the non-negative random variable $\|\mathbf{AB} - \mathbf{CD}\|_F^2$ to prove that, with probability $(1 - \delta)$, BlockBasicMatrixMultiplication achieves error $\|\mathbf{AB} - \mathbf{CD}\|_F \leq \frac{1}{\sqrt{\delta c}}\|\mathbf{A}\|_F\|\mathbf{B}\|_F$. In other words, with $c = O(1/\delta\epsilon^2)$ samples, we obtain error $\epsilon\|\mathbf{A}\|_F\|\mathbf{B}\|_F$ with probability $(1 - \delta)$, as desired.

What happens if we sample with approximately optimal probabilities? From Equation (6), it can be checked directly that, if instead $\mathbf{C}$ and $\mathbf{D}$ are sampled with probabilities $\bar{p}_1, \ldots, \bar{p}_\ell$ satisfying $\bar{p}_i \geq \frac{1}{\beta}\hat{p}_i$ for some constant $\beta \geq 1$, then the expected squared error can be bounded by:

$$\mathbb{E}[\|\mathbf{AB} - \mathbf{CD}\|_F^2] \leq \frac{\beta}{c}\left(\sum_{i=1}^{\ell}\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F\right)^2. \tag{8}$$

In other words, as long as $\bar{p}_1, \ldots, \bar{p}_\ell$ approximate the optimal sampling probabilities $\hat{p}_1, \ldots, \hat{p}_\ell$ up to a constant factor, we obtain expected squared error that is within a multiplicative constant of the bound from Equation (8) achieved by Wu's optimal method.

With this in mind, we focus on showing that the approximate probabilities used in our Hutch AMM method satisfy this multiplicative bound. In particular, we prove:

▶ **Lemma 4.** *For inputs* $\mathbf{A} \in \mathbb{R}^{m\times n}$ *and* $\mathbf{B} \in \mathbb{R}^{n\times p}$*, let* $\bar{p}_1, \ldots, \bar{p}_\ell$ *be computed as in Algorithm 3 with parameter* $h$*, and let* $\hat{p}_1, \ldots, \hat{p}_\ell$ *be the optimal sampling probabilities from Algorithm 2. As long as* $h \geq C\log(\ell/\delta)$ *for a fixed constant* $C$*, then with probability* $1 - \delta$*,*

$$\bar{p}_i \geq \frac{1}{2}\hat{p}_i \qquad \text{for all } i \in 1, \ldots \ell.$$

In other words, as long as $h = O(\log \ell) \leq O(\log n)$, then with high probability we obtain sampling probabilities with a constant factor of the optimal probabilities, and thus expected squared error with a constant of Equation (7), as desired.

To prove 4, we use the following standard bound on the accuracy of Hutchinson's estimator:

▶ **Lemma 5** (See [8] or [21]). *Let $\mathbf{M} \in \mathbb{R}^{d\times d}$ and $\delta \in (0, 1/2]$. Let $H_h(\mathbf{M})$ be Hutchinson's estimator run for $h$ repetition, as in Equation (5). For fixed constants $C_1, C_2$, if $h > C_1 \log(1/\delta)$, then with probability $\geq 1-\delta$*

$$|H_h(\mathbf{M}) - \mathrm{tr}(\mathbf{M})| \leq C_2\sqrt{\frac{\log(1/\delta)}{h}}\|\mathbf{M}\|_F. \tag{9}$$

**Proof of Lemma 4.** Let $\mathbf{X}_i$ denote $\mathbf{X}_i = \mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}$. Let $h = 4\max(C_1, C_2^2)\log(\ell/\delta)$. Then by Lemma 5 it follows that, for any $i \in 1, \ldots, \ell$,

$$\left|H_h(\mathbf{X}_i^T\mathbf{X}_i) - \mathrm{tr}(\mathbf{X}_i^T\mathbf{X}_i)\right| \leq \frac{1}{2}\|\mathbf{X}_i^T\mathbf{X}_i\|_F,$$

with probability $1 - \delta/\ell$. By a union bound, the statement holds simultaneously for all $i \in 1, \ldots, \ell$ with probability $1-\delta$. Since $\mathbf{X}_i^T\mathbf{X}_i$ is a positive semidefinite matrix, we have that $\|\mathbf{X}_i^T\mathbf{X}_i\|_F \leq \mathrm{tr}(\mathbf{X}_i^T\mathbf{X}_i)$. So we can conclude that for all $i \in 1, \ldots, \ell$,

$$.5 \cdot \mathrm{tr}(\mathbf{X}_i^T\mathbf{X}_i) \leq H_h(\mathbf{X}_i^T\mathbf{X}_i) \leq 1.5 \cdot \mathrm{tr}(\mathbf{X}_i^T\mathbf{X}_i).$$

We have that $\bar{p}_i = \frac{\sqrt{H_h(\mathbf{X}_i^T\mathbf{X}_i)}}{\sum_{j=1}^{\ell}\sqrt{H_h(\mathbf{X}_j^T\mathbf{X}_j)}}$, so we conclude that, as desired,

$$\bar{p}_i \geq \frac{\sqrt{.5}\cdot\mathrm{tr}(\mathbf{X}_i^T\mathbf{X}_i)}{\sqrt{1.5}\sum_{j=1}^{\ell}\mathrm{tr}(\mathbf{X}_j^T\mathbf{X}_j)} \geq \frac{1}{2}\hat{p}_i. \qquad \blacktriangleleft$$

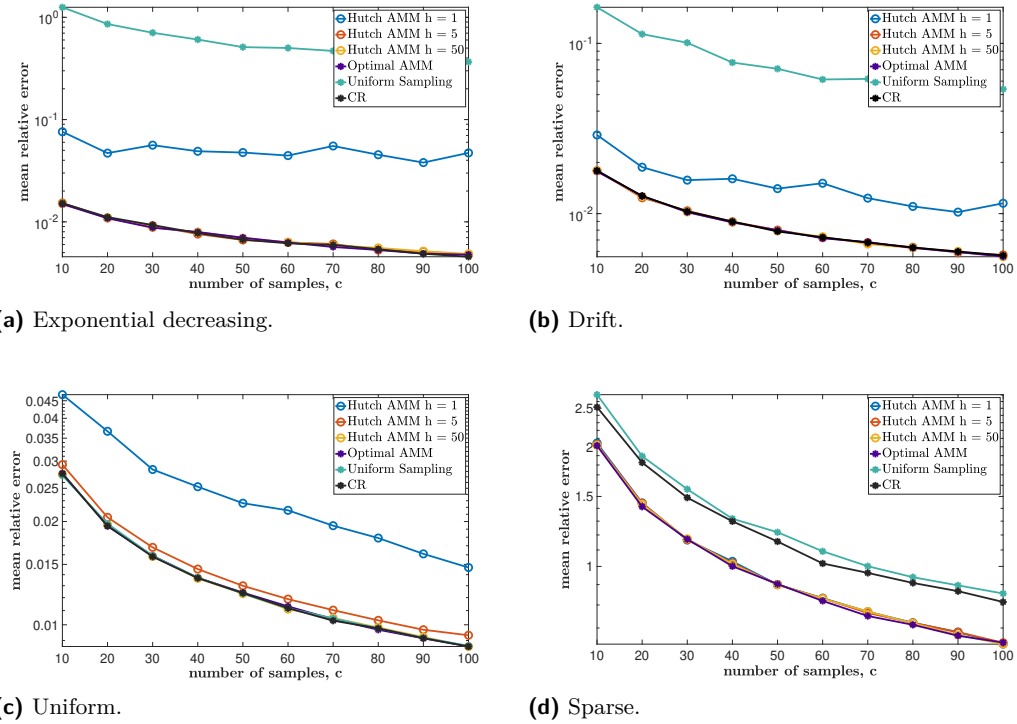
Combined with the bound in Equation (8) and Markov's inequality, Lemma 4 implies that as long as $h = O(\log(\ell/\delta)$, then with probability $1-\delta$, Hutch AMM returns an estimate $\mathbf{CD}$ satisfying $\|\mathbf{AB} - \mathbf{CD}\|_F \leq \frac{1}{\sqrt{\delta c}}\sum_{i=1}^{\ell}\|\mathbf{A}^{(\Theta_i)}\mathbf{B}_{(\Theta_i)}\|_F \leq \frac{1}{\sqrt{\delta c}}\|\mathbf{A}\|_F\|\mathbf{B}\|_F$. Accordingly, we match the guarantees of the BlockBasicMatrixMultiplication method, but with a total computational cost of just $O(n\log(n)(m+p))$ to compute sampling probabilities, which is near linear in the size of the inputs $\mathbf{A} \in \mathbb{R}^{m\times n}$ and $\mathbf{B} \in \mathbb{R}^{n\times p}$.

## 4 Experiments

In this section, we test our algorithm on both synthetic matrices and real-world datasets. We demonstrate its performance by comparing it with the optimal BlockBasicMatrixMultiplication method [28], which in this section we call "Optimal Block AMM" for conciseness. As discussed in the introduction, we also compare with two baseline method: sampling blocks using uniform probabilities $\tilde{p}_i = \frac{1}{\ell}$ and the CR method from [3], which samples with the probabilities shown in Equation (3).[3]

To compare methods, we use mean relative error $\frac{\|\mathbf{CD}-\mathbf{AB}\|_F}{\|\mathbf{AB}\|_F}$ and the total computational time as two performance metrics in estimation accuracy and efficiency. All experiments were conducted in Matlab R2022b on a laptop with a 2.7 GHz Quad-Core Intel Core i7 and 16 GB memory.

