**Case 1.** $\sum_i x_{i,j} < 1$. In this case, $\ell(j) = 1$, $\Delta R = z_j = 1 - f(1) = 0$, and we have

$$\Delta D = \Delta L + \Delta R \leq b(j) \cdot f'(1) \cdot \sum_i x_{i,j} = (1 - f(1) + f'(1)) \cdot \Delta P = \beta \cdot \Delta P$$

**Case 2.** $\sum_i x_{i,j} = 1$, $\ell(j) > k/d$. We have $\Delta R = z_j = b(j) \cdot (1 - f(\ell(j))$ and $\Delta P = b(j)$.

$$\Delta D = \Delta L + \Delta R \leq b(j) \cdot f'(\ell(j)) + b(j) \cdot (1 - f(\ell(j)) = b(j) \cdot (1 - f(\ell(j)) + f'(\ell(j))) = \beta \cdot \Delta P$$

**Case 3.** $\sum_i x_{i,j} = 1$, $\ell(j) \leq k/d$. Again, we have $\Delta P = b(j)$. We know that $\Delta R = z_j = b(u) \cdot (1 - f(k/d))$. Note that $f'(x) = f'(k/d)$ for $x \in [0, k/d]$.

$$\Delta D = \Delta L + \Delta R \leq b(j) \cdot f'(\ell(j)) + b(j) \cdot (1 - f(k/d)) = b(j) \cdot (1 - f(k/d) + f'(k/d)) = \beta \cdot \Delta P.$$ ◀

# 6 Upper Bounds for the Adwords problem

In this section, we prove that $\tau(k,d)$ competitiveness is impossible for the Adwords problem.

▶ **Theorem 11.** *For fractional AdWords in $(k,d)$-graphs, there exists $k,d$ and fixed $\epsilon > 0$, such that no online algorithm can be better than $(\tau(k,d)-\epsilon)$-competitive.*

The hard instance is composed of several scenarios. The intuition behind the scenario is that if for a certain $j$, $b(i_1,j) > b(i_2,j)$, then, on the one hand, the online algorithm should allocate the item to $i_1$ in order not to lose its higher price, and, on the other hand, by doing so the optimal allocation can use item $j$ to $i_2$. We amplify this example and prove an improved upper bound for $\alpha = 1/2$ ($k = d/2$) and $B(i) = 1$ for all $i \in L$. First, we bound the gain of a subset of the bidders after several sequence steps.

## 6.1 Bounding the gain of a subset of the bidders

Let $Q \subseteq L$ be a subset of vertices. After several sequence steps, we bound the total online gain that can be extracted from $Q$, where the degree of $i \in Q$ is already $k$, and the adversary determined how many bidders from $Q$ have already exhausted their budget in previous steps. We compute an upper bound on the total gain of an online algorithm on $Q$ as a function of the average online gain on $Q$ in previous steps by defining the rest of the sequence for this subset $Q$ and bounding the total gain using a linear program. The rest of the sequence for this $Q$ is as the second part of Section 4. Specifically, it defines $Q_{k+1}$ as a subset of $Q$ in which the current gain in OPT is 0. In phase $t \in [k+1, d-1]$, the adversary divides $Q_t$ into $|Q_t|/d$ groups and introduces for each group's bidders a product with an equal bid value of 1. The adversary defines $Q_{t+1}$ by dropping the lowest gain bidder from each group. In the last phase, for each bidder $i \in Q_d$, the adversary introduces a product with a bid of 1.

Formally, given such $Q$ and the decomposition of $Q$ into $Q^e_k, Q^m_k$ where the average gain in $Q^e_k$ is, at most, the average gain of $Q^m_k$ For $t \in [k+1,d]$, the adversarial would define at each phase $t \in [k+1,d]$, $Q_t \subseteq Q$, where $Q_{k+1} = Q^m_k$. The adversary groups each $Q_t$ into $|Q_t|/d$ disjoint groups, each of size $d$, denoted as $Q_{t,s}$, for $s \in [|Q_t|/d]$. In phase $t \in [k+1,,d-1]$, $|Q_t|/d$ products arrive and the $s$'th ($s \in [|Q_t|/d]$) bid $b(i,s) = 1$ to $i \in Q_{t,s}$ (and 0 otherwise). In phase $t \in [k+1,,d-1]$, $|Q_t|/d$ products arrive and the $s$'th ($s \in [|Q_t|/d]$) product bids are $b(i,s) = 1$ to all the bidders in group $i \in Q_{t,s}$. $Q_{t+1}$ for $t \in [k+1,d-1]$ is set as follows: For $s \in \frac{|Q_t|}{d}$, let $Q^e_{k,s} \subset Q_{k,s}$ be the subset containing the lowest gain bidder in $Q_{t,s}$ after phase $t$ and $Q^m_{t,s} = Q_{t,j} \setminus Q^e_{t,j}$. We define $Q_{t+1} = \cup_{s=1}^{|Q_t|/d} Q^m_{t,s}$. note that, $|Q_{t+1}| = (1-1/d)\,|Q_t|$ for $t \in [k+1,d-1]$. Let $G_Q$ be the total gain of $Q$ vertices.

**Bounding $G_Q$ as a function of previous phases.** Next, we bound the total gain of $G_Q$, given that after phase $k$, a decomposition of $Q$ into $Q^e_k, Q^m_k$ exists (i.e., $Q = Q^e_k \cup Q^m_k$) such that $x^m_k$ ($x^e_k$) is the average load on $Q^m_k$ ($Q^e_k$) and $x^e_k \le x^m_k$ (constraint $\tilde{m}_k$). Assuming that the total gain of $Q$ until (not including) step $k+1$ is $G^k_Q$, we have $\frac{|Q^m_k|}{|Q|} \cdot x^m_k + \frac{|Q^e_k|}{|Q|} \cdot x^e_k \le \frac{G^k_Q}{|Q|}$, constraint $\tilde{v}_k$). We will define $Q_{k+1} = Q^m_k$, and accordingly, we have $d \cdot x^m_k \le (d-1) \cdot u^m_{k+1} + u^e_{k+1}$ (constraint $\tilde{n}_k$). Denote $V^Q = \frac{G^Q_k}{|Q|}$, and $r^Q = \frac{|Q^m_k|}{|Q|}$ the following Linear program, will bound $G(V^Q, r^Q)$ the total gain that can be extracted from $Q$.

$G(V^Q, r^Q) = \mathbf{max}\, |Q| \cdot V^Q + \sum_{t=k+1}^{d-1} \frac{|Q_t|}{d} \cdot (x_t^e + (d-1)x_t^m) + |Q_d| \cdot (1 - u_d^m)$,
such that:

$$
\begin{aligned}
& r^Q \cdot x_k^m + (1 - r^Q) \cdot x_k^e \leq V^Q && && (\tilde{v}_k)\\
& (d-1) \cdot x_t^m + x_t^e \leq 1 && \forall t \in [k+1, d-1], && (v_t)\\
& x_k^e \leq x_k^m && && (\tilde{m}_k)\\
& x_t^e + u_t^e \leq x_t^m + u_t^m && \forall t \in [k+1, d-1], && (m_t)\\
& d \cdot x_k^m \leq (d-1) \cdot u_{k+1}^m + u_{k+1}^e && && (\tilde{n}_k)\\
& d \cdot (x_t^m + u_t^m) \leq (d-1) \cdot u_{t+1}^m + u_{t+1}^e && \forall t \in [k+1, d-2], && (c_t)\\
& d \cdot (x_{d-1}^m + u_{d-1}^m) \leq d \cdot u_d^m && && (c_{d-1})\\
& x_t^m, u_t^m, x_t^e, u_t^e \geq 0 && && \forall t \in [k, d]
\end{aligned}
$$

## 6.2 The Scenarios

Let $L = U \cup D$, such that $|U| = |D| = n$, We divide $U(D)$ into $n/k$ disjoint groups $U_{k,s}(D_{k,s})$ such that $|U_{k,s}| = |D_{k,s}| = k$, for $s \in [n/k]$.

**Phase 0.** For each $s \in [n/k]$, introduce a product $j$, such that $b(i,j) = 0.26 \cdot d$ for $i \in U_{k,s}$ and $b(i,j) = 0.24 \cdot d$ for $j \in D_{k,s}$. Any online algorithm must determine $\gamma = \sum_{i \in U_{k,s}, j} x_{i,j}/n$, the average portion of the items of phase 0 assigned to $U$. Next, the adversary introduces products of phase $k$ (phases $[k-1]$ are empty).

**First Scenario.** For each $s \in [n/(2 \cdot k)]$, the adversary introduces two products $j_1, j_2$, such that $b(i, j_1) = 0.24 \cdot d$ for $i \in U_{k,2 \cdot s-1} \cup U_{k,2 \cdot s}$ and $b(i, j_2) = 0.26 \cdot d$ for $i \in D_{k,2 \cdot s-1} \cup D_{k,2 \cdot s}$.

**Second Scenario.** For each $s \in [n/k]$, the adversary introduces a product $j$, such that $b(i,j) = 0.24 \cdot d$ for $i \in U_{k,s}$ and $b(i,j) = 0.26 \cdot d$ for $j \in D_{k,s}$. Any online algorithm must determine $\delta = \sum_{i \in U_{k,s}, j} x_{i,j}/n$, the average portion of the items of phase $k$ of the second scenario assigned to $U$. Note that, in both scenarios, the current degree of each vertex $i \in L$ is $k$. Using the values $\gamma, \delta$, we bound the average gain per bidder of $U(D)$ up to phase $k$ for scenario $o$, denoted as $V^{U(o)}(V^{D(o)})$. For the first scenario:

$$
\begin{aligned}
V^{U(1)} =& \frac{1}{n} \cdot \left( \frac{n}{k} \cdot \gamma \cdot 0.26 \cdot d + \frac{n}{d} \cdot 0.24 \cdot d \right) = 0.52 \cdot \gamma + 0.24\\
V^{D(1)} =& \frac{1}{n} \cdot \left( \frac{n}{k} \cdot (1-\gamma) \cdot d \cdot 0.24 \cdot d + \frac{n}{d} \cdot 0.26 \cdot d \right) = 0.74 - 0.48 \cdot \gamma
\end{aligned}
$$

For the second scenario:

$$
\begin{aligned}
V^{U(2)} =& \frac{1}{n} \cdot \left( \frac{n}{k} \cdot \gamma \cdot 0.26 \cdot d + \frac{n}{k} \cdot \delta \cdot 0.24 \cdot d \right) = 0.52 \cdot \gamma + 0.48 \cdot \delta\\
V^{D(2)} =& \frac{1}{n} \cdot \left( \frac{n}{k} \cdot (1-\gamma) \cdot d) \cdot 0.24 \cdot d + \frac{n}{k} \cdot (1-\delta) \cdot 0.26 \cdot d \right) = 1 - 0.48 \cdot \gamma - 0.52 \cdot \delta
\end{aligned}
$$

Similarly, we denote $\gamma^{\mathrm{OPT}}, \delta^{\mathrm{OPT}}$ as the corresponding values for the optimal allocation. After setting those values (for a certain case), the gain of OPT on this subset would be determined. Then, the adversary can omit bidders in the corresponding subset, i.e., determining $r^Q$ for $Q \in U, D$.

**Continuing the first scenario.** In the first scenario, the adversary sets $\gamma^{\text{OPT}} = 0$ (i.e., uses the products of phase 0 to increase the gain of vertices only in $D$). Taking into account also the products of phase $k$ of the first scenario, it omits the $r^U = 0.24$ portion from $U$ and the $r^D = 0.74$ portion from $D$, and continues the sequence for $U, D$ separately using Subsection 6.1 construction.

Formally, for $s \in [n/k]$, let $U^e_{k,j} \subset U_{k,s}$ be the subset of the $(r^U \cdot k)$-lowest gain vertices in $U_{k,s}$ after phase $k$ and $U^m_{k,s} = U_{k,s} \setminus U^e_{k,s}$ (the subset of the $((1-r^U) \cdot k)$-highest load vertices in $U_{k,j}$), and define $U_{k+1} = \cup_s U^m_{k,s}$. Accordingly, for $s \in [n/k]$, let $D^e_{k,s} \subset D_{k,s}$ be the subset of the $(r^D \cdot k)$-lowest gain vertices in $U_{k,s}$ after phase $k$ and $U^m_{k,j} = U_{k,j} \setminus Q^e_{k,j}$ (the subset of the $((1-r^D) \cdot k)$-highest load vertices in $Q_{k,j}$). We continue the scenario separately for $U$ and $D$ using Subsection 6.1 construction. We bound the total gain of this scenario using the LP $G(V^Q, r^Q)$. Specifically, the total gain is at most (as a function of $\gamma$):

$$G(V^U, r^U) + G(V^D, r^D) = G(0.52 \cdot \gamma + 0.24, 0.24) + G(0.74 - 0.48 \cdot \gamma, 0.74).$$

**Continuing the second scenario.** In the second scenario, the adversary uses $\gamma^{\text{OPT}} = 1$, $\delta^{\text{OPT}} = 0$ (i.e., uses the products of phase 0 to increase the gain of vertices only in $U$ and the products of the second scenario of phase $k$ to increase the gain of vertices only in $D$). In this case, it omits the $r^U = 0.52$ portion from $U$ and the $r^D = 0.52$ portion from $D$. Similarly to the previous case, we have:

$$G(V^U, r^U) + G(V^D, r^D) = G(0.52 \cdot \gamma + 0.48 \cdot \delta, 0.52) + G(1 - 0.48 \cdot \gamma - 0.52 \cdot \delta, 0.52).$$

By our construction definition, in all scenarios, the optimal value is $2 \cdot n$. Therefore, in order to bound $c$, we have the following $LP$

$$\begin{aligned} &\textbf{max}\, c \\ \text{such that: } &G(0.52 \cdot \gamma + 0.24, 0.24) + G(0.74 - 0.48 \cdot \gamma, 0.74) \geq 2 \cdot n \cdot c \\ &G(0.52 \cdot \gamma + 0.48 \cdot \delta, 0.52) + G(1 - 0.48 \cdot \gamma - 0.52 \cdot \delta, 0.52) \geq 2 \cdot n \cdot c \end{aligned}$$

By solving it numerically, we have for $d = 100$, $k = 50$, we have:

$c \leq 0.69485 < \tau(0.5) \approx 0.6967$.

## Abstract

The general adversary dual is a powerful tool in quantum computing because it gives a query-optimal bounded-error quantum algorithm for deciding any Boolean function. Unfortunately, the algorithm uses linear qubits in the worst case, and only works if the constraints of the general adversary dual are exactly satisfied. The challenge of improving the algorithm is that it is brittle to arbitrarily small errors since it relies on a reflection over a span of vectors. We overcome this challenge and build a robust dual adversary algorithm that can handle approximately satisfied constraints. As one application of our robust algorithm, we prove that for any Boolean function with polynomially many 1-valued inputs (or in fact a slightly weaker condition) there is a query-optimal algorithm that uses logarithmic qubits. As another application, we prove that numerically derived, approximate solutions to the general adversary dual give a bounded-error quantum algorithm under certain conditions. Further, we show that these conditions empirically hold with reasonable iterations for Boolean functions with small domains. We also develop several tools that may be of independent interest, including a robust approximate spectral gap lemma, a method to compress a general adversary dual solution using the Johnson-Lindenstrauss lemma, and open-source code to find solutions to the general adversary dual.

## 1 Introduction

The query model of computation has proven a powerful model in which to prove quantum-classical separations [26, 19, 15] and to understand the limits of quantum algorithms [2, 6, 28]. The power and usefulness of this computational model in the quantum setting in part derives from the fact that bounded-error quantum query complexity for Boolean function evaluation is tightly and beautifully described by a semidefinite program (SDP) – the general adversary bound [46, 44]. The dual of this semidefinite program has played an important role in the development and understanding of quantum algorithms. In particular, the dual has been used to show the optimality of span program algorithms, which are a critical element for several algorithm design paradigms [45, 8, 30, 32] and are useful in a wide range of applications [11, 20, 12, 9, 7]. While we have methods to create a bounded-error quantum algorithm for function evaluation based on a set of vectors that exactly satisfy the constraints of the general adversary dual [44], it is natural to ask how robust this algorithm is to transformations and perturbations. For example, can we take a vector set that satisfies the dual adversary constraints and modify it to obtain an algorithm with better space complexity? Or can we create an algorithm from a vector set that satisfies relaxed dual adversary constraints? In this paper, we find criteria under which these modified or approximately satisfying vector sets yield viable algorithms, and we consider two problems where such robustness is useful.

First, we study when we can reduce the space complexity of dual adversary-derived algorithms. Almost all Boolean functions on $n$ bits have unitary space complexity $\Omega(n)$ [31], but we hope to discover conditions under which less space might be required. We do this by determining when we can compress the dimension of a set of vectors that exactly satisfies the dual adversary constraints. While the dual adversary is most commonly studied in the context of query complexity, is it also closely related to unitary space complexity [31], and the dimension of the satisfying vectors to the dual adversary problem determines the space used by the algorithm. As building large quantum computers will likely continue to be a technical challenge in the near to medium term [29], finding ways to minimize the space used by quantum computers is important.

We use two approaches to compress the dimension of a satisfying vector set, and hence reduce the space used by the resulting algorithm. First, we consider using a unitary transformation to rotate the vectors to a smaller space. Next, we analyze applying the Johnson-Lindenstrauss (JL) lemma, which is a powerful tool for compressing the dimension of a vector set while approximately preserving the structure of the vectors. With our analysis, we find the simpler, unitary transformation always results in a better compression than the JL approach. But, with either compression method, we can show for any function with polynomially many 1-valued inputs, or polynomially many 0-valued inputs, there is a query-optimal algorithm that uses logarithmic space. While it is not surprising that there is an algorithm that uses logarithmic space for such problems (one could iterate through possible 1/0-valued inputs and run Grover's search to test each one), it is not obvious that there is a *query-optimal* algorithm that uses logarithmic space.

The second problem we consider is how to create an algorithm using the output of a numerical SDP solver applied to the general adversary dual. One can plug the general adversary dual into a classical SDP solver and find a set of vectors that is close to a query-optimal, exactly satisfying vector set. Due to finite precision, we expect that the numerical solution will almost never be *exactly* satisfying, but we would like to know if we can still produce a query-optimal quantum algorithm. With our tools for creating robust dual adversary algorithms, we bound the error that can be tolerated, and we describe how

to take a vector set that does not quite satisfy the dual adversary constraints, but is within the tolerable error, and use it to create a bounded-error algorithm. In the worst case, our analysis requires an error that scales inversely with the number of 1-valued or 0-valued inputs. While this can be exponential in number of bits in the function, prior to our work, it was not clear how to create *any* algorithm from an approximately satisfying solution. Moreover, the general adversary bound is an SDP with dimension $|X|$ where $X$ is the function domain, so in general, solvers will already take time polynomial in $|X|$ to solve classically [48], so we expect that attaining this level of precision will only contribute polynomially to the overall runtime. Additionally, we show numerically that, at least for small functions, the error bound we require is easily attainable.

One may naturally wonder why a vector set that approximately satisfies the dual adversary constraints does not immediately yield an appropriate algorithm. The challenge is that the standard algorithm is based on a reflection about the span of a subset of those vectors. For example, consider a vector set that should ideally be $\{|0\rangle, |1\rangle, |0\rangle + |1\rangle\}$, but is instead $\{|0\rangle + 10^{-10}|2\rangle, |1\rangle, |0\rangle + |1\rangle\}$. The span of the first set is 2-dimensional, but the span of the second set is 3-dimensional, even though the two vector sets are very close by almost any metric. If the algorithm reflects over a space that is much larger than it should, it might not correctly evaluate the function on all inputs. Our techniques allow us to find appropriate reflections (or in fact unitaries that are close to reflection) so that the algorithms can proceed, even with errors like the example above. Along the way towards proving our main results, we also develop several tools that may be of independent interest, including a robust approximate spectral gap lemma and open-source code to find solutions to the general adversary dual.

## 1.1 Related Work

### Space Complexity and Compression

Reichardt observes that that the space used by the dual adversary algorithm is the log of the rank of $Z$, where $Z$ is the positive semidefinite matrix that optimizes the primal general adversary bound, and he notes that this provides a worst case $\log(n|X|)$ space complexity for $n$-bit functions with domain $X$ [44, 43]. Our exact compression result (Theorem 9) is of a similar flavor, except that we are using the "rank" of the dual. Barnum, Saks, and Szegedy use a different family of SDPs to characterize query complexity [5] (these SDPs can give improved performance in the case of small or zero error algorithms), and their algorithm again depends on the rank of the satisfying positive semidefinite matrix, but in the worst case uses $\log |X| + 1$ qubits.

The key tool we use in our compression application is the Johnson-Lindenstrauss lemma. The lemma guarantees that high-dimensional vectors randomly compressed into a lower-dimensional space approximately preserves the inner products of the vectors [34]. The JL lemma is used in a variety of classical applications including compressed sensing, dimensionality reduction, and machine learning [23, 49, 13], and it works even with sparse compression matrices [35]. In fact, our work, in which we compress the dual solution to an SDP, has similarities to work by So et al. [47], which uses JL compression to reduce the rank of the matrix that is the primal solution to a semidefinite programming problem, at the cost of only approximately satisfying the constraints. It is also known that the compressed dimension given by the Johnson-Lindenstrauss lemma is optimal up to constant factors [39].

The idea of relaxing SDP constraints in order to improve the space used by an algorithm has also been considered in the classical regime. Ding et al. create a storage-optimal SDP solver by relaxing constraints [22].

In the quantum arena, a natural application of the JL lemma would be to compress the size of quantum states, but Harrow et al. found that there is no such mapping that significantly reduces the dimension of quantum states while preserving the Schatten 2-norm distance with high probability [27]. However, the JL lemma was used to compress the space used by a quantum finger printing protocol [25].

Span programs (which are equivalent to the dual adversary [44, 46]) were in fact originally formulated in order to understand classical space complexity [36], and Jeffery shows lower bounds on the space complexity of function evaluation that depend on minimum span program and approximate span program sizes [31].

#### Numerical Solutions to the Dual Adversary

The idea of using classical computers to design quantum algorithms is not new. The variational quantum eigensolver iteratively uses a classical computer to make a ground state ansatz, which is then tested by a quantum computer [42]. A classical machine learning algorithm can be used to guide quantum algorithm design [4]. However, the dual adversary semidefinite programming problem is different in that it automatically produces a query-optimal algorithm, rather than an iterative process guided by classical, heuristic optimization methods.

### 1.2 Open Questions

Our techniques for space compression preserve the quantum query complexity of the original algorithm, while attempting to reduce space complexity. It would be very interesting if they could be modified to reduce space at the cost of increased query complexity; this might provide insight into one of Aaronson's 2021 open query complexity problems [1]: better understanding space and query trade offs, specifically for the problems of collision and element distinctness.

While we analyze dual adversary algorithms, these are closely related to span program algorithms. It should be possible to translate the bounds and conditions we find on the robustness of the general adversary dual into analogous bounds and conditions on span program algorithms. We are especially curious if these relaxed constraints could be related to Approximate Span Programs [30], which are another way of relaxing the constraints of standard span programs.

While we show conditions under which it is possible to create dual adversary algorithms, we do not prove lower bounds. It would be interesting to study whether, with more detailed analysis, or under additional natural conditions, the JL approach to space compression could be improved, or whether the analysis we present is optimal.

Generalizations of the general adversary bound characterize the problems of quantum state conversion [40] and quantum subspace conversion [10]. Perhaps our techniques could be extended to these additional regimes.

## 2 Preliminaries

A few notational conventions: we use $\||\psi\rangle\|$ do denote the $\ell_2$ norm of $|\psi\rangle$, $[n]$ to denote $\{1, 2, \ldots, n\}$, and $\delta_{i,j}$ to denote the Kronecker delta function. If $|\lambda\rangle$ is an eigenvector of $U$ with eigenvalue $e^{i\beta}$, we say the phase of $|\lambda\rangle$ is $\beta$. For any unitary $U$, let $P_\Theta(U)$ be the orthogonal projector onto the eigenvectors of $U$ with phase at most $\Theta$. That is, $P_\Theta(U)$ is the orthogonal projector onto $\text{span}\{|\lambda\rangle : U|\lambda\rangle = e^{i\beta}|\lambda\rangle \text{ with } |\beta| \leq \Theta\}$.

We consider the quantum query complexity and space complexity of evaluating a function $f : X \to \{0,1\}$ where $X \subseteq \{0,1\}^n$. For such a function $f$, we define $f^{-1}(b) = \{x \in X : f(x) = b\}$. For some $x \in X \subseteq \{0,1\}^n$, we are given access to an oracle $O_x$ that acts on $\mathbb{C}^n \otimes \mathbb{C}^2$ as $O_x|i\rangle|b\rangle = |i\rangle|b \oplus x_i\rangle$, where $|i\rangle$ for $i \in [n]$ and $|b\rangle$ for $b \in \{0,1\}$ are standard basis states, and $x_i$ is the $i^{\text{th}}$ bit of $x$. Given $O_x$, we would like to determine $f(x)$. We do this by implementing a bounded-error quantum query algorithm, which without loss of generality takes the form

$$U_T O_x U_{T-1} O_x \cdots U_1 O_x U_0 |\hat{0}\rangle, \tag{1}$$

followed by a two-outcome measurement that determines the output of the algorithm, where $U_0, \ldots U_T$ are unitary operations acting on a Hilbert space of size $S$, such that for every input $x \in X$, the probability of outputting $f(x)$ is at least $2/3$. The algorithm uses $T$ applications of the oracle and $\log S$ qubits of space. The bounded-error query complexity of $f$ is the minimum query complexity of any bounded-error query algorithm for $f$.

The general adversary dual is used in designing query-optimal quantum algorithms for function evaluation:

▶ **Definition 1** (General Adversary Dual). *Let $f : X \to \{0,1\}$ for $X \subseteq \{0,1\}^n$. The following semidefinite optimization problem is called the dual of the general adversary bound, or what we call the general adversary dual:*

$$\min_{\substack{m \in \mathbb{N} \\ |v_{x,j}\rangle \in \mathbb{C}^m}} \left\{ \max_{x \in X} \sum_j \||v_{x,j}\rangle\|^2 \right\} \tag{2}$$

$$s.t.\ \forall x, y \in X : f(x) \neq f(y), \qquad 1 = \sum_{j : x_j \neq y_j} \langle v_{x,j} | v_{y,j} \rangle. \tag{3}$$

While Definition 1 seeks to minimize the dimension $m$ of the vectors $\{|v_{x,j}\rangle\}_{x \in X, j \in [n]}$ (we will drop the set-building subscript and use $\{|v_{x,j}\rangle\}$ when clear from context) that also minimizes $\max_{x \in X} \sum_j \||v_{x,j}\rangle\|^2$, we note that to design an algorithm, we only need a vector set $\{|v_{x,j}\rangle\}$ that satisfies the constraints in Equation (3). This motivates the following definition, similar to converting vector sets in [3].

▶ **Definition 2** (Deciding Vector Set and Related Terms). *Let $f : X \to \{0,1\}$ for $X \subseteq \{0,1\}^n$, and let $m \in \mathbb{N}$. Then $\{|v_{x,j}\rangle \in \mathbb{C}^m\}_{x \in X, j \in [n]}$ is an $f$-deciding vector set if*

$$\forall x, y \in X : f(x) \neq f(y), \qquad 1 = \sum_{j : x_j \neq y_j} \langle v_{x,j} | v_{y,j} \rangle. \tag{4}$$

*We say the* size *of $\{|v_{x,j}\rangle\}$ is $\max_{x \in X} \sum_j \||v_{x,j}\rangle\|^2$, the* dimension *is $m$, and the* maximum rank *is* $\max_{j \in [n]} \quad \text{rank}\{|v_{x,j}\rangle : f(x) = 1\}$.

Given an $f$-deciding vector set, one can design a query algorithm to decide $f$:

▶ **Theorem 3** ([44, 40]). *For $f : X \to \{0,1\}$ with $X \subseteq \{0,1\}^n$ let $\{|v_{x,j}\rangle\}_{x \in X, j \in [n]}$ be an $f$-deciding vector set with size $A$ and dimension $m$. Then there is a bounded-error quantum query algorithm that decides $f$ with query complexity $O(A)$ and space complexity $O(\log(nm))$.*

Because any $n$-bit function can be decided in $n$ queries, we assume $A = O(n)$. Additionally, applying Cauchy-Schwarz to Equation (4), we have $A \geq 1$.

We sketch the proof of Theorem 3 to make it easier to compare with our algorithms. (For a more detailed description using similar notation, see Ref. [14, Chapter 23.6]). The subroutine used in both Theorem 3 and in our algorithms is (parallelized) phase estimation.

▶ **Lemma 4** (Phase Estimation [37, 16, 41]). *Let $U$ be a unitary that acts on $n$ qubits, and let $\delta, \Theta > 0$. Then there is a phase estimation style circuit that has precision $\Theta$, error $\delta$, acts on $n + b$ qubits for $b = O\left(\log \frac{1}{\Theta} \log \frac{1}{\delta}\right)$, and uses $O\left(\frac{1}{\Theta} \log \frac{1}{\delta}\right)$ calls to control-$U$ applied to a single instance of the state $|\psi\rangle$, such that $p_0$, the probability of outcome 0, satisfies*

$$\|P_{\Theta/2}(U)|\psi\rangle\|^2(1-\delta) - \delta \leq p_0 \leq \|P_{\Theta}(U)|\psi\rangle\|^2 + \delta. \tag{5}$$

We prove Lemma 4 in the full version of the paper [17], which relies heavily on prior analyses of phase estimation circuits.

The algorithm of Theorem 3 applies phase estimation with precision $O(1/A)$ on a unitary $U$ with an initial state $|\hat{0}\rangle$. $U$ acts on the space $\mathcal{H} = \mathbb{C} \oplus \mathbb{C}^n \otimes \mathbb{C}^m \otimes \mathbb{C}^2$, and is a product of two reflections: $U = (2\Pi_x - I)(2\Delta - I)$, where $\Pi_x = |\hat{0}\rangle\langle\hat{0}| + \sum_{i\in[n]} |i\rangle\langle i| \otimes I \otimes |x_i\rangle\langle x_i|$ (here $I$ acts on $\mathbb{C}^m$, and $|\hat{0}\rangle$ is orthogonal to $\sum_{i\in[n]} |i\rangle\langle i| \otimes I \otimes (|0\rangle\langle 0| + |1\rangle\langle 1|)$) and $\Delta$ is the orthogonal projector onto the following set of normalized vectors:

$$|\psi_y\rangle = \frac{1}{\sqrt{\nu_y}} \left( |\hat{0}\rangle + \frac{1}{\sqrt{cA}} \sum_{i\in[n]} |i\rangle|v_{y,i}\rangle|y_i\rangle \right) \qquad \forall y : f(y) = 1, \tag{6}$$

$$\text{s.t. } \nu_y = 1 + \frac{1}{cA} \sum_{i\in[n]} \||v_{y,i}\rangle\|^2 \leq 1 + 1/c, \tag{7}$$

where $\nu_y \geq 1$ is chosen to normalize $|\psi_y\rangle$, and $c$ is a constant chosen depending on the desired success probability. We note $(2\Pi_x - I)$ requires 2 uses of $O_x$ to implement, and $(2\Delta - I)$ depends on the choice of the deciding vector set but is independent of the input $x$.

Then when $f(x) = 1$ and $c = 2$, $|\hat{0}\rangle$ has high overlap with $|\psi_x\rangle$, which is easily verified to be a 0-phase eigenvector of $U$, so by Lemma 4, the probability of measuring a phase of 0 when we perform phase estimation is large when $\delta$ (the error of phase estimation) is a small constant.

On the other hand, when $f(x) = 0$, we consider the following normalized vector:

$$|\phi_x\rangle = \frac{1}{\sqrt{\mu_y}} \left( |\hat{0}\rangle - \sqrt{cA} \sum_{i\in[n]} |i\rangle|v_{x,i}\rangle|\bar{x}_i\rangle \right) \tag{8}$$

$$\text{s.t. } \mu_x = 1 + cA \sum_{i\in[n]} \||v_{x,i}\rangle\|^2 \leq 1 + cA^2, \tag{9}$$

where $\mu_y \geq 1$ is chosen to normalize the vector. Because $\{|v_{y,i}\rangle\}$ is a deciding vector set, we have $\forall y : f(y) = 1, \langle\psi_y|\phi_x\rangle = 0$. Thus $\{|\phi_x\rangle\}$ is orthogonal to $\Delta$. Next we use the effective spectral gap lemma:

▶ **Lemma 5** (Effective Spectral Gap Lemma [40]). *Let $\Pi, \Delta$ be orthogonal projectors, let $U = (2\Pi - I)(2\Delta - I)$, and $\Delta|w\rangle = 0$. Then*

$$\|P_{\Theta}(U)\Pi|w\rangle\| \leq \Theta/2\||w\rangle\|. \tag{10}$$

Then the probability of measuring a phase of 0 when we perform phase estimation when $f(x) = 0$, by Lemma 4 is upper bounded by a term that depends on $\|P_{\Theta}(U)|\hat{0}\rangle\|^2 = \mu_y\|P_{\Theta}(U)\Pi_x|\phi_x\rangle\|^2$. Applying Lemma 5, and using the fact that $\mu_y = O(A^2)$, we see this is small when $\Theta$, the precision of phase estimation, is chosen to be $O(1/A)$. Since $\delta$ (the error of phase estimation) is chosen to be a small constant, by Lemma 4 this leads to a bounded-error algorithm with query complexity $O(A)$, and space complexity $\log(1 + 2nm) + O(\log A) = O(\log(nm))$, as claimed in Theorem 3.

## 3 Robust Dual Adversary Algorithm

In this section, we show that the dual adversary algorithm has robustness, in that it tolerates errors and flexibility in how it is defined. As described in Section 2, we want to create a bounded-error quantum query algorithm for a Boolean function $f : X \to \{0,1\}$, for $X \subseteq \{0,1\}^n$. Similar to the standard algorithm, our robust algorithm will involve applying phase estimation to a unitary $U$ that acts on the space $\mathcal{H} = \mathbb{C} \oplus \mathbb{C}^n \otimes \mathbb{C}^m \otimes \mathbb{C}^2$. We perform phase estimation on $U$ with a state $|\hat{0}\rangle \in \mathcal{H}$.

We now describe $U$. As in Section 2, we define the orthogonal projector $\Pi_x = |\hat{0}\rangle\langle\hat{0}| + \sum_{i\in[n]} |i\rangle\langle i| \otimes I \otimes |x_i\rangle\langle x_i|$ on $\mathcal{H}$ where $I$ acts on $\mathbb{C}^m$, and $|\hat{0}\rangle$ is orthogonal to $\sum_{i\in[n]} |i\rangle\langle i| \otimes I \otimes (|0\rangle\langle 0| + |1\rangle\langle 1|)$. Notice that $\Pi_x$ can be implemented with two applications of the oracle $O_x$. Let $R$ be another unitary that acts on the same space as $\Pi_x$, but $R$ need not be a reflection. Let $U = (2\Pi_x - I)R$.

▶ **Theorem 6.** *Let $\delta, \nu_x, \mu_x > 0$, $\varepsilon_\psi, \varepsilon_\phi \geq 0$, and let $U = (2\Pi_x - I)R$ as defined above, so $U$ acts on $O(\log nm)$ qubits. Consider $0 < \theta \leq 1$. Suppose there are sets of (not necessarily normalized) vectors $\{|\psi_x\rangle = \frac{1}{\sqrt{\nu_x}}(|\hat{0}\rangle + |\eta_x\rangle)\}_{x:f(x)=1}$ and $\{|\phi_x\rangle = \frac{1}{\sqrt{\mu_x}}(|\hat{0}\rangle + |\eta_x\rangle)\}_{x:f(x)=0}$ where $\forall x \in X, \langle\eta_x|\hat{0}\rangle = 0$, and furthermore, that*

1. *$\forall x : f(x) = 1, \quad \|(I-U)|\psi_x\rangle\| \leq \varepsilon_\psi$ and*
2. *$\forall x : f(x) = 0, \quad \Pi_x|\eta_x\rangle = 0$ and $\|(I+R)|\phi_x\rangle\| \leq \varepsilon_\phi$.*

*Then the probability of measuring a phase of 0 if we do phase estimation on $U$ with initial state $|\hat{0}\rangle$ with precision $\theta$ and error $\delta$ when $f(x) = 1$ is at least*

$$\left(\sqrt{\nu_x(1 - \frac{5\varepsilon_\psi^2}{\theta^2})} - \sqrt{\nu_x \||\psi_x\rangle\|^2 - 1}\right)^2 (1-\delta) - \delta, \tag{11}$$

*and when $f(x) = 0$ is at most*

$$\mu_x \left(\varepsilon_\phi/2 + \theta/2 \||\phi_x\rangle\|\right)^2 + \delta. \tag{12}$$

*This algorithm uses $O\left(\frac{1}{\theta}\log\frac{1}{\delta}\right)$ queries and $O\left(\log(nm) + \log\frac{1}{\theta}\log\frac{1}{\delta}\right)$ qubits.*

Theorem 6 extends the robustness of the algorithm used to prove Theorem 3 (as described in Section 2) in several ways. In the standard analysis, $\varepsilon_\psi$ and $\varepsilon_\phi$ are both 0, whereas we now allow them to be non-zero. In addition, Theorem 6 allows for imperfect alignment between the vector sets $\{|\psi_x\rangle\}$ and $\{|\phi_x\rangle\}$ and the unitary $U$. This will be the key for our applications in the following sections. Additionally, in the standard algorithm, $R$ is chosen to be a reflection, but in Theorem 6, $R$ can be any unitary that satisfies the criterion of Theorem 6. While none of the applications we describe in this paper use this flexibility in the design of $R$, it might be helpful in future use cases.

To prove Theorem 6, we need the following two lemmas, proved in the full version [17]:

▶ **Lemma 7.** *Let $U$ be a unitary and $0 < \Theta \leq 1$. If $\|(I-U)|\psi_x\rangle\|^2 \leq \varepsilon$, then $\|P_\Theta(U)|\psi_x\rangle\|^2 \geq 1 - \frac{1.1\varepsilon}{\Theta^2}$.*

Lemma 7 tells us that if a unitary $U$ approximately preserves a state $|\psi_x\rangle$, then $|\psi_x\rangle$ has high overlap with the low phase eigenspace of $U$. This gives us flexibility when $f(x) = 1$, in that our initial state need not have high overlap with the 0-phase space of $U$, but instead we only require high overlap with the low-phase-eigenspace of $U$. The proof of Lemma 7 proceeds by decomposing $|\psi_x\rangle$ into its eigenbasis with respect to $U$, and showing that $\epsilon$ serves to bound the amount of amplitude $|\psi_x\rangle$ can have in states with eigenvalues larger than $\Theta$.

▶ **Lemma 8** (Robust Approximate Spectral Gap Lemma). *Let $\varepsilon \geq 0$, $\Pi$ be an orthogonal projector, $R$ be a unitary, and $U = (2\Pi - I)R$. For $\Theta > 0$, if $\|(I+R)|w\rangle\| \leq \varepsilon$, then*

$$\|P_\Theta(U)\Pi|w\rangle\| \leq \frac{\varepsilon}{2} + \frac{\Theta}{2}\||w\rangle\|. \tag{13}$$

Lemma 8 generalizes the standard approximate spectral gap lemma (Lemma 5), in which $R$ is a reflection and $\varepsilon = 0$. In particular, Lemma 8 shows that when $R$ is not a reflection and when $|w\rangle$ is not exactly given a phase of $-1$ by $R$, a variant of the approximate spectral gap lemma still holds.[1] The proof of Lemma 8 closely follows the proof approach of [40, Lemma 4.2], which does not use Jordan's Lemma, but instead directly uses a series of triangle inequalities and observations of preserved subspaces to obtain the result.

**Proof of Theorem 6.** We first consider the case of $x$ such that $f(x) = 1$. By Lemma 4, the probability that we get an outcome of 0 when we perform phase estimation on the unitary $U$ with initial state $|\hat{0}\rangle$ with precision $\Theta$ and accuracy $\delta$ is at least $\|P_{\Theta/2}(U)|\hat{0}\rangle\|^2(1-\delta) - \delta$. Now

$$\begin{aligned}
\|P_{\Theta/2}(U)|\hat{0}\rangle\| &= \|P_{\Theta/2}(U)\sqrt{\nu_x}|\psi_x\rangle - P_{\Theta/2}(U)|\eta_x\rangle\| \\
&\geq \sqrt{\nu_x}\|P_{\Theta/2}(U)|\psi_x\rangle\| - \|P_{\Theta/2}(U)|\eta_x\rangle\| \qquad \text{(reverse triangle inequality)} \\
&\geq \sqrt{\nu_x\left(1 - \frac{5\varepsilon_\psi^2}{\Theta^2}\right)} - \||\eta_x\rangle\|, \qquad (14)
\end{aligned}$$

where the first term in the final line combines Lemma 7 and the assumption that $\|(I - U)|\psi_x\rangle\| \leq \varepsilon_\psi$, so $\|(I-U)|\psi_x\rangle\|^2 \leq \varepsilon_\psi^2$, and the second term uses the fact that projectors can only decrease the $\ell_2$ norm of a vector. Thus, using that $\||\eta_x\rangle\| = \sqrt{\nu_x\||\psi_x\rangle\|^2 - 1}$, we have

$$\|P_{\Theta/2}(U)|\hat{0}\rangle\|^2(1-\delta) - \delta \geq \left(\sqrt{\nu_x(1 - \frac{5\varepsilon_\psi^2}{\Theta^2})} - \sqrt{\nu_x\||\psi_x\rangle\|^2 - 1}\right)^2 (1-\delta) - \delta. \tag{15}$$

When $f(x) = 0$, by Lemma 4, the probability that we get an outcome of 0 when we perform phase estimation on $U$ with initial state $|\hat{0}\rangle$ with precision $\Theta$ and accuracy $\delta$ is at most

$$\|P_\Theta(U)|\hat{0}\rangle\|^2 + \delta = \mu_x\|P_\Theta(U)\Pi_x|\phi_x\rangle\|^2 + \delta, \tag{16}$$

since by assumption, $\Pi_x|\phi_x\rangle = 1/\sqrt{\mu_x}|\hat{0}\rangle$. Then from Lemma 8 and our assumption that $\|(I+R)|\phi_x\rangle\| \leq \varepsilon_\phi$, we have

$$\|P_\Theta(U)\Pi_x|\phi_x\rangle\| \leq \varepsilon_\phi/2 + \Theta/2\||\phi_x\rangle\|. \tag{17}$$

Combining Equation (16) and Equation (17) gives us a probability of outcome 0 of at most

$$\mu_x\left(\varepsilon_\phi/2 + \Theta/2\||\phi_x\rangle\|\right)^2 + \delta. \tag{18}$$

Finally the query complexity and space complexity come from the requirements of phase estimation Lemma 4, and that $2\Pi_x - I$ can be implemented with two uses of the oracle. ◀

[1] We note Lemma 8 is similar to Lemma 3.4 in [33], except we allow $R$ to not be a reflection.

## 4 Compressing the Dual Adversary Algorithm

In this section, we consider how and when it is possible to reduce the space complexity of the quantum algorithm built from the general adversary dual. In particular, our goal is to take an $f$-deciding vector set, reduce its dimension and hence create an algorithm which requires fewer qubits to implement.

Our first result, Theorem 9, is a simple compression scheme that shows that an $f$-deciding vector set on an $n$-bit function with maximum rank $\kappa'$ and size $A$ can be compressed to an $f$-deciding vector set with dimension $\kappa'$ and size at most $A$ (see Definition 2 for terminology). The number of qubits required by the resulting algorithm is then $O(\log(n\kappa'))$ and the query complexity is $O(A)$, by Theorem 3 and using that $A = O(n)$. Notice that $\kappa'$ is at most the number of 1-valued inputs, but if many of the $f$-deciding vectors are linearly dependent, the maximum rank could be much smaller.

We note that an $f$-deciding vector set is also an $\neg f$-deciding vector set by Definition 2, where $\neg f$ is the negation of $f$. Also, a $\neg f$-deciding vector set can be used to design a bounded error quantum algorithm for deciding $f$ by negating the output of the algorithm. Thus for a given deciding vector set, we can minimize the space used by the algorithm by considering either $\neg f$ or $f$.

▶ **Theorem 9.** *Given an $f$-deciding vector set with maximum rank $\kappa'$ and size $A$, we can construct an $f$-deciding vector set with dimension $\kappa'$ and size at most $A$, resulting in an algorithm that decides $f$ with query complexity $O(A)$ and space complexity $O(\log(n\kappa'))$.*

To prove Theorem 9, we apply a series of unitaries to rotate the vectors of the deciding vector set into a smaller dimensional space. This is possible because if we apply the same unitary to two vectors, their inner product is preserved. Our full proof appears in Ref. [17].

The next natural question is whether we can *approximate* the solution to the general adversary dual in a lower dimension. We answer this question by considering a compression of the vectors in a deciding vector set with guarantees from the Johnson-Lindenstrauss lemma, which approximately preserve the inner products of the vectors.

It turns out that this straightforward idea is not trivial to implement. The first challenge is that we must preserve the tensor product structure of our vectors in order to ensure that the query algorithm can apply queries, so we must be careful about the part of the vectors that we compress. The second challenge is that the compression only approximately preserves the inner products of the compressed vectors so we need the robust dual adversary algorithm described in Theorem 6.

Formally stated in Theorem 14, given an $f$-deciding vector set with maximum rank $\kappa'$ and size $A$, we show how to build a quantum algorithm that succeeds with probability $2/3$ and operates in a Hilbert space of dimension $O((\kappa'^2 + A^4\kappa')n)$ with quantum query complexity $O(A)$. Since $A = O(n)$, as discussed below Theorem 3, the number of qubits needed to run the algorithm is no more than $O(\log(\kappa' n))$.

Thus, this approximate compression using the JL lemma achieves the same space complexity as the exact compression of Theorem 9, to within a constant multiplicative factor. This may seem surprising that we are not able to do better, since we are no longer requiring the constraints are exactly satisfied. However, the compression dimension in the JL lemma has a polynomial dependence on the allowed error, and since the amount of error we can tolerate roughly scales with maximum rank, we do not get as much compression as one might hope for.

We now describe at a high level how we prove Theorem 14. While an optimal deciding vector set might use complex vectors, the following lemma, which we prove in Ref. [17], shows that at a small cost in increased vector dimension, we can restrict to real vectors:

▶ **Lemma 10.** *If there is an $f$-deciding vector set with complex numbers of dimension $m$ and size $A$, there exists an $f$-deciding vector set with only real numbers of dimension $2m$ and size $A$.*

The proof of Lemma 10 proceeds by creating a new vector set from the original where each new real vector consists of the real part of the original complex vector stacked on top of the imaginary part of the original complex vector.

While the standard Johnson-Lindenstrauss lemma guarantees that there is a compression matrix that approximately preserves the $l_2$-norm difference of any two vectors in a set, we use the following corollary, which shows that the compression approximately preserves inner products in addition to distances, which we prove in Ref. [17]. Our proof of Corollary 11 is similar to a similar result in [38], except that we do not assume the vectors have norm 1.

▶ **Corollary 11.** *Given $\varepsilon > 0$, a set of finite vectors $V \subset \mathbb{R}^d$, and a number $N > 8\ln(|V|)/\varepsilon^2$, there is a compression matrix $S \in \mathbb{R}^{N\times d}$ such that for $|v\rangle, |u\rangle \in V$,*

$$(S|u\rangle)^\dagger(S|v\rangle) = \langle u|v\rangle \pm 2\varepsilon(\||u\rangle\|^2 + \||v\rangle\|^2). \tag{19}$$

The Johnson-Lindenstrauss lemma guarantees the existence of such a compression matrix $S$, and it can be found probabilistically by sampling random projections. It requires $O(|X|n)$ time to find such a satisfying projection via random sampling [18]. For our purposes, this contributes to classical preprocessing time and space resources, and not towards the quantum query complexity or quantum space use of the quantum algorithm itself. In particular, this sampling requires no queries, so does not contribute to the query complexity.

We now describe how we use Johnson-Lindenstrauss to compress our deciding vector set. Let $\{|v_{x,i}\rangle\}$ be a real $f$-deciding vector set with size $A$, dimension $m$, and maximum rank $\kappa'$. Define $\{|\psi_x\rangle\}_{x:f(x)=1}$ and $\{|\phi_x\rangle\}_{x:f(x)=0}$ as in Equations (6) and (8) in Section 2. Let $\kappa$ be the rank of $\{|\psi_x\rangle\}_{x:f(x)=1}$. (We show in Ref. [17] that $\kappa' \leq \kappa \leq 2n\kappa'$.)

To compress our vectors, it suffices to compress their orthonormal basis. Let $\{|\zeta_j\rangle\}_{j\in[\kappa]}$ be an orthonormal basis for the space spanned by $\{|\psi_x\rangle\}_{x:f(x)=1}$. Then there are (non-unique) real numbers $\{\alpha_{j,x} \in \mathbb{R}\}_{j\in[n],x\in f^{-1}(1)}$ such that

$$|\zeta_j\rangle = \sum_{x:f(x)=1} \alpha_{j,x}|\psi_x\rangle. \tag{20}$$

We will approximately preserve the structure of the vectors $|\zeta_j\rangle$ in the compression. Thus we define their components

$$|v_{j,i,b}\rangle = \sum_{\substack{x:f(x)=1\\ x_i=b}} \frac{\alpha_{j,x}}{\sqrt{\nu}_x}|v_{x,i}\rangle, \quad \forall j \in [\kappa], i \in [n], b \in \{0,1\}. \tag{21}$$

We will use the random compression matrix $S$ from Corollary 11 to compress the following set of vectors to error $\varepsilon$, as in Corollary 11, (and the compression dimension $N$ will be chosen later to achieve the desired value of $\varepsilon$):

$$\{|v_{j,i,b}\rangle\}_{j\in[\kappa],i\in[n],b\in\{0,1\}} \bigcup \{|v_{y,i}\rangle\}_{y:f(y)=0,i\in[n]}. \tag{22}$$

We use these compressed vectors to define

$$\begin{aligned}
\forall x : f(x) = 1, \quad |\psi'_x\rangle &= \left[|\hat{0}\rangle\langle\hat{0}| + (I \otimes S \otimes I)\right]|\psi_x\rangle,\\
\forall x : f(x) = 0, \quad |\phi'_x\rangle &= \left[|\hat{0}\rangle\langle\hat{0}| + (I \otimes S \otimes I)\right]|\phi_x\rangle,\\
\forall j \in [\kappa], \quad |\zeta'_j\rangle &= \left[|\hat{0}\rangle\langle\hat{0}| + (I \otimes S \otimes I)\right]|\zeta_j\rangle.
\end{aligned} \tag{23}$$

As one would expect, the primed, compressed versions of these vectors have approximately the properties of the uncompressed version, as follows:

▶ **Lemma 12.** *For* $\{|\zeta'_j\rangle\}_{j\in[\kappa]}$, $\{|\psi'_x\rangle\}_{x:f(x)=1}$ *and* $\{|\phi'_x\rangle\}_{x:f(x)=0}$ *as described in Equation* (23)*, these vectors have the following properties*

1. $\forall j,l \in [\kappa], \langle\zeta'_j|\zeta'_l\rangle \in \delta_{j,l} \pm 4\varepsilon$
2. $\forall j \in [\kappa], x \in f^{-1}(0), |\langle\zeta'_j|\phi'_x\rangle| \leq 2\varepsilon(c+1)A.$
3. $\forall x : f(x) = 1, \left|\||\psi'_x\rangle\|^2 - 1\right| \leq 4\varepsilon\kappa$ *and* $\forall x : f(x) = 0, |\||\phi'_x\rangle\| - 1| \leq 3\varepsilon.$

The proof of Lemma 12 uses Corollary 11 in fairly straightforward ways.

Let $\Delta'$ be the orthogonal projector onto the space spanned by $\{|\psi'_x\rangle\}_{x:f(x)=1}$ and the reflection $R$ be $2\Delta' - I$. By definition, observe that $R|\psi'_x\rangle = |\psi'_x\rangle$, so Theorem 6 Item 1 is satisfied with $\varepsilon_\psi = 0$. Additionally, because $|\phi'_x\rangle$ has the structure

$$|\phi'_x\rangle \propto |\hat{0}\rangle + \sum_{i\in[n]} |i\rangle|v'_{x,i}\rangle|\bar{x}_i\rangle \tag{24}$$

we have $\Pi_x|\phi'_x\rangle \propto |\hat{0}\rangle$, as required by Theorem 6 Item 2. All that is left is to show that $\|(I+R)|\phi'_x\rangle\| \leq \varepsilon_\phi$.

▶ **Lemma 13.** *Consider* $\varepsilon$ *so that* $\varepsilon\kappa < 1/12$*. For* $R$ *as defined below Lemma 12 and* $|\phi'_x\rangle$ *defined using Equations* (8) *and* (23)*, we have* $\|(I+R)|\phi'_x\rangle\| \leq 8\varepsilon(c+1)A\sqrt{\kappa}$*.*

We prove Lemma 13 in Ref. [17]. The main idea is to write $\Delta'$ in terms of the vectors $\{|\zeta'\rangle\}$, and then use Lemma 12 Item 2. Along the way, we show how to use Gram-Schmidt to build an orthonormal basis from $\{|\zeta'_j\rangle\}$, which is already almost orthonormal by Lemma 12 Item 1 (see Ref. [17] for details).

With Lemma 13 in hand, the conditions of Theorem 6 are satisfied and we apply it to our compressed vectors.

▶ **Theorem 14.** *Consider a Boolean function* $f : X \to \{0,1\}$ *where* $X \subseteq \{0,1\}^n$ *and an* $f$*-deciding vector set with maximum rank* $\kappa$ *and size* $A$*. Using Johnson-Lindenstrauss compression, we can compress the* $f$*-deciding vector set to produce a quantum algorithm that correctly evaluates* $f(x)$ *with probability* $2/3$ *for every input* $x \in X$ *with* $O(A)$ *quantum query complexity. The algorithm uses* $O(\log \kappa n)$ *qubits.*

**Proof of Theorem 14.** We set

$$\Theta = \frac{1}{4\sqrt{c}A}, \quad \varepsilon = \min\left\{\frac{1}{4c\kappa}, \frac{1}{32\sqrt{c}(c+1)A^2\sqrt{\kappa}}\right\}, \quad \delta = \frac{1}{25}, \quad \text{and} \quad c = 100. \tag{25}$$

With these choices, we bound the failure probability below $1/3$ for all inputs $x$. (Note $c$ appears in Equations (6) and (8).)

**Case $f(x) = 1$.** By Theorem 6, for $x$ such that $f(x) = 1$, we have that when $\varepsilon_\psi = 0$, the probability of measuring a phase of 0 is at least

$$\left(\sqrt{\nu_x} - \sqrt{\nu_x\||\psi'_x\rangle\|^2 - 1}\right)^2 (1-\delta) - \delta. \tag{26}$$

We know that $1 \leq \nu_x \leq 1 + 1/c = 1.01$ from Equation (7) and $|\||\psi'_x\rangle\|^2 - 1| \leq 4\varepsilon\kappa \leq 1/100$ from Lemma 12 Item 3 and Equation (25) when $c = 100$, so Equation (26) is at least

$$\left(\sqrt{1} - \sqrt{1.01 \cdot 1.01 - 1}\right)^2 (1-\delta) - \delta \geq 2/3 \tag{27}$$

where the final inequality is satisfied for $\delta = 1/25$.

**Case $\mathbf{f(x) = 0}$.** By Theorem 6, for $x$ such that $f(x) = 0$, we have that the probability of measuring a phase of 0 is at most

$$\mu_x \left( \varepsilon_\phi + \frac{\Theta}{2} \| |\phi'_x\rangle \| \right)^2 + \delta. \tag{28}$$

We know that $\mu_x \leq 1 + cA^2$ from Equation (9), $\varepsilon_\phi \leq 8\varepsilon(c+1)A\sqrt{\kappa}$ from Lemma 13, and $\| |\phi'_x\rangle \| \leq 1 + 3\varepsilon$ from Lemma 12 Item 3. So the probability of measuring a 0 phase is at most

$$(1 + cA^2) \left( 8\varepsilon(c+1)A\sqrt{\kappa} + \frac{\Theta}{2}(1 + 3\varepsilon) \right)^2 + \delta. \tag{29}$$

With $\Theta$, $\varepsilon$, $\delta$, and $c$ as set in Equation (25), continuing from Equation (29), we have that probability of failure when $f(x) = 0$ is at most

$$(1 + cA^2) \left( \frac{1}{4\sqrt{c}A} + \frac{1}{4\sqrt{c}A} \right)^2 + \delta \leq \frac{1}{4cA^2} + \frac{1}{4} + \delta \leq \frac{1}{3} \tag{30}$$

since $A \geq 1$.

To achieve this compression with $\varepsilon$ as desired we look to Corollary 11 to see what compression dimension is achievable. From Equation (22), we see we are compressing at most $3|X|n$ vectors. Thus we require a compression dimension

$$N = O(\log(|X|n)/\varepsilon^2) = O((\kappa^2 + A^4\kappa)\log(|X|n)). \tag{31}$$

Then since our unitary $U$ acts on $O(\log(nN))$ qubits, by Theorem 6, the space complexity is

$$O(\log nN + \log A) = O\left(\log\left(An(\kappa^2 + A^4\kappa)\log(|X|n)\right)\right) = O(\log(\kappa n)). \tag{32}$$

where we've used that $|X| \leq 2^n$ and $A = O(n)$. Also, from Theorem 6, the query complexity is $O(A)$. ◀

▶ **Corollary 15.** *If there are polynomially many 1-valued or 0-valued inputs to a function $f : X \to \{0, 1\}$, then there is a query-optimal quantum algorithm that evaluates $f$, and that uses $O(\log n)$ qubits.*

**Proof.** Notice that $\kappa \leq n_1$ where $n_1$ the number of 1-valued inputs to $f$. When $\kappa = O(n^d)$ for $d = O(1)$, by Theorem 9 or Theorem 14, we have that for any deciding vector set for $f$ with size $A$, we can create an algorithm with query complexity $O(A)$ whose space complexity is $O(\log n)$. Since there is always a deciding vector set for $f$ with size $A$ such that $O(A)$ is the optimal query complexity of $f$ [44], our results imply that there exists a query-optimal algorithm that uses logarithmic space. For the case of polynomially many 0-valued inputs, we use $\neg f$. ◀

## 5 Algorithm from a Numerical Solution

While the dual adversary provides a method of designing optimal query algorithms, in general it might be hard to find an optimal solution. However, since the problem can be formulated as a semidefinite program, we can find a numerical solution. We show that numerical solutions that only approximately satisfy the dual adversary constraints can be used to produce bounded-error quantum algorithms within a constant factor of the objective function value of the numerical solution.

We first provide a theoretical result that shows how an algorithm can be constructed from an *approximate* deciding vector set, a vector set that only approximately satisfies Equation (3). Then we introduce a classical Python package implemented specifically to solve the general adversary dual SDP and show that its solutions often satisfy the error bounds required by our theoretical results.

## 5.1 Application of Robust Dual Adversary Algorithm

In previous sections we assumed access to an exact solution to the general adversary dual which we used to produce approximate solutions. In this section, we use a finite precision SDP solver to obtain an approximate solution and then build a bounded-error quantum algorithm with the robust dual adversary algorithm described in Theorem 6.

▶ **Theorem 16.** *Consider a Boolean function $f : X \to \{0,1\}$ where $X \subseteq \{0,1\}^n$ and an approximate $f$-deciding vector set $\{|v_{x,j}\rangle\}_{x\in X, j\in[n]}$ in the sense that*

$$\varepsilon \coloneqq \max_{x,y:f(x)\neq f(y)} |\langle\psi_x|\phi_y\rangle|, \tag{33}$$

*is small as defined below, where $|\psi_x\rangle$, $|\phi_x\rangle$ are as in Equations (6) and (8). Let $A$ be the size and $m$ be the dimension of the approximate $f$-deciding vector set, with size and dimension defined as in Definition 2. Consider a matrix $M$ with rows $|\psi_x\rangle_{x:f(x)=1}$. Let the singular values of $M$ be $s_1 \geq s_2 \geq \cdots \geq s_\kappa \geq s_{\kappa+1} \coloneqq 0$ and $n_1$ be $|\{x : f(x) = 1\}|$. If there exists $\kappa^* \in [\kappa]$ such that*

$$\varepsilon \leq \frac{1}{\sqrt{n_1}}\left(\frac{s_{\kappa^*}}{2\sqrt{c}A} - s_{\kappa^*+1}\right) \quad \text{and} \quad s_{\kappa^*+1} \leq \frac{1}{2\sqrt{1000c}A}, \tag{34}$$

*then there is a quantum algorithm that correctly evaluates $f$ with probability at least $2/3$ with at most $O(A)$ queries and $O(\log(nm))$ qubits.*

Given any numerical solution, we can simply set $\kappa^* = \kappa$ in which case we require $\varepsilon < s_\kappa/(2\sqrt{cn_1}A)$. However, if the singular values fall off sharply then we can obtain a less stringent constraint on $\varepsilon$, which in turn leads to less precision required by the numerical solver. So in practice, we search for any $\kappa^* \in [\kappa]$ that gives a large enough bound to accommodate the $\varepsilon$ we observe in our numerical solution.

To prove Theorem 16, we apply Theorem 6. For this application, we set $R$ to be equal to a reflection over the space spanned by the first $\kappa^*$ right singular vectors of $M$, the matrix whose rows are the vectors $\{|\psi_x\rangle\}_{x:f(x)=1}$. We use the following two lemmas to show that this reflection approximately preserves the vectors $\{|\psi_x\rangle\}_{x:f(x)=1}$ and mostly destroys vectors that are almost orthogonal to all vectors in $\{|\psi_x\rangle\}_{x:f(x)=1}$. Their proofs, found in Ref. [17], use standard results from the singular value decomposition approach to approximating of matrices.

▶ **Lemma 17.** *Let $M$ be the matrix whose rows are the vectors $\{|\psi_x\rangle\}_{x\in X_1}$ for some set $X_1$, and denote $M$'s singular values by $s_1 \geq s_2 \geq \cdots \geq s_\kappa$. Let $\Delta'$ be the orthogonal projector onto the first $\kappa^*$ right singular vectors of $M$. Then $\forall x \in X_1$, $(2\Delta' - I)|\psi_x\rangle = |\psi_x\rangle + |\eta\rangle$, where $\||\eta\rangle\| \leq 2s_{\kappa^*+1}$ and $s_{\kappa^*+1} = 0$ if $\kappa^* = \kappa$.*

▶ **Lemma 18.** *For disjoint sets $X_1$ and $Y$ and sets of vectors $\{|\psi_x\rangle\}_{x\in X_1}$ and $\{|\phi_y\rangle\}_{y\in Y}$ such that*

$$|\langle\psi_x|\phi_y\rangle| \leq \varepsilon \quad \forall x \in X_1, y \in Y, \tag{35}$$

*let $M$ be the matrix whose rows are the vectors $\{|\psi_x\rangle\}_{x\in X_1}$ and denote its singular values by $s_1 \geq s_2 \geq \cdots \geq s_\kappa$. Let $\Delta'$ be the orthogonal projector onto the first $\kappa^*$ right singular vectors of $M$. Then $\forall y \in Y$, $(2\Delta' - I)|\phi_y\rangle = |\eta\rangle$, where $\||\eta\rangle\| \leq \frac{s_{\kappa^*+1}+\varepsilon\sqrt{|X_1|}}{s_{\kappa^*}}$ and $s_{\kappa^*+1} = 0$ if $\kappa^* = \kappa$.*

We now use Lemmas 17 and 18 to apply Theorem 6 and prove Theorem 16.

**Proof of Theorem 16.** Let $\Delta'$ be the orthogonal projector onto the first $\kappa^*$ right singular vectors of $M$, and set $R = 2\Delta' - I$ so as in Theorem 6, $U = (2\Pi_x - I)R$. Then

$$\begin{aligned}
\varepsilon_\psi &\coloneqq \|(I-U)|\psi_x\rangle\| = \||\psi_x\rangle - (2\Pi_x - I)R|\psi_x\rangle\| \\
&= \||\psi_x\rangle - (2\Pi_x - I)(|\psi_x\rangle + |\eta_x\rangle)\| \\
&= \|(2\Pi_x - I)|\eta_x\rangle\| \leq 2s_{\kappa^*+1} \quad \text{(By Lemma 17 and defs of } \Pi_x, |\psi_x\rangle\text{)} \\
\varepsilon_\phi &\coloneqq \|(I+R)|\phi_y\rangle\| = \|2\Delta'|\phi_y\rangle\| \leq 2\frac{s_{\kappa^*+1} + \varepsilon\sqrt{n_1}}{s_{\kappa^*}}. \quad \text{(By Lemma 18)}
\end{aligned}$$

Then by Theorem 6, if $f(x) = 1$, the probability of measuring a phase of 0 is at least

$$\left(\sqrt{\nu_x(1 - \frac{5\varepsilon_\psi^2}{\Theta^2})} - \sqrt{\nu_x\||\psi_x\rangle\|^2 - 1}\right)^2 (1-\delta) - \delta \tag{36}$$

$$\geq \left(\sqrt{(1 - \frac{20s_{\kappa^*+1}^2}{\Theta^2})} - \sqrt{\nu_x\||\psi_x\rangle\|^2 - 1}\right)^2 (1-\delta) - \delta \tag{37}$$

$$\geq \left(\sqrt{1 - \frac{20s_{\kappa^*+1}^2}{\Theta^2}} - \sqrt{1/c}\right)^2 (1-\delta) - \delta \geq 2/3 \tag{38}$$

where we set $c = 100$, $\delta = 1/25$, and $\Theta = (2\sqrt{c}A)^{-1}$. In addition, we used that $\nu_x$ is between 1 and $1 + 1/c$ and that $\||\psi_x\rangle\| = 1$, both by Equation (6). Recall that $s_{\kappa^*+1}^2 \leq \Theta^2/1000$ by assumption.

In the other case, where $f(x) = 0$, the probability of measuring a phase of 0 is at most

$$\mu_x\left(2\frac{s_{\kappa^*+1} + \varepsilon\sqrt{n_1}}{s_{\kappa^*}} + \Theta/2\||\phi_x\rangle\|\right)^2 + \delta \leq (1+cA^2)\left(2\frac{s_{\kappa^*+1} + \varepsilon\sqrt{n_1}}{s_{\kappa^*}} + \Theta/2\right)^2 + \delta \tag{39}$$

$$= (1+cA^2)\left(\frac{1}{4\sqrt{c}A} + \frac{1}{4\sqrt{c}A}\right)^2 + \delta \tag{40}$$

$$\leq 1/3 \qquad \text{(by the proof of Theorem 14)}$$

when

$$\frac{s_{\kappa^*+1} + \varepsilon\sqrt{n_1}}{s_{\kappa^*}} < \frac{1}{8\sqrt{c}A} \iff \varepsilon < \frac{1}{\sqrt{n_1}}\left(\frac{s_{\kappa^*}}{2\sqrt{c}A} - s_{\kappa^*+1}\right). \tag{41}$$

The algorithm uses within a multiplicative factor of $\frac{1}{\Theta}\log(\frac{1}{\delta}) = 20A\log(20)$ queries by Lemma 4. ◀

The obvious question is whether the conditions in Theorem 16 are met in practice. We show in the next subsection that the conditions are met in the vast majority of numerical solutions to the general adversary dual for the random Boolean functions we find on functions of up to 25 bits with domain size 32.

## 5.2 Experiments

In this section, we describe how the numerical error (defined in Equation (33)) behaves in practice.

The general adversary dual (Definition 1) is a semidefinite programming (SDP) problem. In order to solve the SDP numerically, we first reformulate it in the following standard form:

$$\min_{\mathbf{X}\in\mathbf{S}^n} \operatorname{tr}(\mathbf{C}\mathbf{X}) \quad \text{s.t.} \quad \mathcal{A}(\mathbf{X}) = \mathbf{b} \quad \text{and} \quad \mathbf{X} \succeq 0 \tag{42}$$

where $\mathbf{S}^n$ is the set of $n \times n$ symmetric matrices, $\mathbf{C} \in \mathbf{S}^n$, $\operatorname{tr}(\cdot)$ is the trace, $\mathbf{b} \in \mathbb{R}^m$ is the constraint vector, and

$$\mathcal{A}(\mathbf{X}) \coloneqq [\operatorname{tr}(\mathbf{A}^1\mathbf{X}), \ldots, \operatorname{tr}(\mathbf{A}^m\mathbf{X})]^\top \tag{43}$$

for constraint matrices $\mathbf{A}^i \in \mathbf{S}^n$. The reformulation requires converting the constraints and introducing appropriate slack variables. The constraints for our SDP are particularly sparse which makes it inefficient to use standard packages like CVXOPT and SDPA [21, 24]. Instead, we use the alternating direction method of [50] which is specifically designed for SDP problems with sparse structure and orthogonal constraints. The pseudocode appears in Algorithm 1.

**Algorithm 1** Alternating direction augmented Lagrangian method [50].

**Require:** Constraint matrices $\mathbf{A}, \mathbf{C} \in \mathbf{S}^n$, constraint vector $\mathbf{b} \in \mathbb{R}^m$, iterations $T$, tolerance $t \geq 0$

**Ensure:** Output $\mathbf{X}$ approximately satisfies Equation (42)

$\mathbf{X}^0 \leftarrow \mathbf{0}_{n\times n}$ ▷ Zero matrix

$\mathbf{S}^0 \leftarrow \mathbf{I}_{n\times n}$

**for** $k = 0, 1, \ldots, T-1$ **do**

$y^{k+1} \leftarrow -(\mathcal{A}\mathcal{A}^*)^+(\mathcal{A}(\mathbf{X}^k) - \mathbf{b} + \mathcal{A}(\mathbf{S}^k - \mathbf{C}))$ ▷ $(\cdot)^+$ denotes Moore-Penrose pseudoinverse

$\mathbf{V}^{k+1} \leftarrow \mathbf{C} - \mathcal{A}^*(y^{k+1}) - \mathbf{X}^k$

$\mathbf{S}^{k+1} \leftarrow \mathbf{Q}_+\mathbf{\Sigma}_+\mathbf{Q}_+^\top$ ▷ $\mathbf{Q}_+, \mathbf{\Sigma}_+$ contain the non-negative eigendecomposition of $\mathbf{V}^{k+1}$

$\mathbf{X}^{k+1} \leftarrow \mathbf{S}^{k+1} - \mathbf{V}^{k+1}$

$\mathbf{X}^{k+1} \leftarrow \operatorname{round}(\mathbf{X}^{k+1})$ ▷ For entries within $t$ of 0 or 1, round to nearest integer

**end for**

$\mathbf{X} \leftarrow \mathbf{X}^{T-1}$

We slightly adapt Algorithm 1 to our problem: We store each matrix in a sparse format, round entries of the solution after every iteration, and use the Moore-Penrose pseudoinverse.

The first natural question is how well Algorithm 1 performs. We test this by generating random Boolean functions $f : X \to \{0, 1\}$ where $X \subseteq \{0, 1\}^n$ for different values of $n$. Since the dimension of the SDP grows exponentially with $|X|$, we fix $|X| = 32$ for our experiments. For each instance, we compute the maximum numerical error

$$\varepsilon \coloneqq \max_{x,y:f(x)\neq f(y)} |\langle\psi_x|\phi_y\rangle|. \tag{44}$$

The results in Theorem 16 depend on the error $\varepsilon$ being small so it's important that we can obtain solutions with small error efficiently. Figure 1 shows how $\varepsilon$ decreases with the number of iterations $T$ of the SDP solver.

The next question is whether the error is sufficiently small to satisfy the requirements of Theorem 16. Figure 2 shows how $\varepsilon$ is typically much smaller than the bound required in Theorem 16 for random functions of up to 25 bits with domain size 32. Our experiments test for whether $\varepsilon$ satisfies the bound of Theorem 16 in the case that $\kappa^* = \kappa$. It could be that even larger $\varepsilon$ is tolerated by considering $\kappa^* < \kappa$.

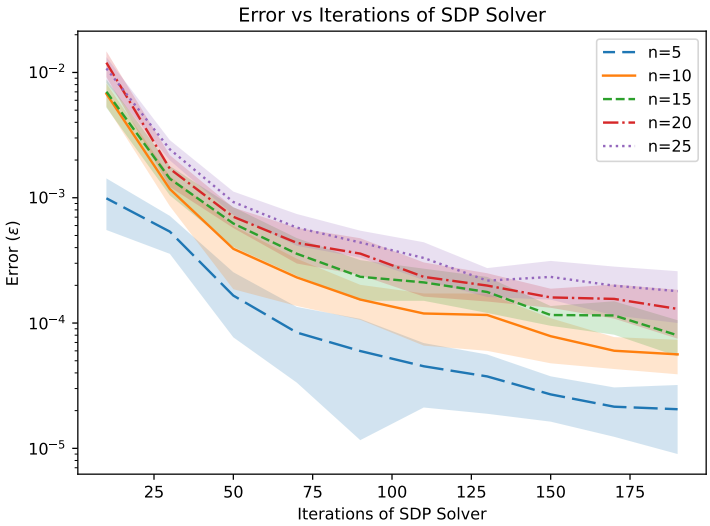

**Figure 1** For random Boolean functions with a domain of fixed size, the maximum numerical error decreases with the number of iterations of the SDP solver. Note: the vertical axis is on a logarithmic scale and the shaded regions contain one standard deviation from 20 random instances.

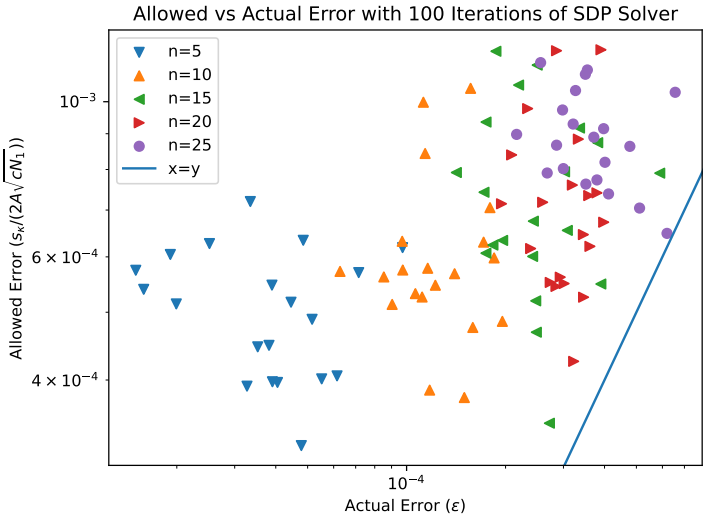

**Figure 2** For random Boolean functions with a domain of fixed size, the maximum numerical error stays below the threshold required to construct a provably correct bounded-error quantum algorithm. Note: both axes are on a logarithmic scale and the green region above the diagonal line indicates the error is small enough.

## Abstract

The average properties of the well-known *Subset Sum Problem* can be studied by means of its randomised version, where we are given a target value $z$, random variables $X_1, \ldots, X_n$, and an error parameter $\varepsilon > 0$, and we seek a subset of the $X_i$s whose sum approximates $z$ up to error $\varepsilon$. In this setup, it has been shown that, under mild assumptions on the distribution of the random variables, a sample of size $\mathcal{O}(\log(1/\varepsilon))$ suffices to obtain, with high probability, approximations for all values in $[-1/2, 1/2]$. Recently, this result has been rediscovered outside the algorithms community, enabling meaningful progress in other fields. In this work, we present an alternative proof for this theorem, with a more direct approach and resourcing to more elementary tools.

## 1 Introduction

In the *Subset Sum Problem (SSP)*, one is given as input a set of $n$ integers $X = \{x_1, x_2, \ldots, x_n\}$ and a target value $z$, and wishes to decide if there exists a subset of $X$ that sums to $z$. That is, one is to reason about a subset $S \subseteq [n]$ such that $\sum_{i \in S} x_i = z$. The special case where $z$ is half of the sum of $X$ is known as the *Number Partition Problem (NPP)*. The converse reduction is also rather immediate.[1]

[1] To find a subset of $X$ summing to $z$, one only needs to solve the NPP for the set $X \cup \{2z, \sum_{i \in [n]} x_i\}$. By doing so, one of the parts must consist of the element $\sum_{i \in [n]} x_i$ alongside the desired subset.

Be it in either of these forms, the SSP finds applications in a variety of fields, ranging from combinatorial number theory [31] to cryptography [20, 26]. In complexity theory, the SSP is a well-known NP-complete problem, being a common base for NP-completeness proofs. In fact, the NPP version figures among Garey and Johnson's six basic NP-hard problems [19]. Under certain circumstances, the SSP can be challenging even for heuristics that perform well for many other NP-hard problems [25, 30], and a variety of dedicated algorithms have been proposed to solve it [10, 17, 22–24]. Nonetheless, it is not hard to solve it in polynomial time if we restrict the input integers to a fixed range [5]. It suffices to recursively list all achievable sums using the first $i$ integers: we start with $A_0 = \{0\}$ and compute $A_{i+1}$ as $A_i \cup \{a + x_{i+1} \mid a \in A_i\}$. For integers in the range $[0, R]$, the search space has size $\mathcal{O}(nR)$.

Studying how the problem becomes hard as we consider larger ranges of integers (relative to $n$) requires a randomised version of the problem, the *Random Subset Sum Problem (RSSP)*, where the input values are taken as independently and identically distributed random variables. In this setup, the work [6] proved that the problem experiences a phase transition in its average complexity as the range of integers increases.

The result we approach in this work comes from related studies on the typical properties of the problem. In [27] the author proves that, under fairly general conditions, the expected minimal distance between a subset-sum and the target value is exponentially small. More specifically, they show the following result.

▶ **Theorem 1** (Lueker, 1998). *Let $X_1, \ldots, X_n$ be independent uniform random variables over $[-1, 1]$, and let $\varepsilon \in (0, 1/3)$. There exists a universal constant $C > 0$ such that, if $n \geq C \log(1/\varepsilon)$, then, with probability at least $1 - \varepsilon$, for all $z \in [-1, 1]$ there exists $S_z \subseteq [n]$ for which*

$$\left| z - \sum_{i \in S_z} X_i \right| \leq \varepsilon.$$

That is, a rather small number (of the order of $\log \frac{1}{\varepsilon}$) of random variables suffices to have a high probability of approximating not only a single target $z$, but all values in an interval.

Even though Theorem 1 is stated and proved for uniform random variables and target values in $[-1, 1]$, it is not hard to extend the result to a broad class of distributions[2] and a wider range of targets. This generality makes the theorem a powerful tool for the analysis of random structures and has recently proven to be particularly useful in the field of Machine Learning, taking part in a proof of the Strong Lottery Ticket Hypothesis [29] and in subsequent related works [11, 13, 14, 18], and in Federated Learning [32].

Generalisations of the RSSP have played important roles in the study of random Knapsack problems [3,4], and to random binary integer programs [7,8]. In particular, the works [2,7,8,14] recently provided an extension of Theorem 1 to multiple dimensions. As for the equivalent Random Number Partitioning Problem, [12] recently generalised [6] and the integer version of the RSSP to non-binary integer coefficients.

The simplicity and ubiquity of the SSP have granted the related results a special didactic place. Be it as a first example of an NP-complete problem [19], a path to science communication [21], or simply as a frame for the demonstration of advanced techniques [28], it has been a tool to make important, but sometimes complicated, ideas easier to communicate.

[2] Distributions whose probability density function $f$ satisfies $f(x) \geq b$ for all $x \in [-a, a]$, for some constants $a, b > 0$ (see Corollary 3.3 from [27]).

This work offers a substantially simpler alternative to the original proof of Theorem 1 by following a general framework introduced in the context of the analysis of Rumour Spreading algorithms [15]. Originally, the work [27] approaches Theorem 1 by considering the random variable associated with the proportion of the values in the interval $[-1, 1]$ that can be approximated up to error $\varepsilon$ by the sum of some subset of the first $t$ variables, $X_1, \ldots, X_t$.

After restricting to some specific types of subsets, they proceed to evaluate the expected per-round growth of this proportion, conditioned on the outcomes of $X_1, \ldots, X_t$. Their strategy is to analyse this expected increase by martingale theory, which only becomes possible after a non-linear transformation of the variables of interest. Those operations hinder any intuition for the obtained martingale. Nonetheless, a subsequent application of the Azuma-Hoeffding bound [1] followed by a case analysis leads to the result.

The argument presented here starts in the same direction as the original one, tracking the mass of values with suitable approximations as we reveal the values of the random variables $X_1, \ldots, X_n$ one by one. However, we quickly diverge from [27], managing to obtain an estimation of the expected growth of this mass without discarding any subset-sum. We eventually restrict the argument to some types of subsets, but we do so at a point where the need for such restriction is clear.

We proceed to directly analyse the estimation obtained, without any transformations. Following [15], this estimation reveals two expected behaviours in expectation, which can be analysed similarly: as we consider the first variables, the proportion of approximated values grows very fast; then, after a certain point, the proportion of non-approximable values decreases very fast.

We remark that, while Theorem 1 crucially relies on tools from martingale theory such as Azuma-Hoeffding's inequality, which are not part of standard Computer Science curricula, our argument makes use of much more elementary results[3] which should make it accessible enough for an undergraduate course on randomised algorithms.

## 2 Our argument

In this section, we provide an alternative argument for proving Theorem 1. It takes shape much like the pseudo-polynomial algorithm we described in the introduction. Leveraging the recursive nature of the problem, we construct a process which, at time $t$, describes the proportion of the interval $[-1, 1]$ that can be approximated by some subset of the first $t$ variables.

We will show that with a suitable number of uniform variables (proportional to $\log(1/\varepsilon)$) a factor of $1 - \varepsilon/2$ of the values in $[-1, 1]$ can be approximated up to error $\varepsilon$. This implies that any $z \in [-1, 1]$ which cannot be approximated within error $\varepsilon$ is at most $\varepsilon$ away from a value that can. Therefore it is possible to approximate $z$ up to error $2\varepsilon$.

### 2.1 Preliminaries

Let $X_1, \ldots, X_n$ be realisations of random variables as in Theorem 1, and, without loss of generality, fix $\varepsilon > 0$. We say a value $z \in \mathbb{R}$ is *$\varepsilon$-approximated at time $t$* if and only if there exists $S \subseteq [t]$ such that $|z - \sum_{i \in S} X_i| < \varepsilon$. For $0 \leq t \leq n$, let $f_t \colon \mathbb{R} \to \{0, 1\}$ be the indicator function for the event "$z$ is $\varepsilon$-approximated at time $t$". Therefore, we have $f_0 = \mathbb{1}_{(-\varepsilon, \varepsilon)}$, since only the interval $(-\varepsilon, \varepsilon)$ can be approximated by an empty set of values. From there, we can

[3] Namely, the intermediate value theorem, Markov's inequality, and standard Hoeffding bounds.

exploit the recurrent nature of the problem: a value $z$ can be $\varepsilon$-approximated at time $t+1$ if and only if either $z$ or $z - X_{t+1}$ could already be approximated at time $t$. This implies that for all $z \in \mathbb{R}$ we have that

$$f_{t+1}(z) = f_t(z) + \big(1 - f_t(z)\big)\, f_t(z - X_{t+1}). \tag{1}$$

To keep track of the proportion of values in $[-1, 1]$ that can be $\varepsilon$-approximated at each step, we define, for each $0 \le t \le n$, the random variable

$$v_t = \frac{1}{2}\int_{-1}^{1} f_t(z)\,\mathrm{d}z.$$

For better readability, throughout the text we will refer to $v_t$ simply as "the volume."

As we mentioned, it suffices to show that, with high probability, at time $n$, enough of the interval is $\varepsilon$-approximated (more precisely, that $v_n \ge 1 - \varepsilon/2$) to conclude that the entire interval is $2\varepsilon$-approximated.

### 2.1.1 Expected behaviour

Our first lemma provides a lower bound on the expected value of $v_t$.

▶ **Lemma 2.** *For all $0 \le t < n$, it holds that*

$$\mathbb{E}\big[v_{t+1} \,\big|\, X_1, \ldots, X_t\big] \ge v_t \left[1 + \frac{1}{4}\,(1 - v_t)\right].$$

**Proof.** The definition of $v_t$ and the recurrence in Equation (1) give us that

$$\begin{aligned}
\mathbb{E}\big[v_{t+1} \,\big|\, X_1, \ldots, X_t\big] &= \mathbb{E}\left[\frac{1}{2}\int_{-1}^{1} f_{t+1}(z)\,\mathrm{d}z \,\middle|\, X_1, \ldots, X_t\right] \\
&= \int_{-1}^{1} \frac{1}{2}\left(\frac{1}{2}\int_{-1}^{1} f_t(z) + \big(1 - f_t(z)\big)\, f_t(z - x)\,\mathrm{d}z\right)\mathrm{d}x \\
&= \frac{1}{2}\int_{-1}^{1} f_t(z)\,\mathrm{d}z \int_{-1}^{1} \frac{1}{2}\,\mathrm{d}x + \frac{1}{2}\int_{-1}^{1}\frac{1}{2}\int_{-1}^{1} \big(1 - f_t(z)\big)\, f_t(z - x)\,\mathrm{d}z\,\mathrm{d}x \\
&= v_t + \frac{1}{4}\int_{-1}^{1} \big(1 - f_t(z)\big) \int_{-1}^{1} f_t(z - x)\,\mathrm{d}x\,\mathrm{d}z \\
&= v_t + \frac{1}{4}\int_{-1}^{1} \big(1 - f_t(z)\big) \int_{z-1}^{z+1} f_t(y)\,\mathrm{d}y\,\mathrm{d}z,
\end{aligned}$$

where the last equality holds by substituting $y = z - x$. For the previous ones, we apply the basic properties of integrals and Fubini's theorem to change the order of integration.

We now look for a lower bound for the last integral in terms of $v_t$. To this end, we exploit that, since all integrands are non-negative, for all $u \in [-1/2, 1/2]$ we have that

$$\begin{aligned}
\int_{-1}^{1} \big(1 - f_t(z)\big) \int_{z-1}^{z+1} f_t(y)\,\mathrm{d}y\,\mathrm{d}z &\ge \int_{u-\frac{1}{2}}^{u+\frac{1}{2}} \big(1 - f_t(z)\big) \int_{z-1}^{z+1} f_t(y)\,\mathrm{d}y\,\mathrm{d}z \\
&\ge \int_{u-\frac{1}{2}}^{u+\frac{1}{2}} \big(1 - f_t(z)\big) \int_{u-\frac{1}{2}}^{u+\frac{1}{2}} f_t(y)\,\mathrm{d}y\,\mathrm{d}z.
\end{aligned}$$

Both inequalities come from range restrictions: in the first, we use that $u \in [-1/2, 1/2]$ implies $[u-1/2, u+1/2] \subseteq [-1, 1]$; for the second, we have that $[u-1/2, u+1/2] \subseteq [z-1, z+1]$ for all $z \in [u-1/2, u+1/2]$.

To relate the expression to $v_t$ explicitly, we choose $u$ in a way that the window $[u-1/2, u+1/2]$ entails exactly half of $v_t$. The existence of such $u$ may become clear by recalling the definition of $v_t$. To make it formal, consider the function given by

$$h(u) = \frac{1}{2} \int_{u-\frac{1}{2}}^{u+\frac{1}{2}} f_t(y)\,\mathrm{d}y,$$

and observe that

$$\min\{h(-1/2),\, h(1/2)\} \leq \frac{v_t}{2}, \qquad \text{and} \qquad \max\{h(-1/2),\, h(1/2)\} \geq \frac{v_t}{2}.$$

Thus, by the intermediate value theorem, there exists $u^* \in [-1/2, 1/2]$ for which $h(u^*) = v_t/2$, that is, for which

$$\frac{1}{2} \int_{u^*-\frac{1}{2}}^{u^*+\frac{1}{2}} f_t(y)\,\mathrm{d}y = \frac{v_t}{2}.$$

Altogether, we can conclude that

$$\begin{aligned}
\mathbb{E}\left[v_{t+1} \,\middle|\, X_1, \ldots, X_t\right] &= v_t + \frac{1}{4} \int_{-1}^{1} \left(1 - f_t(z)\right) \int_{z-1}^{z+1} f_t(y)\,\mathrm{d}y\,\mathrm{d}z \\
&\geq v_t + \frac{1}{2} \int_{u^*-\frac{1}{2}}^{u^*+\frac{1}{2}} \left(1 - f_t(z)\right) \left(\frac{1}{2} \int_{u^*-\frac{1}{2}}^{u^*+\frac{1}{2}} f_t(y)\,\mathrm{d}y\right) \mathrm{d}z \\
&= v_t + \left(\frac{1}{2} - \frac{v_t}{2}\right) \frac{v_t}{2} \\
&= v_t \left[1 + \frac{1}{4}\left(1 - v_t\right)\right].
\end{aligned}$$

◀

Lemma 2 tells us that, if $v_t$ were to behave as expected, it should grow exponentially up to $1/2$, at which point $1 - v_t$ starts to decrease exponentially. The rest of the proof follows accordingly, with Section 2.2 analysing the progress of $v_t$ up to one half, and Section 2.3 analogously following the complementary value, $1 - v_t$, starting from one half. By building on the results from Section 2.2, we obtain fairly straightforward proofs in Section 2.3. Thus, the following subsection comprises the core of our argument.

## 2.2 Growth of the volume up to 1/2

Arguably, the main challenge in analysing the RSSP is the existence of over-time dependencies and deciding how to overcome it sets much of the course the proof will take. Our strategy consists in constructing another process which dominates the original one while being free of dependencies.

Let $\tau_1$ be the first time at which the volume exceeds $1/2$, that is, let

$$\tau_1 = \min\{t \geq 0 : v_t > 1/2\}.$$

We just proved that up to time $\tau_1$ the process $v_t$ enjoys exponential growth in expectation. In the following lemma, we apply a basic concentration inequality to translate this property into a constant probability of exponential growth for $v_t$ itself.

▶ **Lemma 3.** *Given $\beta \in (0, 1/8)$, let $p_\beta = 1 - \frac{7}{8(1-\beta)}$. For all integers $0 \leq t < \tau_1$ it holds that*

$$\Pr\left[v_{t+1} \geq v_t(1+\beta) \,\middle|\, X_1, \ldots, X_t,\, t < \tau_1\right] \geq p_\beta.$$

**Proof.** The result shall follow easily from reverse Markov's inequality [9, Lemma 4] and the bound from Lemma 2. However, doing so requires a suitable upper bound on $v_{t+1}$ and, while $2v_t$ would serve the purpose, such bound does not hold in general.

We overcome this limitation by fixing $t$ and considering how much $v_t$ would grow in the next step if we were to consider only values $\varepsilon$-approximated at time $t$ that happen to lie in $[-1, 1]$ after being translated by $X_{t+1}$. Making it precise by the means of the recurrence in Equation (1), we define

$$\tilde{v} = \frac{1}{2}\int_{-1}^{1} \Big[f_t(z) + \big(1 - f_t(z)\big)\, f_t(z - X_{t+1}) \cdot \mathbb{1}_{[-1,1]}(z - X_{t+1})\Big]\, \mathrm{d}z.$$

This expression differs from the one for $v_{t+1}$ only by the inclusion of the characteristic function of $[-1, 1]$. This not only implies that $\tilde{v} \leq v_{t+1}$, but also that $\tilde{v}$ can replace $v_{t+1}$ in the bound from Lemma 2, since the argument provided there eventually restricts itself to integrals within $[-1, 1]$, trivialising $\mathbb{1}_{[-1,1]}$. Moreover, as we obtain $\tilde{v}$ without the influence of values from outside $[-1, 1]$, we must have $\tilde{v} \leq 2v_t$. Finally, using that $t < \tau_1$ implies $v_t < 1/2$ and chaining the previous conclusions in respective order , we conclude that

$$\begin{aligned}
\Pr\left[v_{t+1} \geq v_t(1+\beta) \,\middle|\, X_1, \ldots, X_t, t < \tau_1\right] &\geq \Pr\left[\tilde{v} \geq v_t(1+\beta) \,\middle|\, X_1, \ldots, X_t, t < \tau_1\right] \\
&\geq \frac{\mathbb{E}[\tilde{v} \,|\, X_1, \ldots, X_t, t < \tau_1] - v_t(1+\beta)}{2v_t - v_t(1+\beta)} \\
&\geq \frac{\frac{9}{8}v_t - v_t(1+\beta)}{2v_t - v_t(1+\beta)} \\
&= 1 - \frac{7}{8(1-\beta)},
\end{aligned}$$

where we applied the reverse Markov's inequality in the second step. ◀

The previous lemma naturally leads us to look for bounds on $\tau_1$, that is, to estimate the time needed for the process to reach volume $1/2$. As expected, the exponential nature of the process yields a logarithmic bound.

▶ **Lemma 4.** *Let $t$ be an integer and given $\beta \in (0, 1/8)$, let $p_\beta = 1 - \frac{7}{8(1-\beta)}$ and $i^* = \left\lceil \frac{\log \frac{1}{2\varepsilon}}{\log(1+\beta)} \right\rceil$. If $t \geq i^*/p_\beta$, then*

$$\Pr\left[\tau_1 \leq t\right] \geq 1 - \exp\left[-\frac{2p_\beta^2}{t}\left(t - \frac{i^*}{p_\beta}\right)^2\right].$$

**Proof.** The main idea behind the proof is to define a new random variable which stochastically dominates $\tau_1$ while being simpler to analyse. We begin by discretising the domain $(0, 1/2]$ of the volume into sub-intervals $\{I_i\}_{0 \leq i \leq i^*}$ defined as follows:

$$\begin{cases}
I_0 = (0, \varepsilon], \\
I_i = \left(\varepsilon(1+\beta)^{i-1},\, \varepsilon(1+\beta)^i\right] \text{ for } 1 \leq i < i^*, \\
I_{i^*} = \left(\varepsilon(1+\beta)^{i^*-1},\, \frac{1}{2}\right],
\end{cases}$$

where $i^*$ is the smallest integer for which $\varepsilon\,(1+\beta)^{i^*} \geq 1/2$, that is, $i^* = \left\lceil \frac{\log \frac{1}{2\varepsilon}}{\log(1+\beta)} \right\rceil$.

Now, for each $i \geq 0$, we direct our interest to the number of steps required for $v_t$ to exit the sub-interval $I_i$ after first entering it. By Lemma 3, this amount is majorised by a geometric random variable $Y_i \sim \text{Geom}(p_\beta)$. Therefore, we can conclude that $\tau_1$ is stochastically dominated by the sum of such variables, that is, for $t \in \mathbb{N}$, we have that

$$\Pr[\tau_1 \geq t] \leq \Pr\left[\sum_{i=1}^{i^*} Y_i \geq t\right]. \tag{2}$$

Let $B_t \sim \text{Bin}(t, p_\beta)$ be a binomial random variable. For the sum of geometric random variables, it holds that $\Pr\left[\sum_{i=1}^{i^*} Y_i \leq t\right] = \Pr[B_t \geq i^*]$. Since $\mathbb{E}[B_t] = tp_\beta$, the Hoeffding bound for binomial random variables [16, Theorem 1.1] implies that, for all $\lambda \geq 0$, we have that $\Pr[B_t \leq tp_\beta - \lambda] \leq \exp(-2\lambda^2/t)$. Setting $t$ such that $tp_\beta - \lambda = i^*$, we obtain that

$$\begin{aligned}
\Pr\left[\sum_{i=1}^{i^*} Y_i \geq t\right] &\leq \Pr[B_t \leq i^*] \\
&\leq \exp\left[-\frac{2}{t}\left(tp_\beta - i^*\right)^2\right] \\
&= \exp\left[-\frac{2p_\beta^2}{t}\left(t - \frac{i^*}{p_\beta}\right)^2\right],
\end{aligned}$$

which holds as long as $\lambda = tp_\beta - i^* \geq 0$, that is, for all $t \geq \frac{1}{p_\beta}\left\lceil \frac{\log \frac{1}{2\varepsilon}}{\log(1+\beta)} \right\rceil$.

The thesis follows by applying this to Equation (2) and considering the complementary events. ◀

Since we are done with the analysis of the first phase, we can fix the value of $\beta$ and rearrange the bound in Lemma 4 to make it easier to apply later.

▶ **Corollary 5.** *Let $\varepsilon \in (0, \frac{1}{3})$, and let $t$ be an integer satisfying $t \geq 264 \log \frac{1}{\varepsilon}$. Then*

$$\Pr[\tau_1 \leq t] \geq 1 - \exp\left[-\frac{2}{225t}\left(t - 264 \log \frac{1}{\varepsilon}\right)^2\right].$$

**Proof.** Setting $\beta = \frac{1}{16}$ in Lemma 4 and, thus, $p_\beta = \frac{1}{15}$, it suffices to notice that

$$\frac{15 \log \frac{1}{2\varepsilon}}{\log \frac{17}{16}} + 15 \leq 264 \log \frac{1}{\varepsilon}.$$ ◀

## 2.3 Growth of the volume from 1/2

Here we study the second half of the process: from the moment the volume reaches $1/2$ up to the time it gets to $1 - \varepsilon/2$. We do so by analysing the complementary stochastic process, i.e., by tracking, from time $\tau_1$ onwards, the proportion of the interval $[-1, 1]$ that cannot be approximated up to error $\varepsilon$. More precisely, we consider the process $\{w_t\}_{t \geq 0}$, defined by $w_t = 1 - v_{\tau_1 + t}$.

We shall obtain results for $w_t$ similar to those we have proved for $v_t$. Fortunately, building on the previous results makes those proofs quite straightforward. We start by noting that a statement analogous to Lemma 2 follows immediately from the definition of $w_{t+1}$ and Lemma 2.

▶ **Corollary 6.** *For all $t \geq 0$, it holds that*

$$\mathbb{E}\big[w_{t+1} \,\big|\, X_1, \ldots, X_{\tau_1+t}\big] \leq w_t \left[1 - \frac{1}{4}\,(1 - w_t)\right].$$

Let $\tau_2$ the first time that $w_t$ gets smaller than or equal to $\varepsilon/2$, that is, let

$$\tau_2 = \min\left\{t \geq 0 : w_t \leq \varepsilon/2\right\}.$$

The following lemma bounds this quantity, in analogy to Lemma 4.

▶ **Lemma 7.** *For all $t > 0$, it holds that*

$$\Pr\left[\tau_2 \leq t\right] \geq 1 - \exp\left[-\frac{1}{8}\left(t - 8\log\frac{1}{\varepsilon}\right)\right].$$

**Proof.** Applying that $1 - w_t = v_{\tau_1+t} > 1/2$ to Corollary 6 gives the bound

$$\mathbb{E}\big[w_{t+1} \,\big|\, X_1, \ldots, X_{\tau_1+t}\big] \leq \frac{7}{8} w_t. \tag{3}$$

Moreover, from the conditional expectation theory, for any two random variables $X$ and $Y$, we have $\mathbb{E}\big[\mathbb{E}[X \,|\, Y]\big] = \mathbb{E}[X]$. From this and Equation (3), we can conclude that

$$\mathbb{E}[w_t] = \mathbb{E}\Big[\mathbb{E}\big[w_t \,\big|\, X_1, \ldots, X_{\tau_1+t-1}\big]\Big] \leq \frac{7}{8}\,\mathbb{E}\big[w_{t-1}\big],$$

which, by recursion, yields that

$$\mathbb{E}[w_t] \leq \left(\frac{7}{8}\right)^t \mathbb{E}[w_0] \leq \frac{1}{2}\left(\frac{7}{8}\right)^t.$$

Finally, by Markov's inequality,

$$\begin{aligned}\Pr\left[\tau_2 \geq t\right] &\leq \Pr\left[w_t \geq \frac{\varepsilon}{2}\right] \\ &\leq \frac{2\,\mathbb{E}[w_t]}{\varepsilon} \\ &\leq \frac{1}{\varepsilon}\left(\frac{7}{8}\right)^t,\end{aligned}$$

and, since $\log\frac{8}{7} > \frac{1}{8}$, it holds that

$$\Pr\left[\tau_2 \geq t\right] \leq \exp\left[-\frac{1}{8}\left(t - 8\log\frac{1}{\varepsilon}\right)\right].$$

The thesis follows by considering the complementary event. ◀

## 2.4 Putting everything together

In this section we conclude our argument, finally proving Theorem 1. We first prove a more general statement and then detail how it implies the theorem.

Let $\tau = \tau_1 + \tau_2$, the first time at which the process $\{v_t\}_{t\geq 0}$ reaches at least $1 - \varepsilon/2$.

▶ **Lemma 8.** *Let $\varepsilon \in (0, 1/3)$. There exist constants $C' > 0$ and $\kappa > 0$ such that for every $t \geq C' \log \frac{1}{\varepsilon}$, it holds that*

$$\Pr[\tau \leq t] \geq 1 - 2\exp\left[-\frac{1}{\kappa t}\left(t - C' \log \frac{1}{\varepsilon}\right)^2\right].$$

**Proof.** The definition of $\tau$ allows us to apply Corollary 5 and Lemma 7 quite directly. Indeed, if, for the sake of Corollary 5, we assume that $t/2 \geq 264 \log \frac{1}{\varepsilon}$, we have that

$$\begin{aligned}
\Pr[\tau \leq t] &= \Pr[\tau_1 + \tau_2 \leq t] \\
&\geq \Pr\left[\tau_1 \leq t/2, \tau_2 \leq t/2\right] \\
&\geq \Pr\left[\tau_1 \leq t/2\right] + \Pr\left[\tau_2 \leq t/2\right] - 1 \\
&\geq 1 - \exp\left[-\frac{4}{225t}\left(\frac{t}{2} - 264 \log \frac{1}{\varepsilon}\right)^2\right] - \exp\left[-\frac{1}{8}\left(\frac{t}{2} - 8\log \frac{1}{\varepsilon}\right)\right] \\
&\geq 1 - \exp\left[-\frac{4}{225t}\left(\frac{t}{2} - 264 \log \frac{1}{\varepsilon}\right)^2\right] - \exp\left[-\frac{1}{4t}\left(\frac{t}{2} - 8 \log \frac{1}{\varepsilon}\right)^2\right],
\end{aligned}$$

where the second inequality holds by the union bound. By setting $\kappa = 225$ and $C' = 512$, we obtain the thesis. ◀

The expression in the claim of Lemma 8 can be reformulated as

$$\Pr\left[v_t \geq 1 - \frac{\varepsilon}{2}\right] \geq 1 - 2\exp\left[-\frac{1}{\kappa t}\left(t - C' \log \frac{1}{\varepsilon}\right)^2\right];$$

hence, Theorem 1 follows by taking $C \geq 3C'$ and observing that once we can approximate all but an $\varepsilon/2$ proportion of the interval $[-1, 1]$, any $z \in [-1, 1]$ either is $\varepsilon$-approximated itself, or is at most $\varepsilon$ away from a value that is, which implies that $z$ is $2\varepsilon$-approximated.

## Abstract

Scheduling with testing falls under the umbrella of the research on optimization with explorable uncertainty. In this model, each job has an upper limit on its processing time that can be decreased to a lower limit (possibly unknown) by some preliminary action (testing). Recently, Dürr et al. [10] has studied a setting where testing a job takes a unit time, and the goal is to minimize total completion time or makespan on a single machine. In this paper, we extend their problem to the budget setting in which each test consumes a job-specific cost, and we require that the total testing cost cannot exceed a given budget. We consider the offline variant (the lower processing time is known) and the oblivious variant (the lower processing time is unknown) and aim to minimize the total completion time or makespan on a single machine.

For the total completion time objective, we show NP-hardness and derive a PTAS for the offline variant based on a novel LP rounding scheme. We give a $(4+\epsilon)$-competitive algorithm for the oblivious variant based on a framework inspired by the worst-case lower-bound instance. For the makespan objective, we give an FPTAS for the offline variant and a $(2+\epsilon)$-competitive algorithm for the oblivious variant. Our algorithms for the oblivious variants under both objectives run in time $\mathcal{O}(poly(n/\epsilon))$. Lastly, we show that our results are essentially optimal by providing matching lower bounds.

# 1 Introduction

With increased interest in applying scheduling algorithms to solve real-life problems, many models and methods have been addressing the uncertainty in the scheduling community. Several elegant models that capture uncertainty have been studied in the past two decades, most of which fall under the umbrella of the research on robust optimization [24, 7, 23, 29] or stochastic optimization [16, 18, 15, 14]. In those settings, the uncertainty is usually described by the input. In robust optimization, the input consists of several scenarios, while the input is sampled from a known distribution in stochastic optimization. In some practical cases, we can gain additional information about the input by paying extra costs, e.g., money, time, energy, memory, etc. This model is also known as *explorable uncertainty*, which aims to study the trade-offs between the exploration cost and the quality of a solution.

An intriguing scheduling model for explorable uncertainty was proposed by Dürr et al. [10] under the name of *scheduling with testing*. In their model, before executing a job, one can invest some time to *test* that job, potentially reducing its processing time. A practical use case is code optimization, where we could either simply run programs/codes (jobs) as they are or preprocess them through a code optimizer to hopefully improve their execution times.

Their model considers the test cost as the time spent by the machine, which is certainly important and captures many applications stated in [10]. However, it may fail to describe some scenarios. For example, in the code optimization problem, the code optimizer may be an expert who might need to be employed by other companies. This situation is usually faced by cloud computing companies [25, 6], which accept some tasks and want to assign them to servers. They can employ experts to optimize some time-intensive tasks to speed up the execution. In this way, the server can finish more tasks, thus creating more profit for the company. After optimizing, the experts return the optimized tasks to the cloud computing company, and the company can start to assign tasks to servers. Thus, optimizing does not use servers' time. Different tasks may require a different amount of effort from the expert to optimize and therefore needs different cost. The company has a fixed budget and aims to select some tasks to optimize (test) such that the total processing time of tasks is minimized.

Informally, we consider a natural variant of the model proposed in [10], in which we are given a set of $n$ jobs and a total budget $B$ for testing. Each job $j$ has an upper limit on the processing time $p_j^\wedge$ and testing cost $c_j$. After testing, the processing time of job $j$ decreases to a lower limit $p_j^\vee$, which is possibly hidden for the algorithms. We refer to the model as the *offline* version if $p_j^\vee$ is known by the algorithm for all jobs $j$; otherwise, it is called *oblivious* version. The paper considers two objectives: the total completion time objective and the makespan objective, which are two well-studied objectives for scheduling problems in the literature [19, 5, 22, 9]. The formal definition of our problem is stated in Section 2.

Note that the offline version of the model in Dürr et al. [10] is easy, even if testing a job $j$ requires a job-specific amount of time $t_j$. Testing a job is then beneficial if $p_j^\wedge - p_j^\vee > t_j$. In contrast, we show that the offline version of our budgeted variant of the problem is NP-hard, assuming each job takes a job-specific amount of budget to be tested. We study both the offline and the oblivious settings. Further, we differentiate between the uniform cost variant, where each job takes one unit of budget to be tested, and a non-uniform variant, where the testing cost is job-specific.

## 1.1 Our Contributions

The paper studies the problem of Scheduling with a Limited Testing Budget (SLTB) under both the total completion time minimization objective ($\text{SLTB}_{\text{TC}}$) and the makespan minimization objective ($\text{SLTB}_{\text{M}}$). For both objectives, we further distinguish the offline and oblivious settings.

Our main results are summarized in Table 1. For the objective of total completion time minimization, in the offline setting, we show that the problem is NP-hard even when all the lower processing times are 0 by a reduction from the PARTITION problem, and then give a PTAS. The PTAS is derived based on a novel LP rounding scheme. Further, we find that there exists an FPTAS if all the jobs share the same lower processing time. For the oblivious setting, we give a $(4+\epsilon)$-competitive deterministic algorithm for any $\epsilon$ (we use the concept of the competitive ratio following the previous work [10]). The ratio is almost tight since we prove that no deterministic algorithm has a competitive ratio strictly better than 4. For the objective of makespan minimization, the main results are derived based on a connection between our problem and the classical 0-1 knapsack problem. We prove that the offline setting is NP-hard and admits an FPTAS, while for the oblivious setting, an almost tight competitive ratio of $2+\epsilon$ can be obtained.

**Table 1** The summary of our results. The vector $\mathbf{p}^\vee := (p_1^\vee, \dots, p_n^\vee)$ is the lower processing time vector, and $\mathbf{p}^\vee \in \mathbb{R}_{\geq 0} \cdot \mathbf{1}$ means that all the entries of the vector share the same value. $\epsilon$ is an arbitrary positive parameter.

| | | UB ($\text{SLTB}_{\text{TC}}$) | LB ($\text{SLTB}_{\text{TC}}$) | UB ($\text{SLTB}_{\text{M}}$) | LB ($\text{SLTB}_{\text{M}}$) |
|---|---|---|---|---|---|
| Offline | $\mathbf{p}^\vee \in \mathbb{R}^n_{\geq 0}$ | PTAS (Thm. 4) | NP-C (Thm. 1) | FPTAS | NP-C |
| | $\mathbf{p}^\vee \in \mathbb{R}_{\geq 0} \cdot \mathbf{1}$ | FPTAS | | | |
| Oblivious | — | $4+\epsilon$ | 4 | $2+\epsilon$ | 2 |

**Paper Organization.** We first state some useful notation in Section 2, and then give an overview of our techniques in Section 3. In the remaining part of the main body (Section 4), we describe a PTAS for the offline SLTB with the total completion time objective, the most interesting and technical part of our work. Due to space limitations, the proofs are omitted in this version. All proofs and our other results can be found in the full version [8].

## 1.2 Related Work

**Explorable Uncertainty.** Scheduling with testing falls under the umbrella of the research on optimization with explorable uncertainty, where some additional information can be obtained through queries. The model under the stochastic setting can be traced back to Weitzman's Pandora's Box problem [28] and it remains an active research area up to the present [17, 11]. The model under the adversarial setting was first coined by Kahan [21] to study the number of queries necessary to obtain an element set's median value. So far, many optimization problems have been considered in this setting, e.g. caching [27], geometric tasks [4], minimum spanning tree [20, 26], knapsack [12] and so on.

**Scheduling with Testing.** The problem of scheduling with testing was first coined by Dürr et al. [10]. They consider a model where each testing operation requires one unit of time and mainly investigate non-preemptive schedules on a single machine to minimize the total completion time or makespan. Since the offline version of the problem (algorithms know the lower processing time of each job) is trivial, they mainly consider the online version. They present a 2-competitive deterministic algorithm for total completion time minimization while the deterministic lower bound is 1.8546. They also gave a 1.7453-competitive randomized algorithm while the randomized lower bound is 1.6257. For makespan minimization, they give a 1.618-competitive deterministic algorithm and show that it is optimal for the deterministic setting. They also present a 4/3-competitive randomized algorithm and show that it is optimal.

Later, Albers and Eckl [2] consider the non-uniform testing case where the testing time depends on the job. They investigate the single-machine preemptive and non-preemptive scheduling to minimize the total completion time or makespan. The offline version of this problem is still trivial, so they mainly consider the oblivious version. They present a 4-competitive deterministic algorithm for total completion time minimization and a 3.3794-competitive randomized algorithm. If preemption is allowed, the deterministic ratio can be further improved to 3.2361. All lower bounds are the same as in the uniform testing case. For makespan minimization, they extend the algorithm proposed in [10] and show that the approximation can be preserved in the non-uniform testing case.

Scheduling with testing on identical machines is also considered in the literature [3]. The authors mainly consider the makespan minimization in both non-preemptive and preemptive settings. They look into the non-uniform testing case. For the preemptive setting, they present a 2 competitive algorithm which is essentially optimal. For the non-preemptive setting, they give a 3.1016-competitive algorithm for the general testing case, and the ratio can be improved to 3 when each test requires one unit of time. Later, Gong et al. [13] improved the non-preemptive ratios to 2.9513 and 2.8081 for non-uniform and uniform testing cases, respectively.

## 2 Preliminaries

An *instance* to Scheduling with a Limited Testing Budget (SLTB) is a 5-tuple $\mathcal{I} = (J, \mathbf{p}^\wedge, \mathbf{p}^\vee, \mathbf{c}, B)$. $J = [n]$ denotes a *set of $n$ jobs*. Each job $j$ has an *upper limit on the processing time* $p_j^\wedge \in \mathbb{R}_{\geq 0}$, a *lower processing time* $p_j^\vee \in [0, p_j^\wedge]$ and a *testing cost* $c_j \in \mathbb{R}_{\geq 0}$. These parameters are collected in the *lower and upper limit processing time vectors* $\mathbf{p}^\vee$ and $\mathbf{p}^\wedge$, respectively, and a *vector of testing costs* $\mathbf{c}$. Additionally, a total amount of *budget* $B \in \mathbb{R}_{\geq 0}$ is given.

Each job $j$ can be executed either in a tested or untested state. When job $j$ is tested, $j$ will take $p_j^\vee$ time to process; otherwise, it requires $p_j^\wedge$ time. If a job is tested, it consumes $c_j$ budget; otherwise, no budget is consumed.

We consider offline and oblivious versions. For the offline version, the algorithm knows the complete instance $\mathcal{I}$. For the oblivious version, the lower processing time vector $\mathbf{p}^\vee$ is hidden from the algorithm, and the remaining information of the instance is known a priori.

In this work, we only consider non-preemptive and, w.l.o.g., gapless schedules on a single machine. Once a job starts executing, other jobs cannot be processed until the current job is finished. Thus, a schedule corresponds to a specific ordering of jobs. We define $I \coloneqq [n]$ to be the *set of positions*. The job in position $i \in I$ will be the $i^{th}$ job executed in the schedule.

A *schedule* $S = (\sigma, J_\vee)$ for an instance $\mathcal{I} = (J, \mathbf{p}^\wedge, \mathbf{p}^\vee, \mathbf{c}, B)$ is defined by a *job order* $\sigma$ and a *testing job set* $J_\vee \subseteq J$. The job order $\sigma : J \to I$ is a bijective function that describes the order in which the jobs are processed (i.e., job $j$ is the $\sigma(j)$-th processed job in the non-preemptive schedule). The testing job set $J_\vee \subseteq J$ represents a set of jobs to test with $\sum_{j \in J_\vee} c_j \leq B$.

Given a schedule $S$, we can indicate whether a job is tested using a *set of types* $T \coloneqq \{\vee, \wedge\}$. We say that $j$ is *of type* $\vee$,$\wedge$ if it is *tested*, *untested*, respectively. If $S$ schedules a job $j$ of type $t$ into position $i$, we also say that *position $i$ is of type $t$*. For a schedule $S = (\sigma, J_\vee)$ and a job $j$, let the *type* $t_S(j)$ *of* $j$ *in* $S$ be $\vee$ if $j \in J_\vee$ and $\wedge$ otherwise. Denote by $C_j \coloneqq \sum_{j' \in J, \sigma(j') \leq \sigma(j)} p_{j'}^{t_S(j')}$ the *completion time* of job $j$ in schedule $S$. The total completion time is the sum of all completion times, i.e., $\sum_{j \in J} C_j$, and the *makespan* is the maximum completion time among all jobs, i.e., $\max_{j \in J}\{C_j\}$.

Given a testing job set $J_\vee$, the optimal ordering of the jobs is easy to determine. The ordering is relevant for the total completion time minimization but not for the makespan minimization. It is a well-known fact that the SPT rule (shortest processing time first) orders the jobs optimally for total completion time minimization. The processing times are in our case $p_j^\vee$ if job $j$ is tested and $p_j^\wedge$ otherwise. Thus, an optimal schedule can be easily constructed from an optimal testing job set $J_\vee$.

# 3 Overview of Techniques

In this section, we focus on the total completion time minimization and give technical overviews for the offline model and the oblivious model.

## 3.1 Offline SLTB under Total Completion Time Minimization

For offline $\text{SLTB}_{\text{TC}}$, we mainly show the following theorem. The NP-hardness is proved via a reduction from the Partition problem. Due to space limitations, the proofs are omitted and can be found in the full version [8], we focus on introducing the high-level ideas of our PTAS, the most interesting and technical part of this paper.

▶ **Theorem 1.** *The offline $SLTB_{TC}$ problem is NP-hard even when the lower processing time of each job is* 0*, and admits a PTAS.*

Our algorithm is based on an integer linear programming (ILP) formulation for offline $\text{SLTB}_{\text{TC}}$. The ILP contains variables $x_{j,i,t}$ that dictate whether job $j \in J$ should be scheduled in position $i \in I$ of type $t \in T$. (See Section 4.1 for the exact definition of this ILP.) The ILP is conceptually similar to the classical matching ILP on bipartite graphs [1], with jobs and positions representing the two disjoint independent sets of the bipartition. A matching would then describe an assignment of jobs to positions. However, there are two main differences. First, we have two variables per pair of job and position (distinguished by the type $t \in T$). This translates to each job-position pair having two edges that connect them in the (multi-)graph. Second, the total cost of jobs tested is restricted by some budget $B$. This causes a dependency when selecting edges in the graph.

Our approach combines a rounding scheme of the ILP with an exploitation of the cost structure of the problem. We relax the ILP to an LP by allowing the variables $x_{j,i,t}$ to take on fractional values between 0 and 1. We start with an optimal LP solution and then continue with our rounding scheme, which consists of two phases. In the first phase, we round the solution such that all fractional variables correspond to the edges of a single cycle in the graph mentioned above. These variables are hard to round directly without overusing the budget. Here we start the second rounding phase. We relax some of the constraints in the LP to be able to continue the rounding process. Specifically, we allow certain positions to schedule two jobs (we call these positions *crowded*). We end up with an integral (but invalid) solution that has some crowded positions. Then, we "decrowd" these positions by moving their jobs to nearby positions (shifting the position of some other jobs one up), and show that we can bound the cost of moving a job this way in terms of its current contribution to the overall cost. Observing that moving a job from position $i$ to position $i'$ (note that positions are counted from right to left) increases that job's contribution by a factor of $i'/i$, if a crowded position lies far to the right ($i$ is small), we cannot afford to move one of its jobs too far away. For example, in the extreme case that the rightmost position is crowded (i.e., $i = 1$), even the smallest possible move of one of its jobs to the second-rightmost position (i.e., $i' = 2$) already doubles that job's contribution. Thus, our algorithm tries to avoid producing crowded positions that lie too far to the right (at small positions).

To this end, the rounding process in this phase is specifically tailored to control where crowded positions can appear in the integral solution. We look at the $f(\epsilon) = 2/\epsilon + 1$ smallest (rightmost) positions that appear on the current path (representing fractional variables), and select one of them (let's call it the cut-position) to cut the path into two halves. This is done such that each half contains $1/\epsilon$ many of the smallest positions on the current path. By shifting workload along each of these two halves, we can make one of them integral. This integral half gives us $1/\epsilon$ positions that are not crowded, while the cut-position might have become crowded (as might any future cut-position in the remaining fractional path). Because we cut somewhere in the $f(\epsilon)$ rightmost positions of the path, we can show that for each crowded position, there are many positions further to the right of the schedule that are not crowded (this is basically what our charging argument formalizes). In the end, this allows us to prove that no job is moved too far from its original position (relative to its original position), keeping the cost increase due to such moves small.

## 3.2 Oblivious SLTB under Total Completion Time Minimization

For the oblivious model where the lower processing time vector $\mathbf{p}^\vee$ is hidden, we show that $(4+\epsilon)$ approximation can be obtained, and further, prove that the ratio is the best possible.

▶ **Theorem 2.** *For oblivious SLTB$_{TC}$ and any $\epsilon > 0$, there exists a deterministic algorithm with a competitive ratio of $(4+\epsilon)$, while no deterministic algorithm can obtain a competitive ratio strictly smaller than 4.*

We start by considering the oblivious uniform $\mathrm{SLTB}_{\mathrm{TC}}$ problem to build some intuition. The uniform case limits the number of tested jobs, i.e., we can test at most $k$ jobs. Clearly, for the worst-case analysis, we can assume that each job $j$ tested by our algorithm has $p_j^\vee = p_j^\wedge$; that is, we exhaust the budget, but no job's processing time gets reduced. In contrast, for all the jobs tested by an optimal solution, their processing times can be reduced to 0. Thus, from this perspective, regardless of which jobs we test, our total completion time remains unchanged, but the optimum depends on our tested jobs because the adversary can only let the job $j$ that is not tested by our algorithm have $p_j^\vee = 0$.

Then we find that the oblivious uniform $\mathrm{SLTB}_{\mathrm{TC}}$ problem is essentially equivalent to the following optimization problem: given a set of jobs $J$ with $\mathbf{p}^\wedge$ and $\mathbf{p}^\vee = \mathbf{0}$, the goal is to select $k$ jobs such that the minimum total completion time obtained by testing at most $k$ unselected jobs is maximized. The selected jobs can be viewed as the jobs tested by our algorithm, while the minimum total completion time obtained by testing unselected jobs is the optimum of oblivious uniform $\mathrm{SLTB}_{\mathrm{TC}}$. When our objective value is fixed, a larger optimum implies a better competitive ratio. For this much easier problem, it is easy to see that the best strategy is selecting the $k$ jobs with the largest upper processing time, which is the set of jobs that would be tested by an optimal solution of $\mathrm{SLTB}_{\mathrm{TC}}$ instance $\mathcal{I} = (J, \mathbf{p}^\wedge, \mathbf{p}^\vee = \mathbf{0}, \mathbf{c} = \mathbf{1}, k)$.

We build on the above argument to give the algorithm for the non-uniform case $\mathcal{I} = (J, \mathbf{p}^\wedge, \mathbf{p}^\vee, \mathbf{c}, B)$. The basic idea is constructing an auxiliary instance $\widetilde{\mathcal{I}} := (J, \mathbf{p}^\wedge, \widetilde{\mathbf{p}^\vee} = \mathbf{0}, \mathbf{c}, B)$, solving the instance optimally or approximately, and returning the obtained solution. Use $\mathrm{ALG}(\cdot)$ and $\mathrm{OPT}(\cdot)$ to denote the objective values obtained by our algorithm and an optimal solution of an input instance, respectively. By the theorem proved in the offline model, we have $\mathrm{ALG}(\widetilde{\mathcal{I}}) \le (1+\epsilon)\mathrm{OPT}(\widetilde{\mathcal{I}})$ for any $\epsilon > 0$. In the analysis, we show that our objective value can be split into two parts: $\mathrm{ALG}(\mathcal{I}) \le 2\mathrm{ALG}(\widetilde{\mathcal{I}}) + 2\mathrm{OPT}(\mathcal{I})$, and therefore, due to $\mathrm{OPT}(\widetilde{\mathcal{I}}) \le \mathrm{OPT}(\mathcal{I})$, a competitive ratio of $(4+2\epsilon)$ can be proved.

The lower bound is shown by a hard instance $\mathcal{I} = (J, \mathbf{p}^\wedge = \mathbf{1}, \mathbf{p}^\vee, \mathbf{c} = \mathbf{1}, B = \frac{n}{2})$, where the adversary always lets our tested jobs have lower processing time 1 and the processing time of any other job be 0. Apparently, any deterministic algorithm's objective value is $n(n+1)/2$, while an optimal solution can achieve a total completion time of $n(n+2)/8$, which implies a lower bound of 4. [2]

## 3.3 $\text{SLTB}_\text{M}$ under Makespan Minimization

▶ **Theorem 3.** *The offline $SLTB_M$ problem is NP-hard and admits an FPTAS, while for oblivious $SLTB_M$, an almost tight competitive ratio of $2+\epsilon$ can be obtained (for any $\epsilon > 0$).*

The offline SLTB problem under makespan minimization is closely related to the classical 0-1 knapsack problem. The classical 0-1 knapsack problem aims to select a subset of items such that (i) the total weight of the selected items does not exceed a given capacity; (ii) the total value of the selected items is maximized. To see the connection, consider the testing cost of each job as the weight of each item and the profit of testing a job $(p_j^\wedge - p_j^\vee)$ as the value of an item. Then we build on the algorithmic idea of the knapsack dynamic programming and design an FPTAS for the offline setting.

We use the same framework as the total completion time minimization model for the oblivious setting and obtain a $(2+\epsilon)$-competitive algorithm. The ratio becomes better here since, for the makespan objective, we have $\text{ALG}(\mathcal{I}) \leq \text{ALG}(\widetilde{\mathcal{I}}) + \text{OPT}(\mathcal{I})$, saving a factor of 2. The lower bound proof is also based on the same hard instance $\mathcal{I} = (J, \mathbf{p}^\wedge = \mathbf{1}, \mathbf{p}^\vee, \mathbf{c} = \mathbf{1}, B = n/2)$. Any deterministic algorithm's makespan is $n$ while the optimum is $n/2$, giving a lower bound of 2.

# 4 Offline Setting for SLTB under Total Completion Time Minimization

This section considers the Scheduling with a Limited Testing Budget problem under total completion time minimization ($\text{SLTB}_\text{TC}$) in the offline setting and aims to show the following theorem.

▶ **Theorem 4.** *There exists a PTAS for $SLTB_{TC}$.*

For convenience, we refer to a problem instance as a pair $\mathcal{I} = (J, B)$, dropping the processing time and cost vectors $\mathbf{p}^\vee$, $\mathbf{p}^\wedge$, and $\mathbf{c}$ (which we assume to be implicitly given). Moreover, in this section, we consider the job positions $I = [n]$ *in reverse order* to simplify the calculations. That is, a job $j$ scheduled in position $i \in I$ is processed as the *$i$-th last* job.

## 4.1 ILP Formulation and Fixations

We start by introducing our ILP formulation of the $\text{SLTB}_\text{TC}$ problem and defining the term *fixation* of a (relaxed) instance of our ILP. Such fixations allow us to formally fix the values of certain variables in the (relaxed) ILP when analyzing our algorithm.

[2] Since in the worst-case, the upper and lower processing times of jobs tested by the algorithm are equal, it does not help if the algorithm can be adaptive, i.e., change its testing strategy based on such an information.

**ILP Formulation.** Our ILP has indicator variables $x_{j,i,t}$ that are 1 if job $j$ is scheduled at position $i$ of type $t$ and 0 otherwise. The *contribution* of such a job to the total completion time is[3] $i \cdot p_j^t$. We have constraints to ensure that each of the $n$ positions schedules one job, that each job is scheduled once, and that the cost of tested jobs do not exceed the budget. The equivalence between ILP solutions and $\text{SLTB}_{\text{TC}}$ schedules is formalized in Lemma 5.

Consider an instance $\mathcal{I} = (J, B)$ of the $\text{SLTB}_{\text{TC}}$ problem. We define an ILP $ILP_{\mathcal{I}}$, with the variables $x_{j,i,t}$ for each job $j \in J$, position $i \in I$ and type $t \in T$.

$$\min \sum_{j \in J, i \in I, t \in T} i \cdot p_j^t \cdot x_{j,i,t}$$

$$\text{s.t.} \sum_{j \in J, t \in T} x_{j,i,t} = 1 \quad \forall i \in I \quad (1) \qquad \sum_{i \in I, t \in T} x_{j,i,t} = 1 \quad \forall j \in J \quad (2)$$

$$\sum_{j \in J, i \in I} c_j x_{j,i,\vee} \leq B \quad (3) \qquad x_{j,i,t} \in \{0, 1\} \ \forall j \in J, i \in I, t \in T \quad (4)$$

For $ILP_{\mathcal{I}}$ with variable set $X_{\mathcal{I}} \coloneqq \{ x_{j,i,t} \mid j \in J, i \in I, t \in T \}$, a *solution* $x : X_{\mathcal{I}} \to \mathbb{R}$ assigns each variable in $X_{\mathcal{I}}$ a value. Solution $x$ is called *valid* if it satisfies the four constraints and *invalid* otherwise. For a (possibly invalid) solution $x$ for $\mathcal{I}$ we define its *cost* as $C_{\mathcal{I}}(x) \coloneqq \sum_{j \in J, i \in I, t \in T} i \cdot p_j^t \cdot x_{j,i,t}$ and its *budget use* $B_{\mathcal{I}}(x) \coloneqq \sum_{j \in J, i \in I} c_j x_{j,i,\vee}$ (we omit $\mathcal{I}$ from $C_{\mathcal{I}}$ and $B$ if it is clear from the context). We refer to the different constraints as (1) *position constraints*, (2) *job constraints*, (3) *budget constraint*, and (4) *integrality constraints*.

▶ **Lemma 5.** *Let $\mathcal{I} = (J, B)$ be an instance for $SLTB_{TC}$. For each valid solution $x$ to $ILP_{\mathcal{I}}$ there exists a schedule $S$ for $\mathcal{I}$ with $C(S) = C(x)$ and vice versa. Each can be computed from the other in polynomial time.*

**Relaxation and Fixations.** Our algorithm and analysis use relaxed variants of $ILP_{\mathcal{I}}$ that *fix* certain ILP variables (indicating that, e.g., certain jobs must be tested). It also keeps track of *crowded* positions, in which our algorithm may (temporarily) schedule two jobs (violating the position constraints). We introduce the notion of a *fixation* $\mathcal{F}$ to formally define these relaxed variants $LP_{\mathcal{I},\mathcal{F}}$ of $ILP_{\mathcal{I}}$. [4]

▶ **Definition 6.** A *fixation* $\mathcal{F} = (J(\mathcal{F}), X(\mathcal{F}), I^C(\mathcal{F}))$ of an $\text{SLTB}_{\text{TC}}$ instance $\mathcal{I}$ consists of:

1. a set of *tested* jobs $J(\mathcal{F}) \subseteq J$,
2. a set of *fully-fixed* variables $X(\mathcal{F}) \subseteq X_{\mathcal{I}}$ where $j \notin J(\mathcal{F})$ for all $x_{j,i,t} \in X(\mathcal{F})$, and
3. a set of *crowded positions* $I^C(\mathcal{F}) \subseteq I$.

For a set operator $\circ \in \{\cup, \cap, \setminus\}$ and a set of positions $\bar{I} \subseteq I$, we use the notation $\mathcal{F} \circ \bar{I} \coloneqq (J(\mathcal{F}), X(\mathcal{F}), I^C(\mathcal{F}) \circ \bar{I})$ to express the change to the crowded positions of $\mathcal{F}$.

Given a fixation $\mathcal{F}$, we define the following relaxed variant $LP_{\mathcal{I},\mathcal{F}}$ of $ILP_{\mathcal{I}}$:

1. For each $x_{j,i,t} \in X_{\mathcal{I}}$ we relax the integrality constraint to $0 \leq x_{j,i,t} \leq 1$ (*unit constraints*).
2. For each $x_{j,i,t} \in X(\mathcal{F})$, we add the constraint $x_{j,i,t} = 1$ (*fully-fixed constraints*).
3. For each $j \in J(\mathcal{F})$, we add the constraint $\sum_{i \in I} x_{j,i,\vee} = 1$ (*tested job constraints*).
4. For each $i \in I^C(\mathcal{F})$, we relax the position constraint to $\sum_{j \in J, t \in T} x_{j,i,t} \in \{0, 1, 2\}$.

The resulting LP is omitted in this version and can be found in the full version [8].

[3] Remember that we consider the position in *reverse* order. Thus, the job at position $i$ is the $i$-th last job.

[4] Our PTAS will enumerate through a polynomial number of fixations, and solve the problem for each one of them. The approximation guarantee is then derived for the fixation that is consistent with the optimal solution.

## 4.2 Graph-theoretic Perspective & Paths

Consider an $\text{SLTB}_{\text{TC}}$ instance $\mathcal{I} = (J, B)$ with fixation $\mathcal{F}$ and a (fractional) solution $x$ to $LP_{\mathcal{I},\mathcal{F}}$. The main building block of our algorithm is a rounding scheme based on the following graph-interpretation of $\mathcal{I}$ and corresponding paths based on the current solution $x$:

▶ **Definition 7.** The *instance graph* $G_{\mathcal{I}} \coloneqq (J \cup I, E)$ is a bipartite multi-graph between the jobs $J$ and positions $I$ with exactly two edges between any pair $j \in J$ and $i \in I$. We identify the edge set $E$ with the variable set $X_{\mathcal{I}}$ and refer to a variable $x_{j,i,t} \in E = X_{\mathcal{I}}$ also as an *edge of type* $t \in \{\vee, \wedge\}$ *between* $j$ *and* $i$.

▶ **Definition 8.** A *path* $P$ *in solution* $x$ is a weighted path from $i_s \in I$ (*start position*) to $i_e \in I$ (*end position*) in $G_{\mathcal{I}}$, where the weight of an edge $x_{j,i,t} \in P$ is its value in $x$. $P$ is called *integral* if all its weights are integral and *fractional* if they are all (strictly) fractional.

Nodes and edges in $P$ must be pairwise distinct, except for possibly equal start and end positions $i_s = i_e$, in which case we refer to $P$ also as a *cycle*. We define $J(P)$ as the path's set of jobs, $I(P)$ as its set of positions, and $K(P) \coloneqq I(P) \setminus \{i_s, i_e\}$. Moreover, $X(P)$ is the sequence of edges/variables from start to end position in $P$. We say the $i$-th edge in $X(P)$ is even/odd if $i$ is even/odd, such that $P$ reaches $j \in J(P)$ via an odd edge $x_j^O$ and leaves $j$ via an even edge $x_j^E$. We similarly use $t_j^O$ and $t_j^E$ to denote the type of $x_j^O$ and $x_j^E$, respectively.

Next, we define *shift operations*, which move workload along paths by increasing the volume of one job at any position $i \in I(P)$ while decreasing the volume of another job at $i$.

▶ **Definition 9.** A $\delta$*-shift* of a path $P$ in $x$ decreases the value of all odd edges (variables) of $P$ by $\delta$ and increases the value of all even edges (variables) of $P$ by $\delta$.

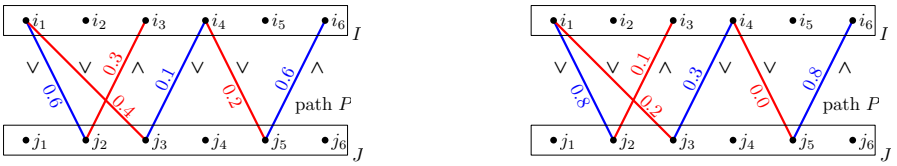
Shift operations (see Figure 1) change the budget use $B(x)$ at a path-dependent (positive or negative) *budget rate* (defined below) and might create crowded positions. Our algorithm's first two phases (Sections 4.3 and 4.4) carefully pair shift operations such that performing paired shifts does not increase the budget and does not create too many crowded positions.

Define the *budget rate* of a path $P$ to be $\Delta(P) \coloneqq \sum_{j \in J(P)} c_j \cdot (\mathbb{1}_{|t_j^E = \vee} - \mathbb{1}_{|t_j^O = \vee})$. Let $P$ be a path in a solution $x$ for $LP_{\mathcal{I},\mathcal{F}}$ without crowded positions (i.e., $I^C(\mathcal{F}) = \varnothing$). $P$ is called $y$*-alternating* (or simply *alternating*) if all odd edges have weight $y$ and all even edges have weight $1 - y$. Lemma 10 below formalizes the effect of a $\delta$-shift in terms of the path's budget rate. Since our analysis can be restricted to paths with very specific, alternating edge values, we also formalize such *alternating paths* and show how they are affected by $\delta$-shifts (see also Figure 2).

▶ **Lemma 10.** *Let $P$ be a path in a solution $x$ for $LP_{\mathcal{I},\mathcal{F}}$ without crowded positions (i.e., $I^C(\mathcal{F}) = \varnothing$). Shifting $P$ in $x$ by $\delta$ yields a (possibly invalid) solution $\tilde{x}$ with $B(\tilde{x}) = B(x) - \delta \cdot \Delta(P)$. If $P$ is $y$-alternating in $x$, then it is $(y - \delta)$-alternating in $\tilde{x}$.*

## 4.3 First Phase: Eliminating all but one cycle

Consider an optimal valid solution $x$ to $LP_{\mathcal{I},\mathcal{F}}$ without crowded positions (i.e., $I^C(\mathcal{F}) = \varnothing$). Lemma 11 below is our main tool for rounding fractional variables in $x$. Consider a set of variables that form a fractional path in $x$. Essentially, we want to use a shift operation from Definition 9 on such a path to make some of its variables integral. If such a shift increases the budget use $B(x)$ (rendering the solution invalid), we can suitably shift a second path (possibly using a negative $\delta$) in parallel to ensure that the budget use $B(x)$ does not increase.



**(a)** Path $P$ with start and end positions $i_3$ and $i_6$. **(b)** Same path $P$ after the shift.

**Figure 1** A path $P$ in a solution $x$ before and after a shift by $\delta = 0.2$. Edges are labeled with their type ($\vee$ or $\wedge$) and weight from a given solution $x$. Odd edges are red, and even edges are blue. The budget rate computes as $\Delta(P) = c_{j_2}(1-0) + c_{j_3}(1-1) + c_{j_5}(0-1) = c_{j_2} - c_{j_5}$.

**(a)** Alternating paths $P$ (solid) and $P'$ (dashed). **(b)** Same paths by $\delta = 0.3$ and $\delta' = 0.6$, respectively.

**Figure 2** Illustration of Lemma 11 for alternating paths $P = (i_3, \dots, i_4)$ (solid) and $P' = (i_4, \dots, i_6)$ (dashed) with budget rates $\Delta(P) = c_{j_3} \coloneqq 2$ and $\Delta(P') = c_{j_5} \coloneqq 1$. Shifting $P$ by $\delta = 0.3$ and $P'$ by $\delta' = 0.6$ keeps the budget use constant. $P$ and $P'$ stay alternating, $P'$ becomes integral, and $i_3, i_4, i_6$ (the start/end positions) violate the position constraints after these shifts.

Such shifts might also cause the violation of the position constraints at the path's start and end positions. We keep track of such violations by adding those positions to the crowded position set $I^C(\mathcal{F})$ of the fixation $\mathcal{F}$. Lemma 11 formalizes this approach (see also Figure 2).

▶ **Lemma 11.** *Consider $x$ a valid solution for $LP_{\mathcal{I},\mathcal{F}}$. Let $P$ be a fractional path in $x$ with $\Delta(P) = 0$ or $P, P'$ be two fractional paths in $x$ with $X(P) \neq X(P')$ and $\Delta(P), \Delta(P') \neq 0$. We can efficiently shift $P$ (and $P'$, if existing) in $x$ to yield a valid solution $\tilde{x}$ for $LP_{\mathcal{I},\tilde{\mathcal{F}}}$ with:*

1. *$C(\tilde{x}) \leq C(x)$ and $B(\tilde{x}) = B(x)$*
2. *$\tilde{\mathcal{F}} = \mathcal{F} \cup I'$, where $I'$ is the set of all start and end positions of non-cyclic paths involved.*
3. *$\tilde{x}$ contains more integral variables than $x$.*

Lemma 11 allows us to shift along general paths (instead of cycles) at the cost of creating crowded positions. We rely on this in Section 4.4 and deal with the crowded positions in Section 4.5. However, to keep the number of crowded positions small and reduce their impact on the final solution, we apply Lemma 11 on cycles for as long as possible. This avoids the creation of crowded positions since shifts along cycles cannot change the net workload at any position. Indeed, note that given any node in a path $P$ that is incident to a fractional edge must have a second fractional edge, or it would violate its job/position constraint. This allows us to complete any fractional path to a cycle. Thus, we can keep applying Lemma 11 to *cycles* (not creating crowded positions) until there is at most one cycle with a non-zero budget rate left (a *blocking cycle*). Let $x$ be a solution to $LP_{\mathcal{I},\mathcal{F}}$. A path $P$ of $x$ is called *critical* if $X(P) = \{ x_{j,i,t} \in X_{\mathcal{I}} \mid x_{j,i,t} \in (0,1) \}$. A *blocking cycle* of $x$ is a critical cycle $P$ with $\Delta(P) \neq 0$. Lemma 12 formalizes the idea above.

▶ **Lemma 12.** *Let $\mathcal{I}$ be an instance, $\mathcal{F}$ be a fixation with $I^C(\mathcal{F}) = \varnothing$, and $x$ be a valid optimal solution to $LP_{\mathcal{I},\mathcal{F}}$. Then we can compute in polynomial time a valid optimal solution $\tilde{x}$ to $LP_{\mathcal{I},\mathcal{F}}$ such that all variables in $\tilde{x}$ are integral, or we find a blocking cycle of $\tilde{x}$. Further, if $P$ is a blocking cycle of $x$, then $P$ is alternating.*

## 4.4 Second Phase: Rounding the blocking cycle

Assume that we used Lemma 12 to compute a blocking cycle $P$ for a solution $x$ to $LP_{\mathcal{I},\mathcal{F}}$ with $I^C(\mathcal{F}) = \varnothing$. Because $P$ is critical, all fractional variables are in $X(P)$. Also, since $\Delta(P) \neq 0$, applying Lemma 11 directly is impossible. Instead, we cut up $P$ repeatedly into two paths $P_1, P_2$, and then use Lemma 11 on these paths (see Algorithm 1). Cutting is done by selecting any position $i \in K(P)$, and separating the path at $i$: $P_1$ will be the path starting at the start position of $P$ and end at $i$. $P_2$ will be the path starting at $i$ and ending at the end position of $P$. We abbreviate this operation by $P_1, P_2 \leftarrow \textsc{Cut}(P, i)$. The drawback of this approach is that Lemma 11 does not guarantee that the resulting solutions still fulfill the position constraints of the start/end positions of $P_1, P_2$, respectively. That is why we add them to $I^C(\mathcal{F})$ in the process.

Algorithm RepeatedCut starts with a solution $\tilde{x}$ and a critical path $\tilde{P}$. It cuts $\tilde{P}$ at some position $i \in K(\tilde{P})$ that is selected by a procedure SelectCutPosition (which is described later in Algorithm 2 in the next subsection). The algorithm then applies Lemma 11 to the two resulting paths, making at least one of them integral (as guaranteed by Lemma 10). After that, $\tilde{x}$ and $\tilde{P}$ are updated accordingly. RepeatedCut finishes when $|K(\tilde{P})| = 0$ (and therefore $\tilde{P}$ cannot be cut into two paths anymore). In such a case, RepeatedCut will reschedule that job to obtain an integral solution. It is also possible that no path remains after the application of Lemma 11. For such a case, $\tilde{x}$ is already integral. Thus, in both cases, the resulting integral solution $\tilde{x}$ is returned.

**Algorithm 1** RepeatedCut.

**Input:** A valid solution $x$ for $LP_{\mathcal{I},\mathcal{F}}$ with $I^C(\mathcal{F}) = \varnothing$, a blocking cycle $P$ of $x$.

$\tilde{P}, \tilde{x} \leftarrow P, x$
**while** $\Delta(\tilde{P}) \neq 0$ **do**
  **if** $K(\tilde{P}) = \varnothing$ **then**
    $j \leftarrow$ unique job in $J(\tilde{P})$; $i_1, i_2 \leftarrow$ remaining two positions in $I(\tilde{P})$
    In $\tilde{x}$, reschedule $j$ into position $\min(i_1, i_2)$ of type $\vee$ if $t_j^O = t_j^E = \vee$ and $\wedge$ else
    **return** $\tilde{x}$
  $i \leftarrow \textsc{SelectCutPosition}(\tilde{P})$
  $P_1, P_2 \leftarrow \textsc{Cut}(P, i)$
  Apply Lemma 11 to $P_1, P_2$ in $\tilde{x}$, changing $\tilde{x}$ accordingly
  **if** both paths became integral **then return** $\tilde{x}$
  $\tilde{P} \leftarrow$ the remaining fractional path
Apply Lemma 11 to $\tilde{P}$ in $\tilde{x}$, changing $\tilde{x}$ accordingly
**return** $\tilde{x}$

In the following, we make statements about the state of the variables involved in the execution of RepeatedCut at the beginning of an iteration of its **while**-loop. Consider the state of RepeatedCut (called on path $P$) at the beginning of the $l$'th iteration of the **while**-loop ($l \geq 1$). We denote by $I_l^C$ the start/end position of $P$ together with all positions selected by SelectCutPosition so far, and $I_*^C$ the start/end position of $P$ together with all positions selected by SelectCutPosition throughout the algorithm. Similarly, denote by $\tilde{x}_l$,$\tilde{P}_l$ the values of $\tilde{x}$,$\tilde{P}$ at that point, respectively, and $\tilde{x}_*$ for the returned solution by RepeatedCut. Denote $\tilde{\mathcal{F}}_l := (J(\mathcal{F}), X(\mathcal{F}), I_l^C)$ and $\tilde{\mathcal{F}}_* := (J(\mathcal{F}), X(\mathcal{F}), I_*^C)$.

▶ **Lemma 13.** *The following is a loop invariant of RepeatedCut for iteration $l \geq 1$: $\tilde{x}_l$ is a valid solution for $LP_{\mathcal{I},\tilde{\mathcal{F}}_l}$ and $\tilde{P}_l$ is a critical fractional alternating path in $\tilde{x}_l$, of which the start and end positions are in $I_l^C$. Also, $\tilde{x}_*$ is an integral valid solution for $LP_{\mathcal{I},\tilde{\mathcal{F}}_*}$.*

Based on Lemma 13, we can analyze the objective obtained by RepeatedCut:

▶ **Lemma 14.** *Consider an application of* RepeatedCut *on solution $x$ for $LP_{\mathcal{I},\mathcal{F}}$ and a blocking cycle $P$. It returns in polynomial time a solution $\tilde{x}$ with $C(\tilde{x}) \leq C(x) + Z$, where $Z$ is either 0 or the contribution of job $j$ rescheduled by* RepeatedCut *in line 5 and $j \notin J(\tilde{\mathcal{F}}_*)$.*

## 4.5 Third Phase: Dealing with crowded positions

Lemma 14 guarantees that applying the algorithm RepeatedCut will return us an integral solution. However, that solution is valid for $LP_{\mathcal{I},\mathcal{F}}$ where $I^C(\mathcal{F})$ still contains some positions. Some of these positions may schedule two jobs, which makes this schedule not valid for $ILP_{\mathcal{I}}$. Our general strategy in this subsection is to move the jobs such that the cost of the solution does not increase too much. In Observation 15, we move each job to a new position and bound the cost created by that operation.

▶ Observation 15. Let $x$ be an integral solution to $LP_{\mathcal{I},\mathcal{F}}$ for some fixation $\mathcal{F}$. Consider a job $j \in J$ that is scheduled in position $i \in I$ of type $t \in T$. Then rescheduling $j$ into position $i'$, i.e., setting $x_{j,i,t} \leftarrow 0$ and $x_{j,i',t} \leftarrow 1$ produces a (possibly invalid) solution $\tilde{x}$, in which the contribution of $j$ increases by a factor of $i'/i$ compared to $x$.

As mentioned above, there are still some positions that schedule two jobs. To obtain an integral valid solution for $ILP_{\mathcal{I}}$, we have to move the jobs in the schedule to new positions, such that there is exactly one job per position scheduled. We want to use Observation 15 to bound the increase in contribution for each job moved this way. Generally, we move the jobs as follows: For a position $i$ that schedules two jobs $j, j'$, we (arbitrarily) distribute $j, j'$ among positions $i, i+1$, thereby moving all jobs from positions $i+1, \ldots, n$ to one higher position. Following this strategy, jobs in higher positions may get moved multiple times.

To bound the contribution in terms of Observation 15, we set up a charging scheme: Each position with two jobs scheduled should be charged to a distinct set of $1/\epsilon$ smaller positions that schedule one job, where $\epsilon$ is the accuracy parameter of our algorithm ($1/\epsilon \in \mathbb{N}$). In the following, we will always use the following function SelectCutPosition for RepeatedCut:

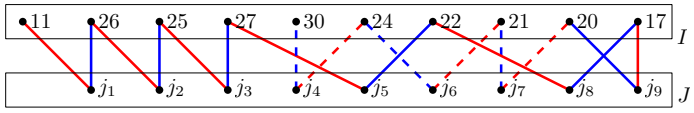
**Algorithm 2** SelectCutPosition.

**Input:** A path $\tilde{P}$ with $|K(\tilde{P})| \geq 1$
**Output:** A position $i \in K(\tilde{P})$
1: **if** $|K(\tilde{P})| \geq 2/\epsilon + 1$ **then**
2: $I' \leftarrow$ the smallest $2/\epsilon + 1$ positions in $K(\tilde{P})$
3: **return** the position that appears as $(1/\epsilon + 1)$-st position in $\tilde{P}$ of the positions in $I'$
4: **else**
5: **return** any position in $K(\tilde{P})$

We care about two properties of the position selected by SelectCutPosition. First, when we cut $\tilde{P}$ into $P_1, P_2$ in line 8 of RepeatedCut, $K(P_1)$,$K(P_2)$ should each contain at least $1/\epsilon$ positions. This way, whichever of these paths becomes integral, there will be $1/\epsilon$ positions that will never be selected by SelectCutPosition in the future. This is important for our charging scheme to have enough positions to charge to. Second, we specifically care about the selected positions being the smallest positions that appear in $K(\tilde{P})$. This essentially allows us to charge each position with two jobs scheduled exclusively to smaller positions, independent of which of the two paths becomes integral.

We represent the charging scheme using a *charging function* (formally defined in Definition 16). Essentially, for a set of positions $\bar{I} \subseteq I$, it charges each position in $\bar{I}$ to its distinct $1/\epsilon$ many smaller positions.

**(a)** Illustration of $\mu_l$ (e.g., $\mu_l(24) = \{16, 23\}$). **(b)** Illustration of $\mu_{l+1}$ (e.g., $\mu_{l+1}(26) = \{16, 23\}$).



**(c)** Path $\tilde{P}_l$ (solid *and* dashed), and path $\tilde{P}_{l+1}$ (solid) after one iteration of the **while**-loop in RepeatedCut.

**Figure 3** An update step of Lemma 17 for $\epsilon = 1/2$. The inner positions of $\tilde{P}_l$ are $K(\tilde{P}_l) = \{17, 20, 21, 22, 24, 25, 26, 27\}$. Its $2/\epsilon + 1 = 5$ smallest positions appear in order $22, 17, 20, 21, 24$. $\tilde{P}_l$ is cut at the $(1/\epsilon + 1) = 3$-rd of these positions (20) into two paths, which are then shifted such that the dashed one becomes integral and the solid one becomes $\tilde{P}_{l+1}$. $I^+_{l+1}$ loses positions 21 and 24 compared to $I^+_l$, as these positions belonged to the dashed path, which became integral. $I^+_{l+1}$ now consists of all remaining $2/\epsilon + 1 = 5$ inner positions $K(\tilde{P}_{l+1}) = \{17, 22, 25, 26, 27\}$. We set $\mu_{l+1}(25) = \mu_l(21)$, $\mu_{l+1}(26) = \mu_l(24)$, and $\mu_{l+1}(27) = \{21, 24\}$ (the lost positions from $I^+_l$).

▶ **Definition 16.** Let $x$ be a solution to $LP_{\mathcal{I},\mathcal{F}}$ for an instance $\mathcal{I}$ and a fixation $\mathcal{F}$. Let $P$ be a critical path in $x$. For a set $\bar{I} \subseteq I$, a *charging function* for $\bar{I}$ is a function $\mu : \bar{I} \to \mathcal{P}(I \setminus \bar{I})$ such that for all $i \in \bar{I}$: (1) $|\mu(i)| = 1/\epsilon$, (2) $\forall i' \in \mu(i) : i' < i$ and (3) $\forall i' \in \bar{I} : \mu(i) \cap \mu(i') = \varnothing$.

Consider the $l$'th iteration of the **while**-loop in RepeatedCut. We define the *charging set* $I^+_l := \bar{I} \cup I^C_l$, where $\bar{I}$ contains the smallest $2/\epsilon + 1$ positions in $K(\tilde{P}_l)$ (or all of them, if $|K(\tilde{P}_l)| < 2/\epsilon + 1$). Similarly, define $I^+_* := I^C_*$.

Lemma 17 shows how to obtain a charging function $\mu_* : I^+_* \to \mathcal{P}(I \setminus I^+_*)$ from a charging function $\mu_1 : I^+_1 \to \mathcal{P}(I \setminus I^+_1)$. We do this by updating the charging function with every iteration of RepeatedCut's loop. Figure 3 exemplifies the update of the charging function.

▶ **Lemma 17.** *If there exists a charging function $\mu_1 : I^+_1 \to \mathcal{P}(I \setminus I^+_1)$, then there also exists a charging function $\mu_* : I^+_* \to \mathcal{P}(I \setminus I^+_*)$.*

We now use Observation 15 together with a charging function (of which we assume the existence for now) on a solution $x$ for $LP_{\mathcal{I},\mathcal{F}}$ produced by RepeatedCut to find a solution for $ILP_{\mathcal{I}}$ with not too much more cost. Lemma 18 will allow us to produce such a solution.

▶ **Lemma 18.** *Let $x$ be a solution returned by RepeatedCut for $LP_{\mathcal{I},\mathcal{F}}$, and let $\mu_*$ be a charging function for $I^+_*$. Then we can find a valid solution $\tilde{x}$ in polynomial time for $ILP_{\mathcal{I}}$ such that the contribution of each job increases by a factor of at most $(1 + \epsilon)$ compared to $x$.*

Consider a solution $x$ returned by RepeatedCut for $LP_{\mathcal{I},\mathcal{F}}$. To be able to apply Lemma 18 and find a solution for $ILP_{\mathcal{I}}$, we need to make sure that we can find a charging function $\mu_1$ for $I^+_1$. Furthermore, we still need to bound the contribution created by the job $j$ in line 5 of RepeatedCut as of Lemma 14. To do this, we choose a proper fixation $\mathcal{F}^*$ and show that a charging function can then be derived.

▶ **Definition 19.** Let $x^*$ be an optimal solution to $ILP_{\mathcal{I}}$ for an instance $\mathcal{I}$. For $i \in I$, let further $j_i \in J$ and $t_i \in T$ such that $x^*_{j_i,i,t_i} = 1$. Using $M := (2/\epsilon + 1)/\epsilon$, we define the fixation $\mathcal{F}^*$ by

$$X(\mathcal{F}^*) = \{ x_{j_i,i,t_i} \mid i \in [M] \} \qquad J(\mathcal{F}^*) = \{ j \in J \mid p^\wedge_j > \min_{i \in [M]} p^{t_i}_{j_i} \} \qquad I^C(\mathcal{F}^*) = \varnothing$$

▶ **Lemma 20.** *Let $x$ be a solution returned by RepeatedCut for $LP_{\mathcal{I},\mathcal{F}^*}$. Then there exists a charging function $\mu_1$ for $I^+_1$.*

Essentially, we brute-force which jobs will be scheduled in the last few positions. This will make sure that these positions are not in $I_1^+$, and as such can be used for the charging function $\mu_1$. Assuming that we brute-forced correctly, an optimal solution will also test all jobs with a larger upper processing time than any of the brute-forced jobs. This is because an optimal solution will always schedule in order of increasing processing times. Finally, we can piece together all of the above lemmas and prove the main theorem (Theorem 4). The detailed proof can be found in [8].

## 5 Conclusion

We initiated the study of Scheduling with a Limited Testing Budget, where we have a limited budget for testing jobs to potentially decrease their processing time. We provided NP-hardness results, a PTAS, as well as tight bounds for a semi-online (oblivious) setting.

Our results open promising avenues for future research. For the setting where we minimize the total completion time, it remains open whether NP-hardness holds for uniform testing cost. Also, while our LP-rounding-based PTAS achieves the best possible approximation, it remains open whether there is a faster, combinatorial algorithm. Another natural direction would be to consider the case of multiple machines.

Another exciting direction is the following *bipartite matching with testing* problem that generalizes our problem, arising from the graph-theoretic perspective in Section 4.2: Consider a bipartite graph $G \coloneqq (L \cup R, E)$ in which each edge $e \in E$ has a cost $c_e$ that can be reduced to $\check{c}_e$ via a testing operation. Given the possibility to test edges before adding them to the matching, we seek a min-cost perfect matching that respects a given testing budget.

## Abstract

One of the most studied extensions of the famous Traveling Salesperson Problem (TSP) is the Multiple TSP: a set of $m \geq 1$ salespersons collectively traverses a set of $n$ cities by $m$ non-trivial tours, to minimize the total length of their tours. This problem can also be considered to be a variant of Uncapacitated Vehicle Routing, where the objective is to minimize the sum of all tour lengths. When all $m$ tours start from and end at a *single* common *depot* $v_0$, then the metric Multiple TSP can be approximated equally well as the standard metric TSP, as shown by Frieze (1983).

The metric Multiple TSP becomes significantly harder to approximate when there is a *set* $D$ of $d \geq 1$ depots that form the starting and end points of the $m$ tours. For this case, only a $(2-1/d)$-approximation in polynomial time is known, as well as a 3/2-approximation for *constant* $d$ which requires a prohibitive run time of $n^{\Theta(d)}$ (Xu and Rodrigues, *INFORMS J. Comput.*, 2015). A recent work of Traub, Vygen and Zenklusen (STOC 2020) gives another approximation algorithm for metric Multiple TSP with run time $n^{\Theta(d)}$, which reduces the problem to approximating metric TSP.

In this paper we overcome the $n^{\Theta(d)}$ time barrier: we give the first efficient approximation algorithm for Multiple TSP with a *variable* number $d$ of depots that yields a better-than-2 approximation. Our algorithm runs in time $(1/\varepsilon)^{\mathcal{O}(d \log d)} \cdot n^{\mathcal{O}(1)}$, and produces a $(3/2+\varepsilon)$-approximation with constant probability. For the graphic case, we obtain a deterministic 3/2-approximation in time $2^d \cdot n^{\mathcal{O}(1)}$.

## 1 Introduction

The Traveling Salesperson Problem (TSP) is one of the best-studied problems in combinatorial optimization: given a complete graph $G$ on $n$ nodes together with edge weights $w : E(G) \to \mathbb{R}_{\geq 0}$, we seek a tour that starts at some node $v_0 \in V(G)$, then visits all other nodes of $G$ exactly once, and returns to the origin $v_0$ in such a way that the overall tour weight is minimized, which is the sum of the weights of the edges traversed by the tour. TSP is one of Karp's 21 NP-complete problems [15], which motivates the design of efficient, polynomial-time approximation algorithms for it. Recall that an $\alpha$-approximation for a minimization problem returns, for any instance $I$, in polynomial time a solution of value at

most $\alpha \cdot \mathrm{OPT}(I)$, where $\mathrm{OPT}(I)$ denotes the value of an optimal solution for $I$. Of special importance in this regard is Metric TSP, when the edge weight function $w$ obeys the triangle inequality. For Metric TSP, the tree doubling heuristic yields a 2-approximation, which was improved to a 3/2-approximation by Christofides [7] and Serdyukov [24] in the 1970s. This approximation factor stood unchallenged for many decades until its recent improvement to a $(3/2 - 10^{-36})$-approximation by Karlin et al. [14].

Due to its ubiquity, a large variety of extensions of the TSP have been studied. Among the most prominent ones is the Multiple TSP, where a set of $m \geq 1$ salespersons (all starting from some common node $v_0$ called a *depot*) jointly traverse the entire set of $n$ nodes, in order to minimize the overall tour length. That is, the goal is to find a collection of $m$ pairwise edge-disjoint cycles $C_1, \ldots, C_m$ (all intersecting in some node $v_0$) in $G$ whose union covers all nodes of the graph and such that the sum of the weights of the cycles is minimized. This character of having to solve both a partitioning and a sequencing problem simultaneously gives rise to considerable added complexity, akin to that encountered in vehicle routing problems. Indeed, one could interpret this problem as a variant of the Uncapacitated Vehicle Routing Problem; we, however, will adhere to the TSP-style naming convention, since this is more prevalent in the literature. Let us just mention here that for metric edge weights, Multiple TSP has the same approximation guarantee as the standard (single-person) metric TSP; in particular, Metric Multiple TSP admits a $(3/2-10^{-36})$-approximation in polynomial time by the results of Karlin et al. [14]. Frieze [10] analysed the case of Metric Multiple TSP when each of the tours has to contain at least one edge and intersect a common depot $v_0$; he provided a 3/2-approximation for this setting in polynomial time. The Multiple TSP is studied in more than 1,300 publications; an extensive survey is provided by Bektaş [1].

In this paper we study an extension of the Multiple TSP, where a *set* $D \subseteq V(G)$ of nodes is distinguished as *depots*. Formally, the Multi-Depot Multiple TSP (mdmtsp) takes as input a complete graph $G$ on $n$ nodes together with edge weights $w : E(G) \to \mathbb{R}_{\geq 0}$, as well as a set $D \subseteq V(G)$ of $d = |D|$ depots and an integer $m \geq 1$ denoting the number of salespersons available. Now again we are seeking a set of $m$ pairwise edge-disjoint cycles $C_1, \ldots, C_m$ in $G$ whose union covers all nodes of the graph and such that the sum of the weights of the cycles is minimized, but in addition each cycle must contain some depot from $D$. Such set of cycles is an optimal solution for the mdmtsp instance, and we denote the value of some optimal solution by $\mathrm{OPT}(G, D, w)$ (or simply OPT if the instance is clear from the context). The mdmtsp is motivated by several applications of high practical impact, like motion planning of a set of unmanned aerial vehicles [17, 21, 31] and the routing of service technicians where the technicians are leaving from multiple depots [20].

The theoretical aspects of mdmtsp have been studied in many research papers [1, 2, 3, 6, 13, 16, 25, 26, 28, 29, 30]. At this point, let us issue a word of caution. There are quite a few other varieties of (mdm)tsp considered in the literature, all subtly different from each other. For a compact overview of possible variations, there is the review paper of Bektaş [1]. For the scope of this paper, we consider the metric mdmtsp where the edge weights form a metric. This allows us to assume that $m = d$ throughout. This assumption is made for the following two reasons: on the one hand, the case $m > d$ is negligible as the objective function (the total weight of all tours) is invariant for multiple tours starting from a single depot (if weights satisfy the triangle inequality, it is easy to show that there is always an optimal solution in which at most one route will start and end at each depot). On the other hand, in the case $m \leq d$ we can try each selection of $d' = m$ depots by paying a multiplicative factor of $\binom{d}{m}$ in the run time only. Thus, any instance of metric mdmtsp is specified by a triple $(G, D, w)$, where $G$ is a complete graph on $n$ nodes, $D \subseteq V(G)$ is the set of depots, and $w : E(G) \to \mathbb{R}_{\geq 0}$ is a metric.

*The polynomial-time approximability of metric* MDMTSP *is not fully understood.* That there is a *set* $D$ of depots (and not just a single depot $v_0$), each one of which must be visited by one of the tours, makes the approximability of the problem much harder compared to metric MULTIPLE TSP (i.e., the version without depots). The added complexity arises from the fact that we not only have to give a good order in which to visit nodes, as in the TSP, but we also have to partition the nodes appropriately. In particular, the Christofides-Serdyukov algorithm [7, 24] no longer yields a 3/2-approximation in this setting. The original analysis of Christofides' and Serdyukov's algorithms relies on all odd-degree nodes of some spanning structure $F$ lying on the same tour, so a parity-correcting edge set $J$ can be computed that weighs at most $\frac{1}{2}$ OPT. This fact is not available in the multi-depot setting, so in polynomial time we can only guarantee a 2-approximation by using the spanner $F$ for $J$ also. However, this only achieves a tight approximation ratio of $2 - \frac{1}{d}$ for the multi-depot setting, as shown by Xu et al. [30] (see Figure 1 for a version of their lower-bound example), because the matching can have weight $\frac{d-1}{d}$ OPT.

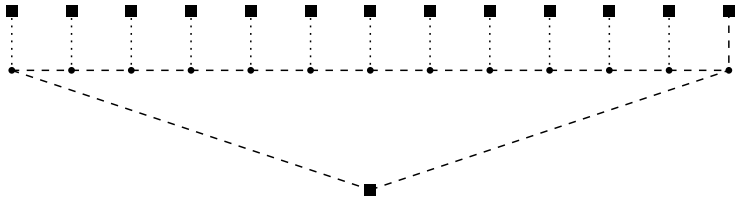

**Figure 1** An instance on which Algorithm 1 achieves approximation ratio arbitrarily close to 2. Square nodes are depots and all edges have unit weight. Dashed edges indicate a tour of length $d$, dotted edges a minimum CSF with weight $d-1$ that requires a join of weight $d-1$ to complete.

To avoid this issue, the constrained spanning forest needs to be rearranged such that there is again a matching of weight $\frac{1}{2}$ OPT, as in the work of Xu and Rodrigues [28] – this rearrangement though requires $n^{\Theta(d)}$ time.

Similarly, the algorithmic approaches to metric TSP based on solving a linear program (LP) are also unlikely to give $\alpha$-approximation algorithms with $\alpha < 2$ for metric MDMTSP. To this end, consider the following multi-depot version of the subtour-elimination LP, MDMTSP-LP:

$$\begin{aligned} \text{minimize} \quad & \sum_{e \in E(G)} w_e x_e & & \\ \text{subject to} \quad & \sum_{e \in \delta(v)} x_e = 2, & \forall\, v \in V(G) \setminus D & \\ & \sum_{e \in \delta(U)} x_e \geq 2, & \forall\, U \subseteq V(G) \setminus D & \\ & x_e \in [0,2], & \forall e \in E(G) & \end{aligned} \tag{MDMTSP-LP}$$

In Figure 2 we give a construction to show that MDMTSP-LP has integrality gap 2.

If one gives up on the polynomial run time of the approximation algorithm, then smaller approximation factors are possible. Xu and Rodrigues [28] show how to obtain a 3/2-approximation, but their algorithm requires time $n^{\Theta(d)}$, which is polynomial only if the number $d = |D|$ of depots is constant. Another 3/2-approximation for MDMTSP with run time $n^{\Theta(d)}$ follows from the recent work of Traub, Vygen and Zenklusen [26]. They in fact show the much stronger result that any $\lambda$-approximation algorithm for metric TSP also gives a $(\lambda + \varepsilon)$-approximation algorithm for metric MDMTSP with an additional run time factor of $n^{\mathcal{O}(d/\varepsilon)}$. In summary, the state-of-the-art for metric MDMTSP is that there is no $\alpha$-approximation known for MDMTSP for any absolute constant $\alpha < 2$ which runs in time $n^{o(d)}$.

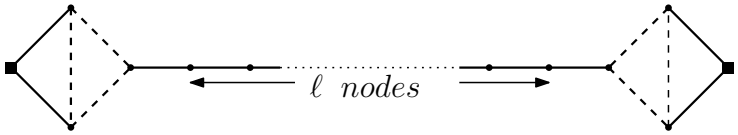

**Figure 2** An instance on which the multi-depot subtour-elimination LP has integrality gap arbitrarily close to 2. The square nodes are the depots and all edges have unit weight. The dashed edges are assigned $x_e = 0.5$ by the LP, the other edges $x_e = 1$. The LP then has optimum value at most $\ell + 6$, whereas the MDMTSP has optimum value $2(\ell + 4)$.

## 1.1 Our Results

Our main result is a novel approximation algorithm for metric MULTIPLE TSP on $d$ depots with a significantly improved run time. That is, we provide the first algorithm for metric MDMTSP which breaks the $n^{\Theta(d)}$ time barrier to obtain an approximation ratio strictly better than 2. Given an instance $(G, D, w)$ of metric MDMTSP, we say a collection $C_1, \ldots, C_d$ of cycles is a *tour* if they jointly cover all nodes of $G$ and each cycle contains exactly one depot from $D$.

▶ **Theorem 1.** *There is an algorithm that, given any $\varepsilon > 0$, in time $(1/\varepsilon)^{\mathcal{O}(d \log d)} \cdot n^{\mathcal{O}(1)}$ computes a tour $T$ for any set of $n$ cities with metric distances and $d$ depots. The algorithm is randomized, and with constant probability the length of the tour $T$ is at most $(3/2+\varepsilon) \cdot \mathrm{OPT}$.*

Thus, our result significantly improves on the previously best run time $n^{\Theta(d)}$ by Xu and Rodrigues [28] at the cost of some small additive $\varepsilon$ in the approximation factor.

To break through the barrier of 2 on the approximation ratio, we need to rework the initial spanner $F$ to be "correctly aligned" with the optimal solution so that each subtour contains an even number of odd-degree nodes, as initially proposed by Xu and Rodrigues [28]. We show that an approximate reworking can be done in time $f(d, \varepsilon) \cdot n^{\mathcal{O}(1)}$ for some suitable function $f$, resulting in a $(3/2+\varepsilon)$-approximation. To this end, firstly, we give a reduction of metric MDMTSP to a related routing problem which is known as the RURAL POSTPERSON PROBLEM (RPP). In the RPP, we are given an edge-weighted graph $G$ and a set $R$ of required edges, and are asked to compute a minimum-weight edge set $F$ such that $R \dot\cup F$ is connected and Eulerian. Our reduction reveals an approximation algorithm with run time $\mathcal{O}(n^3 + t)$ to compute solutions no worse than $\frac{3}{2}\,\mathrm{OPT} + \frac{1}{2}w(T)$, where $w(T)$ is the weight of a single-person TSP tour $T$ through the depots and $t$ denotes the time to compute $T$. Then we use a randomized algorithm of Gutin et al. [11] for the RPP, and an approximate weight reduction scheme of van Bevern et al. [27], to construct a $(1+\varepsilon)$-approximation algorithm for a variant of RPP with depots.

We are then in a position to speed up the reworking of the inital spanner due to two key insights. Firstly, we allow for some misalignment to remain, as long as it is only due to the presence of some *light* edges, limiting the number of edges we have to consider for removal from $F$. Secondly, we employ the constructed approximation algorithm for the RPP to complete our now disconnected spanner to a tour. Doing this provides a large speedup over the algorithm of Xu and Rodrigues, who first need to guess a set of edges to reconnect their spanner, and then employ a matching algorithm to obtain a tour. Using the RPP allows us to do both of these steps simultaneously, and considerably faster.

An important special case of metric TSP is when the metric $w$ is induced by the shortest paths in a graph. This version is also known as GRAPHIC TSP, and has been studied extensively from the perspective of approximation algorithms [18, 23]. For MDMTSP on graphic metrics, we obtain a *deterministic algorithm* with slightly better approximation factor and a reduced run time.

▶ **Theorem 2.** *There is an algorithm that, given any graph $G$ on $n$ nodes and set $D \subseteq V(G)$ of $d$ depots, in time $2^d \cdot n^{\mathcal{O}(1)}$ computes a tour $T$ of length at most $\frac{3}{2} \cdot \mathrm{OPT}$.*

## 1.2 Related work

In the case of a single salesperson, i. e. $m = 1$, Bérczi et al. [4] gave a polynomial-time 3/2-approximation for the *many-visits* version of metric MDMTSP, that is, when each node $v$ is equipped with a request $r(v)$ (encoded in binary) of how many times it should be visited.

In a different work, Bérczi et al. [5] have shown constant-factor approximation algorithms with ratio at most 4 for variants of metric MDMTSP where each tour has to visit exactly one depot (and thus, $d \leq m$).

For the RPP, which asks for a minimum-weight tour traversing all edges of a given subset $R$ of edges of a graph, there is a polynomial-time approximation algorithm (cf. Frederickson [8] or Jansen [12]) similar to the approach of Christofides-Serdyukov for metric TSP. The weight of a solution can be bounded by $(3\,\mathrm{OPT} + w(R))/2$, where $w(R)$ is the weight of $R$.

Oberlin et al. [19] studied heuristic approaches for MDMTSP where $d = m$ and each salesperson is located at its own depot.

For the objective of minimizing the longest tour length of any salesperson (rather than the sum of all the tour lengths), Frederickson et al. [9], among other routing problems, considered the case of a single depot ($d = 1$), and presented a $(\rho + 1 - 1/m)$-approximation algorithm where $\rho$ is the approximation ratio of an algorithm for the single-salesperson TSP.

# 2 Preliminaries

Let $\mathcal{U}$ be a finite universe. For a function $w : \mathcal{U} \to \mathbb{R}$ and a multiset $U \subseteq \mathcal{U}$ we write $w(U)$ to mean $\sum_{u \in U} w(u)$, where the sum has an additional summand for each copy of an element in $U$, i.e. it considers multiplicities. The disjoint union $\dot{\bigcup}_i A_i$ of some sets $\{A_i\}_i$ is considered to be the multiset of all items in the collection. For brevity we often write $2A$ to mean $A \,\dot{\cup}\, A$.

Throughout this paper, we consider the multiple-depot version of the metric MULTIPLE TSP, or metric MDMTSP for short. We will generally represent the metric by an edge-weighted graph whose shortest-path metric we assume to be the metric in use. Notice that this makes no difference in our setting since we are allowed to traverse edges multiple times; only if this is forbidden does the non-metric case become relevant.

▶ **Definition 3.** *An instance $(G, D, w)$ of metric* MDMTSP *consists of a complete graph $G$, a set $D \subseteq V(G)$ of $d$* depots*, and a metric $w : E(G) \to \mathbb{R}_+$ on $V(G)$. A multiset of edges $T \subseteq E(G)$ is called a* tour *of $(G, D, w)$ if*

***(P1)*** *the multigraph $(V(G), T)$ has even degree at every node in $V(G)$,*
***(P2)*** *and each connected component of $(V(G), T)$ contains at least one node from $D$.*

*We denote by $\mathrm{OPT}(G, D, w)$ the minimum weight of any tour of $(G, D, w)$. If the instance is clear from the context, we may only say* OPT*.*

Edge sets are generally allowed to be multisets, and graphs can have parallel edges.

Imitating the general framework of Christofides-Serdyukov [7, 24], we first compute an edge set $F$, called a constrained spanning forest (CSF), that ensures the connectivity property (P2). We then compute an additional set of edges $J$ such that $F \,\dot{\cup}\, J$ has property (P1).

▶ **Definition 4.** *Let $G$ be a graph and let $D \subseteq V(G)$. A* constrained spanning forest *in $(G, D)$ is a set $F \subseteq E(G)$ of edges such that the graph $(V(G), F)$ is acyclic and every connected component of $(V(G), F)$ contains at least one node from $D$.*

We will make use of the following result.

▶ **Theorem 5** (Rathinam et al. [21]). *Given any graph $G$ on $n$ nodes and $m$ edges with weights $w : E(G) \to \mathbb{R}$ and a set $D \subseteq V(G)$, a minimum-weight* CSF *of $(G, D, w)$ can be computed in time $\mathcal{O}((n+m)\log n)$.*

**Proof.** The computation of a minimum-weight CSF for $(G, D, w)$ can be reduced to computing a minimum-weight spanning tree in a graph $G'$ with edge weights $w'$. The graph $G'$ is obtained from $G$ by adding a single root node $r$ connected to every depot by an edge of some weight less than the weight all other edges in $G$. Kruskal's algorithm is guaranteed to choose these edges for the minimum-weight spanning tree in $(G', w')$, and after removing $r$ we are left with a minimum-weight CSF for $(G, D, w)$. ◀

Traditionally, property (P1) is obtained by computing a minimum-weight matching on the odd-degree nodes of the CSF, as in Algorithm 1. However, this algorithm only achieves a

**Algorithm 1** Algorithm Multi-Depot Christofides-Serdyukov.

**Input:** A metric MDMTSP instance $(G, D, w)$.
**Output:** A tour $T$ with $w(T) \leq 2\,\mathrm{OPT}$.
1 Compute a minimum-weight CSF $F$ for $(G, D, w)$;
2 Let $U$ be the set of nodes with odd degree in $F$;
3 Compute a minimum-weight perfect matching $M$ in $G[U]$;
**Result:** $T := F \dot\cup M$

tight approximation ratio of $2 - \frac{1}{d}$ for the multi-depot setting, as shown by Xu et al. [30] (see Figure 1 for a simplified version of their lower bound example), because the matching can have weight $\frac{d-1}{d}\,\mathrm{OPT}$. To avoid needing such an expensive matching, the constrained spanning forest needs to be rearranged such that there is again a matching of weight $\frac{1}{2}\,\mathrm{OPT}$, as in the work of Xu and Rodrigues [28].

## 3 Reducing Multi-Depot Multiple TSP to Rural Postperson Problem

In this section we show a reduction from the metric MDMTSP to the RPP. Recall that in the RPP there is a required set $R$ of edges that a tour should traverse, rather than a set of nodes.

▶ **Definition 6** (Rural Postperson Problem). *An instance $(G, R, w)$ of* RPP *consists of a graph $G$, a set $R \subseteq E(G)$ of required edges, and a metric weight function $w : E(G) \to \mathbb{R}_{\geq 0}$. A* solution *is multiset $J \subseteq E(G)$ for which $(V, R \dot\cup J)$ is Eulerian, and which has only one non-singleton connected component.*[1] *The weight of a solution $J$ is $w(J) = \sum_{e \in J} w(e)$. The goal of* RPP *is to compute an* optimal *solution, which is a solution of minimum weight* $\mathrm{OPT}(G, R, w)$.

There is a polynomial-time approximation algorithm for RPP [8, 12] which computes a solution $J \subseteq E(G)$ such that $w(R \dot\cup J) \leq \frac{3}{2} w(R \dot\cup J^*)$, i. e. $w(J) \leq \frac{3}{2}\,\mathrm{OPT} + \frac{1}{2} w(R)$, where $J^*$ is some optimal solution. Due to the first inequality and the unavoidable weight of $R$, the algorithm is known as a 3/2-approximation for RPP. This situation is very similar to the current approximation status of metric MDMTSP, where we can obtain a 3/2-approximation if we allow for some additional additive term. This observation motivates the following reduction from metric MDMTSP to RPP.

[1] This means that nodes not incident to any edge from $R$ do not need to be visited by the computed tour. For metric cost functions, however, one can always reduce to the case where $R$ spans $G$.

▶ **Observation 7.** *For each instance* $(G, D, w)$ *of* MDMTSP *there is an instance* $(G', R, w')$ *of* RPP *such that any solution to the* RPP *instance can be transformed in polynomial time into a solution to the* MDMTSP *instance of the same weight.*

**Proof.** First, compute any TSP tour $S$ on the depots in $G$, that is, on $G[D]$. Then, for each node $v \in V \setminus D$, introduce a second node $v'$, as well as an edge $e_v = \{v, v'\}$, and set its weight to $w'(e_v) = 0$. For each edge $e \in E(G)$ set $w'(e) = w(e)$, and set $R$ to be the union of $S$ and two copies of each $e_v$. The any solution to the constructed instance of RPP corresponds to an MDMTSP tour for $(G, D, w)$ of the same weight. ◀

Notice that this reduction, together with the 3/2-approximation for RPP, allows us to compute a solution to MDMTSP of weight at most $\frac{3}{2}\,\mathrm{OPT} + \frac{1}{2}w(S)$. In particular, if all depots are pairwise close to each other this is already a better-than-2 approximation.

In Section 5 we will in some sense show a stronger result that there is also a (Turing) reduction from MDMTSP to the special case of RPP where $(V, R)$ has few connected components, which has been shown by Gutin et al. to be tractable [11]:

▶ **Proposition 8** (Gutin et al. [11])**.** *There is a randomized algorithm for* RPP *that for any instance* $(G, R, w)$*, where* $(V(G), R)$ *has* $k$ *connected components and* $w$ *takes only integer values, in time* $2^{\mathcal{O}(k)}(n + \mathrm{OPT}(G, R, w))^{\mathcal{O}(1)}$ *produces a solution. With constant probability, the computed solution is optimal.*

However, as our reduction is only $(1+\varepsilon)$-approximate with respect to the solution qualities, and needs time exponential in $d$ and $\varepsilon$, we need to remove the polynomial dependence on $\mathrm{OPT}(G, R, w)$ in Proposition 8. To this end, we will adapt an approximate weight reduction scheme by van Bevern et al. [27]:

▶ **Lemma 9** (adapted from van Bevern et al. [27, Lemma 2.12])**.** *Let* $(G, R, w)$ *be an instance of* RPP *with integral weighs, let* $\varepsilon > 0$*, and let* $\beta = \max\{w(e) \mid e \in E(G)\}$*. Then in polynomial time we can compute a weight function* $w' : E(G) \to \mathbb{N}_{\geq 0}$ *such that*

- $\max\{w'(e) \mid e \in E(G)\} \leq 2|E(G)|/\varepsilon$*,*
- *and for all* $\alpha \geq 1$*, any solution* $J$ *to* $(G, R, w')$ *with weight* $w'(J) \leq \alpha\,\mathrm{OPT}(G, R, w')$ *also fulfills* $w(J) \leq \alpha\,\mathrm{OPT}(G, R, w) + \varepsilon\beta$*, as long as* $J$ *contains at most two copies of each edge.*

**Proof.** The rounding scheme simply sets $w'(e) := \lfloor w(e) \cdot \frac{2|E(G)|}{\varepsilon \cdot \beta} \rfloor$ for each edge $e$ of $G$. This yields the first condition, by definition. For the second condition, observe that for any $J$ we have

$$\frac{\varepsilon \cdot \beta}{2|E(G)|} w'(J) \leq w(J) \leq \frac{\varepsilon \cdot \beta}{2|E(G)|} w'(J) + \frac{\varepsilon \cdot \beta}{2|E(G)|}|J| \leq \frac{\varepsilon \cdot \beta}{2|E(G)|} w'(J) + \varepsilon\beta \ .$$

Hence, the two weight functions are equivalent up to scaling by a constant and the addition of at most $\varepsilon\beta$. ◀

Notice that the restriction on $J$ having at most two copies of each edge is never a problem: whenever a solution to the RPP has three or more copies of one edge, we can delete two of them to obtain a cheaper solution.

We will combine Proposition 8 and Lemma 9 to obtain an approximation for $k$-component RPP whose run time does not depend on OPT.

▶ **Corollary 10.** *There is a randomized algorithm that, for any $\varepsilon > 0$, in time $2^{\mathcal{O}(k)}(n+\frac{1}{\varepsilon})^{\mathcal{O}(1)}$ computes a solution $J$ for any instance $(G, R, w)$ of* RPP *where $(V(G), R)$ has $k$ connected components. The computed solution $J$ has the property that, with constant probability, $w(J) \leq \mathrm{OPT}(G, R, w) + \varepsilon \max\{w(e) \mid e \in J^* \dot\cup R\}$, where $J^*$ is some optimal solution to the instance.*

**Proof.** We first guess the weight $\beta$ of the most expensive edge in $J^* \dot\cup R$, where $J^*$ is some optimal solution. There are only $|E(G)|$ options, so the guessing generates only polynomial overhead. All edges that are more expensive than $\beta$ can be removed from the instance to get some graph $G'$. Now we apply Lemma 9 to get an instance with weights $w'$ bounded by $2|E(G)|/\varepsilon$ and use the exact algorithm from Proposition 8 to get a solution $J$ to $(G', R, w')$ in time $2^{\mathcal{O}(k)}(n+\frac{1}{\varepsilon})^{\mathcal{O}(1)}$. From Lemma 9 with $\alpha = 1$ we know that

$$w(J) \leq \mathrm{OPT}(G, R, w) + \varepsilon\beta \leq \mathrm{OPT}(G, R, w) + \varepsilon \max\{w(e) \mid e \in J^* \dot\cup R\},$$

which proves the claim. ◀

We will be using this algorithm to complete partial solutions to instances of MDMTSP. We will need only a slight modification that allows for the presence of depots as follows.

▶ **Definition 11** (Depot Rural Postperson Problem)**.** *An instance $(G, D, R, w)$ of the* Depot Rural Postperson Problem *(*DRPP*) consists of an* RPP *instance $(G, R, w)$ and some depots $D \subseteq V(G)$. A* solution *is a multiset $J \subseteq E(G)$ such that $(V, R \dot\cup J)$ is Eulerian and each non-singleton connected component of $(V, R \dot\cup J)$ contains at least one depot. The weight of a solution $J$ is $w(J) = \sum_{e \in J} w(e)$. The goal is to compute an* optimal *solution, which is a solution of minimum weight* $\mathrm{OPT}(G, D, R, w)$.

The depot version DRPP can be reduced to regular RPP quite easily.

▶ **Corollary 12.** *There is a randomized algorithm that, for any instance $(G, D, R, w)$ of* DRPP *where $(V(G), R)$ has $k$ connected components and any $\varepsilon > 0$, in time $2^{\mathcal{O}(k \log k)}(n+\frac{1}{\varepsilon})^{\mathcal{O}(1)}$ computes a solution $J$ such that, with constant probability, $w(J) \leq (1+\varepsilon)\,\mathrm{OPT}(G, D, R, w) + \varepsilon w(R)$.*

**Proof.** Note first that each connected component of $(V(G), R)$ can be assumed to contain at most one depot, so $|D| \leq k$. Some optimum solution $J^*$ induces a partition of the connected components of $(v(G), R)$ where each partition class corresponds to those components connected to some specific depot. There are at most $|D|^k \in 2^{\mathcal{O}(k \log k)}$ possible partitions, so we can try each partition, solve the regular RPP instance on each of the $|D|$ classes of the partition using the algorithm from Corollary 10, and return the best solution we found. ◀

## 4 Intuition for the Algorithm

The algorithm of Xu and Rodrigues [28] executes, at a very high level, the following steps:

1. Compute a minimum-weight constrained spanning forest $F$ for $(G, D, w)$.
2. Guess a set $X$ of at most $|D| - 1$ edges such that they are in $F$ but not in some fixed optimal tour $T$.
3. Discard the guessed edges $X$ from $F$. This leaves at most $2|D|$ connected components in $(V, F \setminus X)$. If we have guessed correctly, every subtour of $T$ now contains an even number of odd-degree nodes. There must exist some edges $A$ from $T$ such that $(F \setminus X) \cup A$ is a CSF for $(G, D)$ with $w((F \setminus X) \cup A) \leq w(T)$. The value $|A|$ is at most $|D|$, so we also guess $A$.

4. Since $A$ contains only edges from $T$, every subtour of $T$ still contains an even number of odd-degree nodes with respect to $(V, (F \setminus X) \cup A)$. If we compute an odd-join $J$ for $(F \setminus X) \cup A$, we have $w(J) \leq \frac{1}{2}\,\mathrm{OPT}$, so return $((F \setminus X) \cup A) \dot\cup J$.

Since the algorithm needs to guess $2|D|$ edges in total (in step 2), it can be implemented in time $n^{\mathcal{O}(d)}$. We modify this guessing step by considering for discarding (in step 3) only very heavy edges, and by sidestepping the guessing of $A$; instead of computing first a connected structure and then a join we do this simultaneously, using the algorithm for RPP. Specifically:

- In step 2, we only consider edges that are very expensive relative to the total weight of the forest $F$. If the targeted edge $e$ is not in this collection, we do not delete it but instead use it as part of the augmenting set $A$, doubling the edge. This also fixes parity, but requires us to relax $w((F \setminus X) \dot\cup A) \leq w(T)$ to $w((F \setminus X) \dot\cup A) \leq (1+\varepsilon)w(T)$. The $\varepsilon$ can be controlled by how expensive relative to $F$ we allow these non-deleted edges to be.
- In step 3, we do not actually guess $A$, we merely use its existence. We instead solve an instance of DRPP with at most $2d$ connected components for which $A \dot\cup J$ is a solution. Using the algorithm from Corollary 12, we can compute a $(1+\varepsilon)$-approximation for the DRPP in time $f(d,\varepsilon) \cdot n^{\mathcal{O}(1)}$. We use the solution $J'$ as a replacement for $A \dot\cup J$ knowing $w(J') \leq (1+\varepsilon)w(A \dot\cup J)$. Combining inequalities for $J$ and $F$ gives:

$$w((F \setminus X) \dot\cup J') \leq (1+\varepsilon)w(((F \setminus X) \dot\cup A) \dot\cup J) \leq (1+\varepsilon)\frac{3}{2}\,\mathrm{OPT} \quad .$$

An illustration of the augmentation scheme can be found in Figure 3.

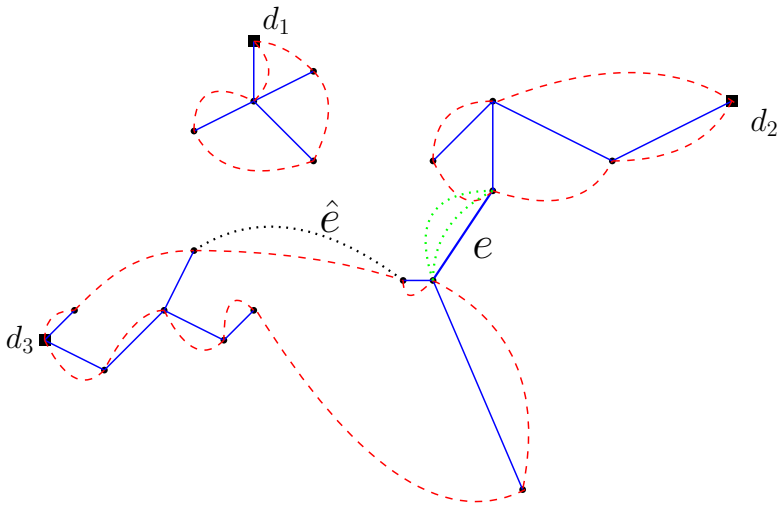

**Figure 3** Illustration of the augmenting edges explored by our algorithm. Blue solid edges represent a CSF, dashed red edges an optimal tour. Note that the tours of $d_2$ and $d_3$ have an odd number of nodes with odd degree in the CSF. Our algorithm considers two options to remedy this. We either add two copies (green, dotted) of the edge $e$ to the optimal tour, if $e$ is considered to be light enough. This joins the tours of $d_2$ and $d_3$ to a single tour with an even number of odd-degree nodes. If $e$ is considered too heavy for this, we remove $e$ from the CSF and replace it with the edge $\hat{e}$ (black, dotted). As $\hat{e}$ comes from the optimal tour, this keeps the cost of the CSF below OPT and it fixes the parities.

## 5 Towards Faster Parity Correction

In this section, we give a formal version of the algorithm described in the previous section, which we state as Algorithm 2. We prove this algorithm to be a $(3/2+\mathcal{O}(\varepsilon))$-approximation for metric MDMTSP in Theorem 17. We will restate and reprove some of the results of Xu and Rodrigues [28] to ensure completeness of the presentation and to integrate properly our changes to their algorithm.

To this end, let us fix some notation throughout this section. Let $(G, D, w)$ be a metric MDMTSP instance with $D = \{d_1, \ldots, d_d\}$, an optimal tour $T$, and the minimum-weight CSF $F$ for $(G, D, w)$ that was computed Algorithm 1. We denote by $T_i$ be the connected component of $T$ containing $d_i$, by $F_i$ the subtree of $F$ containing $d_i$, and $U_i$ the set of nodes in $T_i$ that have odd degree with respect to the edges in $F$. We take $U = \bigcup_i U_i$.

By minimality of $F$, we already know that $w(F) \leq w(T) = \mathrm{OPT}$. To extend $F$ to an MDMTSP tour, we try to compute a minimum-weight matching between the nodes in $U$. It is a standard argument from the analysis of the Christofides-Serdyukov algorithm that if $|U_i|$ is even, $T_i$ contains two disjoint matchings for the nodes in $U_i$. So if every $U_i$ has even cardinality, then any minimum-weight matching has weight at most $\frac{1}{2}\,\mathrm{OPT}$. But this is not the case, since a tree $F_i$ might contain nodes from many different tours, so the odd-degree nodes are distributed arbitrarily. To record this "misalignment" between the trees and subtours we introduce the concept of an *alignment graph*.

▶ **Definition 13** (Alignment Graph). *The alignment graph $H$ for $(G, F, T)$ is constructed as $V(H) = D$, and*

$$E(H) = \{\{d_i, d_j\} \mid \exists e \in F \text{ s.t. } |e \cap V(T_i)| = |e \cap V(T_j)| = 1\} \ .$$

*We also define a weight function $w_H : E(H) \to \mathbb{R}_+$ as*

$$w_H((d_i, d_j)) := \min\{w(e) | e \in F,\ |V(T_i) \cap e| = |V(T_j) \cap e| = 1\} \ .$$

In the following, we assume that $H$ is connected, otherwise the analysis holds independently for each connected component.

Now we take $D_{\mathrm{odd}}$ to be the collection of depots $d_i$ for which $|U_i|$ is odd, and $A_H$ to be any $D_{\mathrm{odd}}$-join in $H$. The join $A_H$ can be used to augment the original tour $T$ to be connected. To do this we transfer the join to the original graph to ensure that it contains a "cheap" matching. For every edge $e = \{d_i, d_j\} \in E(A_H)$, pick an edge in $\hat{e} \in E(F)$ with $w(\hat{e}) = w_H(e)$ and $|\hat{e} \cap V(T_i)| = |\hat{e} \cap V(T_j)| = 1$. Denote by $A$ the collection of these $\hat{e}$. Observe that every node in $T \dot\cup 2A$ has even degree, and every connected component of the graph contains an even number of nodes from $U$. Hence, there exists a $U$-join $J$ in $G$ with $w(J) \leq \frac{1}{2} w(T \dot\cup 2A)$.

Now notice that, if the edges in $A$ have weight at most $\varepsilon w(F)$, this inequality yields that Algorithm 1 already achieves a good approximation ratio, specifically

$$w(F) + w(M) \leq w(F) + w(J) \leq (1+\varepsilon)w(F) + \frac{1}{2}w(T) \leq (\frac{3}{2} + \varepsilon)w(T) \ .$$

Based on this observation, we are willing to augment $T$ with low-weight edges from $F$ to find a low-weight matching. Therefore, we need to distinguish between *heavy* and *light* edges.

▶ **Definition 14.** *Let $\varepsilon > 0$. An edge $e \in F$ is* $\varepsilon$-light *if $w(e) \leq \frac{\varepsilon}{d} \cdot w(F)$; else, it is* $\varepsilon$-heavy.

We now try to replace the $\varepsilon$-heavy edges in $A$ with some other edges from $T$.

**Algorithm 2** Algorithm Extended Multi-Depot Christofides-Serdyukov.

**Input:** A metric MDMTSP instance $(G, D, w)$ and a parameter $\varepsilon > 0$.
**Output:** A tour $T$ such that $w(T) \leq (3/2 + \varepsilon)\,\mathrm{OPT}$ with constant probability.

```
Compute a minimum-weight CSF F for (G, D, w);
Let T be the currently best MDMTSP solution, initially 2F;
Let Y be the set of edges in F which are ε-heavy;
foreach X ⊆ Y, |X| ≤ |D| do
    F' := F \ X;
    Compute a solution M for the DRPP instance (G, D, F', w) using Corollary 12 ;
    if w(M ∪̇ F') < w(T) then
        set T = M ∪̇ F';
    end
end
```

**Result:** $T$

▶ **Lemma 15** (compare [28, Section 2]). *Let $X \subseteq A$. Then there exist a set $\hat{A} \subseteq E(T)$ of edges such that $(F \setminus X) \cup \hat{A}$ is a CSF for $(G, D)$ with $w((F \setminus X) \cup \hat{A}) \leq w(T)$.*

**Proof.** Consider the forest $F'$ obtained from $T$ by removing exactly one edge from each subtour. $F'$ contains only edges from $T$, so it is disjoint from $X$. By a standard matroid exchange argument, for each $e \in X$ there is a $\hat{e} \in F'$ such that $F - e + \hat{e}$ is a CSF and $w(e) \leq w(\hat{e})$. This process can then be iterated to remove all of $X$. The collection of these $\hat{e}$ is $\hat{A}$, giving $w((F \setminus X) \cup \hat{A}) \leq w(F') \leq w(T)$. ◀

This process of replacing augmenting edges from $A$ with edges out of $T$ also fulfills the key goal of putting an even number of odd-degree nodes into every connected component of some augmented MDMTSP solution. Consider the following lemma, which is in substance a version of a statement by Xu and Rodrigues [28, Theorem 2].

▶ **Lemma 16.** *Let $A, X, \hat{A}$ be as in Lemma 15. Then every connected component of $T \cup (A \setminus X)$ contains an even number of nodes that have odd degree in $(F \setminus X) \cup \hat{A}$.*

**Proof.** Notice first that the connected components of $T \cup (A \setminus X)$ are the union of some of the subtours of $T$. Since the edges in $\hat{A}$ belong to some tour, adding them to $F \setminus X$ flips the parity of the degrees of two nodes on the same tour, so the total parity of odd-degree nodes on that tour does not change. We can therefore restrict ourselves to considering the odd-degree nodes with respect to $F \setminus X$.

Recall that originally $A$ was constructed from a $D_{\mathrm{odd}}$-join $A_H$ in the alignment graph $H$. So $X$ corresponds to some edge set $X_H \subseteq A_H$, and we know that $A_H \setminus X_H$ constitutes an $(D_{\mathrm{odd}} \Delta \dot{\bigcup}_{e \in X_H} e)$-join, where $\Delta$ denotes the symmetric difference. For multisets, the symmetric difference of some sets contains an item if and only if it is contained an odd number of times in their disjoint union. At the same time, removing an edge $e \in X$ from $F$ with corresponding $\{d_i, d_j\} \in X_H$ changes the degree of one node in $V(T_i)$ and one node on $V(T_j)$. So, the depots whose tours contain an odd number of odd-degree nodes with respect to $F \setminus X$ are precisely $(D_{\mathrm{odd}} \Delta \dot{\bigcup}_{e \in X_H} e)$, so $A_H \setminus X_H$ joins them correctly. ◀

We are now ready to prove that Algorithm 2 returns a $(3/2 + \mathcal{O}(\varepsilon))$-approximation, with constant probability.

▶ **Theorem 17.** *The tour returned by Algorithm 2 has weight at most $(3/2 + \mathcal{O}(\varepsilon))\,\mathrm{OPT}$, with constant probability.*

**Proof.** Set $T'$ to be the tour returned by the algorithm. Now let $A$ be the augmenting edge set for some optimal tour as before and $X$ the set of $\varepsilon$-heavy edges in $A$. We look at the iteration of the algorithm where that $X$ is considered for removal. From Lemma 15 we know that there exists some edge set $\hat{A}$ with $w(F \setminus X \cup \hat{A}) \leq \mathrm{OPT}$ and Lemma 16 implies that there is an edge set $J$ such that $F \setminus X \dot\cup \hat{A} \dot\cup J$ is Eulerian, contains a depot in each connected component, and $w(J) \leq \frac{1}{2}w(T \cup (A \setminus X))$. Therefore, $\hat{A} \dot\cup J$ is a solution to the DRPP instance $(G, D, F', w)$. Hence, the $M$ computed in the algorithm fulfills $w(M) \leq (1+\varepsilon)w(\hat{A} \dot\cup J) + \varepsilon w(F')$. Putting all these inequalities together yields

$$\begin{aligned} w(T') &= w(M) + w(F \setminus X) \\ &\leq (w(F) - w(X) + w(\hat{A})) + (\frac{1}{2}(w(T) + w(A \setminus X)) + \varepsilon(w(\hat{A}) + w(J) + w(F)) \\ &\leq w(T) + \frac{1}{2}(w(T) + d \cdot \frac{\varepsilon}{d}w(F)) + \varepsilon(w(\hat{A}) + w(J) + w(F)) \leq \frac{3}{2}w(T) + 4\varepsilon w(T), \end{aligned}$$

where we use that $A \setminus X$ contains at most $d$ edges, and all of them are $\varepsilon$-light. ◀

Notice that this algorithm will give a $(3/2+\varepsilon)$-approximation when called with $\varepsilon/4$ as the parameter of approximation. The additional run time cost will vanish in the $\mathcal{O}$-notation. The probability of success for this algorithm is the same as that for the algorithm in Proposition 8. Notice that while that algorithm is called many times, we only need it to succeed for one specific choice of $X$. If it fails in one of the other attempts, we do not care.

It remains to analyze the run time of this algorithm. We see that $Y$, the set of $\varepsilon$-heavy edges, has size at most $\frac{d}{\varepsilon}$, so there are only $(\frac{d}{\varepsilon})^d$ possible values for $X$ to be tried. Note also that each loop iteration requires the approximate solution of a DRPP instance with $\mathcal{O}(d)$ components which can be done in time $2^{\mathcal{O}(d \log d)}(n + \frac{1}{\varepsilon})^{\mathcal{O}(1)}$. The total run time then is $(1/\varepsilon)^{\mathcal{O}(d \log d)} \cdot n^{\mathcal{O}(1)}$, showing Theorem 1.

## 6 A Deterministic 3/2-Approximation for Graphic MDMTSP

In this section we provide a deterministic 3/2-approximation for MDMTSP when the metric is the shortest-path metric of an unweighted graph. The run time of the algorithm is $2^d \cdot n^{\mathcal{O}(1)}$.

Let $(G, D)$ be an instance of graphic MDMTSP, where $G$ this time is the unweighted graph inducing the shortest-path metric. Note that we can assume $G$ to be connected. This allows us to construct TSP tours that are not much more expensive than optimal solutions to MDMTSP, which re-enables the original analysis of the Christofides-Serdyukov Algorithm.

For a given optimal MDMTSP tour $T$, we can extend it to a TSP tour by introducing at most $2(d-1)$ edges. To do this, contract the subtours of $T$, find a spanning tree in the contracted graph, and double all the edges of that tree. We then see that the solution $F \dot\cup M$ returned by Algorithm 1 fulfills

$$w(F \dot\cup M) \leq w(T) + \frac{1}{2}(w(T) + 2(d-1)) = \frac{3}{2}w(T) + d - 1 \ .$$

Notice that the additive term $d-1$ is likely to be very small, since we know $w(T) \geq n - d$. A similar argument can also be made for metrics which are continuous in the sense that the space cannot be partitioned into two very distant parts.

▶ **Observation 18.** *Let $(G, D, w)$ be an* integer-weighted *instance of* MDMTSP *for which there exists a constant $L$ such that, for all $U \subseteq V(G)$, it holds* $\min\{w(u,v) \mid u \in U, v \notin U\} \leq L$. *Then Algorithm 1 returns a solution $T$ for $(G, D, w)$ with $w(T) \leq \frac{3}{2}\,\mathrm{OPT}(G, D, w) + L(d-1)$.*

Since we know $w(T)$ to be in $\Omega(n-d)$ also in this case, Algorithm 1 gives an *asymptotic* 3/2-approximation for any constant $d$ and $L$. We can even get rid of the additive term in the graphic case (i.e. $L = 1$) with some additional run time.

▶ **Observation 19.** *There is a* 3/2*-approximation algorithm for graphic* MDMTSP *with run time* $2^d \cdot n^{\mathcal{O}(1)}$.

**Proof.** Let $T$ be some fixed optimal tour. We start by guessing the set $D' \subseteq D$ of depots whose subtours in $T$ contain at least one edge, generating on overhead of $2^d$. Then we know that $T$ contains a CSF $F'$ for $(G, D')$ with weight $|E(T)| - |D'|$. As before, we connect together all subtours of the depots in $D'$ with $|D'| - 1$ edges, and double these edges. Then the tour $F \dot\cup M$ returned by Algorithm 1 fulfills

$$|E(F \dot\cup M)| \leq |E(T)| - |D'| + \frac{1}{2}(|E(T)| + 2(|D'| - 1)) = \frac{3}{2}|E(T)| - 1,$$

and that proves the claim. ◀

For the special case where we require each depot to have a non-empty tour, we do not even have to guess the correct subset of depots in Observation 19, yielding a 3/2-approximation in truly polynomial time.

## 7 Discussion

We have shown that metric MDMTSP admits a randomized $(3/2+\varepsilon)$-approximation algorithm in time $(1/\varepsilon)^{\mathcal{O}(d \log d)} \cdot n^{\mathcal{O}(1)}$, filling in the gap between the best-known polynomial approximation factor, 2, and the 3/2-approximation of Xu and Rodrigues in time $n^{\Theta(d)}$. However, there remain a number of natural openings for improving on our result:

- Can our algorithm be derandomized? Since we rely on the algorithm of Gutin et al. [11] to solve RPP instances, this would require a derandomization of their result. However, their algorithm relies on the Schwartz-Zippel Lemma [22, 32] for which no deterministic alternatives have been found in the last 40 years.
- Can the approximation factor be improved from $3/2 + \varepsilon$ to 3/2? We loose some approximation quality both when determining which edges to delete from the CSF, and when solving RPP. Improving the first point would require a further refinement of the tree-rearrangement technique introduced by Xu and Rodrigues [28]. For the second point, the RPP algorithm of Gutin et al. would need to be sped up to run in strongly polynomial time. Again, their algorithm relies on algebraic techniques for which derandomization appears difficult, so a major technical innovation for $k$-component RPP is maybe necessary.
- Does there exist some polynomial-time $\alpha$-approximation algorithm for MDMTSP with $\alpha < 2$? We know from Traub et al. [26] that any $\alpha$-approximation algorithm for single-salesperson TSP implies a $(\alpha + \varepsilon)$-approximation for MDMTSP for any constant number of depots, i.e. in time $n^{\Theta(d)}$. For instances with many depots however, the problem remains intractable. It is of particular interest that two major technical tools for the classical TSP, Christofides' Algorithm and the Subtour-Elimination LP, fail to achieve better-than-2-approximations in the multi-depot regime (see Figure 1 and Figure 2). It appears that to make progress on a polynomial-time algorithm some novel structural insights would be required.

## Abstract

In this paper, we study efficient parallel edit distance algorithms, both in theory and in practice. Given two strings $A[1..n]$ and $B[1..m]$, and a set of operations allowed to edit the strings, the edit distance between $A$ and $B$ is the minimum number of operations required to transform $A$ into $B$. In this paper, we use edit distance to refer to the Levenshtein distance, which allows for unit-cost single-character edits (insertions, deletions, substitutions). Sequentially, a standard Dynamic Programming (DP) algorithm solves edit distance with $\Theta(nm)$ cost. In many real-world applications, the strings to be compared are similar to each other and have small edit distances. To achieve highly practical implementations, we focus on output-sensitive parallel edit-distance algorithms, i.e., to achieve asymptotically better cost bounds than the standard $\Theta(nm)$ algorithm when the edit distance is small. We study four algorithms in the paper, including three algorithms based on Breadth-First Search (BFS), and one algorithm based on Divide-and-Conquer (DaC). Our BFS-based solution is based on the Landau-Vishkin algorithm. We implement three different data structures for the longest common prefix (LCP) queries needed in the algorithm: the classic solution using parallel suffix array, and two hash-based solutions proposed in this paper. Our DaC-based solution is inspired by the output-insensitive solution proposed by Apostolico et al., and we propose a non-trivial adaption to make it output-sensitive. All of the algorithms studied in this paper have good theoretical guarantees, and they achieve different tradeoffs between work (total number of operations), span (longest dependence chain in the computation), and space.

We test and compare our algorithms on both synthetic data and real-world data, including DNA sequences, Wikipedia texts, GitHub repositories, etc. Our BFS-based algorithms outperform the existing parallel edit-distance implementation in ParlayLib in all test cases. On cases with fewer than $10^5$ edits, our algorithm can process input sequences of size $10^9$ in about ten seconds, while ParlayLib can only process sequences of sizes up to $10^6$ in the same amount of time. By comparing our algorithms, we also provide a better understanding of the choice of algorithms for different input patterns. We believe that our paper is the first systematic study in the theory and practice of parallel edit distance.

## 1 Introduction

Given two strings (sequences) $A[1..n]$ and $B[1..m]$ over an alphabet $\Sigma$ and a set of operations allowed to edit the strings, the ***edit distance*** between $A$ and $B$ is the minimum number of operations required to transform $A$ into $B$. WLOG, we assume $m \leq n$. The most commonly used metric is the ***Levenshtein distance*** which allows for unit-cost single-character edits (insertions, deletions, substitutions). In this paper, we use *edit distance* to refer to the Levenshtein distance. We use $k$ to denote the edit distance for strings $A$ and $B$ throughout this paper. Edit distance is usually used to measure the similarity of two strings (a smaller distance means higher similarity).

Edit distance is a fundamental problem in computer science, and is introduced in most algorithm textbooks (e.g., [14, 15, 23]). In practice, it is widely used in version-control software [54], computational biology [12, 31, 39], natural language processing [10, 29], and spell corrections [28]. It is also closely related to other important problems such as longest common subsequence (LCS) [50], longest increasing subsequence (LIS) [34], approximate string matching [56], and multi-sequence alignment [59]. The classic dynamic programming (DP) solution can compute edit distance in $O(nm)$ work (number of operations) between two strings of sizes $n$ and $m$. This complexity is impractical if the input strings are large. One useful observation is that, in real-world applications, the strings to be compared are usually *reasonably similar*, resulting in a relatively small edit distance. For example, in many version-control softwares (e.g., Git), if the two committed versions are similar (within a certain number of edits), the "delta" file is stored to track edits. Otherwise, if the difference is large, the system directly stores the new version. Most of the DNA or genome sequence alignment applications also only focus on when the number of edits is *small* [39]. We say an edit distance algorithm is *output-sensitive* if the work is $o(nm)$ when $k = o(n)$. Many more efficient and/or practical algorithms were proposed in this setting with cost bounds parameterized by $k$ [19, 20, 21, 22, 26, 35, 36, 37, 46, 47, 49].

Considering the ever-growing data size and plateaued single-processor performance, it is crucial to consider parallel solutions for edit distance. Although the problem is simple and well-studied in the sequential setting, we observe a *huge gap* between theory and practice in the parallel setting. The few implementations we know of [7, 55, 58] simply parallelize the $O(nm)$-work sequential algorithm and require $O(n)$ span (longest dependence chain), which indicates low-parallelism and redundant work when $k \ll n$. Meanwhile, numerous theoretical parallel algorithms exist [1, 3, 20, 37, 41, 48], but it remains unknown whether these algorithms are practical (i.e., can be implemented with reasonable engineering effort), and if so, whether they can yield high performance. *The goal of this paper is to formally study parallel solutions for edit distance. By carefully studying existing theoretical solutions, we develop* ***new output-sensitive parallel solutions with good theoretical guarantees and high performance in practice****. We also conduct in-depth experimental studies on existing and our new algorithms.*

The classic dynamic programming (DP) algorithm solves edit distance by using the states $G[i, j]$ as the edit distance of transforming $A[1..i]$ to $B[1..j]$. $G[i, j]$ can be computed as:

$$G[i,j] = \begin{cases} G[i-1,j-1] & \text{if } A[i] = B[j] \text{ and } i > 0, j > 0 \\ 1 + \min(G[i-1,j], G[i-1,j-1], G[i,j-1]) & \text{otherwise} \end{cases}$$

$$G[i,j] = \max(i,j) \qquad \text{if } i = 0 \text{ or } j = 0$$

A simple parallelization of this computation is to compute all states with the same $i + j$ value in parallel, and process all $i + j$ values in an incremental order [7, 55, 58]. However, this approach has low parallelism as it requires $n + m$ rounds to finish. Later work [1, 3, 41]

**Table 1 Algorithms in this paper.** $k$ is the edit distance. $b$ is the block size. $^*$: Monte Carlo algorithms due to the use of hashing. "Space$^*$" means auxiliary space used in addition to the input. Here we assume constant alphabet size for BFS-SA.

| Algorithm | Work | Span | Space$^*$ | Algorithm | Work | Span | Space$^*$ |
|---|---|---|---|---|---|---|---|
| **BFS-SA** | $O(n+k^2)$ | $\tilde{O}(k)$ | $O(n)$ | **BFS-Hash**$^*$ | $O(n+k^2\log n)$ | $\tilde{O}(k)$ | $O(n)$ |
| **DaC-SD** | $O(nk\log k)$ | $\tilde{O}(1)$ | $O(nk)$ | **BFS-B-Hash**$^*$ | $O(n+k^2b\log n)$ | $\tilde{O}(kb)$ | $O(n/b+k)$ |

improved parallelism using a ***divide-and-conquer (DaC)*** approach and achieved $\tilde{O}(n^2)$ work and polylog$(n)$ span. These algorithms use the monotonicity of the DP recurrence, and are complicated. There are two critical issues in the DaC approaches. First, to the best of our knowledge, there exist no implementations given the sophistication of these algorithms. Second, they are not output-sensitive ($\tilde{O}(nm)$ work), which is inefficient when $k \ll n$.

Alternatively, many existing solutions, both sequentially [19, 20, 21, 22, 26, 35, 36, 46, 47] and in parallel [20, 37] use output-sensitive algorithms, and achieve $\tilde{O}(nk)$ or $\tilde{O}(n+k^2)$ work and $\tilde{O}(k)$ span. These algorithms view DP table as a grid-like DAG, where each state (cell) $(x, y)$ has three incoming edges from $(x-1, y)$, $(x, y-1)$, and $(x-1, y-1)$ (if they exist). The edge weight is 0 from $(x-1, y-1)$ to $(x, y)$, when $A[x] = B[y]$, and 1 otherwise. Then edit distance is equivalent to the shortest path from $(0, 0)$ to $(n, m)$. An example is given in Fig. 1. Since the edge weights can only be 0 or 1, we can use ***breadth-first search (BFS)*** from the cell $(0, 0)$ until $(n, m)$ is reached. Ukkonen [56] further showed that using ***longest common prefix (LCP)*** queries based on suffix trees or suffix arrays, the work can be improved to $O(n + k^2)$. Landau and Vishkin [37] parallelized this algorithm (see Sec. 3). While the sequential output-sensitive algorithms have been widely used in practice [21, 26, 36, 46, 47], we are unaware of any existing implementations for the parallel version.

We systematically study parallel output-sensitive edit distance, using both the BFS-based and the DaC-based approaches. Our first effort is to implement the BFS-based Landau-Vishkin algorithm with our carefully-engineered parallel suffix array (SA) implementation, referred to as BFS-SA. Although suffix array is theoretically efficient with $O(n)$ construction work, the hidden constant is large. Thus, we use hashing-based solutions to replace SA for LCP queries to improve the performance in practice. We first present a simple approach BFS-Hash in Sec. 3.2 that stores a hash value for all prefixes of the input. This approach has $O(n)$ construction work, $O(\log n)$ per LCP query, and $O(n)$ auxiliary space. While both BFS-SA and BFS-Hash take $O(n)$ extra space, such space overhead can be significant in practice – for example, BFS-Hash requires $n$ 64-bit hash values, which is 4× the input size considering characters as inputs, and 32× with even smaller alphabet such as molecule bases (alphabet as $\{A, C, G, T\}$). To address the space issue, we proposed BFS-B-Hash using *blocking*. Our solution takes a user-defined parameter $b$ as the block size, which trades off between space usage and query time. BFS-B-Hash limits extra space in $O(n/b)$ by using $O(b \log n)$ LCP query time. Surprisingly, despite a larger LCP cost, our hash-based solutions are consistently faster than BFS-SA in all real-world test cases, due to cheaper construction. All of our BFS-based solutions are simple to program.

We also study the DaC-based approach and propose a parallel output-sensitive solution. We propose a non-trivial adaption for the AALM algorithm [1] to make it output-sensitive. Our algorithm is inspired by the BFS-based approaches, and improves the work from $\tilde{O}(nm)$ to $\tilde{O}(nk)$, with polylogarithmic span. The technical challenge is that the states in the computation are no longer a rectangle, but an irregular shape (see Fig. 1 and 3). We then present a highly non-trivial implementation of this algorithm. Among many key challenges,

we highlight our solution to avoid dynamically allocating arrays in the recursive execution. While memory allocation is mostly ignored theoretically, in practice it can easily be the performance bottleneck in the parallel setting. We refer to this implementation as DaC-SD, with details given in Sec. 4 and 5.2 and the full version of this paper [16].

The bounds of our algorithms (BFS-SA, BFS-Hash, BFS-B-Hash, and DaC-SD) are presented in Tab. 1. We implemented them and show an experimental study in Sec. 6. We tested both synthetic and real-world datasets, including DNA, English text from Wikipedia, and code repositories from GitHub, with string lengths in $10^5$–$10^9$ and varying edit distances, many of them with real edits (e.g., edit history from Wikipedia and commit history on GitHub). In most tests, our new BFS-B-Hash or BFS-Hash performs the best, and their relative performance depends on the value of $k$ and the input patterns. Our BFS-based algorithms are faster than the existing parallel output-insensitive implementation in ParlayLib [7], even with a reasonably large $k \approx 10^5$. We believe that our paper is the first systematic study in theory and practice of parallel edit distance, and we give the first publicly available parallel edit distance implementation that can process *billion-scale strings* with small edit distance and our code at [17]. Due to page limit, some details are provided in the full version of this paper [16]. We summarize our contributions as follows:

1. Two new BFS-based edit distance solutions BFS-Hash and BFS-B-Hash using hash-based LCP queries. Compared to the existing SA-based solution in Landau-Vishkin, our hash-based solutions are simpler and more practical. BFS-B-Hash also allows for tradeoffs between time and auxiliary space.
2. A new DaC-based edit distance solution DaC-SD with $O(nk \log k)$ work and polylogarithmic span.
3. New implementations for four output-sensitive edit distance algorithms: BFS-SA, BFS-Hash, BFS-B-Hash and DaC-SD. Our code is publicly available [17].
4. Experimental study of the existing and our new algorithms on different input patterns.

## 2 Preliminaries

We use $O(f(n))$ *with high probability* (*whp*) (in $n$) to mean $O(cf(n))$ with probability at least $1 - n^{-c}$ for $c \geq 1$. We use $\tilde{O}(f(n))$ to denote $O(f(n) \cdot \text{polylog}(n))$. For a string $A$, we use $A[i]$ as the $i$-th character in $A$. We use *string* and *sequence* interchangeably. We use $A[i..j]$ to denote the $i$-th to the $j$-th characters in $A$, and $A[i..j)$ the $i$-th to the $(j-1)$-th characters in $A$. Throughout the paper, we use "auxiliary space" to mean space used in addition to the input.

**String Edit Distance.** Given two strings $A[1..n]$ and $B[1..m]$, Levenshtein's Edit Distance [38] between $A$ and $B$ is the minimum number of operations needed to convert $A$ to $B$ by using insertions, deletions, and substitutions. We also call the operations ***edits***. In this paper, we use ***edit distance*** to refer to Levenshtein's Edit Distance. The classic dynamic programming (DP) algorithm for edit distance uses DP recurrence shown in Sec. 1 with $O(mn)$ work and space.

**Hash Functions.** For the simplicity of algorithm descriptions, we assume a perfect hash function for string comparisons, i.e., a function $h : S \to [1, O(|S|)]$ such that $h(x) = h(y) \iff x = y$. For any alphabet $\Sigma$ with size $|\alpha|$, we use a hash function $h(A[l..r]) = \sum_{i=l}^{r} A[i] \times p^{r-i}$ for some prime numbers $p > |\alpha|$, which returns a unique hash value of the substring $A[l..r]$. The hash values of two consecutive substrings $S_1$ and $S_2$ can be concatenated as $h([S_1, S_2]) =$

$h(S_1)\cdot p^{|S_2|}+h(S_2)$, and the inverse can also be computed as $h(S_2)=h([S_1,S_2])-p^{|S_2|}\cdot h(S_1)$. For simplicity, we denote concatenation and its inverse operation as $\oplus$ and $\ominus$, respectively, as $h([S_1,S_2])=h(S_1)\oplus h(S_2)$ and $h(S_2)=h([S_1,S_2])\ominus h(S_1)$. We assume perfect hashing for theoretical analysis. In practice, we use $p$ as a large prime and modular arithmetic to keep the word-size hash values. In our experiment, we compare different approaches and validate that our implementations are correct in all test cases. However, collisions are possible for other datasets, since different strings may be mapped to the same hash value. If such cases arise, one can either use multiple hash functions for a better success rate in practice, or use the idea of Hirschberg's algorithm [27] to generate the edit sequence and run a correctness check (and restart with another hash function if failed).

**Longest Common Prefix (LCP).** For two sequences $A[1..n]$ and $B[1..m]$, the Longest Common Prefix (LCP) query at position $x$ in $A[1..n]$ and position $y$ in $B[1..m]$ is the longest substring starting from $A[x]$ that match a prefix starting from $B[y]$. With clear context, we also use the term "LCP" to refer to the length of the LCP, i.e., $LCP(A,B,x,y)$ is the length of the longest common prefix substring starting from $A[x]$ and $B[y]$ for $A$ and $B$.

**Computational Model.** We use the ***work-span model*** in the classic multithreaded model with ***binary-forking*** [2, 8, 9]. We assume a set of threads that share the memory. Each thread acts like a sequential RAM plus a `fork` instruction that forks two child threads running in parallel. When both child threads finish, the parent thread continues. A parallel-for is simulated by `fork` for a logarithmic number of steps. A computation can be viewed as a DAG (directed acyclic graph). The ***work $W$*** of a parallel algorithm is the total number of operations, and the ***span (depth) $S$*** is the longest path in the DAG. The randomized work-stealing scheduler can execute such a computation in $W/P+O(S)$ time *whp* in $W$ on $P$ processors [2, 9, 25].

**Suffix Array.** The suffix array (SA) [42] is a lexicographically sorted array of the suffixes of a string, usually used together with the longest common prefix (LCP) array, which stores the length of LCP between every adjacent pair of suffixes. The SA and LCP array can be built in parallel in $O(n)$ work and $O(\log^2 n)$ span *whp* [32, 53].

In edit distance, we need the LCP query between $A[x..n]$ and $B[y..m]$ for any $x$ and $y$. This can be computed by building the SA and LCP arrays for a new string $C[1..n+m]$ that concatenates $A[1..n]$ and $B[1..m]$. The LCP between any pair of suffixes in $C$ can be computed by a range minimum query (RMQ) on the LCP array, which can be built in $O(n+m)$ work and $O(\log(n+m))$ span [8]. Combining all pieces gives the following theorem:

▶ **Lemma 1.** *Given two strings $A[1..n]$ and $B[1..m]$, using a suffix array, the longest common prefix (LCP) between any two substrings $A[x..n]$ and $B[y..m]$ can be reported in $O(1)$ work and span, with $O(n+m)$ preprocessing work and $O(\log^2(n+m))$ span* whp.

# 3 BFS-based Algorithms

## 3.1 Overview of Existing Sequential and Parallel BFS-based Algorithms

Many existing output-sensitive algorithms [19, 20, 21, 22, 26, 35, 36, 37, 46, 47] are based on breadth-first search (BFS). These algorithms view the DP matrix for edit distance as a DAG, as shown in Fig. 1. In this section, we use $x$ and $y$ to denote the row and column

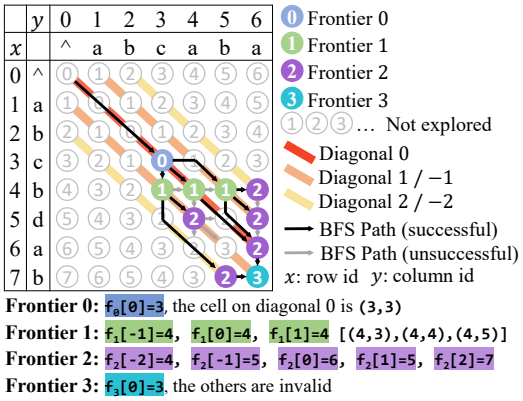

**Figure 1 BFS-based edit distance on $A[1..n]$ and $B[1..m]$.** A more detailed description is in the full version [16]. $f_t[i]$ is the row-id of the last cell on diagonal $i$ with edit distance $t$ (frontier $t$), representing cell $(f_t[i], f_t[i]-i)$.

**Algorithm 1** BFS-based parallel edit distance [37].

```
1  f_0[0] ← LCP(A[1..n], B[1..m])   // Starting point
2  t ← 0
3  while f_t[n − m] ≠ n do
4  |  t ← t + 1
   |  // Find new frontier for diagonal i
5  |  parallel-for-each −t ≤ i ≤ t do
6  |  |  f_t[i] ← f_{t−1}[i]   // Start from the last cell
7  |  |  foreach ⟨dx, dy⟩ ∈ {⟨0,1⟩, ⟨1,0⟩, ⟨1,1⟩} do
   |  |  |  // The previous cell is from diagonal j
   |  |  |  // j = (x − dx) − (y − dy) = i − dx + dy
8  |  |  |  j ← i − dx + dy
9  |  |  |  if |j| ≤ t − 1 then
10 |  |  |  |  The row id x ← f_{t−1}[j] + dx
11 |  |  |  |  The column id y ← x − i
   |  |  |  |  // Skip the common prefix
12 |  |  |  |  x ← x+LCP(A[x+1..n], B[y+1..m])
   |  |  |  |  // Keep the largest row id
13 |  |  |  |  f_t[i] ← max(f_t[i], x)
14 return t
```

ids of the cells in the DP matrix, respectively. Each state (cell) $(x, y)$ has three incoming edges from $(x-1, y)$, $(x, y-1)$, and $(x-1, y-1)$ (if they exist). The edge weight is 0 from $(x-1, y-1)$ to $(x, y)$ when $A[x] = B[y]$, and 1 otherwise. Then edit distance is equivalent to the shortest distance from $(0, 0)$ to $(n, m)$.

Since the edge weights are 0 or 1, we can use a special breadth-first search (BFS) to compute the shortest distance. In round $t$, we process states with edit distance $t$. The algorithm terminates when we reach cell $(n, m)$. First observed by Ukkonen [56], in the BFS-based approach, not all states need to be visited. For example, all states with $|x-y| > k$ will not be reached before we reach $(n, m)$ with edit distance $k$, since they require more than $k$ edits. Thus, this BFS will touch at most $O(kn)$ cells, leading to $O(kn)$ work.

Another key observation is that starting from any cell $(x, y)$, if there are diagonal edges with weight 0, we should always follow the edges until a unit-weight edge is encountered. Namely, we should always find the longest common prefix (LCP) from $A[x+1]$ and $B[y+1]$, and skip to the cell at $(x+p, y+p)$ with no edit, where $p$ is the LCP length. This idea is used in Landau and Vishkin [37] on parallel approximate string matching, and we adapt this idea to edit distance here. Using the modified parallel BFS algorithm by Landau-Vishkin [37] (shown in Alg. 1), only $O(k^2)$ states need to be processed – on each diagonal and for each edit distance $t$, only the last cell with $t$ edits needs to be processed (see Fig. 1). Hence, the BFS runs for $k$ rounds on $2k+1$ diagonals, which gives the $O(k^2)$ bound above. In the BFS algorithm, we can label each diagonal by the value of $x-y$. In round $t$, the BFS visits a *frontier* of cells $f_t[\cdot]$, where $f_t[i]$ is the cell with edit distance $t$ on diagonal $i$, for $-t \le i \le t$. We present the algorithm in Alg. 1 and an illustration in Fig. 1. Note that in the implementation, we only need to maintain two frontiers (the previous and the current one), which requires $O(k)$ space. We provide more details about this algorithm in the full version [16]. If the LCP query is supported by suffix arrays, we can achieve $O(n+k^2)$ work and $O(\log n + k \log k)$ span for the edit distance algorithm.

**Algorithm Based on Suffix Array (BFS-SA).** Using the SA algorithm in [32] and the LCP algorithm in [53] for Landau-Vishkin gives the claimed bounds in Tab. 1. We present details about our SA implementation in Sec. 5.1.

## 3.2 Algorithm Based on String Hashing (BFS-Hash)

Although BFS-SA is theoretically efficient with $O(n)$ preprocessing work to construct the SA, the hidden constant is large. For better performance, we consider string hashing as an alternative for SA. Similar attempts (e.g., locality-sensitive hashing) have also been used in approximate pattern matching problems [43, 44]. In our pursuit of exact output-sensitive edit distance computation, we draw inspiration from established string hashing algorithms, such as the Rabin-Karp algorithm (also known as rolling hashing) [33]. We will first present a simple hash-based solution BFS-Hash with $O(n)$ preprocessing cost and $O(n)$ auxiliary space. Then later in Sec. 3.3, we will present BFS-B-Hash, which saves auxiliary space by trading off more work in LCP queries.

As mentioned in Sec. 2, the hash function $h(\cdot)$ maps any substring $A[l..r]$ to a unique hash value, which provides a fingerprint for this substring in the LCP query. The high-level idea is to binary search the query length, using the hash value as validation. We precompute the hash values for all prefixes, i.e., $T_A[x] = h(A[1..x])$ for the prefix substring $A[1..x]$ (similar for $B$). They can be computed in parallel by using any scan (prefix-sum) operation [6] with $O(n)$ work and $O(\log n)$ span. We can compute $h(A[l..r])$ by $T_A[r] \ominus T_A[l-1]$.

With the preprocessed hash values, we dual binary search the LCP of $A[x..n]$ and $B[y..m]$. We compare the hash values starting from $A[x]$ and $B[y]$ with chunk sizes of $1, 2, 4, 8, \ldots$, until we find value $l$, such that $A[x..x+2^l) = B[y..y+2^l)$, but $A[x..x+2^{l+1}) \neq B[y..y+2^{l+1})$. By doing this with $O(\log n)$ work, we know that the LCP of $A[x..n]$ and $B[y..m]$ must have a length in the range $[2^l, 2^{l+1})$. We then perform a regular binary search in this range, which costs another $O(\log n)$ work. This indicates $O(\log n)$ work in total per LCP query. Combining the preprocessing and query costs, we present the cost bounds of BFS-Hash:

▶ **Theorem 2.** *BFS-Hash computes the edit distance between two sequences of length $n$ and $m \leq n$ in $O(n + k^2 \log n)$ work, $\tilde{O}(k)$ span, and $O(n)$ auxiliary space, where $k$ is the output size (fewest possible edits).*

BFS-Hash is simple and easy to implement. Our experimental results indicate that its simplicity also allows for a reasonably good performance in practice for most real-world input instances. However, this algorithm uses $n$ 64-bit integers as hash values, and such space overhead may be a concern in practice. This is more pronounced when the input is large and/or the alphabet is small (particularly when each input element can be represented with smaller than byte size), as the auxiliary space can be much larger than the input size. This concern also holds for BFS-SA as several $O(n)$-size arrays are needed during SA construction. Note that for shared-memory parallel algorithms, space consumption is also a *key constraint* – if an algorithm is slow, we can wait for longer; but if data (and auxiliary data) do not fit into the memory, then this algorithm is not applicable to large input at all. In this case, the problem size that is solvable by the algorithm is limited by the space overhead, which makes the improvement from parallelism much narrower. Below we will discuss how to make our edit distance algorithms more space efficient.

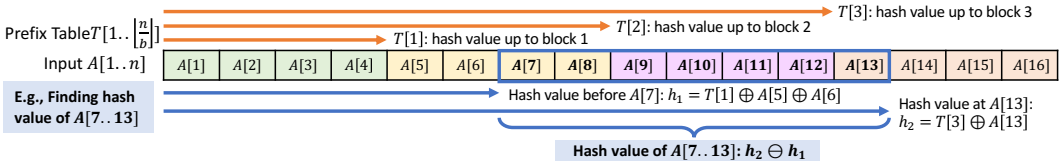

**Figure 2 The illustrations of prefix table values and one specific query**, with key concepts shown when computing the hash value of a range using a prefix table.

**Algorithm 2** The prefix table for finding the longest common prefix of $A[1..n]$ and $B[1..m]$.

```
1  // Table construction
2  Function Construct(A, B)
3      T_A[·] ← Build(A)
4      T_B[·] ← Build(B)
   // The prefix table building process
5  Function Build(A)
6      w ← ⌊|A|/b⌋
7      T[0] ← 0
8      parallel-for-each j ← 1 to w do
9          T[j] ← h(A[(j − 1)b + 1 .. jb])
10     Scan(T)
11     return T[·]
   // Get hash value for prefix sub-
   // sequence A[1..x]
12 Function GetHash(A, T_A, x)
13     if x = 0 then return 0
14     r ← ⌊(x − 1)/b + 1⌋
15     h̄ ← T_A[r]
16     for i ← r · b + 1 to x do
17         h̄ ← h̄ ⊕ h(A[i])
18     return h̄
   // Compare the subsequences A[x..x + l] and B[y..y + l]
19 Function Compare(A, B, x, y, l)
20     h_A ← GetHash(A, T_A, x + l) ⊖ GetHash(A, T_A, x − 1)
21     h_B ← GetHash(B, T_B, y + l) ⊖ GetHash(B, T_B, y − 1)
22     return h_A = h_B
   // Longest Common Prefix from A[x] and B[y]
23 Function LCP(A, B, x, y)
24     l_1 ← 0
       // Find l_1, s.t. the LCP is between 2^{l_1} to 2^{l_1+1}
       blocks
25     while x + 2^{l_1} < n and y + 2^{l_1} < m do
26         if Compare(A, B, x, y, l_1) = false then break
27         l_1 ← l_1 + 1
       // Trivial binary search process on the range
       [2^{l_1}, 2^{l_1+1})
28     s ← 2^{l_1}, t ← 2^{l_1+1}
29     while s < t do
30         if Compare(A, B, x, y, ⌊(s + t)/2⌋) = false then
31             t ← ⌊(s + t)/2⌋
32         else s ← ⌊(s + t)/2⌋ + 1
33     return s
```

## 3.3 Algorithm Based on Blocked-Hashing (BFS-B-Hash)

In this section, we introduce our BFS-B-Hash algorithm that provides a more space-efficient solution by trading off worst-case time (work and span). Interestingly, we observed that on many data sets, BFS-B-Hash can even outperform BFS-Hash and other opponents due to faster construction time, and we will analyze that in Sec. 6.

To achieve better space usage, we divide the strings into blocks of size $b$. As such, we only need to store the hash values for prefixes of the entire blocks $h(A[1..b]), h(A[1..2b]), \cdots, h(A[1..\lfloor (n/b) \rfloor \cdot b])$. Our idea of blocking is inspired by many string algorithms (e.g., [4]). Using this approach, we only need auxiliary space to store $O(n/b)$ hash values, and thus we can control the space usage using the parameter $b$. To compute these hash values, we will first compute the hash value for each block, and run a parallel scan (prefix sum on $\oplus$) on the hash values for all the blocks. Similar to the above, we refer to these arrays as $T_A[i] = h(A[1..ib])$ (and $T_B[i]$ accordingly), and call them ***prefix tables***.

We now discuss how to run LCP with only partial hash values available. The *LCP* function in Alg. 2 presents the process to find the LCP of $A[x..n]$ and $B[y..m]$ using the prefix tables. We present an illustration in Fig. 2. We will use the same dual binary search approach to find the LCP of two strings. Since we do not store the hash values for all prefixes, we use a function $GetHash(A, T_A, x)$ to compute $h(A[1..x])$. We can locate the

closest precomputed hash value and use $r$ as the previous block id before $x$. Then the hash value up to block $r$ is simply $\bar{h} = T_A[r]$. We then concatenate the rest characters to the hash value (i.e., return $\bar{h} \oplus h(A[rb+1]) \oplus \cdots \oplus h(A[x])$). In this way, we can compute the hash value of any prefixes for both $A$ and $B$, and plug this scheme into the dual binary search in BFS-Hash. In each step of dual binary search, the concatenation of hash value can have at most $b$ steps, and thus leads to a factor of $b$ overhead in query time than BFS-Hash.

▶ **Theorem 3.** *BFS-B-Hash computes the edit distance between two sequences of length $n$ and $m \le n$ in $O(n + k^2 \cdot b \log n)$ work and $\tilde{O}(kb)$ span, using $O(n/b + k)$ auxiliary space, where $k$ is the output size (fewest possible edits).*

The term $k$ in space usage is from the BFS (each frontier is at most size $O(k)$). $O(b \log n)$ is the work for each LCP query. Note that this is an upper bound – if the LCP length $L$ is small, the cost can be significantly smaller (a tighter bound is $O(\min(L, b \log L))$). Sec. 6 will show that for normal input strings where the LCP lengths are small in most queries, the performance of BFS-B-Hash is indeed the fastest, although for certain input instances when the worst case is reached, the performance is not as good.

## 4 The Divide-and-Conquer Algorithms

Our parallel output-sensitive algorithm DaC-SD is inspired by the AALM algorithm [1], and also uses it as a subroutine. We first overview the AALM algorithm, and introduce our algorithm in details. We assume $m = n$ is a power of 2 in this section for simple descriptions, but both our algorithm and AALM work for any $n$ and $m$.

**The AALM Algorithm.** As described above, the edit distance problem can be considered as a shortest distance (SD) problem from the top-left cell $(0, 0)$ to the bottom-right cell $(n, n)$ in the DP matrix $G$. Instead of directly computing the SD from $(0, 0)$ to $(n, n)$, AALM computes pairwise SD between any cell on the left/top boundaries and the bottom/right boundaries (i.e., those on $L \cup U$ to $W \cup R$ in Fig. 3(a)). We relabel all cells in $L \cup U$ as a sequence $v = \{v_0, v_1, \ldots v_{2n}\}$ (resp., $W \cup R$ as $u = \{u_0, u_1 \cdots, u_{2n}\}$), as shown in Fig. 3. Therefore, for the DP matrix $G$, the pairwise SD between $v$ and $u$ forms a $(2n+1) \times (2n+1)$ matrix. We call it the ***SD matrix*** of $G$, and denote it as $D_G$. AALM uses a divide-and-conquer approach. It first partitions $G$ into four equal submatrices $G_1$, $G_2$, $G_3$, and $G_4$ (See Fig. 3(b)), and recursively computes the SD matrices for all $G_i$. We use $D_i$ to denote the SD matrix for $G_i$. In the "conquer" step, the AALM algorithm uses a *Combine* subroutine to combine two SD matrices into one if they share a common boundary (our algorithm also uses this subroutine). For example, consider combining $G_1$ and $G_2$. We still use $v_i$ and $u_j$ to denote the cells on the left/top and bottom/right boundaries of $\begin{pmatrix} G_1 \\ G_2 \end{pmatrix}$ (see Fig. 3(c)), and denote the cells on the common boundary of $G_1$ and $G_2$ as $w_1, \cdots, w_{n/2}$, ordered from left to right. For any pair $v_i$ and $u_j$, if they are in the same submatrix, we can directly get the SD from the corresponding SD matrix. Otherwise, WLOG assume $v_i \in G_1$ and $u_j \in G_2$, then we compute the SD between them by finding $\min_l D_1[i, l] + D_2[l, j]$, i.e., for all $w_l$ on the common boundary, we attempt to use the SD between $v_i$ to $w_l$, and $w_l$ to $u_j$, and find the minimum one. Similarly, we can combine $D_3$ with $D_4$, and $D_{1\cup2}$ with $D_{3\cup4}$, and eventually get $D_G$. We note that the *Combine* algorithm, even theoretically, is highly involved. At a high level, it uses the Monge property of the shortest distance (the monotonicity of the DP recurrence), and we refer the readers to [1] for a detailed algorithm description and theoretical analysis. In Sec. 5.2,

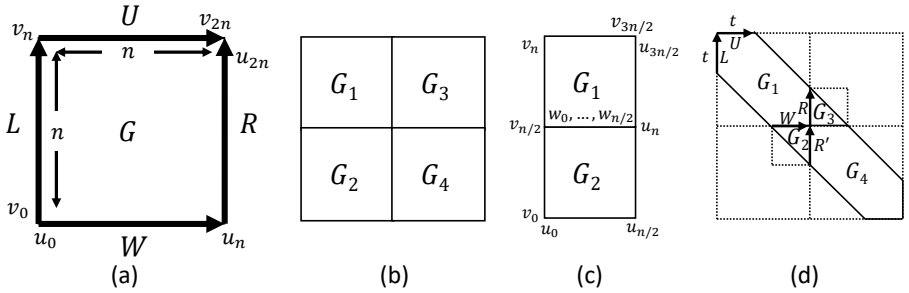

**Figure 3 The illustrations of the key concepts and notation in the AALM algorithm described in Sec. 4.**

we highlight a few challenges and our solutions for implementing this highly complicated algorithm. Theoretically, combining two $n \times n$ SD matrices can be performed in $O(n^2)$ work and $O(\log^2 n)$ span, which gives $O(n^2 \log n)$ work and $O(\log^3 n)$ span for AALM.

**Our algorithm.** The AALM algorithm has $\tilde{O}(n^2)$ work ($\tilde{O}(nm)$ if $n \neq m$) and polylogarithmic span, which is inefficient in the output-sensitive setting. As mentioned in Sec. 3.1, only a narrow width-$O(k)$ diagonal area in $G$ is useful (Fig. 3(d)). We thus propose an output-sensitive DAC-SD algorithm adapted from the AALM algorithm. We follow the same steps in AALM, but restrict the paths to the diagonal area, although the exact size is unknown ahead of time. We first present the algorithm to compute the shortest distance on the diagonal region with width $2t+1$ as function *Check*($t$) in Alg. 3, which restricts the search in diagonals $-t$ to $t$. First, we divide such a region into four sub-regions (see Fig. 3(d)). Two of them ($G_1$ and $G_4$) are of the same shape, and the other two of them ($G_2$ and $G_3$) are triangles. For $G_2$ and $G_3$, we use the AALM algorithm to compute their SD matrices by aligning them to squares. For $G_1$ and $G_4$, we process them recursively, until the base case where the edge length of the matrix is smaller than $t$ and they degenerate to squares, in which case we apply the AALM algorithm. Note that even though the width-$(2t+1)$ diagonal stripe is not a square ($G_1$ and $G_4$ are also of the same shape), the useful boundaries are still the left/top and bottom/right boundaries ($L \cup U$ and $W \cup R$ in Fig. 3(d)). Therefore, we can use the same *Combine* algorithm as in AALM to combine the SD matrices. For example, in Fig. 3(d), when combining $G_1$ with $G_2$, we obtain the pairwise distance between $L \cup U$ and $R \cup R'$ using the common boundary $W$. We can similarly combine all $G_1, G_2, G_3$, and $G_4$ to get the SD matrix for $G$.

However, the output value $k$ is unknown before we run the algorithm. To overcome this issue, we use a strategy based on prefix doubling to "binary search" the value of $k$ without asymptotically increasing the work of the algorithm. We start with $t = 1$, and run the *Check*($t$) in Alg. 3 (i.e., restricting the search in a width-$(2t+1)$ diagonal). Assume that the *Check* function returns $\sigma$ edits. If $\sigma \leq t$, we know that $\sigma$ is the SD from $(0,0)$ to $(n,n)$, since allowing the path to go out of the diagonal area will result in an answer greater than $t$. Otherwise, we know $\sigma > t$, and $\sigma$ is not necessarily the shortest distance from the $(0,0)$ to $(n,n)$, since not restricting the path in the $t$-diagonal area may allow for a shorter path. If so, we double $t$ and retry. Although we need $O(\log k)$ searches before finding the final answer $k$, we will show that the total search cost is asymptotically bounded by the last search. In the last search, we have $t < 2k$.

**Algorithm 3** Divide-and-Conquer edit distance algorithm on $A[1..n]$ and $B[1..n]$.

```
1  Notes: We assume both A and B has size n = 2^c for simple description. Our
       algorithm also works for strings with different lengths with minor changes.
2  Function DAC-SD
3      t ← 1
4      while true do
5          D ← Check(t)
6          if D[t][t] ≤ t then break
7          t ← min(2t, n)
8      return D[t][t]
   // Find the SD in the DP matrix from (0,0) to (n,n) by restricting in the diagonal stripe with width t
9  Function Check(t)
10     D ←GetDistance(0, 0, n, t)
Function GetDistance(i, j, n, t)
    if n/2 < t then
        Computed D by the AALM algorithm
        return D
    // Compute the SD matrices for G1, G2, G3, G4 (as shown in Fig. 3 (d)).
11  D1 ← GetDistance(i, j, n/2, t)
12  Compute D2 and D3 by the AALM algorithm
13  D4 ← GetDistance(i + n/2, j + n/2, n − n/2, t)
    // use the same Combine function as AALM
14  D1∪2 ← Combine(D1, D2)
15  D3∪4 ← Combine(D3, D4)
16  D ← (D1∪2, D3∪4)
17  return D
```

We first analyze the cost for $Check(t)$. It contains two recursive calls, two calls to AALM, and three calls to the *Combine* function. Therefore, the work for $Check(t)$ is $W(n) = 2W(n/2) + O(t^2 \log t)$, with base cases $W(t) = t^2 \log t$, which solves to $W(n) = O(nt \log t)$. For span, note that there are $\log(n/t)$ levels of recursion before reaching the base cases. In each level, the *Combine* function combines $t \times t$ SD matrices with $O(\log^2 t)$ span. In the leaf level, the base case uses AALM with $O(\log^3 t)$ span. Therefore, the total span of a *Check* is:

$$O(\log n/t \cdot \log^2 t + (\log n/t + \log^3 t)) = O(\log^2 t \cdot (\log n/t + \log t)) = O(\log^2 t \log n) \quad (1)$$

We will apply $Check(\cdot)$ for $O(\log k)$ times, with $t = 1, 2, 4, \ldots$ up to at most $2k$. Therefore, the total work is dominated by the last *Check*, which is $O(nk \log k)$. The span is $O(\log n \log^3 k)$.

▶ **Theorem 4.** *The DAC-SD algorithm computes the edit distance between two sequences of length $n$ and $m \le n$ in $O(nk \log k)$ work and $O(\log n \log^3 k)$ span, where $k$ is the output size (fewest possible edits).*

Compared to the BFS-based algorithms with $\tilde{O}(k)$ span, our DAC-SD is also output-sensitive and achieves polylogarithmic span. However, the work is $\tilde{O}(kn)$ instead of $\tilde{O}(n + k^2)$, which will lead to more running time in practice for a moderate size of $k$.

## 5 Implementation Details

We provide all implementations for the four algorithms as well as testing benchmarks at [17]. In this section, we highlight some interesting and challenging parts of our implementations.

### 5.1 Implementation Details of BFS-based Algorithms

For the suffix array construction in BFS-SA, we implemented a parallel version of the DC3 algorithm [32]. We also compared our implementation with the SA implementation in ParlayLib [7], which is a highly optimized version of the prefix doubling algorithm with $O(n \log n)$ work and $O(\log^2 n)$ span. On average, our implementation is about $2\times$ faster than that in ParlayLib when applied to edit distance. We present some results for their comparisons in the full version [16]. For LCP array construction and preprocessing RMQ queries, we use the implementation in ParlayLib [7], which requires $O(n \log n)$ work and $O(\log^2 n)$ span. With them, the query has $O(1)$ cost.

In our experiments on both synthetic and real-world data, we observed that the LCP length is either very large when we find two long matched chunks, or in most of the cases, very short when they are not corresponding to each other. This is easy to understand – for genomes, text or code with certain edit history, it is unlikely that two random starting positions share a large common prefix. Based on this, we add a simple optimization for all LCP implementations such that we first compare the leading eight characters, and only when they all match, we use the regular LCP query. This simple optimization greatly improved the performance of BFS-SA, and also slightly improved the hash-based solutions.

## 5.2 Implementation Details of the DaC-SD Algorithm

Although our DaC-SD algorithm given in Alg. 3 is not complicated, we note that implementing it is highly non-trivial in two aspects. First, in Sec. 4, we assume both strings $A$ and $B$ have the same length $n$, which is a power of two. However, handling two strings with different lengths makes the matrix partition more complicated in practice. Another key challenge is that the combining step in the AALM algorithm is recursive and needs to allocate memory with varying sizes in the recursive execution. While memory allocation is mostly ignored theoretically, frequent allocation in practice can easily be the performance bottleneck in the parallel setting. We discuss our engineering efforts as follows.

**Irregularity.** The general case, when $n$ and $m$ are not powers of two and not the same, is more complicated than the case in Alg. 3. In this case, all four subproblems $G_1$, $G_2$, $G_3$, and $G_4$ will have different sizes. While theoretically, we can always round up, for better performance in practice, we need to introduce additional parameters to restrict the search within the belt region as shown in Fig. 4. Therefore, we use two parameters $t_1$ and $t_2$, to denote the lengths of the diagonal area on each side. We show an illustration in Fig. 4(a) along with how to compute the subproblem sizes. In extreme cases, $t_1$ or $t_2$ can degenerate to 0, which results in three subproblems (Fig. 4(b)). In such cases, we will first merge $G_2$ and $G_4$, then merge $G_1$ and $G_{2\cup4}$.

**The Combining Step.** As mentioned in Sec. 4, achieving an efficient combining step is highly non-trivial. The straightforward solution to combine two matrices is to use the Floyd-Warshall algorithm [18], but it incurs $O(n^3)$ work and will be a bottleneck. The AALM algorithm improves this step to $O(n^2)$ by taking advantage of the Monge property of the two matrices. For page limit, we introduce the details of the combining algorithm in the full version [16]. However, the original AALM algorithm is based on divide-and-conquer and requires memory allocation for every recursive function call. This is impractical as frequent parallel memory allocation is extremely inefficient. To overcome this challenge, we redesign the recursive solution to an iterative solution, such that we can preallocate the memory space before the combining step. No dynamic memory allocation is involved during the computation. We provide the details of this approach in the full version [16].

# 6 Experiments

**Setup.** We implemented all algorithms in C++ using ParlayLib [7] for fork-join parallelism and some parallel primitives (e.g., reduce). Our tests use a 96-core (192 hyperthreads) machine with four Intel Xeon Gold 6252 CPUs, and 1.5 TB of main memory. We utilize `numactl -i all` in tests with more than one thread to spread the memory pages across CPUs in a round-robin fashion. We run each test three times and report the median.

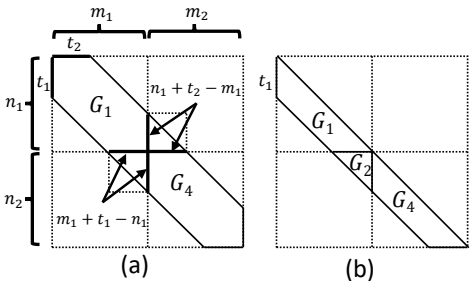

**Figure 4 The illustrations of our output-sensitive DaC-SD algorithm.** (a) Two parameters $t_1$ and $t_2$ are needed to denote the lengths of the diagonal area on each side. (b) The case that $t_2 = 0$ and $G_3$ degenerates.

**Table 2 Real-world datasets in our experiments, including input sizes $|A|$ and $|B|$, number of edits $k$, and alphabet sizes $|\Sigma|$.**

| Data | Alias | $\|A\|$ | $\|B\|$ | $k$ | $\|\Sigma\|$ |
|---|---|---|---|---|---|

**Tested Algorithms and Datasets.** We tested five algorithms in total: four output-sensitive algorithms in this paper (BFS-SA, BFS-Hash, BFS-B-Hash, DaC-SD), and a baseline algorithm from ParlayLib [7], which is a parallel output-insensitive implementation with $O(nm)$ work. The ParlayLib implementation is intended to showcase the simplicity of parallel algorithms, and as a result, it may not be well-ptimized. We are unaware of other parallel implementations that provide output-sensitive cost bounds. We use $b = 32$ for our BFS-B-Hash. As we will show later, the running time is generally stable with $4 \le b \le 64$. We tested the algorithms on both synthetic and real-world datasets. For synthetic datasets, we generate random strings with different string lengths $n = 10^i$ for $6 \le i \le 9$ and $k$ (number of edits) varying from 1 to $10^5$, and set the size of the alphabet as 256. We create strings $A$ and $B$ by generating $n$ random characters, and applying $k$ edits. The $k$ edits are uniformly random for insertion, deletion and substitution. For $k \ll n$, we have $m \approx n$. All values of $k$ shown in the figures and tables are approximate values. Our real-world datasets include Wikipedia [45], Linux kernel [40], and DNA sequences [51]. We compare the edit distance between history pages on Wikipedia and history commits of a Linux kernel file on GitHub. We also compare DNA sequences by adding valid modifications to them to simulate DNA damage or genome editing techniques, as is used in many existing papers [11, 13, 30, 57]. We present the statistics of the real-world datasets in Tab. 2.

**Overall Performance on Synthetic Data.** We present our results on synthetic data in the upper part of Fig. 5. We also present the complete results in the full version [16]. For BFS-based algorithms, we also separate the time for ***building*** the data structures for LCP queries, and the ***query*** time (the BFS process). ParlayLib cannot process instances with $n > 10^6$ due to its $O(nm)$ work bound.

We first *compare our solutions with ParlayLib* [7]. Since ParlayLib is not output-sensitive, its running time remains the same regardless of the value of $k$. Among the tests that ParlayLib can process ($n = 10^6$), our output-sensitive algorithms are much faster than ParlayLib, especially when $k$ is small (up to $10^5\times$). For $n = 10^6$, all our BFS-based algorithms are at least 1.7× faster than ParlayLib even when $k \approx n/10$.

We then *compare our DaC- and BFS-based solutions.* DaC-SD has the benefit of polylogarithmic span, compared to $\tilde{O}(k)$ span for the BFS-based algorithm. Although this seems to suggest that DaC-SD should have better performance when $k$ is large, the result

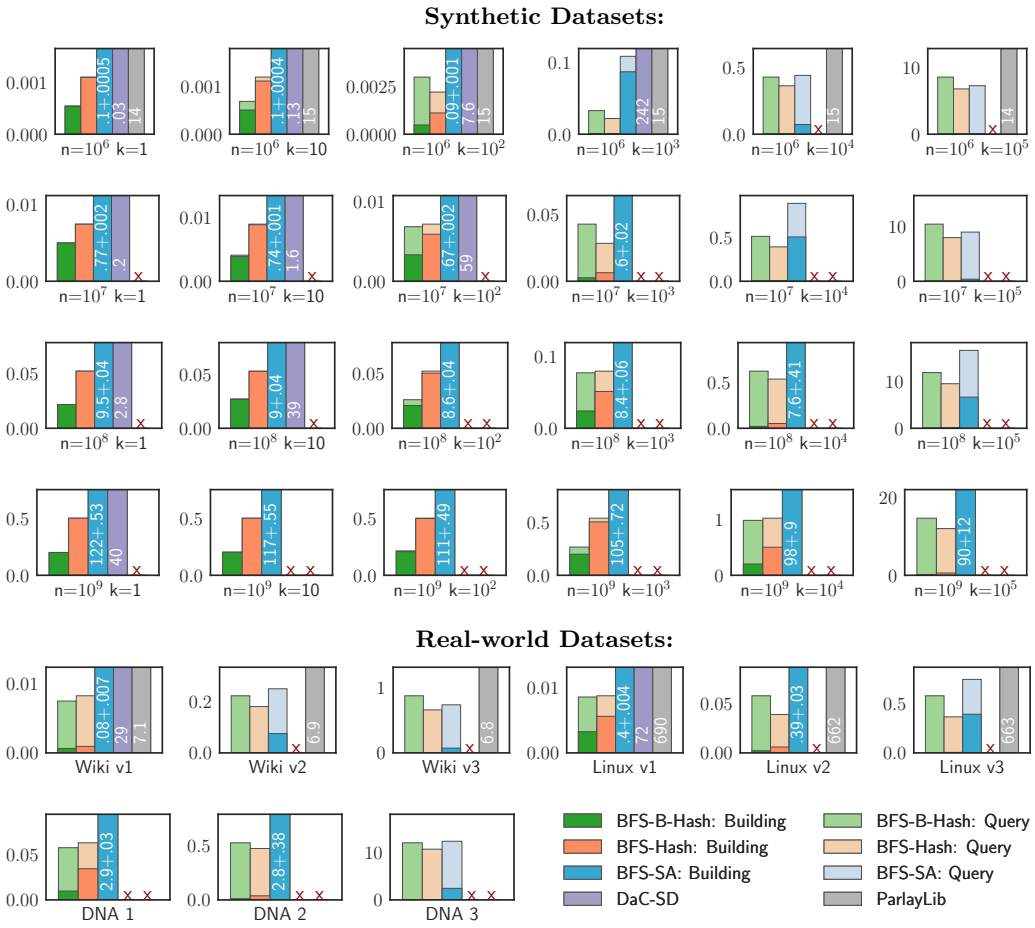

**Figure 5 Running time (in seconds) of synthetic and real-world datasets for all algorithms.** Lower is better. We put an "×" if the algorithm does not finish within 1000 seconds. For BFS-based algorithms, we separate the time into building time (constructing the data structure for LCP queries) and query time (running BFS). All bars out of the range of the y-axis are annotated with numbers. The number is the total running time for DaC-SD and ParlayLib, and is in the format of $a + b$ for BFS-SA, where $a$ is the building time and $b$ is the query time. Full results are presented in the full version [16].

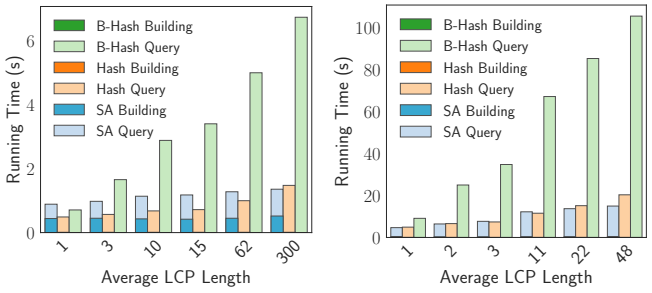
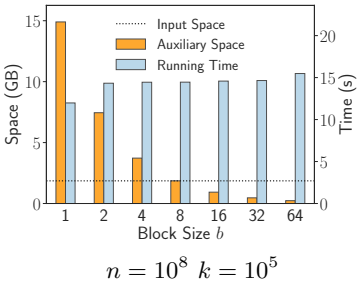
shows the opposite. The reason is that DaC-SD has $\tilde{O}(nk)$ work, compared to $\tilde{O}(n + k^2)$ cost of the BFS-based algorithms. When $k$ becomes larger, the overhead in work is also more significant. On the other hand, when $k$ is small, the $O(nk)$ work becomes linear, which hides the inefficiency in work. Therefore, the gap between DaC-SD and other algorithms is smaller when $k$ is small, but DaC-SD is still slower than BFS-based algorithms in all test cases, especially when $k$ is large. This experiment reaffirms the *importance of work efficiency* on practical performance for parallel algorithms.

Finally, we *compare all our BFS-based solutions.* Our hash-based solutions have significant advantages over the other implementations when $k$ is small, since the pre-processing time for hash-based solutions is much shorter. When $k$ is large, pre-processing time becomes negligible, and BFS-Hash seems to be the ideal choice since its query is also efficient. In particular, for $n \approx m \approx 10^9$, hash-based algorithms use about 1 second for pre-processing while BFS-SA uses about 100 seconds. Although BFS-SA also has $O(n)$ construction time,



**(a)** $n = 10^7$ $k = 10000$. **(b)** $n = 10^7$ $k = 50000$.

**Figure 6 Performance of BFS-based algorithms vs. average LCP length.** Some building times are invisible because they are too small.



$n = 10^8$ $k = 10^5$

**Figure 7 Time-space trade-off in BFS-B-Hash.** The space shown is the memory required for the prefix tables. The dotted line is the input size. Note that by setting $b = 1$, the algorithm is equivalent to BFS-Hash.

the constant is much larger and its memory access pattern is much worse than the two hash-based solutions. We note that in some cases, the query time of BFS-SA can still be faster than BFS-Hash and BFS-B-Hash, especially when $k$ is large, which is consistent with the theory ($O(1)$ vs. $O(\log n)$ or $O(b \log n)$ per LCP query).

In theory, BFS-B-Hash reduces space usage in BFS-Hash by increasing the query time. Interestingly, when $k$ is small, BFS-B-Hash can also be faster than BFS-Hash by up to 2.5×. This is because BFS-B-Hash incurs fewer writes (and thus smaller memory footprints) in preprocessing that leads to faster building time. When $k$ is small, the running time is mostly dominated by the building time, and thus BFS-B-Hash can perform better. When $k$ is relatively large and $k^2$ is comparable to $n$, BFS-Hash becomes faster than BFS-B-Hash due to better LCP efficiency. In fact, when $k$ is large, the running time is mainly dominated by the query (BFS), and all three algorithms behave similarly. It is worth noting that in these experiments with $|\Sigma| = 256$ and random edits, in most of the cases, the queried LCP is small. Therefore, the $O(\log n)$ or $O(b \log n)$ query time for BFS-Hash and BFS-B-Hash are not tight, and they have much better memory access patterns than BFS-SA in LCP queries. As a result, they can have matching or even better performance than BFS-SA. Later we will show that under certain input distributions where the average LCP length is large, BFS-SA can have some advantage over both BFS-Hash and BFS-B-Hash.

**Real-World Datasets.** We now analyze how our algorithms perform on real-world string and edit patterns. The results are shown in the lower part of Fig. 5. The results are mostly consistent with our synthetic datasets, where BFS-B-Hash is more advantageous when $k$ is small, and BFS-Hash performs the best when $k$ is large. When $k$ is large, BFS-SA can also have comparable performance to the hash-based solutions.

**LCP Length vs. Performance.** It seems that for both synthetic and real-world data shown above, our hash-based solutions are always better than BFS-SA. It is worth asking, whether BFS-SA can give the best performance in certain cases, given that it has the best theoretical bounds (see Tab. 1). By investigating the bounds carefully, BFS-SA has better LCP query cost as $O(1)$, while the costs for BFS-Hash and BFS-B-Hash are $O(\log L)$ and $O(b \log L)$, respectively, where $L$ is the LCP length. This indicates that BFS-SA should be advantageous

**Table 3 Self-relative speedup of each implementation in each step.** "Build" = constructing the data structure for LCP queries. "Query" = the BFS process. "t.o." = timeout. We omit query speedup when $k = 10$ because there is little parallelism to be explored for BFS with small $k$, and the BFS time is also small and hardly affects the overall speedup. 192 hyperthreads are used for parallel executions.

| $n$ | $k$ | BFS-B-Hash | | | BFS-Hash | | | BFS-SA | | | DaC-SD |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Build | Query | Total | Build | Query | Total | Build | Query | Total | Total |
| $10^8$ | 10 | 20.4 | - | 19.9 | 46.6 | - | 46.5 | 49.6 | - | 49.4 | 68.2 |
| $10^9$ | $10^5$ | 24.2 | 36.4 | 36.3 | 42.7 | 46.8 | 46.6 | 51.2 | 27.1 | 48.3 | t.o. |

when $k$ and $L$ are both large. To verify this, we artificially created input instances with medium to large values of $k$ and controlled average LCP query lengths, and showed the results in Fig. 6 on two specific settings.

The experimental result is consistent with the theoretical analysis. The running time for BFS-Hash increases slowly with $L$, while the performance of BFS-B-Hash grows *much faster*, since it is affected by a factor of $O(b)$ more than BFS-Hash. The query time for BFS-SA almost stays the same, but also increases slightly with increasing $L$. This is because in general, with increasing $L$, the running time for all three algorithms may increase slightly due to worse cache locality in BFS due to more long matches. In Figure 6(a), the building time for both BFS-Hash and BFS-B-Hash are negligible, while BFS-SA still incurs significant building time. Even in this case, with an LCP length of 300, the query time of the hash-based solutions still becomes larger than the *total* running time of BFS-SA. In Figure 6(b) with a larger $k$, the building time for all three algorithms is negligible. In this case, BFS-SA always has comparable performance with BFS-Hash, and may perform better when $L > 20$. However, such extreme cases (both $k$ and $L$ are large) should be very rare in real-world datasets - when $k$ is large enough so that the query time is large enough to hide SA's building time, $L$ is more likely to be small, which in turn is beneficial for the query bounds in hash-based solutions. Indeed such cases did not appear in our 33 tests on both synthetic and real data.

**Parallelism.** We test the self-relative speedup of all algorithms. We present speedup numbers on two representative tests with different values of $n$ and $k$ in Tab. 3. For BFS-based algorithms, we separate the speedup for building and query. All our algorithms are highly parallelized. Even though BFS-SA and DaC-SD have a longer running time, they still have a 48–68× speedup, indicating good scalability. Our BFS-Hash algorithm has about 40–50× speedup in building, and BFS-B-Hash has a lower but decent speedup of about 20–40×. When $k$ is small, the frontier sizes (and the total work) of BFS are small, and the running time is also negligible. In this case, we cannot observe meaningful speedup. For larger $k = 10^5$, three BFS-based algorithms achieve 27–48× speedup both in query and entire edit distance algorithm.

**Space Usage.** We study the time-space tradeoff of our BFS-B-Hash with different block sizes $b$. We present the *auxiliary space* used by the prefix table in BFS-B-Hash along with running time in Fig. 7 using one test case with $n = 10^8$ and $k = 10^5$ in our synthetic dataset. The dotted line shows the input size. Note that when $b = 1$, it is exactly BFS-Hash. Since the inputs are 8-bit characters and the hash values are 64-bit integers, BFS-Hash incurs 8× space overhead than the input size. Using blocking, we can avoid such overhead and keep the auxiliary space even lower than the input. The auxiliary space decreases linearly with

the block size $b$. Interestingly, although blocking itself incurs time overhead, the impact in time is small: the time grows by 1.19× from $b = 1$ to 2, and grows by 1.08× from $b = 2$ to 64. This is mostly due to two reasons: 1) as mentioned, with 8-bit character input type and random edits, the average LCP length is likely short and within the first block, and therefore the query costs in both approaches are close to $O(L)$ for LCP length $L$, and 2) the extra factor of $b$ in queries (Line 17) is mostly cache hits (consecutive locations in an array). This illustrates the benefit of using blocking in such datasets, since blocking saves much space while only increasing the time by a small fraction.

## 7 Conclusion and Discussions

We proposed output-sensitive parallel algorithms for the edit-distance problem, as well as careful engineering of them. We revisited the BFS-based Landau-Vishkin algorithm. In addition to using SA as is used in Landau-Vishkin (our BFS-SA implementation), we also designed two hash-based data structures to replace the SA for more practical LCP queries (BFS-Hash and BFS-B-Hash). We also presented the first output-sensitive parallel algorithm based on divide-and-conquer with $\tilde{O}(nk)$ work and polylogarithmic span. We have also shown the best of our engineering effort on this algorithm, although its performance seems less competitive than other candidates due to work inefficiency.

We implemented all these algorithms and tested them on synthetic and real-world datasets. In summary, our BFS-based solutions show the best overall performance on datasets with real-world edits or random edits, due to faster preprocessing time and better I/O-friendliness. BFS-Hash performs the best in time when $k$ is large. BFS-B-Hash has better performance when $k$ is small. The blocking scheme also greatly improves space efficiency without introducing much overhead in time. In very extreme cases where both $k$ and the LCP lengths are large, BFS-SA can have some advantages over the hash-based solutions, while BFS-B-Hash can be much slower than BFS-Hash. However, such input patterns seem rare in the real world.

All our BFS-based solutions perform better than the output-insensitive solution in ParlayLib, and the DaC-based solution with $\tilde{O}(nk)$ work and polylogarithmic span, even for large $k > \sqrt{n}$. The results also imply the importance of work efficiency in parallel algorithm designs, consistent with the common belief in the literature [52, 24]. Because the number of cores in modern multi-core machines is small (usually hundreds to thousands) compared to the problem size, an algorithm is less practical if it blows up the work significantly, as parallelism cannot compensate for the performance loss due to larger work.

# Efficient 1-Laplacian Solvers for Well-Shaped Simplicial Complexes: Beyond Betti Numbers and Collapsing Sequences

**Ming Ding**
ETH Zürich, Switzerland

**Peng Zhang**
Rutgers University, New Brunswick, NJ, USA

## Abstract

We present efficient algorithms for solving systems of linear equations in 1-Laplacians of well-shaped simplicial complexes. 1-Laplacians, or higher-dimensional Laplacians, generalize graph Laplacians to higher-dimensional simplicial complexes and play a key role in computational topology and topological data analysis. Previously, nearly-linear time solvers were developed for simplicial complexes with known collapsing sequences and bounded Betti numbers, such as those triangulating a three-ball in $\mathbb{R}^3$ (Cohen, Fasy, Miller, Nayyeri, Peng, and Walkington [SODA'2014], Black, Maxwell, Nayyeri, and Winkelman [SODA'2022], Black and Nayyeri [ICALP'2022]). Furthermore, Nested Dissection provides quadratic time solvers for more general systems with nonzero structures representing well-shaped simplicial complexes embedded in $\mathbb{R}^3$.

We generalize the specialized solvers for 1-Laplacians to simplicial complexes with additional geometric structures but *without collapsing sequences and bounded Betti numbers*, and we improve the runtime of Nested Dissection. We focus on simplicial complexes that meet two conditions: (1) each individual simplex has a bounded aspect ratio, and (2) they can be divided into "disjoint" and balanced regions with well-shaped interiors and boundaries. Our solvers draw inspiration from the Incomplete Nested Dissection for stiffness matrices of well-shaped trusses (Kyng, Peng, Schwieterman, and Zhang [STOC'2018]).

## 1 Introduction

Combinatorial Laplacians generalize graph Laplacian matrices to higher dimensional simplicial complexes – a collection of 0-simplexes (vertices), 1-simplexes (edges), 2-simplexes (triangles), and their higher dimensional counterparts. Simplicial complexes encode higher-order relations between data points in a metric space. By studying the topological properties of these complexes using Combinatorial Laplacians, one can capture higher-order features that go beyond connectivity and clustering.

Given an oriented $d$-dimensional simplicial complex $\mathcal{K}$, for each $0 \leq i \leq d$, let $\mathcal{C}_i$ be the vector space generated by the $i$-simplexes in $\mathcal{K}$ with coefficients in $\mathbb{R}$. We can define a sequence of boundary operators:

$$\mathcal{C}_d \xrightarrow{\partial_d} \mathcal{C}_{d-1} \xrightarrow{\partial_{d-1}} \cdots \xrightarrow{\partial_2} \mathcal{C}_1 \xrightarrow{\partial_1} \mathcal{C}_0,$$

where each $\partial_i$ is a linear map that maps every $i$-simplex to a signed sum of its boundary $(i-1)$-faces. We define the $i$-Laplacian $\boldsymbol{L}_i : \mathcal{C}_i \to \mathcal{C}_i$ to be

$$\boldsymbol{L}_i = \partial_{i+1}\partial_{i+1}^\top + \partial_i^\top \partial_i. \tag{1}$$

In particular, $\partial_1$ is the vertex-edge incidence matrix, and $\boldsymbol{L}_0$ is the graph Laplacian (following the convention, we define $\partial_0 = \mathbf{0}$). One can assign weights to each simplex in $\mathcal{K}$ and define weighted Laplacians.

It is well-known that linear equations in graph Laplacians can be approximately solved in nearly-linear time in the number of nonzeros of the system [50, 30, 31, 29, 36, 46, 16, 34, 32, 27]. These fast Laplacian solvers have led to significant developments in algorithm design for graph problems such as maximum flow [41, 42, 10], minimum cost flow and lossy flow [37, 18], and graph sparsification [49], known as "the Laplacian Paradigm" [52].

Inspired by the success of graph Laplacians, Cohen, Fasy, Miller, Nayyeri, Peng, and Walkington [13] initiated the study of fast solvers for 1-Laplacian linear equations. They designed a nearly-linear time solver for simplicial complexes *with zero Betti numbers*[1] *and known collapsing sequences*. Later, Black, Maxwell, Nayyeri and Winkelman [5], and Black and Nayyeri [6] generalized this algorithm to subcomplexes of such a complex *with bounded first Betti numbers*[2]. One concrete example studied in these papers is convex simplicial complexes that piecewise linearly triangulate a convex ball in $\mathbb{R}^3$, for which a collapsing sequence exists and can be computed in linear time [11, 12]. However, deciding whether a simplicial complex has a collapsing sequence is NP-hard in general [51]; computing the Betti numbers is as hard as computing the ranks of general $\{0,1\}$ matrices [23]. In addition, 1-Laplacian systems for general simplicial complexes embedded in $\mathbb{R}^4$ are as hard to solve as general sparse linear equations [19], for which the best-known algorithms need super-quadratic time [47, 44]. All the above motivates the following question:

> Can we efficiently solve 1-Laplacian systems for other classes of *structured* simplicial complexes, e.g., *without known collapsing sequences and with arbitrary Betti numbers*?

In addition to the specialized solvers for 1-Laplacian systems mentioned above, Nested Dissection can solve 1-Laplacian systems in quadratic time for simplicial complexes in $\mathbb{R}^3$ with additional geometric structures [25, 39, 43] such as bounded aspect ratios[3] of individual tetrahedrons. Furthermore, iterative methods such as Preconditioned Conjugate Gradient approximately solve 1-Laplacian systems in time $\widetilde{O}(n\sqrt{\kappa})$, where $n$ is the number of simplexes and $\kappa$ is the condition number of the coefficient matrix.

Inspired by solvers that leverage geometric structures and spectral properties, we develop efficient 1-Laplacian solvers for well-shaped simplicial complexes embedded in $\mathbb{R}^3$ *without known collapsing sequences and with arbitrary Betti numbers*. Our solver adapts the Incomplete Nested Dissection algorithm, proposed by Kyng, Peng, Schwieterman, and Zhang [33]

---

[1] Informally, the $i$th Betti number is the number of $i$-dimensional holes on a topological surface. For example, the zeroth, first, and second Betti numbers represent the numbers of connected components, one-dimensional "circular" holes, and two-dimensional "voids" or "cavities," respectively.

[2] The solver has cubic dependence on the first Betti number.

[3] The aspect ratio of a geometric shape $S$ is the radius of the smallest ball containing $S$ divided by the radius of the largest ball contained in $S$.

for solving linear equations in well-shaped 3-dimensional truss stiffness matrices. These matrices represent another generalization of graph Laplacians; however, they differ quite from the 1-Laplacians studied in this paper. A primary distinction is that the kernel of a truss stiffness matrix has an explicit and well-understood form, while computing a 1-Laplacian's kernel is as hard as that for a general matrix.

## 1.1 Our Results

We say a simplex is *stable* if it has $O(1)$ aspect ratio and $\Theta(1)$ weight. We focus on a *pure* simplicial complex[4] $\mathcal{K}$ embedded in $\mathbb{R}^3$. We require $\mathcal{K}$ admits a nice division parameterized by $r \in \mathbb{R}_+$, called *$r$-hollowing*. We adopt and adapt the concept of $r$-hollowing introduced in [33] to suit our 1-Laplacian solvers. Informally, our $r$-hollowing for a simplicial complex containing $n$ simplexes divides $\mathcal{K}$ into $O(n/r)$ "separated" regions where each region has $O(r)$ simplexes and $O(r^{2/3})$ boundary simplexes. Only boundary simplexes can appear in multiple regions. Additionally, we mandate that each region's boundary triangulates a spherical shell in $\mathbb{R}^3$, exhibiting a *"hop" diameter* of $O(r^{1/3})$ and a *"hop" shell width* of at least 5. The formal definition is given in Definition 2.9. The bounded aspect ratio of each tetrahedron allows us to employ Nested Dissection for the interior simplexes within every region. The boundary shape requirement facilitates preconditioning the sub-system, derived from partial Nested Dissection, by the boundaries themselves and solving this sub-system using Preconditioned Conjugate Gradient.

Below, we present our main results informally. Firstly, we assume that an $r$-hollowing of a pure 3-complex is provided, which offers the broadest applicability of our algorithm. This assumption is justifiable when one can determine the construction of the simplicial complex; for instance, one can decide how to discretize a continuous topological space or how to triangulate a space given a set of points. Subsequently, we establish sufficient conditions for 3-complexes that allow us to compute $r$-hollowings in linear time.

▶ **Theorem 1.1** (Informal statement). *Let $\mathcal{K}$ be a pure 3-complex embedded in $\mathbb{R}^3$ and composed of $n$ stable simplexes. Given an $r$-hollowing for $\mathcal{K}$, for any $\epsilon > 0$, we can approximately solve a system in the 1-Laplacian of $\mathcal{K}$ within error $\epsilon$ in time $O\left(nr + n^{4/3}r^{5/18}\log(n/\epsilon) + n^2 r^{-2/3}\right)$. The runtime is $o(n^2)$ if $r = o(n)$ and $r = \omega(1)$. In particular, when $r = \Theta(n^{3/5})$, the runtime is minimized (up to constant) and equals $O(n^{8/5}\log(n/\epsilon))$.*

Our runtime in Theorem 1.1 does not depend on the Betti numbers of $\mathcal{K}$ and does not require collapsing sequences. When $r = o(n)$ and $r = \omega(1)$, the runtime is $o(n^2)$, asymptotically faster than Nested Dissection [43]. The solver in [6] for a 1-Laplacian system for the $\mathcal{K}$ stated in Theorem 1.1 is $\widetilde{O}(\beta^3 m)$[5], where $m$ is the number of simplexes in $\mathcal{X} \supset \mathcal{K}$ with a known collapsing sequence and $\beta$ is the first Betti number of $\mathcal{K}$. In the worst-case scenario, $m$ can be as large as $\Omega(n^2)$. But [6] does not require a known $r$-hollowing.

Without assuming prior knowledge about $r$-hollowing, the following theorem presents a solver with the same runtime as Theorem 1.1 when the 3-complex $\mathcal{K}$ satisfies additional geometric restrictions: First, the convex hull of $\mathcal{K}$ has $O(1)$ aspect ratio, and each tetrahedron of $\mathcal{K}$ has $\Theta(1)$ volume. Second, all but one the boundary components of $\mathcal{K}$, which correspond to "holes inside" $\mathcal{K}$, satisfy the following conditions: (1) every boundary component of $\mathcal{K}$ has

[4] A simplicial complex is *pure* if every maximal simplex (i.e., a simplex that is not a proper subset of any other simplex in the complex) has the same dimension. For example, a pure 3-complex is a tetrahedron mesh that consists of tetrahedrons and their sub-simplexes.

[5] We use $\widetilde{O}(\cdot)$ to hide polylog factors on the number of simplexes and the inverse of error parameter.

1-skeleton diameter $O(r^{1/3})$; (2) the total size of boundary components within any $\mathbb{X} \subset \mathbb{R}^3$ of volume $r$ is at most $O(r^{2/3})$, and the total size of boundary components of $\mathcal{K}$ is $O(nr^{-1/3})$; (3) the triangle distance between any two boundary components of $\mathcal{K}$ is greater than 5. These geometric conditions allow us to find an $r$-hollowing of $\mathcal{K}$ in linear time.

▶ **Theorem 1.2** (Informal statement). *Let $\mathcal{K}$ be a pure 3-complex embedded in $\mathbb{R}^3$ and composed of $n$ stable simplexes; assume $\mathcal{K}$ satisfies the aforementioned additional geometric structures with parameter $r$. Then, for any $\epsilon > 0$, we can approximately solve a system in the 1-Laplacian of $\mathcal{K}$ within error $\epsilon$ in time $O\left(nr + n^{4/3}r^{5/18}\log(n/\epsilon) + n^2 r^{-2/3}\right)$. In particular, when $r = \Theta(n^{3/5})$, the runtime is minimized (up to constant) and equals $O(n^{8/5}\log(n/\epsilon))$.*

We then examine unions of pure 3-complexes glued together by identifying certain subsets of simplexes on the boundary components (called exterior simplexes) of 3-complex chunks. Moreover, each 3-complex chunk admits a $\Theta(n_i^{3/5})$-hollowing with $n_i$ being the number of simplexes in this chunk. We remark that such a union of 3-complexes, called $\mathcal{U}$, *may not be embeddable in* $\mathbb{R}^3$. So, the previously established methods from [13, 5, 6] and Nested Dissection are unsuitable for this scenario. Building on our algorithm for Theorem 1.1, we design an efficient algorithm for $\mathcal{U}$ whose runtime depends sub-quadratically on the size of $\mathcal{U}$ and polynomially on the number of chunks and the number of simplexes shared by more than one chunk.

▶ **Theorem 1.3** (Informal statement). *Let $\mathcal{U}$ be a union of $h$ pure 3-complexes that are glued together by identifying certain subsets of their exterior simplexes. Each 3-complex chunk is embedded in $\mathbb{R}^3$, contains $n_i$ stable simplexes, and has a known $\Theta(n_i^{3/5})$-hollowing. For any $\epsilon > 0$, we can solve a system in the 1-Laplacian of $\mathcal{U}$ within error $\epsilon$ in time $\widetilde{O}(n^{8/5}k + h^2k^2 + k^3)$ where $n$ is the number of simplexes in $\mathcal{U}$, $k$ is the number of exterior simplexes shared by more than one complex chunk.*

When $h = \widetilde{O}(1)$ and $k = \widetilde{O}(n^{1/2})$, the solver in Theorem 1.3 has the same runtime as Theorem 1.1. When $h = o(n^{2/5}), k = o(n^{3/5})$, the runtime is $o(n^2)$, asymptotically faster than Nested Dissection.

## 1.2 Motivations and Applications

In the past decade, combinatorial Laplacians have played a crucial role in the development of computational topology and topological data analysis in various domains, such as statistics [28, 45], graphics and imaging [40, 53], brain networks [35], deep learning [8], signal processing [3], and cryo-electron microscope [54]. We recommend readers consult accessible surveys [26, 9, 22, 38] for more information.

Combinatorial Laplacians have their roots in the study of discrete Hodge decomposition [21], which states that the kernel of the $i$-Laplacian $\boldsymbol{L}_i$ is isomorphic to the $i$th homology group of the simplicial complex. Among the many applications of combinatorial Laplacians, a central problem is determining the Betti numbers – the ranks of the homology groups – which are important topological invariants. Additionally, discrete Hodge decomposition allows for the extraction of meaningful information from data by decomposing them into three mutually orthogonal components: gradient (in the image of $\partial_i^\top$), curl (in the image of $\partial_{i+1}$), and harmonic (in the kernel of $\boldsymbol{L}_i$) components. For instance, the three components of edge flows in a graph capture the global trends, local circulations, and "noise".

The computation of both Betti numbers and discrete Hodge decomposition of higher-order flows can be achieved by solving systems of linear equations in combinatorial Laplacians [24, 38]. The rank of a matrix $\boldsymbol{L}_i$ can be determined by solving a logarithmic number of linear

equation systems in $\boldsymbol{L}_i$ [2]. The discrete Hodge decomposition can be calculated by solving least square problems involving boundary operators or combinatorial Laplacians, which in turn reduces to solving linear equations in these matrices.

Furthermore, an important question in numerical linear algebra concerns whether the nearly-linear time solvers for graph Laplacian linear equations can be generalized to larger classes of linear equations. Researchers have achieved success with elliptic finite element systems [7], Connection Laplacians [32], directed Laplacians [15, 14], well-shaped truss stiffness matrices [17, 48, 33]. It would be intriguing to determine what structures of linear equations facilitate faster solvers. Another theoretically compelling reason for developing efficient solvers for 1-Laplacians stems from the "equivalence" of time complexity between solving 1-Laplacian systems and general sparse systems of linear equations [19]. If one can solve all 1-Laplacian systems in time $\widetilde{O}((\#\text{ of simplexes})^c)$ where $c \geq 1$ is a constant, then one can solve all general systems of linear equations in time $\widetilde{O}((\#\text{ of nonzero coefficients})^c)$.

# 2 Preliminaries

## 2.1 Background of Linear Algebra

Given a vector $\boldsymbol{x} \in \mathbb{R}^n$, for $1 \leq i \leq n$, we let $\boldsymbol{x}[i]$ be the $i$th entry of $\boldsymbol{x}$; for $1 \leq i < j \leq n$, let $\boldsymbol{x}[i:j]$ be $(\boldsymbol{x}[i], \boldsymbol{x}[i+1], \ldots, \boldsymbol{x}[j])^\top$. The Euclidean norm of $\boldsymbol{x}$ is $\|\boldsymbol{x}\|_2 \stackrel{\text{def}}{=} \sqrt{\sum_{i=1}^n \boldsymbol{x}[i]^2}$. Given a matrix $\boldsymbol{A} \in \mathbb{R}^{m \times n}$, for $1 \leq i \leq m, 1 \leq j \leq n$, we let $\boldsymbol{A}[i,j]$ be the $(i,j)$th entry of $\boldsymbol{A}$; for $S_1 \subseteq \{1, \ldots, m\}, S_2 \subseteq \{1, \ldots, n\}$, let $\boldsymbol{A}[S_1, S_2]$ be the submatrix with row indices in $S_1$ and column indices in $S_2$. Furthermore, we let $\boldsymbol{A}[S_1, :] = \boldsymbol{A}[S_1, \{1, \ldots, n\}]$ and $\boldsymbol{A}[:, S_2] = \boldsymbol{A}[\{1, \ldots, m\}, S_2]$. The operator norm of $\boldsymbol{A}$ (induced by the Euclidean norm) is $\|\boldsymbol{A}\|_2 \stackrel{\text{def}}{=} \max_{\boldsymbol{v} \in \mathbb{R}^n} \frac{\|\boldsymbol{A}\boldsymbol{x}\|_2}{\|\boldsymbol{x}\|_2}$. The image of $\boldsymbol{A}$ is the linear span of the columns of $\boldsymbol{A}$, denoted by $\mathrm{Im}(\boldsymbol{A})$, and the kernel of $\boldsymbol{A}$ to be $\{\boldsymbol{x} \in \mathbb{R}^n : \boldsymbol{A}\boldsymbol{x} = \boldsymbol{0}\}$, denoted by $\mathrm{Ker}(\boldsymbol{A})$. A fundamental theorem of Linear Algebra states $\mathbb{R}^m = \mathrm{Im}(\boldsymbol{A}) \oplus \mathrm{Ker}(\boldsymbol{A}^\top)$.

▶ **Fact 2.1.** [6] *For any matrix $\boldsymbol{A} \in \mathbb{R}^{m \times n}$, $Im(\boldsymbol{A}) = Im(\boldsymbol{A}\boldsymbol{A}^\top)$.*

### Pseudo-inverse and Projection Matrix

The pseudo-inverse of $\boldsymbol{A}$ is defined to be a matrix $\boldsymbol{A}^\dagger$ that satisfies all the following four criteria: (1) $\boldsymbol{A}\boldsymbol{A}^\dagger\boldsymbol{A} = \boldsymbol{A}$, (2) $\boldsymbol{A}^\dagger\boldsymbol{A}\boldsymbol{A}^\dagger = \boldsymbol{A}^\dagger$, (3) $(\boldsymbol{A}\boldsymbol{A}^\dagger)^\top = \boldsymbol{A}\boldsymbol{A}^\dagger$, (4) $(\boldsymbol{A}^\dagger\boldsymbol{A})^\top = \boldsymbol{A}^\dagger\boldsymbol{A}$. The orthogonal projection matrix onto $\mathrm{Im}(\boldsymbol{A})$ is $\boldsymbol{\Pi}_{\mathrm{Im}(\boldsymbol{A})} = \boldsymbol{A}(\boldsymbol{A}^\top\boldsymbol{A})^\dagger\boldsymbol{A}^\top$.

### Eigenvalues and Condition Numbers

Given a square matrix $\boldsymbol{A} \in \mathbb{R}^{n \times n}$, let $\lambda_{\max}(\boldsymbol{A})$ be the maximum eigenvalue of $\boldsymbol{A}$ and $\lambda_{\min}(\boldsymbol{A})$ the minimum *nonzero* eigenvalue of $\boldsymbol{A}$. The condition number of $\boldsymbol{A}$, denoted by $\kappa(\boldsymbol{A})$, is the ratio between $\lambda_{\max}(\boldsymbol{A})$ and $\lambda_{\min}(\boldsymbol{A})$. A symmetric matrix $\boldsymbol{A}$ is *positive semi-definite (PSD)* if all eigenvalues of $\boldsymbol{A}$ are non-negative. Let $\boldsymbol{B} \in \mathbb{R}^{n \times n}$ be another square matrix. We say $\boldsymbol{A} \succcurlyeq \boldsymbol{B}$ if $\boldsymbol{A} - \boldsymbol{B}$ is PSD. The *condition number of $\boldsymbol{A}$ relative to $\boldsymbol{B}$* is

$$\kappa(\boldsymbol{A}, \boldsymbol{B}) \stackrel{\text{def}}{=} \min\left\{\frac{\alpha}{\beta} : \beta\boldsymbol{\Pi}_{\mathrm{Im}(\boldsymbol{A})}\boldsymbol{B}\boldsymbol{\Pi}_{\mathrm{Im}(\boldsymbol{A})} \preccurlyeq \boldsymbol{A} \preccurlyeq \alpha\boldsymbol{B}\right\}.$$

[6] All the facts in this section are well-known. For completeness, we include their proofs in the Appendix of the full paper [20].

▶ **Fact 2.2.** *Let $\boldsymbol{A}, \boldsymbol{B} \in \mathbb{R}^{n\times n}$ be symmetric matrices such that $\boldsymbol{A} \preccurlyeq \boldsymbol{B}$. Then, for any $\boldsymbol{V} \in \mathbb{R}^{m\times n}$, $\boldsymbol{V}\boldsymbol{A}\boldsymbol{V}^\top \preccurlyeq \boldsymbol{V}\boldsymbol{B}\boldsymbol{V}^\top$.*

### Schur Complement

Let $\boldsymbol{A} \in \mathbb{R}^{n\times n}$, and let $F \cup C$ be a partition of $\{1, \ldots, n\}$. We write $\boldsymbol{A}$ as a block matrix:

$$\boldsymbol{A} = \begin{pmatrix} \boldsymbol{A}[F,F] & \boldsymbol{A}[F,C] \\ \boldsymbol{A}[C,F] & \boldsymbol{A}[C,C] \end{pmatrix}. \tag{2}$$

We define the (generalized) Schur complement of $\boldsymbol{A}$ onto $C$ to be

$$\mathrm{Sc}[\boldsymbol{A}]_C = \boldsymbol{A}[C,C] - \boldsymbol{A}[C,F]\boldsymbol{A}[F,F]^\dagger \boldsymbol{A}[F,C].$$

The Schur complement appears in performing a block Gaussian elimination on matrix $\boldsymbol{A}$ to eliminate the indices in $F$.

▶ **Fact 2.3.** *Let $\boldsymbol{A}$ be a PSD matrix defined in Equation* (2)*. Then,*

$$\boldsymbol{A} = \begin{pmatrix} \boldsymbol{I} & \\ \boldsymbol{A}[C,F]\boldsymbol{A}[F,F]^\dagger & \boldsymbol{I} \end{pmatrix} \begin{pmatrix} \boldsymbol{A}[F,F] & \\ & Sc[\boldsymbol{A}]_C \end{pmatrix} \begin{pmatrix} \boldsymbol{I} & \boldsymbol{A}[F,F]^\dagger \boldsymbol{A}[F,C] \\ & \boldsymbol{I} \end{pmatrix}.$$

▶ **Fact 2.4.** *Let $\boldsymbol{A}$ be a PSD matrix defined in Equation* (2)*. Let $\boldsymbol{A} = \boldsymbol{B}\boldsymbol{B}^\top$, and we decompose $\boldsymbol{B} = \begin{pmatrix} \boldsymbol{B}_F \\ \boldsymbol{B}_C \end{pmatrix}$ accordingly. Then, $Sc[\boldsymbol{A}]_C = \boldsymbol{B}_C \boldsymbol{\Pi}_{Ker(\boldsymbol{B}_F)} \boldsymbol{B}_C^\top$, where $\boldsymbol{\Pi}_{Ker(\boldsymbol{B}_F)}$ is the projection onto the kernel of $\boldsymbol{B}_F$.*

### Solving Linear Equations

We will need Fact 2.5 for relations between different error notations for linear equations and Theorem 2.6 for Preconditioned Conjugate Gradient.

▶ **Fact 2.5.** *Let $\boldsymbol{A}, \boldsymbol{Z} \in \mathbb{R}^{n\times n}$ be two symmetric PSD matrices, and let $\boldsymbol{\Pi}$ be the orthogonal projection onto $Im(\boldsymbol{A})$.*
1. *If $(1-\epsilon)\boldsymbol{A}^\dagger \preccurlyeq \boldsymbol{Z} \preccurlyeq (1+\epsilon)\boldsymbol{A}^\dagger$, then $\|\boldsymbol{A}\boldsymbol{Z}\boldsymbol{b} - \boldsymbol{b}\|_2 \le \epsilon\sqrt{\kappa(\boldsymbol{A})}\,\|\boldsymbol{b}\|_2$ for any $\boldsymbol{b} \in Im(\boldsymbol{A})$.*
2. *If $\|\boldsymbol{A}\boldsymbol{Z}\boldsymbol{b} - \boldsymbol{b}\|_2 \le \epsilon\,\|\boldsymbol{b}\|_2$ for any $\boldsymbol{b} \in Im(\boldsymbol{A})$, then $(1-\epsilon)\boldsymbol{A}^\dagger \preccurlyeq \boldsymbol{\Pi}\boldsymbol{Z}\boldsymbol{\Pi} \preccurlyeq (1+\epsilon)\boldsymbol{A}^\dagger$.*

▶ **Theorem 2.6** (Preconditioned Conjugate Gradient [1])**.** *Let $\boldsymbol{A}, \boldsymbol{B} \in \mathbb{R}^{n\times n}$ be two symmetric PSD matrices, and let $\boldsymbol{b} \in \mathbb{R}^n$. Each iteration of Preconditioned Conjugate Gradient multiplies one vector with $\boldsymbol{A}$, solves one system of linear equations in $\boldsymbol{B}$, and performs a constant number of vector operations. For any $\epsilon > 0$, the algorithm outputs an $\boldsymbol{x}$ satisfying $\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{\Pi}_{\boldsymbol{A}}\boldsymbol{b}\|_2 \le \epsilon\,\|\boldsymbol{\Pi}_{\boldsymbol{A}}\boldsymbol{b}\|_2$ in $O(\sqrt{\kappa}\log(\kappa/\epsilon))$ such iterations, where $\boldsymbol{\Pi}_{\boldsymbol{A}}$ is the orthogonal projection matrix onto the image of $\boldsymbol{A}$ and $\kappa = \kappa(\boldsymbol{A}, \boldsymbol{B})$.*

## 2.2 Background of Topology

### Simplex and Simplicial Complexes

We consider a *d-simplex* (or $d$-dimensional simplex) $\sigma$ as an ordered set of $d+1$ vertices, denoted by $\sigma = [v_0, \ldots, v_d]$. A *face* of $\sigma$ is a simplex obtained by removing a subset of vertices from $\sigma$. A *simplicial complex* $\mathcal{K}$ is a finite collection of simplexes such that (1) for every $\sigma \in \mathcal{K}$ if $\tau \subset \sigma$ then $\tau \in \mathcal{K}$, and (2) for every $\sigma_1, \sigma_2 \in \mathcal{K}$, $\sigma_1 \cap \sigma_2$ is either empty or

a face of both $\sigma_1, \sigma_2$. The *dimension* of $\mathcal{K}$ is the maximum dimension of any simplex in $\mathcal{K}$. A *d-complex* is a $d$-dimensional simplicial complex. For $1 \leq i \leq d$, the *i-skeleton* of a $d$-complex $\mathcal{K}$ is the subcomplex consisting of all the simplexes of $\mathcal{K}$ of dimensions at most $i$. In particular, the 1-skeleton of $\mathcal{K}$ is a graph.

A *piecewise linear embedding* of a 3-complex in $\mathbb{R}^3$ maps a 0-simplex to a point, a 1-simplex to a line segment, a 2-simplex to a triangle, and a 3-simplex to a tetrahedron. In addition, the interior of the images of simplices are disjoint and the boundary of each simplex is mapped to the appropriate simplices. Such an embedding of a simplicial complex $\mathcal{K}$ defines an *underlying topological space* $\mathbb{K}$ – the union of the images of all the simplexes of $\mathcal{K}$. We say $\mathcal{K}$ is *convex* if $\mathbb{K}$ is convex. We say $\mathcal{K}$ *triangulates* a topological space $\mathbb{X}$ if $\mathbb{K}$ is homeomorphic to $\mathbb{X}$. A simplex $\sigma$ of $\mathcal{K}$ is a *exterior* simplex if $\sigma$ is contained in the boundary of $\mathbb{K}$, and $\sigma$ is an *interior* simplex otherwise. A connected component of exterior simplexes is called a *boundary component* of $\mathcal{K}$.

The *aspect ratio* of a set $S \subset \mathbb{R}^3$ is the radius of the smallest ball containing $S$ divided by the radius of the largest ball contained in $S$. The aspect ratio of $S$ is always greater than or equal to 1. We say a simplex $\sigma$ is *stable* if it has $O(1)$ aspect ratio and $\Theta(1)$ weight. Miller and Thurston proved the following lemma. As a corollary, the numbers of the vertices, the edges, the triangles, and the tetrahedrons of a 3-complex $\mathcal{K}$ that is composed of stable tetrahedrons are all equal up to a constant factor.

▶ **Lemma 2.7** (Lemma 4.1 of [43]). *Let $\mathcal{K}$ be a 3-complex in $\mathbb{R}^3$ in which each tetrahedron has $O(1)$ aspect ratio. Then, each vertex of $\mathcal{K}$ is contained in at most $O(1)$ tetrahedrons.*

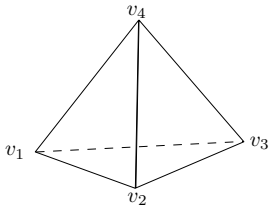
## Boundary Operators

An *i-chain* is a weighted sum of the oriented $i$-simplexes in $\mathcal{K}$ with the coefficients in $\mathbb{R}$. Let $\mathcal{C}_i$ denote the $i$th chain space. The *boundary operator* is a linear map $\partial_i : \mathcal{C}_i \to \mathcal{C}_{i-1}$ such that for an oriented $i$-simplex $\sigma = [v_0, v_1, \ldots, v_i]$,

$$\partial_i(\sigma) = \sum_{j=0}^{i} (-1)^j [v_0, \ldots, \hat{v}_j, \ldots, v_i],$$

where $[v_0, \ldots, \hat{v}_j, \ldots, v_i]$ is the oriented $(i-1)$-simplex obtained by removing $v_j$ from $\sigma$.

The operator $\partial_i$ can be written as a matrix in $|\mathcal{C}_{i-1}| \times |\mathcal{C}_i|$ dimensions, where the $(r, l)$th entry of $\partial_i$ is $\pm 1$ if the $r$th $(i-1)$-simplex is a face of the $l$th $i$-simplex and 0 otherwise. See Figure 1 for an example.



$$\partial_2 = \begin{array}{c} \\ [v_1,v_2] \\ [v_1,v_3] \\ [v_1,v_4] \\ [v_2,v_3] \\ [v_2,v_4] \\ [v_3,v_4] \end{array} \begin{array}{c} \begin{array}{cccc} [v_1,v_4,v_2] & [v_2,v_4,v_3] & [v_1,v_3,v_4] & [v_1,v_2,v_3] \end{array} \\ \begin{bmatrix} -1 & 0 & 0 & 1 \\ 0 & 0 & 1 & -1 \\ 1 & 0 & -1 & 0 \\ 0 & -1 & 0 & 1 \\ -1 & 1 & 0 & 0 \\ 0 & -1 & 1 & 0 \end{bmatrix} \end{array}$$

**Figure 1** An example of boundary operator. The left side is a 3-simplex (a tetrahedron) with vertices $v_1, v_2, v_3, v_4$. The right side is the corresponding second boundary operator $\partial_2$, where each column corresponds to an oriented 2-simplex (a triangle) and each row corresponds to an oriented 1-simplex (an edge).

An important property of boundary operators is $\partial_i \partial_{i+1} = \mathbf{0}$, which implies $\mathrm{Im}(\partial_{i+1}) \subseteq \mathrm{Ker}(\partial_i)$. So, we can define the quotient space $H_i = \mathrm{Ker}(\partial_i) \backslash \mathrm{Im}(\partial_{i+1})$, called the *ith homology space* of $\mathcal{K}$. The rank of $H_i$ is called the $i$th Betti number of $\mathcal{K}$. If the $i$th Betti number of $\mathcal{K}$ is 0, then $\mathrm{Im}(\partial_i^\top) \oplus \mathrm{Im}(\partial_{i+1}) = \mathbb{R}^{|\mathcal{C}_i|}$. The first and second Betti numbers of a triangulation of a three-ball are both 0.

### Hodge Decomposition and Combinatorial Laplacians

Combinatorial Laplacians arise from the discrete Hodge decomposition.

▶ **Theorem 2.8** (Hodge decomposition [38]). *Let $\boldsymbol{A} \in \mathbb{R}^{m \times n}$ and $\boldsymbol{B} \in \mathbb{R}^{n \times p}$ be matrices satisfying $\boldsymbol{AB} = \mathbf{0}$. Then, there is an orthogonal direct sum decomposition*

$$\mathbb{R}^n = \mathit{Im}(\boldsymbol{A}^\top) \oplus \mathit{Ker}(\boldsymbol{A}^\top \boldsymbol{A} + \boldsymbol{B}\boldsymbol{B}^\top) \oplus \mathit{Im}(\boldsymbol{B}).$$

Since $\partial_i \partial_{i+1} = \mathbf{0}$, it is valid to set $\boldsymbol{A} = \partial_i$ and $\boldsymbol{B} = \partial_{i+1}$. The matrix we get in the middle term is the *combinatorial Laplacian*: $\boldsymbol{L}_i \stackrel{\text{def}}{=} \partial_i^\top \partial_i + \partial_{i+1} \partial_{i+1}^\top$.

The weighted combinatorial Laplacian generalizes combinatorial Laplacian. For each $1 \le i \le d$, we assign each $i$-simplex of $\mathcal{K}$ with a *positive* weight, and let $\boldsymbol{W}_i : \mathcal{C}_i \to \mathcal{C}_i$ be a diagonal matrix where $\boldsymbol{W}_i[\sigma, \sigma]$ is the weighted of the $i$-simplex $\sigma$. Then the weighted *$i$-Laplacian* of $\mathcal{K}$ is a linear operator $\boldsymbol{L}_i : \mathcal{C}_i \to \mathcal{C}_i$ defined as

$$\boldsymbol{L}_i \stackrel{\text{def}}{=} \partial_i^\top \boldsymbol{W}_{i-1} \partial_i + \partial_{i+1} \boldsymbol{W}_{i+1} \partial_{i+1}^\top.$$

Note that Hodge decomposition also applies to weighted combinatorial Laplacian (by setting $\boldsymbol{A} = \boldsymbol{W}_{i-1}^{1/2} \partial_i$ and $\boldsymbol{B} = \partial_{i+1} \boldsymbol{W}_{i+1}^{1/2}$, we have $\boldsymbol{AB} = \mathbf{0}$). We call $\boldsymbol{L}_i^{\text{down}} \stackrel{\text{def}}{=} \partial_i^\top \boldsymbol{W}_{i-1} \partial_i$ the $i$th *down-Laplacian* operator and $\boldsymbol{L}_i^{\text{up}} \stackrel{\text{def}}{=} \partial_{i+1} \boldsymbol{W}_{i+1} \partial_{i+1}^\top$ the $i$th *up-Laplacian* operator. Sometimes, we use subscripts to specify the complex on which these operators are defined: $\partial_{i,\mathcal{K}}$, $\boldsymbol{W}_{i,\mathcal{K}}$, $\boldsymbol{L}_{i,\mathcal{K}}^{\text{down}}$, $\boldsymbol{L}_{i,\mathcal{K}}^{\text{up}}$.

### $r$-Hollowings

Let $\mathcal{K}$ be a pure 3-complex with $n$ simplexes. A set of triangles $\hat{\triangle}_1, \ldots, \hat{\triangle}_k$ form a *triangle path* of length $k-1$ if for any $1 \le i \le k-1$, $\hat{\triangle}_i$ and $\hat{\triangle}_{i+1}$ share an edge. The *triangle distance* between two triangles $\triangle_1$ and $\triangle_2$ is the shortest triangle path length between $\triangle_1$ and $\triangle_2$. The *triangle diameter* of $\mathcal{K}$ is the longest triangle distance between any two triangles. A *spherical shell* is $\{\boldsymbol{x} \in \mathbb{R}^3 : R_1 \le \|\boldsymbol{x}\|_2 \le R_2\}$ where $R_1 < R_2$. If $\mathcal{K}$ triangulates a spherical shell, we define the *shell width* to be the shortest triangle distance between any two triangles where one is on the outer sphere and one is on the inner sphere.

▶ **Definition 2.9** ($r$-hollowing). *Let $\mathcal{K}$ be a 3-complex with $n$ simplexes, and let $r = o(n)$ be a positive number. We divide $\mathcal{K}$ into $O(n/r)$* regions *each of $O(r)$ simplexes and $O(r^{2/3})$ boundary simplexes. Only boundary simplexes can appear in more than one region. The boundary of each region triangulates a spherical shell in $\mathbb{R}^3$ and has triangle diameter $O(r^{1/3})$ and shell width at least 5. The union of all boundary simplexes of each region is referred to as an* $r$-hollowing *of $\mathcal{K}$.*

In addition, this paper also examines sufficient conditions for 3-complexes that enable us to compute an $r$-hollowing in linear time (Algorithm 2 and refer to Figure 2 for an illustration). Specifically, we consider a pure 3-complex $\mathcal{K}$ embedded in $\mathbb{R}^3$ with $n$ stable simplexes possessing the following additional geometric structures:

1. The aspect ratio of the convex hull of $\mathcal{K}$ is $O(1)$, and the volume of each tetrahedron in $\mathcal{K}$ is $\Theta(1)$.
2. All but one boundary component has 1-skeleton diameter $O(r^{1/3})$.
3. The total number of exterior simplexes of $\mathcal{K}$ within any $\mathbb{X} \subset \mathbb{R}^3$ of volume $r$ is $O(r^{2/3})$; the total number of exterior simplexes of $\mathcal{K}$ is $O(nr^{-1/3})$.
4. The triangle distance between any two boundary components of $\mathcal{K}$ is greater than 5.

It is worth noting that fulfilling the aforementioned assumptions is not excessively challenging. On one end of the spectrum, there are scenarios where $\mathcal{K}$ contains at most $O(n/r)$ 2-dimensional holes, each with an interior volume of $O(r)$. On the other end, there are instances where $\mathcal{K}$ encompasses $O(nr^{-1/3})$ uniformly distributed small holes, each with a constant interior volume. Moreover, it is likely that all scenarios lying between these extremes would also meet these assumptions.

## 3 Main Theorems

We formally state our main results as follows.

▶ **Theorem 3.1.** *Let $\mathcal{K}$ be a pure 3-complex embedded in $\mathbb{R}^3$ consisting of $n$ stable simplexes and with a known $r$-hollowing. Let $\boldsymbol{L}_1$ be the 1-Laplacian operator of $\mathcal{K}$, and let $\boldsymbol{\Pi}_1$ be the orthogonal projection matrix onto the image of $\boldsymbol{L}_1$. For any vector $\boldsymbol{b}$ and $\epsilon > 0$, we can find a solution $\tilde{\boldsymbol{x}}$ such that $\|\boldsymbol{L}_1\tilde{\boldsymbol{x}} - \boldsymbol{\Pi}_1\boldsymbol{b}\|_2 \leq \epsilon \|\boldsymbol{\Pi}_1\boldsymbol{b}\|_2$ in time $O\left(nr + n^{4/3}r^{5/18}\log(n/\epsilon) + n^2r^{-2/3}\right)$.*

We will overview our algorithm for Theorem 3.1 in Section 4 and prove in Section 5.

▶ **Theorem 3.2.** *Let $\mathcal{K}$ be a pure 3-complex embedded in $\mathbb{R}^3$ consisting of $n$ stable simplexes. Suppose $\mathcal{K}$ satisfies the additional geometric structures 1-4 with parameter $r = o(n)$. Let $\boldsymbol{L}_1$ be the 1-Laplacian operator of $\mathcal{K}$, and let $\boldsymbol{\Pi}_1$ be the orthogonal projection matrix onto the image of $\boldsymbol{L}_1$. For any vector $\boldsymbol{b}$ and $\epsilon > 0$, we can find a solution $\tilde{\boldsymbol{x}}$ such that $\|\boldsymbol{L}_1\tilde{\boldsymbol{x}} - \boldsymbol{\Pi}_1\boldsymbol{b}\|_2 \leq \epsilon \|\boldsymbol{\Pi}_1\boldsymbol{b}\|_2$ in time $O\left(nr + n^{4/3}r^{5/18}\log(n/\epsilon) + n^2r^{-2/3}\right)$.*

The known $r$-hollowing assumption is replaced with geometric structures in Theorem 3.2, and a linear time algorithm for finding $r$-hollowing is presented in Section 6. It is worth mentioning that the additional geometric structures are introduced to ensure the feasibility of finding an $r$-hollowing in linear time. However, the algorithm for solving the system of linear equations remains the same.

▶ **Theorem 3.3.** *Let $\mathcal{U}$ be a union of $h$ pure 3-complexes glued together by identifying certain subsets of their exterior simplexes. Each 3-complex chunk is embedded in $\mathbb{R}^3$ and comprises $n_i$ stable simplexes, and has a known $\Theta(n_i^{3/5})$-hollowing. Let $\boldsymbol{L}_1$ be the 1-Laplacian operator of $\mathcal{U}$, and let $\boldsymbol{\Pi}_1$ be the orthogonal projection matrix onto the image of $\boldsymbol{L}_1$. For any vector $\boldsymbol{b}$ and $\epsilon > 0$, we can find a solution $\tilde{\boldsymbol{x}}$ such that $\|\boldsymbol{L}_1\tilde{\boldsymbol{x}} - \boldsymbol{\Pi}_1\boldsymbol{b}\|_2 \leq \epsilon \|\boldsymbol{\Pi}_1\boldsymbol{b}\|_2$ in time $\widetilde{O}(n^{8/5}k + h^2k^2 + k^3)$, where $n$ is the number of simplexes in $\mathcal{U}$, $k$ is the number of exterior simplexes shared by more than one chunk.*

Due to space constraints, the proof of Theorem 3.3 can be found in the full version of the paper [20].

# 4 Algorithm Overview

Cohen, Fasy, Miller, Nayyeri, Peng, and Walkington [13] observed that

$$\boldsymbol{L}_1^{\dagger} = \left(\boldsymbol{L}_1^{\text{down}}\right)^{\dagger} + \left(\boldsymbol{L}_1^{\text{up}}\right)^{\dagger},$$

where $\boldsymbol{L}_1^{\text{down}} = \partial_1^{\top} \boldsymbol{W}_0 \partial_1$ is the down-Laplacian and $\boldsymbol{L}_1^{\text{up}} = \partial_2 \boldsymbol{W}_2 \partial_2^{\top}$ is the up-Laplacian. The orthogonal projection matrices onto $\text{Im}(\partial_1^{\top})$ and $\text{Im}(\partial_2)$ are:

$$\boldsymbol{\Pi}_1^{\text{down}} \stackrel{\text{def}}{=} \partial_1^{\top}(\partial_1 \partial_1^{\top})^{\dagger}\partial_1, \ \boldsymbol{\Pi}_1^{\text{up}} \stackrel{\text{def}}{=} \partial_2(\partial_2^{\top}\partial_2)^{\dagger}\partial_2^{\top}.$$

▶ **Lemma 4.1** (Lemma 4.1 of [13]). *Let $\boldsymbol{b}$ be a vector. Consider the systems of linear equations: $\boldsymbol{L}_1\boldsymbol{x} = \boldsymbol{\Pi}_1\boldsymbol{b}$, $\boldsymbol{L}_1^{up}\boldsymbol{x}^{up} = \boldsymbol{\Pi}_1^{up}\boldsymbol{b}$, $\boldsymbol{L}_1^{down}\boldsymbol{x}^{down} = \boldsymbol{\Pi}_1^{down}\boldsymbol{b}$. Then, $\boldsymbol{x} = \boldsymbol{\Pi}_1^{up}\boldsymbol{x}^{up} + \boldsymbol{\Pi}_1^{down}\boldsymbol{x}^{down}$.*

Lemma 4.1 implies that four operators are needed to approximate $\boldsymbol{L}_1^{\dagger}$: (1) an approximate projection operator $\widetilde{\boldsymbol{\Pi}}_1^{\text{down}} \approx \boldsymbol{\Pi}_1^{\text{down}}$, (2) an approximate projection operator $\widetilde{\boldsymbol{\Pi}}_1^{\text{up}} \approx \boldsymbol{\Pi}_1^{\text{up}}$, (3) a down-Laplacian solver $\boldsymbol{Z}_1^{\text{down}}$ such that $\boldsymbol{L}_1^{\text{down}}\boldsymbol{Z}_1^{\text{down}}\boldsymbol{b} \approx \boldsymbol{b}$ for any $\boldsymbol{b} \in \text{Im}(\boldsymbol{L}_1^{\text{up}})$, and (4) an up-Laplacian solver $\boldsymbol{Z}_1^{\text{up}}$ such that $\boldsymbol{L}_1^{\text{up}}\boldsymbol{Z}_1^{\text{up}}\boldsymbol{b} \approx \boldsymbol{b}$ for any $\boldsymbol{b} \in \text{Im}(\boldsymbol{L}_1^{\text{up}})$.

We will apply the same approximate orthogonal projection $\widetilde{\boldsymbol{\Pi}}_1^{\text{down}}$ given in [13], which does not depend on Betti numbers. Our solver for the down 1-Laplacian is a slight modification of the one in [13] to incorporate the simplex weights. We state the two lemmas below.

▶ **Lemma 4.2** (Down-projection operator, Lemma 3.2 of [13]). *Let $\mathcal{K}$ be a 3-complex with $n$ simplexes. For any $\epsilon > 0$, there exists a linear operator $\widetilde{\boldsymbol{\Pi}}_1^{down}$ such that*

$$(1-\epsilon)\boldsymbol{\Pi}_1^{down} \preccurlyeq \widetilde{\boldsymbol{\Pi}}_1^{down}(\epsilon) \preccurlyeq \boldsymbol{\Pi}_1^{down}.$$

▶ **Lemma 4.3** (Down-Laplacian solver). *Let $\mathcal{K}$ be a weighted simplicial complex, and let $\boldsymbol{b} \in Im(\boldsymbol{L}_1^{down})$. There exists an operator $\boldsymbol{Z}_1^{down}$ such that $\boldsymbol{L}_1^{down}\boldsymbol{Z}_1^{down}\boldsymbol{b} = \boldsymbol{b}$. In addition, we can compute $\boldsymbol{Z}_1^{down}\boldsymbol{b}$ in linear time.*

## 4.1 Solver for Up-Laplacian

One of our primary technical contributions is the development of an efficient solver for the up-Laplacian system, stated in Lemma 4.4. We will describe the key idea behind our solver in this section.

▶ **Lemma 4.4** (Up-Laplacian solver). *Let $\mathcal{K}$ be a pure 3-complex embedded in $\mathbb{R}^3$ and composed of $n$ stable simplexes. Suppose we are given an $r$-hollowing for $\mathcal{K}$. Then for any $\epsilon > 0$, there exists an operator $\boldsymbol{Z}_1^{up}$ such that*

$$\forall \boldsymbol{b} \in Im(\boldsymbol{L}_1^{up}), \ \left\|\boldsymbol{L}_1^{up}\boldsymbol{Z}_1^{up}\boldsymbol{b} - \boldsymbol{b}\right\|_2 \le \epsilon \left\|\boldsymbol{b}\right\|_2.$$

*In addition, $\boldsymbol{Z}_1^{up}\boldsymbol{b}$ can be computed in time $O\left(nr + n^{4/3}r^{5/18}\log(n/\epsilon) + n^2 r^{-2/3}\right)$.*

We remark that Lemma 4.4 can be improved to $\widetilde{O}(n^{3/2})$ by using a slightly different $r$-hollowing (proved in the full version [20]), which might be of independent interest. Since the bottleneck of our solver for 1-Laplacians is from the projection for up 1-Laplaicans, we use the same $r$-hollowing here.

The given $O(n^{3/5})$-hollowing suggests a partition of the edges in $\mathcal{K}$ into $F \cup C$. We will explain the concrete partition shortly. We have the following matrix identity:

$$\boldsymbol{L}_1^{\text{up}} = \begin{pmatrix} \boldsymbol{I} & \\ \boldsymbol{L}_1^{\text{up}}[C,F]\boldsymbol{L}_1^{\text{up}}[F,F]^{\dagger} & \boldsymbol{I} \end{pmatrix} \begin{pmatrix} \boldsymbol{L}_1^{\text{up}}[F,F] & \\ & \text{Sc}[\boldsymbol{L}_1^{\text{up}}]_C \end{pmatrix} \begin{pmatrix} \boldsymbol{I} & \boldsymbol{L}_1^{\text{up}}[F,F]^{\dagger}\boldsymbol{L}_1^{\text{up}}[F,C] \\ & \boldsymbol{I} \end{pmatrix},$$

where

$$\mathrm{Sc}[\boldsymbol{L}_1^{\mathrm{up}}]_C = \boldsymbol{L}_1^{\mathrm{up}}[C,C] - \boldsymbol{L}_1^{\mathrm{up}}[C,F]\boldsymbol{L}_1^{\mathrm{up}}[F,F]^{\dagger}\boldsymbol{L}_1^{\mathrm{up}}[F,C].$$

The following Lemma 4.5 reduces (approximately) solving a system in $\boldsymbol{L}_1^{\mathrm{up}}$ to (approximately) solving two systems in $\boldsymbol{L}_1^{\mathrm{up}}[F,F]$ and one system in $\mathrm{Sc}[\boldsymbol{L}_1^{\mathrm{up}}]_C$, whose proof can be found in the Appendix of the full version [20]. It is worth noting that Lemma 4.5 holds if we replace $\boldsymbol{L}_1^{\mathrm{up}}$ with an arbitrary symmetric PSD matrix, and we will apply it or its variants for different PSD matrices in our solvers. To avoid introducing additional notations, we state the lemma below in terms of $\boldsymbol{L}_1^{\mathrm{up}}$.

▶ **Lemma 4.5.** *Suppose we have two operators (1)* UpLapFSolver$(\cdot)$ *such that given any* $\boldsymbol{b} \in Im(\boldsymbol{L}_1^{up}[F,F])$, UpLapFSolver$(\boldsymbol{b})$ *returns a vector* $\boldsymbol{x}$ *satisfying* $\boldsymbol{L}_1^{up}[F,F]\boldsymbol{x} = \boldsymbol{b}$, *and (2)* SchurSolver$(\cdot,\cdot)$ *such that for any* $\boldsymbol{h} \in Im(Sc[\boldsymbol{L}_1^{up}]_C)$ *and* $\delta > 0$, SchurSolver$(\boldsymbol{h},\delta)$ *returns* $\tilde{\boldsymbol{x}}$ *satisfying* $\|Sc[\boldsymbol{L}_1^{up}]_C\tilde{\boldsymbol{x}} - \boldsymbol{h}\|_2 \le \delta\|\boldsymbol{h}\|_2$. *Given any* $\boldsymbol{b} = \begin{pmatrix}\boldsymbol{b}_F\\ \boldsymbol{b}_C\end{pmatrix} \in Im(\boldsymbol{L}_1^{up})$ *and any* $\epsilon > 0$, *let*

$$\begin{aligned}
&\boldsymbol{h} = \boldsymbol{b}_C - \boldsymbol{L}_1^{up}[C,F]\cdot \textsc{UpLapFSolver}(\boldsymbol{b}_F),\\
&\tilde{\boldsymbol{x}}_C = \textsc{SchurSolver}(\boldsymbol{h},\delta),\\
&\tilde{\boldsymbol{x}}_F = \textsc{UpLapFSolver}\left(\boldsymbol{b}_F - \boldsymbol{L}_1^{up}[F,C]\tilde{\boldsymbol{x}}_C\right),
\end{aligned} \tag{3}$$

*where* $\delta \le \frac{\epsilon}{1+\left\|\boldsymbol{L}_1^{up}[C,F]\boldsymbol{L}_1^{up}[F,F]^{\dagger}\right\|_2}$. *Then,*

$$\|\boldsymbol{L}_1^{up}\tilde{\boldsymbol{x}} - \boldsymbol{b}\|_2 \le \epsilon\|\boldsymbol{b}\|_2,$$

*where* $\tilde{\boldsymbol{x}} = \begin{pmatrix}\tilde{\boldsymbol{x}}_F\\ \tilde{\boldsymbol{x}}_C\end{pmatrix}$. *Let* $m_F = |F|$ *and* $m_C = |C|$, *and let* UpLapFSolver *have runtime* $t_1(m_F)$ *and* SchurSolver *have runtime* $t_2(m_C)$. *Then, we can compute* $\tilde{\boldsymbol{x}}$ *in time* $O(t_1(m_F) + t_2(m_C) + m_F + m_C)$.

### 4.1.1 Partitioning the Edges

As suggested by Lemma 4.5, we want to partition the edges of $\mathcal{K}$ into $F \cup C$ so that both systems in $\boldsymbol{L}_1^{\mathrm{up}}[F,F]$ and the Schur complement $\mathrm{Sc}[\boldsymbol{L}_1^{\mathrm{up}}]_C$ can be efficiently solved. The given $O(n^{3/5})$-hollowing divides $\mathcal{K}$ into *"disjoint" and balanced* regions with *small* boundary. Let $F$ be the set of the "interior" edges of the regions and $C$ be the set of the "boundary" edges.

We first show the interiors of different regions are "disjoint" in the sense that $\boldsymbol{L}_1^{\mathrm{up}}[F,F]$ is a block diagonal matrix where each diagonal block corresponds to the interior of a region. We can write $\boldsymbol{L}_1^{\mathrm{up}}$ as the sum of rank-1 matrices that each corresponds to a triangle in $\mathcal{K}$:

$$\boldsymbol{L}_1^{\mathrm{up}} = \partial_2 \boldsymbol{W}_2 \partial_2^{\top} = \sum_{\sigma:\text{triangle in } \mathcal{K}} \boldsymbol{W}_2[\sigma,\sigma]\cdot\partial_2[:,\sigma]\partial_2[:,\sigma]^{\top}. \tag{4}$$

For any two edges $e_1, e_2$, $\boldsymbol{L}_1^{\mathrm{up}}[e_1,e_2] = 0$ if and only if no triangle in $\mathcal{K}$ contains both $e_1, e_2$. By our definition of $r$-hollowing in Definition 2.9, for different regions $R_1, R_2$ of $\mathcal{K}$ w.r.t. an $r$-hollowing, no triangle contains both an edge from $R_1$ and an edge from $R_2$.

In addition, the following lemma shows that the boundaries of the regions well approximate the Schur complement onto the boundaries. We give a formal proof of Lemma 4.6 in the full version [20].

▶ **Lemma 4.6** (Spectral bounds for $r$-hollowing)**.** *Let* $\mathcal{K}$ *be a pure* 3*-complex embedded in* $\mathbb{R}^3$ *composed of stable simplexes. Let* $\mathcal{T}$ *be an* $r$*-hollowing of* $\mathcal{K}$, *and let* $C$ *be the edges of* $\mathcal{T}$. *Then,* $\boldsymbol{L}_{1,\mathcal{T}}^{up} \preccurlyeq Sc[\boldsymbol{L}_1^{up}]_C \preccurlyeq O(r)\boldsymbol{L}_{1,\mathcal{T}}^{up}$.

### 4.1.2 Proof of Lemma 4.4 for Up-Laplacian Solver

Algorithm 1 sketches a pseudo-code for our up-Laplacian solver.

**Algorithm 1** UpLapSolver$(\mathcal{K}, \mathcal{T}, \boldsymbol{b}, \epsilon)$.

**Input:** A pure 3-complex $\mathcal{K}$ of $n$ stable simplexes with up-Laplacian $\boldsymbol{L}_1^{\text{up}}$, an $O(n^{3/5})$-hollowing $\mathcal{T}$, a vector $\boldsymbol{b} \in \text{Im}(\boldsymbol{L}_1^{\text{up}})$, an error parameter $\epsilon > 0$

**Output:** An approximate solution $\tilde{\boldsymbol{x}}$ such that $\|\boldsymbol{L}_1^{\text{up}}\tilde{\boldsymbol{x}} - \boldsymbol{b}\|_2 \leq \epsilon \|\boldsymbol{b}\|_2$

1 $F \leftarrow$ the interior edges of regions of $\mathcal{K}$ w.r.t. $\mathcal{T}$, $C \leftarrow$ the boundary edges of regions.

2 UpLapFSolver$(\cdot) \leftarrow$ a solver by Nested Dissection that satisfies the requirement in Lemma 4.5.

3 SchurSolver$(\cdot,\cdot) \leftarrow$ a solver by Preconditioned Conjugate Gradient with the preconditioner being the up-Laplacian of $\mathcal{T}$ that satisfies the requirement in Lemma 4.5.

4 $\tilde{\boldsymbol{x}} \leftarrow$ computed by Equation (3)

5 **return** *solution* $\tilde{\boldsymbol{x}}$

By Lemma 4.5, the $\tilde{\boldsymbol{x}}$ returned by Algorithm 1 satisfies $\|\boldsymbol{L}_1^{\text{up}}\tilde{\boldsymbol{x}} - \boldsymbol{b}\|_2 \leq \epsilon \|\boldsymbol{b}\|_2$. To bound the runtime of Algorithm 1, we need the following lemmas for lines 2 and 3.

▶ **Lemma 4.7** (Solver for the "$F$" part)**.** *Let $\mathcal{K}$ be a pure 3-complex embedded in $\mathbb{R}^3$ and composed of $n$ stable simplexes. Let $\mathcal{T}$ be an $r$-hollowing of $\mathcal{K}$, and let $F$ be the set of interior edges in each region of $\mathcal{K}$ w.r.t. $\mathcal{T}$. Then, with a pre-processing time $O(nr)$, there exists a solver UpLapFSolver$(\cdot)$ such that given any $\boldsymbol{b}_F \in im(\boldsymbol{L}_1^{up}[F,F])$, UpLapFSolver$(\boldsymbol{b}_F)$ returns an $\boldsymbol{x}_F$ such that $\boldsymbol{L}_1^{up}[F,F]\boldsymbol{x}_F = \boldsymbol{b}_F$ in time $O(nr^{1/3})$.*

By our choice of $F$, the matrix $\boldsymbol{L}_1^{\text{up}}[F,F]$ can be written as a block diagonal matrix where each block corresponds to a region of $\mathcal{K}$ w.r.t. the $r$-hollowing $\mathcal{T}$. Since each region is a 3-complex in which every tetrahedron has an aspect ratio $O(1)$, we can construct the solver UpLapFSolver by Nested Dissection [43]. However, since each row or column of $\boldsymbol{L}_1^{\text{up}}[F,F]$ corresponds to an edge, we need to turn the good *vertex separators* in [43] into good *edge separators* for regions of $\mathcal{K}$. The proof of Lemma 4.7 can be found in the full version [20].

▶ **Lemma 4.8** (Solver for the Schur complement)**.** *Let $\mathcal{K}$ be a pure 3-complex embedded in $\mathbb{R}^3$ and composed of $n$ stable simplexes. Let $\mathcal{T}$ be an $r$-hollowing of $\mathcal{K}$, and let $C$ be the set of boundary edges of each region of $\mathcal{K}$ w.r.t. $\mathcal{T}$. Then, with a pre-processing time $O(nr + n^2r^{-2/3})$ there exists a solver SchurSolver$(\cdot,\cdot)$ such that for any $\boldsymbol{h} \in Im(Sc[\boldsymbol{L}_1^{up}]_C)$ and $\delta > 0$, SchurSolver$(\boldsymbol{h}, \delta)$ returns an $\tilde{\boldsymbol{x}}_C$ such that $\|Sc[\boldsymbol{L}_1^{up}]_C\tilde{\boldsymbol{x}}_C - \boldsymbol{h}\|_2 \leq \delta \|\boldsymbol{h}\|_2$ in time $\widetilde{O}\left(nr^{5/6} + n^{4/3}r^{5/18}\right)$.*

Our solver SchurSolver is based on the Preconditioned Conjugate Gradient (PCG) with the preconditioner $\boldsymbol{L}_{1,\mathcal{T}}^{\text{up}}$, the up-Laplacian operator of $\mathcal{T}$. By Theorem 2.6 and Lemma 4.6, the number of PCG iterations is $\widetilde{O}(\sqrt{r})$. In each PCG iteration, we solve the system in $\boldsymbol{L}_{1,\mathcal{T}}^{\text{up}}$ via Nested Dissection. Again, the proof of Lemma 4.8 can be found in the full version of the paper [20].

Given the above lemmas, we prove Lemma 4.4.

**Proof of Lemma 4.4.** The correctness of Algorithm 1 is by Lemma 4.5. By Lemma 4.7 and 4.8, the total runtime of the algorithm is

$$\widetilde{O}\left(nr^{5/6} + n^{4/3}r^{5/18} + nr + n^2r^{-2/3}\right). \qquad \blacktriangleleft$$

## 4.2 Projection for Up 1-Laplacian

As the first Betti number of $\mathcal{K}$ can be arbitrary, the approximate projection operators for the up 1-Laplacian provided in [13, 5, 6] are not applicable here. Our approximate projection operator follows a similar approach to our up 1-Laplacian solver, which is based on an incomplete Nested Dissection for *triangles*, instead of edges.

▶ **Lemma 4.9** (Up-projection operator). *Let $\mathcal{K}$ be a pure 3-complex embedded in $\mathbb{R}^3$ and composed of $n$ stable simplexes. Suppose we are given an $r$-hollowing for $\mathcal{K}$. Then, for any $\epsilon > 0$, there exists an operator $\widetilde{\mathbf{\Pi}}_1^{up}$ such that*

$$\forall \boldsymbol{b}, \left\| \widetilde{\mathbf{\Pi}}_1^{up} \boldsymbol{b} - \mathbf{\Pi}_1^{up} \boldsymbol{b} \right\|_2 \leq \epsilon \left\| \mathbf{\Pi}_1^{up} \boldsymbol{b} \right\|_2 .$$

*In addition, $\widetilde{\mathbf{\Pi}}_1^{up} \boldsymbol{b}$ can be computed in time $O\left(nr + n^{4/3} r^{5/18} \log(n/\epsilon) + n^2 r^{-2/3}\right)$.*

The proof of Lemma 4.9 can be found in the full paper [20]. The subsequent Lemma offers a helpful formula for $\mathbf{\Pi}_1^{\text{up}}$, the orthogonal projection matrix onto the image of $\boldsymbol{L}_1^{\text{up}}$.

▶ **Lemma 4.10.** *Let $\mathcal{K}$ be a simplicial complex with boundary operator $\partial_2$. For any partition $F \cup C$ of the 2-simplexes of $\mathcal{K}$, the orthogonal projection $\mathbf{\Pi}_1^{up}$ for $\mathcal{K}$ can be decomposed as*

$$\mathbf{\Pi}_1^{up} = \mathbf{\Pi}_{Im(\partial_2[:,F])} + \mathbf{\Pi}_{Ker(\partial_2^\top[F,:])} \partial_2[:,C] (Sc[\boldsymbol{L}_2^{down}]_C)^\dagger \partial_2^\top[C,:] \mathbf{\Pi}_{Ker(\partial_2^\top[F,:])},$$

*where $\boldsymbol{L}_2^{down}$ is the down 2-Laplacian.*

Once more, an $r$-hollowing offers a natural partition of the triangles within $\mathcal{K}$. We assign all the "interior" triangles to $F$ and all the "boundary" triangles to $C$. As such, Nested Dissection can be utilized to compute $\mathbf{\Pi}_{\text{Im}(\partial_2[:,F])}$ and $\mathbf{\Pi}_{\text{Ker}(\partial_2^\top[F,:])}$. The primary technical challenge arises when solving a system in the Schur complement $\text{Sc}[\boldsymbol{L}_2^{\text{down}}]_C$. We precondition it using the boundary $\partial_2^\top[C,:]\partial_2[:,C]$ and apply Preconditioned Conjugate Gradient, which requires a distinct approach to bound the relative condition numbers.

# 5 Proof of Main Theorem 3.1

Given all the four operators in Lemma 4.2, 4.3, 4.4, and 4.9, we prove Theorem 3.1.

**Proof of Theorem 3.1.** Let $\kappa$ be the maximum of $\kappa(\boldsymbol{L}_1^{\text{down}})$ and $\kappa(\boldsymbol{L}_1^{\text{up}})$. Let $\delta > 0$ be a parameter to be determined later. Let $\widetilde{\mathbf{\Pi}}_1^{\text{down}} = \widetilde{\mathbf{\Pi}}_1^{\text{down}}(\delta), \widetilde{\mathbf{\Pi}}_1^{\text{up}} = \widetilde{\mathbf{\Pi}}_1^{\text{up}}(\delta)$ be defined in Lemma 4.2 and 4.9, and let $\boldsymbol{Z}_1^{\text{down}}$ be the operator in Lemma 4.3 with no error and $\boldsymbol{Z}_1^{\text{up}}$ in Lemma 4.4 with error $\delta$. Let

$$\begin{aligned}
&\tilde{\boldsymbol{b}}^{\text{up}} \stackrel{\text{def}}{=} \widetilde{\mathbf{\Pi}}_1^{\text{up}} \boldsymbol{b}, \ \tilde{\boldsymbol{b}}^{\text{down}} \stackrel{\text{def}}{=} \widetilde{\mathbf{\Pi}}_1^{\text{down}} \boldsymbol{b}, \\
&\widetilde{\boldsymbol{x}}^{\text{up}} \stackrel{\text{def}}{=} \boldsymbol{Z}_1^{\text{up}} \tilde{\boldsymbol{b}}^{\text{up}}, \ \widetilde{\boldsymbol{x}}^{\text{down}} \stackrel{\text{def}}{=} \boldsymbol{Z}_1^{\text{down}} \tilde{\boldsymbol{b}}^{\text{down}}, \\
&\tilde{\boldsymbol{x}} \stackrel{\text{def}}{=} \widetilde{\mathbf{\Pi}}_1^{\text{up}} \widetilde{\boldsymbol{x}}^{\text{up}} + \widetilde{\mathbf{\Pi}}_1^{\text{down}} \widetilde{\boldsymbol{x}}^{\text{down}}.
\end{aligned}$$

Then,

$$\begin{aligned}
&\left\| \boldsymbol{L}_1 \tilde{\boldsymbol{x}} - \mathbf{\Pi}_1 \boldsymbol{b} \right\|_2 \\
&\quad \leq \left\| \boldsymbol{L}_1^{\text{up}} \widetilde{\mathbf{\Pi}}_1^{\text{up}} \widetilde{\boldsymbol{x}}^{\text{up}} - \tilde{\boldsymbol{b}}^{\text{up}} \right\|_2 + \left\| \boldsymbol{L}_1^{\text{down}} \widetilde{\mathbf{\Pi}}_1^{\text{down}} \widetilde{\boldsymbol{x}}^{\text{down}} - \tilde{\boldsymbol{b}}^{\text{down}} \right\|_2 + \left\| \tilde{\boldsymbol{b}}^{\text{up}} + \tilde{\boldsymbol{b}}^{\text{down}} - \mathbf{\Pi}_1 \boldsymbol{b} \right\|_2 .
\end{aligned}$$

- For the first term,

$$\left\|\boldsymbol{L}_1^{\text{up}}\widetilde{\boldsymbol{\Pi}}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}-\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2 \le \left\|\boldsymbol{L}_1^{\text{up}}\widetilde{\boldsymbol{\Pi}}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}-\boldsymbol{L}_1^{\text{up}}\boldsymbol{\Pi}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}\right\|_2 + \left\|\boldsymbol{L}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}-\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2.$$

  By Lemma 4.9,

$$\begin{aligned}\left\|\boldsymbol{L}_1^{\text{up}}\widetilde{\boldsymbol{\Pi}}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}-\boldsymbol{L}_1^{\text{up}}\boldsymbol{\Pi}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}\right\|_2 &\le \|\boldsymbol{L}_1^{\text{up}}\|_2\left\|(\widetilde{\boldsymbol{\Pi}}_1^{\text{up}}-\boldsymbol{\Pi}_1^{\text{up}})\boldsymbol{\Pi}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}\right\|_2\\ &\le \delta\|\boldsymbol{L}_1^{\text{up}}\|_2\|\boldsymbol{\Pi}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}\|_2.\end{aligned}$$

  Let $\boldsymbol{y} \stackrel{\text{def}}{=} (\boldsymbol{L}_1^{\text{up}})^{\dagger}\tilde{\boldsymbol{b}}^{\text{up}}$. By Lemma 4.4,

$$\|\boldsymbol{\Pi}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}-\boldsymbol{y}\|_2 \le \|(\boldsymbol{L}_1^{\text{up}})^{\dagger}\|_2\left\|\boldsymbol{L}_1^{\text{up}}\boldsymbol{\Pi}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}-\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2 \le \delta\|(\boldsymbol{L}_1^{\text{up}})^{\dagger}\|_2\left\|\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2.$$

  By the triangle inequality,

$$\|\boldsymbol{\Pi}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}\|_2 \le \|\boldsymbol{y}\|_2+\delta\|(\boldsymbol{L}_1^{\text{up}})^{\dagger}\|_2\left\|\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2 \le (1+\delta)\|(\boldsymbol{L}_1^{\text{up}})^{\dagger}\|_2\left\|\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2.$$

  So, $\left\|\boldsymbol{L}_1^{\text{up}}\widetilde{\boldsymbol{\Pi}}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}-\boldsymbol{L}_1^{\text{up}}\boldsymbol{\Pi}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}\right\|_2 \le \delta(1+\delta)\kappa\left\|\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2$.
  By Lemma 4.4, $\left\|\boldsymbol{L}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}-\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2 \le \delta\left\|\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2$.
  So, $\left\|\boldsymbol{L}_1^{\text{up}}\widetilde{\boldsymbol{\Pi}}_1^{\text{up}}\widetilde{\boldsymbol{x}}^{\text{up}}-\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2 \le 3\delta\kappa\left\|\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2$.
- For the second term, the operator $\boldsymbol{Z}_1^{\text{down}}$ has no error, which means $\boldsymbol{L}_1^{\text{down}}\widetilde{\boldsymbol{x}}^{\text{down}} = \tilde{\boldsymbol{b}}^{\text{down}}$. Then,

$$\begin{aligned}\left\|\boldsymbol{L}_1^{\text{down}}\widetilde{\boldsymbol{\Pi}}_1^{\text{down}}\widetilde{\boldsymbol{x}}^{\text{down}}-\tilde{\boldsymbol{b}}^{\text{down}}\right\|_2 &= \left\|\boldsymbol{L}_1^{\text{down}}\widetilde{\boldsymbol{\Pi}}_1^{\text{down}}\widetilde{\boldsymbol{x}}^{\text{down}}-\boldsymbol{L}_1^{\text{down}}\widetilde{\boldsymbol{x}}^{\text{down}}\right\|_2\\ &\le \delta(1+\delta)\kappa\left\|\tilde{\boldsymbol{b}}^{\text{down}}\right\|_2.\end{aligned}$$

- For the third term,

$$\begin{aligned}\left\|\tilde{\boldsymbol{b}}^{\text{up}}+\tilde{\boldsymbol{b}}^{\text{down}}-\boldsymbol{\Pi}_1\boldsymbol{b}\right\|_2^2 &= \left\|(\widetilde{\boldsymbol{\Pi}}^{\text{up}}-\boldsymbol{\Pi}^{\text{up}})\boldsymbol{b}\right\|_2^2+\left\|(\widetilde{\boldsymbol{\Pi}}^{\text{down}}-\boldsymbol{\Pi}^{\text{down}})\boldsymbol{b}\right\|_2^2\\ &\le \delta^2\left(\|\boldsymbol{\Pi}^{\text{up}}\boldsymbol{b}\|_2^2+\left\|\boldsymbol{\Pi}^{\text{down}}\boldsymbol{b}\right\|_2^2\right) \text{ (by Lemma 4.2, 4.9, Fact 2.5)}\\ &= \delta^2\|\boldsymbol{\Pi}_1\boldsymbol{b}\|_2^2.\end{aligned}$$

  Combining all the above inequalities,

$$\begin{aligned}\|\boldsymbol{L}_1\tilde{\boldsymbol{x}}-\boldsymbol{\Pi}_1\boldsymbol{b}\|_2 &\le 3\delta\kappa\left\|\tilde{\boldsymbol{b}}^{\text{up}}\right\|_2+2\delta\kappa\left\|\tilde{\boldsymbol{b}}^{\text{down}}\right\|_2+\delta\|\boldsymbol{\Pi}_1\boldsymbol{b}\|_2\\ &\le 3\delta\kappa(1+\delta)\|\boldsymbol{\Pi}_1^{\text{up}}\boldsymbol{b}\|_2+2\delta\kappa(1+\delta)\left\|\boldsymbol{\Pi}_1^{\text{down}}\boldsymbol{b}\right\|_2+\delta\|\boldsymbol{\Pi}_1\boldsymbol{b}\|_2\\ &\le 11\delta\kappa\|\boldsymbol{\Pi}_1\boldsymbol{b}\|_2.\end{aligned}$$

  Choosing $\delta \le \frac{\epsilon}{11\kappa}$, we have

$$\|\boldsymbol{L}_1\tilde{\boldsymbol{x}}-\boldsymbol{\Pi}_1\boldsymbol{b}\|_2 \le \epsilon\|\boldsymbol{\Pi}_1\boldsymbol{b}\|_2.$$

◀

## 6 Computing an $r$-Hollowing

In this section, we describe a linear time algorithm (Algorithm 2) that finds an $r$-hollowing of a pure 3-complex $\mathcal{K}$ embedded in $\mathbb{R}^3$ with $n$ stable simplexes that satisfies the additional geometric structures stated at the end of Section 2. We restate them below:

1. The aspect ratio of the convex hull of $\mathcal{K}$ is $O(1)$, and the volume of each tetrahedron in $\mathcal{K}$ is $\Theta(1)$.
2. All but one boundary component has 1-skeleton diameter $O(r^{1/3})$.
3. The total number of exterior simplexes of $\mathcal{K}$ within any $\mathbb{X} \subset \mathbb{R}^3$ of volume $r$ is $O(r^{2/3})$; the total number of exterior simplexes of $\mathcal{K}$ is $O(nr^{-1/3})$.
4. The triangle distance between any two boundary components of $\mathcal{K}$ is greater than 5.

▶ **Lemma 6.1** (Finding an $r$-hollowing). *Let $\mathcal{K}$ be a pure 3-complex embedded in $\mathbb{R}^3$ and composed of $n$ stable simplexes. If $\mathcal{K}$ possesses additional geometric structures 1-4 with parameter $r = o(n)$, then we can find an $r$-hollowing of $\mathcal{K}$ in linear time.*

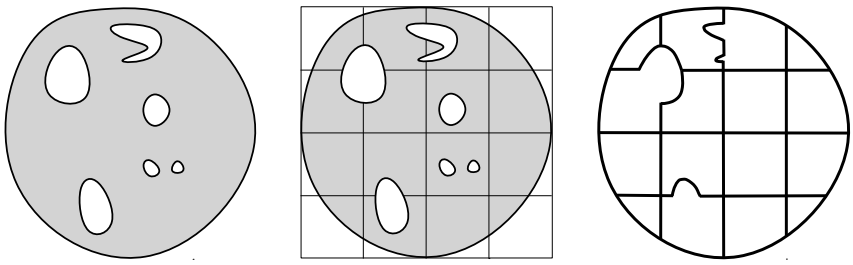
In the rest of the section, we will show Algorithm 2 satisfies Lemma 6.1. Let $\mathbb{K}$ be the convex hull of the underlying topological space of $\mathcal{K}$. Algorithm 2 first finds a *nice bounding box* – a box encompasses $\mathbb{K}$ and its volume and aspect ratio are within constant factors of those of $\mathbb{K}$. Lemma 6.3 provides a linear time algorithm for finding a nice bounding box for $\mathbb{K}$ when the aspect ratio of $\mathbb{K}$ is $O(1)$. Then, Algorithm 2 "cuts" the bounding box into $O(n/r)$ smaller boxes of equal volume using 2-dimensional planes and turns these cutting planes into an $r$-hollowing. Figure 2 illustrates the process of finding an $r$-hollowing.

We need the following lemma from [4] to construct a nice bounding box.

▶ **Lemma 6.2** (Lemma 3.4 of [4]). *Given a set $X$ of points in $\mathbb{R}^3$, we can compute in linear time a bounding box $\mathcal{B}$ with $vol(\mathcal{B}) \leq 6\sqrt{6}vol(\mathcal{B}^*)$, where $vol(\cdot)$ is the volume and $\mathcal{B}^*$ is a bounding box of $X$ with the minimum volume.*

▶ **Corollary 6.3** (Nice bounding box). *Let $\mathcal{K}$ be a 3-complex embedded in $\mathbb{R}^3$ whose underlying topological space has aspect ratio $O(1)$. We can compute a nice bounding box of the convex hull of $\mathcal{K}$ in linear time.*

The proof of Corollary 6.3 can be found in the full version [20].



(a) (b) (c)

**Figure 2** (a) An 2-dimensional illustration of a 3-complex $\mathcal{K}$ with several holes inside; (b) A nice bounding box of $\mathcal{K}$ with $\lfloor n^{1/3}r^{-1/3} \rfloor$ evenly-spaced 2-dimensional planes; (c) An $r$-hollowing $\mathcal{T}$ generated by Algorithm 2 consisting of simplexes that are "close" to the two-dimensional planes and parts of the boundaries of the intersecting holes inside with the planes.

**Proof of Lemma 6.1.** We can check that Algorithm 2 has linear runtime. In the rest of the proof, we will show $\mathcal{T}$ returned by Algorithm 2 is an $r$-hollowing of $\mathcal{K}$.

By Assumption 1, 2 and 3, the volume of the convex hull of $\mathcal{K}$, denoted by $\mathrm{CH}(\mathcal{K})$, is $\Theta(n)$; the maximum volume is attained when $\mathcal{K}$ has $\Theta(n/r)$ boundary components and each corresponds to a "hole" of volume $\Theta(r)$. By Lemma 6.3, we have $\mathrm{vol}(\mathcal{B}) = \Theta(\mathrm{vol}(\mathrm{CH}(\mathcal{K}))) = \Theta(n)$. In Algorithm 2, the 2-dimensional planes divide the box $\mathcal{B}$ into $O(n/r)$ smaller boxes

**Algorithm 2** HOLLOWING$(\mathcal{K}, r)$.

**Input:** A pure 3-complex $\mathcal{K}$ embedded in $\mathbb{R}^3$ with $n$ stable simplexes satisfying assumption 1-4 with a known parameter $r = o(n)$

**Output:** An $r$-hollowing $\mathcal{T}$

Find a nice bounding box $\mathcal{B}$ for $\mathcal{K}$ by Corollary 6.3.

For each pair of parallel faces of $\mathcal{B}$, find $\lfloor n^{1/3} r^{-1/3} \rfloor$ evenly-spaced 2-dimensional planes parallel to the face which divide $\mathcal{B}$ into equal-volume pieces. We can slightly perturb the planes so that no plane intersects with any vertex of $\mathcal{K}$ (see Figure 2(b)).

$\mathcal{T} \leftarrow$ all the tetrahedrons on the boundary of $\mathcal{K}$ that form a spherical shell.

**for** *each 2-dimensional plane* $P$ **do**

  $\mathcal{Q} \leftarrow$ all the tetrahedrons of $\mathcal{K}$ that intersect $P$.

  **if** $\mathcal{Q}$ *is not connected (i.e.,* $P$ *intersects some holes inside)* **then**

    $\mathcal{Q} \leftarrow \mathcal{Q} \cup \bigcup_{\mathcal{H} \in \text{intersected holes inside}}$ all the tetrahedrons on the boundary of $\mathcal{H}$, which are on one side of $P$ and form half of a spherical shell (see Figure 2(c)).

  **end**

  $\mathcal{T} \leftarrow \mathcal{T} \cup \mathcal{Q}$.

**end**

Expand $\mathcal{T}$ such that its width reaches 5.

**return** $\mathcal{T}$

each of volume $O(r)$ and surface area $O(r^{2/3})$. By our construction of $\mathcal{T}$, each smaller box corresponds to a region; thus, there are $O(n/r)$ regions. By Assumption 3, each region of $\mathcal{T}$ has $O(r)$ simplexes and $O(r^{2/3})$ boundary simplexes. Moreover, the boundary of each region triangulates a spherical shell in $\mathbb{R}^3$ by construction. Additionally, the diameter of the underlying topological space of each region is upper bounded by the triangle diameter of the small box plus $\Theta(1)$ times the 1-skeleton diameter of boundary components. By Assumption 2, each region has diameter $O(r^{1/3})$.

To conclude, $\mathcal{T}$ satisfies all the conditions in Definition 2.9 and is an $r$-hollowing of $\mathcal{K}$. ◀

## Abstract

A weighted directed graph $G = (V, A, c)$, where $A \subseteq V \times V$ and $c : A \to \mathbb{R}$, naturally describes a road network in which an electric car, or vehicle (EV), can roam. An arc $uv \in A$ models a road segment connecting the two vertices (junctions) $u$ and $v$. The cost $c(uv)$ of the arc $uv$ is the amount of *energy* the car needs to travel from $u$ to $v$. This amount can be positive, zero or negative. We consider both the more realistic scenario where there are no negative cycles in the graph, as well as the more challenging scenario, which can also be motivated, where negative cycles may be present.

The electric car has a battery that can store up to $B$ units of energy. The car can traverse an arc $uv \in A$ only if it is at $u$ and the charge $b$ in its battery satisfies $b \geq c(uv)$. If the car traverses the arc $uv$ then it reaches $v$ with a charge of $\min\{b - c(uv), B\}$ in its battery. Arcs with a positive cost deplete the battery while arcs with negative costs may charge the battery, but not above its capacity of $B$. If the car is at a vertex $u$ and cannot traverse any outgoing arcs of $u$, then it is stuck and cannot continue traveling.

We consider the following natural problem: Given two vertices $s, t \in V$, can the car travel from $s$ to $t$, starting at $s$ with an initial charge $b$, where $0 \leq b \leq B$? If so, what is the maximum charge with which the car can reach $t$? Equivalently, what is the smallest *depletion* $\delta_{B,b}(s, t)$ such that the car can reach $t$ with a charge of $b - \delta_{B,b}(s, t)$ in its battery, and which path should the car follow to achieve this? We also refer to $\delta_{B,b}(s, t)$ as the *energetic cost* of traveling from $s$ to $t$. We let $\delta_{B,b}(s, t) = \infty$ if the car cannot travel from $s$ to $t$ starting with an initial charge of $b$. The problem of computing energetic costs is a strict generalization of the standard shortest paths problem.

When there are no negative cycles, the single-source version of the problem can be solved using simple adaptations of the classical Bellman-Ford and Dijkstra algorithms. More involved algorithms are required when the graph may contain negative cycles.

## 1 Introduction

A weighted directed graph $G = (V, A, c)$, where $A \subseteq V \times V$ and $c : A \to \mathbb{R}$, naturally describes a road network in which an electric car can roam. An arc $uv \in A$ models a road segment connecting the two vertices (junctions) $u$ and $v$. The cost $c(uv)$ of the arc $uv$ is the

amount of *energy* the electric car needs to travel from $u$ to $v$. This amount can be positive, e.g., if the road segment is uphill; zero; or negative, e.g., if the road segment is downhill. We consider both the more realistic scenario where there are no negative cycles in the graph, as well as the more challenging scenario, which can also be motivated, where the graph may contain negative cycles. (A cycle is negative if the sum of its arc costs is negative.)