[3] We note that there has been some recent follow-up work in [22] on modifications of the BlockBasicMatrixMultiplication method. However, the algorithms in that work ultimately perform individual row/column sampling within each block, so they are not directly comparable to the other methods studied in this paper, which always sampled contiguous blocks of rows or columns together.



**(a)** Exponential decreasing.

**(b)** Drift.

**(c)** Uniform.

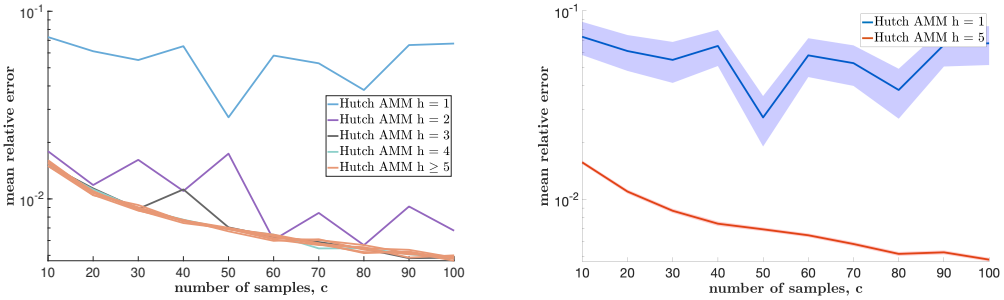
**(d)** Sparse.

**Figure 1** Performance comparison of different block approximate matrix multiplication methods on matrices generated by different procedures. The matrices for plots (a-c) have size of $100 \times 10000$, with a sampling block size $q = 100$, (d) involves matrices of size of $10 \times 100000$, with sampling block size $q = 1000$. Our results show that, when comparing the number of samples $c$ to average relative error for 200 trials, the Hutch AMM method with $h \geq 5$ consistently performs as well as the optimal Optimal Block AMM method for matrices with significant differences in row/column norms (a,b), while the Hutch AMM with $h = 1$ and uniform sampling methods perform worse. The CR methods perform similarly to the optimal block AMM, except for the sparse case (d).

## 4.1 Data sets

For our synthetic data, we generate $\mathbf{B} \in \mathbb{R}^{10000\times 100}$ with all entries uniform random in $[0, 1]$. For two data sets, we generate $\mathbf{A} \in R^{100\times 10000}$ with random Gaussian entries with variance 1, and mean depending on the column index, $i$. For (a) Exponential decreasing, the means are uniformly spaced on an exponential grid from $\exp(50)$ down to 1. For (b) Drift, the means follow two trends. For the first 5000 columns they are exponentially decreasing as in (a), and for the next 5000 columns the means are linearly decreasing. A similar matrix was used in [9]. These first two data sets have columns and blocks of columns with widely varying magnitudes. For our third dataset, (c) Uniform, $\mathbf{A}$ is simply generated with entries uniform random in $[0, 1]$ like $\mathbf{B}$. Finally, for (d) Sparse, we construct a sparse matrix $\mathbf{A} \in \mathbb{R}^{10\times 100000}$ with 0.1% non-zero entries selecting uniformly at random in $[0, 1]$. We construct $\mathbf{B} \in \mathbb{R}^{100000\times 10}$ with entries drawn from a standard normal distribution, but with 1% entries randomly replaced with larger values uniformly distributed between 0 and an arbitrary positive number (we used $\exp(4)$ in this paper).

For real-world data, we consider two different application scenarios: (1) Natural language processing: We extracted TF-IDF matrices from a subset of the TDT2 corpus (Nist Topic Detection and Tracking corpus)[2]. (2) Time series: We formed the whole-month (February



**(a)** Mean relative error comparison of Hutch AMM from h=1 to h=10.

**(b)** Estimation error for selected h plotted in shaded region, shaded region ranges between plus and minus one standard deviation from mean.

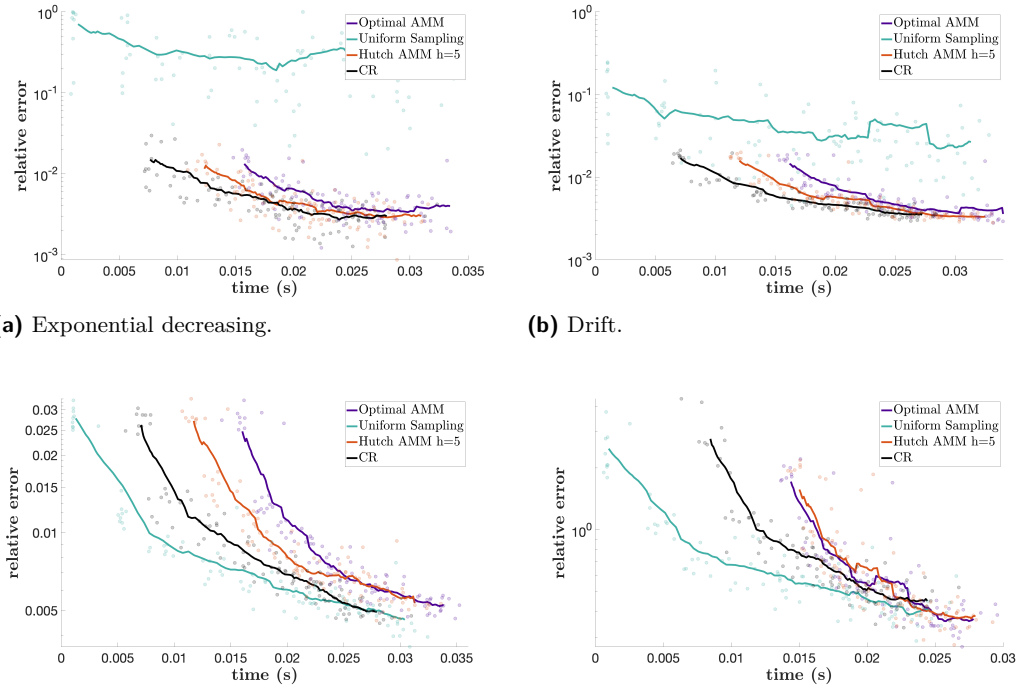
**Figure 2** This figure investigates the impact of $h$ on the estimation accuracy of Hutch AMM methods. The graph shows the average relative estimation error against sampling number $c$ for 200 trials for the Exponential Decreasing synthetic data. Higher choices of $h$ generally lead to better average error, but there is little to no benefit of choosing a value of $h$ larger than 5. Similarly, low choices of $h$ lead to higher variance, as shown in (b). The shaded region represents the plus and minus one standard deviation from the mean relative estimation error among the 200 trials. As we can see, this region is much narrower for $h = 5$ in comparison to $h = 1$.

2022) yellow taxi trip records as a matrix using NYC Taxi and Limousine Commission (TLC) Trip Record Data[26], the columns are sorted by pick-up time. We include numerical features such as trip distances, itemized fares, and driver-reported passenger counts, as well as one-hot-encoded categorical features such as VendorID and payment type. For the TF-IDF experiments, we construct a matrix $\mathbf{A}$ of size $1000 \times 36763$; for the trip record experiments, $\mathbf{A}$ has size $24 \times 2877693$. In both cases we set $\mathbf{B} = \mathbf{A}^T$ and use block size $q = 100$.

## 4.2 Results

We first compare the accuracy of block approximate matrix multiplication methods as a function of the number of samples $c$. As shown in Figure 1, our Hutch AMM method run with $h$ as small as 5 consistently matches the Optimal Block AMM method from [28]. Both methods outperform uniform sampling, except when $\mathbf{A}$ and $\mathbf{B}$ have uniform column norms, in which case there is limited value in importance sampling. The CR method also performs quite well, although is worse than our Hutch AMM method for the sparse synthetic data. Running Hutch AMM with $h = 1$ shows worse performance. In Figure 2, we take a closer look at the impact of varying $h$, and the choice of $h = 5$ seems to be a sweet spot – lower values lead to higher error (due to worse approximation of the optimal sampling probabilities) whereas high values offer little improvement, and lead to higher computation cost.

Having settled on $h = 5$ as a default parameter for our Hutch AMM method, we proceed to compare the runtime against all baselines. We do so in Figure 3 for the synthetic data and Figure 4 for the real-world data sets. In both cases, we perform repeated trials with various choices of $c$. Since runtime and accuracy are not deterministic functions of $c$, this leads to a scatter plot comparing running time vs. accuracy, which we visualize plot plotting a moving average trend for each method tested. Overall, the plots show that Hutch AMM offers improved computation time over Optimal Block AMM, and typically much better accuracy than uniform sampling. However, while it showed better performance than the CR method in terms of accuracy for a given number of samples for some problems (e.g. the Sparse data), the slightly lower computational complexity of the CR method comes through



**(a)** Exponential decreasing.

**(b)** Drift.

**(c)** Uniform.

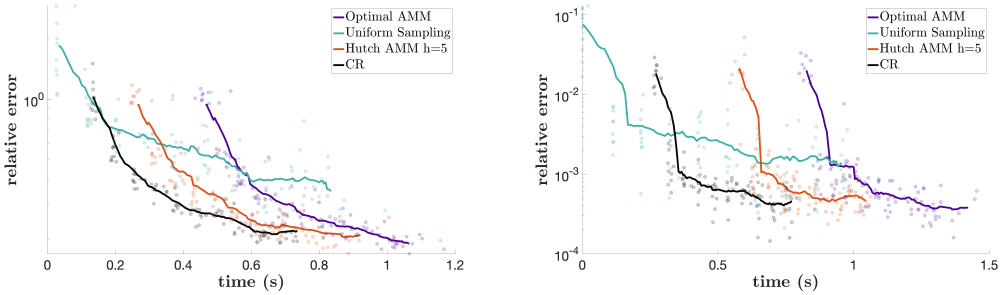
**(d)** Sparse.