An electric car is equipped with a battery that can store up to $B$ units of energy, where $B > 0$ is a parameter. We assume that the electric car cannot be charged along the way and has to rely on the initial charge available in its battery. If the car is currently at vertex $u$ with charge $b$ in its battery, where $0 \leq b \leq B$, then it can traverse an arc $uv \in A$ if and only if $c(uv) \leq b$. If this condition holds, and the car traverses the arc, then it reaches $v$ with a charge of $\min\{b - c(uv), B\}$. In particular, the charge in the battery cannot be negative and cannot exceed $B$. The car can traverse $uv$ if $b - c(uv) > B$ (which can hold only if $c(uv) < 0$), but the battery will not charge beyond its capacity of $B$. We may assume that $c(uv) \in [-B, B]$ for every $uv \in A$, as arcs with $c(uv) > B$ can never be used, and thus can be removed, and costs $c(uv) < -B$ can be changed to $c(uv) = -B$.

We consider the following natural problem: Given two vertices $s, t \in V$, can the car travel from $s$ to $t$, starting at $s$ with an initial charge $b$, where $0 \leq b \leq B$? If so, what is the *maximum final charge* $\alpha_{B,b}(s,t)$ with which the car can reach $t$? Equivalently, what is the *minimum depletion* $\delta_{B,b}(s,t)$ such that the car can reach $t$ with a charge of $b - \delta_{B,b}(s,t)$ in its battery, and which path should the car follow to achieve this? (If $b < B$ then the minimum depletion $\delta_{B,b}(s,t)$ may be negative.) We also refer to $\delta_{B,b}(s,t)$ as the *energetic cost* of traveling from $s$ to $t$. Note that $\delta_{B,b}(s,t) = b - \alpha_{B,b}(s,t)$. We let $\alpha_{B,b}(s,t) = -\infty$ and $\delta_{B,b}(s,t) = \infty$ if the car cannot travel from $s$ to $t$ starting with an initial charge of $b$.

We also consider the related problem of finding the *minimum initial change* at $s$, if any, that will allow the car to travel to $t$, ending with a charge of at least $b$ in the battery. We denote this quantity by $\beta_{B,b}(s,t)$. We show that minimum initial charges can be computed by computing maximum final charges, or minimum energetic costs, on the *reversed* graph.

If all arc costs are non-negative, then $\delta_{B,b}(s,t) = \delta(s,t)$, if $\delta(s,t) \leq b \leq B$, where $\delta(s,t)$ is the standard distance, i.e., the length of a shortest path, from $s$ to $t$ in the graph $G$, where $c(uv)$ is the length of $uv$. Otherwise, $\delta_{B,b}(s,t) = \infty$. If there are negative arc costs but no negative cycles, $\delta_{B,b}(s,t) = \delta(s,t)$ if and only if there exists a shortest path $P$ from $s$ to $t$ such that the length of every prefix of $P$ is in the interval $[b - B, b]$. In general, energetic costs may be larger than distances, since the charge in the battery is constrained to remain in the interval $[0, B]$, i.e., it is not allowed to go negative and it is capped at $B$. (For example, the electric car may not be able to traverse a mountain pass and may need to take a detour.) It is always true that $\delta_{B,b}(s,t) \geq \delta(s,t)$.

The problem of computing minimum energetic costs is thus a strict generalization of the standard shortest paths problem, even if there are no negative cycles in the graph. Interestingly, the energetic costs $\delta_{B,b}(s,t)$ are well-defined even if there are negative cycles in the graph. The problem is then an interesting variant of one-player *energy games* with a reachability objective. It is also related to the 1-VASS (Vector Addition Systems with States) problem. (See references Section 1.2.) The presence of negative cycles poses interesting algorithmic challenges. The corresponding minimum energetic paths are still finite, but are not necessarily simple. A minimum energy path from $s$ to $t$ may need to go through a sequence of negative cycles, using each one of them to gain sufficient energy to reach the next negative cycle, and eventually the target $t$.

When there are no negative cycles, the single-source version of the energetic cost problem can be solved using simple, but subtle, adaptations of the classical Bellman-Ford [4, 15] and Dijkstra [11] algorithms. Similar algorithms, some less efficient, are explicit or implicit

in previous papers (see Section 1.2). We present simpler, self-contained versions of these algorithms with simpler correctness proofs. We also present efficient algorithms for finding minimum energetic paths in the presence of negative cycles.

Unlike the standard shortest paths problem, the single-target version of the minimum energetic paths problem is *not* equivalent to the single-source version. In particular, one cannot solve the single-target problem by running a single-source algorithm backward. Although there is always a tree of minimum energetic paths from a source vertex $s$ to all other vertices reachable from it, there are simple examples in which there is no tree of minimum energetic paths to a target vertex $t$ from all vertices that can reach it.

## 1.1 Our results

We show that the single-source version of the minimum energetic paths problem with negative arc costs but no negative cycles can be solved in $O(mn)$ time using a simple adaptation of the Bellman-Ford [4, 15] algorithm, where $m = |A|$ and $n = |V|$. Furthermore, if a *valid potential function* $p : V \to \mathbb{R}$ is given, i.e., a function for which $c(uv) + p(u) - p(v) \geq 0$ for every $uv \in A$, then the single-source version can be solved in $O(m + n \log n)$ time using an adaptation of Dijkstra's [11] algorithm equivalent to the $A^*$ search heuristic (see, e.g., Hart et al. [21]). Since a valid potential function can be found in $O(mn)$ time using the standard Bellman-Ford algorithm, the all-pairs version of the minimum energetic paths problem can be solved $O(mn + n^2 \log n)$ time.

The $O(mn)$ bound matches the time bound of the standard Bellman-Ford algorithm, which is still the fastest known algorithm for the single-source shortest paths problem in a directed graph with general (real) arc costs, and no negative cycles. The $O(mn + n^2 \log n)$ bound almost matches the best time bound of $O(mn + n^2 \log \log n)$ obtained by Pettie [31] for the standard APSP problem with general arc costs. (For a survey of other related results, see Zwick [38].)

Much faster algorithms are known for the standard single-source shortest paths problem when arc costs are integral. Bringmann et al. [8], improving a breakthrough result of Bernstein et al. [5], obtained an $O(m \log^2 n \log(nW) \log \log n)$-time algorithm when arc costs are integers that are at least $-W$, where $W \geq 1$. By using these algorithms to find a valid potential function, and then using the energetic version of Dijkstra's algorithm, we get the same improved time bound for the single-source version of the minimum energetic paths problem with negative arc costs but no negative cycles.

We also present a more involved $O(mn + n^2 \log n)$-time algorithm for solving the single-source minimum energetic cost problem in the presence of negative cycles. This gives, of course, an $O(mn^2 + n^3 \log n)$-time algorithm for the all-pairs and single-target versions of the problem.

When the capacity $B$ of the battery is sufficiently large, we show that the all-pairs version of the minimum energetic cost problem can be solved in $O(mn + n^2 \log n)$ time.

## 1.2 Related results

Various adaptations of the Bellman-Ford and Dijkstra algorithms for problems similar or equivalent to the minimum energetic paths problem defined here, when there are no negative cycles in the graph, were given by several authors. Eisner et al. [14], improving upon Artmeier et al. [2], and Brim and Chalupka [6] give versions of these algorithms with the same running times as ours, but using a slightly different approach. Baum et al. [3] give a version of Dijkstra's algorithm but with a much slower running time. They also show that the maximum charge with which $t$ can be reached when starting at $s$ with charge $b$ is a piece-wise linear function of $b$ with at most $O(n)$ breakpoints.

Brim and Chalupka [6] consider the related problem of solving one-player *energy games* and the more complicated problem of solving two-player *energy games*. (For more on energy games, see also Brim et al. [7] and Dorfman et al. [12].) The problem of finding minimum energy paths in the presence of negative cycles may be seen as a variant of one-player energy games with a reachability objective. The minimum energetic paths problem is also related to the 1-VASS problem. (See, e.g., Almagor et al. [1] and Künnemann et al. [26].)

Khuller et al. [23] consider a related problem in which the battery (or the fuel tank) can be recharged at intermediate vertices, with a possibly different price per unit of charge at each intermediate vertex. All arc costs are non-negative. They give various algorithms for computing a cheapest path from $s$ to $t$. Among these algorithms is a $O(n^2\Delta \log n)$-time algorithm for the single-target version, where $\Delta$ is a bound on the number of rechargings allowed, and an $O(n^3)$-time algorithm for the single-target version when the number of rechargings is unbounded.

Several authors, including Lehmann [27], Tarjan [33] and Mohri [30] considered generalized versions of the shortest paths problem defined by *semirings*. If $(R, \oplus, \otimes)$ is a semiring and $P$ is an $s$-$t$ path whose arcs have costs $c_i$, the cost of $P$ is defined to be $c(P) = \otimes_{i=1}^{k} c_i$. The goal is to find $\oplus_P c(P)$, where $P$ ranges over all $s$-$t$ paths, assuming this quantity is well defined. The standard shortest paths problem corresponds to the *tropical* semiring $(\mathbb{R}, \min, +)$. All these results assume, as part of the definition of a semiring, that $\otimes$ is associative. Thus, as we shall see, none of these results apply to our problem, as our operation $\otimes$ is not associative.

Generalized versions of Dijkstra's algorithm were obtained by various authors, most notably by Knuth [25]. These generalizations are of a different nature and are apparently not related to the version given here.

Other non-standard versions of the shortest paths problem were also considered. Perhaps the most famous one is the *bottleneck* shortest paths problem. See, e.g., [17, 9] for the single-pair version, and [36, 13] for the all-pairs version. Vassilevska [35] considered an interesting non-standard *non-decreasing* version of the shortest paths problem related to reading train schedules. Finally, Madani et al. [29] considered the *discounted* shortest paths problem. All these problems are quite different from the problem considered here.

## 2 Minimum energetic paths

To simplify the presentation, we concentrate on the computation of $\delta_B(s,t) = \delta_{B,B}(s,t)$, i.e., the energetic cost of traveling from $s$ to $t$ when starting with a fully charged battery of capacity $B$. Computing $\delta_{B,b}(s,t)$, for an arbitrary $0 \le b \le B$, can easily be reduced to computing $\delta_B(s,t)$: Add a new vertex $s'$ and an arc $s's$ of cost $c(s's) = B - b$. Then, it is easy to see that $\delta_{B,b}(s,t) = \delta_B(s',t) - (B-b)$. A similar idea can be incorporated directly into the algorithms that we describe. We begin by defining the energetic cost of a path.

▶ **Definition 2.1** (Energetic cost of a path). *A path $P = u_0u_1 \dots u_k$ is* traversable *if it can be traversed when starting from $u_0$ with a fully charged battery. If $P$ is traversable, the final charge in the battery when reaching $u_k$ is $B - d_B(P)$, where $d_B(P)$ is defined to be the* depletion*, or the* energetic cost *of the path. Note that $0 \le d_B(P) \le B$. If the path is not traversable, we let $d_B(P) = \infty$.*

To obtain a simple formula for $d_B(P)$ we define the following operations:

$$x \oplus_B y \;=\; [x+y]_0^B \quad , \quad [z]_0^B \;=\; \begin{cases} 0 & \text{if } z < 0 \\ z & \text{if } 0 \le z \le B \\ \infty & \text{otherwise} \end{cases}$$

We assume that $x+\infty = \infty+x = \infty$ for every $x \in [-B, B] \cup \{\infty\}$. For brevity, we sometimes write $x \oplus y$ instead of $x \oplus_B y$ when $B$ is understood from the context. [1] Note that for every $x, y \in \mathbb{R}$ and $B > 0$ we have $x+y \le x \oplus_B y$. It is important to note that $\oplus_B$ is *not* associative. (For example, $B \oplus (B \oplus -B) = B$ while $(B \oplus B) \oplus -B = \infty$, and $(-1 \oplus -2) \oplus 2 = 2$ while $-1 \oplus (-2 \oplus 2) = 0$, assuming $B \ge 2$.)

▶ **Lemma 2.2.** *Let $P = u_0 u_1 \dots u_k$ be a directed path, let $P' = u_0 \dots u_{k-1}$, and let $c_i = c(u_{i-1}u_i)$, for $i = 0, 1, \dots, k$. Let $B$ be the capacity and initial charge of battery at $u_0$. If $k = 0$ then $d_B(P) = 0$. If $k > 0$ then*

$$d_B(P) \;=\; d_B(P') \oplus c_k \;=\; ((\cdots((0 \oplus c_1) \oplus c_2) \oplus \cdots) \oplus c_{k-1}) \oplus c_k \;.$$

**Proof.** Let $b_i$ be the charge of the battery at $u_i$ and let $d_i = B - b_i$ be the depletion of the battery at $u_i$, for $i = 0, 1, \dots, k$. Clearly $d_0 = 0$. It is easy to prove by induction that $d_i = d_{i-1} \oplus_B c_i$. The lemma follows. ◀

As mentioned, the operation $\oplus_B$ is *not* associative. Thus, in general, $d_B(P) \ne 0 \oplus (c_1 \oplus (\cdots \oplus (c_{k-2} \oplus (c_{k-1} \oplus c_k)) \cdots))$. In Section 7 we show, however, that $c_1 \oplus (c_2 \oplus (\cdots \oplus (c_{k-1} \oplus (c_k \oplus 0)) \cdots))$ also has an interesting meaning.

▶ **Definition 2.3** (Energetic costs, minimum energetic paths)**.** *The* energetic cost $\delta_B(s,t)$ *of traveling from $s$ to $t$, starting from $s$ with a fully charged battery of capacity $B$, is defined as*

$$\delta_B(s,t) \;=\; \min\{\, d_B(P) \mid P \text{ is an } s\text{-}t \text{ path in } G \,\} \;.$$

*If $\delta_B(s,t) < \infty$ and $P$ is an $s$-$t$ path satisfying $\delta_B(s,t) = d_B(P)$, then $P$ is said to be a* minimum energetic path *from $s$ to $t$.*

If there are no negative cycles in the graph, then for every path $P$ from $s$ to $t$ there is a simple path $P'$ such that $d_B(P') \le d_B(P)$. (It is in fact enough to require that there are no traversable negative cycles in the graph.) Thus, the minimum in the definition above can be taken over simple paths only. The definition of $\delta_B(s,t)$ is also meaningful in the presence of negative cycles, though minimum energetic paths are not necessarily simple.

It is not difficult to see, and it will also follow from the correctness of the algorithms that we present in the next sections, that for every source vertex $s \in V$ there is always a tree of minimum energetic paths to all other vertices that can be reached from it. The simple example given in Figure 1 shows that a tree of minimum energetic paths to a given target vertex $t$ does not always exist.

To deal with negative cycles, we need the following definition.

▶ **Definition 2.4** (Entry-exit pairs)**.** *Let $C$ be a negative cycle in $G = (V, A, c)$ and let $B$ be the maximum capacity of the battery. A pair of vertices $(x, y)$ on $C$ is an* entry-exit *pair of $C$ if the car can start at $x$ with an empty battery and eventually reach $y$, possibly after going several times around the cycle, with a full battery, i.e., with a charge of $B$.*

The following lemma, similar to the *gasoline puzzle* of Lovász [28, p. 31] (see also Klarner [24, p. 283] and Winkler [37, p. 2]), says that every negative cycle has an entry-exit pair.

▶ **Lemma 2.5.** *Any negative cycle $C$ in $G = (V, A, c)$ contains at least one entry-exit pair. Such a pair can be found in $O(|C|)$ time.*

[1] Note that $\oplus$ is not related to the semiring framework mentioned in Section 1.2.

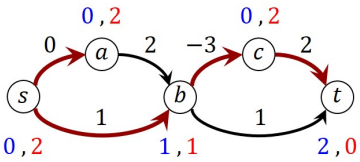

**Figure 1** A simple but illustrative example. Assume $B \geq 3$. The two numbers next to each vertex $u$ are $\delta_B(s,u)$ and $\delta_B(u,t)$. The bold arcs constitute a tree of minimum energetic paths from the source vertex $s$ to all other vertices. Another such tree can be obtained by replacing the arc $ct$ by $bt$. On the other hand, the only minimum path from $a$ to $t$ is $abct$, while the only minimum path from $b$ to $t$ is the arc $bt$. Thus, there is no tree of minimum paths to $t$ from all other vertices.

**Proof.** We show first that every negative cycle has an entry $x$, i.e., a vertex $x$ from which the cycle can be traversed, starting with an empty battery, when the capacity of the battery is ignored. We next show that the entry $x$ has a corresponding exit $y$ when the capacity of the battery is not ignored.

Let $C = v_0 v_1 \cdots v_{\ell-1} v_0$ be a negative cycle in $G$ of length $\ell$. Let $c_j = c(v_j v_{j+1})$, for $j = 0, 1, \ldots, \ell-1$. (We let $v_\ell = v_0$.) For $j \geq \ell$, let $c_j = c_{j \bmod \ell}$. Let $s_i = \sum_{j=0}^{i-1} c_j$ be the prefix sums of the costs around the cycle, starting from $v_0$. (We allow $i > \ell$ by wrapping around the cycle.) Note that $s_\ell = \sum_{j=0}^{\ell-1} c_j < 0$ as the cycle is negative. This also implies that $s_{\ell+i} < s_i$ for every $i$. Vertex $v_0$ is an entry if and only if $s_1, \ldots, s_{\ell-1} \leq 0$. If $v_0$ is not an entry, let $k$ be the index for which $s_k$ is maximized. Note that $0 \leq k < \ell$. We claim that $v_k$ is an entry. Let $s'_i = \sum_{j=0}^{i-1} c_{k+j}$ be the prefix sums starting from $v_k$. Then $s'_i = s_{k+i} - s_k \leq 0$, by the definition of $k$, for every $i$.

Assume, without loss of generality, that $v_0$ is an entry on $C$. Let $s_i = \sum_{j=0}^{i-1} c_j$ as above and let $i = \min\{j \mid s_j \leq -B\} (\mathrm{mod}\ \ell)$. Then $(v_0, v_i)$ is an entry-exit pair. It is not difficult to find $i$ in $O(\ell)$ time. ◀

The following lemma characterizes the structure of minimum energetic paths when the graph may contain negative cycles. It is not difficult to give a direct proof of the lemma. Its correctness also follows from the correctness of the algorithms that we present.

▶ **Lemma 2.6.** *If there is an $s$-$t$ path $P$ with $d_B(P) \leq B$, then there is an $s$-$t$ path $P'$ such that $d_B(P') \leq d_B(P)$ and such that $P'$ has the following form (see Figure 2): either $P'$ is simple, or there is a sequence $C_1, C_2, \ldots, C_k$ of simple negative cycles, where $k < n$, with entry-exit pairs $(x_1, y_1), (x_2, y_2), \ldots, (x_k, y_k)$ on them, such that $P'$ is composed of a simple path from $s$ to $x_1$, followed by sufficiently many traversals of $C_1$ that end in $y_1$ with a full battery, followed by a simple path from $y_1$ to $x_2$, followed by sufficiently many traversals of $C_2$ that end in $y_2$ with a full battery, and so on, and finally a simple path from $y_k$ to $t$. Furthermore, all entries $x_1, x_2, \ldots, x_k$ are distinct, and all exits $y_1, y_2, \ldots, y_k$ are distinct.*

## 3 An energetic version of the Bellman-Ford algorithm

Recall that for any $x$ and $y$, $x \oplus_B y \geq x + y$. This implies that in a graph without negative cycles, if there is a traversable path from $s$ to $t$, there is such a path that is simple and hence contains at most $n-1$ arcs. This means that if there are no negative cycles, we can solve the single-source minimum energetic paths problem using the Ford-Bellman [4, 15] shortest path algorithm: We merely replace $+$ by $\oplus_B$.

We base our description of the algorithm on that in [34], which uses a queue as suggested by Gilsinn and Witzgall [18].

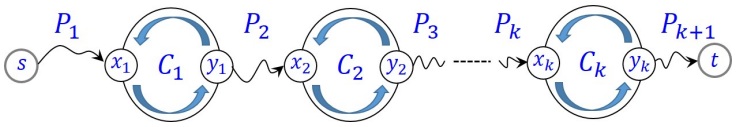

**Figure 2** Generic structure of minimum energetic paths in the presence of negative cycles. If $\delta_B(s,t) \leq B$, then there is a minimum energetic path from $s$ to $t$ of the form shown, where $C_1, \ldots, C_k$ are simple negative cycles and $(x_i, y_i)$ is an entry-exit pair on $C_i$, for $i = 1, 2, \ldots, k$. All entries $x_1, x_2, \ldots, x_k$ are distinct and all exits $y_1, y_2, \ldots, y_k$ are distinct. The paths $P_1, P_2, \ldots, P_{k+1}$ are simple but necessarily disjoint from the cycles $C_1, C_2, \ldots, C_k$.

The algorithm maintains a tentative energetic cost $d(v)$ for each vertex $v$, equal to the minimum of the energetic costs of paths from $s$ to $v$ found so far. Initially $d(s) = 0$ and $d(v) = \infty$ for $v \neq s$, where $s$ is the source. It also maintains a queue $Q$, initially containing $s$. The algorithm repeats the following step until $Q$ is empty:

> Scan a vertex: Delete the front vertex $u$ on $Q$. For each arc $uv$, if $\delta(u) \oplus_B c(uv) < \delta(v)$, *relax* $uv$: Set $\delta(v) \leftarrow \delta(u) \oplus_B c(uv)$, set $\pi(v) \leftarrow u$, and add $v$ to the back of $Q$ if it is not on $Q$.

Pseudocode of the algorithm, which we call *e-BF*, is given on the left of Figure 3. The correctness proof and analysis of the standard Bellman-Ford algorithm in the absence of negative cycles (see e.g., Tarjan [34]) translates directly to this version.

▶ **Theorem 3.1.** *If $G = (V, A, c)$ has no traversable negative cycles then e-BF finds minimum energetic paths from $s$ to all vertices in $O(mn)$ time.*

**Proof.** We define *passes* over the queue. Pass 0 is the first scan step of $s$. Given that pass $k$ is defined, pass $k+1$ is the sequence of scan steps of vertices added to $Q$ during pass $k$. A straightforward induction on $k$ shows that for each vertex $v$ that has a minimum-energy path of at most $k$ arcs, $d(v)$ is the energetic cost of such a path after $k$ passes. It follows that the energetic costs are correctly computed. The $\pi$ values computed describe a tree of minimum-energy paths from $s$ to all vertices reachable from $s$ using a fully charged battery of capacity $B$. Since each pass takes $O(m)$ time, the total time of the algorithm is $O(mn)$. ◀

In addition to the non-existence of negative cycles, the only thing required for correctness of the algorithm is that $\oplus_B$ is non-decreasing in its second argument: If $y \leq z$, $x \oplus y \leq x \oplus z$.

As in the standard version of the Bellman-Ford algorithm, one can add *subtree disassembly* [32, 10], which does not improve the worst-case time bound but is likely to speed up the algorithm in practice. It is also easy to modify the algorithm so that it finds a traversable negative cycle that can be reached from $s$, if one exists.

The correctness of *e-BF* implies the following corollary, which we use to prove the correctness of the energetic variant of Dijkstra's algorithm:

▶ **Corollary 3.2.** *If each $d(v) < \infty$ corresponds to the energetic cost of some path from $s$ to $v$, and $d(v) \leq d(u) \oplus_B c(uv)$ for every $uv \in A$, then $d(v) = \delta_B(s, v)$, for every $v \in V$.*

## 4 An energetic version of Dijkstra's algorithm

If all arc costs are non-negative, Dijkstra's algorithm [11] with $+$ replaced by $\oplus_B$ will solve the single-source problem. This algorithm replaces the queue $Q$ in the Bellman-Ford algorithm by a heap $H$. The key of a vertex $v$ in the heap is $d(v)$. Each scan step deletes a vertex of minimum key from the heap. When a relaxation decreases the key of a vertex in the heap,

```
e-BF(G = (V, A, c), B, s):
    for u ∈ V do
        d(u) ← ∞
        π(u) ← null
    d(s) ← 0
    Q ← Queue()
    Q.insert-last(s)
    while Q ≠ ∅ :
        u ← Q.DeleteFirst()
        for uv ∈ A do
            if d(v) > d(u) ⊕_B c(uv) :
                d(v) ← d(u) ⊕_B c(uv)
                π(v) ← u
                if v ∉ Q :
                    Q.InsertLast(v)
    return d
```

```
e-Dijkstra(G = (V, A, c), p, B, s):
    for u ∈ V do
        d(u) ← ∞
        π(u) ← null
    d(s) ← 0
    H ← min-heap()
    H.insert(s, −p(s))
    while H ≠ ∅ :
        v ← H.delete-min()
        for uv ∈ A do
            if d(v) > d(u) ⊕_B c(uv) :
                d(v) ← d(u) ⊕_B c(uv)
                π(v) ← u
                if v ∉ H :
                    H.insert(u, d(v)−p(v))
                else:
                    H.decrease-key(u, d(v)−p(v))
    return d
```

**Figure 3** Energetic variants of the Bellman-Ford and Dijkstra algorithms.

the algorithm does the appropriate *decrease-key* operation on the heap. If all arc costs are non-negative, the algorithm deletes each vertex from $H$ at most once, and when a vertex $v$ is deleted from $H$, $d(v)$ is the minimum energetic cost of a path from $s$ to $v$. The proof of correctness mimics that of the standard Dijsktra algorithm. The algorithm does at most $n$ heap insertions, at most $n$ heap deletions, and at most $m$ decrease-key operations. If the heap is a Fibonacci heap [16] or equally efficient data structure, e.g., [20], the total running time is $O(m + n \log n)$. In fact, the algorithm is identical to the standard algorithm with $d(v)$ values greater than $B$ replaced by $\infty$.

More interesting is that if arc costs can be negative, but there are no negative cycles, we can use a variant of the $A^*$ search algorithm, which is a modification of Dijkstra's algorithm, to solve the single-source minimum energetic paths problem in $O(m + n \log n)$ time, provided that we have a *valid potential function* $p : V \to \mathbb{R}$. A potential $p$ is *valid* if $c(uv) + p(u) - p(v) \geq 0$ for every arc $uv \in A$. It is well-known that a valid potential function exists if and only if the graph contains no negative cycles.

The $A^*$ search algorithm is almost identical to Dijkstra's algorithm. The only difference is that the *key* of vertex $v$ in the heap is $d(v) - p(v)$, and not just $d(v)$, where $p$ is a valid potential function. In the original setting of the $A^*$ search heuristic, $-p(v)$ is an estimate of the distance from $v$ to the destination $t$. The correctness of the algorithm only requires, however, that $p$ is a valid potential function. If $p$ is valid, the $A^*$ algorithm deletes each vertex $v$ from the heap at most once, and when $v$ is deleted, $d(v) = \delta_B(s, v)$, the energetic cost of traveling from $s$ to $v$.

An energetic version of the $A^*$ is obtained simply by replacing $+$ by $\oplus_B$ in relaxations. We assume the algorithm is given a potential $p$ that is valid for $+$, not $\oplus_B$. The algorithm begins with $d(s) = 0$ and $d(v) = \infty$ for each vertex $v \in V \setminus \{s\}$, and $H$ containing $s$. The key of a vertex $v$ in $H$ is $d(v) - p(v)$. The algorithm repeats the following step until $H$ is empty:

Scan a vertex: Delete from $H$ a vertex $u$ with minimum key $d(u) - p(u)$. For each arc $uv$, if $d(u) \oplus_B c(uv) < d(v)$, *relax* $uv$: Set $d(v) \leftarrow d(u) \oplus_B c(uv)$; $\pi(v) \leftarrow u$; add $v$ to $H$ with key $d(v) - p(v)$ if $v \notin H$, or decrease the key of $v$ to $d(v) - p(v)$ if $v \in H$.

Pseudocode of the resulting algorithm, which we call *e-Dijkstra*, is given on the right of Figure 3. The main step towards establishing the correctness of *e-Dijkstra* is the following:

▶ **Lemma 4.1.** *If $p$ is a valid potential then e-Dijkstra maintains the following invariant: if $u$ has been deleted from $H$ while $v$ has not been deleted from $H$ yet, then $d(u)-p(u) \le d(v)-p(v)$. As a consequence, each vertex $u$ is inserted and deleted from $H$ at most once.*

**Proof.** We prove the lemma by induction on the number of heap operations. The lemma is true initially, as no vertex was deleted from $H$ yet. Suppose it is true just before $u$ is deleted from $H$. Since $d(u) - p(u)$ is *minimum* among all $u \in H$, and since $d(v) = \infty$ for all vertices not yet inserted into $H$, the invariant holds just after $u$ is deleted from $H$. By the induction hypothesis, $d(u) - p(u)$ is now *maximum* over all $u'$ already deleted from $H$. Suppose the invariant holds just before the relaxation of an arc $uv$. Just after the relaxation, $d(v) = d(u) \oplus_B c(uv) \ge d(u) + c(uv)$. Hence

$$d(v) - p(v) \;\ge\; d(u) + c(uv) - p(v) \;\ge\; d(u) - p(u)\ ,$$

where the last inequality follows by the validity of $p$. Since the relaxation strictly decreased $d(v)$, it follows that $v$ could not have already been deleted from $H$, since it would violate the claim that $d(u) + p(u)$ is maximum over all vertices already deleted from $H$. Thus, $v$ is either in $H$ or was not inserted into $H$ yet. Decreasing the key of $v$ to $d(v) - p(v)$, or inserting $v$ into $H$ with this key, does not violate the invariant. ◀

The proof of Lemma 4.1 is the same as the proof of the corresponding lemma for the standard version of $A^*$ except for the use of the inequality $x \oplus_B y \ge x + y$. Using Lemma 4.1 we can easily prove the correctness of the algorithm.

▶ **Theorem 4.2.** *If $G = (V, A, c)$ has no negative cycles and $p$ is a valid potential for $G$, then e-Dijkstra finds minimum energetic paths from $s$ to all vertices in $O(m + n \log n)$ time.*

**Proof.** When a vertex $u$ is removed from $H$, all outgoing arcs $uv$ are scanned and all appropriate relax operations are performed. By Lemma 4.1, $d(u)$ will not be changed again. Thus, when the algorithm terminates $d(v) \le d(u) \oplus_B c(uv)$ for every arc $uv \in A$. By Corollary 3.2, we have $d(v) = \delta_B(s, v)$, for every $v \in V$. As in the proof of Theorem 3.1 we get that the $\pi$ values describe a tree of minimum energetic paths from $s$ to all vertices that can be reached from $s$.

The algorithm performs at most $n$ heap insertions, at most $n$ heap deletions, and at most $m$ decrease-key operations. With an efficient heap implementation the total running time is $O(m + n \log n)$. ◀

To obtain a valid potential function we can use any standard shortest path algorithm: If $s$ is an arbitrary source from which all vertices are reachable, there are no negative cycles, and $p(v) = \delta(s, v)$, where $\delta(s, v)$ is the standard distance from $s$ to $v$, then $c(uv) + p(u) - p(v) \ge 0$, for every arc $uv$, by the triangle inequality. (If there is no such vertex $s$ in the graph, add a new vertex $s$ and connect it with zero-cost arcs to all other vertices.)

Thus we can compute minimum energetic paths from $k$ sources in $O(m + n \log n)$ time per source plus the time to solve one standard single-source shortest path problem with the given arc costs. The extra time needed for this preprocessing is $O(mn)$ if we use Bellman-Ford,

or $O(m \log^2 n \log(nW) \log\log n)$ if all arc costs are integral and we use the algorithm of Bringmann et al. [8]. (The faster algorithm is helpful only if $k = \Omega(\log^2 n \log(nW) \log\log n)$, where $k$ is the number of sources.)

▶ **Corollary 4.3.** *The all-pairs minimum energetic paths problem on a graph $G = (V, A, c)$ with no negative cycles can be solved in $O(mn + n^2 \log n)$ time.*

The resulting all-pairs algorithm is very similar to Johnson's [22] algorithm for the standard all-pairs shortest paths problem.

## 5 Finding minimum paths in the presence of negative cycles

In this section we describe an algorithm *e-Negative*$(G, B, s)$ that finds minimum energetic costs from a source vertex $s \in V$ to all other vertices in a directed graph $G = (V, A, c)$ that may contain negative cycles. It is not difficult to extend the algorithm to return a succinct description of the minimum energetic paths. We assume that $s$ has no incoming arcs. (Incoming arcs of $s$ are not useful as we start from $s$ with a full battery.)

Algorithm *e-Negative* maintains a set $R$ of reachable vertices that were already processed, a set of reachable vertices $Q$ that are waiting to be processed, and a set $Y \subseteq R$ of exits. Initially $R = \emptyset$, $Q = \{s\}$ and $Y = \emptyset$. Let $G_{R,Y}$ be the graph obtained from $G$ by removing the outgoing arcs of vertices not in $R$, removing the incoming arcs of vertices in $Y$, and for every $y \in Y$, adding a 0-cost arc $sy$. (Note that vertices in $V \setminus R$ may have incoming arcs in $G_{R,Y}$, but no outgoing arcs.) We may assume that the vertex set of $G_{R,Y}$ is $V_{R,Y} = R \cup N(R)$, where $N(R)$ are the out-neighbors of the vertices of $R$. We also have $Q \subseteq N(R)$.) The algorithm maintains the invariant that $G_{R,Y}$ has no negative cycles and $p : V_{R,Y} \to \mathbb{R}$ is a valid potential function for it, and that all vertices in $R \cup Q$ can be reached when starting from $s$ with a full battery.

The algorithm is composed of rounds. In each round the algorithm removes a vertex $u \in Q$ and processes it, i.e., adds it to the set $R$. If $G_{R\cup\{u\},Y}$ does not contain negative cycles, all we need to do is find a valid potential function for $G_{R\cup\{u\},Y}$ and update the set $Q$ of vertices reachable in $G_{R\cup\{u\},Y}$ when starting from $s$ with a full battery.

To check whether $G_{R\cup\{u\},Y}$ contains a negative cycle we construct a graph $\bar{G} = \bar{G}_{R,Y,u}$ as follows. The graph is obtained by starting from $G_{R,Y}$, adding a new source vertex $\bar{u}$, and for every $uv \in A$, adding an arc $\bar{u}v$ with $c(\bar{u}v) = c(uv)$. We also remove $s$ and its outgoing arcs. (Note that $u \notin R$ has no outgoing arcs in $\bar{G}$.) The new graph $\bar{G}$ does not contain negative cycles. The function $p$ is a valid potential function for $\bar{G}$ if we let $p(\bar{u}) = \max_{uv\in A}(p(v) - c(uv))$.[2] All negative cycles in $G_{R\cup\{u\},Y}$ must pass through $u$. Thus, $G_{R\cup\{u\},Y}$ contains a negative cycle if and only if $\delta_{\bar{G}}(\bar{u}, u) < 0$.

We thus run Dijkstra on $\bar{G}$ staring from the source $\bar{u}$ using the potential function $p$. If $\delta_{\bar{G}}(\bar{u}, u) < 0$ then a shortest path from $\bar{u}$ to $u$ becomes a negative cycle $C$ in $G_{R\cup\{u\},Y}$ when we replace $\bar{u}$ with $u$. (Any path of negative cost from $\bar{u}$ to $u$ will do. We can thus stop the algorithm as soon as such a path is discovered.) In $O(|C|)$ time we find an exit $y$ on $C$ and add it to $Y$. This removes the incoming arcs of $y$ from $G_{R\cup\{u\},Y}$ and adds a 0-cost arc $sy$. We update the graph $\bar{G}$ accordingly, i.e., remove the incoming arcs of $y$, and run Dijkstra again. (Note that $p$ is still a valid potential function for $\bar{G}$, since $s$ is not included in it.)

[2] This works as $\bar{u}$ has no incoming arcs. Equivalently we can use the fact that Dijkstra's algorithm works correctly even if the reduced costs of some of the outgoing arcs of the source are negative, which follows as $p(\bar{u})$ does not really affect the running of the algorithm. (It only affects the key of $\bar{u}$ when it is alone in the heap.

When no more negative cycles are found, the graph $G_{R\cup\{u\},Y'}$, where $Y'$ is the new set of exits, does not contain negative cycles. We still need to find a valid potential function for it. To do this it is enough to find distances from $s$ to all other vertices. Let $\delta(s,v)$ be the distance from $s$ to $v$ in $G_{R\cup\{u\},Y'}$. Let $\delta'(s,v)$ be the distance from $s$ to $v$ in $G_{R,Y'}$. Finally, let $\delta''(\bar{u},v)$ be the distance from $\bar{u}$ to $v$ in $\bar{G}_{R,Y',u}$. Clearly, $\delta(s,v) = \min\{\delta'(s,v), \delta'(s,u) + \delta''(\bar{u},v)\}$, since each shortest path in $G_{R\cup\{u\},Y'}$ either does not pass through $u$, in which case its length is $\delta'(s,v)$, or it does pass through $u$ in which case its length is $\delta'(s,u) + \delta''(\bar{u},v)$.

To find the distances $\delta'(s,v)$ we simply run Dijkstra on $G_{R,Y'}$ using the potential function $p$, after we set $p(s) = \max_{sv\in A}(p(v) - c(sv))$. The distances $\delta''(\bar{u},v)$ were already computed. Thus we can easily compute the distances $\delta(s,v)$ in $G_{R\cup\{u\},Y'}$ and then set $p(v) = \delta(s,v)$, for every $v \in V_{R\cup\{u\},Y'}$.

Given the newly computed potential function $p$, we can now run *e-Dijkstra* on $G_{R\cup\{u\},Y'}$ to compute energetic costs and the new set of vertices $Q'$ that are reachable from $s$ but are not in $R\cup\{u\}$. The algorithm then lets $R \leftarrow R\cup\{u\}$, $Y \leftarrow Y'$ and $Q \leftarrow Q'$. This completes the round. If $Q = \emptyset$ the algorithm terminates. Otherwise it proceeds to the next round, processing the next vertex from $Q$.

We claim that the energetic costs computed by the last *e-Dijkstra*, which are also the values returned by *e-Negative*, are exactly the energetic costs $\delta_B(s,v)$ in the input graph $G = (V,A,c)$. (If $v \notin R$, then $\delta_B(s,v) = \infty$.)

▶ **Theorem 5.1.** *Algorithm e-Negative$(G,B,s)$ finds minimum energetic costs in a graph $G = (V,A,c)$ that may contain negative cycles when the capacity of the battery is $B$. Its running time is $O(mn + n^2 \log n)$.*

**Proof.** The correctness of the algorithm follows from the explanations above combined with a few simple observations. It follows by induction that at the beginning of each round $G_{R,Y}$ contains no negative cycles, $p$ is a valid potential function for it, and all vertices in $R\cup Q$ can be reached when starting from $s$ with a full battery.

In each round, the algorithm moves a vertex $u$ from $Q$ to $R$. To do this, it repeatedly finds negative cycles in the graph $G_{R\cup\{u\},Y}$. All such negative cycles must pass through $u$. As explained, there is such a negative cycle in $G_{R\cup\{u\},Y}$ if and only if $\delta_{\bar{G}}(\bar{u},u) < 0$, where $\bar{G} = \bar{G}_{R,Y,u}$. A negative path from $\bar{u}$ to $u$ corresponds to a negative cycle $C$, since $\bar{u}$ and $u$ represent the same vertex. If a negative cycle $C$ is found, an exit $y$ on $C$ is identified and added to $Y$. (Note that this removes arcs from $\bar{G}$ since the incoming arcs of $y$ are removed.) The arc $sy$ is added to $G_{R\cup\{u\},Y\cup\{y\}}$ but not to $\bar{G} = \bar{G}_{R,Y\cup\{y\},u}$.

We next argue that $\delta_B(s,y) = 0$, for every $y \in Y$. Indeed, each vertex $y$ added to $Y$ is an exit on a negative cycle $C$ all whose vertices can be reached when starting from $s$ with a full battery. In particular, the entry $x$ on $C$ corresponding to $y$ can be reached, and by the definition of entry-exit pairs, $y$ can be reached with full battery, i.e., $\delta_B(s,y) = 0$. This also justifies the addition of the 0-cost arc $sy$.

Let $\delta'_B(s,v)$ be the energetic costs computed by the last call to *e-Dijkstra* on the final $G_{R,Y}$. We assume that $\delta'(s,v) = \infty$ for every $v \notin R$. Let $\delta_B(s,v)$ be the energetic costs in the input graph $G$. It is easy to see that $\delta_B(s,v) \le \delta'(s,v)$, for every $v \in V$. This follows as $G_{R,Y}$, without the arcs $\{sy \mid y \in Y\}$, is a subgraph of $G$, and the addition of the arcs $\{sy \mid y \in Y\}$, as argued, does not change the energetic costs.

We next show that when the algorithm terminates we have $\delta_B(s,v) = \delta'_B(s,v)$, for every $v \in V$. Suppose, for the sake of contradiction, that there is a vertex $v$ for which $\delta_B(s,v) < \delta'_B(s,v)$. Let $P$ be a minimum energetic path from $s$ to $v$ in $G$. If $P$ passes through a vertex of $Y$, let $y$ be the last vertex from $Y$ on $P$ and let $P'$ be path composed

of the arc $sy$ followed by the portion of $P$ from the last occurrence of $y$ on $P$ to $v$. Since $\delta_B(s,v) < \delta'_B(s,v)$, it follows that $P'$ is not a path in $G_{R,Y}$. Thus, $P'$ must contain a vertex not in $R$. Let $u$ be the first vertex not in $R$ on $P'$. It follows that $\delta'_B(s,u) < \infty$, since the portion of $P'$ from $s$ to $u$ is also a path in $G_{R,Y}$. Since $u \notin R$, we must have $u \in Q$ and the algorithm should not have terminated.

The algorithm performs at most $2n$ calls to Dijkstra, since following each such call either an exit is added to $Y$ or a vertex is added to $R$. The algorithm performs at most $n$ calls to *e-Dijkstra*. Thus, the running time of the algorithm is $O(mn + n^2 \log n)$. ◀

# 6 A faster all-pairs algorithm for large batteries

In this section we obtain an $O(mn + n^2 \log n)$-time algorithm for the all-pairs energetic cost problem, in graphs that may contain negative cycles, when the capacity of the battery $B$ is sufficiently large relative to the arc costs in the graph. The initial charge $b$ may be arbitrary. More specifically, we assume that $B \geq 3nM$, where $M = \max_{uv \in A} |c(uv)|$.

Recall that $\delta_{B,b}(s,t)$ is the energetic cost of getting from $s$ to $t$, starting from $s$ with a charge $b$, where $0 \leq b \leq B$, when the capacity of the battery is $B$. The energetic cost is the difference between the initial charge, in this case $b$, and the final charge. Recall that $\delta_{B,b}(s,t) \in [b - B, b]$. (In particular, when $b < B$, the energetic cost may be negative.)

We started Section 2 with a simple reduction from the computation of $\delta_{B,b}(s,t)$ to that of $\delta_B(s,t) = \delta_{B,B}(s,t)$. The reduction introduces an arc of cost $B - b$, which may be much larger than $M$, so we cannot use it when the battery capacity is large. To make our results more general we work directly with $\delta_{B,b}(s,t)$.

The improved algorithm is obtained by using a preprocessing step, described in Section 6.1, that finds sets of entries or exits that *hit* all negative cycles. When the battery is large, such sets can be used to efficiently solve the single-source problem, from any source, in $O(m + n \log n)$ time.

We first describe, in Section 6.2, an efficient algorithm when $b \geq nM$. We then use this algorithm in Section 6.3 to obtain an efficient algorithm when $B \geq 3nM$ and $b$ is arbitrary.

## 6.1 Finding sets of entries or exits that hit all negative cycles

A vertex $x$ is an entry if it is an entry on some negative cycle. Similarly, a vertex $y$ is an exit if it is an exit on some negative cycle.

A set of vertices $Z \subset V$ is said to hit all negative cycles in a graph $G$ if there are no negative cycles in the graph $G \setminus Z$, or equivalently in the graphs $G \setminus in(Z)$ or $G \setminus out(Z)$, where $G \setminus Z$ is the graph obtained by removing all the vertices of $Z$ from $G$ and $G \setminus in(Z)$ and $G \setminus out(Z)$ are the graphs obtained just by removing the incoming or outgoing arcs, respectively, of the vertices in $Z$.

We are interested in hitting all negative cycles with either a set of entries, or a set of exits. We show that this can be done efficiently.

▶ **Lemma 6.1.** *A set $Y \subseteq V$ of exits that hit all negative cycles in $G$, and a valid potential function $p$ for $G \setminus in(Y)$, can be found in $O(mn + n^2 \log n)$ time.*

**Proof.** Add to $G$ an auxiliary source vertex $\bar{s}$ and connect it with 0-cost arcs to all other vertices of $G$. Running *e-Negative* of Section 5 on the resulting graph will construct a set $Y$ of exits that hit all negative cycles in $G$ and a valid potential function $p$. ◀

By a slight adaptation of the algorithm, i.e., finding an entry on each negative cycle found and removing its outgoing arcs, we can also get:

▶ **Lemma 6.2.** *A set $X \subseteq V$ of entries that hit all negative cycles in $G$, and a valid potential function $p$ for $G \setminus out(X)$, can be found in $O(mn + n^2 \log n)$ time.*

## 6.2 An algorithm for large initial charges

We assume that $nM \leq b \leq B$, i.e., the initial charge is sufficient to traverse any path of at most $n$ arcs. Let $u \rightsquigarrow v$ denote that there is a directed path from $u$ to $v$ in the graph.

Suppose that $C$ is a negative cycle in $G$ and that $(x, y)$ is an entry-exit pair on it. Suppose that $s$ is the current source. Since $x$ and $y$ are on a cycle we clearly have $s \rightsquigarrow x$ if and only if $s \rightsquigarrow y$. Furthermore, if $s \rightsquigarrow y$ then there is also a simple path from $s$ to $x$, i.e., a path that uses at most $n - 1$ arcs. Since we start from $s$ with a sufficiently large initial charge, we can reach $x$ and eventually, by the definition of entry-exit pairs, reach $y$ with a fully charged battery. This justifies the following algorithm.

Find a set $Y$ of exits that hit all negative cycles and find a valid potential function $p$ for $G \setminus in(Y)$. For any given source $s$, find the set $Y_s \subseteq Y$ of exits reachable from $s$. (This can be easily done in linear time.) Next, construct a graph $G_s$ obtained from $G \setminus in(Y)$ by adding arcs of cost $b - B$ from $s$ to every $y \in Y_s$. (These arcs ensure that we reach $y$ with a fully charged battery without needing to use the incoming arcs of $y$.) Run *e-Dijkstra* on $G_s$ using $p$, after suitably adjusting the potential of $s$. (We need a slight modification of *e-Dijkstra* that works when starting from $s$ with an initial charge $b$. Alternatively, we can add an auxiliary source $\bar{s}$, add an arc $\bar{s}s$ of cost $B - b$, and run *e-Dijkstra* from $\bar{s}$.) This takes only $O(m + n \log n)$ time per vertex, giving an $O(mn + n^2 \log n)$-time algorithm for the all-pairs problem.

## 6.3 An algorithm for large batteries

We now describe an algorithm for $3nM \leq B$, and any value of $b$. If $nM \leq b$, we can use the algorithm of the previous section. We can thus assume that $b \leq nM$ and thus $B - b \geq 2nM$, i.e., the battery is initially far from being fully charged.

Start by using the algorithm from Section 6.1 to find a set $X$ of entries that hit all negative cycles of $G$.

Let $P$ be a minimum energetic path from $s$ to $t$. We may assume that all cycles on $P$, if any, are negative, since otherwise they can be removed without increasing the energetic cost. If $P$ does not pass through any vertex of $X$, then it is also a path in $G \setminus out(X)$. Otherwise, let $x \in X$ be the first entry appearing on $P$. Suppose that $x$ is an entry of a negative cycle $C$ and that $y$ is a corresponding exit on $C$. In general, the path $P$ may not pass through $y$. This is one of the main difficulties that algorithm *e-Negative* had to deal with. However, when $B - b \geq 2nM$, we show that there must exist a minimum energetic path $P'$ from $s$ to $t$ that passes through both $x$ and $y$. We can further assume that during the last visit of $y$, the battery is fully charged.

The path $P$ must reach the first entry $x \in X$ after traversing at most $n - 1$ arcs. If $P$ is simple, this is obviously true. Otherwise, a cycle $C'$ must be formed after traversing at most $n$ arcs. By definition, there is an entry $x \in C' \cap X$. (Note that $x$ is not necessarily an entry of $C'$, but it is an entry of some negative cycle $C$ with a corresponding exit $y$.)

If $b_x$ is the charge in the battery when reaching the first entry $x$ on $P$, then $B - b_x \geq nM$. (The additional charge gained by traversing the portion of $P$ from $s$ to $x$ is at most $nM$.) Since $x$ is an entry of $C$, we can traverse $C$ and get back to $x$, passing $y$ along the way, with a charge that is at least $b_x$. (Note that it is important here that the battery is not close to being fully charged when starting from $x$, otherwise the claim is not necessarily true.) This gives us the path $P'$.

This suggests the following algorithm. Start, as mentioned, by finding a set $X$ of entries that hit all negative cycles and a potential function $p$ for $G \setminus out(X)$.

For each vertex $s \in V$, run *e-Dijkstra* on $G \setminus out(X)$ starting from $s$ using the potential function $p$. This finds minimum energetic paths from $s$ that do not pass through $X$. It also finds the set $X_s$ of entries that can be reached when staring from $s$ with an initial charge of $b$. Let $Y_s$ be the set of exits that correspond to the entries in $X_s$. Construct a new graph $G_s$ as follows. Remove from $G$ all the outgoing arcs of $s$. For each $y \in Y_s$ add a 0-arc from $s$ to $y$. Now run the algorithm of Section 6.2, staring from $s$ with a fully charged battery. (Assuming that a set $Y$ of exits that hit all negative cycles of $G$ was already precomputed.) Subtract $B - b$ from the results obtained, to adjust for the fact that the initial charge is actually $b$ and not $B$, and take the minimum with the results returned by *e-Dijkstra* call.

The computation of the hitting sets $X$ and $Y$ takes $O(mn + n^2 \log n)$. For every source we need only $O(m + n \log n)$ time. The total time of the algorithm is thus $O(mn + n^2 \log n)$.

## 7 Minimum initial charges and maximum final charges

To end the paper, we consider two problems that are closely related to the minimum energetic paths problem. Let $G = (V, A, c)$ be a graph with no (traversable) negative cycles and let $B$ be the capacity of the battery. For two vertices $s, t \in V$, we let $\alpha_B(s, t)$ be the *maximum final charge* with which it is possible to reach $t$ when starting at $s$ with a full battery, or $-\infty$, if it is not possible to travel from $s$ to $t$. We also let $\beta_B(s, t)$ be the *minimum initial charge* required at $s$ for getting to $t$, or $\infty$, if no initial charge (of at most $B$) is sufficient.

The maximum final charge problem is not really a new problem as $\alpha_B(s, t) = B - \delta_B(s, t)$. As noted in the introduction, $\beta_B(s, t)$ is the smallest $b$ such that $\delta_{B,b}(s, t) \leq b$, or equivalently $\delta_{B,b}(s, t) < \infty$, if there is such a $b$. Thus, if $B$ and all arc costs are integral, then we can find $\beta_B(s, t)$, for a specific pair $s$ and $t$, by a binary search.

There is, however, a more interesting relation between the minimum initial-charge problem and the minimum energetic cost problem. Namely, $\beta_B(s, t)$ is equal to $\delta_B^{\overleftarrow{G}}(t, s)$ the energetic cost of traveling from $t$ to $s$ in the *reversed graph* $\overleftarrow{G}$, the graph obtained by reversing all the arcs in the graph $G$ and retaining all arc costs. This relation follows easily from the following lemma, analogous to Lemma 2.2, whose simple proof is omitted. For a path $P$ from $s$ to $t$, let $b_B(P)$ be the minimum initial charge at $s$ with which the path $P$ can be traversed.

▶ **Lemma 7.1.** *Let $P = u_0 u_1 \dots u_k$ be a directed path, let $P' = u_1 \dots u_k$, and let $c_i = c(u_{i-1}u_i)$, for $i = 1, \dots, k$. Let $B$ be the capacity of the battery. If $k = 0$ then $b_B(P) = 0$. If $k > 0$ then*

$$b_B(P) \;=\; c_1 \oplus_B b_B(P') \;=\; c_1 \oplus (c_2 \oplus (\cdots \oplus (c_{k-1} \oplus (c_k \oplus 0)) \cdots)) \,.$$

▶ **Corollary 7.2.** *For every $s, t \in V$, $\beta_B(s, t) = \delta_B^{\overleftarrow{G}}(t, s)$.*

As immediate corollaries, it follows that we can solve the single-target version of the minimum initial-charge paths problem in $O(m+n \log n)$ time, if we are given a valid potential, and the all-pairs version of the problem in $O(mn + n^2 \log n)$.

## 8 Concluding remarks and open problems

We have presented a clear definition of the minimum energetic paths problem, which is a strict extension of the standard shortest paths problem, and explained its relation to two other related problems: minimum initial-charge paths and maximum final-charge paths. We have also presented efficient algorithms for the minimum energetic paths problem in three different settings.

When there are no negative cycles in the graph, the minimum energetic paths problem can be solved using relatively simple adaptations of the classical Bellman-Ford and Dijkstra algorithms. We present simple descriptions and simple correctness proofs of these algorithms. In particular, we have obtained an $O(mn)$-time algorithm for the single-source version, when arc costs may be negative but there are no negative cycles, and an $O(mn + n^2 \log n)$-time algorithm for the all-pairs version.

An interesting feature of the minimum energetic paths problem is that it is well defined even if the graph contains negative cycles. Furthermore, minimum energetic costs are always obtained by finite length, though not necessarily simple, minimum energetic paths. (This is not the case for the standard shortest paths problem.) Using new algorithmic techniques, we have obtained an $O(mn + n^2 \log n)$-time algorithm for the single-source version of the problem. Our best algorithm for the all-pairs version runs the single-source algorithm from each vertex, yielding a running time of $O(mn^2 + n^3 \log n)$.

We have obtained a more efficient algorithm for the all-pairs version when the capacity of battery is sufficiently large, i.e., $B \geq 3nM$, where $M = \max_{uv \in A} |c(uv)|$ is the maximum absolute value of an arc cost. The running time of the improved algorithm is $O(mn+n^2 \log n)$.

The obvious open problems are whether any of our time bounds can be improved. In particular, is it possible to get an $O(mn)$-time algorithm for the single-source version when the graph may contain negative cycles? Is there an $O(n^3)$-time algorithm for the all-pairs version when the graph may contain negative cycles?

Another interesting problem is whether the new techniques of Bernstein et al. [5] and Bringmann et al. [8], or the older technique of Goldberg [19] can be used to obtain an improved algorithm for the single-source version of the minimum energetic paths problem, when negative cycles may be present in the graph.

Finally, as mentioned, the single-target version of the minimum energetic paths problem is not equivalent to the single-source version. Currently, our fastest algorithms for the single-target version actually solve the all-pairs version. Is there a faster solution? The fact that there may not be a tree of minimum energetic paths to a given target may indicate that the single-target version is harder than the single-source version.

## Abstract

It is known that first-order logic with some counting extensions can be efficiently evaluated on graph classes with bounded expansion, where depth-$r$ minors have constant density. More precisely, the formulas are $\exists x_1 \dots x_k \# y\, \varphi(x_1, \dots, x_k, y) > N$, where $\varphi$ is an FO-formula. If $\varphi$ is quantifier-free, we can extend this result to *nowhere dense* graph classes with an almost linear FPT run time. Lifting this result further to slightly more general graph classes, namely almost nowhere dense classes, where the size of depth-$r$ clique minors is subpolynomial, is impossible unless FPT = W[1]. On the other hand, in almost nowhere dense classes we can approximate such counting formulas with a small additive error. Note those counting formulas are contained in $\mathrm{FOC}(\{>\})$ but not $\mathrm{FOC}_1(\mathbf{P})$.

In particular, it follows that partial covering problems, such as partial dominating set, have fixed parameter algorithms on nowhere dense graph classes with almost linear running time.

## 1 Introduction

First-order logic can be used to express algorithmic problems. FO-model checking on certain classes of structures is therefore a meta-algorithm, which solves many problems at the same time. For example, the three classical problems that started the research on parameterized complexity are all FO-expressible: Vertex Cover, Independent Set, and Dominating Set [6, 7]. Dominating Set with the natural parameter – the size of the minimal dominating set – is W[2]-complete on general graphs, but fixed parameter tractable (fpt) on many special graph classes. The study of *sparsity*, initiated by Nešetřil and Ossona de Mendez, has led to the concept of *bounded expansion* and *nowhere dense* graph classes [21]. They generalize many well-known notions of sparsity, such as bounded degree, planarity, bounded genus, bounded treewidth, (topological) minor-closed, etc. and have led to quite general algorithmic results [23, 11, 4, 10]. Most notably, Grohe, Kreutzer, and Siebertz showed that FO-model checking is fpt on nowhere dense graph classes [15]. This shows, e.g., that dominating set is fpt on nowhere dense graphs, a result that was already known: Dawar and Kreutzer were able to find a specific algorithm several years earlier [5] that solves generalizations of the dominating set problem. All of them are FO-expressible, which shows how strong meta-algorithms are.

Partial dominating set, also called $t$-dominating set, is another generalization of dominating set: The input is a graph $G$ and two numbers $k$ and $t$. The question is, whether $G$ contains $k$ vertices that dominate at least $t$ vertices. The parameter is $k$, as in the classical dominating set problem. (If you choose $t$ as the parameter – which also makes sense – the problem becomes fixed-parameter tractable even on general graphs [18].) The length of an FO-formula expressing the existence of a partial dominating depends on $t$, which is not bounded by any function of $k$ and therefore all the results on first-order model checking do not help when we parameterize by $k$ only. Golovach and Villanger showed that partial dominating set remains hard on degenerate graphs [13], while Amini, Fomin, and Saurabh have shown that partial dominating set is fixed-parameter tractable in minor-closed graph classes, which generalized earlier positive results [1]. Very recently, this was improved to graph classes with bounded-expansion, while simultaneously using only linear fpt time instead of polynomial fpt time, i.e, the running time is now only $f(k)n$ [8].

This result was achieved by another meta-theorem for the counting logic FOC($\{>\}$) on classes of bounded expansion. FOC($\{>\}$) is a fragment of the logic FOC($\mathbf{P}$), introduced by Kuske and Schweikardt in order to generalize first-order logic to counting problems [20]. FOC($\mathbf{P}$) is a very expressive counting logic and allows counting quantifiers $\#\bar{y}\varphi(\bar{x},\bar{y})$, which count for how many $\bar{y}$ the FOC($\mathbf{P}$)-formula $\varphi(\bar{x},\bar{y})$ is true. Moreover, arithmetic operations are allowed as well as all predicates in $\mathbf{P}$, which might contain comparisons, equivalence modula a number, etc. Kuske and Schweikardt showed that the FOC($\mathbf{P}$)-model checking problem is fixed parameter tracktable on graphs of bounded degree and hard on trees of bounded depth. The fragment FOC($\{>\}$) is more restrictive and allows only counting quantifiers of single variables and no arithmetic operations. The only predicate is comparison against an arbitrary number, but not between counting terms. While FOC($\{>\}$)-model checking is still hard on trees of bounded depth, there is an "approximation scheme" for FOC($\{>\}$) on classes of bounded expansion [8]: An algorithm gives either the right answer or says "mayby," but only if the formula is both almost satisfied and not satisfied. For a fragment of FOC($\{>\}$), which captures in particular the partial dominating set problem, we can compute even an exact answer to the model checking problem in linear fpt time [8]. That fragment consists of formulas of the form

$$\exists x_1 \dots \exists x_k \# y\, \varphi(y, x_1, \dots, x_k) > N, \tag{1}$$

where $\varphi$ is a first-order formula and $N$ an arbitrary number. The semantics of the *counting quantifier* $\#y\,\varphi(y, v_1, \dots, v_k)$ is the number of vertices $u$ in $G$ such that $G$ satisfies $\varphi(u, v_1, \dots, v_k)$. As an example, the existence of partial dominating set can be expressed as

$$\exists x_1 \dots \exists x_k \# y \bigvee_{i=1}^{k} E(y, x_i) \vee y = x_i > t, \tag{2}$$

where $k$ is the number of the dominating, and $t$ the number of dominated vertices. The length of the formula only depends on $k$. This implies that partial dominating set can be solved in linear fpt time on classes of bounded expansion.

There is another fragment of FOC($\mathbf{P}$), which should not be confused with FOC($\{>\}$). In FOC$_1$($\mathbf{P}$), introduced by Grohe and Schweikardt [16], the counting terms may contain at most one free variable. They show that FOC$_1$($\mathbf{P}$) is fixed-parameter tractable on nowhere dense graph classes [16]. Note that formula 2 is in FOC($\{>\}$) but not in FOC$_1$($\mathbf{P}$) as the counting term relies on $k$ free variables. Hence, FOC($\{>\}$) and FOC$_1$($\mathbf{P}$) are orthogonal in there expressiveness.

**Table 1** Results of this paper (in boldface) and some related known results. *Hard* means at least W[1]-hard. *PDS like* indicates problems similar to the partial dominating set problems: All problems that can be expressed by a FOC({>}) formula of the form (1). The mentioned approximation results are quite different. Numbers are approximated either with a relative or an absolute error.

[a] Corollary 22, [b] Corollary 2, [c] Theorem 1

There has been some research about *low degree graphs*. A graph class has low degree if every (sufficiently large) graph has degree at most $n^\varepsilon$ for every $\varepsilon > 0$. Examples are classes with bounded degree or classes with degree bounded by a polylogarithmic function. These graph classes are incomparable to nowhere dense classes. Especially, classes of low degree are not closed under subgraphs. On those classes, Grohe has shown that first-order model-checking can be solved in almost linear time [14]. Recently, Durand, Schweikardt, and Segoufin have generalized the result to query counting with constant delay and almost linear preprocessing time [9]. Vigny explores dynamic query evaluation on graph classes with low degree [24].

*Almost nowhere dense* is a property which subsumes both low degree and nowhere dense classes. Whereas a nowhere dense class $\mathcal{C}$ can be characterized that for every $r$ graphs do not contain up to $r$ times subdivided cliques of arbitrary sizes, for an almost nowhere dense class arbitrary sizes are allowed, but their growth must be bounded by subpolynomial function in the size of the graph.

Due to space limitations in this extended abstract many proofs, definitions, results, and comments can be found only in the appendix, which contains a full version of this paper. Of course, all main results are presented in this short version as well.

## 1.1 Our Results

In this work, we consider a fragment of FOC({>}), which we will call *PDS-like formulas*, namely formulas of the form

$$\exists x_1 \dots \exists x_k \# y \, \varphi(y, x_1, \dots, x_k) > N$$

for a quantifier-free FO-formula $\varphi$ and an (arbitrarily big) number $N \in \mathbf{Z}$. This logic is strong enough to express the partial dominating set problem as formula (2) is contained in the fragment described above. Remember that this fragment and $\mathrm{FOC}_1(\mathbf{P})$ are orthogonal. Table 1 contains an overview of most of the results in this paper.

In formulas that start with existential quantifier it is natural to ask for a witness, if we can indeed fulfill the formula. For example, in the partial dominating set problem we are usually interested in actually finding the dominating set rather than verify than one exists. Often, this is not an issue as problems are self-reducible. Using self-reducibility to find a witness incurs a runtime penalty. The next theorem shows that solving the model checking problem, and finding a witness, for formulas in the form of 1 is possible.

▶ **Theorem 1.** *Let $C$ be a nowhere dense graph class. For every $\varepsilon > 0$, every graph $G \in \mathcal{C}$ and every quantifier-free first-order formula $\varphi(y\bar{x})$ we can compute a vertex tuple $\bar{u}^*$ that maximizes $[\![\#y\,\varphi(y\bar{u}^*)]\!]^G$ in time $O(n^{1+\varepsilon})$.*

As an immediate corollary, we get that the model-checking problem for PDS-like formulas and thus, also the partial dominating set problem are solvable in almost linear fpt time on nowhere dense graph classes, where the parameter is the length of the formulas or the solution size $k$ respectively. Moreover, our meta-algorithm does not only work for partial dominating set, but for variants such as partial total or partial connected dominating set as well.

Note that Theorem 1 does not follow from the fact that model-checking for $\mathrm{FOC}_1(\mathbf{P})$ or that query-counting for FO-logic is fixed-parameter tractable [16] as we do not count the number of solutions to a query, but the number of witnesses to some solution. Also, PDS-like formulas form a fragment orthogonal to $\mathrm{FOC}_1(\mathbf{P})$. Moreover, we were not able to prove Theorem 1 by using the result from [16] as a subroutine: formulas inside a counting quantifier are allowed to have at most one free variable and this weakens self-reducibility or similar techniques drastically.

The above theorem cannot be extended to the more general case of almost nowhere dense graph classes. It turns out that even for non-counting formulas this is not possible, as the (classical) dominating set problem becomes W[1]-hard on some almost nowhere dense graph classes. This lower bound implies as a special case that plain FO-model checking is intractable on some almost nowhere dense graph classes. As far as we are aware this does not follow directly from previously known results.

However, we can go beyond nowhere dense classes if we do not insist on an exact solution: The model-checking problem for PDS-like formulas can be approximated with an *additive* subpolynomial error in almost linear fpt time on almost nowhere dense classes of graphs. To be more precise, we get the following, slightly more general result.

▶ **Corollary 2.** *Let $\mathcal{C}$ be an almost nowhere dense class of graphs. For every $\varepsilon > 0$, every graph $G \in \mathcal{C}$ and every quantifier-free first-order formula $\varphi(y\bar{x})$, we can compute in time $O(n^{1+\varepsilon})$ a vertex tuple $\bar{u} \in V(G)^{|\bar{x}|}$ with*

$$|\max_{\bar{u}} [\![\#y\,\varphi(y\bar{u})]\!]^G - [\![\#y\,\varphi(y\bar{u}^*)]\!]^G| \leq n^{\varepsilon}.$$

Talking about characterizations of almost nowhere dense graph classes, we provide a plethora of different characterizations, similar to the ones for bounded expansion and nowhere denseness. We show that a class is almost nowhere dense classes if and only if measures like $r$-shallow (topological) minor, forbidden $r$-subdivisions and (weak) $r$-coloring numbers are bounded by $f(r,\varepsilon)n^{\varepsilon}$.

We also examine almost nowhere dense classes from an algorithmic point of view: Whereas it is "natural" to consider monotonicity as closure property for nowhere dense graph classes, it is similarly natural to consider closure under edge deletion for almost nowhere dense graph classes. Consider a graph class $\mathcal{C}$ which is closed under deleting edges. Then we show that the problem of finding an $r$ times subdivided $k$-clique is fpt for every fixed $r$ on $\mathcal{C}$ if and only if $\mathcal{C}$ is almost nowhere dense. In particular, for every graph class that is not almost nowhere dense, but closed under deletion of edges, there exists a number $r$ such that finding $r$-subdivided $k$-cliques cannot be solved in fpt time under some complexity theoretic assumption, and, therefore, the FO model checking problem for formulas of the form $\exists\bar{x}\varphi(\bar{x})$ where $\varphi(\bar{x})$ is quantifier free and has predicates for adjacency and distance-$r$ adjacency, cannot be solved either. The situation for distance-$r$ independent set is different: Like finding an $r$-times subdivided clique it is fpt on almost nowhere dense graph classes, but there exists a graph class which is not almost nowhere dense and is closed under edge deletion where the problem is fpt.

## 1.2 Techniques

For Theorem 1, we use a novel dynamic programming technique on game trees of Splitter games. Splitter games were introduced by Grohe, Kreutzer, and Siebertz [15] to solve the first-order model-checking problem on nowhere dense classes. Together with their new concept of sparse neighborhood covers they achieved small recursion trees of constant depth.

Splitter games can be understood as a localized variation of the cops and robbers game for bounded treedepth (not to be confused with locally bounded treedepth). In contrast to [15] we apply a dynamic programming approach, similar to the ones used on bounded tree-depth decompositions. In contrast to bounded treedepth, a graph decomposes into neighborhoods of small radius instead of connected components when removing vertices according to Splitter's winning strategy. A challenge is that the resulting neighborhoods – in contrast to connected components – are not disjoint and lead to double counting for counting problems (an issue that does not occur in FO-model checking). To avoid double counting we introduce so-called cover systems specifically for the subgraph "induced" by the solution. The existence of such cover systems shows that there is a disjoint selection of small neighborhoods that cover all the vertices relevant to our counting problem. By solving a certain variation of the independent set problem, we can find such a selection and can safely combine the results of local parts of the graph as in dynamic programs for bounded tree-depth.

To achieve our second result Corollary 2, we adapt the techniques of the proof for solving the corresponding exact counting problem on classes of bounded expansion [8]: We replace $\#y\,\varphi(y\bar{x})$ by a sum of gradually simpler counting terms until they are simple enough to be easily evaluated. During this process we use transitive fraternal augmentations and a functional representation to encode necessary information into the graph, which is needed during the above simplification of counting terms. Along the way some difficult to handle literals appear in only a few number of terms. Ignoring them leads to the imprecision of our approximation. As the number of functional symbols in (almost) nowhere dense graph classes is not bounded by a constant as it is the case in classes of bounded expansion, the techniques from [8] have to adapted and extended. The main problem why their proof cannot be used directly is that the replacement of formulas leads to formulas of constant size in the case of bounded expansion, but to a non-constant size in our case. Here we use some new tricks and observe, that even though the transformed formulas can be of subpolynomial length, they can basically be replaced by many short formulas.

# 2 Preliminaries

## 2.1 Weak coloring numbers

A central concept in this paper are generalized coloring numbers, especially the weak coloring numbers introduced by Kierstead and Yang [17]. An *ordering* $\pi$ of a graph $G$ is a linear ordering of its vertex set and the set of all such orderings is denoted by $\Pi(G)$.

▶ **Definition 3** (Kierstead and Yang [17]). *A vertex $u \in V$ is* weakly $r$-reachable *from a vertex $v \in V$ with respect to $\pi \in \Pi(G)$ if $u \leq_\pi v$ and there exists a path $P$ from $u$ to $v$ of length at most $r$ such that $u \leq_\pi w$ for each $w \in V(P)$. The set of weakly $r$-reachable vertices from $v$ with respect to $\pi$ is denoted by $\mathrm{WReach}_r[G, \pi, v]$. Note that $v$ is always included in this set. We write $\mathrm{wdist}_{G,\pi}(u, v) \leq d$ if $u \in \mathrm{WReach}_r[G, \pi, v]$ or $v \in \mathrm{WReach}_r[G, \pi, u]$.*

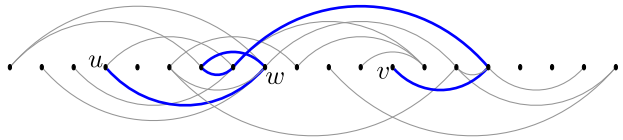

**Figure 1** $u$ is weakly 5-reachable from $v$ by the highlighted path, but $w$ is not weakly reachable from $v$.

*The* weak $r$-coloring number *of a graph $G$ (and an ordering $\pi$) is defined as*

$$\mathrm{wcol}_r(G,\pi) := \max_{v\in V(G)} |\mathrm{WReach}_r[G,\pi,v]|$$

$$\mathrm{wcol}_r(G) := \min_{\pi\in\Pi(G(V))} \mathrm{wcol}_r(G,\pi).$$

The weak 1-coloring number of a graph is one more than its degeneracy, which is the smallest number $d$ such that every subgraph $H \subseteq G$ has a vertex of degree at most $d$ in $H$. The weak coloring number can be seen as a localized version of tree-depth, as

$$\mathrm{wcol}_1(G) \leq \mathrm{wcol}_2(G) \leq \cdots \leq \mathrm{wcol}_\infty(G) = \mathrm{td}(G) \text{ [21].}$$

Figure 1 contains an example of weak $r$-reachability. Weak coloring numbers can be used to characterize nowhere dense graph classes:

▶ **Proposition 4** ([25, 22]). *A graph class $\mathcal{C}$ is nowhere dense if and only if there exists a function $f$ such that for every $r \in \mathbf{N}$, every $\varepsilon > 0$, every graph $G \in \mathcal{C}$ satisfies* $\mathrm{wcol}_r(H) \leq f(r,\varepsilon)|H|^\varepsilon$ *for every $H \subseteq G$.*

## 2.2 Splitter game

We will use a game-based characterization of nowhere denseness introduced by Grohe, Kreutzer and Siebertz [15]. Given a graph $G$, a radius $r$ and a number of rounds $\ell$, *the $(\ell,r)$-Splitter game* on $G$ is an alternating game between two players called *Splitter* and *Connector*. The game starts on $G_0 = G$. In the $i$th round, the Connector chooses a vertex $v_i$ from $G_i$. Then the Splitter chooses a vertex $s_i$ from the radius-$r$ neighborhood of $v_i$ in $G_i$. The game continues on $G_{i+1} = G_i[v_i] - s_i$. Splitter wins if after $\ell$ rounds the graph is empty. Grohe, Kreutzer and Siebertz showed that nowhere dense graph classes can be characterized by Splitter games:

▶ **Proposition 5** ([15]). *Let $\mathcal{C}$ be a nowhere dense class of graphs. Then, for every $r > 0$, there is $\ell > 0$, such that for every $G \in \mathcal{C}$, Splitter has a strategy to win the $(\ell,r)$-splitter game on $G$.*

Note that a winning move of Splitter in a current play can be computed in almost linear time [15, Remark 4.7].

## 2.3 Sparse neighborhood covers

Even though the splitter game ends after a bounded number of rounds $\ell$ for nowhere dense classes, the game tree, i.e. the tree spanned by all possible plays of Splitter and Connector, can still be large, e.g. in the dimensions of $n^\ell$. To make the game trees small and useful for algorithmic use, Grohe, Kreutzer and Siebertz introduced sparse neighborhood covers [15]. These covers group "similar" neighborhoods into a small number cluster of bounded radius. These clusters can be used instead of the neighborhoods, reducing the size of the game tree to $O(n^{1+\varepsilon})$.

▶ **Definition 6** ([15]). *For a radius $r \in \mathbf{N}$, an* $r$-neighborhood cover *$\mathcal{X}$ of a graph $G$ is a set of connected subgraphs of $G$ called* clusters*, such that for every vertex $v \in V(G)$ there is some $X \in \mathcal{X}$ with $N_r[v] \subseteq V(X)$. The degree of $v$ in $\mathcal{X}$ is the number of clusters that contain $v$ and the radius of $\mathcal{X}$ is the maximal radius of a cover in $\mathcal{X}$. A class $\mathcal{C}$ admits* sparse neighborhood covers *if there exists $c \in \mathbf{N}$ and for all $r \in \mathbf{N}$ and all $\varepsilon > 0$ a number $d = d(r, \varepsilon)$ such that every graph $G \in \mathcal{C}$ admits an $r$-neighborhood cover of radius at most $c$ and degree at most $d|G|^{\varepsilon}$.*

▶ **Proposition 7** ([15]). *Every nowhere dense class $\mathcal{C}$ of graphs admits a sparse neighborhood cover. For a graph $G \in \mathcal{C}$ and $r \in \mathbf{N}$ such an $r$-neighborhood cover can be computed in time $f(r, \varepsilon)n^{1+\varepsilon}$ for every $\varepsilon > 0$.*

Indeed, the existence of such covers is another characterization of nowhere dense classes.

▶ **Definition 8.** *For a graph $G$ with a vertex order $\pi$, $r \in \mathbf{N}$ and a vertex $v \in V(G)$, we define $X_r[G, \pi, v]$ as $\{u \in V(G) \mid v \in \mathrm{WReach}_r[G, \pi, u]\}$. We let $\mathcal{X}_r = \{X_{2r}[G, \pi, v] \mid v \in V(G)\}$.*

From the proof of Proposition 7 it follows, that the set family $\mathcal{X}_r$ is such a sparse neighborhood cover.

## 2.4 Low treedepth colorings

A crucial algorithmic tool in the study of bounded expansion and nowhere dense graph classes are *low treedepth colorings*, also known as $r$-centered colorings.

▶ **Definition 9.** *An $r$-treedepth coloring of a graph $G$ is a coloring of vertices of $G$ such that any $r' \leq r$ color classes induce a subgraph with treedepth at most $r'$.*

The following statement by Zhu [25] is modified such that it is constructive and holds also for a given vertex ordering $\pi$. It follows from the original proof.

▶ **Proposition 10** ([25, Proof of Thm. 2.6]). *If $\pi$ is a vertex ordering of a graph $G$ with $\mathrm{wcol}_{2^{r-2}}(G, \pi) \leq m$, an $r$-treedepth coloring can be computed with at most $m$ colors in time $O(mn)$.*

Graph classes of bounded expansion can be characterized by low treedepth colorings, i.e., each graph has an $r$-treedepth coloring with at most $f(r)$ many colors.

# 3 Exact Evaluation on Nowhere Dense Classes

In this section we consider the model-checking problem for formulas $\exists x_1 \dots x_k \# y\, \varphi(y\bar{x}) > N$ on nowhere dense graph classes for quantifier-free first-order formulas $\varphi$. We show that this problem can be solved in almost linear fpt time by solving its optimization variant $\max_{\bar{u} \in V(G)^{\bar{x}}} \# y\, [\![\varphi(y\bar{u})]\!]$.

## 3.1 Radius-$r$ Decomposition Tree

In the following, we will introduce a new kind of decomposition, which heavily relies on the ideas from [15]. We call it the radius-$r$ decomposition tree. For illustration, consider a tree-depth decomposition of a graph $G$. It has the property that after the removal of the root $v$ in the decomposition, for each connected component $C$ of $G - v$ there exists a child of $v$ in the decomposition that contains $C$. In the radius-$r$ decomposition tree, not every connected component is represented by a child but every radius-$r$ neighborhood of $G - v$

instead. Another difference is that these neighborhoods are not necessarily disjoint. We will use this radius-$r$ decomposition tree as the structure on which a dynamic program will solve $\max_{\bar{u}} [\![\#y\, \varphi(y\bar{u})]\!]^G$.

▶ **Definition 11.** *Let $G$ be a graph. Let $r, \ell \in \mathbf{N}$ be such that splitter has a winning strategy for the $\ell$-round radius-$2r$ splitter game on $G$. Let $\pi$ be an ordering of $G$.*

*A* radius-$r$ decomposition tree $T_r(G, \pi, \ell)$ *is a pair $(T, \beta)$ where $T$ is a tree of depth $\ell$ and $\beta\colon V(T) \to V(G)$. We construct it recursively. If $G$ is empty, $T_r(G, \pi, \ell)$ is the empty tree.*

*Let $s \in V(G)$ be the first move of the winning strategy of splitter for the $(\ell, 2r)$-splitter game on $G$. The root is a node $t$ with $\beta(t) = s$. For every $v \in V(G)$ we append the decomposition tree $T_r(G[X_v], \pi, \ell - 1)$ where $X_v = X_{2r}[G - s, \pi, v]$.*

Note that the case $\ell = 0$ while the graph is not empty, cannot happen due to the Splitter having a winning strategy.

▶ **Corollary 12.** *Let $G$ be a graph, $\pi$ a vertex ordering of $G$, $r, \ell \in \mathbf{N}$ and $T = T_r(G, \pi, \ell)$ a radius-$r$ decomposition tree. Let $t \in V(T)$ be a node and $T_t$ be the subtree of $T$ starting at $t$. Then for every $u \in W := \beta(V(T_t)) \setminus \{\beta(t)\}$ there exists a child $t'$ of $t$ such that $N_r^{G[W]}[u] \subseteq \beta(T_{t'})$.*

▶ **Lemma 13.** *Let $G$ be a graph, $\pi$ a vertex ordering of $G$ and $r, \ell \in \mathbf{N}$. Then, the radius-$r$ decomposition tree $T = T_r(G, \pi, \ell)$ (Definition 11) has size $|T| \leq \mathrm{wcol}_{2r}(G, \pi)^\ell n$ and depth $\ell$. The construction time is linear in $|T|$.*

**Proof.** By construction, the depth of the tree is determined by the depth of the splitter game, which is $\ell$.

Consider the root path $P_t$ of some node $t \in V(T)$. Then $\beta(P_t) \subseteq \mathrm{WReach}_{2r}[G, \pi, \beta(t)]$. As the length of $P_t$ is at most $\ell$, $\beta(t)$ appears at most $\mathrm{WReach}_{2r}[G, \pi, \beta(t)]^\ell \leq \mathrm{wcol}_{2r}(G, \pi)^\ell$ times (as a $\beta$-label of nodes) in $T$. Thus, $|T| \leq \mathrm{wcol}_{2r}(G, \pi)^\ell n$. ◀

▶ **Corollary 14.** *Let $\mathcal{C}$ be a nowhere dense graph class. For every $r \in \mathbf{N}$ the $r$-decomposition tree has constant depth, almost linear size and can be computed in almost linear time.*

## 3.2 Cover Systems

Given a subgraph $H$ in $G$ with a vertex ordering $\pi$ of $G$. A *cover system* of $H$ in $G$ is a family $\mathcal{Z}$ of clusters $Z_i = X_r[G, \pi, v] \in Z$ for some $r \in \mathbf{N}$ such that every connected component $C$ of $H$ is contained in some $Z_i$. A cover system is *non-overlapping* if all distinct clusters have an empty intersection.

▶ **Lemma 15.** *For every graph $G$ with a vertex ordering $\pi$, every $D \subseteq V(G)$ of size $k$, there exists a cover system of $G[N[D]]$ in $G$ of size at most $k$ where each cluster has the same radius $r \leq 2^k$.*

**Proof.** We start with the clusters $X_2[G, \pi, \min_\pi N[d]]$ for every $d \in D$. Call this collection $\mathcal{Z}$. Note that $\mathcal{Z}$ is already a valid cover system of $G[N[D]]$ in $G$. If two distinct clusters $X_r[G, \pi, z]$ and $X_r[G, \pi, z']$ from $\mathcal{Z}$ intersect, we replace both with a new cluster $X_{2r}[G, \pi, \min_\pi\{z, z'\}]$ in $\mathcal{Z}$. Every vertex or edge covered by the two old clusters stays covered in the new one. Also, if two clusters $X_r[G, \pi, z]$ and $X_{r'}[G, \pi, z']$ are of a different radius, say, $r' < r$, we replace $X_{r'}[G, \pi, z']$ with $X_r[G, \pi, z']$ to match the radii of all the clusters.

We repeat this until no intersecting clusters remain. As the number of clusters decreases with every step, the radius is at most $2^k$ at the end. ◀

For Theorem 1, one needs to find clusters from $\mathcal{X}_r$ which are disjoint and maximize the sum of weights of clusters. This is captured by the following definition. We can solve this problem in almost linear time on nowhere dense graph classes, by noticing that the intersection graphs of the sparse neighborhood covers $\mathcal{X}_r$ are almost nowhere dense. Then, one can use treedepth colorings and LinEMSOL.

▶ **Definition 16** (Disjoint Cluster Maximization). *Given a graph, a set system $\mathcal{X}_r$ as defined in Definition 8, labelled by a function $\Lambda : \mathcal{X}_r \to 2^\Lambda$ of size $k$. Each combination of a cluster $X \in \mathcal{X}_r$ and label $\lambda \in \Lambda(X)$ is weighted by a function $w$.*

*Problem: Find pairwise disjoint clusters $X_1, \dots, X_k \in \mathcal{X}_r$ such that for each label $\lambda_i \in \Lambda$ the cluster $X_i$ is labeled $\lambda_i$ and $X_1, \dots, X_k$ maximize $\sum_{i=1}^{k} w(X_i, \lambda_i)$ for such cluster sets.*

*Parameter: $r, k$*

Let $\Omega$ be the set of weighted positive conjunctive clauses $(\mu, \omega(y\bar{x}))$, $\bar{z} \subseteq \bar{x}$ and $\bar{u} \in V(G)^{|\bar{x}|}$. With $\Omega|_{\bar{z}}$ we denote a subset of $\Omega$ with weighted clauses $(\mu, \omega(y\bar{z}))$ where every variable occurring in $\omega$ is from $\bar{z}$. We define $\Omega|_{\bar{z}}[Z, \bar{u}]$ as $\sum_{v \in Z} \sum_{(\mu,\omega) \in \Omega|_{\bar{z}}} \mu[\![\omega(v\bar{u})]\!]^G$. Note that $\Omega|_{\bar{z}}[Z, \bar{u}]$ depends only on the assignment of $\bar{z}$ and does not need the full assignment $\bar{u}$ of $\bar{x}$.

To illustrate the following lemma, consider a positive conjunctive clause $\omega(y\bar{x}\bar{z})$, sets $P, W \subseteq V(G)$ and $\bar{u} \in P^{\bar{x}}, \bar{w} \in W^{\bar{z}}$. To count the fulfilling vertices $v \in W$ of $\omega$, i.e. $\Omega[W, \bar{u}]$, we want to reduce this task to counting on cover systems of $N[\bar{w}]$. However, as not all fulfilling vertices in $W$ are adjacent to $\bar{w}$, we need to be more careful.

▶ **Lemma 17.** *Let $G$ be a graph, $\Omega$ a set of weighted positive conjunctive clauses $(\mu, \omega(y\bar{x}\bar{z}))$, $P, W \subseteq V(G)$ disjoint, $\bar{u} \in P^{\bar{x}}, \bar{w} \in W^{\bar{z}}$ such that $N[\bar{w}] \subseteq P \cup W$. For every cover system $\mathcal{Z}$ of $G[N[\bar{w}]]$ in $G[W]$ it holds that*

$$\Omega[W, \bar{u}\bar{w}] = \Omega|_{y\bar{x}}[W, \bar{u}\bar{w}] + \sum_{Z \in \mathcal{Z}} (\Omega|_{y\bar{x}\bar{z}_Z}[Z, \bar{u}\bar{w}] - \Omega|_{y\bar{x}}[Z, \bar{u}])$$

*where $\bar{z}_Z$ are the variables $z_i$ from $\bar{z}$ which are assigned to a vertex in $Z$.*

Let us consider how a solution $\bar{u}$ for $\#y\,\varphi(y\bar{x})$ interacts with a radius-$r$ decomposition of the input graph $G$ where $r$ is chosen appropriately big, e.g. $2^k$ resulting from Lemma 15. First, we transform $\varphi$ into a set of positive clauses $\Omega$, making the application of Lemma 17 possible.

Consider some node $t$ in $T_r$. When applying Lemma 17 with $P$ as the vertices of the root path of $t$ and $W$ as $T_t$, we see that the resulting cover system $\mathcal{Z}$ corresponds to a selection of children of $t$ in $T_r$, as both use the sets $X_r$ from Definition 8. Now imagine that we know $\Omega_{y\bar{x}\bar{z}_Z}[Z, \bar{u}]$ for every $Z \in \mathcal{Z}$. Note that this number only depends on the assignment of $\bar{x}\bar{z}_z$ and not the vertices assigned outside $P$ and $Z$. With Lemma 17 we can combine these numbers into $\Omega[W, \bar{u}]$ without needing to know the actual assignments of $\bar{z}_Z$ in the cover system anymore! Note that $\Omega_{y\bar{x}}[Z]$ is easily computable while only knowing $\bar{u}$ and not $\bar{w}$.

Thus, we can compute $[\![\#y\,\varphi(y\bar{u})]\!]$ bottom-up using the radius-$r$ decomposition while only considering the vertices assigned in $\bar{u}$ which are contained in the root path of the considered vertex.

## 3.3 Dynamic Program

To determine $\max_{\bar{u}} \#y\,\varphi(y\bar{u})$ for a quantifier-free formula $\varphi(y\bar{x})$ we recursively compute the following information in the decomposition tree of $G$ (bottom-up, if you will). Consider some node $t$ of $T$ and a partial assignment $\alpha$ of $\bar{x}$ to the root path $\beta(P_t)$. The interesting

information is: How many vertices underneath $t$, i.e. in $V(G_t)$, fulfill $\varphi$ under the "best" choice on completing the assignment $\alpha$ to vertices in $V(G_t)$. Then the answer to the problem can be read off the information for the root node.

Assume we already know this kind of information for every child $t'$ of $t$. To compute this information for $t$, we branch how the variables $x_i$ that are not assigned under $\alpha$ are distributed among the children of $t$. Then the table entries of these children are combined in a suitable way. We do this for every distribution among children and take the maximum of the resulting values. If a vertex corresponding to $t$ fulfills with the assignment the formula $\varphi$, it gets counted towards the number of "fulfilling" vertices.

However, we have to take more into consideration. First, branching on the distribution of the unassigned variables $x_i$s under $\alpha$ among the children of $t$ is not fast enough, as there are around $n^k$ possibilities for that. Instead, we branch on how the unassigned variables are partitioned. For every such partition, we formalize the optimal choice of children $t_i$ such that they contain exactly the unassigned variables from the $i$-th part, as an optimization problem.

Secondly, the graphs $G_{t'}$ spanned by each child $t'$ of $t$ are in general not disjoint. Combining the counts of two overlapping graphs yields to double counting. We circumvent this in the above optimization problem.

Thirdly, we need to keep track of how the vertices in the root path $P_t$ are adjacent to the variables $x_i$ that are assigned underneath $t$. We cannot branch on the complete assignment as the number of those is too high.

Before we turn to the dynamic program on the decomposition tree, we consider something simpler:

Let $G$ be a graph and $\varphi(y\bar{x})$ be quantifier-free FO formula. Consider the pair $(P, W)$ which is a set of vertices $P = \{v_1, \dots, v_k\} \subseteq V(G)$ and a set $W \subseteq V(G)$ that is disjoint with $P$. We are interested in how many vertices $v$ in $G[P \cup W]$ satisfy $\varphi(v\bar{u})$ for an optimal choice of $\bar{u} \in (P \cup W)^{|\bar{u}|}$. For this, we keep track of $M_\alpha^{(P,W)}[S]$, which is the number of fulfilling vertices $v \in W$ wrt. $\varphi$, $\hat{\alpha}$ and $S$, maximizing over $S$-completions $\hat{\alpha}$ on $W$.

We can "forget" a vertex $v$, i.e., derive the information of $(P, W \cup \{v\})$ from the information $(P \cup \{v\}, W)$ as follows: Assume the maximum number of fulfilling vertices in $W$ is $x$ for a given partial assignment $\alpha$ on $P \cup \{v\}$ and adjacency profile $S$ on $P \cup \{v\}$. Then the number of fulfilling vertices in $W \cup \{v\}$ is $x + 1$ if $v$ satisfies $\varphi$ with the assignment $\alpha$ and adjacency profile $S$, or $x$ otherwise. However, neither $\alpha$ nor $S$ are valid assignments or adjacency profiles for $P$. Hence, we need to adjust these so that we can formulate this information for $(P, W \cup \{v\})$. For this, we need to remove $v$ from $\alpha$ and add the neighborhood of $v$ in $P$ to $S$ as $S_i$, for every $i$ with $\alpha(x_i) = v$. Then, $M_\alpha^{(P\cup\{v\},W)}[S] = M_{\alpha|_P}^{(P,W\cup\{v\})}[S'](+1)$ where $\alpha|_P$ is the assignment $\alpha$ without $v$ and $S'$ is the adjacency profile as described above.

One can also combine the information of two structures $(P, W_1)$ and $(P, W_2)$ to get the information of $(P, W_1 \uplus W_2)$ if $W_1$ and $W_2$ are disjoint. This is also known as "merge." Consider some assignment $\alpha$ on $P$ and some adjacency profile $S$ on $P$. Then the number of fulfilling vertices in $U \uplus W$ wrt $\varphi$, $\alpha$ and $S$ is the $\max\{M_\alpha^{P,W_1}[S_1] + M_\alpha^{P,W_2}[S_2] \mid S_1 \uplus S_2 = S\}$.

Indeed however, the algorithm does not take a quantifier-free formula $\varphi$ but a set of weighted positive conjunctive clauses. Instead of just counting the fulfilled vertices, it computes the added up weight of them wrt. to the weights of the clauses.

▶ **Theorem 1.** *Let $C$ be a nowhere dense graph class. For every $\varepsilon > 0$, every graph $G \in \mathcal{C}$ and every quantifier-free first-order formula $\varphi(y\bar{x})$ we can compute a vertex tuple $\bar{u}^*$ that maximizes $[\![\#y\, \varphi(y\bar{u}^*)]\!]^G$ in time $O(n^{1+\varepsilon})$.*

## 4 Characterizing Almost Nowhere Dense Graph Classes

In this section, we provide various characterizations of almost nowhere dense classes, i.a. via bounded depth minors and generalized coloring numbers.

▶ **Definition 18** (Almost nowhere dense). *A graph class $\mathcal{C}$ is* almost nowhere dense *if for every $r \in \mathbf{N}$, $\varepsilon > 0$ there exists $n_0$ such that no graph $G \in \mathcal{C}$ with $|G| \geq n_0$ contains $K_{\lceil |G|^\varepsilon \rceil}$ as a depth-$r$ minor.*

▶ **Theorem 19.** *Let $\mathcal{C}$ be a graph class. The following statements are equivalent.*

1. *$\mathcal{C}$ is almost nowhere dense.*
2. *For every $r \in \mathbf{N}$, $\varepsilon > 0$ there exists $n_0$ such that no graph $G \in \mathcal{C}$ with $|G| \geq n_0$ contains $K_{\lceil |G|^\varepsilon \rceil}$ as a depth-$r$ minor.*
3. *For every $r \in \mathbf{N}$, $\varepsilon > 0$ there exists $n_0$ such that no graph $G \in \mathcal{C}$ with $|G| \geq n_0$ contains $K_{\lceil |G|^\varepsilon \rceil}$ as a depth-$r$ topological minor.*
4. *For every $r \in \mathbf{N}$, $\varepsilon > 0$ there exists $n_0$ such that no graph $G \in \mathcal{C}$ with $|G| \geq n_0$ contains an $r'$-subdivision of $K_{\lceil |G|^\varepsilon \rceil}$ as a subgraph for any $r' \leq r$.*
5. *For every $r \in \mathbf{N}$, $\varepsilon > 0$ there exists $n_0$ such that $\operatorname{wcol}_r(G) \leq |G|^\varepsilon$ for every graph $G \in \mathcal{C}$ with $|G| \geq n_0$.*
6. *For every $r \in \mathbf{N}$, $\varepsilon > 0$ there exists $n_0$ such that $\operatorname{col}_r(G) \leq |G|^\varepsilon$ for every graph $G \in \mathcal{C}$ with $|G| \geq n_0$.*

The characterizations from Theorem 19 are very similar to those for nowhere dense classes. The only difference in the characterizations 1. to 4. would be the size of the forbidden cliques: for nowhere dense classes, the size would be $f(r)$ instead of $\lceil |G|^\varepsilon \rceil$. Similarly, if we would substitute "for every $G \in \mathcal{C}$" with "for every subgraph $G \subseteq H \in \mathcal{C}$" in characterizations 5 and 6 would characterize nowhere dense classes. Note that every almost nowhere dense class which is monotone, i.e. closed under taking subgraphs, is also nowhere dense.

Conversely, if a class $\mathcal{C}$ is almost nowhere dense, then its subgraph-closure $\mathcal{C}_\subseteq$ is not almost nowhere dense in general. Consider for this the class of graphs which for every $n \in \mathbf{N}$ contains independent set of size $n$ with a clique of size $\log n$, i.e. the graph $I_n \cup K_{\log n}$. This class is almost nowhere dense but its subgraph-closure contains cliques $K_n$ of every size $n$ as member, and so, all graphs.

## 5 Approximation on Almost Nowhere Dense

In this section we consider the same problem as before, i.e., finding vertices for $\bar{x}$ that satisfy $\#y\,\varphi(\bar{x}y) > N$ but on almost nowhere dense classes of graphs. Here, we give an approximation algorithm with an additive error. For this, we use completely different techniques compared to Section 3. We first show how to reduce the corresponding model-checking problem to approximate sums over unary functions. Then we present the approximate optimization algorithm in Theorem 20.

The main result of this section is the following approximate optimization algorithm with additive error.

▶ **Theorem 20.** *There exists a computable function $f$ such that for every graph $G$ and every quantifier-free first-order formula $\varphi(y\bar{x})$ we can compute a vertex tuple $\bar{u}^*$ with*

$$|\max_{\bar{u}} [\![\#y\,\varphi(y\bar{u})]\!]^G - [\![\#y\,\varphi(y\bar{u}^*)]\!]^G| \leq 4^{|\varphi|} \operatorname{wcol}_2(G)^{O(|\varphi|)}$$

*in time $\operatorname{wcol}_{f(|\varphi|)}(G)^{f(|\varphi|)} n$.*

For the *approximate model-checking* problem with an additive error $\delta$, similar to [8], we want an algorithm such that

1. the algorithm returns "yes" only if $G$ satisfies the formula,
2. returns "no" only if $G$ does not satisfy the formula,
3. returns $\perp$ only if the optimum is within $\delta$ to $N$.

The option $\perp$ can be seen as "I do not know" as the computed result and the desired result are so close that the difference falls into the additive error $\delta$.

Given the approximate optimization algorithm from Theorem 20, we can easily build an approximate model-checking algorithm as described above for the formula $\exists \bar{x} \# y\, \varphi(y\bar{x}) > N$ by computing a vertex tuple $\bar{u}^*$ from the theorem. If $N - [\![\#y\, \varphi(y\bar{u}^*)]\!]^G \leq \delta$, answer $\perp$. Otherwise, answer "yes" or "no" according whether $[\![\#y\, \varphi(y\bar{u}^*)]\!]^G > N$ or not. Note that $\delta$ cannot be chosen freely as it depends on the graph (respectively, its weak coloring numbers).

The runtime of the algorithm from Theorem 20 is fpt if the weak $r$-coloring numbers are bounded by $n^\varepsilon$ for $r \leq f(|\varphi|)$. This is the case for almost nowhere dense classes. This is in contrast to the results of [8] where the running time of their algorithms is bounded by $f(\mathrm{wcol}_{f(|\varphi|)})||G||$ which is fpt on classes of bounded expansion but is not fpt on nowhere dense and almost nowhere dense classes.

This gives us the following corollary.

▶ **Corollary 2.** *Let $\mathcal{C}$ be an almost nowhere dense class of graphs. For every $\varepsilon > 0$, every graph $G \in \mathcal{C}$ and every quantifier-free first-order formula $\varphi(y\bar{x})$, we can compute in time $O(n^{1+\varepsilon})$ a vertex tuple $\bar{u} \in V(G)^{|\bar{x}|}$ with*

$$|\max_{\bar{u}} [\![\#y\, \varphi(y\bar{u})]\!]^G - [\![\#y\, \varphi(y\bar{u}^*)]\!]^G| \leq n^\varepsilon.$$

## 6 Hardness Results

In this section, we try to see how far the above result can or cannot be extended to either a bigger class of problems or to more general graph classes. Exemplary, we examine the distance-$r$ versions of the dominating set, independent set and clique problem. Note that in contrast to the section before, we do not consider the partial problem versions. We see that each of these problems behave differently in this context. The distance-$r$ dominating set problem is already hard for distance 1 on some almost nowhere dense graph classes, whereas distance-$r$ independent set and distance-$r$ clique are both fpt on almost nowhere dense graph classes.

As for graph classes, we consider classes that are closed under removing edges because monotone graph classes are very well understood and the notions of nowhere dense and almost nowhere dense coincide on those classes. Interestingly, for graph classes closed under removing edges the distance-$r$ clique problem is fpt for all distances $r$ if and only if the class is almost nowhere dense (under some complexity theoretic assumptions). However, there exist graph classes which are closed under removing edges but not almost nowhere dense that allow for fpt algorithms for the distance-$r$ independent set problem. The difference of behavior between distance-$r$ clique and distance-$r$ independent set is also intriguing as the FO-formulation of these problems has exactly one quantifier alternation for both.

### 6.1 Exact Evaluation Beyond Nowhere Dense Classes

The following lemma proves that dominating set is W[1]-hard on almost nowhere dense classes.

The class of bipartite graphs with sides $L$ and $R$ where $L$ has polylogarithmic size is almost nowhere dense: A witness for this is a vertex ordering that starts with $L$ and starts . Only the vertices from $L$ are weakly $r$-reachable from any vertex. Hence, $\mathrm{wcol}_r(G) \leq |L| + 1$ for each $r$.

▶ **Theorem 21.** *In bipartite graphs whose left side has $2k(k-1)\lceil\log(n)\rceil$ vertices and whose right side has $n$ vertices it is W[1]-hard to decide whether there are $\binom{k}{2}$ right-side vertices dominating all left-side vertices.*

**Proof.** We reduce from colorful clique. Assume we have a $k$-partite graph $G$ of size $n$ consisting of parts $V_0, \dots, V_{k-1}$ (each of a different color) and want to find a colorful clique of size $k$. Without loss of generality, we can assume $n$ to be large enough that $\binom{2\lceil\log(n)\rceil}{\lceil\log(n)\rceil-1} \geq n$. This means, we can find for each $v \in V(G)$ a unique binary encoding $\mathrm{enc}(v)$ of length $2\lceil\log(n)\rceil$ such that the first bit is set to one and in total exactly half the bits are set to one. Let $\overline{\mathrm{enc}}(v)$ be the binary complement of $\mathrm{enc}(v)$. We construct a bipartite graph $H$, whose left side is partitioned into cells $C_{ij}$ for $0 \leq i \neq j < k$, each of size $2\lceil\log(n)\rceil$, and whose right side will be specified soon. The vertices of each cell are ordered. When we say for a given vertex $v$ from the right side and cell $C$ that *$v$ is connected to $C$ according to a specified encoding*, we mean that for $1 \leq l \leq 2\lceil\log(n)\rceil$, $v$ is connected to the $l$th vertex of $C$ if and only if the $l$th bit in the encoding is set to one. For $0 \leq i < k$ we define

$$\mathrm{succ}_i(j) = \begin{cases} j+1 \bmod k & i \neq j+1 \bmod k \\ j+2 \bmod k & \text{otherwise.} \end{cases}$$

For all $0 \leq i < j < k$ and all $u \in V_i$ and $v \in V_j$ such that $uv \in E(G)$, add a vertex $x_{u,v}$ to the right side and

- connect $x_{u,v}$ to $C_{i,j}$ according to $\mathrm{enc}(u)$,
- connect $x_{u,v}$ to $C_{i,\mathrm{succ}_i(j)}$ according to $\overline{\mathrm{enc}}(u)$,
- connect $x_{u,v}$ to $C_{j,i}$ according to $\mathrm{enc}(v)$,
- connect $x_{u,v}$ to $C_{j,\mathrm{succ}_j(i)}$ according to $\overline{\mathrm{enc}}(v)$. ◀

We can reduce the aforementioned dominating set variation to the classical dominating set problem by connecting the right side to a fresh vertex.

▶ **Corollary 22.** *There exists an almost nowhere dense graph class $\mathcal{C}$ where the dominating set problem is $W[1]$-hard and cannot be solved in time $n^{o(k)}$ assuming ETH. This implies also the hardness of the fragments PDS-like, $\mathrm{FOC}_1(\mathbf{P})$, and $\mathrm{FOC}(\{>\})$ of $\mathrm{FOC}(\mathbf{P})$ on $\mathcal{C}$.*

Note that this result does not follow from the intractability result of FO-logic on subgraph-closed somewhere dense classes, i.e. not nowhere dense classes.

## 6.2 Beyond Distance One

We showed that the dominating set problem is $W[1]$-hard on some almost nowhere dense graph class. However, this is not true for the distance-$r$ clique and independent set problem.

Distance-$r$ clique and independent set on the other hand are fpt on almost nowhere dense graph classes. Here, we use low treedepth colorings to solve existential FO formulas. With the right formulation and inclusion-exclusion this works even for distance-$r$ independent set which cannot be expressed as a purely existential FO formula.

▶ **Theorem 23.** *There exists a computable function $f$ such that for every graph $G$ the distance-$r$ clique problem can be solved in time $\mathrm{wcol}_{f(k,r)}(G)^{f(k,r)}n$.*

**Proof.** We can solve this problem with the help of subgraph queries where each subgraph is an $\leq r$-subdivision of a $k$-clique. These subgraphs have less than $k^2(r+1)$ vertices and there are at most $(r+1)^{k^2}$ of them. Subgraph queries can be done by checking an existential FO-formula using Theorem 20. ◀

▶ **Theorem 24.** *There exists a computable function $f$ such that for each graph $G$ the distance-$r$ independent set problem can be solved in time* $\mathrm{wcol}_{f(k,r)}(G)^{f(k,r)}n$.

**Proof sketch.** We count specially designed subgraphs to solve this problem. These subgraphs encode that there are vertices $v_1, \dots v_k$ which have some distance $d(v_i, v_j)$ from each other. As the distance constraint "$d(v_i, v_j) \geq r+1$" for the distance-$r$ independent set problem cannot be expressed this way, we use inclusion-exclusion to compute the number of such graphs. To count them, we use low treedepth colorings whose number of colors are bounded by weak coloring numbers. ◀

▶ **Corollary 25.** *For every almost nowhere dense graph class $\mathcal{C}$, every $r \in \mathbf{N}$ and every real $\varepsilon > 0$ both the distance-$r$ clique problem and the distance-$r$ independent set problem can be solved in time $O(n^{1+\varepsilon})$ given a graph $G \in \mathcal{C}$.*

## 6.3 Beyond Almost Nowhere Dense

For graph classes that are closed under removing *vertices and edges*, i.e., monotone graph classes, we know a lot already. Most importantly, FO-model checking is fpt on such classes if and only if the class is nowhere dense (unless FPT = $W[1]$) [15]. We now want to consider graph classes that are only closed under removing *edges*. Here the concept of almost nowhere dense graph classes becomes interesting.

The following observation follows directly from characterization 6 in Theorem 19. If $\mathcal{P}$ is a parameterized problem that can be solved in time $\mathrm{col}_{f(k)}(G)^{f(k)}n$ and $\mathcal{C}$ is an almost nowhere dense graph class, then $\mathcal{P}$ can be solved on $\mathcal{C}$ in almost linear fpt time $f(k,\varepsilon)n^{1+\varepsilon}$ for every $\varepsilon > 0$. We complement this by showing that the distance-$r$ clique problem is most likely not fpt on all graph classes that are not almost nowhere dense, but closed under removing edges. Hence, under certain common complexity theoretic assumptions, if a graph class $\mathcal{C}$ is closed under removal of edges then distance-$r$ clique is fpt on $\mathcal{C}$ iff $\mathcal{C}$ is almost nowhere dense.

▶ **Theorem 26.** *Let $\mathcal{C}$ be a graph class that is not almost nowhere dense, but closed under removing edges. Then there exists a number $r$, such that one cannot solve the distance-$r'$ clique problem parameterized by solution size in fpt time on $\mathcal{C}$ for all $r' \leq r$ unless* i.o.W[1] $\subseteq$ FPT.

Similar hardness results in parameterized complexity are usually built on the hardness assumption FPT $\neq W[1]$. The complexity class *i.o.*W[1] should be read as "infinitely often in W[1]" and needs to be explained.

▶ **Definition 27.** *For a language $L$ and an integer $n$ let $L_n = L \cap \{0,1\}^n$. A language $L$ is in i.o.$C$ for a complexity class $C$ if there is some $L' \in C$ such that $L'_n = L_n$ for infinitely many input lengths $n$.*

Considering the infinite often variant *i.o.*$C$ of a complexity class $C$ is an established technique in complexity theory (i.e., [3, 2]). To prove our result, we show that a graph class $\mathcal{C}$ that is not almost nowhere dense, contains an infinite sequence of graphs having cliques of polynomial size as bounded depth topological minors. If $\mathcal{C}$ is also closed under removal of edges then

having bounded depth topological clique minors of size $n$ implies the existence of subdivisions of arbitrary graphs $H$ of size $n$ as induced subgraphs. Extra care needs to be taken to make sure that all paths connecting the principal vertices should be of equal length, since otherwise a reduction would need to try out an exponential number of possible length combinations to finally find the correct subdivision of $H$ that is contained in $\mathcal{C}$. The following corollary is a direct consequence of Theorem 19.4.

▶ **Corollary 28.** *Let $\mathcal{C}$ be some graph class that is not almost nowhere dense. Then there are $r$, $\varepsilon$ and an infinite sequence of strictly ascending numbers $n_0, n_1, \ldots$ such that for all $i \in \mathbf{N}$ there is a graph $G \in \mathcal{C}$ of order at most $n_i$ that contains an $r'$-subdivision of $K_{\lceil n_i^\varepsilon \rceil}$ as a subgraph for some $r' \leq r$.*

The consequence i.o.W[1] $\subseteq$ FTP is weaker than W[1] $\subseteq$ FPT. We could use the latter in Theorem 26 if we required a stronger precondition, i.e., that $\mathcal{C}$ has "witnesses" for input lengths $n_0, n_1, n_2, \ldots$ such that the gap between $n_i$ and $n_{i+1}$ is only polynomial. This approach has been used, e.g., in proving lower bounds on the running time of MSO-model checking in graph classes where the treewidth grows polylogarithmically [19, 12].

**Proof of Theorem 26.** Let $r$ and $\varepsilon$ be the constants (depending on $\mathcal{C}$) from Corollary 28. Assume that the distance-$(r+1)$ clique problem on $\mathcal{C}$ is fpt when parameterized by solution size. We will present a Turing reduction showing that the (usual) clique problem on the class of all graphs is infinitely often in FPT.

By Corollary 28 for infinitely many $n_0, n_1, \cdots \in \mathbf{N}$ there exists a graph from $\mathcal{C}$ of size at most $n_i^{1/\varepsilon}$ that contains an $r'$-subdivision of a clique of size $n_i$ as a subgraph for some $r' \leq r$. Let us pick one $n = n_i$. Suppose we want to decide whether a graph $G$ with $n$ vertices contains a clique of size $k$. Since $\mathcal{C}$ is closed under removal of edges, there exist $r' \leq r$, and $n \leq N \leq n^{1/\varepsilon}$ such that $\mathcal{C}$ contains a graph $H_{r',N}$ consisting of an $r'$-subdivision of $G$ together with $N$ isolated vertices. Now for all $k$, $G$ contains a clique of size $k$ iff $H_{r',N}$ contains a distance-$(r'+1)$ clique of size $k$. Assume for contradiction we had an algorithm that decides in time at most $f(r',k)n^c$ whether a graph in $\mathcal{C}$ of size $n$ contains an distance-$(r'+1)$ clique for $r' \leq r$. (For graphs not in $\mathcal{C}$, the algorithm may give a wrong answer, but we can modify it to construct and test a witness of a distance-$(r'+1)$ clique on yes-instances. Hence, we can assume that the algorithm never returns "no" on yes-instances.)

The existence of such an algorithm yields us an FPT algorithm for the $k$-clique problem on general graphs: For all $r' \leq r$, and $n \leq N \leq n^{1/\varepsilon}$, we run this (hypothetical) fpt algorithm in parallel on $H_{r',N}$ for $f(r',k)N^c$ time steps. Then $G$ contains a clique of size $k$ iff for at least one value of $r'$ and $N$ we have $H_{r',N} \in \mathcal{C}$ and $H_{r,N}$ contains a distance-$(r'+1)$ $k$-clique.

As the $k$-clique problem is $W[1]$-hard, we get the desired result. ◀

Note that this result does not extend to the distance-$r$ independent set problem. Consider the class of graphs where at least half of its vertices are isolated. Then the distance-$r$ independent set problem is trivially FPT for this graph class. However, this graph class is closed under removing edges, but it is not almost nowhere dense.

## Abstract

We introduce a novel method for the rigorous quantitative evaluation of online algorithms that relaxes the "radical worst-case" perspective of classic competitive analysis. In contrast to prior work, our method, referred to as randomly infused advice (RIA), does not make any assumptions about the input sequence and does not rely on the development of designated online algorithms. Rather, it can be applied to existing online randomized algorithms, introducing a means to evaluate their performance in scenarios that lie outside the radical worst-case regime.

More concretely, an online algorithm ALG with RIA benefits from pieces of advice generated by an omniscient but not entirely reliable oracle. The crux of the new method is that the advice is provided to ALG by writing it into the buffer $\mathcal{B}$ from which ALG normally reads its random bits, hence allowing us to augment it through a very simple and non-intrusive interface. The (un)reliability of the oracle is captured via a parameter $0 \leq \alpha \leq 1$ that determines the probability (per round) that the advice is successfully infused by the oracle; if the advice is not infused, which occurs with probability $1 - \alpha$, then the buffer $\mathcal{B}$ contains fresh random bits (as in the classic online setting).

The applicability of the new RIA method is demonstrated by applying it to three extensively studied online problems: paging, uniform metrical task systems, and online set cover. For these problems, we establish new upper bounds on the competitive ratio of classic online algorithms that improve as the infusion parameter $\alpha$ increases. These are complemented with (often tight) lower bounds on the competitive ratio of online algorithms with RIA for the three problems.

## 1 Introduction

*Competitive ratio* is a widely used metric for evaluating the performance of *online algorithms*. It measures the ratio between the performance of an online algorithm and that of an optimal offline (clairvoyant) algorithm, assuming a worst-case (i.e., adversarial) input sequence. Early on, it has been observed (see, e.g., [53]) that in practice, many online algorithms outperform their theoretical worst-case guarantees. Indeed, in realistic scenarios, the online algorithms tend to "enjoy a good fortune" and rarely encounter the theoretical pitfalls that realize the competitiveness lower bounds (cf. [41]).

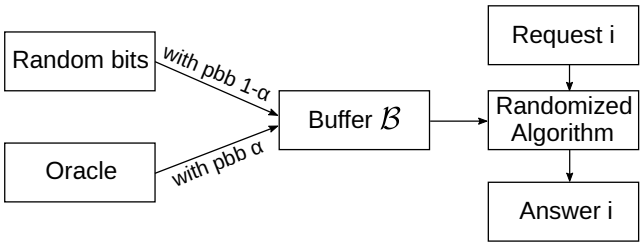

**Figure 1** In each round, the algorithm reads its random bits from buffer $\mathcal{B}$. Under the RIA model, the content of this buffer is replaced by the oracle's advice for that round with probability $\alpha$, independently of other rounds.

This phenomenon has led to extensive research on the analysis of online algorithms beyond the extreme worst-case nature of traditional competitive analysis (see [38] for a recent survey). A prominent approach in this regard is to restrict the power of the adversary that decides on the input sequence, giving rise to the methods of locality of reference [3, 7, 2], access graph [20], smoothed analysis [47, 15], random arrival order [4, 6, 5], independent sampling [27], diffused adversaries [41], and distributional analysis [48, 34]. Another approach is to relax the competitive analysis definition, as done in resource augmentation [50], loose competitiveness [53], and competitiveness with high probability [39]. See also the surveys [29, 23] for additional measures.

In this paper, we wish to advance the study of (randomized) online algorithms beyond worst-case competitive analysis by offering a radically new point of view on the concept of "enjoying a good fortune" (in terms of avoiding the competitiveness pitfalls). Our approach does not restrict the power of the adversary, hence we do not need to justify any assumptions on the request sequence. Moreover, we use the standard definition of competitive analysis (with no relaxations). Last but not least, in contrast to some existing "beyond worst-case" methods, which are limited to certain types of online problems (e.g., locality of reference and access graph), our new method is very general and can be applied to seemingly any online problem.

So, how do we interpret "good fortune" on behalf of a randomized online algorithm ALG without making any assumptions on ALG's input sequence? The answer is simple: we look at the outcome of ALG's random coin tosses. That is, to make ALG more fortunate, all we have to do is to increase the chances of getting good such outcomes.

This raises another question: what makes one outcome of ALG's random coin tosses better than another? To answer this question, we recruit an omniscient *oracle* that generates *advice* for ALG in each round of the execution. The crux of our method, called *randomly infused advice (RIA)*, is that the oracle attempts to write this advice into the buffer $\mathcal{B}$ from which ALG normally reads its random bits. To quantitatively control ALG's good fortune, we introduce an *infusion parameter* $0 \leq \alpha \leq 1$, which determines the probability that the advice is (successfully) infused by the oracle in each round (independently); if the advice is not infused – an event occurring with probability $1 - \alpha$ – then the buffer $\mathcal{B}$ contains fresh random bits (as in the classic online setting). Refer to Figure 1 for an illustration.

We emphasize that the interface between the randomized online algorithm ALG and the oracle is "non-intrusive", i.e., it is defined on top of the standard computational model of (randomized) online algorithms (a.k.a. request-answer games). Therefore, the RIA method is suitable for the analysis of **existing** online algorithms (including classic ones), facilitating the evaluation of their performance beyond the extreme worst-case nature of traditional competitive analysis. This is in contrast to other advice models for online algorithms

(discussed in Section 1.2) in which the oracle-algorithm interface is based on a designated buffer (or tape) from which the algorithm reads the advice. As such, these models require the development of **new**, model-specific, algorithms and cannot be applied to existing ones.

Notice that the RIA model does not impose any limitations on the size of the buffer $\mathcal{B}$, and through it, on the advice size (or the number of random bits) provided to ALG in each round. This raises the concern of making the online algorithm "too powerful" as the (successfully) infused advice may hold excessive information regarding the future requests. To overcome this concern, we restrict our attention to randomized online algorithms which are *randomness-oblivious*, namely, in each round, ALG has access to past requests, past answers, the current request, and the current content of the buffer $\mathcal{B}$ (which contains the current advice or random bits), however ALG cannot access the content of $\mathcal{B}$ in previous rounds. Indeed, all algorithms analyzed in this paper are randomness-oblivious.

The main motivation for studying the RIA method comes from analyzing the performance of randomized online algorithms in scenarios that lie outside the "radical worst-case" regime, assumed in the classic online computation literature. In particular, this new method allows us to compare between different online algorithms that exhibit the same performance guarantees in worst-case scenarios, possibly separating between them in terms of their performance once the scenarios get "a little bit better", and to so without making any explicit assumptions about the request sequence (or the probability distribution thereof).

Another motivation is that the RIA model provides an abstraction for an unreliable predictor (whose role is assumed by the oracle) whose "mistakes" take a random (rather than worst-case) flavor, where the infusion parameter $\alpha$ indicates the (expected) fraction of rounds in which the predictor is correct. In this regard, the non-intrusive interface between the online algorithm and the oracle gives the RIA model a distinctive advantage over existing advice models for online algorithms as it enables the analysis of standard online algorithms in scenarios that include an unreliable predictor, while retaining their worst-case guarantees.

## 1.1 Our Contribution

On top of the conceptual contribution that lies in introducing the RIA model, we make the following technical contribution.

### Upper bounds

The applicability of the new RIA model is demonstrated on three extensively studied online problems: the *paging* problem [50], for which we analyze the classic RandomMark algorithm [32]; the uniform *metrical task system (MTS)* problem [21], for which we analyze the classic UnifMTS algorithm;[1] and the unweighted *online set cover* problem [9], for which we analyze the influential primal-dual algorithm [24, Ch. 4] with randomized rounding (referred to as RandSC). In all cases, our findings are similar to what is called "robustness" and "consistency" in the literature dedicated to online algorithms with predictions [42, 46]: when augmented with RIA, the competitive ratio of these algorithms is never worse than the original, and improves asymptotically as $\alpha \to 1$. Our results are cast in the following three theorems, where we denote the $k$-th harmonic number by $H_k \approx \log k$; we emphasize that in all cases, neither the online algorithm nor the oracle are aware of the infusion parameter $\alpha$.

[1] Due to spatial considerations, the upper bound for uniform MTS is omitted from this version of the paper. Refer to the full version [31] for the upper bound description and analysis.

▶ **Theorem 1.1.** *The competitive ratio of RandomMark augmented with RIA with infusion parameter* $0 \leq \alpha \leq 1$ *on instances of cache size* $k$ *is at most* $\min\{2H_k, \frac{2}{\alpha}\}$.

▶ **Theorem 1.2.** *The competitive ratio of UnifMTS augmented with RIA with infusion parameter* $0 \leq \alpha \leq 1$ *on* $n$*-state instances is at most* $\min\{2H_n, \frac{2}{\alpha} + 2\}$.

▶ **Theorem 1.3.** *The competitive ratio of RandSC augmented with RIA with infusion parameter* $0 \leq \alpha \leq 1$ *on instances with* $n$ *elements and maximum element degree* $d$ *is at most* $O(\min\{\log d \log n, \frac{\log n}{\alpha}\})$.

### Lower bounds

On the negative side, we prove that the upper bound promised in Theorem 1.1 is asymptotically tight for the class of *lazy* algorithms, which are not allowed to change their cache configuration unless there is a page miss.

▶ **Theorem 1.4.** *There does not exist a lazy (randomness-oblivious) online paging algorithm augmented with RIA with infusion parameter* $0 \leq \alpha \leq 1$ *whose competitive ratio on instances of cache size* $k$ *is better than* $\min\{H_k, \frac{1}{\alpha}\}$.

Omitting the restriction to lazy algorithms, we can establish a weaker lower bound.

▶ **Theorem 1.5.** *There does not exist a (randomness-oblivious) online paging algorithm augmented with RIA with infusion parameter* $0 \leq \alpha \leq 1$ *whose competitive ratio on instances of cache size* $k$ *is better than* $\min\{H_k, \frac{1}{k \cdot \alpha}\}$.

The uniform MTS problem generalizes the paging problem on instances that include $n = k + 1$ pages. As Theorems 1.4 and 1.5 hold (already) for such instances, their promised lower bounds are transferred to the uniform MTS problem, where laziness translates to online MTS algorithms that may switch state only when the processing cost is positive [33] (an algorithm class that includes UnifMTS).

▶ **Theorem 1.6.** *There does not exist a lazy (randomness-oblivious) online uniform MTS algorithm augmented with RIA with infusion parameter* $0 \leq \alpha \leq 1$ *whose competitive ratio on* $n$*-state instances is better than* $\min\{H_{n-1}, \frac{1}{\alpha}\}$.

▶ **Theorem 1.7.** *There does not exist a (randomness-oblivious) online uniform MTS algorithm augmented with RIA with infusion parameter* $0 \leq \alpha \leq 1$ *whose competitive ratio on* $n$*-state instances is better than* $\min\{H_{n-1}, \frac{1}{(n-1) \cdot \alpha}\}$.

For online set cover, we establish a lower bound for lazy algorithms, namely, online algorithms which are allowed to buy a set only if it contains the current (uncovered) element (an algorithm class that includes RandSC).

▶ **Theorem 1.8.** *There does not exist a lazy (randomness-oblivious) unweighted online set cover algorithm augmented with RIA with infusion parameter* $0 \leq \alpha \leq 1$ *whose competitive ratio on instances with maximum element degree* $d$ *is better than* $\min\{\frac{1}{2} \log d, \frac{1}{2 \cdot \alpha}\}$.

## 1.2 Novelty and Additional Related Work

### Models of Advice

A well-known and suitable advice model for machine-learned predictions is the model of online algorithms with untrusted advice introduced by Lykouris and Vassilvitskii [42], where the existing literature includes papers on paging [42, 49, 37, 13], metrical task system [11],

and online set cover via the primal-dual approach [12]. In this model, the predictor may be faulty, and the competitive ratio depends on its error so that for low error, the algorithm should perform close to the offline optimum (a.k.a. *consistency*), while even for large error, the algorithm should still fallback to guarantees similar to those of non-augmented online algorithms (a.k.a. *robustness*).

Another well-known advice model is the *perfect* advice model [30, 18] under which many online problems have been studied, including paging, metrical task system [22], and online set cover [28]. In this model, the oracle is fully trustworthy, and its power is therefore quantified via the size (i.e., number of bits) of the advice provided to the online algorithm. This model is related to lookahead [35], where an algorithm is given some number of future requests in advance. The model of perfect advice was later extended to untrusted advice, retaining its focus on measuring the required advice size [10].

Unlike these two advice models, the RIA model does not require any new algorithmic features (e.g., a designated advice tape) and is therefore applicable to existing (standard) online algorithms. Furthermore, our model does not limit the advice size, unlike the perfect advice model, and still allows to arrive at asymptotically tight lower bounds under natural assumptions, in contrast to the machine-learned prediction model where no general lower bounds are known.

#### Online algorithms for paging, MTS, and set cover

Two optimally competitive algorithms for paging are known: PARTITION [43] and EQUITABLE [1]. For the uniform MTS problem, a $(2H_n)$-competitive algorithm was presented in [21], later improved to $H_n + O(\sqrt{\log n})$ in [36]; the latter result nearly matches the $H_n$ lower bound of [21].

For online set cover, the state-of-the-art competitive ratio upper bounds are $O(\log m \log n)$ for the weighted case [9] and $O(\log m \log(n/\mathsf{OPT}))$ for the unweighted case [25], where $m$ and $n$ denote the number of sets (an upper bound on the maximum element degree $d$) and the number of elements, respectively; interestingly, both bounds can be realized by deterministic online algorithms. On the negative side, no (randomized) online algorithm has a competitive ratio better than $\Omega(\log m)$ [40] and no deterministic online algorithm has a competitive ratio better than $\Omega(\log m \log n/(\log\log m + \log\log n))$ [9]. If the (randomized) online algorithm is required to admit a polynomial time implementation, then the competitiveness lower bound improves to $\Omega(\log m \log n)$ assuming that $NP \not\subseteq BPP$ [40].

## 2 Online Algorithms with Randomly Infused Advice

We begin by recalling standard definitions of online algorithms as request-answer games [17]. Our model of online algorithms with randomly infused advice is then defined as a generalization of this model.

### 2.1 Online Algorithms as Request-Answer Games

Consider a finite sequence $\sigma = \langle r_1, \ldots, r_{|\sigma|}\rangle$ of *requests*, where each request $r_i$ is taken from a set $\mathcal{R}$. A *solution* for $\sigma$ is a sequence $\lambda = \langle a_1, \ldots, a_{|\sigma|}\rangle$ of *answers*, where each answer $a_i$ is taken from a set $\mathcal{A}$. For a given minimization problem, the quality of a solution $\lambda$ for a request sequence $\sigma$ is determined by means of a *cost function* $f : \mathcal{R}^{|\sigma|} \times \mathcal{A}^{|\sigma|} \to \mathbb{R} \cup \{\infty\}$.[2] Let $\mathsf{OPT}(\sigma) = \inf_{\lambda \in \mathcal{A}^{|\sigma|}} f(\sigma, \lambda)$ denote the cost of an *optimal solution* for $\sigma$.

[2] We restrict our attention to minimization problems as these are the problems addressed in the current paper. Extending our setting to maximization problems is straightforward.

In the realm of online algorithms, the requests are revealed one-by-one, in discrete *rounds*, so that upon receiving request $r_i$ in round $i$, a (randomized) online algorithm ALG outputs the (random) answer $a_i$ irrevocably. That is, the solution $\lambda_{\mathsf{ALG}} = \langle a_1, \ldots, a_{|\sigma|} \rangle$ produced by ALG is defined so that each answer $a_i$ is computed as a function of (1) the request subsequence $r_1, \ldots, r_i$; (2) the answer subsequence $a_1, \ldots, a_{i-1}$; and (3) round $i$'s random bit string $\mathcal{B}_i \in_R \{0,1\}^L$, where the parameter $L \in \mathbb{Z}_{\geq 0}$ is specified by the algorithm's designer (possibly as a function of the parameters of the problem).[3]

The performance of an online algorithm ALG is measured via competitive analysis: we say that ALG is *c-competitive* if there exists a constant $b$ (that may depend on the parameters of the problem) such that $\mathbb{E}[\mathsf{ALG}(\sigma)] \leq c \cdot \mathsf{OPT}(\sigma) + b$ for any request sequence $\sigma$, where $\mathsf{ALG}(\sigma)$ is the random variable that takes on the cost of the solution produced by ALG in response to a request sequence $\sigma$. The request sequence $\sigma$ is assumed to be determined by a malicious *adversary*; we stick to the convention of an *oblivious adversary* [19, Ch. 4] which means that the adversary knows ALG's description, but is unaware of the outcome of ALG's random coin tosses.

## 2.2 Randomly Infused Advice

In this paper, we introduce an extension of online algorithms, referred to as online algorithms with *randomly infused advice (RIA)*. In the RIA model, an algorithm ALG is assisted by a powerful, yet not entirely reliable, *oracle* that has access to the entire request sequence $\sigma$. Formally, for any request sequence $\sigma = \langle r_1, \ldots, r_{|\sigma|} \rangle$ and round $1 \leq i \leq |\sigma|$, the oracle $\mathcal{O}$ is defined by an *advice function* $\mathcal{O}_{\sigma,i} : \mathcal{A}^{i-1} \to \{0,1\}^L$ that maps each answer subsequence $\langle a_1, \ldots, a_{i-1} \rangle$ to a bit string $\mathcal{O}_{\sigma,i}(a_1, \ldots, a_{i-1}) \in \{0,1\}^L$, referred to as the round $i$'s *advice*. Notice that the length of the advice bit string is equal to the length $L$ of ALG's random bit string.

The RIA model is associated with an *infusion parameter* $0 \leq \alpha \leq 1$ that quantifies the (un)reliability of the oracle $\mathcal{O}$. Specifically, in each round $i$, the bit string $\mathcal{B}_i$ (provided to the online algorithm in that round) is now determined based on the following random experiment (independently of the other rounds): with probability $\alpha$, the round $i$'s advice is *infused* into $\mathcal{B}_i$, that is, $\mathcal{B}_i \leftarrow \mathcal{O}_{\sigma,i}(a_1, \ldots, a_{i-1})$; with probability $1 - \alpha$, the bit string $\mathcal{B}_i$ is picked uniformly at random, that is, $\mathcal{B}_i \in_R \{0,1\}^L$.

In other words, in each round $i$ where the infusion is successful (an event occurring with probability $\alpha$), the oracle's advice "smoothly" substitutes the random bit string $\mathcal{B}_i$ before it is provided to ALG; if the infusion is not successful, then $\mathcal{B}_i$ remains a random bit string. We emphasize that ALG and $\mathcal{O}$ are not aware (at least not directly) of whether the advice is successfully infused in the round $i$, nor are they aware of the infusion parameter $\alpha$ itself.

The competitive ratio of online algorithms ALG with RIA is typically expressed as a function of the infusion parameter $\alpha$, where the extreme case of $\alpha = 0$ corresponds to standard online computation (with no advice). The ultimate goal is to provide guarantees on the competitiveness of ALG for any $0 \leq \alpha \leq 1$.

[3] We use a single parameter $L$ (that is often kept implicit in the online algorithm's description) for simplicity of the exposition; it can be easily generalized to a (not necessarily bounded) sequence $L_1, L_2, \ldots$ of round-dependent parameters.

## 2.3 Randomness-Oblivious Online Algorithms

Recall that the aforementioned definition of online algorithms dictates that when the online algorithm ALG determines the answer $a_i$ associated with round $i$, it is aware of the requests $r_{i'}$ and answers $a_{i'}$ associated with past rounds $i' < i$, as well as the request $r_i$ and random bit string $\mathcal{B}_i$ associated with the current round $i$, however it is not aware (at least not directly) of the random bit strings $\mathcal{B}_{i'}$ associated with past rounds $i' < i$. This model choice is made to prevent an online algorithm ALG with RIA from passing information received through the (successfully infused) advice to future rounds, thus over-exploiting the lack of an explicit (model specific) bound on the length of the random / advice bit strings. To distinguish the online algorithms that adhere to this formulation from general online algorithms (that may maintain a persistent memory that encodes past random bits), we refer to the former as *randomness-oblivious* online algorithms.

# 3 Paging

In the *online paging* problem [50], we manage a two-level memory hierarchy, consisting of a slow memory that stores the set of all $n$ pages, and a fast memory, called the *cache*, that stores any size $k$ subset of pages. We are given a sequence $\sigma$ of requests to the pages. If a requested page is not in the cache, a *page fault* occurs, and the page must be moved to the cache. Since the cache is limited in size, we must specify which page to evict to make space for the requested page. The goal is to minimize the number of page faults.

In this section, we analyze an elegant randomized online algorithm RandomMark, introduced by Fiat, Karp, Luby, McGeoch, Sleator and Young [32], in the randomly infused advice framework. The algorithm RandomMark maintains a bit associated with each page in the cache. Initially the bits of all pages are set to 0 (the pages are *unmarked*), and after requesting a page, we bring it to the cache if it is not in the cache yet, and we set its bit to 1 (we *mark* the page). To bring a page to the cache, we may need to evict another page to make space for it. In such a case, RandomMark evicts a page uniformly at random chosen from the unmarked pages. If no unmarked page exists, we unmark all pages. This strategy has been shown to be $2H_k$-competitive [32], where $H_k$ is the harmonic number, and no randomized algorithm can be better than $H_k$-competitive.

## 3.1 RandomMark With Infused Advice

With help of randomness, the classic RandomMark decides on the final candidate to evict: a random node among unmarked pages. With infused advice, in some rounds the randomness source used by RandomMark contains advice instead of random bits. The presence of clairvoyent advice brings obvious advantages, but also brings challenges: not all pages can be evicted, only the unmarked ones.

### Unmarked Longest-Forward-Distance Oracle

An optimal offline algorithm for paging is to evict the item with the access time furthest in the future [16], also known as *longest forward distance* (LFD) algorithm. However, we cannot directly design an oracle for RandomMark around LFD, as it may advise to evict a marked page, but RandomMark never evicts marked pages. Hence, we propose a variant of this algorithm that can act as an oracle for RandomMark. Such an oracle, denoted $O_{ULFD}$, advises RandomMark to evict the page with the longest forward distance *among the unmarked items* of RandomMark.

### Analysis of RandomMark

How well can RandomMark perform with infused advice? To find out, we consider the RandomMark algorithm assisted with the oracle $O_{ULFD}$, and we express the algorithm's competitive ratio of in terms of the infusion parameter $\alpha$ (the probability of receiving advice in each round). Later in this paper, we will show that RandomMark with $O_{ULFD}$ is asymptotically optimal (Theorem 5.4).

▶ **Theorem 3.1.** *The competitive ratio of RandomMark with the oracle $O_{ULFD}$ with RIA on instances of cache size $k$ (against the oblivious adversary) is at most $\min\{2H_k, \frac{2}{\alpha}\}$, where $H_k$ is the $k$-th harmonic number, and $0 \leq \alpha \leq 1$ is the infusion parameter.*

Before proving this theorem, we recall the definition of a $k$-phase partitioning of an input sequence, and we derive sufficient conditions to stop incurring further page faults in a phase.

We begin by recalling basic definitions from the analysis of RandomMark by [32]. We consider the *$k$-phase partition* of the input sequence $\sigma$, following the notation from [19]: phase 0 is the empty sequence, and each phase $i > 0$ is the maximal sequence following the phase $i-1$ that contains at most $k$ distinct page requests since the start of the $i$th phase. In a phase of any marking algorithm, a page requested in the phase is *stale* if it is unmarked but was marked in the previous phase, and a page is *clean* if it is neither stale nor marked.

In addition to these standard definitions, we define the set of *vanishing pages* as the set of the pages requested in the previous phase, but not in the current phase. We claim that after evicting all vanishing pages, marking algorithms incur no further cost in the phase, since a configuration is reached where all the remaining requests in the current phase are free (page hits).

▶ **Lemma 3.2.** *Fix an input sequence $\sigma$, consider its $k$-phase partition, and fix any phase $P$ that is not the first or the last phase. Then, (1) we have exactly $c$ vanishing pages, where $c$ is the number of clean pages in the phase; and (2) after evicting all vanishing pages, no marking algorithm for paging incurs further cost in the phase.*

**Proof.** In the phase $P$, we have exactly $k$ requests to distinct pages: to $k-c$ stale pages and to $c$ clean pages. Only the clean pages can replace the vanishing pages, hence we have exactly $c$ vanishing pages. Hence, the first claim holds.

If at any point all $c$ vanishing pages are evicted, this means that all $c$ clean pages were requested in the phase already. The remaining requests in the phase can concern only stale pages. As no vanishing pages remain in the cache, the cache consists of $c$ clean pages and $k-c$ stale pages. Hence, after evicting all vanishing pages, any marking algorithm incurs no further cost in the phase, and the second claim holds. ◀

Finally, we prove our main claim for paging: RandomMark is $\min\{2H_k, \frac{2}{\alpha}\}$-competitive. We repeat the classic arguments of [32] to arrive at the bound $2H_k$, and we analyze the offline algorithm *unmarked longest forward distance*, employed by the oracle that probabilistically interacts with the oracle, to arrive at the bound $\frac{2}{\alpha}$.

**Proof of Theorem 3.1.** Fix any input sequence $\sigma$ and consider its $k$-phase partition. Consider any phase that is not the first or the last one. Let $c$ be the number of clean pages in the phase.

We claim that the expected number of page faults is upper bounded by $c/\alpha$. If the algorithm incurs a page fault, and it receives the oracle's advice, and there are still some vanishing pages in the cache, then the algorithm evicts a vanishing page; this follows since

the vanishing pages are not requested in the current phase, hence they have larger forward distance than other stale pages, and the vanishing pages are unmarked. By Lemma 3.2, evicting all vanishing pages means that no further cost is incurred throughout the phase, hence the number of page faults in the phase is upper bounded by the number of page faults until the algorithm receives $c$ rounds of advice from the oracle (not necessarily consecutive). The expected number of page faults until receiving $c$ rounds of advice is $c/\alpha$, since this is the expected number of independent tosses of $\alpha$-biased coin until getting $c$ heads outcomes.

Next, we repeat the classic arguments of [32]: the expected number of page faults of the algorithm is also upper bounded by $c \cdot H_k$. Consider an $i$-th request to a stale page in the phase for $i = 1, 2, 3, \ldots, s$. Let $c(i)$ denote the number of clean pages requested in the phase immediately before the $i$-th request to a stale page, and let $S(i)$ denote the set stale pages that remain in the cache before the $i$-th request to a stale page, and let $s(i) = |S(i)|$. For $i = 1, 2, 3, \ldots, s$, we compute the expected cost of the $i$-th request to a stale page. When the algorithm serves the $i$-th request to a stale page, exactly $s(i) - c(i)$ of the $s(i)$ stale pages are in the cache. The stale pages are in the cache with equal probability, say $p$, since these are never evicted with the help of advice, but are evicted uniformly from unmarked pages when a page fault occurs in rounds without advice. The vanishing pages are in the cache with probability at most $p$, since they can be evicted both in the rounds with and without the advice. For the all $s(i)$ stale pages the probability of being in the cache sums to 1, hence $p \leq 1/s(i)$. Fix a request to a stale page. The page is in the cache with probability $(s(i) - c(i)) \cdot p$, hence the expected cost of the request is

$$1 - (s(i) - c(i)) \cdot p \leq 1 - \frac{s(i) - c(i)}{s(i)} = \frac{c(i)}{s(i)} \leq \frac{c}{k - i + 1}.$$

Hence, the total cost of the request to the stale pages is $\sum_{i=1}^{s} c/(k - i + 1) \leq \sum_{i=2}^{k} c/i = c \cdot (H_k - 1)$. The total cost in the phase includes the cost of serving the clean page and stale pages, in total $c \cdot H_k$.

We conclude that the number of page faults of the algorithm in a phase is upper-bounded by both $c \cdot H_k$ and $c/\alpha$. By arguments of [32, Theorem 1], the amortized number of faults made by OPT during the phase is at least $c/2$. Summing over all phases but the first and the last one, the competitive ratio is at most $\min\{2H_k, \frac{2}{\alpha}\}$. The first and the last phase incurs cost bounded by $2k$, which we account in the additive in the competitive ratio. ◀

The above analysis is asymptotically tight with the lower bound given in Theorem 5.3. However, for the special case $n = k + 1$, the result is tight: the competitive ratio of RandomMark with the oracle $O_{ULFD}$ is $\min\{H_k, \frac{1}{\alpha}\}$, since in each phase but the last phase, any offline algorithm pays at least 1, and the number of clean pages is also 1.

The algorithm RandomMark with perfect advice ($\alpha = 1$) is equivalent to an offline algorithm that evicts the unmarked item with the longest forward distance. The Theorem 3.1 implies that this algorithm is optimal for $n = k + 1$, and a 2-approximation for any $n$.

## 4 Set Cover

In the *set cover* problem, we are given a universe $\mathcal{U}$ of $n$ elements and a set $\mathcal{F} = \{S_1, \ldots, S_m\}$ of $m$ subsets $S_1, \ldots, S_m \subseteq \mathcal{U}$ such that $S_1 \cup \cdots \cup S_m = \mathcal{U}$. For each element $e \in \mathcal{U}$, let $\mathcal{F}(e) = \{S \in \mathcal{F} \mid e \in S\}$ be the collection of sets that cover it. In the online setting, a subset

$\mathcal{U}' \subseteq \mathcal{U}$ of elements arrive one by one in an arbitrary order.[4] Upon the arrival of an element $e$, the algorithm is required to cover it (i.e., if $e$ was not previously covered by the algorithm, then the algorithm must select a set from $\mathcal{F}(e)$). We emphasize that the algorithm does not know $\mathcal{U}'$ (or its size) in advance and that any previously selected set cannot be removed from the solution obtained by the online algorithm. The cost of a solution to the set cover problem is the number of sets selected.

In the standard linear program (LP) relaxation for set cover, each set $S \in \mathcal{F}$ is associated with a variable $x_S$. The objective is to minimize the sum $\sum_{S \in \mathcal{F}} x_S$ subject to the constraints $\sum_{S \in \mathcal{F}(e)} x_S \geq 1$ for each element $e \in \mathcal{U}'$, and $x_S \geq 0$ for all $S \in \mathcal{F}$.

Recall that in the context of set cover in the RIA model, we focus on *lazy* algorithms, i.e., algorithms that adhere to the following restrictions upon the arrival of an elemnt $e$: (1) if $e$ is already covered by the algorithm, then in the current round the algorithm does not select any additional sets to its solution; and (2) if $e$ is not covered yet, then in the current round the algorithm may only select sets from $\mathcal{F}(e)$. Notice that this restriction prevents the trivial oracle strategy of simply advising to select all the sets of an optimal set cover at each round.

We describe an online algorithm with RIA for set cover in three stages. First, we present an algorithm that obtains a fractional solution $\mathbf{x}$ to the relaxed LP. Then, we present an online randomized rounding scheme that can be incorporated into the fractional set cover algorithm to obtain an integral solution which is feasible with high probability. Finally, we present the oracle's advice.

### Fractional set cover algorithm

We use the basic discrete algorithm presented by Buchbinder and Naor in [24, Chapter 4.2, Algorithm 1].[5] The algorithm operates as follows. Initially, set $x_S = 0$ for all $S \in \mathcal{F}$. Upon arrival of an element $e$, if $\sum_{S \in \mathcal{F}(e)} x_S < 1$, then update $x_S \leftarrow 2 \cdot x_S + 1/|\mathcal{F}(e)|$ for all $S \in \mathcal{F}(e)$. Observe that at the end of the round, it is guaranteed that the fractional primal solution maintained by the algorithm satisfies the constraint since the algorithm adds at least $1/|\mathcal{F}(e)|$ to the variable $x_S$ for each set $S \in \mathcal{F}(e)$.

Let $d = \max_{e \in \mathcal{U}'} |\mathcal{F}(e)|$ be the maximum degree of an element. The following assertion on the competitive ratio is established by Buchbinder and Naor in [24].

▶ **Lemma 4.1** ([24]). *The fractional set cover algorithm is $O(\log d)$-competitive.*

### Randomized rounding

An online rounding scheme that randomly obtains an integral solution from the fractional set cover algorithm was constructed by Alon et al. in [8]. The solution produced by the rounding scheme of [8] is feasible with high probability while incurring a multiplicative factor of $O(\log n)$ to the expected cost. However, this rounding method does not fit our advice framework. This is because all random coins are tossed in the beginning to compute a threshold for each set. Thus, we present a slightly different rounding method that fits our framework while maintaining similar guarantees.

The rounding procedure operates as follows. Consider an element $e$ and let $\mathbf{x}$ and $\mathbf{x}_{int}$ be the solution maintained by the fractional algorithm and the (integral) solution maintained by the rounding scheme, respectively, at the time of $e$'s arrival. If $e$ is already covered

[4] While our results in the current section are expressed in terms of the size of the universe $n$, it can be modified to obtain the same asymptotic bounds in terms of the length of the element sequence $|\mathcal{U}'|$.

[5] We note that the algorithm presented in [24] is designed for weighted set cover. The algorithm presented in this paper is its application for the case of unit weights.

by either the current fractional solution or the current integral solution produced by the rounding, then we do nothing (we will later show that the feasibility of $\mathbf{x}_{int}$ is maintained with high probability in this case). Otherwise ($e$ is not covered by both solutions), we update $\mathbf{x}$ according to the fractional algorithm. For each $S \in \mathcal{F}(e)$, let $x_S^{beg}$ be the value of the variable $x_S$ at the beginning of the round and let $\delta(S) = x_S^{beg} + 1/|\mathcal{F}(e)|$ be the additive increase to $x_S$ that occurs during the round. The rounding is obtained by independently selecting each set $S \in \mathcal{F}(e)$ to the cover with probability $\min\{1, \delta(S) \cdot \Theta(\log n)\}$.

We refer to the randomized algorithm described above (i.e., the fractional set cover algorithm combined with the rounding scheme) as RandSC. The properties of RandSC are described in the following lemma.

▶ **Lemma 4.2.** *RandSC is $O(\log n \log d)$-competitive and computes a feasible solution with high probability.*[6]

**Proof.** Let $\mathbf{x}$ be the solution obtained by the fractional algorithm at termination. Recall that in each round, set $S$ is selected with probability at most $\delta(S) \cdot c \log n$ (for a constant $c > 0$). By linearity of expectation, the total expected cost associated with $S$ is $O(\log n) \cdot x_S$. Thus, the expected cost of RandSC is $O(\log n) \cdot \sum_{S \in \mathcal{F}} x_S = O(\log n \log d) \cdot \mathsf{OPT}$.

We now bound the probability that there exists an element that was not covered by the integral solution produced by RandSC when it arrived. Consider an element $e'$ arriving at round $r$. Notice that by construction, $e'$ must be covered by the fractional solution at the end of round $r$. We argue that this implies that $e'$ is covered by the integral solution with high probability. Let $\ell = |\mathcal{F}(e')|$ and let $S^1, \ldots S^\ell$ denote the sets in $\mathcal{F}(e')$. Let us denote by $\delta_{i,j}$ the increase to the variable $x_{S^i}$ associated with set $S^i$ in round $j$ and let $p_{i,j}$ the probability that $S^i$ was selected to the integral solution at round $j$. If $p_{i,j} = 1$ for some $i \leq \ell$ and $j \leq r$, then $e'$ is covered by the end of round $r$ with probability 1. Otherwise, due to the independence of selection events, the probability that $e'$ is not covered by the integral solution at the end of round $r$ is

$$\prod_{i=1}^{\ell} \prod_{j=1}^{r} (1 - p_{i,j}) \leq e^{-\sum_{i=1}^{\ell} \sum_{j=1}^{r} p_{i,j}} = e^{-c \log n \sum_{i=1}^{\ell} \sum_{j=1}^{r} \delta_{i,j}} \leq n^{-c},$$

where the final inequality holds because the fractional algorithm guarantees that $e'$ is covered at round $r$ and thus $\sum_{i=1}^{\ell} \sum_{j=1}^{r} \delta_{i,j} \geq 1$. By a union bound argument, the probability that there exists a set that is not covered by the integral solution is at most $n^{1-c}$. Thus, RandSC produces a feasible solution with probability at least $1 - 1/n^{c-1}$. ◀

## Oracle's advice

The idea of the oracle's advice is to boost the probability of selecting "good" sets while not losing the probabilistic feasibility guarantee of Lemma 4.2. For the sake of analysis, let us assume that the oracle is randomized (observe that this assumption does not enhance the oracle's power since the oracle can deterministically compute an optimal realization of the randomized selection). Let $\mathcal{A}^* \subseteq \mathcal{F}$ be an optimal solution for the set cover instance. Consider the arrival of an element $e$ that was not covered yet by both the fractional and integral solutions and let $p_S$ be the probability that set $S$ is selected in the current round of

[6] For simplicity, RandSC is described as a Monte Carlo algorithm. It can be easily transformed into a Las Vegas algorithm as follows: whenever an element $e$ is not covered by RandSC upon the end of a round, select an arbitrary set that covers $e$ into the solution. Notice that the added expected cost is negligible.

RandSC for each set $S \in \mathcal{F}(e)$. The oracle's advice is as follows: (1) each set $S \in \mathcal{F}(e) \cap \mathcal{A}^*$ is selected to the advice; and (2) each set $S \in \mathcal{F}(e) - \mathcal{A}^*$ is independently selected to the advice with probability $p_S$. Notice that the argument used in Lemma 4.2 regarding the feasibility of the solution still holds since the oracle does not decrease the selection probability of any set at a given round. Denoting this oracle by $O_{boost}$, we can establish the following theorem.

▶ **Theorem 4.3.** *The competitive ratio of RandSC with the oracle $O_{boost}$ against an oblivious adversary is $O(\log n) \cdot \min\{1/\alpha, \log d\}$, where $0 \leq \alpha \leq 1$ is the infusion parameter.*

**Proof.** We start by showing that RandSC with $O_{boost}$ is $O(\log n \log d)$-competitive. Notice that by Lemma 4.2, the total expected cost associated with sets $S \in \mathcal{F} - \mathcal{A}^*$ is $O(\log n \log d) \cdot \mathsf{OPT}$. In addition, the total cost of sets in $\mathcal{A}^*$ is bounded by $|A^*| = \mathsf{OPT}$. Therefore, the expected cost of the solution produced by RandSC with $O_{boost}$ is $O(\log n \log d) \cdot \mathsf{OPT}$.

We now show that RandSC with $O_{boost}$ is $O(\frac{\log n}{\alpha})$-competitive. Consider the run of RandSC with $O_{boost}$ on some element sequence. We refer to a round as a selection round if there exists a set that is selected with a positive probability in that round. Notice that we can bound the cost of RandSC with $O_{boost}$ only in selection rounds (for non-selection rounds no cost is incurred). Observe that in each selection round, the probability of selecting a set from $\mathcal{A}^*$ is at least $\alpha$ (the probability of receiving advice). Moreover, if at some point in the execution all sets from $\mathcal{A}^*$ were selected, then there are no selection rounds after that point (since $\mathcal{A}^*$ covers all elements). Hence, the expected number of selection rounds during the execution is at most $|\mathcal{A}^*|/\alpha$.

To complete our analysis, we argue that the expected cost associated with sets that are not in $\mathcal{A}^*$ at each selection round is $O(\log n)$. Consider a selection round in which an elements $e$ arrived. Recall that for each set $S \in \mathcal{F}(e) - \mathcal{A}^*$, we define $\delta(S) = x_S^{beg} + 1/|\mathcal{F}(e)|$, where $x_S^{beg}$ is the value of variable $x_S$ at the beginning of the round, and select each set $S \in \mathcal{F}(e) - \mathcal{A}^*$ to the cover with probability $\min\{1, \delta(S) \cdot \Theta(\log n)\}$. Thus, the total expected cost that comes from the sets $S \in \mathcal{F}(e) - \mathcal{A}^*$ in the round is bounded by $O(\log n) \cdot \sum_{S \in \mathcal{F}(e) - \mathcal{A}^*} x_S^{beg} + \frac{1}{|F(e)|} \leq O(\log n) \cdot 2 = O(\log n)$. Since the total cost associated with sets from $\mathcal{A}^*$ is at most $|\mathcal{A}^*|$, we get that the total expected cost of RandSC with $O_{boost}$ is $O(\log n) \cdot |\mathcal{A}^*|/\alpha = O(\frac{\log n}{\alpha}) \cdot \mathsf{OPT}$. ◀

# 5 Lower Bounds

In this section we show fundamental limitations of online algorithms with RIA. First, we give a lower bound for competitiveness with RIA for online set cover, under the assumption that the algorithm is lazy (buys sets only when they are needed to cover the current element). Second, we give a lower bound for competitiveness with RIA for paging, that we improve to an asymptotically tight lower bound for the case of lazy algorithms. The lower bound for paging implies the lower bound for the uniform metrical task system.

## 5.1 Online Set Cover

We give a lower bound for the competitive ratio of any online randomized algorithm with RIA for online set cover. The construction of the input sequence is similar to the lower bounds given in [40, Theorem 2.2.1] and [24, Lemma 4.6]. The bound is given for randomness-oblivious (defined in Section 2.3) and lazy algorithms (lazy algorithms are allowed to buy a set only if it contains the current element).

▶ **Theorem 5.1.** *Assume that an online randomized algorithm with RIA for online set-cover is lazy, randomness-oblivious and strictly $c$-competitive against the oblivious adversary. Then $c \geq \min\{\frac{1}{2}\log n, \frac{1}{2\alpha}\}$, where $n$ is the size of the universe of element, and $\alpha$ is the infusion parameter.*

**Proof.** Fix any lazy, randomness-oblivious online randomized algorithm ALG with RIA, its oracle $O$ and the infusion parameter $\alpha$. The adversary is oblivious to random choices of the algorithm, but it has access to the description of the algorithm, the oracle and the infusion parameter, hence can maintain the probability distribution of ALG's cache configurations.

Consider a complete binary tree with $d$ leaves. The items to be covered are the nodes of the tree, and the sets are the $d$ root-leaf paths. Our sequence $\sigma$ will be the items on one root-leaf path, starting from the root and going downward.

We chose the sequence of items to request corresponding to a path in the complete binary tree as follows. Let $F(e)$ be the family of sets that cover the item $e$, and let $p_S$ be the probability that ALG currently has the set $S$ in the solution. The first request is to the root of the tree. For the $i$-th request, we choose one of the children, $x$ or $y$ of the item requested in the $(i-1)$-th request, depending on the probability distribution of the sets that cover these items. To decide between $x$ and $y$, we choose the item $r \in \{x, y\}$ with no smaller sum of the probability mass $\sum_{F(x)} p_S$.

We consider two cases depending on whether or not the algorithm received advice for $\sigma$.

1. Assume the algorithm did not receive advice for $\sigma$. In such case, the algorithm acts as an online algorithm without advice. Notice that the total probability mass of sets that do not appear in subsequent iterations add up to at least $1/2$. Each path has length $\log n$, and the algorithm pays at least $\frac{1}{2}$ for each such round, hence overall the algorithm pays $\frac{1}{2}\log d$.
2. Assume the algorithm received advice for $\sigma$. In expectation, the number of rounds before getting advice is $\frac{1}{\alpha}$, and the algorithm pays at least $\frac{1}{2}$ for each such round, hence in total the algorithm pays at least $\frac{1}{2} \cdot \frac{1}{\alpha} = \frac{1}{2\alpha}$.

Note that $\sigma$ can be covered by a single set, namely the one that corresponds to the leaf where the path ends, hence $\mathsf{OPT}(\sigma) = 1$. The online algorithm pays at least $\min\{\frac{1}{2}\log d, \frac{1}{\alpha}\}$ for any sequence $\sigma$ of the form described above, hence ALG is at least strictly $\min\{\frac{1}{2}\log d, \frac{1}{2\alpha}\}$-competitive. ◀

For lazy algorithms, we can obtain a lower bound in terms of the number of $d$. We say that an online algorithm for online set cover is *lazy* if it buys a set only if the current element is not yet covered, and then it may buy only sets that cover the current element. The next bound is stronger than the previous one, as it the bound is on the competitive ratio in the classic sense, with the possible additive constant, as opposed to the previous bound on the strict competitiveness.

▶ **Theorem 5.2.** *Assume that an online randomized algorithm with RIA for online set-cover is lazy, randomness-oblivious and $c$-competitive against the oblivious adversary. Then $c \geq \min\{\frac{1}{2}\log d, \frac{1}{2\alpha}\}$, where $d$ is the maximum element degree, and $\alpha$ is the infusion parameter.*

**Proof.** We repeat the construction from the previous proof of Theorem 5.1 in phases, in each phase using a binary tree of $2d$ items.

As the algorithm is lazy, it cannot buy sets from future phases, and the sets used in different phases are disjoint, hence advice received in any phase cannot decrease the cost of the algorithm in any future phase.

Fix any phase. We consider two cases depending on whether or not the algorithm received advice in this phase. If the algorithm received advice, then it pays at least $\frac{1}{2} \cdot \frac{1}{\alpha} = \frac{1}{2\alpha}$, as the expected number of rounds in this phase before receiving advice concerning sets in this phase is $\frac{1}{\alpha}$. Otherwise, if the algorithm did not receive advice, then it pays at least $\frac{1}{2} \cdot \log d$, following the arguments from the previous proof.

In total, the algorithm pays at least $\min\{\frac{1}{2}\log d, \frac{1}{2\alpha}\}$ in each phase, and an optimal algorithm can cover the items in each phase using a single set, hence the algorithm is at least $\min\{\frac{1}{2}\log d, \frac{1}{2\alpha}\}$-competitive.

Note that we can repeat this construction arbitrary number of iterations to obtain a lower bound on the competitive ratio, as opposed to a lower bound on strict competitive ratio. In each iteration, we use a new set of items and sets corresponding to a binary balanced tree, and the maximum number of sets that cover any item $d$ does not increase by repeating the construction. Hence, no randomized algorithm with infused advice can be better than $\min\{\frac{1}{2}\log d, \frac{1}{2\alpha}\}$-competitive. ◀

## 5.2 Paging and Metrical Task Systems

In this section we give a lower bound for competitiveness of randomized online algorithms with RIA for paging. The uniform metrical task system problem generalizes the paging problem on instances that include $n = k + 1$ pages, hence the lower bound for paging is a common lower bound for paging and uniform metrical task system. We restrict our attention to randomness-oblivious algorithms, as defined in Section 2.3. Our lower bound for any randomness-oblivious algorithm is loose by a factor of $1/k$; but with the natural assumption that the algorithm is *lazy*, we get rid of the $1/k$ factor, and for lazy algorithms the upper bounds for paging (Theorem 3.1) and uniform metrical task systems (Theorem 11 in the full version [31]) are asymptotically optimal.

To show the lower bound in this section, we apply Yao's Minimax Principle [52] to competitiveness of randomized online algorithms. In the case of classic online algorithms, the lower bound for the competitiveness of the best *deterministic* online algorithm on a distribution of inputs implies a lower bound on the competitiveness of any randomized online algorithm on any input sequence.

We define a deterministic equivalent of algorithms with RIA. To this end, we add to each request the information whether the request is served by a deterministic online algorithm or by the oracle. We will analyze performance of such an algorithm on a distribution of requests, where each round is served by the algorithm with probability $1 - \alpha$, and by the oracle with probability $\alpha$. To give a lower bound for randomness-oblivious algorithms (as defined in Section 2.3), we need to define a deterministic equivalent of such algorithms that we refer to as *deterministic advice-oblivious* algorithms: the answer for each request not served by the oracle is determined by the current request, previous requests and previous answers.

To apply Yao's priciple to competitiveness of randomized online algorithms with RIA, we construct a matrix representation of the game, where the row player corresponds to a deterministic advice-oblivious algorithm combined with the offline oracle algorithm, and the column player represents the adversary who specifies the input sequence. The value in each row-column pair of the matrix equals the expected cost incurred by the algorithm-oracle pair on the input sequence, divided by the cost of an optimal offline solution for the input sequence. The choice of whether the online algorithm or the oracle serves a request is beyond the control of both the adversary and the online algorithm, and to compute the value for a row-column pair we take the expectation over all possibilities where for each request independently, the deterministic algorithm serves the request with probability $1 - \alpha$, and the oracle serves the request with probability $\alpha$. Notably, a randomness-oblivious algorithm is no more powerful than a distribution over the deterministic advice-oblivious algorithms.

▶ **Theorem 5.3.** *Assume that an online randomized algorithm with RIA for online paging is randomness-oblivious and c-competitive against the oblivious adversary. Then* $c \geq \min\{H_k, \frac{1}{k\cdot\alpha}\}$, *where* $\alpha$ *is the infusion parameter.*

**Proof.** To prove the theorem, we apply Yao's Minimax Principle [52] to competitiveness of randomized algorithms. Consider any deterministic advice-oblivious algorithm $A$ for paging, and construct the following distribution over input sequences. Each round is served by $A$ with probability $1-\alpha$, and by the oracle with probability $\alpha$. The distribution over requests to pages is constructed as follows. Let $S = \{p_1, p_2, p_3, \ldots, p_{k+1}\}$ be a set of $k+1$ pages. We construct a probability distribution for choosing a request sequence. The first request $\sigma(1)$ is chosen uniformly at random from $S$. Every other request $\sigma(t)$, $t > 1$, is made to a page that is chosen uniformly at random from $S \setminus \{\sigma(t-1)\}$. A phase starting with $\sigma(i)$ ends with $\sigma(j)$, where $j, j > i$ is the smallest integer such that $\{\sigma(i), \sigma(i+1), \ldots, \sigma(j)\}$ contains $k+1$ distinct pages.

We claim that for any advice-oblivious algorithm, the advice received in past phases cannot reduce the cost of the algorithm in future phases. We argue as follows. First, the advice-oblivious algorithm is forbidden to store past advice in its internal memory for future use. Second, no algorithm can store meaningful advice for the future in its cache configuration: each phase contains requests to $k+1$ different items, so for any cache configuration at the start of the phase, there is always at least 1 *clean page*: a page that is requested in the phase that the algorithm does not have in the cache at the start of the phase.

In our bounds, we use that the average cost of the algorithm for each request is $1/k$; this follows because the requested page is random and each of its pages is outside the cache with equal probability.

We lower-bound the cost of the algorithm in each phase in two ways, depending on whether or not the algorithm receives advice in any round of the phase.

1. Assume that the algorithm does not receive advice in any round of the phase. In such case, the algorithm acts as an online algorithm without advice throughout the phase, and the expected cost of the algorithm in the phase is at least $H_k$, following the standard arguments [44]: the expected length of the phase is $k \cdot H_k$, the average cost of the algorithm for each request is $1/k$, therefore the cost of the algorithm within a phase is at least $H_k$.
2. Assume that the algorithm receives advice in some round of the phase. To receive advice, we need in expectation $1/\alpha$ rounds prior to the advice round. The average cost of the algorithm for each request is $1/k$, hence the expected cost is at least $\frac{1}{k \cdot \alpha}$.

An optimal offline algorithm OPT incurs 1 page fault during each phase, the algorithm pays at least $\min\{H_k, \frac{1}{k \cdot \alpha}\}$, hence by summing over all phases of $\sigma$, we arrive at the desired competitive ratio. ◀

Next, we give an improved lower bound for lazy algorithms for paging. Recall that lazy algorithms for paging are the algorithms that are never allowed to change its cache configuration unless there is a page miss. This class includes RandomMark as well as most other known online paging algorithms. Note that this definition is slightly more general than the usual definition of lazy algorithms, where the algorithm is only allowed to fetch one page per request [19]; the intention of this definition is that the lower bound holds for metrical task systems as well. In the classic setting without infused advice, any algorithm can be turned to a lazy algorithm without increasing its cost; note, however, that the transformed algorithm may not be randomness-oblivious. If we restrict our attention to randomness-oblivious algorithms, the non-lazy algorithms may have an advantage over the lazy algorithms due to non-lazy algorithm's potentially frequent interaction with the oracle, which could be used by the oracle to give advice to prefetch some items even before the first cache miss occurs.

▶ **Theorem 5.4.** *Assume that an online randomized algorithm with RIA for online paging is lazy, randomness-oblivious and c-competitive against the oblivious adversary. Then* $c \geq \min\{H_k, \frac{1}{\alpha}\}$*, where* $\alpha$ *is the infusion parameter.*

**Proof.** To prove the theorem, we apply Yao's Minimax Principle [52] to competitiveness of randomized algorithms. Consider any deterministic advice-oblivious online algorithm and the probability distribution for choosing a request sequence as in the proof of Theorem 5.3.

We claim that for any advice-oblivious algorithm, the advice received in past phases cannot reduce the cost of the algorithm in future phases. We argue as follows. First, the advice-oblivious algorithm is forbidden to store past advice in its internal memory for future use. Second, no algorithm can store meaningful advice for the future in its cache configuration: each phase contains requests to $k+1$ different items, so for any cache configuration at the start of the phase, there is always at least 1 *clean page*: a page that is requested in the phase that the algorithm does not have in the cache at the start of the phase.

We will show that the expected cost of the algorithm is at least $\min\{H_k, \frac{1}{\alpha}\}$ in any phase. We lower-bound the cost of the algorithm in each phase in two ways, depending on whether in this phase the algorithm receives advice in some round with a cache miss or not.

1. Assume that the algorithm does not receive advice in any round with a cache miss. Since the algorithm is lazy, advice received in rounds without cache misses does not influence the algorithm's cache configuration, and since the algorithm is advice-oblivious, it cannot store such advice either. In such case, the algorithm acts as an online algorithm without advice throughout the phase, and the expected cost of the algorithm in the phase is at least $H_k$, following the standard arguments [44]: the expected length of the phase is $k \cdot H_k$, the average cost of the algorithm for each request is $1/k$ because the requested page is random and each of its pages is outside the cache with equal probability, therefore the cost of the algorithm within a phase is $H_k$.
2. Assume that the algorithm receives advice in a round with a cache miss. To receive advice at a round with a cache miss, we need in expectation $1/\alpha$ rounds with cache misses. Each round with a cache miss costs 1, hence the expected cost of the algorithm is at least $1/\alpha$.

An optimal offline algorithm OPT incurs a single page fault during each phase, and the algorithm pays at least $\min\{H_k, \frac{1}{\alpha}\}$, hence by summing over all phases of $\sigma$, we arrive at the desired competitive ratio. ◀

The bound given in Theorem 5.4 is asymptotically tight for lazy algorithms. However, a gap of a constant factor of 2 remains. To address this gap, an optimal randomized algorithm for paging [43] may be a possible direction for future studies.

## 6 Future Work

Our work opens interesting avenues for future research. In particular it will be interesting to further explore the utility of our method applied to other randomized online algorithms. Randomness-oblivious online algorithms are known for many online problems, e.g., all randomized memoryless algorithms [26] such as the COINFLIP algorithm for file migration [51] or the HARMONIC algorithm for $k$-server [14, 45] are randomness-oblivious.

## Abstract

For a given polygonal region $P$, the Lawn Mowing Problem (LMP) asks for a shortest tour $T$ that gets within Euclidean distance $1/2$ of every point in $P$; this is equivalent to computing a shortest tour for a unit-diameter cutter $C$ that covers all of $P$. As a generalization of the Traveling Salesman Problem, the LMP is NP-hard; unlike the discrete TSP, however, the LMP has defied efforts to achieve exact solutions, due to its combination of combinatorial complexity with continuous geometry.

We provide a number of new contributions that provide insights into the involved difficulties, as well as positive results that enable both theoretical and practical progress. (1) We show that the LMP is algebraically hard: it is not solvable by radicals over the field of rationals, even for the simple case in which $P$ is a $2 \times 2$ square. This implies that it is impossible to compute exact optimal solutions under models of computation that rely on elementary arithmetic operations and the extraction of $k$th roots, and explains the perceived practical difficulty. (2) We exploit this algebraic analysis for the natural class of polygons with axis-parallel edges and integer vertices (i.e., polyominoes), highlighting the relevance of turn-cost minimization for Lawn Mowing tours, and leading to a general construction method for feasible tours. (3) We show that this construction method achieves theoretical worst-case guarantees that improve previous approximation factors for polyominoes. (4) We demonstrate the practical usefulness *beyond polyominoes* by performing an extensive practical study on a spectrum of more general benchmark polygons: We obtain solutions that are better than the previous best values by Fekete et al., for instance sizes up to 20 times larger.

# 1 Introduction

Many geometric optimization problems are NP-hard: the number of possible solutions is finite, but there may not be an efficient method for systematically finding a best one. A different kind of difficulty considered in geometry is rooted in the impossibility of obtaining solutions with a given set of construction tools: Computing the length of a diagonal of a square is not possible with only rational numbers; trisecting any given angle cannot be done with ruler and compass, and neither can a square be constructed whose area is equal to that of a given circle.

In this paper, we consider the *Lawn Mowing Problem* (LMP), in which we are given a polygonal region $P$ and a disk cutter $C$ of diameter 1; the task is to find a closed roundtrip of minimum Euclidean length, such that the cutter "mows" all of $P$ , i.e., a shortest tour that moves the center of $C$ within distance $1/2$ from every point in $P$. The LMP naturally occurs in a wide spectrum of practical applications, such as robotics, manufacturing, farming, quality control, and image processing, so it is of both theoretical and practical importance. As a generalization of the classic Traveling Salesman Problem (TSP), the LMP is also NP-hard; however, while the TSP has shown to be amenable to exact methods for computing provably optimal solutions even for large instances [1], the LMP has defied such attempts, with only recently some first practical progress by Fekete et al. [26].

## 1.1 Related Work

There is a wide range of practical applications for the LMP, including manufacturing [5, 31, 32], cleaning [12], robotic coverage [13, 15, 29, 35], inspection [21], CAD [20], farming [6, 16, 40], and pest control [9]. In Computational Geometry, the Lawn Mowing Problem was first introduced by Arkin et al. [3], who later gave the currently best approximation algorithm with a performance guarantee of $2\sqrt{3}\alpha_{\mathrm{TSP}} \approx 3.46\alpha_{\mathrm{TSP}}$ [4], where $\alpha_{\mathrm{TSP}}$ is the performance guarantee for an approximation algorithm for the TSP.

Optimally covering even relatively simple regions such as a disk by a set of $n$ *stationary* unit disks has received considerable attention, but is excruciatingly difficult; see [10, 11, 28, 33, 36, 38]. As recently as 2005, Fejes Tóth [22] established optimal values for the maximum radius of a disk that can be covered by $n = 8, 9, 10$ unit circles. Recent progress on covering by (not necessarily equal) disks has been achieved by Fekete et al. [23, 24].

A first *practical* breakthrough on computing provably good Lawn Mowing tours was achieved by Fekete et al. [26], who established a primal-dual algorithm for the LMP by iteratively covering an expanding *witness set* of finitely many points in $P$. In each iteration, their method computes a lower bound, which involves solving a special case of a TSP instance with neighborhoods, the *Close-Enough TSP* (CETSP) to provable optimality; for an upper bound, the method is enhanced to provide full coverage. In each iteration, this establishes both a valid solution and a valid lower bound, and thereby a bound on the remaining optimality gap. They also provided a computational study, with good solutions for a large spectrum of benchmark instances with up to 2000 vertices. However, this approach encounters scalability issues for larger instances, due to the considerable number of witnesses that need to be placed.

A seminal result on algebraic aspects of geometric optimization problems was achieved by Bajaj [7], who established algebraic hardness for the Fermat-Weber problem of finding a point in $\mathbb{R}^2$ that minimizes the sum of Euclidean distances to all points in a given set. Others have studied the Galois complexity for geometric problems like Graph Drawing or the Weighted Shortest Path Problem [8, 14, 39].

As we will see in the course of our algorithmic analysis the number of turns in a tour is of crucial importance for the overall cost; this has been previously studied by Arkin et al. [2] in a discrete setting. This objective is also of practical importance in the context of physical coverage, e.g., in the context of efficient drone trajectories [9].

## 1.2 Our Results

We provide a spectrum of new theoretical and practical results for the Lawn Mowing Problem.

- We prove that computing an optimal Lawn Mowing tour is algebraically hard, even for the case of mowing a $2 \times 2$ square by a unit-diameter disk, as it requires computing zeroes of high-order irreducible polynomials.
- We exploit the algebraic analysis to achieve provably good trajectories for polyominoes, based on the consideration of turn cost, and provide a method for general polygons.
- We show that this construction method achieves theoretical worst-case guarantees that improve previous approximation factors for polyominoes.
- We demonstrate the practical usefulness *beyond polyominoes* on a spectrum of more general benchmark polygons, obtaining better solutions than the previous values by Fekete et al. [26], for instance sizes up to 20 times larger.

## 1.3 Definitions

A (simple) *polygon* $P$ is a (non-self-intersecting) shape in the plane, bounded by a finite number $n$ of line segments. The *boundary* of a polygon $P$ is denoted by $\partial P$. A *polyomino* is a polygon with axis-parallel edges and vertices with integer coordinates; any polyomino can be canonically partitioned into a finite number $N$ of unit-squares, called *pixels*. A *tour* is a closed continuous curve $T : [0, 1] \to \mathbb{R}^2$ with $T(0) = T(1)$. The *cutter* $C$ is a disk of diameter $d$, centered in its midpoint. Without loss of generality, we assume $d = 1$ for the rest of the paper. The *coverage* of a tour $T$ with the disk cutter $C$ is the Minkowski sum $T \oplus C$. A *Lawn Mowing tour* $T$ of a polygon $P$ with a cutter $C$ is a tour whose coverage contains $P$. An *optimal* Lawn Mowing tour is a Lawn Mowing tour of shortest length.

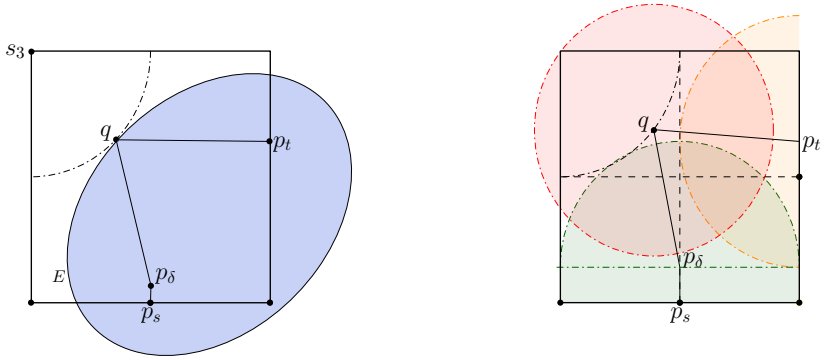
# 2 Algebraic Hardness

In their recent work, Fekete et al. [26] prove that an optimal Lawn Mowing tour for a polygonal region is necessarily polygonal itself; on the other hand, they show that optimal tours may need to contain vertices with irrational coordinates corresponding to arbitrary square roots, even if $P$ is just a triangle. In the following, we show that if $P$ is a $2 \times 2$ square, an optimal tour may involve coordinates that cannot even be described with radicals. See Figure 2 for the structure of optimal trajectories.

▶ **Theorem 1.** *For the case in which $P$ is a $2 \times 2$ square, the Lawn Mowing Problem is algebraically hard: an optimal tour involves coordinates that are zeroes of polynomials that cannot be expressed by radicals.*

## 2.1 Optimal Tours at Corners

For the $2 \times 2$ square $P$, consider the upper left $1 \times 1$ subsquare $S_0$ with corners $(0, 0)$, $(0, 1)$, $(1, 1)$, $(0, 1)$, further subdivided into four $1/2 \times 1/2$ quadrants $S_{0,0}, \ldots, S_{0,3}$, and an optimal path $\omega$ that enters $S_0$ at the bottom and leaves it to the right. Let $p_s = (p_s^x, 0)$, $p_t = (1, p_t^y)$



**(a)** Any $0 \le \delta \le 1$ defines $p_\delta, p_t, q$ and ellipse $E$. **(b)** The optimal path $\omega$ through $S_0$.

**Figure 1** Visualizations for Lemma 4.

be the points where $\omega$ enters and leaves $S_0$, respectively. For the following lemmas, we assume that a covering path exists that obeys the above conditions. We will later determine that path and show that it covers $S_0$. The proofs of Lemmas 2, 3, and 5 can be found in the full version [27].

▶ **Lemma 2.** *$p_s^x \le 1/2$ and $p_t^y \ge 1/2$ and either $p_s^x = 1/2$ or $p_t^y = 1/2$.*

Without loss of generality, we assume that $p_s^x = 1/2$. The next step is to find the optimal position of $p_t$. As an optimal path $\omega$ must enter the quadrant $S_{0,3}$ once, we can subdivide the path into two parts. For some $\delta > 0$, let $p_t^y = 1/2 + \delta$ and $p_\delta = (1/2, \delta)$.

▶ **Lemma 3.** *For any $\delta > 0$, $\omega$ has a subpath $p_s p_\delta$.*

▶ **Lemma 4.** *The uniquely-shaped optimal Lawn Mowing path $\omega$ between two adjacent sides of $S_0$ has length $L_{S_0} \approx 1.309$ with $\omega = (p_s, p_\delta, q, p_t)$ and*

$$p_s = (1/2, 0) \quad p_\delta = (1/2, \delta) \approx (1/2, 0.168) \quad q \approx (0.386, 0.682) \quad p_t = (1, 1/2+\delta) \approx (1, 0.668).$$

**Proof.** Let $s_3$ be the top left corner of $S_0$. We identify a shortest path for visiting one point $q$ on a circle $U$ with diameter 1 centered in $s_3$ dependent on $\delta$, a necessary condition for a feasible path. Let $c = d(p_\delta, q) + d(q, p_t)$ be the distance from both points to $U$. Consider an ellipse $E$ with foci $p_\delta, p_t$ that touches $U$ in a single point, see Figure 1a. By definition, the intersection point $q$ minimizes the distance $c$. For $\delta \in [0, 1]$ we want to find an intersection point between $E$ and $U$ that minimizes distance $c$. We can solve this problem with an exact optimization approach using Mathematica, see the full version of our paper [27]. It turns out that $\delta, q^x, q^y$ can only be expressed as the first, third, and first roots of three irreducible high-degree polynomials $f_\delta, f_{q^x}, f_{q^y}$, see Equation (1) and the full version [27].

$$\begin{aligned} f_\delta(x) =& 589\,824x^{16} - 7\,077\,888x^{15} + 41\,189\,376x^{14} - 154\,386\,432x^{13} + \\ & 416\,788\,480x^{12} - 857\,112\,576x^{11} + 1\,383\,417\,856x^{10} - 1\,779\,354\,624x^9 + \\ & 1\,834\,437\,632x^8 - 1\,514\,108\,928x^7 + 992\,782\,336x^6 - 509\,312\,064x^5 + \\ & 199\,354\,208x^4 - 57\,160\,752x^3 + 11\,200\,088x^2 - 1\,313\,928x + 67\,417 \end{aligned} \tag{1}$$

The value for $\delta \approx 0.167876$ defines the points $p_\delta$ and $p_t$. Together with the values for $q^x, q^y$, we obtain the path above. The combined length of the path is $\delta + c \approx 1.308838224$. As $\omega$ contains a subpath that crosses the full height of $S_{0,0}$ and another subpath that crosses the full width

of $S_{0,2}$, both quadrants are covered by $\omega$, see Figure 1b. By construction, the bottom right quadrant is covered by the segment $p_s p_\delta$ and the point $p_t$. The top left quadrant is covered by $q$, because $S_{0,3}$ is fully contained in a disk with diameter 1 centered in $q$. Therefore, $\omega$ is a feasible path between two adjacent edges of $S_0$ with a length of $L \approx 1.309$. ◀

▶ **Lemma 5.** *A square $P$ of side length 2 has a uniquely-shaped optimal Lawn Mowing tour $T$ of length $L = 4L_{S_0}$, where $L_{S_0} \approx 1.309$.*

## 2.2 Galois Group of the Polynomial

Now we show that the coordinates of the optimal path $\omega$ can not be expressed by radicals. We employ a similar technique as Bajaj [7] for the generalized Weber problem. A *field* $K$ is said to be an *extension* (written as $K/\mathbb{Q}$) of $\mathbb{Q}$ if $K$ contains $\mathbb{Q}$. Given a polynomial $f(x) \in \mathbb{Q}[x]$, a finite extension $K$ of $\mathbb{Q}$ is a *splitting field* over $\mathbb{Q}$ for $f(x)$ if it can be factorized into linear polynomials $f(x) = (x - a_1) \cdots (x - a_k) \in K[x]$ but not over any proper subfield of $K$. Alternatively, $K$ is a splitting field of $f(x)$ of degree $n$ over $\mathbb{Q}$ if $K$ is a minimal extension of $\mathbb{Q}$ in which $f(x)$ has $n$ roots. Then the *Galois group* of the polynomial $f$ is defined as the Galois group of $K/\mathbb{Q}$. In principle, the Galois group is a certain permutation group of the roots of the polynomial. From the fundamental theorem of Galois theory, one can derive a condition for solvability by radicals of the roots of $f(x)$ in terms of algebraic properties of its Galois group. We state three additional theorems from Galois theory and Bajaj's work. The proofs can be found in [7, 34].

▶ **Lemma 6** ([34])**.** *$f(x) \in \mathbb{Q}[x]$ is solvable by radicals over $\mathbb{Q}$ iff the Galois group over $\mathbb{Q}$ of $f(x)$, $Gal(f(x))$, is a solvable group.*

▶ **Lemma 7** ([34])**.** *The symmetric group $S_n$ is not solvable for $n \geq 5$.*

▶ **Lemma 8** ([7])**.** *If $n \equiv 0 \mod 2$ and $n > 2$ then the occurrence of an $(n-1)$-cycle, an $n$-cycle, and a permutation of type $2 + (n-3)$ on factoring the polynomial $f(x)$ modulo primes that do not divide the discriminant of $f(x)$ establishes that $Gal(f(x))$ over $\mathbb{Q}$ is the symmetric group $S_n$.*

**Proof of Theorem 1.** It suffices to show that $f_\delta$ is not solvable by the radicals as it describes the y-coordinates of two points in the solution. We provide three factorizations of $f_\delta$ modulo three primes that do not divide the discriminant $disc(f_\delta(x))$.

$$\begin{aligned} f_\delta(x) \equiv\ & 12(x^{16} + 11x^{15} + 20x^{14} + 20x^{13} + 12x^{12} + 15x^{11} + 20x^{10} + 22x^9 + 19x^8 + 2x^7 + \\ & 18x^6 + 10x^5 + 12x^4 + 19x^3 + 16x^2 + 9x + 8) \mod 23 \\ f_\delta(x) \equiv\ & 21(x + 44)(x^2 + 34x + 39)(x^{13} + 4x^{12} + x^{11} + 41x^{10} + 12x^9 + 21x^8 + 24x^7 + \\ & 32x^5 + 22x^4 + 10x^3 + 24x^2 + 18x + 13) \mod 47 \\ f_\delta(x) \equiv\ & (x + 39)(x^{15} + 8x^{14} + 43x^{13} + 23x^{12} + 19x^{11} + 38x^{10} + 9x^9 + 6x^8 + 17x^7 + \\ & 34x^6 + 46x^5 + 43x^4 + 27x^3 + 50x^2 + 56x + 1) \mod 59 \end{aligned}$$

For the good primes $p = 23, 47$, and 59, the degrees of the irreducible factors of $f_\delta(x)$ mod $p$ gives us an $16 - cycle$, a $2 + 13$ permutation and a 15-cycle, which is enough to show with Lemma 8 and $n = 16$ that $Gal(f_\delta) = S_{16}$. By Lemma 7, $S_{16}$ is not solvable; with Lemma 6, this proves the theorem. ◀

# 3 Mowing Polyominoes

In the following, we analyze good tours for *polyominoes*, which naturally arise when a geometric (or geographic) region is mapped, resulting in axis-parallel edges and integer vertices. In the subsequent two sections, we describe the ensuing theoretical worst-case guarantees (Section 4) and the practical performance (Section 5).

## 3.1 Combinatorial Bounds

For a unit-square cutter, the LMP on polyominoes naturally turns into the TSP on the dual grid graph induced by pixel centers.

▶ **Lemma 9.** *Let $N \geq 2$ be the area of a polyomino $P$ to be mowed with a unit-square cutter, and let $L$ be the minimum length of a Lawn Mowing tour. Then $L \geq N$. In the case of a unit-square cutter, $L = N$ iff the dual grid graph of $P$ has a Hamiltonian cycle.*

This follows from Lemma 2 in the paper by Arkin et al. [4] (which argues that there is an optimal LMP tour for a polyomino whose vertices are pixel centers) and implies the NP-hardness of the LMP (Theorem 1 in [4]). In particular, they focused on grid graphs without a *cut vertex*, which is a node $v$ whose removal disconnects $G$: "If $G$ has a cut vertex $v$, then we can consider separately the approximation problem in each of the components obtained by removing $v$, and then splice the tours back together at the vertex $v$ to obtain a tour in the entire graph $G$. Thus, we concentrate on the case in which $G$ has no cut vertices."

For a simply connected polyomino consisting of $N$ pixels, the corresponding grid graph $G$ does not have any *holes*, i.e., the complement of $G$ in the infinite integer lattice is connected. These allow a tight combinatorial bound on the tour length. If $G$ has no cut vertices, then a combinatorially bounded tour of $G$ exists, as noted by Arkin et al. [4] as follows.

▶ **Theorem 10** (Theorem 5 in [4]). *Let $G$ be a simple grid graph, having $N$ nodes at the centerpoints, $V$, of pixels within a simple rectilinear polygon, $R$, having $n$ (integer-coordinate) sides. Assume that $G$ has no cut vertices. Then, in time $O(n)$, one can find a representation of a tour, $T$, that visits all $N$ nodes of $G$, of length at most $\frac{6N-4}{5}$.*

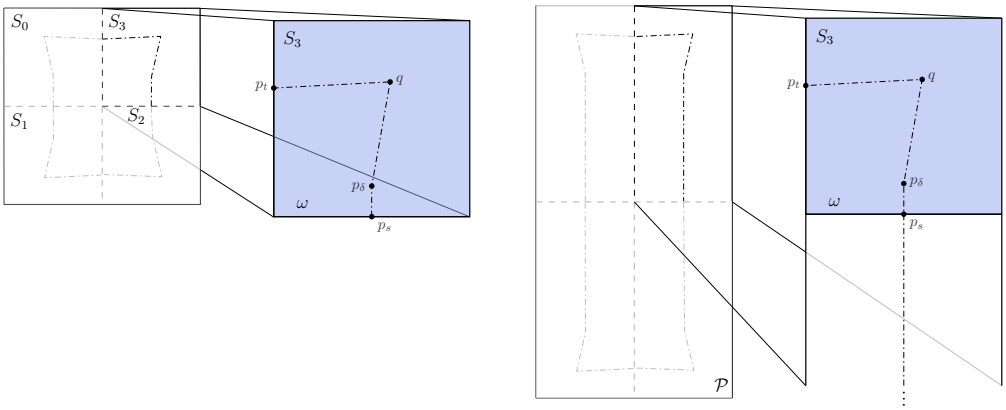
For polyominoes with holes, there is a slightly worse, but still relatively tight combinatorial bound of $\frac{53N}{40} = 1.325N$ for the tour length, as follows.

▶ **Theorem 11** (Theorem 7 in [4]). *Let $G$ be a connected grid graph, having $N$ nodes at the centerpoints, $V$, of pixels within a (multiply connected) rectilinear polygon, $R$, having $n$ (integer-coordinate) sides. Assume that $G$ has no local cut vertices. Then, in time $O(n)$, one can find a representation of a tour, $T$, that visits all $N$ nodes of $G$, of length at most $1.325N$.*

## 3.2 Mowing with a Disk

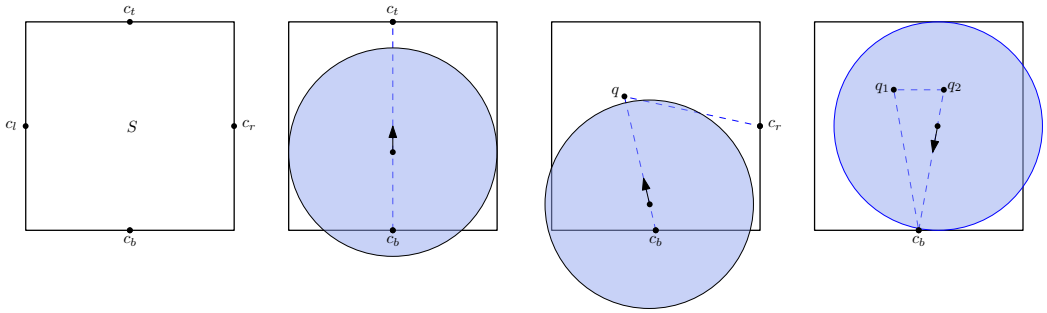
The natural lower bound of Lemma 9 still applies when mowing with a circular cutter, because any unit distance covered by the cutter can at most cover a unit area. However, meeting (or approximating) this bound is no longer possible by simply finding a Hamiltonian cycle (or a good tour) in the underlying grid graph, as a circular cutter may cover already mowed area or area outside of $P$ when dealing with pixel corners. Minimizing this effect ultimately leads to the algebraic analysis from the previous section.

A starting point for further insights is illustrated in Figure 2: The optimal path from Lemma 4 with length $L_{S_0}$ can be used for rectangles with width 2 and arbitrary height $h \geq 2$.



**(a)** Optimal Lawn Mowing tour for a $2 \times 2$ square. **(b)** Optimal Lawn Mowing tour for a rectangle.

**Figure 2** Optimal Lawn Mowing tours for a square and a rectangle.



**(a)** A pixel $S$ with transition points. **(b)** A straight-line covering, with zero turn. **(c)** A covering for a single, 90-degree turn. **(d)** A covering for a double, 180-degree U-turn.

**Figure 3** A pixel $S$ with three elementary covering trajectories.

▶ **Corollary 12.** *Any rectangle $P$ with width 2 and height $h > 2$ has a uniquely-shaped optimal Lawn Mowing tour $T$ of length $L = 4L_{S_0} + 2h - 8$.*

Extending this idea to more general polyominoes leads to realizing a tour of the dual grid with locally optimal "puzzle pieces": a limited set of locally good trajectories that mow each visited pixel, which are merged at transition points on the pixel boundaries; see Figure 3a. The construction of the puzzle pieces is done in Section 3.3.

## 3.3 Constructing Puzzle Pieces

In order to analyze locally good trajectories for mowing visited pixels, consider the four corners of a pixel with coordinates $(0,0), (1,0), (1,1), (0,1)$. We consider *transition points* $c_b = (1/2, 0)$, $c_r = (1, 1/2)$, $c_t = (1/2, 1)$, and $c_l = (0, 1/2)$ at the edge centers to ensure an overall connected trajectory, as shown in Figure 3a. There are three combinatorially distinct ways for visiting a pixel, corresponding to Figures 3b–3d. These are (i) a straight path with length 1, (ii) a simple turn with length $\approx 1.32566$, and (iii) a U-turn with length $\approx 1.611183$, see the full version [27] for details on how to obtain these paths. Note that we do not use the optimal path from Lemma 4, because it uses transition points that are slightly off center, $p_t \neq c_r$, with the imbalance canceled out between two adjacent simple turns. Thus, using central transition points incurs a small marginal cost when compared to an optimal trajectory (1.32566 vs. 1.309, or about 1.2% longer for each simple turn), but it sidesteps the higher-order difficulties of combining longer off-center strips.

### 3.4 Building an Overall Tour

Making use of the puzzle pieces, we can now approach the LMP in three steps, as follows.

**A** Find a cheap roundtrip on the dual grid graph.
**B** Carry out the individual pixel transitions based on the above puzzle pieces as building blocks to ensure coverage of all pixels and thus a feasible tour.
**C** Perform post-processing sensitive to the transition costs on the resulting tour to achieve further improvement.

In the following sections, we describe how the involved steps can be carried out either with an emphasis on worst-case runtime and worst-case performance guarantee (giving rise to theoretical approximation algorithms, as discussed in the following Section 4), or with the goal of good practical performance in reasonable time for a suite of benchmark instances (leading to the experimental study described in Section 5).

## 4 Theoretical Performance: Approximation

For constant-factor approximation, we start with a low-cost roundtrip in the dual grid graph (Step A), e.g., with the previous results of Arkin et al. [4]. Step B is realized using the puzzle pieces of Section 3.3 for a feasible tour, at a cost of $1 + \tau := 1.32566$ for each 90-degree turn in the grid tour (corresponding to piece (ii)); note that the turn cost for a U-turn of 1.61118 (corresponding to piece (iii)) does not exceed $1 + 2\tau$. By using combinatorial arguments for the post-processing Step C, we can prove that a limited number of covering turns (with an additional turn cost $\tau$) suffices for overall feasibility.

▶ **Theorem 13.** *Let $P$ be a polyomino with $N > 5$ pixels, and let $T$ be a tour of the dual grid graph of length $L$. Then we can find a feasible Lawn Mowing tour for a unit-diameter disk of length at most $L(1 + \tau)$.*

**Proof.** Let $T$ be a tour of the dual grid graph; let $L$ be the length of $T$. $L$ is the total number of visits of individual pixels, inducing the following three categories of pixel visits.

1. $L_0$ "free" visits of pixels, in which no covering turn occurs, and no turn cost is incurred.
2. $L_1$ "one-turn" visits of pixels, in which one covering turn occurs, for a turn cost of $\tau$.
3. $L_2$ "U-turn" visits of pixels, in which a double covering turn occurs, for a turn cost of not more than $2\tau$.

Let $p_i$ be a pixel that is visited in step $i$ of the tour by a U-turn of $T$. Then $p_i$ is adjacent to a pixel $q = p_{i-1} = p_{i+1}$ that was left in step $i$ and entered in step $i + 1$. Because no pixel visited by a U-turn needs to be visited more than once, as well as $N > 5$, the pixel $q$ cannot only have neighbors that are visited by U-turns. Therefore, $q$ has a predecessor in the tour that is not a U-turn, (w.l.o.g., $p_{i-2}$); this visit from $p_{i-2}$ is either a one-turn visit with a covering turn, or a free visit. In either case, $q$ is already covered when visited from $p_i$, and we can simply follow the grid path at only the distance cost of 1.

As a consequence, each U-turn visit (incurring a cost not exceeding $2\tau$) can be uniquely mapped to a free visit of its successor (incurring no turn cost), and the overall cost for all covering turns does not exceed $L\tau$, for a total length of at most $L(1 + \tau)$, as claimed. ◀

For simple polyominoes without cut vertices, Theorem 10 provides a tour $T$ in the dual grid graph of length at most $\frac{6N-4}{5}$, implying the following.

▶ **Corollary 14.** *Let $P$ be a simple polyomino with $n$ vertices and $N$ pixels, whose dual grid graph does not have any cut vertices. Then, in time $O(n)$, one can find a representation of a feasible Lawn Mowing trajectory $T$ for a unit-diameter disk of length at most $\frac{6N-4}{5}\tau$, which is within* 1.5908 *of the optimum.*

For polyominoes with holes, we can apply the same line of argument to a tour $T$ of the dual grid graph obtained from Theorem 11.

▶ **Corollary 15.** *Let $P$ be a (not necessarily simple) polyomino with $n$ vertices and $N$ pixels, whose dual grid graph does not have any cut vertices. Then, in time $O(n)$, one can find a representation of a feasible Lawn Mowing trajectory $T$ for a unit-diameter disk of length at most $\frac{53N}{40}\tau$, which is within* 1.7565 *of the optimum.*

As the number of turns is of critical importance for the overall cost of a Lawn Mowing tour obtained from a tour of the dual grid graph, we can consider optimizing a linear combination of tour length and turn cost. Arkin et al. [2] gave a PTAS for this problem, as follows.

▶ **Theorem 16** (Theorem 5.17 in [2])**.** *Define the cost of a tour to be its length plus $C$ times the number of (90-degree) turns. For any fixed $\varepsilon > 0$, there is a $(1+\varepsilon)$-approximation algorithm, with running time $2^{O(h)}N^{O(C)}$, for minimizing the cost of a tour for an integral orthogonal polygon $P$ with $h$ holes and $N$ pixels.*

Combining tour length and turns allows providing more explicit bounds, as follows. Additional local considerations are possible, but these do not necessarily improve the worst-case bounds. Instead, they are employed heuristically in the practical section.

▶ **Theorem 17.** *Let $P$ be a polyomino with $n$ vertices and $N$ pixels, and let $T$ be a tour of the dual grid graph of length $L$ and a total of $t$ (weighted) turns. Then there is a feasible Lawn Mowing tour of cost at most $L + t\tau$.*

# 5 Practical Performance: Algorithm Engineering

## 5.1 Algorithmic Tools

Here we exploit the algorithmic approach of Section 3.4 for good *practical* performance for general polygonal regions, starting with a preprocessing step: For a given polygonal region $Q$, find a suitable polyomino $P$ that covers it.

We can then aim for practical minimization of tour length and turn cost for **A** (analogous to the theoretical Theorem 16), and use puzzle pieces in **B** for a feasible tour. In principle, we can approach **A** by considering an integer program (IP); however, solving this IP becomes too costly for larger instances, so we use a more scalable approach: **(A)** Find a good TSP solution on the dual grid graph; **(B)** insert puzzle pieces; **(C)** minimize the induced turn cost by Integer Programming and Large Neighborhood Search (LNS).

### 5.1.1 Choosing a Suitable Grid

Consider a non-degenerate polygonal region $Q$, and a minimal covering polyomino $P$ of cell size $\ell$. Without loss of generality, $Q$ contains only pixels with a point of $Q$ in their interior; furthermore, we can assume that both an $x$- and a $y$-coordinate of a grid point coincide with a coordinate of $Q$. This limits the number of relevant grid positions to a quadratic number of choices, from which one can choose the one with the smallest number of pixels contained in the resulting polygon $P$.

### 5.1.2 Minimizing Tour and Turn Cost

Finding a covering tour of minimum combined tour length and turn cost can be formulated as an IP. As the cost for each turn can be specified individually in this IP, we can also minimize the final tour length directly instead of just approximating it based on the number of turns. In principle, this IP can be solved with CPLEX [17] or Gurobi [30]; however, this fails when aiming for truly large instances. (Even without the length of the tour, the turn-cost problem is notoriously difficult [25].) Thus, we have pursued an alternative approach that starts with a cheap roundtrip on the dual grid graph in which we ignore the turn cost. We then use this IP as part of a Large Neighborhood Search (described in Section 5.1.4) to minimize the actual costs of this solution, and for computing lower bounds on the best possible solution based on puzzle pieces.

**Formulating the Integer Program.** To formulate the integer program, let $\widehat{uvw}$ with $uv, vw \in E_H$ be the puzzle piece covering the pixel $v$ and connecting $c_{uv}$ and $c_{vw}$, and $\overline{uvw}$ be the direct path between $c_{uv}$ and $c_{vw}$. We call these tour elements (*covering* and *non-covering*) *tiles*. We use the variables $x_{\widehat{uvw}} \in \mathbb{B}, uv, vw \in E_H$ to denote which covering tile, i.e., puzzle piece, is used for $v \in V_P$ is in the tour. For simplicity, $x_{\widehat{uvw}}$ is also defined for $v \in V \setminus V_P$, but fixed to 0. Analogously, we are using the variables $x_{\overline{uvw}} \in \mathbb{N}_0, uv, vw \in E_H$ to denote how often which non-covering tiles, i.e., direct paths, for $v \in V$ are used in the tour. Because we may need to pass a pixel multiple times, this is an integer variable.

Finding the shortest set of cycles that cover all pixels $t \in V_P$ can be expressed as follows. Enforcing a single cycle, i.e., tour, is done later by some more complex constraints that need additional discussion.

$$\min \sum_{uv,vw \in E_H} ||\overline{uvw}|| \cdot x_{\overline{uvw}} + ||\widehat{uvw}|| \cdot x_{\widehat{uvw}} \tag{2}$$

$$\text{s.t.} \sum_{u,w \in N(v)} x_{\widehat{uvw}} = 1 \qquad \forall v \in V_P \tag{3}$$

$$\begin{aligned} &2 \cdot (x_{\overline{wvw}} + x_{\widehat{wvw}}) + \sum_{n \in N(v), n \neq w} (x_{\overline{nvw}} + x_{\widehat{nvw}}) \\ &= 2 \cdot (x_{\overline{vwv}} + x_{\widehat{vwv}}) + \sum_{n \in N(w), n \neq v} (x_{\overline{vwn}} + x_{\widehat{vwn}}) \end{aligned} \qquad \forall vw \in E_H \tag{4}$$

$$x_{\widehat{vwv}} \in \mathbb{B}, x_{\overline{vwv}} \in \mathbb{N}_0 \qquad \forall uv, vw \in E_H \tag{5}$$

The objective function (2) minimizes the sum of lengths of the used tiles (the length of a tile is denoted by $||\cdot||$). Equation (3) enforces that every pixel $v \in V_P$ that intersects the polygon $P$ has one covering tile; $N(v)$ are the neighbors of $v$. Equation (4) ensures that every tile has a matching incident tile on each end, i.e., connecting all tiles yields feasible cycles.

**Subtour Elimination.** Next, we have to add constraints that enforce a single tour. A simple, but insufficient, constraint is similar to the classical subtour elimination constraint of the Dantzig-Fulkerson-Johnson formulation [18] for the Traveling Salesman Problem. For every non-empty subset $S \subset V, S \neq \emptyset, V \not\subset S, V \setminus S \neq \emptyset$ that contains a real part of $V_P$, there has to be some path leaving the set to connect to $V \setminus S$.

$$\sum_{uv,vw \in E_H, v \in S, w \notin S} x_{\overline{uvw}} + x_{\widehat{uvw}} \geq 1$$

Unfortunately, this is not sufficient as we can have cycles that cross but are not connected, e.g., for the tiles $\overline{uvw}$ and $\widehat{svt}$ with $\{u, w\} \cap \{s, t\} = \emptyset$. While they share the same pixel $v$ in the grid graph, the paths themselves do not have to intersect. We can also not expect them to be exchangeable as this may increase the objective. Let $O$ be a cycle of tiles that cover only a real subset of $V_P$, $E(O)$ denote the edges in the grid graph, and $\widehat{abc} \in O$ be a covering tile of $O$ with $b \in V(O) \cap V_P$. The following constraint now forces the path that covers $v$ to change and connect to exterior parts.

$$\sum_{u,w \in N(b), \widehat{ubw} \notin O} x_{\widehat{ubw}} + \sum_{vw \in E(O), u \in N(v), \overline{uvw} \notin O, \widehat{uvw} \notin O} (x_{\overline{uvw}} + x_{\widehat{uvw}}) \geq 1$$

This constraint is sufficient as it can be applied to any cycle that is covering only a subset of $V_P$, but generally less efficient.

### 5.1.3 Finding a Cheap Roundtrip and Ensure Coverage

We consider two different methods for computing different initial tours.

**$\mathsf{TSP}_{\mathsf{Small}}$.** Previous authors [12, 37, 42, 44] have suggested using a grid graph $H'$ with smaller cell size $\ell = \frac{\sqrt{2}}{2}$ for covering $P$, or simply assumed square-shaped tools. This eliminates the need to consider any turn cost, as smaller pixels are covered when the cutter visits their centers. This yields $\mathrm{TSP}_{\mathrm{Small}}$, which we use as a baseline. Because of the smaller grid size, this may result in double coverage when parallel unit strips suffice to cover the $P$, for a worst-case overhead of $\sqrt{2} - 1$, or about 41.4 %.

**$\mathsf{TSP}_{\mathsf{Cov}}$.** As described in the preceding Section 3, we can use a cheap tour for the grid graph $H$ with cell size $\ell = 1$, and perform the puzzle piece modification. This combined solver is called $\mathrm{TSP}_{\mathrm{Cov}}$. As shown in Section 4, we can limit the worst-case overhead for performing turns of $\mathrm{TSP}_{\mathrm{Cov}}$ to $\tau = 0.32566$ per length of the tour, or about 32.6 %.

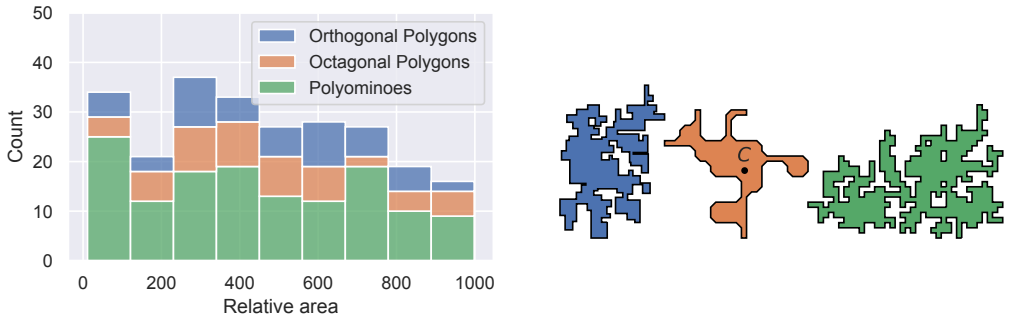
### 5.1.4 Improving the Tour

For a feasible tour from $\mathrm{TSP}_{\mathrm{Cov}}$, we use an LNS-algorithm [41], which iteratively fixes a large part of the IP and only optimizes a small region of tiles; this yields $\mathrm{TSP}_{\mathrm{Turn}}$. We select a random tile from the current tour and a fixed number of adjacent pixels. This yields a limited-size integer program, in which only the involved puzzle pieces are allowed to change. To escape local minima, we tune the size (and runtime) of the IP after each iteration based on the runtime of the previous iteration. In the end, we attempt to solve the IP on the complete instance, using the start solution from the LNS. This provides lower bounds on the best placement of puzzle pieces.

## 5.2 Experimental Setup

Our practical implementation was tested on a workstation with an AMD Ryzen 7 5800X ($8 \times 3.8$ GHz) CPU and 128 GB of RAM. The code and data are publicly available[1]. We used the *srpg_iso*, *srpg_iso_aligned* and *srpg_octa* instances and generated additional polyominoes with the open-source code from the Salzburg Database of Geometric Inputs [19].

[1] https://github.com/tubs-alg/lawn-mowing-from-algebra-to-algorithms



**(a)** Distribution of instances. **(b)** Three instances with the cutter $C$.

**Figure 4** Examples of the used polygons and their size distribution.

See Figure 4 for the overall distribution and Figure 12 in the full version [27] for examples. We considered polygons with up to $n = 300$ vertices and a cutter with diameter 1. Overall, this resulted in 327 instances. All experiments were carried out with a maximum runtime of 300 s for TSP, LNS and final IP computation. To solve the TSP efficiently, we used the python binding *pyconcorde* of the Concorde TSP Solver [43]. All components of $\text{TSP}_{\text{Cov}}$ and $\text{TSP}_{\text{Turn}}$ were implemented in Python 3.10 and used the IP solver Gurobi (v10.0) [30]. As in previous work [26] the *relative area* (ratio of convex hull area of $P$ and cutter area $A(C)$) is more significant for the difficulty of an instance than number of vertices of $P$.

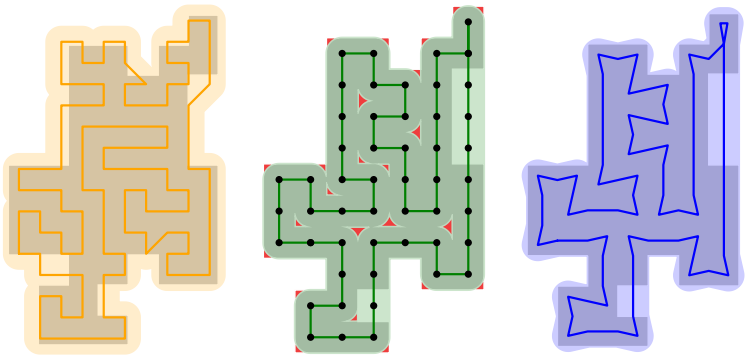


**Figure 5** (Left) A $\text{TSP}_{\text{Small}}$ tour yields a feasible but expensive LMP tour. (Middle) A TSP tour of the underlying dual grid graph, with uncovered patches shown in red. (Right) A feasible LMP tour after puzzle piece modification of the TSP tour.

## 5.3 Evaluation

We discuss our practical results along a number of research questions (RQ).

**RQ1: How does $\text{TSP}_{\text{Cov}}$ compare to $\text{TSP}_{\text{Small}}$ in practice?** We compared the worst-case bound of 32.6 % for $\text{TSP}_{\text{Cov}}$ to the actual performance, using the total cost of $\text{TSP}_{\text{Small}}$ as a baseline. See Figure 5 for an example and Figure 6 for the average relative modification cost. This shows not more than an additional 19 % cost, with only small variation over size and

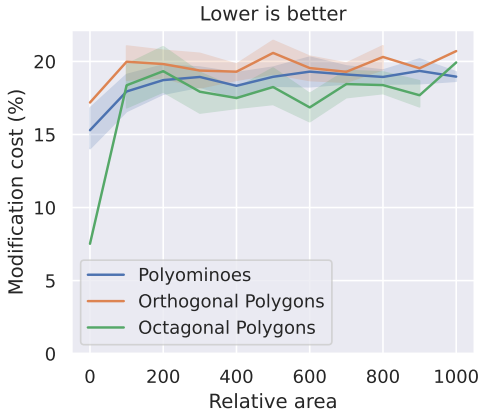

**Figure 6** Modification cost over size and instance type. The modification induces a cost of around 19 % over all instance types and sizes. The plot shows the average modification cost and the 95 % confidence interval.

type. Figure 7b shows that the practical average reduction from $\text{TSP}_{\text{Small}}$ is independent of the size of the polygon, but differs strongly for the different instance classes; we save $\approx 27\,\%$ for polyominoes, $\approx 24\,\%$ for octagonal polygons, and $\approx 5\,\%$ for orthogonal polygons.

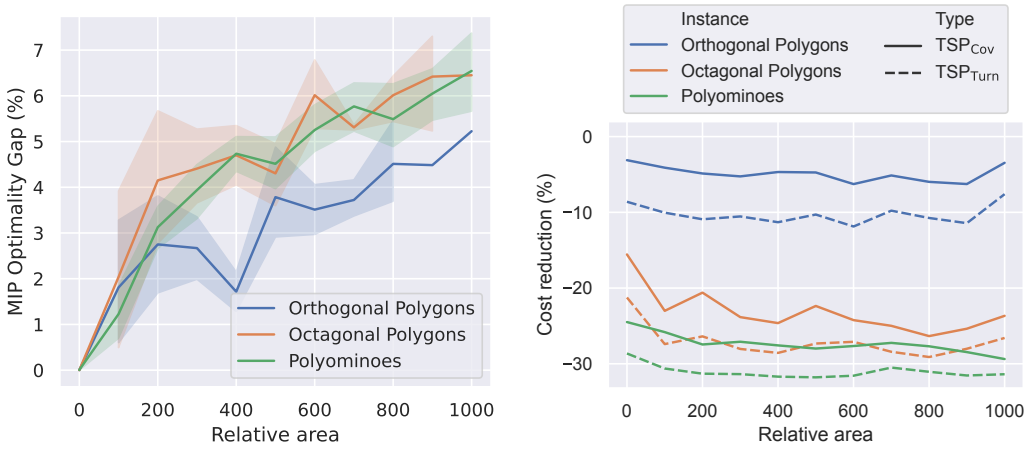
**RQ2: How good are the solutions achieved by $\text{TSP}_{\text{Turn}}$?** For the considered large instances, provably optimal solutions for the turn-cost minimizing IP are hard to find, so we considered the remaining optimality gap in the IP. Figure 7a shows that gaps remain below 7 % even for large instances, and below 5 % on average for medium-sized instances.

We also compared the tours from $\text{TSP}_{\text{Cov}}$ with the cheapest tours obtained by $\text{TSP}_{\text{Turn}}$ and $\text{TSP}_{\text{Small}}$. As shown in Figure 7b, on average we obtain $\approx 5\,\%$ shorter tours when compared to the $\text{TSP}_{\text{Cov}}$ tours, independent of instance size and type. For orthogonal polygons, this doubles the cost reduction.

**RQ3: How far are we from the geometric area lower bound?** A remaining gap between $\text{TSP}_{\text{Turn}}$ and the area bound may result from two sources, both from (i) the quality of the upper bound (and thus $\text{TSP}_{\text{Turn}}$) and (ii) the quality of the area lower bound, for the following reasons. (i) The optimal LMP tour is not restricted to the grid graph $H$, so there may be cheaper tours than what we obtain from $\text{TSP}_{\text{Turn}}$. (ii) The simple area bound (corresponding to Lemma 9) is relatively weak, so it is conceivable that a serious gap to this lower bound remains.

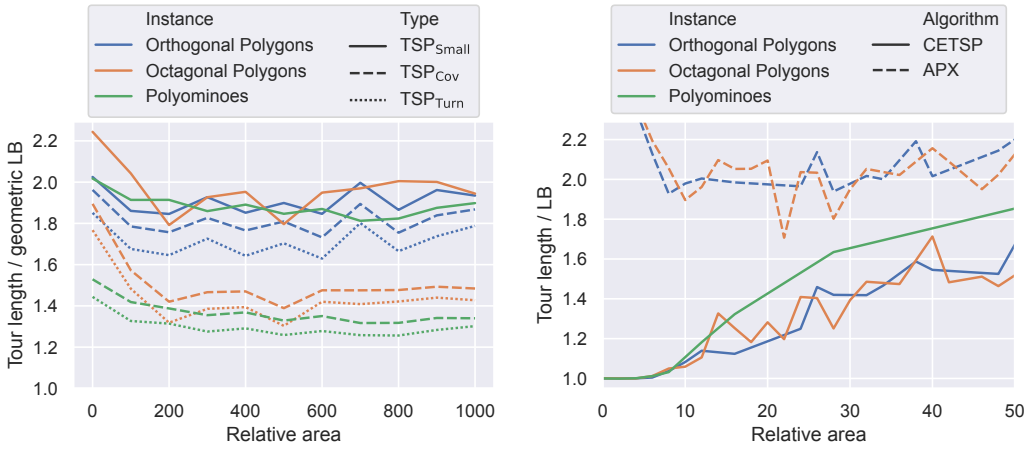
Overall, the combination of both effects remains limited, as can be seen from Figure 8 (showing the ratio of $\text{TSP}_{\text{Turn}}$ value and area bound): For the octagonal polygons and polyominoes, we are on average at most 50 % above the area bound. For orthogonal polygons, the relative gap is on average below 80 %.

**RQ4: How do our solutions compare to previous practical work?** As shown before, our results are already considerably better than work based on $\text{TSP}_{\text{Small}}$. A comparison to the previous best practical results by Fekete et al. [26] (whose instances were used as a subset of our benchmarks) is shown in Figure 8; plotted are the ratios between the achieved solution values and the respective lower bounds. Fekete et al. [26] employ a more sophisticated lower bound based on an evaluation of a series of Close-Enough TSP (CETSP) instances. The



**(a)** Optimality gap of the IP. **(b)** Cost reduction.

**Figure 7** (a) Remaining average optimality gaps for the integer program and the 95 % confidence interval. (b) Comparison of the average cost reduction for different approaches and polygon types.

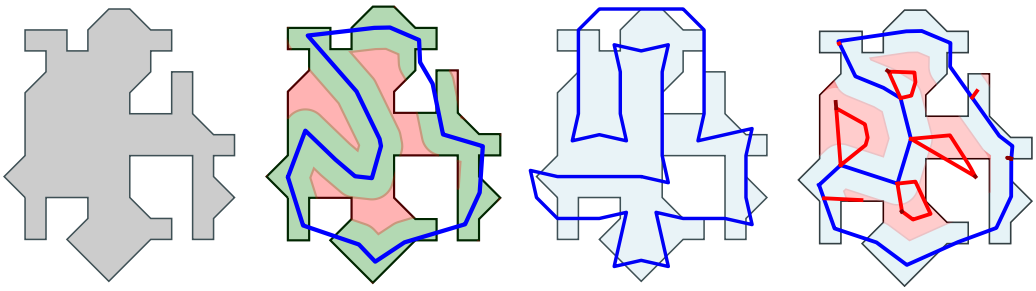


**(a)** Tour length compared to the area bound. **(b)** Solution quality of [26].

**Figure 8** (a) Tour length compared to the (weaker) area lower bound in terms of the average ratio. For octagonal polygons and polyominoes, we can get below 50 % on average. (b) Comparable results for the average solution quality of [26] based on a (stronger) CETSP bound; here APX denotes the performance of the approximation algorithm by [4]. Note the considerably larger relative area in comparison to [26].

authors pointed out that the lower bound computation becomes very expensive even for instances with relative area smaller than 50, see Figures 11 and 12 in [26]. Because we evaluate much larger instances, our ratios only use the relatively straightforward area bound. As a consequence, the denominators of these ratios favor the evaluation for [26], which are shown in Figure 8b; see Figures 9a and 9b for a comparison on a relatively small example that was also shown in [26]. In addition, we were able to achieve results for instances with a relative area 20 times larger than [26].

Despite these additional challenges (of weaker bounds and larger instance sizes), our results compare favorably to the ones reported by [26]. The main reason lies in our structurally simpler approach that still yields good results when the complex evaluation of the CETSP from [26] reaches computational limitations. As can be seen from a comparison of computed trajectories for the visual example (Figures 9c and 9d), this is also reflected in simpler trajectories obtained from $\text{TSP}_{\text{Turn}}$.



**(a)** Area (LB): 36.25. **(b)** LB: 40.94 [26]. **(c)** $\text{TSP}_{\text{Turn}}$ (UB): 66.71. **(d)** UB: 68.16 [26].

**Figure 9** Comparison of $\text{TSP}_{\text{Turn}}$ with lower and upper bounds from Fekete et al. [26].

## 6 Conclusion

We have presented new insights for the Lawn Mowing Problem, starting with an algebraic analysis of the structure of optimal trajectories. As a consequence, we can pinpoint a particular source of the perceived overall difficulty of the problem, and prove that constructing optimal tours necessarily involves operations that go beyond simple geometric means; we can also use these insights to come up with better construction methods for tours, both on the theoretical and the practical side, with minimizing overall turn cost playing a crucial role.

Our results also clear the way for a number of important followup questions. Is it possible to improve our approach for polyominoes? As discussed in the text, considering higher-order connectivity between turns and using slightly off-center, axis-parallel strips appears to be a relatively easy way for (albeit marginal) improvement. It may very well be that this ultimately leads to optimal tours for polyominoes; however, final success on this fundamental challenge will require another breakthrough in establishing lower bounds, as neither the polygon area (which may incur a gap from the optimal value, similar to the number of vertices in a grid graph does from a TSP solution) nor the Close-Enough TSP bound for a finite set of witness points may suffice to certify optimality. Given that an optimal tour may also involve portions that are not axis-parallel, it will also require further algebraic analysis of turns that are not multiples of 90 degrees.

For the Lawn Mowing Problem on general regions (which may not even have to be connected), our hardness result hints at further difficulties. It is quite conceivable that the general LMP is not just algebraically hard, but even $\exists\mathbb{R}$-complete. Even in that case, we believe that further engineering of the tile-based mowing of polyominoes (with attention to turn cost) and Close-Enough TSP may be the most helpful tools for further systematic improvement.

## Abstract

A Monotone Minimal Perfect Hash Function (MMPHF) constructed on a set $S$ of keys is a function that maps each key in $S$ to its rank. On keys not in $S$, the function returns an arbitrary value. Applications range from databases, search engines, data encryption, to pattern-matching algorithms.

In this paper, we describe LeMonHash, a new technique for constructing MMPHFs for integers. The core idea of LeMonHash is surprisingly simple and effective: we learn a monotone mapping from keys to their rank via an error-bounded piecewise linear model (the PGM-index), and then we solve the collisions that might arise among keys mapping to the same rank estimate by associating small integers with them in a retrieval data structure (BuRR). On synthetic random datasets, LeMonHash needs 34% less space than the next larger competitor, while achieving about 16 times faster queries. On real-world datasets, the space usage is very close to or much better than the best competitors, while achieving up to 19 times faster queries than the next *larger* competitor. As far as the construction of LeMonHash is concerned, we get an improvement by a factor of up to 2, compared to the competitor with the next best space usage.

We also investigate the case of keys being variable-length strings, introducing the so-called LeMonHash-VL: it needs space within 13% of the best competitors while achieving up to 3 times faster queries than the next larger competitor.

## 1 Introduction

Given a set $S$ of $n$ keys drawn from a universe $[u] = \{0, \ldots, u-1\}$, a *Monotone Minimal Perfect Hash Function* (MMPHF) is a hash function that maps keys from $S$ to their rank, and returns an arbitrary value for keys not in $S$. As the name suggests, such a function is both *perfect* because it has no collisions on $S$, and *minimal* because its output range is $[n]$. Differently from a *Minimal Perfect Hash Function* (MPHF) [4, 12, 16, 26, 40, 42, 44, 50], which maps keys from $S$ bijectively to $[n]$ in any order, and from an *Order-Preserving MPHF* (OPMPHF) [25], which retains a given (arbitrary) order on the keys, an MMPHF takes advantage of the natural order of the universe to rank the keys in $S$ in small space, i.e. without encoding them. Indeed, encoding $S$ needs $\log \binom{u}{n}/n = \Omega(\log \frac{u}{n})$ bits per key, and encoding the ranks via an OPMPHF needs $\log(n!)/n = \Omega(\log n)$ bits per key, whilst an MMPHF may use as few as $\mathcal{O}(\log \log \log u)$ bits per key [2], which was recently proven to be optimal [1]. Throughout this paper, $\log x$ stands for $\log_2 x$, and we use the $w$-bit word RAM model.

MMPHFs have numerous applications [1]. They enable efficient queries both in encrypted data [11] and databases [39, 41]. Further applications can be found in information retrieval, where MMPHFs can be used to index the lexicon [54] or to compute term frequencies [6, 46], and in pattern matching [5, 27, 32], where MMPHFs are applied mostly to integer sequences representing the occurrences of certain characters in a text.

Despite the widespread use of MMPHFs and recent advancements on their asymptotic bounds [1], the practical implementations have not made significant progress in terms of new designs and improved space-time performance since their introduction more than a decade ago [3], with only some exceptions targeting query time [33]. As a matter of fact, the solutions in [3] are very sophisticated and well-optimised, and they offer a vast number of efficient space-time trade-offs that were hard to beat.

In this paper, we offer a fresh new perspective on MMPHFs that departs from existing approaches, which are mostly based on a trie-like data structure on the keys. We build upon recent advances in (learning-based) indexing data structures, namely the PGM-index [20, 24], and in retrieval data structures (or static functions), namely BuRR [14]. The former learns a piecewise linear approximation mapping keys in $S$ to their rank estimate. The latter allows associating a small fixed-width integer to each key in $S$, without storing $S$. We combine these two seemingly unrelated data structures in a surprisingly simple and effective way. First, we use the PGM to monotonically map keys to buckets according to their rank estimate, and we store the global rank of each bucket's first key in a compressed data structure. Second, since the rank estimate of some keys might coincide, we solve such bucket collisions by storing the local ranks of these keys using BuRR. We call our proposal *LeMonHash*, because it *learns* and *leverages* the smoothness of the input data to build a space-time efficient *monotone* MPHF. On the theoretical side, this achieves $\mathcal{O}(1)$ bits per key for inputs which are sufficiently random within buckets – breaking the superlinear lower bound. Practically, on various integer datasets tried, it needs about one-third less space than previous approaches and is an order of magnitude faster. We also extend LeMonHash to support variable-length string keys. This approach needs space within 13% of the best competitors while being up to 3× faster.

**Outline.** We first describe the basic building blocks of LeMonHash in Section 2 and discuss related work in Section 3. In Section 4, we describe LeMonHash for integers and then extend it to variable-length strings in Section 5. In Section 6, we discuss variants and refinements, before proving the space-time guarantees of LeMonHash in Section 7. In Section 8, we present our experiments. In Section 9, we summarise the paper and give an outlook for future work.

## 2 Preliminaries

In this section, we describe the basic building blocks of LeMonHash.

**Bit Vectors.** Given a bit vector of size $n$ and $b \in \{0,1\}$, the $rank_b(x)$ operation returns the number of $b$-bits before position $x$, and the $select_b(i)$ operation returns the position of the $i$th $b$-bit. These operations can be executed in constant time using as little as $o(n)$ bits on top of the bit vector [13, 34], and they have very space-time efficient implementations [30, 38, 52].

**Elias-Fano.** Elias-Fano Coding [15, 17] is a way to efficiently store a non-decreasing sequence of $n$ integers over a universe of size $u$. An integer at position $i$ is split into two parts. The $\log n$ upper bits $x$ are stored in a bit vector $H$ as a 1-bit in $H[i+x]$. The remaining lower bits are directly stored in an array $L$. Integers can be accessed in constant time by finding the $i$th 1-bit in $H$ using a $select_1$ data structure and by looking up the lower bits in $L$. Predecessor queries are possible by determining the range of integers that share the same upper bits of the query key using two $select_0$ queries, and then performing a binary search on that range. If there are no duplicates, this binary search takes $\mathcal{O}\big(\min\{\log n, \log \frac{u}{n}\}\big)$ time. The space usage of an Elias-Fano coded sequence is $n\lceil \log \frac{u}{n} \rceil + 2n + o(n)$ bits (see [47, §4.4]). Partitioned Elias-Fano [49] is an extension that uses dynamic programming to partition the input into multiple independent Elias-Fano sequences to minimise the overall space usage.

**PGM-index.** The PGM-index [24] is a space-efficient data structure for predecessor and rank queries on a sorted set of $n$ keys from an integer universe $[u]$. Given a query $q \in [u]$, it computes a rank estimate that is guaranteed to be close to the correct rank by a given integer parameter $\varepsilon$. If one stores the input keys, then the correct rank can be recovered via an $\mathcal{O}(\log \varepsilon)$-time binary search on $2\varepsilon + 1$ keys around the rank estimate. The PGM is constructed in $\mathcal{O}(n)$ time by first mapping the sorted integers $x_1, \ldots, x_n$ in $S$ to points $(x_1, 1), \ldots, (x_n, n)$ in a key-position Cartesian plane, and then learning a piecewise linear $\varepsilon$-approximation of these points, i.e. a sequence of $m$ linear models each approximating the rank of the keys in a certain sub-range of $[u]$ with a maximum absolute error $\varepsilon$. The value $m$, which impacts on the space of the PGM, can range between 1 and $m \leq n/(2\varepsilon)$ [24, Lemma 2] depending on the "approximate linearity" of the points. In practice, it is very low and can be proven to be $m = \mathcal{O}\big(n/\varepsilon^2\big)$ when the gaps between keys are random variables from a proper distribution [20]. The time complexity to compute the rank estimate with a PGM is given by the time to search for the linear model that contains the searched key $q$, which boils down to a predecessor search on $m$ integers from a universe of size $u$. For this, there exist many trade-offs in various models of computations [24, 48].

**Retrieval Data Structures.** A *retrieval data structure* or *static function* on a set $S$ of $n$ keys denotes a function $f : S \to \{0,1\}^r$ that returns a specific $r$-bit value for each key. Applying the function on a key not in $S$ returns an arbitrary value. Retrieval data structures take $(1+\eta)rn$ bits, where $\eta \geq 0$ is the *space overhead* over the space lower bound of $rn$ bits.

*MWHC* [43] is a retrieval data structure based on hypergraph peeling, has an overhead $\eta = 0.23$ and can be evaluated in constant time. 2-step MWHC [3] can have a smaller overhead than MWHC by using two MWHC functions of different widths.

The more recently proposed *Bumped Ribbon Retrieval* (BuRR) data structure [14] basically consists of a matrix. The output value for a key can be obtained by multiplying the hash of the key with that matrix. The matrix can be calculated by solving a linear equation

system. Because BuRR uses hash functions with *spacial coupling* [53], the equation system is almost a diagonal matrix, which makes it very efficient to solve. When some rows of the equation system would prevent successful solving, BuRR *bumps* these rows (and the corresponding keys) to the next layer of the same data structure. BuRR has an overhead $\eta = \mathcal{O}\big(\log W/(rW^2)\big)$ and can be evaluated in $\mathcal{O}(1 + rW/\log n)$ time, where $W = \mathcal{O}(\log n)$ is a parameter called ribbon width. In practice, BuRR achieves space overheads well below $\eta = 1\%$ while being faster than widely used data structures with much larger overhead [14].

## 3 Related Work

Non-monotone perfect hash functions are a related and very active area of research [4, 7, 12, 16, 26, 40, 42, 44, 50]. Due to space constraints, we do not review them in detail. For a more detailed list, refer to Ref. [40]. We also do not describe order-preserving minimal perfect hash functions [25] because their theoretical lower bound can trivially be reached by using a retrieval data structure taking $\log n$ bits per key (plus a small overhead). Another loosely related result is using learned models as a replacement for hash functions in traditional hash tables [37, 51], but it generally has a negative impact on the probe/insert throughput (and most likely on the space too, due to the storage of the models' parameters, which these studies do not evaluate). We now look at monotone minimal perfect hash functions, first describing the idea of bucketing before then continuing with specific MMPHF constructions.

**Bucketing.** Bucketing [3] is a general technique to break down MMPHF construction into smaller sub-problems. The idea is to store a simple monotone, but not necessarily minimal or perfect *distributor* function that maps input keys to buckets. Each bucket receives a smaller number of keys that can then be handled using some (smaller) MMPHF data structure. To determine the global rank of a key, we need the prefix sum of the bucket sizes. For equally-sized buckets, this is trivial. Otherwise, this sequence can be stored with Elias-Fano coding. In the paper by Belazzougui et al. [3], where many of the following techniques are described, the authors use MWHC [43] to explicitly store the ranks within each bucket. LeMonHash uses a learned distributor and buckets of expected size 1 (see Section 4).

**Longest Common Prefix.** Bucketing with Longest Common Prefixes (LCP) [2] maps keys to equally sized buckets. A first retrieval data structure maps all keys to the *length* of the LCP among all keys in its bucket. A second one then maps the *value* of the LCP to the bucket index. Overall, it uses $\mathcal{O}(\log \log u)$ bits per key and query time $\mathcal{O}((\log u)/w)$, and in practice it has been shown to be the fastest but the most space-inefficient MMPHF [3].

**Partial Compacted Trie.** First map the keys to equally sized buckets and consider the last key of each bucket as a *router* indexed by a *compacted trie*, e.g., a binary tree where every node contains a bit string denoting the common prefix of its descending keys. During queries, the trie is traversed by comparing the bit string of the traversed nodes with the key to decide whether to stop the search operation at some node (if the prefix does not match), or descend into the left or right subtree based on the next bit of the key. A *Partial Compacted Trie* (PaCo Trie) [3] compresses the compacted trie above by 30–50% by exploiting the fact that, in an MMPHF, the trie needs to correctly rank only the keys from the input set. Therefore, each node can store a shorter bit string just long enough to correctly route all input keys.

**Hollow Trie.** A *Hollow Trie* [3] only stores the *position* of the next bit to look at. Hollow tries can be represented succinctly using balanced parentheses [45]. To use hollow tries for bucketing, and thus allow the routing of not-indexed keys, we need a modification to the data structure. The *Hollow Trie Distributor* [3] uses a retrieval data structure that maps the compacted substrings of each key in each tree node to the behaviour of that key in the node (stopping at the left or right of the node, or following the trie using the next bit of the key). Overall, it uses $\mathcal{O}(\log\log\log u)$ bits per key and query time $\mathcal{O}(\log u)$.

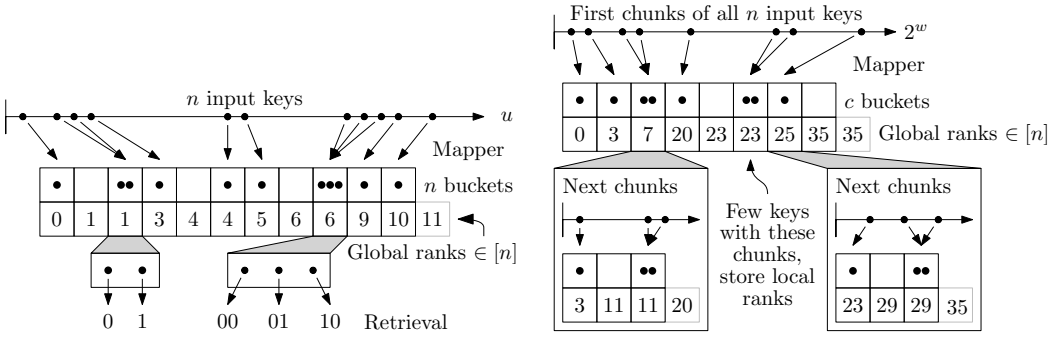
**ZFast Trie.** To construct a *ZFast Trie* [2], we first generate a path-compacted trie. Then, for prefixes of a specific length (*2-fattest number*) of all input keys, a dictionary stores the trie node that represents that prefix. A query can then perform a binary search over the length of the queried key. If there is no node in the dictionary for a given prefix, the search can continue with the pivot as its upper bound. If there is a node, the lower bound of the search can be set to the length of the longest common prefix of all keys represented by that node. The ZFast trie uses $\mathcal{O}(\log\log\log u)$ bits per key and query time $\mathcal{O}((\log u)/w + \log\log u)$.

**Path Decomposed Trie.** In the previous paragraphs, we described binary tries with a rather high height. However, those tries are inefficient to query because of the pointer chasing to non-local memory areas. The main idea behind *Path Decomposed Tries* [18], which can be used as an MMPHF [33], is to reduce the height of the tries. We first select one path all the way from the root node to a leaf. This path is now contracted to a single node, which becomes the root node in our new path decomposed trie. The remaining nodes in the original trie form subtries branching from every node in that path. We take all of these subtries, make them children of the root node, and annotate them by their branching character with respect to the selected path. The subtries are then converted to path decomposed tries recursively. In *centroid* path decomposition, the path to be contracted is always the one that descends to the node with the most leaves in its subtree.

## 4 LeMonHash

We now introduce the main contribution of this paper – the MMPHF LeMonHash. The core idea of LeMonHash is surprisingly simple. We take all the $n$ input integers and map them to $n$ buckets using some *monotone* mapping function, that we will describe later. We store an Elias-Fano coded sequence with the *global ranks* of the first key in each bucket using $2n + o(n)$ bits. Given a bucket of size $b$, we use a $\lceil \log b \rceil$-bit retrieval data structure (see Section 2) to store the *local ranks* of all its keys. Note that we do not need to store local ranks if the bucket has only 0 or 1 keys. For squeezing space, instead of storing one retrieval data structure per bucket, we store a collection of retrieval data structures so that the $i$th one stores the local ranks of all keys mapped to buckets whose size $b$ is such that $i = \lceil \log b \rceil$. An illustration of the overall data structure is given in Figure 1a.

**Bucket Mapping Function.** The space efficiency of LeMonHash is directly related to the quality of the monotone mapping function. For uniform random integers, a linear mapping from input keys to $n$ buckets, i.e. a mapping from a key $x$ to the bucket number $\lfloor xn/u \rfloor$, leads to an MMPHF with a space usage of just 2.915 bits per key (see Theorem 1). Intuitively, such a linear mapping returns a rank estimate in $[n]$ for a given key. However, for skewed distributions, the rank estimate can be far away which can create large buckets whose local ranks are expensive to store. For example, if the majority of the keys are such that $x < u/n$,



**(a)** LeMonHash. Keys are mapped to buckets. Ranks within buckets are stored in (a collection of) retrieval data structures.

**(b)** LeMonHash-VL. Global ranks in each level are stored together. Buckets that are not handled recursively use retrieval data structures like before.

**Figure 1** Illustration of the LeMonHash and LeMonHash-VL data structures.

then the first bucket will be large enough to require $\Theta(\log n)$ bits per key, i.e. our MMPHF degenerates to a trivial OPMPHF. To tackle this problem, we implement the mapping function with a *PGM-index* [24]. As we observed in Section 2, the PGM was originally designed as a predecessor-search data structure. Here, we use the PGM as a *rank estimator* that, for a given key, returns an $\varepsilon$-bounded estimate of its rank. To achieve this result in LeMonHash, we do not store the list of indexed keys and simply use the PGM's rank estimate as the bucket index. The PGM internally adapts to the input data by learning the smoothness in the distribution via a piecewise linear $\varepsilon$-approximation model, thus it can be thought of as a "local" approximation of the linear mapping above. Real-world data sets can often be approximated using piecewise linear models, as discussed in the literature [20] and also demonstrated by the good space efficiency of our experiments (see Section 8). There is a trade-off between the amount of space needed to represent the PGM and the quality of the mapping, which depends on both the input data distribution and the given integer parameter $\varepsilon$. In Section 8, we test both a version with a constant $\varepsilon$ value and a version that auto-tunes its value by constructing multiple PGMs and then selecting the optimal $\varepsilon$. Finally, we observe that with the PGM mapper, unlike for the linear mapping and other non error-bounded learning-based approaches [23, 36], the number of retrieval data structures we need to keep is bounded by $\mathcal{O}(\log \varepsilon)$ regardless of the input key distribution (see Theorem 2).

**Queries.** Given a key $q$, we obtain its bucket $i$ using the mapping function. The global rank of the (first key in the) bucket is the $i$th integer in the Elias-Fano coded sequence of global ranks, which can be accessed in constant time, and the bucket size is computed by subtraction from the next integer in that sequence. The bucket size $b$ directly tells us which retrieval data structure to query, i.e. the $\lceil \log b \rceil$th one. Evaluating the retrieval data structure with $q$ gives us its local rank in the bucket. Adding this to the global rank of the bucket gives us the rank of $q$. As we show in Section 7, for uniform data, the linear bucket mapper gives constant time queries, while for other inputs we use the PGM mapper and the query time is $\mathcal{O}(\log \log u)$.

**Comparison to Known Solutions.** Known MMPHFs in the literature typically divide the keys into equal-size buckets and build a compact trie-based distributor. Unlike them, LeMonHash learns the data linearities and leverages them to distribute keys to buckets close to their rank. Whenever some keys collide into a bucket, LeMonHash handles these keys via

a (small) collection of succinct retrieval structures. In contrast to known solutions, whenever a key is the only one mapped to its bucket, no information needs to be stored in (and no query is issued on) a retrieval data structure. These features allow LeMonHash to possibly achieve reduced space occupancy compared to classic MMPHFs, which are oblivious to data linearities. Also, LeMonHash can reduce the query time by replacing the cache-inefficient traversal of a trie with the PGM mapper, which in practice is fast to evaluate.

## 5 LeMonHash-VL

Of course, the idea of LeMonHash can be immediately applied to keys whose maximum longest common prefix (LCP) is less than $w$ bits. In this case, each string prefix and the following bit (which are sufficient to distinguish every string from each other) fit into one machine word and thus can be handled efficiently in time and in space by the PGM mapper. For strings with longer LCPs, we introduce a tree data structure that we call *LeMonHash-VL* (since it handles Variable-Length strings). The main idea is to simply compute the bucket mapping on a length-$w$ substring of each string, which we call a *chunk*. Buckets that receive many keys using this procedure are then handled recursively. Details follow.

**Overview.** We start with a root node representing all the string keys in $S$ and consider the set of chunks extracted from each key starting from position $|p|$ (which we store), where $p$ is the LCP among the keys in $S$. Given these $c$ distinct chunks, we construct a PGM mapper to distribute the keys to buckets in $[c]$, and we store an Elias-Fano coded sequence with the global ranks of the first key in each bucket. Clearly, different keys can be mapped to the same bucket because the PGM mapper is not perfect (as in the integer case) and because they share the same chunk value (unlike in the integer case). For example, for the strings $S = \{\texttt{cherry}, \texttt{cocoa}, \texttt{coconut}\}$ with $p = \texttt{c}$ and chunks composed of 3 characters, the keys `cocoa` and `coconut` share the chunk value `oco` and will be mapped to the same bucket.

If a bucket of size $b$ contains fewer input strings than a specific threshold $t$, we store the local ranks of the strings in the bucket in a $\lceil \log b \rceil$-bit retrieval data structure. Once again, we do not need to store local ranks if the bucket has only 0 or 1 keys. If instead the bucket is large (i.e. $b \geq t$), we create a *child node* in the tree data structure by applying the same idea recursively on the strings $S'$ of that bucket. This means that we compute a PGM mapper on the chunks extracted from each string in $S'$ starting from position $|p'|$, where $p'$ is the LCP among the bucket strings $S'$. Notice that $|p'| \geq |p|$ but we always guarantee that $S' \subsetneq S$, so the recursion is bounded. In practice, we set the threshold $t = 128$ (see Section 8.1).

At query time, we can use the sequence of global ranks to calculate the bucket size $b$, which allows determining whether we need to continue recursively on a child (because $b \geq t$) or directly return the global rank of the bucket plus the local rank stored in the $\lceil \log b \rceil$-bit retrieval data structure. Figure 1b gives an overview of the data structure.

We observe that the global ranks of each node increase monotonically from left to right in each level of the overall tree. Therefore, we merge all these global ranks in a level into one Elias-Fano sequence, thereby avoiding the space overhead of storing many small sequences.

Of course, each inner node of the tree needs some extra metadata, like the encoding of its bucket mapper, the value of $|p|$, and an offset to its first global rank in the per-level Elias-Fano sequence. We associate a node to its metadata via a minimal perfect hash function, where the identifier of a node is given by the path of the buckets' indices leading to it.

Given the overall idea, there is a wide range of optimisations that we use. In the following, we outline the main algorithmic ones and refer the interested reader to our implementation [28] and the extended version [19] for the many other small-and-tricky optimisations, such as the use of specialised instructions like `popcount` and `bextr`, or lookup tables.

**Alphabet Reduction.** The number of nodes and the depth of LeMonHash-VL depend on both the length and distribution of the input strings, and on how well the PGM mapper at each node can map strings to distinct buckets given their $w$-bit chunks. Therefore, we should aim to fit as much information as possible in the $w$-bit chunks. We do so by exploiting the fact that, in real-world data sets, often only a very small alphabet $\Sigma$ of branching characters distinguish the strings in each bucket, and that we do not care about the other characters. We extract chunks from the suffix of each string starting from the position following the LCP $p$, as before, but interpret the suffix as a number in radix $\sigma = |\Sigma|$ where each character is replaced by its 0-based index in $\Sigma$ if present, or by 0 if not present. For example, for a node on the strings $\{\texttt{shoppers}, \texttt{shopping}, \texttt{shops}\}$ whose LCP is $p = \texttt{shop}$, we would store the alphabet $\Sigma = \{\texttt{e}, \texttt{i}, \texttt{p}, \texttt{s}\}$ and map the suffix "`pers`" of "`shoppers`" to $\text{index}(\texttt{p})\sigma^3 + \text{index}(\texttt{e})\sigma^2 + \text{index}(\texttt{r})\sigma^1 + \text{index}(\texttt{s})\sigma^0 = 2\sigma^3 + 0\sigma^2 + 0\sigma^1 + 3\sigma^0$. Observe that the chunks computed in this way still preserve the lexicographic order of the strings. The number of characters we extract is computed to fit as many characters as possible in a $w$-bit word, i.e. $\lfloor w / \log \sigma \rfloor$ characters. In our implementation over bytes, we store $\Sigma$ via a bitmap of size 128 or 256, depending on whether its characters are a subset of ASCII or not. Finally, we mention that a mapping from strings to numbers in radix $\sigma$ has also been used to build compressed string dictionaries [8], but the twist here is that we are considering only the alphabet of the branching characters since we do not need to store the keys.

**Elias-Fano Sequences.** The large per-level Elias-Fano sequences of global ranks have a very irregular structure. For example, if many of the strings in a node share the same chunks, there is a large gap between two of the stored ranks. We can deal with these irregularities and reduce the overall space usage by using partitioned Elias-Fano [49]. Furthermore, the PGM mappers do not always provide a very uniform mapping, which thus results in empty buckets. An empty bucket corresponds to a duplicate offset value being stored in the Elias-Fano sequences (see e.g. the duplicate offset 23 in Figure 1b). To optimise the space usage of such duplicates, we filter them out before constructing the partitioned Elias-Fano sequence. We do this by grouping the stored numbers in groups of 3 numbers. If all 3 numbers are duplicates of the number before that group, we do not need to store the group. A bit vector with rank support indicates which groups were removed.

**Perfect Chunk Mapping.** In many datasets, there might be only a small number of different chunks, even if the number of strings they represent is large. For instance, chunks computed on the first bytes of a set of URLs might be a few due to the scarcity of hostnames, but each host may contain many distinct pages. In these cases, instead of a PGM, it might be more space-efficient to build a (perfect) map from chunks to buckets in $[c]$ via a retrieval data structure taking $c\lceil \log c \rceil$ bits overall (plus a small overhead), where $c$ is the number of distinct chunks. In practice, we apply this optimisation whenever $c < 128$ (see Section 8.1).

**Comparison to Known Solutions.** In essence, LeMonHash-VL applies the idea of LeMonHash recursively to handle variable-length strings. Therefore, unlike known solutions, it can leverage data linearities to distribute $w$-bit chunks from the input strings to buckets using small space, and use additional child nodes only whenever a bucket contains many strings that thus require inspecting the following chunks to be distinguished. Additionally, it performs an adaptive alphabet reduction within the buckets to fit more information in the $w$-bit chunks, thus leveraging the presence of more regularities in the input data. Overall, these features result in a data structure that has a small height and is efficient to be traversed.

## 6 Variants and Refinements

LeMonHash can be refined in numerous ways, which we only mention briefly due to space constraints. Looking at a possible external memory implementation, LeMonHash can be constructed trivially by a linear sweep and queries are possible using a suitable representation of the predecessor and bucket-size data structures. LeMonHash can also be constructed in parallel without affecting the queries, in contrast to the trivial parallelisation by partitioning the input. In LeMonHash-VL, extracting chunks from non-contiguous bytes reduces the height of the trees but has worse trade-offs in practice. Finally, we present an alternative to storing the local ranks explicitly. The idea is to recursively split the universe size of that bucket and record the number of keys smaller than that midpoint. Despite its query overhead, this technique might be of general interest for MMPHFs. Refer to the extended version [19] for details.

## 7 Analysis

We now prove some properties of our LeMonHash data structure for integers. In our analysis, we use succinct retrieval data structures taking $rn + o(n)$ bits per stored value and answering queries in constant time (see Section 2 and [14]). Furthermore, since our bucket mappers need multiplications and divisions, we make the simplifying assumption $u = 2^w$ to avoid dealing with the increased complexity of these arithmetic operations over large integers.

▶ **Theorem 1.** *A LeMonHash data structure with a bucket mapper that simply performs a linear interpolation of the universe on a list of $n$ uniform random keys needs $\approx n(2.91536 + o(1))$ bits on average*[1] *and answers queries in constant time.*

**Proof.** We approximate the number of keys per bucket using a Poisson distribution which results in $0.91536n + o(n)$ bits of space for the retrieval data structures. On top of that, an Elias-Fano coding of the global bucket ranks gives $2n + o(n)$ bits. Refer to the extended version [19] for the full proof. ◀

While this result is formally only valid for a global uniform distribution, for use in LeMonHash it suffices if each segment computed by the PGM-index is sufficiently smooth. It need not even be uniformly random as long as each local bucket has a constant expected size. As long as the space for encoding the segments is in $\mathcal{O}(n)$ bits, we retain the linear space bound of Theorem 1. Moreover, the following worst-case analysis gives us a fallback position that holds regardless of any assumptions.

▶ **Theorem 2.** *A LeMonHash data structure with the PGM mapper takes $n(\lceil \log(2\varepsilon+1) \rceil + 2 + o(1)) + \mathcal{O}\left(m \log \frac{u}{m}\right)$ bits of space in the worst case and answers queries in $\mathcal{O}\left(\log \log_w \frac{u}{m}\right)$ time, where $m$ is the number of linear models in a PGM with an integer parameter $\varepsilon \geq 0$ constructed on the $n$ input keys.*

[1] Numerically, we find that a better space usage of $\approx 2.902n$ bits can be achieved by mapping the $n$ keys to only $\approx 0.909n$ buckets, but this difference is irrelevant in practice. It is also interesting to note that this is close to the space requirements of most of the practical non-monotone MPHFs [4,7,12,16,26,40,42,44,50]. Using an MMPHF can be useful when indexing an array through an MPHF, because sorting the hash values can be more cache efficient than a large number of random accesses to the array.

**Proof.** The basic idea is that the rank estimate returned by the PGM is guaranteed to be far from the correct rank by $\varepsilon$, which limits the space of the retrieval data structures. The $\mathcal{O}\left(m \log \frac{u}{m}\right)$-term in the space bound is given by a compressed encoding of the linear models in the PGM, and the query time is given by a predecessor search structure on the linear models' keys. Refer to the extended version [19] for the full proof. ◀

The worst-case bounds obtained in Theorem 2 are hard to compare with the ones of classic MMPHF (see Section 3) due to the presence of $m$ (and $\varepsilon$), which depends on (and must be tuned according to) the approximate linearity of the input data, which classic MMPHFs are oblivious to.[2] Refer to Section 2 for bounds on $m$. Our experiments show that we obtain better space or space close to the best classic MMPHFs, while being much faster (we use a weaker but practical predecessor search structure than the one in Theorem 2). Refer to Section 8 for details.

## 8 Experiments

In the following section, we first compare different configurations of LeMonHash and LeMonHash-VL before comparing them with competitors from the literature.

**Experimental Setup.** We perform our experiments on an Intel Xeon E5-2670 v3 with a base clock speed of 2.3 GHz running Ubuntu 20.04 with Linux 5.10.0. We use the GNU C++ compiler version 11.1.0 with optimisation flags `-O3 -march=native`. As a retrieval data structure, we use BuRR [14] with 64-bit ribbon width and 2-bit bumping info. To store the bucket sizes, we use the select data structure by Kurpicz [38] in LeMonHash and Partitioned Elias-Fano [49] in LeMonHash-VL. To map tree paths to the node metadata, we use the MPHF PTHash [50]. For the PGM implementation in LeMonHash, we use the encoding from Theorem 2 and use a predecessor search on the Elias-Fano sequence (Section 2). In LeMonHash-VL, since the number of linear models in a node is typically small, we encode them explicitly as fixed-width triples (*key*, *slope*, *intercept*) and find the predecessor via a binary search on the keys. All our experiments are executed on a single thread. Because the variation is very small, we run each experiment only twice and report the average. We run the Java competitors on OpenJDK 17.0.4 and perform one warm-up run for the just-in-time compiler that is not measured. With this, the Java performance is expected to be close to C++ [3]. Because Java does not have an unsigned 64-bit integer type, we subtract $2^{63}$ from each input key to keep their relative order.

The code and scripts needed to reproduce our experiments are available on GitHub under the General Public License [28, 29].

**Datasets.** Our datasets, as in previous evaluations [3, 33], are a *text* dataset that contains terms appearing in the text of web pages [3] and *urls* crawled from .uk domains in 2007 [10]. Additionally, we also test with *dna* sequences consisting of 32-mers [22]. Regarding real-world integer datasets, *5gram* contains positions of the most frequent letter in the BWT of a text file containing 5-grams found in books indexed by Google [9, 31]. The *fb* dataset contains Facebook user IDs [35] and *osm* contains OpenStreetMap locations [35]. As synthetic integer datasets, we use 64-bit *uniform*, *normal*, and *exponential* distributions. Refer to Table 1 for details.

[2] This happens also in other problems in which data is encoded with linear models [9, 21].

**Table 1** Datasets used for the experiments, together with their length or average (ø) length. Top: real-world string datasets. Middle: real-world integer datasets. Bottom: synthetic integer datasets.

| Dataset | $n$ | Length | Description |
|---|---|---|---|
| text | 35M | ø 11 bytes | Terms appearing in the text of web pages, GOV2 corpus [3] |
| dna | 367M | 32 bytes | 32-mer from a DNA sequence, Pizza&Chili corpus [22] |
| urls | 106M | ø 105 bytes | Web URLs crawled from .uk domains in 2007 [10] |
| 5gram | 145M | 32 bits | Positions of the most frequent letter in the BWT of a text file containing 5-grams found in books indexed by Google [9, 31] |
| fb | 200M | 64 bits | Facebook user IDs [35] |
| osm | 800M | 64 bits | OpenStreetMap locations [35] |
| uniform | 100M | 64 bits | Uniform random |
| normal | 100M | 64 bits | Normal distribution ($\mu = 10^{15}$, $\sigma^2 = 10^{10}$) |
| exponential | 100M | 64 bits | Exponential distribution ($\lambda = 1$, scaled with $10^{15}$) |

## 8.1 Tuning Parameters

In the following section, we compare several configuration parameters of LeMonHash and show how they provide a trade-off between space usage and performance.

**LeMonHash.** Different ways of mapping the keys to buckets have their own advantages and disadvantages. Table 2 gives measurements of the construction and query throughput, as well as the space consumption of different bucket mappers. Our implementation of LeMonHash with a linear bucket mapper achieves a space usage of $2.94n$ bits, which is remarkably close to the theoretical space usage of $2.91n$ bits (see Theorem 1). Of course, a global, linear mapping does not work for all datasets. A bucket mapper that creates equal-width segments by interpolating between sampled keys (denoted as "Segmented" in the table) is fast to construct and query, and it achieves good space usage. But, as for the global linear mapping, this approach is not robust enough to manage arbitrary input distributions. In particular, for this heuristic mapper, it is easy to come up with a worst-case input that degenerates the space usage. Conversely, with the PGM mapper, LeMonHash still achieves $2.96n$ and $2.98n$ bits on uniform random integers but it is more performant and robust on other datasets (except on osm, where the heuristic mapper obtains a good enough mapping with only its equal-width segments, which are inexpensive to store). In fact, we explicitly avoided heuristic design choices in our PGM mapper (such as sampling input keys, removing outliers, or using linear regression) to not inflate our performance on the tested datasets at the expense of robustness on unknown ones (see Ref. [36]). Finally, on most input distributions, auto-tuning the value of $\varepsilon \in \{15, 31, 63\}$ does not have a large effect on the space usage.

**LeMonHash-VL.** Table 3 lists the effect of alphabet reduction on the query and construction performance. In general, alphabet reduction enables noticeable space improvements with only a small impact on the construction time. For the dna dataset, which uses only 15 different characters, the alphabet reduction has the largest effect, saving 1.3 bits per key and simultaneously making the queries 40% faster. The faster queries can be explained by the reduced tree height. Note that alphabet reduction makes the queries slightly slower for the other datasets. The reason is that instead of one single `bswap` instruction for chunk extraction, it needs multiple arithmetic operations (including `popcount`) for each input character. The

**Table 2** Comparison of different bucket mappers. The space usage is given in bits per key, the query throughput in kQueries/second, and the construction throughput (c.t.) in MKeys/second.

| Dataset | Linear mapper | | | PGM $\varepsilon = \text{auto}$ | | | PGM $\varepsilon = 31$ | | | Segmented | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | bpk | kq/s | c.t. | bpk | kq/s | c.t. | bpk | kq/s | c.t. | bpk | kq/s | c.t. |
| 5gram | 5.60 | 1833.5 | 6.2 | 2.62 | 1747.0 | 3.8 | 2.63 | 1779.4 | 8.5 | 2.64 | 2145.9 | 14.5 |
| fb | 34.35 | 0.8 | 5.1 | 4.91 | 1156.1 | 2.8 | 4.91 | 1150.7 | 5.1 | 4.93 | 1441.3 | 7.2 |
| osm | 12.92 | 1525.3 | 5.5 | 4.42 | 999.6 | 2.8 | 4.42 | 998.6 | 5.0 | 4.33 | 1272.9 | 6.8 |
| uniform | 2.94 | 3244.6 | 8.7 | 2.96 | 1903.3 | 3.5 | 2.98 | 1850.5 | 6.5 | 3.03 | 2192.0 | 8.7 |
| normal | 34.27 | 105.3 | 4.8 | 2.95 | 1935.0 | 3.6 | 2.97 | 1858.0 | 6.6 | 3.00 | 1727.7 | 8.7 |
| exponential | 5.42 | 2715.9 | 6.0 | 2.95 | 1876.9 | 3.6 | 2.98 | 1791.5 | 6.6 | 3.01 | 2085.1 | 8.8 |

**Table 3** Comparison of different variants of LeMonHash-VL. The space usage is given in bits per key, the query throughput in kQueries/second, and the construction throughput (c.t.) in MKeys/second. Variants with and without alphabet reduction (AR), a special indexed variant (Idx, see the extended version [19]), and a variant with fixed instead of auto-tuned parameter $\varepsilon$ for the bucket mapper.

| Dataset | $\varepsilon = \text{auto}$, no AR | | | $\varepsilon = \text{auto}$, AR | | | $\varepsilon = 63$, AR | | | Idx, $\varepsilon = \text{auto}$, AR | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | bpk | kq/s | c.t. | bpk | kq/s | c.t. | bpk | kq/s | c.t. | bpk | kq/s | c.t. |
| text | 6.52 | 1062.9 | 1.7 | 6.03 | 1005.8 | 1.6 | 6.08 | 1001.8 | 2.5 | 6.10 | 933.2 | 2.3 |
| dna | 7.66 | 452.8 | 2.0 | 6.32 | 631.3 | 1.7 | 6.25 | 644.8 | 2.7 | 6.27 | 601.1 | 2.4 |
| urls | 7.14 | 282.7 | 2.3 | 6.37 | 298.8 | 1.8 | 6.46 | 295.1 | 2.3 | 6.63 | 298.1 | 1.6 |

indexed variant that builds chunks from the distinguishing bytes instead of a contiguous byte range (see the extended version [19]) is slower to construct but does not show clear space savings, which can be explained by larger per-node metadata. We also experimented with different thresholds for when to stop recursion, as well as the perfect chunk mapping (see Section 5). Given that the space overhead from each bucket mapper is the same for all data sets, it is not surprising that the same threshold (128 keys) works well for all datasets (see the extended version [19]). Finally, making the $\varepsilon$ value of the PGM mapper constant instead of auto-tuned, we naturally get faster construction. As in the integer case, one would expect a fixed $\varepsilon$ value to always produce results that are the same or worse than the auto-tuned version. This is not the case because, in the recursive setting, it is hard to estimate the effect of a mapper on the overall space usage. Therefore, an $\varepsilon$ value that needs more space locally can lead to a mapping that proves useful on a later level of the tree. This is why $\varepsilon = 63$ can achieve better space usage than the auto-tuned version on the dna dataset.

## 8.2 Comparison with Competitors

In this section, we compare the performance of LeMonHash and LeMonHash-VL with competitors from the literature. Competitors include the C++ implementation by Grossi and Ottaviano [33] of the Centroid Hollow Trie, Hollow Trie, and Path Decomposed Trie. Because that implementation only supports string inputs, we convert the integers to a list of fixed-length strings. We point out that the Path Decomposed Trie crashes at an internal assertion when being run on integer datasets. For the Hollow Trie, we encode the skips with either Gamma or Elias-Fano coding, whatever is better on the dataset. We also include the Java

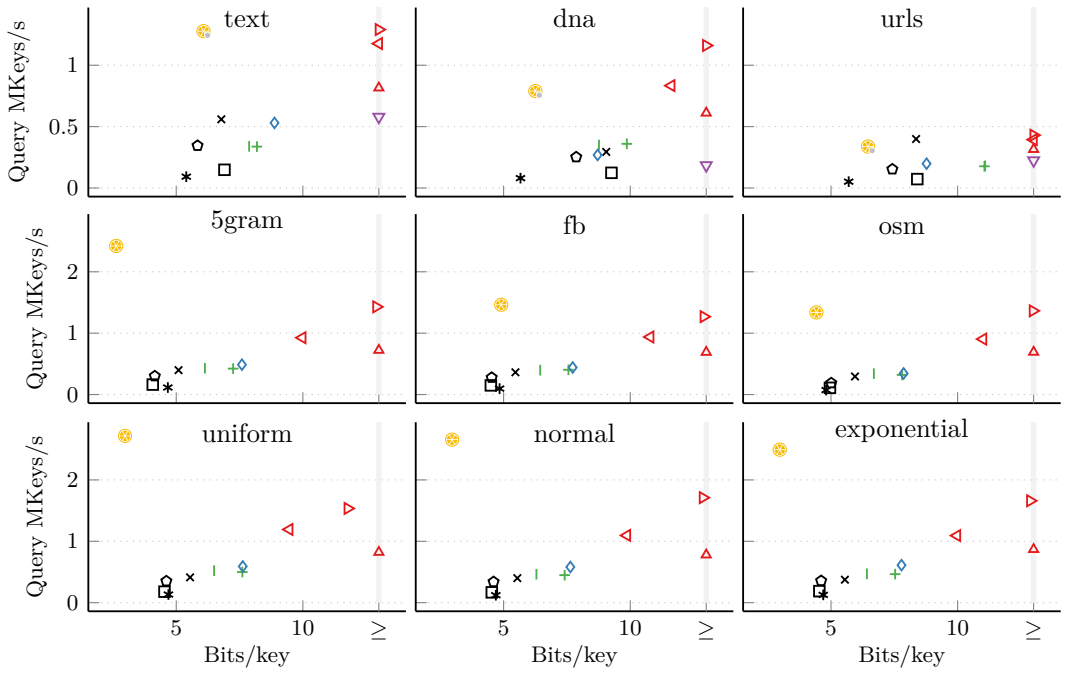


**Figure 2** Query throughput for string, integer, and synthetic integer datasets vs space usage. The top-left corner of every plot shows the top-performing solutions in terms of space-time efficiency.

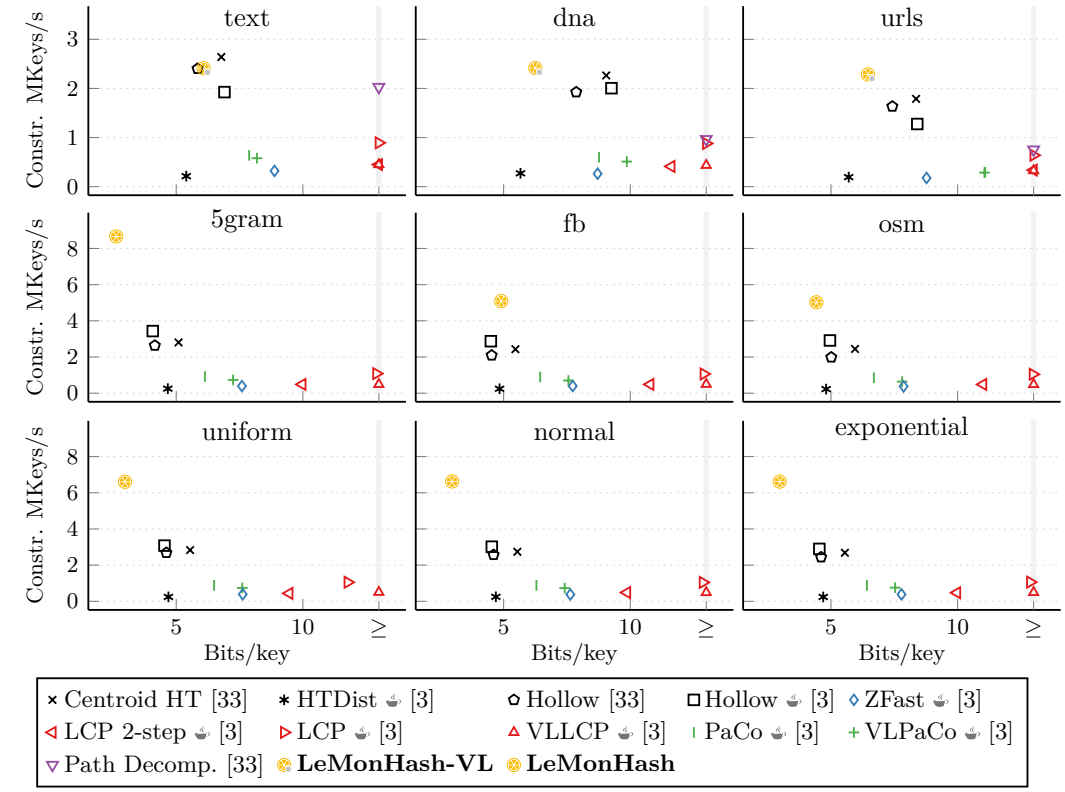

**Figure 3** Construction throughput for string, integer, and synthetic integer datasets. Competitors with the ☕ symbol in the legend are implemented in Java.

implementations by Belazzougui et al. [3] of a range of techniques (see Section 3). We use either the FixedLong or PrefixFreeUtf16 transformation, depending on the data type of the input. For LeMonHash, we use the PGM mapper with $\varepsilon = 31$. For LeMonHash-VL, we use the PGM mapper with $\varepsilon = 63$, alphabet reduction and a recursion threshold $t = 128$.

**Queries.** Figure 2 plots the query throughput against the achieved storage space. In the extended version [19], we additionally detail the numbers in tabular format. The LCP-based methods (see Section 3) have very fast queries but also need the most space (in fact, they appear to the top-right of the plots). At the same time, LeMonHash matches or even outperforms the query throughput of LCP-based methods, while being significantly more space efficient (in fact, it appears towards the top-left of the plots). Compared to competitors with similar space usage, LeMonHash offers significantly higher query throughput.

**Construction.** Figure 3 plots the construction throughput against the space needed. On most synthetic integer datasets, LeMonHash provides a significant improvement to the state-of-the-art approaches, whereas it matches or outperforms the competitors on real-world datasets. LeMonHash improves the construction throughput by up to a factor of 2, compared to the competitor with the next best space usage (typically, variants of the Hollow Trie). While LeMonHash-VL does not achieve the same space usage as the Hollow Trie Distributor, its construction is significantly faster, and still it is the second best in space usage.

## 9 Conclusion and Future Work

In this paper, we have introduced the monotone minimal perfect hash function LeMonHash. LeMonHash, unlike previous solutions, learns and leverages data smoothness to obtain a small space usage and significantly faster queries. On most synthetic and real-world datasets, LeMonHash dominates all competitors – simultaneously – on space usage, construction and query throughput. Our extension to variable-length strings, LeMonHash-VL, consists of trees that are significantly more flat and efficient to traverse than competitors. This enables extremely fast queries with space consumption similar to competitors.

**Future Work.** Many MMPHF construction algorithms are based on the idea of explicitly storing ranks of keys within a small bucket. The idea to split small buckets recursively that we mention in Section 6 can help to reduce the space usage. It remains an open problem whether the idea works in practice, especially when the distribution of keys inside the bucket is skewed. It is also worth investigating a different construction of the piecewise linear approximation in the PGM that minimises the overall space given by the segments *and* the local ranks stored in retrieval data structures, rather than the current approach that maximises the length of the segment (thus minimising just the segments space). Applying non-linear transformations like low-degree polynomials within each segment would also be interesting future work. Finally, it would be interesting to apply smoothed analysis to formally show that many real-world distributions locally behave as if they were uniform random, therefore leading to tighter space bounds.

## Abstract

For solving NP-hard problems there is often a huge gap between theoretical guarantees and observed running times on real-world instances. As a first step towards tackling this issue, we propose an approach to quantify the correlation between theoretical and observed running times.

We use two NP-hard problems related to finding large "cliquish" subgraphs in a given graph as demonstration of this measure. More precisely, we focus on finding maximum $s$-clubs and $s$-plexes, i. e., graphs of diameter $s$ and graphs where each vertex is adjacent to all but $s$ vertices. Preprocessing based on Turing kernelization is a standard tool to tackle these problems, especially on sparse graphs. We provide a parameterized analysis for the Turing kernelization and demonstrate their usefulness in practice. Moreover, we demonstrate that our measure indeed captures the correlation between these new theoretical and the observed running times.

## 1 Introduction

Highly engineered solvers often perform much better than the known theoretical results would suggest. This is especially true when dealing with NP-hard problems. Unless P = NP, no efficient (i. e. polynomial-time) algorithm exists that solves all input instances correctly. However, optimized implementations can often solve instances with millions of vertices, variables, etc. as demonstrated frequently at algorithm engineering conferences [4, 35]. Of course, these implementations are not polynomial-time algorithms for NP-hard problems – the real-world instances are simply not worst-case instances but have algorithmically exploitable structures. On the other hand, there are usually relatively small instances making these solvers struggle. So theoretical running time bounds can often not predict observed running times on the given data set. Obviously, a better correlation between theoretical results and empirical findings would be highly desirable.

A multivariate (i. e. parameterized) analysis of the algorithm allows for a more nuanced picture of running time bounds. In principle, it could provide us with a much better prediction for the running time. However, a comparison to the theoretical parameterized running time is rarely made in practice (although there are notable exceptions [39, 21]). This is probably due to the multitude of issues arising here; let us mention just a few: For example, most theoretical bounds are stated using the $O$-notation that hides constants. Matching these to observed running times (which depend also on the used hardware) is not straightforward. Moreover, optimized solvers often combine several tricks that work well in different cases. The effect of these tricks is often hard to analyze and the observed running times most likely depend on a large (possibly unknown) set of parameters.

In this work, we use the Pearson correlation coefficient to quantify the correlation between theoretical bounds and observed running times. Our approach allows us to compare which theoretical running-time bound fits "better" to the observed running times for a given data set. Hence, it is relatively easy (but tedious) to generate hypotheses for theoretical bounds that fit well to experimental observations. Although proving such bounds is a different story, our approach can be used to transform practical results into impulses for theory.

We exemplify our approach on the $s$-Club and $s$-Plex problems and show how for various solver variants different theoretical explanations can be used. To this end, we follow the approach of Walteros and Buchanan [39] who demonstrated by means of a multivariate analysis why Clique is often efficiently solvable in relatively sparse graphs.

## 1.1 Related work

**Clique on Sparse Graphs.** Clique is one of Karp's 21 NP-complete problems [18]. As such, it is well studied, both in theory and practice; see Wu and Hao [40] for a survey. The currently fastest exact algorithm has running time $O(1.20^n)$ [41], where $n$ is the number of vertices. While 1.20 seems very small, for a graph with 400 vertices the number of steps has more than 30 *digits* which is still infeasibly large. In contrast, a maximum clique can be found in real-world graphs with millions of vertices [8, 14, 31, 38].

It is easy to see that any clique is contained in the neighborhood of each of its vertices. Thus, a very basic approach solving clique on a sparse graph $G = (V, E)$ is the following. Take a vertex $v$ of minimum degree and find the largest clique in $N[v]$ (the closed neighborhood of $v$). Then, remove $v$ and continue in the same fashion. In the end, output the largest found clique. The *degeneracy* $d$ of a graph is the size of the largest neighborhood encountered in the above algorithm. Hence, the above algorithm can be implemented to run in $1.20^d \cdot n^{O(1)}$ time which is on large sparse graphs far better than the $O(1.20^n)$ bound. Many of the graphs considered by Walteros and Buchanan [39] have several hundred thousand vertices and can be solved in less than a minute (often less than a second). Yet, some of these graphs have a degeneracy of well above 400 (again resulting in an infeasibly large number of steps). To rectify this, Walteros and Buchanan [39] provide an algorithm running in $1.28^g n^{O(1)}$ time, where $g := d - k + 1$ is called the *core-gap* and $k$ denotes the number of vertices in a maximum clique (see Section 3 for a more detailed explanation). Clearly $g$ can be much smaller than $d$. In fact, Walteros and Buchanan [39] observe that all their relatively small but hard-to-solve instances have a large core-gap.

**Clubs and Plexes.** An $s$-club is a graph of diameter $s$. An $s$-plex is a graph with $\ell$ vertices where every vertex has degree at least $\ell - s$. While not required by definition, in this work we only consider *connected* $s$-plexes. The task in $s$-Club / $s$-Plex is to find the largest $s$-club / $s$-plex in a given graph. Both $s$-Club and $s$-Plex are NP-hard as they contain Clique as

special case ($s = 1$). Both problems are well-studied in the literature, both from theoretical and practical perspective. For example, $s$-Plex is W[1]-hard with respect to the parameter solution size $k$ for all $s \geq 1$ [19, 23]. In contrast, if $s > 1$, then $s$-Club is fixed-parameter tractable with respect to the solution size $k$ [33, 9]. We refer to Komusiewicz [22] for a further overview on the parameterized complexity of these problems. Several algorithmic approaches (heuristics and exact algorithms) have been proposed and examined to find maximum-cardinality clubs [6, 5, 7, 9, 15, 28, 32, 25, 24] or plexes [3, 12, 11, 36, 29]. Variants of the above-mentioned Turing kernelization approach are employed in engineered solvers for finding clubs [15, 32] and plexes [3, 29].

## 1.2 Our results

We start by transferring the approach of Walteros and Buchanan [39] to $s$-Club and $s$-Plex. To this end, introducing a new graph parameter, we describe and analyze the Turing kernelization for both problems in Section 3. Moreover, we provide simple branching algorithms showing fixed-parameter tractability with respect to a gap parameter. In Section 4, we then analyze the impact of the Turing kernelization in computational experiments for $s \in \{2, 3\}$. To this end, we use ILP-formulations with and without Turing kernelization and basic lower bounds. For $s$-Club significant speedups are observed whereas for $s$-Plex the improvements are not as clear (though still a speedup factor of more than 2.5 is achieved on average). Finally, in Section 5 we use correlations (more precisely the Pearson correlation coefficient) to analyze how well our theoretical findings fit to our practically observed running times. While this measure makes no statement about the efficiency of the algorithms, we can observe that even with the use of black boxes such as ILP-solvers our theoretical findings are reflected in the experimental results, in particular for the $s$-Club problem.

# 2 Preliminaries

For an integer $a \in \mathbb{N}$, we denote by $[a]$ the set $\{1, \ldots, a\}$. For a graph $G = (V, E)$, let $n := |V|$ and $m := |E|$ be the number of vertices and edges, respectively. Let $u, v \in V$ be two vertices of $G$. Let $\mathrm{dist}_G(u, v)$ denote the length of any shortest path between $u$ and $v$. For $x \in \mathbb{N}$, let $N_{x,G}(v)$ be the $x$th neighborhood of $v$, i. e., the set of vertices $u$ with $1 \leq \mathrm{dist}_G(u, v) \leq x$, $N_{x,G}[v] = \{v\} \cup N_{x,G}(v)$, and $\deg_{x,G}(v)$ be the size of its $x$th neighborhood, i. e., $\deg_{x,G}(v) = |N_{x,G}(v)|$. For a set $X \subseteq V$ of vertices, let $G[X]$ denote the subgraph induced by $X$. We drop the subscript $\cdot_x$ for $x = 1$. Also, we omit the subscript $\cdot_G$ when $G$ is clear from context.

**Clique relaxations.** Let $X$ be a set of vertices. If the vertices of $X$ are pairwise adjacent, then we say that $X$ is a *clique*. Let $s \in \mathbb{N}$ be an integer. We say that $X$ is an *$s$-club* if the vertices of $X$ have pairwise distance at most $s$, i. e., $\max_{u,v \in X} \mathrm{dist}_{G[X]}(u, v) \leq s$ and that $X$ is an *$s$-plex* if $G[X]$ is connected and every vertex $v$ in $X$ has at most $s - 1$ vertices nonadjacent to $v$ in $X \setminus \{v\}$, i. e., $\max_{v \in X} |X \setminus N(v)| \leq s$. (Note that a 1-club and a 1-plex are each a clique.) We sometimes abuse these terms to refer to the subgraph induced by an $s$-club or $s$-plex. The decision problems $s$-Club and $s$-Plex ask, given a graph $G$ and an integer $k \in \mathbb{N}$, whether $G$ contains an $s$-club and $s$-plex, respectively, of size at least $k$.

**Degeneracy.** We say that a graph $G = (V, E)$ is *$d$-degenerate* if for every subgraph $G'$ of $G$, there exists a vertex with $\deg_{G'}(v) \leq d$. Equivalently, $G$ is $d$-degenerate if there is an ordering of $V$ in which every vertex has at most $d$ neighbors that appear later in the ordering.

We say that such an ordering is a *degeneracy ordering* of $G$. The degeneracy $d_G$ of $G$ is the smallest number $d$ such that $G$ is $d$-degenerate. For a vertex $v \in V$ and an ordering $\sigma$ of $V$, we denote by $Q_G^\sigma(v)$ (and $Q_G^\sigma[v]$) the set of vertices in $N_G(v)$ (and $N_G[v]$) that appear after $v$ in $\sigma$. We also omit the superscript $\cdot^\sigma$ when it is clear.

**Parameterized complexity.** Here, we list several relevant notions from parameterized complexity. See e. g., Cygan et al. [13] for a more comprehensive exposition of parameterized complexity. A parameterized problem is *fixed-parameter tractable* or *FPT* for short if every instance $(I, k)$ can be solved in time $f(k) \cdot |I|^{\mathcal{O}(1)}$ for some computable function $f$. Such an algorithm is called an *FPT algorithm*. It is widely believed that a parameterized problem is not FPT if it is *W[i]-hard* for $i \in \mathbb{N}$. One way to show fixed-parameter tractability is via the notion of *Turing kernel*. For $t \in \mathbb{N}$, a *$t$-oracle* for a parameterized problem is an oracle that solves any instance $(I, k)$ in constant time, provided that $|I| + k \leq t$. We say that a parameterized problem admits a Turing kernel of size $f(k)$ if there is an algorithm with access to an $f(k)$-oracle that solves $(I, k)$ in time $(|I| + k)^{\mathcal{O}(1)}$. It is straightforward to turn a Turing kernel into an FPT algorithm by simply replacing an $f(k)$-oracle with a brute-force algorithm. The brute-force algorithm runs in $f'(k)$ time for some computable function $f'$, resulting in an $f'(k) \cdot (|I| + k)^{\mathcal{O}(1)}$-time algorithm.

## 3 Theory

In this section, we provide theoretical analysis of clique relaxations based on the notion of Turing kernels. We first describe in Section 3.1 the algorithm for Clique outlined by Walteros and Buchanan [39], which runs in $1.28^g n^{\mathcal{O}(1)}$ time for the gap $g := d - k + 1$. The algorithms have two components. The first component is the Turing kernel parameterized by the degeneracy $d$. In short, we show that Clique is polynomial-time solvable when we have access to $f(d)$-oracle (see Section 2). In practice, there is no such convenient oracle so we have to provide some algorithm – this is the second component. One way to substitute the oracle is to use a brute-force algorithm. Since every oracle call takes an input whose size is bounded by $d$, we already obtain an FPT algorithm parameterized by $d$. We can actually make a more refined analysis by considering the gap parameter $g = d - k + 1$. Essentially, we use an FPT algorithm parameterized by $g$ rather than relying on brute force. Walteros and Buchanan [39] showed that many Clique instances that can be solved efficiently in practice indeed have small values of $g$.

We want to adapt this approach to clique relaxations, namely, $s$-Club and $s$-Plex. However, there is one issue: Under standard complexity assumptions, there is no FPT algorithm for $s$-Club or $s$-Plex. More precisely, $s$-Club is known to be NP-hard for $s = 2$ and $d = 6$ [16] and $s$-Plex is known to be W[1]-hard when parameterized by $d + s$ [20]. For this reason, we consider a broader notion of degeneracy, which we call *$x$-degeneracy* for $x \in \mathbb{N}$ (1-degeneracy coincides with the standard degeneracy). We give the formal definition in Section 3.2. With the notion of $x$-degeneracy at hand, we describe how to adapt the approach employed by Walteros and Buchanan [39] to $s$-Club and $s$-Plex in Section 3.3.

### 3.1 Algorithm for Clique

We subsequently sketch the algorithmic approach of Walteros and Buchanan [39] for Clique.

**Turing kernel.** The Clique problem admits a Turing kernel, in which every input to the oracle has at most $d+1$ vertices (thus size $\mathcal{O}(d^2)$) as follows: For an instance $(G, k)$ of Clique, consider a degeneracy ordering of $\sigma = (v_1, \ldots, v_n)$ of $G$. We will assume that $k \leq d + 1$ since

a $d$-degenerate graph has no clique of size $d+2$. Observe that for every clique $C$ of $G$, we have $C \subseteq Q^\sigma[v]$, where $v \in C$ is the vertex that appears first in a degeneracy ordering $\sigma$. Thus, $G$ has a clique of size $k$ if and only if there exists a vertex $v \in V$ such that $G[Q^\sigma[v]]$ has a clique of size $k$. Since $G$ is $d$-degenerate, $G[Q^\sigma[v]]$ has at most $d+1$ vertices and size $\mathcal{O}(d^2)$. This leads to a Turing kernel for the parameter $d$: Simply call the oracle for the instances $(Q^\sigma[v_1], k), \ldots, (Q^\sigma[v_n], k)$ and return yes iff at least one oracle answer was yes.

**Oracle algorithm.** Every oracle can be replaced with a brute-force algorithm running in $\mathcal{O}(2^d d^2)$ time: Since $Q^\sigma[v]$ is of size at most $d+1$, there are $\mathcal{O}(2^d)$ subsets of $Q^\sigma[v]$ and for every subset, it takes $\mathcal{O}(d^2)$ time to check if every pair of vertices are adjacent. Thus, Clique can be solved in $\mathcal{O}(2^d \cdot d^2 n)$ time. In fact, we can refine the analysis for the oracle algorithm in terms of the *gap* parameter $d-k+1$: To that end, we solve the Deletion to Clique problem: Given a graph $G$ and an integer $\ell$, the task is to find a set of at most $\ell$ vertices whose deletion results in a clique. There is a simple $\mathcal{O}(2^\ell n^2)$-time algorithm for this problem: If all vertices are pairwise adjacent and $\ell \geq 0$, then we have a yes-instance at hand. Otherwise, there exist two nonadjacent vertices, say $u$ and $v$. If $\ell = 0$, then we can conclude that there is no solution. If $\ell \geq 1$, then we recursively solve two instances $(G-u, \ell-1)$ and $(G-v, \ell-1)$. This algorithm runs in $\mathcal{O}(2^\ell \cdot n^2)$ time. Since we need to solve this problem on $G[Q^\sigma(v)]$ with $\ell := |Q^\sigma[v]| - k \leq d-k+1$, we have an $\mathcal{O}(2^{d-k+1} \cdot d^2 n)$-time algorithm for Clique. We remark that an instance $(G, \ell)$ of Deletion to Clique is equivalent to the Vertex Cover instance $(\overline{G}, \ell)$ where $\overline{G}$ is the complement graph of $G$. Thus, using a faster known FPT algorithm for Vertex Cover [10], we obtain an $\mathcal{O}^*_d(1.28^{d-k+1} n)$-time algorithm for Clique ($\mathcal{O}^*_d$ hides factors polynomial in $d$).

## 3.2 Extending degeneracy

As mentioned in the beginning of this section, we consider a broader notion of degeneracy that can defined in two ways.

▶ **Definition 3.1.** *Let $G$ be a graph and $x \in \mathbb{N}$. The* $x$-degeneracy *of $G$ is the smallest integer $d_x \in \mathbb{N}$ such that for each subgraph $G'$ of $G$, there exists a vertex $v$ with $|N_{x,G'}(v)| \leq d_x$.*

▶ **Definition 3.2.** *Let $G$ be a graph and $x \in \mathbb{N}$. The* $x$-degeneracy *of $G$ is the smallest integer $d_x$ such that there is an ordering $\sigma = (v_1, \ldots, v_n)$ of $G$ such that for every $i \in [n]$, the $x$th neighborhood of $v_i$ in $G[v_i, \ldots, v_n]$ has size at most $d_x$. The ordering $\sigma$ is called an* $x$-degeneracy ordering. *The set of vertices in $N_{x,G}[v]$ that appear after $v$ in $\sigma$ is $Q^\sigma_{x,G}[v]$.*

It is not difficult to show that these two definitions are equivalent. We remark that the notion of 2-degeneracy has been proposed by Trukhanov et al. [36] in the context of finding $s$-plexes. The $x$-degeneracy and an $x$-degeneracy ordering can be found in polynomial time:

▶ **Theorem 3.3.** *Given a graph $G$ and an integer $x \in \mathbb{N}$, we can compute the $x$-degeneracy of $G$ and an $x$-degeneracy ordering of $G$ in $\mathcal{O}(n^2 m)$ time.*

**Proof.** Repeat the following until the graph is empty: for every vertex $v$, compute the $x$th neighborhood of $v$. Find a vertex whose $x$th neighborhood has the smallest size and delete it from the graph. The ordering in which vertices are deleted is an $x$-degeneracy ordering. The $x$-degeneracy is the maximum over all vertices of the $x$th neighborhood size when they are deleted. Note that we spend $\mathcal{O}(nm)$ time to compute the $x$th neighborhood of every vertex using e.g., BFS. Since we repeat this $n$ times, the algorithm runs in the claimed time. ◀

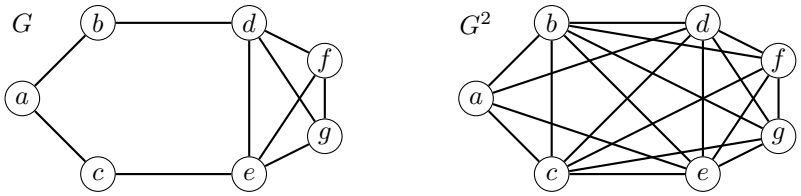

**Figure 1** An example showing the difference between the 2-degeneracy of $G$ (which is 5) and the degeneracy of $G^2$ (which is 6). The ordering $a, b, \ldots, g$ is a 2-degeneracy ordering in $G$ and a degeneracy ordering in $G^2$. Note that $\{b, c, \ldots, g\}$ forms a clique in $G^2$ but not a 2-club in $G$.

We remark that a very similar graph parameter has been studied in the context of $x$-Club [25, 24]: the degeneracy of the $x^{\text{th}}$ power graph $G^x$ of $G$. The power graph $G^x$ has the same vertices as $G$. Moreover, two vertices $u$ and $v$ are adjacent in $G^x$ if and only if $u$ and $v$ have distance at most $x$ in $G$. Note that every $s$-club in $G$ is a clique in $G^x$. The converse, however, is not true; see Figure 1 for an example. While the degeneracy of $G^x$ is in general larger than the $x$-degeneracy, it can be computed faster: in $O(nm)$ time [32]. In fact, the degeneracy of $G^x$ has already been used in Turing kernelization for finding $s$-clubs [32]. Subsequently, we use the smaller $x$-degeneracy for stronger algorithmic results.

## 3.3 Algorithm for $s$-Club and $s$-Plex

**Turing kernel.** For $s$-Club, we adapt the Turing kernel for Clique as follows. For every $s$-club $C$ of $G$, we have $C \subseteq Q_s^\sigma[v]$, where $v \in C$ is the first vertex of $C$ in an $s$-degeneracy ordering $\sigma$. Thus, $G$ has an $s$-club of size $k$ if and only if there exists a vertex $v \in V$ such that $G[Q_s^\sigma[v]]$ has an $s$-club of size $k$. By the definition of $x$-degeneracy, we have $|Q_s^\sigma(v)| \leq d_s$. Thus, we have a Turing kernel in which every oracle call involves at most $d_s + 1$ vertices.

**Oracle algorithm.** Again, we can replace every oracle call with a brute-force algorithm. The input to every oracle call has at most $d_s + 1$ vertices and hence there are $2^{d_s+1}$ subsets. Moreover, for every subset, it takes $\mathcal{O}(d_s^3)$ time to determine whether the vertices have pairwise distance at most $s$, resulting in an algorithm running in $\mathcal{O}(2^{d_s} d_s^3)$ time. As in Section 3.1, we can also refine the algorithm substituting for the oracle using the parameter $d_s - k + 1$. To this end, we solve the Deletion to $s$-Club problem: Given a graph $G$ and an integer $\ell$, the task is to find a set of at most $\ell$ vertices whose deletion results in an $s$-club. There is a simple $\mathcal{O}(2^\ell n^3)$-time algorithm for this problem. If $G$ has diameter at most $s$ and $\ell \geq 0$, then we have a yes-instance at hand. Otherwise there exist two vertices, say $u$ and $v$, with $\text{dist}_G(u, v) > s$. If $\ell = 0$, then we can conclude that there is no solution. If $\ell \geq 1$, then we recursively solve two instances $(G - u, \ell - 1)$ and $(G - v, \ell - 1)$. Since it takes $\mathcal{O}(n^3)$ time to compute all pairwise distances, this algorithm runs in $\mathcal{O}(2^\ell \cdot n^3)$ time. Since we need to solve this problem on $G[Q_s^\sigma[v]]$ with $\ell := |Q_s^\sigma[v]| - k \leq d_s - k + 1$, we obtain:

▶ **Theorem 3.4.** *Given the subgraph $G[Q_s^\sigma[v]]$ for every $v \in V$ for an $s$-degeneracy ordering $\sigma$, $s$-Club can be solved in $\mathcal{O}(2^{d_s - k} \cdot d_s^3 n)$ time.*

**Turing kernel.** For $s$-Plex, we will provide two adaptations. First, note that every $s$-plex is also an $s$-club (recall that we only consider connected $s$-plex). Thus the Turing kernel with the parameterization by $d_s$ follows analogously. For another adaptation, we use the fact that any $s$-plex with at least $2s - 1$ vertices have diameter at most two, as observed by Seidman

and Foster [34]: Suppose that two vertices $u$ and $v$ in an $s$-plex $C$ have distance three in $G[C]$. Then, every vertex in $C$ is nonadjacent to either $u$ or $v$. Since for each of $u$ and $v$, there are at most $s-1$ vertices nonadjacent to it, we have $|C| \leq 2s-2$. This leads to a Turing kernel with respect to the parameter $d_2$ when $k \geq 2s-1$. For every $s$-plex of size at least $2s-1$, we have $C \subseteq Q_2^\sigma[v]$, where $v \in C$ is the first vertex of $C$ in a 2-degeneracy ordering $\sigma$. Thus, we have again a Turing kernel where every oracle call involves at most $d_2+1$ vertices. (Small $s$-plex of size at most $2s-2$ can be found in $O(n^{2s-1})$.)

**Oracle algorithm.** Again, we can replace every oracle call on $h$ vertices with a brute-force algorithm. The input to every oracle call has at most $h+1$ vertices and hence there are $2^{h+1}$ subsets. Moreover, for every subset, it takes $\mathcal{O}(h^2)$ time to determine whether it is an $s$-plex, resulting an algorithm running in $\mathcal{O}(2^h h^2)$ time. As in Section 3.1, we can also refine the algorithm substituting for the oracle using the parameter $h-k+1$. To that end, we solve the Deletion to $s$-Plex problem: Given an $n$-vertex graph $G$ and an integer $\ell$, the task is to find a set of at most $\ell$ vertices whose deletion results in an $s$-plex. There is a simple $\mathcal{O}((s+1)^\ell n^2)$-time algorithm for this problem. If $G$ is an $s$-plex and $\ell \geq 0$, then we have a yes-instance at hand. Otherwise there exist a vertex $v$ and $s$ vertices nonadjacent to $v$. If $\ell = 0$, then we can conclude that there is no solution. If $\ell \geq 1$, then we recursively solve $s+1$ instances $(G-v, \ell-1)$ and $(G-u, \ell-1)$ where $u$ is one of $s$ vertices nonadjacent to $v$. Since it takes $\mathcal{O}(n^2)$ time to check if the graph is an $s$-plex, this algorithm runs in $\mathcal{O}((s+1)^\ell \cdot n^2)$ time. Since we need to solve this problem on graphs with $h$ vertices with $\ell := h-k$, we obtain the following:

▶ **Theorem 3.5.** *Given the subgraph $G[Q_s^\sigma[v]]$ for every $v \in V$ for an $s$-degeneracy ordering $\sigma$, $s$-Plex can be solved in time $\mathcal{O}((s+1)^{d_s-k} \cdot d_s^2 n)$ and $\mathcal{O}(n^{2s-1} + (s+1)^{d_2-k} \cdot d_2^3 n)$.*

We remark that for very small $s$, the first term $n^{2s-1}$ can be ignored in practice, because most instances contain an $s$-plex of size at least $2s-1$.

## 4 Experiments

In this section we present the results of our computational experiments for $s$-Club and $s$-Plex for $s \in \{2,3\}$ on a large dataset of real-world graphs. We did not optimize every aspect of the implementations as our goal is to investigate the effect of Turing kernelization and the extent to which our theoretical findings are reflected in the running time (this is discussed in Section 5). We will see, that the Turing kernelization is quite beneficial for $s$-Club but for $s$-Plex the situation is not as clear.

**Setup & Dataset.** All experiments were performed on a machine running Ubuntu 18.04 LTS, with an Intel Xeon® W-2125 CPU and 256GB of RAM. A maximum running time of 1 hour per instance was set. We used Gurobi 8.1 to solve ILP-formulations, limited to a single thread of execution. The program that was used to build the ILP models was implemented in C++ and compiled with g++ 7.5.

The static graphs from the Network Repository [30] were used for all experiments. Graphs for which at least one solver configuration timed out, ran out of memory, or completed in less than 0.05 seconds were omitted. The last case (less than 0.05 s) is to not deal with the effect of noise in the small running time measurements. The resulting dataset consists of 259 graphs, with 1033 vertices on average. The source code is available at `https://git.tu-berlin.de/afigiel/splex-sclub-correl`.

We remark that $s$-Club and $s$-Plex have been solved for small $s$ on much larger graphs within minutes [15, 12, 11]. The reason we focus on smaller graphs is to have a meaningful multivariate analysis. More precisely, we want to see if the running time grows (as suggested by theory) with growing $x$-degeneracy and gap. Having running times for large graphs with small $x$-degeneracy and gap but not for large graphs with large $x$-degeneracy and gap would give misleading results in our analysis in Section 5.

**Solvers.** We used an ILP solver as oracle for $s$-Club and $s$-Plex in the Turing kernelization. The ILP formulations were taken from the literature: For $s$-Plex we used a straight-froward formulation with $\mathcal{O}(n)$ variables and constraints and $\mathcal{O}(n+m)$ non-zeroes[1] [27].

| | |
|---|---|
| maximize: | $y$ |
| subject to: | $x_v \in \{0,1\}, y \in \{0,\dots,n\}$ |
| | $y = \sum_{v \in V} x_v$ |
| $\forall v \in V$: | $\lvert V\rvert(1-x_v) + \sum_{u \in N(v)} x_u \geq y - s$ |

For 2-Club a simplified formulation by Bourjolly et al. [6] was used. It has $\mathcal{O}(n)$ variables, $\mathcal{O}(n^2)$ constraints, and $\mathcal{O}(n^3)$ non-zeroes.

| | |
|---|---|
| maximize: | $\sum_{v \in V} x_v$ |
| subject to: | $x_v \in \{0,1\}$ |
| $\forall u,v \in V, \mathrm{dist}(u,v) > 2$: | $x_u + x_v \leq 1$ |
| $\forall u,v \in V, \mathrm{dist}(u,v) = 2$: | $x_u + x_v \leq 1 + \sum_{c \in N(u) \cap N(v)} x_c$ |

For 3-Club the neighborhood formulation from Almeida and Carvalho [1, 2] was used, with $\mathcal{O}(n)$ binary variables, $\mathcal{O}(m)$ continuous variables, at most $\mathcal{O}(n^2)$ and $\mathcal{O}(n^3)$ constraints and non-zeroes, respectively[2].

| | |
|---|---|
| maximize: | $\sum_{v \in V} x_v$ |
| subject to: | $x_v \in \{0,1\}$ |
| $\forall u,v \in V, \mathrm{dist}(u,v) > 3$: | $x_u + x_v \leq 1$ |
| $\forall u,v \in V, \mathrm{dist}(u,v) \in \{2,3\}$: | $x_u + x_v \leq 1 + \sum_{c \in N(u) \cap N(v)} x_c + \sum_{e \in E_{uv}} z_e$ |
| $\forall e = \{a,b\} \in E$: | $z_e \leq x_a,\ z_e \leq x_b$ |
| $\forall e \in E$: | $0 \leq z_e \leq 1$ |

[1] An $s$-plex of size $\ell > 2s-1$ is guaranteed to be connected and of diameter two [34]. As we only consider $s \in \{2,3\}$, we do not add constraints enforcing connectedness to the ILP. Unsurprisingly, all found subgraphs were still connected.

[2] For compact and general ILP formulations for $s$-Club ($s \geq 2$) we refer to Salemi and Buchanan [32] and Veremyev et al. [37].

**Table 1** Average running times in seconds of various solver configurations.

| | noTK | full | default | hint |
|---|---|---|---|---|
| 2club | 294.3 | 18.7 | 1.9 | 0.9 |
| 3club | 641.8 | 296.0 | 81.4 | 41.7 |
| 2plex | 26.4 | 63.8 | 10.1 | 10.2 |
| 3plex | 39.6 | 260.6 | 81.4 | 77.6 |
| 3plex-2 | 39.6 | 63.4 | 12.4 | 12.0 |

where $E_{uv} = \{\{p, q\} \in E \mid p \in N(u) \setminus N(v), q \in N(v) \setminus N(u)\}$. We remark that different ILP-formulations for these problems are discussed in the literature [3, 27, 32]. However, analyzing them is beyond the scope of this work.

**Solver variants.** We tested several approaches using these ILP models to cover all concepts discussed in Section 3. To this end, we use four different solver configurations, namely `noTK`, `full`, `default` and `hint` (described below). We will refer to, for example, `2club_noTK` as the benchmark results of the `noTK` solver configuration on the 2-Club problem.

The `noTK` variant (no Turing kernel) simply built a single ILP model for the entire graph. All other variants use the Turing kernelization to some extent. The `full` variant makes only basic use of Turing kernelization, utilizing the 2/3-degeneracy as described in Section 3. There, each oracle call is solved via an ILP. For 2-Club and 2-Plex the Turing kernelization using 2-degeneracy is employed, for 3-Club and 3-Plex the one using 3-degeneracy. As there is only one connected 3-plex of diameter three (the $P_4$) which was never the largest 3-plex in our experiments we also used the 2-degeneracy based Turing kernelization for 3-Plex. We report the results of this variant under `3plex-2` (thus `3plex-2_noTK` is the same as `3plex_noTK`).

The `default` variant uses the Turing kernel approach in combination with a simple lower bound: It uses the maximum solution size of already solved ILPs as a lower bound on the global solution size by adding a constraint to the ILPs enforcing that the solution has to be larger than the current lower bound. Note that this lower bound does not appear in the algorithm descriptions in Section 3. The order in which the ILPs are solved can therefore have an impact on the overall running time. We used a fixed 2/3-degeneracy ordering and did not analyze the impact of the order. Instead, we remove this effect in the `hint` variant. There, we added a constraint to each ILP model in the Turing kernels which enforced that the solution size to the Turing kernel is at least the size of the optimal solution size for the entire graph. Thus, one can think of (heuristically) optimizing in the `default` variant the order in the Turing kernelization so that the oracle calls giving the largest results come first. Alternatively, this shows the maximum speedup possible by a "perfect" lower-bound heuristic. Note that in the `hint` variant at least one ILP model still has a feasible solution.

**Results.** In Table 1 we summarize the average running time of the different solver configurations on the four considered problems. The approach without Turing kernels is significantly slower for 2- and 3-Club but not so much for 2- and 3-Plex. This can also be seen in the detailed comparisons in Figure 2. Interestingly, the `noTK` variants are much faster in finding plexes than in finding clubs (more than 10 times larger average running time). However, the average running time of `2club_default` is five times smaller than that of `2plex_default`. Thus, on the one hand the ILP-formulation we use for finding 2/3-clubs may have a room for

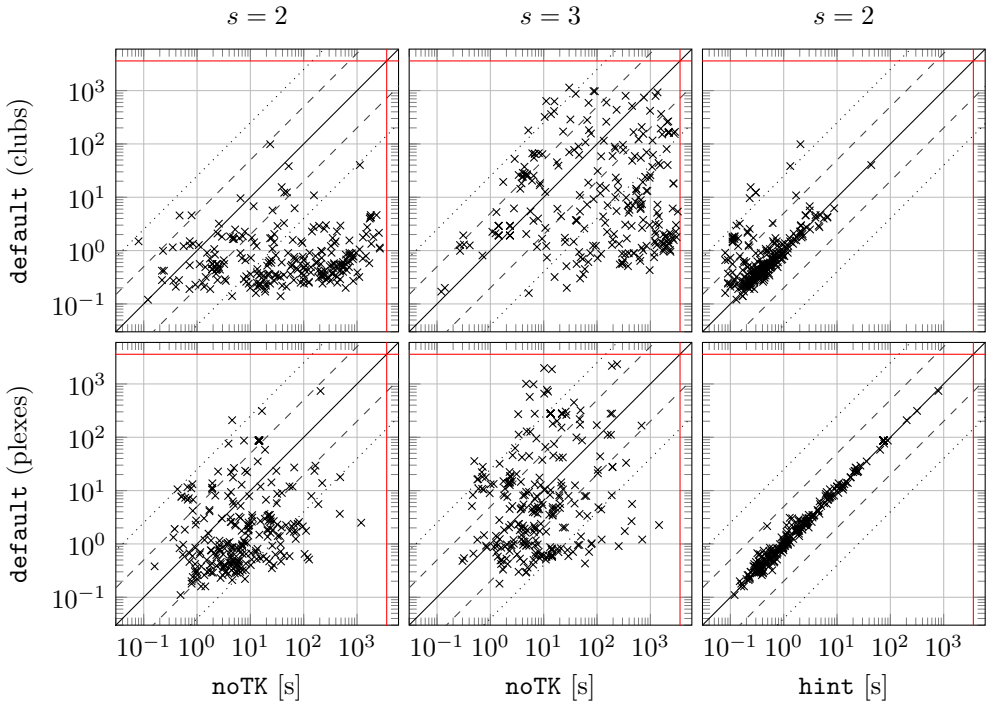

**Figure 2** Running time comparison (in seconds) of different variants (top row for 2- and 3-Club, second row for 2- and 3-Plex). Each cross represents one instance with the $x$- and $y$-coordinates indicating the running time of the respective variant (in seconds): `default` and `noTK` resp. `hint`. Thus, a cross above (below) the solid diagonal indicates that the solver on the $x$-axis ($y$-axis) is faster on the corresponding instance. The diagonal lines mark factors of 1 (solid), 5 (dashed) and 25 (dotted). The solid horizontal red lines indicate the time limit (1 hour). For 2- and 3-Club a significant running time improvement is visible. For 2- and 3-Plex the picture is not so clear.

improvement. On the other hand, the Turing kernel approach works much better for clubs than plexes. The reason is most likely that the Turing kernels are built based on distance, which fits better with clubs than plexes. This can be seen in the gap-parameter: for 73 resp. 57 instances the gap-parameter was zero for 2-Club resp. 3-Club whereas for the plexes the gap-parameter was never zero.

Unsurprisingly, the `hint` variant is the fastest one. However, the `default` variant is not much slower than `hint` (see also right column of Figure 2), even though it does not receive the solution size as input, and instead uses the maximum solution of the previously solved ILPs to update the lower bound. Moreover, the `default` variant is considerably faster than the `full` variant. This shows the strength of providing lower bounds to the ILP-solver. Remarkably, for finding 2/3-clubs even the `full` variant brings a decent speedup compared to the `noTK` variant.

## 5 Correlation between Theory and Practice

We now analyze correlations between the theoretical running time bounds in Section 3 and the measured running times in Section 4. Since we have NP-hard problems, our working hypothesis is that the running time should depend exponentially on some parameter(s).

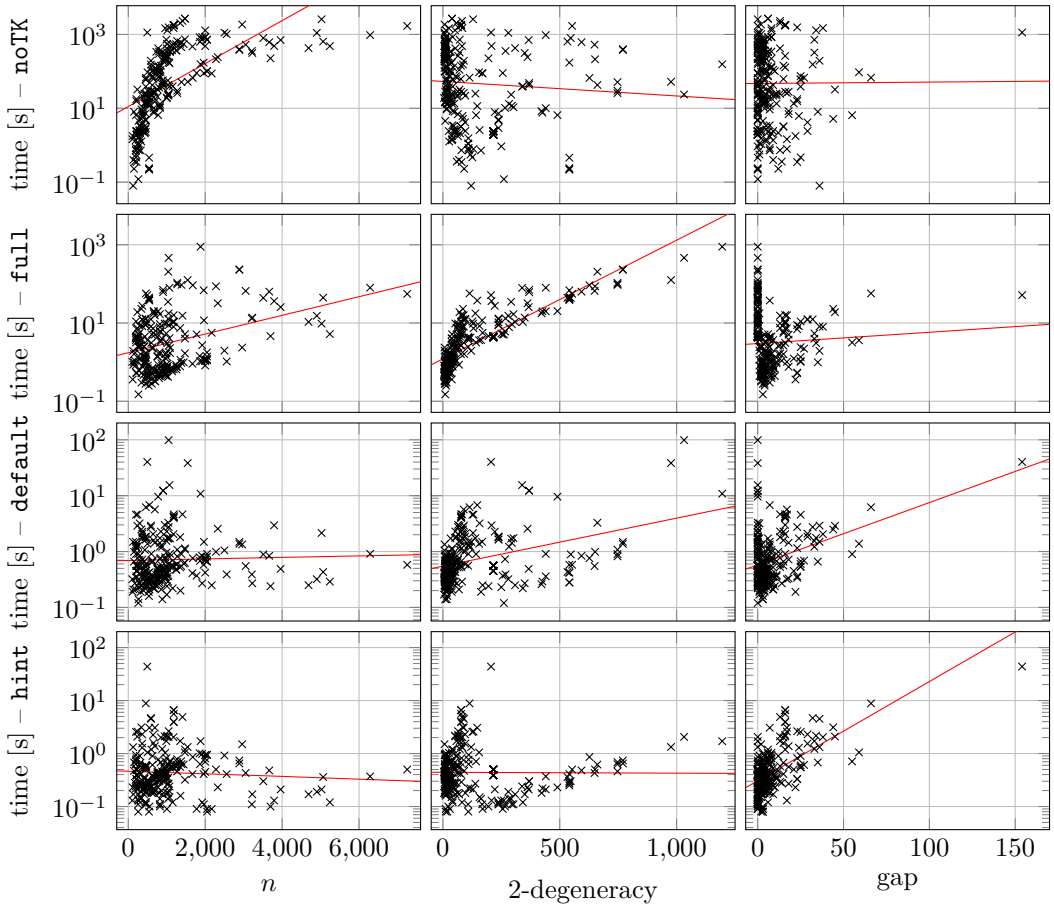

**Figure 3** The running times of `2club_noTK`, `2club_full`, `2club_default`, and `2club_hint` plotted against the number $n$ of vertices, the 2-degeneracy, and the gap of the input graph. The solid red lines are linear regressions best fitting to the data points (where the logarithm of the running times is taken).

Natural parameter candidates are the number $n$ of vertices, the 2- resp. 3-degeneracy, and the gap parameter (suggested by our theoretical findings). Note that there is a multitude of other viable parameters[3]; however, studying them is beyond the scope of this work.

We studied five problems (counting `3plex` and `3plex-2` as two) with four different solvers of each problem. Thus, there are $5 \cdot 4 \cdot 3 = 60$ different (parameter, running time)-pairs to analyze. We illustrate the 12 pairs for `2club` in Figure 3 with the red lines depicting the exponential function of the form $\alpha^p \cdot \beta$ that best fit the data; these lines are computed via linear regression (logarithm of the running time versus parameter value $p$). Obviously, the suggested running time function on the bottom left (`2club_hint` with parameter $n$) is useless: our implementation will in general not become faster the larger the input gets. The red lines on the top left and bottom right seem far more sensible.

[3] See for example `https://manyu.pro/assets/parameter-hierarchy.pdf` or `https://www.graphclasses.org/` for dozens of graph parameters.

## 5.1 Method

Instead of "carefully looking" at each of the plots in Figure 3 and finding arguments for each one of them, we want an automated way of distinguishing useful from useless suggestions. To this end, we suggest using the Pearson correlation coefficient which we subsequently just call correlation coefficient. It is a standard measure of linear correlation between two sets of data. Simply put, given the (running time, parameter) data points the correlation coefficient computes a number between -1 and 1. If there is no correlation at all, then the coefficient is 0. With perfect correlation (i. e. the data points are on a straight line with positive slope) the coefficient is 1. With perfect negative correlation (i. e. the data points are on a straight line with negative slope) it is -1.

We report correlations between the logarithm of the running time and the parameter (in our case either the number of vertices, the generalized degeneracy, or the gap). Thus, values close to 1 represent good correlations (i.e. some exponential dependency between the running time and the parameter). However, note that a better correlation value does not imply a better running time. There are several specifics with our measure that we like to address before reporting the results.

**Exponential Dependency.** Note that our approach "ignores" the base of the exponential functions, in the following sense: A "perfect correlation" of 1 with, say the gap parameter $g$, implies that the measured running time $t$ satisfies the following linear relation for some constant $a$ and $b$: $\log t = a \cdot g + b \iff t = 2^{a \cdot g + b} = \beta \cdot \alpha^g$ where $\beta = 2^b$ and $\alpha = 2^a$ are again two constants. Of course, $\alpha$ has to be nowhere close to the bases of the exponential functions we describe in Section 3. Thus, a "perfect correlation" just indicates that there is *some* exponential dependency between the parameter and the running time.

Our justification here is that the measure needs to be somewhat imprecise: The measured running times can be greatly impacted by the configuration of the ILP-solver [17] or by the experimental setup [26]. Hence, hitting the theorized worst-case running time seems rather unlikely. Since we deal with NP-hard problems we expect (despite all heuristic improvements) some exponential function describing the running time. With our setting we can get suggestions for the base of the exponential function from experimental results.

**Restricted Setting.** We restrict ourselves to correlations between one parameter and the running time. While correlations between multiple parameters and the running time are possible, our theoretical results in Section 3 only suggest exponential dependencies between one parameter (2/3-degeneracy or gap) and the running time and not two parameters. Incorporating the polynomial factors of $n$ in the running times of Section 3 is easily doable. However, in our analysis it changed the coefficients only marginally (by less than 5%, usually much less than 1%), probably due to the relatively small size of the graphs. As we are (for now) only interested in simple exponential dependencies, the Pearson correlation coefficient suffices as we can take the logarithm of all measured running times. Note that there are different correlation coefficients that can also measure non-linear correlations and might be better suited to other settings (e. g. when dealing with polynomial-time solvable problems).

**Simplistic Analysis.** We use a very simplistic statistical analysis. For example, we ignore confidence intervals, $p$-values, or similar issues. The reason being that any "good" correlation between a parameter (or a combination of parameters) and the measured running time is only an *indication* for such a correlation. In particular, if some "new" correlations are discovered with this method, then this only gives *suggestions*. Using our theoretical tools, we

**Table 2** Tables summarizing the correlation of different graph parameters $n$ (left table), $d_2/d_3$ (middle table), and the gap $g$ (right table) with the logarithm of the measured running times of various solver configurations (def abbreviates default). In the middle the correlation with 2-degeneracy is shown for `2club, 2plex` and `3plex-2`, and with 3-degeneracy for `3club` and `3plex`).

| | Correlation with $n$ | | | | Correlation with $d_2/d_3$ | | | | Correlation with gap | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | noTK | full | def | hint | noTK | full | def | hint | noTK | full | def | hint |
| 2club | 0.59 | 0.34 | 0.03 | −0.06 | −0.08 | 0.84 | 0.38 | −0.01 | 0.01 | 0.06 | 0.35 | 0.61 |
| 3club | 0.48 | 0.16 | 0.08 | −0.22 | −0.12 | 0.67 | 0.46 | 0.22 | 0.14 | 0.34 | 0.46 | 0.72 |
| 2plex | 0.53 | 0.07 | 0.08 | 0.07 | 0.21 | 0.63 | 0.46 | 0.46 | 0.22 | 0.60 | 0.44 | 0.45 |
| 3plex | 0.52 | 0.06 | −0.02 | −0.01 | 0.02 | 0.65 | 0.40 | 0.39 | 0.02 | 0.63 | 0.39 | 0.38 |
| 3plex-2 | 0.52 | 0.08 | 0.07 | 0.06 | 0.02 | 0.62 | 0.45 | 0.44 | 0.02 | 0.59 | 0.42 | 0.42 |

can prove (e. g. show a running time bound) or disprove (e. g. NP-hardness for a constant parameter value) such suggestions. This ability of theoretical verification allows us to ignore "safety"-features from statistical analysis.

## 5.2 Results

Table 2 summarizes the 60 correlation coefficients of three graph parameters with the logarithm of the measured running times.

Consider the first row corresponding to 2-Club in the three parts of Table 2. The first columns display the correlation with $n$ which is best for the `noTK` variant. This well reflects our observations for the plots in the left column of Figure 3: The `default` and `hint` variant do not display any reasonable correlation with $n$, only `noTK` does to some extent. Similarly, in the right column of Figure 3 the correlations of the `default` and `hint` variant with the gap-parameter are quite decent, but not for the `noTK` variant. Moreover, in the plot for the `default` variant of the right column in Figure 3 there are a few instances that have a high running time despite a parameter value of zero. This is an argument against the suggested regression being a "good" explanation. Also, in the bottom right plot one can see that there are no such (drastic) outliers. Hence, the correlation with the `hint` variant with the gap is considerably "better" than with the slower `default` variant (despite only small differences in the average running time, see Table 1). This is also reflected in the corresponding correlation coefficients of 0.61 and 0.35 respectively (see two rightmost columns in Table 2) and, thus, supports the correlation coefficient as reasonable measure. All in all, the results for 2-Club indicate that the correlation coefficients reveal exponential dependencies between the running time and the considered parameter.

**Correlations with number of vertices.** The results for the other problems are somewhat similar to the ones for 2-Club. The correlation coefficient for the number of vertices is highest for all problems with the `noTK` configuration, whereas with the configurations based on Turing kernels it is significantly lower (or even negative). This is somehow expected, as all our ILP formulations use $\mathcal{O}(n)$ binary variables. State-of-the-art ILP solvers are highly complex ("a bag of tricks") and able to solve instances with millions of integer variables efficiently. Thus, the correlation of around 0.5 (for `noTK`) with the number of vertices is higher than for the other variants, but not the overall highest correlations (see second row and second column in Figure 3 for the plot corresponding to the highest correlation).

**Correlations with generalized degeneracy.** The Turing kernel approaches correlate in general better with the 2/3-degeneracy, notable exceptions are the `2club_hint` and `3club_hint` variants. As expected, across all problems the highest correlations with the 2/3-degeneracy are achieved by the `full` variants: The 2-degeneracy (3-degeneracy) is in our dataset on average more than five times (more than three times) smaller than $n$. Hence, the high correlations for the `noTK` variants with $n$ translate to high correlations for the `full` variants with 2/3-degeneracy. For the `noTK` configuration there is barely any correlation with the 2/3-degeneracy. It thus seems that the ILP solver cannot exploit the 2/3-degeneracy – at least with the given ILP formulations.

**Correlations for `default` and `hint` variants.** As discussed in Section 4, the `default` and `hint` variants are considerably faster than the `full` variants due to having access to some (perfect) lower bound. As we use the black box of an ILP-solver we do not have theoretical running time bounds covering the effect of this lower bound. Also note that the running time differences between the `default` and `hint` variants are much smaller than the differences between other pairs of variants (see Table 1). However, we can observe significant differences in the correlations of the `default` and `hint` variants for 2-Club and 3-Club with respect to the generalized degeneracy and the gap parameter. Moreover, the correlation coefficients support some speculations: The correlations in the middle table of Table 2 suggest that this running time improvement is not (so much) correlated to the 2/3-degeneracy but to another parameter. For finding clubs the gap-parameter is a good explanation: `2club_hint` and `3club_hint` have high correlations with the gap parameter; this can also be seen in the bottom right $2 \times 2$ plot subgrid of Figure 3. Thus, with a better lower bound computation (i. e., some actual heuristic) we suspect the correlation of the `default` variant with the degeneracy to decrease and increase with the gap parameter.

For plexes this argumentation does not hold. There is rarely any difference in the correlation coefficients of the `default` and `hint` variant with the 2/3-degeneracy and the gap-parameter. The reason is simple: while the gap is considerably smaller than the 2/3-degeneracy for 2/3-Club (the clubs are rather large), this is not the case for 2/3-Plex (the plexes are quite small), see Figure 4 (in the appendix). Thus, for 2/3-Plex the correlations differ only marginally between the `hint` and `default` variants. Moreover, this explains very well why despite `2club_noTK` being quite slow compared to `2plex_noTK` the variant `2club_hint` is much faster than `2plex_hint`: The average gap for our 2-club instances is 7.9, hence the exponential running time dependency on the gap is manageable. For 3-club instances, the average gap is 18.6 which, apparently, is one of the reasons why the `3club` variants are much slower than the `2club` variants.

## 6 Conclusion

We provided theoretical bounds for algorithms solving $s$-Club and $s$-Plex and experimentally tested the employed Turing kernelization for $s \in \{2, 3\}$. We found that the Turing kernel approach improves the running time significantly more for clubs than plexes. We believe that this is due to the fact that the $x$-degeneracy is defined based on distance. This suggests the need for exploring notions more suitable for finding plexes.

We also discussed the correlation between the observed running times and the theoretical bounds. Yet, there is still a large gap between theory and practice: for example, the bases of the exponential function obtained by regression are all below 1.1 – much smaller than current theoretical results suggest. We are confident that our approach based on correlation coefficients can help to close this gap. The approach is easy to employ and quite flexible.

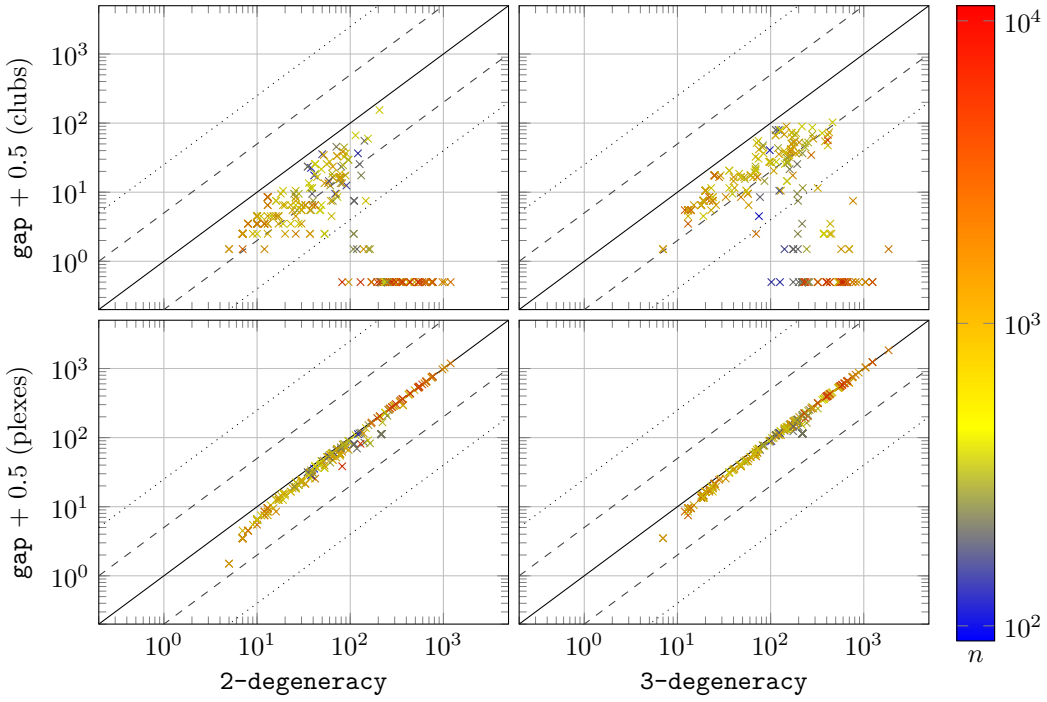

**Figure 4** Relation between 2-degeneracy, gap, and number of vertices. We added 0.5 to the gap as we use log scale and several instances have a gap of zero (for `2club` and `3club`). The diagonal lines mark factors of 1 (solid), 5 (dashed) and 25 (dotted).

Finally, we discuss some directions for future work:

- Checking whether the running times correlate with multiple parameters is an easy (but tedious) extension. The whole process should allow for relatively easy automation. An automated tool could generate a list of likely correlations from experimental results. These can then be analyzed theoretically with the parameterized complexity framework. This way, practice could give more impulses for theory.
- Our approach is not limited to analyzing running times. Other objectives could be the size of preprocessed instances (using the kernelization framework from parameterized algorithmics) or approximation factors of heuristics or approximation algorithms.
- While we use worst-case analysis, average case analysis or smoothed analysis are further natural candidates.
- Improving our general approach: For example, how to incorporate timeouts? Or are different correlation coefficients better suited?

## Abstract

We consider the following problem about dispersing points. Given a set of points in the plane, the task is to identify whether by moving a small number of points by small distance, we can obtain an arrangement of points such that no pair of points is "close" to each other. More precisely, for a family of $n$ points, an integer $k$, and a real number $d > 0$, we ask whether at most $k$ points could be relocated, each point at distance at most $d$ from its original location, such that the distance between each pair of points is at least a fixed constant, say 1. A number of approximation algorithms for variants of this problem, under different names like distant representatives, disk dispersing, or point spreading, are known in the literature. However, to the best of our knowledge, the parameterized complexity of this problem remains widely unexplored. We make the first step in this direction by providing a kernelization algorithm that, in polynomial time, produces an equivalent instance with $\mathcal{O}(d^2k^3)$ points. As a byproduct of this result, we also design a non-trivial fixed-parameter tractable (FPT) algorithm for the problem, parameterized by $k$ and $d$. Finally, we complement the result about polynomial kernelization by showing a lower bound that rules out the existence of a kernel whose size is polynomial in $k$ alone, unless NP $\subseteq$ coNP /poly.

## 1 Introduction

The problem of dispersing a family of objects is a common theme in many situations in computational geometry. It appears naturally in the wide range of settings that require assigning elements to locations. In many scenarios, dispersing has two often contradicting objectives. On the one hand, it is desirable not to place the objects too close to each other. This can be due to a variety of reasons, e.g., placing customers in a restaurant in socially distant manner, to placing wireless sensors far from each other in order to avoid interference. On the other hand, we may already have an existing placement of the objects, and wish to optimize the resources spent on moving the objects.

With this motivation, we consider the following mathematical model of the dispersing problems. In this model, our aim is to modify a given arrangement of points in the plane, by moving some of the points into new positions within a given distance, such that the Euclidean distance between each pair of points in the final arrangement is at least a fixed constant, say 2. Equivalently, the problem can be reformulated in terms of finding a non-overlapping arrangement of unit disks, formulated below as the problem Disk Dispersal.

Disk Dispersal

| | |
|---|---|
| *Input:* | A family $\mathcal{S}$ of $n$ unit disks, an integer $k \geq 0$, and a real $d \geq 0$. |
| *Task:* | Decide whether it is possible to obtain from $\mathcal{S}$ a family of non-overlapping unit disks $\mathcal{P}$ by moving at most $k$ disks into new positions in such a way that each unit disk is moved a distance at most $d$. [1] |

Disk Dispersal– and therefore, the problem of spreading points – is closely related to the problem of finding a system of *q-distant representatives*. This problem was introduced by Fiala, Kratochvíl, and Proskurowski [14] as a geometric extension of the classic combinatorial notion of the "systems of distinct representatives". For a set of geometric objects in a metric space and a number $q > 0$, the task is to choose one representative point from each object such that the selected points are at a distance at least $q$ from each other. For $k = n$, an instance $(\mathcal{S}, d, k)$ of Disk Dispersal can be viewed as an instance of the problem of finding a system of $q$-distance representatives by setting $q = 2$ and defining the set of geometric objects as follows: for each disk $D \in \mathcal{S}$, create a disk with the same center but with radius $d$ (instead of 1). This yields that Disk Dispersal is also NP-hard for $d = 2$ from the result of [14].

The problem of computing the distant representatives has applications in map labeling and data vizualization, where the goal is to place labels as close as possible to the specified features of the map but avoiding overlapping (thus the centers of labels are the centers of non-intersecting disks, ensuring that they are sufficiently separated) [9, 20, 21]. The problem is also related to problems of "imprecise points" [22, 23], the settings where locations of points are given with some precision. Approximation algorithms for this and related point spreading problems – where the goal is to place the specified number of points within a certain region so as to maximize the smallest pairwise distance between the points – were developed in [3, 4, 6, 10, 11, 12, 13, 19, 2, 18].

[1] All (unit) disks considered in the paper are open unless specified otherwise. In particular, two unit disks touching each other are not considered to be overlapping. Due to this simplifying assumption, we avoid the discussion about placing disks such that the distance between their boundaries is infinitesimally small.

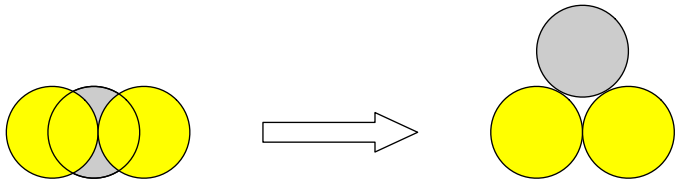

**Figure 1** An example of Disk Dispersal with $k = 1$ and $d = \sqrt{3}$. A non-overlapping arrangement of disks obtained from a family of three disks by moving the central disk at distance $\sqrt{3}$.

To the best of our knowledge, the parameterized complexity of dispersal problems are widely unexplored. The notable exception is the work of Demaine, Hajiaghayi, and Marx [7] on dispersion in graphs. In this problem, we are given an underlying edge-weighted graph, called the *connectivity graph* $G$, and a set of $k$ "agents" or "pebbles", located at a subset of vertices $G$. The task is to move the pebbles to distinct vertices and such that no two pebbles are adjacent. The movement problem is W[1]-hard parameterized by the number of pebbles, even in the case when each pebble is allowed to move at most one step.

## 1.1 Our Results

Our first result concerns kernelization (polynomial compression) of Disk Dispersal. Informally speaking, in parameterized complexity, the polynomial kernel is a polynomial-time algorithm that compresses the instance of a parameterized problem to the instance whose size is bounded by a polynomial of the parameter. Theorem 1 gives an algorithm that runs in polynomial time, and reduces the number of disks to some polynomial of $d$ and $k$.

▶ **Theorem 1.** *There is a polynomial-time algorithm that, given an instance $(\mathcal{S}, k, d)$ of Disk Dispersal, outputs an equivalent instance $(\mathcal{S}', k, d)$ of the same problem, where the number of unit disks is $|\mathcal{S}'| = \mathcal{O}((d+1)^2k^3)$, and $\mathcal{S}' \subseteq \mathcal{S}$.*

Strictly speaking, the algorithm in Theorem 1 is not a polynomial kernel according to the standard definition of this notion – we do not guarantee that the coordinates of disks, and thus the overall size of the compressed instance, is bounded by a polynomial in $k$ and $d$. We call such a compression algorithm a *partial kernel*. Further, we observe in Theorem 12 that the partial kernel from Theorem 1 can be modified to be a polynomial kernel if the centers of input disks are constrained to be rationals and we parameterize the problem by $k$, $d$, and the maximum denominator of coordinates of centers.

For a parameterized problem, given the existence of a (partial) kernel, it is usually straightforward to design a fixed-paramter tractable (FPT) algorithm by an exhaustive enumeration of all candidate solutions. For Disk Dispersal, however, this is not entirely obvious. After computing an equivalent reduced instance by applying Theorem 1, one can enumerate all possible subsets of at most $k$ unit disks that are to be moved. Now, for each such subset, we want to decide whether each unit disk in the subset can be moved by a distance of at most $d$ that results in a non-overlapping configuration. Since there are infinitely many possible target locations for each unit disk, this step requires some additional work. We show that this decision subroutine can be reduced to checking whether a system of polynomial inequalities has a solution over real numbers, which can then be determined in FPT time by using classical results from computational real algebra. Thus, we obtain the following non-trivial corollary.

▶ **Corollary 2.** *Disk Dispersal is* FPT *when parameterized by $d + k$. Specifically, it is solvable in time $(dk)^{\mathcal{O}(k)} \cdot |I|^{\mathcal{O}(1)}$.*

Our next result is a companion lower bound to the partial kernelization of Theorem 1, which shows that one cannot remove the dependence on $d$ from the kernel size.

▶ **Theorem 3.** *Disk Dispersal parameterized by $k$ does not admit a polynomial kernel unless* coNP $\subseteq$ NP/poly. *This result holds even if the distance $d$ is an integer, and the centers of the given disks have rational coordinates.*

As we already mentioned, by the result of Fiala, Kratochvíl, and Proskurowski about $q$-distant representatives, Disk Dispersal is NP-hard for $d = 2$. Thus the problem is in the class para-NP for parameter $d$. However, the complexity of parameterization by $k$ is more interesting, which remains open. However, in the appendix, we show that a *rectilinear* version of Disk Dispersal is indeed W[1]-hard parameterized by $k$.

### Organization

In Section 2 we introduce basic notions. In Section 3, we consider kernelization for Disk Dispersal. Further, we give complexity lower bounds. In Section 4, we show that it is unlikely that Disk Dispersal admits a polynomial kernel when parameterized by $k$ only. Finally, in Section 5, we provide some concluding remarks and future directions.

## 2 Preliminaries

As it is common in computational geometry, we assume the *real RAM* computational model, that is, we are working with real numbers and assume that basic operations can be executed in unit time.

### Disks and Segments

For two points $A$ and $B$ in the plane, we use $AB$ to denote the line segment with endpoints at $A$ and $B$. The *distance* between $A = (x_1, y_1)$ and $B = (x_2, y_2)$ or the *length* of $AB$, is $|AB| = \|A-B\|_2 = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$. The *(open unit) disk* with a *center* $C = (c_1, c_2)$ in the plane is the set of points $(x, y)$ satisfying the inequality $(x - c_1)^2 + (y - c_2)^2 < 1$. Whenever we write "disk" we mean an *open unit disk*, unless radius or closed-ness is specified explicitly. Clearly, two disks with centers $A$ and $B$ are disjoint if and only if the distance between $A$ and $B$ is at least two. We say that the disks *touch* if $|AB| = 2$. For real numbers $a \leq b$, we use $[a, b] = \{x \in \mathbb{R} \mid a \leq x \leq b\}$ to denote a *closed interval*. For $a_1 \leq b_1$ and $a_2 \leq b_2$, $[a_1, b_1] \times [a_2, b_2] = \{(x, y) \in \mathbb{R}^2 \mid a_1 \leq x \leq b_1 \text{ and } a_2 \leq y \leq b_2\}$. A point $X$ is *properly inside* of a polygon $P$ if it is inside $P$ but $X$ is not on the boundary; if we say that $X$ is inside $P$, we allow it to be on the boundary. A disk is *(properly) iniside* of a polygon $P$ if every point of the disk is (properly) inside of $P$.

### Graphs

We use standard graph-theoretic terminology and refer to the textbook of Diestel [8] for definitions of standard notions. Let $\mathcal{S}$ be a set of geometric objects in the plane (i.e., non-empty subsets of $\mathbb{R}^2$). Then, it is possible to define an intersection graph $G(\mathcal{S})$ as follows: $G(\mathcal{S})$ contains a unique vertex corresponding to every object in $\mathcal{S}$, and there is an edge between the two vertices iff the corresponding two objects in $\mathcal{S}$ have a non-empty intersection. *Unit disk graphs* are the intersection graphs of unit disks in the plane. Note that, given a family $\mathcal{S}$ of unit disks, we can construct the corresponding unit disk graph $G(\mathcal{S})$ in quadratic time.

### Parameterized Complexity

We refer to the standard textbooks ([5, 17]) for introduction to the area and formal definitions. Here, we only give a brief overview. Let $(\mathcal{I}, k)$ be an instance of a decision problem $\Pi$, where $k$ is a non-negative integer. We say that $\Pi$ is *fixed-parameter tractable* by $k$, if there exists an algorithm that can decide whether $\mathcal{I}$ is a yes-instance of $\Pi$ in time $f(k) \cdot |\mathcal{I}|^{\mathcal{O}(1)}$ for some computable function $f$, where $|\mathcal{I}|$ denotes the size of the instance $\mathcal{I}$. A common way to show that it is unlikely that a parameterized problem is in FPT, one can prove that it is W[1]-hard by demonstrating a *parameterized reduction* from a known W[1]-hard problem; we refer to [5] for the formal definitions of the class W[1] and parameterized reductions.

A *kernelization* (or *kernel*) for $\Pi$ is a polynomial time algorithm that, given an instance $(\mathcal{I}, k)$ of $\Pi$, outputs an equivalent instance $(\mathcal{I}', k')$ of $\Pi$ such that $|\mathcal{I}'| + k' \leq g(k)$ for a computable function $g$. A kernel is *polynomial* if $g$ is a polynomial. It can be shown that every decidable FPT problem admits a kernel. However, it is unlikely that all FPT problems have polynomial kernels. In particular, there is the now standard *cross-composition* technique to show that a parameterized problem does not admit a polynomial kernel unless NP $\subseteq$ coNP /poly.

### Systems of Polynomial Inequalities

In our FPT algorithm, we will need to find suitable locations for new disks that need to be added such that the locations are "compatible" with an existing arrangement of disks. We will achieve this by solving systems of polynomial inequalities. We use the following result.

▶ **Proposition 4** (Theorem 13.13 in [1]). *Let $R$ be a real closed field, and let $\mathcal{P} \subseteq R[X_1, \ldots, X_k]$ be a finite set of $s$ polynomials, each of degree at most $c$, and let*

$$(\exists X_1)(\exists X_2) \ldots (\exists X_k) F(X_1, X_2, \ldots, X_k)$$

*be a sentence, where $F(X_1, \ldots, X_k)$ is a quantifier-free boolean formula involving $\mathcal{P}$-atoms of type $P \odot 0$, where $\odot \in \{=, \neq, >, <\}$, and $P$ is a polynomial in $\mathcal{P}$. Then, there exists an algorithm to decide the truth of the sentence with complexity $s^{k+1}c^{\mathcal{O}(k)}$ in $D$,[2] where $D$ is the ring generated by the coefficients of the polynomials in $\mathcal{P}$.*

Furthermore, a point $(X_1^*, \ldots, X_k^*)$ satisfying $F(X_1, \ldots, X_k)$ can be computed in the same time by Algorithm 13.2 (sampling algorithm) of [1] (see Theorem 13.11 of [1]).

## 3 Kernelization and FPT Algorithms for Disk Dispersal

In this section, we first prove Theorem 1 on partial kernel for Disk Dispersal parameterized by $k+d$. Specifically, the output instance of the partial kernel is guaranteed to consist of only $\mathcal{O}(d^2k^3)$ unit disks. In case the coordinates of the disks in the input instance are rationals of the form $a + \frac{b}{c}$ where $b, c$ are bounded by a fixed constant (or a polynomial in $k + d$), our partial kernel in fact yields a (normal) kernel. Finally, using our partial kernel, we prove in Corollary 2 that Disk Dispersal is FPT parameterized by $k + d$.

The proofs of our partial kernels begin with the simple observation that if we are given a yes-instance, then the unit disk graph corresponding to the input set of unit disks admits a vertex cover of size at most $k$. So, in polynomial time we obtain a vertex cover $U$ of size at

[2] That is, the algorithm performs $s^{k+1}c^{\mathcal{O}(k)}$ operations in $D$.

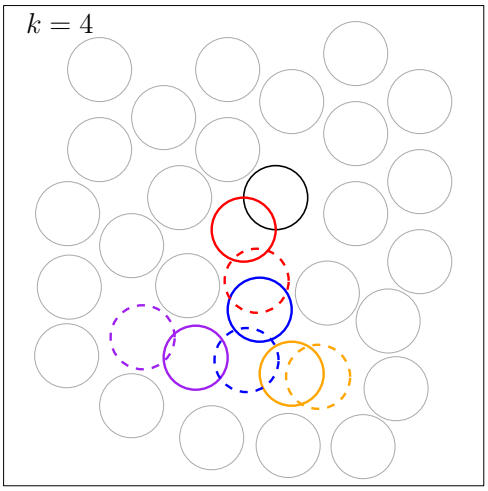

**Figure 2** Example of the propagation effect. The dotted objects correspond to a solution where an object of a certain color is replaced by the dashed object of the same color.

most $2k$. At first glance, one may think to remove all input unit disks that do not intersect any unit disk in $U$. However, we might be forced to perform movement operations that make some neighborhood sets larger (e.g., see Figure 2), which, in turn, can have a propagating effect that forces us to move unit disks that are "quite far" from all unit disks in $U$. Still, we can prove by induction on $k$ that if the input instance is a yes-instance, then it admits a solution where all the unit disks that are moved are at distance at most $\mathcal{O}(d^2k^2)$ from at least one unit disk in $U$. This gives rise to a reduction rule where we only keep the unit disks within this distance from at least one unit disk in $U$ as well as additional unit disks at some (almost negligible) distance from them.

After having reduced the number of unit disks, we can shift the unit disks that we keep so that the coordinates of their centers will be polynomial in $k + d$, under the assumption that the coordinates of the unit disks in the input instance are rationals of the form $a + \frac{b}{c}$ where $b, c$ are bounded by a fixed constant (or a polynomial in $k + d$). To obtain FPT algorithms, we first apply our partial kernels. Afterwards, we guess which disks to move. Then, we determine how to move them by solving a corresponding system of polynomial inequalities.

For the sake of formality, we will use the notion of a solution in this section as follows.

▶ **Definition 5.** *Let $(\mathcal{S}, k, d)$ be an instance of* Disk Dispersal. *A* solution *is a bijective function* $\mathsf{move}\colon \mathcal{S} \to \mathcal{P}$ *such that:*

1. *$\mathcal{P}$ is a* packing*, i.e., a non-overlapping set of unit disks.*
2. *$|\{D \in \mathcal{S} : \mathsf{move}(D) \neq D\}| \leq k$.*
3. *For every $D \in \mathcal{S}$: The distance between the centers of $D$ and $\mathsf{move}(D)$ is at most $d$.*

*We define the* set of unit disks moved by move *as $\{D \in \mathcal{S} : \mathsf{move}(D) \neq D\}$, and the* size of move *as the size of this set.*

Notice that any set of unit disks that is moved by a solution to Disk Dispersal is in particular a vertex cover (though not necessarily a minimal one) for the intersection graph of the input set of unit disks. As previously discussed, since the Vertex Cover problem admits a 2-approximation algorithm in polynomial time, this yields the following observation.

▶ **Observation 6.** *There exists a polynomial-time algorithm that, given an instance $(\mathcal{S}, k, d)$ of* Disk Dispersal*, either correctly concludes that $(\mathcal{S}, k, d)$ is a no-instance, or outputs a vertex cover of size at most $2k$ for the unit disk graph corresponding to $\mathcal{S}$.*

We will also need the following observation, which is directly implied by the fact that the area of a disk of radius $r$ is $\pi r^2$, while the area of a unit disk (whose radius is 1) is $\pi$.

▶ **Observation 7.** *The number of pairwise non-intersecting unit disks in a disk of radius $r$ is at most $r^2$.*

Towards the presentation of our partial kernel, we need to prove one lemma. Informally speaking, this lemma shows that the set of disks that may be potentially moved in a yes-instance is contained in a bounded area around a small number of disks, in particular the disks that form a vertex cover in the intersection graph. Furthermore, since all such disks, except that forming the vertex cover, are non-intersecting, this lemma eventually helps us bound the number of such disks by a polynomial in $k$ and $d$.

▶ **Lemma 8.** *Let $(\mathcal{S}, d, k)$ be a yes-instance of Disk Dispersal. Let $U$ be a vertex cover for the intersection graph of $\mathcal{S}$. Then, any minimum-sized solution to $(\mathcal{S}, k, d)$ only moves unit disks whose center is at distance at most $(d+2) \cdot k$ from the center of at least one unit disk in $U$.*

**Proof.** We prove the lemma by induction on $k$. When $k = 0$, the only minimum-sized solution to $(\mathcal{S}, k, d)$ is the one that moves no unit disk, and hence the claim trivially follows. Now, suppose that the claim holds for $k - 1 \geq 0$, and let us prove it for $k$. If the intersection graph of $\mathcal{S}$ is edgeless, then the only minimum-sized solution to $(\mathcal{S}, k, d)$ is the one that moves no unit disk, and hence the claim trivially follows as in the base case. So, we can next suppose that there exist two different unit disks $D, D' \in \mathcal{S}$ that intersect each other. See Figure 3 for an illustration.

Since $U$ is a vertex cover, it must contain at least one unit disk among $D$ and $D'$, denoted by $X$. Moreover, any solution to $(\mathcal{S}, k, d)$ must move at least one unit disk among $D$ and $D'$. Let $\mathsf{move} : \mathcal{S} \to \mathcal{P}$ be an arbitrary minimum-sized solution to $\mathcal{I} = (\mathcal{S}, k, d)$, and let $Y$ be a unit disk among $D$ and $D'$ that $\mathsf{move}$ moves to attain $\mathcal{P}$. Let $Y' = \mathsf{move}(Y)$, and let $\mathcal{S}' = (\mathcal{S} \setminus \{Y\}) \cup \{Y'\}$. We attain solution $\mathsf{move}' : \mathcal{S}' \to \mathcal{P}'$ to a new instance $\mathcal{I}' = (\mathcal{S}', k-1, d)$ as follows: for every $\tilde{D} \in \mathcal{S} \setminus \{Y\}, \mathsf{move}'(\tilde{D}) = \mathsf{move}(\tilde{D})$; $\mathsf{move}'(Y') = Y'$. Note that $\mathsf{move}'$ must be a minimum-sized solution to $(\mathcal{S}', k-1, d)$, otherwise we can obtain a solution for the original instance $(\mathcal{S}, k, d)$ that is smaller than $\mathsf{move}$, contradicting its optimality. Further, note that $(U \setminus \{Y\}) \cup \{Y'\}$ is a (not necessarily minimal) vertex cover for the intersection graph of $\mathcal{S}'$. By the inductive hypothesis, this means that $\mathsf{move}'$ only moves unit disks whose center is at distance at most $(d+2) \cdot (k-1)$ from the center of at least one unit disk in $(U \setminus \{Y\}) \cup \{Y'\}$. Moreover, the distance between the centers of $Y$ and $X$ is at most 2 (since they intersect) and the distance between the centers of $Y'$ and $Y$ is at most $d$, so the distance between the centers $Y'$ and $X$ is at most $d+2$. In turn, this means that $\mathsf{move}$ only moves unit disks at distance at most $(d+2) \cdot k$ from at least one unit disk in $U$, which concludes the proof. ◀

We are now ready to present the partial kernel for Disk Dispersal. For the reader's convenience, we restate Theorem 1 here.

▶ **Theorem 1.** *There is a polynomial-time algorithm that, given an instance $(\mathcal{S}, k, d)$ of Disk Dispersal, outputs an equivalent instance $(\mathcal{S}', k, d)$ of the same problem, where the number of unit disks is $|\mathcal{S}'| = \mathcal{O}((d+1)^2 k^3)$, and $\mathcal{S}' \subseteq \mathcal{S}$.*

**Proof.** Given an instance $(\mathcal{S}, k, d)$ of Disk Dispersal, the (partial kernel) kernelization algorithm works as follows. Based on Observation 6, it computes a vertex cover $U$ of size at most $2k$ for the intersection graph of $\mathcal{S}$. Then, it obtains $\mathcal{S}'$ from $\mathcal{S}$ by removing from $\mathcal{S}$ all

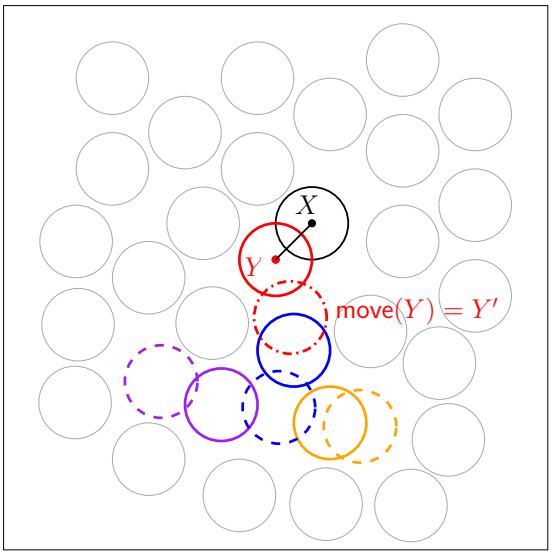

**Figure 3** Illustration for Proof of Lemma 8. A vertex cover $U$ contains disk $X$ and a solution $\mathcal{S}$ moves a disk $Y$ to its new location, $Y' = \mathsf{move}(Y)$, denoted in dash-dotted disk in red color. A new instance $\mathcal{I}'$ is obtained by replacing $Y$ with $Y'$ and reducing the budget by 1, and $U' = X \cup Y'$ is a vertex cover for the resulting intersection graph. A solution to $\mathcal{I}'$ moves the solid blue, purple, and orange disks to their new locations, shown in dashed disks of corresponding color. By inductive hypothesis, the new locations are at distance at most $(d+2)\cdot(k-1)$ from $U'$, and the distance between $X$ and $Y'$ is at most $d+2$.

the unit disks at distance more than $(d+2)\cdot(k+1)$ from all unit disks in $U$. The output instance is $(\mathcal{S}', k, d)$. Clearly, the kernelization algorithm works in polynomial time. So, it suffices to prove that $(\mathcal{S}, k, d)$ and $(\mathcal{S}', k, d)$ are equivalent and that $|\mathcal{S}'| = \mathcal{O}(d^2k^3)$.

We first prove the equivalence. In one direction, suppose that $(\mathcal{S}, k, d)$ is a yes-instance, and let $\mathsf{move} : \mathcal{S} \to \mathcal{P}$ be a solution to it. In particular, the restriction of $\mathsf{move}$ to $\mathcal{S}'$ clearly yields a packing (being a subset of $\mathcal{P}$) and moves at most as many disks as $\mathsf{move}$ does. So, the restriction of $\mathsf{move}$ to $\mathcal{S}'$ is a solution to $(\mathcal{S}', k, d)$.

In the other direction, suppose that $(\mathcal{S}', k, d)$ is a yes-instance. By Lemma 8, $(\mathcal{S}', k, d)$ admits a solution $\mathsf{move}' : \mathcal{S}' \to \mathcal{P}'$ that only moves unit disks whose centers are at distance at most $(d+2)\cdot k$ from the center of at least one unit disk in $U$.[3] Define $\mathsf{move} : \mathcal{S} \to \mathcal{P}$ for $\mathcal{P} = \mathcal{P}' \cup (\mathcal{S} \setminus \mathcal{S}')$ as follows: for every $D \in \mathcal{S}'$, $\mathsf{move}(D) = \mathsf{move}'(D)$, and for every $D \in \mathcal{S} \setminus \mathcal{S}'$, $\mathsf{move}(D) = D$. We claim that $\mathsf{move}$ is a solution to $(\mathcal{S}, k, d)$. To this end, first note that none of the unit disks in $\mathcal{P}'$ intersect each other (since $\mathsf{move}'$ is a solution to $(\mathcal{S}', k, d)$). In particular, the unit disks in $\{D \in U : \mathsf{move}(D) = D\}$ do not intersect any other unit disk in $\mathcal{P}'$. However, all unit disks in $\mathcal{S}$ that do not belong to $U$ do not intersect each other (since $U$ is a vertex cover for the intersection graph of $\mathcal{S}$). So, in $\mathcal{P}$, the only pairs of unit disks that can potentially intersect each other are pairs where one is a unit disk that was moved by $\mathsf{move}$ and the other belongs to $\mathcal{S} \setminus \mathcal{S}'$. However, the center of any unit disk $D$ that is moved by $\mathsf{move}$ is at distance at most $(d+2)\cdot k$ from the center of at least one unit disk $D'$ in $U$, and hence the center of $\mathsf{move}(D)$ is at distance at most $d + (d+2)\cdot k$ from the center of $D'$, while the center of any unit disk in $\mathcal{S} \setminus \mathcal{S}'$ is at distance more than

[3] Note that $\mathcal{S}'$ may contains unit disks whose centers are at distance larger than $(d+2)\cdot k$ (but at most $(d+2)\cdot(k+1)$) from the centers of all unit disks in $U$.

$(d+2)\cdot(k+1)$ from the centers of all unit disks in $U$. Thus, $\mathcal{P}$ cannot have a pair of unit disks that intersect each other, such that one is a unit disk that was moved by move and the other belongs to $\mathcal{S}\setminus\mathcal{S}'$. So, move is indeed a solution to $(\mathcal{S},k,d)$.

Now, note that for every $D\in U$, the unit disks whose center is at distance at most $(d+2)\cdot(k+1)$ from $D$ are contained in a disk $D'$ of radius $(d+2)\cdot(k+1)+1$ and whose center is the same as the center of $D$. So, by Observation 7 and since $U$ is a vertex cover for the intersection graph of $\mathcal{S}$, this means that there exist at most $((d+2)\cdot(k+1)+2)^2=\mathcal{O}(d^2k^2)$ unit disks in $\mathcal{S}\setminus U$ that intersect $D'$. As $|U|\leq 2k$, we conclude that $|\mathcal{S}'|\leq|U|+|U|\cdot((d+2)\cdot(k+1)+2)^2=\mathcal{O}(d^2k^3)$. ◀

To reduce the bitsize of encoding the coordinates of the unit disks in the output instance, we make use of the following lemma.

▶ **Lemma 9.** *There exists a polynomial-time algorithm that, given a set $\mathcal{D}$ of unit disks whose centers have rational coordinates, a partition $(\mathcal{D}_1,\mathcal{D}_2,\ldots,\mathcal{D}_\ell)$ of $\mathcal{D}$, and $r\in\mathbb{N}$, outputs a set $\mathcal{D}'$ of unit disks whose centers have rational coordinates and a bijective function $f:\mathcal{D}\to\mathcal{D}'$ with the following properties.*

- *For all $i\in\{1,2,\ldots,\ell\}$, $\mathcal{D}_i$ and $\{f(D):D\in\mathcal{D}_i\}$ are* isometric*, that is, for all $D,D'\in\mathcal{D}_i$, we have* $\mathsf{distance}(D,D')=\mathsf{distance}(f(D),f(D'))$.
- *For all distinct $i,j\in\{1,2,\ldots,\ell\}$, $D\in\mathcal{D}_i$ and $D'\in\mathcal{D}_j$, we have* $\mathsf{distance}(D,D')>r$.
- *Encoding the coordinates (in unary) of all the unit disks in $\{f(D):D\in\mathcal{D}_i\}$ requires space polynomial in $r,|\mathcal{D}|,m=\max\limits_{i=1}^{\ell}\max\limits_{D,D'\in\mathcal{D}_i}\mathsf{distance}(D,D')$ and $N=\max_{b,c}(b+c)$ over every $b,c\in\mathbb{N},b<c$, and $b,c$ are coprime, such that $a+\frac{b}{c}$ is a coordinate of a center of a unit disk in $\mathcal{D}$.*

**Proof.** For every $i\in\{1,2,\ldots,\ell\}$, let $L_i$ be a leftmost unit disk in $\mathcal{D}_i$ (i.e., with a smallest $x$-coordinate of its center), and let $D_i$ be a bottommost unit disk in $\mathcal{D}_i$ (i.e., with a smallest $y$-coordinate of its center), and denote their centers by $(x_i^{\mathsf{left}},y_i^{\mathsf{left}})$ and $(x_i^{\mathsf{bottom}},y_i^{\mathsf{bottom}})$, respectively. Now, for every $i\in\{1,2,\ldots,\ell\}$ and every $D\in\mathcal{D}_i$ with center $(x,y)$, define $f(D)$ as the unit disk whose center is $(x-x_i^{\mathsf{left}}+(i-1)\cdot(m+r),y-y_i^{\mathsf{bottom}}+(i-1)\cdot(m+r))$. We define $\mathcal{D}'$ as the set of unit disks assigned by $f$. Clearly, $f:\mathcal{D}\to\mathcal{D}'$ is bijective and the third property in the lemma holds.