**Figure 3** Relative estimation error against computation time, with a moving average line generated using window length 20. Matrices are generated using the same procedures as in Figure 1. For interpretation: A line to the left indicates the corresponding method's superior computational efficiency; a line towards the bottom indicates the corresponding method's superior estimation accuracy. Our observations indicate that both our Hutch AMM method and the CR method improve on the Optimal Block Matrix multiplication method in terms of efficiency/accuracy tradeoff. They also beat uniform sampling in all cases except for (c). Overall, the CR method shows the best overall performance, despite its use of non-uniform sampling probabilities.

in the plots. In terms of overall computational complexity, in our experiments, it was more efficient to run the CR method. The lack of optimal sampling probabilities is made up for by including a slightly larger number of samples $c$ in $\mathbf{C}$ in $\mathbf{D}$.

## 5 Summary and Conclusion

In this study, we present the Hutchinson-estimated block Approximate Matrix Multiplication (Hutch AMM) method, which is a more computationally efficient variant of the existing BlockBasicMatrixMultiplication method. Our proposed method utilizes Hutchinson's estimator to calculate a near-optimal sampling probability, which reduces computation cost while maintaining a high level of estimation accuracy when an appropriate $h$ parameter is chosen. We validate our method through a detailed complexity analysis and proof of bounded squared error. Additionally, we perform experiments on both synthetic and practical data. Our results demonstrate that the Hutch AMM method is more computationally efficient and provides accurate estimation on par with the optimal BlockBasicMatrixMultiplication in all cases. Furthermore, we show that our proposed method can offer better performance in terms of estimation accuracy than the similarly efficient CR block matrix multiplication method.



**(a)** TDT2 corpus. **(b)** NYC Yellow Taxi Trip.

**Figure 4** The figure shows scatter points of relative estimation error plotted against computation time, with a moving average line generated using smoothing window length 20. The matrices used are practical datasets: (a) TF-IDF matrices from a subset of the TDT2 corpus, and (b) the February 2022 Trip Record Data from the NYC Taxi and Limousine Commission (TLC). Despite the different characteristics of these datasets, we still observe that Hutch AMM is more computationally efficient and achieves close estimation accuracy to optimal block AMM.

We acknowledge that our proposed Hutch AMM method has potential for improvement. Although our current partitioning strategy splits matrix columns into blocks by a natural sequence, it may be possible to optimize this process by implementing alternative partitioning strategies tailored for specific matrix factors. Moreover, we can explore alternative estimators for near-optimal sampling probabilities or even consider biased estimators to further enhance the computational efficiency of AMM. These are promising avenues for future research in this area.

# A Simple Boosting Framework for Transshipment

**Goran Zuzic**
Google Research, Zürich, Switzerland
ETH Zürich, Switzerland

## Abstract

Transshipment is an important generalization of both the shortest path problem and the optimal transport problem. The task asks to route a demand using a flow of minimum cost over (uncapacitated) edges. Transshipment has recently received extensive attention in theoretical computer science as it is the centerpiece of all modern theoretical breakthroughs in parallel and distributed (approximate) shortest-path computation, a classic and well-studied problem.

The key advantage of transshipment over shortest paths is the so-called *boosting* property: one can often boost a crude approximate solution to a (near-optimal) $(1+\varepsilon)$-approximate solution. However, our understanding of this phenomenon is limited: it is not clear which approximators can be boosted. Moreover, all current boosting frameworks are built with a specific type of approximator in mind and are relatively complicated.

The main takeaway of our paper is conceptual: *any* black-box oracle that computes an approximate *dual* solution can be boosted to an $(1+\varepsilon)$-approximator. This decouples and simplifies all known near-optimal $(1+\varepsilon)$-approximate transshipment and shortest paths results: they all (implicitly) construct approximate dual solutions and boost them.

We provide a very simple analysis based on the multiplicative weights framework. Furthermore, to keep the paper completely self-contained, we provide a new (and arguably much simpler) analysis of multiplicative weights that leverages well-known optimization tools to bypass the ad-hoc calculations used in the standard analyses.

## 1 Introduction

Suppose we are given a weighted graph $G=(V,E)$ and a *demand vector* $d \in \mathbb{R}^V$ satisfying $\sum_{v\in V} d(v) = 0$, where $d(v)$ denotes the number of units of some (single) commodity that are either available (if $d(v) > 0$) or required (if $d(v) < 0$) at the node $v$. *Transshipment* asks to distribute the available units of the commodity until it perfectly matches the requirement. The goal is to minimize the total cost of movement, where moving a single unit over an edge $e$ has a cost of $w(e)$ ($w(e) \geq 0$ is the weight of $e$).

Transshipment is a strong generalization of multiple problems, including the $s-t$ shortest path problem, optimal transport, or the assignment problem on metric spaces.

▶ **Example 1.** Given two nodes $s, t$ in a weighted graph $G$, the shortest path can be modeled as transshipment for the demand $d(v) := \mathbb{I}[v = s] - \mathbb{I}[v = t]$.

▶ **Example 2.** Let $(V, d)$ be a metric space and let $A, B \subseteq V$ be two disjoint subsets. The minimum cost perfect matching between $A$ and $B$ (the so-called assignment problem [14]) can be modeled as transshipment on the complete bipartite graph $(A \cup B, A \times B)$ with weights $w(\{a, b\}) = d(a, b)$ and the demand vector $d(v) := \mathbb{I}[v \in A] - \mathbb{I}[v \in B]$. This also models the Wasserstein distance (also known as the earth mover's distance or optimal transport [18]).

Perhaps surprisingly, transshipment has proven to be extremely useful for uncovering the distance structure (i.e., shortest paths) of a graph. Indeed, the problem has been the centerpiece of all near-optimal approaches to the single-source shortest path problem in the parallel and distributed settings [5, 10, 2, 19, 15].

The key property that differentiates transshipment from other similar problems like shortest path is the so-called *boosting* property – one can boost a crude, say $\text{poly}(\log n)$-approximate solution, to a near-optimal $(1 + \varepsilon)$-approximate solution. This conceptually reduces $(1+\varepsilon)$-transshipment (and shortest path computation) to approximate transshipment. However, not all approximators can be boosted and a more principled understanding of which approaches are susceptible to boosting is required. Moreover, the current boosting algorithms are coupled together with the specific approximators they use, making them non-modular, complicated, and hard to reuse.

The main takeaway of our paper is conceptual: *any* black-box oracle that computes a $\alpha$-approximate *dual* solution can be boosted to a $(1 + \varepsilon)$-approximate dual solution. This significantly simplifies current transshipment results by decoupling them into two independent questions: (1) how to obtain an approximate dual solution (which is often model-specific), and (2) how to boost this approximate solution (which can be reused). The scope of this paper is to develop a simple framework for the latter question.

We provide a very simple algorithm and analysis based on the *multiplicative weights framework*. Furthermore, to keep the paper completely self-contained, we provide a new (and arguably much simpler) analysis of multiplicative weights that leverages well-known optimization tools to bypass the ad-hoc calculations used in the standard analyses. (deferred to the full version).

We now provide several examples that show how prior approaches all (implicitly) construct approximate dual and then boost them.

▶ **Example 3.** Sherman [17] gave the first sequential almost-linear[1] $(1 + \varepsilon)$-transshipment algorithm. The main insight was the construction of a so-called *linear cost approximator*, which is a linear operator $R$ (i.e., matrix) such that $\|Rd\|_1$ approximates the optimal transshipment cost in the sense that $\text{OPT}(d) \leq \|Rd\|_1 \leq n^{o(1)}\text{OPT}(d)$ for all demands $d \in \mathbb{R}^V$. Their paper uses linear cost approximators with subgradient descent to show one can obtain a $(1 + \varepsilon)$-approximate solution. We provide a conceptual decoupling and reinterpretation of their paper: one can use any linear cost approximator $R$ to directly obtain an approximate dual solution, which can, in turn, be boosted to an $(1 + \varepsilon)$-approximate solution via our framework.

[1] We refer to $m\text{poly}(\log n)$ as near-linear and $m^{1+o(1)}$ as almost-linear runtimes.

▶ **Example 4.** Haeupler and Li [8] solve $n^{o(1)}$-approximate transshipment in the distributed setting and leave the possibility of boosting to an $(1+\varepsilon)$-approximation as the main open problem, which would have yielded important consequences in the distributed setting. Our paper provides a partial explanation to why their approach was not susceptible to boosting: their approach, based on low-stretch spanning trees, only computes a *primal* solution (i.e., an approximate flow), whereas a dual solution is required. A dual-based solution was later recently developed by Rozhon et al. [15].