For the first property, consider two unit disks $D,D'\in\mathcal{D}_i$ for some $i\in\{1,2,\ldots,\ell\}$ with centers $(x,y)$ and $(x',y')$, respectively. Then, $\mathsf{distance}(f(D),f(D'))$ is equal to the square root of $((x-x_i^{\mathsf{left}}+(i-1)\cdot(m+r))-(x'-x_i^{\mathsf{left}}+(i-1)\cdot(m+r)))^2+((y-y_i^{\mathsf{bottom}}+(i-1)\cdot(m+r))-(y'-y_i^{\mathsf{bottom}}+(i-1)\cdot(m+r)))^2$, which is precisely $\sqrt{(x-x')^2+(y-y')^2}=\mathsf{distance}(D,D')$. So, the first property in the lemma holds.

For the second property, consider two unit disks $D\in\mathcal{D}_i,D'\in\mathcal{D}_j$ for some $i,j\in\{1,2,\ldots,\ell\}$, $i<j$, with centers $(x,y)$ and $(x',y')$, respectively. Then, $\mathsf{distance}(f(D),f(D'))$ is equal to the square root of $((x'-x_j^{\mathsf{left}}+(j-1)\cdot(m+r))-(x-x_i^{\mathsf{left}}+(i-1)\cdot(m+r)))^2+((y'-y_j^{\mathsf{bottom}}+(j-1)\cdot(m+r))-(y-y_i^{\mathsf{bottom}}+(i-1)\cdot(m+r)))^2$. Observe that $x'\geq x_j^{\mathsf{left}},y'\geq y_j^{\mathsf{bottom}},x\leq x_i^{\mathsf{left}}+m,y\leq y_i^{\mathsf{bottom}}+m$. So, the above expression is lower bounded by

$$\sqrt{2\left((j-1)\cdot(m+r)-(m+(i-1)\cdot(m+r))\right)^2}=\sqrt{2}\cdot((j-i)(m+r)-m)\geq\sqrt{2}r.$$

In particular, $\mathsf{distance}(f(D),f(D'))>r$. So, the second property in the lemma holds. ◀

We will also need the following simple observation.

▶ **Observation 10.** *Let $\mathcal{S}$ be a set of unit disks in the Euclidean plane. Let $D \in \mathcal{S}$. Then, by moving $D$ by a distance of at most some $d \in \mathbb{N}$, $D$ cannot intersect unit disks whose centers are at distance at least $d+2$ from the original position of the center of $D$.*

Based on Lemma 9 and Observation 10, we prove the following.

▶ **Lemma 11.** *There exists a polynomial-time algorithm that, given an instance $(\mathcal{S}, k, d)$ of* Disk Dispersal *where the centers of all disks have rational coordinates, and a partition $(\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_\ell)$ of $\mathcal{S}$ such that for all $i, j \in \{1, 2, \ldots, \ell\}, D \in \mathcal{S}_i$ and $D' \in \mathcal{S}_j$, we have $\mathsf{distance}(D, D') \geq 2d+2$, outputs an equivalent instance of* Disk Dispersal*, respectively, with the same parameters $k, d$ and number of unit disks, where encoding the coordinates of all the unit disks (in unary) requires space polynomial in $d$, $|\mathcal{S}|$, $m = \max_{i=1}^{\ell} \max_{D,D' \in \mathcal{S}_i} \mathsf{distance}(D, D')$ and $N = \max_{b,c}(b+c)$ over every $b, c \in \mathbb{N}, b < c$, such that $a + \frac{b}{c}$ is a coordinate of a center of a unit disk in $\mathcal{D}$.*

**Proof.** The algorithm simply applies the algorithm in Lemma 9 with $r = 2d+2$, and obtains $f : \mathcal{S} \to \mathcal{S}'$. Then, it returns $\mathcal{D}'$. From Lemma 9, it directly follows that encoding the coordinates of all the unit disks requires space polynomial in $d, |\mathcal{D}|, m$ and $N$. Recall that for all $i, j \in \{1, 2, \ldots, \ell\}, D \in \mathcal{S}_i$ and $D' \in \mathcal{S}_j$, we have $\mathsf{distance}(D, D') \geq 2d+2$, and this property is preserved under the mapping $f$ (by our choice of $r$). So, Observation 10 implies that the sub-instances induced by the different sets $\mathcal{S}_i$ are "independent" from each other: we cannot move unit disks in one set $\mathcal{S}_i$ so that they intersect unit disks in another set $\mathcal{S}_j$. Also, the same holds for the sub-instances they are mapped to by $f$. As every sub-instance induced by some set $\mathcal{S}_i$ is equivalent to the sub-instance it is mapped to by $f$ since $\mathcal{S}_i$ and $\{f(D) : D \in \mathcal{S}_i\}$ are isometric, we conclude that $(\mathcal{S}, k, d)$ and $(\mathcal{S}', k, d)$ are equivalent. ◀

We our now ready to present our (non-partial) kernel for Disk Dispersal. In particular, if $N$ is a constant (or polynomial in $k+d$), the parameterization can be assumed to be only by $k+d$.

▶ **Theorem 12.** *Disk Dispersal, restricted to instances where the centers of all disks have rational coordinates, admits a polynomial kernel with respect to $k+d+N$, where $N = \max_{b,c}(b+c)$ over every $b, c \in \mathbb{N}, b < c$, such that $a + \frac{b}{c}$ is a coordinate of a center of a unit disk in $\mathcal{S}$.*

**Proof.** Given an instance $(\mathcal{S}, k, d)$ of Disk Dispersal, restricted to instances where the centers of all disks have rational coordinates, the kernelization algorithm works as follows. First, we call the algorithm in Theorem 1 to obtain an equivalent instance $(\mathcal{S}', k, d)$ of Disk Dispersal. Here, $k, d$ remain unchanged, and $\mathcal{S}'$ is a subset of $\mathcal{S}$. Let $\mathcal{W} = \{W_D : D \in \mathcal{S}'\}$ where $W_D$ is a disk whose center is the same as the center of $D$ and whose radius is $d+1$. Let $\mathcal{C}$ be the set of connected components of the intersection graph of $\mathcal{W}$. Let $\mathcal{P}$ be the partition of $\mathcal{S}'$ such that two unit disks in $\mathcal{S}'$ belong to the same part if and only if there exists a connected component in $\mathcal{C}$ such that both are intersected by (possibly different) disks that belong to that component. It should be clear, from the definitions of $\mathcal{S}'$ and $\mathcal{W}$, that this is indeed a partition, and that if two unit disks in $\mathcal{S}'$ belong to different parts in this partition, then the distance between their centers is larger than $2d+2$. So, the kernelization algorithm then calls the algorithm in Lemma 11 on $(\mathcal{S}', k, d)$ and $\mathcal{P}$ as the partition of $\mathcal{D}'$, and returns its output. ◀

Lastly, based on Theorem 1 and Proposition 4, we prove Corollary 2 stating that Disk Dispersal is FPT when parameterized by $d+k$. We restate the theorem here.

▶ **Corollary 2.** *Disk Dispersal is* FPT *when parameterized by* $d + k$*. Specifically, it is solvable in time* $(dk)^{\mathcal{O}(k)} \cdot |I|^{\mathcal{O}(1)}$*.*

**Proof.** Given an instance $(\mathcal{S}, k, d)$ of Disk Dispersal, the algorithm first calls the algorithm in Theorem 1 to obtain (in polynomial time) an equivalent instance $(\mathcal{S}', k, d)$ of Disk Dispersal, where $\mathcal{S}' \subseteq \mathcal{S}$ is of size $\mathcal{O}(d^2k^3)$. Then, for every $\mathcal{A} \subseteq \mathcal{S}'$ of size at most $k$ such that $\mathcal{S}' \setminus \mathcal{A}$ is a packing, the algorithm tests whether it is possible to move each unit disk in $\mathcal{A}$ by a distance of at most $d$ so that, afterwards, $\mathcal{S}'$ becomes a packing. This can be done by using the algorithm in Proposition 4 to solve the following system of polynomial inequalities, which has variables $x_A, y_A$ for every $A \in \mathcal{A}$:

- For every $S \in \mathcal{S}' \setminus \mathcal{A}$ and $A \in \mathcal{A}$: $(x_A - a)^2 + (y_A - b)^2 \geq 4$, where $(a, b)$ denotes the center of $S$.
- For every distinct $A_1, A_2 \in \mathcal{A}$: $(x_{A_1} - x_{A_2})^2 + (y_{A_1} - y_{A_2})^2 \geq 4$.
- For every $A \in \mathcal{A}$, where $(a, b)$ denotes the center of $A$ in $\mathcal{S}'$: $(x_A - a)^2 + (y_A - b)^2 \leq d^2$.

The correctness of the algorithm is immediate. For its running time analysis, notice that there are only $\sum_{i=0}^{k} \binom{|\mathcal{S}'|}{i} \leq (dk)^{\mathcal{O}(k)}$ choices for $\mathcal{A}$. Further, each of the systems of polynomial equations that are solved has at most $2k$ variables, degree 2, and $\mathcal{O}(|\mathcal{A}| \cdot |\mathcal{S}'|) \leq (dk)^{\mathcal{O}(1)}$ equations. So, by Proposition 4, it is solvable in time $(dk)^{\mathcal{O}(k)} \cdot |I|^{\mathcal{O}(1)}$. In turn, we conclude that the algorithm runs in time $(dk)^{\mathcal{O}(k)} \cdot |I|^{\mathcal{O}(1)}$. ◀

## 4 Kernelization lower bound for Disk Dispersal

In this section, we prove Theorem 3. To this end, we show that from several instances of Disk Appending (defined below), we can construct a single instance $\mathcal{I}'$ of Disk Dispersal such that there is a solution to $\mathcal{I}'$ if and only if there is a solution to at least one of the instances of Disk Appending. The result then follows from the cross-composition technique (see [17], Chapter 17 for more details). Disk Appending is defined as follows.

Disk Appending

| | |
|---|---|
| *Input:* | A packing $\mathcal{P}$ of $n$ unit disks inside a rectangle $R$ and an integer $\kappa \geq 0$. |
| *Task:* | Decide whether there is a packing $\mathcal{P}^*$ of $n + \kappa$ unit disks inside $R$ obtained from $\mathcal{P}$ by adding $\kappa$ new disks. |

A recent result of Fomin et al. [15, 16] shows that the problem is NP-hard. In particular, they show the following result.

▶ **Proposition 13** (Corollary 2 in [15])**.** *Disk Appending is* NP*-hard. Furthermore, it remains* NP*-hard, even when restricted to instances* $(R, \mathcal{P}, \kappa)$ *of the following form.*

- *Rectangle* $R$ *is* $[0, 2a] \times [0, 2b]$ *for integers* $a, b > 0$*. It can also be assumed that* $a = b$*.*
- *A packing* $\mathcal{P}$ *of disks with their centers inside* $R$ *such that (i) for every* $i \in \{0, \ldots, a\}$*, the disks with centers* $(2i, 0)$ *and* $(2i, 2b)$ *are in* $\mathcal{P}$ *and (ii) for every* $j \in \{0, \ldots, b\}$*, the disks with centers* $(0, 2j)$ *and* $(2a, 2j)$ *are in* $\mathcal{P}$*.*

**Proof of Theorem 3.** The reader may wish to refer to Figure 4, which explains the schematics of the reduction. We consider instances $(R, \mathcal{P}, n, \kappa)$ of Disk Appending, where $R$ is an $[0, a] \times [0, a]$ square, where $a$ is an even positive integer, $\mathcal{P}$ is a packing of $n$ disks with their centers inside $R$, such that the centers of the disks are rational, and $\kappa$ is the number of disks that need to be added inside $R$, which is compatible with $\mathcal{P}$, to obtain a packing of $n + k$ disks. We also assume that for every $i \in \{1, \ldots, a/2\}$, the disks with centers $(2i - 1, 1)$, $(2i - 1, a - 1)$, $(1, 2i - 1)$ and $(a - 1, 2i - 1)$ are in $\mathcal{P}$.

For the cross-composition, we first show the polynomial equivalence relation $\mathcal{R}$, over instances $(R_i, \mathcal{P}_i, n_i, \kappa_i)$ of Disk Appending. The instances $(R_i, \mathcal{P}_i, n_i, \kappa_i)$ and $(R_j, \mathcal{P}_j, n_j, \kappa_j)$ go to the same equivalence classes if (1) the squares $R_i$ and $R_j$ have the same dimension, (2) $\mathcal{P}_i$ and $\mathcal{P}_j$ is a packing of $n_i = n_j$ disks inside $R_i$ and $R_j$ respectively with centers having rational coordinates, and (3) $\kappa_i = \kappa_j$. All the other malformed instances go into another equivalence class (see [17] for the formal requirements of the equivalence relation). Note that $\mathcal{R}$ satisfies the properties of polynomial equivalence relation, since the equivalence can be checked in polynomial time, and (2) $\mathcal{R}$ partitions the elements of $S$ into at most $(\max_{x \in S} |x|)^{\mathcal{O}(1)}$ classes in a well-formed instance, since $\kappa_i \leq n_i$ (this can be assumed w.l.o.g. by padding the instance as required, as per Proposition 13).

Now we give a cross-composition algorithm for instances belonging to the same equivalence class. For the last equivalence class of malformed instances, we output a trivial no-instance. Thus, from now on, we focus on an equivalence class $(R_1, \mathcal{P}_1, n, \kappa), \ldots, (R_t, \mathcal{P}_t, n, \kappa)$, such that $a$ is the sidelength of every square $R_1, \ldots, R_t$. We assume w.l.o.g. that $t$ is odd, and $a$ is an even integer that is at least $10\kappa$.

For every $1 \leq i \leq t$, we construct a gadget $G_i$ as follows; see Figure 4. Let $R$ be a rectangle of height 6 and width $2\kappa + 6$. Suppose the cartesian coordinates of the bottom-left corner of $G_i$ are $(0, 0)$ (note that this coordinate system is defined only for explaining the gadget structure, and should not be confused with the coordinate system in the next paragraph). Then, we place $2(k + 3)$ disks centered at points $(1, 1), (3, 1), \ldots, (2k + 5, 1)$, as well as $(1, 5), (3, 5), \ldots, (2\kappa + 5, 5)$, and 2 additional disks centered at $(1, 3)$, and $(2\kappa + 5, 3)$. These disks lie along the perimeter of the rectangle, with centers at distance 1 from the perimeter. We call these disks *surrounding disks* (shown in green). Additionally, we place $\kappa$ disks with centers at $(4, 3), (6, 3), \ldots, (2\kappa + 2, 3)$, which are termed as *interesting disks* (shown in blue). Note that this leaves a horizontal gap of 1 between the leftmost (resp. rightmost) interesting disk and the surrounding disks with center $(1, 3)$ (resp. $(2\kappa + 5, 3)$). Now, we pad the gadget horizontally by adding columns of 3 disks on both sides of the surrounding disks in a symmetric manner, such that the width of the gadget becomes exactly $a$.

Now we describe the construction of the instance of Disk Dispersal. It might be useful to refer to a schematic description shown in Figure 4. Let $d$, the distance by which a disk can be moved, be equal to $\frac{9}{4}t^2a^2$. We place the first square $R_1$ and the corresponding packing of disks $\mathcal{P}_1$ from the first instance by placing the bottom-left of $R_1$ corner at the origin $(0, 0)$. Next, we place the instances $(R_2, \mathcal{P}_2), (R_3, \mathcal{P}_3), \ldots, (R_t, \mathcal{P}_t)$ by aligning their bottom edge along the $x$-axis, and leaving a horizontal gap of $s := \sqrt{2ad}$ between the adjacent squares. Then, we place the gadgets $G_i$ directly above the rectangle $R_i$ such that the vertical distance between the top edge of $R_i$ and the top edge of $G_i$ is equal to $h := \sqrt{d^2 - a^2}$. Since the width of every gadget $G_i$ is equal to $a$ after padding, the vertical boundaries of $R_i$ and the corresponding $G_i$ are aligned. Next, we place a set $C$ of $\kappa + 2$ co-located disks such that (1) the vertical distance between the bottom edge of $G_{(t+1)/2}$ and the centers of disks in $C$ is equal to $d/2$, and (2) the centers of the disks in $C$ are aligned with the horizontal center of the gadget $G_i$. We place a rectangle tightly enclosing the instance constructed thus far, and pack all the empty spaces outside the gadgets using disks with integral coordinates on the centers (not shown in the figure). Finally, we set the budget $k$, the number of disks that can be moved, to be $(\kappa + 1) + \kappa = 2\kappa + 1$. This finishes the construction of the instance of Disk Dispersal.

The proof of the following claim follows from the careful choice of $d$, $h$ and $s$ in terms of $a$ and $t$.

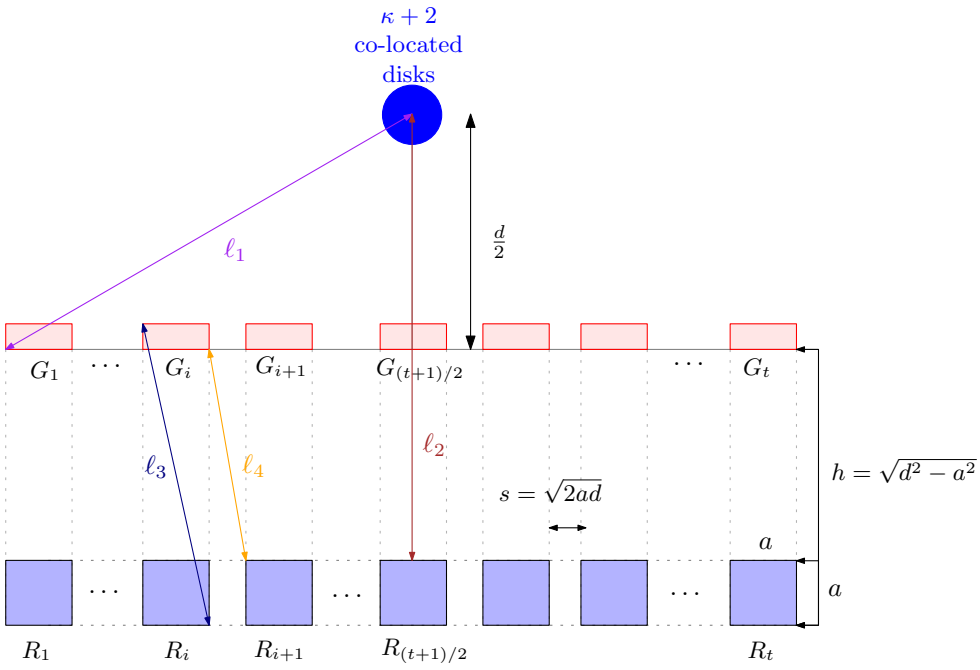

**Figure 4** Schematic depiction of an instance of Disk Dispersal obtained by OR-composition of instances $(R_i, \mathcal{P}_i, n, \kappa)$ of Disk Appending. Each instance $(R_i, \mathcal{P}_i, n, \kappa)$ is shown in a blue square of sidelength $a$. Red rectangles are gadgets $G_i$, and an example gadget is shown below. Lengths $\ell_1, \ell_2, \ell_3, \ell_4$ are defined in Claim 14, and the values of $s$, $h$, and $d$ are carefully chosen functions of $t$ and $a$, in order to ensure that $\ell_1, \ell_3 \leq d < \ell_2, \ell_4$ (note that the figure is not to scale). All the empty spaces are filled with padding disks with integral coordinates of centers. This ensures that an interesting disk from $G_i$ cannot be moved into an adjacent $R_{i\pm1}$, and thus different instances remain "isolated". In the gadget $G_i$, the *surrounding disks* are shown in green and *interesting disks* are shown in blue. Finally, purple disks are added on either side of the gadget in order to make the total width of the gadget exactly $a$. Then, the gadget $G_i$ and the corresponding square $R_i$ can be horizontally aligned as shown in the figure.

▷ Claim 14.

1. The maximum distance between the centers of disks in $C$ and any point in any $G_i$ is at most $d$ (shown as $\ell_1$ in Figure 4).
2. The minimum distance between the centers of disks in $C$ and any point in any $R_i$ is more than $d$ ($\ell_2$).
3. The maximum distance between a point in $G_i$ and a point in the corresponding $R_i$ is at most $d$ ($\ell_3$).
4. The minimum distance between a point in $G_i$ and a point in another $R_j$ is more than $d$ ($\ell_4$).

Proof. The values of $d, h$, and $s$ are chosen carefully in terms of $a$ and $t$ in order to ensure these properties. First we observe that $s = \sqrt{2ad} \geq a$, since $d = \frac{9}{4}t^2a^2$.

1. Note that the horizontal distance between the midpoint of $G_{(t+1)/2}$ and the leftmost point in $G_1$ can be upper bounded by $(t/2)(a+s) \leq (t/2)\cdot(2s) = t\cdot\sqrt{2ad}$. The vertical distance between the bottom edge of $G_{(t+1)/2}$ and the centers of disks in $C$ is $d/2$. Therefore, it suffices to show that $\left(\frac{d}{2}\right)^2 + \left(t\sqrt{2ad}\right)^2 \leq d^2$, i.e., $t^2 \cdot 2ad \leq \frac{3d^2}{4}$, i.e., $2at^2 \leq \frac{3}{4}\cdot\frac{9}{4}\cdot t^2a^2$. This holds assuming $a \geq 216$.
2. It suffices to consider the vertical distance between the centers of $C$ and the top edge of $R_{(t+1)/2}$. This vertical distance is $\frac{d}{2} + h - a$, which we want to show is greater than $d$. Note that it suffices to show that $h = \sqrt{d^2 - a^2} > \frac{d}{2}$, i.e., $a^2 < \frac{3d^2}{4}$, i.e., $\frac{243}{64}t^4a^2 > 1$. However, since $t, a \geq 1$, this is true.
3. $\ell_3^2 = h^2 + a^2 = d^2 - a^2 + a^2 = d^2$, since $h = \sqrt{d^2 - a^2}$.
4. It suffices to consider adjacent $G_i$, $R_{i+1}$ pairs (argument for $R_{i-1}$ is identical). Then, $\ell_4^2 = (h-a)^2 + s^2 = (\sqrt{d^2 - a^2} - a)^2 + 2ad = d^2 - 2a\sqrt{d^2 - a^2} + 2ad$, which we want to show is at least $d^2$. This holds since $d > \sqrt{d^2 - a^2}$. ◁

Now we explain the implications of Claim 14. In any yes-instance, at least $\kappa + 1$ disks from $C$ must be moved by a distance at most $d$. Let $C'$ be this set of disks from the set of $\kappa + 2$ co-located disks, that are moved. Note that in any gadget $G_i$, if all the $\kappa$ interesting disks are moved, then this creates an available space for placing $\kappa + 1$ disks of $C'$. On the other hand, if any set of fewer than $\kappa$ disks inducing a connected component in the *contact graph* (i.e., a special kind of intersection graph wherein there is an edge between the vertices corresponding to two disks iff their boundaries touch each other) of the disks is moved, then this creates space for at most $\kappa$ disks from $C'$ (note that the distance between $C'$ and an $R_i$ is more than $d$ by item 2 of Claim 14). However, since the budget is $2\kappa + 1$, this cannot correspond to a feasible solution. Thus, in a solution to a yes-instance, $C'$ can only be moved in the place of $\kappa$ interesting disks corresponding to a gadget $G_i$. Next, an interesting disk can be moved anywhere in the corresponding square $R_i$ (item 3), but cannot be moved to a different square $R_j$ (item 4). Then, using an argument used for the disks in $C'$, we conclude that the $k$ interesting disks can only be moved in the empty spaces in the corresponding $R_i$. Thus, the created instance of Disk Dispersal is a yes-instance iff there exists some yes-instance $(R_i, \mathcal{P}_i, n, \kappa)$ of Disk Appending. Finally, we note that Proposition 13 implies that the coordinates of the centers of the disks in each instance of Disk Dispersal can be assumed to be rational. Furthermore, by letting $s \approx \sqrt{2ad}$, and $h \approx \sqrt{d^2 - a^2}$ as rational approximations of their original values with small enough error, we can ensure that the coordinates of all the centers of the disks in the constructed instance become rational, and furthermore, the inequalities from Claim 14 continue to hold. This concludes the proof of Theorem 3. ◀

## 5 Conclusion and Open Problem

In this paper, we initiate the study of the problem of spreading points from the perspective of parameterized complexity and kernelization. We reformulate the problem in terms of moving at most $k$ unit disks by a distance of at most $d$, which we call Disk Dispersal. We design a (partial) polynomial kernel for Disk Dispersal parameterized by $k$ and $d$. Furthermore, we show that this can be transformed into a (true) kernel, assuming the coordinates of the centers of the unit disks are rational numbers with bounded denominators. We complement this result by showing that Disk Dispersal does not admit a polynomial kernel parameterized by $k$ alone, assuming coNP $\subseteq$ NP /poly. These results provide a complete picture of the kernelization complexity of Disk Dispersal.

We show that Disk Dispersal is FPT parameterized by $k+d$, by combining the (partial) kernel with a non-trivial subroutine that involves solving a system of polynomial inequalities. It is natural to ask whether the problem is fixed-parameter tractable by the individual parameters $d$ and $k$. Fiala et al. [14] have shown that Disk Dispersal is NP-hard even when $d = 2$. However, the parameterized complexity of Disk Dispersal parameterized by $k$ alone remains open. We make some preliminary progress in this direction. In the full version of the paper, we prove that the *rectilinear* version of Disk Dispersal is W[1]-hard when parameterized by $k$. This is a constrained version of Disk Dispersal, called Rectilinear Disk Dispersal, which is defined as follows.

Rectilinear Disk Dispersal

| | |
|---|---|
| *Input:* | A family $\mathcal{S}$ of $n$ unit disks, an integer $k \geq 0$, and a real $d \geq 0$. |
| *Task:* | Decide whether it is possible to obtain from $\mathcal{S}$ a family of non-overlapping disks $\mathcal{P}$ by moving at most $k$ disks into new positions parallel to the axes in such a way that each disk is moved at distance at most $d$. |

By examining our algorithmic results, namely, the (partial) kernels and the FPT algorithm parameterized by $k + d$ also hold for Rectilinear Disk Dispersal. Thus we have a complete picture of the complexity of Rectilinear Disk Dispersal, with parameters $k$ and $d$. Given this state of affairs, we conjecture that Disk Dispersal is also W[1]-hard when parameterized by $k$.

## Abstract

We re-visit the complexity of polynomial time pre-processing (kernelization) for the $d$-Hitting Set problem. This is one of the most classic problems in Parameterized Complexity by itself, and, furthermore, it encompasses several other of the most well-studied problems in this field, such as Vertex Cover, Feedback Vertex Set in Tournaments (FVST) and Cluster Vertex Deletion (CVD). In fact, $d$-Hitting Set encompasses any deletion problem to a hereditary property that can be characterized by a finite set of forbidden induced subgraphs. With respect to bit size, the kernelization complexity of $d$-Hitting Set is essentially settled: there exists a kernel with $\mathcal{O}(k^d)$ bits ($\mathcal{O}(k^d)$ sets and $\mathcal{O}(k^{d-1})$ elements) and this it tight by the result of Dell and van Melkebeek [STOC 2010, JACM 2014]. Still, the question of whether there exists a kernel for $d$-Hitting Set with *fewer elements* has remained one of the most major open problems in Kernelization.

In this paper, we first show that if we allow the kernelization to be *lossy* with a qualitatively better loss than the best possible approximation ratio of polynomial time approximation algorithms, then one can obtain kernels where the number of elements is linear for every fixed $d$. Further, based on this, we present our main result: we show that there exist approximate Turing kernelizations for $d$-Hitting Set that even beat the established bit-size lower bounds for exact kernelizations – in fact, we use a *constant* number of oracle calls, each with *"near linear"* ($\mathcal{O}(k^{1+\epsilon})$) bit size, that is, almost the best one could hope for. Lastly, for two special cases of implicit 3-Hitting set, namely, FVST and CVD, we obtain the "best of both worlds" type of results – $(1+\epsilon)$-approximate kernelizations with a linear number of vertices. In terms of size, this substantially improves the exact kernels of Fomin et al. [SODA 2018, TALG 2019], with simpler arguments.

## 1 Introduction

In $d$-Hitting Set, the input consists of a universe $U$, a family $\mathcal{F}$ of sets over $U$, where each set in $\mathcal{F}$ is of size at most $d$, and an integer $k$. The task is to determine whether there exists a set $S \subseteq U$, called a *hitting set*, of size at most $k$ that has a nonempty intersection with every set of $\mathcal{F}$. The $d$-Hitting Set problem is a classical optimization problem whose computational complexity has been studied for decades from the perspectives of different algorithmic paradigms. Notably, $d$-Hitting Set is a generic problem, and hence, in particular, various computational problems can be re-cast in terms of it. Of course, Vertex Cover, the most well-studied problem in Parameterized Complexity, is the special case of $d$-Hitting Set with $d = 2$. More generally, $d$-Hitting Set encompasses a variety of (di)graph modification problems, where the task is to delete at most $k$ vertices (or edges) from a graph such that the resulting graph does not contain an induced subgraph (or a subgraph) from a family of forbidden graphs $\mathcal{F}$. Examples of some such well-studied problems include Cluster Vertex Deletion, $d$-Path Vertex Cover, $d$-Component Order Connectivity, $d$-Bounded-Degree Vertex Deletion, Split Vertex Deletion and Feedback Vertex Set in Tournaments.

Kernelization, a subfield of Parameterized Complexity, provides a mathematical framework to capture the performance of polynomial time preprocessing. It makes it possible to quantify the degree to which polynomial time algorithms succeed at reducing input instances of NP-hard problems. More formally, every instance of a parameterized problem $\Pi$ is associated with an integer $k$, which is called the *parameter*, and $\Pi$ is said to admit a *kernel* if there is a polynomial-time algorithm, called a *kernelization algorithm*, that reduces the input instance of $\Pi$ down to an equivalent instance of $\Pi$ whose size is bounded by a function $f(k)$ of $k$. (Here, two instances are equivalent if both of them are either Yes-instances or No-instances.) Such an algorithm is called an $f(k)$-*kernel* for $\Pi$. If $f(k)$ is a polynomial function of $k$, then we say that the kernel is a *polynomial kernel*. Over the last decade, Kernelization has become a central and active field of study, which stands at the forefront of Parameterized Complexity, especially with the development of complexity-theoretic lower bound tools for kernelization. These tools can be used to show that a polynomial kernel [3, 12, 18, 23], or a kernel of a specific size [9, 10, 21] for concrete problems would imply an unlikely complexity-theoretic collapse. We refer to the recent book on kernelization [17] for a detailed treatment of the area of kernelization. In this paper, we provide a number of positive results on the kernelization complexity of $d$-Hitting Set, as well as on several special cases of 3-Hitting Set.

The most well-known example of a polynomial kernel, which, to the best of our knowledge, is taught in the first class/chapter on kernelization of any course/book that considers this subject, is the classic kernel for Vertex Cover (2-Hitting Set) that is based on Buss rule. More generally, one of the most well-known examples of a polynomial kernel is a kernel with $\mathcal{O}(k^d)$ sets and elements for $d$-Hitting Set (when $d$ is a fixed constant) using the Erdös-Rado Sunflower lemma.[1] Complementing this positive result, originally in 2010, a celebrated result by Dell and van Melkebeek [10] showed that unless co-NP $\subseteq$ NP/poly, for any $d \geq 2$ and any $\epsilon > 0$, $d$-Hitting Set does not admit a kernel with $\mathcal{O}(k^{d-\epsilon})$ sets. Hence, the kernel with $\mathcal{O}(k^d)$ sets is essentially tight with respect to size. However, when it comes to the bound on the number of elements in a kernel, the situation is unclear. Abu-Khzam [1]

[1] The origins of this result are unclear. The first kernel with $\mathcal{O}(k^d)$ sets appeared in 2004 [13], but the authors do not make use of the Sunflower Lemma. To the best of our knowledge, the first exposition of the kernel based on the Sunflower Lemma appears in the book of Flum and Grohe [15].

showed that $d$-Hitting Set admits a kernel with at most $(2d-1)k^{d-1}+k$ elements. However, we do not know whether this bound is tight or even close to that. As it was written in [17, page 470]:

> *Could it be that $d$-Hitting Set admits a kernel with a polynomial in $k$ number of elements, where the degree of the polynomial does not depend on $d$? This does not look like a plausible conjecture, but we do not know how to refute it either.*

The origins of this question can be traced back to the open problems from WorKer 2010 [4, page 4]. Moreover, in the list of open problems from WorKer 2013 and FPT School 2014 [7, page 4], the authors asked whether $d$-Hitting Set admits a kernel with $f(d) \cdot k$ elements for some function $f$ of $d$ only. After being explicitly stated at these venues, this question and its variants have been re-stated in a considerable number of papers (see, e.g., [11, 17, 29, 2]), and is being repeatedly asked in annual meetings centered around parameterized complexity. Arguably, this question has become the most major and longstanding open problem in kernelization for a specific problem. In spite of many attempts, even for $d = 3$, the question whether $d$-Hitting Set admits a kernel with $\mathcal{O}(k^{2-\varepsilon})$ elements, for some $\epsilon > 0$, has still remained open.

From an approximation perspective, the optimization version of $d$-Hitting Set admits a trivial $d$-approximation. Up to the Unique Game Conjecture, this bound is tight – for any $\varepsilon > 0$, $d$-Hitting Set does not admit a polynomial time $(d-\varepsilon)$-approximation [22]. So, at this front, the problem is essentially resolved.

With respect to kernelization, firstly, the barrier in terms of number of sets, and secondly, the lack of progress in terms of the number of elements, coupled with the likely impossibility of $(d-\varepsilon)$-approximation of $d$-Hitting Set, bring lossy kernelization as a natural tool for further exploring of the complexity of this fundamental problem. We postpone the formal definition of lossy kernelization to Section 2. Informally, a polynomial size $\alpha$-approximate kernel consists of two polynomial-time procedures. The first is a pre-processing algorithm that takes as input an instance $(I, k)$ to a parameterized problem, and outputs another instance $(I', k')$ to the same problem, such that $|I'| + k' \leq k^{\mathcal{O}(1)}$. The second transforms, for every $c \geq 1$, a $c$-approximate solution $S'$ to the pre-processed instance $(I', k')$ into a $(c \cdot \alpha)$-approximate solution $S$ to the original instance $(I, k)$. Then, the main question(s) that we address in this paper is:

> Is it possible to obtain a lossy kernel for $d$-Hitting Set with a qualitatively better loss than $d$ and with $\mathcal{O}(k^{d-1-\varepsilon})$ bit-size, or at least with $\mathcal{O}(k^{d-1-\varepsilon})$ elements?

In this paper, we present a surprising answer: *not only the number of elements can be bounded by $\mathcal{O}(k)$ (rather than just $\mathcal{O}(k^{d-1-\varepsilon})$), but even the bit-size can "almost" be bounded by $\mathcal{O}(k)$!* From the perspective of the size of the kernel, this is essentially the best that one could have hoped for. Still, we only slightly (though non-negligibly) improve on the approximation ratio $d$. For example, for $d = 2$ (Vertex Cover), we attain an approximation ratio of 1.721. So, while we make a critical step that is also the first – in particular, we show that, conceptually, the combination of kernelization and approximation breaks their independent barriers – we also open up the door for further research of this kind, on this problem as well as other problems.

More precisely, we present the following results and concept. We remark that for all of our results, we use an interesting fact about the natural Linear Programming (LP) relaxation of $d$-Hitting Set: the support of any optimal LP solution to the LP-relaxation of $d$-Hitting Set is of size at most $d \cdot \mathsf{frac}$ where $\mathsf{frac}$ is the optimum (minimum value) of the

LP [20]. Furthermore, to reduce bit-size rather than only element number, we introduce an "adaptive sampling strategy" that is, to the best of our knowledge, also novel in parameterized complexity. We believe that these ideas will find further applications in kernelization in the future. More information on our methods can be found in the next section.

- **Starting Point: Linear-Element Lossy Kernel for** $d$-Hitting Set**.** First, we show that $d$-Hitting Set admits a $(d - \frac{d-1}{d})$-approximate $d \cdot \mathsf{opt}$-element kernel, where $\mathsf{opt} \leq k$ is the (unknown) optimum (that is, size of smallest solution).[2] For example, when $d = 3$, the approximation ratio is $d - \frac{d-1}{d} = 2\frac{1}{3}$, which is a notable improvement over 3. When $d = 2$, this result encompasses the classic (exact) $2 \cdot \mathsf{opt}$-vertex kernel for Vertex Cover [6, 27]. We also remark that our linear-element lossy kernel for $d$-Hitting Set is a critical component (used as a black box) in all of our other results.
- **Conceptual Contribution: Lossy Kernelization Protocols.** We extend the notions of lossy kernelization and kernelization protocols[3] to *lossy kernelization protocols*. Roughly speaking, an $\alpha$-approximate kernelization protocol can perform a bounded in $k$ number of calls (called *rounds*) to an oracle that solves the problem on instances of size (called *call size*) bounded in $k$, and besides that it runs in polynomial time. Ideally, the number of calls is bounded by a fixed constant, in which case the protocol is called *pure*. Then, if the oracle outputs $c$-approximate solutions to the instances it is given, the protocol should output a $(c \cdot \alpha)$-approximate solution to the input instance. In particular, a lossy kernel is the special case of a lossy protocol with one oracle call. The *volume* of a lossy kernelization protocol is the sum of the sizes of the calls it performs.
- **Main Contribution: Near-Linear Volume and Pure Lossy Kernelization Protocol for** $d$-Hitting Set**.** We remark that the work of Dell and van Melkebeek [10] further asserts that also the existence of an exact (i.e., 1 approximate in our terms) kernelization protocol for $d$-Hitting Set of volume $\mathcal{O}(k^{d-\epsilon})$ is impossible unless $\mathsf{co\text{-}NP} \subseteq \mathsf{NP}/\operatorname{poly}$.
  First, we show that Vertex Cover admits a (randomized) 1.721-approximate kernelization protocol of 2 rounds and call size $\mathcal{O}(k^{1.5})$. This special case is of major interest in itself: Vertex Cover is the most well-studied problem in Parameterized Complexity, and, until now, no result that breaks both bit-size and approximation ratio barriers simultaneously has been known.
  Then, we build upon the ideas exemplified for the case of Vertex Cover to significantly generalize the result: while Vertex Cover corresponds to $d = 2$, we are able to capture *all* choices of $d$. Thereby, we prove our main result: for any $\epsilon > 0$, $d$-Hitting Set admits a (randomized) pure $(d - \delta)$-approximate kernelization protocol of call size $\mathcal{O}(k^{1+\epsilon})$. Here, the number of rounds and $\delta$ are fixed constants that depend only on $d$ and $\epsilon$. While the improvement over the barrier of $d$ in terms of approximation is minor (though still notable when $d = 2$), it is a *proof of concept* – that is, it asserts that $d$ is not an impassable barrier.[4] Moreover, it does so with almost the best possible (being almost linear) output size.
- **Outlook: Relation to Ruzsa-Szemerédi Graphs.** Lastly, we present a connection between the possible existence of a $(1+\epsilon)$-approximate kernelization protocol for Vertex Cover of call size $\mathcal{O}(k^{1.5})$ and volume $\mathcal{O}(k^{1.5+o(1)})$ and a known open problem about Ruzsa-Szemerédi graphs. We discuss this result in more detail in Section 3.

[2] In fact, when the parameter is $k$, we show that the bound is better.
[3] We remark that kernelization protocols are a highly restricted special case of Turing kernels, that yet generalizes kernels.
[4] Possibly, building upon our work, further improvements on the approximation factor (though perhaps at the cost of an increase in the output size) may follow.

**Kernels for Implicit 3-Hitting Set Problems.** Lastly, we provide better lossy kernels for two well-studied graph problems, namely, Cluster Vertex Deletion and Feedback Vertex Set in Tournaments, which are known to be implicit 3-Hitting Set problems [8]. Notably, both our algorithms are based on some of the ideas and concepts that are part of our previous results, and, furthermore, we believe that the approach underlying the parts common to both these algorithms may be useful when dealing also with other hitting and packing problems of constant-sized objects. In the Cluster Vertex Deletion problem, we are given a graph $G$ and an integer $k$. The task is to decide whether there exists a set $S$ of at most $k$ vertices of $G$ such that $G - S$ is a cluster graph. Here, a cluster graph is a graph where every connected component is a clique. It is known that this problem can be formulated as a 3-Hitting Set problem where the family $\mathcal{F}$ contains the vertex sets of all *induced* $P_3$*'s* of $G$. (An induced $P_3$ is a path on three vertices where the first and last vertices are non-adjacent in $G$.) In the Feedback Vertex Set in Tournaments problem, we are given a tournament $G$ and an integer $k$. The task is to decide whether there is a set $S$ of $k$ vertices such that each directed cycle of $G$ contains a member of $S$ (i.e., $G - S$ is acyclic). It is known that Feedback Vertex Set in Tournaments can be formulated as a 3-Hitting Set problem as well, where the family $\mathcal{F}$ contains the vertex sets of all directed cycles on three vertices (triangles) of $G$.

In [16], it was shown that Feedback Vertex Set in Tournaments and Cluster Vertex Deletion admit kernels with $\mathcal{O}(k^{\frac{3}{2}})$ vertices and $\mathcal{O}(k^{\frac{5}{3}})$ vertices, respectively. This answered an open question from WorKer 2010 [4, page 4], regarding the existence of kernels with $\mathcal{O}(k^{2-\epsilon})$ vertices for these problems. The question of the existence of linear-vertex kernels for these problems is open. In the realm of approximation algorithms, for Feedback Vertex Set in Tournaments, Cai , Deng and Zang [5] gave a factor 2.5 approximation algorithm, which was later improved to 7/3 by Mnich, Williams and Végh [26]. Recently, Lokshtanov, Misra, Mukherjee, Panolan, Philip and Saurabh [24] gave a 2-approximation algorithm for Feedback Vertex Set in Tournaments. For Cluster Vertex Deletion, You, Wang and Cao [29] gave a factor 2.5 approximation algorithm, which later was improved to 7/3 by Fiorini, Joret and Schaudt [14]. It is open whether Cluster Vertex Deletion admits a 2-approximation algorithm. We remark that both problems admit approximation-preserving reductions from Vertex Cover, and hence they too do not admit $(2-\epsilon)$-approximation algorithms up to the Unique Games Conjecture.

We provide the following results for Feedback Vertex Set in Tournaments and Cluster Vertex Deletion.

- **Cluster Vertex Deletion.** For any $0 < \epsilon < 1$, the Cluster Vertex Deletion problem admits a $(1+\epsilon)$-approximate $\mathcal{O}(\frac{1}{\epsilon} \cdot \mathsf{opt})$-vertex kernel.
- **Feedback Vertex Set in Tournaments.** For any $0 < \epsilon < 1$, the Feedback Vertex Set in Tournaments problem admits a $(1+\epsilon)$-approximate $\mathcal{O}(\frac{1}{\epsilon} \cdot \mathsf{opt})$-vertex kernel.

**Reading Guide.** First, in Section 2, we present basic terminology regarding lossy kernelization. Due to lack of space, we omit the formal proofs and technical details. Instead, in Section 3, we present an overview of our proofs Afterwards, in Section 4, we conclude the extended abstract with some open problems.

## 2 Lossy Kernelization: Algorithms and Protocols

**Lossy Kernelization Algorithms.** We follow the framework of lossy kernelization presented in [25]. Here, we deal only with minimization problems where the value of a solution is its size, and where the computation of an arbitrary solution (where no optimization is enforced)

is trivial. Thus, for the sake of clarity of presentation, we only formulate the definitions for this context, and remark that the definitions can be extended to the more general setting in the straightforward way (for more information, see [25]). To present the definitions, consider a parameterized problem $\Pi$. Given an instance $I$ of $\Pi$ with parameter $k = \kappa(I)$, denote: if $k$ is a structural parameter, then $\pi_I(\mathsf{opt}) = \mathsf{opt}$, and otherwise (if $k$ is a bound on the solution size given as part of the input) $\pi_I(\mathsf{opt}) = \min\{\mathsf{opt}, k+1\}$. Moreover, for any solution $S$ to $I$, denote: if $k$ is a structural parameter, then $\pi_I(S) = |S|$, and otherwise $\pi_I(S) = \min\{|S|, k+1\}$. We remark that when $\pi$ is irrelevant (e.g., when the parameter is structural), we will drop it. A discussion of the motivation behind this definition of $\pi_I$ can be found in [25]; here, we only briefly note that it signifies that we "care" only for solutions of size at most $k$ – all other solutions are considered equally bad, treated as having size $k+1$.

▶ **Definition 1.** *Let $\Pi$ be a parameterized minimization problem. Let $\alpha \geq 1$. An* $\alpha$-approximate kernelization algorithm *for $\Pi$ consists of two polynomial-time procedures:* **reduce** *and* **lift**. *Given an instance $I$ of $\Pi$ with parameter $k = \kappa(I)$,* **reduce** *outputs another instance $I'$ of $\Pi$ with parameter $k' = \kappa(I')$ such that $|I'| \leq f(k,\alpha)$ and $k' \leq k$. Given $I, I'$ and a solution $S'$ to $I'$,* **lift** *outputs a solution $S$ to $I$ such that $\frac{\pi_I(S)}{\pi_I(\mathsf{opt}(I))} \leq \alpha \frac{\pi_{I'}(S')}{\pi_{I'}(\mathsf{opt}(I'))}$. If $\frac{\pi_I(S)}{\pi_I(\mathsf{opt}(I))} \leq \max\{\alpha, \frac{\pi_{I'}(S')}{\pi_{I'}(\mathsf{opt}(I'))}\}$ holds, then the algorithm is termed* strict.

In case $\Pi$ admits an $\alpha$-approximate kernelization algorithm where the output has size $f(k,\alpha)$, or where the output has $g(k,\alpha)$ "elements" (e.g., vertices), we say that $\Pi$ admits an $\alpha$-approximate kernel of size $f(k,\alpha)$, or an $\alpha$-approximate $g(k,\alpha)$-element kernel, respectively. When it is clear from context, we simply write $f(k)$ and $g(k)$. When it is guaranteed that $|I'| \leq f(k',\alpha)$ rather than only $|I'| \leq f(k,\alpha)$, then we say that the lossy kernel is *output-parameter sensitive*.

We only deal with problems that have constant-factor polynomial-time approximation algorithms, and where we may directly work with (the unknown) $\mathsf{opt}$ as the parameter (then, $\pi$ can be dropped). However, working with $k$ (and hence $\pi$) has the effect of artificially altering kernel sizes, but not so if one remembers that $k$ and $\mathsf{opt}$ are different parameterizations. The following lemma clarifies a relation between these two parameterizations.

▶ **Lemma 2.** *Let $\Pi$ be a minimization problem that, when parameterized by the optimum, admits an $\alpha$-approximate kernelization algorithm $\mathfrak{A}$ of size $f(\mathsf{opt})$ (resp., an $\alpha$-approximate $g(\mathsf{opt})$-element kernel). Then, when parameterized by $k$, a bound on the solution size that is part of the input, it admits an $\alpha$-approximate kernelization algorithm $\mathfrak{B}$ of size $f(\frac{k+1}{\alpha})$ (resp., an $\alpha$-approximate $g(\frac{k+1}{\alpha})$-element kernel).*

**Proof.** We design $\mathfrak{B}$ as follows. Given an instance $(I,k)$ of $\Pi$, **reduce** of $\mathfrak{B}$ calls **reduce** of $\mathfrak{A}$ on $I$. If the output instance size is at most $f(\frac{k+1}{\alpha})$ (resp., the output has at most $g(\frac{k+1}{\alpha})$ elements), then it outputs this instance with parameter $k' = k$. Otherwise, it outputs a trivial constant-sized instance. Given $(I,k), (I',k')$ and a solution $S'$ to $(I',k')$, if $I'$ is the output of the **reduce** procedure of $\mathfrak{A}$ on $I$, then **lift** of $\mathfrak{B}$ calls **lift** of $\mathfrak{A}$ on $I, I', S'$ and outputs the result. Otherwise, it outputs a trivial solution to $I$.

The **reduce** and **lift** procedures of $\mathfrak{B}$ clearly have polynomial time complexities, and the definition of $\mathfrak{B}$ implies the required size (or element) bound on the output of **reduce**. It remains to prove that the approximation ratio is $\alpha$. To this end, consider an input $(I,k), (I',k'), S'$ to **lift** of $\mathfrak{B}$. Let $S$ be its output. We differentiate between two cases.

- First, suppose that $\mathsf{opt}(I) \geq \frac{k+1}{\alpha}$. Then, $\frac{\pi_I(S)}{\pi_I(\mathsf{opt}(I))} \leq \frac{k+1}{\frac{k+1}{\alpha}} = \alpha \leq \alpha \frac{\pi_{I'}(S')}{\pi_{I'}(\mathsf{opt}(I'))}$ (where the last inequality follows because $|S'| \geq \mathsf{opt}(I')$ and hence $\pi_{I'}(S') \geq \pi_{I'}(\mathsf{opt}(I'))$).

- Second, suppose that $\mathsf{opt}(I) < \frac{k+1}{\alpha}$. Then, it necessarily holds that $I'$ is the output of the **reduce** procedure of $\mathfrak{A}$ on $I$. Moreover, note that $\mathsf{opt}(I') \leq \mathsf{opt}(I)$ and $k' = k$. So, if $|S'| \geq k' + 2$, then $\frac{\pi_I(S)}{\pi_I(\mathsf{opt}(I))} \leq \frac{k+1}{\pi_I(\mathsf{opt}(I))} = \frac{k'+1}{\mathsf{opt}(I)} \leq \frac{k'+1}{\mathsf{opt}(I')} = \frac{\pi_{I'}(S')}{\pi_{I'}(\mathsf{opt}(I'))}$. Else, we suppose that $|S'| \leq k' + 1$ and hence $\pi_{I'}(S') = |S'|$. Then,

$$\frac{\pi_I(S)}{\pi_I(\mathsf{opt}(I))} \leq \frac{|S|}{\pi_I(\mathsf{opt}(I))} = \frac{|S|}{\mathsf{opt}(I)} \leq \alpha \frac{|S'|}{\mathsf{opt}(I')} = \alpha \frac{\pi_{I'}(S')}{\pi_{I'}(\mathsf{opt}(I'))}.$$

Here, the second inequality follows because the approximation ratio of $\mathfrak{A}$ is $\alpha$.
This completes the proof. ◀

Approximate kernelization algorithm often use strict reduction rules, defined as follows.

▶ **Definition 3.** *Let $\Pi$ be a parameterized minimization problem. Let $\alpha \geq 1$. An $\alpha$-strict reduction rule for $\Pi$ consists of two polynomial-time procedures:* **reduce** *and* **lift**. *Given an instance $I$ of $\Pi$ with parameter $k = \kappa(I)$,* **reduce** *outputs another instance $I'$ of $\Pi$ with parameter $k' = \kappa(I') \leq k$. Given $I, I'$ and a solution $S'$ to $I'$,* **lift** *outputs a solution $S$ to $I$ such that $\frac{\pi_I(S)}{\pi_I(\mathsf{opt}(I))} \leq \max\{\alpha, \frac{\pi_{I'}(S')}{\pi_{I'}(\mathsf{opt}(I'))}\}$.*

▶ **Proposition 4** ([25]). *Let $\Pi$ be a parameterized problem. For any $\alpha \geq 1$, an approximate kernelization algorithm for $\Pi$ that consists only of $\alpha$-strict reduction rules has approximation ratio $\alpha$. Furthermore, it is strict.*

**Lossy Kernelization Protocols.** We extend the notion of lossy kernelization algorithms to lossy kernelization protocols as follows.

▶ **Definition 5** (Lossy Kernelization Protocol). *Let $\Pi$ be a parameterized minimization problem with parameter $k$. Let $\alpha \geq 1$. An* $\alpha$-approximate kernelization protocol *of* call size $f(k, \alpha)$ *and* $g(k, \alpha)$ rounds *for $\Pi$ is defined as follows. First, the protocol assumes to have access to an oracle $\mathfrak{O}$ that, given an instance $I'$ of $\Pi$ of size at most $f(k, \alpha)$, returns a solution $S'$ to $I'$ such that $\pi_{I'}(S') \leq \beta \pi_{I'}(\mathsf{opt}(I'))$ for minimization and $\pi_{I'}(S') \geq \frac{1}{\beta}\pi_{I'}(\mathsf{opt}(I'))$ for maximization, for some fixed $\beta > 0$. Second, for the same fixed $\beta > 0$, given an instance $I$ of $\Pi$, the protocol may perform $g(k, \alpha)$ calls to $\mathfrak{O}$ and other operations in polynomial time, and then output a solution $S$ to $I$ such that $\frac{\pi_I(S)}{\pi_I(\mathsf{opt}(I))} \leq \alpha\beta$.*

*The* volume *(or* size*) of the protocol is $f(k, \alpha)g(k, \alpha)$. In case $g(k, \alpha) = g(\alpha)$ (i.e., $g$ depends only on $\alpha$), the protocol is called* pure.

Notice that an $\alpha$-approximate kernelization algorithm is the special case of an $\alpha$-approximate kernelization protocol when the number of rounds is 1.

Practically, we think that (lossy) kernelization protocols can often be as useful as standard (lossy) kernels, and, in some cases, more useful. Like standard (lossy) kernels, they reduce the total size of what we need to solve, only that now what we need to solve is split into several instances, to be solved one after another. On the one hand, this relaxation seems to, in most cases, not be restrictive (as what we really care about is the total size of what we need to solve). On the other hand, it might be helpful if by using this relaxation one can achieve better bounds than what is known (or, even, what is possible) on the sizes of the reduced instances, or to simplify the algorithm. For example, for the case of $d$-Hitting Set, we do not know how to beat $\mathcal{O}(k^d)$ using a lossy kernel rather than a protocol.

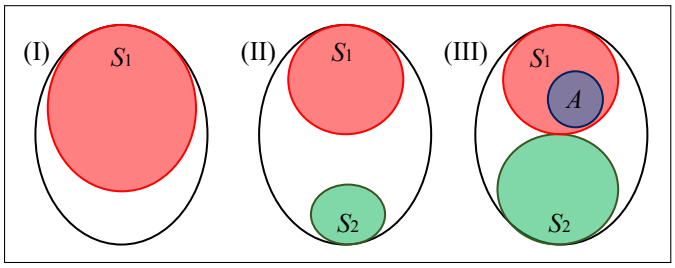

**Figure 1** The three cases encountered by our 2-call lossy kernelization protocol for Vertex Cover: (I) $|S_1|$ is large, and we return $V(G)$; (II) $|S_1|$ is small and $|S_2|$ is small, and we return $S_1 \cup S_2$; (III) $|S_1|$ is small and $|S_2|$ is large, and we return $(V(G) \setminus S_1) \cup A$.

## 3 Overview of Our Proof Ideas

In this section, we present a high-level overview of our proof ideas.

### 3.1 Linear-Element Lossy Kernel for $d$-Hitting Set

We make use of a known result about the natural LP relaxation of $d$-Hitting Set: the support of any optimal LP solution to the LP-relaxation of $d$-Hitting Set is of size at most $d \cdot \mathsf{frac}$ where $\mathsf{frac}$ is the optimum (minimum value) of the LP [20]. For the sake of completeness, we provide a proof. We then provide a lossy reduction rule that computes an optimal LP solution, and deletes all vertices assigned values at least $\frac{1}{d-1}$. Having applied this rule exhaustively, we arrive at an instance having an optimal LP solution that assigns only values strictly smaller than $\frac{1}{d-1}$. Then, it can be shown that all hitting sets are contained within the support of this LP solution. In turn, in light of the aforementioned known result, this yields an approximate $d \cdot \mathsf{frac}$-element and $(d\mathsf{frac})^d$-set kernel that is output-parameter sensitive.

The analysis that the approximation factor is $d - \frac{d-1}{d}$ is slightly more involved, and is based on case distinction. In case the number of vertices deleted is "small enough", the cost of adding them is "small enough" as well. In the more difficult case where the number of vertices deleted is "large", by making use of the already established bound on the output size as well as the drop in the fractional optimum, we are able to show that, in fact, we return a solution of approximation factor $d - \frac{d-1}{d}$ irrespective of the approximation ratio of the solution we are given. More generally, the definition of "small enough" and "large" gives rise to a trade-off that is critical for our kernelization protocol for $d$-Hitting Set, which in particular yields that we can either obtain a *negligible additive error* or directly a solution of the desired (which is some fixed constant better than $d$ but worse than $d - \frac{d-1}{d}$) approximation ratio. Specifically, this means that it is "safe" to compose our element kernel as part of other kernelization algorithms or protocols.

### 3.2 2-Round $\mathcal{O}(\mathsf{frac}^{1.5})$-Call Size Lossy Kernelization Protocol for Vertex Cover

Towards the presentation of our near-linear call size lossy kernelization protocol for $d$-Hitting Set, we abstract some of the ideas using a simpler 2-round $\mathcal{O}(\mathsf{frac}^{1.5})$-call size 1.721-approximate kernelization protocol for Vertex Cover (where $\mathsf{frac} \leq \mathsf{opt} \leq k$ is the optimum of the natural LP relaxation of Vertex Cover). First, we apply an (exact) kernelization algorithm to have a graph $G$ on at most $2\mathsf{frac}$ vertices. The purpose of having

only 2frac vertices is twofold. First, it means that to obtain a "good enough" approximate solution, it suffices that we do not pick a "large enough" (linear fraction) of vertices of $G$ to our solution. Second, it is required for a probability bound derived using union bound over vertex subsets to hold. Then, roughly speaking, the utility of the first oracle call is mainly, indirectly, to uncover a "large" (linear in $n = |V(G)|$) induced subgraph of $G$ that is "sparse", and hence can be sent to the second oracle call to be solved optimally.

More precisely, after applying the initial kernelization, we begin by sampling roughly $\mathsf{frac}^{1.5}$ edges from $G$. Then, we call the oracle on the sampled graph to obtain a solution $S_1$ to it (but not to $G$). In case that solution $S_1$ is "large" compared to the size of the vertex set of $G$ (that is, sufficiently larger than $n/2 \leq \mathsf{frac}$), we can just return the entire vertex set of $G$ (see Fig. 1). Else, we know that the subgraph of the sampled graph that is induced by $V(G) \setminus S_1$ is edgeless. In addition, we can show (due to the initial kernelization) that with high probability, every set of edges of size (roughly) at least $\mathsf{frac}^{1.5}$ that is the edge set of some induced subgraph of $G$ has been hit by our edge sample. Together, this implies that the subgraph of $G$ induced by $V(G) \setminus S_1$ has at most $\mathsf{frac}^{1.5}$ edges, and hence can be solved optimally by a second oracle call. Then, because we know that this subgraph is large compared to $G$ (else $S_1$ is large), if the oracle returned a "small" solution $S_2$ to it, we may just take this solution together with $S_1$ (which will form a vertex cover), and yet not choose sufficiently many vertices so that this will be good enough in terms of the approximation ratio achieved. Else, also because we know that this subgraph is large compared to $G$, if the second oracle returned a "large" solution $S_2$, then we know that every optimal solution must take many vertices from this subgraph, and hence, to compensate for this, the optimum of $G[S_1]$ must be "very small". So, we compute a 2-approximate solution $A$ to $G[S_1]$, which we know should not be "too large", and output the union of $A$ and $V(G) \setminus S_1$ (which yields a vertex cover).

## 3.3 Near-Linear Volume and Pure Lossy Kernelization Protocol for $d$-Hitting Set

For any fixed $\epsilon > 0$, we present a pure $d(1 - h(d, \epsilon))$-approximate (randomized) kernelization protocol for $d$-Hitting Set with call size $\mathcal{O}((\mathsf{frac})^{1+\epsilon})$ where $h(d, \epsilon)$ is a fixed positive constant that depends only on $d, \epsilon$. On a high-level, the idea of our more general lossy kernelization protocol is to compute a nested family of solutions based on the approach described above for Vertex Cover (see Fig. 2). Intuitively, as we now can sample only few sets (that is, $\mathsf{frac}^{1+\epsilon}$), when we compute a solution that hits them using an oracle call, the number of sets it misses can still be huge, and hence we will need to iteratively use the oracle (a constant number of times) until we reach a subuniverse such that we can optimally solve the subinstance induced by it by a single oracle call. Below, we give a more elaborate overview.

First, we apply our linear-element lossy kernel to have an instance $I_0 = (U_0, \mathcal{T}_0)$ where the universe $U_0$ consists of at most $d\mathsf{frac}$ elements. Here, the error of this application is not multiplied by the error attained next, but will only yield (as mentioned earlier) a negligible additive error (or directly a solution of the desired approximation ratio). The purpose of having only $d\mathsf{frac}$ elements is twofold, similarly as it is in the protocol described earlier for Vertex Cover. Afterwards, we begin by sampling a family $\mathcal{F}_1$ of roughly $\mathsf{frac}^{1+\epsilon}$ sets from $\mathcal{T}_0$. Then, we call the oracle on the sampled family $\mathcal{F}_1$ to obtain a solution $S_1$ to it. In case that solution $S_1$ is "large" (sufficiently larger than $|U_0|/d \leq \mathsf{frac}$), we can just return $U_0$. Else, we know that the family of sets corresponding to the subinstance $I_1$ induced by $U_1 = U_0 \setminus S_1$ – that is, the family of all sets in $\mathcal{T}_0$ contained in $U_1$, which we denote by $\mathcal{T}_1$ –

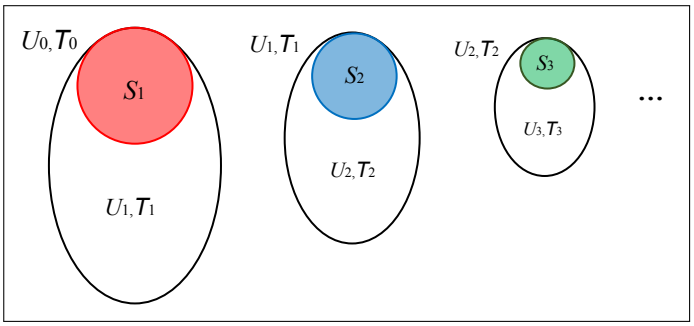

**Figure 2** The nested solutions computed by oracle calls in our lossy kernelization protocol for $d$-Hitting Set. Each $S_i$ is a solution to a subinstance $(U_{i-1}, \mathcal{F}_{i-1})$ sampled from $(U_{i-1}, \mathcal{T}_{i-1})$.

was missed by our set sample. In addition, we can show (due to the initial kernelization) that with high probability, every family of sets of size (roughly) at least $\mathsf{frac}^{d-\epsilon}$ that corresponds to a subinstance induced by a subset of $U_0$ has been hit by our set sample. Together, this implies that $\mathcal{T}_1$ has at most $\mathsf{frac}^{d-\epsilon}$ (rather than $\mathsf{frac}^{d}$) sets. Hence, in some sense, we have made progress towards the discovery of a sparse subinstance that we can optimally solve.

Due to important differences, let us describe also the second iteration – among at most $\frac{1}{\epsilon}(d-1)$ iterations performed in total – before skipping to the (last) one where we have a subinstance that we can optimally solve by an oracle call. The last iteration may not even be reached, if we find a "good enough" solution earlier. We remark that it is critical to stop and return a solution as soon as we find a "large enough" one by an oracle call[5] as for our arguments to work, we need to always deal with subinstances whose universe is large (a linear fraction of $|U_0|$), and these are attained by removing oracle solutions we got along the way. We begin the second iteration by sampling a family $\mathcal{F}_2$ of roughly $\mathsf{frac}^{1+\epsilon}$ sets from $\mathcal{T}_1$. Then, we call the oracle on the sampled family $\mathcal{F}_2$ to obtain a solution $S_2$ to it. On the one hand, in case that solution $S_2$ is "large" (sufficiently larger than $|U_1|/d$), we cannot just return $U_0$ as in the first iteration, as now it may not be true that the optimum of $I_0$ is large compared to $|U_0|$. Still, it is true that the optimum of $I_1$ is large compared to $|U_1|$. So, every optimal solution (to $I_0$) must take many elements from $U_1 \setminus S_2$, and hence, to compensate for this, the optimum of the subinstance induced by $S_1$ must be "very small". So, we compute a $d$-approximate solution to this subinstance, which we know should not be "too large" , and output the union of it and $U_1$ (which yields a hitting set). On the other hand, in case $S_2$ is "small", we proceed as follows. We observe that the family of sets corresponding to the subinstance $I_2$ induced by $U_2 = U_1 \setminus S_2$, whose family of sets we denote by $\mathcal{T}_2$, was missed by our set sample. In addition, we can show (due to the initial kernelization) that with high probability, every family of sets of size (roughly) at least $\mathsf{frac}^{d-2\epsilon}$ that corresponds to a subinstance induced by a subset of $U_1$ has been hit by our set sample. Together, this implies that $\mathcal{T}_2$ has at most $\mathsf{frac}^{d-2\epsilon}$ (rather than just $\mathsf{frac}^{d-\epsilon}$ as in the first iteration) sets. Hence, in some sense, we have made further progress towards the discovery of a sparse subinstnace that we can optimally solve.

Finally, we arrive at a subinstance $I'$ induced by a subuniverse $U' \subseteq U_0$ that is of size linear in $U_0$ (else we should have returned a solution earlier) and where the family of sets, $\mathcal{F}'$, is of size at most $\mathsf{frac}^{1+\epsilon}$. Then, we call the oracle on $I'$ to obtain a solution $S'$ to it. On

[5] The solution we return is not the one given by the oracle call, but its union with another solution, as will be clarified immediately, or just $U_0$ in case of the first iteration describe above.

the one hand, in case that solution $S'$ is "large" (sufficiently larger than $|U'|/d$), we compute a $d$-approximate solution to the subinstance induced by $U_0 \setminus U'$ (which is the union of all solutions returned by oracle calls except the last one), and output the union of it and $U'$. Otherwise, we output $(U_0 \setminus U') \cup S'$, which is "good enough" because $U'$ is sufficiently large while $S'$ is sufficiently small compared to it, it does not contain a "large enough" number of elements from $U_0$.

## 3.4 Outlook: Relation to Ruzsa-Szemerédi Graphs

A graph $G$ is an $(r,t)$-*Ruzsa-Szemerédi graph* if its edge set can be partitioned into $t$ edge-disjoint induced matchings, each of size $r$. These graphs were introduced in 1978 [28], and have been extensively studied since then. When $r$ is a function of $n$, let $\gamma(r)$ denote the maximum $t$ (which is a function of $n$) such that there exists an $(r,t)$-Ruzsa-Szemerédi graph. In [19], the authors considered the case where $r = cn$. They showed that when $c = \frac{1}{4}$, $\gamma(r) \in \Theta(\log n)$, and when $\frac{1}{5} \leq c \leq \frac{1}{4}$, $t \in \mathcal{O}(\frac{n}{\log n})$. It is an open problem whether whenever $c$ is a fixed constant, $t \in \mathcal{O}(n^{1-\epsilon})$. For any fixed constant $0 < c < \frac{1}{4}$, we present a $(1+4c)$-approximate (randomized) kernelization protocol for Vertex Cover with $t+1$ rounds and call size $\mathcal{O}(t(\mathsf{frac})^{1.5})$. Clearly, this result makes sense only when $t \in o(\sqrt{n})$, preferably $t \in \mathcal{O}(n^{\frac{1}{2}-\lambda})$ for $\lambda$ as close to $1/2$ as possible, because the volume is $\mathcal{O}(\mathsf{opt}^{2-\lambda})$. If $t$ is "sufficiently small" (depending on the desired number of rounds) whenever $c$ is a fixed constant (specifically, substitute $c = \frac{\epsilon}{4}$), this yields a $(1+\epsilon)$-approximate kernelization protocol.

We observe that, for a graph $G$, $r = r(n), t = t(n) \in \mathbb{N}$ and $U_1, U_2, \ldots, U_t \subseteq V(G)$ such that for all $i \in \{1,2,\ldots,t\}$, $G[U_i]$ has a matching $M_i$ of size at least $r$, and for all distinct $i,j \in \{1,2,\ldots,t\}$, $E(G[U_i]) \cap E(G[U_j]) = \emptyset$, we have that $G$ is a supergraph of an $(r,t)$-Ruzsa-Szemerédi graph. Having this observation in mind, we devise our protocol as follows. After applying an exact $2\mathsf{frac}$-vertex kernel, we initialize $E' = \emptyset$, and we perform $t+1$ iterations of the following procedure. We sample a set of roughly $\mathsf{frac}^{1.5}$ edges from $G$, and call the oracle on the subgraph of $G$ whose edge set is the set of samples edges union $E'$ to obtain a solution $S$ to it (but not to $G$), and compute a maximal matching $M$ in $G - S$. If $|M|$ is smaller than $cn \leq 2c\mathsf{frac}$, then we return the union of the set of vertices incident to edges in $M$ (which is a solution to $G - S$) and $S$. Else, similarly to the first protocol we described for Vertex Cover, we can show that with high probability, $G - S$ has (roughly) at most $k^{1.5}$ edges, and we add this set of edges to $E'$. The crux of the proof is in the argument that, at the latest, at the $(t+1)$-st iteration the computed matching will be of size smaller than $cn \leq 2c\mathsf{frac}$, as otherwise we can use the matchings we found, together with the vertex sets (of the form $G - S$) we found them in, to construct an $(r, t+1)$-Ruzsa-Szemerédi graph based on the aforementioned observation, which contradicts the choice of $t$.

## 3.5 $(1+\epsilon)$-Approximate $\mathcal{O}(\frac{1}{\epsilon} \cdot \mathsf{opt})$-Vertex Kernel for Implicit 3-Hitting Set Problems

Both of our lossy kernels share a common scheme, which might be useful to derive $(1+\epsilon)$-approximate linear-vertex kernels for other implicit hitting and packing problems as well. Essentially, they both consist of two rules (although in the presentation, they are merged for simplicity). To present them, we remind that a module (in a graph) is a set of vertices having the same neighborhood relations with all vertices outside the set. Now, our first rule reveals some modules in the graph, and our second rule shrinks their size. The first rule in both of our lossy kernels is essentially the same.

Now, we elaborate on the first rule. We start by computing an optimal solution $\alpha$ to the LP-relaxation of the corresponding 3-Hitting Set problem. Notice that $\mathsf{support}(\alpha)$ is a solution, and its size is at most $3\mathsf{frac}$ (in fact, we show that it is at most $3\mathsf{frac} - 2|\alpha^{-1}(1)|$). Then, the first rule is as follows. At the beginning, no vertex is marked. Afterwards, one-by-one, for each vertex $v$ assigned 1 by $\alpha$ (i.e., which belongs to $\alpha^{-1}(1)$), we construct a graph whose vertex set is the set of yet unmarked vertices in $V(G) \setminus \mathsf{support}(\alpha)$ and where there is an edge between every two vertices that create an obstruction together with $v$ (that is, an induced $P_3$ in Cluster Vertex Deletion and a triangle in Feedback Vertex Set in Tournaments). We compute a maximal matching in this graph, and decrease its size to $\frac{1}{\epsilon}$ if it is larger (in which case, it is no longer maximal). The vertices incident to the edges in the matching are then considered marked. We prove that among the vertices in $\alpha^{-1}(1)$ whose matching size was decreased, whose set is denoted by $D$, any solution can only exclude an $\epsilon$ fraction of its size among the vertices in $D$, and hence it is "safe" (in a lossy sense) to delete $D$. Let $M$ be the set of all marked vertices. Then, we show that $(\mathsf{support}(\alpha) \cup M) \setminus \{v\}$, for any $v \in \mathsf{support}(\alpha)$ (including those not in $\alpha^{-1}(1)$), is also a solution.

For Cluster Vertex Deletion, we prove that the outcome of the first rule means that the vertex set of every clique in $G - (\mathsf{support}(\alpha) \cup M)$ is a module in $G - D$, and that for every vertex in $\mathsf{support}(\alpha)$, the set of its neighbors in $V(G - (\mathsf{support}(\alpha) \cup M))$ is the vertex set of exactly one of these cliques. So, for Cluster Vertex Deletion, this gives rise to the following second reduction rule (which is, in fact, exact) to decrease the size of module. For every clique among the aforementioned cliques whose size is larger than that of its neighborhood, we arbitrarily remove some of its vertices so that its size will be equal to the size of its neighborhood. This rule is safe since if at least one of the vertices in such a clique is deleted by a solution, then because it is a module, either that deletion is irrelevant or the entire clique is deleted, and in the second case we might just as well delete its neighborhood instead. Because the neighborhoods of the cliques are pairwise-disjoint (since for every vertex in $\mathsf{support}(\alpha)$, the set of its neighbors in $V(G - (\mathsf{support}(\alpha) \cup M))$ is the vertex set of exactly one of the cliques), this means that now their total size is at most $(\mathsf{support}(\alpha) \setminus D) \cup M$, and hence we arrive at the desired kernel.

For Feedback Vertex Set in Tournaments, we consider the unique (because $G$ is a tournament) topological ordering of the vertices in $G - \mathsf{support}(\alpha)$, so that all arcs are "forward" arcs. We prove that the outcome of the first rule means that each vertex $v \in \mathsf{support}(\alpha)$ has a unique position within this ordering when restricted to $G - (\mathsf{support}(\alpha) \cup M)$, so that still all arcs (that is, including those incident to $v$) are forward arcs in $G - (\mathsf{support}(\alpha) \cup M) \cup \{v\}$. (Further, the vertex set of each subtournament induced by the vertices "between" any two marked vertices in $G - \mathsf{support}(\alpha)$ is a module in $G - D$.) We are thus able to characterize all triangles in $G - D$ as follows: each either consists of three vertices in $(\mathsf{support}(\alpha) \setminus D) \cup M$, or it consists of a vertex $v \in \mathsf{support}(\alpha) \setminus D$, a vertex $u \in (\mathsf{support}(\alpha) \setminus D) \cup M$ and a vertex $w \in V(G) \setminus (\mathsf{support}(\alpha) \cup M)$ with a backward arc between $v$ and $u$ and where $w$ is "in-between" the positions of $v$ and $u$. This gives rise to a reduction rule for module shrinkage whose presentation and analysis are more technical than that of Cluster Vertex Deletion (in particular, unlike the second rule of Cluster Vertex Deletion, the second rule of Feedback Vertex Set in Tournaments is lossy) and of the first rule; hence, due to lack of space, we omit them.

## 4 Conclusion

In this paper, we presented positive results on the kernelization complexity of $d$-Hitting Set, as well as for its special cases Cluster Vertex Deletion and Feedback Vertex Set in Tournaments. First, we proved that if we allow the kernelization to be *lossy* with

a qualitatively better loss than the best possible approximation ratio of polynomial time approximation algorithms, then one can obtain kernels where the number of elements is linear for every fixed $d$. Further, we extended the notion of lossy kernelization algorithms to *lossy kernelization protocols* and, then, presented our main result: For any $\epsilon > 0$, $d$-Hitting Set admits a (randomized) pure $(d - \delta)$-approximate kernelization protocol of call size $\mathcal{O}(k^{1+\epsilon})$. Here, the number of rounds and $\delta$ are fixed constants (that depend only on $d$ and $\epsilon$). Finally, we complemented the aforementioned results as follows: for the special cases of 3-Hitting Set, namely, Cluster Vertex Deletion and Feedback Vertex Set in Tournaments, we showed that for any $0 < \epsilon < 1$, they admits a $(1+\epsilon)$-approximate $\mathcal{O}(\frac{1}{\epsilon} \cdot \mathsf{opt})$-vertex kernel.

We conclude the paper with a few interesting open problems.

1. Does $d$-Hitting Set admit a kernel with $f(d) \cdot k^{d-1-\epsilon}$ elements for some fixed $\epsilon > 0$, or, even, with just $f(d) \cdot k$ elements?
2. Does $d$-Hitting Set admit a $(1+\epsilon)$-approximate $\mathcal{O}(f(\epsilon) \cdot k)$-element kernel (or protocol)?
3. Does $d$-Hitting Set admit a $(1+\epsilon)$-approximate $\mathcal{O}(f(\epsilon) \cdot k)$-bits kernel (or protocol)?
4. Do Feedback Vertex Set in Tournaments and Cluster Vertex Deletion admit linear vertex kernels?
5. Are lossy kernelization protocols "more powerful" than lossy kernelization algorithms?

## Abstract

Designing approximate all-pairs distance oracles in the fully dynamic setting is one of the central problems in dynamic graph algorithms. Despite extensive research on this topic, the first result breaking the $O(\sqrt{n})$ barrier on the update time for any non-trivial approximation was introduced only recently by Forster, Goranci and Henzinger [SODA'21] who achieved $m^{1/\rho+o(1)}$ amortized update time with a $O(\log n)^{3\rho-2}$ factor in the approximation ratio, for any parameter $\rho \geq 1$.

In this paper, we give the first *constant-stretch* fully dynamic distance oracle with small polynomial update and query time. Prior work required either at least a poly-logarithmic approximation or much larger update time. Our result gives a more fine-grained trade-off between stretch and update time, for instance we can achieve constant stretch of $O(\frac{1}{\rho^2})^{4/\rho}$ in amortized update time $\tilde{O}(n^{\rho})$, and query time $\tilde{O}(n^{\rho/8})$ for any constant parameter $0 < \rho < 1$. Our algorithm is randomized and assumes an oblivious adversary.

A core technical idea underlying our construction is to design a black-box reduction from decremental approximate hub-labeling schemes to fully dynamic distance oracles, which may be of independent interest. We then apply this reduction repeatedly to an existing decremental algorithm to bootstrap our fully dynamic solution.

## 1 Introduction

The All-Pairs Shortest Paths (APSP) problem is one of the cornerstone graph problems in combinatorial optimization. It has a wide range of applications, for instance in route planning, navigation systems, and routing in networks, and it has been extensively studied from both practical and theoretical perspectives. In theoretical computer science, this problem enjoys much popularity due to its historic contributions to the development of fundamental algorithmic tools and definitions as well as being used as a subroutine for solving other problems.

[1] This work was conducted when this author was a postdoc at University of Salzburg.

The APSP problem has also been studied extensively in *dynamic* settings. Here, the underlying graph undergoes edge insertions and deletions (referred to as edge *updates*), and the goal is to quickly report an approximation to the shortest paths between *any* source-target vertex pair. The dynamic setting is perhaps even more realistic for some of the applications of the APSP problem, e.g., in navigation systems, as link statistics of road networks are prone to changes because of evolving traffic conditions. A naive (but rather expensive) solution to handle these updates is achieved by running an exact static algorithm after each update. However, at an intuitive level, one would expect to somehow exploit the fact that a single update is small compared to the size of the network, and thus come up with much faster update times.

Much of the research literature in dynamic APSP has focused on the *partially* dynamic setting. In contrast to the *fully* dynamic counterpart, this weaker model restricts the types of updates to edge insertions or deletions only. Some reasons for studying partially dynamic algorithms include their application as a subroutine in speeding up static algorithms (e.g., flow problems [36]), or their utilization as a stepping stone for designing fully-dynamic algorithms, something that we will also exploit in this work. The popularity of the partially dynamic setting can also attributed to the fact that dealing with only one type of update usually leads to better algorithmic guarantees. In fact, the fully dynamic APSP problem admits strong conditional lower bounds in the *low approximation* regimes: under plausible hardness assumptions, Abboud and Vassilevska Williams [3], and later Henzinger, Krinninger, Nanongkai, and Saranurak [32] show that there are no dynamic APSP algorithms achieving a $(3-\epsilon)$ approximation with sublinear query time and the update time being a small polynomial.

From an upper bounds perspective, there are only two works that achieve sublinear update time for fully dynamic APSP. Abraham, Chechik, and Talwar [5] showed that there is an algorithm that achieves constant approximation and sublinear update time. However, their algorithm cannot break the $O(\sqrt{n})$ barrier on the update time. Forster, Goranci, and Henzinger [25] gave different trade-offs between approximation and update time. In particular, in $n^{o(1)}$ amortized update time and polylogarithmic query time they achieve $n^{o(1)}$ approximation. These two works suffer from either a large approximation guarantee or update time, leaving open the following key question:

*Is there a fully dynamic APSP algorithm that achieves* constant *approximation with a very small polynomial update and query time?*

## 1.1 Our result

In this paper, we answer the question of achieving constant approximation with a very small polynomial update time for the fully dynamic APSP in the affirmative, also known as the *fully dynamic distance oracle* problem. More generally, we obtain a trade-off between approximation, update time, and query time as follows:

▶ **Theorem 1.** *Given a weighted undirected graph $G = (V, E, w)$ with polynomial weights*[2]*, and a constant parameter $0 < \rho < 1$, there is a randomized fully dynamic distance oracle with constant stretch $(\frac{256}{\rho^2})^{4/\rho}$ that w.h.p. achieves $\tilde{O}(n^{\rho})$ amortized update time and $\tilde{O}(n^{\rho/8})$ query time. These guarantees hold against an oblivious adversary.*

[2] In this paper, we assume for ease of notation that the edge weights are integers in the range from 1 to $W$, where $W$ is polynomial in $n$. Using a standard approach (see e.g., [8]) this extends to rational edge weights in some range from the minimum weight $W_{\min}$ to the maximum weight $W_{\max}$, where $W_{\max}/W_{\min}$ is polynomial in $n$.

Our distance oracle can also be extended to report the actual (approximate) shortest path when answering queries (see the full version [26] for a sketch). In addition to the constant stretch regime, we obtain several interesting tradeoffs, as shown in Theorem 5. For example, our algorithm achieves $O(\log \log n)$ stretch with a much faster query time of $n^{o(1)}$ and very small polynomial update time (see Corollary 6).

Our result brings the algorithmic guarantees on fully dynamic distance oracles closer to the recent conditional hardness result by Abboud, Bringmann, Khoury, and Zamir [2] (and the subsequent refinement in [1]), who showed that there is no fully dynamic algorithm that simultaneously achieves constant approximation and $n^{o(1)}$ update and query time. We also remark that our results are consistent with their lower bound since if we insist on constant approximation, the above trade-off shows that the update time cannot be made as efficient as $n^{o(1)}$.

On the technical side, our result follows the widespread "high-level" approach of extending decremental algorithms to the fully dynamic setting (see e.g. [33, 38, 39, 40, 10, 30, 5, 25]) and it is inspired by recent developments on the dynamic distance oracle literature that rely on vertex sparsification [25, 18, 27]. Specifically, we design a reduction that turns a decremental hub-labeling scheme with some specific properties into a fully dynamic distance oracle, which may be of independent interest. Our key observation is that an existing state-of-the-art decremental distance oracle that works against an oblivious adversary can serve as such hub-labeling scheme. The fully dynamic distance oracle is then obtained by repeatedly applying the reduction whilst carefully tuning various parameters across levels in the hierarchy.

More generally, our reduction does not make any assumptions on the adversary and is based on properties that are quite natural. At a high-level, we consider decremental approximate hub-labeling schemes with the following properties. (1) For every vertex $v \in V$, maintain a set $S(v)$, called a *hub set*, that has bounded size. (2) For every vertex $v \in V$, maintain distance estimates $\delta(v, u)$ for each $u \in S(v)$, with bounded *recourse*, which is defined as the number of times such distance estimates are affected during the execution of the algorithm. (3) Return the final estimate between a pair of vertices $s, t \in V$, by minimizing estimates over elements in $S(s) \cap S(t)$.

Many known distance oracles (e.g. variants of the well-known distance oracle of [44]) have a query mechanism that satisfies the first and third properties, while efficient dynamic distance oracles are often based on bounded recourse structures satisfying the second property.

Hence we hope that this reduction can be further utilized in the future by characterizing deterministic decremental distance oracles or the ones with different stretch/time tradeoffs as such hub-labeling schemes. Similar reductions have been previously proposed in [5] and then refined in [25] in slightly different contexts. In this work, in addition to refining this approach for obtaining a constant stretch distance oracle, we aim to keep the reduction as modular as possible to facilitate potential future applications.

## 1.2 Related Work

In the following, we give an overview of existing works on fully dynamic all-pairs distance oracles by dividing them into several categories based on their stretch guarantee. Unless noted otherwise, all algorithms cited in the following are randomized and have amortized update time. We report running time bounds for constant accuracy parameter $\epsilon$ and assume that we are dealing with graphs with positive integer edge weights that are polynomial in the number of vertices. We would also like to point out that all "combinatorial" algorithms discussed in the following (i.e., algorithms that do not rely on "algebraic" techniques like

dynamic matrix inverse) are internally employing decremental algorithms. Decremental algorithms have also been studied on their own with various tradeoffs [40, 10, 31, 16, 35, 24], and competitive deterministic algorithms have been devised, e.g., [30, 11, 19].

**Exact.** After earlier attempts on the problem [34, 23], Demetrescu and Italiano [22] presented their seminal work on exact distance maintenance achieving $\tilde{O}(n^2)$ update time (with log-factor improvements by Thorup [42]) and constant query time for weighted directed graphs.

Subsequently, researchers have developed algorithms with subcubic worst-case update time and constant query time [43, 4] with some of them being deterministic [28, 17]. Note that one can construct a simple update sequence for which any fully dynamic algorithm maintaining the distance matrix or the shortest path matrix explicitly needs to perform $\Omega(n^2)$ changes to this matrix per update.

Algorithms breaking the $n^2$ barrier at the cost of large query time have been obtained in unweighted directed graphs by Roditty and Zwick [39] (update time $\tilde{O}(mn^2/t^2)$ and query time $O(t)$ for any $\sqrt{n} \leq t \leq n^{3/4}$), Sankowski [41] (worst-case update time $O(n^{1.897})$ and query time $O(n^{1.265})$), and van den Brand, Nanongkai, and Saranurak [15] (worst-case update time $O(n^{1.724})$ and query time $O(n^{1.724})$). The latter two approaches are algebraic and their running time bounds depend on the matrix multiplication coefficient $\omega$.

**$(1+\epsilon)$-approximation.** In addition to exact algorithms, combinatorial and algebraic algorithms have also been developed for the low stretch regime of $(1+\epsilon)$-approximation. In particular, Roditty and Zwick [40] obtained the following trade-off with a combinatorial algorithm: update time $\tilde{O}(mn/t)$ and query time $O(t)$ for any $\delta > 0$ and $t \leq m^{1/2-\delta}$. Subsequently, for $t \leq \sqrt{n}$, a deterministic variant was developed [30] and it was generalized to weighted directed graphs [10]. Furthermore, by a standard reduction (see e.g. [12]) using a decremental approximate single-source shortest paths algorithm [31, 11], one obtains a combinatorial, deterministic algorithm with update time $O(nm^{1+o(1)}/t)$ and query time $O(t)$ for any $t \leq n$, for the fully dynamic all-pairs problem in weighted undirected graphs. Conditional lower bounds [37, 3, 32] suggest that the update and the query time cannot be both small polynomials in $n$. For example, no algorithm can maintain a $(5/3-\epsilon)$-approximation with update time $O(m^{1/2-\delta})$ and query time $O(m^{1-\delta})$ for any $\delta > 0$, unless the OMv conjecture fails [32].

Algebraic approaches can achieve subquadratic update time and sublinear query time, namely worst-case update time $O(n^{1.863})$ and query time $O(n^{0.666})$ in weighted directed graphs [14], or worst-case update time $O(n^{1.788})$ and query time $O(n^{0.45})$ in unweighted undirected graphs [13]. As the conditional lower bound by Abboud and Vassilevska Williams [3] shows, algebraic approaches seem to be necessary in this regime: unless one is able to multiply two $n \times n$ Boolean matrices in $O(n^{3-\delta})$ time for some constant $\delta > 0$, no fully dynamic algorithm for *st* reachability in directed graphs can have $O(n^{2-\delta'})$ update and query time and $O(n^{3-\delta'})$ preprocessing time (for some constant $\delta' > 0$). While not explicitly stated in the paper, the same conditional lower bound extends to fully dynamic $(1+\epsilon)$-approximate *st* distances on undirected unweighted graphs for a small enough constant $\epsilon$.

**$(2+\epsilon)$-approximation.** Apart from earlier work [34], the only relevant algorithm in the $(2+\epsilon)$-approximation regime is by Bernstein [9] and achieves update time $m^{1+o(1)}$ and query time $O(\log\log\log n)$ in weighted undirected graphs. It can be made deterministic using the deterministic approximate single-source shortest path algorithm by Bernstein, Probst Gutenberg, and Saranurak [11]. The only conditional lower bound in this regime that we are aware of states that no algorithm can maintain a $(3-\epsilon)$-approximation with update time $O(n^{1/2-\delta})$ and query time $O(n^{1-\delta})$ for any $\delta > 0$, unless the OMv conjecture fails [32].

**Larger approximation.** In the regime of stretch at least 3, the following trade-offs between stretch and update time have been developed: Abraham, Chechik, and Talwar [5] designed an algorithm for unweighted undirected graphs with stretch $2^{O(\rho k)}$, update time $\tilde{O}(m^{1/2}n^{1/k})$, and query time $O(k^2\rho^2)$, where $k \geq 1$ is a freely chosen parameter and $\rho = 1 + \lceil \log n^{1-1/k} / \log(m/n^{1-1/k}) \rceil$. Forster, Goranci, and Henzinger [25] designed an algorithm for weighted undirected graphs with stretch $O(\log n)^{3k-2}$, update time $m^{1/k+o(1)} \cdot O(\log n)^{4k-2}$, and query time $O(k(\log n)^2)$, where $k \geq 2$ is an arbitrary integer parameter. Very recently, Chuzhoy and Zhang [20] independently obtained a deterministic algorithm for weighted undirected graphs with stretch $(\log\log n)^{2^{1/\rho^3}}$, update time $\tilde{O}(n^{O(\rho)})$, and query time $\tilde{O}(2^{O(1/\rho)})$ for any choice of $\frac{2}{(\log n)^{1/200}} < \rho < \frac{1}{400}$. Similar to our work, they also achieve sublogarithmic stretch but their guarantee cannot be reduced all the way to a constant. While our algorithm has the advantage of achieving constant stretch, their algorithm is deterministic, and thus works against an adaptive adversary. Finally, note that any algorithm whose update time depends on the sparsity of the graph (possibly also a static one) can be run on a spanner of the input graph maintained by a fully dynamic spanner algorithm [7]. These upper bounds are complemented by the following conditional lower bound: for any integer constant $k \geq 2$, there is no dynamic approximate distance oracle with stretch $2k-1$, update time $O(m^u)$ and query time $O(m^q)$ with $ku + (k+1)q < 1$, unless the 3-SUM conjecture fails [1].

## 2 Preliminaries

We consider weighted undirected graphs $G = (V, E, w)$ with positive integer edge weights. We denote by $n = |V|$ the number of vertices, by $m = |E|$ the number of edges, and by $W$ the maximum weight of an edge. For every pair of vertices $u, v \in V$, the *distance* $\text{dist}_G(u, v)$ between $u$ and $v$ in $G$ is the length of a shortest path from $u$ to $v$ in $G$. For a path $P$, we denote by $w_G(P)$ the length of $P$ in $G$, by $E(P)$ the edges of $P$, and by $|P| = |E(P)|$ the number of edges of $P$. Also for a graph $H$, we denote by $V(H)$ and $E(H)$ the vertex and the edge set of $H$ respectively.

In dynamic graph algorithms, the graph is subject to updates and the algorithm has to process these updates by spending as little time as possible. In this paper, we consider updates that insert a single edge to the graph or delete a single edge from the graph. Moreover, observe that an update that changes the weight of an edge can be simulated by two updates, where the first update deletes the corresponding edge and the second update re-inserts the edge with the new weight. Let $G^{(0)}$ be the initial graph, and $G^{(\tau)}$ be the graph at time $\tau$ which is the time after $\tau$ updates have been performed to the graph.

In this paper we are interested in designing *fully dynamic* algorithms which can process edge insertions and edge deletions, and thus, weight changes as well. A *decremental* algorithm can process only edge deletions and weight increases. We assume that the updates to the graph are performed by an *oblivious adversary* who fixes the sequence of updates before the algorithm starts. Namely, the adversary cannot adapt the updates based on the choices of the algorithm during the execution. We say that an algorithm has *amortized update time* $u(n, m)$ if its total time spent for processing any sequence of $\ell$ updates is bounded by $\ell \cdot u(n, m)$, when it starts from an empty graph with $n$ vertices and during all the updates has at most $m$ edges (the time needed to initialize the algorithm on the empty graph before the first update is also included). An algorithm is *path reporting* if after a query can also return the corresponding path explicitly.

In our analysis we use $\tilde{O}(1)$ to hide factors polylogarithmic in $nW$. Namely, we write $\tilde{O}(1)^d$ to represent the term $O(\log^{cd} nW)$, for a constant $c$ and a parameter $d$.

# 3 Fully Dynamic Distance Oracle

The technical details of our distance oracle are divided into three parts. Initially in Section 3.1, we give the definition of a hub-labeling scheme together with other useful definitions. Afterwards, we provide a reduction for extending a decremental approximate hub-labeling scheme with some properties to a fully dynamic distance oracle. Then in Section 3.2, we explain how an existing decremental algorithm gives us an approximate hub-labeling scheme that we can use in this reduction, and finally in Section 3.3 we put everything together by applying our reduction repeatedly, in order to get a family of fully dynamic distance oracles.

## 3.1 From decremental hub-labeling scheme to fully dynamic distance oracle via reduction

We start by defining approximate hub-labeling schemes, and then explain how they are used in our reduction. Hub-labeling schemes were formally defined by [6] (and were previously introduced under the name 2-hop cover[3] in [21]). We are slightly modifying the definition for our purpose, for instance by considering an approximate variant.

▶ **Definition 2** (Approximate Hub-Labeling Scheme). *Given a graph $G = (V, E)$, a* hub-labeling scheme $\mathcal{L}$ *of* stretch $\alpha$ *consists of*

1. *for every vertex $v \in V$, a* hub set $S(v) \subseteq V$ *and*
2. *for every pair of vertices $u, v \in V$, a distance estimate $\delta(v, u)$ such that $\text{dist}_G(v, u) \leq \delta(v, u) < \infty$ if $u \in S(v)$ and $\delta(v, u) = \infty$ otherwise.*

*and for every pair of vertices $s$ and $t$ guarantees that*

$$\delta_{\mathcal{L}}(s, t) := \min_{v \in S(s) \cap S(t)} (\delta(s, v) + \delta(t, v)) \leq \alpha \cdot \text{dist}_G(s, t)\,.$$

The *distance label* of a vertex $v$ consists of the hub set $S(v)$ and the corresponding distance estimates $\delta(v, u)$, for all $u \in S(v)$.

Note that the definition implies $\delta_{\mathcal{L}}(s, t) \geq \text{dist}_G(s, t)$ for every pair of vertices $s$ and $t$. Furthermore, a hub-labeling scheme of stretch $\alpha$ directly implements a distance oracle of stretch $\alpha$ with query time $O(\max_{v \in V} |S(v)|)$ that consists of the collection of distance labels for all vertices $v \in V$. We also remark that the entries of value $\infty$ in the distance estimate $\delta(\cdot, \cdot)$ do not need to be stored explicitly if the hub sets are stored explicitly and that the distance estimate $\delta(\cdot, \cdot)$ is not necessarily symmetric.

In the following we consider *decremental* algorithms for maintaining approximate hub-labeling schemes, that is, *decremental approximate hub-labeling schemes* which process each edge deletion in the graph by first updating their internal data structures and then outputting the changes made to the hub sets and the distance estimates $\delta(\cdot, \cdot)$. Namely for a vertex $v \in V$, vertices may leave or join $S(v)$, or the distance estimates of vertices belonging to $S(v)$ may change, since the decremental algorithm has to update this information for maintaining correctness at query time.

Denote by $S^{(\tau)}(v)$ the hub set of a vertex $v \in V$ after $\tau$ updates have been processed by the decremental approximate hub-labeling scheme (we may omit the superscript $\tau$ whenever time is fixed), where $\tau \geq 1$ is an integer parameter. Then for a pair of vertices $u, v \in V$, the distance estimate $\delta(v, u)$ after $\tau$ updates is defined based on Definition 2 and $S^{(\tau)}(v)$. Namely, if $u$ is inside the hub set of $v$ after $\tau$ updates (i.e., $u \in S^{(\tau)}(v)$) then $\text{dist}_{G^{(\tau)}}(v, u) \leq \delta(v, u) < \infty$, otherwise $\delta(v, u) = \infty$.

[3] The concept of 2-hop cover or hub-labeling should not be confused with the (related) concept of a hopset that we will later see in Section 3.2.

After $\tau$ edge deletions have been processed by the decremental approximate hub-labeling scheme, there are three possible types of changes to the distance estimates $\delta(v,\cdot)$ that correspond to a vertex $v \in V$, due to the last edge deletion. (1) The distance estimate $\delta(v,u)$ changes for a vertex $u \in S^{(\tau-1)}(v) \cap S^{(\tau)}(v)$ that remains inside the hub set of $v$. (2) The distance estimate $\delta(v,u)$ becomes $\infty$ because a vertex $u \in S^{(\tau-1)}(v) \setminus S^{(\tau)}(v)$ leaves the hub set of $v$. (3) The distance estimate $\delta(v,u)$ receives a finite value because a vertex $u \in S^{(\tau)}(v) \setminus S^{(\tau-1)}(v)$ enters the hub set of $v$. Let $\chi^{(\tau)}(v)$ be the number of all these changes to $\delta(v,\cdot)$ corresponding to $v$ at time $\tau$. In other words, for a fixed vertex $v \in V$, the value of $\chi^{(\tau)}(v)$ is equal to the number of vertices $u$ whose corresponding value of $\delta(v,u)$ changes due to the last edge deletion. Moreover, let $X(v) = \sum_\tau \chi^{(\tau)}(v)$ be the total number of such changes to $\delta(v,\cdot)$ corresponding to $v$ over the course of the algorithm.

In the following lemma, we present a reduction from a decremental approximate hub-labeling scheme to a fully dynamic distance oracle.

▶ **Lemma 3.** *Consider a decremental hub-labeling scheme $\mathcal{A}$ of stretch $\alpha$ with total update time $T_{\mathcal{A}}(n,m,W)$ and query time $Q_{\mathcal{A}}(n,m,W)$, with the following properties:*

1. *$\forall v \in V$ and $\forall \tau : |S^{(\tau)}(v)| \leq \gamma$. In other words, the size of the hub set of any vertex is bounded by $\gamma$ at any moment of the algorithm.*
2. *$\forall v \in V : X(v) \leq \zeta$. In other words, for every vertex $v \in V$ the total number of changes to $\delta(v,\cdot)$ is at most $\zeta$ over the course of the algorithm. Moreover the algorithm detects and reports these changes explicitly.*

*Then given $\mathcal{A}$ and a fully dynamic distance oracle $\mathcal{B}$ of stretch $\beta$ with amortized update time $t_{\mathcal{B}}(n,m,W)$ and query time $Q_{\mathcal{B}}(n,m,W)$, for any integer $\ell \geq 1$, there is a fully dynamic distance oracle $\mathcal{C}$ of stretch $\alpha\beta$ with amortized update time $t_{\mathcal{C}}(n,m,W) = T_{\mathcal{A}}(n,m,W)/\ell + t_{\mathcal{B}}(\min(\ell(2+2\mu),n), \ell(1+2\mu), nW) \cdot (2+4\mu)$ and query time $Q_{\mathcal{C}}(n,m,W) = Q_{\mathcal{A}}(n,m,W) + \gamma^2 \cdot Q_{\mathcal{B}}(\min(\ell(2+2\mu),n), \ell(1+2\mu), nW)$, where $\mu = \gamma + \zeta$.*

**Proof.** We organize the proof in three parts. The first part gives the reduction from $\mathcal{A}$ and $\mathcal{B}$ to $\mathcal{C}$, and the second and third part concern the correctness and the running times respectively.

**Reduction.** The fully dynamic distance oracle $\mathcal{C}$ proceeds in phases of length $\ell$. For each phase, we denote by $\tau$ the number of updates processed by $\mathcal{A}$ during the phase. At the beginning of the first phase (which is also the beginning of the algorithm), $\mathcal{C}$ initializes the fully dynamic distance oracle $\mathcal{B}$ on the initially empty graph $G$ consisting of $2\ell$ vertices[4], and sets an update counter to 0. Whenever an update to $G$ occurs in the first phase, the update is directly processed by $\mathcal{B}$.[5] As soon as the number of updates is more than $\ell$, the second phase is started. We define several sets and the graph $H$ that the fully dynamic distance oracle $\mathcal{C}$ maintains during each subsequent phase:

- Let $F$ be the set of edges present in $G$ at the beginning of the phase, $E$ be the current set of edges in $G$, and $D$ be the set of edges deleted from $G$ during the phase.
- Let $I = E \setminus (F \setminus D)$ be the set of edges inserted to $G$ since the beginning of the phase without subsequently having been deleted during the phase, and $U = \{v \in V \mid \exists e \in I : v \in e\}$ be the set of endpoints of edges in $I$.

[4] This minor technical detail makes sure that $\mathcal{B}$ does not have to deal with vertex insertions.
[5] The special treatment of the first $\ell$ updates is just a technical necessity for a rigorous amortization argument in the running time analysis.

- Let $H$ be the auxiliary graph that consists of all edges $(u, v) \in I$, together with their hub sets $S^{(\tau)}(u)$ and $S^{(\tau)}(v)$ after $\tau$ edge deletions have been processed by $\mathcal{A}$. Specifically, $V(H) = \{v \in V \mid v \in U \text{ or } (u \in U \text{ and } v \in S^{(\tau)}(u))\}$ and $E(H) = \{(u, v) \mid (u, v) \in I \text{ or } (v \in U \text{ and } u \in S^{(\tau)}(v))\}$. Note that at any fixed moment, the size of $V(H)$ is at most $\ell \cdot (2 + 2\gamma)$ and the size of $E(H)$ is at most $\ell \cdot (1 + 2\gamma)$.

At the beginning of each subsequent phase, $\mathcal{C}$ stores the sets $F, E, D, I, U$, and the auxiliary graph $H$, and sets an update counter to 0. Furthermore, $\mathcal{C}$ initializes the decremental approximate hub-labeling scheme $\mathcal{A}$ on the current graph $G$, and the fully dynamic distance oracle $\mathcal{B}$ on $H$ which is initially an empty "sketch" graph on $\ell \cdot (2 + 2\mu)$ vertices. The graph $H$ can be thought of as responsible for maintaining estimates for paths that use inserted edges.

Whenever an update to $G$ occurs, $\mathcal{C}$ first checks via the update counter whether the number of updates since the beginning of the phase is more than $\ell$. If this is the case, then $\mathcal{C}$ starts a new phase. Otherwise, after an update the fully dynamic distance oracle $\mathcal{C}$ does the following. On the insertion of an edge $(u, v)$ to $G$, $\mathcal{C}$ adds $(u, v)$ to $I$, adds $u$ and $v$ to $U$, and adds the edge $(u, v)$ to $H$, together with the edges $(u, p)$ for every $p \in S^{(\tau)}(u)$ and $(v, p)$ for every $p \in S^{(\tau)}(v)$. Any time an edge $(u, v)$ is added to $H$, its weight is set to:

$$w_H(u, v) = \min(w_G(u, v), \delta(u, v), \delta(v, u)).$$

Whenever the first edge incident to some vertex $v$ is added to $H$, the algorithm finds a "fresh" vertex (of degree 0) in $H$ and henceforth identifies it as $v$. This is always possible, since by the two properties of $\mathcal{A}$, the number of such vertices in a phase of length $\ell$ is at most $\ell \cdot (2 + 2\mu)$.

On the deletion of an edge $(u, v) \in E$ from $G$, there are two cases to consider.

1. If the edge $(u, v)$ was not present at the beginning of the current phase, or has been deleted and re-inserted (i.e., $(u, v) \in I$), then $\mathcal{C}$ removes $(u, v)$ from $I$, adds $(u, v)$ to $D$, and updates the set $U$ and the graph $H$ accordingly. In particular, if $u \in U$ and $v \in S^{(\tau)}(u)$, or $v \in U$ and $u \in S^{(\tau)}(v)$, $\mathcal{C}$ updates the weight of the edge $(u, v)$ in $H$ to $w_H(u, v) = \min(\delta(u, v), \delta(v, u))$ (as $w_G(u, v) = \infty$ after the deletion), otherwise $\mathcal{C}$ removes $(u, v)$ from $H$. Also, for all the vertices $v$ that left $U$ and all the edges $(v, p) \in E(H)$ such that $p \in S^{(\tau)}(v)$, if $p \in U$ and $v \in S^{(\tau)}(p)$, then $\mathcal{C}$ updates the weight of $(v, p)$ in $H$ to $w_H(v, p) = \delta(p, v)$ (as $v \notin U$ after the deletion), and otherwise $\mathcal{C}$ removes $(v, p)$ from $H$.
2. If the edge $(u, v)$ was present at the beginning of the current phase and has not been deleted yet (i.e., $(u, v) \in F \setminus D$), then $\mathcal{C}$ adds $(u, v)$ to $D$ and the deletion is processed by $\mathcal{A}$. Whenever $\mathcal{A}$ changes some distance estimates $\delta(v, \cdot)$ that correspond to a vertex $v \in U$ (i.e, $v$ is a vertex of $H$ and an endpoint of an edge in $I$) and its hub set, $\mathcal{C}$ updates the graph $H$ accordingly. In particular, there are three possible scenarios at time $\tau$ of $\mathcal{A}$.[6] (1) Whenever the value of $\delta(v, u)$ changes for a vertex $u \in S^{(\tau-1)}(v) \cap S^{(\tau)}(v)$ that remains inside the hub set of $v$, $\mathcal{C}$ updates the weight of the edge $(v, u)$ in $H$ to $w_H(v, u) = \min(w_G(v, u), \delta(v, u), \delta(u, v))$. (2) Whenever a vertex $u \in S^{(\tau-1)}(v) \setminus S^{(\tau)}(v)$ leaves the hub set of $v$, then if $(v, u) \in I$ or $u \in U$ and $v \in S^{(\tau)}(u)$, $\mathcal{C}$ updates the weight of the edge $(v, u)$ in $H$ to $w_H(v, u) = \min(w_G(v, u), \delta(u, v))$ (as $\delta(v, u) = \infty$ after the deletion), otherwise $\mathcal{C}$ removes $(v, u)$ from $H$. (3) Whenever a vertex $u \in S^{(\tau)}(v) \setminus S^{(\tau-1)}(v)$ enters the hub set of $v$, $\mathcal{C}$ adds the edge $(v, u)$ to $H$ (unless it exists already) and updates its weight to $w_H(v, u) = \min(w_G(v, u), \delta(v, u), \delta(u, v))$. Note that the number of these

[6] Note that $\tau$ is the number of updates processed only by $\mathcal{A}$ during the phase.

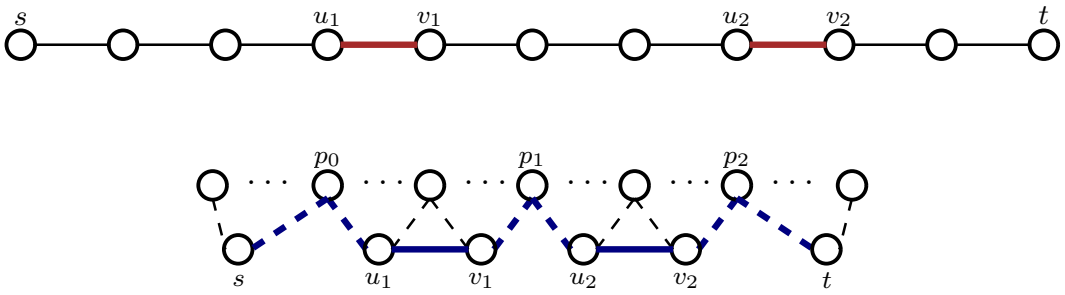

**Figure 1** Illustration of an $s$-$t$ shortest path. The brown thick edges have been inserted since the beginning of the phase. The corresponding subgraph of the auxiliary graph $H$ is also depicted (note that the vertices $s$ and $t$ are not necessarily part of $H$). The blue thick edges are the ones that participate in the correctness analysis of the query. Dashed edges depict edges inside the hub sets.

changes at time $\tau$ of $\mathcal{A}$ is equal to $\chi^{(\tau)}(v)$ for a vertex $v \in V$. Observe also that based on the two properties of $\mathcal{A}$, the number of vertices that participate in $H$ during a phase of length $\ell$ is at most $\ell \cdot (2 + 2\mu)$. Thus we can always find a "fresh" vertex (of degree 0) in $H$.

Finally, all the changes performed to $H$ are processed by the fully dynamic distance oracle $\mathcal{B}$ running on $H$, where edge weight changes are simulated by a deletion followed by a re-insertion.

Now a query for the approximate distance between any pair of vertices $s$ and $t$ is answered by returning:

$$\delta_{\mathcal{C}}(s,t) = \min\left(\min_{p \in S^{(\tau)}(s) \cap V(H), q \in S^{(\tau)}(t) \cap V(H)} \left(\delta(s,p) + \delta_{\mathcal{B}}(p,q) + \delta(t,q)\right), \delta_{\mathcal{A}}(s,t)\right).$$

Whenever $S^{(\tau)}(s) \cap V(H) = \emptyset$ or $S^{(\tau)}(t) \cap V(H) = \emptyset$, we let the inner term $\min(\cdot)$ to be $\infty$.

**Correctness.** To prove the correctness of this algorithm, we need to show that $\text{dist}_G(s,t) \leq \delta_{\mathcal{C}}(s,t) \leq \alpha\beta \cdot \text{dist}_G(s,t)$. The lower bound $\text{dist}_G(s,t) \leq \delta_{\mathcal{C}}(s,t)$ is immediate, since for each approximate distance returned by $\mathcal{C}$, the corresponding path uses edges from $G$ or distance estimates from the decremental approximate hub-labeling scheme which are never an underestimation of the real distance. To prove the upper bound, consider a shortest path $\pi$ from $s$ to $t$ in $G$, and let $G_{\mathcal{A}}$ be the graph maintained by $\mathcal{A}$ (i.e., the edge set of $G_{\mathcal{A}}$ is $E(G_{\mathcal{A}}) = F \setminus D$). If the path $\pi$ contains only edges from the set $F \setminus D$, then $\delta_{\mathcal{C}}(s,t) \leq \delta_{\mathcal{A}}(s,t) \leq \alpha \cdot \text{dist}_{G_{\mathcal{A}}}(s,t) = \alpha \cdot \text{dist}_G(s,t)$, and the claim follows. Otherwise, let $(u_1,v_1),\ldots,(u_j,v_j) \in I$ denote the edges of $\pi$ that have been inserted since the beginning of the current phase in order of appearance on $\pi$. Furthermore, let $p_0 \in S^{(\tau)}(s) \cap S^{(\tau)}(u_1)$ be the vertex that "certifies" $\delta_{\mathcal{A}}(s,u_1)$, that is, $\delta_{\mathcal{A}}(s,u_1) = \delta(s,p_0) + \delta(u_1,p_0)$. Similarly, let $p_j \in S^{(\tau)}(v_j) \cap S^{(\tau)}(t)$ be the vertex that "certifies" $\delta_{\mathcal{A}}(v_j,t)$, and for every $1 \leq i \leq j-1$, let $p_i \in S^{(\tau)}(v_i) \cap S^{(\tau)}(u_{i+1})$ be the vertex that "certifies" $\delta_{\mathcal{A}}(v_i,u_{i+1})$ (see Figure 1). These vertices must exist by the definition of an approximate hub-labeling scheme. Furthermore, by the construction of $H$, the edges $(u_1,p_0)$ and $(v_j,p_j)$ have been inserted to $H$, because $u_1 \in U$ and $p_0 \in S^{(\tau)}(u_1)$, and $v_j \in U$ and $p_j \in S^{(\tau)}(v_j)$ respectively. Hence, the vertices $p_0$ and $p_j$ belong to $V(H)$, and the sum $\delta(s,p_0) + \delta_{\mathcal{B}}(p_0,p_j) + \delta(t,p_j)$ participates in the inner term $\min(\cdot)$. Therefore to analyze the claimed upper-bound on the stretch, we proceed as follows:

$$
\begin{aligned}
\delta_{\mathcal{C}}(s,t) &\leq \delta(s,p_0) + \delta_{\mathcal{B}}(p_0,p_j) + \delta(t,p_j) \\
&\quad \text{(stretch guarantee of } \mathcal{B}\text{)} \\
&\leq \delta(s,p_0) + \beta \cdot \mathrm{dist}_H(p_0,p_j) + \delta(t,p_j) \\
&\quad \text{(triangle inequality)} \\
&\leq \delta(s,p_0) + \beta \cdot \mathrm{dist}_H(p_0,u_1) \\
&\quad + \sum_{1 \leq i \leq j-1} \beta \cdot (\mathrm{dist}_H(u_i,v_i) + \mathrm{dist}_H(v_i,p_i) + \mathrm{dist}_H(p_i,u_{i+1})) \\
&\quad + \beta \cdot (\mathrm{dist}_H(u_j,v_j) + \mathrm{dist}_H(v_j,p_j)) + \delta(t,p_j) \\
&\quad (\mathrm{dist}_H \leq w_H) \\
&\leq \delta(s,p_0) + \beta \cdot w_H(p_0,u_1) + \sum_{1 \leq i \leq j-1} \beta \cdot (w_H(u_i,v_i) + w_H(v_i,p_i) + w_H(p_i,u_{i+1})) \\
&\quad + \beta \cdot (w_H(u_j,v_j) + w_H(v_j,p_j)) + \delta(t,p_j)
\end{aligned}
$$

By the construction of $H$, the edges $(u_i, v_i)$ of $\pi$ and the corresponding edges $(p_{i-1}, u_i)$ and $(v_i, p_i)$ have been inserted to $H$[7], because $(u_i, v_i) \in I$, $u_i \in U$ and $p_{i-1} \in S^{(\tau)}(u_i)$, and $v_i \in U$ and $p_i \in S^{(\tau)}(v_i)$ respectively. Hence by the definition of $w_H(\cdot)$, we can replace $w_H(u_i, v_i)$ with $w_G(u_i, v_i)$, $w_H(p_{i-1}, u_i)$ with $\delta(u_i, p_{i-1})$ and $w_H(v_i, p_i)$ with $\delta(v_i, p_i)$. As a result, we have that (where $\alpha \geq 1$ and $\beta \geq 1$):

$$
\begin{aligned}
\delta_{\mathcal{C}}(s,t) &\leq \delta(s,p_0) + \beta \cdot \delta(u_1,p_0) + \sum_{1 \leq i \leq j-1} \beta \cdot (w_G(u_i,v_i) + \delta(v_i,p_i) + \delta(u_{i+1},p_i)) \\
&\quad + \beta \cdot (w_G(u_j,v_j) + \delta(v_j,p_j)) + \delta(t,p_j) \\
&\quad (\pi \text{ is a shortest path}) \\
&= \delta(s,p_0) + \beta \cdot \delta(u_1,p_0) + \sum_{1 \leq i \leq j-1} \beta \cdot (\mathrm{dist}_G(u_i,v_i) + \delta(v_i,p_i) + \delta(u_{i+1},p_i)) \\
&\quad + \beta \cdot (\mathrm{dist}_G(u_j,v_j) + \delta(v_j,p_j)) + \delta(t,p_j) \\
&\leq \beta \cdot (\delta(s,p_0) + \delta(u_1,p_0)) + \sum_{1 \leq i \leq j-1} \beta \cdot (\mathrm{dist}_G(u_i,v_i) + \delta(v_i,p_i) + \delta(u_{i+1},p_i)) \\
&\quad + \beta \cdot (\mathrm{dist}_G(u_j,v_j) + \delta(v_j,p_j) + \delta(t,p_j)) \\
&\quad \text{(definition of approximate hub-labeling scheme)} \\
&= \beta \cdot \delta_{\mathcal{A}}(s,u_1) + \sum_{1 \leq i \leq j-1} \beta \cdot (\mathrm{dist}_G(u_i,v_i) + \delta_{\mathcal{A}}(v_i,u_{i+1})) \\
&\quad + \beta \cdot (\mathrm{dist}_G(u_j,v_j) + \delta_{\mathcal{A}}(v_j,t))
\end{aligned}
$$

From the stretch guarantee of $\mathcal{A}$, it holds that $\delta_{\mathcal{A}}(u,v) \leq \alpha \cdot d_{G_{\mathcal{A}}}(u,v)$ for any pair of vertices $u, v \in V$. For any two vertices $v_i, u_{i+1}$ from the previous sum, the subpath of $\pi$ from $v_i$ to $u_{i+1}$ uses edges only from the set $F \setminus D$, implying that $d_{G_{\mathcal{A}}}(v_i, u_{i+1}) = d_G(v_i, u_{i+1})$. The same argument holds for the pairs $s, u_1$ and $v_j, t$, thus it follows that:

$$
\begin{aligned}
\delta_{\mathcal{C}}(s,t) &\leq \alpha\beta \cdot \mathrm{dist}_G(s,u_1) + \sum_{1 \leq i \leq j-1} \beta \cdot (\mathrm{dist}_G(u_i,v_i) + \alpha \cdot \mathrm{dist}_G(v_i,u_{i+1})) \\
&\quad + \beta \cdot (\mathrm{dist}_G(u_j,v_j) + \alpha \cdot \mathrm{dist}_G(v_j,t))
\end{aligned}
$$

[7] If $v_i = u_{i+1}$ then $p_i = v_i$, and so $w_H(v_i, p_i) = w_H(p_i, u_{i+1}) = 0$.

$$\leq \alpha\beta \cdot \text{dist}_G(s, u_1) + \sum_{1 \leq i \leq j-1} \alpha\beta \cdot (\text{dist}_G(u_i, v_i) + \text{dist}_G(v_i, u_{i+1}))$$
$$+ \alpha\beta \cdot (\text{dist}_G(u_j, v_j) + \text{dist}_G(v_j, t)) = \alpha\beta \cdot \text{dist}_G(s, t).$$

**Update and Query time.** To analyze the running times, consider a fixed phase of length $\ell$. During the first phase, the query time is $Q_{\mathcal{B}}(2\ell, \ell, W)$ and the amortized update is $t_{\mathcal{B}}(2\ell, \ell, W)$, as the initially empty graph $G$ can have at most $2\ell$ vertices and $\ell$ edges after $\ell$ updates. For the subsequent phases we proceed as follows. By the construction of $H$ and the two properties of $\mathcal{A}$, the graph $H$ has at most $\min(\ell(2+2\mu), n)$ vertices and $\ell(1+2\mu)$ edges during the phase, and the maximum edge weight in $H$ is $nW$ (the maximum distance in $G$).[8] Moreover by the first property we have that $|S^{(\tau)}(s) \cap V(H)| \leq \gamma$ and $|S^{(\tau)}(t) \cap V(H)| \leq \gamma$. Therefore the query time is equal to:

$$Q_{\mathcal{C}}(n, m, W) = Q_{\mathcal{A}}(n, m, W) + \gamma^2 \cdot Q_{\mathcal{B}}(\min(\ell(2+2\mu), n), \ell(1+2\mu), nW).$$

Let us now analyze the amortized update time. Since the total update time of $\mathcal{A}$ is $T_{\mathcal{A}}(n, m, W)$ and the amortized update time of $\mathcal{B}$ is $t_{\mathcal{B}}(\min(\ell(2+2\mu), n), \ell(1+2\mu), nW)$ during the phase, it remains to bound the total number of updates to $H$ per phase. Whenever an edge $e = (u, v)$ is inserted to $G$, we add to $H$ the two endpoints $u$ and $v$ together with their hub sets $S^{(\tau)}(u)$ and $S^{(\tau)}(v)$, and at most $1 + 2\gamma$ updates can occur to $H$. Until $(u, v)$ is deleted from $H$, every update to $H$ between $u$, $v$ and their hub sets modifies an entry of the distance estimate $\delta(u, \cdot)$ or $\delta(v, \cdot)$. By the definition of $\chi^{(\tau)}(\cdot)$, the number of entries of the distance estimates $\delta(u, \cdot)$ and $\delta(v, \cdot)$ that are modified at time $\tau$ of $\mathcal{A}$ is equal to $\chi^{(\tau)}(u) + \chi^{(\tau)}(v)$. Hence until $(u, v)$ is deleted from $H$, the total number of updates to $H$ between $u$, $v$ and their hub sets is equal to $2 \cdot (\sum_\tau \chi^{(\tau)}(u) + \sum_\tau \chi^{(\tau)}(v)) = 2 \cdot (X(u) + X(v))$,[9] which is at most $4\zeta$ based on the second property of Lemma 3. Moreover, when the edge $e$ is deleted from $G$, at most $1 + 2\gamma$ updates can occur to $H$. Therefore, the total number of updates to $H$ that correspond to an inserted edge in $G$, is at most $2 + 4\gamma + 4\zeta = 2 + 4\mu$ per phase. Since there can be at most $\ell$ inserted edges per phase, the total number of updates to $H$ during a phase is at most $\ell(2 + 4\mu)$. This implies that the total time for processing all updates during a phase is $T_{\mathcal{A}}(n, m, W) + t_{\mathcal{B}}(\min(\ell(2+2\mu), n), \ell(1+2\mu), nW) \cdot \ell(2+4\mu)$, which (when amortized over the $\ell$ updates of the previous phase) amounts to an amortized update time of:

$$T_{\mathcal{C}}(n, m, W) = \frac{T_{\mathcal{A}}(n, m, W)}{\ell} + t_{\mathcal{B}}(\min(\ell(2+2\mu), n), \ell(1+2\mu), nW) \cdot (2+4\mu). \quad \blacktriangleleft$$

## 3.2 Decremental approximate hub-labeling scheme

In this section, we argue that an existing decremental distance oracle from [35] also provides an approximate hub-labeling scheme whose properties make the reduction of Lemma 3 quite efficient. This decremental algorithm is based on the well-known static Thorup-Zwick (TZ) distance oracle [44].

**Thorup-Zwick distance oracle.** Given a graph $G = (V, E)$, the construction starts by defining a non-increasing sequence of sets $V = A_0 \supseteq A_1 \supseteq \cdots \supseteq A_k = \emptyset$, where for each $1 \leq i < k$, the set $A_i$ is obtained by subsampling each element of $A_{i-1}$ independently with probability $n^{-1/k}$.

[8] We can assume that $\delta(\cdot, \cdot)$ is upper bounded by $nW$ whenever it has a finite value, since the maximum distance in $G$ is at most $nW$. Likewise, we can use the value $nW + 1$ instead of $\infty$.

[9] We multiply by 2 because edge weight changes are simulated by a deletion followed by a re-insertion.

For every vertex $v \in V$ and $1 \leq i < k$, let $\delta(v, A_i) = \min_{u \in A_i} \text{dist}_G(v, u)$ be the minimum distance from $v$ to a vertex in $A_i$. As $A_k = \emptyset$, we let $\delta(v, A_k) = \infty$. Moreover, let $p_i(v) \in A_i$ be a vertex in $A_i$ closest to $v$, that is, $\text{dist}_G(v, p_i(v)) = \delta(v, A_i)$. Then, the bunch $B(v) \subseteq V$ of each $v \in V$ is defined as:

$$B(v) = \bigcup_{i=0}^{k-1} B_i(v) \ , \ \text{ where } \ B_i(v) = \{u \in A_i \setminus A_{i+1} : \text{dist}_G(v, u) < \text{dist}_G(v, A_{i+1})\}.$$

The cluster of a vertex $u \in A_i \setminus A_{i+1}$ is defined as $C(u) = \{v \in V : \text{dist}_G(v, u) < \text{dist}_G(v, A_{i+1})\}$. Observe that $u \in B(v)$ if and only if $v \in C(u)$, for any $u, v \in V$.

As noted in [44], this construction is a hub-labeling scheme of stretch $2k-1$ (see Definition 2), where the hub set $S(v)$ of a vertex $v \in V$ is $S(v) = B(v) \cup (\bigcup_{i=0}^{k-1} \{p_i(v)\})$. In other words, bunches and pivots of all the $k$ levels form a hub set for $v$. For obtaining the distance estimates $\delta(v, \cdot)$ for all $v \in V$ as in Definition 2, we need the associated distances $\delta(v, u) = \text{dist}_G(v, u)$ for all $u \in S(v)$. It can be shown that with a simple modification of the stretch argument (e.g. see [29]), it is enough to only use the bunches as the hub sets, and explicit access to pivots is not necessary. Hence for simplifying the presentation in this section we assume that the hub sets are equivalent with the bunches. As shown in [44], the size of the bunch of any vertex is w.h.p. bounded by $\tilde{O}(n^{1/k})$. Recall that the maximum hub set size is one of the parameters governing the efficiency of our reduction.

In the next lemma we present the decremental algorithm of [35] which has good properties for the reduction of Lemma 3. For a more detailed explanation of the lemma see the full version [26].

▶ **Lemma 4** (Implicit in [35]). *Given a weighted undirected graph $G = (V, E)$ and $k > 1, 0 < \epsilon < 1$, there is a decremental hub-labeling scheme of stretch $(2k-1)(1+\epsilon)$ and w.h.p. the total update time is $\tilde{O}(mn^{1/k}) \cdot O(\log nW/\epsilon)^{2k+1}$. Moreover, w.h.p. we have the following two properties:*

1. *$\forall v \in V$ and $\forall \tau : |S^{(\tau)}(v)| \leq \tilde{O}(n^{1/k})$. In other words, the size of the bunch of any vertex is bounded by $\tilde{O}(n^{1/k})$ at any moment of the algorithm.*
2. *$\forall v \in V : X(v) \leq \tilde{O}(n^{1/k}) \cdot O(\log nW/\epsilon)^{2k+1}$. In other words, for every vertex $v \in V$ the total number of changes to $\delta(v, \cdot)$ is at most $\tilde{O}(n^{1/k}) \cdot O(\log nW/\epsilon)^{2k+1}$ over the course of the algorithm. Moreover the algorithm detects and reports these changes explicitly.*

## 3.3 Putting it together

In this section we explain how to obtain our final fully dynamic distance oracle by using the decremental algorithm of Section 3.2 in our reduction of Lemma 3.

▶ **Theorem 5.** *For any integer parameters $i \geq 0, k > 1$, there is a fully dynamic distance oracle $\mathcal{B}_i$ with stretch $(4k)^i$ and w.h.p. the amortized update time is $t_{\mathcal{B}_i}(n, m, W) = \tilde{O}(1)^{ki} \cdot m^{3/(3i+1)} \cdot n^{4i/k}$ and the query time $Q_{\mathcal{B}_i}(n, m, W) = \tilde{O}(1)^i \cdot n^{2i/k}$.*

**Proof.** The proof is by induction on the parameter $i$. For the base case $i = 0$, let $\mathcal{B}_0$ be the trivial fully dynamic distance oracle that achieves stretch 1, amortized update time $t_{\mathcal{B}_0}(n, m, W) = O(n^3)$, and query time $Q_{\mathcal{B}_0}(n, m, W) = O(1)$, by recomputing all-pairs shortest paths from scratch after each update (e.g., with the Floyd–Warshall algorithm).

For the induction step, let $\mathcal{A}$ denote the decremental approximate hub-labeling scheme from Lemma 4 with stretch $\alpha = 4k$ and w.h.p. total update time $T_{\mathcal{A}}(n, m, W) = \tilde{O}(1)^k \cdot mn^{1/k}$ and query time $Q_{\mathcal{A}}(n, m, W) = \tilde{O}(1) \cdot n^{1/k}$, where $\epsilon$ has been replaced with any value strictly smaller than $\frac{1}{2}$. By inductive hypothesis, we have that $\mathcal{B}_i$ (with $i \geq 0$) is a fully dynamic

distance oracle of stretch $\beta_i = (4k)^i$ with amortized update time $\tilde{O}(1)^{ki} \cdot m^{3/(3i+1)} \cdot n^{4i/k}$ and query time $\tilde{O}(1)^i \cdot n^{2i/k}$. Based on Lemma 4, w.h.p. the decremental approximate hub-labeling scheme $\mathcal{A}$ satisfies the properties of Lemma 3 with $\gamma = \tilde{O}(1) \cdot n^{1/k}$ and $\zeta = \tilde{O}(1)^k \cdot n^{1/k}$. By applying then Lemma 3 to $\mathcal{A}$ and $\mathcal{B}_i$ with $\ell = m^{(3i+1)/(3i+4)}$, the resulting fully dynamic distance oracle $\mathcal{B}_{i+1}$ has stretch $(4k)^{i+1}$, and amortized update time: $t_{\mathcal{B}_{i+1}}(n,m,W) = T_{\mathcal{A}}(n,m,W)/\ell + t_{\mathcal{B}_i}(n,\ell(1+2\mu),nW)\cdot(2+4\mu)$. The first term is equal to: $\tilde{O}(1)^k \cdot mn^{1/k}/\ell = \tilde{O}(1)^k \cdot m^{3/(3i+4)} \cdot n^{1/k} = \tilde{O}(1)^k \cdot m^{3/(3(i+1)+1)} \cdot n^{1/k}$, and the second term is equal to (where $\mu = \tilde{O}(1)^k \cdot n^{1/k}$):

$$
\begin{aligned}
&t_{\mathcal{B}_i}(n,\ell(1+2\mu),nW)\cdot(2+4\mu) = \tilde{O}(1)^{ki}\cdot(\ell\cdot\tilde{O}(1)^k\cdot n^{1/k})^{3/(3i+1)}\cdot n^{4i/k}\cdot\tilde{O}(1)^k\cdot n^{1/k}\\
&\text{(Replace } \ell \text{ with } m^{(3i+1)/(3i+4)})\\
&= \tilde{O}(1)^{ki}\cdot(m^{(3i+1)/(3i+4)}\cdot\tilde{O}(1)^k\cdot n^{1/k})^{3/(3i+1)}\cdot n^{4i/k}\cdot\tilde{O}(1)^k\cdot n^{1/k}\\
&\text{(Replace } n^{3/(3i+1)k} \text{ with } n^{3/k} \text{ and } \tilde{O}(1)^{3k/(3i+1)} \text{ with } \tilde{O}(1)^{3k})\\
&= \tilde{O}(1)^{ki}\cdot m^{3/(3i+4)}\cdot\tilde{O}(1)^{3k}\cdot n^{3/k}\cdot n^{4i/k}\cdot\tilde{O}(1)^k\cdot n^{1/k}\\
&= \tilde{O}(1)^{ki+k}\cdot m^{3/(3i+4)}\cdot n^{(4i+4)/k} = \tilde{O}(1)^{k(i+1)}\cdot m^{3/(3(i+1)+1)}\cdot n^{4(i+1)/k}.
\end{aligned}
$$

Therefore the amortized update time of $\mathcal{B}_{i+1}$ is:

$$t_{\mathcal{B}_{i+1}}(n,m,W) = \tilde{O}(1)^{k(i+1)}\cdot m^{3/(3(i+1)+1)}\cdot n^{4(i+1)/k}.$$

Finally the query time of $\mathcal{B}_{i+1}$ is (where $\gamma^2 = \tilde{O}(1)^2 \cdot n^{2/k}$):

$$
\begin{aligned}
Q_{\mathcal{B}_{i+1}}(n,m,W) &= Q_{\mathcal{A}}(n,m,W) + \gamma^2\cdot Q_{\mathcal{B}_i}(n,\ell(1+2\mu),nW)\\
&= \tilde{O}(1)\cdot n^{1/k} + \tilde{O}(1)^2\cdot n^{2/k}\cdot\tilde{O}(1)^i\cdot n^{2i/k} = \tilde{O}(1)^{i+1}\cdot n^{2(i+1)/k}.
\end{aligned}
$$

and so the distance oracle $\mathcal{B}_{i+1}$ has the desired guarantees. ◀

**Proof of Theorem 1.** By Theorem 5, for any $i \geq 1, k > 1$, there is a fully dynamic distance oracle $\mathcal{B}_i$ of stretch $(4k)^i$ that w.h.p. achieves $\tilde{O}(1)^{ki}\cdot m^{1/i}\cdot n^{4i/k}$ amortized update time and $\tilde{O}(1)^i \cdot n^{2i/k}$ query time. Since $m \leq n^2$, by setting $i = \frac{4}{\rho}$ and $k = \frac{64}{\rho^2}$ the claim follows. ◀

In Theorem 5, we can set $i$ to be a constant and set $k = O(\log\log n)^{1/i}$ to obtain another tradeoff, which is summarized in the following corollary.

▶ **Corollary 6.** *Given a weighted undirected graph $G = (V,E)$, there is a fully dynamic distance oracle with stretch $O(\log\log n)$ that w.h.p. achieves $n^{o(1)}$ query time and $\tilde{O}(n^\rho)$ amortized update time, for an arbitrarily small constant $\rho$.*

Finally note that we can also obtain similar tradeoffs as [25] where all three of stretch, amortized update time and query time are $n^{o(1)}$, by setting $k = O(\log\log n)^2$ and $i = O(\log\log n)$ in Theorem 5.

# A Sweep-Plane Algorithm for Calculating the Isolation of Mountains

**Daniel Funke**
Karlsruhe Institute of Technology, Germany

**Peter Sanders**
Karlsruhe Institute of Technology, Germany

## Abstract

One established metric to classify the significance of a mountain peak is its isolation. It specifies the distance between a peak and the closest point of higher elevation. Peaks with high isolation dominate their surroundings and provide a nice view from the top. With the availability of worldwide Digital Elevation Models (DEMs), the isolation of all mountain peaks can be computed automatically. Previous algorithms run in worst case time that is quadratic in the input size. We present a novel sweep-plane algorithm that runs in time $\mathcal{O}(n \log n + pT_{\text{NN}})$ where $n$ is the input size, $p$ the number of considered peaks and $T_{\text{NN}}$ the time for a 2D nearest-neighbor query in an appropriate geometric search tree. We refine this to a two-level approach that has high locality and good parallel scalability. Our implementation reduces the time for calculating the isolation of every peak on Earth from hours to minutes while improving precision.

## 1 Introduction

High-resolution digital elevation models (DEMs) are an interesting example of large datasets with a big potential for applications but equally big challenges due to their enormous size. For example, WorldDEM provided by the TanDEM-X mission covers the entire globe with a resolution of 0.4 arcsecond and is currently the highest-resolution worldwide DEM available [39]. It consists of $6 \cdot 10^{12}$ individual sample points and amounts to approximately 25 TB of data. Modern LIDAR technology allows $< 1\,\text{m}^2$ samples, resulting in more than 300 TB of data for the land surface of the Earth. The algorithm engineering community has greatly contributed to unlocking the potential of DEMs by developing scalable algorithms for features such as contour lines, watersheds, and flooding risks [1, 11, 31]. This paper continues this line of research by studying the isolation of mountain peaks which is a highly nonlocal feature and requires us to deal with the Earth's complicated (not-quite spherical) shape.

A mountain's significance is typically characterized using three properties – elevation, isolation, and prominence [23]. Whereas elevation is a fundamental property, isolation and prominence are derived measures. Isolation – also referred to as dominance – measures the

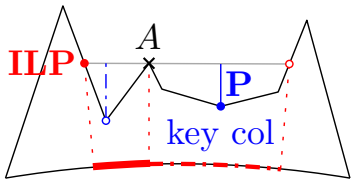

**Figure 1** Illustration of a mountain $A$'s isolation (red) and prominence (blue). The isolation is measured along the sea-level surface of the Earth.

distance along the sea-level surface of the Earth between the peak and the closest point of higher elevation, known as the *isolation limit point* (ILP). Prominence measures the minimum difference in elevation from a peak and the lowest point on a path to reach higher ground – called the *key col*. Refer to Figure 1 for an illustration.

Whereas previously both measures had to be determined manually by laboriously studying topographic maps, they can now be computed algorithmically using DEMs. Kirmse and de Ferranti [28] present the current state-of-the-art to compute both measures. They use an algorithm to determine a peak's isolation by searching in concentric rectangles of increasing size around the peak for higher ground. To determine the isolation of every peak on Earth, their algorithm has a worst case running time of $\mathcal{O}(n^2)$, with $n$ being the number of sample points in the DEM. For high-resolution DEMs of the Earth and other celestial bodies, e. g. the Moon [6] or Mars [24], algorithms with better scalability are needed. Also, Continuously Updated Digital Elevation Models (CUDEMs), such as NOAA's DEM of North America's coastal regions [2], require efficient algorithms for frequent reprocessing. In particular, parallel and external algorithms are required.

**Contribution and Outline.** After presenting basic concepts in Section 2 and related work in Section 3 we describe the main algorithmic result in Section 4. We begin with a sequential algorithm that sweeps the surface of the Earth top-down with a sweep-plane storing the points having surfaces at that elevation. Processing a peak then amounts to a nearest neighbor query in the sweep-plane data structure. This results in an algorithm with running time $\mathcal{O}(n \log n + pT_{\text{NN}})$ where $n$ is the input size, $p$ the number of considered peaks and $T_{\text{NN}}$ the time for a 2D nearest-neighbor query in an appropriate geometric search tree. To make this more scalable, we then develop an algorithm working on the natural hierarchy of the data which is specified in *tiles*. This algorithm performs most of its work in two scans of the data which can work independently and in parallel tile-by-tile. Only the highest points in each tile need to be processed in an intermediate global phase. Each of these three phases has a structure similar to the simple sequential algorithm.

In Section 5 we then explain how 2D-geometric search trees can be adapted to work on the surface of the Earth by deriving the required geometric predicates. After outlining implementation details in Section 6, in Section 7 we evaluate our approach using the largest publicly available DEM data.

## 2 Preliminaries

**Spherical Geometry.** Planets can generally be approximated by spheres. In the geographic coordinate system, a point $p = (\phi, \lambda)$ on the surface of a sphere is identified by its latitude $\phi$ and longitude $\lambda$. Latitude describes $p$'s north-south location, measured from the equator, $\phi \in [-90°, 90°]$ with negative values south of the equator. Longitude describes $p$'s east-west location, measured from the prime meridian through Greenwich, $\lambda \in (-180°, 180°]$ with negative values west of the prime meridian.

For close distances, Earth's surface is sufficiently flat to use planar Euclidean distances between points. For longer distances, spherical distance calculations are necessary, which are computationally more expensive. On the surface of the sphere, two points are always connected by at least two great circle segments. The shortest such segment, the *geodesic*, can be computed for points $p_1 = (\lambda_1, \phi_1)$ and $p_2 = (\lambda_2, \phi_2)$ with sphere radius $R$ according to

$$\begin{aligned} \alpha &= \sin^2\left(\frac{\phi_2 - \phi_1}{2}\right) + \sin^2\left(\frac{\lambda_1 - \lambda_2}{2}\right)\cos(\lambda_1)\cos(\lambda_2) \\ d(p_1, p_2) &= R\tan^{-1}\left(\frac{\sqrt{\alpha}}{\sqrt{(1-\alpha)}}\right) \end{aligned} \tag{1}$$

As the Earth and most other planets are not perfect spheres, ellipsoids are a more accurate approximation of their shape. The World Geodetic System (WGS) [29] defines such an ellipsoidal approximation of the Earth, requiring the following – even more computationally expensive – distance formula:

$$\begin{aligned} \Delta\lambda &= (\lambda_2 - \lambda_1)/2 \qquad \Delta\phi = (\phi_2 - \phi_1)/2 \qquad \Lambda = (\lambda_2 + \lambda_1)/2 \\ s &= \sin^2\Delta\phi \cdot \cos^2\Delta\lambda + \cos^2\Lambda \cdot \sin^2\Delta\lambda \\ c &= \cos^2\Delta\phi \cdot \cos^2\Delta\lambda + \sin^2\Lambda \cdot \sin^2\Delta\lambda \\ w &= \tan^{-1}(\sqrt{s}/\sqrt{c}) \qquad r = \frac{\sqrt{sc}}{w} \\ d(p_1, p_2) &= 2aw\left(1 + f\frac{3r-1}{2c}\sin^2\Lambda \cdot \cos^2\Delta\phi - f\frac{3r+1}{2s} \cdot \sin^2\Delta\phi \cdot \cos^2\Lambda\right) \end{aligned} \tag{2}$$

with $a$ and $f$ denoting the equatorial radius and flattening of the WGS84 ellipsoid [29].

**Digital Elevation Models.** Digital Elevation Models (DEMs) have become one of the most important tools to analyze the Earth's surface in geographic information systems. They represent the surface of the Earth by providing elevation measurements on a grid of sample points. The data is mostly stored in files of 1 square degree of coverage each, called tiles. A tile is addressed by its smallest latitude and longitude. In order to enable seamless processing of several tiles, each tile stores one sample row/column overlap with its neighbors. The resolution of DEMs is given by the length of one sample at the equator in arcseconds ($''$).

State-of-the-art worldwide DEMs, such as WorldDEM, provide a resolution of $0.4''$ spacing between sample points – about 12 m at the equator [39]. Local DEMs, such as the swissALTI$^{3D}$, even have a resolution of only 0.5 m sample point spacing [21]. Freely available DEMs, such as The Shuttle Radar Topography Mission (SRTM) [25], provide a resolution of $3''$ – about 90 m at the equator – and an absolute vertical height error of no more than 16 m for 90 % of the data [32]. Unfortunately, it does not provide global coverage[1] and contains large void areas, especially in mountainous regions, which are of particular interest for us. In a laborious process, de Ferranti [12] fused raw SRTM data with other publicly available datasets [14, 36] and digitized topographic maps to create a worldwide, void-free DEM available at `www.viewfinderpanoramas.org`.

[1] Only areas between 60° North and 56° South are covered.

## 3 Related work

Graff et al. [22] are the first to use DEM data to classify terrain into mounts, plains, basins or flats. As there is no definitive definition of these terrain features, several methods for terrain classification are studied in the literature [38], including fuzzy logic [16, 17] or, more recently, deep learning [37].

Prominence has received most of the attention when it comes to algorithmic computation of mountain metrics [26, 28]. Kirmse and de Ferranti [28] present the current state-of-the-art regarding isolation and prominence computation. As their main focus lies on the prominence calculation, they present a rather simple $\mathcal{O}(n^2)$ time isolation calculation algorithm.

In their algorithm they first calculate potential peaks which are samples that are at least as high as their eight neighboring samples. Afterwards, a search for the closest higher ground (ILP) is conducted, where, centered on each peak, concentric rectangles of increasing size are checked to find a sample with higher elevation. Since the closest higher ground of a peak could also be on a neighboring tile, these might be checked as well. If a higher ground was found, the distance to this sample is used to constrain the search in neighboring tiles. If not, tiles in increasing rectangles around the peak-tile are checked until an ILP is found or the complete world has been checked. Before searching a neighboring tile, the maximum elevation of the tile is checked. When it is smaller than the peak elevation, the tile can be ignored. Tiles and their maximum elevation are cached, because they need to be loaded rather frequently. Inside the tile that contains the peak, planar Euclidean distance approximations are used to find an ILP, for neighboring tiles, distances are computed according to the spherical distance function. Because a majority of peaks have a small isolation, the ILP is often within the same tile as the peak, so mostly planar Euclidean distance approximations are used to determine a peak's ILP. This reduces computational costs but also the accuracy for peaks with small isolation. Only in a final step before output is the distance between a peak and its determined ILP calculated using the precise, but expensive, ellipsoid distance function. Kirmse and de Ferranti's algorithm is unnamed, we refer to it as ConcIso for brevity.

Sweepline algorithms are introduced by Bentley and Ottmann [7] to compute line segment intersections. The technique is generalized by Anagnostou et al. to three-dimensional space [3]. Sweepline algorithms have been applied to various geometric problems in two- and three-dimensional space, such as computing Voronoi diagrams [18] or route mining [40]. R-Trees are often used in spatial databases and have been adapted to geodetic distance computations by Schubert et al. [33].

## 4 Algorithm

In this section we present our novel sweep-plane algorithm to calculate the isolation of mountain peaks. The algorithm takes as input the search area – a quadrilateral $A$ defined by its north-west and south-east corners – as well as the DEM data. We will first present a single-sweep algorithm that processes the entire search area in one sweep-plane pass. Subsequently, we present a scalable three-pass algorithm that reads the DEM-tiles of $A$ twice and can process tiles in parallel.

### 4.1 Single-Sweep Algorithm

To determine the isolation of a peak, its closest point with higher elevation – the Isolation Limit Point (ILP) – needs to be found. Given the search area $A$, each sample point $p$ of the DEM within $A$ has two associated events: an *insert* event at $p$'s elevation and a *remove* event at the elevation of its lowest immediate (NESW) neighbor. Additionally, if a point is

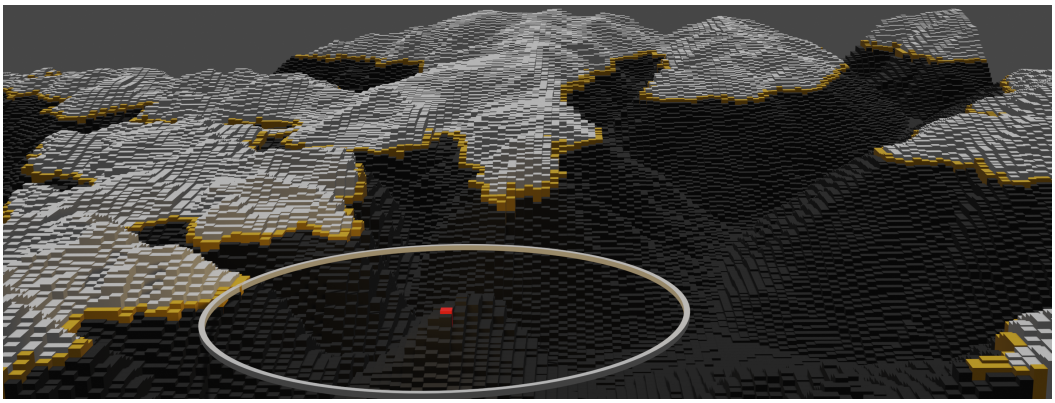

**Figure 2** Illustration of DEM grid and sweep-plane algorithm by using a voxel representation. Red represents the current peak. Orange DEM points are active and contained in the sweep-plane data structure. White points are inactive and already removed from the data structure. Black points have not yet been processed.

the high-point of its 3x3 neighborhood it is associated with a *peak* event at its elevation. We describe the peak detection routine in more detail in Section 6. All events are created at the beginning of the algorithm and can therefore be added to a static sequence sorted by descending elevation. Peak events are processed before other events at the same elevation.

The sweep-plane then moves downward from the highest sample point to the lowest and traces the contour lines of the terrain, refer to Figure 2. The sweep-plane data structure $SL$ is a two-dimensional geometric search tree that maintains a set of currently *active* points. A sample point $p$ becomes active at its insert event, when it is swept by the sweep-plane and inserted into $SL$. Point $p$ becomes *inactive* and is removed from $SL$ at its remove event, at which point its lowest neighboring point is activated and thus all of $p$'s neighboring points are either active or have already been deactivated. When a peak event for sample point $p$ is processed, a nearest neighbor query for the closest active sample point to $p$ in $SL$ is performed. The returned point $w$ is the ILP for the peak: Since $w$ is active and peaks are processed before other events, $w$ must be higher than $p$. There cannot be any closer ILP as points activated later are not higher than $p$ and since higher points $v$ that are already deactivated are surrounded by points that are all higher than $p$. At least one of them must be closer to $p$ than $v$.

**Analysis.** Given a DEM with $n$ points, we can detect its $p$ peaks in time $\mathcal{O}(n)$. The resulting $2n + p$ events can be sorted in $\mathcal{O}(n \log n)$ time by elevation. Insertion and removal operations take $\mathcal{O}(\log n)$ worst case time in several geometric search trees [8, 15, 35]. Nearest neighbor search complexity is more complicated and still an open problem in many respects. Therefore, we describe it abstractly as $T_{\text{NN}}$. Simple trees used in practice such as $k$-D-Trees [8] or Quadtrees [15] achieve logarithmic time "on average". Cover trees [9] achieve logarithmic time when an *expansion parameter* of the input set is bounded by a constant. Approximate queries within a factor of $1 + \epsilon$ are possible in time $\mathcal{O}\big(\log(n)/\epsilon^2\big)$ [4]. Overall, we get the claimed time $\mathcal{O}(n \log n + pT_{\text{NN}})$.

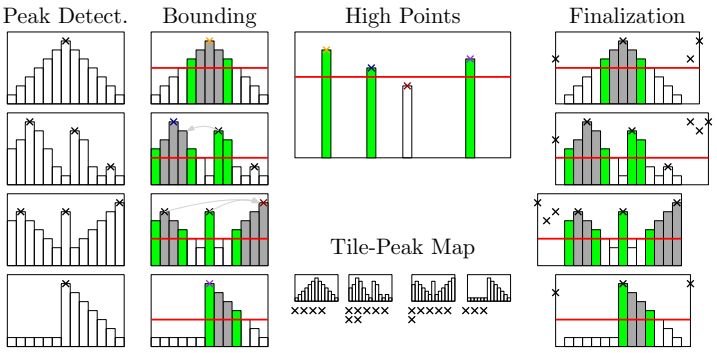

**Figure 3** Overview of our scalable multi-pass algorithm for four tiles in two dimensions. Peaks are detected for each tile with the peak finding algorithm of ConcIso. The bounding pass determines an upper bound on the isolation for each peak and assigns it to tiles that could contain closer ILPs in the Tile-Peak map. The high-points of each tile without a local upper bound are processed by a separate pass considering only the high-points. In the finalization pass, all peaks assigned to a tile are checked for an ILP within the tile. The final determination of the closest ILP out of the found candidates for each peak is not depicted. For the sweep-plane passes, green points are active in the sweep-plane data structure, gray points are inactive and hollow points are not yet processed. Peaks are marked by crosses. The high-point of each tile is marked by a different color cross for each tile.

## 4.2 Scalable Multi-Pass Algorithm

High-resolution DEMs are massive data sets of currently up to 25 TB that require scalable algorithms. The algorithm described in the previous section can be parallelized to some extent but its sweeping character limits parallelism. Moreover, a geometric search tree covering the entire Earth could get quite large. We therefore develop a two-level algorithm that allows for more coarse-grained parallelism and better locality. We adopt the natural hierarchy of the input data using tiles of a fixed area but note that reformatting into smaller or finer tiles would be possible in principle. Furthermore, a more general multi-level algorithm could be developed using a similar approach.

Multi-level algorithms start at the finest level to extract information for global[2] processing at coarser level. The global results are then passed down to compute the final solution. In our two-level algorithm this implies that we have two passes reading the DEM tiles from external memory while a single global pass works with simple per-tile information. The first (*bounding*) and last (*finalization*) pass can work in parallel on each tile. The global (*high-point*) pass works in internal memory and is also parallelized. The first two passes establish a global Tile-Peak map that stores for each tile which peaks *can* have an ILP in it. The third pass processes these assigned peaks for a tile and determines their ILPs. All passes follow a very similar structure to our single-sweep algorithm from Section 4.1. They are described in detail in the following. Additionally, Figure 3 provides an overview of our algorithm.

**Bounding Pass.** The purpose of the first pass is to establish an upper bound on the isolation of a peak and therefore limit the the number of tiles that need to be searched for its ILP in the finalization pass. To establish this upper bound, we find a tile-local ILP for each peak using our single-sweep algorithm. Only the highest point in each tile will not have a tile-local ILP and is treated separately in the high-point pass. Given the upper bound on the isolation

[2] Pun intended.

of a peak $p$, we can assign $p$ to all tiles within radius of the upper bound that could contain a closer ILP for $p$. In the third pass, these neighboring tiles then need to process $p$ in order to find ILP candidates within them. To link peaks to tiles for processing in the third pass, we build a Tile-Peak map that stores for each tile a list of peaks that could have an ILP within it.

**High-Point Pass.** As there is no local ILP for the high-point $h$ of each tile, we address high-points separately in the second pass. This pass uses only one type of event – a combination of insert and peak event from the other passes – and processes only one point per tile, namely their high-points. For each high-point $h$, we perform a nearest neighbor query in the sweep-plane data structure for $h$'s closest higher point $p$. The distance between $h$ and $p$ is an upper bound on $h$'s isolation. The sweep-plane data structure is then traversed again to find all tiles whose closest point to $h$ is at least as close to $h$ as $p$ and $h$ is linked to these tiles in the Tile-Peak map. Finally, $h$ is inserted into the sweep-plane data structure and the next lower high-point is processed.

**Finalization Pass.** In the third pass, each tile is processed again by a sweep-plane algorithm similar to the single-sweep variant. The peak events of this pass are all peaks that have been assigned to the tile in the Tile-Peak map. For each assigned peak, the ILP candidate within the processed tile is determined. After all tiles have been processed by the third pass, each peak has as many ILP candidates as tiles it has been linked to. Thus, in a final step, for each peak the closest found ILP candidate is set as the true ILP of the peak.

**Algorithmic Details and Outline of Analysis.** Let us first look at the total **work** performed to process $A$ tiles containing $n$ sample points overall. The bounding pass performs a similar amount of work as the global algorithm except that it defers nonlocal nearest neighbor searches to the subsequent passes. More precisely, the high-points of each tile are deferred to the high-point pass while other peaks are deferred to neighboring tiles. On average, there is a constant number of such neighbor tiles.[3]

The high-point pass potentially defers nearest-neighbor-search work for the highest point of each tile to a potentially large number of tiles. However, this is not so different from what a search-tree based nearest neighbor search in a global tree data structure would do. Our two-level algorithm can be viewed as a vertically split (quad-)tree algorithm where updates and nearest neighbor searches are reordered to improve locality. The overall amount of work done is quite similar though.

The finalization pass can be viewed as completing the deferred nearest neighbor searches. Thus, the main overhead of the two-pass algorithm compared to the global algorithm is that the data is swept through search trees twice. We mitigate this effect by building only a coarse search tree in the bounding pass. This has no negative effect on precision as the bounding pass is only needed to identify the tiles where an ILP can be. Only the finalization pass computes the actual ILPs.

Let us now look at **I/O-costs**. Assume one tile and the high-points fit in internal memory. This is similar to a "semi-external"-assumption used in previous algorithm engineering papers on DEM processing, e. g. [1]. The I/O volume of our two pass algorithm is dominated by

[3] Near the poles, there are many candidate tiles that may be closer than a local ILP. However, averaged over all tiles, this effect is not large. It is interesting to note though that this is an artifact of a pseudo-high longitudinal resolution that is not reflected in the actual precision of the sensors but stems from artificially mapping the data using a Mercator projection. Meshes with more uniform cells are possible, for example the icosahedral grid used in some modern climate/weather models [27].

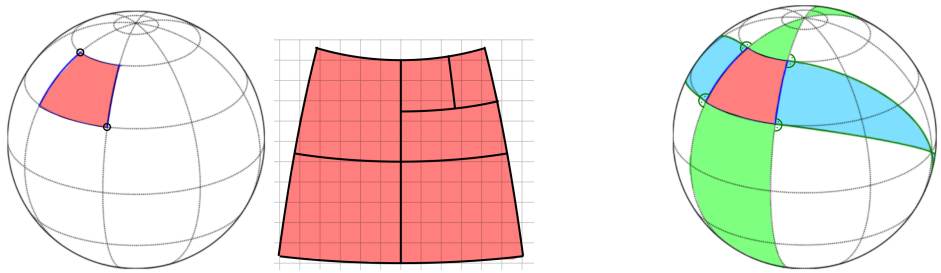

**Figure 4** Representation of a latitude-longitude aligned quadrilateral and areas for the different min-distance cases between a quadrilateral and a point.

reading all tiles twice.[4] This is actually better than an external-memory implementation of the global algorithm as that algorithm would have to sort the data by altitude before being able to scan the input in the right order for the sweep. Even using pipelining [13], sorting would require at least two reading and one writing pass over the DEM data.

Finally let us consider **parallelization**. Bounding and finalization passes can work on $A$ tiles in parallel. In order to also parallelize the high-point pass, we implement a variant that uses a static search tree with subtrees augmented by the maximum elevation occuring in a subtree. Then the $A$ nearest-dominating-point searches can be done in parallel. See Section 6 for details.

## 5 Predicates for Search Trees on Spherical Surfaces

The sweep-plane data structure needs to be a dynamic data structures that supports efficient nearest neighbor queries. Space-partitioning trees such as $k$-D trees or Quadtrees are well-suited data structures for this application [8, 15]. These trees recursively divide the input space into smaller and smaller blocks. For a spherical surface, the space is divided into quadrilaterals which are aligned with latitude and longitude, refer to Figure 4a. A quadrilateral is defined by its north-west and south-east corners. Each quadrilateral can then be further subdivided into smaller quadrilaterals. The root of a space-partitioning tree covers the entire input area.

Our sweep-plane algorithm requires two geometric primitives for these trees: a) whether a given point $p$ lies inside a quadrilateral $Q$ and b) the shortest distance between $p$ and $Q$. The former can be easily answered by comparing $p$'s latitude and longitude with $Q$'s north-east and south-west corner. For the latter, there are four configurations of $p$ and $Q$ that need to be considered, refer to Figure 4b:

1. $p \in Q$ (red area),
2. $p$ is between the longitude lines of $Q$ (green area),
3. $p$ is between the four great circles through the corners of $Q$, which are perpendicular to the longitude edges of $Q$ (blue area),
4. all other positions (white area).

[4] In comparison, the Tile-Peak map has negiligible data volume and can be handled in an I/O-efficient way by observing that the first two passes only insert to it and the third pass only reads it tile by tile. Thus, we can first buffer its data in an external log which is sorted by tile before the finalization pass.

For case 1 the distance is zero. In case 2, the closest point $s \in Q$ to $p$ is on the intersection between the longitude line of $p$ and one of the latitude-edges of the quadrilateral, as the shortest distance between two latitudes is along the longitude lines. The shortest distance of $p$ to $Q$ is thus the shorter distance between $p$ and the north and south latitude of $Q$.

In the remaining cases, $s$ must lie on one of the longitude lines of the quadrilateral. To determine the longitude edge closest to $p$, we calculate the center longitude of $Q$ and rotate it to align with the meridian. We rotate $p$ by the same amount. If the longitude of $p$ is now positive, the west longitude-edge of $Q$ is closer to $p$, otherwise the east one.[5] Having determined the closest longitude edge, we can now calculate point $s$ using linear algebra in Euclidean space as described in the accompanying technical report [20, Appendix A.2]. If the latitude of $s$ is between the top and bottom latitude of $Q$, $s$ is the point with the shortest distance to $p$ in $Q$ (case 3). Otherwise one of the corners is the point with the shortest distance to $p$ (case 4).

Given these primitives, insert and query operations on space-partitioning trees for spherical surfaces are identical to the ones for Euclidean space.

## 6 Implementation

We implement our new sweep-plane algorithm in the MOUNTAINS C++ framework by Kirmse and de Ferranti [28].[6] The framework provides essential functionalities for the work with tiled DEM data, such as data loading and conversion, peak discovery and distance computations. Our code is available on Github.[7] In the following we provide details our implementation.

**Data Structure.** We implement a fully dynamic $k$-D-Tree, that supports insert and remove operations in $\mathcal{O}(\log n)$ worst case time and nearest neighbor searches in $\mathcal{O}(\log n)$ expected time [19] using the predicates described in the previous section.[8] Points are stored in the leaves of the tree, which have a fixed capacity of $C$ points. On exceeding capacity $C$, a leaf is split according to a center-split policy along the longer side of the quadrilateral. The first points inserted into the tree often belong to the highest peak in a tile and are thus close to each other. In order to prevent the tree from degenerating, we pre-build the first $k$ levels in a Quadtree-like manner.[9] To improve cache-efficiency, tree nodes are allocated in blocks and are re-used after deletion.

Another data structure used is the Tile-Peak map, which we implement as an internal memory hash map with the latitude and longitude of a tile as key and a list of peaks as value.

**Algorithm.** Given the search area $A$, all contained DEM tiles can be processed in parallel. We use a work queue and thread pool to distribute the computations among the available processing elements. The Tile-Peak map is initialized in advance with all tiles. To sort the events of a pass, we use the efficient sorting algorithm ips4o of Axtmann et al. [5].

[5] This is possible because we split the Earth at the antimeridian. Therefore, the western longitude of $Q$ is always smaller than the eastern one.
[6] `https://github.com/akirmse/mountains`
[7] `https://github.com/dfunke/mountains`
[8] We also adapted a Quadtree using our predicates, which was however outperformed by the $k$-D-Tree in our experiments.
[9] Our experiments show $k = 4$ to be a good choice.

**Bounding Pass.** We use the peak detection algorithm of Kirmse and de Ferranti [28, Sec. 2.2] to find all peaks within a tile. It considers all points to be peaks that have eight neighboring points of lower or equal elevation. If a peak consists of several equally high sample points, only a single one is added to the set of peaks.[10] Since only an upper bound is calculated during the bounding pass, we down-sample the resolution of the DEM after peak detection. Since all peaks are within the tile which is processed, distances are rather small and can be approximated using planar Euclidean geometry during the nearest-neighbor search. The upper bound is computed using the spherical distance function according to Equation (1). If the determined upper bound on the isolation of a peak is below a threshold $I_{\min}$ we discard the peak as insignificant. Peaks with an upper bound above $I_{\min}$ are added to the Tile-Peak map for processing in the finalization pass as described in Section 4.2.

**High-Point Pass.** While processing the tiles in the bounding pass, we build a geometric search tree $T$ that partitions the entire search area down to the tile level. Internal nodes of $T$ save the highest elevation in its sub-tree. After all tiles have been processed, we can use this information to efficiently determine upper bounds on the isolation of the high-points of each tile. For each high-point $h$, we find the closest tile containing a point of higher elevation than $h$ in search tree $T$. The maximum distance between $h$ and any point within the found tile serves as an upper bound on $h$'s isolation. Given this upper bound we can add $h$ to all tiles containing potential ILPs in the Tile-Peak map. This approach is trivially parallelizable over the number of high-points in the search area.

**Finalization Pass.** In this pass we use the full resolution of the input DEM. For each tile, the peaks processed in this pass are the ones that are assigned to it in the Tile-Peak map. We use ellipsoid distance computations according to Equation (2).

## 7 Evaluation

In this section we evaluate our novel sweep-plane algorithm to calculate the isolation of mountain peaks, which we named SweepIso. We evaluate it with regard to runtime behavior and solution quality and compare it against ConcIso from Kirmse and de Ferranti [28].

[10] The algorithm by Kirmse and de Ferranti always chooses the north-west corner of a peak.

**Table 1** DEM models of the Earth, Mars and the Moon used in our experiments. The reported runtime is the single-threaded runtime for the entire data set.

| Name | Resolution | Pixels | Size | Coverage | Runtime |
|---|---|---|---|---|---|
| Earth SRTM | $3''$ (90 m) | $20 \times 10^9$ | 71 GB | Global | 2.07 h |
| Earth SRTM NA-EU | $1''$ (30 m) | $49 \times 10^9$ | 105 GB | Cont. US+CAN+EU | 3.8 h |
| Moon SLDEM2015 | $7''$ (59 m) | $11 \times 10^9$ | 22 GB | $[60°N, 60°S]$ | 2.5 h |
| Mars MGS MOLA - MEX HRSC Blended | $12''$ (197.6 m) | $5.7 \times 10^9$ | 11 GB | Global | 1.3 h |

**Experimental Setup.** All benchmarks are conducted on a machine with an AMD EPYC Rome 7702P with 64 cores and 1024 GB of main memory. The DEM data is stored on a Intel P4510 2 TB NVMe SSD. We use the 3″ data set from viewfinderpanoramas [12] with worldwide coverage. To build smaller test instances from the worldwide data set, we choose a random starting tile and add neighboring tiles in a spiraling manner around it until the desired number of tiles is reached. For each instance size, we generate several instances to cover a wide range of terrain. Additionally, we use the 3″ and 1″ DEM for the USA, Canada and most of Europe from viewfinderpanoramas [12] to study the scaling behavior for higher-resolution DEMs. This data set corresponds to 4294 tiles or roughly 16 % of the total test data set. We will call this data set NA-EU. We also use data sets from other celestial bodies: Mars [24] and the Moon [6]. Table 1 lists some properties of the studied data sets along with the runtime of our algorithm to determine the isolation of every peak contained in them.

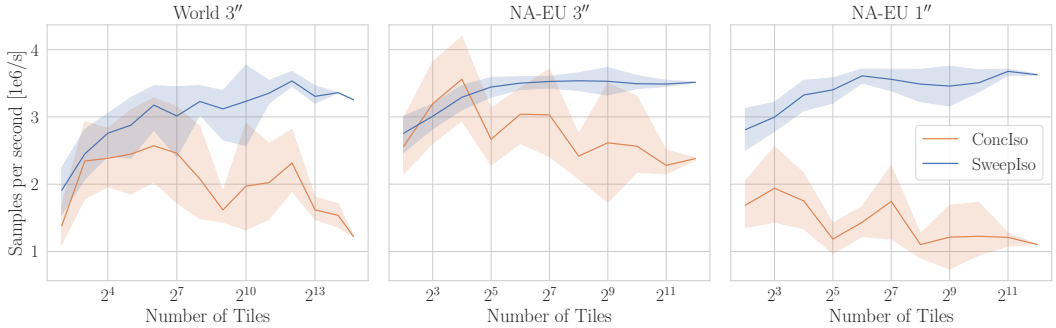
For all benchmarks we use an isolation threshold $I_{\min}$ of 1 km and report the mean runtime of 5 runs. I/O costs are not part of the reported figures as we use the MOUNTAINS framework [28] for them without an attempt at optimization. They are about the same time as computation for 3″ DEMs and about 10 % of computation time for 1″ ones and thus could be overlapped with the computation in an optimized framework.

## 7.1 Runtime and Scaling Behavior

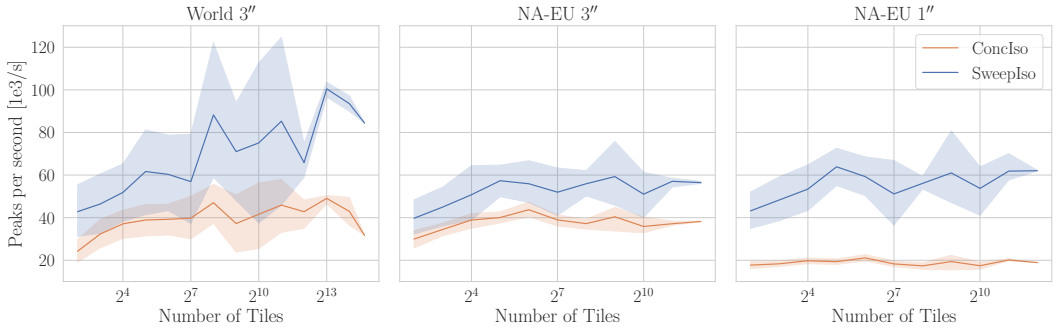
The runtime of the algorithms depends on the number of sample points in the DEM. These can either increase due to a larger search area or a higher-resolution DEM. Another factor is the number of processed peaks, since every peak starts a local search in ConcIso and a nearest neighbor query in SweepIso. A larger search area increases the number of tiles and the number of peaks, whereas higher-resolution data mostly increases the number of points per tile. High-resolution DEMs can contain more peaks than lower-resolution ones due to the more truthful representation of the terrain, however these are predominantly low-isolation peaks and are filtered out in the first pass. We study both effects in our experiments by using different resolution DEMs as well as increasing search areas.

SweepIso exhibits a nearly constant throughput of sample points per second with increasing search area, while ConcIso's throughput degrades – refer to Figure 5a. Figure 8a shows that SweepIso outperforms ConcIso by a factor of 2 to 3 in terms of sample point throughput. For instance, we reduce the time required to compute the isolation of every peak on Earth from 9 h down to 3.5 h. However, ConcIso's runtime scales significantly better than its $\mathcal{O}(n^2)$ worst case runtime bound would suggest. This is because most peaks have a relatively low isolation. In fact 99.996 % of discovered peaks on the world data set have an isolation below 50 km and more than 99 % below 10 km. Since one tile covers on average an area of 70 km × 111 km, the nearest higher point is most of the time within the same tile as the peak, where fast approximations for the distance calculation are used. Nevertheless, for high-resolution DEMs the computation cost per peak is significantly higher for ConcIso than for SweepIso, refer to Figure 5b. A more in-depth analysis of the runtime behavior of both algorithms can be found in the accompanying technical report [20, Appendix B].

Figure 6 shows the runtime composition of the bounding and the finalization pass. As the DEM resolution is reduced in the bounding pass, the finalization pass requires the majority of the runtime, especially for higher-resolution inputs. Geometric computations only make a small fraction of the runtime. The high-point pass requires just 0.001 % of the total execution time and is therefore omitted in the figure.



**(a)** Throughput in sample points per second over number of tiles.



**(b)** Throughput in processed peaks per second over number of tiles.

**Figure 5** Single-threaded runtime comparison of SweepIso and ConcIso.

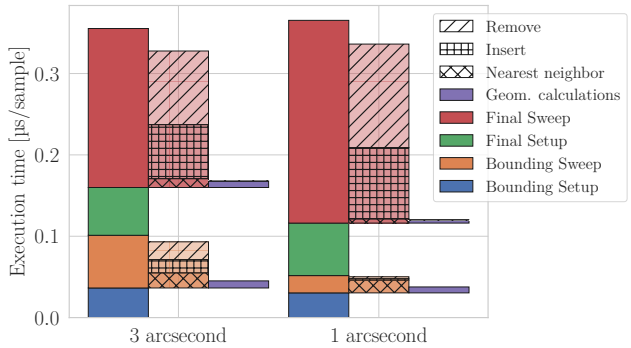


**Figure 6** Runtime composition of the bounding and finalization pass for 3″ and 1″ data. The sweep-plane operations of these passes are further subdivided into remove, insert, nearest neighbor search operations as well as the time for distance calculations.

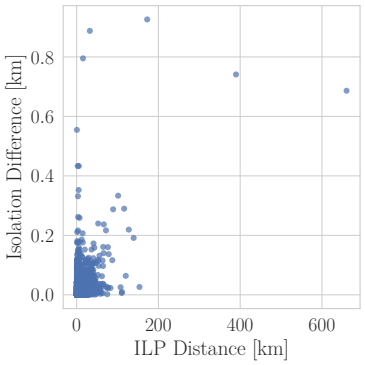

**Figure 7** Comparison of difference in isolation between SweepIso and ConcIso and distance between found ILPs.

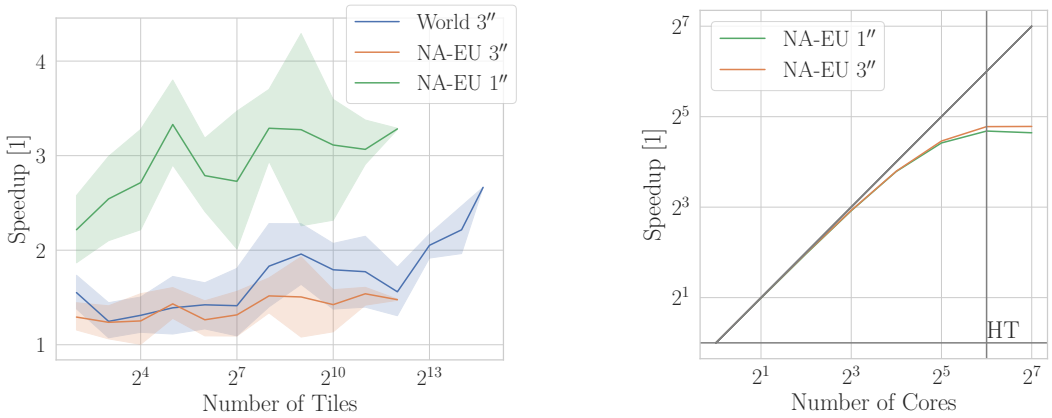

**(a)** Single-threaded speedup.

**(b)** Multi-threaded relative speedup.

**Figure 8** Single-threaded speedup of SweepIso over ConcIso and relative speedup of SweepIso for multi-threaded execution.

Figure 8b shows the results of our multi-threaded runtime experiments with the NA-EU data set. SweepIso scales well with physical cores, but does not benefit from hyper-threading (HT). For 64 cores it reaches a speedup of 25. We verified the scaling behavior of the algorithm for the entire Earth and were able to confirm a speedup of 25 on 64 cores. This corresponds to a runtime of 8 min to calculate the isolation of every peak on Earth. We were not able to execute ConcIso with multiple threads due to issues in the implementation.

## 7.2 Solution Quality

In principle, at any particular time, the isolation and witnessing ILP of a peak are a well defined. However, the actually computed values depend on imprecisions in both the data and the used algorithms.

Due to the design of SweepIso, more expensive distance approximations can be used to find the ILP than in ConcIso. This results in closer ILPs being found, as shown in Figure 7, which displays the distribution of the difference in isolation and the distance between the found ILPs between SweepIso and ConcIso, using the same data. Even if the isolation values between the two algorithms do not vary greatly, the distances between the ILPs do. For example for the Cerro Gordo summit in Mexico both algorithms find ILPs that are more than 600 km apart while SweepIso's ILP is merely 0.8 km closer to the peak.

To further evaluate the results, we used the collection of peaks with more than 300 km isolation from the website `peakbagger.com` [34]. The comparison showed that for about 75 % of peaks in this list the isolation deviation is below 2 km. In a DEM, a sample point corresponds to the average elevation of the area it represents. This often leads to an underestimation of a peak's elevation, sometimes significantly [28]. For instance, according to our DEM data, Galdhøpiggen (the highest point of Scandinavia) is 11 m lower than Glittertind. This causes a significant change in isolation of both mountains. Table 2 lists the five summits with the biggest differences in isolation between peakbagger and our calculation. The five most isolated peaks on Mars and the Moon as determined by our algorithm are presented in Table 3. To the best of our knowledge, this is the first such list.

**Table 2** Biggest isolation differences between discovered and peakbagger (PB) data.

| Mountain | PB Rank | PB Isolation | SweepIso Isolation | Notes |
|---|---|---|---|---|
| Galdhøpiggen (Norway) | 47 | 1568.3 | 12.9 | *Galdhøpiggen*<br>DEM elev.: 2455 m – real elev.: 2469 m [30]<br>*Glittertind*<br>DEM elev.: 2466 m – real elev.: 2457 m [30]<br>Isolation 1563.5 km |
| Mt. Kirkpatrick (Antarctica) | 45 | 1585.2 | 53.5 | found ILP at -83.8967;168.3733<br>DEM elev.: 4416 m – real elev.: 4528 m [30]<br>ILP elev.: 4416 m |
| Mt. Hope (Antarctica) | 75 | 1113.5 | 203.4 | No data found in other sources |
| Dome Charlie (Antarctica) | 92 | 971.8 | 248.6 | found ILP at -76.3783;116.3708<br>DEM elev.: 3265 m – real elev.: 3233 m [10]<br>ILP elev. 3266 m |
| Mauga Silisili (Samoa) | 23 | 2245.1 | 2502.8 | DEM elev.: 1854 m – real elev.:1863 m [30]<br>PB ILP elev.: 1879 m<br>found ILP elev.: 1836 m |
| Cocos Islands High Point | 94 | 961.4 | 947.4 | Found ILP at Enggano Island |

**Table 3** Most isolated peaks on Mars and the Moon according to the DEM data listed in Table 1.

| Name | Coordinates | | Elevation | ILP | | Isolation |
|---|---|---|---|---|---|---|
| *Mars* | | | | | | |
| Olympus Mons | 17.33°N | 133.42°W | 21 226 m | | - | $\infty$ |
| Cruls crater wall | 42.27°S | 163.78°E | 4331 m | 46.79°S | 147.63°W | 2037.43 km |
| Near Cyclopia | 6.34°S | 129.19°E | 3806 m | 18.59°N | 149.99°E | 1913.59 km |
| Huygens crater wall | 10.06°S | 54.62°E | 4604 m | 10.50°S | 85.09°E | 1776.76 km |
| Ascraeus Mons | 11.76°N | 104.53°W | 18 321 m | 17.89°N | 131.64°W | 1593.92 km |
| *The Moon* | | | | | | |
| Engel'gardt crater wall | 5.41°N | 158.63°W | 10 783.3 m | | - | $\infty$ |
| Between Tacitus and Fermat craters | 18.93°S | 19.17°E | 4832.33 m | 60.0°S | 72.65°W | 2261.5 km |
| Near Lewis crater | 21.04°S | 112.33°W | 9459.83 m | 5.26°N | 157.98°W | 1574.56 km |
| Near Calippus crater | 39.09°N | 9.46°E | 3625.68 m | 9.63°S | 2.06°E | 1492.13 km |
| Dellinger crater wall | 7.25°S | 142.0°E | 7561.73 m | 12.91°S | 170.22°W | 1434.95 km |

## 8 Conclusion and Future Work

We have presented SweepIso, a scalable and efficient algorithm to compute the isolation of peaks. SweepIso considerably outperforms the previous, more brute-force, state-of-the-art approach. The performance gains also enable more accurate distance calculations at decisive places resulting in higher accuracy. SweepIso is able to process the entire Earth for currently publicly available data within minutes. This is relevant as it indicates that SweepIso can also handle higher-resolution data that is available commercially or that will be available in the future. SweepIso's two-level semi-external sweeping architecture may also be an interesting design pattern for other computations on massive DEM data. Furthermore, SweepIso could serve as a benchmark for dynamic nearest neighbor search data structures.

**Future Work.** From an application perspective, it would be interesting to compute not only isolations for a given, necessarily imprecise data set but to compute confidence bounds that take into account error margins in the input data. This would be possible at a moderate increase in cost. Peaks could be replaced by enclosing boxes/circles while vertical errors could be handled by having "may-be-there" and "must-be-there" insertion events and sweep-plane data structures. Geographically most interesting would be those isolations that change a lot depending on how high exactly particular pairs of peaks are. Those pairs could then be valuable targets for additional data cleaning or new measurements.

For algorithm engineering, it would be interesting to close the gap between theory and practice with respect of nearest-neighbor data structures. We have reasonable empirical performance of simple data structures like $k$-D trees but no well-fitting performance guarantees applicable to SweepIso. For example, one could look for a more general characterization of inputs where cover trees [9] work provably well.

## Abstract

In this paper we consider the online Submodular Welfare (SW) problem. In this problem we are given $n$ bidders each equipped with a general non-negative (not necessarily monotone) submodular utility and $m$ items that arrive online. The goal is to assign each item, once it arrives, to a bidder or discard it, while maximizing the sum of utilities. When an adversary determines the items' arrival order we present a simple randomized algorithm that achieves a tight competitive ratio of $1/4$. The algorithm is a specialization of an algorithm due to [Harshaw-Kazemi-Feldman-Karbasi MOR'22], who presented the previously best known competitive ratio of $3 - 2\sqrt{2} \approx 0.171573$ to the problem. When the items' arrival order is uniformly random, we present a competitive ratio of $\approx 0.27493$, improving the previously known $1/4$ guarantee. Our approach for the latter result is based on a better analysis of the (offline) Residual Random Greedy (RRG) algorithm of [Buchbinder-Feldman-Naor-Schwartz SODA'14], which we believe might be of independent interest.

## 1 Introduction

Submodularity is a mathematical notion that captures the concept of diminishing returns. Formally, a set function $f : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ over a ground set $\mathcal{N}$ is submodular, if for all $A, B \subseteq \mathcal{N}$: $f(A \cup B) + f(A \cap B) \leq f(A) + f(B)$. An equivalent definition, which is called the diminishing returns property, is the following: $f(A \cup \{u\}) - f(A) \geq f(B \cup \{u\}) - f(B)$, for every $A \subseteq B \subseteq \mathcal{N}$ and every $u \in \mathcal{N} \setminus B$. Submodular functions naturally arise in many different settings, e.g., combinatorics, graph theory, information theory and economics.

We consider the Submodular Welfare (SW) problem. In this problem we are given a set $\mathcal{N} = \{1, \ldots, m\}$ of $m$ unsplittable items and a set $B = \{1, \ldots, n\}$ of $n$ bidders. Each bidder $j$ has a non-negative (and not necessarily monotone) submodular utility function $f_j$ and the goal is to assign items to the bidders while maximizing the sum of the utilities: $\sum_{j=1}^{n} f_j(S_j)$. Here $S_j$ is the set of items allocated to bidder $j$, and the requirement is that $S_j \cap S_{j'} = \emptyset$ for every $j \neq j'$ (since the items are unsplittable) and $\cup_{j=1}^{n} S_j \subseteq \mathcal{N}$ (note that not all items must be assigned). SW with monotone utilities has been extensively studied for more than two decades, e.g., [13, 15, 19, 25, 43, 52, 62, 68, 69]. Submodular maximization

with general (not necessarily monotone) objectives is also the focus of extensive theoretical research, e.g., [24, 30, 32, 34, 36, 50, 51, 63, 68, 70]. Moreover, maximization of non-monotone submodular objectives has found numerous practical applications, e.g., network inference [39], mobile crowdsensing [55], summarization of documents and video [53, 54, 59], marketing in social networks [64], and even gang violence reduction [65], to name a few. In particular, non-monotone utilities in the context of SW can model soft budget constraints, where each bidder $j$ needs to pay a price $p_{i,j}$ when item $i$ is allocated to it. Additional related problems were also studied, including: SW with demand queries [26], and other utilities such as XOS and subadditive [18, 23].

When considering the offline version, SW is typically viewed as a special case of maximizing a submodular objective subject to a partition matroid independence constraint: (1) the ground set is $\mathcal{N} \times B$; (2) the partition matroid is defined over $\mathcal{N} \times B$ where each part in the partition corresponds to an item, *i.e.*, the part that corresponds to item $i \in \mathcal{N}$ is $\{(i,j)\}_{j=1}^{n}$; and (3) the objective $f : 2^{\mathcal{N}\times B} \to \mathbb{R}_{\geq 0}$ is defined as: $f(S) \triangleq \sum_{j=1}^{n} f_j(\{i : (i,j) \in S\})$. In case the utilities are monotone a tight (asymptotic) approximation of $(1 - 1/e)$ was given by [14] by introducing the celebrated continuous greedy algorithm, a tight approximation of $(1 - (1 - 1/n)^n)$ for any number $n$ of bidders was given by [31], and the matching hardness result was given by [60]. For a general and not necessarily monotone objective the current best known offline approximation is also based on the continuous approach and achieves an approximation of $(1/e) + 0.0171$ [8], which improved upon the previous works of [21, 31].

In the online version of SW items arrive one by one. Whenever an item arrives, one has to decide immediately and irrevocably whether to assign it to one of the bidders or not assign it at all (the latter decision is relevant only when the utilities are not necessarily monotone). There are two natural settings that differ in the order in which items arrive. First, in the online adversarial setting an adversary can choose the order in which items arrive (the adversary knows the algorithm and how it operates, however if the algorithm is randomized it does not know the outcome of its random choices). Second, in the online random order setting items arrive one by one in a uniform random order.

When considering the online version, as opposed to the offline version, worse results are known. For monotone utilities, in the adversarial setting, a $(1/2)$-competitive greedy algorithm is known and additionally it is the best possible algorithm for this setting [41]. However, if one assumes the online random order setting, it is known that one can achieve a competitive ratio of $(1/2) + 0.0096$ [9], which improved the result of [46] who were the first to break the $1/2$ barrier obtaining a competitive ratio of $(1/2) + 0.005$.

Unfortunately, when considering general submodular (and not necessarily monotone) utilities, worse results are known. In the adversarial setting, the special case of a single bidder is of particular interest since it is equivalent to online Unconstrained Submodular Maximization (USM): given a general submodular objective $f$ items arrive one by one in an online manner and once an item arrives the algorithm needs to decide whether to choose or discard it where the goal is to maximize $f(S)$ ($S$ denotes the chosen elements). An (implicit) competitive ratio of $1/4$ was given by [24] for online USM (the algorithm simply chooses every element independently with a probability of half). This result was proved to be tight [11]. For the general case of multiple bidders an algorithm achieving a competitive ratio of $3 - 2\sqrt{2} \approx 0.171573$ was given by [38] (this algorithm handles a general matroid independence constraint and assumes elements of the ground set arrive in an online manner).

In the random order setting, an (implicit) result follows from analyzing the offline Residual Random Greedy (RRG) algorithm of [10] for maximizing a non-monotone submodular objective subject to a matroid independence constraint. When considering SW, the RRG algorithm

operates as follows: it chooses a uniform random order over the items and goes over the items in this order, and assigns each item to the bidder with the highest marginal value (if this marginal value is negative then the item is discarded). Thus, if the RRG algorithm achieves an approximation of $\alpha$ in the offline setting, then the deterministic greedy achives a competitive ratio of $\alpha$ in the online random order setting. [10] prove that the RRG algorithm achieves an approximation of $1/4$, therefore implying a competitive ratio of $1/4$ for SW in the random order setting. It is worth noting that better algorithms than RRG are known in the offline setting, e.g., [8, 21, 31], however, they do not apply to the online random order setting.

In this work, we assume the standard *value oracle* model: each submodular function $f$ is not given explicitly but rather the algorithm can query for every subset $S$ the value of $f(S)$. The running time of the algorithm is measured not only by the number of arithmetic operations, but also by the number of value queries. In the online version, for both adversarial and random order settings, the algorithm can query subsets $S$ only of items that already arrived. Thus, intuitively, the algorithm has no information regarding future items.

## 1.1 Our Results

Focusing first on the adversarial setting, we present the following positive result.

▶ **Theorem 1.** *There exists a randomized polynomial time algorithm achieving a competitive ratio of $1/4$ for online SW in the adversarial setting with general (not necessarily monotone) utilities.*

There are three things to note regarding Theorem 1. First, the competitive ratio of $1/4$ is tight as even for the special case of a single bidder (which is equivalent to online USM) [11] provide a matching hardness of $1/4$. Second, Theorem 1, to the best of our knowledge, improves the previous best known competitive ratio of $3 - 2\sqrt{2} \approx 0.171573$ [38]. Third, for the special case of a single bidder the competitive ratio of Theorem 1 matches the $1/4$ guarantee of the simple algorithm that just chooses independently for every item to include it in the solution with a probability of half [24]. However, we note that the algorithm we present in order to prove Theorem 1, even in the special case of a single bidder, differs from the algorithm that just chooses a uniform random subset.

We complement the above result by showing that the randomness of the online algorithm in Theorem 1 is needed. This is summarized in the following theorem that gives a hardness result that tends to zero.

▶ **Theorem 2.** *For every $M > 0$, no deterministic algorithm can achieve a competitive ratio better than $1/M$ for online SW in the adversarial setting with general (not necessarily monotone) utilities.*

Focusing on the random order setting, the following theorem proves that one can achieve an improved competitive ratio over the previously (implicit) known $1/4$ [10]. We note that the following theorem separates the random order and adversarial settings, since one should recall there is a hardness of $1/4$ in the adversarial setting even when only a single bidder is present.

▶ **Theorem 3.** *The deterministic greedy algorithm achieves a competitive ratio of $\approx 0.27493$ for online SW in the random order setting with general (not necessarily monotone) utilities.*

The above theorem is achieved by a better analysis of the offline randomized RRG algorithm of [10]. This improved analysis can be easily extended to a general matroid independence constraint, as the following theorem states (its proof is deferred to a full version of the paper).

▶ **Theorem 4.** *The RRG algorithm of [10] achieves an approximation guarantee of* $\approx 0.27493$ *for maximizing a general (not necessarily monotone) submodular function given a matroid independence constraint.*

## 1.2 Our Approach

The online algorithm for the adversarial setting adopts a simple randomized approach: once item $i$ arrives it defines a distribution over the bidders and assigns the item to a random bidder sampled from this distribution. Surprisingly, we prove that a remarkably simple distribution suffices to obtain a tight competitive ratio of $1/4$: item $i$ is assigned to the bidder with the highest marginal value with a probability of $1/2$, to the bidder with the second highest marginal with a probability of $1/4$, and so forth as long as the marginal value is non-negative. With the remainder probability item $i$ is discarded. It is important to note that the *ordering* of the bidders according to their marginal values (as long as the marginal values are non-negative) dictates the distribution. However, as long as the ordering remains the same, the distribution is independent of the actual marginal values themselves. We prove that the above simple approach suffices to obtain a tight competitive ratio of $1/4$ for the adversarial setting.

It should be noted that the above randomized approach is based on the streaming algorithm of [38], which obtains a competitive ratio of $3 - 2\sqrt{2} \approx 0.171573$. Intuitively, we specialize the algorithm of [38] to online SW in the adversarial setting. The reason is that once item $i$ arrives one can perform the following process in order to obtain the distribution over bidders that was defined above: sort the bidders in a non-increasing order of marginal values and assign the item to the first bidder with a probability of half, if the item was not assigned to this bidder then with a probability of half assign the item to the next bidder, and so forth as long as the marginal value is non-negative. This process describes how the algorithm of [38] operates in the special case the online order of elements of the ground set $\mathcal{N} \times B$ satisfies: (1) all elements $\{(i,j)\}_{j=1}^{n}$ are consecutive in the online order; and (2) elements $\{(i,j)\}_{j=1}^{n}$ are sorted in a non-increasing order of marginal values of the bidders.

Focusing on the random order setting, we present an improved analysis of the RRG algorithm for a general matroid independence constraint. As a preliminary step, which is not required but is mathematically convenient, we present a "smooth" version of the RRG algorithm. The difference between the original and smooth versions is that in the smooth version the distribution of the steps the algorithm can perform does not change as the algorithm progresses. However, in the original version this distribution evolves as the algorithm progresses. We note that the analysis of both versions is very similar (assuming the smooth version performs enough steps). Nonetheless, we believe it is easier to analyze the smooth version.[1]

A key insight in analyzing the RRG algorithm (as well as other closely related algorithms, e.g., the Random Greedy algorithm of [10]), is lower bounding the expected value of a fixed optimal solution $OPT$ when a random subset of elements $S$ is added to it. More precisely, if each element $u$ satisfies $\Pr[u \in S] \leq p$ then standard known arguments, e.g., Lemma 2.2 [10] which is based on Lemma 2.2 [24], imply that $\mathbb{E}[f(OPT \cup S)] \geq (1-p)f(OPT)$. It is important to note that this general insight works for *any* distribution of $S$ that satisfies $\Pr[u \in S] \leq p$ for every $u$. This general insight by itself enabled [10] to prove that the RRG algorithm achieves an approximation of $1/4$. We are able to improve upon the above

[1] For a detailed comparison of the two versions we defer to a full version of the paper.

by exploiting the specific probabilistic behavior of the smooth version of the algorithm, as opposed to the general insight which works for any distribution of $S$. This results in an improved analysis of the smooth version of the RRG algorithm via two jointly related recursive relations that together bound the performance of the algorithm.

## 1.3 Additional Related Work

The literature regarding submodular maximization, *i.e.*, problems of the form $\max\{f(S) : S \in \mathcal{F}\}$ ($\mathcal{F}$ is the collection of feasible solutions), is rich, e.g., [4, 7, 8, 10, 14, 21, 22, 24, 44, 47, 48, 60, 61, 66], and dates back to the late 70's. Moreover, the online SW problem naturally generalizes many online problems such as online matching [1, 29, 40, 42, 57], online weighted matching [1, 28], budgeted allocation [12, 16, 35, 58], and more general classes of online allocation problems [2, 17, 27, 67]. Other related problems include the extensively studied class of secretary problems, e.g., [3, 5, 6, 20, 31, 33, 37, 45, 49, 56], where the goal is to solve an optimization problem assuming the arrival order of the input is uniform and random.

## 1.4 Preliminaries

In our analysis we require the following known lemma.

▶ **Lemma 5** (Lemma 2.2 [10] which is based on Lemma 2.2 [24]). *Let $f : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ be submodular. Denote by $A(p)$ a random subset of $A$ where each element appears with probability at most $p$ (not necessarily independently). Then $\mathbb{E}[f(A(p))] \geq (1-p)f(\emptyset)$.*

## 1.5 Paper Organization

Section 2 deals with the adversarial setting, proving Theorems 1 and 2. Section 3 focuses on the random order setting, proving Theorem 3 and 4.

# 2 Adversarial Setting

In this section we consider the adversarial setting, and present both a tight randomized algorithm proving Theorem 1 and hardness for any deterministic algorithm (Theorem 2).

## 2.1 Tight Randomized Algorithm

In this section we consider the adversarial setting, and start by presenting our algorithm which appears in Algorithm 1. For simplicity of presentation, we assume the items are numbered according to the order the adversary chooses, *i.e.*, item 1 is the first to arrive, item 2 is the second to arrive and so forth. Hence, the algorithm performs $m$ iterations where in iteration $i$ the algorithm chooses what to do with item $i$: with a probability of $1/2$ it assigns it to the bidder with highest marginal value, with a probability of $1/4$ is assigns it to the bidder with the second highest marginal value, and so forth as long as the marginal value is non-negative. With the remainder probability item $i$ is discarded and not assigned to any bidder. Therefore, if there are $\ell$ bidders with non-negative marginal with respect to item $i$, item $i$ is discarded with a probability of $2^{-\ell}$. In what follows we use the notation $f_j(i|S)$ to denote the marginal value of item $i$ with respect to bidder $j$ assuming bidder $j$ was already assigned a subset $S \subseteq \mathcal{N}$ of items, *i.e.*, $f_j(i|S) \triangleq f_j(S \cup \{i\}) - f_j(S)$.

**Algorithm 1** Online Adversarial Algorithm.

$\forall j = 1, \ldots, n : S_j^0 \leftarrow \emptyset$.
**for** $i = 1, ..., m$ **do**
  $\forall j = 1, \ldots, n$: $S_j^i \leftarrow S_j^{i-1}$.
  $\forall r = 1, \ldots, n$: let $j_r$ be the bidder with the $r^{\text{th}}$ highest marginal w.r.t item $i$:
    $f_{j_1}(i|S_{j_1}^{i-1}) \geq f_{j_2}(i|S_{j_2}^{i-1}) \geq \ldots \geq f_{j_n}(i|S_{j_n}^{i-1})$.
  let $j^i$ be a random bidder such that $\Pr[j^i = j_r] = 2^{-r}$.
  **if** $f_{j^i}(i|S_{j^i}^{i-1}) \geq 0$ **then**
    $S_{j^i}^i \leftarrow S_{j^i}^i \cup \{i\}$
  **end**
**end**
return $S_1^m, S_2^m, \ldots, S_n^m$.

Let $O$ denote an offline optimal allocation for the problem: $O = (O_1, \ldots, O_n)$, where $O_j$ is the collection of items assigned to bidder $j$ in the optimal solution. Formally, $O$ is defined as follows[2]:

$$\underset{(O_1,\ldots,O_n)}{\arg\max} \left\{ \sum_{j=1}^{n} f_j(O_j) : \forall j \neq r \quad O_j \cap O_r = \emptyset, \quad \forall j = 1, \ldots, n \quad O_j \subseteq \mathcal{N} \right\}.$$

Let $S^i$ be the allocation induced by the algorithm at the end of the $i^{\text{th}}$ iteration, *i.e.*, $S^i = (S_1^i, S_2^i, \ldots, S_n^i)$. For every bidder $j$, define $H_j^i$ as follows:

$$H_j^i \triangleq (O_j \cap \{1, \ldots, i\}) \cup S_j^i,$$

and let $H^i = (H_1^i, \ldots, H_n^i)$. It is important to note that $H^i$ is not necessarily a feasible solution, since an item might be assigned to up to two bidders. For simplicity of presentation we use the notation of $f(S^i)$ to denote the value of the allocation $S^i$, *i.e.*, $f(S^i) \triangleq \sum_{j=1}^n f_j(S_j^i)$. Similarly, we use $f(H^i)$ to denote $\sum_{j=1}^n f_j(H_j^i)$ (though $H^i$ is not an allocation since items might be assigned to more than a single bidder).

In order to analyze the algorithm we denote by $P^i$ the profit gained during the $i^{\text{th}}$ iteration: $P^i \triangleq f(S^i) - f(S^{i-1})$. Note that $P^1 + \ldots + P^m = f(S^m) - f(S^0)$, where $S^m$ is the output of Algorithm 1 and $S^0$ is the empty allocation that does not assign any item to any of the bidders. Finally, we define the sequence: $K^i \triangleq f(H^i) - f(H^{i-1})$. Note that $K^1 + \ldots + K^m = f(H^m) - f(S^0)$ (note that $H^0 = S^0$).

The analysis of the competitive ratio of Algorithm 1 is essentially based on a single observation, which for every iteration upper bounds $K^i$ as a function of the expected gained profit. This is summarized in Lemma 6.

▶ **Lemma 6.** *$\forall i = 1, \ldots, m$ the following holds:* $\mathbb{E}[K^i] \leq 2 \cdot \mathbb{E}[P^i]$.

We use Lemma 6 to prove Theorem 1. The proof is essentially by summation over all iterations of the algorithm.

[2] Note that formally speaking this is actually a set, but for notational convenience, in this paper, when we refer to something as equalling the arg max, we will always mean it equals an element of the arg max set.

**Proof of Theorem 1.** We prove that the competitive ratio of Algorithm 1 is $1/4$. Lemma 6, when applied for every iteration $i$, implies that: $\mathbb{E}\left[\sum_{i=1}^{m} K^i\right] \leq 2 \cdot \mathbb{E}\left[\sum_{i=1}^{m} P^i\right]$. Hence, it follows that: $\mathbb{E}\left[f(H^m) - f(S^0)\right] \leq 2 \cdot \mathbb{E}\left[f(S^m) - f(S^0)\right]$. In fact, since $f(S^0)$ is non-negative, we have that:

$$\mathbb{E}\left[f(H^m)\right] \leq 2 \cdot \mathbb{E}\left[f(S^m)\right].$$

For every bidder $j$ and item $i$ we have that the probability that item $i$ is assigned to bidder $j$ is at most $1/2$, *i.e.*, $\Pr[i \in S_j^m] \leq 1/2$. Therefore, using Lemma 5 applied to the submodular function $h_j$, where $h_j : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ and $h_j(S) \triangleq f_j(S \cup O_j)$ for every $S \subseteq \mathcal{N}$, we can conclude that: $\mathbb{E}[f_j(S_j^m \cup O_j)] = \mathbb{E}[h_j(S_j^m)] \geq (1/2) \cdot h_j(\emptyset) = (1/2) \cdot f_j(O_j)$. Therefore,

$$\mathbb{E}[f(H^m)] = \sum_{j=1}^{n} \mathbb{E}[f_j(H_j^m)] = \sum_{j=1}^{n} \mathbb{E}[f_j(S_j^m \cup O_j)] \geq \frac{1}{2} \sum_{j=1}^{n} f_j(O_j) = \frac{1}{2} \cdot f(O).$$

Combining the above, we conclude that: $(1/4) \cdot f(O) \leq \mathbb{E}[f(S^m)]$. ◀

All that remains is to prove Lemma 6.

**Proof of Lemma 6.** For proof simplicity, let us start by adding a dummy bidder whose utility is the zero function. Clearly, this does not change the algorithm's performance or the value of $f(O)$, but it lets us assume (without loss of generality) that: (1) for every item $i$ the optimal solution $O$ allocates item $i$ to some bidder $k$, *i.e.*, $i \in O_k$; and (2) for every item $i$ at least one bidder has a non-negative marginal value, *i.e.*, $f_j(i|S_j^{i-1}) \geq 0$ for some bidder $j$.

Fix an iteration $i = 1, \ldots, m$ and condition on any possible realization $R_{i-1}$ of the random choices of the algorithm in the first $i-1$ iterations. Thus, $S^{i-1}$, $H^{i-1}$, and $j_1$ up to $j_m$ are deterministic and fixed given this conditioning, whereas $j^i$ is a random variable.

Recall that (without loss of generality) item $i$ is assigned to bidder $k$ by the optimal solution and that $j_r$ denotes the bidder with the $r^{\text{th}}$ highest marginal value with respect to item $i$ given the elements previously assigned to the bidder. Let us assume that the first $\ell \geq 1$ bidders have a non-negative marginal value with respect to item $i$, *i.e.*, $f_{j_1}(i|S_{j_1}^{i-1}) \geq f_{j_2}(i|S_{j_2}^{i-1}) \geq \ldots \geq f_{j_\ell}(i|S_{j_\ell}^{i-1}) \geq 0$ and if $\ell < m$: $f_{j_{\ell+1}}(i|S_{j_{\ell+1}}^{i-1}) < 0$. Moreover, assume that bidder $k$ has the $t^{\text{th}}$ largest marginal, *i.e.*, $k = j_t$. Let us now bound the expected change from $f(H^{i-1})$ to $\mathbb{E}[f(H^i)|R_{i-1}]$, *i.e.*, $\mathbb{E}[K^i|R_{i-1}]$, given the assumption that $t \leq \ell$, *i.e.*, bidder $k$ to which the optimal solution assigned item $i$ is among the $\ell$ bidders who have a non-negative marginal value:

$$\begin{aligned}
&\mathbb{E}[f(H^i)|R_{i-1}] - f(H^{i-1}) \\
=&f_k(S_k^{i-1} \cup (O_k \cap \{1, \ldots, i-1\}) \cup \{i\}) - f_k(S_k^{i-1} \cup (O_k \cap \{1, \ldots, i-1\})) + \qquad (1) \\
&\sum_{r=1}^{\ell} \frac{\mathbf{1}_{\{j_r \neq k\}}}{2^r} \left\{ f_{j_r}((O_{j_r} \cap \{1, \ldots, i-1\}) \cup S_{j_r}^{i-1} \cup \{i\}) - f_{j_r}((O_{j_r} \cap \{1, \ldots, i-1\}) \cup S_{j_r}^{i-1}) \right\}.
\end{aligned}$$

The equality in (1) follows from the definitions of $H^i$ and the algorithm, as well as the fact that $i \in O_k$. We note that that (1) can be upper bounded as follows:

$$\leq f_k(i|S_k^{i-1}) + \sum_{r=1}^{\ell} \frac{\mathbf{1}_{\{j_r \neq k\}} f_{j_r}(i|S_{j_r}^{i-1})}{2^r}. \qquad (2)$$

The inequality in (2) follows from the decreasing marginals property of the submodular utilities. Next, let us rewrite (2):

$$= f_{j_t}(i|S_{j_t}^{i-1}) \cdot \left(1 - \frac{1}{2^t}\right) + \sum_{r=1}^{\ell} \frac{f_{j_r}(i|S_{j_r}^{i-1})}{2^r} \tag{3}$$

$$= f_{j_t}(i|S_{j_t}^{i-1}) \cdot \left(\sum_{r=1}^{t} 2^{-r}\right) + \sum_{r=1}^{\ell} \frac{f_{j_r}(i|S_{j_r}^{i-1})}{2^r}. \tag{4}$$

The equality in (3) holds since bidder $k$ has the $t^{\text{th}}$ largest marginal, *i.e.*, $k = j_t$, and $t \leq \ell$. Also, the equality in (4) follows from the value of a geometric sum. Moreover, we note that (4) can be further upper bounded:

$$\leq \sum_{r=1}^{t} \frac{f_{j_r}(i|S_{j_r}^{i-1})}{2^r} + \sum_{r=1}^{\ell} \frac{f_{j_r}(i|S_{j_r}^{i-1})}{2^r}. \tag{5}$$

In the above, the inequality in (5) is true since bidder $j_r$ has the $r^{\text{th}}$ largest marginal value, *i.e.*, for every $r \leq t$: $f_{j_r}(i|S_{j_r}^{i-1})) \geq f_{j_t}(i|S_{j_t}^{i-1})$. Next, we upper bound (5) as follows:

$$\leq 2 \cdot \sum_{r=1}^{\ell} \frac{f_{j_r}(i|S_{j_r}^{i-1})}{2^r}. \tag{6}$$

We note that the inequality in (6) follows since we assumed $t \leq \ell$, *i.e.*, bidder $k$ is among the $\ell$ bidders with non-negative marginal values. Hence, the first sum in (5) can be extended to include all $\ell$ bidders with non-negative marginal value. Finally, we note that (6) equals the following by the definition of Algorithm 1:

$$= 2 \cdot \mathbb{E}[P^i|R_{i-1}].$$

Hence, we can conclude that $\mathbb{E}[K^i|R_{i-1}] \leq 2 \cdot \mathbb{E}[P^i|R_{i-1}]$ as desired.

We note that if $t > \ell$ then the latter inequality trivially holds (the above proof works until (2) in which the first term is negative and thus can be dropped which implies that $\mathbb{E}[K^i|R_{i-1}] \leq \mathbb{E}[P^i|R_{i-1}]$ and hence that $\mathbb{E}[K^i|R_{i-1}] \leq 2 \cdot \mathbb{E}[P^i|R_{i-1}]$, since $P_i$ is non-negative). Thus, using the law of total expectation over all possible outcomes $R_{i-1}$ the proof is complete. ◀

## 2.2 Deterministic Hardness

**Proof of Theorem 2.** We present an instance for which any online deterministic algorithm cannot achieve a competitive ratio better than $1/M$ for every $M > 0$ versus an adversary. We consider an instance with a single bidder $B = \{b\}$ and two items $\mathcal{N} = \{v_1, v_2\}$. The items arrive according to their index in an online manner, *i.e.*, item $v_1$ is the first to arrive, and item $v_2$ is the second to arrive. Once item $v_1$ arrives, any deterministic algorithm can query $f$ on subsets of elements that can contain only $v_1$. Hence, we only need to define $f$ on $\emptyset$ and $\{v_1\}$. We define $f$ as follows: $f(\emptyset) = 0, f(\{v_1\}) = 1$. How this utility function is extended to a submodular function over all subsets of items depends on what the algorithm chooses to do once item $v_1$ arrives.

The first case is when the algorithm chooses not to assign $v_1$ to $b$. In this case we extend the above definition of $f$ by setting the contribution of $v_2$ to be linearly zero, *i.e,*, $f(\{v_2\}) \triangleq 0$ and $f(\{v_1, v_2\}) \triangleq 1$. One can verify that the resulting utility function $f$ is indeed submodular.

In this case, the value of an optimal solution to the instance equals 1, since item $v_1$ can be assigned to bidder $b$ by the optimal solution. However, every deterministic algorithm that does not assign $v_1$ to $b$ has a value of 0. Thus, we conclude a competitive ratio of 0 in this case.

The second case is when the algorithm chooses to assign $v_1$ to bidder $b$. In this case we extend the above definition of $f$ as follows: $f(\{v_2\}) \triangleq M$ and $f(\{v_1, v_2\}) \triangleq 0$. One can verify that the resulting utility function $f$ is indeed submodular. In this case, the value of an optimal solution to the instance equals $M$, since the optimal solution can choose to assign only $\{v_2\}$ to $b$. However, every deterministic algorithm that assigns $v_1$ to bidder $b$ achieves a value of at most 1. Thus, we conclude a competitive ratio of at most $1/M$ in this case.

In conclusion, for this instance, no deterministic algorithm can achieve any competitive ratio better than $1/M$ in the online adversarial setting, for every constant $M$. ◀

# 3 Uniform Random Order Setting

In this section we focus on the uniform random order setting. Recall that it is known that if the RRG algorithm provides an approximation of $\alpha$ for maximizing a general submodular function given a partition matroid independence constraint, then it also provides an online algorithm in the random order setting which achieves a competitive ratio of $\alpha$ (see brief discussion in Section 1).

To simplify the presentation of our improved analysis, we present a "smooth" version of the RRG algorithm of [10]. Though the analysis of the smoothed version is similar to the original RRG (assuming enough iterations are performed), we believe it is easier to analyze since all iterations have the same probabilistic distribution (whereas in the original RRG this is not the case). For simplicity of presentation, we focus on the case the matroid is a partition matroid (for a general matroid we defer to a full version of the paper). Recall that this special case already captures SW.

## 3.1 Partition Matroid

We are given a partition matroid $\mathcal{M} = (\mathcal{N}, \mathcal{I})$ over a ground set $\mathcal{N}$ which is partitioned into disjoint non-empty sets $P_1, P_2, \ldots, P_k$. The goal is to choose a subset $S \subseteq \mathcal{I}$, *i.e.*, $S$ contains at most one element from each set $P_j$, that maximizes a given non-negative (general) submodular function $f$.

We call our algorithm smooth since the random choices of the algorithm are always uniform, no matter how many iterations the algorithm performed so far. Specifically, the smooth algorithm chooses in every iteration a part uniformly at random from *all* $k$ parts of $\mathcal{N}$, and adds the best element in the chosen part assuming that part does not intersect what the algorithm chose so far. The original RRG chooses a part uniformly at random from parts that do not intersect what the algorithm chose so far, and adds the best element in the chosen part. Thus, the number of iterations the smooth algorithm can perform is unlimited. A formal description of the algorithm for partition matroids is given as Algorithm 2, and we note that the number of iterations $T$ is a parameter given to the algorithm. For a comparison of Algorithm 2 and the original RRG we defer to to a full version of the paper.

Given any $S \subseteq \mathcal{N}$, we denote the parts of the partition of $\mathcal{N}$ that do not intersect $S$ by $I(S)$ ,*i.e.*, $I(S) \triangleq \{j = 1, ..., k | P_j \cap S = \emptyset\}$. Without loss of generality, we assume every part $P_j$ is padded with a dummy element (a different dummy element for every $P_j$) that linearly contributes zero to the objective $f$. Hence, without loss of generality, $|OPT| = k$, where we denote by $OPT$ an optimal solution to the problem: $OPT \triangleq \arg\max\{f(S) | S \in \mathcal{I}\}$.

**Algorithm 2** Smooth Residual Random Greedy (Partition Matroid).

$S_0 \leftarrow \emptyset$.
**for** $i = 1, ..., T$ **do**
  $S_i \leftarrow S_{i-1}$.
  $M_i \leftarrow \bigcup_{j \in I(S_{i-1})} \{\arg\max \{f(S_{i-1} \cup \{u\}) - f(S_{i-1}) | u \in P_j\}\}$.
  Let $j$ be a uniformly random number from $\{1, ..., k\}$.
  **if** $j \in I(S_{i-1})$ **then**
    Let $u_i$ be the element from $P_j$ in $M_i$ and $S_i \leftarrow S_i \cup \{u_i\}$.
  **end**
**end**
Return $S_T$.

For every set $S \in \mathcal{I}$ we denote $O_S \triangleq \arg\max_A \{f(S \cup A) | S \cup A \in \mathcal{I}, A \subseteq \mathcal{N} \setminus S\}$, *i.e.*, $O_S$ is the best extension of $S$ to an independent set. Recalling that every part $P_j$ is padded with a dummy element that linearly contributes zero to the objective implies that $|O_S| = k - |S|$. One should note that $O_\emptyset = OPT$, and thus $O_{S_0} = OPT$. Our analysis tracks $f(O_{S_i} \cup S_i)$ as $S_i$ changes throughout the algorithm. Intuitively, $f(O_{S_i} \cup S_i)$ deteriorate as more elements are added to $S_i$. Building on the above intuition, the following two lemmas establish a system of joint recursive formulas for $\mathbb{E}[f(S_i)]$ and $\mathbb{E}[f(O_{S_i} \cup S_i)]$.

▶ **Lemma 7.** *For every $i = 1, \ldots, T$:*

$$\mathbb{E}[f(S_i)] - \mathbb{E}[f(S_{i-1})] \geq \frac{1}{k} \cdot \mathbb{E}\left[f\left(O_{S_{i-1}} \cup S_{i-1}\right) - f(S_{i-1})\right].$$

**Proof.** Fix $i = 1, \ldots, T$ and condition on any possible realization of the choices of the algorithm in the first $i-1$ iterations. Thus, $S_{i-1}$, $M_i$, and $O_{S_{i-1}}$ are deterministic and fixed given this conditioning, and $u_i$ and $S_i$ are the only random variables. For the remainder of the proof all the probabilities and expectations are conditioned on this possible realization.

$$\mathbb{E}[f(S_i)] - f(S_{i-1}) = \frac{1}{k} \sum_{u \in M_i} \{f(S_{i-1} \cup \{u\}) - f(S_{i-1})\} \tag{7}$$

$$\geq \frac{1}{k} \sum_{u \in O_{S_{i-1}}} \{f(S_{i-1} \cup \{u\}) - f(S_{i-1})\} \tag{8}$$

$$\geq \frac{1}{k} \left\{f(S_{i-1} \cup O_{S_{i-1}}) - f(S_{i-1})\right\} \tag{9}$$

In the above, the equality in (7) follows from the algorithm's definition. The inequality in (8) follows from the greedy choice of $M_i$, and the inequality in (9) follows from the submodularity of $f$. We conclude the proof by unfixing the conditioning and taking an expectation over all possible such events (the law of total expectation). ◀

The following lemma provides a recursive formula for $\mathbb{E}[f(O_{S_i} \cup S_i)]$ whose novelty is in the added contribution of $f(S_{i-1})$. Without the added $\mathbb{E}[f(S_{i-1})]/k$ term the resulting approximation will be $1/4$ as in [10].

▶ **Lemma 8.** *For every $i = 1, \ldots, T$:*

$$\mathbb{E}[f(O_{S_i} \cup S_i)] \geq \left(1 - \frac{2}{k}\right) \cdot \mathbb{E}\left[f\left(O_{S_{i-1}} \cup S_{i-1}\right)\right] + \frac{1}{k} \cdot \mathbb{E}[f(S_{i-1})].$$

**Proof.** Fix $i = 1, \ldots, T$ and condition on any possible realization of the choices of the algorithm in the first $i-1$ iterations. Thus, $S_{i-1}$, $M_i$, and $O_{S_{i-1}}$ are deterministic and fixed given this conditioning, and $u_i$, $S_i$, and $O_{S_i}$ are the only random variables. For the remainder of the proof all the probabilities and expectations are conditioned on this possible realization.

For every element $u \in M_i$ we denote by $P(u)$ the index of the part of the partition of $\mathcal{N}$ which $u$ belongs to. Formally, $P(u) = j$ if and only if $u \in P_j$. We define $h : M_i \to O_{S_{i-1}}$ to be a bijection mapping every element $u \in M_i$ to an element of $O_{S_{i-1}}$ in such a way that $P(u) = P(h(u))$. One should note that our assumption that every $P_j$ contains a dummy element that contributes zero to the objective implies that $I(S_{i-1}) = I(O_{S_{i-1}})$, and hence $h$ is well defined. Thus,

$$\begin{aligned}
&\mathbb{E}\left[f\left(O_{S_i} \cup S_i\right)\right] - f\left(O_{S_{i-1}} \cup S_{i-1}\right) \\
=&\frac{1}{k}\sum_{u \in M_i}\left\{f\left(S_{i-1} \cup \{u\} \cup O_{S_{i-1}\cup\{u\}}\right) - f\left(O_{S_{i-1}} \cup S_{i-1}\right)\right\} && (10)\\
\geq&\frac{1}{k}\sum_{u \in M_i}\left\{f\left(S_{i-1} \cup \{u\} \cup \left(O_{S_{i-1}} \setminus \{h(u)\}\right)\right) - f\left(O_{S_{i-1}} \cup S_{i-1}\right)\right\}. && (11)
\end{aligned}$$

In the above, the equality in (10) follows from the algorithm's definition. The inequality in (11) follows from the observation that $O_{S_{i-1}\cup\{u\}}$ is the best extension of $S_{i-1} \cup \{u\}$ whereas $O_{S_{i-1}} \setminus \{h(u)\}$ is just an extension of $S_{i-1} \cup \{u\}$, *i.e.*,

$$f(S_{i-1} \cup \{u\} \cup O_{S_{i-1}\cup\{u\}}) \geq f(S_{i-1} \cup \{u\} \cup (O_{S_{i-1}} \setminus \{h(u)\})).$$

We note that (11) equals the following:

$$=\frac{1}{k}\sum_{u \in M_i | u \neq h(u)}\left\{f\left(S_{i-1} \cup \{u\} \cup \left(O_{S_{i-1}} \setminus \{h(u)\}\right)\right) - f\left(O_{S_{i-1}} \cup S_{i-1}\right)\right\}. \quad (12)$$

The equality in (12) holds since if $u = h(u)$ then $\{u\} \cup (O_{S_{i-1}} \setminus \{h(u)\}) = O_{S_{i-1}}$, and therefore summation can be reduced to all candidate elements $u \in M_i$ satisfying $u \neq h(u)$. Moreover, we note that (12) can be lower bounded as follows:

$$\begin{aligned}
\geq&\frac{1}{k}\sum_{u \in M_i | u \neq h(u)}\left\{f\left(S_{i-1} \cup \{u\} \cup O_{S_{i-1}}\right) - f\left(S_{i-1} \cup O_{S_{i-1}}\right)\right\}+ && (13)\\
&\frac{1}{k}\sum_{u \in M_i | u \neq h(u)}\left\{f\left(S_{i-1} \cup \left(O_{S_{i-1}} \setminus \{h(u)\}\right)\right) - f\left(S_{i-1} \cup O_{S_{i-1}}\right)\right\}.
\end{aligned}$$

The inequality in (13) follows from submodularity since summation is restricted only to candidates $u \in M_i$ satisfying $u \neq h(u)$ and hence: $f(S_{i-1} \cup \{u\} \cup (O_{S_{i-1}} \setminus \{h(u)\})) + f(S_{i-1} \cup O_{S_i-1}) \geq f(S_{i-1} \cup \{u\} \cup O_{S_{i-1}}) + f(S_{i-1} \cup (O_{S_{i-1}} \setminus \{h(u)\}))$.

We further lower bound (13) in the following way:

$$\begin{aligned}
\geq&\frac{1}{k}\sum_{u \in M_i}\left\{f\left(S_{i-1} \cup \{u\} \cup O_{S_{i-1}}\right) - f\left(S_{i-1} \cup O_{S_{i-1}}\right)\right\}+ && (14)\\
&\frac{1}{k}\sum_{u \in M_i}\left\{f\left(S_{i-1} \cup \left(O_{S_{i-1}} \setminus \{h(u)\}\right)\right) - f\left(S_{i-1} \cup O_{S_{i-1}}\right)\right\}.
\end{aligned}$$

When examining the inequality in (14) let us start with the first sum. We note that if $u = h(u)$ for some $u \in M_i$ then $u \in O_{S_{i-1}}$, *i.e.*, $\{u\} \cup O_{S_{i-1}} = O_{S_{i-1}}$. Thus, extending the first sum to all $u \in M_i$ (regardless of whether $u$ equals $h(u)$ or not) does not change the

first sum. Focusing on the second sum, we note that for every $u \in M_i$, regardless of whether $u$ equals $h(u)$ or not, the following holds: $f(S_{i-1} \cup (O_{S_{i-1}} \setminus \{h(u)\})) \leq f(S_{i-1} \cup O_{S_{i-1}})$. The reason for the latter is that $O_{S_{i-1}}$ is the best extension of $S_{i-1}$ whereas $O_{S_{i-1}} \setminus \{h(u)\}$ is some extension of $S_{i-1}$. Hence, adding to the second sum all terms corresponding to $u \in M_i$, where $u = h(u)$, can only decrease the second sum. Therefore, we conclude that the inequality in (14) holds. Finally, we lower bound (14) as follows:

$$\geq \frac{1}{k}\{f\left(S_{i-1} \cup O_{S_{i-1}} \cup M_i\right) - f\left(S_{i-1} \cup O_{S_{i-1}}\right)\} + \tag{15}$$
$$\frac{1}{k}\{f\left(S_{i-1} \cup O_{S_{i-1}} \setminus O_{S_{i-1}}\right) - f\left(S_{i-1} \cup O_{S_{i-1}}\right)\}$$
$$\geq \frac{1}{k}\{f(S_{i-1}) - 2 \cdot \left(f\left(S_{i-1} \cup O_{S_{i-1}}\right)\right)\} \tag{16}$$

The inequality in (15) follows from submodularity which implies the following two:

$$\sum_{u \in M_i} \{f\left(S_{i-1} \cup \{u\} \cup O_{S_{i-1}}\right) - f\left(S_{i-1} \cup O_{S_{i-1}}\right)\} \geq f\left(S_{i-1} \cup O_{S_{i-1}} \cup M_i\right) - f\left(S_{i-1} \cup O_{S_{i-1}}\right)$$

$$\sum_{u \in M_i} \{f\left(S_{i-1} \cup O_{S_{i-1}} \setminus \{h(u)\}\right) - f\left(S_{i-1} \cup O_{S_{i-1}}\right)\} \geq f\left(S_{i-1} \cup O_{S_{i-1}} \setminus O_{S_{i-1}}\right) - f\left(S_{i-1} \cup O_{S_{i-1}}\right).$$

We note that the inequality in (16) follows from the non-negativity of $f$ which implies that: $f\left(S_{i-1} \cup O_{S_{i-1}} \cup M_i\right) \geq 0$ and the fact that $S_{i-1} \cup O_{S_{i-1}} \setminus O_{S_{i-1}} = S_{i-1}$.

We conclude the proof by unfixing the conditioning and taking an expectation over all possible such events (the law of total expectation). ◀

The following lemma lower bounds the solution to the system of joint recursive formulas presented in Lemmas 7 and 8 (its proof is deferred to a full version of the paper). For simplicity of presentation we introduce two absolute constants: $a \triangleq (3 - \sqrt{5})/2 \approx 0.381966$ and $b \triangleq (3 + \sqrt{5})/2 \approx 2.61803$.

▶ **Lemma 9.** *For every $i = 0, 1, \ldots, T$ the following hold:*

$$\mathbb{E}[f(S_i)] \geq \frac{f(OPT)}{\sqrt{5}} \left(\left(1 - \frac{a}{k}\right)^i - \left(1 - \frac{b}{k}\right)^i\right) \tag{17}$$

$$\mathbb{E}\left[f(O_{S_i} \cup S_i)\right] \geq \frac{f(OPT)}{2\sqrt{5}} \left((\sqrt{5} - 1)\left(1 - \frac{a}{k}\right)^i + (\sqrt{5} + 1)\left(1 - \frac{b}{k}\right)^i\right). \tag{18}$$

The following lemma establishes the approximation guarantee of Algorithm 2.

▶ **Lemma 10.** *Algorithm 2 achieves an approximation ratio of at least* 0.27493 *for the problem of maximizing a non-monotone submodular function subject to a partition matroid independence constraint.*

**Proof.** By our assumption of the existence of dummy elements, no element of $M_i$ has a negative marginal value, in any iteration $i$. We get that always for every $i$, $f(S_i) \geq f(S_{i-1})$ (note that this inequality holds for the random variables $S_i$ and $S_{i-1}$). Therefore, it suffices to show that $\mathbb{E}[f(S_i)] \geq 0.274 \cdot f(OPT)$ for some $i = 1, \ldots, T$.

Observe that setting $i = x^*k$, where $x^* = \ln(b/a)/\sqrt{5} = \ln\left((3 + \sqrt{5})/(3 - \sqrt{5})\right)/\sqrt{5} \approx 0.86$, alongside Lemma 9, implies that:

$$\mathbb{E}[f(S_{x^*k})] \geq \frac{f(OPT)}{\sqrt{5}} \left(\left(1 - \frac{a}{k}\right)^{x^*k} - \left(1 - \frac{b}{k}\right)^{x^*k}\right) \geq \frac{f(OPT)}{\sqrt{5}} \left(e^{-x^*a} - e^{-x^*b}\right). \tag{19}$$

The inequality above follows from the observation that $(1-a/k)^{x^*k} - (1-b/k)^{x^*k}$, as a function of $k$, is monotone decreasing for every $k \geq 3$ (the proof of this technical observation is deferred to a full version of the paper). Thus, the inequality follows by taking the limit $k \to \infty$. The lemma follows by plugging in the above values of $a$, $b$, and $x^*$. ◀

**Proof of Theorem 3.** Follows immediately from Lemma 10. ◀

## Abstract

We characterise the classes of tournaments with tractable first-order model checking. For every hereditary class of tournaments $\mathcal{T}$, first-order model checking either is fixed parameter tractable, or is AW[$*$]-hard. This dichotomy coincides with the fact that $\mathcal{T}$ has either bounded or unbounded twin-width, and that the growth of $\mathcal{T}$ is either at most exponential or at least factorial. From the model-theoretic point of view, we show that NIP classes of tournaments coincide with bounded twin-width. Twin-width is also characterised by three infinite families of obstructions: $\mathcal{T}$ has bounded twin-width if and only if it excludes at least one tournament from each family. This generalises results of Bonnet et al. on ordered graphs.

The key for these results is a polynomial time algorithm which takes as input a tournament $T$ and computes a linear order $<$ on $V(T)$ such that the twin-width of the birelation $(T, <)$ is at most some function of the twin-width of $T$. Since approximating twin-width can be done in FPT time for an ordered structure $(T, <)$, this provides a FPT approximation of twin-width for tournaments.

## 1 Introduction

Tournaments can represent the outcome of a ranking of candidates, which need not be a total order. E.g., in the Condorcet voting paradox, three referees whose preference lists are $(A, B, C)$, $(B, C, A)$, and $(C, A, B)$, lead to a cycle $A \leftarrow B \leftarrow C \leftarrow A$ in the preference relation. Classical algorithmic problems arise from trying to choose a subset of winners: the Dominating Set (DS) problem asks for a subset $D$ which is preferred to any other candidate, i.e. for any $y \notin D$, there is some $x \in D$ which is preferred to $y$; and the Feedback Vertex Set (FVS) problem asks to build a preference order by ignoring a subset of candidates.

These problems can be parameterized by the size $k$ of the desired solution. A problem is *fixed parameter tractable* (FPT) if it admits an algorithm running in time $O(f(k) \cdot n^c)$, for some function $f$ and constant $c$. It is known that FVS is FPT for tournaments [18], whereas DS is unlikely to be FPT. However general tournaments may not be representative of usual instances: for example, majority voting tournaments with a fixed number $r$ of referees form a very restricted class. A cornerstone paper by Alon et al. [2], based on Vapnik-Chervonenkis dimension, shows that $k$-DS is trivially FPT on $r$-majority tournaments, because the size of a minimum dominating set is bounded by $f(r)$. This exemplifies how difficult problems can become easy on restricted classes, here bounded VC-dimension.

To put these questions in a much broader perspective, remark that the previous problems can be expressed in first-order logic (FO). A $k$-DS is described by the formula

$$\exists x_1, x_2, \dots, x_k. \forall y.\ (y = x_1) \vee (y \to x_1) \vee \dots \vee (y = x_k) \vee (y \to x_k).$$

That $k$-FVS is also expressible in first-order logic is only true in tournaments, and not in general graphs. It is based on the simple remark that a tournament is acyclic if and only if it is transitive, i.e. it has no directed 3-cycle, which is easily expressed in FO. Thus $k$-DS and $k$-FVS are instances of the FO Model Checking (or FOMC) problem: given as input a tournament $T$ and a first-order formula $\phi$, does $T$ satisfies $\phi$? FO model checking is difficult on the class of all graphs [12], and using back-and-forth FO encodings, one can show that it is just as hard on tournaments. We investigate which subclasses of tournaments admit an FPT algorithm for FO model checking.

## 1.1 Main results

We prove a dichotomy: in any class $\mathcal{T}$ of tournaments (closed under subtournaments), FOMC is either FPT or AW[$*$]-complete. The key of this dichotomy is *twin-width* (tww), a complexity parameter introduced by Bonnet et al. [7]: FOMC in $\mathcal{T}$ is FPT if $\mathcal{T}$ has bounded twin-width, and AW[$*$]-complete otherwise. This dichotomy coincides with a model theoretic characterisation: the class $\mathcal{T}$ has bounded twin-width if and only if it is NIP, meaning that arbitrary graphs cannot be described from tournaments in $\mathcal{T}$ through a fixed FO formula. This equivalence of twin-width and NIP, called *delineation*, was conjectured for tournaments in [4]. The equivalence between NIP and FPT FO model checking also confirms the *nowhere FO dense* conjecture of Gajarský et al. [15] for tournaments.

Furthermore, the dichotomy for FO model checking coincides with a gap in the growth function of the class $\mathcal{T}$, i.e. the number of tournaments of $\mathcal{T}$ on $n$ vertices up to isomorphism. If $\mathcal{T}$ has bounded twin-width, then its growth is at most $2^{O(n)}$, whereas it is at least $(\lfloor n/2 \rfloor - 1)!$ when twin-width is unbounded. This exponential/factorial gap generalises the Marcus-Tardos theorem on permutations avoiding a fixed pattern [19]. It may also be compared to results of Boudabbous and Pouzet [9] which show that hereditary classes of tournaments have growth either at most polynomial or at least exponential.

▶ **Theorem 1.1.** *Let $\mathcal{T}$ be a hereditary class of tournaments. Under the assumption FPT $\neq$ AW[$*$], the following are equivalent:*

1. *$\mathcal{T}$ has bounded twin-width,*
2. *FO model checking in $\mathcal{T}$ is FPT,*
3. *FO model checking in $\mathcal{T}$ is not AW[$*$]-complete,*
4. *$\mathcal{T}$ does not FO interpret the class of all graphs,*
5. *$\mathcal{T}$ is monadically NIP, i.e. does not FO transduce all graphs,*
6. *the growth of $\mathcal{T}$ is at most $c^n$ for some constant $c$,*
7. *the growth of $\mathcal{T}$ is less than $(\lfloor \frac{n}{2} \rfloor - 1)!$.*

These equivalences are completed by three minimal classes of obstructions, characterising twin-width by excluded substructures. These obstructions encode arbitrary permutations.

▶ **Theorem 1.2.** *There are three hereditary classes $\mathcal{F}_=, \mathcal{F}_\leqslant, \mathcal{F}_\geqslant$ such that a hereditary class $\mathcal{T}$ of tournaments has unbounded twin-width if and only if one of $\mathcal{F}_=, \mathcal{F}_\leqslant, \mathcal{F}_\geqslant$ is a subclass of $\mathcal{T}$.*

Finally, we show that there is a fixed parameter tractable algorithm which approximates twin-width of tournaments up to some function.

▶ **Theorem 1.3.** *There is a function $f : \mathbb{N} \to \mathbb{N}$ and an FPT algorithm, which given as input a tournament $T$, produces either a witness* $\mathrm{tww}(T) \leqslant f(k)$*, or a witness that* $\mathrm{tww}(T) \geqslant k$*.*

These results can be generalised to oriented graphs with bounded independence number, and to relational structures consisting of a tournament augmented by arbitrary binary relations, see the full version of this paper.

## 1.2 Overview of the proof

A fundamental idea regarding twin-width is that upper bounds on twin-width can be witnessed by orders on vertices which exclude grid-like structures in the adjacency matrix. This appears in the founding works of Guillemot and Marx [17] and Bonnet et al. [7], and the relation between twin-width and orders has been deeply explored in [6]. However it is difficult to witness *lower bounds* on twin-width with this approach: one needs to somehow prove that *all* orders contain grids. To this purpose, we want to construct in any tournament $T$ an order $<$ which, if $T$ has small twin-width, is a witness of this fact, i.e. $\mathrm{tww}(T, <) \leqslant f(\mathrm{tww}(T))$.

A tentative approach to obtain such an order is to describe it in FO logic. Indeed, FO transductions preserve twin-width up to some function [7, Theorem 39]. Thus, if $\Phi$ is a transduction which on any tournament $T$ gives some order $<$, then $\mathrm{tww}(T, <) \leqslant f(\mathrm{tww}(T))$ as desired. With a few additional requirements, such as $<$ being efficiently computable, it would be straightforward to obtain our results from the case of ordered graphs [6]. However this approach is impossible: to transduce a total order on the iterated lexicographic product of the 3-cycle with itself, one needs a first-order formula with size increasing in the number of iterations [3]. Remark that this counter-example has twin-width 1.

Instead, our approach is the following: we design a candidate total order $<$ on $T$, computable in polynomial time. If the bi-relation $(T, <)$ has small twin-width, we are done. On the other hand, if $(T, <)$ has large twin-width, then its adjacency matrix w.r.t. $<$ must contain a large high-rank grid by [6]. We then extract a subtournament $T' \subset T$ which still has a substantial (but logarithmically smaller) high-rank grid, and in which $<$ is roughly described by a FO transduction. This is enough to witness that $T$ has large twin-width. Using Ramsey arguments, we extract from $T'$ an obstruction $\mathcal{F}_=$, $\mathcal{F}_\leqslant$, or $\mathcal{F}_\geqslant$. The construction of the order is remarkably simple: we consider a binary search tree (BST), i.e. a tree in which the left, resp. right, branch of a node $x$ consists only of in-, resp. out-neighbours of $x$. The order $<$ is the left-to-right order on nodes of the tree. To summarize, the crucial property is

▶ **Lemma 1.4.** *There is a function $f$ such that for any tournament $T$ and BST order $<$ on $T$,* $\mathrm{tww}(T, <) \leqslant f(\mathrm{tww}(T))$*.*

Lemma 1.4 implies Theorem 1.3: to approximate the twin-width of $T$, it suffices to compute any BST order, which takes polynomial time, and then apply the approximation algorithm for ordered structures [6, Theorem 2], which is FPT. This last algorithm produces either a contraction sequence (which is valid for $(T, <)$ and a fortiori for $T$), or a witness that $(T, <)$ has large twin-width, which in turn implies that $T$ has large twin-width by Lemma 1.4.

Our main technical result is about extracting the obstructions $\mathcal{F}_=, \mathcal{F}_\leqslant, \mathcal{F}_\geqslant$.

▶ **Theorem 1.5.** *Let $\mathcal{T}$ be a hereditary class of tournaments with the property that there are tournaments $T \in \mathcal{T}$ and BST orders $<$ such that* $\mathrm{tww}(T, <)$ *is arbitrarily large. Then $\mathcal{T}$ contains one of the classes $\mathcal{F}_=, \mathcal{F}_\leqslant, \mathcal{F}_\geqslant$ as a subclass.*

Finally, the classes $\mathcal{F}_=, \mathcal{F}_\leqslant, \mathcal{F}_\geqslant$ are complex in all the senses considered by Theorem 1.1.

▶ **Theorem 1.6.** *For each $R \in \{=, \leqslant, \geqslant\}$, the class $\mathcal{F}_R$*

1. *has unbounded twin-width;*
2. *contains at least $(\lfloor \frac{n}{2} \rfloor - 1)!$ tournaments on $n$ vertices counted up to isomorphism;*
3. *contains at least $(\lfloor \frac{n}{2} \rfloor - 1)! \cdot n!$ tournaments on vertex set $\{1, \dots, n\}$ counted up to equality;*
4. *efficiently interprets the class of all graphs;*
5. *and has AW[$*$]-hard FO model checking problem.*

Theorems 1.5 and 1.6 together imply Theorem 1.2. They also imply Lemma 1.4 when applied to the class of tournaments with twin-width at most $k$: this class cannot contain any of $\mathcal{F}_=, \mathcal{F}_\leqslant, \mathcal{F}_\geqslant$, hence its tournaments must still have bounded twin-width when paired with BST orders. Finally, Theorems 1.2 and 1.6 directly imply that if $\mathcal{T}$ is a hereditary class with unbounded twin-width, then $\mathcal{T}$ satisfies none of the conditions of Theorem 1.1. The remaining implications of Theorem 1.1 – that is, when $\mathcal{T}$ has bounded twin-width, all other conditions hold – follow from known results on twin-width. By [7, Theorem 1], FO model checking has an FPT algorithm when a witness of bounded twin-width is given. Combined with Theorem 1.3, this gives an FPT algorithm for classes of tournaments with bounded twin-width. By [7, Theorem 39], a class of structures with bounded twin-width cannot transduce all graphs. Finally, by [8, Corollary 7.3], a class of structures with bounded twin-width contains at most $c^n$ structures on $n$ vertices up to isomorphism, for some constant $c$.

## 1.3 Context and related parameters

It is interesting to compare twin-width to other classical complexity measures for tournaments. Bounded twin-width implies bounded VC-dimension, since classes with unbounded VC-dimension contain all possible bipartite subgraphs, which is against single-exponential growth. *Cutwidth* was introduced by Chudnovsky, Fradkin and Seymour [11] to study tournament immersions. Bounded cutwidth is certified by a vertex ordering which can be shown to exclude grids, hence it is also a witness of bounded twin-width. Another parameter, closely related to subdivisions in tournaments, is *pathwidth*, studied by Fradkin and Seymour [14]. Bounded pathwidth of tournaments implies bounded cliquewidth, which in turn also implies bounded twin-width, see [7]. Thus, we have the following chain of inclusions (if a parameter is bounded, all the ones listed after are also bounded): cutwidth, pathwidth, cliquewidth, twin-width, and VC-dimension. For more on the subject, see Fomin and Pilipczuk [13, 21].

Regarding the binary search tree method for ordering tournaments, it corresponds to the KwikSort algorithm of Ailon, Charikar and Newman for approximating the minimum feedback arc set [1]. A difference is that their result requires the BST to be randomly chosen, whereas arbitrary BST provide approximations of twin-width.

## 1.4 Organisation of the paper

Section 2 summarises our definitions and notations. In section 3 the classes $\mathcal{F}_=, \mathcal{F}_\leqslant, \mathcal{F}_\geqslant$ of obstructions to twin-width are defined, and we prove Theorem 1.6. Section 4 defines binary search trees, the associated orders, and some related notions. We then prove a crucial lemma which, from a partition into intervals of a BST order, extracts some FO definable substructure. Section 5 proves Lemma 1.4 using the former lemma, combined with results of [6]. See the extended version of this paper [16] for the full proof of Theorem 1.5, which builds on that of Lemma 1.4.

## 2 Preliminaries

This section summarizes the notions and notations used in this work. For $n \in \mathbb{N}$, we denote by $[n]$ the interval of integers $\{1, \dots, n\}$.

### 2.1 Tournaments, relational structures

A *tournament* $T$ consists of a set of vertices $V(T)$, and for each $u \neq v \in V(T)$, an arc oriented either $u \to v$ or $v \to u$ (but not both). If $x \in V(T)$, then $N^+(x) = \{y \mid x \to y\}$ and $N^-(x) = \{y \mid y \to x\}$ are the *in-* and *out-neighbourhood* respectively. A tournament is *transitive* if it contains no directed cycle, in which case it defines a total order on its vertices. We call *chain* a subset $X \subset V(D)$ which induces a transitive tournament.

Relational structures generalise graphs and tournaments. A relational *signature* is a finite set $\Sigma$ of *relation symbols* $R$, each with an arity $r \in \mathbb{N}$. A $\Sigma$-structure consists of a domain $A$ (vertices), and for each symbol $R \in \Sigma$ of arity $r$, an interpretation $R^S \subseteq A^r$ (hyperedges). E.g., tournaments and graphs are structures over a signature with a single binary relation. We restrict ourselves to *binary* structures, i.e. where all relation symbols have arity 2. An *ordered structure* $S$ is a structure over a relation $\Sigma$ with a special symbol $<$, whose interpretation $<^S$ is a total order on the domain of $S$.

If $S$ is a structure with domain $A$ and $B \subseteq A$, the substructure $S[B]$ *induced* by $B$ has domain $B$, and interprets each relation $R$ as the restriction of $R^S$ to $B$. All classes of structures considered here are *hereditary*, i.e. closed under induced substructures.

### 2.2 Matrices

A matrix is a map $M : R \times C \to \Gamma$, where $R, C$ are the *ordered sets* of rows and columns of the matrix, and $\Gamma$ and its alphabet (usually, $\Gamma = \{0, 1\}$). A submatrix of $M$ is the restriction of $M$ to some subsets of rows and columns. A *division* $\mathcal{D}$ of $M$ consist of partitions $\mathcal{R}, \mathcal{C}$ of the rows and columns respectively into *intervals*. It is a $k$-division if the partitions have $k$ parts each. A *cell* of the division is the submatrix induced by $X \times Y$ for some $X \in \mathcal{R}, Y \in \mathcal{C}$. A *$k$-grid* in a 0,1-matrix is a division in which every cell contains a "1".

For a tournament $T$ and a total order $<$ on $V(T)$, the adjacency matrix $A_{(T,<)}$ has $V(T)$ ordered by $<$ as rows and columns, and contains a "1" at position $(u, v)$ if and only if $u \to v$. This generalises to binary structures over any signature $\Sigma$, with $\{0, 1\}^\Sigma$ as alphabet.

### 2.3 Orders, Quasi-orders

A *quasi-order* $\preceq$ is a reflexive and transitive binary relation. The associated equivalence relation is $x \sim y$ iff $x \preceq y \wedge y \preceq x$. The strict component of the quasi-order is $x \prec y$ iff $x \preceq y$ and $y \not\preceq x$. The quasi-order is *total* if for all $x, y$, either $x \preceq y$ or $y \preceq x$. An *interval* of a quasi-order $\preceq$ is a set of the form $\{z \mid x \preceq z \preceq y\}$ for some $x, y$, called *endpoints*. An interval is a union of equivalence classes of $\sim$. Two subsets $X, Y$ are *overlapping* if there exist $x_1, x_2 \in X$ and $y_1, y_2 \in Y$ such that $x_1 \preceq y_1$ and $x_2 \succeq y_2$. Equivalently, $X, Y$ are non-overlapping iff there are disjoint intervals $I_X$,$I_Y$ such that $X \subseteq I_X$ and $Y \subseteq I_Y$.

### 2.4 Permutations

We denote by $\mathfrak{S}_n$ the group of permutations on $n$ elements. The *permutation matrix* $M_\sigma$ has a "1" at position $(i, j)$ if and only if $j = \sigma(i)$. A permutation $\tau$ is a *pattern* of $\sigma$ if $M_\tau$ is a submatrix of $M_\sigma$. We say that $\sigma$ contains a $k$-grid if $M_\sigma$ contains a $k$-grid. When this is the case, any permutation in $\mathfrak{S}_k$ is a pattern of $\sigma$. For example, the permutation $\sigma$ on $k^2$ elements defined by $\sigma(ki + j + 1) = kj + i + 1$ for any $0 \leqslant i, j < k$ contains a $k$-grid.

A permutation can be represented as a *bi-order*, i.e. the superposition of two total orders. Precisely, for $\sigma \in \mathfrak{S}_n$, the structure $\mathcal{O}_\sigma$ has domain $[n]$, and has for relations the natural order $<$, and the permuted order $<_\sigma$ defined as $i <_\sigma j$ if and only if $\sigma(i) < \sigma(j)$. Any bi-order is isomorphic to some $\mathcal{O}_\sigma$. Remark that $\tau$ is a pattern of $\sigma$ if and only if $\mathcal{O}_\tau$ is isomorphic to an induced substructure of $\mathcal{O}_\sigma$. We write $\mathcal{O}_{\mathfrak{S}}$ for the class of all finite bi-orders.

## 2.5 Twin-width

Twin-width, denoted e.g. $\mathrm{tww}(G)$, is a complexity parameter defined on graphs, and more generally on binary structures. We refer the reader to [7] for the definition, based on contraction sequences – it will not be used in this work. Instead, we rely on the following characterisation by grid-like structures in adjacency matrices. Recall that a division of a matrix is a partition of rows and columns into intervals. We say that a matrix is *$k$-diverse* if it contains at least $k$ different rows and $k$ different columns – which is equivalent to having rank at least $k'$ up to single-exponential bounds. Then, a *rank-$k$ division* is a $k$-division in which every cell is $k$-diverse. Bonnet et al. proved

▶ **Theorem 2.1** ([6, Theorem 2]). *There are functions $f, g$ such that for any graph (or binary structure) $G$ and any order $<$ on $V(G)$,*
- *if $\mathrm{tww}(G, <) \geqslant f(k)$ then the matrix $A_{(G,<)}$ has a rank-$k$ division, and*
- *if the matrix $A_{(G,<)}$ has a rank-$g(k)$ division, then $\mathrm{tww}(G, <) \geqslant k$.*

*Furthermore there is an FPT algorithm which given $G$, $<$, and $k$, finds either a rank-$k$ division in $A_{(G,<)}$ or a contraction sequence of width $f(k)$ for $(G, <)$.*

## 2.6 First-order logic

Recall from the introduction that we are interesting in FO Model Checking: given as input a structure $S$ and a first-order formula $\phi$, test if $S \models \phi$. We consider the complexity of this problem parametrized by the size $|\phi|$. In general, this problem is AW[$*$]-complete.

▶ **Theorem 2.2** ([12]). *FO Model Checking is AW[$*$]-complete on the class of all graphs.*

On the other hand, FO model checking is FPT for classes of structures with bounded twin-width, as long as a witness of twin-width is given.

▶ **Theorem 2.3** ([7, Theorem 1]). *Given a binary structure $S$ on $n$ vertices, a contraction sequence of width $k$ for $S$, and a FO formula $\phi$, one can test if $S \models \phi$ in time $f(k, \phi) \cdot n$.*

*Interpretations* are transformations of structures described using logical formulæ. For two relational signatures $\Sigma, \Delta$, a FO interpretation $\Phi$ from $\Sigma$ to $\Delta$ consists of, for each relation $R \in \Delta$ of arity $r$, a FO formula $\phi_R(x_1, \ldots, x_r)$ over the language $\Sigma$, and one last formula $\phi_{dom}(x)$ again over $\Sigma$. If $S$ is a $\Sigma$-structure, the result $\Phi(S)$ is obtained by
- choosing the same domain as $S$,
- interpreting $R \in \Delta$ as $\{(v_1, \ldots, v_r) \mid S \models \phi_R(v_1, \ldots, v_r)\}$, the tuples satisfying $\phi_R$,
- and finally taking the substructure induced by $\{v \mid S \models \phi_{dom}(v)\}$.

For instance, the square of a graph $G$ has the same vertices as $G$, with an edge $xy$ iff the distance of $x$ and $y$ in $G$ is at most 2. This is a FO interpretation with edges defined by

$$\phi(x, y) = E(x, y) \vee (\exists z.\ E(x, z) \wedge E(z, y))$$

where $E(x, x)$ denotes adjacency. The domain formula just "true" since we do not wish to delete vertices in this case. FO interpretations are closed under composition.

*Transductions* generalise interpretation with a non-deterministic coloring step. Let $\Sigma^+$ be the signature obtained by adding $r$ new *unary* relations $C_1, \dots, C_r$ to $\Sigma$. If $S$ is a $\Sigma$-structure, we denote by $S^+$ the set of $\Sigma^+$-structures obtained from $S$ by choosing an arbitrary interpretation of each $C_i$ as a subset of $V(S)$. Now a FO transduction $\Phi : \Sigma \to \Delta$ is described by the choice of $\Sigma^+$ augmenting $\Sigma$ with unary relations, and a FO interpretation $\Phi_I$ from $\Sigma^+$ from $\Delta$. The result of $\Phi$ is the set of $\Delta$-structures $\Phi(S) = \{\Phi_I(T) \mid T \in S^+\}$. That is, the interpretation of the unary relations $C_1, \dots, C_r$ on $S$ are chosen non-deterministically, and then $\Phi_I$ is applied.[1] Like interpretations, transductions can be composed.

Given classes $\mathcal{C}, \mathcal{D}$ of structures, we say that $\mathcal{C}$ *interprets* (resp. *transduces*) $\mathcal{D}$ if there is a FO interpretation (resp. transduction) $\Phi$ such that $\Phi(\mathcal{C}) \supseteq \mathcal{D}$. We furthermore say that $\mathcal{C}$ *efficiently interprets* $\mathcal{D}$ if there is also an algorithm which given as input $D \in \mathcal{D}$, finds in polynomial time some $C \in \mathcal{C}$ such that $\Phi(C) = D$. It is straightforward to show that this additional condition gives an FPT reduction for model checking.

▶ **Lemma 2.4.** *If $\mathcal{C}$ efficiently interprets $\mathcal{D}$, then there is an FPT reduction from FO Model Checking on $\mathcal{D}$ to FO Model Checking on $\mathcal{C}$.*

Recall that $\mathcal{O}_{\leqslant}$ denotes the class of bi-orders, which are encodings of permutations. The following is a folklore result, see e.g. [6, Lemma 10] for a very similar claim.

▶ **Lemma 2.5.** *The class $\mathcal{O}_{\leqslant}$ of bi-orders efficiently interprets the class of all graphs.*

Thus, using Lemma 2.4 and Theorem 2.2, FO Model Checking on $\mathcal{O}_{\leqslant}$ is AW[$*$]-complete.

FO transductions also preserve twin-width, up to some function.

▶ **Theorem 2.6** ([7, Theorem 39])**.** *If $\mathcal{S}$ is a class of binary structures with bounded twin-width and $\Phi$ is a FO transduction defined on $\mathcal{S}$, then $\Phi(\mathcal{S})$ also has bounded twin-width.*

A class of structures $\mathcal{S}$ is said to be *monadically NIP* if $\mathcal{S}$ does not transduce the class of all graphs. Theorem 2.6 implies that classes with bounded twin-width are monadically NIP. The weaker notion of (non-monadically) NIP also exists, however Braunfeld and Laskowski recently proved that NIP and monadically NIP are equivalent for hereditary classes [10].

## 2.7 Enumeration

A class $\mathcal{S}$ of graphs (or binary relational structures) is *small* if there exists $c$ such that $\mathcal{S}$ contains at most $c^n \cdot n!$ structures on the vertex set $[n]$. For instance, the class of trees is small, and more generally proper minor closed classes of graphs are small as shown by Norine et al. [20]. This was further generalised to classes of bounded twin-width by Bonnet et al.

▶ **Theorem 2.7** ([5, Theorem 2.4])**.** *Classes of structures with bounded twin-width are small.*

# 3 Forbidden classes of tournaments

This section defines the three minimal classes $\mathcal{F}_=$, $\mathcal{F}_\leqslant$, and $\mathcal{F}_\geqslant$ of obstructions to twin-width in tournaments. Each of them corresponds to some encoding of the class of all permutations. For $R \in \{=, \leqslant, \geqslant\}$ and any permutation $\sigma$, we will define a tournament $\mathcal{F}_R(\sigma)$. The class $\mathcal{F}_R$ is the hereditary closure of all $\mathcal{F}_R(\sigma)$.

[1] Additional operations such as duplication of vertices are often allowed in transductions, but these will not be needed in this work.

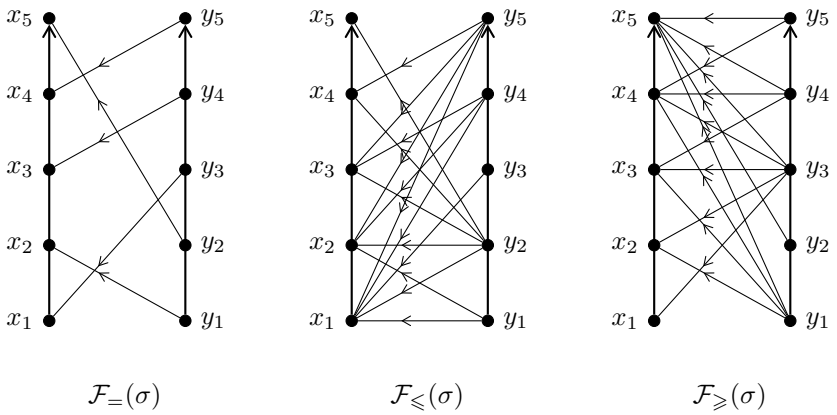

**Figure 1** The three classes of obstructions to twin-width in tournaments. For readability, edges oriented from some $x_i$ to some $y_j$ have been omitted. Each class consists of some encoding of the class of all permutations, represented here with the permutation $\sigma = 31452$.

Let $R \in \{=, \leqslant, \geqslant\}$, and let $\sigma \in \mathfrak{S}_n$ be a permutation on $n$ elements. The tournament $\mathcal{F}_R(\sigma)$ consists of $2n$ vertices, called $x_1, \dots, x_n, y_1, \dots, y_n$. Let $X = \{x_1, \dots, x_n\}$ and $Y = \{x_1, \dots, y_n\}$. Each of $X, Y$ is a chain under the natural order, i.e. there is an edge from $x_i$ to $x_j$, resp. from $y_i$ to $y_j$, if and only if $i < j$. The edges between $X$ and $Y$ encode $\sigma$ in a way specified by the relation $R$: there is an edge oriented from $y_j$ to $x_i$ if and only if $i \, R \, \sigma^{-1}(j)$. See Figure 1 for an example.

Thus in $\mathcal{F}_{=}(\sigma)$ the edges oriented from $Y$ to $X$ form a matching which encodes $\sigma$. In $\mathcal{F}_{\leqslant}(\sigma)$ and $\mathcal{F}_{\geqslant}(\sigma)$, these edges form a half-graph which orders $X$ and $Y$ by inclusion of neighbourhoods, so that the order on $X$ is the natural one, and the order on $Y$ encodes $\sigma$. Precisely, in $\mathcal{F}_{\geqslant}(\sigma)$, for any $i, j \in [n]$, we have

$$\big(N^-(x_i) \cap Y\big) \subseteq \big(N^-(x_j) \cap Y\big) \iff i \leqslant j \tag{1}$$

$$\text{and} \quad \big(N^-(y_i) \cap X\big) \subseteq \big(N^-(y_j) \cap X\big) \iff \sigma^{-1}(i) \leqslant \sigma^{-1}(j), \tag{2}$$

while in $\mathcal{F}_{\leqslant}(\sigma)$, the direction of inclusions is reversed.

▶ **Lemma 3.1.** *For each $R \in \{=, \leqslant, \geqslant\}$, the class $\mathcal{F}_R$ efficiently interprets the class $\mathcal{O}_{\mathfrak{S}}$ of bi-orders. Precisely, there is an interpretation $\Phi_R$, and for any permutation $\sigma \in \mathfrak{S}_n$, $n \geqslant 2$, there is a $\sigma' \in \mathfrak{S}_{n+1}$ computable in polynomial time such that $\mathcal{O}_\sigma = \Phi_R(\mathcal{F}_R(\sigma'))$.*

**Proof.** We will first show that $\mathcal{F}_R(\sigma)$ transduces $\mathcal{O}_\sigma$, and then how to remove the coloring step of the transduction by slightly extending $\sigma$.

Let $X = \{x_1, \dots, x_n\}$ and $Y = \{y_1, \dots, y_n\}$ be as in the definition of $\mathcal{F}_R(\sigma)$. The transduction uses coloring to guess the set $X$. It then defines two total orders on $Y$, which together describe $\sigma$. The first ordering is given by the direction of edges inside $Y$. The second depends on $R$:

- If $R$ is $=$, edges oriented from $Y$ to $X$ are a perfect matching. The direction of edges in $X$, interpreted through this matching, defines the second order on $Y$.
- If $R$ is $\geqslant$ or $\leqslant$, the second order is inclusion, respectively inverse inclusion, of in-neighbourhoods intersected with $X$, see (2).

With the knowledge of which subset is $X$, each of these orders is clearly definable with a first-order formula. Finally, the transduction deletes vertices of $X$, leaving only $Y$ and the two orders which encode $\sigma$.

Let us now show how to deterministically define the partition $X, Y$, at the cost of extending $\sigma$ with one fixed value. Here, we assume $n \geqslant 2$.

- If $R$ is $=$, define $\sigma' \in \mathfrak{S}_{n+1}$ by $\sigma'(n+1) = n+1$ and $\sigma'(i) = \sigma(i)$ for any $i \leqslant n$. Then, in $\mathcal{F}_=(\sigma')$, the unique vertex with out-degree 1 is $y_{n+1}$. Its out-neighbour is $x_{n+1}$, which verifies $X = N^-(x_{n+1}) \cup \{x_{n+1}\} \setminus \{y_{n+1}\}$.
- If $R$ is $\leqslant$, define $\sigma'(1) = n+1$ and $\sigma'(i+1) = \sigma(i)$. Then $y_{n+1}$ is the unique vertex with out-degree 1, and its out-neighbour is $x_1$, which satisfies $X = N^+(x_1) \cup \{x_1\}$.
- If $R$ is $\geqslant$, we once again define $\sigma'(1) = n+1$ and $\sigma'(i+1) = \sigma(i)$. Then $x_1$ has in-degree 1, and its in-neighbour is $y_{n+1}$. The only other vertex which may have in-degree 1 is $y_1$, and this happens if and only if $\sigma'(2) = 1$. When this is the case, the direction of the edge $x_1 \to y_1$ still allows to distinguish $x_1$ in FO logic. Then, having defined $x_1$, we obtain $y_{n+1}$ as its in-neighbour, which satisfies $X = N^+(y_{n+1})$.

In all three cases, $\mathcal{F}_R(\sigma')$ contains two extra vertices compared to $\mathcal{F}_R(\sigma)$. These extra vertices can be uniquely identified in first-order logic, and can then be used to define $X$. Combined with the previous transduction, this gives an interpretation of $\mathcal{O}_\sigma$ in $\mathcal{F}_R(\sigma')$. ◀

We can now prove that the classes $\mathcal{F}_R$ are complex.

▶ **Theorem 1.6.** *For each $R \in \{=, \leqslant, \geqslant\}$, the class $\mathcal{F}_R$*

1. *has unbounded twin-width;*
2. *contains at least $(\lfloor \frac{n}{2} \rfloor - 1)!$ tournaments on $n$ vertices counted up to isomorphism;*
3. *contains at least $(\lfloor \frac{n}{2} \rfloor - 1)! \cdot n!$ tournaments on vertex set $\{1, \dots, n\}$ counted up to equality;*
4. *efficiently interprets the class of all graphs;*
5. *and has AW[$*$]-hard FO model checking problem.*

**Proof.** Item 4 is straightforward by Lemmas 2.5 and 3.1, since efficient interpretations can be composed. By Lemma 2.4 and Theorem 2.2, this in turn implies Item 5. Item 3 implies Item 2 by a simple counting argument: in an isomorphism class, there are at most $n!$ choices of labelling of vertices with $\{1, \dots, n\}$ (less if there are automorphisms). Furthermore, each of Items 3 and 4 implies Item 1, by Theorem 2.7 and Theorem 2.6 respectively. Thus it only remains to prove Item 3.

By Lemma 3.1, for any permutation $\sigma \in \mathfrak{S}_n$ there is some $\mathcal{F}_R(\sigma')$ on $2n+2$ vertices such that $\Phi_R(\mathcal{F}_R(\sigma')) = \sigma$, where $\Phi_R$ is a fixed interpretation. Since interpretations preserve isomorphism, it follows that there are at least $n!$ non-isomorphic tournaments on $2n+2$ vertices in $\mathcal{F}_R$. Furthermore, the arguments of Lemma 3.1, it is easy to show that these $\mathcal{F}_R(\sigma')$ have no non-trivial automorphism. Thus, there are exactly $(2n+2)!$ distinct labellings of $\mathcal{F}_R(\sigma')$ with $\{1, \dots, 2n+2\}$. In total, this gives $(2n+2)! \cdot n!$ distinct graphs on vertices $\{1, \dots, 2n+2\}$ in $\mathcal{F}_R$, proving Item 3. ◀

Thus the classes $\mathcal{F}_=, \mathcal{F}_\leqslant, \mathcal{F}_\geqslant$ are obstructions to fixed parameter tractability of FO model checking and twin-width. The rest of the paper shows that they are the only obstructions. One may also verify that all three are minimal, i.e. none of them is contained in another.

## 4 Binary search tree orders

This section presents the good order for twin-width in tournaments. It is based on *binary search trees* (BST), which we define in a tournament $T$ as a rooted ordered binary tree $S$ (meaning that each node has a left and right child, either of which may be missing), whose nodes are the vertices of $T$, and such that for any $x \in S$

- the left child of $x$ (if any) and its descendants are in $N_T^-(x)$, and
- the right child of $x$ (if any) and its descendants are in $N_T^+(x)$, see Figure 2.

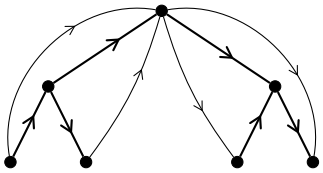

**Figure 2** A binary search tree in a tournament. The direction of omitted edges is not constrained.

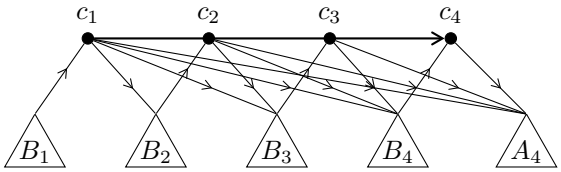

**Figure 3** Example of construction of the quasi-order $\preceq_C^+$. The quasi-order is from left to right, and the triangles are equivalence classes. The direction of omitted edges (from $B_i$ to $B_j \cup \{c_j\}$ for $i < j$) is not constrained. For $\preceq_C^-$, the direction of all edges would be reversed.

The *order* associated to $S$, denoted $<_S$, is the left-to-right order, i.e. the one which places a node $x$ after its left child and its descendants, but before its right child and its descendants. Such an order is called a *BST order*.

Remark that because $T$ is only a tournament and not an order as in a standard BST, there is no restriction on the direction of edges between the left and right subtrees of $x$. On the other hand, if $x$ is an ancestor of $y$, then there is an edge oriented from $x$ to $y$ if and only if $x <_S y$. Thus we have

▶ Remark 4.1. In a tournament $T$, any branch $B$ of a BST $S$ forms a chain which coincides with $<_S$. That is, for $x, y \in B$, the edge in $T$ is oriented from $x$ to $y$ if and only if $x <_S y$.

We will now define *chain quasi-orders*, which are FO definable quasi-orders with which we will approximate BST orders. Let $C$ be a chain in $T$. Its *chain quasi-order* $\preceq_C^+$ is defined as follows. Enumerate the vertices of $C$ as $c_1, \dots, c_k$ so that edges are oriented from $c_i$ to $c_j$ when $i < j$. Define $A_i = \bigcap_{j \leqslant i} N^+(c_j)$, and $B_i = A_{i-1} \cap N^-(c_i)$. Then each of $B_1, \dots, B_k$ and $A_k$ is an equivalence class of $\preceq_C^+$, and the classes are ordered as

$$B_1 \prec_C^+ c_1 \prec_C^+ B_2 \prec_C^+ c_2 \prec_C^+ \dots B_k \prec_C^+ c_k \prec_C^+ A_k,$$

see Figure 3. This can be seen as the left-to-right order of a partial BST consisting only of a single branch $c_1, \dots, c_k$, with $c_1$ as root and $c_k$ as leaf. It is also a coarsening of the lexicographic order: the latter would refine the order inside each class $B_i$ using $c_{i+1}, \dots, c_k$.

The dual quasi-order $\preceq_C^-$ is defined in the same way, but reversing the direction of all edges. Thus, we now enumerate $C$ so that edges are from $c_i$ to $c_j$ when $i > j$, while $A_i = \bigcap_{j \leqslant i} N^-(c_i)$ and $B_i = A_{i-1} \cap N^+(c_i)$. The rest of the definition is the same.

▶ **Lemma 4.2.** *There is a first-order transduction $\Phi$ which non-deterministically computes any chain quasi-order. That is, for any tournament $T$ and chain quasi-order $\preceq_C^o$, $(T, \preceq_C^o) \in \Phi(T)$.*

**Proof.** The transduction first guesses $C$ and $o$, and obtains the order within $C$ from the edges of $T$. It is then simple to express the definition of $\preceq_C^o$ in first-order logic. ◀

We now prove our main technical lemma on BSTs, which shows that BST orders can to some extent be approximated by chain quasi-orders.

▶ **Lemma 4.3.** *Let $T$ be a tournament and $S$ be a BST with order $<_S$. There is a function $f(k) = 2^{O(k)}$ independent of $T$ and $S$ such that for any family $\mathcal{P}$ of at least $f(k)$ disjoint intervals of $<_S$, there is a chain $C$ in $T$, an orientation $o \in \{+,-\}$ and a subfamily $\mathcal{P}' \subset \mathcal{P}$ such that $|\mathcal{P}'| \geqslant k$ and such that the intervals of $\mathcal{P}'$ are non-overlapping for $\preceq_C^o$.*

*Furthermore, $C$, $o$, and $\mathcal{P}'$ can be computed in linear time.*

**Proof.** Let $T$ be a tournament, $S$ a BST of $T$ and $<_S$ the corresponding order. Let $\mathcal{P}$ be a family of at least $f(k)$ disjoint intervals of $<_S$, where $f(k) = 2^{O(k)}$ will be determined later.

We choose a branch $B = b_0, \dots, b_p$ of $S$ by the following process. First $b_0$ is the root of $S$. For each (yet to be determined) $b_i$, let $S_i$ be the subtree of $S$ rooted in $b_i$, and define the weight $w_i$ to be the number of classes of $\mathcal{P}$ intersected by $S_i$. Then $b_{i+1}$ is chosen to be the child of $b_i$ which maximizes $w_{i+1}$. This choice ensures that

$$2w_{i+1} + 1 \geqslant w_i. \tag{3}$$

For each $i < p$, let $d_i$ be the child of $b_i$ other than $b_{i+1}$ (sometimes $d_i$ does not exist), and let $D_i$ be the subtree of $S$ rooted at $d_i$ ($D_i$ is empty if $d_i$ does not exist). Furthermore, let $L, R$ be the sets of vertices which are before, resp. after the leaf $b_p$ in the order $<_S$. For any $0 \leqslant i \leqslant j \leqslant p$, let

$$L_{i,j} \stackrel{\text{def}}{=} \bigcup_{\substack{i \leqslant \ell < j \\ b_\ell \in L}} \{b_\ell\} \cup D_\ell, \qquad \text{and} \qquad R_{i,j} \stackrel{\text{def}}{=} \bigcup_{\substack{i \leqslant \ell < j \\ b_\ell \in R}} \{b_\ell\} \cup D_\ell.$$

Roughly speaking, $L_{i,j}$, resp. $R_{i,j}$ consists of subtrees branching out of $B$ on the left, resp. right, between $b_i$ and $b_j$.

▷ Claim 4.4. For any $i, j$, the subtree $S_i$ is partitioned into $L_{i,j} <_S S_j <_S R_{i,j}$.

Proof. Clearly $L_{i,j}, S_j, R_{i,j}$ partition $S_i$. Furthermore, if $\ell < j$ and $b_\ell \in L$, then $b_\ell <_S S_j$, and in turn $D_\ell <_S b_\ell$. This proves $L_{i,j} <_S S_j$, and symmetrically $S_j <_S R_{i,j}$. ◁

▷ Claim 4.5. For $0 \leqslant i < j \leqslant p$, if $w_i \geqslant w_j + 3$, then there is a part $P \in \mathcal{P}$ such that $P \subset L_{i,j}$ or $P \subset R_{i,j}$.

Proof. At least three parts of $\mathcal{P}$ intersect $S_i$ but not $S_j$. Since these three parts and $S_i$ are all intervals of $<_S$, one of these parts, say $P$, is contained in $S_i$. Thus $P$ is a subset of $S_i$ but does not intersect $S_j$, which by Claim 4.4 implies $P \subset L_{i,j}$ or $P \subset R_{i,j}$. ◁

Construct a sequence $i_0 < \cdots < i_{2k}$ of indices in $\{0, \dots, p\}$ inductively by taking $i_0 = 0$, and choosing $i_{\ell+1}$ minimal such that $w_{i_{\ell+1}} \leqslant w_{i_\ell} - 3$. Using (3) and the minimality of $i_{\ell+1}$, we obtain for all $\ell$ that $2w_{i_{\ell+1}} + 1 \geqslant w_{i_{\ell+1}-1} > w_{i_l} - 3$, hence

$$2w_{i_{\ell+1}} + 3 \geqslant w_{i_l}. \tag{4}$$

We can now define $f$ by $f(0) = 1$ and $f(k+1) = 4f(k) + 9$. By assumption, $w_0 = |\mathcal{P}| \geqslant f(k)$, and it follows from (4) that the construction of $i_\ell$ can be carried out up to $i_{2k}$.

Define $L'_\ell = L_{i_{\ell-1}, i_\ell}$, and similarly $R'_\ell = R_{i_{\ell-1}, i_\ell}$, see Figure 4. By Claim 4.5, for any $\ell \in [2k]$, either $L'_\ell$ or $R'_\ell$ contains a part of $\mathcal{P}$. Thus, either there are at least $k$ distinct $L'_\ell$ containing a part of $\mathcal{P}$, or there are at least $k$ distinct $R'_\ell$ containing a part of $\mathcal{P}$. Assume the former case without loss of generality. We will now forget the vertices which are not in $L$.

Define $C = L \cap B$. By Remark 4.1, this is a chain, whose order coincides with $<_S$. Furthermore, at any node $x$ of $C$, the branch $B$ does descend on the right side, since $x <_S b_p$. Thus, the order in $C$ also coincides with the ancestor-descendent order of $S$. (Remark here

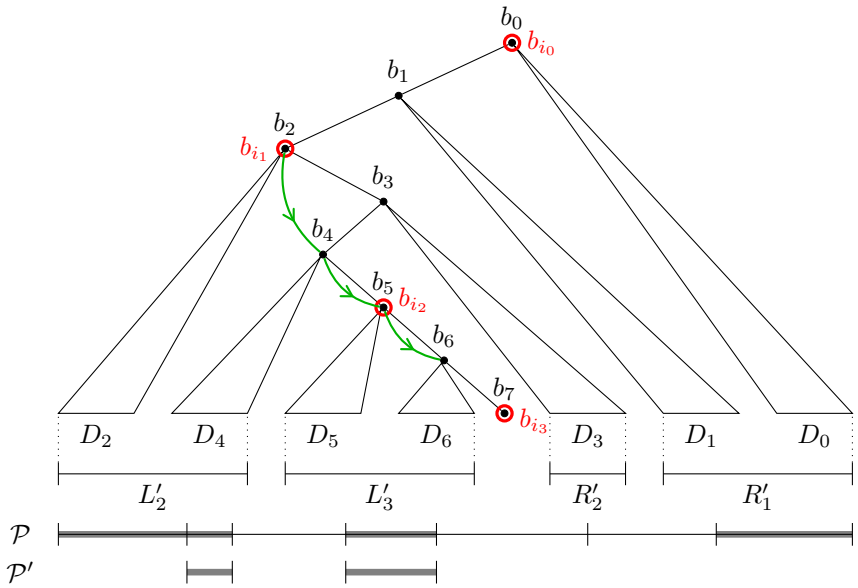

**Figure 4** Sketch of the proof of Lemma 4.3. In the upper half, the BST $T$ with the extracted branch $B$; circled in red, the extracted subsequence $b_{i_\ell}$; in green arrows, the chain $C = B \cap L = \{b_2, b_4, b_5, b_6\}$. Below the tree, from top to bottom: the partition in $L'_\ell$ and $R'_\ell$; the initial family (here partition) $\mathcal{P}$, with the parts contained in some $L'_\ell$ or $R'_\ell$ highlighted; the final family $\mathcal{P}'$, obtained by selecting a part of $\mathcal{P}$ inside each possible $L'_\ell$.

that if we were in $R$ instead of $L$, the order of $C$ would be the inverse of the ancestor-descendant order.) Now, if $C$ is enumerated as $c_0 <_S \cdots <_S c_t$, and $C_i$ is the subtree branching out on the left of $c_i$, defined similarly to $D_i$, then the chain quasi-order $\preceq^+_C$ restricted to $L$ is exactly

$$C_0 \prec^+_C c_0 \prec^+_C C_1 \prec^+_C c_1 \prec^+_C \dots \prec^+_C c_t$$

where each subtree $C_i$ is an equivalence class. (In $R$, we would instead use $\preceq^-_C$.) From this description, we obtain that any $L_{i,j}$ is an interval of $\preceq^+_C$ restricted to $L$.

For each $L'_\ell$, select a part of $\mathcal{P}$ included in $L'_\ell$ if any, and define $\mathcal{P}'$ as the collection of selected parts. Thus $\mathcal{P}' \subset \mathcal{P}$, and we know from the choice of the family $\{L'_\ell\}_{\ell \in [2k]}$ that $|\mathcal{P}'| \geqslant k$. Furthermore, if $X \neq Y$ are parts of $\mathcal{P}'$, there are $s \neq t$ such that $X \subseteq L'_s$ and $Y \subseteq L'_t$. Since each $L'_\ell$ is an interval of $(L, \preceq^+_C)$, this implies that $X$ and $Y$ are non-overlapping for $\preceq^+_C$. Thus $\mathcal{P}'$ satisfies all desired properties.

Finally, given the BST $S$ and the family $\mathcal{P}$, it is routine to compute the weights $w_i$ of all nodes in $S$ by a bottom-up procedure; this only requires to compute the left-most and right-most parts of $\mathcal{P}$ intersecting each subtree. From this, one can in linear time choose the branch $B$, the indices $i_\ell$, the better side $L$ or $R$, and finally compute $C$ and $\mathcal{P}'$. ◀

## 5 BST orders witness twin-width

In this section, we prove Lemma 1.4, i.e. that BST orders are good for twin-width. The proof heavily uses model-theoretic results from [6]. Due to space constraints, the combinatorial proof of the stronger result Theorem 1.5 is omitted, see the extended version of this paper [16].

If $\mathcal{T}$ is a class of tournaments, we denote by $\mathcal{T}^{BST}$ the class of ordered tournaments $(T, <_S)$ where $T \in \mathcal{T}$ and $<_S$ is the order of some BST $S$ on $T$. With this notation, Lemma 1.4 can be restated as

▶ **Lemma 5.1.** *If $\mathcal{T}$ is a hereditary class of tournaments with bounded twin-width, then $\mathcal{T}^{BST}$ also has bounded twin-width.*

**Proof.** Fix $\mathcal{T}$ a class of tournaments with twin-width at most $t$, and assume by contradiction that $\mathcal{T}^{BST}$ has unbounded twin-width. Then by Theorem 2.1, for any $k$ there is some $(T, <_S) \in \mathcal{T}^{BST}$ whose adjacency matrix contains a rank-$k$ division. That is, there are partitions $A_1, \dots, A_k$ and $B_1, \dots, B_k$ of $V(T)$ into intervals of $<_S$ such that the adjacency matrix of any $A_i$ versus $B_j$ is $k$-diverse.

If $k$ is chosen to be $k = f(\ell)$ where $f$ is the function of Lemma 4.3, then we obtain two chain quasi-orders $\preceq^A, \preceq^B$ in $T$, and subfamilies $A_{i_1}, \dots, A_{i_\ell}$ and $B_{j_1}, \dots, B_{j_\ell}$ which are non-overlapping for $\preceq^A$ and $\preceq^B$ respectively. We can in fact assume that $A_{i_1}, \dots, A_{i_\ell}$ are disjoint intervals of $\preceq_A$, by replacing them by their closure

$$\bar{A}_{i_t} \stackrel{\text{def}}{=} \{x \mid \exists y, z \in A_{i_t},\ y \preceq_A x \preceq_A z\}$$

Let $T^+$ be the structure $T$ augmented by the quasi-orders $\preceq_A$ and $\preceq_B$. In $T^+$, each interval $\bar{A}_{i_t}$ can be described by its two endpoints. Using the terminology of [6, section 9], this means that $\bar{A}_{i_1}, \dots, \bar{A}_{i_\ell}$ is a *definable disjoint family*. Naturally, the same holds for $\bar{B}_{j_1}, \dots, \bar{B}_{j_\ell}$. Finally, $A_i$ versus $B_j$ being $k$-diverse is a very special case of the model-theoretic notion of $A$ having $k$ *distinct* $\Delta$*-types over* $B$, when $\Delta$ consists only of the formula "being adjacent".

Let $\mathcal{T}^+$ denote the class of tournaments in $\mathcal{T}$ augmented by any two chain quasi-orders. We have just proved that for arbitrary large $k, \ell$, there are structures $T^+ \in \mathcal{T}^+$ containing two families of $\ell$ disjoint subsets $\left(\bar{A}_{i_t}\right)_{t\in[\ell]}$ and $\left(\bar{B}_{j_t}\right)_{t\in[\ell]}$ definable by a fixed formula, and such that each $\bar{A}_{i_t}$ has $k$ distinct $\Delta$-types over each $\bar{B}_{j_t}$. That is, the class $\mathcal{T}^+$ is *unrestrained* in the sense of [6, Definition 50]. By [6, Theorem 54], it follows that $\mathcal{T}^+$ is not monadically NIP, hence has unbounded twin-width. But it follows from Lemma 4.2 that $\mathcal{T}^+$ is obtained from $\mathcal{T}$ by a first-order transduction, contradicting that $\mathcal{T}$ has bounded twin-width. ◀

## Abstract

A searcher faces a graph with edge lengths and vertex weights, initially having explored only a given starting vertex. In each step, the searcher adds an edge to the solution that connects an unexplored vertex to an explored vertex. This requires an amount of time equal to the edge length. The goal is to minimize the weighted sum of the exploration times over all vertices. We show that this problem is hard to approximate and provide algorithms with improved approximation guarantees. For the general case, we give a $(2e + \varepsilon)$-approximation for any $\varepsilon > 0$. For the case that all vertices have unit weight, we provide a 2e-approximation. Finally, we provide a PTAS for the case of a Euclidean graph. Previously, for all cases only an 8-approximation was known.

## 1 Introduction

A vital issue faced by disaster-relief teams sent to regions devastated by natural or man-made catastrophes is to decide where to search for buried or isolated people. The fundamental issues behind these decisions are that, in emergency situations, technical means for probing and for clearing areas are often limited, there is no full knowledge concerning the whereabouts of potential survivors, and rescue operations are time-critical since the chances of survival decrease with the time needed for rescue; see also the discussion in Averbakh and Pereira [13]. Mathematically, we model this problem using an undirected graph with edge lengths. The

vertices of the graph correspond to different locations in the disaster area, and the edges between them correspond to possible connections between the locations. The length of an edge corresponds to the time that is needed to clear the connection. Clearing a connection may mean to clear a road connection of rubble or explosives, or to dig in snow, dirt, or debris. There is a single rescue team initially located at a designated root vertex. Based on experience, the rescue team has knowledge about the number of survivors that is located at the different locations. The goal is to minimize the average time at which the survivors are reached.

A solution to the problem is given by a sequence of edges to clear until all vertices (with non-zero weight) can be reached. Once an edge is cleared, it can be traveled along in negligible time by the rescue team, so that only the time needed to clear edges is considered. A search problem of this kind is called *expanding search problem* (ESP) since the set of vertices accessible by the rescue team expands in every step. This is in contrast to *pathwise search problems* where the actual movement of the searcher is modeled and traversing an edge always requires time equal to the length of the edge, no matter whether it is the first traversal or not.

Generally speaking, expanding search problems are a suitable model when the time needed to traverse an edge for the first time is significantly higher than the time needed to traverse this edge any time after the first time, and, thus, the time needed for further movements can be neglected. Further applications of expanding search problems are in mining where the time needed to dig a new tunnel is much higher than moving via already dug tunnels to previously explored locations (Alpern and Lidbetter [4]) and when securing an area from a hidden explosive where the time needed to move within a safe region can be neglected compared to the time needed to secure a new area (Angelopoulos et al. [6]).

**Our contribution.** In this work, we provide polynomial-time approximation algorithms with improved approximation guarantees for ESP. We first give an approximation algorithm for the general case with arbitrary vertex weights with an approximation guarantee of $2\mathrm{e} + \varepsilon$ for any $\varepsilon > 0$ where $2\mathrm{e} \approx 5.44$ (Theorem 1). For the unweighted case where all vertices have the same weight, we provide an approximation algorithm with an approximation guarantee of $2\mathrm{e}$ (Theorem 6). The result for the unweighted case is obtained by concatenating $k$-minimum spanning trees ($k$-MSTs) for varying values of $k$ and of exponentially increasing length. Using the probabilistic method on lengths with random factor finally yields an additional factor of e. This technique has been used for pathwise search problems [16, 26]; we here adapt it to the case of expanding search. For the weighted case, instead of $k$-MSTs, we use the quota version of the $k$-MST problem where vertices have non-negative weights and, given $q \in \mathbb{N}$, the task is to find a length-minimal tree with vertex weight at least $q$. Johnson et al. [31] noted that any approximation algorithm for $k$-MST that relies on the Goemans–Williamson algorithm [27] for the prize-collecting Steiner-tree problem can be turned into an approximation algorithm for the quota version with the same approximation guarantee. We follow this line of reasoning and show that also the approximation algorithm of Garg [25] that relies on a modified version of the Goemans–Williamson algorithm can be turned into a 2-approximation algorithm for the quota version of the problem. Relying on this result, we solve the quota version for a polynomial number of quotas (thereby losing the factor of $1 + \varepsilon$) and use these solutions to construct a sequence of spanning trees of exponentially increasing length. Concatenating these solutions yields the claimed factor.

We then give a polynomial-time approximation scheme (PTAS) for the case of a Euclidean graph (Theorem 7). For this result, we use a decomposition approach by Sitters [40] for the pathwise search problem that relies on partitioning an instance into subinstances. A

central challenge when adapting this approach to the expanding search setting is that, unlike pathwise search, expanding search is not memoryless as points contained in one subinstance may be used as Steiner points in another subinstance. We address this difficulty by keeping such points in the subinstance with zero weight so that the partitions become overlapping. To obtain a PTAS for the subproblem, we adapt techniques developed by Arora [9] for Euclidean TSP. As a byproduct, we obtain a $(1+\varepsilon)$-approximate reduction from general ESP to unweighted ESP, implying an alternative $(2\mathrm{e}+\varepsilon)$-aproximation which may be of independent interest.

For all variants considered in this paper, i.e., the unweighted case, the weighted case, and the Euclidean case, the best approximation algorithm was an 8-approximation due to Hermans et al. [29].

Finally, we show that there is no PTAS for ESP unless $\mathsf{P}=\mathsf{NP}$ (Theorem 14). The proof follows a similar idea as the hardness proof for the traveling repairperson problem suggested in [15]. However, in comparison to the pathwise search, in our setting the solution needs to be structured. Showing this property turns out to be rather elaborate. Previously, it was only known that the expanding search problem is NP-hard [13]. Due to space constraints, we defer some proofs and more detailed descriptions to the full version of this paper [28].

**Further related work.** The unweighted pathwise search problem where all vertices have unit weight is also known as the *traveling repairperson problem*. Sahni and Gonzales [38] showed that the problem cannot be efficiently approximated within a constant factor unless $\mathsf{P}=\mathsf{NP}$ on complete non-metric graphs when the searcher is required to take a Hamiltonian tour. Afrati et al. [1] considered the problem in metric spaces and gave an exact algorithm with quadratic runtime when the metric is induced by a path. This can be improved to linear runtime as shown by García et al. [24]. Minieka [36] proposed an exact polynomial algorithm for the case that the metric is induced by an unweighted tree. Sitters [39] showed that the problem is NP-hard when the metric is induced by a tree with edge lengths 0 and 1.

The first approximation algorithm of the metric traveling repairperson problem is due to Blum et al. [15] who gave a 144-approximation. After a series of improvements [7, 8, 10, 26, 33], the best factor so far is a 3.59-approximation for general metrics [16], and a polynomial-time approximation scheme for trees [40] and on the Euclidean plane [40]. Further variants of the problem have been studied both in terms of exact solution methods and in terms of competitive algorithms, among other settings with directed edges [20, 21, 37], with processing times and time windows [43], with profits at vertices [18], with multiple searchers [17, 19, 35], and online variants [34]. The vertex-weighted version of the problem is often referred to as *the* pathwise search problem. It has been shown to be NP-hard in metric graphs by Trummel and Weisinger [42] and was further studied in [33]. The approximation schemes in [40] apply to the weighted case as well.

The expanding search problem has received considerably less attention in the literature than the pathwise problem. It has been shown to be NP-hard by Averbakh and Pereira [13]. Alpern and Lidbetter [4] introduced a polynomial-time algorithm for the case when the graph is a tree and gave heuristics for general graphs. Averbakh et al. [12] considered a generalization of the problem with multiple searchers when the underlying graph is a path; Tan et al. [41] considered multiple searchers in a tree network. The first constant-factor approximation for general metrics is the 8-approximation due to Hermans et al. [29], based on an exact algorithm on trees [4]. Angelopoulos et al. [6] studied the expanding search ratio of a graph. This value is defined as the minimum over all expanding searches of the maximum ratio of the time to reach a vertex by the search algorithm and the time to reach the same vertex by a shortest path. Angelopoulos et al. showed that this ratio is NP-hard to compute and gave a search strategy that achieves a $(4\ln 4)$-approximation of the optimum.

The pathwise and expanding search problems appear naturally as strategies of the seeker in a two-player zero sum game between hider and seeker where the hider chooses a vertex that maximizes the expected search time whereas the seeker aims to minimize the search time. Gal [22] computed the value (i.e., the unique search time in an equilibrium of the game) of the pathwise search game on a tree; Alpern and Lidbetter [4] computed this value for the expanding search game; see also [5] for approximations of this value for general graphs. For more details on search games, we refer to [2, 3, 23, 30, 32].

## 2 Preliminaries

We consider a connected undirected graph $G = (V, E)$ with $|V| = n$ and a designated root vertex $r \in V$. Every vertex $v \in V$ has a weight $w_v \in \mathbb{N} = \{0, 1, 2, \dots\}$, and we denote by $V^* \subseteq V$ the set of vertices with $w_v > 0$. Every edge $e \in E$ has a length $\ell_e \in \mathbb{N}$. We use $\mathbb{N}_{>0}$ when we refer to $\mathbb{N} \setminus \{0\}$. We consider an agent that is initially located at the root and performs an *expanding search pattern* $\sigma$. Such a pattern is given by a sequence of distinct edges $\sigma = (e_1, \dots, e_m)$ for some $m \leq n-1$ such that $r \in e_1$ and the set $\{e_1, \dots, e_i\}$ forms a tree in $G$ for all $i \in \{1, \dots, m\}$. For a vertex $v \in V^* \setminus \{r\}$, let $k_v(\sigma) = \inf\{i \in \{1, \dots, m\} : v \in e_i\}$ be the index of the first edge that contains $v$ and set $k_r(\sigma) = 0$. We then call $L_v(\sigma) = \sum_{i=1}^{k_v(\sigma)} \ell_{e_i}$ the *latency* of the vertex $v \in V^*$ under expanding search pattern $\sigma$. Our goal is to find an expanding search pattern $\sigma$ that minimizes the *total latency* $L(\sigma) = \sum_{v \in V^*} w_v L_v(\sigma)$. Note that vertices $v$ with $w_v = 0$ do not appear in the objective function, and, hence, do not need to be visited. They may, however, be used as Steiner vertices in the constructed search trees and, hence, cannot be contracted as in the pathwise search problem. When the pattern $\sigma$ is clear from context, we drop the dependency on $\sigma$ and simply write $L$, $L_v$, and $k_v$. The *length* $\ell(\sigma)$ of a search pattern $\sigma$ is given by the sum of edge costs, i.e., $\ell(\sigma) = \sum_{e \in \sigma} \ell_e$. Finally, for two expanding search patterns $\sigma = (e_1, \dots, e_m), \sigma' = (e'_1, \dots, e'_{m'})$, we denote by $\sigma + \sigma'$ their concatenation, i.e., the subsequence of $(e_1, \dots, e_m, e'_1, \dots, e'_{m'})$ in which any edge closing a cycle is skipped.

## 3 The weighted case

In this section, we consider the general case of the expanding search problem where the weights $w_v \in \mathbb{N}$ are arbitrary for all $v \in V \setminus \{r\}$, and $w_r = 0$. We prove the following theorem.

▶ **Theorem 1.** *For every $\varepsilon > 0$, there is a polynomial-time $(2\mathrm{e} + \varepsilon)$-approximation algorithm for the expanding search problem.*

The approximation algorithm that we devise in this section is based on the approximate solution of several quota versions of the prize-collecting Steiner tree problem. In this problem, we are given a connected undirected graph $G = (V, E)$ with designated root vertex $r \in V$, non-negative edge lengths $\ell_e \in \mathbb{R}_{\geq 0}, e \in E$, vertex weights $w_v \in \mathbb{N}$, $v \in V \setminus \{r\}$, and a quota $q \in [0, W]$, where $W \coloneqq \sum_{v \in V} w_v$. The task is to find a subgraph that is a tree $T = (V_T, E_T)$ such that $r \in V_T$ and $\sum_{v \in V_T} w_v \geq q$ minimizing $\ell(T) \coloneqq \sum_{e \in E_T} \ell_e$. We argue that this problem admits a 2-approximation. The proof can be found in the full version [28].

▶ **Lemma 2.** *For the quota version of the prize-collecting Steiner tree problem, a 2-approximation can be computed in polynomial time.*

To approximate ESP, fix $\varepsilon > 0$. For notational convenience, we show an approximation algorithm with guarantee $2(1+\varepsilon)\mathrm{e}$. We solve the quota problem for quotas $W - W(1+\varepsilon)^{-i}$ for all $i \in \{0, \dots, \omega\}$, where we let $\omega := \left\lceil \frac{\log W}{\log(1+\varepsilon)} \right\rceil$. Note that, for fixed $\varepsilon$, the number

$\omega$ is polynomial in the encoding length of the input. In this way, we obtain $\omega + 1$ trees $T_0, T_1, \dots, T_\omega$. By construction, tree $T_0$ has to collect a total weight of 0, so $T_0$ is the tree $T_0 = (\{r\}, \emptyset)$ consisting only of the root vertex. By the choice of $\omega$, the tree $T_\omega$ has to collect a total weight of $W - W(1+\varepsilon)^{-\omega} > W - 1$. This implies that the tree $T_\omega$ collects all weight since the weights are integers. We then construct a directed auxiliary graph $H = (V_H, A_H)$ with vertex set $V_H = \{0, \dots, \omega\}$ and arc set $A_H = \{(i,j) : i < j\}$. We set the cost of arc $(i,j)$ equal to $c_{i,j} = W(1+\varepsilon)^{-i}\ell(T_j)$. Next, we compute a shortest $(0,\omega)$-path $P = (n_0, \dots, n_l)$ with $n_0 = 0$ and $n_l = \omega$ for some $l \in \mathbb{N}$. We construct from this path an expanding search pattern with $l$ phases. In phase $j \in \{1, \dots, l\}$, we explore all edges in $e \in E[T_{n_j}]$ with $|e \cap (\bigcup_{i=0}^{j-1} V[T_{n_i}])| < 2$ in an order such that the subgraph of explored vertices is connected at all times. In that fashion, when phase $j$ is finished, all vertices in $V[T_{n_j}]$ have been explored. Since $n_l = \omega$ and $T_\omega$ collects the total weight $W$, all vertices $v$ with $w_v > 0$ have been explored when the algorithm terminates. Formally, the algorithm is given as follows:

1) For all $i \in \{0, 1, \dots, \omega\}$ solve the quota version of the prize-collecting Steiner tree problem with quota $q = W - W(1+\varepsilon)^{-i}$ with the 2-approximation algorithm of Lemma 2 and obtain $\omega + 1$ trees $T_0, T_1, \dots, T_\omega$.
2) Construct an auxiliary weighted directed graph $H = (V_H, A_H)$ with $V_H = \{0, 1, \dots, \omega\}$, $A_H = \{(i,j) \in V_H^2 : i < j\}$, and $c_{i,j} \coloneqq W(1+\varepsilon)^{-i}\ell(T_j)$.
3) Compute a shortest $(0,\omega)$-path $P = (n_0, n_1, \dots, n_l)$ with $n_0 = 0$ and $n_l = \omega$ in $H$.
4) For each phase $j \in \{1, \dots, l\}$ explore all unexplored vertices of $V[T_{n_j}]$ in any feasible order using the edge set of $E[T_{n_j}]$.

Let $\sigma_{\text{ALG}}$ be the expanding search pattern given by this algorithm. Let $q \in [0, W]$ be arbitrary and let $j(q) \in \{1, \dots, l\}$ be such that $W - W(1+\varepsilon)^{-n_{j(q)-1}} \leq q < W - W(1+\varepsilon)^{-n_{j(q)}}$. Then we define $\pi(q) \coloneqq \sum_{i=0}^{j(q)} \ell(T_{n_i})$. By $L_q(\sigma_{\text{ALG}})$ we denote the latency of quota $q$ in $\sigma_{\text{ALG}} = (e_1, ..., e_m)$, i.e., the sum of the edge cost of the shortest subsequence $(e_1, ..., e_k)$ of $\sigma_{\text{ALG}}$, such that the tree spanned by $(e_1, ..., e_k)$ has weight at least $q$. The following lemma gives an upper bound on the latency for each quota. Its proof uses the intuitive argument that the worst case for the latency is obtained when all trees are nested and exploration takes place only at the end of each tree. The formal proof can be found in the full version [28].

▶ **Lemma 3.** *The latency of quota $q \in [0, W]$ in $\sigma_{\text{ALG}}$ can be bounded by $L_q(\sigma_{\text{ALG}}) \leq \pi(q)$.*

We can now give an upper bound on $L(\sigma_{\text{ALG}})$. The proof relies on the specific way how the length of the arcs in $H$ are defined. Its proof can be found in the full version [28].

▶ **Lemma 4.** *For the total latency of the algorithm, we have $L(\sigma_{\text{ALG}}) \leq z$ where $z$ is the cost of a shortest $(0,\omega)$-path in $H$.*

The technically most challenging part of the analysis of the algorithm is to bound the cost of a shortest path in relation to the total latency of the optimal expanding search pattern. To this end, we use a probabilistic argument where a distribution over paths in $H$ corresponding to the exploration of trees with exponentially increasing weight is considered.

▶ **Lemma 5.** *Let $\sigma^*$ be an optimal expanding search pattern with total latency $L^* \coloneqq L(\sigma^*)$. Then, a shortest $(0,\omega)$-path in $H$ has cost at most $2(1+\varepsilon)\mathrm{e}L^*$.*

**Proof.** First, we give a lower bound on $L^*$. For this purpose, let $q \in [0, W]$ be arbitrary, and let $\lambda^*(q)$ denote the length of the optimal solution to the instance of the quota version of the rooted prize-collecting Steiner tree problem with quota $q$. Note that there are only finitely many trees $T$ that are subgraphs of $G$ and contain $r$, so $\lambda^*$ is a piece-wise constant function. The optimal expanding search pattern cannot achieve a total weight of $q$ with a latency smaller than $\lambda^*(q)$. Therefore, $L^* \geq \int_0^W \lambda^*(q)\,\mathrm{d}q$.

To show that the cost of the shortest $(0,\omega)$-path in $H$ is bounded from above by $2(1+\varepsilon)\mathrm{e}L^*$, we construct a random path and compute its expected cost. Let $\gamma > 1$ be a parameter whose value will be determined later, and let $b = \gamma^U$ where $U$ is a random variable uniformly drawn from $[0,1)$. We set $\tilde{m} \in \mathbb{N}$ to be the smallest number such that $\lambda^*(W) \leq b\gamma^{\tilde{m}}$. For $j \in \{0,\dots,\tilde{m}\}$, let $\tilde{n}_j \coloneqq \max\{k \in \{0,\dots,\omega\} : \ell(T_k) \leq 2b\gamma^j\}$. These values are well-defined as $\ell(T_0) = 0$. Note that the sequence $\tilde{n}_0, \tilde{n}_1, \dots, \tilde{n}_{\tilde{m}}$ is non-decreasing. We denote by $n_0, n_1, \dots, n_m$ the longest increasing subsequence of $\tilde{n}_0, \tilde{n}_1, \dots, \tilde{n}_{\tilde{m}}$. In the following, we compute the cost of the path $P = (n_0, n_1, \dots, n_m)$. Let $i \in \{0,\dots,m\}$ be such that $W - W(1+\varepsilon)^{-i} \leq q < W - W(1+\varepsilon)^{-(i+1)}$. Recall that $\pi(q) = \sum_{j=0}^{i+1} \ell(T_{n_j})$ is an upper bound on the latency of quota $q$, i.e., the sum of the lengths of all trees that lie on path $P$ up to the first tree that collects a quota of size $q$ all by itself.

For a quota $q \in [0,W]$ we find it convenient to denote by $\bar{q} \coloneqq W - q$ the quota left aside. Let $\bar{q} \in [W(1+\varepsilon)^{-\omega}, W]$ be arbitrary, and let $j \in \{0,\dots,m\}$ and $d \in [1,\gamma)$ be such that $\lambda^*(W-\bar{q}) = d\gamma^j$. We distinguish two cases regarding the relation between $b$ and $d$.

**First case: $d \leq b$.** Since $\lambda^*(q) = \lambda^*(W-\bar{q}) = d\gamma^j$, there is a tree of cost $d\gamma^j$ that contains the root and explores a total weight of at least $W - \bar{q}$. When computing the 2-approximation for the quota version of the prize-collecting Steiner tree problem with quota $W - W(1+\varepsilon)^{-i}$, we obtain a tree $T_i$ with length $\ell(T_i) \leq 2\lambda^*\big(W - W(1+\varepsilon)^{-i}\big) \leq 2\lambda^*(W-\bar{q}) = 2d\gamma^j$. The first inequality is obtained by using the 2-approximation and the second inequality from $\lambda^*$ being non-decreasing. Since $\ell(T_i) \leq 2d\gamma^j \leq 2b\gamma^j$, we have that $n_j \geq i$. Using that $\pi(q)$ is non-decreasing, that $W - W(1+\varepsilon)^{-i} \geq W - (1+\varepsilon)\bar{q}$, and that $\gamma > 1$, we obtain

$$\pi\big(W - (1+\varepsilon)\bar{q}\big) \leq \sum_{k=0}^{j} \ell(T_{n_k}) \leq \sum_{k=0}^{j} 2b\gamma^k = 2b\frac{\gamma^{j+1}-1}{\gamma-1} \leq 2b\gamma^j\frac{\gamma}{\gamma-1}.$$

**Second case: $d > b$.** Analogously to the first case we obtain $\ell(T_i) \leq 2d\gamma^j$. However, with $1 \leq b$ and $d < \gamma$ we have $d < b\gamma$ which yields $\ell(T_i) \leq 2d\gamma^j < 2b\gamma^{j+1}$. Hence, we have that $n_{j+1} \geq i$. Again, using that $\pi(q)$ is non-decreasing, that $W - W(1+\varepsilon)^{-i} \geq W - (1+\varepsilon)\bar{q}$, and that $\gamma > 1$, we obtain

$$\pi\big(W - (1+\varepsilon)\bar{q}\big) \leq \sum_{k=0}^{j+1} \ell(T_{n_k}) \leq \sum_{k=0}^{j+1} 2b\gamma^k = 2b\frac{\gamma^{j+2}-1}{\gamma-1} \leq 2b\gamma^{j+1}\frac{\gamma}{\gamma-1}.$$

Note that we are in the first case when $U \in [\log_\gamma d, 1]$ and in the second case when $U \in [0, \log_\gamma d)$. Taking the expectation over $U$, we obtain

$$\begin{aligned}
\mathbb{E}_U\big[\pi\big(W-(1+\varepsilon)\bar{q}\big)\big] &\leq \int_{\log_\gamma d}^{1} 2b\gamma^j\frac{\gamma}{\gamma-1}\,\mathrm{d}U + \int_{0}^{\log_\gamma d} 2b\gamma^{j+1}\frac{\gamma}{\gamma-1}\,\mathrm{d}U \\
&= 2\gamma^j\frac{\gamma}{\gamma-1}\left[\int_{\log_\gamma d}^{1}\gamma^U\,\mathrm{d}U + \gamma\int_{0}^{\log_\gamma d}\gamma^U\,\mathrm{d}U\right] = 2\gamma^j\frac{\gamma}{\gamma-1}\left[\frac{\gamma-d}{\ln\gamma} + \gamma\frac{d-1}{\ln\gamma}\right] \\
&= 2\gamma^j d\frac{\gamma}{\ln\gamma} = 2\frac{\gamma}{\ln\gamma}\lambda^*(W-\bar{q}).
\end{aligned}$$

Next, consider the case that $\bar{q} < W(1+\varepsilon)^{-\omega}$ is arbitrary. Let $j \in \{0,\dots,m\}$ and $d \in [1,\gamma)$ be such that $\lambda^*(W-\bar{q}) = d\gamma^j$. By the choice of $\omega$, we have $W - \bar{q} > W - W(1+\epsilon)^{-\omega} > W - 1$, and, hence, $\lambda^*(W) = \lambda^*(W-\bar{q})$. We distinguish two cases regarding the relation of $b$ and $d$.

**First case: $d \leq b$.** Since $\lambda^*(W) = d\gamma^j$, there is a tree of cost $d\gamma^j$ containing the root that explores a total weight of at least $W - \bar{q}$. When computing the 2-approximation for the quota version of the prize-collecting Steiner tree problem with quota $W - W(1+\varepsilon)^{-\omega}$, we obtain a tree $T_\omega$ with length $\ell(T_\omega) \leq 2\lambda^*(W) = 2d\gamma^j \leq 2b\gamma^j$, which yields $n_j \geq \omega$, and thus, $j = m$. By using $\gamma > 1$, we obtain

$$\pi\big(W\big) \leq \sum_{k=0}^{m} \ell(T_{n_k}) \leq \sum_{k=0}^{m} 2b\gamma^k = 2b\frac{\gamma^{m+1}-1}{\gamma-1} \leq 2b\gamma^m \frac{\gamma}{\gamma-1}.$$

**Second case: $d > b$.** Analogously to the first case, we obtain $\ell(T_\omega) \leq 2d\gamma^j$. However, with $1 \leq b$ and $d < \gamma$ we have $d < b\gamma$ which yields $\ell(T_\omega) \leq 2d\gamma^j < 2b\gamma^{j+1}$. Hence, we have that $n_{j+1} \geq \omega$, i.e., $j \geq m-1$. In any case, by using that $\gamma > 1$, we obtain

$$\pi(W) \leq \sum_{k=0}^{m} \ell(T_{n_k}) \leq \sum_{k=0}^{m} 2b\gamma^k = 2b\frac{\gamma^{m+1}-1}{\gamma-1} \leq 2b\gamma^m \frac{\gamma}{\gamma-1}.$$

Again, we are in the first case when $U \in [\log_\gamma d, 1]$ and in the second case when $U \in [0, \log_\gamma d)$. Taking the expectation over $U$, we obtain

$$\begin{aligned}
\mathbb{E}_U\big[\pi\big(W\big)\big] &\leq \int_{\log_\gamma d}^{1} 2b\gamma^j \frac{\gamma}{\gamma-1}\,\mathrm{d}U + \int_{0}^{\log_\gamma d} 2b\gamma^{j+1}\frac{\gamma}{\gamma-1}\,\mathrm{d}U \\
&= 2\gamma^j \frac{\gamma}{\gamma-1}\left[\int_{\log_\gamma d}^{1} \gamma^U\,\mathrm{d}U + \gamma\int_{0}^{\log_\gamma d}\gamma^U\,\mathrm{d}U\right] = 2\gamma^j\frac{\gamma}{\gamma-1}\left[\frac{\gamma-d}{\ln\gamma} + \gamma\frac{d-1}{\ln\gamma}\right] \\
&= 2\gamma^j d\frac{\gamma}{\ln\gamma} = 2\frac{\gamma}{\ln\gamma}\lambda^*(W). \qquad (1)
\end{aligned}$$

The expected cost of the $(0,\omega)$-path $P = (n_0, n_1, \ldots, n_m)$ is then given by

$$\mathbb{E}\big[c(P)\big] = \mathbb{E}\left[\int_0^W \pi(q)\,\mathrm{d}q\right] = \mathbb{E}\left[\int_0^W \pi(W-\bar{q})\,\mathrm{d}\bar{q}\right].$$

As $\pi(q)$ is piece-wise constant, we exchange the order of expectation and integral such that

$$\begin{aligned}
\mathbb{E}\big[c(P)\big] &= \int_0^W \mathbb{E}\big[\pi(W-\bar{q})\big]\,\mathrm{d}\bar{q} \\
&= -(1+\varepsilon)\left(\int_{W(1+\varepsilon)^{-1}}^{W(1+\varepsilon)^{-\omega}} \mathbb{E}\big[\pi\big(W-(1+\varepsilon)\bar{q}\big)\big]\,\mathrm{d}\bar{q} + \int_{W(1+\varepsilon)^{-\omega}}^{0} \mathbb{E}\big[\pi\big(W-(1+\varepsilon)\bar{q}\big)\big]\,\mathrm{d}\bar{q}\right) \\
&\leq (1+\varepsilon)\int_{W(1+\varepsilon)^{-\omega}}^{W(1+\varepsilon)^{-1}} \mathbb{E}\big[\pi\big(W-(1+\varepsilon)\bar{q}\big)\big]\,\mathrm{d}\bar{q} + W(1+\varepsilon)^{-(\omega-1)}\mathbb{E}\big[\pi(W)\big],
\end{aligned}$$

where we further used the substitution rule for integrals and the fact that $\pi$ is non-decreasing. Using (1), we further obtain

$$\begin{aligned}
\mathbb{E}\big[c(P)\big] &\leq \frac{2\gamma(1+\varepsilon)}{\ln\gamma}\left[\int_{W(1+\varepsilon)^{-\omega}}^{W(1+\varepsilon)^{-1}} \lambda^*(W-\bar{q})\,\mathrm{d}\bar{q} + W(1+\varepsilon)^{-\omega}\mathbb{E}\big[\lambda^*(W)\big]\right] \\
&= \frac{2\gamma(1+\varepsilon)}{\ln\gamma}\int_0^{W(1+\varepsilon)^{-1}} \lambda^*(W-\bar{q})\,\mathrm{d}\bar{q},
\end{aligned}$$

where for the equation we used that $W(1+\varepsilon)^{-\omega} < 1$ and, hence, $\lambda^*$ is constant on the interval $[W - W(1+\varepsilon)^{-\omega}, W]$. Finally, we obtain

$$\mathbb{E}\big[c(P)\big] \leq \frac{2\gamma(1+\varepsilon)}{\ln\gamma}\int_0^W \lambda^*(W-\bar{q})\,\mathrm{d}\bar{q} = \frac{2\gamma(1+\varepsilon)}{\ln\gamma}\int_0^W \lambda^*(q)\,\mathrm{d}q \leq \frac{2\gamma(1+\varepsilon)}{\ln\gamma}L^*.$$

This shows that, in the expectation over $U$, $P$ has an expected cost of at most $\frac{2\gamma(1+\varepsilon)}{\ln\gamma}L^*$. Therefore, we obtain the same bound on the cost of the shortest path. This term is minimized for $\gamma = \mathrm{e}$, which implies the result. ◀

Theorem 1 now follows from combining Lemma 4 and Lemma 5.

## 4 The unweighted case

Compared to the weighted case we do the following adjustments in order to obtain a 2e-approximation. First, instead of using the quota problem of $k$-MST, for all $k \in \{1,\dots,n\}$ we solve the original $k$-MST problem with the 2-approximation algorithm of Garg [25] and obtain $n$ trees $T_1,\dots,T_n$. The auxiliary weighted directed graph $H = (V_H, A_H)$ is then defined by $V_H = \{1,2,\dots,n\}$, $A_H = \{(i,j) \in V_H^2 : i < j\}$, and $\ell_{i,j} := (n-i)c(T_j)$. Finally, we compute a shortest $(1,n)$-path $P = (n_0, n_1, \dots, n_l)$ with $n_0 = 1$ and $n_l = n$ in $H$. For each phase $j \in \{1,\dots,l\}$, we explore all unexplored vertices of $V[T_{n_j}]$ in any feasible order using the edge-set of $E[T_{n_j}]$. The better approximation factor is due to the fact that we save the factor of $(1+\varepsilon)$ since we can compute the $k$-MSTs for all relevant values of $k$, whereas before we needed a rounding technique. We then obtain the following result, which we prove in the full version [28].

▶ **Theorem 6.** *There is a polynomial-time* 2e*-approximation algorithm for the unweighted expanding search problem.*

## 5 The Euclidean case

In this section, we show the following theorem.

▶ **Theorem 7.** *On Euclidean graphs, there exists a PTAS for ESP.*

Our approach has three steps, corresponding to the three subsections of this section. The first two steps are reductions inspired by Sitters [40]. In the first step, we show a reduction from ESP to a problem called $\delta$-bounded ESP, for some constant $\delta \in \mathbb{R}_+$, in the sense that a PTAS for $\delta$-bounded ESP implies a PTAS for ESP. In the next step, we reduce the latter problem to another problem called $\kappa$-segmented ESP, for some constant $\kappa \in \mathbb{N}$, with weights in $\{0,1\}$, in the same sense as before. Finally, we provide a PTAS for the latter problem in the Euclidean case using ideas by Arora [9] as well as Sitters [40].

We define the auxiliary subproblems as modifications of ESP. First, in $\delta$-bounded ESP, the input comes with an additional delay parameter $D \geq 0$, and it is guaranteed that there exists a solution visiting all nonzero-weight vertices and completing by time $\delta D$, i.e. this solution has length $\delta D$ (recall definition in Section 2). The objective is minimizing $L'(\sigma) = \sum_{v\in V^*} w_v L'_v(\sigma)$ where $L'_v(\sigma) = D + L_v(\sigma)$. Second, in $\kappa$-segmented ESP, the output needs to come with $\kappa+1$ additional numbers $0 = t^{(0)} \leq t^{(1)} \leq \cdots \leq t^{(\kappa)}$. For $v \in V$, its rounded search time is then $\bar{L}_v(\sigma) = \inf\{t^{(i)} : 0 \leq i \leq \kappa,\, L_v(\sigma) \leq t^{(i)}\}$, and the objective is minimizing $\bar{L}(\sigma) = \sum_{v\in V^*} w_v \bar{L}_v(\sigma)$.

We assume $0 < \varepsilon \leq 1$ and use $O_\varepsilon(f)$ to denote $O(f)$ when $\varepsilon$ is a constant.

## 5.1 Reducing ESP to $\delta$-Bounded ESP

In this subsection, we show the following lemma.

▶ **Lemma 8.** *Consider any class $\mathcal{C}$ of metric spaces and constants $\alpha > 1, \varepsilon > 0$. There exists a constant $\delta$ such that, if there exists a polynomial-time $\alpha$-approximation algorithm for $\delta$-bounded ESP on $\mathcal{C}$, then there exists an $(\alpha + \varepsilon)$-approximation algorithm for ESP on $\mathcal{C}$.*

We follow the decomposition approach by Sitters [40] and adapt it to ESP at several places. To do so, we assume that a polynomial-time $\alpha$-approximation algorithm for $\delta$-bounded ESP on $\mathcal{C}$, denoted $\textsc{Approx}_{\delta\text{-bd}}$ in the following, is given for a yet-to-be-determined value of $\delta$. In the remainder of this subsection we describe, given any $\varepsilon > 0$, a polynomial-time algorithm for ESP on $\mathcal{C}$ based on this, and we show that it is a $(\alpha + O(\varepsilon))$-approximation algorithm.

For some constant $\beta$, we need, in addition to $\textsc{Approx}_{\delta\text{-bd}}$, a polynomial-time $\beta$-approximation algorithm $\textsc{Approx}_\beta$ for ESP on $\mathcal{C}$ as a subroutine. We emphasize that *any* constant $\beta$ is sufficient to obtain an approximation guarantee of $\alpha + \varepsilon$ in polynomial time. Therefore, we can pick, e.g., the algorithm from Section 3. For notational purposes, we assume $\alpha \neq \beta$.

In our algorithm, we apply $\textsc{Approx}_\beta$ to obtain an order of the vertices according to their search times in the solution, and we obtain a partition of the vertices by cutting this order at several places. We run $\textsc{Approx}_{\delta\text{-bd}}$ on the (carefully defined) emerging subinstances. We can, however, not simply concatenate all these solutions because any of these solutions may, despite its low cost, have large total length, which would delay the solutions of all later subinstances. We solve this issue by cutting the solution at a certain point and using the solution given by $\textsc{Approx}_\beta$ from then on – a solution with a length bound.

In the following, we present our algorithm which is given some $\varepsilon > 0$ as well as an instance $I$ of ESP on $\mathcal{C}$. Our algorithm has five steps.

1) **Approximate:** Apply $\textsc{Approx}_\beta$ to the instance to obtain a solution $\sigma_\beta$.
2) **Partition:**
   - Define $\gamma := 3/\varepsilon$, $a := \beta\gamma/\varepsilon$, and pick $b$ uniformly at random in $[0, a]$.
   - Define time points $t_i := \mathrm{e}^{(i-2)a+b}$ for $i \in [q+1]$, where $q$ is as small as possible such that $L_v(\sigma_\beta) < t_{q+1}$ for all $v \in V$.
   - For $i \in [q]$, let $V_i := \{v \in V : t_i \leq L_v(\sigma_\beta) < t_{i+1}\}$ and $U_i := V_1 \cup \cdots \cup V_i$.
   - For $i \in [q]$, define $I_i$ to be an instance which is obtained from $I$ by setting the weight of all vertices in $V \setminus V_i$ to zero. Note that $I_i$ with delay parameter $\gamma t_i$ is an instance of $(\mathrm{e}^a/\gamma)$-bounded ESP. Indeed, the prefix $\sigma_{\beta,i+1}$ of $\sigma_\beta$ visiting $U_{i+1}$ has total length at most $(\mathrm{e}^a/\gamma)\gamma t_i = t_{i+1}$.
3) **Approximate subproblems:** For $i \in [q]$, apply $\textsc{Approx}_{\delta\text{-bd}}$ to $I_i$ to obtain an $\alpha$-approximation $\sigma_{\alpha,i}$.
4) **Modify:** For each $i \in [q]$, define $\sigma_i$ to be $\sigma'_{\alpha,i} + \sigma_{\beta,i+1}$ where:
   - $\sigma'_{\alpha,i}$ is the longest prefix of $\sigma_{\alpha,i}$ of length at most $(1 + \mathrm{e}^a/\varepsilon\gamma)\gamma t_i$.
   - $\sigma_{\beta,i+1}$ is the prefix of $\sigma_\beta$ visiting $U_{i+1}$.
5) **Concatenate:** Return $\sigma_1 + \cdots + \sigma_q$.

We show Lemma 8 by establishing two lemmata on the above algorithm. We first prove that partitioning the instance into multiple instances of $(\mathrm{e}^a/\gamma)$-bounded ESP is only at the loss of a $1 + \varepsilon$ factor in the achievable (total) objective-function value. Formally, we denote by $\sigma^*$ an optimal solution for $I$ and, for all $i \in [q]$, by $\sigma_i^*$ an optimal solution for $I_i$. The proofs of the following two lemmata can be found in the full version [28].

▶ **Lemma 9.** *It holds that* $\mathbb{E}\left[\sum_{i\in[q]} L'(\sigma_i^*)\right] \leq (1+\varepsilon)L(\sigma^*)$.

The next lemma is concerned with Step 4 of the algorithm. For all $i \in [q]$, it bounds the cost of $\sigma_i$ against the cost of $\sigma_i^*$, and it also bounds the total length of $\sigma_i$.

▶ **Lemma 10.** *For each $i \in [q]$, the total length of $\sigma_i$ is at most $\gamma t_{i+1} - \gamma t_i$. Furthermore, it holds that $L'(\sigma_i) \leq \alpha(1+\varepsilon)L'(\sigma_i^*)$.*

With these lemmata at hand, Lemma 8 easily follows.

**Proof of Lemma 8.** Note that Lemma 10 implies that, in the concatenation of $\sigma_1, \ldots, \sigma_q$, $\sigma_i$ starts after a total length of at most $\gamma t_i$, for all $i \in [q]$. Therefore, again by Lemma 10, the cost of the concatenation, as a solution to $I$, has expected cost at most the left-hand side of the inequality in Lemma 10 summed over all $i \in [q]$. Hence, applying this inequality, taking expectation, and then applying Lemma 9 completes the proof. ◀

The partition as stated in the decomposition algorithm is a random partition. We note that the algorithm can be derandomized using the same techniques as in [40], i.e., by enumerating all partitions.

We also observe that, from now on, we may also assume that all weights are in $\{0, 1\}$. This is due to the following lemma, proven by Sitters [40] for pathwise search, but the same proof works in our case as shown in the full version [28].

▶ **Lemma 11** (See [40], Lemma 2.10)**.** *Consider any class $\mathcal{C}$ of metric spaces and any constants $\alpha > 0, \delta, \varepsilon > 0$. If there exists a polynomial-time $\alpha$-approximation algorithm for $\delta$-bounded ESP with weights in $\{0, 1\}$, then there exists a polynomial-time $(\alpha+\varepsilon)$-approximation algorithm for $\delta$-bounded ESP.*

Note that Lemma 10 and 11, together with Theorem 6, yields an alternative polynomial-time $(2\mathrm{e} + \varepsilon)$-approximation algorithm for the general ESP (Theorem 1).

## 5.2 Reducing $\delta$-Bounded ESP to $\kappa$-Segmented ESP

The following lemma can be proven analogously to a lemma of Sitters [40].

▶ **Lemma 12** (See [40], Lemma 2.14)**.** *Consider any class of metric spaces $\mathcal{C}$, any class of weights $\mathcal{W}$, and any constants $\alpha > 1, \delta, \varepsilon > 0$. If, for each constant $\kappa$, there exists a polynomial-time $\alpha$-approximation algorithm for $\kappa$-segmented ESP on $\mathcal{C}$ with weights $\mathcal{W}$, then there exists a polynomial-time $(\alpha + \varepsilon)$-approximation algorithm for $\delta$-bounded ESP $\mathcal{C}$ with weights $\mathcal{W}$.*

In the proof of the lemma, a similar idea as for the proof of Lemma 10 is used to show that there is a cheap solution that completes before time $O_\varepsilon(1+\delta)D$, where $D$ is the given delay of the instance. Then, by considering appropriate time points starting at $D$ and growing exponentially with base $(1 + \Theta(\varepsilon))$, one can show that for $\kappa \in O_\varepsilon(\log(1+\delta))$, an $\alpha$-approximate solution for the $\kappa$-segmented version of the instance can be transformed into the desired $((1+\varepsilon)\alpha)$-approximate solution for the original instance.

## 5.3 A PTAS for $\kappa$-Segmented ESP in the Euclidean Case

Sitters [40] observed that, in Euclidean space, the QPTAS for the traveling repairperson problem [10] (which is based on the well-known PTAS by Arora for TSP [9]) can be turned into a PTAS for the segmented version of the traveling repairperson problem. In this section, we observe that an adapted approach yields a PTAS for Euclidean segmented ESP with

weights in $\{0, 1\}$. We focus on the two-dimensional case; an extension to the $d$-dimensional case for constant $d$ is straightforward. The following description is self-contained up to parts deferred to the full version [28], but familiarity with Arora's PTAS [9] may still be helpful.

### 5.3.1 Setup

The core of our PTAS for segmented ESP is the dynamic-programming procedure. Before this procedure is called, however, there are several preprocessing steps. First, consider a smallest axis-aligned square that contains all weight-1 vertices from the input. We denote it by $S_0$ and its side length by $d_0$. Note that $d_0$ is a lower bound on the cost of an optimal solution. An optimal solution is, however, not necessarily entirely contained in the square as it may use a weight-0 vertex outside the square as a "Steiner" vertex. We therefore enlarge the square from its center by a factor of $3n^2 + 1$, yielding a new square $S$ with side length $d = (3n^2 + 1)d_0$. The scaling factor is chosen such that all points whose distance from $S_0$ is at least $\sqrt{2}n^2 d_0$ are included. Note that there exists an optimal solution that is entirely contained in $S$ because a trivial upper bound on the cost of the optimal solution of $\sqrt{2}n^2 d_0$ can be obtained by connecting all weight-1 vertices to $r$. We can therefore ignore all input points outside $S$.

**Round the instance.** We place a grid of granularity $\Theta(\varepsilon d/n^4)$ within $S$ and move each input point to a closest grid point. Note that, this way, several input points may end up at the same location. In the same way as in the literature [10], any solution for the rounded instance can be turned into a solution for the original instance at a cost of $O(\varepsilon)\mathrm{OPT}$ in the objective-function value: The additional cost of $O(\varepsilon d/n^3)$ per vertex can be charged to the objective as it is $\Omega(d/n^2)$ by construction of $S$.

**Build random quadtree.** We first obtain an even larger square from $S$ by enlarging it by an additional factor of 2 from its center and then shifting it to the left by a value $a$ chosen uniformly at random from $\{-d/2, -d/2 + 1, \ldots, d/2 - 1, d/2\}$ and to the top by a value $b$ chosen uniformly at random from the same set, independently from $a$. Note that, in any event, the resulting square $S'$ contains $S$.

We partition $S'$ into four equal-sized squares, which are recursively partitioned in the same way until they only contain a single grid point at which there is a vertex (but possibly many vertices). From this partition, a so-called quadtree naturally emerges by identifying each of the squares (also called cells in the following) with a node and making a node a child of another node if its corresponding square is one of the four smaller squares within that node's square. We root the quadtree at the node corresponding to $S'$. Since the minimum distance between any two vertices not at the same grid point is $\Theta(\varepsilon d/n^4)$ by the rounding step, the quadtree has depth $O(\log d)$.

**Derandomization.** We remark that the randomization is only for a simpler analysis. Indeed, our algorithm can be derandomized in the same way as Arora's PTAS and its variants: Simply try all, polynomially many, values for the random variables $a$ and $b$, and output the cheapest solution obtained this way.

### 5.3.2 Portal-respecting solutions and the structural result

The set of solutions over which the dynamic-programming procedure optimizes are so-called portal-respecting solutions. Such solutions only cross cell boundaries at so-called portals, and they do so only a constant number of times at each portal. For each cell, we place

$\Theta(\log n/\varepsilon)$ equidistant portals on each side of that cell, from corner to corner and including the corners. Additionally, each cell inherits all portals from all its ancestors in the quadtree. The following structural result states that we only lose a $1 + O(\varepsilon)$ factor when restricting to portal-respecting solutions.

▶ **Lemma 13.** *With constant probability (over the random placement of the quadtree), there exists a $(1 + O(\varepsilon))$-approximate portal-respecting solution.*

The result can be proved precisely in the same way as in [10], by applying Arora's structural result [9] to each segment. In [10], the pathwise version of our problem is considered, but this difference does not affect the proof.

### 5.3.3 Further setup

Before we describe the dynamic program, we need two additional setup steps.

**Additional rounding.** Since we guess lengths of parts of the solution, we assume at the loss of another $1+O(\varepsilon)$ factor that the distance between any two relevant points (i.e., input points or portals) is a polynomially bounded integer. This is possible because the objective-function value is the sum of polynomially many distances.

**Guessing of segment lengths.** It will be useful to know the completion times $t^{(1)}, \dots, t^{(\kappa)}$ before running the dynamic-programming procedure. By our rounding procedure, we know that there are only $n^{O(1)}$ options for each of these $O(1)$ lengths, meaning that there are $n^{O(1)}$ combinations of different completion times for each of the segments, which we can all guess.

### 5.3.4 Dynamic programming

For each cell $z$ of the quadtree we additionally "guess" the following pieces of information relevant for the other quadtree cells (reflected in the fact that there is a DP entry for each combination). Specifically, for each segment $i \in [\kappa]$, we guess

- **(i)** the total length $\ell_i$ of segment $i$ within the cell,
- **(ii)** the number $m_i$ of times that the segment crosses the boundary of the cell, and for each $j \in [m_i]$ of these crossing a *type* $\tau_{i,j}$ for the $j$-th such time, containing
  - the portal $p_{i,j}$ at which the cell is intersected, and
  - whether the segment enters or leaves the cell at $p_{i,j}$.

Note that, again, there are only polynomially many options for each of the parameters (in particular, $m_i$ can be assumed to be at most $O(\log n/\varepsilon)$, and we only have constantly many options for the type of each crossing) and therefore only polynomially many DP entries.

Any DP entry $\mathrm{DP}[z, (\ell_i, (\tau_{i,j})_{j\in[m_i]})_{i\in[\kappa]}]$ is supposed to contain the cost of the cheapest portal-respecting solution restricted to the corresponding cell obeying the constraints imposed by the guessed parameters and visiting all vertices within the cell. Note that such a solution may not exist (e.g., the cell does not contain the root but some other vertices, and no segment ever enters the cell), in which case the cost is $\infty$. Otherwise, the cost of a solution restricted to a cell refers to the sum over all vertices in that cell of the completion time of the segment that they are visited in.

With this definition, the entry $\mathrm{DP}[z_0, (t^{(i)} - \sum_{i'<i} t^{(i')}, ())_{i\in[\kappa]}]$ is supposed to contain the cost of the optimal portal-respecting solution, where $z_0$ is the root of the quadtree and $()$ is the empty tuple. By standard techniques, the actual solution can be recovered from these entries. The DP entries can be computed in a fairly standard manner. A more detailed description can be found in the full version [28].

## 6 Hardness of approximation

This section is dedicated to the following theorem.

▶ **Theorem 14.** *There exists some constant $\varepsilon > 0$ such that there is no polynomial-time $(1+\varepsilon)$-approximation algorithm for the expanding search problem, unless* P = NP.

The hardness result for ESP follows by a reduction from a variant of the Steiner tree problem which is defined as follows. Given a graph $G = (V, E)$ with non-negative edge costs and a set $T \subseteq V$ of vertices, the so-called terminals, the Steiner tree problem on graphs asks for a minimum-cost tree that is a subgraph of $G$ and that contains all vertices in $T$. The variant that we consider and use is the so-called SteinerTree(1,2), short ST(1,2), where $G$ is a complete graph and all edge costs are either 1 or 2. Bern and Plassmann [14] showed the following theorem.

▶ **Theorem 15** (Theorem 4.2 in [14]). *SteinerTree(1,2) is* MaxSNP*-hard.*

It was shown in [11] that there exists no polynomial-time approximation scheme for any MaxSNP-hard problem, unless P = NP. Hence, there exists some constant $\rho > 0$ such that there is no polynomial-time $(1+\rho)$-approximation algorithm for ST(1,2), unless P = NP. We use this to show the hardness result for ESP.

The main idea of the proof of Theorem 14 is as follows. Given a $\beta$-approximation algorithm Alg$'$ for the expanding search problem for any $\beta > 1$, we construct a $\gamma$-approximation algorithm Alg for ST(1,2) with $\gamma < 1 + \rho$. With the approximation hardness of ST(1,2), this contradicts the existence of a $\beta$-approximation algorithm Alg$'$ for the expanding search problem for any $\beta > 1$. The construction of the ESP instance in the reduction from ST(1,2) is similar to the one used for the travelling repairperson problem. Therein, we construct several copies of the ST(1,2) instance, which are then connected to a root vertex with an edge of high cost. However, a significant challenge is that we need to prove that the obtained expanding search sequence fulfills a property which we call *structured*. Intuitively, this property means that no copy of the original ST(1,2) instance is visited more than once and that all edges belonging to one copy are contiguous within the expanding search pattern. This property is trivial for the travelling repairperson problem since here using an expensive edge from the root to one of the copies more than once increases the total cost significantly. In the expanding search problem, however, these costs are not paid multiple times. The exact construction of the ESP instance and the proof of Theorem 14 can be found in the full version [28].

## Abstract

The $k$-means++ algorithm by Arthur and Vassilvitskii [SODA 2007] is a classical and time-tested algorithm for the $k$-means problem. While being very practical, the algorithm also has good theoretical guarantees: its solution is $O(\log k)$-approximate, in expectation.

In a recent work, Bhattacharya, Eube, Roglin, and Schmidt [ESA 2020] considered the following question: does the algorithm retain its guarantees if we allow for a slight adversarial noise in the sampling probability distributions used by the algorithm? This is motivated e.g. by the fact that computations with real numbers in $k$-means++ implementations are inexact. Surprisingly, the analysis under this scenario gets substantially more difficult and the authors were able to prove only a weaker approximation guarantee of $O(\log^2 k)$. In this paper, we close the gap by providing a tight, $O(\log k)$-approximate guarantee for the $k$-means++ algorithm with noise.

## 1 Introduction

The $k$-means problem is a classical problem in computer science: given a *point set* $X \subseteq \mathbb{R}^d$ consisting of $n$ points and a parameter $k$, we are asked to return a set of $k$ *clusters* with corresponding cluster centers $C \subseteq \mathbb{R}^d$ so as to minimize the sum of the squared distances of points of $X$ with respect to their closest cluster center in $C$. Formally, we are asked to minimize the function $\varphi(X, C)$ defined by $\varphi(x, C) = \min_{c \in C} ||x - c||^2$ for a single point $x$ and as $\varphi(X, C) = \sum_{x \in X} \varphi(x, C)$ for a set of points.

There exists some fixed constant $c > 1$ such that it is NP-hard to find a $c$-approximate solution to the $k$-means objective [2, 4]. On the other hand, a substantial amount of work has been devoted to finding polynomial time algorithms with a good approximation guarantee, with the currently best approximation ratio being 5.912 [12]. On the practical side, the celebrated clustering algorithm $k$-means++ by Arthur and Vassilvitskii [3] is one of the classical algorithms for the $k$-means problem. Due to its simplicity, it is widely used in practice, for example in the well-known Python Scikit-learn library [18]. It is also very appealing from the theoretical perspective, as it returns a solution that is $O(\log k)$-approximate, in expectation.

The $k$-means++ algorithm (Algorithm 1 with $\varepsilon = 0$) is indeed very simple: we sample $C \subseteq X$ in $k$ steps. The first center is taken as a uniformly random point of $X$. To get each subsequent center, we always first compute the current costs $\varphi(x, C_i)$ for each $x \in X$; then we sample each point of $X$ as the next center with probability proportional to $\varphi(x, C_i)$.

In [10], the authors made an intriguing observation: the classical analysis of the algorithm by Arthur and Vassilvitski [3] fails to work if we allow small errors in the sampling probabilities. That is, consider Algorithm 1: this is the $k$-means++ algorithm, however, with an additional small positive parameter $\varepsilon$. In every step, before we sample, we allow an adversary to perturb the sampling distribution such that the multiplicative change of each probability is within $1 \pm \varepsilon$ of its original value.

**Algorithm 1** $(1+\varepsilon)$-noisy $k$-means++.

Input: $X$, $k$, $0 \le \varepsilon < 1/2$

1: Sample $x \in X$ w.p. in $\left[(1-\varepsilon)\cdot\frac{1}{n}, (1+\varepsilon)\cdot\frac{1}{n}\right]$, set $C_1 = \{x\}$.
2: **for** $i \leftarrow 0, 1, \ldots, k-1$ **do**
3: Sample $x \in X$ w.p. in $\left[(1-\varepsilon)\cdot\frac{\varphi(x,C_i)}{\varphi(X,C_i)}, (1+\varepsilon)\cdot\frac{\varphi(x,C_i)}{\varphi(X,C_i)}\right]$ and set $C_{i+1} = C_i \cup \{x\}$.
**return** $C := C_k$

Does the noisy $k$-means++ algorithm retain the original guarantees? This question is natural since in every implementation, there are small numerical errors associated with the distance computations made by Algorithm 1. It would be shocking if these errors could substantially affect the quality of the algorithm's output! From a more theoretical perspective, the authors of [10] considered this problem as a first step towards understanding other questions related to the $k$-means++ algorithm, in particular the analysis of the *greedy* variant of $k$-means++, a related algorithm later analyzed in [14].

Going back to noisy $k$-means++, the authors of [10] proved that Algorithm 1 remains $O(\log^2 k)$-approximate even for small constant $\varepsilon$ (think e.g. $\varepsilon = 0.01$). In this paper, we improve their analysis to recover the tight $O(\log k)$-approximation guarantee. That is, we show that the adversarial noise worsens the approximation guarantee by at most a constant multiplicative factor.

▶ **Theorem 1.** *Algorithm 1 is $O(\log k)$-approximate, in expectation.*

▶ Remark 2. It would be interesting to see an analysis of the approximation ratio of Algorithm 1 that would be within a $1 + O(\varepsilon)$-factor of the classical $k$-means++ analysis from [3], or a counterexample showing this is not possible. In our analysis, we lose a very large constant factor even for very small $\varepsilon$.

**Related Work.** There is a lot of work related to the $k$-means++ algorithm, both improving the algorithm or its analysis [16, 11, 1, 20, 17, 10, 14] and adapting it to other setups [8, 6, 19, 17, 5, 7, 9, 15].

## 2 Reduction to a Sampling Game

To analyze Algorithm 1, the authors of [10] follow the proof of [3] (more precisely, they follow the proof from [13]) and show that most arguments of that proof, in fact, work even in the adversarial noise scenario. The part of the proof that does not generalize from $\varepsilon = 0$ to $\varepsilon > 0$ can be distilled into a simple sampling process that we analyze in this paper. We next describe this process and state its relation to the analysis of noisy $k$-means++ (cf. the discussion on page 15 of [10]).

▶ **Definition 3** ($(1+\varepsilon)$-adversarial sampling process). *Let $0 < \varepsilon < 1/2$. We define the* $(1+\varepsilon)$-adversarial sampling process *as follows. At the beginning, there is a set $E_0$ of $k$ elements where each element $e \in E_0$ has some nonnegative weight $w_0(e)$. The process has $k$ rounds where in each round, we form the new set $E_{i+1}$ from $E_i$ as follows:*

1. *We define the distribution $D_i$ over $E_i$ where the probability of selecting $e \in E_i$ is defined as $w_i(e)/\sum_{e\in E_i} w_i(e)$. Next, an adversary chooses an arbitrary distribution $D_i^\varepsilon$ over $E_i$ that satisfies for any $e \in E_i$ that*

$$(1-\varepsilon)P_{D_i}(e) \le P_{D_i^\varepsilon}(e) \le (1+\varepsilon)P_{D_i}(e). \tag{1}$$

   *We sample an element $e_{i+1} \in E_i$ according to $D_i^\varepsilon$ and set $E_{i+1} = E_i \setminus \{e_{i+1}\}$.*
2. *Next, an adversary chooses a new weight function $w_{i+1}(e)$ for every element $e \in E_{i+1}$ as an arbitrary function that satisfies*

$$0 \le w_{i+1}(e) \le w_i(e).$$

We will be interested in the expected average weight of an element after some number of steps in this process, that is, we need to understand the value of $\mathrm{E}\left[\frac{\sum_{e\in E_i} w_i(e)}{k-i}\right]$ for $0 \le i < k$. If $\varepsilon = 0$, one can prove that

$$\mathrm{E}\left[\frac{\sum_{e\in E_i} w_i(e)}{k-i}\right] \le \frac{\sum_{e\in E_{i-1}} w_{i-1}(e)}{k-(i-1)} \tag{2}$$

where the randomness is over the sampling in the $i$-th step (we always regard the adversary as fixed in advance). Why is Equation (2) true? The inequality would clearly hold with equality if the distribution $D_i$ were a uniform one and there was no adversary; we in fact give larger sampling probabilities to heavier elements in $D_i$ and, moreover, the adversary can lower the weights arbitrarily after we sample, but both of these operations can make the left-hand side of Equation (2) only smaller.

However, this monotonic behavior is no longer true for $\varepsilon > 0$. The question that needs to be analyzed as a part of the analysis of noisy $k$-means++ is whether the adversarial choices can make the average size of an element drift so that in the end the left-hand side of Equation (2) is substantially larger than $\sum_{e\in E_0} w_0(e)/k$. More precisely, we will need to bound the following quantity that we call the adversarial advantage.

▶ **Definition 4** (Adversarial advantage). *We say that the adversarial advantage is at most some function $f$ if the following conclusion holds: Consider a $(1+\varepsilon)$-adversarial sampling process on $k$ elements for any $0 < \varepsilon < \frac{1}{2}$, any starting set $E_0$, and any adversary. For any $0 \le i < k$, we have*

$$E\left[\frac{\sum_{e\in E_i} w_i(e)}{k-i}\right] \le f(k) \cdot \frac{\sum_{e\in E_0} w_0(e)}{k}. \tag{3}$$

Although we require the inequality Equation (3) to hold for all $i$, note that for all $0 \le i \le (1-\delta)k$ we can choose $f(k) = 1/\delta$ in Equation (3) and it will be satisfied for those values of $i$ simply because $\sum_{e\in E_i} w_i(e) \le \sum_{e\in E_0} w_0(e)$ is true deterministically. Thus, intuitively, $i = k-1$ is the hardest case.

In [10], the authors proved that if we adapt the analysis of $k$-means++ to the noisy $k$-means++, it only picks up the multiplicative factor of $f(k)$. That is, analyzing the $(1+\varepsilon)$-adversarial sampling process is enough to get an upper bound for noisy $k$-means++. The following theorem is proven in [10] (it is proven only for $f(k) = O(\log k)$, but it directly generalizes to any $f(k)$).

▶ **Theorem 5** (Theorem 2 in [10]). *For any $0 < \varepsilon < 1/2$, $(1+\varepsilon)$-noisy k-means++ is $O(f(k) \cdot \log k)$-approximate, in expectation.*

In Lemma 10 of [10], the authors prove that $f(k) = O(\log k)$. The reason for this is that if an element $e \in E_0$ is $\Theta(\log k)$ times larger than the average size of an element of $E_0$, it will be sampled in the first $k/2$ steps of the process with probability $1 - 1/k^{O(1)}$. Thus, the contribution of elements $\Omega(\log k)$ larger than the average to the left-hand side of Equation (3) is negligible even for $i = k - 1$. Hence, $f(k) = O(\log k)$.

▶ **Lemma 6** (Lemma 10 in [10]). *The adversarial advantage is at most $O(\log k)$.*

Our technical contribution is to show that the adversarial advantage is bounded by $O(1)$.

▶ **Lemma 7.** *The adversarial advantage is at most $O(1)$.*

Theorem 1 then follows from Theorem 5 and Lemma 7.

## 3 Analysis of the Sampling Process

This section is devoted to the proof of Lemma 7. We view the adversary as a function fixed at the beginning of the argument. We start by normalizing the starting weights $w_0$ so that the average at the beginning is one, i.e., from now on we assume that $(\sum_{e \in E_0} w_0(e))/k = 1$. For every $E \subseteq E_i$, we define $w_i(E) = \sum_{e \in E} w_i(e)$ and similarly $P_{D_i^\varepsilon}(E) = \sum_{e \in E} P_{D_i^\varepsilon}(e)$. In every step $i$, we consider the partition $E_i = B_i \sqcup M_i \sqcup S_i$ where $e \in E_i$ is in

1. the big set $B_i$ iff $w_i(e) \geq 80$,
2. the medium set $M_i$ iff $2 < w_i(e) < 80$ and
3. the small set $S_i$ iff $w_i(e) \leq 2$.

The main idea of the analysis is to show that $w_i(B_i) = O(|S_i|)$, and thus $\frac{w_i(E_i)}{k-i} = \frac{O(|S_i|)}{|S_i|+|M_i|+|B_i|} = O(1)$, with probability $1 - e^{-\Omega(|S_i|)}$. This turns out (see the proof of Lemma 7) that this is sufficient to show that the adversarial advantage is $O(1)$, i.e., that $\mathrm{E}\left[\frac{w_i(E_i)}{k-i}\right] = O(1)$.

Roughly speaking, we call an iteration with $\ell$ small elements bad, if the total weight of the big elements is greater than $4\ell$, which intuitively means the average drifted way above 1. In general we use the number of the small elements as our main way to refer to the iterations. Then in Lemma 9 we denote with $\ell_{max}$ the number of small elements at the first bad iteration. Using that the previous iterations were good, and $w_{i_{2\ell}}(B_{i_{2\ell}}) \leq 8\ell$ for the bad iterations (Definition 8), we provide an upper bound on the average element size for the following iterations. Even though this bound is depending on the number of the small elements $\ell$, we show in Lemma 10 that an iteration is bad with probability at most $e^{-\frac{\ell}{40}}$, which is enough to show the constant average in expectation.

The following definition is crucial for our analysis.

▶ **Definition 8.** *For every $\ell \in \{1, 2, \ldots, |S_0|\}$, we define $i_\ell$ as the smallest $i$ for which $|S_i| = \ell$. We refer to a given $\ell \in \{1, 2, \ldots, \lfloor |S_0|/2 \rfloor\}$ as bad if both $w_{i_{2\ell}}(B_{i_{2\ell}}) \leq 8\ell$ and $w_{i_\ell}(B_{i_\ell}) > 4\ell$ and otherwise we refer to $\ell$ as good.*

Note that $i_\ell$ is well-defined in the sense that there has to exist at least one $i$ with $|S_i| = \ell$ for every $\ell \in \{1, 2, \ldots, |S_0|\}$. This follows from $|S_{i+1}| \geq |S_i| - 1$ for every $i \in \{1, 2, \ldots, k-1\}$ and $|S_{k-1}| \leq 1$.

▶ **Lemma 9.** *Let $\ell_{max}$ be defined as the largest $\ell \in \{1, 2, \ldots, \lfloor |S_0|/2 \rfloor\}$ such that $\ell$ is bad, if there exists such an $\ell$, and otherwise let $\ell_{max} = 1$. Then, for every $i \in \{0, 1, \ldots, k-1\}$, we have $\frac{w_i(E_i)}{k-i} \leq 90\ell_{max}$.*

**Proof.** We first prove by induction that $w_i(B_i) \leq \max(4|S_i|, 8\ell_{max})$ for every $i \in \{0, 1, \ldots, k-1\}$. As our base case, we consider any $i$ with $|S_i| \geq |S_0|/2$. Using that the average weight is 1 at the beginning, we get $|S_0| \geq k/2$ by Markov's inequality and therefore $w_i(B_i) \leq k \leq 2|S_0| \leq 4|S_i|$. For our induction step, consider some arbitrary $i$ with $|S_i| < |S_0|/2$. Let $\ell := |S_i|$. First, we consider the case that $\ell_{max} \geq \ell$. In particular, this implies $|S_{i-1}| \leq |S_i| + 1 \leq \ell + 1 \leq \ell_{max} + 1$ and therefore we get by induction that

$$w_i(B_i) \leq w_{i-1}(B_{i-1}) \leq \max(4|S_{i-1}|, 8\ell_{max}) \leq \max(4(\ell_{max}+1), 8\ell_{max}) \leq 8\ell_{max}.$$

Thus, it suffices to consider the case that $\ell > \ell_{max}$, which in particular implies that $\ell$ is good. We have $i_{2\ell} < i_\ell \leq i$ (since $\ell \leq |S_0|/2 \leq i$) and therefore we can assume by induction that $w_{i_{2\ell}}(B_{i_{2\ell}}) \leq \max(4(2\ell), 8\ell_{max}) = 8\ell$. As $\ell$ is good, this implies that $w_{i_\ell}(B_{i_\ell}) \leq 4\ell$ and therefore $w_i(B_i) \leq w_{i_\ell}(B_{i_\ell}) \leq 4\ell = 4|S_i|$. This finishes the induction and thus we indeed have $w_i(B_i) \leq \max(4|S_i|, 8\ell_{max})$ for every $i \in \{0, 1, \ldots, k-1\}$. Therefore,

$$\frac{w_i(E_i)}{k-i} \leq \frac{w_i(E_i)}{|S_i|+|M_i|+|B_i|} \leq \frac{w_i(B_i)}{\max(|S_i|,1)} + \frac{80(|S_i|+|M_i|)}{|S_i|+|M_i|} \leq \max(4, 8\ell_{max}) + 80 \leq 90\ell_{max}.$$

◀

▶ **Lemma 10.** *Let $\ell \in \{1, 2, \ldots, \lfloor |S_0|/2 \rfloor\}$. Then, $\ell$ is bad with probability at most $e^{-\frac{\ell}{40}}$.*

For the proof of Lemma 10, we need the following Chernoff-bound variant.

▶ **Lemma 11** (Chernoff bound). *Let $X_1, \ldots, X_\ell$ be independent Bernoulli-distributed random variables, each equal to one with probability $p$. Then,*

$$P\left(\sum_{i=1}^{\ell} X_i < \frac{p\ell}{2}\right) \leq e^{-p\ell/8}.$$

**Proof of Lemma 10.** Throughout the proof, we assume that $w_{i_{2\ell}}(B_{i_{2\ell}}) \leq 8\ell$. In particular,

$$|B_{i_{2\ell}}| \leq \frac{w_{i_{2\ell}}(B_{i_{2\ell}})}{80} \leq \frac{\ell}{10}.$$

Below, we will define for every $j \in \{1, 2, \ldots, \ell\}$ an indicator variable $X_j$ in such a way that

1. $\mathrm{E}[X_j | X_1, X_2, \ldots, X_{j-1}] \geq \frac{1}{5}$ for every $j \in \{1, 2, \ldots, \ell\}$ and
2. if $X := \sum_{j=1}^{\ell} X_j \geq \frac{\ell}{10}$, then $w_{i_\ell}(B_{i_\ell}) \leq 4\ell$.

The first property implies that $X$ stochastically dominates a random variable $X'$ which is the sum of $\ell$ independent Bernoulli-distributed random variables, each equal to one with probability 1/5. Thus, using Lemma 11, we get

$$\mathrm{P}\left[X < \frac{\ell}{10}\right] \leq \mathrm{P}\left[X' < \frac{\ell}{10}\right] \leq e^{-\frac{\ell}{40}}.$$

Thus, we can now use the second property to deduce that $\ell$ is bad with probability at most $e^{-\frac{\ell}{40}}$. It thus remains to define the random variables and show that they indeed satisfy the two properties. To that end, fix some $j \in \{1, 2, \ldots, \ell\}$. We define $i'_j$ as the smallest $i \in \{i_{2\ell}, i_{2\ell}+1, \ldots, i_\ell - 1\}$ with $|S_i| = 2\ell - j + 1$ and $e_{i+1} \notin M_i$. Note that there exists at least one such $i$ as there exists some $i$ with $|S_i| = 2\ell - j + 1$ and $|S_{i+1}| = 2\ell - j$, and for this $i$ it holds that $e_{i+1} \in S_i$ and therefore $e_{i+1} \notin M_i$. Note that it furthermore holds that $i'_1 < i'_2 < \ldots < i'_\ell$. We set $X_j = 1$ if $w_{i'_j}(B_{i'_j}) \leq 4\ell$ or $e_{i'_j+1} \in B_{i'_j}$ and otherwise we set $X_j = 0$. We start by showing that the second property holds by proving the contrapositive.

To that end, assume that $w_{i_\ell}(B_{i_\ell}) > 4\ell$. In particular, we have for every $j$ that $w_{i'_j}(B_{i'_j}) > 4\ell$. Thus, if $X_j = 1$, we get $e_{i'_j+1} \in B_{i'_j}$ and therefore $|B_{i'_j+1}| \leq |B_{i'_j}| - 1$. As $|B_{i_{2\ell}}| < \frac{\ell}{10}$, we therefore get that $X < \frac{\ell}{10}$, as needed.

It remains to show the first property. To that end, consider any $i$ and assume we have already sampled $e_1, \ldots, e_i$ in an arbitrary manner such that $|S_i| \leq 2\ell$ and $w_i(B_i) \geq 4\ell$. Then, conditioned on $e_{i+1} \notin M_i$, we get $e_{i+1} \in B_i$ with probability at least

$$\frac{D_i^\varepsilon(B_i)}{D_i^\varepsilon(B_i) + D_i^\varepsilon(S_i)} \geq \frac{(1-\varepsilon)w_i(B_i)}{(1-\varepsilon)w_i(B_i) + (1+\varepsilon)w_i(S_i)} \geq \frac{0.5 \cdot 4\ell}{0.5 \cdot 4\ell + 1.5 \cdot 2 \cdot 2\ell} \geq \frac{1}{5}.$$

In particular, this directly implies $\mathrm{E}[X_j | X_1, X_2, \ldots, X_{j-1}] \geq \frac{1}{5}$ for every $j \in \{1, 2, \ldots, \ell\}$. ◀

Finally, we are ready to prove Lemma 7 by combining Lemmas 9 and 10.

**Proof of Lemma 7.** Fix some $i \in \{0, 1, \ldots, k-1\}$. Let $\ell_{max}$ be defined as in Lemma 9. Lemma 9 gives that for every $\ell$ with $Pr[\ell_{max} = \ell] > 0$, we have

$$\mathrm{E}\left[\frac{\sum_{e \in E_i} w_i(e)}{k-i} | \ell_{max} = \ell\right] \leq 90\ell.$$

Moreover, for $\ell > 1$ , we can use Lemma 10 to deduce that $\mathrm{P}[\ell_{max} = \ell] \leq \mathrm{P}[\ell \text{ is bad}] \leq e^{-\frac{\ell}{40}}$. Therefore,

$$\mathrm{E}\left[\frac{\sum_{e \in E_i} w_i(e)}{k-i}\right] \leq \sum_{\ell=1}^{\infty} 90\ell \cdot e^{-\frac{\ell-1}{40}} = O(1).$$ ◀

## Abstract

Boob et al. [7] described an iterative peeling algorithm called Greedy++ for the Densest Subgraph Problem (DSG) and conjectured that it converges to an optimum solution. Chekuri, Qaunrud and Torres [10] extended the algorithm to supermodular density problems (of which DSG is a special case) and proved that the resulting algorithm Super-Greedy++ (and hence also Greedy++) converges. In this paper we revisit the convergence proof and provide a different perspective. This is done via a connection to Fujishige's quadratic program for finding a lexicographically optimal base in a (contra) polymatroid [18], and a noisy version of the Frank-Wolfe method from convex optimization [17, 25]. This yields a simpler convergence proof, and also shows a stronger property that Super-Greedy++ converges to the optimal dense decomposition vector, answering a question raised in Harb et al. [24]. A second contribution of the paper is to understand Thorup's work on ideal tree packing and greedy tree packing [46, 47] via the Frank-Wolfe algorithm applied to find a lexicographically optimum base in the graphic matroid. This yields a simpler and transparent proof. The two results appear disparate but are unified via Fujishige's result and convex optimization.

## 1 Introduction

In this paper we consider iterative greedy algorithms for two different combinatorial optimization problems and show that the convergence of these algorithms can be understood by combining two general tools, one coming from the theory of submodular functions, and the other coming from convex optimization. This yields simpler proofs via a unified perspective, while also yielding additional properties that were previously unknown.

**Densest subgraph and supermodularity.** We start with the problem that motivated this work, namely, the densest subgraph problem (DSG). The input to DSG is an undirected graph $G = (V, E)$ with $m = |E|$ and $n = |V|$. The goal is to return a subset $S \subseteq V$ that maximizes $\frac{|E(S)|}{|S|}$ where $E(S) = \{uv \in E : u, v \in S\}$ is the set of edges with both end points

in $S$. Throughout the paper, we let $\lambda(G) = \frac{|E(G)|}{|V(G)|}$ denote the density of graph $G(V, E)$. We treat the unweighted case for simplicity; all the results generalize to edge-weighted graphs. Goldberg [22] and Picard and Queyranne [37] showed that DSG can be efficiently solved via a reduction to the $s$-$t$ maximum-flow problem.

A different connection that shows polynomial-time solvability of DSG is important to this paper. Consider a real-valued set function $f : 2^V \to \mathbb{R}_+$ defined over the vertex set $V$, where $f(S) = |E(S)|$. This function is *supermodular*. A function $f$ is supermodular iff $-f$ is *submodular*. A real-valued set function $f : 2^V \to \mathbb{R}$ is submodular iff $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$ for all $A, B \subseteq B$. Submodular and supermodular set functions are fundamental in combinatorial optimization – see [41, 19].