▶ **Example 5.** Other successful $(1+\varepsilon)$-transshipment approaches either approximate the solution by solving the original problem on a spanner [5], or by constructing a linear cost approximator on an emulator of the original graph [10, 2] (an emulator of $G$ is a graph $H$ whose distance structure multiplicatively approximates the one of $G$, see Section 4.1). We show all of these approaches can be reinterpreted as obtaining an approximate dual solution.

**Comparison with Becker et al. [5].** The paper contributed the first polylog-competitive existentially-optimal shortest path algorithm in the distributed setting (up to $\tilde{O}(1)$-factors). Crucially, they develop a boosting framework for transshipment which, similar to this paper, uses an approximate dual solver to construct a near-optimal solution. The main drawbacks of their solver are that (1) the analysis of [5] is quite involved, stemming from it being based on projected gradient descent, and (2) as written, the interface of the [5] solver relies on solving a modified version of transshipment which is harder to interpret and work with than the original one. As stated in the journal version of [5], their interface can be significantly simplified (by working with projections), but this degrades the runtime to have an $\alpha^4$-dependency w.r.t. the approximation quality $\alpha$ of the approximator (we provide an $\alpha^2$-dependency) and requires non-explicit modifications to the solver that might be difficult for non-experts.[2] On the other hand, the approach presented in our paper has several drawbacks compared to [5], such as: (1) our solver requires a guess on the optimal solution, which is obtained using binary search, while their solver does not need adapting the internal parameters during the optimization process, and (2) our dual-only solver needs to perform extra steps to return a feasible primal solution. However, independent of the drawbacks, we believe the user-friendly interface, better runtime, and a simpler analysis make our conceptual contribution worthwhile.

**Potential impact.** Ultimately, we hope that this paper will encourage an ongoing effort to simplify deep algorithmic results that use continuous optimization tools. Such an effort would potentially yield a dual benefit: it would both lower the barrier to entry for newcomers by conceptually simplifying the current approaches, as well as help to transfer the modern theoretically-optimal algorithms into real-world state-of-the-art by allowing practitioners to independently combine the theoretical ideas with the many heuristics necessary for an algorithm to perform well in practice.

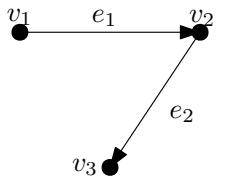
**Organization of the paper.** We present a model-oblivious boosting framework for transshipment in Section 3 and apply it in Section 4 to simplify previous results. These applications are loosely grouped by the method of computing the approximate dual solution: Section 4.1 presents results when the approximate solution is computed on a spanner or emulator (i.e.,

[2] Specifically, they require the returned dual solution be orthogonal to the demand vector. However, as they note in the journal version of their paper, this issue can be mitigated by projecting a general solution to the space of vectors orthogonal to the demand: this can be shown to work with a loss in approximation factor and time complexity if one appropriately initializes the solution.

on graphs that approximate the original metric). Section 4.2 presents results that compute the dual solution via (aforementioned) linear cost approximators. Finally, the full version of the paper gives a simple and self-contained analysis of multiplicative weights.

## 2 Preliminaries

**Graph Notation.** Let $G = (V, E)$ be a undirected graph and let $n := |V|, m := |E|$. It is often convenient to direct $E$ consistently. For simplicity and without loss of generality, we assume that $V = \{v_1, v_2, \ldots, v_n\}$ and define $\vec{E} = \{(v_i, v_j) \mid (v_i, v_j) \in E, i < j\}$. We identify $E$ and $\vec{E}$ by the obvious bijection. We chose this orientation for simplicity and concreteness: arbitrarily changing the orientations does not influence the results (if done consistently). We denote with $B \in \{-1, 0, 1\}^{V \times \vec{E}}$ the node-edge incidence matrix of $G$, which for any $v \in V$ and $e = (s, t) \in \vec{E}$ assigns $B_{s,e} = 1$, $B_{t,e} = -1$, and $B_{u,e} = 0$ when $u \notin \{s, t\}$. A weight or length function $w$ assigns each edge $e \in \vec{E}$ a weight $w(e) > 0$. The weight function can also be interpreted as a diagonal *weight matrix* $W \in \mathbb{R}^{\vec{E} \times \vec{E}}_{\geq 0}$ which assigns $W_{e,e} = w(e) \geq 1$ for any $e \in \vec{E}$ (and 0 on all off-diagonal entries). In this paper, it is often more convenient to specify weighted graphs via $G \cong (B, W)$, i.e., by specifying its matrices $B$ and $W$ as defined above.



$$B = \begin{array}{c} \\ v_1 \\ v_2 \\ v_3 \end{array} \begin{array}{c} \begin{array}{cc} e_1 & e_2 \end{array} \\ \begin{bmatrix} +1 & 0 \\ -1 & +1 \\ 0 & -1 \end{bmatrix} \end{array}$$

**Figure 1** A simple graph $G$ and its corresponding node-edge incidence matrix $B$.

**Flows and Transshipment (TS).** A *demand* is a $d \in \mathbb{R}^V$. We say a demand is *proper* if $\sum_{v \in V} d_v = 0$. A *flow* is a vector $f \in \mathbb{R}^{\vec{E}}$, where $f(\vec{e}) > 0$ if flowing in the direction of the arc $\vec{e}$ and negative otherwise. A flow $f$ *routes* a demand $d$ if $Bf = d$. It is easy to see only proper demands are routed by flows. The cost of a flow $f$ is $\|Wf\|_1$. For a weighted graph $G$ and a given proper demand $d$ the *transshipment problem* (or TS, for short) asks to find a flow $f^*_d$ of minimum-cost among flows that route $d$. In other words, the tuple $(B, W, d)$ specifies a transshipment instance. When the underlying graph $G \cong (B, W)$ is clear from the context, we define $\|d\|_{\text{OPT}} := \|Wf^*_d\|_1$ to denote the cost of the optimal flow for routing demand $d$. The transshipment problem naturally admits the following LP formulation and its dual. The primal asks us to optimize over all *flows* $f \in \mathbb{R}^{\vec{E}}$, while the dual asks us to optimize over all vectors $\phi : \mathbb{R}^V$, which we refer to as *potentials*.

$$\textbf{Primal:} \quad \min \ \|Wf\|_1 : Bf = d, \qquad \textbf{Dual:} \quad \max \ \langle d, \phi \rangle : \left\|W^{-1}B^\top \phi\right\|_\infty \leq 1. \tag{1}$$

Scalar products are denoted as $\langle x, y \rangle = x^T \cdot y$. Finally, we assume the weights and demands are polynomially-bounded, hence $\|d\|_{\text{OPT}} \leq n^{O(1)}$. Any feasible primal and dual values provide an upper and lower bound on $\|d\|_{\text{OPT}}$, formally stated in the following well-known result.

▶ **Fact 6.** *Let $f \in \mathbb{R}^{\vec{E}}$ and $\phi \in \mathbb{R}^V$ be any feasible primal and dual solution: i.e., $Bf = d$ and $\left\|W^{-1}B^T\phi\right\|_\infty \leq 1$. Then $\langle d, \phi \rangle \leq \|d\|_{\text{OPT}} \leq \|Wf\|_1$.*

For example, consider the $s$-$t$ shortest path subproblem where $d(v) = \mathbb{I}[v = s] - \mathbb{I}[v = t]$ specifies the demand. One optimal solution to the primal/dual pair is to set $f(\vec{e})$ to 1 iff $\vec{e}$ is on some fixed shortest path from $s$ to $t$; $\phi(v)$ is set to the distance in $G$ from $t \in V$. Note that in this case the primal and dual objectives are equal, and correspond to the weight of the shortest path from $s$ to $t$.

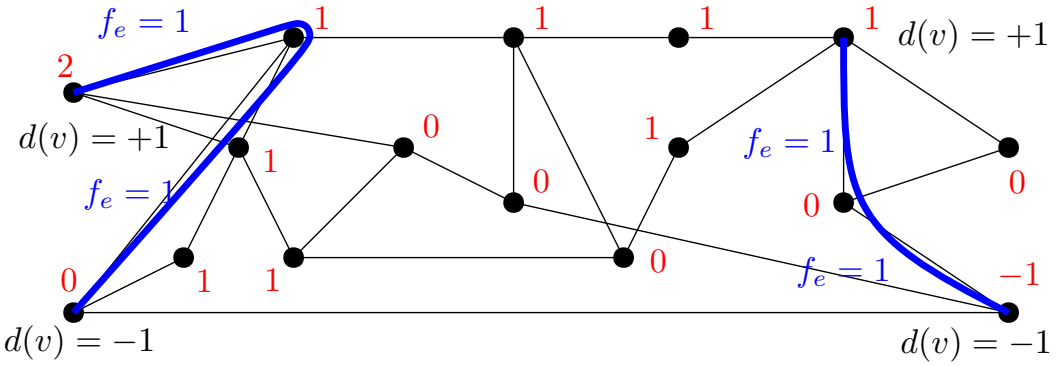


**Figure 2** A example transshipment graph with its exact solution. The original graph is unit weight $w_e = 1$ and undirected. The demand $d$ is non-zero at four nodes. The optimal primal flow $f$ is depicted in blue and is non-zero for four edges. One of many optimal vectors $\phi$ is depicted in red. The optimal value of the solution is OPT = 4.

**Asymptotic Notation.** We use $\tilde{O}$ to hide polylogarithmic factors in $n$, i.e., $\tilde{O}(1) = \text{polylog } n$.

**Algorithmic model and basic vector operations.** To facilitate both simplicity and generality, we specify our algorithms using high-level operations. Specifically, in a unit operation, we can perform the following so-called **basic vector operations**: (1) assign vectors in $\mathbb{R}^n$ or $\mathbb{R}^m$ to variables, (2) add two (vector) variables together, (3) apply any scalar function $\lambda : \mathbb{R} \to \mathbb{R}$ to each component of a vector separately, and (4) compute matrix-vector products with matrices $B$, $B^T$, $W$, and $W^{-1}$. Note that each basic vector operation can be near-optimally compiled into standard parallel/distributed models. In PRAM: each operation can be performed in $\tilde{O}(1)$ depth and near-linear work. In the standard distributed model of computation CONGEST [12] basic vector operations can be computed in a single round of distributed computation (where the variables are stored in the obvious distributed fashion).

**Multiplicative weights (MW) framework** is a powerful meta-algorithm that allows for (among other things) solving various optimization tasks by reducing them to simpler (so-called "linearized") versions of the original problem [3]. For the purposes of this paper, we define the following pair of tasks.

▶ **Definition 7.** *Let $\gamma \in \mathbb{R}$ be a scalar, $A \in \mathbb{R}^{m \times n}$ be a matrix, and $b \in \mathbb{R}^n$ be a vector. We define the following* ***Feasibility task****:*

$$\exists ? x \in \mathbb{R}^n \mid \quad \|Ax\|_\infty + \langle b, x \rangle \leq \gamma. \tag{2}$$

*Given additionally a vector $p \in \mathbb{R}^m$ satisfying $\|p\|_1 \leq 1$ and an accuracy parameter $\varepsilon > 0$, we also define the following* ***Linearized task****:*

$$\exists ? x \in \mathbb{R}^n \mid \quad \langle p, Ax \rangle + \langle b, x \rangle \leq \gamma - \varepsilon. \tag{3}$$

Note that if the Feasibility task (Equation (2)) is feasible, then the Linearized task (Equation (3)) is also feasible for every $p$ (satisfying $\|p\|_1 \leq 1$) and every $\varepsilon > 0$.

Suppose we want to solve some fixed Feasibility task (Equation (2)) and assume we know how to solve the accompanying (typically much easier!) Linearized task (Equation (3), for any $p$ and $\varepsilon$) via some *black-box Oracle*. Then, there exists a simple algorithm that computes a solution to the Feasibility task by repeatedly querying the Oracle with different values of $p$ that satisfy $\|p\|_1 \leq 1$ (the accuracy $\varepsilon$ stays fixed); the oracle is assumed to return a feasible solution $x$ for each queried Linearized task.

We define the **width of the Oracle** $\rho > 0$ to be (any upper bound on) the largest width of a solution $\|Ax\|_\infty$ that can be returned by the Oracle, i.e., $\rho \geq \|Ax\|_\infty$ during the course of the algorithm. Oracles with larger widths need to be queried more times, hence we aim to construct Oracles with their width being as small as possible. The following Theorem 8 and Algorithm 1 give a solver for the Feasibility task (Equation (2)) assuming the Oracle. We defer the proof to the full version of the paper.

▶ **Theorem 8.** *Let $(A, b, \gamma)$ be a feasible Feasibility task (Equation (2)) and fix $\varepsilon > 0$. Suppose we have access to an Oracle that will solve the accompanying Linearized task Equation (3) specified by $(A, b, \gamma, p, \varepsilon)$ for any $\|p\|_1 \leq 1$. Then, Algorithm 1 constructs a feasible solution for Equation (2) and queries the Oracle at most $4\varepsilon^{-2}\rho^2 \ln(2m)$ times. Here, $\rho > 0$ is the width of the Oracle.*

**Algorithm 1** Solver for the Feasibility task using an oracle for the Linearized task.

1. **Input:** Feasbility task $(A \in \mathbb{R}^{m\times n}, b \in \mathbb{R}^n, \gamma \in R)$ and $\varepsilon > 0$.
2. Initialize $x_* \leftarrow \vec{0} \in \mathbb{R}^n$ and $\beta := \varepsilon/(2\rho^2)$.
3. For $t = 1, \ldots, T$ rounds, where $T := 4\varepsilon^{-2}\rho^2 \ln(2m)$:
   a. Let $q \leftarrow \begin{bmatrix} A \\ -A \end{bmatrix} x_* \in \mathbb{R}^{2m}$.
   b. Let $q'_i \leftarrow \exp(\beta q_i)_i$ for $i \in [2m]$.
   c. Let $p_t \leftarrow (1/\sum_{i=1}^{2m} q'_i)(q'_i - q'_{i+m})$. (Normalization and flattening.)
   d. MW outputs $p_t \in \mathbb{R}^m$ to Oracle. (Note that $\|p_t\|_1 \leq 1$.)
   e. Oracle returns a solution $x_t \in \mathbb{R}^n$ to the Linearized task w.r.t. $p_t$. ($\rho$ must be set large enough such that $\|Ax\|_\infty \leq \rho$.)
   f. We update $x_* \leftarrow x_* + x_t$.
4. MW outputs $(1/T) \cdot x_* \in \mathbb{R}^n$.

## 3 A Boosting Framework for Transshipment

We describe how to compute an $(1+\varepsilon)$-approximate solution for transshipment given only a black-box oracle which computes an $\alpha$-approximate dual solution. This oracle is called the dual-only $\alpha$-approximator (where the dual is defined as in Equation (1)).

▶ **Definition 9** (Dual-Only Approximator). *Let $G \cong (B, W)$ be a weighted graph. A dual-only $\alpha$-approximator for transshipment over $G$ is an oracle which, given any proper demand $d \in \mathbb{R}^V$, outputs a dual solution $\phi \in \mathbb{R}^V$ satisfying the following properties:*

- *(Dual feasibility)* $\left\|W^{-1}B^T\phi\right\|_\infty \leq 1$.
- *(Approximation guarantee):* $\langle d, \phi\rangle \geq \frac{1}{\alpha}\|d\|_{\mathrm{OPT}}$ .

Note that, directly from its definition, a dual-only $\alpha$-approximator can be used to obtain an $\alpha$-approximate value of the solution.

We typically want poly$(\log n)$-approximators or $n^{o(1)}$-approximators that can be constructed and queried efficiently. However, for pedagogical purposes, we first show that the minimum spanning tree (MST) is a non-trivial $n$-approximator.

▶ **Example 10** (MST). Let $d \in \mathbb{R}^V$ be an arbitrary proper demand. The MST $T$ of $G$ can be used as a simple $n$-approximator for transshipment. First, root the MST $T$ in an arbitrary $r \in V$ and assume without loss of generality (up to re-orientation of edges in $E$) that all edges point from parent to child nodes in this rooted tree. Next, let $f_T$ be the unique flow supported on $T$ that perfectly routes $d$. We now define $\phi \in \mathbb{R}^V$ by saying $\phi(r) := 0$ and proceeding in a top-to-bottom order. For each parent-child tree-edge $e = (p, c)$, set $\phi(c) := \phi(p) - \text{sign}(f_T(e))w(e)$. Now, by construction, we have $\|Wf_T\|_1 = \langle \phi, d \rangle$ (decompose the flow $f_T$ into a positive combination of oriented paths such that all of them cross each tree edge with the same orientation; the claim is true for each one of them and, therefore, for their sum). Furthermore, $\left\|W^{-1}B^T\phi\right\|_\infty \leq n$ by the following argument: consider each edge $e = \{u, v\} \in E_G$ and consider the unique $u - v$ tree-path. This path is composed of at most $n$ edges, and each one of them have weight at most $w(e)$ (since $T$ is the MST). Hence, $|\phi(u) - \phi(v)| \leq w(e) \cdot n$, which is equivalent to the claim above. Finally, defining $\phi_* := \frac{1}{n}\phi$ we get a feasible dual solution that is $n$-approximate: Using Fact 6 we have $||d||_{\text{OPT}} \leq \|Wf_T\|_1 = \langle \phi, d \rangle = n \cdot \langle \phi_*, d \rangle$, as required.

We now show the central claim of our framework: given a dual-only $\alpha$-approximator we can leverage the multiplicative weights framework (Definition 7) to provide feasible potentials (i.e., a dual solution) $\phi \in \mathbb{R}^V$ that are $(1+\varepsilon)$-approximate, i.e., $\langle d, \phi \rangle \geq \frac{1}{1+\varepsilon} \|d\|_{\text{OPT}}$. The existence of the boosting procedure is formalized in Lemma 11, while the explicit algorithm is deferred to the full version of the paper.

As an assumption to simplify the exposition, we can safely assume that we know the value of $g := \|d\|_{\text{OPT}}$ (up to a multiplicative $1+\varepsilon$) as this value can be "guessed" via a standard binary search since our method will either certify that $\|d\|_{\text{OPT}} \leq (1+\varepsilon)g$ (telling us our guess $g$ is too low), or will otherwise construct a feasible solution $\phi$ with $\langle d, \phi \rangle \geq g$ (telling us we can increase our guess).