Coming back to DSG, maximizing $|E(S)|/|S|$ is equivalent to finding the largest $\lambda$ such that $\lambda|S| - |E(S)| \geq 0$ for all $S \subseteq V$. This corresponds to minimizing the submodular set function $g$ where $g(S) = \lambda|S| - |E(S)|$. A classical result in combinatorial optimization is that the minimum of a submodular set function can be found in polynomial-time in the value oracle setting [41]. Thus, DSG can be solved via reduction to submodular set function minimization and binary search. The preceding connection also motivates the definition of a generalization of DSG called the densest supermodular set problem (DSS) [10]. The input is a non-negative supermodular function $f : 2^V \to \Re_+$, and the goal is to find $S \subseteq V$ that maximizes $\frac{f(S)}{|S|}$. DSS is polynomial-time solvable via submodular set function minimization. DSG, DSS and its variants have several applications in practice, and they are routinely used in graph and network analysis to find dense clusters or communities. We refer the reader to the extensive literature on this topic [32, 7, 14, 48, 43, 1, 49, 16, 34, 39, 6, 27, 2, 42, 30, 28]. DSG is also of interest in algorithms via its connection to arboricity and related notions – see [40, 13] for recent work.

**Faster algorithms, Greedy and Greedy++.** Although DSG is polynomial-time solvable via maxflow or submodular function minimization, the corresponding algorithms are not yet practical for the large graphs that arise in many applications; this is despite the fact that we now have very fast theoretical algorithms for maxflow and mincost flow [12]. For this reason there has been considerable interest in fast (approximation) algorithms. More than 20 years ago Charikar [9] showed that a simple "peeling" algorithm (Greedy) yields a 1/2-approximation for DSG. An ordering of the vertices as $v_{i_1}, v_{i_2}, \ldots, v_{i_n}$ is computed as follows: $v_{i_1}$ is a vertex of minimum degree in $G$ (ties broken arbitrarily), $v_{i_2}$ is a minimum degree vertex in $G - v_{i_1}$ and so on[1]. After creating the ordering, the algorithm picks the best suffix, in terms of density, among the $n$-possible suffixes of the ordering. Charikar also developed a simple exact LP relaxation for DSG. Charikar's results have been quite influential. Greedy can be implemented in (near)-linear time and has also been adapted to other variants. The LP relaxation has also been used in several algorithms that yield a $(1 - \epsilon)$-approximate solution [5, 8], and has led to a flow-based $(1 - \epsilon)$-approximation [10]. More recently, Boob et al. [7] developed an algorithm called Greedy++ that is based on combining Greedy with ideas from multiplicative weight updates (MWU); the algorithm repeatedly applies a simple peeling algorithm with the first iteration coinciding with Greedy but later iterations depending on a weight vector that is maintained on the vertices – the formal algorithm is described in a later section. The advantage of the algorithm is its simplicity, and Boob et al. [7] showed that it has good empirical performance. Moreover

[1] This peeling order is the same as the one used to create the so-called core decomposition of a graph [33] and the Greedy algorithm itself was suggested by Asahiro et al. [4].

they conjectured that GREEDY++ converges to a $(1-\epsilon)$-approximation in $O(1/\epsilon^2)$ iterations. Although their strong conjecture is yet unverified, Chekuri, Quanrud and Torres [10] proved that GREEDY++ converges in $O(\frac{\Delta \log |V|}{\epsilon^2 \lambda^*(G)})$ iterations where $\Delta$ is the maximum degree of $G$ and $\lambda^*(G)$ is the optimum density.

The convergence proof in [10] is non-trivial and relies crucially in considering DSS and supermodularity. [10] shows that GREEDY and GREEDY++ can be generalized to SUPERGREEDY and SUPERGREEDY++ for DSS, and that SUPERGREEDY++ converges to a $(1-\epsilon)$-approximation solution in $O(\alpha_f/\epsilon^2)$ iterations where $\alpha_f$ depends (only) on the function $f$.

**Dense subgraph decomposition and connections.** As we discussed, DSG is a special case of DSS and hence DSG inherits certain nice structural properties from supermodularity. One of these is the fact that the vertex set $V$ of every graph $G = (V, E)$ admits a unique decomposition into $S_1, S_2, \ldots, S_k$ for some $k$ using the following procedure: $S_1$ is the vertex set of the *unique maximal* densest subgraph, $S_2$ is the unique maximal densest subgraph after "contracting" $S_1$, and so on. The existence of such a unique decomposition is more transparent in the setting of DSS. The fact that there is a *unique* maximal densest set $S_1$ follows from supermodularity; if $A$ and $B$ are optimum dense sets then so is $A \cup B$. One can then consider a new supermodular function $f_{S_1} : 2^{V-S_1} \to \mathbb{R}$ defined over $V - S_1$ where $f_{S_1}(A) = f(S_1 \cup A) - f(S_1)$ for all $A \subseteq V - S_1$. The new function is also supermodular. Then $S_2$ is the unique maximal densest set for $f_{S_1}$. We iterate this process until we obtain an empty set. The decomposition also allows us to assign a density value $\lambda_v$ to each $v \in V$ (which corresponds to the density of the set when $v$ is in the maximal set). We call this the density vector associated with $f$. Dense decompositions follow from the theory of principal partitions of submodular functions [35, 36, 20]. In the context of graphs and DSG this was rediscovered by Tatti and Gionis who called it the locally-dense decomposition [45, 44], and gave algorithms for computing it. Subsequently, Danisch et al. [14] applied the well-known Frank-Wolfe algorithm for constrained convex optimization to a quadratic program derived from Charikar's LP relaxation for DSG. More recently, Harb et al. [24] obtained faster algorithms for computing the dense decomposition in graphs via Charikar's LP; they used a different method called FISTA for constrained convex optimization based on acceleration. Although DSS was not the main focus, [24] also made an important connection to Fujishige's result on lexicographically optimal base in polymatroids [18] which elucidated the work of Danisch et al. on DSG. We describe this next.

**Lexicographical optimal base and dense decomposition.** We briefly describe Fujishige's result [18] and its connection to dense decompositions. Let $f : 2^V \to \mathbb{R}_+$ be a monotone submodular set function ($f(A) \leq f(B)$ if $A \subset B$) that is also normalized ($f(\emptyset) = 0$). Following Edmonds, the polymatroid associated with $f$, denote by $P_f$ is the polyhedron $\{x \in \mathbb{R}^V \mid x \geq 0, x(S) \leq f(S) \quad \forall S \subseteq V\}$, where $x(S) = \sum_{i \in S} x_i$. The base polyhedron associated with $f$, denote by $B_f$, is the polyhedron $P_f \cap \{x \in \mathbb{R}^V \mid x(V) = f(V)\}$ obtained by intersecting $P_f$ with the equality constraint $x(V) = f(V)$. Each vector $x$ in $B_f$ is called a base. If $f$ is a monotone normalized *supermodular* function, we consider the contrapolymatroid $P_f = \{x \in \mathbb{R}^V \mid x \geq 0, x(S) \geq f(S) \quad \forall S \subseteq V\}$ (the inequalities are reversed), and similarly $B_f$ is the base contrapolymatroid obtained by intersecting $P_f$ with equality constraint $x(V) = f(V)$. Fujishige proved that there exists a unique lexicographically minimal base in any polymatroid, and morover it can found by solving the quadratic program: $\min \sum_v x_v^2$ s.t $x \in B_f$. In the context of supermodular functions, one obtains a similar result;

the quadratic program $\min \sum_v x_v^2$ s.t $x \in B_f$ where $B_f$ is contrapolymatroid associated with $f$ has a unique solution. As observed explicity in [24], the lexicographically optimal base gives the dense decomposition vector for DSS. That is, if $x^*$ is the optimal solution to the quadratic program then for each $v$, $x_v^* = \lambda_v$. In particular, as noted in [24], one can apply the well-known Frank-Wolfe algorithm to the quadratic program and it converges to the dense decomposition vector. As we will see later, each iteration corresponds to finding a maximum weight base in a contrapolymatroid which is easy to find via the greedy algorithm.

**(Ideal) Tree packings in graphs and the Tutte–Nash-Williams theorem.** Our discussion so far focused on DSG. Now we describe a different problem on graphs and relevant background. Our goal is to present a unified perspective on these two problems. The well-known Tutte–Nash-Williams theorem in graph theory (see [41]) establishes a min-max result for the maximum number of edge-disjoint spanning trees in a multi-graph $G$. Given an undirected graph $G = (V, E)$, and a partition $P$ of the vertices, let $E(P)$ denote the set of edges crossing the partition. The strength of a partition $P$ is defined as $\frac{|E(P)|}{|P|-1}$. Let $\mathcal{T}(G)$ denote all possible spanning trees of $G$. Let $\tau^*(G)$ denote the maximum number of edge-disjoint spanning trees in $G$. Then $\tau^*(G) = \min_P \lfloor \frac{|E(P)|}{|P|-1} \rfloor$. Further, if we define $\tau(G)$ to be the maximum *fractional* packing of spanning trees, then the floor can be removed and we have $\tau(G) = \min_P \frac{|E(P)|}{|P|-1}$. We note that the graph theoretic result is a special case of matroid base packing. Tree packings are useful for a number of applications. In particular, Karger [26] used tree packings and other ideas in his well-known near-linear randomized algorithm for computing the global minimum cut of a graph. We are mainly concerned here with Thorup's work in [46, 47] that was motivated by dynamic mincut and $k$-cut problems. He defined the so-called *ideal* edge loads and ideal tree packing (details in later section) by recursively decomposing the graph via Tutte–Nash-Williams partitions [46]. He also proved that a simple iterative greedy tree packing algorithm converges to the ideal loads [47]. He used the approximate ideal tree packing to obtain new deterministic algorithms for the $k$-cut problem, and his approach has been quite influential in a number of subsequent results [21, 11, 31, 29, 23]. Thorup obtained his tree packing result from first principles. We ask: is there a connection between ideal tree packing and DSG?

## 1.1 Contributions of the paper

This paper has two main contributions. The first is a new proof of the convergence of SuperGreedy++ for DSS. Our proof is based on showing that SuperGreedy++ can be viewed as a "noisy" or "approximate" variant of the Frank-Wolfe algorithm applied to the quadratic program defined by Fujishige. The advantage of the new proof is twofold. First, it shows that SuperGreedy++ not only converges to a $(1-\epsilon)$-approximation to the densest set, but that in fact it converges to the densest decomposition vector. This was empirically observed in [24] for DSG, and was left as an open problem to resolve. The proof in [10] on convergence of SuperGreedy++ is based on the MWU method via LPs, and does not exploit Fujishige's result which is key to the stronger property that we prove here. Second, the proof connects two powerful tools directly and at a high-level: Fujishige's result on submodular functions, and a standard method for constrained convex optimization.

▶ **Theorem 1.** *Let $b^*$ be the dense decomposition vector for a non-negative monotone supermodular set function $f : 2^V \to \mathbb{R}_+$ where $|V| = n$. Then, SuperGreedy++ converges in $O(\alpha_f/\epsilon^2)$ iterations to a vector $b$ such that $||b - b^*||_2 \leq \epsilon$, where $\alpha_f$ depends only on $f$. For a graph with $m$ edges and $n$ vertices, Greedy++ converges in $O(mn^2/\epsilon^2)$ iterations for unweighted multigraphs.*

▶ Remark 2. The new convergence gives a weaker bound than the one in [10] in terms of convergence to a $(1-\epsilon)$ *relative* approximation to the maximum density. However, it gives a strong *additive* guarantee to the *entire* dense decomposition vector.

Our second contribution builds on our insights on DSG and DSS, and applies it towards understanding ideal tree packing and greed tree packing. We connect the ideal tree packing of Thorup to the dense decomposition associated with the rank function of the underlying graphic matroid (which is submodular). We then show that greedy tree packing algorithm can be viewed as the Frank-Wolfe algorithm applied to the quadratic program defined by Fujishige, and this easily yields a convergence guarantee.

▶ **Theorem 3.** *Let $G = (V, E)$ be a graph. The ideal edge load vector $\ell^* : E \to \mathbb{R}_+$ for $G$ is given by the lexicographically minimal base in the polymatroid associated with the rank function of the graphic matroid of $G$. The Frank-Wolfe algorithm with step size $\frac{1}{k+1}$, when applied to the quadratic program for computing the lexicographically minimal base in the graphic matroid of $G$, coincides with the greedy tree packing algorithm. For unweighted graphs on $m$ edges, the generic analysis of Frank-Wolfe method's convergence shows that greedy tree packing converges to a load vector $\ell : E \to \mathbb{R}_+$ such that $||\ell - \ell^*||_2 \leq \epsilon$ in $O(\frac{m \log(m/\epsilon)}{\epsilon^2})$ iterations. The standard step size algorithm converges in $O(\frac{m}{\epsilon^2})$ iterations.*

▶ Remark 4. Although the algorithm is the same (greedy tree packing), Thorup's analysis guarantees a strongly polynomial-bound even in the capacitated case [47]. However we obtain a stronger additive guarantee via a *generic* Frank-Wolfe analysis and our analysis has a $1/\epsilon^2$ dependence while Thorup's has a $1/\epsilon^3$ dependence. We give a more detailed comparison in Section 5.

**Organization.** The rest of the paper is devoted to proving the two theorems. The paper relies on tools from theory of submodular functions and an adaptation of the analysis of Frank-Wolfe. We first describe the relevant background and then prove the two results in separate sections. Due to space constraints, most of the proofs are provided in the full version.

## 2 Background on Frank-Wolfe algorithm and a variation

Let $\mathcal{D} \subseteq \Re^d$ be a compact convex set, and $f : \mathcal{D} \to \Re$ be a convex, differentiable function. Consider the problem of $\min_{x \in \mathcal{D}} f(x)$. Frank-Wolfe [17] is a first order method and it relies on access to a linear minimization oracle, LMO, for $f$ that can answer $\text{LMO}(w) = \arg\min_{s \in \mathcal{D}} \langle s, \nabla f(w) \rangle$ for any given $w \in \mathcal{D}$. In several applications such oracles with fast running times exist. Given $f, \mathcal{D}$ as above, the Frank-Wolfe algorithm is an iterative algorithm that converges to the minimizer $\mathbf{x}^* \in \mathcal{D}$ of $f$. See Algorithm 1. The algorithm starts with a guess of the minimizer $b^{(0)} \in \mathcal{D}$. In each iteration, it finds a direction $d^{(k+1)}$ to move towards by calling the linear minimization oracle on the current guess $b^{(k)}$. It then moves slightly towards that direction using a convex combination to ensure that the new point is in $\mathcal{D}$. The amount the algorithm moves towards the new direction decreases as $k$ increases signifying the "confidence" in its current guess as the minimizer.

The original convergence analysis for the Frank-Wolfe algorithm is from [17]. Jaggi [25] gave an elegant and simpler analysis. His analysis characterizes the convergence rate in terms of the *curvature constant* $C_f$ of the function $f$.

**Algorithm 1** FRANK-WOLFE-ORIGINAL.

Initialize $b^{(0)} \in \mathcal{D}$
**for** $k \leftarrow 0$ to $T-1$ **do**
  $\gamma \leftarrow \frac{2}{k+2}$
  $d^{(k+1)} \leftarrow \arg\min_{s \in \mathcal{D}}(\langle s, \nabla f(b^{(k)})\rangle)$ ▷ Call oracle on $b^{(k)}$
  $b^{(k+1)} \leftarrow (1-\gamma)b^{(k)} + \gamma d^{(k+1)}$
**return** $b^{(T)}$

▶ **Definition 5.** *Let $\mathcal{D} \subseteq \Re^d$ be a compact convex set, and $f : \mathcal{D} \to \Re$ be a convex, differentiable function. The curvature constant $C_f$ of $f$ is defined as*

$$C_f = \sup_{x,s \in D, \gamma \in [0,1], y = x+\gamma(s-x)} \frac{2}{\gamma^2}(f(y) - f(x) - \langle y - x, \nabla f(x)\rangle).$$

▶ **Definition 6.** *Let $g : \mathcal{D} \to \Re$ be a differentiable function. Then $g$ is Lipschitz with constant $L$ if for all $x, y \in \mathcal{D}$, $\|g(\mathbf{x}) - g(\mathbf{y})\|_2 \leq L \|x - y\|_2$.*

Let $\text{diam}(\mathcal{D}) = \max_{x,y \in \mathcal{D}} \|x - y\|_2$ be the diameter of $\mathcal{D}$. One can show that $C_f \leq L \cdot \text{diam}(\mathcal{D})^2$ where $L$ is the Lipschitz constant of $\nabla f$.

▶ **Theorem 7** ([25])**.** *Let $\mathcal{D} \subseteq \Re^d$ be a compact convex set, and $f : \mathcal{D} \to \Re$ be a convex, differentiable function with minimizer $\mathbf{b}^*$. Let $\mathbf{b}^{(k)}$ denote the guess on the $k$-th iteration of the Frank-Wolfe algorithm. Then $f(\mathbf{b}^{(k)}) - f(\mathbf{b}^*) \leq \frac{2C_f}{k+2}$.*

Jaggi's proof technique can be used to prove the convergence rate of "noisy/approximate" variants of the Frank-Wolfe algorithm. This motivates the following definition. An $\epsilon$-*approximate linear minimization oracle* is an oracle that for any $\mathbf{w} \in \mathcal{D}$, returns $\hat{\mathbf{s}}$ such that $\langle \hat{\mathbf{s}}, \nabla f(\mathbf{w})\rangle \leq \langle \mathbf{s}^*, \nabla f(\mathbf{w})\rangle + \epsilon$, where $s^* = \text{LMO}(\mathbf{w})$. While an efficient *exact* linear minimization oracle exists in some applications, in others one can only $\epsilon$-approximate it (using numerical methods or otherwise). Jaggi's proof technique extends to show that an approximate linear minimization oracles suffices for convergence as long as the approximation quality improves with the iterations. Suppose the oracle, in iteration $k$, provides a $\frac{\delta C_f}{k+2}$-approximate solution where $\delta > 0$ is some fixed constant. The convergence rate will only deteriorate by a $(1+\delta)$ multiplicative factor. Qualitatively, this says that we can afford to be inaccurate in computing the Frank-Wolfe direction in early iterations, but the approximation should approach $\text{LMO}(b^{(k)})$ as $k \to \infty$.

Another question of interest is the resilience of the Frank-Wolfe algorithm to changes in the learning rate $\gamma_k = \frac{2}{k+2}$. Indeed, the variants we will look at will *require* $\gamma_k = \frac{1}{k+1}$. Jaggi's proof can again be adapted to handle this case, with only an $O(\log k)$ multiplicative deterioration in the convergence rate. We state the following theorem whose proof we defer to the appendix.

▶ **Theorem 8.** *Let $\mathcal{D} \subseteq \Re^d$ be a compact convex set, and $f : \mathcal{D} \to \Re$ be a convex, differentiable function with minimizer $\mathbf{b}^*$. Suppose instead of computing $\mathbf{d}^{(k+1)}$ by calling LMO$(\mathbf{b}^{(\mathbf{k})})$ in iteration $k$, we call a $\frac{\delta C_f}{k+2}$-approximate linear minimization oracle, for some fixed $\delta > 0$. Also, suppose instead of using $\gamma_k = \frac{2}{k+2}$, we use $\gamma_k = \frac{1}{k+1}$ as a step size. Then $f(\mathbf{b}^{(k)}) - f(\mathbf{b}^*) \leq \frac{2C_f(1+\delta)H_{k+1}}{k+1}$, where $H_n$ is the $n$-th Harmonic term.*

We refer to the variant of Frank-Wolfe algorithm, as described by Theorem 8, as *noisy* Frank-Wolfe.

## 3 Sub and supermodular functions, and dense decompositions

We already defined submodular and supermodular set functions, polymatroids and contrapolymatroids. We restrict attention to functions satisfying $f(\emptyset) = 0$ which together with supermodularity and non-negativity implies monotonocity, that is, $f(A) \leq f(B)$ for $A \subseteq B$. An alternative definition of submodularity is via diminishing marginal values. We let $f(v \mid A) = f(A \cup \{v\}) - f(A)$ denote the marginal value of $v$ to $A$. Submodularity is equivalent to $f(v \mid A) \geq f(v \mid B)$ whenever $A \subseteq B$ and $v \in V \setminus B$; the inequality is reversed for supermodular set functions. We need the following simple lemma.

▶ **Lemma 9.** *For a submodular function $f : 2^V \to \Re$, the function $g(X) = f(V) - f(V \setminus X)$ is supermodular. In particular if $f$ is a normalized monotone submodular function then $g$ is a normalized monotone supermodular function.*

**Deletion and contraction, and non-negative summation.** Sub and supermodular functions are closed under a few simple operations. Given $f : 2^V \to \mathbb{R}$, restricting it to a subset $V'$ corresponds to deleting $V \setminus V'$. Given $A \subset V$, contracting $f$ to $A$ yields the function $g : 2^{V \setminus A} \to \mathbb{R}$ where $g(X) = g(X \cup A) - g(A)$. Given two functions $f$ and $g$ we can take their non-negative sum $af + bg$ where $a, b \geq 0$. Monotonicity and normalization is also preserved under these operations.

### 3.1 Dense decompositions for submodular and supermodular functions

Following the discussion in the introduction, we are interested in decompositions of supermodular and submodular functions. Dense decompositions follow from the theory of principal partitions of submodular functions that have been explored extensively. We refer the reader to Fujishige's survey [20] as well as Naraynan's work [35, 36]. The standard perspective comes from considering the minimizers of the function $f_\lambda$ for a scalar $\lambda$ where $f_\lambda(S) = f(S) - \lambda|S|$. As $\lambda$ varies from $-\infty$ to $\infty$ the minimizers change only at a finite number of break points. In this paper we are interested in the notion of density, in the form of ratios, for non-negative submodular and supermodular functions. For this reason we follow the notation from recent work [44, 14, 10, 24] and state lemmas in a convenient form, and provide proofs in the appendix for the sake of completeness.

**Supermodular function dense decomposition.** The basic observation is the following.

▶ **Lemma 10.** *Let $f : 2^V \to \Re_+$ be a non-negative supermodular set function. There exists a* unique maximal *set $S \subseteq V$ that maximizes $\frac{f(S)}{|S|}$.*

The preceding lemma can be used in a simple fashion to derive the following corollary (this was explicitly noted in [10] for instance).

▶ **Corollary 11.** *Let $f : 2^V \to \Re_+$ be a non-negative supermodular set function. There is a unique partition $S_1, S_2, \ldots, S_h$ of $V$ with the following property. Let $V_i = V - \cup_{j<i} S_j$ and let $A_i = \cup_{j<i} S_i$. Then, for each $i = 1$ to $h$, $S_i$ is the unique maximal densest set for the function $f_{D_i} : 2^{V_i} \to \mathbb{R}_+$. Moroever, letting $\lambda_i$ be the optimum density of $f_{D_i}$, we have $\lambda_1 > \lambda_2 \ldots > \lambda_h$.*

Based on the preceding corollary, we can associated with each $v \in V$ a value $\lambda(v)$: $\lambda(v) = \lambda_i$ where $v \in S_i$. See Figure 1 (full version) for an example of a dense decomposition of the function $f(S) = |E(S)|$.

**Dense decomposition for submodular functions.** We now discuss submodular functions. We consider two variants. We start with a basic observation.

▶ **Lemma 12.** *Let $f : 2^V \to \Re_+$ be a monotone non-negative submodular set function such that $f(v) > 0$ for all $v \in V$. There is a unique minimal set $S \subseteq V$ that minimizes $\frac{|V|-|S|}{f(V)-f(S)}$ for submodular function $f$.*

Consider the following variant of a decomposition of $f$. We let $S_0 = V$ and find $S_1$ as the unique *minimal* set $S \subseteq V$ that minimizes $\frac{|V|-|S|}{f(V)-f(S)}$. Then we "delete" $\hat{S}_1 = V \setminus S_1$, and find the minimal set $S_2 \subseteq S_1$ that minimizes $\frac{|S_1|-|S|}{f(S_1)-f(S)}$. In iteration $i$, we find the unique minimal set $S_i \subset S_{i-1}$ that minimizes $\frac{|S_{i-1}|-|S_i|}{f(S_{i-1})-f(S_i)}$. Notice that $S_k \subset S_{k-1} \subset ... \subset S_1 \subset V$. We say the relative density of $\hat{S}_i = S_{i-1} \setminus S_i$ is $\lambda_i = \frac{|S_{i-1}|-|S_i|}{f(S_{i-1})-f(S_i)}$. For $u \in \hat{S}_i$, we say the density of $u$ is $\lambda_u = \lambda_i$. Hence the dense decomposition of $f$ is $\hat{S}_1, ..., \hat{S}_k$ with densities $\lambda_1, \ldots, \lambda_k$. We refer to this decomposition as the first variant which is based on deletions.

We now describe a second dense decomposition for submodular functions. Let $f : 2^V \to \mathbb{R}_+$ be a monotone submodular function. Consider the supermodular function $g : 2^V \to \mathbb{R}_+$ where $g(X) = f(V) - f(V \setminus X)$ for all $X \subseteq V$. From Lemma 9, $g$ is monotone supermodular. We can then apply Corollary 11 to obtain a dense decomposition of $g$. Let $T_1, T_2, \ldots, T_{k'}$ be the unique decomposition obtained by considering $g$ and let $\hat{\lambda}_1, ..., \hat{\lambda}_{k'}$ be the corresponding densities. Note that this second decomposition is based on contractions.

Not too surprisingly, the two decompositions coincide, as we show in the next theorem. The main reason to consider them separately is for technical ease in applications where one or the other view is more natural.

▶ **Theorem 13.** *Let $\hat{S}_1, ..., \hat{S}_k$ be a dense decomposition (using deletion variant) of a submodular function $f$ with densities $\lambda_i, \ldots, \lambda_k$. Let $T_1, ..., T_{k'}$ be a dense decomposition (using contraction variant) of the same function with densities $\hat{\lambda}_1, ..., \hat{\lambda}_{k'}$. We have (i) $k' = k$, (ii) $\hat{S}_1, ...\hat{S}_k$ is exactly $T_1, ..., T_k$, and (iii) $\hat{\lambda}_i = \frac{1}{\lambda_i}$ for $1 \leq i \leq k$.*

## 3.2 Fujishige's results on lexicographically optimal bases

Fujishige [18] gave a polyhedral view of the dense decomposition which is the central ingredient in our work. He stated his theorem for polymatroids, however, it can be easily generalized to contrapolymatroids. We restrict attention to the unweighted case for notational ease – [18] treats the weighted case.

Vectors in $\mathbb{R}^n$ can be totally ordered by sorting the coordinates in increasing order of value and considering the lexicographical ordering of the two sorted sequences of length $n$. In the following, for $a, b \in \mathbb{R}^n$ we use $a \prec_\uparrow b$ and $a \preceq_\uparrow b$ to refer to this order. We say that a vector $x$ in a set $D$ is lexicographically maximum if for all $y \in D$ we have $y \preceq_\uparrow x$.

Fujishige proved the following theorem for polymatroids.

▶ **Theorem 14** ([18])**.** *Let $f : 2^V \to \mathbb{R}_+$ be a monotone submodular function (a polymatroid) and let $B_f$ be its base polytope. Then there is a unique lexicographically maximum base $b^* \in B_f$ and for each $v \in V$, $b^*_v = \lambda_v$. Moroever, $b^*$ is the optimum solution to the quadratic program: $\min \sum_v x_v^2$ subject to $x \in B_f$.*

Another ordering is to sort the coordinates in decreasing order of value and then taking the lexicographic ordering on the two sorted sequences. We denote this ordering by $\prec_\downarrow, \preceq_\downarrow$ for strict and non-strict ordering respectively. We say that a vector $x$ in a set $D$ is lexicographically minimum if for all $y \in D$ we have $x \preceq_\downarrow y$. The preceding theorem can be generalized to contrapolymatroids in a straight forward fashion and this was explicitly pointed out in [24]. We paraphrase it to be similar to the preceding theorem statement.

▶ **Theorem 15.** *Let $f : 2^V \to \mathbb{R}_+$ be a monotone supermodular function (a contrapolymatroid) and let $B_f$ be its base polytope. Then there is a unique lexicographically minimum base $b^* \in B_f$ and for each $v \in V$, $b^*_v = \lambda_v$. Moreover, $b^*$ is the optimum solution to the quadratic program: $\min \sum_v x_v^2$ subject to $x \in B_f$.*

## 3.3 Approximating a lexicographically optimal base using Frank-Wolfe

Consider the convex quadratic program $\min \sum_{v \in V} x_v^2$ subject to $x \in B_f$ where $B_f$ is the base polytope of $f$ (could be submodular of supermodular). We can use the Frank-Wolfe method to approximately solve this optimization problem. The gradient of the quadratic function is $2x$ and it follows that in each iteration, we need to answer the linear minimization oracle of $\text{LMO}(w) = \arg\min_{\mathbf{s} \in B_f} \langle \mathbf{s}, 2\mathbf{w} \rangle$ for $\mathbf{w} \in B_f$. This is equivalent to $\arg\min_{\mathbf{s} \in B_f} \langle \mathbf{s}, \mathbf{w} \rangle$, in other words optimizing a linear objective over the base polytope. Edmonds [15] showed that the simple greedy algorithm is an $O(|V| \log |V|)$ time exact algorithm (assuming $O(1)$ time oracle access to $f$).

▶ **Theorem 16** ([15])**.** *Fix a polymatroid $f : 2^V \to \Re_+$. Given a weight vector $\mathbf{w} \in \Re^n$, let $v_{j_1}, v_{j_2}, \ldots, v_{j_n}$ be a sort of $V = \{v_1, ..., v_n\}$ in ascending order of $\mathbf{w}_i$ values. Let $A_i = \{v_{j_1}, ..., v_{j_i}\}$ for $1 \leq i \leq n$ with $A_0 = \emptyset$. Define $\mathbf{s}^*_i = f(A_i) - f(A_{i-1})$. Then $\mathbf{s}^* = \arg\min_{\mathbf{s} \in B_f} \langle \mathbf{s}, \mathbf{w} \rangle$.*

The theorem also holds for supermodular functions but by reversing the order from ascending to descending order of $\mathbf{w}$ and complimenting the set $A_i$.

▶ **Theorem 17** ([15])**.** *Fix a contrapolymatroid $f : 2^V \to \Re_+$. Given a weight vector $\mathbf{w} \in \Re^n$, let $v_{j_1}, v_{j_2}, \ldots, v_{j_n}$ be a sort of $V = \{v_1, ..., v_n\}$ in descending order of $\mathbf{w}_i$ values. Let $A_i = \{v_{j_i}, ..., v_{j_n}\}$ for $1 \leq i \leq n$ with $A_{n+1} = \emptyset$. Define $\mathbf{s}^*_i = f(A_i) - f(A_{i+1})$. Then $\mathbf{s}^* = \arg\min_{\mathbf{s} \in B_f} \langle \mathbf{s}, \mathbf{w} \rangle$.*

Both algorithms are dominated by the sorting step and thus takes $O(|V| \log |V|)$ time. These simple algorithms imply that the Frank-Wolfe algorithm can be used on the quadratic program to obtain an approximation to the lexicographically maximum (respectively minimum) bases of submodular (respectively supermodular) functions. The standard Frank-Wolfe algorithm would need $O(\frac{\text{diam}(B_f)^2}{\epsilon^2})$ iterations to converge to a vector $\hat{b}$ satisfying $\left\| \hat{b} - b^* \right\|_2 \leq \epsilon$.

# 4 Application 1: Convergence of Greedy++ and SuperGreedy++

We begin by describing Greedy++ [7] and its generlization SuperGreedy++ [10]. Greedy++ is built upon the peeling idea of Greedy, and applies it over several iterations. The algorithm initializes a weight/load on each $v \in V$, denoted by $w(v)$, to 0. In each iteration it creates an ordering by peeling the vertices: the next vertex to be chosen is $\arg\min_{v \in V(G')}(w(v) + \deg_{G'}(v))$ where $G'$ is the current graph (after removing the previously peeled vertices). At the end of the iteration, $w(v)$ is increased by the degree of $v$ when it was peeled in the current iteration. A precise description can be found below. SuperGreedy is a natural generalization of Greedy, and SuperGreedy++ generalizes Greedy++. A formal description of SuperGreedy++ is given below.

**Algorithm 2** GREEDY++$(G(V,E),T)$ [7].

Initialize $w(u) \leftarrow 0$ for all $u \in V$
$G^* \leftarrow G$
**for** $k \leftarrow 0$ to $T-1$ **do**
  $G' \leftarrow G$
  **while** $|G'| > 1$ **do**
    $u \leftarrow \arg\min_{u \in G'}(w(u) + deg_{G'}(u))$
    $w(u) \leftarrow w(u) + deg_{G'}(u)$
    $G' \leftarrow G' - \{u\}$
    **if** $\lambda(G') > \lambda(G^*)$ **then**
      $G^* \leftarrow G'$
**return** $G^*$

**Algorithm 3** SUPER-GREEDY++$(f,T)$ [10].

Initialize $w(u) \leftarrow 0$ for all $u \in V$
$S^* \leftarrow V$
**for** $k \leftarrow 0$ to $T-1$ **do**
  $V' \leftarrow V$
  **while** $|V'| > 1$ **do**
    $u \leftarrow \arg\min_{u \in V'}(w(u) + f(V') - f(V'-u))$
    $w(u) \leftarrow w(u) + f(V') - f(V'-u)$
    $V' \leftarrow V' - u$
    **if** $\frac{f(V')}{|V'|} > \frac{f(S^*)}{|S^*|}$ **then**
      $S^* \leftarrow V'$
**return** $S^*$

The goal of this section is to prove Theorem 1 on the convergence of SUPERGREEDY++ and GREEDY++ to the lexicographically maximal base.

## 4.1 Intuition and main technical lemmas

As we saw in Section 3.3, if one applies the Frank-Wolfe algorithm to solve the qaudratic program $\min \sum_{v \in V} x_v^2$ subject to $x \in B_f$, each iteration corresponds to finding a minimum weight base of $f$ where the weights are given by the current vector $x$. Finding a minimum weight base corresponds to sorting $V$ by $x$. However, SUPERGREEDY++ and GREEDY++ use a more involved peeling algorithm in each iteration; the peeling is based on the weights as well as the degrees of the vertices and it is not a static ordering (the degrees change as peeling proceeds). This is the difficulty in formally analyzing these algorithms. In [10], the authors used a connection to the multiplicative weight update method via LP relaxations. Here we rely on the quadratic program and noisy Frank-Wolfe. The high-level intuition, that originates in [10], is the following. As the algorithm proceeds in iterations, the weights on the vertices accumulate; recall that the total increase in the weight in the case of DSG is $m = |E|$. The degree term, which influences the peeling, is dominant in early iterations, but its influence on the ordering of the vertices decreases eventually as the weights of the vertices get larger. It is then plausible to conjecture that the algorithm behaves like the standard Frank-Wolfe method in the limit. The main question is how to make this intuition precise. [10] relies on a connection to the MWU method while we use a connection to noisy Frank-Wolfe.

For this purpose, consider an iteration of GREEDY++ and SUPERGREEDY++. The algorithm peels based on the current weight vector and the degrees. We isolate and abstract this peeling algorithm and refer to it as Weighted-Greedy and Weighted-SuperGreedy respectively, and formally describe them with the weight vector $w$ as a parameter.

**Algorithm 4** WEIGHTED-GREEDY($G$, $w$).

Input: $G(V, E)$ and $w(u)$ for $u \in V$
  $G' \leftarrow G$
  Initialize $\hat{d}(u) = 0$ for all $u \in V$.
  **while** $|G'| > 1$ **do**
    $u \leftarrow \arg\min_{u \in G'}(w(u) + deg_{G'}(u))$
    $\hat{d}(u) \leftarrow deg_{G'}(u)$
    $G' \leftarrow G' - \{u\}$
  **return** $\hat{d}$

**Algorithm 5** WEIGHTED-SUPERGREEDY($f$, $w$).

Input: Supermodular $f : 2^V \to \Re_+$, $w(u)$ for $u \in V$
  $V' \leftarrow V$
  Initialize $\hat{d}(u) = 0$ for all $u \in V$.
  **while** $|V'| > 1$ **do**
    $u \leftarrow \arg\min_{u \in G'}(w(u) + f(V') - f(V' - u)$
    $\hat{d}(u) \leftarrow f(V') - f(V' - u)$
    $V' \leftarrow V' - u$
  **return** $\hat{d}$

The peeling algorithms also compute a base $\hat{d} \in B_f$. In the case of graphs and DSG, $\hat{d}(u)$ is set to the degree of the vertex $u$ when it is peeled. One can alternatively view the base as an orientation of the edges of $E$. Define for each edge $uv \in G$ two weights $x_{uv}, x_{vu}$. We say that $\mathbf{x}$ is *valid* if $x_{uv} + x_{vu} = 1$ and $x_{uv}, x_{vu} \geq 0$ for all $\{u, v\} \in E(G)$. For $b \in \Re^{|V|}$, we say $x$ *induces* $b$ if $b_u = \sum_{v \in \delta(u)} x_{uv}$ for all $u \in V$. We say a vector $d$ is an *orientation* if there is a valid $x$ that induces it.

▶ **Lemma 18** ([24]). *For $f(S) = |E(S)|$, $b \in B_f$ if and only if $b$ is an orientation.*

Recall that the Frank-Wolfe algorithm, for a given weight vector $w : V \to \mathbb{R}_+$, computes the minimum-weight base $b$ with respect to $w$ since $\langle w, b\rangle = \min_{y \in B_f} \langle w, y\rangle$. It is worth taking a moment to note that this base (or orientation due to Lemma 18) is easily computable: we orient each edge integrally (i.e $x_{vu} = 1, x_{uv} = 0$) from $v$ to $u$ if $w(u) \geq w(v)$, and from $u$ to $v$ otherwise. A simple exchange argument yields a proof of correctness and is implicit in many works [14][2]. This induces an optimal base $d^*_w$ with respect to $w$. Our goal is to compare how the peeling order created by Weighted-Greedy (and Weighted-SuperGreedy) compares with the best base. The following two technical lemmas formalize the key idea. The first is tailored to DSG and the second applies to DSS.

▶ **Lemma 19.** *Let $\hat{d}$ be the output from WEIGHTED-GREEDY$(G, w)$ and $d^*_w$ be the optimal orientation with respect to $w$. Then $\langle w, \hat{d}\rangle \leq \langle w, d^*_w\rangle + \sum_u deg_G(u)^2$. In particular, the additive error **does not depend** on the weight vector $w$.*

▶ **Lemma 20.** *For a supermodular function $f : 2^V \to \Re_+$, let $\hat{d}$ be the output from WEIGHTED-SUPERGREEDY$(f, w)$ (Algorithm 5) and $d^*_w$ be the optimal vector with respect to $w$ as described in Theorem 17. Then $\langle w, \hat{d}\rangle \leq \langle w, d^*_w\rangle + n\sum_{u \in V} f(u \mid V - u)^2$. In particular, the additive error **does not depend** on the weight vector $w$.*

## 4.2 Convergence proof for Greedy++

Why is Lemma 19 crucial? First, observe that the minimizer $d^*_w$ of $\langle w, d\rangle$ is exactly the same minimizer as $\langle Kw, d\rangle$ for any constant $K > 0$ (and vice-versa).

▶ **Lemma 21.** *Let $\hat{d}_K$ be the output of WEIGHTED-GREEDY$(G, Kw)$. Then $\langle w, \hat{d}_K\rangle \leq \langle w, d^*_w\rangle + \frac{\sum_u deg_G(u)^2}{K}$.*

[2] Since the optimal orientation is easily computable, one can replace the "peeling" iteration of GREEDY++ with the optimum base. This would result in the Frank-Wolfe based algorithm of [14].

**Proof.** By Lemma 19, $\sum_{u\in V} Kw(u)\hat{d}_K(u) \leq \min_{\text{orientation } d} \left(\sum_{u\in V} Kw(u)d(u)\right) + \sum_u deg_G(u)^2$. Dividing by $K$ implies the claim. ◀

We are now ready to view GREEDY++ as a noisy Frank-Wolfe algorithm. Algorithm 6 shows how GREEDY++ could be interpreted.

**Algorithm 6** GREEDY++$(G(V,E))$.

Input: $G=(V,E)$ and $w(u)$ for $u \in V$
  Initialize $b^{(0)} \leftarrow$ WEIGHTED-GREEDY$(G, \mathbf{0})$ ▷ $b^{(0)}$ is a valid orientation
  **for** $k \leftarrow 0$ to $T-1$ **do**
    $\gamma \leftarrow \frac{1}{k+1}$
    $d^{(k+1)} \leftarrow$ WEIGHTED-GREEDY$(G, (k+1)b^{(k)})$
    $b^{(k+1)} \leftarrow (1-\gamma)b^{(k)} + \gamma d^{(k+1)}$
  **return** $b^{(T)}$

The algorithm is exactly the same as the one described in Algorithm 2. Indeed, one can prove that $kb^{(k)}$ is precisely the weights that GREEDY++ ends with at round $k$ by induction. Observe that $(k+1)b^{(k+1)} = kb^{(k)} + d^{(k+1)}$ which is precisely the load as described in Algorithm 2 (via induction). We note that $\gamma \leftarrow 1/(k+1)$ is crucial here to ensure we are taking the average. Lemma 25 in the appendix (full version) implies that each peel in Algorithm 2 is $\frac{\delta C_f}{k+2}$-approximate linear minimization oracle. Using Theorem 8, this implies that GREEDY++ (as described in Algorithm 2) converges to $b^*$ in $\tilde{O}(\frac{mn^2}{\epsilon^2})$ iterations since $\delta = O(\frac{\sum_u d_G(u)^2}{m})$ and $C_f = O(\sum_u d_G(u)^2)$. We use the probabilistic method to bound $C_f$ in the full version.

**Extension to SuperGreedy++.** An essentially similar analysis works for SUPERGREEDY++. Instead of Lemma 19, we rely on Lemma 20. For technical reasons, the convergence analysis of SUPERGREEDY++ is slightly weaker than for GREEDY++.

## 5 Application 2: Greedy Tree Packing interpreted via Frank-Wolfe

Let $G=(V,E)$ be a graph with non-negative edge capacities. The goal of this section is to view Thorup's definitions of ideal edge loads and the associated tree packing from a different perspective, and to derive an alternate convergence analysis of his greedy tree packing algorithm [46, 47]. In previous work, Chekuri, Quanrud and Xu [11] obtained a different tree packing based on an LP relaxation for $k$-cut, and used it in place of ideal tree packing. Despite this, there was a gap in our understanding which we address here.

We restrict our attention to unweighted multi-graphs throughout this section, and comment on the capacitated case at the end of the section. Let $G=(V,E)$ be a connected multi-graph, with $n$ vertices and $m$ edges. Consider the graphic matroid $\mathcal{M}_G(E,\mathcal{F})$ induced by $G$; $E$ is the ground set, and $\mathcal{F}$ consists of all sub-forests of $G$. The bases of the matroid are precisely the spanning trees of $G$. Consider the rank function $r: 2^E \to \mathbb{Z}_+$ of $\mathcal{M}_G$. $r$ is submodular, and it is well-known that for a edge subset $X \subseteq E$, $r(X) = n - \kappa(X)$ where $\kappa(X)$ is the number of connected components induced by $X$.

## 5.1 Thorup's recursive algorithm as dense decomposition

For consistency with previous notation, we use $f$ to denote the submodular rank function $r$. We first describe ideal loads as defined by Thorup. Consider the Tutte–Nash-Williams partition $P$ for $G$. Recall that $P$ minimizes the ratio $\frac{|E(P)|}{|P|-1}$ among all partitions, and this ratio is $\tau(G)$. For each edge $e \in E(P)$, assign $\ell^*(e) = \frac{1}{\tau(G)}$. Remove the edges in $E(P)$ to obtain a graph $G'$ which now consists of several disconnected components. Recursively compute ideal loads for the edges in each connected component of $G'$ (the process stops when $G$ has no edges).

We claim that Thorup's recursive decomposition coincides with the dense decomposition of $f$ (the first variant). To see this, it suffices to see the first step of the dense decomposition. We find the minimal set $S_1 \subseteq E$ that minimizes $\frac{|E|-|S|}{f(E)-f(S)}$. We let $\hat{S}_1 = E \setminus S_1$ and assign the edges in $\hat{S}_1$ the density $\frac{f(E)-f(S)}{|E|-|S|}$. Then, we "delete" $\hat{S}_1$. Observe that $\hat{S}_1 = E \setminus S_1$ is just the edges crossing the partition $P(S_1)$ defined by the $\kappa(S_1)$ connected components spanned by $S_1$. Also, recall that $\frac{f(E)-f(S_1)}{|E|-|S_1|} = \frac{\kappa(S_1)-1}{|E\setminus S_1|} = \frac{|P(S_1)|-1}{E(P(S_1))} = \frac{1}{\tau(G)}$. Hence, the density assigned to edges in $\hat{S}_1$ is exactly $\frac{1}{\tau(G)}$ by the Tutte–Nash-Williams theorem. The next step is deleting $\hat{S}_1 = E \setminus S_1$, which, as discussed above, are the edges crossing the partition $P(S_1)$.

Via induction we prove the following lemma.

▶ **Lemma 22.** *The weights given to the edges by the dense decomposition algorithm on $f$ coincide with $\ell^*$.*

## 5.2 Greedy tree packing converge to ideal relative loads

Thorup considered the following greedy tree packing algorithm. For each edge define a load $\ell(e)$ which is initialized to 0. The algorithm proceeds in iterations. In iteration $i$ the algorithm computes an MST $T_i$ in $G$ with respect to edge weights $w(e) = \ell(e)$. The load of each edge $e \in T_i$ is increased by 1. Thorup showed that as $k \to \infty$, the quantity $\ell(e)/k$ converges to $\ell^*(e)$ for each edge $e$. His proof is fairly technical. In this section, we present a different proof of this fact that uses the machinery we have built thus far.

▶ **Lemma 23.** *The vector $\ell^*$ is the lexicographically maximal base of the spanning tree polytope.*

**Proof.** We showed that Thorup's definition of ideal loads is obtained by simply running the dense decomposition on the rank function of the graphic matroid induced by $G$. The bases of the graphic matroid are the spanning trees of $G$ and hence the base polytope of $f$ is the spanning tree polytope of $G$. The dense decomposition of $f$ gives us the lexicographically maximum base, and hence $\ell^*$ is the lexicographically maximal base in the spanning tree polytope of $G$. ◀

Hence, $\ell^*$ is the unique solution to the quadratic program: min $\sum_e \ell(e)^2$ subject to $\ell \in \mathrm{SPT}(G)$ where $\mathrm{SPT}(G)$ is the spanning tree base polytope. We can thus apply a noisy Frank-Wolfe algorithm to the quadratic program to obtain Algorithm 7.

The main observation is that this algorithm is **exactly** the same as Thorup's greedy tree packing algorithm. Indeed, observe that $(k+1)\ell^{(k+1)} \leftarrow k\ell^{(k)} + d^{(k+1)} = k\ell^{(k)} + \mathbb{1}\{e \in \mathrm{MST}(G, \ell^{(k)})\}$ where $\mathrm{MST}(G, w)$ is a minimum spanning tree of $G$ with respect to edge weights $w$. Since noisy Frank-Wolfe converges, then $\ell^{(k)}$ converges to $\ell^*(e)$, and greedy tree packing converges.

**Algorithm 7** FRANK-WOLFE-GREEDY-TREEPACK($G(V, E)$).

Input: $G(V, E)$
  Initialize $l^{(0)}(u) = \mathbb{1}\{e \in T\}$ for any spanning tree $T$.
  **for** $k \leftarrow 0$ to $T - 1$ **do**
    $\gamma \leftarrow \frac{1}{k+1}$
    $d^{(k+1)} \leftarrow \min_{s \in \mathrm{SPT}(G)} \langle l^{(k)}, s \rangle$ ▷ This is the minimum spanning tree with respect to $l^{(k)}$
    $l^{(k+1)} \leftarrow (1-\gamma) l^{(k)} + \gamma d^{(k+1)}$
  **return** $b^{(T)}$

We now establish the convergence guarantee for greedy tree packing. For the spanning tree polytope of an $m$ edge graph, the curvature constant $C_f \leq 4m$ because for $x, y \in B_f$, $2(x-y)^T(x-y) = \sum_{e \in E}(x_e - y_e)^2 \leq 4m$. Plugging this bound into Theorem 8, after $k = O(\frac{m \log(m/\epsilon)}{\epsilon^2})$ iterations, $\left\|\ell^{(k)} - \ell^*\right\|_2 \leq \epsilon$.

Suppose we run the standard Frank-Wolfe algorithm with $\gamma = 2/(k+2)$. Then, the convergence guarantee improves to $O(\frac{m}{\epsilon^2})$. Note that each iteration still corresponds to finding an MST in the graph with weights. However, the load vector is no longer a simple average of the trees taken so far.

**Comparison to Thorup's bound and analysis.** Thorup [47] considered ideal tree packings in capacitated graphs; let $c(e) \geq 1$ (via scaling) denote the capacity of edge $e$. Via [18], one sees that the optimum solution of the quadratic program $\sum_e x_e^2/c(e)$ subject to $x \in SP(G)$ is the ideal load vector $\ell^*$. Greedy tree packing generalizes to the capacitated case easily; in each iteration we compute the MST with respect to weights $w(e) = \ell(e)c(e)$. Thorup proved the following.

▶ **Theorem 24** ([47]). *Let $G = (V, E)$ be capacitated graph. Greedy tree packing after $O(\frac{m \log(mn/\epsilon)}{\epsilon^3})$ iterations ouputs a load vector $\ell$ such that for each edge $e \in E$, $\ell(e) \leq (1+\epsilon)\ell^*(e)$.*

We observe that if all capacities are 1 (or identical) then Thorup's guarantee is that $\ell(e) - \ell^*(e) \leq O(\epsilon)$ for each edge $e$. For this case, via Frank-Wolfe, we obtain the much stronger guarantee that $||\ell - \ell^*||_2 \leq \epsilon$ which easily implies the per edge condition, however the per edge guarantee does not imply a guarantee on the norm. Further, in the unweighted case, our iteration complexity dependence on $\epsilon$ is $1/\epsilon^2$ while Thorup's is $1/\epsilon^3$. Thorup's guarantee works for the capacitated case in strongly polynomial number of iterations. We can adapt the Frank-Wolfe analysis to the capacitated case but it would yield a bound that depends on $C = \sum_e c(e)$ (in the unweighted case $C = m$); on the other hand the guarantee provided by Frank-Wolfe is stronger.

It may seem surprising that the same greedy tree packing algorithm yields different types of guarantees based on the type of analysis used. We do not have a completely satisfactory explanation but we point out the following. Thorup's analysis is a non-trivial refinement of the standard MWU type analysis of tree packing [38, 50, 3]. As already noted in [24], if one uses Frank-Wolfe (with $\gamma = 1/(k+1)$) with the softmax potential function that is standard in the MWU framework, then the resulting algorithm would also be greedy tree packing. Fujishige's uses a quadratic objective to guarantee that the optimum solution is the unique maximal base but in fact any increasing strongly convex function would suffice. In the context of optimizing a linear function over $B_f$, due to the optimality of the greedy algorithm, the only thing that determines the base is the ordering of the elements of $V$ according to the weight vector; the weights themselves do not matter. Thus, Frank-Wolfe applied to different

convex objectives can result in the same greedy tree/base packing algorithm. However, the specific objective can determine the guarantee one obtains after a number of iterations. The softmax objective is better suited for obtaining relative error guarantees while the quadratic objective is better suited for obtaining additive error guarantees. Thorup's analysis is more sophisticated due to the per edge guarantee in the capacitated setting. A unified analysis that explains both the relative and additive guarantees is desirable. We leave this is an interesting direction for future research.

# Algorithms for Matrix Multiplication via Sampling and Opportunistic Matrix Multiplication

**David G. Harris**
University of Maryland, College Park, MD, USA

## Abstract

Karppa & Kaski (2019) proposed a novel type of "broken" or "opportunistic" multiplication algorithm, based on a variant of Strassen's algorithm, and used this to develop new algorithms for Boolean matrix multiplication, among other tasks. For instance, their algorithm can compute Boolean matrix multiplication in $O(n^{\log_2(6+6/7)} \log n) = O(n^{2.778})$ time. While faster matrix multiplication algorithms exist asymptotically, in practice most such algorithms are infeasible for practical problems.

We describe an alternative way to use the broken matrix multiplication algorithm to approximately compute matrix multiplication, either for real-valued matrices or Boolean matrices. In brief, instead of running multiple iterations of the broken algorithm on the original input matrix, we form a new larger matrix by sampling and run a single iteration of the broken algorithm. Asymptotically, the resulting algorithm has runtime $O(n^{\frac{3 \log 6}{\log 7}} \log n) \leq O(n^{2.763})$, a slight improvement of Karppa-Kaski's algorithm.

Since the goal is to obtain new practical matrix-multiplication algorithms, these asymptotic runtime bounds are not directly useful. We estimate the runtime for our algorithm for some sample problems which are at the upper limits of practical algorithms; it appears that for these parameters, further optimizations are still needed to make our algorithm competitive.

## 1 Introduction

Consider the fundamental computational problem of *matrix multiplication*: given matrices $A, B$ of dimensions $d_1 \times d_3$ and $d_3 \times d_2$ respectively, our goal is to compute the matrix $C$ given by

$$C_{ij} = \sum_k A_{ik} B_{kj}$$

When the matrices are square, we write $n = d_1 = d_2 = d_3$. There is an obvious $O(d_1 d_2 d_3)$ algorithm (the so-called "naive algorithm"), which simply iterates over all values $i, j, k$. There is a long line of research into a variety of asymptotically faster algorithms. For square matrices, the runtime is given as $n^{\omega+o(1)}$, where $\omega$ is the linear algebra constant. Currently, the best bound [2] is $\omega \leq 2.38$, coming from a variant of Coppersmith-Winograd's algorithm [6]. There are also fast algorithms for rectangular matrix multiplication, although they are less heavily studied [12, 7].

Unfortunately, nearly all the fast matrix multiplications algorithms are completely impractical due to large hidden constants. There are a small handful of algorithms which are efficient *in practice*; by far the most important is Strassen's algorithms and its variants,

which have runtime $O(n^{\log_2 7})$. Depending on the matrix shape, a few rectangular algorithms may also be practical [5]. There is an extensive literature on optimizing and implementing Strassen's algorithm in various computational platforms, see e.g [4, 8, 10].

There is an important special case of *Boolean* matrix multiplication (BMM). Here, the entries of $A, B$ come from the algebra $\{0, 1\}$ with binary operations $\vee, \cdot$, and our goal is to compute the matrix $C$ given by

$$C_{ij} = \bigvee_k A_{ik} B_{kj}$$

This problem, along with some variants, is a primitive used in algorithms for transitive closures, parsing context-free grammars, and shortest path problems in unweighted graphs, among other applications. Again, the obvious $O(d_1 d_2 d_3)$ naive algorithm can be used. There are a number of other specialized algorithms based on combinatorial optimizations; most recently, [13] described an algorithm with runtime roughbly $O(n^3/\log^4 n)$.

There is a standard reduction from BMM to integer matrix multiplication: compute the matrix product $\tilde{C} = AB$ over the integers, and then set $C_{ij} = 1$ if $\tilde{C}_{ij} \geq 1$. Alternatively, there is a randomized reduction from BMM to matrix multiplication over the finite field GF(2): each non-zero entry of $B$ is set to zero with probability 1/2, and then we compute the matrix product $\tilde{C} = AB$ over GF(2). Then $\tilde{C}_{ij} = 1$ with probability 1/2 whenever $C_{ij} = 1$, else $\tilde{C}_{ij} = 0$ with probability one. With further $O(\log n)$ repetitions the error probability can be reduced to a negligible level. The advantage of this approach is that a variety of additional optimizations are possible for GF(2) arithmetic, most importantly, the Four Russians method [3]. These can often be combined with asymptotically fast algorithms such as Strassen. For example, [1] provides an optimized bitsliced implementation which uses Strassen for the high-level iterations.

It seems difficult to make progress on better practical algorithms for matrix multiplication. In [11], Karppa & Kaski proposed an innovative and novel approach to break this impasse: they described a "broken" or "opportunistic" form of matrix multiplication, which computes the matrix product with some high failure probability. This broken multiplication, in turn, can be computed more efficiently, both asymptotically and practically, by a variant of Strassen's algorithm. For brevity, we refer to their algorithm as the *KK algorithm*.

By iterating for sufficiently many repetitions, this procedure an be used to solve BMM with high probability. With appropriate choice of parameters, the overall runtime is $O(n^{\log_2(6+6/7)} \log n) \approx n^{2.776}$, a notable improvement over Strassen. See also [10] for further details.

In this paper, we describe an alternative way to use the KK algorithm: instead of executing multiple independent iterations, we combine them all into a single larger randomized broken multiplication. Each term of the original matrix multiplication product gets sampled multiple times into the larger matrix.

For Boolean matrix multiplication, this gives the following crisp result (given here in a slightly simplified form):

▶ **Theorem 1.** *For square matrices, we can compute BMM using* $O(n^{\frac{3\log 3}{\log 7}} (\log n)^{\frac{\log 6}{\log 7}}) \leq O(n^{2.763})$ *bit operations with high probability*

Our algorithm can also be used to obtain a randomized approximation for real-valued matrix multiplication. The precise approximation guarantees depend on the values input matrices. For general matrices, the accuracy of the estimated matrix term $\tilde{C}_{ij}$ depends on the value $C_{ij}$ as well as the "second moment" of matrix, namely

$$\tilde{C}_{ij}^{(2)} = \sum_k A_{ik}^2 B_{kj}^2$$

When the input matrices $A, B$ (and hence $C$) are non-negative, then note that $\tilde{C}_{ij}^{(2)} \leq C_{ij}^2$; in this case, we have the following crisp statement (again, in simplified form):

▶ **Theorem 2.** *For non-negative square matrices of dimension $n$, we can obtain an approximating matrix $\tilde{C}$ using $O(n^{2.763}/\varepsilon^2)$ operations with high probability, satisfying $(1-\epsilon)C_{ij} \leq \tilde{C}_{ij} \leq (1+\epsilon)C_{ij}$ for all $i, j$.*

For example, in the setting of Boolean matrix multiplication, we can not only *detect* if there is any value $k$ with $A_{ik} = B_{kj} = 1$, but we can *estimate* the number of such values of $k$, up to any desired relative accuracy.

The new algorithm is quite simple, and also has a number of advantages from the viewpoint of practical implementations. First, it lends itself easily to rectangular (non-square) input matrices; we will show a more general theorem which describes the runtime scaling for matrices of arbitrary shape. Second, the algorithm itself internally uses square matrices, and is flexible about the precise dimensions used; this avoids a number of tedious issues with padding in matrix algorithms.

We emphasize that this paper is structured somewhat differently from a typical paper in theoretical computer science. Since our goal is to develop a new *practical* algorithm (we already have good theoretical algorithms!), we cannot afford to look only at asymptotic estimates, ignoring constant factors in runtime. Instead, we have developed our formlas and calculations much more preicsely to get concrete runtime estimates in addition to the usual asymptotic bounds.

In Section 7, we illustrate with some computational estimates for large problem instances which are at the limit of practicality. Unfortunately, as we will see, the asymptotic behavior does not seem to fully kick in even at such large scales. At the current time, it appears that the new algorithm is unlikely to beat alternative algorithms; further optimizations and improvements may be needed.

We note that [11] also discussed generalizations to other types of broken matrix multiplication tensors. We will restrict our attention of the Strassen-based pseudo-multiplication, for three reasons. First, much of our analysis depends on certain structural properties of Strassen-type tensor; unlike the analysis in [11], which only depended on the gross *number of terms* in the pseudo-multiplication, we need to track the distribution of terms carefully. Second, it is not clear if any other tensors are practical, especially in light of the fact that Strassen's algorithm appears to be the only truly practical fast multiplication algorithm known. Finally, many of the "generic" amplification techniques for general tensors, which "only" lose constant factors, are too crude for understanding practical implementations.

## 2 Pseudo-multiplication

To describe our BMM algorithm, we need to discuss the underlying broken multiplication algorithm in depth. We call this procedure "pseudo-multiplication", to distinguish it from the overall KK algorithm itself. We begin by quoting the algorithmic result of [11].

▶ **Theorem 3.** *Consider* $2 \times 2$ *matrices* $A, B$ *over a ring* $R$. *Using* 14 *additions and* 6 *multiplications in* $R$, *we can compute the following quantities:*

$$C_{11} = A_{12}B_{21}$$
$$C_{12} = A_{11}B_{12} + A_{12}B_{22}$$
$$C_{21} = A_{21}B_{11} + A_{22}B_{21}$$
$$C_{22} = A_{21}B_{12} + A_{22}B_{22}$$

This formula differs from the computation of $C = AB$, in that the term $C_{11}$ is missing the summand $A_{11}B_{11}$. This computation is achieved by a variant of a Strassen step, except that one of the 7 multiplications is omitted.

Now consider integer matrices $A, B$ of dimension $n = 2^s$. We can identify the integers in the range $[n] = \{0, \dots, n-1\}$ with binary vectors $\{0,1\}^s$; thus, we may write $A_{xy}$ for vectors $x, y \in \{0,1\}^s$. We write $z = x \vee y$ where $z_i$ is zero iff $x_i = y_i = 0$, i.e. the disjunction is done coordinate-wise. Also, we let $|x|$ denote the Hamming weight of a binary vector $x$. By iterating the algorithm of Theorem 3 for $s$ levels, we get the following:

▶ **Theorem 4.** *Using* $7(6^s - 4^s)$ *additions and* $6^s = n^{\log_2 6}$ *multiplications, we can compute the matrix pseudo-product* $C = A \boxtimes B$ *defined as* $C_{xy} = \sum_{x \vee y \vee z = \vec{1}^s} A_{xz}B_{zy}$, *where* $\vec{1}^s$ *denotes the vector of dimension* $s$ *whose entries are all equal to* 1. *The computation of* $C$ *can be performed over any ring.*

**Proof.** See full paper. ◀

In particular, this implies the following result (which was the only thing shown directly in [11]):

▶ **Corollary 5.** *The pseudo-product* $C = A \boxtimes B$ *contains* $(7/8)^s$ *of the summands in the full matrix product* $C = AB$.

**Proof.** There are precisely $7^s$ triples of vectors $x, y, z \in \{0,1\}^s$ with $x \vee y \vee z = \vec{1}^s$. ◀

Note that [11] includes an additional randomization step, where the entries of the matrices are randomly permuted at each level. We omit this step, since we will later include more extensive randomization in the overall algorithm. (For practical purposes, this shuffling step can be awkward to implement efficiently). For given $s$, we define $T_s \subseteq \{0,1\}^s \times \{0,1\}^s \times \{0,1\}^s$ to be the set of triples $x, y, z$ with $x \vee y \vee z = \vec{1}^s$.

It is sometimes useful to use Strassen's algorithm, or naive matrix multiplication, for some of the low-level iterations. Let us suppose that we use $s$ steps of pseudo-multiplication, followed by true matrix multiplication on the resulting submatrices of dimension $b_i = d_i/2^s$ (the *base case*). We can view any integer $x \in \{1, \dots, d_i\}$ as equivalent to an ordered pair $(x', x'')$ where $x' \in \{0,1\}^s$ and $x'' \in \{1, \dots, b_i\}$. The resulting matrix, denoted still by $C = A \boxtimes B$, then satisfies

$$C_{xy} = \sum_{\substack{z=(z',z'') \in \{0,1\}^s \times \{1,\dots,b\} \\ x' \vee y' \vee z' = \vec{1}^s}} A_{(x',x''),(z',z'')} B_{(z',z'')(y',y'')}$$

The proof is completely analogous to Theorem 4 so we omit it here. For convenience, let us say that, for integers $x, y, z$, we have $x \vee y \vee z = \vec{1}$ if, when we write $x = (x', x''), y = (y', y''), z = (z', z'')$, we have $x' \vee y' \vee z' = \vec{1}^s$, i.e. $(x', y', z') \in T_s$. When $s, d_1, d_2, d_3$ are understood, we also define $T^* \subseteq [d_1] \times [d_2] \times [d_3]$ to be the resulting set of triples $(x, y, z)$ with this property. With these conventions, we can define $C = A \boxtimes B$ more compactly as $C_{xy} = \sum_{z:(x,y,z) \in T^*} A_{xz}B_{zy}$.

If the matrices are square, then the base case would also likely be square $b = b_1 = b_2 = b_3$. From a theoretical point of view, $b$ may be viewed as a constant. When working in the field GF(2), the base case multiplication would likely involve switching to a Four Russians method and/or bitsliced operations. These optimizations are very powerful in practice, possibly more important than the asymptotic gains from a fast matrix multiplication algorithm. Consequently, in practical implementations, $b$ may be very large; for instance, in the implementation of [1], they choose $b \approx 2^{11}$ (roughly matching the L2 cache size).

## 3 Algorithm overview

Consider matrices $A, B$ of dimension $d_1 \times d_3$ and $d_3 \times d_2$; here the matrices are either real-valued or Boolean-valued, and our goal is to approximate the product $C = AB$. The algorithms we use are very similar for these two cases: we choose some parameter $s$ and base sizes $b_1, b_2, b_3$. For $\ell = 1, 2, 3$ we define $m_\ell = 2^s b_\ell$, and draw random functions $f_\ell : [m_\ell] \to [d_\ell]$. We then form matrices $\bar{A}, \bar{B}$ of dimension $m_1 \times m_3, m_3 \times m_2$ by sampling from matrices $A, B$ according to the function $f$, i.e. we will have

$$\bar{A}_{xz} = A_{f_1(x) f_3(z)}, \qquad \bar{B}_{zy} = B_{f_3(z) f_2(y)}$$

(the actual matrices $\bar{A}, \bar{B}$ will have some additional scaling factors)

We then compute the pseudo-product $\bar{C} = \bar{A} \boxtimes \bar{B}$, with the given base case sizes, and produce an estimated matrix $\tilde{C}$, where, for each entry $ij$, the estimate $\tilde{C}_{ij}$ is derived by aggregating the entries $\bar{C}_{xy}$ where $x \in f_1^{-1}(i), y \in f_2^{-1}(j)$.

The runtime for this process will be $O(6^s)$ field operations, and the memory required is $O(4^s)$ to store the matrices $\bar{A}, \bar{B}, \bar{C}$ (assuming $b$ is constant). For any triple $i, j, k$ in the matrix product $A_{ik} B_{kj}$, there are roughly $\frac{7^s b_1 b_2 b_3}{d_1 d_2 d_3}$ entries $u = (x, y, z) \in T^*$ which get mapped to $i, j, k$, i.e. $f_1(x) = i, f_2(y) = j, f_3(z) = k$. Thus, as long as $7^s b_1 b_2 b_3 \gg d_1 d_2 d_3$, we should expect that the sampled matrix "covers" the original matrix, and so we get accurate answers. However, to analyze it formally, we need to take account of some potentially problematic dependencies between entries in the matrix. This was not an issue encountered in the original analysis [11], which only worked expectation-wise.

There are a number of other details to work out for the algorithms. For the real-valued case, we need certain weighting factors to account for the fact that some entries of the product $\bar{A} \boxtimes \bar{B}$ are over-represented in the the pseudo-multiplication. For the Boolean case, we need to have an additional randomization to handle the Boolean-to-GF(2) reduction. We provide the details next.

**Real-valued algorithm.** Having chosen the parameter $s$ and the random functions $f$, we will choose scaling matrices $G^A, G^B, G^C$ of dimensions $m_1 \times m_3, m_3 \times m_2, m_1 \times m_2$ respectively (their role will be discussed shortly). We then define

$$\bar{A}_{xz} = G^A_{xz} A_{f_1(x), f_3(z)}, \qquad \bar{B}_{zy} = G^B_{zy} B_{f_3(z) f_2(y)}$$

and, after computing the pseudo-product $\bar{C} = \bar{A} \boxtimes \bar{B}$ over $\mathbb{R}$, we estimate $C$ by

$$\tilde{C}_{ij} = \sum_{x \in f^{-1}(i), y \in f_2^{-1}(j)} G^C_{xy} \bar{C}_{xy}$$

Importantly, for values $x = (x', x'') \in \{0,1\}^s \times [b_1], z = (z', z'') \in \{0,1\}^s \times [b_2]$, the value of each term $G^A_{xz}$ should only depend $x', z'$, in particular, it should depend on the Hamming weights of $|x'|, |z'|, |x' \vee z'|$;. A similar criterion should hold for $G^B, G^C$ matrices. Thus, with

a slight abuse of notation, we write $G^A_{x',z'}$ and similarly $G^B_{z',y'}, G^C_{x',y'}$. Thus, the matrices $G$ really only have $O(s^3)$ degrees of freedom; we discuss later how to choose their values (both for asymptotic analysis and practical parameters).

**Boolean algorithm.** In this case, after drawing random functions $f$, we will also draw a uniformly random $m_3 \times m_2$ binary matrix $D$. We then form matrices $\bar{A}, \bar{B}$ by setting:

$$\bar{A}_{xz} = A_{f_1(x)f_3(z)}, \qquad \bar{B}_{zy} = B_{f_3(z)f_2(y)} D_{zy}$$

We then compute the pseudo-product $\bar{C} = \bar{A} \boxtimes \bar{B}$ over the finite field GF(2), with the given base case sizes, and produce an estimated matrix $\tilde{C}$ by $\tilde{C}_{ij} = \bigvee_{x \in f_1^{-1}(i), y \in f_2^{-1}(j)} \bar{C}_{xy}$.

**Analysis overview.** We will analyze the algorithms in three main steps. First, we derive some non-asymptotic bounds on the accuracy, in terms of parameters which can be computed explicitly as functions of $s$. Next, we use these to derive asymptotic bounds on the algorithm complexity. While illuminating as to the basic algorithm shape, these asymptotic bounds are not optimized and not of direct relevance for practical-scale computations. So we finish with some cases studies on very large problem parameters pushing the limits of practical computations, with concrete bounds.

Throughout, we define parameters

$$\psi_1 = d_1 + d_2 + d_3, \psi_2 = d_1 d_2 + d_2 d_3 + d_1 d_3, \psi_3 = d_1 d_2 d_3$$

Also, for each $\ell = 1, 2, 3$, we define $q_\ell = b_\ell / d_\ell$.

## 4 Analysis: the real-valued case

Consider some entry $i, j$; we can see that

$$\tilde{C}_{ij} = \sum_k \sum_{(x,y,z) \in T^*} G^A_{xz} G^B_{yz} G^C_{xy} [f_1(x) = i][f_2(y) = j][f_3(z) = k] A_{ik} B_{kj}$$

where we use Iverson notation for any boolean predicate here and throughout the paper, i.e. $[E] = 1$ if $E$ holds, otherwise $[E] = 0$. Our strategy to analyze $\tilde{C}_{ij}$ is to compute the mean and variance. We will show that $\mathbb{E}[\tilde{C}_{ij}] \propto C_{ij}$ (with known proportionality constants). Thus, by rescaling the matrix entries $G$ as needed, we can obtain an unbiased estimate of $C_{ij}$. Likewise, the variance of $\tilde{C}_{ij}$ will depend on $C_{ij}$ as well as its "second moment"

$$C^{(2)}_{ij} = \sum_k A^2_{ik} B^2_{kj}$$

To simplify the notation, let us write

$$G_{xyz} := G^A_{xz} G^B_{yz} G^C_{xy}$$

for a triple $(x, y, z) \in T$. We have the following main estimate:

▶ **Lemma 6.** *Define the sums $r_0, \dots, r_7$ by:*

$$r_0 = \sum_{(x,y,z)\in T_s} G_{xyz} \qquad r_1 = \sum_{x\in\{0,1\}^s} \Big( \sum_{y,z:(x,y,z)\in T_s} G_{xyz} \Big)^2$$

$$r_2 = \sum_{y\in\{0,1\}^s} \Big( \sum_{x,z:(x,y,z)\in T_s} G_{xyz} \Big)^2, \qquad r_3 = \sum_{z\in\{0,1\}^s} \Big( \sum_{x,y:(x,y,z)\in T_s} G_{xyz} \Big)^2$$

$$r_4 = \sum_{x,y\in\{0,1\}^s} \Big( \sum_{z:(x,y,z)\in T_s} G_{xyz} \Big)^2, \qquad r_5 = \sum_{x,z\in\{0,1\}^s} \Big( \sum_{y:(x,y,z)\in T_s} G_{xyz} \Big)^2$$

$$r_6 = \sum_{y,z\in\{0,1\}^s} \Big( \sum_{x:(x,y,z)\in T_s} G_{xyz} \Big)^2, \qquad r_7 = \sum_{(x,y,z)\in T_s} G_{xyz}^2$$

*Then, for any $i, j$, there holds $\mathbb{E}[\tilde{C}_{ij}] = q_1q_2q_3r_0C_{ij}$ and*

$$\mathbb{V}[\tilde{C}_{ij}] \le q_1q_2q_3^2(q_2r_1 + q_1r_2 + r_4)C_{ij}^2 + q_1q_2q_3(q_1q_2r_3 + q_2r_5 + q_1r_6 + r_7)C_{ij}^{(2)}$$

**Proof.** See full paper. ◀

For non-negative matrices, the statistic $\tilde{C}_{ij}$ can be used to estimate the value $C_{ij}$ up to some relative accuracy. We summarize this as follows:

▶ **Corollary 7.** *If matrices $A, B$ are non-negative, then*

$$\frac{\mathbb{V}[\tilde{C}_{ij}]}{\mathbb{E}[\tilde{C}_{ij}]^2} \le \frac{(q_3q_2r_1 + q_3q_1r_2 + q_1q_2r_3) + (q_3r_4 + q_2r_5 + q_1r_6) + r_7}{q_1q_2q_3r_0^2}$$

**Proof.** We know $C_{ij} \ge 0$ and $C_{ij}^{(2)} \le C_{ij}^2$ for each entry $i, j$. ◀

## 5 Analysis: the Boolean case

In the Boolean case, it does not make sense to talk about how close the matrices entries $\tilde{C}_{ij}$ are to the true value $C_{ij}$. Instead, we will argue that, with high probability, we have $\tilde{C}_{ij} = C_{ij}$ exactly. It is clear that if $C_{ij} = 0$, then $\tilde{C}_{ij} = 0$ with probability one. Thus, consider some pair $i, j$ with $C_{ij} = 1$ and some witness value $k$ with $A_{ik} = B_{kj} = 1$. We want to find a triple of values $(x, y, z) \in T^*$ such that $f_1(x) = i, f_2(y) = j, f_3(z) = k$. If such a triple exists, then the randomization involved in the $D$ matrix should ensure that $\bar{C}_{xy} = 1$ with probability $1/2$, in which case $\tilde{C}_{ij} = 1$ as well.

To show the existence of such a triple $(x, y, z)$, we will use an important general probabilistic inequality of Janson [9]. We summarize it in the following form:

▶ **Theorem 8** ([9])**.** *Suppose that $X_1, \dots, X_N$ are independent Bernoulli variables, and suppose $\mathcal{E}$ is a collection of monomial events over ground set $[N]$, i.e. each event $E \in \mathcal{E}$ is a conjunction of the form $\bigwedge_{r\in R_E} X_r$ for a given subset $R_E \subseteq [n]$. For events $E, E' \in \mathcal{E}$, we write $E \sim E'$ if $R_E \cap R_{E'} \neq \emptyset$, and we write $\bar{E}$ for the complement of $E$ (i.e. that event $E$ does not hold.)*

*If we define*

$$\kappa = \sum_{E\in\mathcal{E}} \mathbb{E}\Big[\frac{[E]}{\sum_{E'\sim E}[E']}\Big]$$

*then we have*

$$\Pr(\bigwedge_{E\in\mathcal{E}} \bar{E}) \le e^{-\kappa}$$

We use it to get the following main result:

▶ **Theorem 9.** *Define values*

$$q'_1 = 1 - (1 - 1/d_1)^{b_1}, q'_2 = 1 - (1 - 0.5/d_2)^{b_2}, q'_3 = 1 - (1 - 1/d_3)^{b_3}$$

*Consider independent Bernoulli variables $I_{\ell,x}$ for $\ell = 1, 2, 3$ and $x \in \{0,1\}^s$, wherein each $I_{\ell,x}$ has expected value $q'_\ell$. For each tuple $u = (x, y, z) \in T_s$, define associated event $E_u$ to be the conjunction $I_{1,x} = I_{2,y} = I_{3,z} = 1$.*

*Then, for any pair $i, j$ with $C_{ij} = 1$, there holds* $\Pr(\tilde{C}_{ij} = 0) \leq \Pr(\bigwedge_{u \in T_s} \bar{E}_u)$.

**Proof.** We divide the analysis into two parts. first, we consider the random functions $f_\ell$, and then consider the random matrix $D$. Let us fix some arbitrary value $k$ with $A_{ik} = B_{kj} = 1$. Suppose that we chosen the functions $f_\ell$, and let $P$ denote the set of triples $(x, y, z) \in T^*$ with $f_1(x) = i, f_2(y) = j, f_3(z) = k$. From this, let $S$ denote the number of *distinct* values $y$ encountered, i.e. $S = |\{y : (x, y, z) \in P\}|$.

We claim that, having fixed the functions $f_\ell$, the probability that $C_{ij} = 0$ is at most $2^{-S}$. For, suppose that $P$ contains triples $(x_1, y_1, z_1), \ldots, (x_S, y_S, z_S)$ where $y_1, \ldots, y_S$ are distinct. In forming each entry $\bar{C}_{x_\ell y_\ell}$, we are adding in $D_{z_\ell y_\ell} A_{ik} B_{kj} = D_{z_\ell y_\ell}$ as well as potentially other entries $D_{z' y_\ell}$. These are all independent random bits, and hence their sum over GF(2) is equal to 1 with probability precisely $1/2$; in this case we would have $\bar{C}_{x_\ell y_\ell} = 1$ and hence $\tilde{C}_{ij} = 1$. Furthermore, since $y_1, \ldots, y_S$ are distinct, all such events are independent.

We also define independent Bernoulli random variables $I'_{1,x}, I'_{2,y}, I'_{3,z}$ to be the events that, respectively, $f_1(x) = i$, or $f_2(y) = j$, or $f_3(z) = k$; these have means $\frac{1}{d_1}, \frac{1}{d_2}, \frac{1}{d_3}$ respectively. Note that $P$, and hence $S$, is determined by these variables. Integrating over them, we have

$$\Pr(\tilde{C}_{ij} = 0) \leq \mathbb{E}[2^{-S}]$$

For each $x \in \{0,1\}^s$, we define events

$$I_{1,x} = \bigvee_{x'} I'_{1,(x,x')}, \qquad I_{2,y} = \bigvee_{y'} I'_{2,(y,y')} J_{(y,y')}, \qquad I_{3,z} = \bigvee_{z'} I'_{3,(z,z')},$$

where $x', y', z'$ range over $[b_1], [b_2], [b_3]$ respectively, and where $J_{(y,y')}$ are independent Bernoulli-1/2 random variables. Observe that $I_{1,x}, I_{2,y}, I_{3,z}$ are all independent Bernoulli random variables with means $q'_1, q'_2, q'_3$ respectively. Now consider the probability of the event $\bar{E}_u$. Suppose we reveal random variables $I'_{1,x}, I'_{2,y}, I'_{3,z}$. Conditional on these values, the only way for $\bigwedge_u \bar{E}_u$ to occur is that $J_y = 0$ holds for all tuples $u = (x, y, z) \in P$. This has probability precisely $2^{-S}$. Integrating over variables $I'$, we get:

$$\Pr(\bigwedge_u \bar{E}_u) = \mathbb{E}[2^{-S}]$$

Putting the inequalities together gives the claimed result

$$\Pr(\tilde{C}_{ij} = 0) \leq \mathbb{E}[2^{-S}] = \Pr(\bigwedge_u \bar{E}_u)$$ ◀

Observe that events $E_u$ of Theorem 9 are precisely the types of monomial events covered by Theorem 8; this will be used for asymptotic and concrete bounds later.

## 6 Asymptotic analysis

The asymptotic analysis of both the real-valued and Boolean use similar arguments. For this section, we let $b_1 = b_2 = b_3 = 1$, since the base cases should only affect analysis by constant factors.

We want to determine the number of triples $(x, y, z) \in T_s$ with $f_1(x) = i, f_2(y) = j, f_3(z) = k$ for values $i, j, k$; the relevant quantities ($r_0, \dots, r_7$ for the real-valued case and $\kappa$ for the Boolean case) are in effect counting these triples. Our basic strategy is to restrict the analysis to "typical" triples, specifically, let us define $H \subseteq T_s$ to be the set of triples $(x, y, z) \in T$ satisfying the following conditions:

1. $|x| \le 4s/7$ and $|y| \le 4s/7$ and $|z| \le 4s/7$
2. $|x \vee y| \le 6s/7$ and $|x \vee z| \le 6s/7$ and $|y \vee z| \le 6s/7$

▶ **Lemma 10.** *There holds* $|H| \ge \Omega(7^s)$.

**Proof.** There are precisely $7^s$ triples $(x, y, z)$ in $T_s$. Let us consider the probability space which is the uniform distribution on $T_s$; equivalently, for each coordinate $i$, the values $(x_i, y_i, z_i)$ are chosen uniformly at random among the 7 non-zero values. We need to show that the conditions on the densities of $x, y, z, x \vee y, x \vee z, y \vee z$ are satisfied with constant probability.

For each coordinate $i$, consider the 6-dimensional random vector $V_i = (x_i, y_i, z_i, x_i \vee y_i, x_i \vee z_i, y_i \vee z_i)$ and let $V = \sum_i V_i$. We need to show that $V - \beta s$ has non-positive entries where $\beta = (4/7, 4/7, 4/7, 6/7, 6/7, 6/7)$. For this, we use the multidimensional Central Limit Theorem. Since the variables $V_i$ are i.i.d. and each has mean $\beta$, the scaled value

$$\sqrt{s}(V/s - \beta)$$

approaches to a 6-dimensional normal distribution $N(0, \Sigma)$ with covariance matrix given by

$$\Sigma = \frac{1}{49}\begin{bmatrix} 12 & -2 & -2 & 4 & 4 & -3 \\ -2 & 12 & -2 & 4 & -3 & 4 \\ -2 & -2 & 12 & -3 & 4 & 4 \\ 4 & 4 & -3 & 6 & -1 & -1 \\ 4 & -3 & 4 & -1 & 6 & -1 \\ -3 & 4 & 4 & -1 & -1 & 6 \end{bmatrix}$$

as $s \to \infty$.

Note that $\Sigma$ is non-singular. Hence, for the corresponding distribution $N(0, \Sigma)$ there is positive probability that all six coordinates are negative. For large enough $s$, the probability that $V - \beta s$ has negative entries converges; in particular, it approaches to some constant value as $s \to \infty$. (The lemma holds vacuously when $s = O(1)$.) ◀

We will define two constants which show up repeatedly in the analysis:

$$\alpha_1 = 14 \cdot 2^{1/7} \cdot 3^{3/7} \approx 24.75$$

$$\alpha_2 = 7 \cdot 2^{6/7} \approx 12.68$$

▶ **Lemma 11.** *For* $i = 1, 2$, *there are* $O(\frac{\alpha_i^s}{\sqrt{s}})$ *pairs* $(x, y, z), (x', y', z') \in H$ *with* $[x = x'] + [y = y'] + [z = z'] \ge i$.

**Proof.** For $i = 1$, we will count the pairs $(x, y, z), (x', y', z') \in H$ with $x = x'$; the cases with the other two coordinates are completely symmetric. Let us suppose that, among the $s$ entries of $x$, there are $\ell$ coordinated equal to one; since $(x, y, z) \in H$ we must have $\ell \le 4s/7$.

For each coordinate $i$ with $x_i = x'_i = 1$, the values $y_i, y'_i, z_i, z'_i$ can be arbitrary (giving $16^\ell$ choices); for each coordinate $i$ with $x_i = x'_i = 0$, there are three non-zero choices for $(y_i, z_i)$ and three non-zero choices for $(y'_i, z'_i)$. Overall, there are $16^\ell 9^{s-\ell}$ choices for the vectors $y, z, y', z'$. Summing over $\ell$, we get that the total contribution is

$$\sum_{\ell=0}^{\lfloor 4s/7 \rfloor} \binom{s}{\ell} 16^\ell 9^{s-\ell}$$

Let $h(\ell) = \binom{s}{\ell} 16^\ell 9^{s-\ell}$ be the summand corresponding to $\ell$; we can observe that $h(\ell)/h(\ell-1) = \frac{16(s+1-\ell)}{9}$. In particular, for $\ell \le 4s/7$, this ratio is at least $4/3$. Hence, the entire sum $\sum_{\ell=0}^{4s/7} h(\ell)$ is within a constant factor of $h(4s/7)$. In turn, by Stirling's formula, we can calculate $h(4s/7) \le O(\alpha_1^s/\sqrt{s})$.

For $i = 2$, we count the pairs $(x, y, z), (x', y', z') \in H$ with $x = x', y = y'$; the cases with the other two coordinates are again completely symmetric. Let us suppose that, among the $s$ entries of $x, y$, there are $\ell$ coordinates with $x_i \vee y_i = 1$; since $(x, y, z) \in H$ we must have $\ell \le 6s/7$. For each such coordinate $i$, there are 4 choices for $z, z'$ and 3 choices for $x, y$; for each coordinate with $x_i \vee y_i = x'_i \vee y'_i = 0$, we must have $z_i = z'_i = 1$. Summing over $\ell$, the total contribution is

$$\sum_{\ell=0}^{\lfloor 6s/7 \rfloor} \binom{s}{\ell} 3^\ell 4^\ell$$

Let $h(\ell) = \binom{s}{\ell} 12^\ell$ be the summand corresponding to value $\ell$; note that $h(\ell)/h(\ell-1) = \frac{12(s+1-\ell)}{\ell}$. For $\ell \le 6s/7$, this ratio is at least 2, and hence the entire sum is within a constant factor of $h(6s/7)$. In turn, by Stirling's formula, we get $h(6s/7) \le O(\alpha^2 s/\sqrt{s})$. ◀

▶ **Proposition 12.** *Suppose we define matrices $G^A, G^B, G^C$ by*

$$G^A_{xz} = [|x| \le 4s/7][|z| \le 4s/7][|x \vee z| \le 6s/7]$$
$$G^B_{yz} = [|y| \le 4s/7][|z| \le 4s/7][|y \vee z| \le 6s/7]$$
$$G^C_{xy} = [|x| \le 4s/7][|y| \le 4s/7][|x \vee y| \le 6s/7]$$

*Then the real-valued algorithm satisfies*

$$\mathbb{E}[\tilde{C}_{ij}] = \nu C_{ij} 7^s/\psi_3 \qquad \text{for a known proportionality constant } \nu$$
$$\mathbb{V}[\tilde{C}_{ij}] = O\Big(q_1 q_2 q_3^2 (q_1+q_2)\alpha_1^s/\sqrt{s} + \alpha_2^s/\sqrt{s}\Big) C_{ij}^2 + O\Big(q_1 q_2 q_3 (q_1 q_2 \alpha_1^s/\sqrt{s} + (q_1+q_2)\alpha_2^s/\sqrt{s} + 7^s\Big) C_{ij}^{(2)}$$

**Proof.** With this definition of the matrices $G^A, G^B, G^C$, we have $G_{xyz} = [(x, y, z) \in H]$. Now let us compute the sums $r_0, \ldots, r_7$. For $r_0$, we have $r_0 = \sum_{(x,y,z)\in T_s} G_{x,y,z} = \sum_{(x,y,z)\in H} 1 = |H|$; by Lemma 10 this is $\Omega(7^s)$.

For $r_1$, we compute

$$r_1 = \sum_{x\in 0,1^s} \Big( \sum_{y,z:(x,y,z)\in T_s} G_{xyz} \Big)^2 = \sum_{x\in 0,1^s} \Big( \sum_{y,z:(x,y,z)\in H} 1 \Big)^2 = \sum_{\substack{(x,y,z)\in H,(x',y',z')\in H \\ x=x'}} 1$$

By Lemma 11, this is $O(\alpha_1^s/\sqrt{s})$. By completely analogous reasoning, we have $r_2, r_3 \le O(\alpha_1^s/\sqrt{s})$ and $r_4, r_5, r_6 \le O(\alpha_2^s/\sqrt{s})$. For $r_7$, we have

$$r_7 = \sum_{(x,y,z)\in T_s} G^2_{xyz} = \sum_{(x,y,z)\in H} 1 = |H| \le |T_s| \le 7^s$$

Now we directly apply Lemma 6. ◀

By collecting terms in Proposition 12, and noting that $q_i = 1/d_i$ for $i = 1, 2, 3$, we immediately get the following corollary:

▶ **Corollary 13.** *Suppose that* $C^{(2)}_{ij} \leq C^2_{ij}$, *and that* $(\alpha_1/7)^s/\sqrt{s} \leq O(\psi_3/\psi_1)$ *and* $(\alpha_2/7)^s/\sqrt{s} \leq O(\psi_3/\psi_2)$. *Then*

$$\frac{\mathbb{V}[\tilde{C}_{ij}]}{\mathbb{E}[\tilde{C}_{ij}]^2} \leq O(\psi_3/7^s)$$

▶ **Theorem 14.** *Suppose that matrices* $A, B$ *are non-negative. Let* $\epsilon \in (0, 1)$, *and define parameters* $\gamma = \psi_3/\epsilon^2$ *and* $\beta_1 = \psi_3/\psi_1$ *and* $\beta_2 = \psi_3/\psi_2$. *With appropriate choice of parameters, we can obtain an estimated matrix* $\tilde{C}$, *such that, for any entry* $i, j$, *there holds*

$$\Pr(\tilde{C}_{ij} \in [(1-\epsilon)C_{ij}, (1+\epsilon)C_{ij}]) \geq 3/4,$$

*with overall runtime*

$$O\Big(\gamma^{\frac{\log 6}{\log 7}} + \gamma\big((\beta_1\sqrt{\log\beta_1})^{\frac{\log(6/7)}{\log(\alpha_1/7)}} + (\beta_2\sqrt{\log\beta_2})^{\frac{\log(6/7)}{\log(\alpha_2/7)}}\big)\Big)$$

**Proof.** Our strategy will be to take multiple independent executions and average them so that the resulting sample means have relative variance $\epsilon^2/4$. By Chebyshev's inequality, the resulting sample means are then within $(1 \pm \epsilon)C_{ij}$ with probability at least $3/4$. To that end, let us set

$$s = \Big\lfloor \min\{\log_7 \gamma, \log_{\alpha_1/7}(\beta_1\sqrt{\log\beta_1}), \log_{\alpha_2/7}(\beta_2\sqrt{\log\beta_2})\}\Big\rfloor$$

It can be shown that $(\alpha_1/7)^s/\sqrt{s} \leq O(\psi_3/\psi_1)$ and $(\alpha_2/7)^s/\sqrt{s} \leq O(\beta_2)$. Now, by collecting terms in Proposition 12, and noting that $q_i = 1/d_i$ for $i = 1, 2, 3$, and using the bounds $(\alpha_1/7)^s/\sqrt{s} \leq O(\psi_3/\psi_1)$ and $(\alpha_2/7)^s/\sqrt{s}$ as well as the observation that $C^{(2)}_{ij} \leq C_{ij}$, we get the estimate:

$$\frac{\mathbb{V}[\tilde{C}_{ij}]}{\mathbb{E}[\tilde{C}_{ij}]^2} \leq O(\psi_3/7^s)$$

Thus, if we repeat the process for $\Omega(1 + \epsilon^{-2}/(7^s/\psi_3))$ iterations and take the mean of all observations, the overall relative variance of the resulting sample mean is reduced to $\epsilon^2/4$, and hence satisfies the required bounds. (We can scale by a known proportionality constant to get an unbiased estimator). Overall, the runtime is then

$$O(6^s(1 + \epsilon^{-2}/(7^s/\psi_3)))$$

which after some simplifications, gives the claimed runtime bounds. ◀

▶ **Corollary 15.** *Suppose matrices* $A, B$ *are non-negative. With appropriate choice of parameters, the real-valued algorithm can compute* $C$ *with relative error* $1 \pm \epsilon$ *with probability* $3/4$ *in runtime*

$$O\Big((\psi_3/\epsilon^2)^{\frac{\log 6}{\log 7}} + \frac{\psi_1^{0.122}\psi_3^{0.878} + \psi_2^{0.259}\psi_3^{0.741}}{\epsilon^2}\Big)$$

*In particular, if the matrix is square of dimension* $n$, *then the runtime is* $O(n^{2.77}/\epsilon^2)$.

As usual, we can boost the success probability to any desired value $1-\delta$ by using median amplification, with a further $O(\log(1/\delta))$ increase in runtime. Despite the (relatively) crisp formula, Corollary 15 is not directly relevant to practical parameter sizes. Many of the hidden constants are large, and the bounds are all somewhat crude. Since our main goal is to obtain a *practical* algorithm we need to consider more finely how the algorithm scales for *small* values of $n$ and $s$; we consider this in the next section.

The analysis for the Boolean case is similar to the real-valued case.

▶ **Theorem 16.** *Let $\delta \in (0,1)$, and define parameters $\gamma = \psi_3 \log(1/\delta)$ and $\beta_1 = \psi_3/\psi_1$ and $\beta_2 = \psi_3/\psi_2$. With appropriate choice of parameters, we can obtain an estimated matrix $\tilde{C}$, such that, for any entry $i, j$, there holds*

$$\Pr(\tilde{C}_{ij} = C_{ij}) \geq 1 - \delta,$$

*with overall runtime*

$$O\Big(\gamma^{\frac{\log 6}{\log 7}} + \gamma\big((\beta_1\sqrt{\log\beta_1})^{\frac{\log(6/7)}{\log(\alpha_1/7)}} + (\beta_2\sqrt{\log\beta_2})^{\frac{\log(6/7)}{\log(\alpha_2/7)}}\big)\Big)$$

**Proof.** The proof is completely analogous to Theorem 14 and is omitted. ◀

▶ **Corollary 17.** *With appropriate choice of parameters, we can compute the overall matrix $C$ correctly with probability at least $1 - 1/\operatorname{poly}(\psi_3)$ using runtime*

$$O\Big((\psi_3 \log \psi_3)^{\frac{\log 6}{\log 7}} + \psi_1^{0.122}\psi_3^{0.878} + \psi_2^{0.259}\psi_3^{0.741}\Big)$$

We mention one important difference in our analysis of the real-valued and Boolean cases. For both algorithms, the analysis depends on the set $H \subseteq T_s$. For the Boolean algorithm, this is only used for purposes of analysis; the actual algorithm does not need to use $H$. For the real-valued algorithm, we need $H$ to define the matrices $G^A, G^B, G^C$ (which are part of the algorithm itself)

## 7 Concrete complexity estimates

Since our goal is to get a new practical algorithm, the asymptotic estimates are of limited value on their own. In this section, we consider costing the matrix multiplication algorithms for problem sizes which are at the upper limits of a practical problem size. In particular, we want to compare our algorithm to Strassen's algorithm and the KK algorithm. There are two main issues to consider. First, we need a realistic estimate of the runtime; second, we need a realistic estimate of the algorithm accuracy and/or success probability. The asymptotic estimates are much too crude for our purposes here.

Let us first consider the runtime. The work for the algorithm will involve $6^s$ many iterations of the recursive partitioning as given in Theorem 3. The cost of this step will have a quadratic component (adding and rearranging the relevant submatrices) as well as a nearly-cubic component (coming from the recursive subproblems). Assuming that the base case parameters are chosen to be sufficiently large, the first of these should be negligible; overall, we can estimate the work as $6^s W_b$ where $W_b$ is the base-case cost.

Let us compare this runtime with other matrix-multiplication algorithms. To avoid issues with padding, let us assume for convenience that $d_1 = d_2 = d_3$ and $d$ is a power of two. In this case, both Strassen's algorithm and the KK algorithm would run $s$ many recursive iterations, and then again pass to a base case. Assuming again that the base case is sufficiently large to hide the quadratic parts of the algorithm, these would have costs of $7^s W_b$ and $6^s W_b$ respectively.

Estimating $W_b$ itself is much trickier. As a starting point, we might estimate $W_b \approx b_1 b_2 b_3$ in terms of arithmetic operations. But there are many additional factors to consider: a CPU with SIMD registers of width $w$ may be able to perform $w$ operations in parallel, which is especially powerful for GF(2) arithmetic. Furthermore, for GF(2), there are other optimizations such as Four-Russians. Fortunately, in order to compare our algorithm with Strassen or KK, the precise value of $W_b$ does not matter; it is common to all the algorithms.

To simplify further, let us assume that $b_1 = b_2 = b_3$, and let $b$ denote this common value, which we regard as a fixed constant. In this case, for Strassen and KK, the parameter $s$ must be set to a fixed value $s = s_0 = \log_2(n/b)$. Summarizing, the runtimes of our algorithm, Strassen's algorithms, and the KK algorithm, are proportional to values $6^s, 7^{s_0}, 6^{s_0}$, where $s_0 = \log_2(n/b)$, respectively.

At this point, let us bring up another important issue with costing the algorithms. As $s$ increases, the memory used by the algorithm also increases. Storing the original matrices requires roughly $n^2$ memory, and both Strassen and KK algorithms use essentially this same amount of memory as well. Our algorithm, by contrast, may require $6^s$ memory to store the expanded $\bar{A}, \bar{B}$; if $s$ is large, this may significantly increase the memory cost. Note that, for very large scale problems, the computational costs of the algorithm (i.e. total number of arithmetic operations) are dominatedc by the communication costs (i.e. moving memory across multiple nodes of a computer cluster.) In order to keep this section relatively contained, we will not investigate further the memory costs.

Next, we need to analyze the algorithm accuracy. Let us first consider the Boolean algorithm, where the comparison between our algorithm and the other candidate algorithms is more straightforward. Assuming we are using the reduction from Boolean matrix multiplication to GF(2) matrix multiplication, all three algorithms are randomized. Let us denote by $f$ the maximum failure probability for any entry $C_{ij}$, if we use the matrix multiplication algorithm directly. Assuming we want to boost the algorithm to a much lower failure probability $\delta$, we need to repeat for $\lceil \log(1/\delta)/\log(1/f) \rceil$ iterations. Indeed, if we want to compute the entire matrix $C$ correctly, the value $\delta$ may need to be quite small (on the order of $1/n^2$). In order to put the algorithms on an even footing, let us therefore define a cost parameter

$$M = \frac{\text{Runtime}}{\log(1/f)} \tag{1}$$

The value $f$ may depend on the number of witness $k$ with $A_{ik}B_{kj} = 1$. The extremal case for all the algorithms appears to be the case where there is only one witness. In this case, the KK algorithm has failure probability $f = 1 - (7/8)^s/2$ and Strassen's algorithm has failure probability $1/2$. We thus have

$$M_{\text{Strassen}} = 7^s/\log 2, \qquad M_{\text{KK}} = \frac{6^s}{-\log(1-(7/8)^s/2)} \sim 2 \cdot (48/7)^s \approx 2 \cdot 6.857^s$$

To compare, we will compute the value $M$ for our algorithm in the next section.

Next, let us consider a scenario for real-valued matrix multiplication. To make things concrete, let us suppose that $A, B$ are non-negative matrices and we want to estimate the value $C_{ij}$ up to $(1 \pm \epsilon)$ for some constant value $\epsilon = 1/2$ and with success probability $3/4$. In order to do so, we need to run the matrix multiplication algorithm for

$$L = \frac{4\mathbb{V}[\tilde{C}_{ij}]}{\epsilon^2 \mathbb{E}[\tilde{C}_{ij}]^2} = \frac{16\mathbb{V}[\tilde{C}_{ij}]}{\mathbb{E}[\tilde{C}_{ij}]^2}$$

trials. The runtime for our algorithm will thus be

$$6^s \cdot 16\mathbb{V}[\tilde{C}_{ij}]/\mathbb{E}[\tilde{C}_{ij}]^2$$

This comparison is among the favorable possible for our algorithm. Strassen's algorithm has error probability zero and has perfect accuracy.

Although [11] did not discuss it, it is also possible to use KK for real-valued matrix multiplication (where we assume a random permutation of the rows and columns of $A, B$). We can estimate its runtime as $6^{s_0} \cdot 16(8/7)^{s_0}$, while Strassen's algorithm will take time $7^{s_0}$.

## 7.1 Case study: non-negative matrix multiplication

Let us consider a sample problem instance with $d_1 = d_2 = d_3 = 2^{25}$; as a reasonable choice for base case, let us take $b_1 = b_2 = b_3 = 2^7$. Note that storing the matrices already requires $2^{51}$ words of memory, which is at the upper limit of practical. Beyond this size, the problem would likely require a highly distributed memory system, and the runtime would be mostly determined by scheduling communications (as opposed to counting arithmetic operations).

With these parameters, Strassen and KK will set $s_0 = 18$, and they have runtimes of respectively

$$2^{50.5}, 2^{54.0}$$

In order to compare our algorithm to these two algorithms, to need to choose parameter $s$ and we also need to determine the matrices $G^A, G^B, G^C$. We do not know how to select the matrices $G$ in the optimal way, and the choice in Proposition 12 would be suboptimal by large constant factors. For our purposes, we used a local search method to select $G$, in order to minimize relative variance. (We note that, if instead we simply fixed all entries of $G^A, G^B, G^C$ to be equal to one, the variance would only increase by roughly 10% – 20%)

Figure 1, following, shows the relative variance and runtime for various choices of parameter $s$, and for our chosen accuracy parameter $\varepsilon = 1/2$ and success probability 3/4.

| $s$ | $\mathbb{V}[\tilde{C}_{ij}]/\mathbb{E}[\tilde{C}_{ij}]^2$ | Runtime |
|---|---|---|
| 10 | 25.9 | 55.8 |
| 11 | 23.1 | 55.6 |
| 12 | 20.3 | 55.4 |
| 13 | 17.6 | 55.2 |
| 14 | 14.8 | 55.0 |
| 15 | 12.1 | 54.8 |
| 16 | 9.4 | 54.8 |
| 17 | 6.9 | 54.8 |
| 18 | 4.5 | 55.0 |
| 19 | 2.4 | 55.6 |
| 20 | 0.7 | 56.4 |
| 21 | −0.7 | 57.6 |

**Figure 1** Runtime of our algorithm for the sample problem. To handle the wide dynamic range, all figures are given in log base two; e.g., for $s = 10$, relative variance is $2^{25.9}$ and runtime is $2^{55.8}$.

The optimal value appears to be roughly $s \approx 15$, with runtime $2^{54.8}$. This is slightly worse than KK algorithm, and much worse than Strassen's algorithm. We emphasize that this comparison is still unfair to Strassen's algorithm, which provides precise and deterministic calculations of $C_{ij}$. Also, the base case choice here is still probably smaller than optimal, again making the comparisons unfairly favorable to the randomized algorithms.

Thus, despite the asymptotic advantages, it will probably never be profitable to our algorithm, or the KK algorithm, for real-valued matrix multiplication.

## 7.2 Estimating performance for Boolean matrix multiplication

We now turn to estimating the failure probability of our algorithm for the Boolean setting. Unlike the KK algorithm, the random process involved is much more complex and we cannot obtain a simple closed-form expression. Our starting point is to consider the random process of Theorem 9, and to try to estimate the probability $p$ of the event $\bigwedge_{u \in T_s} \bar{E}_u$; note that $f \leq p$.

Let us consider a sample problem with $d_1 = d_2 = d_3 = 2^{25}$; following heuristics of [1], we might take the base case size as $b_1 = b_2 = b_3 = 2^{10}$. With these parameters, we can calculate

$$M_{\text{Strassen}} = 2^{42.64}, M_{\text{KK}} = 2^{42.61}$$

with both algorithms using $s_0 = 15$. (Recall the definition of $M$ from Eq. (1).) To compare these with our algorithm, we use both empirical simulations (with $10^6$ trials) on the hand, and Theorem 8 combined with Theorem 9 on the other hand, to obtain estimates of failure probability. Specifically, we write $\tilde{\kappa}$ for the estimate coming from Theorem 8 and we write $\hat{\kappa} = \log(1/\hat{p})$ for the Monte Carlo estimate.

By way of comparison, we can also calculate $\mu = 7^s q_1' q_2' q_3'$ to be the expected number of events $E_u$ which hold. In an ideal setting, if the events $E_u$ were completely independent, the failure probability would be $e^{-\mu}$, and we would have $\kappa = \mu$. See Figure 2.

| $s$ | $\mu$ | $\tilde{\kappa}$ | $\hat{\kappa}$ | $M$ (upper bound) | $M$ (empirical) |
|---|---|---|---|---|---|
| 7 | −26.3 | −26.4 | | 44.5 | |
| 8 | −23.5 | −23.6 | | 44.2 | |
| 9 | −20.7 | −20.8 | −19.9 | 44.0 | 43.2 |
| 10 | −17.9 | −18.0 | −18.9 | 43.8 | 44.8 |
| 11 | −15.1 | −15.2 | −15.2 | 43.6 | 43.5 |
| 12 | −12.3 | −12.5 | −12.5 | 43.5 | 43.5 |
| 13 | −9.5 | −9.8 | −9.7 | 43.4 | 43.3 |
| 14 | −6.7 | −7.3 | −7.1 | 43.5 | 43.2 |
| 15 | −3.9 | −5.0 | −4.5 | 43.7 | 43.3 |
| 16 | −1.1 | −2.9 | −2.1 | 44.3 | 43.5 |
| 17 | 1.7 | −1.2 | −0.1 | 45.2 | 44.0 |
| 18 | 4.5 | 0.2 | 1.6 | 46.4 | 44.9 |
| 19 | 7.3 | 14 | 3.0 | 47.7 | 46.1 |
| 20 | 10.1 | 2.5 | | 49.2 | |
| 21 | 13.0 | 3.5 | | 50.8 | |

**Figure 2** Possible failure parameters for the algorithm. Figures are given in log base two. Some empirical estimates are left blank because statistically significant estimates could not be obtained.

The optimal value $s$ appears to be roughly $s = 14$, and for this value we indeed have $\tilde{\kappa} \approx \hat{\kappa}$. Thus, a good heuristic to select $s$ would be to use the calculated value $\tilde{\kappa}$ and choose $s$ to minimize the resulting value $M$. This is much faster than empirical estimation, and it is also safer in that the resulting failure probability is a provable upper bound on the true failure probability.

## 8 Potential improvements

In the algorithms as we describe, the hash functions $f_\ell$ are chosen uniformly at random. The number of preimages of any $i \in [d_\ell]$ is thus a Binomial random variable with mean

$$\mu = \frac{2^s b_\ell}{d_\ell} = 2^s q_\ell$$

There are likely better ways to choose the random hash functions. For example, one could use a dependent rounding scheme to ensure that each $i \in [d_\ell]$ has precisely $\lfloor \mu \rfloor$ or $\lceil \mu \rceil$ preimages. One could even go further, aiming to ensure that the set of preimages $x \in f_\ell^{-1}(i)$ is "balanced" in terms of the Hamming weight of its elements.

These types of modifications would likely reduce the variance of the statistical estimates we develop. For practical parameter sizes, they could make a critical difference in the performance of the algorithm. However, these modifications are also much harder to analyze precisely. We leave as an open question the benefit of such improvements and whether they can make this algorithm fully practical.

## Abstract

We present the first polynomial-time algorithm to exactly compute the number of labeled chordal graphs on $n$ vertices. Our algorithm solves a more general problem: given $n$ and $\omega$ as input, it computes the number of $\omega$-colorable labeled chordal graphs on $n$ vertices, using $O(n^7)$ arithmetic operations. A standard sampling-to-counting reduction then yields a polynomial-time exact sampler that generates an $\omega$-colorable labeled chordal graph on $n$ vertices uniformly at random. Our counting algorithm improves upon the previous best result by Wormald (1985), which computes the number of labeled chordal graphs on $n$ vertices in time exponential in $n$.

An implementation of the polynomial-time counting algorithm gives the number of labeled chordal graphs on up to 30 vertices in less than three minutes on a standard desktop computer. Previously, the number of labeled chordal graphs was only known for graphs on up to 15 vertices.

## 1 Introduction

Generating random graphs from a prescribed graph family is a fundamental task for running simulations and testing conjectures. Although generating a random labeled graph on $n$ vertices is easy (just flip an unbiased coin for each potential edge), the first polynomial-time algorithm for generating an *unlabeled* graph uniformly at random was only given in 1987, by Wormald [36]. The algorithm of Wormald runs in polynomial time in expectation, and to the best of our knowledge, the existence of a worst-case polynomial-time sampler of random unlabeled graphs remains open.

Naturally, when we wish to sample from a specified graph family, there are many interesting families of graphs for which this problem is nontrivial, even when the graphs are labeled. For the class of labeled trees, a sampling algorithm using Prüfer sequences [27] was discovered in 1918. More recently, a fast (exact) uniform sampler was presented by Gao and Wormald for $d$-regular graphs with $d = o(\sqrt{n})$ in 2017 [11], and then for power-law graphs in 2018 [12]. A

more general problem is the following: given an arbitrary degree sequence, generate a random graph with those specified degrees – this has been resolved for bipartite graphs [21, 3] as well as for general graphs when the maximum degree is not too large [16, 1]. See Greenhill [15] for a survey of random generation of graphs with degree constraints. For planar graphs, Bodirsky, Gröpl, and Kang presented a polynomial-time algorithm [6], which uses dynamic programming to exactly compute the number of labeled planar graphs on $n$ vertices and generate a planar graph uniformly at random in time $\widetilde{O}(n^7)$. This was improved to $O(n^2)$ expected time by Fusy [10], using a Boltzmann sampler.

Our results fall naturally within this line of work. We consider the problem of generating a labeled *chordal* graph on $n$ vertices uniformly at random. A graph is chordal if it has no induced cycles of length at least 4. Despite being one of the most fundamental and well-studied graph classes, prior to our work, the fastest uniform sampling algorithm for labeled chordal graphs was the exponential-time algorithm of Wormald from 1985 [35]. (To be precise, optimizing the running time of an algorithm for counting chordal graphs was not the main focus of Wormald; rather, the main goal of the paper was to determine the asymptotic number of chordal graphs with given connectivity, and the exponential-time algorithm is a corollary of these results.) Since then, various algorithmic approaches have been proposed for generating chordal graphs (e.g., [23, 32, 33, 8, 24]), but these algorithms do not come with any formal guarantees about their output distribution. In particular, [32] specifically asks for the existence of a polynomial-time algorithm to sample chordal graphs uniformly at random as an open problem. In a recent abstract, Sun and Bezáková [33] proposed a Markov chain for sampling chordal graphs, but this Markov chain comes with few mixing time guarantees.

We obtain the first polynomial (in $n$) time algorithm to exactly count the number of labeled chordal graphs on $n$ vertices, as well as the first polynomial-time uniform sampling algorithm for the class of labeled chordal graphs. Our algorithm also easily extends to counting and sampling $\omega$-*colorable* labeled chordal graphs. A graph $G$ is $\omega$-colorable if there exists a function $c\colon V(G) \to \{1, \dots, \omega\}$ such that every edge $uv \in E(G)$ satisfies $c(u) \neq c(v)$.

▶ **Theorem 1.** *There is a deterministic algorithm that given positive integers $n$ and $\omega \leq n$, computes the number of $\omega$-colorable labeled chordal graphs on $n$ vertices using $O(n^7)$ arithmetic operations. Moreover, there is a randomized algorithm that generates a graph uniformly at random from the set of all $\omega$-colorable labeled chordal graphs on $n$ vertices using $O(n^7)$ arithmetic operations.*

By the known equivalence between chromatic number, maximum clique size, and treewidth of chordal graphs [5], Theorem 1 can be reinterpreted as counting and sampling labeled chordal graphs of clique size at most $\omega$, or treewidth at most $\omega - 1$. The running time bound of Theorem 1 is stated in terms of the number of arithmetic operations. Since there are at most $2^{n^2}$ labeled graphs on $n$ vertices, the arithmetic operations need to deal with $n^2$-bit integers. Therefore, using the $O(n \log n)$-time algorithm for multiplying two $n$-bit integers [19] yields an $O(n^9 \log n)$-time upper bound for our algorithm in the RAM model.

A straightforward implementation of our counting algorithm gives the number of labeled chordal graphs on up to $n = 30$ vertices in less than three minutes on a standard desktop computer. Previously, the number of labeled chordal graphs was only known for graphs on up to 15 vertices [25]. In addition, we use our implementation to compute the number of $\omega$-colorable labeled chordal graphs for $n \leq 12$ and $\omega \leq 12$. We chose to stop at $n = 12$ to keep the table at a reasonable size, not because of the computation time. We present the computational results in Section 4.

## 1.1 A Brief Survey on Chordal Graphs

The literature on chordal graphs is so vast that it would be impossible to fully do it justice. Discussions of chordal graphs in the literature go as far back as 1958 [18]. What follows is a summary of some of the most notable problems and milestones.

Many NP-hard optimization problems (such as *coloring* [13] and *maximum independent set* [9]), as well as #P-hard counting problems (such as *independent sets* [26, 4]), and many others [29], are polynomial-time solvable on chordal graphs. Chordal graphs have a wide variety of applications, including phylogeny in evolutionary biology [17, 28] and Bayesian networks in machine learning [34]. When doing Gaussian elimination on a symmetric matrix, the set of matrix entries that are nonzero for at least one time-point of the elimination process corresponds to the edge set of a chordal graph. Thus the problem of finding an ordering in which to do Gaussian elimination that minimizes the number of nonzero matrix entries can be reduced to finding a chordal supergraph of a given graph with the minimum number of edges [30]. This problem, known as *minimum fill-in*, was shown to be NP-complete by Yannakakis [37]. Chordal graphs have a central place in graph theory [7], both through their connection to treewidth [20] and through their connection to perfect graphs [14]. From an algorithms perspective, chordal graphs can be recognized in linear time [31].

An interesting and relevant result by Bender et al. [2] is that a random $n$-vertex labeled chordal graph is a split graph with probability $1 - o(1)$, i.e., the fraction of labeled chordal graphs that are not split is $o(1)$. This yields a simple *approximately uniform* sampler for labeled chordal graphs: simply sampling a random labeled split graph leads to an output distribution with total variation distance $o(1)$ from the uniform distribution on labeled chordal graphs. This simple sampling algorithm is unsatisfactory because it can never output a non-split chordal graph. Nevertheless, this result suggests two things: The first is that it might be possible to find a simple and efficient uniform random sampler for labeled chordal graphs. The second is that the type of chordal graphs that one usually envisions when thinking of a chordal graph (namely those with relatively small treewidth) are different from those most likely to be generated by a uniform random sampler (namely split graphs). Therefore, to generate the type of chordal graphs that one usually envisions, one should be sampling not from the set of all chordal graphs but rather from a subset, e.g., the set of all $\omega$-colorable chordal graphs. Fortunately, Theorem 1 provides this functionality.

## 1.2 Methods

Our exact counting algorithm is based on dynamic programming. While clique trees and tree decompositions are never explicitly mentioned in the description of the algorithm, the intuition behind the algorithm is based on these notions. Essentially, we generate a rooted clique tree where the dynamic-programming table encodes certain properties of the graph, including how it relates to the root node of the clique tree. A *clique tree* of a graph $G$ is a tree $T$ together with a function $f$ that maps each vertex of $G$ to a connected vertex subset of $T$, such that for every pair $u$,$v$ of vertices in $G$, $uv$ is an edge in $G$ if and only if $f(u) \cap f(v) \neq \emptyset$. It is well known that a graph $G$ has a clique tree if and only if it is chordal [5].

The main difficulty with this approach is that different chordal graphs have different numbers of clique trees, so if we count the total number of clique trees, this will not give us an accurate count of the number of $n$-vertex chordal graphs. Therefore, the key idea behind our algorithm is to assign to each labeled chordal graph a unique "canonical" clique tree and to only count these canonical clique trees. The information stored in the dynamic-programming table is sufficient to ensure that every clique tree that we do count is the canonical tree of

some chordal graph, and that the canonical clique tree of every chordal graph is counted. As it turns out, the best way to phrase our algorithm is not in terms of clique trees at all, but rather in terms of an (essentially) equivalent notion that we call an "evaporation sequence." An evaporation sequence is closely related to the standard notion of a perfect elimination ordering (PEO) of a chordal graph. A *simplicial* vertex is a vertex whose neighborhood is a clique, and a PEO is an ordering of the vertices such that each is simplicial in the current induced subgraph, if we delete the vertices in that order (see Section 3.1 for more details). An evaporation sequence is a type of "canonical" PEO: at each step, we remove *all* simplicial vertices from the current subgraph, rather than making an arbitrary choice of a single simplicial vertex. We say that all of the simplicial vertices evaporate at time 1. Next, all of the vertices that become simplicial once the first set of simplicial vertices has been removed are said to evaporate at time 2, and so on. It is easy to see that every labeled chordal graph has a unique evaporation sequence, and that this sequence does not depend on the labeling of the vertices.

Therefore, the number of chordal graphs on $n$ vertices is the sum over all evaporation sequences of the number of labeled chordal graphs with that evaporation sequence. While different evaporation sequences correspond to different numbers of chordal graphs, because this number is independent of the labels, we can simply guess the *number* $x$ of vertices that evaporate at any given time, and then without loss of generality assign the labels $1, \ldots, x$ to those vertices.

In our dynamic-programming algorithm, the recursive subproblems deal with counting *rooted* clique trees. In this context, the root of a clique tree is the set of vertices that evaporate last. Just as we would like to "force" a set of nodes to be in the root of the tree, we will sometimes want to force a set of nodes to evaporate last. This is done using what we call an *exception set*, i.e., a set of vertices that do not evaporate even if they are simplicial.

The random sampling algorithm in Theorem 1 follows from our counting algorithm using the standard sampling-to-counting reduction of [22].

## 1.3 Overview of the Paper

Our dynamic-programming algorithm, including the associated recurrences, is presented in Section 3. For a glimpse of the proof of correctness, one can find the proof of the first recurrence (the reduction to counting *connected* chordal graphs) in Section 3.4. The complete proof of correctness, as well as the details of how to obtain the random sampling algorithm using the counting algorithm, can be found in the full version of the paper.

# 2 Preliminaries

Our algorithm counts vertex-labeled chordal graphs. For simplicity of notation, we assume the vertex set of each graph is a subset of $\mathbb{N} = \{1, 2, 3, \ldots\}$, which allows the labels to also serve as the names of the vertices. For example, we will speak of the vertex $5 \in V(G)$ rather than a vertex $v$ with label 5.

▶ **Definition 2.** *A* labeled graph *is a pair $G = (V, E)$, where the vertex set $V$ is a finite subset of $\mathbb{N}$ and the edge set $E$ is a set of two-element subsets of $V$.*

Henceforth, we implicitly assume *all graphs that we consider are labeled graphs.* For nonnegative integers $n$, we use the notation $[n] \coloneqq \{1, 2, \ldots, n\}$. Intervals of integers will often appear in our algorithm as the vertex set of a graph or subgraph, so we also define

$$[a, b] \coloneqq \{a, a + 1, \ldots, b\}$$

for nonnegative integers $a, b$. If $b < a$, then $[a, b] = \emptyset$.

▶ **Definition 3.** *Let $A = \{a_1, \ldots, a_r\}$ and $B = \{b_1, \ldots, b_r\}$ be finite subsets of $\mathbb{N}$ such that $|A| = |B|$, where the elements $a_i$ and $b_i$ are listed in increasing order. We define $\phi(A, B)\colon A \to B$ as the bijection that maps $a_i$ to $b_i$ for all $i \in [r]$.*

▶ **Definition 4.** *Let $G_1$, $G_2$ be two graphs, and suppose $C \coloneqq V(G_1) \cap V(G_2)$ is a clique in both $G_1$ and $G_2$. When we say we* glue $G_1$ and $G_2$ together at $C$ *to obtain $G$, this indicates that $G$ is the union of $G_1$ and $G_2$: the vertex set is $V(G) = V(G_1) \cup V(G_2)$, and the edge set is $E(G) = E(G_1) \cup E(G_2)$.*

For a graph $G$ and a vertex subset $S \subseteq V(G)$, $G[S]$ denotes the induced subgraph on the vertices of $S$. For a vertex $v \in V(G)$, we denote the neighborhood of $v$ in $G$ by $N_G(v)$, or by $N(v)$ if the graph is clear from the context. For $S \subseteq V(G)$, the open neighborhood of $S$ is denoted by

$$N_G(S) \coloneqq \{v \in V(G) \setminus S : uv \in E(G) \text{ for some } u \in S\}$$

and the closed neighborhood of $S$ is denoted by $N_G[S] \coloneqq S \cup N_G(S)$, or simply $N(S)$ and $N[S]$, respectively. For $S, T \subseteq V(G)$, we say *$S$ sees all of $T$* if $T \subseteq N(S)$.

# 3 Counting labeled chordal graphs

## 3.1 The evaporation sequence

▶ **Definition 5.** *A vertex $v$ in a graph $G$ is* simplicial *if $N(v)$ forms a clique.*

A *perfect elimination ordering* of a graph $G$ is an ordering $v_1, \ldots, v_n$ of the vertices of $G$ such that for all $i \in [n]$, $v_i$ is simplicial in the subgraph induced by the vertices $v_i, \ldots, v_n$. It is well known that a graph is chordal if and only if it has a perfect elimination ordering [5]. For our counting algorithm, we define the notion of the evaporation sequence of a chordal graph, which can be viewed as a canonical version of the perfect elimination ordering. In the evaporation sequence, rather than making an arbitrary choice for which of the simplicial vertices in $G$ will go first in the ordering, we place the set of all simplicial vertices as the first item in the sequence. As an example, if $G$ is a tree, then the set of all simplicial vertices would be exactly the leaves of $G$.

To build the evaporation sequence, we use the fact that given a chordal graph $G$, if we repeatedly remove all simplicial vertices, then eventually no vertices remain. By observing at which time step each vertex is deleted, we obtain a partition of $V(G)$, which allows us to classify and understand the structure of $G$. In our algorithm, it will also be useful to set aside a set of exceptional vertices which are never deleted, even if they are simplical.

To formalize this, suppose we are given a chordal graph $G$ and a vertex subset $X \subseteq V(G)$. We define the *evaporation sequence* of $G$ with *exception set* $X$ as follows: If $X = V(G)$, then the evaporation sequence of $G$ is the empty sequence. If $X \subsetneq V(G)$, then let $\widetilde{L}_1$ be the set of all simplicial vertices in $G$, and let $L_1 = \widetilde{L}_1 \setminus X$. Suppose $L_2, \ldots, L_t$ is the evaporation sequence of $G \setminus L_1$ (with exception set $X$). Then $L_1, L_2, \ldots, L_t$ is the evaporation sequence of $G$.

For this definition to make sense, there is one caveat: we must choose $X$ so that all vertices outside of $X$ eventually evaporate. For example, $X = \emptyset$ is always a valid choice since every chordal graph contains a simplicial vertex [5]. Without this assumption, we could potentially reach a point where $X \subsetneq V(G)$ but $X$ contains all of the simplicial vertices of $G$, in which case the evaporation sequence would not be well-defined (we never reach the base case $X = V(G)$). In our algorithm, we will always choose a valid $X$ such that all other vertices eventually evaporate.

If the evaporation sequence $L_1, L_2, \ldots, L_t$ of $G$ has length $t$, then we say $G$ *evaporates* at time $t$ with *exception set* $X$, and $t$ is called the *evaporation time*. We define $L_G(X) \coloneqq L_t$ to be the last set in the evaporation sequence of $G$, and we let $L_G(X) = \emptyset$ if the sequence is empty. Similarly, we define the evaporation time of a vertex subset: Suppose $G$ has evaporation sequence $L_1, L_2, \ldots, L_t$ with exception set $X$, and suppose $S \subseteq V(G) \setminus X$ is a nonempty vertex subset. Let $t_S$ be the largest index $i$ such that $L_i \cap S \neq \emptyset$. We say $S$ *evaporates* at time $t_S$ in $G$ with exception set $X$.

## 3.2 Setup for the counting algorithm

Given positive integers $n$ and $\omega$, we wish to count the number of $\omega$-colorable chordal graphs on $n$ vertices. This can easily be reduced to the problem of counting *connected* $\omega$-colorable chordal graphs on at most $n$ vertices (see Lemma 17 in Section 3.4). Therefore, our main focus is to describe the following algorithm:

▶ **Theorem 6.** *There is an algorithm that given $n \in \mathbb{N}$, computes the number of $\omega$-colorable labeled connected chordal graphs $G$ with vertex set $[n]$ using $O(n^7)$ arithmetic operations.*

We first give an overview of this algorithm and describe the various dynamic-programming tables (Definition 7). Next, we describe the recurrences in detail in Section 3.3. In Section 3.4, we show that the counting portion of Theorem 1 (counting chordal graphs) follows from Theorem 6 (counting connected chordal graphs). For the complete proof of Theorem 6, see the full version of the paper.

**Algorithm overview.** To count $\omega$-colorable connected chordal graphs $G$, we classify these graphs based on the behavior of their evaporation sequence. We make use of several *counter functions* (these are our dynamic-programming tables), each of which keeps track of the number of chordal graphs in a particular subclass. The arguments of the counter functions tell us the number of vertices in the graph, the evaporation time, the size of the exception set $X$, the size of the last set of simplicial vertices $L_G(X)$, etc. Initially, we consider all possibilities for the evaporation time of $G$ with exception set $X = \emptyset$. Then, using several of our recursive formulas, we reduce the number of vertices by dividing up the graph into smaller subgraphs and counting the number of possibilities for each subgraph. As we do so, the exception set $X$ increases in size. When we consider these various subgraphs, we also make sure that in each subgraph, the maximum clique size is at most $\omega$. In the end, the algorithm understands the possibilities for the entire graph, including the cliques that make up the very first set in its evaporation sequence.

The purpose of the exception set is to allow us to restrict to smaller subgraphs without distorting the evaporation behavior of the graph. For example, suppose we wish to count the number of connected chordal graphs on $n$ vertices that evaporate at time $t$, such that the vertices $1, 2, \ldots, \ell$ make up the last set to evaporate, i.e., $L_G(\emptyset) = [\ell]$. Let $L = [\ell]$. One subproblem of interest would be to count the number of possibilities for the first connected component of $G \setminus L$. Formally, we count the number of possibilities for $G' \coloneqq G[L \cup C]$, where $C$ is the connected component of $G \setminus L$ that contains the vertex $\ell + 1$. For each possible number of vertices in $G'$, we make a recursive call to count the number of possible subgraphs $G'$ of that size. However, if we were to restrict to $G'$ with a still-empty exception set, then the evaporation time of $G'$ alone could be much less than the evaporation time of $V(G')$ in $G$. Indeed, there may be vertices in $G \setminus G'$ adjacent to $L$ that prevent $L$ from evaporating before time $t$, so when we restrict to the subgraph $G'$, $L$ would now evaporate too soon. This would cause a cascading effect, causing vertices near $L$ to evaporate as well, and changing the entire evaporation sequence of $G'$. To resolve this, we add the vertices of $L$ to the exception set to preserve the evaporation behavior of $G'$.

The list of counter functions is given in Definition 7. As shown below, the number of $\omega$-colorable connected chordal graphs on $n$ vertices is the sum of various calls to the fourth function $\tilde{g}_1$, since $\tilde{g}_1(t,0,n)$ is the number of $\omega$-colorable connected chordal graphs on $n$ vertices that evaporate at time $t$ with empty exception set. To remember the names of these counter functions, one can think of them as follows: The $g$-functions keep track of the size of the exception set $X$, but these do not have information about the size of $L_G(X)$. The $f$-functions have an additional argument $\ell$, which is the size of $L_G(X)$. As a mnemonic, one can say that $g$ stands for "glued" and $f$ stands for "free." In the $g$-functions, $X$ is the "root," and all of the vertices of $X$ are glued, in the sense that they cannot evaporate. In the $f$-functions, $X \cup L_G(X)$ is the "root," and some of the vertices in the root are free, since the vertices in $L_G(X)$ are allowed to evaporate.

▶ **Definition 7.** *The following functions count particular subclasses of chordal graphs. Unless stated otherwise, the arguments $t, x, \ell, k, z$ are nonnegative integers.*

1. *$g(t,x,k,z)$ is the number of $\omega$-colorable connected chordal graphs $G$ with vertex set $[x+k]$ that evaporate in time at most $t$ with exception set $X=[x]$, where $X$ is a clique, with the following property: every connected component of $G \setminus X$ (if any) has at least one neighbor in $X \setminus [z]$.* ***Domain:*** *$t \geq 0$, $x \geq 1$, $z < x$.*
2. *$\tilde{g}(t,x,k,z)$ is the same as $g(t,x,k,z)$, except every connected component of $G \setminus X$ (if any) evaporates at time* exactly *$t$ in $G$.* Note: A graph with $V(G)=X$ would be counted because in that case, $\tilde{g}$ is the same as $g$. ***Domain:*** *$t \geq 1$, $x \geq 1$, $z < x$.*
3. *$\tilde{g}_p(t,x,k,z)$ is the same as $\tilde{g}(t,x,k,z)$, except no connected component of $G \setminus X$ sees all of $X$.* ***Domain:*** *$t \geq 1$, $x \geq 1$, $z < x$.*
4. *$\tilde{g}_1(t,x,k)$ and $\tilde{g}_{\geq 2}(t,x,k)$ are the same as $\tilde{g}(t,x,k,z)$, except every connected component of $G \setminus X$ sees all of $X$ (hence we no longer require every component of $G \setminus X$ to have a neighbor in $X \setminus [z]$), and furthermore, for $\tilde{g}_1$ we require that $G \setminus X$ has exactly one connected component, and for $\tilde{g}_{\geq 2}$ we require that $G \setminus X$ has at least two components.* ***Domain for $\tilde{g}_1$:*** *$t \geq 1$, $x \geq 0$.* ***Domain for $\tilde{g}_{\geq 2}$:*** *$t \geq 1$, $x \geq 1$.*
5. *$f(t,x,\ell,k)$ is the number of $\omega$-colorable connected chordal graphs $G$ with vertex set $[x+\ell+k]$ that evaporate at time* exactly *$t$ with exception set $X=[x]$, such that $G \setminus X$ is connected, $L_G(X)=[x+1,x+\ell]$, and $X \cup L_G(X)$ is a clique.* ***Domain:*** *$t \geq 1$, $x \geq 0$, $\ell \geq 1$.*
6. *$\tilde{f}(t,x,\ell,k)$ is the same as $f(t,x,\ell,k)$, except every connected component of $G \setminus (X \cup L_G(X))$ evaporates at time* exactly *$t-1$ in $G$, and there exists at least one such component, i.e., $X \cup L_G(X) \subsetneq V(G)$.* ***Domain:*** *$t \geq 2$, $x \geq 0$, $\ell \geq 1$.*
7. *$\tilde{f}_p(t,x,\ell,k)$ is the same as $\tilde{f}(t,x,\ell,k)$, except no connected component of $G \setminus (X \cup L_G(X))$ sees all of $X \cup L_G(X)$.* ***Domain:*** *$t \geq 2$, $x \geq 0$, $\ell \geq 1$.*
8. *$\tilde{f}_p(t,x,\ell,k,z)$ is the same as $\tilde{f}_p(t,x,\ell,k)$, except every connected component of $G \setminus (X \cup L_G(X))$ has at least one neighbor in $(X \cup L_G(X)) \setminus [z]$.* ***Domain:*** *$t \geq 2$, $x \geq 0$, $\ell \geq 1$, $z \leq x$.*

## 3.3 Recurrences for the counting algorithm

We implicitly assume *all graphs in this section are connected and $\omega$-colorable.* For $k \in \mathbb{N}$, let $c(k)$ denote the number of $\omega$-colorable connected chordal graphs with vertex set $[k]$. To compute $c(n)$, we first consider all possibilities for the evaporation time. Initially, the exception set is empty. We observe that $\tilde{g}_1(t,0,n)$ is the number of (connected, $\omega$-colorable) chordal graphs with vertex set $[n]$ that evaporate at time exactly $t$ with empty exception set.

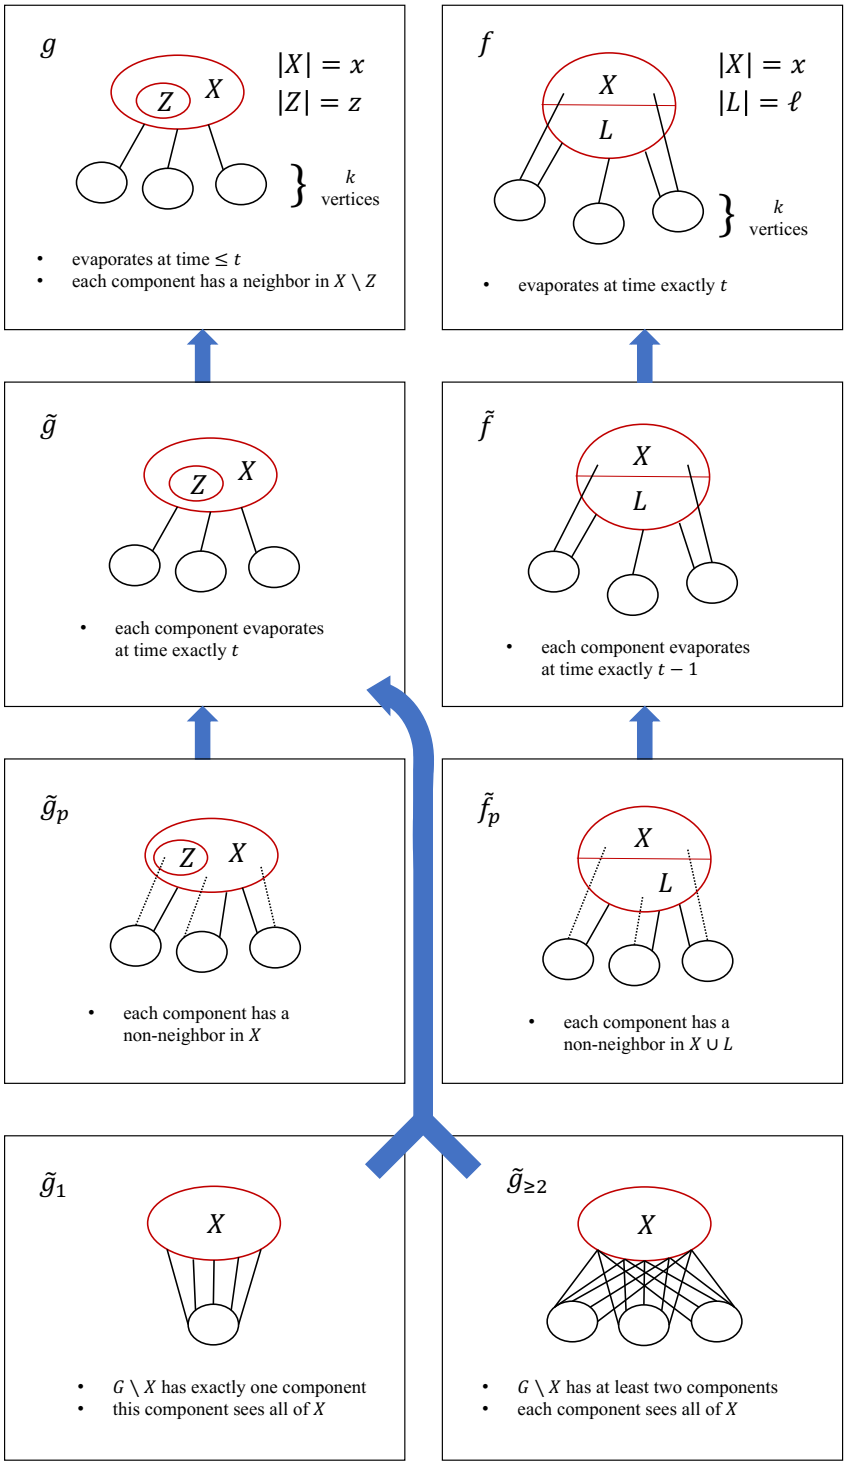

**Figure 1** The counter functions. Here $L = L_G(X)$ and $Z = [z]$. An arrow from one function to another, say from $\tilde{g}$ to $g$, indicates that the definition of $\tilde{g}$ is the same as that of $g$, except where indicated otherwise. The drawing of $\tilde{f}_p$ represents $\tilde{f}_p(t, x, \ell, k)$. The function $\tilde{f}_p(t, x, \ell, k, z)$ is similar but also keeps track of the argument $z$.

Therefore,

$$c(n) = \sum_{t=1}^{n} \tilde{g}_1(t, 0, n).$$

We compute the necessary values of $\tilde{g}_1$ by evaluating the following recurrences top-down using memoization. We take this approach rather than bottom-up dynamic programming to simplify the description slightly, since by memoizing we do not need to specify in what order the entries of the various dynamic-programming tables are computed. We simply compute each value of the counter functions as needed. For the following recurrences, let $X = [x]$ according to the current value of the argument $x$, and let $L = L_G(X)$.

To compute $\tilde{g}_1(t, 0, n)$, the number of chordal graphs that evaporate at time exactly $t$, we consider all possibilities for the size $\ell$ of $L$. Once the size $\ell$ is given, there are $\binom{n}{\ell}$ possibilities for the label set of $L$. Recall that $f$ counts the number of chordal graphs where $L$ is fixed and evaporates at time $t$, and $G \setminus X$ is connected. Formally, we have the following recurrence – the first time this is used, the arguments are $t$, $x = 0$ and $k = n$.

▶ **Lemma 8.** *For $\tilde{g}_1$, we have*

$$\tilde{g}_1(t, x, k) = \sum_{\ell=1}^{k} \binom{k}{\ell} f(t, x, \ell, k - \ell).$$

The proof of Lemma 8, along with the proofs of all of the other recurrences, can be found in the full version of the paper. To see the intuition behind Lemma 8, recall that in the definition of $f(t, x, \ell, k)$ we require a specific label set for $L_G(X)$, namely $[x + 1, x + \ell]$. If we were to replace that requirement with $L_G(X) = L'$ for any other subset $L'$ of $[x+1, x+\ell+k]$ of size $\ell$, this would not change the value of $f(t, x, \ell, k)$. Therefore, in the recurrence for $\tilde{g}_1$, it is sufficient to compute $f(t, x, \ell, k - \ell)$ and multiply by $\binom{k}{\ell}$, rather than computing $\binom{k}{\ell}$ distinct counter functions.

For $f$, to count chordal graphs where $L$ is fixed and evaporates at time $t$, and $G \setminus X$ is connected, we consider all possibilities for the set of labels that appear in components of $G \setminus (X \cup L)$ that evaporate at time exactly $t - 1$. Recall that $\tilde{f}$ counts the number of chordal graphs where $L$ is fixed and evaporates at time $t$, $G \setminus X$ is connected, and all components of $G \setminus (X \cup L)$ evaporate at time exactly $t - 1$. For each possible $k'$ (the size of this label set), $\tilde{f}$ allows us to count the number of possibilities for the subgraph $G_1$ consisting of $X \cup L$ and all components of $G \setminus (X \cup L)$ that evaporate at time exactly $t - 1$, and $g$ allows us to count the number of possibilities for the subgraph $G_2$ consisting of $X \cup L$ and all other components.

▶ **Lemma 9.** *For $f$, we have*

$$f(t, x, \ell, k) = \sum_{k'=1}^{k} \binom{k}{k'} \tilde{f}(t, x, \ell, k') g(t - 2, x + \ell, k - k', x).$$

When $f$ is called for the first time in the initial steps of the algorithm, this is the first moment when $X$ becomes nonempty, since at this point we are restricting to a subgraph with fewer than $n$ vertices. When we restrict to the subgraph $G_2$, we want to ensure that its vertices have the same evaporation behavior as they did in $G$. In particular, we need to ensure that the vertices of $L$ do not evaporate too soon, since their presence may be essential for preventing other vertices from evaporating. For this reason, we let $X \cup L$ be the exception set for $G_2$. For $G_1$, the exception set is simply $X$ because the components that evaporate at time exactly $t - 1$ are still present in $G_1$, preventing the vertices of $L$ from evaporating before time $t$.

For the subgraph $G_2$, now that all of $L$ has been pushed into the exception set, we no longer have information about the argument $\ell$ since the last set of simplicial vertices in $G_2$ evaporates further back in time. This is why we call $g$ rather than $f$ to count the possibilities for $G_2$. In fact, $G_2 \setminus [x + \ell]$ might not even be connected, which is required by $f$. Finally, the fourth argument of $g$ indicates that every connected component of $G_2 \setminus (X \cup L)$ has at least one neighbor in $L$. This ensures that $G \setminus X$ is connected.

For $g$, to count chordal graphs that evaporate in time at most $t$, we consider all possibilities for the set of labels that appear in connected components of $G \setminus X$ that evaporate at time exactly $t$. Recall that $\tilde{g}$ counts the number of chordal graphs where all connected components of $G \setminus X$ evaporate at time exactly $t$.

▶ **Lemma 10.** *For $g$, we have*

$$g(t, x, k, z) = \sum_{k'=0}^{k} \binom{k}{k'} \tilde{g}(t, x, k', z) g(t-1, x, k-k', z).$$

For $\tilde{g}$, to count chordal graphs where all connected components of $G \setminus X$ evaporate at time exactly $t$, we consider all possible label sets for the component $C$ of $G \setminus X$ that contains the lowest label not in $X$. The constraint $x' \geq 1$ ensures that $G$ is connected. We also subtract all ways of selecting $x'$ elements from $[z]$ to ensure that $N(C)$ is not entirely contained in $[z]$.

▶ **Lemma 11.** *For $\tilde{g}$, we have*

$$\tilde{g}(t, x, k, z) = \sum_{k'=1}^{k} \sum_{x'=1}^{x} \left( \binom{x}{x'} - \binom{z}{x'} \right) \binom{k-1}{k'-1} \tilde{g}_1(t, x', k') \tilde{g}(t, x, k-k', z).$$

We subtract 1 in the binomial coefficient $\binom{k-1}{k'-1}$ because the label set for $C$ always contains the lowest non-$X$ label, along with $k' - 1$ other labels.

For $\tilde{f}$, we need to count chordal graphs where $L$ is fixed and evaporates at time $t$, $G \setminus X$ is connected, and all components of $G \setminus (X \cup L)$ evaporate at time exactly $t-1$. The number of such graphs in which zero components see all of $X \cup L$ is $\tilde{f}_p(t, x, \ell, k)$. Now if there is at least one all-seeing component, then we break this down into two further cases: either exactly one component sees all of $X \cup L$, or at least two components see all of $X \cup L$. Recall that $\tilde{f}_p$ counts the number of chordal graphs where $L$ is fixed and evaporates at time $t$, all components of $G \setminus (X \cup L)$ evaporate at time exactly $t-1$, and no component sees all of $X \cup L$. Also, recall that $\tilde{g}_{\geq 2}$ counts the number of chordal graphs where all components of $G \setminus X$ evaporate at time exactly $t$, every component sees all of $X$, and there are at least two such components. In the first (resp. second) case, $\tilde{g}_1$ (resp. $\tilde{g}_{\geq 2}$) corresponds to the all-seeing component(s), and $\tilde{f}_p$ (resp. $\tilde{g}_p$) corresponds to the remaining components.

▶ **Lemma 12.** *For $\tilde{f}$, we have*

$$\begin{aligned}\tilde{f}(t, x, \ell, k) = \tilde{f}_p(t, x, \ell, k) &+ \sum_{k'=1}^{k} \binom{k}{k'} \tilde{g}_1(t-1, x+\ell, k') \tilde{f}_p(t, x, \ell, k-k') \\ &+ \sum_{k'=1}^{k} \binom{k}{k'} \tilde{g}_{\geq 2}(t-1, x+\ell, k') \tilde{g}_p(t-1, x+\ell, k-k', x).\end{aligned}$$

The above cases are relevant because if at least two components of $G \setminus (X \cup L)$ see all of $X \cup L$, then this prevents the vertices of $L$ from evaporating before time $t$. Indeed, each vertex $u \in L$ has a neighbor in each of those two components, meaning $u$ has two non-adjacent neighbors. Otherwise, if there is at most one such component, then the neighborhoods of

the remaining components of $G \setminus (X \cup L)$ must together cover $L$ to ensure that $L$ does not evaporate until time $t$. In that case, for each vertex $u \in L$ that is covered by a proper-subset neighborhood $N(C)$ of a component $C$, $u$ has a neighbor $v \in C$ as well as a neighbor $w \in (X \cup L) \setminus N(C)$, and $v$ and $w$ are non-adjacent.

The reason we require $G \setminus X$ to be connected in the definition of $f$ (rather than just requiring $G$ to be connected) can be seen from the recurrence for $\tilde{f}$. Since in the first sum over $k'$ we only wish to consider graphs with exactly one all-seeing component, in the definition of $\tilde{g}_1$ we require $G \setminus X$ to be connected. The recurrence for $\tilde{g}_1$ depends on $f$, so this carries over into requiring $G \setminus X$ to be connected in the definition of $f$. This explains the need for the argument $z$ (for example, in $g$): as mentioned above, keeping track of $z$ lets us ensure that $G \setminus X$ is connected in all graphs counted by $f$.

For $\tilde{g}_{\geq 2}$, to count chordal graphs where all components of $G \setminus X$ evaporate at time exactly $t$, every component sees all of $X$, and there are at least two such components, we consider all possibilities for the label set of the component that contains the lowest label not in $X$. For the remaining components, there is either exactly one of them, or at least two.

▶ **Lemma 13.** *For $\tilde{g}_{\geq 2}$, we have*

$$\tilde{g}_{\geq 2}(t,x,k) = \sum_{k'=1}^{k-1} \binom{k-1}{k'-1} \tilde{g}_1(t,x,k') \Big( \tilde{g}_1(t,x,k-k') + \tilde{g}_{\geq 2}(t,x,k-k') \Big).$$

For $\tilde{g}_p$, to count chordal graphs where all components of $G \setminus X$ evaporate at time exactly $t$ and no component sees all of $X$, we proceed as we did for $\tilde{g}$, except we require $x' < x$ rather than $x' \leq x$.

▶ **Lemma 14.** *For $\tilde{g}_p$, we have*

$$\tilde{g}_p(t,x,k,z) = \sum_{k'=1}^{k} \sum_{x'=1}^{x-1} \left( \binom{x}{x'} - \binom{z}{x'} \right) \binom{k-1}{k'-1} \tilde{g}_1(t,x',k') \tilde{g}_p(t,x,k-k',z).$$

For $\tilde{f}_p$, to count chordal graphs where $L$ is fixed and evaporates at time $t$, all components of $G \setminus (X \cup L)$ evaporate at time exactly $t-1$, and no component sees all of $X \cup L$, we first declare that no component can see only into $X$ (since $G \setminus X$ is connected).

▶ **Lemma 15.** *We have $\tilde{f}_p(t,x,\ell,k) = \tilde{f}_p(t,x,\ell,k,x)$.*

The following recurrence for $\tilde{f}_p$ counts the number of such graphs in which every component of $G \setminus (X \cup L)$ has at least one neighbor in $(X \cup L) \setminus [z]$. On the first reading, one can skip the two "otherwise" cases in Lemma 16. In this lemma, we consider all possibilities for the label set of the component $C$ of $G \setminus (X \cup L)$ that contains the lowest label not in $X \cup L$. Additionally, we consider all possibilities for the size $x'$ of $N(C) \cap X$ and the size $\ell'$ of $N(C) \cap L$, and we consider all possibilities for their respective label sets. If $\ell' > 0$, then $N(C)$ is automatically not contained in $[z]$ since $z \leq x$, so there are $\binom{x}{x'}$ possible label sets for $N(C) \cap X$.

The intuition behind the two "otherwise" cases is as follows. If $\ell' = 0$, then we must subtract $\binom{z}{x'}$ from the number of possible label sets for $N(C) \cap X$ to ensure that $N(C) \subsetneq [z]$. If $\ell' = \ell$, then all of the vertices of $L$ have now been pushed into the exception set, so the evaporation time of the subgraph formed from the remaining components is $t-1$. In this case, we call $\tilde{g}_p$ since we no longer know the size of the last set of simplicial vertices.[1]

[1] One might wonder whether we depart from the domain of $\tilde{g}_p$ in the term $\tilde{g}_p(t-1, x+\ell', k-k', z)$, since $x + \ell' = z$ when $\ell' = 0$ and $x = z$. However, if $\ell' = 0$ and $x = z$, then we observe that $\binom{x}{x'} - \binom{z}{x'} = 0$. Thus, for this value of $\ell'$, we do not need to evaluate the calls to $\tilde{g}_1$, $\tilde{f}_p$, and $\tilde{g}_p$.

▶ **Lemma 16.** *For $\tilde{f}_p(t,x,\ell,k,z)$, we have*

$$\tilde{f}_p(t,x,\ell,k,z) = \sum_{k'=1}^{k} \sum_{\substack{0\le x'\le x\\ 0\le \ell'\le \ell\\ 0<x'+\ell'<x+\ell}} \binom{k-1}{k'-1}\binom{\ell}{\ell'}\tilde{g}_1(t-1,x'+\ell',k') \cdot \begin{cases} \binom{x}{x'} & \text{if } \ell'>0 \\ \binom{x}{x'}-\binom{z}{x'} & \text{otherwise} \end{cases} \cdot \begin{cases} \tilde{f}_p(t,x+\ell',\ell-\ell',k-k',z) & \text{if } \ell'<\ell \\ \tilde{g}_p(t-1,x+\ell',k-k',z) & \text{otherwise.} \end{cases}$$

The base cases are as follows. We reach the base case for $g$ when $t=0$:

$$g(0,x,k,z) = \begin{cases} 1 & \text{if } k=0 \\ 0 & \text{if } k>0. \end{cases}$$

For $\tilde{g}$ and $\tilde{g}_p$, we have $\tilde{g}(t,x,0,z)=1$ and $\tilde{g}_p(t,x,0,z)=1$ when $k=0$. For, $\tilde{g}_1$ we observe that $\tilde{g}_1(t,x,k)=0$ if $t=0$ or $k=0$. Similarly, for $\tilde{g}_{\ge 2}$ we have $\tilde{g}_{\ge 2}(t,x,k)=0$ if $t=0$ or $k=0$. We reach the base case for $f$ when $x+\ell>\omega$, $t=1$, or $k=0$. If $x+\ell>\omega$, then $f(t,x,\ell,k)=0$. Remarkably, this is the only place where $\omega$ appears in the algorithm. If $x+\ell\le\omega$, then we have

$$f(1,x,\ell,k) = \begin{cases} 1 & \text{if } k=0 \\ 0 & \text{otherwise.} \end{cases}$$

If $x+\ell\le\omega$ and $t\ge 2$, then $f(t,x,\ell,0)=0$. For $\tilde{f}$, we have $\tilde{f}(t,x,\ell,k)=0$ if $t=1$ or $k=0$. Similarly, for $\tilde{f}_p$ we have $\tilde{f}_p[t,x,\ell,k,z]=0$ if $t=1$ or $k=0$. For the version of $\tilde{f}_p$ without the fifth argument $z$, we do not need a base case since we always immediately call $\tilde{f}_p$ with $z$.

The control flow formed by these recurrences is shown in Figure 2. The algorithm terminates because either the value of $t$ or the number of vertices in the graph (i.e., $x+k$ or $x+\ell+k$) decreases each time we return to the same function. For the running time, this is dominated by the arithmetic operations needed to compute $\tilde{f}_p$. The recurrence for $\tilde{f}_p$ involves a triple summation, and there are five arguments, so a naive implementation uses $O(n^8)$ arithmetic operations. However, in the full version of the paper, we show that the running time can in fact be improved to $O(n^7)$ arithmetic operations.

## 3.4 Proof of Theorem 1 (counting)

In this section, we prove the counting portion of Theorem 1 using Theorem 6. (See the full version of the paper for the proof of the sampling portion of Theorem 1.) In other words, we describe an algorithm to count chordal graphs, assuming we have an algorithm to count connected chordal graphs. Theorem 6 – counting connected chordal graphs – is proved in the full version of the paper.

For $k\in\mathbb{N}$, let $a(k)$ denote the number of $\omega$-colorable chordal graphs with vertex set $[k]$. Recall that $c(k)$ is the number of $\omega$-colorable connected chordal graphs with vertex set $[k]$.

▶ **Lemma 17.** *The number of $\omega$-colorable chordal graphs with vertex set $[n]$ is given by*

$$a(n) = \sum_{k=1}^{n} \binom{n-1}{k-1} c(k)a(n-k)$$

*for all $n\in\mathbb{N}$.*

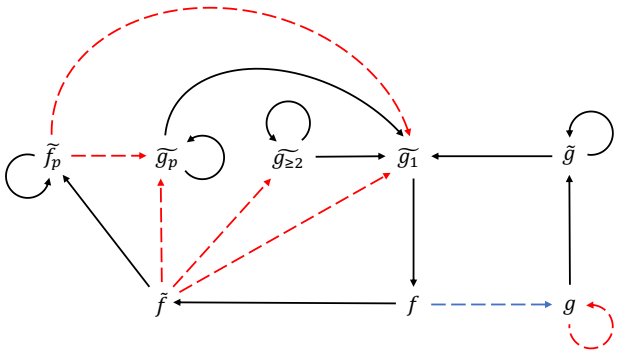

**Figure 2** The control flow of the counting algorithm. An arrow from $f$ to $g$ indicates that the recursive formula for $f$ depends on $g$. The arrow is red (and dashed) if $t$ decreases by 1, blue (and dashed) if $t$ decreases by 2, and black if $t$ does not change. The black self-loops do not cause an infinite loop because in those recursive calls, the number of vertices decreases.

**Proof.** Suppose $G$ is an $\omega$-colorable chordal graph with vertex set $[n]$. Let $G_1$ be the graph formed by the connected component of $G$ that contains the label 1, and let $G'$ be the graph formed by all other connected components of $G$ (which can potentially be empty). Let $C$ be the set of labels that appear in $G_1$, let $k = |C|$, and let $D = [n] \setminus C$, i.e., $D$ is the set of labels that appear in $G'$. Now relabel $G_1$ by applying $\phi(C, [k])$ to the labels in $C$, and relabel $G'$ by applying $\phi(D, [n-k])$ to the labels in $D$. (Recall that $\phi(A, B)$ is defined in Section 2.) We can see that $G_1$ is now a connected $\omega$-colorable chordal graph with vertex set $[k]$, and $G'$ is a connected $\omega$-colorable chordal graph with vertex set $[n-k]$. The map that takes any chordal graph $G$ to the resulting pair $(G_1, G')$ is injective since $\phi(C, [k])$ and $\phi(D, [n-k])$ are both bijections. Therefore, $a(n)$ is at most the number of possible triples $(G_1, G', C)$, which is given by the summation above.

To see that $a(n)$ is bounded below by the same summation, suppose we are given $1 \leq k \leq n$, a connected $\omega$-colorable chordal graph $G_1$ with vertex set $[k]$, a chordal $\omega$-colorable graph $G'$ with vertex set $[n-k]$, and a subset $C \subseteq [n]$ of size $k$ that contains 1. Let $D = [n] \setminus C$. We construct an $\omega$-colorable chordal graph $G$ with vertex set $[n]$ as follows: Relabel $G_1$ by applying $\phi([k], C)$ to its label set, and relabel $G'$ by applying $\phi([n-k], D)$ to its label set. Now let $G$ be the union of $G_1$ and $G'$ (by taking the union of the vertex sets and the edge sets). The map that takes the triple $(G_1, G', C)$ to the resulting graph $G$ is injective, so $a(n)$ is at least the summation above, as desired. ◀

Lemma 17 directly gives a dynamic-programming algorithm to compute the number of $\omega$-colorable chordal graphs with vertex set $[n]$, given $n$ as input. First, by Theorem 6, we can compute $c(k)$ for all $k \in [n]$ at a cost of $O(n^7)$ arithmetic operations. Next, we use the recurrence in Lemma 17 to compute $a(n)$ at a cost of $O(n^2)$ arithmetic operations. For the base case, we observe that $a(0) = 1$. Therefore, we have an algorithm to count $\omega$-colorable chordal graphs on $n$ vertices using $O(n^7)$ arithmetic operations.

## 4 Implementation of the counting algorithm

An implementation of the counting algorithm in C++ can be successfully run for inputs as large as $n = 30$ in about 2.5 minutes on a standard desktop computer.[2] Previously, the number of labeled chordal graphs was only known up to $n = 15$. Table 1 shows the number of

[2] Our implementation is available on GitHub at `https://github.com/uhebertj/chordal`.

connected chordal graphs on $n$ vertices for $n \leq 30$, with the chromatic number unrestricted. Table 2 shows the number of $\omega$-colorable connected chordal graphs on $n$ vertices for various values of $n$ and $\omega$.

## 5 Conclusion

Our main result is an algorithm that given $n$, computes the number of labeled chordal graphs on $n$ vertices using $O(n^7)$ arithmetic operations (and in $O(n^9 \log n)$ time in the RAM model). This yields a sampling algorithm that generates a labeled chordal graph on $n$ vertices uniformly at random. For the sampling algorithm, once we have run the counting algorithm as a preprocessing step, each sample can be obtained using $O(n^4)$ arithmetic operations.

The main open problem is to design a substantially faster algorithm for counting or sampling labeled chordal graphs. We presented exact counting and sampling algorithms; nevertheless, allowing for approximate counting/sampling might enable even faster algorithms.

To be precise, for approximate sampling we are aiming for an algorithm that, given $n$ and $\delta > 0$, samples from a distribution $\delta$-close to uniform (say in total variation distance) in time polynomial in $n$ and $\log(1/\delta)$, where the dependence on $n$ is significantly less than $n^7$. Two interesting approaches to consider are Markov Chain Monte Carlo (MCMC) algorithms, such as the chain proposed in [33], and the Boltzmann sampling scheme used in [10] for planar graphs.

Moving beyond chordal graphs, there are many interesting graph classes for which the problem of counting/sampling $n$-vertex labeled graphs in polynomial time appears to be open, including perfect graphs, weakly chordal graphs, strongly chordal graphs, and chordal bipartite graphs, as well as many graph classes characterized by a finite set of forbidden minors, subgraphs, or induced subgraphs. It is worth noting that for some well-known graph classes of this form, such as planar graphs, polynomial-time algorithms are known [6, 10].

**Stefan Kratsch**
Humboldt-Universität zu Berlin, Germany

## Abstract

The complexity of problems involving global constraints is usually much more difficult to understand than the complexity of problems only involving local constraints. In the realm of graph problems, connectivity constraints are a natural form of global constraints. We study connectivity problems from a fine-grained parameterized perspective. In a breakthrough result, Cygan et al. (TALG 2022) first obtained Monte-Carlo algorithms with single-exponential running time $\alpha^{\mathrm{tw}}n^{\mathcal{O}(1)}$ for connectivity problems parameterized by treewidth by introducing the cut-and-count-technique, which reduces many connectivity problems to locally checkable counting problems. Furthermore, the obtained bases $\alpha$ were shown to be optimal under the Strong Exponential-Time Hypothesis (SETH).

However, since only sparse graphs may admit small treewidth, we lack knowledge of the fine-grained complexity of connectivity problems with respect to dense structure. The most popular graph parameter to measure dense structure is arguably clique-width, which intuitively measures how easily a graph can be constructed by repeatedly adding bicliques. Bergougnoux and Kanté (TCS 2019) have shown, using the rank-based approach, that also parameterized by clique-width many connectivity problems admit single-exponential algorithms. Unfortunately, the obtained running times are far from optimal under SETH.

We show how to obtain optimal running times parameterized by clique-width for two benchmark connectivity problems, namely Connected Vertex Cover and Connected Dominating Set. These are the first tight results for connectivity problems with respect to clique-width and these results are obtained by developing new algorithms based on the cut-and-count-technique and novel lower bound constructions. Precisely, we show that there exist one-sided error Monte-Carlo algorithms that given a $k$-clique-expression solve

- Connected Vertex Cover in time $6^k n^{\mathcal{O}(1)}$, and
- Connected Dominating Set in time $5^k n^{\mathcal{O}(1)}$.

Both results are shown to be tight under SETH.

## 1 Introduction

One way to cope with the NP-hardness of a problem is the theory of parameterized complexity, where we seek to solve structured instances faster than worst-case instances; an additional parameter quantifies how structured an instance is. Ideally, we obtain fixed-parameter

tractable algorithms with running time[1] $\mathcal{O}^*(f(k))$, where $k$ is the parameter and $f$ some computable function. Having established the existence of such an algorithm, the next natural step is to take a fine-grained perspective and to determine the smallest possible function $f$, which quantifies the precise impact of the considered structure on problem complexity.

We apply this approach to connectivity problems. Our investigation starts with the breakthrough results of Cygan et al. [16], who for the first time obtained Monte-Carlo algorithms with running time $\mathcal{O}^*(\alpha^{\mathrm{tw}})$, for some constant *base* $\alpha > 1$, for connectivity problems parameterized by *treewidth* (tw). These algorithms are obtained via the so-called cut-and-count-technique, which reduces connectivity problems to locally checkable counting problems. In addition, the obtained bases $\alpha$ were proven to be optimal assuming the Strong Exponential-Time Hypothesis (SETH) [14].

As only sparse graphs may have small treewidth, we lack knowledge of the precise complexity of connectivity problems with respect to dense structure. In the regime of dense graphs, *clique-width* (cw) is one of the most popular parameters. Bergougnoux [2] applied cut-and-count to several width-parameters based on structured neighborhoods with clique-width among these. Moreover, Bergougnoux and Kanté [4], building upon the rank-based approach of Bodlaender et al. [8], obtain single-exponential running times $\mathcal{O}^*(\alpha^{\mathrm{cw}})$ for a large class of connectivity problems parameterized by clique-width. As both articles are aimed at obtaining a breadth of single-exponential algorithms for a large class of problems, the Connected (Co-)$(\sigma,\rho)$-Dominating Set problems, the obtained bases for particular problems are far from being optimal. For example, the former article implies an $\mathcal{O}^*(128^{\mathrm{cw}})$-time algorithm for Connected Dominating Set and the latter yields an $\mathcal{O}^*((27 \cdot 2^{\omega+1})^{\mathrm{cw}})$-time algorithm for Connected Vertex Cover and an $\mathcal{O}^*((8 \cdot 2^{\omega+1})^{\mathrm{cw}})$-time algorithm for Connected Dominating Set, where $\omega$ is the matrix multiplication exponent, see e.g. Alman and Vassilevska W. [1]. Even if $\omega = 2$, this only yields the large bases 216 and 64 respectively.

We show that the running times for Connected Vertex Cover and Connected Dominating Set parameterized by clique-width can be considerably optimized by providing novel algorithms. These faster algorithms again rely on the cut-and-count-technique and are fine-tuned by precisely analyzing which cut-and-count states are necessary to consider. Moreover, we use further techniques such as fast subset convolution, inclusion-exclusion states, and distinguishing between live and dead labels to obtain the improved running times.

▶ **Theorem 1.1.** *There are one-sided error Monte-Carlo algorithms that, given a $k$-expression[2] for a graph $G$, can solve*

- *Connected Vertex Cover in time $\mathcal{O}^*(6^k)$,*
- *Connected Dominating Set in time $\mathcal{O}^*(5^k)$.*

We show that these algorithms are essentially the correct ones for these problem-parameter-combinations by proving that the obtained running times are optimal under SETH. To prove these lower bounds, we follow the by now standard construction principle of Lokshtanov et al. [35] for lower bounds relative to width-parameters. To apply this principle for clique-width, we closely investigate the problem behavior across *joins*, i.e., the edge-structures via which clique-width is defined, and the results of this investigation strongly guide us in designing appropriate gadgets. Precisely, we obtain the following tight lower bounds:

[1] The $\mathcal{O}^*$-notation hides polynomial factors in the input size.
[2] A $k$-expression witnesses that the clique-width of $G$ is at most $k$.

**Table 1** Optimal running-times of several connectivity problems with respect to various width-parameters listed in increasing generality. The results in the last column are obtained in this paper. Between modular-treewidth and clique-width, we only have the relationship $\text{cw}(G) \leq 3 \cdot 2^{\text{mod-tw}(G)-1}$, but the same results are also tight for the more restrictive modular-pathwidth, where we have $\text{cw}(G) \leq \text{mod-pw}(G) + 2$ by Hegerfeld and Kratsch [26]. The "?" marks problem-parameter combinations, where an algorithm with single-exponential running time is known by Bergougnoux and Kanté [4], but a gap between the lower bound and algorithm remains.

| Parameters | cutwidth | treewidth | modular-tw | clique-width |
|---|---|---|---|---|
| Connected Vertex Cover | $\mathcal{O}^*(2^k)$ | $\mathcal{O}^*(3^k)$ | $\mathcal{O}^*(5^k)$ | $\mathcal{O}^*(6^k)$ |
| Connected Dominating Set | $\mathcal{O}^*(3^k)$ | $\mathcal{O}^*(4^k)$ | $\mathcal{O}^*(4^k)$ | $\mathcal{O}^*(5^k)$ |
| Steiner Tree | $\mathcal{O}^*(3^k)$ | $\mathcal{O}^*(3^k)$ | $\mathcal{O}^*(3^k)$ | ? |
| Feedback Vertex Set | $\mathcal{O}^*(2^k)$ | $\mathcal{O}^*(3^k)$ | $\mathcal{O}^*(5^k)$ | ? |
| References | [9] | [15, 16] | [26] | here |

▶ **Theorem 1.2.** *Assuming SETH*[3]*, the following statements hold for all* $\varepsilon > 0$*:*

- *Connected Vertex Cover (with unit costs) cannot be solved in time* $\mathcal{O}^*((6-\varepsilon)^{\text{cw}})$*.*
- *Connected Dominating Set (with unit costs) cannot be solved in time* $\mathcal{O}^*((5-\varepsilon)^{\text{cw}})$*.*

This work is part of a research program to determine the optimal running times for connectivity problems relative to several width-parameters ranging from restrictive to more and more general ones, hence yielding a *fine-grained* understanding of the *price of generality*. We summarize the known results in Table 1. The cut-and-count-technique by Cygan et al. [15, 16] together with their lower bounds settle the complexity relative to treewidth (and pathwidth) for many connectivity problems. Bojikian et al. [9] consider the more restrictive *cutwidth* and combine cut-and-count with the rank-based approach to improve upon the treewidth-algorithms or provide new lower bound constructions with low cutwidth when no improved algorithm exists. Hegerfeld and Kratsch [26] consider the parameter *modular-treewidth* which lifts treewidth into the dense regime by combining tree decompositions with modular decompositions and thus serves as a natural intermediate step between treewidth and clique-width. The results on modular-treewidth are obtained by reducing directly to the treewidth-case or by applying the cut-and-count-technique and the modular structure to essentially reduce to a more involved problem parameterized by treewidth; in the latter case, new lower bound constructions are provided that follow similar high-level principles as here, but that have to adhere to different design restrictions. Cygan et al. [16] observe that connectivity increases the base by at most 1 in the sparse setting, e.g., Vertex Cover has optimal base 2, see Lokshtanov et al. [35], and Connected Vertex Cover has optimal base 3 parameterized by treewidth. For clique-width, this increase can be larger and the impact of connectivity can even flip the relative complexities, e.g., the optimal bases of Vertex Cover and Dominating Set are 2 and 4 [29, 32] which increase to 6 and 5, respectively, upon adding the connectivity constraint.

**Further Related Work.** Beyond these tight results, the cut-and-count-technique has also been applied to branchwidth [42] and treedepth [23, 38]. Due to its reliance on the isolation lemma, the cut-and-count-technique yields randomized algorithms. The rank-based approach of Bodlaender et al. [8] and the matroid-based techniques of Fomin et al. [19, 20] deal

[3] If we instead assume an appropriate random variant of SETH, then these reductions also rule out Monte-Carlo algorithms with such running times.

with this shortcoming at the cost of a higher running time and the rank-based approach can also be applied in other contexts. By combining the rank-based approach with other techniques to avoid Gaussian elimination, optimal running times can be obtained in some cases, such as for Hamiltonian Cycle parameterized by pathwidth [12, 13] or coloring problems parameterized by cutwidth [22, 31]. There are further applications of the rank-based approach to connectivity problems relative to dense width-parameters, such as rankwidth [5] and mim-width [3]. We also refer to the survey of Nederlof on rank-based methods [37].

Moving away from connectivity problems, we survey some more of the literature obtaining tight fine-grained parameterized algorithms for dense parameters. Iwata and Yoshida show that for any $\varepsilon > 0$ Vertex Cover can be solved in time $\mathcal{O}^*((2-\varepsilon)^{\mathrm{tw}})$ if and only if Vertex Cover can be solved in time $\mathcal{O}^*((2-\varepsilon)^{\mathrm{cw}})$ [29]; as the bases differ for treewidth and clique-width in our case, it seems difficult to transfer their techniques to our setting. Lampis [34] obtains the tight running time of $\mathcal{O}^*((2^q-2)^{\mathrm{cw}})$ for $q$-Coloring and a tight result for $q$-Coloring parameterized by a more restrictive variant of modular-treewidth. Generalizing to homomorphism problems, Ganian et al. [21] obtain tight results for parameterization by clique-width, where the obtained base depends on a special measure of the target graph. Katsikarelis et al. [32] obtain tight results for $(k,r)$-Center parameterized by clique-width and, in particular, the tight running time $\mathcal{O}^*(4^{\mathrm{cw}})$ for Dominating Set. Jacob et al. [30] and Hegerfeld and Kratsch [24] show that the running time $\mathcal{O}^*(4^{\mathrm{cw}})$ is tight for Odd Cycle Transversal, where the latter article also considers a generalization to more colors and contains tight results for parameters that do not fall into the class of width-parameters.

**Organization.** We discuss the preliminaries in Section 2. Section 3 covers the algorithms (Theorem 1.1) and Section 4 the lower bounds (Theorem 1.2); both sections first outline the used techniques and present more details for Connected Vertex Cover. For space reasons, we only give a few remarks regarding Connected Dominating Set. We conclude in Section 5. Proofs and sections that are delegated to the full version [25] are denoted by $\star$.

## 2 Preliminaries

For two integers $a, b$ we write $a \equiv_c b$ to indicate equality modulo $c \in \mathbb{N}$. We use Iverson's bracket notation: for a boolean predicate $p$, we have that $[p]$ is 1 if $p$ is true and 0 otherwise. For a function $f$ we denote by $f[v \mapsto \alpha]$ the function $(f \setminus \{(v, f(v))\}) \cup \{(v, \alpha)\}$, viewing $f$ as a set; we also write $f[v \mapsto \alpha, w \mapsto \beta]$ instead of $(f[v \mapsto \alpha])[w \mapsto \beta]$. By $\mathbb{Z}_2$ we denote the field of two elements. For $n_1, n_2 \in \mathbb{Z}$, we write $[n_1, n_2] = \{x \in \mathbb{Z} : n_1 \leq x \leq n_2\}$ and $[n_2] = [1, n_2]$. For a function $f\colon V \to \mathbb{Z}$ and a subset $W \subseteq V$, we write $f(W) = \sum_{v \in W} f(v)$. For functions $g\colon A \to B$, where $B \not\subseteq \mathbb{Z}$, and $A' \subseteq A$, we still denote the *image of $A'$ under $g$* by $g(A') = \{g(v) : v \in A'\}$. If $f\colon A \to B$ is a function and $A' \subseteq A$, then $f\big|_{A'}$ denotes the *restriction* of $f$ to $A'$ and for a subset $B' \subseteq B$, we denote the *preimage of $B'$ under $f$* by $f^{-1}(B') = \{a \in A : f(a) \in B'\}$. An ordered tuple of sets $(A_1, \ldots, A_\ell)$ is an *ordered subpartition* if $A_i \cap A_j = \emptyset$ for all $i \neq j \in [\ell]$. The *power set* of a set $A$ is denoted by $\mathcal{P}(A)$.

**Graph Notation.** We use common graph-theoretic notation and the essentials of parameterized complexity. Let $G = (V, E)$ be an undirected graph. For a vertex set $X \subseteq V$, we denote by $G[X]$ the subgraph of $G$ that is induced by $X$. The *open neighborhood* of a vertex $v$ is given by $N_G(v) = \{u \in V : \{u, v\} \in E\}$, whereas the *closed neighborhood* is given by $N_G[v] = N_G(v) \cup \{v\}$. For sets $X \subseteq V$ we define $N_G[X] = \bigcup_{v \in X} N_G[v]$ and $N_G(X) = N_G[X] \setminus X$. For two disjoint vertex subsets $A, B \subseteq V$, we define $E_G(A, B) = \{\{a, b\} \in E(G) : a \in A, b \in B\}$

and adding a *join* between $A$ and $B$ means adding an edge between every vertex in $A$ and every vertex in $B$. For a vertex set $X \subseteq V$, we define $\delta_G(X) = E_G(X, V \setminus X)$ and we write $\delta_G(v) = \delta_G(\{v\})$ for single vertices $v$. We denote the *number of connected components* of $G$ by $\mathtt{cc}(G)$. A *cut* of $G$ is a partition $V = V_L \cup V_R$, $V_L \cap V_R = \emptyset$, of its vertices into two parts.

**Clique-Expressions and Clique-Width.** A *labeled graph* is a graph $G = (V, E)$ together with a *label function* $\mathtt{lab}\colon V \to \mathbb{N} = \{1, 2, 3, \ldots\}$; we usually omit mentioning $\mathtt{lab}$ explicitly. A labeled graph is *$k$-labeled* if $\mathtt{lab}(v) \leq k$ for all $v \in V$. We consider the following four operations on labeled graphs:

- the *introduce*-operation $\ell(v)$ constructs a single-vertex graph whose vertex $v$ has label $\ell$,
- the *union*-operation $G_1 \oplus G_2$ constructs the disjoint union of labeled graphs $G_1$ and $G_2$,
- the *relabel*-operation $\rho_{i \to j}(G)$ changes the label of all vertices in $G$ with label $i$ to label $j$,
- the *join*-operation $\eta_{i,j}(G)$, $i \neq j$, which adds an edge between every vertex in $G$ with label $i$ and every vertex in $G$ with label $j$.

A valid expression that only consists of introduce-, union-, relabel-, and join-operations is called a *clique-expression*. The graph constructed by a clique-expression $\mu$ is denoted $G_\mu$ and the constructed label function is denoted $\mathtt{lab}_\mu\colon V(G_\mu) \to \mathbb{N}$. We associate to a clique-expression $\mu$ the syntax tree $T_\mu$ in the natural way and to each node $t \in V(T_\mu)$ the corresponding operation. For any node $t \in V(T_\mu)$ the subtree rooted at $t$ induces a *subexpression* $\mu_t$. When $\mu$ is fixed, we define $G_t = G_{\mu_t}$, $V_t = V(G_t)$, $E_t = E(G_t)$, and $\mathtt{lab}_t = \mathtt{lab}_{\mu_t}$ for any $v \in V(T_\mu)$. We write $V_t^\ell = \mathtt{lab}_t^{-1}(\ell)$ for the set of all vertices with label $\ell$ at node $t$ and we write $L_t = \{\ell \in \mathbb{N} : V_t^\ell \neq \emptyset\}$ for the set of *nonempty labels at node $t$*.