▶ **Lemma 11.** *Let $(B, W, d)$ be a transshipment instance and let $\varepsilon > 0$. Given any $g \geq 0$, and any dual-only $\alpha$-approximator, there is a $4\varepsilon^{-2}\alpha^2 \ln(2m)$-round algorithm that, in each round, queries the approximator once and performs $O(1)$ basic vector operations. At termination, the algorithm either:*

1. *outputs (feasible) potentials $\phi_* \in \mathbb{R}^V$ satisfying $\left\|W^{-1}B^T\phi_*\right\|_\infty \leq 1$ and $\langle d, \phi_* \rangle \geq g$, or,*
2. *detects that $\|d\|_{\text{OPT}} \leq (1+\varepsilon)g$; indeed, it outputs an (infeasible) flow $f_* \in \mathbb{R}^E$ satisfying $\|Wf_*\|_1 \leq g$ and $\|d - Bf_*\|_{\text{OPT}} \leq \varepsilon g$.*

**Remark.** If one is only concerned about finding an $(1+\varepsilon)$-approximate dual solution, one can completely ignore the infeasible flow that is being outputted and simply use the fact that the second condition guarantees $\|d\|_{\text{OPT}} \leq (1+\varepsilon)g$, which is sufficient for binary search. Furthermore, we note that any such (infeasible) flow $f_*$ satisfying the above properties guarantees $\|d\|_{\text{OPT}} \leq (1+\varepsilon)g$ by the following argument. First, by definition of $\|d - Bf_*\|_{\text{OPT}} \leq \varepsilon g$, there exists a flow $f_{\text{residual}}$ that routes $d - Bf_*$ and has cost $\|Wf_{\text{residual}}\|_1 \leq \varepsilon g$. Then, the flow $f_* + f_{\text{residual}}$ routes demand $d$ (since $Bf_* + Bf_{\text{residual}} = Bf_* + d - Bf_* = d$) and has cost at most $\|Wf_*\|_1 + \|Wf_{\text{residual}}\|_1 \leq g + \varepsilon g = (1+\varepsilon)g$, implying that $\|d\|_{\text{OPT}} \leq (1+\varepsilon)g$.

**Proof.** First, finding potentials $\phi \in \mathbb{R}^V$ satisfying $\left\|W^{-1}B^T\phi\right\|_\infty \leq 1$ and $\langle d, \phi\rangle \geq g$ is equivalent to finding potentials $\exists ?\phi \in \mathbb{R}^V \mid \left\|W^{-1}B^T\phi\right\|_\infty - \left\langle \frac{1}{g}d, \phi\right\rangle \leq 0$ (one direction is immediate, the other direction follows by the fact that we can scale $\phi$ such that $\langle d, \phi\rangle = g$). Therefore, it is sufficient to solve the following so-called TS Feasibility task (see Figure 3).

| | | |
|---|---|---|
| **TS feasbility task**: | $\exists ?\phi \in \mathbb{R}^V \mid$ | $\left\|W^{-1}B^T\phi\right\|_\infty \leq 1$ and $\langle d, \phi\rangle \geq g$. |
| **TS feasbility task** (equivalent): | $\exists ?\phi \in \mathbb{R}^V \mid$ | $\left\|W^{-1}B^T\phi\right\|_\infty - \left\langle \frac{1}{g}d, \phi\right\rangle \leq 0$. |
| **Linearized TS task** (given $\|p\|_1 \leq 1$): | $\exists ?\phi \in \mathbb{R}^V \mid$ | $\left\langle p, W^{-1}B^T\phi\right\rangle - \left\langle \frac{1}{g}d, \phi\right\rangle \leq -\varepsilon$. |
| **Linearized TS task** (equivalent): | $\exists ?\phi \in \mathbb{R}^V \mid$ | $\langle d_{\text{residual}}, \phi\rangle \geq \varepsilon \cdot g$, where $d_{\text{residual}} := d - B(g \cdot W^{-1}p)$. |

**Figure 3** The (second, equivalent form of the) TS Feasibility task is a subcase of the Feasibility task defined in Definition 7 with $A := W^{-1}B^T, b := (1/g)d, \gamma := 0$, and renaming $x \to \phi$. The equivalent forms of the tasks follow by straightforward algebraic manipulation.

We apply the MW framework by interpreting the TS Feasbility task as a Feasibility Task in the sense of Definition 7, solving it via Algorithm 1 where we have to implement the Oracle.

First, we note that the TS Feasibility task directly corresponds to a $(A := W^{-1}B^T, b := -\frac{1}{g}d, \gamma := 0)$-Feasibility task. We aim to implement the Oracle for the corresponding Linearized TS task with a small width $\rho$. To recap, $\rho$ is the maximum value of $\left\|W^{-1}B^T\phi\right\|_\infty$ ever returned by the Oracle – we later determine that setting $\rho := \alpha$ suffices.

The Oracle, upon receiving $p$ by Algorithm 1, queries the dual-only $\alpha$-approximator with the (so-called) residual demand $d_{\text{residual}} := d - B(g \cdot W^{-1}p)$. Intuitively, we can interpret $p$, or more specifically $g \cdot W^{-1}p$, as the "current" iterate of the final flow solution. Specifically, $\left\|g \cdot W^{-1}p\right\|_1 \leq g$, i.e., it has a small cost since $g$ is a guess for OPT. If the residual demand can be routed with a small cost of at most $\varepsilon g$ (which can be estimated via the approximator), it means that $\|d_{\text{residual}}\| \leq \varepsilon g$, hence $f_* := g \cdot W^{-1}p$ satisfies the second output condition.

The appoximator, being asked to route $d_{\text{residual}}$, returns the $\alpha$-approximate feasible dual, i.e., a vector $\phi_{\text{residual}} \in \mathbb{R}^V$ satisfying $\langle d_{\text{residual}}, \phi_{\text{residual}}\rangle \geq \frac{1}{\alpha}\|d_{\text{residual}}\|_{\text{OPT}}$ and $\left\|W^{-1}B^T\phi_{\text{residual}}\right\|_\infty \leq 1$. The Oracle outputs $\phi' := \alpha \cdot \phi_{\text{residual}}$. Note that the width of the oracle is exactly $\left\|W^{-1}B\phi'\right\|_\infty = |\alpha| \left\|W^{-1}B\phi_{\text{residual}}\right\|_\infty \leq \alpha \cdot 1 = \alpha$.

Either $\langle d_{\text{residual}}, \phi'\rangle \geq \varepsilon \cdot g$, and the Oracle successfully solves the Linearized TS task by returning $\phi_{\text{residual}}$, in which case the MW loop continues. If this is always the case, Algorithm 1 outputs $\phi_*$ satisfying $\left\|W^{-1}B^T\phi_*\right\|_\infty \leq 1$ and $\langle d, \phi_*\rangle \geq g$, as required. Regarding the width of the solution, we have that $\left\|W^{-1}B^T\phi'\right\|_\infty \leq \alpha$, hence setting $\rho := \alpha$ suffices, leading to at most $4\varepsilon^{-2}\alpha^2 \ln 2m$ rounds of the algorithm.

On the other hand, if this is (ever) not the case, we say the Oracle fails. In this case, at the moment of failure, we define $f_* := g \cdot W^{-1}p$ and have that $\langle d_{\text{residual}}, \phi'\rangle \leq \varepsilon \cdot g$. Since $\phi' = \alpha\phi_{\text{residual}}$, we have $\langle d_{\text{residual}}, \phi_{\text{residual}}\rangle \leq \frac{\varepsilon}{\alpha} \cdot g$. Since $\phi_{\text{residual}}$ is an $\alpha$-approximate dual w.r.t. $d_{\text{residual}}$, we have that $\left\|d - B(g \cdot W^{-1}p)\right\|_{\text{OPT}} = \|d_{\text{residual}}\|_{\text{OPT}} \leq \alpha \cdot \frac{\varepsilon}{\alpha}g = \varepsilon \cdot g$. Therefore, $f_*$ satisfies the second condition and we are done. ◀

The full algorithm is deferred to the full version.

**Reducing the residual error of the primal.** While the booster of Lemma 11 returns a feasible $(1+\varepsilon)$-approximate dual solution, it does not return a feasible primal solution (i.e., flow). However, this issue can be resolved by repeatedly routing the residual demand $d - Bf_*$

until the cost of routing the residual demand drops to an insignificant $1/\text{poly}(n)$-fraction of the original cost, at which point any trivial reparation scheme suffices (like routing along the MST). See the full version of the paper for more details. Combining the above result with binary searching the guess $g$ and with the residual error reduction (but without the model-specific trivial routing), we immediately yield the following result (proof deferred to the full version).

▶ **Corollary 12.** *Let $(B, W, d)$ be a transshipment instance. Given any $1/2 \geq \varepsilon > 0$, $C > 0$ and dual-only $\alpha$-approximator, there is an $\tilde{O}(C \cdot \varepsilon^{-2}\alpha^2)$-round algorithm computing (both):*

- *a feasible dual $\phi_*$ satisfying $(1+\varepsilon)^{-1} \|d\|_{\text{OPT}} \leq \langle d, \phi \rangle \leq \|d\|_{\text{OPT}}$, and,*
- *an (infeasible) primal $f_*$ satisfying $\|Wf\|_1 \leq (1+\varepsilon)\|d\|_{\text{OPT}}$ and $\|d - Bf_*\|_{\text{OPT}} \leq n^{-C}\|d\|_{\text{OPT}}$.*

*In each round, the algorithm performs $O(1)$ basic vector operations and queries to the approximator.*

## 4 Applications

In this section, we show how to apply the boosting framework of Section 3 to simplify and decouple several landmark results in the parallel and distributed settings. First, we describe results that approximate transshipment by solving it on a compact graph representation called a spanner or emulator (Section 4.1). Then, we describe results that use linear cost approximators (Section 4.2).

### 4.1 Approximating via spanners and emulators

A $\beta$-approximate **emulator** of a graph $G = (V, E_G)$ is a weighted graph $H = (V, E_H)$ on the same vertex set where the distances are approximated with a distortion of $\beta$; i.e., $\text{dist}_G(u,v) \leq \text{dist}_H(u,v) \leq \beta \cdot \text{dist}_G(u,v)$ for all $u, v \in V$. A spanner is simply an emulator that is a subgraph of $G$, i.e., where $E_H \subseteq E_G$, making it particularly well-studied in some settings.

Approximating with emulators is conceptually straightforward: faced with a transshipment instance on $G$, we (approximately) solve the instance on $H$, which yields an approximate solution on $G$. This is captured by the following result.

▶ **Theorem 13.** *Let $H$ be a $\beta$-approximate emulator of $G$. Any dual-only $\alpha$-approximator on $H$ is a dual-only $(\alpha \cdot \beta)$-approximator on $H$.*

**Proof.** Fix a demand $d$ on $G$. Querying the $H$-approximator, we obtain a dual solution $\phi_H$ satisfying $\left\|W_H^{-1} B_H^T \phi_H\right\|_\infty \leq 1$; we also know an accompanying primal solution $f_H$ exists with $W_H(f_H) \leq \alpha \langle d, \phi_H \rangle$.

*Primal solution.* We construct a flow $f_G$ in $G$ as follows. For each edge $e \in E_H$ we know, due to $\text{dist}_G(u,v) \leq \text{dist}_H(u,v)$, that there exists a path in $G$ of length at most $w_H(e)$; we add $f_H(e)$ amount of flow along this path. It is easy to check that, $f_G$ routes $d$ (i.e., $B_G f_G = d$, hence it is feasible) and that $W_G(f_G) \leq W_H(f_H)$, hence $\|d\|_{\text{OPT}(G)} \leq \alpha \langle d, \phi_H \rangle$.

*Dual solution.* Let $\phi_G := \frac{1}{\beta}\phi_H$. Note that $\|d\|_{\text{OPT}(G)} \leq (\alpha\beta) \cdot \langle d, \phi_G \rangle$, hence it is sufficient to deduce $\left\|W_G^{-1} B_G^T \phi_G\right\|_\infty \leq 1$. Since $\phi_H$ is feasible in $H$, we have for each $e' = \{u', v'\} \in E_H$ that $(B_H^T \phi_G)_{e'} = |\phi_G(u') - \phi_G(v')| \leq \frac{|\phi_H(u') - \phi_H(v')|}{\beta} = \frac{w_H(u',v')}{\beta}$. Fix an edge $e = \{u, v\} \in E_G$; since $\text{dist}_H(u,v) \leq \beta \cdot \text{dist}_G(u,v)$ there exists a path

$(u = p'_0, p'_1, p'_2, \ldots, p'_k = v)$ in $H$ of length at most $\beta \cdot w_G(e)$. Therefore, we can deduce that $\left\|W_G^{-1} B_G^T \phi_G\right\|_\infty \leq 1$ in the following way: $|(W_G^{-1} B_G^T \phi_G)_e| = \frac{|\phi_G(u) - \phi_G(v)|}{w_G(e)} \leq \frac{\sum_{i=1}^{T} |\phi_G(p'_{i-1}) - \phi_G(p'_i)|}{w_G(e)} \leq \frac{\sum_{i=1}^{T} w_H(p'_{i-1}, p'_i)}{\beta w_G(e)} \leq \frac{\beta w_G(e)}{\beta w_G(e)} = 1.$ ◀

**Remark.** There are a few immediate extensions to the above proof. Given a primal-dual approximator (one that returns both a primal and a dual) on a *spanner*, we can immediately obtain a primal-dual approximator on $G$ since the returned primal $f_H$ is also a feasible primal in $G$. A similar property holds for emulators, but one would need to provide a mapping that embeds each edge $e \in E_G$ into (paths of) $H$ that are of length at most $\beta \cdot w(e)$ in order to construct the flow $f_G$ on $G$.

**Application: TS in Broadcast congested clique [5].** Using algorithms from prior work, a Broadcast congested clique can compute an $\tilde{O}(1)$-approximate Baswana-Sen [4] spanner $H$ in $\tilde{O}(1)$ rounds. The edges of such a spanner are naturally partitioned into $n$ parts of size $\tilde{O}(1)$, where each part is associated with a unique node, and that node knows the edges in its part. Therefore, the spanner can be made global knowledge in $\tilde{O}(1)$ rounds using broadcasts. Therefore, each node can solve a transshipment instance on $H$, providing an $\tilde{O}(1)$-approximator for the original graph via Theorem 13, culminating in an $\tilde{O}(\varepsilon^{-2})$-round solution for $(1+\varepsilon)$-transshipment.

**Application: existentially-optimal SSSP in Broadcast CONGEST [5].** Consider the single-source shortest path (SSSP) problem where each node wants to compute $(1+\varepsilon)$-approximate from some source $s \in V$. From prior work, we can compute an *overlay graph* $G' = (V', E')$ where $V' \subseteq V$ and $|V'| = \tilde{O}(\varepsilon^{-1}\sqrt{n})$ such that the SSSP task on $G$ reduces to SSSP on $G'$, and $G'$ can be computed in $\tilde{O}(D + \varepsilon^{-1}\sqrt{n})$ rounds. As was shown in [5], an SSSP instance can be solved by solving $\tilde{O}(1)$ transshipment instances (the details are non-trivial and out of scope of this paper), hence the problem reduces to solving TS on $G'$. However, any $T$-round Broadcast congested clique algorithm can be simulated on $G'$ in $T \cdot O(D + |V'|) = T \cdot \tilde{O}(D + \varepsilon^{-1}\sqrt{n})$ rounds of Broadcast CONGEST: we simulate a single round by constructing a BFS tree on $G$ (of depth $O(D)$ and in $O(D)$ rounds), and then pipelining all $|V'|$ messages (that are to be broadcasted in the current round) to the root and them down to all other nodes, taking $O(D + |V'|)$ rounds in Broadcast CONGEST per round of Broadcast congested clique. Combining with the Broadcast congested clique result, we obtain an $\tilde{O}(\varepsilon^3)(D + \sqrt{n})$-round algorithm.

**Application: near-optimal TS in PRAM [2].** The paper introduces a concept called *low-hop emulator* $H = (V, E_H)$ of $G = (V, E)$ satisfying (i) $H$ is an $\tilde{O}(1)$-approximate emulator of $G$, (ii) $|E_H| = \tilde{O}(n)$, and (iii) $\text{dist}_H^{O(\log\log n)}(u, v) = \text{dist}_H(u, v)$, i.e., every (exact) shortest path in $H$ has at most $O(\log\log n)$ hops (edges). Moreover, low-hop emulators can be computed in PRAM in $\tilde{O}(1)$ depth and $\tilde{O}(m)$ work. Low hop emulators are particularly useful since Property (iii) implies that one can compute (exact) SSSP on them in $\tilde{O}(1)$ depth and $\tilde{O}(n)$ work (e.g., using $O(\log\log n)$ rounds of Bellman-Ford). The ability to compute exact SSSP enables each node of $H$ to be embedded into $\ell_1$ space of dimension $\tilde{O}(1)$ with (worst-case) distortion $\tilde{O}(1)$ (via so-called Bourgain's embedding [6] via $\tilde{O}(1)$ SSSP oracle calls). Since $H$ is an emulator of $G$, the same embedding is an $\tilde{O}(1)$-distortion embedding of $G$. Using Theorem 13, this reduces $(1+\varepsilon)$-TS to finding an $\tilde{O}(1)$-approximator in $\ell_1$ space. This can be done in $\tilde{O}(1)$ depth and $\tilde{O}(n)$ work using linear cost approximators (explained in Section 4.2) by utilizing the so-called *randomly shifted grids* method [9]. This culminates in an $\tilde{O}(\varepsilon^{-2})$ depth and $\tilde{O}(\varepsilon^{-2}m)$ work $(1+\varepsilon)$-transshipment algorithm.

## 4.2 Approximating by linear cost approximators

A particularly successful type of approximator for transshipment has been the linear cost approximator. The successes of such an approximator include the first $m^{1+o(1)}$ algorithm for transshipment in the centralized model [17] and the first $\tilde{O}(m)$-work and $\tilde{O}(1)$-depth parallel shortest path algorithm [2, 10].

▶ **Definition 14.** *An $\alpha$-approximate linear cost approximator for a weighted graph $G$ is a $k \times n$ matrix $P$, such that, for any proper demand $d$ it holds that $\|d\|_{\text{OPT}} \leq \|Pd\|_1 \leq \alpha \|d\|_{\text{OPT}}$.*

Our insight is that one can immediately convert a linear cost approximator $P$ to a dual-only approximator. Note that the sign function is applied entry-wise to a vector.

▶ **Theorem 15.** *Let $P$ be an $\alpha$-approximate linear cost approximator. Consider the function $\phi(d)$ that maps a demand $d$ to $\phi(d) := \frac{1}{\alpha} P^T \text{sign}(Pd)$. Then, $\phi$ is a dual-only $\alpha$-approximator.*

**Proof.** Let $G \cong (B, W)$ be the underlying graph. First, we show that the following subclaim about a linear-algebraic guarantee that characterizes $P$: we have that $\left\|yPBW^{-1}\right\|_\infty \leq \alpha$ over all $\|y\|_\infty \leq 1$. Specifically, for each oriented edge $\vec{e} \in \vec{E}$, consider how $P$ approximates the cost of routing a unit from the head to the tail of $\vec{e}$. Formally, we define the demand $d_{\vec{e}}$ to be $d_{\vec{e}}(x) := \mathbb{I}[x = s] - \mathbb{I}[x = t]$ for an edge $\vec{e} = (s, t) \in \vec{E}$. Clearly, $\|d_{\vec{e}}\|_{\text{OPT}} \leq w(e)$, hence it is necessary that $\left\|Pd_{\vec{e}} w(e)^{-1}\right\|_1 \leq \alpha$. Furthermore, it is easy to see that the columns of $B$ are exactly $d_{\vec{e}}$ over all $\vec{e} \in \vec{E}$, hence each column of $PBW^{-1}$ has $\ell_1$-norm at most $\alpha$. This is equivalent to $\left\|y^T PBW^{-1}\right\|_\infty \leq \alpha$ over all $\|y\|_\infty \leq 1$. This proves the subclaim.

We now prove the complete result. Let $y := \text{sign}(Pd)$ and $\phi(d) := \frac{1}{\alpha} P^T y$. Since, $\|d\|_{\text{OPT}} \leq \|Pd\|_1$, there must exists a flow $f$ satisfying $d$ such that $\|d\|_{\text{OPT}} \leq \|Wf\|_1 \leq \|Pd\|_1$. We verify all properties Definition 9. (Dual feasibility) $\left\|W^{-1}B^T\phi(d)\right\|_\infty = \frac{1}{\alpha}\left\|W^{-1}B^T P^T y\right\|_\infty \leq \frac{1}{\alpha} \cdot \alpha = 1$ via the subclaim. (Approximation guarantee) $\langle d, \phi(d)\rangle = \frac{1}{\alpha}\langle Pd, y\rangle = \frac{1}{\alpha}\langle Pd, \text{sign}(Pd)\rangle = \frac{1}{\alpha}\|Pd\|_1 \geq \frac{1}{\alpha}\|d\|_{\text{OPT}}$. ◀

Having a dual-only $\alpha$-approximator that can be evaluated in $M$ time, we construct (via Corollary 12) an $\tilde{O}(\varepsilon^{-2}\alpha^2 \cdot M)$ time $(1+\varepsilon)$-approximate algorithm for transshipment.

▶ **Corollary 16.** *Let $P$ be an $\alpha$-approximate linear cost approximator on a weighted graph $G$ and suppose that we can evaluate matrix-vector multiplications with $P$ and $P^T$ (and other basic vector operations) in $M$ time. Given any TS instance, there is an $\tilde{O}(\varepsilon^{-2}\alpha^2 M)$-time algorithm that computes a $(1+\varepsilon)$-approximate primal-dual pair $(f, \phi)$ satisfying the properties listed in Corollary 12.*

**Application: almost-optimal sequential TS [17].** The goal is to construct $\varepsilon^{-2}m^{1+o(1)}$-time $(1+\varepsilon)$-TS solver in the sequential setting. Following Corollary 16, it is sufficient to construct a $n^{o(1)}$-approximate linear cost approximator $P$, which is accomplished as follows. Each vertex of a weighted graph $G$ is embedded into $\ell_1$ space of dimension $O(\log^2 n)$ with (worst-case) distortion $O(\log n)$ (via so-called Bourgain's embedding [6] in $\tilde{O}(m)$ sequential time). Then, the dimension of the embedding is reduced to $d := O(\sqrt{\log n})$ via a simple Johnson-Lindenstrauss projection [7], increasing the distortion of the embedding to $\exp(O(d)) = n^{o(1)}$. Finally, the paper constructs a $O(\log^{1.5} n)$-approximate linear cost approximator in this (virtual) $\ell_1$ space of dimension $d$ that can be evaluated efficiently, leading to a $\exp(O(d)) \cdot O(\log^{1.5} n) = n^{o(1)}$-approximate linear cost approximator in $G$, which yields the result. **Approximator in $\ell_1$ space:** We give a short cursory description on how to construct the approximator $P$. Re-scale and round the $\ell_1$ space such that all coordinates are integral.

Then, each point $x$ calculates the distance $c(x)$ to the closest point with all-even coordinates. Then, $x$ uniformly spreads its demand $d(x)$ among all points with all-even coordinates that are of distance exactly $c(x)$ to $x$. Finally, repeat the algorithm on points with all-even coordinates (delete other points, divide all coordinates by 2). After $O(\log n)$ iterations, the entire remaining demand will be supported on $2^d$ vertices of the hypercube, which can be routed to a common vertex yielding a $O(d)$ approximation. It can be shown that the cost incurred by spreading the demand at any particular step $O(d)$-approximates the optimal solution, and that the optimal solution does not increase in-between two steps, leading to a $O(d \log n) = O(\log^{1.5} n)$-approximate linear cost approximator. **Efficiency:** Evaluating the approximator requires computing the demands at each step in the above algorithm. Evaluating even the first step requires $n2^d$ time since each point $x$ sends its demand to (potentially) $2^d = n^{o(1)}$ closest all-even points. Therefore, the dimension of the embedding is reduced to $O(\sqrt{\log n})$. Moreover, the paper (implicitly) claims this approximator in $\ell_1$ can be evaluated in $m^{1+o(1)}$ time. Finally, we remark that the approximator does not yield a flow in the original graph in any meaningful way, (i.e., it only approximates costs), confirming that it is dual-only. Together, we solve $(1+\varepsilon)$-TS in $\varepsilon^{-2}m^{1+o(1)}$ time.

**Application: near-optimal TS in PRAM [10].** The goal is to solve $(1+\varepsilon)$-TS in $\tilde{O}(1)$ depth and $\tilde{O}(m)$ work in PRAM. The paper constructs an $\tilde{O}(1)$-approximate linear cost approximator $P$ with sparsity $\tilde{O}(m)$, meaning it can be evaluated in $\tilde{O}(1)$ depth and $\tilde{O}(m)$ work, which would yield the result. To do so, the paper follows [17] by embedding $G$ in $\ell_1$ space with distortion $\tilde{O}(1)$ and dimension $d := \tilde{O}(1)$ and then uses the randomly shifted grids methods of [9] to approximate the cost in this virtual space. **Approximator in $\ell_1$ space:** We define a *randomly shifted grid* of scale $W$ to be the set $W(\mathbb{Z}^d + u) \subseteq \mathbb{R}^d$, where each coordinate of $u \in \mathbb{R}^d$ is uniformly drawn from $[0, 1)$ (i.e., one obtains a randomly shifted grid by taking all integral $d$-dimensional points, randomly translating them along each axis, them multiplying all coordinates by $W$). Initially, set $W \leftarrow \tilde{O}(1)$. The routing works by sampling $s := \tilde{O}(1)$ randomly shifted grids of scale $W$ and, for each grid, each point $x$ sends $1/s$ of its demand $d(x)$ to the closest point in the grid. The scale $W$ is increased by a polylogarithmic factor and the algorithm is repeated for $O(\log n)$ steps until all demand is supported on a hypercube, at which point it can be $O(d)$-approximated by aggregating it at a single vertex. It can be shown that the cost incurred by routing the demand at any particular step $\tilde{O}(1)$-approximates the optimal solution, and that the optimal solution increases only by a multiplicative $1 + 1/\text{poly}(\log n)$ factor, hence after $O(\log n)$ iterations we obtain an $\tilde{O}(1)$-approximate linear cost approximator $P$ that has sparsity $\tilde{O}(m)$. **Vertex reduction framework:** On its face, the above approach simply shows that in order to get $(1+\varepsilon)$-transshipment (and $(1+\varepsilon)$-shortest paths, as arduously shown in the paper), it is sufficient to find an $\tilde{O}(1)$-distortion $\ell_1$-embedding. However, to find an $\ell_1$-embedding, one needs $\tilde{O}(1)$-approx shortest paths (with some additional technical requirements concerning the violation of the triangle inequality). To resolve this cycle, the paper goes through the vertex reduction framework of [11, 13] which reduces the number of vertices by a polylogarithmic factor, recursively solves transshipment, lifts the solution to the original graph, and repairs it using the boosting framework. The details are out-of-scope.

**Future work.** The ideas used for solving transshipment have historically paralleled the ideas used for solving maximum flow problems. Adding to the connection between these two problems, approximate solutions to maximum flow can also be boosted in a similar way to transshipment [16] via linear cost approximators (called *congestion approximators*). However,

no framework that can handle black-box approximators has been developed – creating such a framework would conceptually simplify the task of designing approximate maximum flow solutions. Furthermore, both transshipment and maximum flow are special cases of the so-called $\ell_p$-norm flow, which also seems to support boosting [1].