A clique-expression $\mu$ is a *$k$-clique-expression* or just *$k$-expression* if $G_t$ is $k$-labeled for all $t \in V(T_\mu)$. The *clique-width* of a graph $G$, denoted by $\mathrm{cw}(G)$, is the minimum $k$ such that a $k$-expression $\mu$ with $G = G_\mu$ exists. A clique-expression $\mu$ is *linear* if in every union-operation the second graph consists only of a single vertex. Accordingly, we define the *linear-clique-width* of a graph $G$, denoted $\text{lin-cw}(G)$, by only considering linear expressions.

**Strong Exponential-Time Hypothesis.** The *Strong Exponential-Time Hypothesis* (SETH) [10, 28] concerns the complexity of $q$-SATISFIABILITY, i.e., every clause contains at most $q$ literals. We define $c_q = \inf\{\delta : q\text{-SATISFIABILITY can be solved in time } \mathcal{O}(2^{\delta n})\}$ for all $q \geq 3$. The weaker *Exponential-Time Hypothesis* (ETH) of Impagliazzo and Paturi [27] posits that $c_3 > 0$ and the Strong Exponential-Time Hypothesis states that $\lim_{q \to \infty} c_q = 1$. Equivalently, for every $\delta < 1$, there is some $q$ such that $q$-SATISFIABILITY cannot be solved in time $\mathcal{O}(2^{\delta n})$. For our lower bounds, the following weaker variant of SETH is sufficient.

▶ **Conjecture 2.1** (CNF-SETH). *For every $\varepsilon > 0$, there is no algorithm solving SATISFIABILITY with $n$ variables and $m$ clauses in time $\mathcal{O}(\mathrm{poly}(m)(2-\varepsilon)^n)$.*

**Cut and Count.** Let $G = (V, E)$ denote a connected graph. For easy reference, we repeat the key definition and lemmas of the cut-and-count-technique here.

▶ **Definition 2.2** ([16]). A cut $(V_L, V_R)$ of an undirected graph $G = (V, E)$ is *consistent* if $u \in V_L$ and $v \in V_R$ implies $\{u, v\} \notin E$, i.e., $E_G(V_L, V_R) = \emptyset$. A *consistently cut subgraph* of $G$ is a pair $(X, (X_L, X_R))$ such that $X \subseteq V$ and $(X_L, X_R)$ is a consistent cut of $G[X]$. We denote the set of consistently cut subgraphs of $G$ by $\mathcal{C}(G)$.

▶ **Lemma 2.3** ([16]). *Let $X$ be a subset of vertices such that $v_* \in X \subseteq V$. The number of consistently cut subgraphs $(X, (X_L, X_R))$ such that $v_* \in X_L$ is equal to $2^{\mathtt{cc}(G[X])-1}$.*

▶ **Corollary 2.4** (⋆). *Let $\mathcal{R} \subseteq \mathcal{P}(V)$ be a family of vertex sets so that every $X \in \mathcal{R}$ contains $v_*$. If the set $\mathcal{A} = \{(X, (X_L, X_R)) \in \mathcal{C}(G) : X \in \mathcal{R}, v_* \in X_L\}$ has odd cardinality, then there exists an $X \in \mathcal{R}$ such that $G[X]$ is connected.*

With the isolation lemma we avoid unwanted cancellations in the cut-and-count-technique.

▶ **Definition 2.5.** A function $\mathbf{w}\colon U \to \mathbb{Z}$ *isolates* a set family $\mathcal{F} \subseteq \mathcal{P}(U)$ if there is a unique $S' \in \mathcal{F}$ with $\mathbf{w}(S') = \min_{S \in \mathcal{F}} \mathbf{w}(S)$; recall that $\mathbf{w}(X) = \sum_{u \in X} \mathbf{w}(u)$ for subsets $X$ of $U$.

▶ **Lemma 2.6** (Isolation Lemma, [36]). *Let $\mathcal{F} \subseteq \mathcal{P}(U)$ be a nonempty set family over a universe $U$. Let $N \in \mathbb{N}$ and for each $u \in U$ choose a weight $\mathbf{w}(u) \in [N]$ uniformly and independently at random. Then $\mathbb{P}[\mathbf{w}$ isolates $\mathcal{F}] \geq 1 - |U|/N$.*

## 3 Dynamic Programming Algorithms

**Cut and Count.** The cut-and-count-technique by Cygan et al. [16] allows us to reduce the global connectivity constraint to a locally checkable counting problem. Consistent cuts, cf. Definition 2.2, are the main driver of the cut-and-count-technique. Any graph $G = (V, E)$ admits exactly $2^{\mathsf{cc}(G)}$ distinct consistent cuts, where $\mathsf{cc}(G)$ is the number of connected components of $G$. By fixing a vertex $v_*$ and only considering consistent cuts $(V_L, V_R)$ with $v_* \in V_L$, this number reduces to $2^{\mathsf{cc}(G)-1}$, so that $G$ admits an odd number of such consistent cuts if and only if $G$ is connected. This behavior implies that if we count pairs $(X, (X_L, X_R))$, where $v_* \in X \subseteq V$ is a partial solution and $(X_L, X_R)$ a consistent cut of $G[X]$ with $v_* \in X_L$, modulo two, that all disconnected solutions cancel. When multiple connected solutions exist, they could also cancel modulo two, but this issue can be avoided at the cost of randomization by using the isolation lemma, cf. Lemma 2.6. So, if there exists a connected solution, then we can assume that Lemma 2.3 applies and let the algorithm answer accordingly.

**Lifting Vertex States to Label States.** For dynamic programming along clique-expressions, we have to characterize the relevant interactions of a partial solution with the *labels* which govern which *joins* can be constructed by the expression. In the considered problems, a single vertex $v$ can take a constant number of different states with respect to a partial solution which we capture with a problem-dependent set $\Omega$; e.g., for Connected Vertex Cover, we have $\Omega = \{\mathbf{0}, \mathbf{1}_L, \mathbf{1}_R\}$, representing $v \notin X$ (state $\mathbf{0}$), $v \in X_L$ (state $\mathbf{1}_L$), and $v \in X_R$ (state $\mathbf{1}_R$), respectively. A clique-expression repeatedly adds *joins* between pairs of vertex sets, say $A$ and $B$, i.e., all possible edges between $A$ and $B$ are added, and the algorithm must check whether a partial solution remains feasible after adding a join and possibly update some states. A priori, each choice of vertex states in a label could yield different behaviors for partial solutions. However, for the considered problems the precise multiplicity of a vertex state in $A$ or in $B$ is irrelevant for a join; it suffices to distinguish for each side which vertex states appear and which do not. Therefore, the label states are captured by the subsets of $\Omega$. The next two techniques will allow us to reduce the number of considered states further.

**Nice Clique-Expressions.** We refine and augment standard clique-expressions to distinguish between *live* and *dead* labels. When performing dynamic programming along a clique-expression, we consider the induced subgraphs defined by subexpressions of the given clique-expression. At a subexpression, we say that a label $\ell$ is *live* if in the remaining expression the vertices with label $\ell$ receive further edges that are not present in the current subexpression, otherwise $\ell$ is *dead*. First, we observe that we do not need to track the states of a partial solution at the dead labels, as they only have trivial interactions with

the other states in the remaining expression. Hence, we only need to consider the states that can be attained at live labels which allows us to reduce the number of considered states for Connected Vertex Cover. To simplify the algorithms and avoid handling of edge cases, we transform the clique-expressions so that no degenerate cases occur and add a dead-operation $\bot_\ell$ which handles label $\ell$ turning from live to dead. The dead-operation is similar to *forget vertex nodes* in *nice tree decompositions* [33]. Distinguishing live and dead labels has been used before [21, 32, 34] to obtain improved running times, but handling the label types explicitly via an additional operation is new to the best of the authors' knowledge.

**Inclusion-Exclusion States.** For Connected Dominating Set, we transform to a different set of vertex states, called *inclusion-exclusion states*, which have proven helpful for domination problems before [23, 39, 41, 43]. These states do not track whether a vertex is *undominated* or *dominated* by a partial solution, but *allow* a vertex to be dominated or *forbid* it. A solution to the original problem can usually be recovered by an inclusion-exclusion argument, however when lifting to label states this argument does not directly transfer. We show that the argument can be adapted for label states when working modulo two, whereas for vertex states the argument is known to also work for non-modular counting. The advantage of the inclusion-exclusion states is that at joins we do not have to update vertex states from undominated to dominated, thus simplifying the algorithm and also allowing us to collapse several label states into a single one. The dead-operations of nice clique-expressions serve as suitable timepoints to apply the adapted inclusion-exclusion argument.

**Fast Convolutions.** To quickly compute the recurrences for union-operations, we utilize algorithms for *fast subset convolution*. We tailor the techniques developed by Björklund et al. [6] on trimmed subset convolutions to obtain a fast algorithm for the union-recurrence appearing in the Connected Vertex Cover algorithm. For Connected Dominating Set, we employ the lattice-based results of Björklund et al. [7].

## 3.1 Nice Clique-Expressions

Let $\mu$ be a $k$-expression for $G = (V, E)$; the associated syntax tree is $T_\mu$. We say that a clique-expression $\mu$ is *irredundant* if for any join-operation $\eta_{i,j}(G_{t'}) = t \in V(T_\mu)$, it holds that $E_{G_{t'}}(V^i_{t'}, V^j_{t'}) = \emptyset$, i.e., no edge added by the join existed before.

▶ **Theorem 3.1** ([11]). *Any $k$-expression $\mu$ can be transformed into an equivalent, i.e., $G_{\mu'} = G_\mu$, irredundant $k$-expression $\mu'$ in polynomial time.*

Irredundancy still allows several edge cases regarding empty labels to occur, which require special handling in the dynamic programming algorithms. To avoid this extra effort in the algorithms, we transform any clique-expression so that these edge cases do not occur.

▶ **Definition 3.2.** A clique-expression $\mu$ of $G$ is *nice* if $\mu$ satisfies the following properties:

- $\mu$ is irredundant,
- for every join-node $\eta_{i,j}(G_{t'}) = t \in V(T_\mu)$, where $t'$ is the child of $t$, we have that $G_t \neq G_{t'}$, i.e., $t$ adds at least one edge and $V^i_{t'} \neq \emptyset$ and $V^j_{t'} \neq \emptyset$,
- for every relabel-node $\rho_{i\to j}(G_{t'}) = t \in V(T_\mu)$, where $t'$ is the child of $t$, we have that $V^i_{t'} \neq \emptyset$ and $V^j_{t'} \neq \emptyset$.

In the full version of the paper, we give a short proof how to transform a $k$-expression into an equivalent nice $k$-expression. However, Ducoffe [17] has also shown how to perform such a transformation in only linear time with a more involved proof.

▶ **Lemma 3.3** (⋆, [17]). *Any $k$-expression $\mu$ can be transformed into an equivalent, i.e., $G_{\mu'} = G_\mu$, nice $k$-expression $\mu'$ in polynomial time.*

For nice clique-expressions, we will now present how we augment the associated syntax tree to distinguish between live and dead labels. For the remainder of this section, we assume that $G$ is a connected graph with at least two vertices. We begin with the following definition.

▶ **Definition 3.4.** Given a clique-expression $\mu$ for $G = (V, E)$ and a node $t \in V(T_\mu)$, the set of *dead vertices at* $t$ is defined by $D_t = \{v \in V_t : \delta_G(v) \subseteq E_t\}$. A vertex $v \in V_t \setminus D_t$ is called *live at* $t$.

The next lemma shows that in an irredundant clique-expression either none or all vertices in a label are dead, thus allowing us to sensibly speak of dead and live labels.

▶ **Lemma 3.5** (⋆). *Given an irredundant $k$-expression $\mu$ for $G = (V, E)$, a node $t \in V(T_\mu)$, and a nonempty label $\ell \in L_t$, we have that either $V_t^\ell \cap D_t = \emptyset$ or $V_t^\ell \subseteq D_t$.*

The following definition formalizes the handling of live and dead labels and the dead nodes that are added when a label turns from live to dead.

▶ **Definition 3.6.** Given an irredundant $k$-expression $\mu$ for $G = (V, E)$, the *augmented syntax tree* $\hat{T}_\mu$ of $\mu$ is obtained from $T_\mu$ by inserting up to two *dead nodes* directly above every join node $t = \eta_{i,j}(G_{t'})$, where $t'$ is the child of $t$ in $T_\mu$, based on the following criteria:

- if $V_t^i \subseteq D_t \setminus D_{t'}$, then the node $\bot_i$ is inserted,
- if $V_t^j \subseteq D_t \setminus D_{t'}$, then the node $\bot_j$ is inserted,
- if both nodes $\bot_i$ and $\bot_j$ are inserted, then we insert them in any order.

We extend the notations $G_t$, $V_t$, $D_t$, $V_t^\ell$, for $\ell \in [k]$, to dead nodes by inheriting the values of the child node. For every node $t \in V(\hat{T}_\mu)$, we inductively define the *live labels* $L_t^{live} \subseteq L_t$ by

$$
\begin{array}{llll}
L_t^{live} = \{\ell\} & \text{if } t = \ell(v), & L_t^{live} = L_{t'}^{live} \setminus \{i\} & \text{if } t = \rho_{i\to j}(G_{t'}),\\
L_t^{live} = L_{t'}^{live} & \text{if } t = \eta_{i,j}(G_{t'}), & L_t^{live} = L_{t'}^{live} \setminus \{\ell\} & \text{if } t = \bot_\ell(G_{t'}),\\
L_t^{live} = L_{t_1}^{live} \cup L_{t_2}^{live} & \text{if } t = G_{t_1} \oplus G_{t_2}. & &
\end{array}
$$

Dually, the set of *dead labels* $L_t^{dead} \subseteq L_t$ is given by $L_t^{dead} = L_t \setminus L_t^{live}$.

The next lemma shows that, up to pending dead nodes, $L_t^{live}$ contains all nonempty labels that only consist of live vertices at $t$. Due to Lemma 3.5, no label of an irredundant $k$-expression can contain both live and dead vertices simultaneously.

▶ **Lemma 3.7** (⋆). *Let $\mu$ be a nice $k$-expression of $G = (V, E)$ and $\hat{T}_\mu$ its augmented syntax tree. For any node $t \in V(\hat{T}_\mu)$ and $\ell \in L_t$, we have that $V_t^\ell \cap D_t = \emptyset$ implies $\ell \in L_t^{live}$. If $t$ is not the child of a dead node, then we even have that $V_t^\ell \cap D_t = \emptyset$ if and only if $\ell \in L_t^{live}$.*

## 3.2 Connected Vertex Cover

| Connected Vertex Cover | |
|---|---|
| **Input:** | An undirected graph $G = (V, E)$, a cost function $\mathbf{c}\colon V \to \mathbb{N} \setminus \{0\}$ and an integer $\overline{b}$. |
| **Question:** | Is there a set $X \subseteq V$, $\mathbf{c}(X) \leq \overline{b}$, such that $G - X$ contains no edges and $G[X]$ is connected? |

Let $(G = (V, E), \mathbf{c}, \overline{b})$ be a Connected Vertex Cover instance with $\mathbf{c}(v) \leq |V|^{\mathcal{O}(1)}$ for all $v \in V$. Furthermore, we assume that $G$ is connected and contains at least two vertices.

Let $\mu$ be a nice $k$-expression for $G$. To apply the cut-and-count-technique, we first pick an edge in $G$, branch on one of its endpoints $v_*$, and in this branch only consider solutions containing $v_*$. Furthermore, we sample a weight function $\mathbf{w}\colon V \to [2|V|]$ for the isolation lemma, cf. Lemma 2.6. We perform bottom-up dynamic programming along the augmented syntax tree $\hat{T}_\mu$. At every node $t \in V(\hat{T}_\mu)$, we consider the following family of partial solutions

$$\mathcal{A}_t = \{(X, (X_L, X_R)) \in \mathcal{C}(G_t) : G_t - X \text{ contains no edges and } (v_* \in V_t \Rightarrow v_* \in X_L)\}.$$

In other words, $\mathcal{A}_t$ contains all consistently cut vertex covers of $G_t$ such that $v_*$ is on the left side of the cut if possible. For every $t \in V(\hat{T}_\mu)$, $\overline{c} \in [0, \mathbf{c}(V)]$, $\overline{w} \in [0, \mathbf{w}(V)]$, we define $\mathcal{A}_t^{\overline{c},\overline{w}} = \{(X, (X_L, X_R)) \in \mathcal{A}_t : \mathbf{c}(X) = \overline{c}, \mathbf{w}(X) = \overline{w}\}$. Let $\hat{r}$ denote the root node of the augmented syntax tree $\hat{T}_\mu$. By Corollary 2.4, there exists a connected vertex cover $X$ of $G$ with $\mathbf{c}(X) \leq \overline{b}$ if there exist $\overline{c} \in [0, \overline{b}]$ and $\overline{w} \in [0, \mathbf{w}(V)]$ such that $\mathcal{A}_{\hat{r}}^{\overline{c},\overline{w}}$ has odd cardinality.

We proceed by analyzing the behavior of a partial solution $(X, (X_L, X_R)) \in \mathcal{A}_t$ with respect to a label $V_t^\ell$, $\ell \in L_t$. A vertex $v \in V_t^\ell$ can take one of the states $\Omega = \{\mathbf{0}, \mathbf{1}_L, \mathbf{1}_R\}$, meaning respectively $v \notin X$, or $v \in X_L$, or $v \in X_R$. To check the feasibility of $(X, (X_L, X_R))$, it suffices to store for each label which vertex states appear and which do not, as the constraints implied by $\mathcal{A}_t$ are "CSP-like", i.e., they apply to every edge, and they can be evaluated for every join by considering all pairs of involved vertex states. Hence, the power set $\mathcal{P}(\Omega)$ of $\Omega$ captures all possible label states.

The power set $\mathcal{P}(\Omega)$ a priori yields eight different states per label. However, we can exclude the state $\emptyset$ and the state $\Omega = \{\mathbf{0}, \mathbf{1}_L, \mathbf{1}_R\}$ from consideration. The former can be excluded, since we only need to store the state for nonempty labels, i.e., containing at least one vertex. The exclusion of the state $\Omega = \{\mathbf{0}, \mathbf{1}_L, \mathbf{1}_R\}$ is more subtle: any additional incident join would lead to an infeasible solution for this state, hence only dead labels, cf. Definition 3.6, may sensibly take this state. We return to this issue in a moment. Since it suffices to store the states of live labels, we set $\mathbf{States} = \mathcal{P}(\Omega) \setminus \{\emptyset, \Omega\} = \{\{\mathbf{0}\}, \{\mathbf{1}_L\}, \{\mathbf{1}_R\}, \{\mathbf{0}, \mathbf{1}_L\}, \{\mathbf{0}, \mathbf{1}_R\}, \{\mathbf{1}_L, \mathbf{1}_R\}\}$.

Given a node $t \in V(\hat{T}_\mu)$, a *$t$-signature* is a function $f\colon L_t^{live} \to \mathbf{States}$. For every node $t \in V(\hat{T}_\mu)$, $\overline{c} \in [0, \mathbf{c}(V)]$, $\overline{w} \in [0, \mathbf{w}(V)]$, and $t$-signature $f$, we define

$$\begin{aligned}\mathcal{A}_t^{\overline{c},\overline{w}}(f) = \{(X, (X_L, X_R)) \in \mathcal{A}_t^{\overline{c},\overline{w}} : \; & \mathbf{0} \in f(\ell) \Leftrightarrow V_t^\ell \not\subseteq X \text{ for all } \ell \in L_t^{live}, \\ & \mathbf{1}_L \in f(\ell) \Leftrightarrow X_L \cap V_t^\ell \neq \emptyset \text{ for all } \ell \in L_t^{live}, \\ & \mathbf{1}_R \in f(\ell) \Leftrightarrow X_R \cap V_t^\ell \neq \emptyset \text{ for all } \ell \in L_t^{live}\}.\end{aligned}$$

We claim that excluding the state $\Omega$ does not cause issues. Consider some node $t$ whose parent is not a dead node, and $(X, (X_L, X_R)) \in \mathcal{A}_t^{\overline{c},\overline{w}}$ such that there is a live label $\ell \in L_t^{live}$ for which the three cases $V_t^\ell \not\subseteq X$, $X_L \cap V_t^\ell \neq \emptyset$, and $X_R \cap V_t^\ell \neq \emptyset$ simultaneously occur. Since $\ell$ is live, there is some $v \in N_G(V_t^\ell) \setminus N_{G_t}(V_t^\ell)$ by Lemma 3.7. We claim that $(X, (X_L, X_R))$ cannot be extended to a consistently cut vertex cover $(X', (X'_L, X'_R))$ of $G' = G[V_t \cup \{v\}]$ (hence also not of $G$). If $v \notin X'$, then there is an uncovered edge in $G'$ between $V_t^\ell$ and $v$. If $v \in X'$, then some edge in $G'$ crosses the cut $(X'_L, X'_R)$ and so the cut cannot be consistent. Hence, partial solutions attaining the state $\{\mathbf{0}, \mathbf{1}_L, \mathbf{1}_R\}$ at a live label can be discarded.

Instead of computing the sets $\mathcal{A}_t^{\overline{c},\overline{w}}(f)$ directly, we only compute the quantities $A_t^{\overline{c},\overline{w}}(f) = |\mathcal{A}_t^{\overline{c},\overline{w}}(f)| \mod 2$. The recurrences for computing $A_t^{\overline{c},\overline{w}}(f)$, for every $t \in V(\hat{T}_\mu)$, $t$-signature $f$, $\overline{c} \in [0, \mathbf{c}(V)]$, $\overline{w} \in [0, \mathbf{w}(V)]$ depend on the type of the considered node $t$:

**Introduce node.** If $t = \ell(v)$ for some $\ell \in [k]$, then $L_t^{live} = \{\ell\}$ and

$$\begin{aligned}A_t^{\overline{c},\overline{w}}(f) = {} & [v \neq v_* \vee f(\ell) = \{\mathbf{1}_L\}] \\ & \cdot [(f(\ell) = \{\mathbf{0}\} \wedge \overline{c} = \overline{w} = 0) \vee (f(\ell) \in \{\{\mathbf{1}_L\}, \{\mathbf{1}_R\}\} \wedge \overline{c} = \mathbf{c}(v) \wedge \overline{w} = \mathbf{w}(v))],\end{aligned}$$

since in a singleton graph any choice of singleton state leads to a valid solution, but if $v = v_*$ then only the solution with $v_*$ on the left side of the cut is allowed.

**Relabel node.** If $t = \rho_{i\to j}(G_{t'})$, where $t'$ is the child of $t$, for some $i, j \in [k]$, then by niceness of $\mu$ it follows that $i \in L_{t'}$, $j \in L_{t'}$, $L_t = L_{t'} \setminus \{i\}$ and either $i, j \in L_{t'}^{live}$ or $i, j \in L_{t'}^{dead}$.

- If labels $i$ and $j$ are live at $t'$, then label $j$ is live at $t$ and the recurrence is given by

$$A_t^{\overline{c},\overline{w}}(f) = \sum_{\substack{\mathbf{S}_1,\mathbf{S}_2\in\mathbf{States}:\\ \mathbf{S}_1\cup\mathbf{S}_2=f(j)}} A_{t'}^{\overline{c},\overline{w}}(f[i\mapsto \mathbf{S}_1, j\mapsto \mathbf{S}_2]),$$

  since $V_t^j = V_{t'}^i \cup V_{t'}^j$ and we simply have to iterate over all possible combinations of previous states at labels $i$ and $j$ that yield the desired state $f(j)$.
- If labels $i$ and $j$ are dead at $t'$, then label $j$ is dead at $t$ and since we do not track the state of dead labels, we can simply copy the previous table, i.e., $A_t^{\overline{c},\overline{w}}(f) = A_{t'}^{\overline{c},\overline{w}}(f)$.

**Join node.** To check whether two states can lead to a feasible solution after adding a join between their labels, we introduce a helper function feas: $\mathbf{States} \times \mathbf{States} \to \{0,1\}$ defined by $\text{feas}(\mathbf{S}_1, \mathbf{S}_2) = [\mathbf{0} \notin \mathbf{S}_1 \vee \mathbf{0} \notin \mathbf{S}_2][\mathbf{1}_L \in \mathbf{S}_1 \Rightarrow \mathbf{1}_R \notin \mathbf{S}_2][\mathbf{1}_R \in \mathbf{S}_1 \Rightarrow \mathbf{1}_L \notin \mathbf{S}_2]$. There are two reasons for infeasibility: a join edge is not covered, i.e., $\mathbf{0}$ appears on both sides, or a join edge connects both sides of the cut, i.e., $\mathbf{1}_L$ appears on one side and $\mathbf{1}_R$ on the other.

We have $t = \eta_{i,j}(G_{t'})$ for some $i \neq j \in L_{t'}$, where $t'$ is the child of $t$. We have $i, j \in L_{t'}^{live}$ and if vertices turn dead at $t$, i.e., $D_{t'} \subsetneq D_t$, then a future dead node will handle it. Hence, we simply filter out all partial solutions that become infeasible due to the new join:

$$A_t^{\overline{c},\overline{w}}(f) = \text{feas}(f(i), f(j)) A_{t'}^{\overline{c},\overline{w}}(f).$$

**Dead node.** We have that $t = \bot_\ell(G_{t'})$, where $t'$ is the child of $t$, $\ell \notin L_t^{live}$, and $L_t^{live} = L_{t'}^{live} \setminus \{\ell\}$. Since the only change is that $t$-signatures do not track the state of label $\ell$ anymore, we add up the contributions of all previous states of label $\ell$. Hence, the recurrence is given by

$$A_t^{\overline{c},\overline{w}}(f) = \sum_{\mathbf{S}\in\mathbf{States}} A_{t'}^{\overline{c},\overline{w}}(f[\ell\mapsto \mathbf{S}]).$$

Although this recurrence looks simple, its correctness proof is nontrivial as it relies on the previous argument why label state $\Omega$ can be excluded.

**Union node.** We omit the standard, but somewhat technical, description of the union-recurrence here. After handling labels that are nonempty at only one of the children, a trimmed subset convolution remains that we can solve in time $\mathcal{O}^*(6^{|L_t^{live}|})$ for all $\overline{c}$, $\overline{w}$, and $f$ simultaneously via the convolution algorithms developed in the appendix of the full version.

▶ **Lemma 3.8** (⋆). *Given a nice $k$-expression $\mu$ of $G = (V, E)$, the quantities $A_t^{\overline{c},\overline{w}}(f)$ for all nodes $t \in V(\hat{T}_\mu)$, $t$-signatures $f$, and appropriate $\overline{c}$, $\overline{w}$, can be computed in time $\mathcal{O}^*(6^k)$.*

**Proof sketch.** For introduce nodes, relabel nodes, or join nodes, the recurrence for $A_t^{\overline{c},\overline{w}}(f)$ can be computed in polynomial time, as additions and multiplications in $\mathbb{Z}_2$ take constant time. For union nodes $t$, we compute the recurrence for all $f$, $\overline{c}$, $\overline{w}$ simultaneously in time $\mathcal{O}^*(6^{|L_t^{live}|})$ as discussed. As $\mu$ is a $k$-expression, we have $|L_t^{live}| \leq k$ for all $t \in V(\hat{T}_\mu)$ and in particular at most $6^k$ $t$-signatures for any node $t \in V(T_\mu)$. Hence, the running time follows.

The proof of correctness for introduce nodes, relabel nodes, join nodes, and union nodes is straightforward. For dead nodes, the proof of correctness follows from the discussion on the exclusion of state $\{\mathbf{0}, \mathbf{1}_L, \mathbf{1}_R\}$ and the construction of the augmented syntax tree $\hat{T}_\mu$. ◀

▶ **Theorem 3.9** (⋆). *There is a randomized algorithm that given a nice $k$-expression $\mu$ for a graph $G = (V, E)$ can solve* Connected Vertex Cover *in time $\mathcal{O}^*(6^k)$. The algorithm does not return false positives and returns false negatives with probability at most $1/2$.*

**Proof.** We sample a weight function $\mathbf{w}\colon V \to [2n]$ uniformly at random. Then, we pick an edge in $G$ and branch on its endpoints; the chosen endpoint takes the role of $v_*$ in the current branch. Using Lemma 3.8, we compute the quantities $A_t^{\overline{c},\overline{w}}(f)$. At the root node $\hat{r}$, we have that $L_{\hat{r}}^{live} = \emptyset$. The algorithm returns true if in one of the branches there is some choice of $\overline{c} \leq \overline{b}$, $\overline{w} \in [0, 2n^2]$, such that $A_{\hat{r}}^{\overline{c},\overline{w}}(\emptyset) \neq 0$, otherwise the algorithm returns false.

The running time directly follows from Lemma 3.8. The correctness and error probability follow from Corollary 2.4, Lemma 2.3 and the isolation lemma, Lemma 2.6. Since these arguments are standard for the cut-and-count-technique, we omit them here. ◀

## 3.3 Remarks on Connected Dominating Set Algorithm (⋆)

| Connected Dominating Set | |
|---|---|
| **Input:** | An undirected graph $G = (V, E)$, a cost function $\mathbf{c}\colon V \to \mathbb{N} \setminus \{0\}$ and an integer $\overline{b}$. |
| **Question:** | Is there a set $X \subseteq V$, $\mathbf{c}(X) \leq \overline{b}$, such that $N(X) \cup X = V$ and $G[X]$ is connected? |

To obtain our algorithm for Connected Dominating Set, we transform to the inclusion-exclusion states and apply the cut-and-count-technique. We again have the vertex states $\mathbf{1}_L$ and $\mathbf{1}_R$, but the state $\mathbf{0}$ splits into the *allowed* ($\mathbf{A}$) and *forbidden* state ($\mathbf{F}$), which denote that a vertex is allowed or forbidden to be dominated. Lifting to label states, we see that the presence of allowed vertices is irrelevant, as they impose no constraint on future joins, and that all label states containing at least two distinct non-allowed states behave in the same way. This allows us to collapse the number of considered label states down to five.

To count solutions dominating a vertex $v$ with the inclusion-exclusion states, one usually subtracts the number of solutions where $v$ is forbidden from the solutions where $v$ is allowed. This argument fails when applied to labels, i.e., *groups* of vertices. Instead, our dynamic program counts solutions with a label containing $u$ undominated vertices exactly $2^u$ times, so that all solutions with $u > 0$ cancel modulo two. Whenever a label turns dead, we apply this argument to ensure that all vertices in dead labels are dominated.

# 4 Lower Bounds

**Construction Principle.** The high-level construction principle of the lower bounds follows the style of Lokshtanov et al. [35]. That means the resulting graphs can be interpreted as a *matrix of blocks*, where each block spans several rows and columns. Every row is a long *path-like gadget* that simulates a constant number of variables of the Satisfiability instance and which contributes 1 unit of clique-width. The number of simulated variables is tied to the running time that we want to rule out. For technical reasons, we consider bundles of rows simulating a *variable group* of appropriate size. Every column corresponds to a clause and consists of gadgets that *decode* the states on the path gadgets and check whether the resulting assignment satisfies the clause. As a consequence of the construction principle, the lower bounds already apply to *linear* clique-width.

**Path Gadgets and State Transitions.** Our main contribution is the design of the *path gadgets* that lie at the intersection of every row and column, whereas the *decoding gadgets* can be adapted from Cygan et al. [15]. To ensure that each row contributes one unit of

clique-width, adjacent path gadgets in a row are connected by a join. Our goal is to design a path gadget admitting as many states as possible. An important issue is how the state of the path gadgets may transition along each row, as the reduction only works when the state transitions follow some *transition order*, i.e, state $i$ can transition to state $j$ only if $i \leq j$.

**Determining the Transition Order.** For sparse width-parameters such as pathwidth, determining an appropriate transition order is much simpler, as the number of possible states is very small, e.g., there are at most four vertex states for the considered benchmark problems. The possible set of states for clique-width is much larger and we must select a specific subset of states, as not all of them admit a transition order. Hence, we analyze the possible state transitions across a join, obtaining a *transition/compatibility* matrix showing which pairs of states can lead to a globally feasible solution and which cannot. After possibly reordering the rows and columns of the compatibility matrix, a transition order must induce a *triangular submatrix* with ones on the diagonal. From a largest possible such triangular submatrix of the compatibility matrix, we can then deduce an appropriate transition order which guides the design of the path gadget.

**Anatomy of a Path Gadget.** Our path gadgets consist of a *central clique* communicating with the decoding gadgets, and two *boundary* parts, i.e., the *left* and *right* part connecting to the previous and following join. In the central clique, each solution avoids exactly one vertex representing the state of the path gadget. To implement the transition order, the left and right part have to communicate appropriate states to the two adjacent path gadgets. By *pairing* states along the main diagonal of the triangular submatrix, we see which states must be communicated in each case. The central idea behind designing the left and right part is to isolate the constituent state properties of the boundary vertices, such as, whether they are contained in the partial solution or whether they are dominated. This simplifies the communication with the central clique and expedites implementing the transition order.

**Root-Connectivity.** To capture the connectivity constraint, we create a distinguished vertex $\hat{r}$ called the *root* and attach a vertex of degree 1 to ensure that every connected vertex cover or connected dominating set must contain $\hat{r}$. Given a vertex subset $X \subseteq V(G)$ with $\hat{r} \in X$, we say that a vertex $v \in X$ is *root-connected* in $X$ if there is a $v, \hat{r}$-path in $G[X]$. We will just say *root-connected* if $X$ is clear from the context. The graph $G[X]$ is connected if and only if all vertices of $X$ are root-connected in $X$. For the state of a partial solution $X$, it is important to consider which vertices are root-connected in $X$ and which are not.

## 4.1 Path Gadget for Connected Vertex Cover

This subsection is devoted to constructing and analyzing the path gadget used to prove that Connected Vertex Cover (with unit costs) cannot be solved in time $\mathcal{O}^*((6-\varepsilon)^{\text{lin-cw}(G)})$ for some $\varepsilon > 0$ unless the CNF-SETH fails. The remaining parts of the construction are standard and can be found in the full version. We build a path gadget admitting 6 distinct states which narrows down to a single label/join, so that each row contributes one unit of linear clique-width. Each single vertex $v$ has one of 3 states with respect to a partial solution $X$: $v \notin X$ (state $\mathbf{0}$), $v \in X$ and $v$ is root-connected (state $\mathbf{1}_1$) or not root-connected (state $\mathbf{1}_0$). The state of a label can be described as a subset of $\{\mathbf{0}, \mathbf{1}_0, \mathbf{1}_1\}$.

We proceed by studying the compatibility of theses label states across a join, but we will only give an informal description here. Essentially, we assume that the considered join is the final opportunity for two partial solutions $X_1, X_2 \subseteq V$ with $\hat{r} \in X_i$, $i \in [2]$, living on

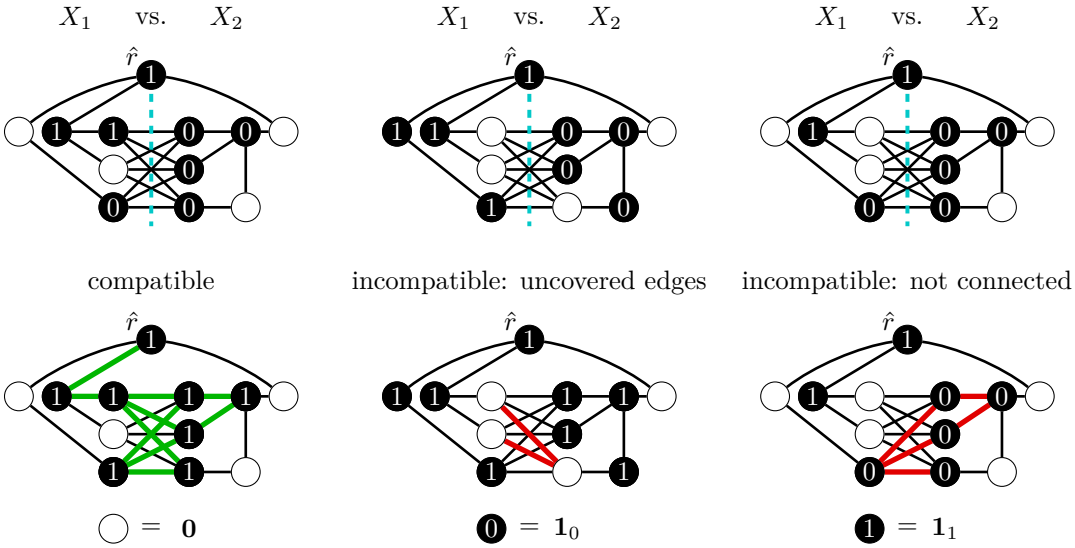

**Figure 1** Several cases of partial solution compatibility across a join. The first row depicts the vertex states in $X_1$ and $X_2$, separated by the dashed line. The second row depicts the vertex states in $X_1 \cup X_2$ and highlights, from left to right, the induced edges, the uncovered edges, and a connected component not containing the root $\hat{r}$.

**Table 2** A large triangular submatrix in the compatibility matrix of Connected Vertex Cover. The rows and columns have been reordered.

| $X_1$ vs. $X_2$ | $\{\mathbf{0}\}$ | $\{\mathbf{1}_0, \mathbf{0}\}$ | $\{\mathbf{1}_0\}$ | $\{\mathbf{1}_1, \mathbf{0}\}$ | $\{\mathbf{1}_1, \mathbf{1}_0\}$ | $\{\mathbf{1}_1\}$ |
|---|---|---|---|---|---|---|
| $\{\mathbf{1}_1\}$ | 1 | 1 | 1 | 1 | 1 | 1 |
| $\{\mathbf{1}_1, \mathbf{1}_0\}$ | 0 | 1 | 1 | 1 | 1 | 1 |
| $\{\mathbf{1}_1, \mathbf{0}\}$ | 0 | 0 | 1 | 0 | 1 | 1 |
| $\{\mathbf{1}_0\}$ | 0 | 0 | 0 | 1 | 1 | 1 |
| $\{\mathbf{1}_0, \mathbf{0}\}$ | 0 | 0 | 0 | 0 | 1 | 1 |
| $\{\mathbf{0}\}$ | 0 | 0 | 0 | 0 | 0 | 1 |

separate sides of the join (with the exception of $\hat{r}$) to connect. Hence, the partial solutions $X_1$ and $X_2$ are considered to be *compatible* when in $X_1 \cup X_2$ every vertex incident to the considered join has state $\mathbf{0}$ or $\mathbf{1}_1$ and every edge of the join is covered by $X_1 \cup X_2$; see Figure 1. Since the interaction of $X_i$, $i \in [2]$, with the respective side of the join is captured by the aforementioned states, we obtain a compatibility matrix of size $7 \times 7$.

In this compatibility matrix, we find the triangular submatrix depicted in Table 2, after reordering rows and columns. Independent sets of size two are sufficient to generate the relevant label states and they are represented by the following ordered pairs of vertex states: $(\mathbf{0}, \mathbf{0})$, $(\mathbf{1}_0, \mathbf{0})$, $(\mathbf{1}_0, \mathbf{1}_0)$, $(\mathbf{1}_1, \mathbf{0})$, $(\mathbf{1}_1, \mathbf{1}_0)$, $(\mathbf{1}_1, \mathbf{1}_1)$. Pairing these states along the diagonal, we learn which states should be communicated to the left and right boundary in each case.

**States.** We define the three atomic states $\mathbf{Atoms} = \{\mathbf{0}, \mathbf{1}_0, \mathbf{1}_1\}$, with their usual interpretation, and two predicates $\mathtt{sol}, \mathtt{conn}\colon \mathbf{Atoms} \to \{0, 1\}$ by $\mathtt{sol}(\mathbf{a}) = [\mathbf{a} \in \{\mathbf{1}_0, \mathbf{1}_1\}]$ and $\mathtt{conn}(\mathbf{a}) = [\mathbf{a} = \mathbf{1}_1]$. We define six (gadget) states consisting of four atomic states each:

$$\mathbf{s}^1 = (\mathbf{0}\ , \mathbf{0}\ , \mathbf{1}_1, \mathbf{1}_1), \quad \mathbf{s}^2 = (\mathbf{1}_0, \mathbf{0}\ , \mathbf{1}_1, \mathbf{1}_0), \quad \mathbf{s}^3 = (\mathbf{1}_0, \mathbf{1}_0, \mathbf{1}_1, \mathbf{0}\ ),$$
$$\mathbf{s}^4 = (\mathbf{1}_1, \mathbf{0}\ , \mathbf{1}_0, \mathbf{1}_0), \quad \mathbf{s}^5 = (\mathbf{1}_1, \mathbf{1}_0, \mathbf{1}_0, \mathbf{0}\ ), \quad \mathbf{s}^6 = (\mathbf{1}_1, \mathbf{1}_1, \mathbf{0}\ , \mathbf{0}\ ).$$

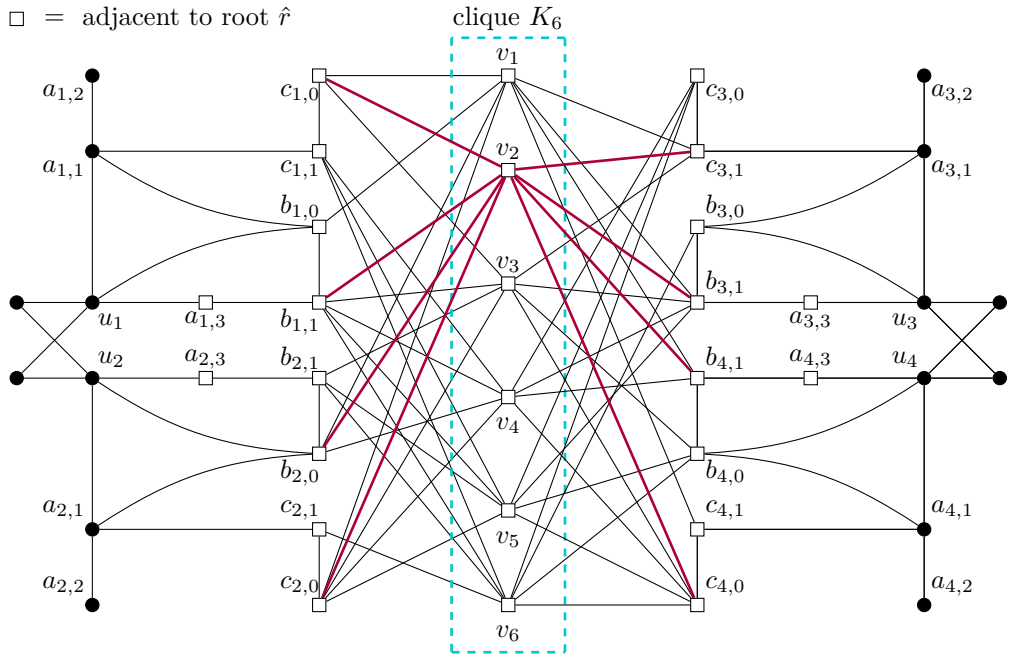

**Figure 2** The path gadget $P$ with the join vertices $u_1, u_2$ and $u_3, u_4$ joined to further vertices. All vertices depicted by a rectangle are adjacent to the root $\hat{r}$. The vertices inside the cyan dashed rectangle induce a clique. We have highlighted the edges incident to $v_2$ as an example.

The gadget states are numbered in the transition order. We collect the six gadget states in the set $\mathbf{States} = \{\mathbf{s}^1, \ldots, \mathbf{s}^6\}$ and use the notation $\mathbf{s}^\ell_i \in \mathbf{Atoms}$, $i \in [4]$, $\ell \in [6]$, to refer to the $i$-th atomic component of state $\mathbf{s}^\ell$. Given a partial solution $Y \subseteq V(G)$, we associate to each vertex its state in $Y$ with the map $\mathbf{state}_Y \colon V(G) \setminus \{\hat{r}\} \to \mathbf{Atoms}$, which is defined by $\mathbf{state}_Y(v) = \mathbf{0}$ if $v \notin Y$; $\mathbf{state}_Y(v) = \mathbf{1}_0$ if $v \in Y$ and $v$ is not root-connected in $Y \cup \{\hat{r}\}$; $\mathbf{state}_Y(v) = \mathbf{1}_1$ if $v \in Y$ and $v$ is root-connected in $Y \cup \{\hat{r}\}$.

**Construction.** The construction of the path gadget $P$ is as follows. We create 4 *join* vertices $u_1, \ldots, u_4$, 12 *auxiliary* vertices $a_{1,1}, a_{1,2}, a_{1,3}, a_{2,1}, \ldots, a_{4,3}$, 8 *solution indicator* vertices $b_{1,0}, b_{1,1}, b_{2,0}, b_{2,1}, \ldots, b_{4,1}$, 8 *connectivity indicator* vertices $c_{1,0}, c_{1,1}, c_{2,0}, c_{2,1}, \ldots, c_{4,1}$ and 6 *clique* vertices $v_1, \ldots, v_6$. We add edges so that the clique vertices $v_\ell$, $\ell \in [6]$, induce a clique of size 6. Next, we explain how to connect the indicator vertices to the clique vertices. The clique vertex $v_\ell$ corresponds to choosing state $\mathbf{s}^\ell$ on the join vertices $(u_1, u_2, u_3, u_4)$. The desired behavior of $P$ is that a partial solution $X$ of $P + \hat{r}$ contains $b_{i,1}$ if and only if $X$ contains $u_i$ and for the connectivity indicators, that $X$ contains $c_{i,1}$ if and only if $X$ contains $u_i$ and $u_i$ is root-connected in $X$. Accordingly, for all $i \in [4]$ and $\ell \in [6]$, we add the edges $\{v_\ell, b_{i,\mathtt{sol}(\mathbf{s}^\ell_i)}\}$ and $\{v_\ell, c_{i,\mathtt{conn}(\mathbf{s}^\ell_i)}\}$. For the remaining edges, we refer to Figure 2.

**Behavior of a Single Path Gadget.** We assume that $G$ is a graph that contains $P + \hat{r}$ as an induced subgraph and that only the join vertices $u_i, i \in [4]$, and clique vertices $v_\ell, \ell \in [6]$, have neighbors outside this copy of $P + \hat{r}$. Furthermore, let $X$ be a connected vertex cover of $G$ with $\hat{r} \in X$; we abuse notation and write $X \cap P$ instead of $X \cap V(P)$.

We begin by showing a lower bound for $|X \cap P|$ via a vertex-disjoint packing of subgraphs.

▶ **Lemma 4.1** (⋆). *We have that* $|X \cap P| \geq 21 = 4 \cdot 4 + 5$ *and more specifically* $a_{i,1} \in X$, $|X \cap \{u_i, a_{i,3}, b_{i,1}, b_{i,0}\}| \geq 2$, $|X \cap \{c_{i,0}, c_{i,1}\}| \geq 1$ *for all* $i \in [4]$ *and* $|X \cap \{v_1, \ldots, v_6\}| \geq 5$.

Using Lemma 4.1, we precisely analyze the solutions that match the lower bound of 21 on $P$ and show that these have the desired state behavior. We define for any $Y \subseteq V(P)$ the 4-tuple $\mathbf{state}(Y) = (\mathbf{state}_Y(u_1), \mathbf{state}_Y(u_2), \mathbf{state}_Y(u_3), \mathbf{state}_Y(u_4))$ and show that the states communicated to the boundary depend on the state of the central clique as desired.

▶ **Lemma 4.2** (⋆). *If* $|X \cap P| \leq 21$, *then* $|X \cap P| = 21$ *and* $a_{i,1} \in X$, $X \cap \{u_i, a_{i,3}, b_{i,1}, b_{i,0}\} \in \{\{u_i, b_{i,1}\}, \{a_{i,3}, b_{i,0}\}\}$, $|X \cap \{c_{i,0}, c_{i,1}\}| = 1$ *for all* $i \in [4]$ *and* $|X \cap \{v_1, \ldots, v_6\}| = 5$. *Furthermore, we have* $\mathbf{state}(X \cap P) = \mathbf{s}^\ell$ *for the unique integer* $\ell \in [6]$ *with* $v_\ell \notin X$.

**Proof sketch.** The first part follows by observing that the inequalities of Lemma 4.1 must be tight and that we must pick an antipodal pair in the cycle $\{u_i, a_{i,3}, b_{i,1}, b_{i,0}\}$. For the second part, we show that $\mathbf{state}_{X \cap P}(u_i) = \mathbf{s}_i^\ell$ for all $i \in [4]$. If $v_\ell \notin X$, then $b_{i,\mathtt{sol}(\mathbf{s}_i^\ell)}, c_{i,\mathtt{conn}(\mathbf{s}_i^\ell)} \in X$ by construction of $P$ and because $X$ is a vertex cover. Using the packing equations, we can propagate this information to $u_i$ and obtain the desired state. ◀

Similarly, we also establish that for every state $\mathbf{s}^\ell \in \mathbf{States}$ a partial solution $X_P^\ell$ attaining $\mathbf{s}^\ell$ actually exists. This is made precise by the following Lemma 4.3, which also shows that for these partial solutions it is sufficient to establish root-connectivity for the join vertices.

▶ **Lemma 4.3.** *For every* $\ell \in [6]$, *there exists a vertex cover* $X_P^\ell$ *of* $P$ *such that* $|X_P^\ell| = 21$, $X_P^\ell \cap \{v_1, \ldots, v_6\} = \{v_1, \ldots, v_6\} \setminus \{v_\ell\}$, *and* $\mathbf{state}(X_P^\ell) = \mathbf{s}^\ell$. *If* $X$ *is a vertex cover of* $G$ *with* $\hat{r} \in X$ *and* $X \cap P = X_P^\ell$ *and for every* $i \in [4]$ *either* $u_i \notin X$ *or* $u_i$ *is root-connected in* $X$, *then every vertex of* $X_P^\ell$ *is root-connected in* $X$.

**State Transitions.** To study the state transitions, suppose that we have two copies $P^1$ and $P^2$ of $P$ such that the vertices $u_3$ and $u_4$ in $P^1$ are joined to the vertices $u_1$ and $u_2$ in $P^2$. We denote the vertices of $P^1$ with a superscript 1 and the vertices of $P^2$ with a superscript 2, e.g., $u_3^1$ refers to the vertex $u_3$ of $P^1$. Again, suppose that $P^1$ and $P^2$ are embedded as induced subgraphs in a larger graph $G$ with a root vertex $\hat{r}$ and that only the vertices $u_1^1, u_2^1, u_3^2, u_4^2$ and the clique vertices $v_\ell^1, v_\ell^2$, $\ell \in [6]$, have neighbors outside of $P^1 + P^2 + \hat{r}$.

Using the previous lemmas, we show that the state transitions respect the transition order and that it is also feasible for the state to remain stable.

▶ **Lemma 4.4** (⋆). *Suppose that* $|X \cap P^1| \leq 21$ *and* $|X \cap P^2| \leq 21$, *then* $\mathbf{state}(X \cap P^1) = \mathbf{s}^{\ell_1}$ *and* $\mathbf{state}(X \cap P^2) = \mathbf{s}^{\ell_2}$ *with* $\ell_1 \leq \ell_2$. *Additionally, for each* $\ell \in [6]$, *the set* $X^\ell = X_{P^1}^\ell \cup X_{P^2}^\ell$ *is a vertex cover of* $P^1 + P^2$ *with* $\mathbf{state}_{X^\ell}(\{u_3^1, u_4^1, u_1^2, u_2^2\}) \subseteq \{\mathbf{0}, \mathbf{1}_1\}$.

**Proof sketch.** By Lemma 4.2, we have $\mathbf{state}(X \cap P^1) = \mathbf{s}^{\ell_1}$ and $\mathbf{state}(X \cap P^2) = \mathbf{s}^{\ell_2}$ for some $\ell_1, \ell_2 \in [6]$. Showing $\ell_1 \leq \ell_2$ corresponds to proving that all entries below the main diagonal of the chosen submatrix of the compatibility matrix are zero, i.e., that the submatrix is *triangular*. The second part corresponds to checking that all diagonal entries are ones. Both parts are proved by case checking. ◀

## 4.2 Remarks on Connected Dominating Set Lower Bound (⋆)

The path gadget construction for Connected Dominating Set is very similar to Connected Vertex Cover as large parts of the gadget can be reused by subdividing edges. For Connected Dominating Set, we have to work with 4 vertex states instead of 3 due to tracking whether a vertex is dominated or not. Hence, we have to contend with, a priori,

$15 = 2^4 - 1$ possible label states instead of $7 = 2^3 - 1$. Surprisingly however, there are only five different behaviors for these label states, so that we obtain a smaller base, namely 5, for Connected Dominating Set compared to Connected Vertex Cover.

## 5 Conclusion and Open Problems

We have provided the first tight results under SETH for connectivity problems parameterized by clique-width, namely the problems Connected Vertex Cover and Connected Dominating Set. For several important benchmark problems such as Steiner Tree, Connected Odd Cycle Transversal, and Feedback Vertex Set, we are not able to achieve tight results with the current techniques. For Steiner Tree, our algorithmic techniques readily yield an $\mathcal{O}^*(4^{\mathrm{cw}})$-time algorithm, but the compatibility matrix for the lower bound only contains a triangular submatrix of size $3 \times 3$, hence we are not able to prove a larger lower bound than for treewidth. Similarly for Connected Odd Cycle Transversal, the techniques for Connected Vertex Cover yield an $\mathcal{O}^*(14^{\mathrm{cw}})$-time algorithm and a larger lower bound can be proven by adapting the gadgets for Connected Vertex Cover and adding a gadget to detect the used color at join-vertices, however there is again no large enough triangular submatrix that would allow us to show that $\mathcal{O}^*(14^{\mathrm{cw}})$ is optimal. For Feedback Vertex Set, a problem with a negative connectivity constraint in the form of acyclicity, the usual cut-and-count approach involves counting the edges induced by a partial solution, but this immediately leads to an XP-algorithm parameterized by clique-width as already noted by Bergougnoux and Kanté [4, 5]. Hence, a different approach is required to obtain plausible running times for tight results.

A big caveat in applying algorithms parameterized by clique-width is that we are lacking good algorithms for computing clique-expressions. The currently best algorithms rely on approximating clique-width via rankwidth, see Oum and Seymour [40] for the first such algorithm and Fomin and Korhonen [18] for the most recent one. However, the approximation via rankwidth introduces an exponential error, therefore all single-exponential algorithms parameterized by clique-width become double-exponential algorithms unless we are given a clique-expression by other means. A first step towards better approximation algorithms for clique-width could be a fixed-parameter tractable algorithm with subexponential error.

## Abstract

In bi-criteria optimization problems, the goal is typically to compute the set of Pareto-optimal solutions. Many algorithms for these types of problems rely on efficient merging or combining of partial solutions and filtering of dominated solutions in the resulting sets. In this paper, we consider the task of computing the Pareto sum of two given Pareto sets $A, B$ of size $n$. The Pareto sum contains all non-dominated points of the Minkowski sum $M = \{a + b | a \in A, b \in B\}$. Since the Minkowski sum has a size of $n^2$, but the Pareto sum $C$ can be much smaller, the goal is to compute $C$ without having to compute and store all of $M$. We present several new algorithms for efficient Pareto sum computation, including an output-sensitive one with a running time of $\mathcal{O}(n \log n + nk)$ and a space consumption of $\mathcal{O}(n + k)$ for $k = |C|$. We also describe suitable engineering techniques to improve the practical running times of our algorithms and provide a comparative experimental study. As one showcase application, we consider preprocessing-based methods for bi-criteria route planning in road networks. Pareto sum computation is a frequent task in the preprocessing phase. We show that using our algorithms with an output-sensitive space consumption allows to tackle larger instances and reduces the preprocessing time compared to algorithms that fully store $M$.

## 1 Introduction

Solving multi-objective combinatorial optimization problems demands to find the set of non-dominated solutions, also referred to as skyline, Pareto frontier or Pareto set. To solve problem instances of substantial size, solution approaches often rely on efficient combination and filtering of partial solutions. In particular, non-dominance filtering of unions or Minkowski sums of intermediate Pareto sets occur as a frequent subtasks in optimization algorithms. Examples include decomposition approaches for multi-objective integer programming [16], dynamic programming methods for multi-objective knapsack [7], bi-directional search algorithms for multi-criteria shortest path problems [4], or Pareto local search for multi-objective set cover [14].

**Figure 1** Example instance with input Pareto sets $A, B$ of size 10. The Minkowski sum has 100 elements. The Pareto sum $C$ consists of 27 elements (marked green in the plot as well as in the matrix representation).

In this paper, we focus on the efficient computation of the filtered Minkowski sum of two-dimensional Pareto sets $A, B$. The Minkowski sum $M$ is defined as the set of elements derived from pairwise addition of elements in $A$ and $B$. However, the Minkowski sum often contains many dominated elements. In fact, it was proven in [12] that for $A, B$ of size $n$, the set of non-dominated elements in $M$ – which we refer to as Pareto sum of $A, B$ – might have a size in $o(n)$. Thus, algorithms that first compute all elements of $M$ and subsequently apply non-dominance filtering might be unnecessarily wasteful as they come with a running time and space consumption in $\Omega(n^2)$. The goal of the paper is to design practical algorithms for Pareto sum computation with output-sensitive space consumption, and to evaluate their performance on realistic inputs. As one particular use case of our methods, we will consider the bi-criteria route planning problem in road networks. There exists a plethora of algorithms to compute the set of Pareto-optimal paths between a given source and a target node in the network, see e.g. [8, 2]. The currently fastest methods rely on preprocessing. In particular, variants of contraction hierarchies (CH) have been proven to be very useful in this context [17, 19]. In a CH, the input graph is augmented with so called shortcut edges that represent sets of Pareto-optimal paths between their end points. The shortcuts store the costs of these paths in the form of Pareto sets. On query time, shortcuts are instrumented to decrease the search space size of a Pareto-Dijkstra run, resulting in significantly faster query times and reduced space consumption. In the preprocessing phase, the shortcuts are inserted incrementally. The base operation is to concatenate two shortcut or original edges $e = \{u, v\}$ and $e' = \{v, w\}$ to form a new shortcut $\{u, w\}$. The Pareto set of the new shortcut is the set of non-dominated elements in the Minkowski sum of the Pareto sets corresponding to $e$ and $e'$. Thus, the preprocessing time crucially depends on an efficient Pareto sum computation. In [9],

it was discussed that computing the Minkowski sum and filtering all dominated elements in a naive fashion is too time-consuming. Therefore, filtering strategies were proposed that prune dominated elements. However, these strategies are not guaranteed to retrieve the Pareto sum but usually produce a superset thereof. Keeping supersets slows down later stages of the preprocessing as well as query answering. We will propose novel algorithms that allow for fast and exact Pareto sum computation.

## 1.1 Related Work

Non-dominance filtering in point sets is a well-studied task in computational geometry [6], also referred to as skyline or maxima computation. There exist output-sensitive algorithms for the two-dimensional case as e.g. the one proposed by Kirkpatrick and Seidel [11] with a running time of $\mathcal{O}(N \log k)$ where $N$ denotes the size of the point set and $k$ the size of the skyline. The basic idea is to first partition the input points into $k$ sets of size $\approx N/k$ with non-overlapping ranges with respect to their $x$-coordinates. Then, the sets are processed individually in sorted order. As $k$ is typically not known beforehand, a more intricate version of the algorithm allows to achieve the same asymptotic running time by starting with a coarse partition and refining it on demand as soon as a certain number of non-dominated points are identified. With a worst-case running time of $\mathcal{O}(N \log N)$ and close-to-linear running time for small $k$, this algorithm seems to be well-suited for Pareto sum computation. However, in our application we have $N = |M|$ where $M$ is the Minkowski sum of the input sets $A, B$; and any approach that relies on access to $M$ as a whole is bound to a running time and space consumption in $\Omega(n^2)$.

Using the interpretation of input elements as two-dimensional points, Pareto sum computation can also be reduced to computing the Minkowski sum of the orthogonal hulls of $A$ and $B$ (where both sets are augmented with a dummy point based on the maximum coordinate values in the respective set). The Minkowski sum of two convex polygons can be computed in linear time [15]. For non-convex inputs $P, Q$, the polygons are first decomposed into convex subpolygons $P_1, \ldots, P_s$ and $Q_1, \ldots, Q_t$. Then, the linear time algorithm is applied to all pairs $P_i, Q_j$, and finally the union of all partial results is computed. The running time depends on the applied decomposition technique and the number and complexity of the resulting subpolygons [1]. However, if $P$ and $Q$ are orthogonal convex hulls of size $n$, their convex decomposition cannot contain fewer than $n$ subpolygons, and thus the approach needs to compute the union of $\Theta(n^2)$ partial solutions.

Recently, new algorithms for Pareto sum computation with the potential to achieve subquadratic running time and space consumption were proposed in [12]. The so called NonDomDC algorithm exploits the structure of the matrix that represents the Minkowski sum (see Figure 1). In particular, it makes use of the fact that columns in the matrix are Pareto sets themselves. Assuming the Pareto sum $P_i$ of elements occurring in the first $i$ columns is known, $P_{i+1}$ can be computed by merging $P_i$ and column $i+1$ and pruning dominated elements in $\mathcal{O}(|P_i| + n)$ time. Thus, with $P := \max_{i=1}^{n} |P_i|$ denoting the maximum size of an intermediate solution, the total running time is in $\mathcal{O}(Pn)$ and the space consumption is in $\mathcal{O}(n + P)$. However, this does not constitute an output-sensitive algorithm as the size of the intermediate Pareto sum can be significantly larger than the final result size. So even for small $k$, the algorithm might have cubic running time and quadratic space consumption. However, their experimental study demonstrates good performance in practice. Similar methods, as the box-based method proposed in [10], were shown to be outperformed.

**Table 1** Running time and space consumption of different algorithms for Pareto sum computation. The input size is denoted by $n$ and the output size by $k$.

## 1.2 Contribution

In this paper, we consider the problem of efficient Pareto sum computation in theory and practice. First, we present an algorithm that has the ability to identify a subset of the Pareto sum $C$ in linear time. This algorithm can be used as a preprocessing step for all other approaches for Pareto sum computation. Additionally, we show that for certain kinds of inputs, the algorithm already returns whole set $C$. Then, we present and thoroughly analyze several algorithms for Pareto sum computation with a special focus on achieving an output-sensitive space consumption. Table 1 provides an overview of the characteristics of our proposed algorithms as well as existing baseline approaches. In an extensive experimental study, we compare their scalability. We consider randomly generated data as well as real inputs that stem from bi-criteria route planning instances. For both input types alike, our output-sensitive successive sweep search proves to be the most efficient algorithm. This aligns well with our theoretical analysis, as it turns out, especially for large input sizes, that the Pareto sum $C$ contains only a small fraction of the elements in the Minkowski sum.

# 2 Problem Definition

In this section, we formally define the notion of a Pareto sum and provide notation used throughout the paper.

▶ **Definition 1** (Domination). *Given two points $p, p' \in \mathbb{R}^2$, we say that $p$ dominates $p'$, or $p \prec p'$, if $p \neq p'$ and $p.x \leq p'.x$ as well as $p.y \leq p'.y$.*

▶ **Definition 2** (Pareto set). *A set $S \subset \mathbb{R}^2$ is a Pareto set if no point in $S$ dominates another point in $S$, that is $\nexists s, s' \in S$ with $s \prec s'$.*

We always assume that Pareto sets are sorted in lexicographic order. We use $S_i$ to refer to the element with rank $i$ in set $S$.

▶ **Definition 3** (Minkowski sum). *Given two Pareto sets $A, B \subset \mathbb{R}^2$, their Minkowski sum $M = A \oplus B$ is defined as $M := \{a + b |\ a \in A, b \in B\}$.*

In a slight abuse of notation, we will use $M$ to refer to the set of elements in the Minkowski sum as well as the matrix where $M_{ij} = A_i + B_j$.

▶ **Definition 4** (Pareto sum). *Let $A, B \subset \mathbb{R}^2$ be two Pareto sets of size $n$ and let $M = A \oplus B$ denote their Minkowski sum. Then the Pareto sum $C$ of $A, B$ is defined as the set of all non-dominated points in $M$.*

Figure 1 illustrates the concepts of Minkowski and Pareto sums. Throughout the paper, we will use $k$ to denote the size of $C$.

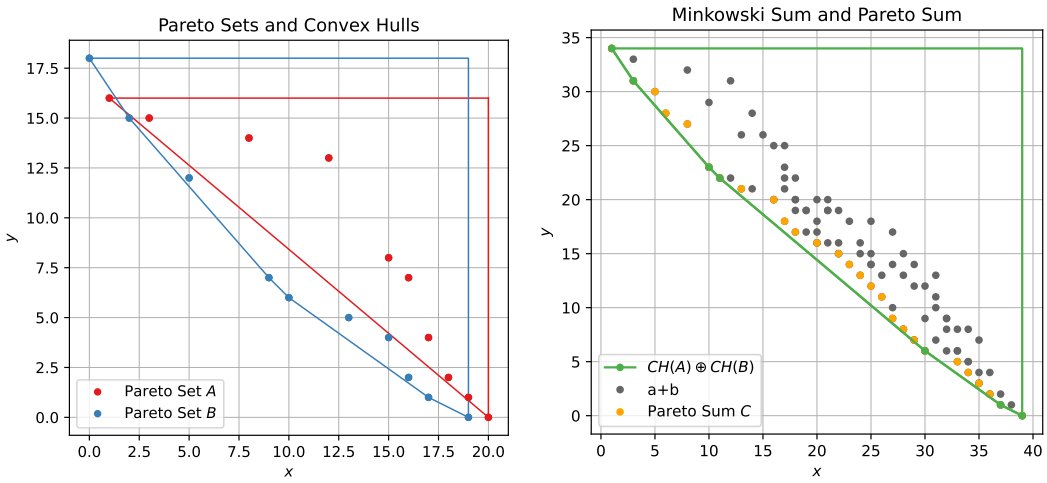

**Figure 2** Left: Pareto sets $A, B$ together with their convex hulls. Right: The Minkowski sum $CH(A) \oplus CH(B)$ of the convex hulls encloses all pairwise vector additions $a + b$ with $a \in CH(A)$ and $b \in CH(B)$. The respective vertices (green points) are a subset of the Pareto Sum $C$.

## 3 Minkowski Sum of Convex Hulls

In this section, we present an algorithm that for given Pareto sets $A, B$ computes part of their Pareto sum in linear time. Thus, this algorithm can be used as an efficient preprocessing method before applying other (more costly) techniques.

For two convex polygons $P, Q \in \mathbb{R}^2$, their Minkowski sum $P \oplus Q$ is a convex polygon with at most $|P| + |Q|$ vertices and these vertices can be computed in linear time [15]. Let now $A, B$ be sorted Pareto sets augmented with dummy points $(x, y)$ where $x := \max_{s \in S} s.x$ and $y := \max_{s \in S} s.y$ for $S = A$ and $S = B$, respectively. We use $CH(A)$ and $CH(B)$ to refer to the convex hulls of these two sets. The following observation captures the connection between these convex hulls and the Pareto sum.

▶ **Observation 5.** *The vertices of the Minkowski sum $CH(A) \oplus CH(B)$ are a subset of the Pareto sum of $A$ and $B$ (excluding the dummy point sum).*

For a sorted Pareto set, its convex hull can be computed in linear time using Andrew's algorithm [3]. Then, using the linear time Minkowski sum algorithm on the two convex hulls and extracting the respective polygon vertices, we obtain a subset of the Pareto sum $C$, see Figure 2. If both $A, B$ are convex, then this procedure already returns all of $C$. We thus get the following corollary.

▶ **Corollary 6.** *The Pareto sum of two convex, sorted Pareto sets can be computed in $\mathcal{O}(n)$.*

For non-convex $A, B$, we might only get part of the Pareto sum. However, as this step only takes linear time (assuming the Pareto sets are presorted), it can always be used as an initial step before applying other algorithms. We will discuss below in more detail how the knowledge of $C' \subset C$ can be exploited to decrease the practical running time of several of the algorithms we propose.

# 4 Base Algorithms

In this section, we discuss three simple base algorithms for Pareto sum computation along with engineering concepts for their acceleration and space consumption reduction. The algorithms all proceed by checking for each element $p \in M$ whether there exists $p' \in M$ that dominates $p$. If there is no such $p'$, the point $p$ is added to the Pareto sum $C$. The only difference between the algorithms is the implementation of the dominance check.

## 4.1 Brute Force (BF)

The easiest way to check for a point $p \in M$ whether it is non-dominated is by pairwise comparison to all other elements in $M$. This dominance check takes $\mathcal{O}(|M|)$ time per point, accumulating to a total time of $\mathcal{O}(|M|^2) = \mathcal{O}(n^4)$. As the elements $M_{ij}$ can be computed on demand, the space consumption is linear in the input size $n$ and the output size $k$.

▶ **Corollary 7.** *The BF algorithm runs in $\mathcal{O}(n^4)$ time using $\mathcal{O}(n+k)$ space.*

## 4.2 Binary Search (BS)

To decrease the time needed for the dominance check, we take the structure of $M$ into account. Based on the assumption that $A$ and $B$ are sorted and that $M_{ij}$ is defined as $A_i + B_j$, we have the property that each column (and each row) of the matrix $M$ forms a sorted Pareto set on its own. Thus, if we want to check whether column $M_j$ contains an element dominating $p$, we simply have to find the entry $M_{ij}$ with the largest index $i$ such that $M_{ij}.x \leq p.x$ as well as the entry $M_{i'j}$ with the smallest index $i'$ such that $M_{i'j}.y \leq p.y$. Then all elements in $M_j$ with a row index in $[i', i]$ dominate $p$ (or are equal to $p$). Accordingly, the dominance check for $M_j$ boils down to evaluating whether $i' \leq i$ holds. These two indices can each be identified via a binary search over the respective coordinates in the column. Hence the dominance check time per column is in $\mathcal{O}(\log n)$, resulting in a total time of $\mathcal{O}(n \log n)$ per element in $M$. Entries of $M$ that need to be accessed can be computed on demand.

▶ **Corollary 8.** *BS runs in $\mathcal{O}(n^3 \log n)$ time using $\mathcal{O}(n+k)$ space.*

To reduce the practical running time of the BS algorithm, we propose the following engineering techniques.

**Pruning.** Whenever we identify a non-dominated point $p$ and add it to $C$, we can also compute all entries in $M$ dominated by $p$ in time $\mathcal{O}(n \log n)$, again with the help of two binary searches per column. For those points, dominance does not need to be checked again. However, if we simply store a flag for each entry in $M$ whether it needs to be further considered or not, the space consumption increases to $n^2$. Instead we can store for each column the set of intervals of dominated points in an interval tree. The number of intervals per column is upper bounded by $k$. Then, for a point $p = M_{ij}$ we can query the interval tree in time $\mathcal{O}(\log k)$ to see whether the point lies in a dominated region. Intervals can also be added or merged within the same time. However, the space consumption would still increase to $\mathcal{O}(nk)$. To keep the space consumption linear, one might only want to store a constant number of intervals per column (e.g. only the largest one) and then merge or replace intervals if possible or needed. If pruning is applied, we can also disregard fully dominated columns in the binary searches of the remaining elements.

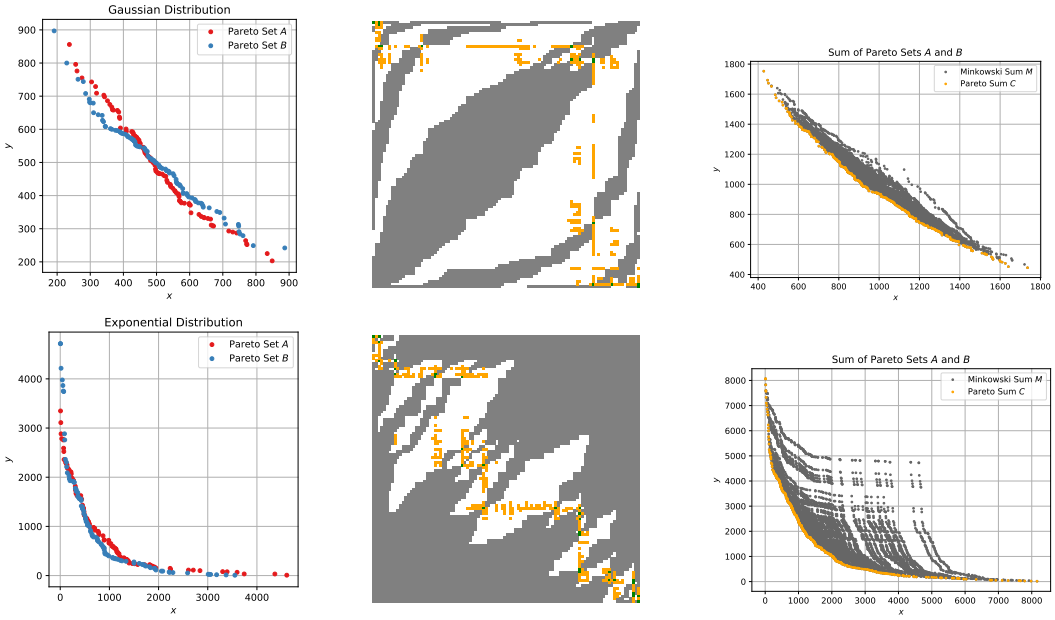

**Figure 3** Input Pareto sets following different kinds of distributions (left) and schematic depiction of the corresponding Minkowski matrix $M$ (middle). Green dots indicate entries in $M$ that are points on the Minkowski sum of the convex hulls of $A$ and $B$, black dots indicate entries that are dominated by the green ones, and orange dots encode the remaining elements of the Pareto sum which then together dominate the white dots. In the right images, the Minkowski sum and the Pareto sum are illustrated based on point coordinates.

**Priority Binary Search (PBS).** As soon as dominance checks might be avoided for some of the elements based on the pruning techniques described above, the order in which the points are considered impacts the running time. Identifying points that dominate many other points early on can significantly reduce the total number of checks. For that purpose, we will use the preprocessing step described in Section 3 to get an initial set of points $C' \subset C$. We can directly exclude any points dominated by the points in $C'$. Furthermore, we conjecture that points in the same rows or columns as the points of $C'$ occupy in $M$ are likely to be also part of $C$. Thus, we give priority to these points in our search. Figure 3 shows some visual support for this hypothesis.

## 4.3 Sort & Compare (SC)

Given a sorted set of points, extracting the set of non-dominated points can be accomplished in constant time per point. The smallest element is always added to $C$. For each other element in sorted order, we check whether it is dominated by (or equal to) the currently last element in $C$. If that is not the case, the element is added to $C$.

Computing and sorting $M$ as a whole takes time $\mathcal{O}(n^2 \log n)$ and requires quadratic space. But we can exploit the structure of $M$ to improve the space consumption to linear as follows: We use a min-heap data structure and initialize it with the first row of $M$. Each element in the heap remembers its position in $M$. When we extract the min element $M_{ij}$ from the heap and $C$ is empty so far, we add the element to $C$. Otherwise, we compare $M_{ij}$ to the element added to $C$ last. If $M_{ij}$ is not dominated, we also add it to $C$. In any case, we add its column successor $M_{i+1j}$ to the heap (as long as $i < n$). As each column is a sorted Pareto

set in itself, we know that $M_{i+1j}$ has to have larger $x$-value than $M_{ij}$. Thus, we extract the elements from the heap exactly according to their global lexicographic order. As the heap never contains more than $n$ elements, its space consumption is in $\mathcal{O}(n)$ and the heap operations take $\mathcal{O}(\log n)$ per round.

In conclusion, the heap-based variant has the same asymptotic running time as the one where we fully compute and sort $M$, but a significantly reduced space consumption.

▶ **Corollary 9.** *SC runs in $\mathcal{O}(n^2 \log n)$ time using $\mathcal{O}(n+k)$ space.*

## 5 Output-Sensitive Algorithms

If the Pareto sum $C$ contains (almost) all elements of the Minkowski sum $M$, a quadratic running time is needed already to report $C$. In this case, the running time of SC is asymptotically optimal up to logarithmic factors. However, in case $C$ is small, subquadratic running times might be possible. We will present two output-sensitive algorithms in this section that have a running time asymptotically faster than SC for $k \in o(n)$ or $k \in o(n \log n)$, respectively. Both algorithms detect the elements in $C$ successively. This is a well-established paradigm for output-sensitive skyline computation, see e.g. [13, 18]. However, known algorithms rely on the explicit availability of the point set to construct an efficient search data structure. Based on the following lemma, we will design successive algorithms that do not need access to $M$ as a whole.

▶ **Lemma 10.** *Let $A, B$ be two Pareto sets and $c, c' \in C$ two elements of their Pareto sum with $c.x < c'.x$. Then the lexicographically smallest element $m$ in $M$ that dominates $(c'.x - \varepsilon, c.y - \varepsilon)$ for $\varepsilon > 0$ is also part of $C$ (if such an element exists).*

**Proof.** We first argue that for any $m \in M$, the smallest point $p \in M$ dominating $m$ (or being equal to $m$) is part of the Pareto sum $C$. Assume otherwise for contradiction. Then there is a point $p' \in C$ that dominates $p$ and thus also $m$. But in this case $p'$ is smaller than $p$ which contradicts the choice of $p$ as smallest element to dominate $m$.

Now, if there is any point $m \in M$ that dominates the dummy point $(c'.x - \varepsilon, c.y - \varepsilon)$ the above argumentation applies. ◀

Clearly, $M_{11}$ and $M_{nn}$ are always part of the Pareto sum, as those are the points with smallest global $x$-value and $y$-value, respectively. All other elements in $C$ must have an $x$-value in the open interval $(M_{11}.x, M_{nn}.x)$. Thus, if we have an oracle that returns the smallest point $m \in M$ (with respect to lexicographic ordering) in a given range $[x_{\min}, x_{\max}) \times [y_{\min}, y_{\max})$, we can compute $C$ based on Lemma 10 as follows. We initialize $C = M_{11}, M_{nn}$ and $x_{\min} = M_{11}.x, x_{\max} = M_{nn}.x, y_{\min} = M_{nn}.y, y_{\max} = M_{11}.y$. Then we query the oracle to get the smallest point $m$ in the respective range. If such a point does not exist, we abort. Otherwise we add the point $m$ to $C$ and set $x_{\min} = m.x, y_{\max} = m.y$ before repeating the process. Figure 4 illustrates the core concept.

Thus, the algorithm discovers the points in $C$ one-by-one in increasing order of their $x$-values (except for $M_{nn}$ which is known from the start) using $k$ calls to the range-minimum oracle. A naive oracle implementation would be to check all points in $M$ for containment in the range and to keep track of the minimum among them. Then each call to the oracle costs $\mathcal{O}(n^2)$ and the overall running time of the successive algorithm would be $\mathcal{O}(n^2 k)$. Next, we describe how to implement the oracle more efficiently.

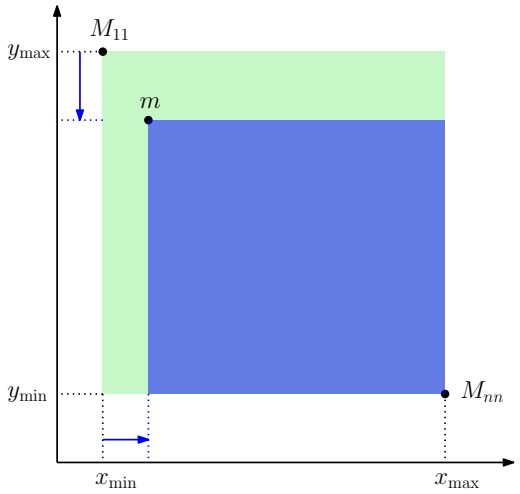

**Figure 4** Initial search range (green rectangle) spanned by $M_{11}$ and $M_{nn}$. The range-minimum element $m$ then leads to a reduction of $y_{\max}$ and an increase of $x_{\min}$ (blue arrows) which tightens the search range for the next element of $C$.

## 5.1 Successive Binary Search (SBS)

In the BS approach described in Section 4.2, we use two binary searches per column of $M$ to check for a query point $m \in M$ whether an element dominating $m$ exists in that column. We can use the same concept to implement a range-minimum oracle: For each column, we identify via binary searches the first position $f_x$ with an $x$-coordinate larger or equal to $x_{\min}$, the last position $l_x$ with an $x$-coordinate smaller than $x_{\max}$, the first position $f_y$ with a $y$-coordinate smaller than $y_{\max}$, and the last position $l_y$ with a $y$-coordinate larger or equal to $y_{\min}$. If $[f_x, l_x] \cap [f_y, l_y] \neq \emptyset$, we return $\max(f_x, f_y)$. The entry at that position is the smallest point dominating $m$ in the column. Keeping track of the smallest returned point over all columns provides the desired result in $\mathcal{O}(n \log n)$ per oracle call.

▶ **Corollary 11.** *Successive BS runs in $\mathcal{O}(nk \log n)$ time using $\mathcal{O}(n + k)$ space.*

For standard BS we can use the Minkowski sum of the convex hulls of $A$ and $B$ to already identify a subset $C'$ with size $k' \leq k$ of the Pareto sum $C$ without the need of binary searches. We can apply the same initialization here and then simply use the successive algorithm independently in each of the $k' - 1$ ranges induced by any two consecutive points in $C'$ (in sorted order). By that, the number of oracle calls increases to at most $k + k' - 1 < 2k$ as in each of the $k - 1$ ranges the respective last oracle call will return no point. This does not affect the asymptotic running time, though. But it allows to conduct up to $k' - 1$ oracle calls in parallel.

To further foster parallelization, we can weaken the oracle requirement to always return the smallest point in a given range to the requirement to return any non-dominated point in the range. The new point then splits the previous range into two subranges that can be queried independently. With that, the oracle might be called up to $k + 2k' - 2 < 3k$ times as now in each of the $k' - 1$ ranges the call to its leftmost induced subrange and the call to its rightmost induced subrange will return no point. Again, the asymptotic running time remains unaffected. To implement the weaker oracle, we propose the so called Cascading BS (CBS) algorithm. Again, we consider the columns one after each other. But now, as soon as we find a column entry $p$ in the given query range, we update the range immediately and then search for a point dominating $p$ in the remaining columns. If we find such a point,

we immediately update again. Note that it can never happen that a point $p'$ in an already visited column dominates $p$, as then we would have selected one point from said column to tighten the query range and there can never be two points in one column dominating one another. Thus, after we considered all columns, we can safely add the current point $p$ to $C$.

For an example of the difference between SBS and CBS, consider the matrix in Figure 1 and assume the current search range is $[14, 53) \times [15, 44)$. SBS discovers the element $A_6 + B_1 = (15, 43)$ next as this is the point with smallest $x$-value that dominates the dummy point $(53 - \varepsilon, 44 - \varepsilon)$. CBS, however, first detects the point $A_1 + B_{10} = (28, 41)$ as it already dominates the dummy point. It then proceeds by trying to find an element that dominates $(28, 41)$. It thus detects $A_3 + B_5 = (17, 41)$ next and tightens the search range accordingly. As this is a Pareto sum point, no further dominating elements are found in the remaining columns and $(17, 41)$ is returned and added to $C$. The search range is then split into $[14, 17) \times [41, 44)$ and $[17, 53) \times [15, 41)$, which can be processed independently.

## 5.2 Successive Sweep Search (SSS)

To improve the oracle time of SBS, we observe that the binary searches in the columns are somewhat redundant. If $M$ was fully available, we could apply fractional cascading [5] to the column vectors. This would reduce the running time to compute the positions $f_x, l_x, f_y, l_y$ in all columns from $\mathcal{O}(n \log n)$ to $\mathcal{O}(n)$. Thus, the $k$ oracle calls cost $\mathcal{O}(nk)$. Unfortunately, computing $M$ and the data structure for fractional cascading requires space and time in $\Theta(n^2)$. Fortunately, we can also achieve linear oracle time without the need to access $M$ as a whole. Based on the structure of $M$, we know that for an entry $M_{ij}$ all elements $M_{st}$ with $s \geq i$ and $t \geq j$ have a larger $x$-coordinate than $M_{ij}$ but a smaller $y$-coordinate. Vice versa, all elements in $M_{st}$ with $s \leq i$ and $t \leq j$ have a smaller $x$-coordinate than $M_{ij}$ but a larger $y$-coordinate. This implies, for example, that the position of $f_x$ in some column cannot be larger than the position of $f_x$ in the neighboring column to its left. Similar relationships hold for the positions of $l_x, f_y$ and $l_y$ in neighboring columns. Accordingly, we can find the respective column values by a single left-to-right sweep, where the search path forms a monotone staircase structure and is thus bounded in length by $2n$.

Even better, we can have a single unified sweep to find the range-minimum $m$ in linear time: We start at $M_{n1}$, that is, the last entry of the first column. Whenever we enter a new column $j$, we apply upwards linear search in that column until we reach an entry $M_{ij}$ where either $M_{ij}.x > x_{\min}$ and $M_{i-1j}.x \leq x_{\min}$ or where $M_{ij}.y < y_{\max}$ and $M_{i-1j}.y \geq y_{\max}$. Thus, we get $i = \max(f_x, f_y)$; except if the entry we start from already has a too small $x$-value or a too large $y$-value or both which means that the column contains no point in the query range. In the former case, we check whether $M_{ij}$ is contained in the range. If the check is passed, $M_{ij}$ is a valid candidate for the range-minimum $m$. We keep track of the smallest viable candidate over the course of the algorithm. We then go from element $M_{ij}$ to its right neighbor $M_{ij+1}$ and proceed with the new column as described above. After processing the last column, we return the current $m$ as the range-minimum element.

▶ **Lemma 12.** *The sweep algorithm computes the smallest $m \in M$ in a given range in $\mathcal{O}(n)$.*

**Proof.** To prove correctness, we need to argue that for a column $j$ entered at row $i$ and exited at row $i' \leq i$, the range-minimum $m$ can not be an entry $M_{i^*j}$ with $i^* < i'$ or $i^* > i$.

Clearly, checking elements in column $j$ with a row index smaller than $i'$ cannot give us any viable candidates, as either their respective $x$-value is too small or their $y$-value is too large by definition. Hence we only need to consider $i^* > i$. If $M_{ij}$ is in the query range, then the entries in column $j$ with $i^* > i$ cannot constitute the range-minimum as they all have an $x$-value larger than that of $M_{ij}$. If $M_{ij}$ is not in the query range, we have the following cases:

- $M_{ij}.x > x_{\max}$. But then $M_{i^*j}.x > x_{\max}$ holds as well.
- $M_{ij}.x < x_{\min}$ or $M_{ij}.y > y_{\max}$. This case only occurs if $i = n$. Thus there is no $i^* > i$.
- $M_{ij}.y < y_{\min}$. But then $M_{i^*j}.y < y_{\min}$ holds as well.

Accordingly, if column $j$ contains the range minimum it needs to be an element with a row index in $[i', i]$. If $M_{i'j}$ is in the range, it is clearly the best candidate in column $j$ for the range-minimum $m$. If $M_{i'j}$ is not in the query range, then the same applies to all entries in the same column with larger row index as argued above. Thus, it is sufficient to check $M_{i'j}$ for each column $j$. The running time is determined by the number of elements in $M$ that are accessed. As the interval of elements checked for each column only overlaps with the intervals of all columns to its left in a single row index, at most $2n$ elements in $M$ are considered in total. ◀

Based on this sweep search (SS) oracle, we now get a successive algorithm with better running time than SBS.

▶ **Corollary 13.** *Successive SS runs in $\mathcal{O}(n \log n + nk)$ using $\mathcal{O}(n + k)$ space.*

In fact, if $k \in o(\log n)$, the running time is dominated by the initial sorting step of the elements in $A, B$. For $k \in o(n)$, we achieve a subquadratic running time.

For acceleration of sweep search in practice, we observe that if we enter a column at row $i$ and confirm for some value $i' < i$ that $M_{i'j}$ is still feasible with respect to $x_{\min}$ and $y_{\max}$, we do not have to check intermediate rows to get the correct range-minimum by virtue of Lemma 12. Similarly, if we have not found any $M_{ij}$ in column $j$ with $M_{ij}.x \geq x_{\min}$ and $M_{ij}.y < y_{\max}$ and the same inequalities apply to some $M_{ij'}$ with $j' > j$, we do not need to check intermediate columns for range-minimum candidates. Thus, in both cases we can introduce a skip threshold $\Delta > 1$ and check for $i' = i - \Delta$ or $j' = j + \Delta$, respectively, whether the necessary conditions apply. If that is the case we skip intermediate rows or columns and then try to skip ahead again. If skipping is no longer possible, we simply fall back to linear search. Accordingly, in the worst case, we check at most one superfluous element for each row and column. This does not increase the asymptotic running time of the oracle but might reduce its running time in practice if skipping is successful.

Furthermore, similar to CBS, we also propose Cascading Sweep Search (CSS). Here again, whenever we found a temporary range-minimum candidate $m$ we immediately tighten the search range to enforce that further candidates need to dominate the current $m$ to be considered. The sweep search then also guarantees to return an element of the Pareto sum $C$. The Minkowski hull preprocessing and the split of search intervals to foster parallelization as described for CBS can be applied here as well.

## 6 Experimental Evaluation

We implemented the seven algorithms for Pareto sum computation listed in Table 1 in C++: The two existing approaches, namely the Kirkpatrick-Seidel algorithm (KS) [11] and NonDomDC (ND) [12], the three base algorithms (BF, BS, SC), and the two successive algorithms (SBS, SSS). For KS, we implemented the simpler (and thus faster) variant, where the output size $k$ (used for partitioning) is given as an input. We simply compute $k$ with one of our other algorithms and then feed the result into KS. For ND, we actually implemented two variants described in [12]: In the first variant (described in more detail in Section 1.1), one always merges the current result with the next column (Sequential ND, SND). In the second variant, columns are combined in a MergeSort like fashion (Doubling ND, DND). As benchmark data we use randomly generated inputs as well as real inputs. Both types of data sets are described in more detail below. All experiments were conducted on a single core of a 3.4 GHz AMD Ryzen Threadripper 1950X 16-core processor with 126 GB of RAM.

## 6.1 Results for Generated Data

To generate Pareto sets, we take two random samples of $n$ unique values from a given range. The first sample is sorted increasingly and represents the $x$-coordinates within the Pareto set. The second sequence is sorted decreasingly and represents the $y$-coordinates. We consider uniform, Gaussian and exponentially distributed samples over the range $[0, n]$. In addition, we investigate $A$ and $B$ where the respective $x$-coordinates are drawn from vastly different intervals, namely with upper bounds $\sqrt{n}$ and $n^2$. We call this a shifted distribution. Figures 3 and 5 show example instances for each input type. Running times are always averaged over 100 generated instances per tested value of $n$.

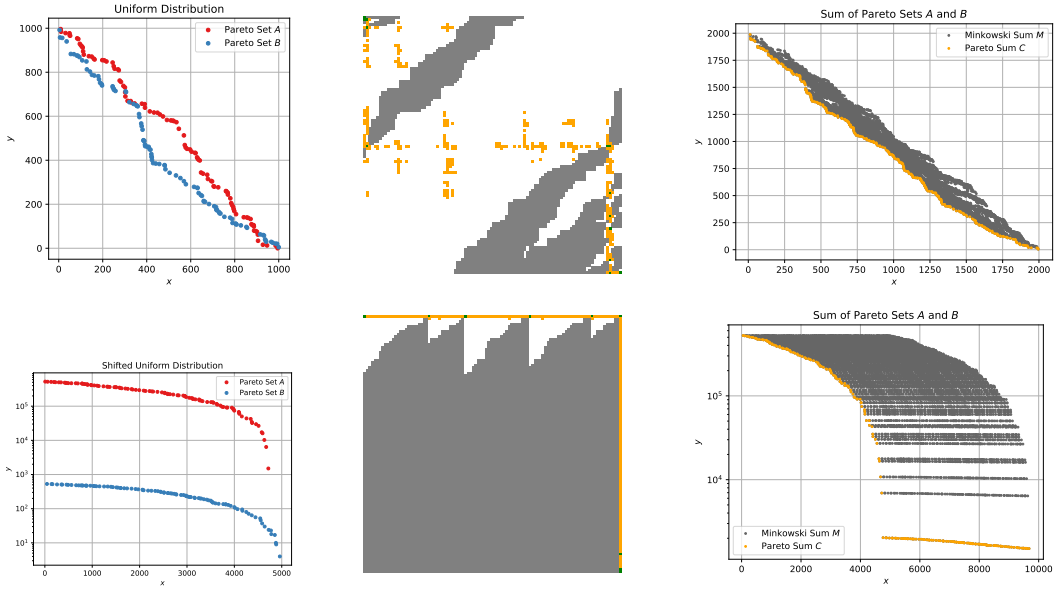

**Figure 5** Example instances for uniform and shifted uniform point distributions For the latter, note the logscale of the y-axis. The color coding is the same as in Figure 3.

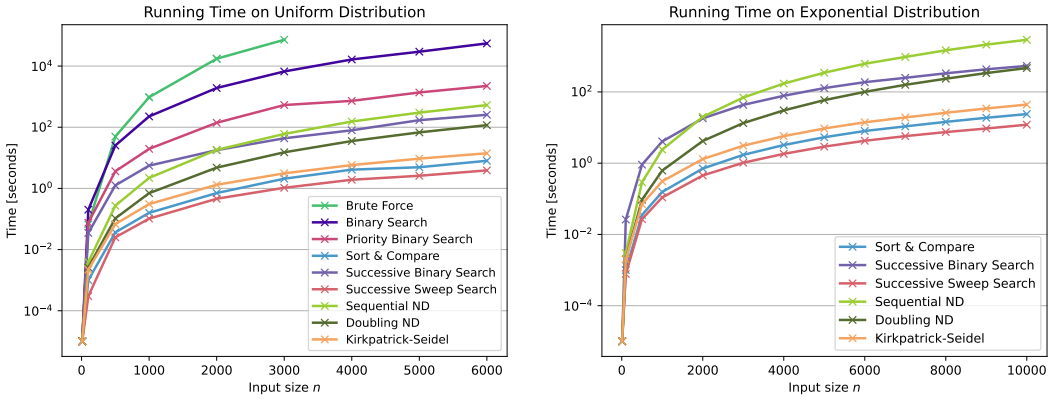

**Figure 6** Average running times of all algorithms on uniform distributions (left) and of the top six algorithms on exponential distributions (right). Note the logscale of the y-axis.

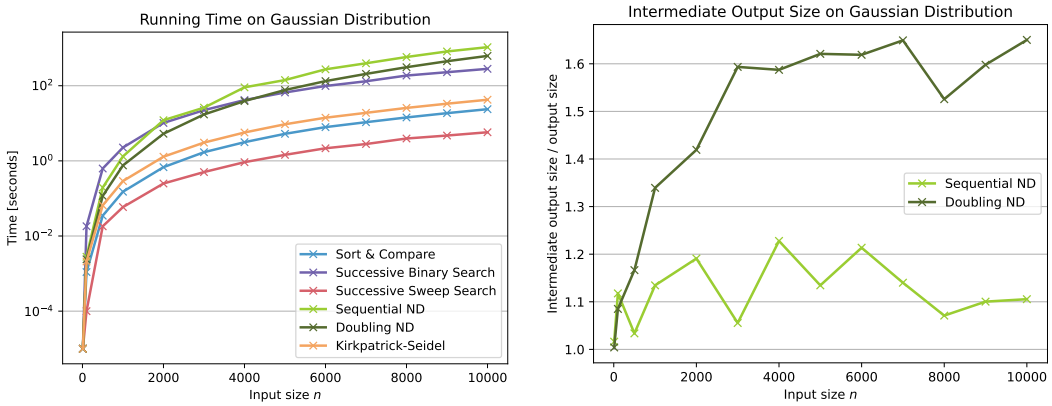

**Figure 7** Left: Average running times of selected algorithms on Gaussian distribution. Right: Intermediate output size of the Sequential ND and Doubling ND algorithms.

Figure 6, left, shows the running times of all algorithms on uniformly distributed instances. In line with our theoretical analysis, the Brute Fore approach is by far the slowest. Instances larger than $n = 3000$ were not tested as those already took over an hour. The engineered Binary Search algorithm (PBS) is faster than BS by an order of magnitude but not as fast as the other competitors. Note that we used the variant here that guarantees output-sensitive space consumption by storing the borders of at most on block of dominated elements per column. In compliance with the experimental results in [12], we see that DND is faster than SND. However, they are both slower than the Kirkpatrick-Seidel and the Sort & Compare algorithm, which exhibit very similar running times. SSS is faster than the second best algorithm, Sort & Compare, by a factor of 2-5. On exponential distributions the results are similar, see Figure 6, right. But the ND variants perform slightly worse. On Gaussian distributions, the ND variants are about two orders of magnitude slower than SSS and even scale worse than SBS, see Figure 7, left. The reason for this behavior is investigated in Figure 7, right, which depicts the intermediate solution sizes of the ND algorithms. On uniform and exponential distributions, the space overhead is less than 1%. However, on Gaussian distributions, SND and DND require 20% and 65% more space than the output (and our output-sensitive algorithms), respectively. Also note that even if intermediate sizes are not much larger than the final size, it might be that the maximum intermediate size is reached early and persists close to that value, thereby increasing the running times of the individual column merge steps. Thus, the ND algorithms are both very sensitive to the distribution of the input points and the position of the Pareto sum points within the matrix. In contrast, the performance of our sweep algorithms depends primarily on the size of the output, which was within $4n$ across all tested instances and distributions.

On uniform, Gaussian and exponential distributions, our engineered SSS variant with $\Delta$-skipping had little impact. On shifted distributions, however, this concept proved to be very effective due to the Pareto sum points being mostly located either in the first few rows or the last few columns of the matrix (see Figure 5), and Pareto sum sizes being small in general. Using $\Delta = \sqrt{n}$, we achieved speeds-ups of two orders of magnitude over all other approaches on instances with $n = 10000$.

**Table 2** Experimental results for BCH computation on three road networks of different size. The table shows the input graph sizes, the number of edges in the augmented graph (original + shortcuts), the number of non-trivial Pareto sum computations, as well as the running times for conducting these computations with four different algorithms. The final row shows the preprocessing time spent on operations other than Pareto sum computation.

| | ROAD1 | ROAD2 | ROAD3 |
|---|---|---|---|

## 6.2 Results for Real Data

As a real-world application of Pareto sum computation, we consider bi-criteria route planning in road networks. Here, given an input graph $G(V, E)$ and costs $c_1, c_2 : E \to \mathbb{R}^+$, the goal is to either compute all Pareto-optimal paths with respect to $c_1, c_2$ between two nodes $s, t \in V$, or the path optimal with respect to one cost while not exceeding a budget on the other (also known as the constrained shortest path problem). To accelerate query answering, a bi-criteria contraction hierarchy (BCH) data structure can be used. In the preprocessing phase of a BCH, the input graph is augmented with additional edges, also called shortcuts. The shortcut insertion is guided by a node permutation $\pi : V \to \{1, \dots, n\}$. For nodes $u, w \in V$, a shortcut $\{u, w\}$ is inserted if and only if there exists a simple path from $u$ to $w$ on which no node has a higher $\pi$ value than $\max(\pi(u), \pi(w))$. The shortcut represents all simple paths $p$ between $u$ and $w$ with that property. For each Pareto-optimal $p$, the respective cost tuple $(c_1(p), c_2(p))$ should be assigned to the shortcut. To compute these Pareto sets for all shortcuts in an efficient manner, a bottom-up approach is used. Let $u$ be the inner node on a path $p$ from $u$ to $w$ with maximum $\pi$-value. If the Pareto sets $A$ and $B$ of the shortcuts $\{u, v\}$ and $\{v, w\}$ are known, respectively, the Pareto set of $\{u, w\}$ is the Pareto sum $C$ of $A$ and $B$. If there are multiple paths $p$, the final Pareto set of $\{u, w\}$ is formed by the non-dominated elements of the union of all these Pareto sums. The non-dominated union of two Pareto sets can be computed in linear time by merging the presorted sets to obtain the sorted union and then applying the simple non-dominance check as described in the SC approach. In the final BCH, queries can be answered with a bi-directional Pareto-Dijkstra run that relaxes shortcut edges instead of many original edges whenever possible. This significantly reduces the search space and allows to answer queries orders of magnitude faster [17, 9].

In our experiments, we use test graphs extracted from OpenStreetMap with Euclidean distance and positive height difference as edge costs (in compliance with [17]). Based on our results on generated data, we use the best four algorithms (KS, SC, DND and SSS) for Pareto sum computation. Note that Pareto sets $A$ and $B$ do not necessarily have the same size here, but all proposed Pareto sum computation algorithms can be easily adapted. Table 2 shows the characteristics of the three road network instances we considered in our experiments and the outcomes. The number of Pareto sum computations in the preprocessing phase of the BCH reported in the table excludes trivial inputs where either $A$ or $B$ has size 1. We

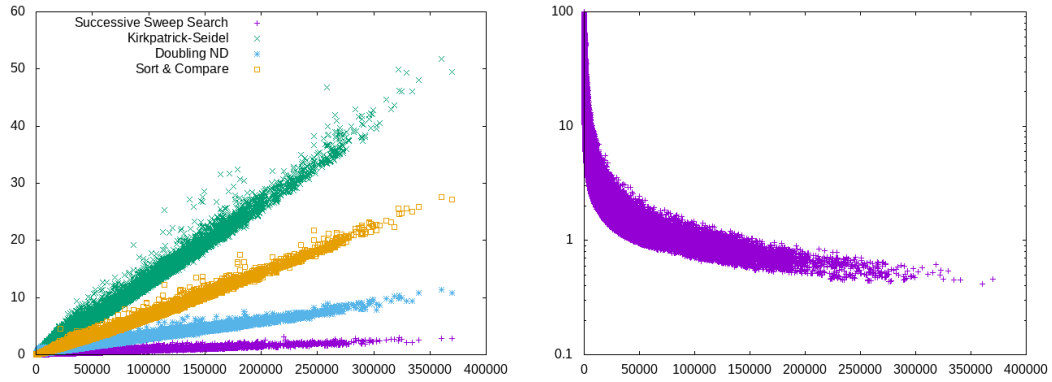

**Figure 8** Detailed results for the ROAD2 instance. Left: Running times in seconds per Pareto sum computation in dependency of the size of the Minkowski sum. Right: Pareto sum size as percentage (logscale) of the size of the Minkowski sum.

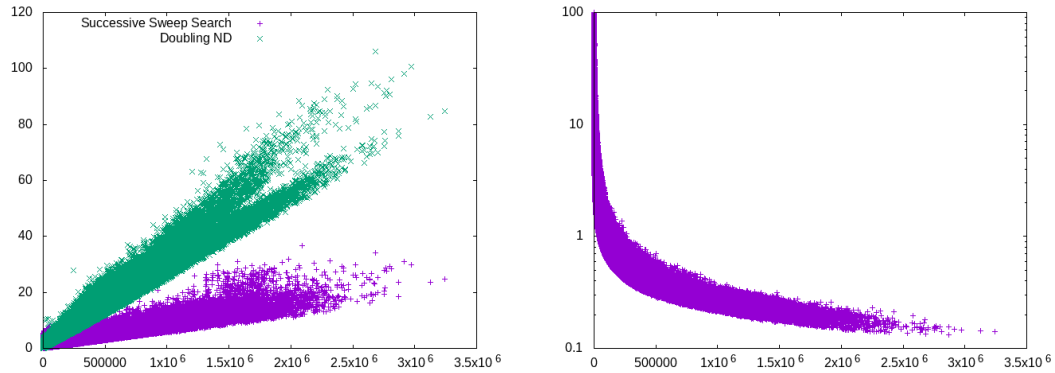

**Figure 9** Detailed results for the ROAD3 instance. Left: Running times in seconds per Pareto sum computation in dependency of the size of the Minkowski sum. Right: Pareto sum size as percentage (logscale) of the size of the Minkowski sum.

observe that the time spent on non-trivial Pareto sum computations dominates the overall preprocessing time, especially on larger networks. There are significant differences in running time between the algorithms we tested, though. On all instances, SSS is the fastest approach. It is roughly an order of magnitude faster than the KS algorithm which fully computes and stores $M$. With KS, we could not compute a BCH data structure within a day on our largest instance with about 4 million nodes. Interestingly, in contrast to the experiments on generated data, DND outperforms SC. Figure 8 shows the running times for all individual Pareto sum computations as well as the size of the respective results for the ROAD2 instance. We observe that the larger the Minkowski sum $M$, the smaller the relative output size. This explains why SSS consistently outperforms the other approaches, especially on larger inputs. Figure 9 shows results for the two best algorithms, DND and SSS, on ROAD3. Here, $|M|$ was up to $3 \cdot 10^6$ and the percentage of elements in the Pareto sum $C$ even approached 0.1. This is very beneficial for the SSS algorithm as the smaller the output size the fewer range minimum oracle calls are needed.

Furthermore, we used DND and SSS in query answering to combine Pareto sets in the bi-directional Pareto-Dijkstra run whenever the forward and the backward search meet. On the ROAD3 instance, a speed-up of up to 5 over DND was achieved when using SSS.

## 7 Conclusions and Future Work

We introduced scalable algorithms for Pareto sum computation which avoid the computation of the whole Minkowski sum. Our successive sweep search algorithm was shown to perform best across all instances, generated or real, while guaranteeing an output-sensitive space consumption. One direction for future work is to carefully parallelize all discussed algorithms. We also implemented and tested the cascading sweep search variant, which enables parallel successive search, and observed that the sequential running time matches that of successive sweep search while splitting the search ranges in many subranges which could be processed in parallel. Furthermore, even in a parallel implementation, the sweep search algorithm keeps its output-sensitive space consumption. Another direction for future work is the consideration of higher-dimensional input points. While some algorithms are easily generalizable, novel range minimum oracles need to be designed for the successive algorithms to work.

## Abstract

The edge clique cover (ECC) problem – where the goal is to find a minimum cardinality set of cliques that cover all the edges of a graph – is a classic NP-hard problem that has received much attention from both the theoretical and experimental algorithms communities. While small sparse graphs can be solved exactly via the branch-and-reduce algorithm of Gramm et al. [JEA 2009], larger instances can currently only be solved inexactly using heuristics with unknown overall solution quality. We revisit computing minimum ECCs exactly in practice by combining data reduction for both the ECC *and* vertex clique cover (VCC) problems. We do so by modifying the polynomial-time reduction of Kou et al. [Commun. ACM 1978] to transform a reduced ECC instance to a VCC instance; alternatively, we show it is possible to "lift" some VCC reductions to the ECC problem. Our experiments show that combining data reduction for both problems (which we call *synergistic data reduction*) enables finding exact minimum ECCs orders of magnitude faster than the technique of Gramm et al., and allows solving large sparse graphs on up to millions of vertices and edges that have never before been solved. With these new exact solutions, we evaluate the quality of recent heuristic algorithms on large instances for the first time. The most recent of these, EO-ECC by Abdullah et al. [ICCS 2022], solves 8 of the 27 instances for which we have exact solutions. It is our hope that our strategy rallies researchers to seek improved algorithms for the ECC problem.

# 1 Introduction

In the *edge clique cover (ECC) problem*, also called the *clique cover* problem, we are given an unweighted, undirected, simple graph $G = (V, E)$ and asked to find a minimum cardinality set of cliques that cover the edges of $G$. The ECC problem is NP-hard, however its decision variant did not appear in Karp's original list of NP-complete problems [23], though the *vertex clique cover (VCC) problem* did. Compared to the VCC problem, the ECC problem has received the lion's share of attention from researchers, in part because it has many applications. For instance, edge clique covers can be used to succinctly represent constraints for integer program solvers [5] and to detect communities in networks [12].

Data reduction rules, which allow one to transform an input instance to a smaller equivalent instance of the same problem, are powerful tools for solving NP-hard problems in practice [4, 26]. Of particular interest in the field of parameterized algorithms is whether the repeated application of data reduction rules produces a *kernel* – which is a problem instance that has size bounded by a function $O(f(k))$ of some parameter $k$ of the input. Gramm et al. [19] show that repeated application of four simple reduction rules produce a kernel of size $2^k$, where the parameter $k$ is the number of cliques in the cover. When intermixed with branch-and-bound (a so-called *branch-and-reduce* algorithm), these reduction rules enable solving sparse graphs of up to 10,000 vertices quickly in practice. Since their seminal work, no progress has been made on solving larger instances exactly. Indeed, the prospect of doing so is grim since polynomial kernels are unlikely to exist for the ECC problem, when parameterized on the solution size [13]. Although researchers have found further FPT algorithms (and smaller kernels) with other parameters [6, 32], these algorithms are still only able to solve relatively small instances in practice. The outlook for the VCC problem is even worse in theory: it is unlikely to have any problem kernel when parameterized on the number of cliques $k$ in the cover, as it is already NP-hard for $k = 3$ (since it is equivalent to 3-coloring the complement graph).

However, recent data reductions for the VCC problem have been shown to significantly accelerate computing minimum VCCs exactly in practice. Strash and Thompson [31] introduce a suite of reduction rules and show that data reduction can solve real-world sparse graphs with up to millions of vertices in seconds.

## Our Results

We show that combining VCC and ECC data reductions enables the ECC problem to be solved exactly on large instances not previously solvable by Gramm et al. [19]. We do so by modifying the polynomial-time transformation of Kou et al. [25] to transform a reduced ECC instance to a VCC instance, but also show that some VCC data reductions can be "lifted" to ECC data reductions. Their combined reduction power (which we call *synergistic data reduction*) reduces an ECC instance significantly more than Gramm et al.'s reductions alone, enabling us to exactly solve graphs with millions of vertices and edges. With these exact results, we objectively evaluate the quality of heuristic algorithms recently introduced in the literature. On instances not solvable exactly with our method, we give upper and lower bounds for use by future researchers.

# 2 Related Work

We now briefly review the relevant previous work on the ECC and VCC problems, as well as practical data reduction in related problems.

## 2.1 Edge Clique Cover

The goal of the edge clique cover (ECC) problem is to cover the edges of the graph $G$ with a minimum number of cliques, denoted $\theta_E(G)$. That is, to find a set of cliques $\mathcal{C} = \{C_1, C_2, \ldots, C_k\}$ such that each edge is in at least one clique in $\mathcal{C}$ and $k = \theta_E(G)$. Although closely related to the VCC problem (to cover *vertices* with a minimum number of cliques, denoted $\theta(G)$), Brigham and Dutton [8] showed that $\theta(G) \leq \theta_E(G)$, and that these cover numbers can differ significantly: $\theta_E(G)$ can be as large as $\theta(G)(n - \theta(G))$. Gramm et al. [19] introduced four data reductions for the ECC problem, which they show can solve real-world sparse graphs of hundreds of vertices, as well as synthetic instances on up to 10K vertices in practice, when interleaved with branch and bound. Furthermore, they showed that their data reductions produce a kernel of size $2^k$, where $k$ is the number of cliques. Cygan et al. [13] showed that it is unlikely that a polynomial-size kernel exists when parameterized by the number of cliques in the cover, as otherwise the polynomial hierarchy collapses to its third level. However, Blanchette et al. [6] gave a linear-time algorithm having running time $O(2^{\binom{k}{2}}n)$ where $k$ is the treewidth of the graph. In practice, their algorithm is effective on graphs with hundreds of vertices and small treewidth. For larger graphs, heuristic methods are used to compute inexact ECCs [12, 2, 1] in practice. No heuristic algorithm performs best on all instances, and their overall quality is unclear.

## 2.2 Vertex Clique Cover

The vertex clique cover (VCC) problem is NP-hard, and closely related to the maximum independent set and graph coloring problems. The size of a minimum VCC (also called the clique cover number) $\theta(G)$ is lower bounded by the size of a maximum independent set (the independence number $\alpha(G)$) and equivalent to the chromatic number of the complement graph, $\chi(\overline{G})$. There is a rich line of research on the graph coloring problem, which seeks to compute the chromatic number; many of the theoretical results for the VCC problem come via the graph coloring problem. The fastest exact exponential-space algorithm for computing the chromatic number on an $n$-vertex graph has time $O^*(2^n)$ (where $O^*$ hides polynomial factors) using a generalization of the exclusion-inclusion principle [24], and in polynomial space the problem can be solved in time $O(2.2356^n)$ [18]. Furthermore, there exists no polynomial-time algorithm with approximation ratio better than $n^{1-\epsilon}$ for $\epsilon > 0$ unless $P = NP$ [34].

In terms of data reduction, we note that it is unlikely that a kernel exists when parameterized on the (vertex) clique cover number. Deciding if a cover with even 3 cliques exists is NP-complete (since 3-coloring the complement is NP-hard). A polynomial kernel would have size $O(1)$ and could be computed in polynomial time. Solving the kernel with brute-force computation would solve the VCC problem in polynomial time, implying $P = NP$. However, in practice, the VCC problem can be solved on large, sparse real-world graphs using the data reductions by Strash and Thompson [31].

## 2.3 Data Reduction in Practice for Related Problems

Other classical NP-hard problems have large suites of data reductions that are effective in practice, including minimum vertex cover [4, 15], maximum cut [16], and cluster editing [7]. Popular data reductions include variations of simplicial vertex removal, degree-2 folding, twin, domination, unconfined, packing, crown, and linear-programming-relaxation-based reductions [4]. Even the simplest reductions can be highly effective when combined with

other techniques [10, 30]. Data reductions are most effective in sparse graphs, which are the graphs that we consider here. Finally, similar to what we propose here, other NP-hard problems are solved by first applying a problem transformation. In particular, algorithms for minimum dominating set problem first transform the problem to an instance of the set cover problem [33].

## 3 Preliminaries

We consider a simple finite undirected graph $G = (V, E)$ with vertex set $V$ and edge set $E \subseteq \{\{u, v\} \mid u, v \in V\}$. For brevity, we denote by $n = |V|$ and $m = |E|$ the number of vertices and edges in the graph, respectively. When more specificity is needed, we denote the vertex and edge set of a graph $G$ by $V(G)$ and $E(G)$ respectively. We say two vertices $u, v \in V$ are *adjacent* (or *neighbors*) when $\{u, v\} \in E$. The *open neighborhood* of a vertex $v \in V$ is the set of its neighbors $N(v) := \{u \mid \{u, v\} \in E\}$, and the *degree* of $v$ is $|N(v)|$. We further define the *closed neighborhood* of a vertex $v \in V$ to be $N[v] := N(v) \cup \{v\}$. Extending these definitions, the open neighborhood of a set $A \subseteq V$ is $N(A) := \bigcup_{v \in A} N(v) \setminus A$ and the closed neighborhood of $A$ is $N[A] := \bigcup_{v \in A} N[v]$. The subgraph of $G$ induced by a vertex set $V' \subseteq V$, denoted $G[V']$, has vertex set $V'$ and edge set $E' = \{\{u, v\} \in E \mid u, v \in V'\}$. The *degeneracy* $d$ of a graph $G$ is the smallest value such that every nonempty subgraph of $G$ has a vertex of degree at most $d$ [27]. It is possible to order the vertices of a graph $G$ in time $O(n + m)$ so that every vertex has $d$ or fewer neighbors later in the ordering; such an ordering is called a *degeneracy* ordering [14].

A vertex set $C \subseteq V$ is called a *clique* if, for each pair of distinct of vertices $u, v \in C$, $\{u, v\} \in E$. A set of cliques $\mathcal{C}$ is called an *edge clique cover (ECC)* (or just a *clique cover*) of $G$ if for every edge $\{u, v\} \in E$ there exists at least one $C \in \mathcal{C}$ such that $\{u, v\} \subseteq C$. That is, there is some clique in $\mathcal{C}$ that *covers* $\{u, v\}$. The set of cliques $\mathcal{C}$ is said to cover the graph $G$. An ECC of minimum cardinality is called a *minimum ECC*, and its cardinality is denoted by $\theta_E(G)$, called the edge clique cover number.

Similarly, in a *vertex clique cover (VCC)*, every *vertex* $v \in V$ is covered by some clique. The cardinality of a minimum VCC is the *clique cover number*, denoted by $\theta(G)$.

## 4 Existing Tools Discussion

In this section, we discuss basic tools that we will use to solve the ECC problem, together with insights into their behavior on sparse graphs. We begin by describing the existing ECC data reductions by Gramm et al. [19]. We then discuss how to convert an input ECC instance to an equivalent VCC instance using the technique of Kou et al. [25]. We will extend these tools to develop our full algorithm combining ECC and VCC reductions in the next section.

### 4.1 ECC Reduction Rules

Gramm et al. [19] introduce four data reduction rules that either cover edges by a clique known to be in a minimum cardinality ECC or add edges to the input graph $G$. Once all of a vertex $v$'s incident edges are covered, $v$ can be removed from the graph.

With each edge $\{u, v\}$, Gramm et al. store the common neighbors in $G$, denoted by $N_{\{u,v\}}$, as well as a count $c_{\{u,v\}} = |E(G[N_{\{u,v\}}])|$ of the edges between common neighbors. These values are updated in ECC Reduction 1 and are used in ECC Reduction 2.

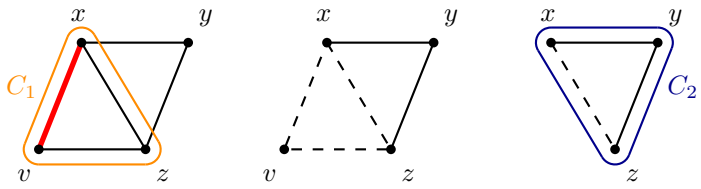

**Figure 1** Illustrating Gramm et al. [19]'s data reductions: (left) edge $\{v, x\}$ is in exactly one maximal clique $C_1$, triggering ECC Reduction 2 and covering edges $\{v, x\}$, $\{v, z\}$, and $\{x, z\}$ (middle). Vertex $v$ can then be removed with ECC Reduction 1. The remaining triangle (right) is covered by clique $C_2$ by applying ECC Reduction 2 to either $\{x, y\}$ or $\{y, z\}$.

Throughout the application of data reductions, vertices are removed from $G$ and edges are covered. Figure 1 illustrates an example of the reductions. Set let edge set $E' \subseteq E$ be the set of uncovered edges (by extension, $E \setminus E'$ are the covered edges). The graph $G$ only changes when a vertex is removed.

We note that the data reductions by Gramm et al. [19] are particularly effective for sparse graphs; however, the original data reductions were not written with efficiency in mind. Although these reductions have (very) slow theoretical running times, we offer insights as to why their reductions are faster in practice than indicated by the theoretical running time from Gramm et al. [19].

▶ **ECC Reduction 1** ([19]). *Let $v \in V$ be a vertex whose incident edges are all covered (i.e., in $E \setminus E'$). Then remove $v$ from the graph $G$, along with its incident edges, and update values $c_{\{w,x\}}$ and $N_{\{w,x\}}$ for all uncovered edges $\{w, x\} \in E'$ whose endpoints are both adjacent to $v$, i.e., $\{w, x\} \subseteq N(v)$.*

As noted by Gramm et al. [19], this step can be applied to all vertices in running time $O(n^2m)$ by iterating over each vertex $v$ and updating $N_{\{u,w\}}$ for all edges $\{u, w\} \in E'$ whose endpoints are adjacent to $v$. However, in sparse graphs the maximum degree in $G$, denoted $\Delta$, is significantly smaller than $n$. Each edge $\{u, w\}$ has its set $N_{\{u,w\}}$ updated at most $\Delta$ times, taking $O(\Delta)$ time to update each time, giving a more reasonable running time of $O(\Delta^2 m)$. We note that with adjustments, this can be run faster by enumerating all triangles in $G$ in time $O(dm)$ using the triangle listing by Chiba and Nishizeki [11] and updating $N_{\{u,w\}}$ for edge $\{u, w\}$ in each triangle; however, this is a different implementation than that done by Gramm et al. [19] and not our focus here.

▶ **ECC Reduction 2** ([19]). *Let edge $\{u, v\} \in E'$ be an uncovered edge such that $c_{\{u,v\}} = \binom{|N_{\{u,v\}}|}{2}$ (i.e., the edge is in exactly one maximal clique in $G'$). Then $C = N_{\{u,v\}} \cup \{u, v\}$ is a maximal clique of $G$ in some minimum ECC. Add the clique $C$ to the clique cover, and cover any uncovered edges in $C$ in $G$.*

As noted by Gramm et al. [19], ECC Reduction 2 can be implemented in time $O(n^2m)$ by iterating over each edge $\{u, v\} \in E'$, checking if $c_{\{u,v\}} = \binom{|N_{\{u,v\}}|}{2}$ in $O(1)$ time, and covering the edges of $\{u, v\}$'s clique in time $O(n^2)$ time.

However, when run on sparse graphs, which tend to have low degeneracy $d$ [14], this rule is much faster. Graphs with degeneracy $d$ have cliques of at most $d + 1$ vertices, therefore the reduction is only triggered when $|N_{\{u,v\}}| < d$. Hence, in practice, we should observe the much faster running time of $O(d^2m)$.

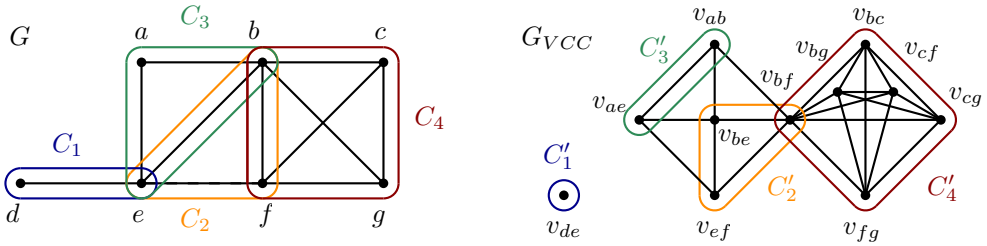

**Figure 2** An example graph $G$ with minimum ECC and its transformed graph $G_{VCC}$ with a corresponding minimum VCC.

Gramm et al. introduce two more ECC reductions (which we'll refer to as ECC Reductions 3 and 4), however, they are more complex and less effective than ECC Reductions 1 and 2 in practice. Experiments by Gramm et al. show that these reductions are very slow, and only improve the search tree size by a constant factor when incorporated into branch and reduce [19]. We therefore omit them from our discussion and implementation.

## 4.2 Transforming an ECC Instance to a VCC Instance

Kou et al. [25] showed that the ECC problem is NP-hard via a polynomial-time reduction from the VCC problem. Furthermore, they gave a polynomial-time reduction *to* the VCC problem, which we use as the basis of our transformation. We describe their transformation and briefly justify why it works.

Given an input graph $G = (V, E)$ for the ECC problem Kou et al. [25] transform $G$ to a new graph $G_{VCC} = (V_{VCC}, E_{VCC})$ that is an equivalent VCC instance as follows. For each edge $\{x, y\} \in E$, create a new vertex $v_{xy} \in V_{VCC}$, then add an edge $\{v_{xy}, v_{wz}\}$ to $E_{VCC}$ if and only if there exists a clique $C$ in $G$ containing both $\{x, y\}$ and $\{w, z\}$. Now, for any given subset $C \subset V_{VCC}$, $C$ is a clique in $G_{VCC}$ iff its vertices' corresponding edges in $E$ also induce a clique in $G$. Hence, a minimum cardinality VCC in $G_{VCC}$ corresponds to a minimum cardinality ECC in $G$. (See Figure 2.)

To determine if two edges are in a clique together in $G$, Kou et al. [25] make the following observation:

▶ **Observation 1** ([25]). *Two distinct edges $\{x, y\}, \{w, z\}$ are in a clique together in $G$ iff $\{x, y\}$ and $\{w, z\}$ are incident and $\{x, y\} \cup \{w, z\}$ induce a triangle, or $\{x, y\}$ and $\{w, z\}$ are not incident and $\{w, x, y, z\}$ form a 4-clique.*

However, there is a clear issue when using this transformation: $G_{VCC}$ can be very large. We briefly discuss its size and sparsity.

### 4.2.1 The Effect of Transformation on Graph Size and Sparsity

In the worst case, the size of $G_{VCC}$ is a quadratic factor larger than $G$. Indeed, if the graph $G$ is itself the complete graph $K_n$, on $n$ vertices and $\Theta(n^2)$ edges, then the transformed graph is the complete graph $K_{n(n-1)/2}$ having $\Theta(n^2)$ nodes and $\Theta(n^4)$ edges. However, we show that the size of the graph only increases by a factor of $O(d^2)$, where $d$ is the degeneracy of the graph. Real-world sparse graphs have low degeneracy [14], and thus this is a significant improvement over the worst case.

▶ **Theorem 2.** *Let the degeneracy of $G = (V, E)$ be $d$. Then $|V_{VCC}| = m \leq dn$ and $|E_{VCC}| = O(d^2 m)$.*

**Proof.** By construction $|V_{VCC}| = m$; hence, to bound $|V_{VCC}|$, we bound the number of edges in $G$. In a degeneracy ordering of the graph, each vertex has at most $d$ later neighbors in the ordering. Therefore, $|V_{VCC}| = m \leq dn$. To bound $|E_{VCC}|$, we compute an upper bound on the number of triangles and 4-cliques in $G$. Following Observation 1, each edge in $E_{VCC}$ corresponds to a pair of edges in $E$ contained in a triangle or a pair of non-incident edges in a 4-clique. Each triangle has 3 edges, and each 4-clique has 3 pairs of non-incident edges. Therefore, an asymptotic upper bound of the number of triangles and 4-cliques in $G$ gives an upper bound for $|E_{VCC}|$.

In any triangle, some vertex must come first in a degeneracy ordering, and can be in a triangle with at most $\binom{d}{2}$ of its at most $d$ later neighbors. Therefore each vertex is in $O(d^2)$ triangles with its later neighbors and, summing up over all vertices, contributes at most $O(d^2 n)$ edges to $E_{VCC}$. Similarly, for each edge $\{u, v\}$ we count the number of 4-cliques it is in with (non-incident) edges that come lexicographically after it in the degeneracy ordering. The number of triangles the second vertex can be in with later neighbors is $\binom{d}{2}$ and hence the edge is in at most $O(d^2)$ 4-cliques with $v$'s at most $d$ later neighbors, giving at most $O(d^2 m)$ 4-cliques total. Thus, we conclude that $|E_{VCC}| = O(d^2 m)$. ◀

Thus, $G_{VCC}$ has at size at most $O(d^2 m)$, a factor $O(d^2)$ larger than $G$. As a consequence, the average degree of the graph may increase, but by no more than a factor $O(d)$: whereas $G$ has average degree $2|E|/|V| = O(dn)/n = O(d)$, graph $G_{VCC}$ has average degree $2|E_{VCC}|/|V_{VCC}| = O(d^2 m)/m = O(d^2)$. Therefore, for input graphs with small degeneracy, the transformed graph is expected to be sparse as well.

However, even if the degeneracy $d$ is small, the graph $G_{VCC}$ may be very large in practice. Hence, to use this transformation, we require techniques to keep the graph size manageable.

## 5 Synergistic Reductions: Applying ECC and VCC Reductions

We propose to handle the blow-up by Kou et al. [25] by applying both ECC and VCC reductions to the problem, which we call *synergistic* data reduction. We first show how to adjust the transformation to work on reduced ECC instances, after which we can apply VCC reductions. We also explore the possibility of "lifting" VCC reductions to ECC reductions.

### 5.1 Transforming a Partially-Covered ECC Problem Kernel

Recall that the data reductions from Gramm et al. [19] result in a graph in which some edges are covered, which is not supported by the transformation of Kou et al. [25]. While it is tempting to modify the transformation to operate on *only* the uncovered edges $E'$, this does not necessarily result in an equivalent instance, as already-covered edges may still be needed to compute a minimum number of cliques covering $E'$. For instance, in Figure 1, covering edges $\{x, y\}$ and $\{y, z\}$ with the single clique $C_2$ uses the already-covered edge $\{x, z\}$.

One way to correct for this is to first perform the transformation on the entire graph $G = (V, E)$, and then take the subgraph induced by the vertices corresponding to uncovered edges in $E'$. However, this strategy is slow when the edge set $E$ is significantly larger than $E'$. We show that it is possible to perform the transformation without making vertices for all edges in $E$. Note that since all that remains is to cover the edges in $E'$, we now focus on covering all $E'$ using a minimum number of cliques in $G$. Taken together with already-chosen cliques from ECC reductions, this gives us a covering of all of $G$. (See Figure 3.)

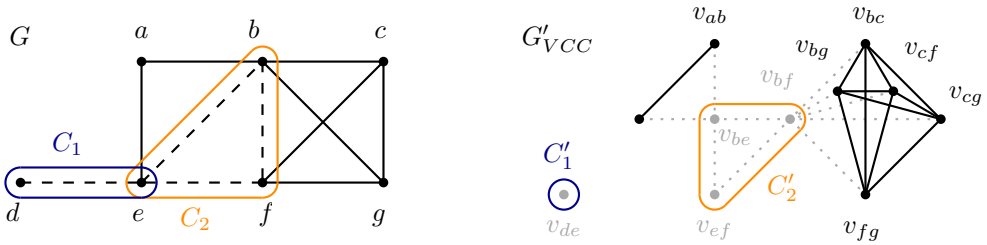

**Figure 3** A partially-covered graph $G$ with cliques $C_1$, $C_2$ already added to the cover, and its transformed graph $G'_{VCC}$. Grayed vertices and (dotted) edges are those in $G_{VCC}$, but not $G'_{VCC}$.

We transform $G$ to a graph $G'_{VCC} = (V'_{VCC}, E'_{VCC})$, where $V'_{VCC} = \{v_{xy} \mid \{x, y\} \in E'\}$ and $E'_{VCC} = \{\{v_{xy}, v_{wz}\} \mid \{x, y\}, \{w, z\} \in E'$ and $\{x, y\} \cup \{w, z\}$ is a clique in $G\}$. This transformation preserves cliques in $G$ that cover edges in $E'$, which we capture with the following observation.

▶ **Observation 3.** *If $C'$ is a clique in $G'_{VCC}$ then $C = \cup_{v_{xy} \in C'} \{x, y\}$ is a clique covering $|C'|$ edges of $E'$ in $G$.*

Furthermore, the transformation gives a correspondence between cliques covering $E'$ in $G$ and VCCs in $G'_{VCC}$.

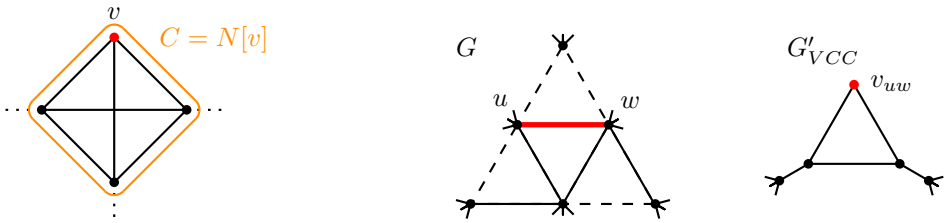
▶ **Theorem 4.** *If $\mathcal{C}'$ is a VCC in $G'_{VCC}$ then $\mathcal{C} = \{\cup_{v_{xy} \in C'} \{x, y\} \mid C' \in \mathcal{C}'\}$ is a set of cliques covering $E'$ in $G$.*

**Proof.** By Observation 3, every clique $C' \in \mathcal{C}'$ in $G'_{VCC}$ corresponds to a clique $C = \cup_{v_{xy} \in C'} \{x, y\}$ in $G$ that covers its corresponding edges of $E'$. Hence, a VCC that covers all $V'_{VCC}$ of $G'_{VCC}$ corresponds to a collection of cliques covering all edges $E'$ in $G$. ◀

Note that in Theorem 4, $|\mathcal{C}| = |\mathcal{C}'|$. Hence, a minimum VCC in $G'_{VCC}$ corresponds to a minimum-cardinality set of cliques covering $E'$ in $G$. This transformation gives us a technique for computing a minimum ECC: First apply the data reductions of Gramm et al., then compute $G'_{VCC}$ and use VCC reductions and any VCC solver to compute a minimum VCC in $G'_{VCC}$, giving us cliques covering $E'$ in $G$ and, ultimately an entire ECC of $G$. While applying VCC reductions to $G'_{VCC}$ may produce a smaller instance, these data reductions are not actually producing a smaller *ECC instance*. However, as we now show, we can also "lift" some VCC reductions to the ECC problem, by keeping the equivalence between cliques in the transformation in mind.

## 5.2 Lifting VCC Reduction Rules to ECC

Unlike the ECC problem, the VCC problem has many data reduction rules [31]. These include reductions based on simplicial vertices, dominance, twins, degree-2 folding, and crowns. We briefly discuss two classes of VCC reductions: clique-removal-based rules and folding-based rules. We place them in the context of the ECC problem, discuss whether it is viable to "lift" them to the ECC problem, and consider if the graph transformation is needed. By combining existing ECC reductions with VCC reductions, we aim to reduce ECC instances even further.



**(a)** $C$ is in a minimum VCC.

**(b)** Edge $\{u, w\} \in E'$ is in two cliques in $G$, but $v_{uw}$ in $G'_{VCC}$ is simplicial.

**Figure 4** The simplicial vertex VCC reduction can be applied after transforming $G$ to $G'_{VCC}$.

### 5.2.1 Clique-Removal-Based VCC Reductions

We call a VCC reduction that removes a set of cliques from the graph a *clique-removal-based* rule. Four VCC reductions (simplicial vertex, dominance, twin removal, and crown) are clique-removal-based rules [31]. Such rules can be easily transformed into an ECC reduction: By the equivalence between cliques in the problem transformation, stated in Observation 3, removing a clique in $G'_{VCC}$ is equivalent to covering its corresponding clique in $G$. Thus, to apply clique-removal-based VCC reductions directly to the ECC problem, we can compute $G'_{VCC}$, apply any clique-removal-based rules, and then cover these cliques in $G$. We capture this with the following theorem.

▶ **Theorem 5.** *Any clique-removal-based VCC reduction can be lifted to an ECC reduction.*

Of course, we could try to apply these reductions more efficiently to $G$ directly. We discuss two clique-removal-based VCC reductions and discuss whether they are worth implementing for ECC directly, or if we should transform $G$ to $G'_{VCC}$ first.

#### Simplicial Vertex Reduction

A vertex $v$ is *simplicial* if $N[v]$ forms a clique. In this case, the clique $C = N[v]$ is in some minimum VCC. (See Figure 4a.)

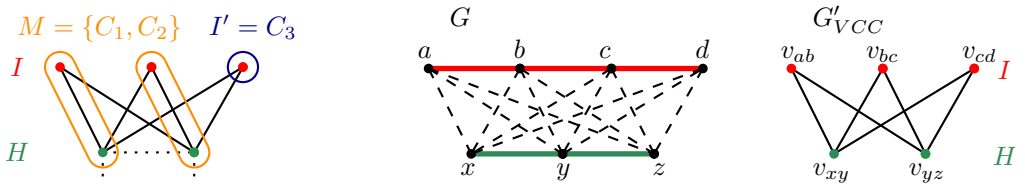
▶ **VCC Reduction 1** (Simplicial Vertex Reduction [31]). *Let $v \in V$ be a simplicial vertex. Then $C = N[v]$ is a clique in some minimum VCC. Add $C$ to the clique cover and remove $C$ from the graph.*

Applying VCC Reduction 1 on $G'_{VCC}$ is reminiscent of applying ECC Reduction 2 on the untransformed graph $G$. While it is true that for $\{u, w\} \in E'$, if $N_{\{u,w\}}$ is a clique in $G$, then $v_{uw}$ is simplicial in $G'_{VCC}$, the converse is not true in general. Hence, VCC Reduction 1 is more powerful. Consider the counterexample in Figure 4b. Vertex $v_{uw}$ is simplicial in $G'_{VCC}$, but $\{u, w\} \in E'$ is in two cliques of $G$.

Thus, we have a new data reduction for the ECC problem, which subsumes ECC Reduction 2:

▶ **ECC Reduction 5** (Lifted Simplicial Vertex Reduction). *Let edge $\{u, w\} \in E'$ and let set $C = \{x, y \in V \mid \{x, y\} \in E'$ and $\{u, w\} \cup \{x, y\}$ is a clique in $G\}$ be the set of vertices of edges in some clique with $\{u, w\}$. If $C$ is a clique, then add $C$ to the clique cover, and cover any uncovered edges of $C$ in $G$.*

To apply our lifted reduction, we could of course first compute $G'_{VCC}$ and then apply VCC Reduction 1. However, we can also apply it directly to $G$ with a slight modification to ECC Reduction 2. For each edge $\{u, w\} \in E'$ compute the common neighborhood $N_{\{u,w\}}$. Instead of checking that the common neighborhood is a clique, collect the uncovered edges



**(a)** A flared crown. Cliques $C_1$, $C_2$, and $C_3$ are in some minimum VCC.

**(b)** A partially-covered $G$ where $G'_{VCC}$ is a flared crown.

**Figure 5** The crown removal VCC reduction can be applied after transforming $G$ to $G'_{VCC}$.

between vertices in $N_{\{u,w\}}$, and check if they induce a clique. Since $|N_{\{u,w\}}| \leq \Delta$, it takes $O(d\Delta)$ to collect uncovered edges by iterating through the at most $d$ later neighbors of each vertex, which dominates the running time of this step. Exhaustively applying the reduction to all edges takes time $O(d\Delta m)$, which is slightly slower than the $O(d^2 m)$ time for ECC Reduction 2.

Is it worth applying ECC Reduction 5 directly to $G$, or should we first transform $G$ and run VCC Reduction 1 instead? The transformation can be done in time $O(d^2 m)$ by enumerating all of the triangles and 4-cliques of $G$ [11], hence performing the transformation is faster in theory than applying ECC Reduction 5 to $G$ directly. However, in $G'_{VCC}$ the largest clique may have as many as $\Theta(d^2)$ vertices and $\Theta(d^4)$ edges since a clique of size $d+1$ in $G$ has $\Theta(d^2)$ edges in $G$. Therefore, the time to apply VCC Reduction 1 for each of the $m$ vertices of $G'_{VCC}$ is $O(d^4 m)$. Thus, in theory, it is more efficient to apply ECC Reduction 5 directly, rather than first applying a conversion.

However, there are compelling reasons to perform the conversion. For one, most implementations of simplicial vertex reductions limit the degree of the vertex considered – in some cases to as small as two – since large-degree simplicial vertices rarely appear in sparse graphs. Therefore, in practice, it is unlikely that we would observe this large running time. However, a more compelling reason to perform the transformation is that there are two highly effective VCC reductions that we do not currently know how to apply directly to $G$. The first is the crown removal reduction (a clique-removal-based reduction) and the second is the degree-2 folding-based reduction.

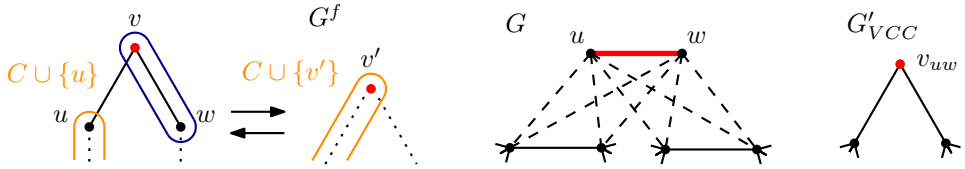
### Crown Removal Reduction

The crown removal reduction is arguably one of the most powerful data reductions, successfully reducing sparse instances for the minimum vertex cover and VCC problems [3, 4, 10].

In a pair of vertex sets $(H, I)$, $H$ is called a *head* and $I$ a *crown* if: $I$ is an independent set, $N(I) = H$, and there exists a matching from $H$ to $I$ of size $|H|$. Figure 5a shows a crown structure. Note that, due to the matching requirement, $|I| \geq |H|$. If $|I| = |H|$, the crown is called *straight*, otherwise it is *flared*. Strash and Thompson [31] give the following data reduction for the VCC problem, adapting a data reduction for the dual coloring problem [17].

▶ **VCC Reduction 2** (Crown Removal Reduction [31]). *Let $(H, I)$ be a head and crown with matching $M$ and unmatched vertices $I' \subseteq I$. Then add cliques in $M$ and $I'$ to the clique cover and remove $N[I]$ from the graph. (See Figure 5a.)*

Note that it is possible to identify flared crowns by applying a reduction based on an LP relaxation, originally introduced for the minimum vertex cover problem by Nemhauser and Trotter [29]. A variant of this algorithm due to Iwata et al. [21] identifies and removes *all* flared crowns at once by computing a maximum matching on a bipartite graph with $2n$ vertices and $2m$ edges using the Hopcroft-Karp algorithm [20] with running time $O(m\sqrt{n})$.



**(a)** The degree-2 folding VCC reduction.

**(b)** Edge $\{u, w\} \in E'$ in $G$ transforms into a degree-2 vertex $v_{uw}$ with non-adjacent neighbors in $G'_{VCC}$.

**Figure 6** The degree-2 folding VCC reduction can be applied after transforming $G$ to $G'_{VCC}$.

As Figure 5b illustrates, after exhaustively applying Gramm et al.'s [19] ECC reductions it is possible to have a crown structure after transforming to $G'_{VCC}$. Thus, lifting the crown removal reduction can further reduce an ECC instance. However, algorithms for computing a maximum matching for the LP relaxation use an explicit representation of $G'_{VCC}$ and therefore it is unclear how to run this reduction without first transforming $G$ to $G'_{VCC}$. The transformation and maximum matching can be computed in time $O(d^2m + d^2m\sqrt{m}) = O(d^2m^{3/2})$, since there are $O(m)$ vertices and $O(d^2m)$ edges in $G'_{VCC}$. We leave the question of whether the LP relaxation reduction can be more efficiently lifted to an ECC reduction as an open problem.

### 5.2.2 Folding-Based VCC Reductions

In contrast to clique-removal-based reductions, *folding-based* reductions contract a subset $S \subseteq V$ of vertices into a single vertex $v'$. *Folding* $S$ produces a new graph $G^f = (V^f, E^f)$ with $V^f = (V \setminus S) \cup \{v'\}$ and $E^f = (E \setminus \{\{v, x\} \in E \mid v \in S\}) \cup \{\{v', x\} \mid \exists v \in S, x \notin S, \{v, x\} \in E\}$. We discuss the connections between the ECC problem and the simplest folding-based reduction, folding vertices of degree two.

#### Degree-2 Folding

The degree-2 folding reduction for VCC contracts a degree-2 vertex $v$ with non-adjacent neighbors $u$ and $w$ that are *crossing independent* [31]. That is, for each edge $\{x, y\} \subseteq N(u) \cup N(w)$ either $\{x, y\} \subseteq N(u)$ or $\{x, y\} \subseteq N(w)$. This condition ensures that no spurious cliques are formed after folding. A vertex $v$ meeting these conditions is *foldable*.

▶ **VCC Reduction 3** (Degree-2 Folding Reduction [31]). *Let $v \in V$ be a foldable degree-2 vertex with non-adjacent neighbors $N(v) = \{u, w\}$. Let $G^f$ be the graph obtained by folding $\{v, u, w\}$. Let $\mathcal{C}^f$ be a minimum VCC of $G^f$ with clique $C_{v'} \in \mathcal{C}^f$ covering vertex $v'$ and let $C = C_{v'} \setminus \{v'\}$. Then, the clique cover*

$$\mathcal{C} = \begin{cases} (\mathcal{C}^f \setminus \{C_{v'}\}) \cup \{C \cup \{u\}, \{v, w\}\} & \text{if } C \subseteq N(u), \\ (\mathcal{C}^f \setminus \{C_{v'}\}) \cup \{C \cup \{w\}, \{v, u\}\} & \text{otherwise,} \end{cases}$$

*is a minimum VCC of $G$.*

See Figure 6a for an example of the degree-2 folding VCC reduction. We note that the transformation from an ECC instance to a VCC instance by Kou et al. [25] does not produce any degree-2 vertices with non-adjacent neighbors, as edges forming a triangle or 4-clique in $G$ form a triangle or 6-clique in $G_{VCC}$. However, our transformation with covered edges can result in such vertices (see Figure 6b). Thus, the degree-2 folding VCC reduction can be used to further reduce the instance when applied to $G'_{VCC}$.

We leave as an open problem whether folding-based rules can be lifted to new ECC reductions; we conjecture that it is possible to lift at least degree-2 folding. However, given how effective the degree-2 folding reduction is in practice for the VCC problem, we highly recommend applying it, even though it incurs the overhead of the transformation to $G'_{VCC}$.

### 5.3 Wrapping It All Up

With the tools in this section in hand, we have a clear path to solving the ECC problem on sparse graphs: first apply the data reductions due to Gramm et al. [19], then transform the partially-covered graph into a VCC instance, then apply VCC reductions and solve what remains with any VCC solver. We next perform experiments to evaluate this method.

## 6 Experimental Evaluation

We now compare our technique to the state of the art through extensive experiments on both synthetic instances and real-world graphs.

### 6.1 Experimental Setup

We implemented the ECC reductions and ECC to VCC transformation in C++ and integrated our methods with the VCC reductions and VCC algorithms by Strash and Thompson[2] [31], which we then compiled with `g++` version 11 using the `-O3` optimization flag. Our source code is available under the open source MIT license[3]. All experiments were conducted on Hamilton College's High Performance Computing Cluster (HPCC), on a machine running CentOS Linux 7.8.2003, with four Intel Xeon Gold 6248 processors running at 2.50GHz with 20 cores each, and 1.5TB of memory. Each algorithm is run sequentially on its own core.

We run experiments on six different algorithms. Gramm is the original branch-and-reduce code by Gramm et al. [19] written in OCaml, which we compiled with `ocamlc` version 3.10.2, and provided a sufficiently large stack size due to its heavy use of recursion. We implement three algorithms in C++ that first exhaustively apply ECC Reductions 1 and 2, perform a problem reduction to a VCC instance, apply VCC reductions, and then run a VCC solver: Redu$^3$BnR solves with the VCC branch-and-reduce algorithm by Strash and Thompson [31], Redu$^3$IG solves with the VCC iterated greedy (IG) heuristic algorithm by Chalupa [9], and Redu$^3$ILP solves with an assignment-based ILP formulation [22, 28] for VCC and Gurobi version 9.5.1. Finally, the two heuristic algorithms Conte [12] and EO-ECC [1] are from their respective authors and are compiled with `javac` version 8 and `g++` version 11 with `-O3`, respectively. Unless stated otherwise, we run each algorithm with a 24-hour time limit. Our stated running times do not include I/O time such as graph reading and writing.

In our tables, "Kernel" denotes the relevant size of the graph after reductions as either uncovered edges (Gramm) or vertices remaining (for VCC-based algorithms). "Time" is the time (in seconds) the solver takes to exactly solve the instance. A "–" indicates that the solver did not finish in the 24-hour time limit. **Bold** values indicate the value is the smallest among all algorithms in the table.

We run our experiments on randomly-generated instances as well as real-world graphs.

[3] `https://github.com/darrenstrash/Redu3ECC`

**Erdős-Rényi Graphs.** We generate 70 instances of varying density using the $G(n, p)$ model of generating an $n$-vertex graph where each edge is selected independently with probability $p$. We use values of $n$ that are powers of two from 64 to 2048, with two different values of $p$ for each to show the effect of density on the tested algorithms. We generate 5 graphs with each $n$, $p$ pair using different random seeds to observe the behavior of algorithms on multiple instances of similar size and density.

**Real-World Instances.** We run our experiments on 52 large, sparse, complex networks from the Stanford Network Data Repository (SNAP)[4], the Laboratory for Web Algorithmics (LAW)[5], and the Koblenz Network Collection (KONECT)[6]. These graphs include citation networks, web-crawl graphs, and social networks; the largest graph has 18M vertices, and most graphs follow a scale-free degree distribution: there are many low degree vertices and few high degree vertices. The number of vertices and edges for each instance can be found with experimental results in Tables 2 and 3.

## 6.2 Results on Synthetic Instances

We begin by comparing the performance of Gramm and Redu$^3$BnR on synthetic instances generated with the Erdős-Rényi $G(n, p)$ model. In Table 1, we present the average kernel size and running time executing Gramm and Redu$^3$BnR on the 5 instances of each pair of $n$ and $p$. We disable ECC Reduction 3 in Gramm, since this configuration enables it to solve the largest number of synthetic instances within the time limit.

Focusing on running time, Gramm and Redu$^3$BnR are equally matched on very sparse graphs, quickly solving many instances in significantly less than one second. Though, as the density increases even slightly, which can be seen when fixing $n$ but increasing $p$, Gramm is no longer able to solve even small instances in a 24-hour time limit. However, on all instances, Redu$^3$BnR easily computes exact solutions. The reason why is clear: on instances that Gramm is unable to solve, Gramm's kernel is large (for the highest density instance with $n = 64, p = 0.2$, even a kernel of average size 100 is too large for Gramm to solve), whereas the VCC kernels for Redu$^3$BnR are significantly smaller in all cases. Indeed, for the densest graphs of each value of $n$, Gramm is unable to solve every instance in 24 hours, but Redu$^3$BnR solves all graphs in less than a second. This illustrates that the combined reduction power of ECC and VCC reductions is able to handle denser instances than running ECC reductions alone.

## 6.3 Solving Large Real-World Instances Exactly

We now see which graphs can be solved exactly by one of three algorithms: Gramm, Redu$^3$BnR, and Redu$^3$ILP. We disable ECC Reductions 3 and 4 in Gramm, since this configuration enables it to reduce all instances within the time limit. The results are presented in Table 2. Gramm was able to solve 12 of the 27 instances exactly; 10 of these graphs were solved because the kernel had 0 uncovered edges and the other two instances (`ca-CondMat` and `ca-GrQc`) had small kernels of less than 100 uncovered edges. However, Gramm exceeds the 24-hour time limit on the 15 other instances, even those with as few as 176 uncovered edges.

[6] `http://konect.cc/`

**Table 1** Results on small Erdős-Rényi graphs of varying density. A "*" indicates that not all runs finished in the 24-hour time limit, "–" indicates that no runs finished in the 24-hour time limit.

| Graph | | | Gramm | | Redu$^3$BnR | |
|---|---|---|---|---|---|---|
| $n$ | $p$ | $m$ | Kernel | Time (s) | Kernel | Time (s) |
| 64 | 0.15 | 300 | 1 | < **0.01** | **0** | < **0.01** |
| 64 | 0.2 | 404 | 100 | 1 324.52* | **10** | < **0.01** |
| 128 | 0.1 | 805 | **0** | < **0.01** | **0** | < **0.01** |
| 128 | 0.15 | 1 218 | 491 | – | **51** | **0.03** |
| 256 | 0.075 | 2 433 | 42 | 0.02 | **0** | < **0.01** |
| 256 | 0.1 | 3 264 | 1 105 | – | **12** | **0.02** |
| 512 | 0.05 | 6 557 | 137 | 0.21 | **1** | **0.02** |
| 512 | 0.065 | 8 513 | 2 281 | – | **5** | **0.04** |
| 1 024 | 0.0365 | 19 072 | 1 259 | 153.21* | **4** | **0.08** |
| 1 024 | 0.0375 | 19 596 | 1 704 | – | **4** | **0.07** |
| 2 048 | 0.025 | 52 245 | 3 147 | 5.18 | **4** | **0.18** |
| 2 048 | 0.0275 | 57 488 | 7 235 | – | **5** | **0.20** |

In contrast, Redu$^3$BnR solves 18 of the instances. On all instances, the kernel computed by Redu$^3$BnR was smaller than that of Gramm, the smallest of which is on `zhishi-hudong-int`, which is reduced to 2% of the size of Gramm's kernel. With the exception of three instances (`email-EuAll`, `web-NotreDame`, and `web-Stanford`), every instance was reduced to at most 10% of Gramm's kernel size. However, the limitations of branch and reduce for the VCC problem begin to show on these instances. Similar to Gramm, Redu$^3$BnR only finishes within the 24-hour time limit on graphs with kernel size less than 100, and therefore its success is largely due to the reduction of the input instance (a pattern observed in other problems [30]). On the other hand, the Gurobi solver with an ILP formulation is able to solve kernels of much larger size, even up to 536 209 vertices (in the case of `eu-2005`).

## 6.4 Solving Remaining Instances Heuristically

We now look at the instances that could not be solved in the 24-hour time limit by any exact method. The results are presented in Table 3. Nine instances were reduced to VCC within the time limit of 24 hours, and the remaining instances were too large to finish in the time limit (not in the table). After fully transforming the input ECC instance to a reduced VCC instance, we ran the iterated greedy approach IG due to Chalupa et al. [9], which we call Redu$^3$IG, and compare its best solution with a lower bound from KaMIS, a state-of-the-art evolutionary algorithm for finding near-maximum independent sets on huge networks [26]. Four instances were solved to within 300 cliques of optimum, two of which (`soc-Slashdot0811` and `soc-Slashdot0902`) are within 100 cliques. The remaining instances are solved to within 6 000 cliques of optimum.

## 6.5 Summarizing the Quality of Existing Heuristic Solvers

Finally, using our exact results, we evaluate the quality of two heuristic solvers designed for large sparse graphs. We compare Conte, an algorithm by Conte et al. [12] designed for large sparse graphs, and EO-ECC by Abdullah et al. [1]. We run Conte and EO-ECC on all instances that were solved exactly (i.e., those from Table 2). The results are presented in Table 4.

**Table 2** Comparing exact algorithms Gramm, Redu$^3$BnR, and Redu$^3$ILP on real-world instances solved by at least one of the algorithms in a 24-hour time limit. Times marked with a "*" indicate that the algorithm's speed was due to programming language differences and not algorithmic improvements.

From among the 27 graphs, Conte solves five instances exactly. A further nine instances are solved within 50 cliques of optimal, and eight additional graphs are solved within 2 000 of optimal. EO-ECC, on the other hand, solves eight instances exactly (a superset of Conte's five) and solves these faster than Conte. Furthermore, EO-ECC finds 14 smaller solutions faster than Conte (Conte only finds four smaller solutions faster). However, a distinct negative is EO-ECC's running time and solution quality on `cnr-2000`, `eu-2005`, and `web-BerkStan`, which is much worse than Conte. We conclude that Conte gives consistently fast results with reasonable solutions, and EO-ECC is sometimes very fast and accurate, and other times not.

**Table 4** Evaluation of the quality of heuristic solvers Conte and EO-ECC on all graphs with known edge clique cover number $\theta_E(G)$. "ub" is the solution found by the given algorithm, and "Time" is the algorithm's time in seconds. Values of "ub" marked in **bold** indicates the algorithm found an optimal solution, with its time in **bold** if it did so faster than its competitor. Values of "ub" in *italics* indicate that an algorithm found an ECC smaller than its competitor, with its time in *italics* if it did so faster than its competitor.

## 7 Conclusion and Future Work

We introduced a technique to further reduce ECC problem instances via VCC data reductions, enabling us to solve large sparse real-world graphs that could not be solved before. Critical to this technique is the ability to transform reduced ECC instances to the VCC problem,

through a modification of the polynomial-time reduction of Kou et al. [25]. The combined reduction power of ECC and VCC reductions, which we call *synergistic* data reduction, produces significantly smaller kernels than ECC reductions alone. Of particular interest for future work is integrating data reduction rules with existing heuristic algorithms for the ECC problem, trying to implement a more efficient LP relaxation ECC reduction without a transformation, and to see if folding-based reductions can be lifted to the ECC problem.

# Threshold Testing and Semi-Online Prophet Inequalities

**Martin Hoefer**

## Abstract

We study *threshold testing*, an elementary probing model with the goal to choose a large value out of $n$ i.i.d. random variables. An algorithm can *test* each variable $X_i$ once for some threshold $t_i$, and the test returns binary feedback whether $X_i \geq t_i$ or not. Thresholds can be chosen adaptively or non-adaptively by the algorithm. Given the results for the tests of each variable, we then select the variable with highest conditional expectation. We compare the expected value obtained by the testing algorithm with expected maximum of the variables.

Threshold testing is a semi-online variant of the gambler's problem and prophet inequalities. Indeed, the optimal performance of *non-adaptive* algorithms for threshold testing is governed by the standard i.i.d. prophet inequality of approximately $0.745 + o(1)$ as $n \to \infty$. We show how *adaptive* algorithms can significantly improve upon this ratio. Our adaptive testing strategy guarantees a competitive ratio of at least $0.869 - o(1)$. Moreover, we show that there are distributions that admit only a constant ratio $c < 1$, even when $n \to \infty$. Finally, when each box can be tested multiple times (with $n$ tests in total), we design an algorithm that achieves a ratio of $1 - o(1)$.

## 1 Introduction

Consider an application process in which $n$ job candidates are interviewed sequentially one by one for a single position. For each candidate, we assume the qualification for the job can be expressed by an i.i.d. non-negative random variable $X_i$ with known distribution $F$. The goal is to maximize the expected value of the selected candidate. To which extent is the optimal achievable value harmed by the online arrival of the candidates? This is the classic *gambler's problem*, in which the loss in expected value is expressed by prophet inequalities [22, 26, 9]. More precisely, in this model one usually assumes (i) an interview fully reveals the realization of the respective variable, and (ii) the requirement of timely feedback forces the decision maker to irrevocably accept or reject the candidate upon seeing its realization. For i.i.d. variables, the best-possible prophet inequality states that a candidate $\sigma$ can be selected such that $\mathbb{E}[X_\sigma] \geq \beta \cdot \mathbb{E}[\max\{X_1, \ldots, X_n\}]$, where $\beta \approx 0.745$ [19, 10].

The gambler's problem has been extremely popular over the last decades, but assumptions (i) and (ii) are often unrealistic. Even after a long interview, an interviewer is usually not fully aware of the entire set of exact qualifications of a candidate. Moreover, in many selection processes a decision does not have to be taken instantaneously. In this paper, we examine the consequences of an arguably more realistic set of conditions. First, instead of (i), we assume that each candidate only partly reveals their realization in the form of a *single bit of information*. As we observe rather directly, this assumption is asymptotically equivalent to allowing to make a single threshold query to each candidate. Second, instead of (ii), we assume that the selection must be made only at the end of the process.

More formally, we consider the *threshold testing* model. We assume that (i′), instead of revelation of $X_i$, we perform a single *threshold test* with some arbitrary threshold $t_i$, and the feedback is binary ("positive" in case $X_i \geq t_i$ or "negative" otherwise), and (ii′) a candidate must be chosen only after completing *all* threshold tests. Again denoting the selected candidate by $\sigma$, we are interested in bounding the loss in expected value using an inequality of the form $\mathbb{E}[X_\sigma] \geq c \cdot \mathbb{E}[\max\{X_1, \ldots, X_n\}]$ for $c \in (0, 1)$. We call this a *semi-online prophet inequality*. A testing algorithm that satisfies it is called *c-competitive* and has a *competitive ratio* of $c$.

There are four possible models emerging from the different choices of (i) vs. (i′) and (ii) vs. (ii′). The remaining two models do not require substantial analytical efforts. Indeed, when we only replace (i) by (i′), the consequences are trivial: There is an optimal algorithm for the standard gambler's problem that uses threshold tests. Thus, the existing optimal algorithm and its guarantees continue to apply because the space of algorithms only shrinks when we require threshold tests. Also, only replacing (ii) by (ii′) implies a trivial problem – one can see and choose an option with maximum value at the end, a 1-competitive strategy. In contrast, the main contribution of this paper is to show that, with (i′) and (ii′) simultaneously, a mathematically interesting model arises.

Our results also imply a stark qualitative distinction to the standard model. It is well known that adaptivity, i.e., allowing decisions to depend on past observations, does not help for the standard gambler's problem. In our model, we observe rather easily that non-adaptive testing algorithms are unable to asymptotically improve upon the ratio of $\beta \approx 0.745$. Our main result is a set of adaptive algorithms that improves significantly upon this bound and achieves a ratio of approximately 0.869. To complement this result, we show that there are distributions that imply a non-trivial asymptotical upper bound on the ratio, i.e., there is no $(1 - o(1))$-competitive algorithm. We proceed to discuss our contributions in more detail.

## 1.1 Techniques and Contribution

Let $F$ be the cumulative distribution function of the variables. For most of the paper we assume (essentially w.l.o.g.) that $F$ is continuous. Our algorithms perform quantile testing, i.e., they use thresholds of the form $F^{-1}(1 - q)$ for $q \in (0, 1)$, oblivious of other properties of the distribution. It is straightforward to achieve a competitive ratio of $1 - 1/\mathsf{e} > 0.632$ by using threshold $t_i = F^{-1}(1 - 1/n)$ for all variables and then choosing any variable that has been tested positively (if any); see, e.g., [19]. The analysis of this strategy is asymptotically tight for each of the following two parametric distributions[1]:

**$F_A$:** For some small $\varepsilon > 0$, with probability $1/\sqrt{n}$ choose a value uniformly from $[1-\varepsilon, 1+\varepsilon]$, and 0 otherwise. As $\varepsilon \to 0$ and $n \to \infty$, the algorithm gets a positive test and therefore value 1 with probability $1 - 1/\mathsf{e}$ while $\mathbb{E}[\max\{X_1, \ldots, X_n\}] = 1$.

[1] Strictly speaking, $F_A$ and $F_B$ are not continuous. For a rigorous argument, one can resort to an arbitrarily close continuous approximation of the distributions to obtain the same result.

$F_B$: Choose the value 1 with probability $1/n^2$ and 0 otherwise. The algorithm obtains a value 1 with probability $(1-(1-1/n)^n)/n$ while $\max\{X_1,\dots,X_n\}=1$ with probability $1-(1-1/n^2)^n$. As $n\to\infty$, the ratio of both probabilities approaches $1-1/\mathsf{e}$.

To improve upon $1-1/\mathsf{e}$, an algorithm needs to test for *both* smaller and larger thresholds than $F^{-1}(1-1/n)$. Thresholds that are all larger than $F^{-1}(1-1/n)$ decrease the ratio for $F_A$; thresholds that are all smaller than $F^{-1}(1-1/n)$ decrease the ratio for $F_B$.

The class of algorithms we consider here is parameterized by $\alpha_1,\dots,\alpha_k\in(0,1)$ with $\alpha_1>\alpha_2>\dots>\alpha_k$. In the beginning, such an algorithm uses $F^{-1}(1-\alpha_1/n)$ as a threshold until it sees a positive test. Generally, after $i<k$ positive tests, it sets $F^{-1}(1-\alpha_{i+1}/n)$ as a threshold. After $k$ positive tests (i.e., on $F^{-1}(1-\alpha_1/n),\dots,F^{-1}(1-\alpha_k/n)$), the algorithm can make arbitrary tests. Indeed, we eventually choose $\alpha_1>1$ and $\alpha_2<1$.

In our analysis, we exactly calculate the asymptotic probability that the algorithm sees precisely $i$ positive tests. Note that these probabilities asymptotically determine the probability density function of $X_\sigma$, the chosen variable. It is a step function in quantile space: The probability of making precisely $i$ positive tests is spread uniformly over the interval $[1-\alpha_i/n,1]$ for all $i\in\{1,\dots,k\}$.

We compare this probability density function of $X_\sigma$ with that of $\max\{X_1,\dots,X_n\}$ by stochastic dominance, leading to a tight analysis of such algorithms. For fixed values of $\alpha_1,\dots,\alpha_k$, we can analyze the competitive ratio of the respective strategy by solving a piecewise convex optimization problem, where the $k+1$ pieces correspond to the $k+1$ steps of the step function. We numerically maximize the minimum of this function.

We execute this analysis in detail for $k\in\{2,3\}$. For $k=3$, we obtain a competitive ratio of approximately 0.869 by setting $\alpha_1\approx 2.035$, $\alpha_2\approx 0.506$, and $\alpha_3\approx 0.057$. Our numerical results for $k=4$ indicate only negligible improvement by further increasing $k$.

We complement this result by a constant upper bound on the competitive ratio, i.e., an impossibility of achieving a competitive ratio of $1-o(1)$. Intuitively, there is a trade-off inherent in every test: Testing for a smaller value yields a fallback option in case only one positive test is found at the end; testing for a larger value allows to differentiate between different variables when multiple of them have been tested positively. There are instances in which, irrespective of how the algorithm solves this trade-off, it loses a constant in the competitive ratio. For the proof we consider a distribution where values 1, 2, or 3 occur with probability $1/n$ each, and 0 otherwise. It is minimal in the sense that a competitive ratio of $1-o(1)$ is achievable for any distribution that uses only three values in the support, or whose parameters do not depend on $n$.

Finally, we establish that a competitive ratio of $1-o(1)$ *can* be achieved using $n$ tests when a single variable can be tested multiple times (recall that the realization of each variable is only drawn *once initially* from the distribution). The idea is to drop $o(n)$ variables from consideration and test the remaining ones with a threshold such that, with high probability, $\max\{X_1,\dots,X_n\}$ is larger than this threshold, but only $o(n)$ of these tests are positive. The additional $o(n)$ tests can then be used to find the maximum variable among those that have been tested positively.

## 1.2 Further Related Work

The original prophet inequality [22] states that there is a 1/2-competitive algorithm in the setting of independent random variables with arbitrary distributions. Initiated by the work of Hajiaghayi, Kleinberg, and Sandholm [18], prophet inequalities have seen a surge of interest in the TCS community over the past 15 years. This has, for instance, led to the development of the tight i.i.d. prophet inequality with competitive ratio approximately 0.745 [10] as

well as almost-tight random-order [11, 5] and free-order [2, 25, 29, 5] prophet inequalities. Optimal or near-optimal prophet inequalities can be recovered without knowledge of the distribution but with $O(n)$ samples [7, 31, 8, 6]. Several works considered multiple-choice prophet inequalities with combinatorial constraints, e.g., [3, 13, 21, 12]. We also refer to the (at this point slightly outdated) surveys of Lucier [26] as well as Correa et al. [9] for additional references.

We compare our work with the two works from the prophet-inequality literature that seem closest. Orthogonally to samples, Li, Wu, and Wu [24] considered a version of the unknown i.i.d. setting in which quantile queries to the distribution can be made *before* the sequence of variables arrives. They as well as Perez-Salazar, Singh, and Toriello [30] also used a limited number of (quantile-based) thresholds to achieve near-optimal i.i.d. prophet inequalities. We are not aware of any version of the single-choice prophet inequality with general i.i.d. distributions to which the impossibility of approximately 0.745 does not apply.

In stochastic probing (e.g., [4, 15, 1, 16, 17]), information is also revealed online according to known distributions. The standard models are, however, quite different from our model: The decision maker gets to choose which variables to probe, and each probe entirely reveals the realization of the variable at hand. Eventually, the decision maker can pick a (set of) variable(s), much like in our model. Comparing with an omniscient optimum (like in the prophet inequality) is, however, usually hopeless in this setting. Instead, one focusses on computing or approximating the strategy that maximizes the expected selected (total) value, a task that is straightforward for our model.

In these probing models, the adaptivity gap measures the worst-case multiplicative gap between the value of the best adaptive and that of the best non-adaptive strategy. Note that, while our result does imply a nontrivial adaptivity gap (i.e., larger than 1) for our problem, we are studying a different question as we compare both adaptive and non-adaptive strategies with an omniscient optimum.

We are aware of two works in the probing literature in which tests do not eradicate all uncertainty about the respective variable. Hoefer, Schmand, and Schewior [20] considered a stochastic-probing model in which the first test to a variable only reveals whether the realization is above or below the median of the distribution, and additional tests can be used to further narrow down the realization in the same way applied to the conditional distribution. Gupta et al. [14] generalized the related classic Pandora's box problem due to Weitzman [32] and considered the Markovian model. There, a set of Markov chains, which correspond to variables that can eventually be chosen, is given and, in each step, a probe can be used to advance one of the Markov chains.

Threshold tests have also been considered in the context of estimating (properties of) a probability distribution. For example, Paes Leme et al. [23] gave bounds on the sample complexity, i.e., required number of such tests, to estimate the approximately optimal reserve price for certain types of distributions. Meister and Nietert [27] as well as Okoroafor et al. [28] investigated the sample complexity of estimating other objects, e.g., mean, median, or even full CDF, of the *empirical* distribution in a non-stochastic setting.

## 2 Preliminaries

We consider *threshold testing* defined as follows. We are given a distribution $F$ on $\mathbb{R}_{\geq 0}$ with finite expectation. There are $n$ *boxes*. Each box $i$ contains a hidden realization $X_1, \dots, X_n$ drawn *once upfront* i.i.d. from $F$. A *testing algorithm* can apply a *threshold test* to each box $i \in [n] = \{1, \dots, n\}$ exactly once, in that order. To apply a test to box $i$, the algorithm

chooses a threshold $t_i \geq 0$ and receives a binary feedback whether $X_i \geq t_i$ or not. Upon testing $i$, the algorithm learns if $X_i \geq t_i$ or not, but *not the precise value of* $X_i$. If $X_i \geq t_i$ we say the test was *positive*, otherwise it was *negative*. The algorithm may choose thresholds adaptively based on the feedback from earlier tests. Finally, after testing each box, the algorithm chooses one box $\sigma \in [n]$ and receives a reward of $X_\sigma$. Here, $\sigma$ is a random variable based on the observed feedback and the internal randomization of the algorithm. We call an algorithm $c$-competitive if $\mathbb{E}[X_\sigma] \geq c \cdot \mathbb{E}[\max\{X_1, \ldots, X_n\}]$. We are interested in maxmimizing $c$ in the limit as $n \to \infty$.

**Non-adaptive Algorithms and Prophet Inequalities.** Our testing problem has inherent connections to the classic prophet inequality for i.i.d. random variables. Consider the *non-adaptive* variant, in which the algorithm chooses thresholds $t_1, \ldots, t_n$ upfront. We observe that this problem is essentially the standard gambler's problem governed by prophet inequalities. The optimal algorithm for the gambler's problem emerges from straightforward backwards induction. For each box $i \in [n]$, the gambler sets a threshold $t_i$ to the expected profit from the optimal algorithm for boxes $i+1, \ldots, n$. The algorithm accepts $i$ if and only if $X_i \geq t_i$. It is straightforward to verify that this implies $t_1 \geq \ldots \geq t_n$. All $t_i$-values can be computed in advance. As such, a non-adaptive algorithm for threshold testing can use these thresholds and imitate the optimal algorithm for the gambler's problem.

▶ **Observation 1.** *The optimal non-adaptive testing algorithm for $n$ boxes obtains at least the expected reward of the optimal algorithm for the gambler's problem with $n$ boxes.*

We also observe the converse – for large $n$, the optimal reward of non-adaptive threshold testing is essentially the optimal reward in the gambler's problem.

▶ **Proposition 2.** *The optimal non-adaptive testing algorithm for $n$ boxes obtains at most the expected reward of the optimal algorithm for the gambler's problem with $n+1$ boxes.*

**Proof.** Consider the optimal non-adaptive algorithm for threshold testing. W.l.o.g. we can assume that the chosen thresholds are ordered such that $t_1^* \geq \ldots \geq t_n^*$. If at least one test is positive, then among the positively tested boxes, the algorithm chooses the one with the highest threshold – which is the earliest one in the sequence. The gambler can imitate this in the online model by using thresholds $t_1^*, \ldots, t_n^*$ and accepting the first one with $X_i \geq t_i^*$. If all tests are negative, then the testing algorithm accepts $X_1$ – it failed the test with the highest threshold and, as such, has the highest conditional expectation. Clearly, this is less than the apriori expectation of $F$, which can be obtained by the gambler from accepting box $X_{n+1}$. Hence, the gambler with $n+1$ boxes obtains more expected value. ◀

For large $n$ the best competitive ratio is approximately 0.745 by the optimal prophet inequality [19, 10]. For the rest of the paper we focus on *adaptive* testing algorithms.

**Threshold Testing vs. General Binary Feedback.** We discuss our scenario in the context of a more general model. In binary-feedback testing, the algorithm can choose a set $Y_i \subset \mathbb{R}_{\geq 0}$ and learns whether or not $X_i \in Y_i$. Note this model generalizes threshold testing – setting a threshold $t_i$ can be simulated by choosing $Y_i = \{x \in \mathbb{R} \mid x \geq t_i\}$. Nevertheless, the competitive ratio achievable is asymptotically the same as for threshold testing. As such, we restrict attention to threshold testing.

▶ **Proposition 3.** *The optimal algorithm for binary-feedback testing with $n$ boxes obtains at most the expected reward of the optimal algorithm for threshold testing with $n+1$ boxes.*

**Table 1** Numerically optimized parameters and competitive ratios for different values of $k$.

| $k$ | $\alpha_1$ | $\alpha_2$ | $\alpha_3$ | $\alpha_4$ | comp. ratio as $n \to \infty$ |
|---|---|---|---|---|---|
| 1 | 1 | – | – | – | $1 - 1/e \approx 0.63212$ |
| 2 | 1.83298 | 0.35932 | – | – | $> 0.84005$ |
| 3 | 2.035135 | 0.5063 | 0.05701 | – | $> 0.86933$ |
| 4 | 2.038 | 0.508 | 0.058 | 0.0002 | $> 0.86956$ |

**Proof.** Consider an optimal algorithm for binary-feedback testing with $n$ boxes. We modify this algorithm to obtain an algorithm for threshold testing with $n+1$ boxes. We assume w.l.o.g. that, whenever the original algorithm chooses a set $Y_i$ to test the $i$-th box, then $\mathbb{E}[X_i \mid X_i \in Y_i] \geq \mathbb{E}[X_i]$ and, therefore, $\mathbb{E}[X_i \mid X_i \notin Y_i] \leq \mathbb{E}[X_i]$. We replace any such test with a threshold test for a threshold $t_i$ such that $\Pr[X_i \geq t_i] = \Pr[X_i \in Y_i]$, i.e., both tests are positive with precisely the same probability and $\mathbb{E}[X_i \mid X_i \geq t_i] \geq \mathbb{E}[X_i \mid X_i \in Y_i]$. We continue in the same way as the original algorithm would upon a positive or negative test, modifying subsequent tests in the same way. If the original algorithm eventually picks a box $i^\star$ with a positive test result, the new algorithm picks the same box. Thereby it obtain at least the same value since, by our choice of $t_{i^\star}$, $\mathbb{E}[X_{i^\star} \mid X_{i^\star} \geq t_{i^\star}] \geq \mathbb{E}[X_{i^\star} \mid X_{i^\star} \in Y_{i^\star}]$. Similarly, if the original algorithm would pick a box with a negative result, the new algorithm picks box $n+1$, obtaining $\mathbb{E}[X_{n+1}] = \mathbb{E}[X_{i^\star}] \geq \mathbb{E}[X_{i^\star} \mid X_{i^\star} \notin Y_{i^\star}]$ by our assumption above. ◀

## 3 Adaptive Testing

In this section, we prove the following theorem. For simplicity, we consider a continuous distribution $F$ throughout the proof. In the following section, we discuss that the result also generalizes to finite discrete distributions.

▶ **Theorem 4.** *There is an efficient* $(0.869 - o(1))$*-competitive algorithm for threshold testing with a continuous distribution.*

**Proof.** We consider a class of algorithms that is parameterized by a monotone sequence of quantile parameters $q_1, \ldots, q_k \in (0,1)$ where $q_1 > \ldots > q_k$. For convenience, we assume $q_0 = 1$ and $q_{k+1} = \ldots = q_n = 0$. The algorithm starts by testing for the $1 - q_1$ quantile of $F$. Since the distribution is continuous, $q_1$ corresponds to a threshold $\tau_1$ (i.e., $\tau_1$ is such that $Pr[X_i \geq \tau_1] = q_1$). Then for any $j \geq 1$, if the algorithm sees a negative test for $\tau_j$, it continues testing with $\tau_j$. If it sees a positive test for $\tau_j$, it increments $j$ to $j+1$ (i.e., continues testing with the next threshold $\tau_{j+1}$). After having tested each box, it selects the one with the best conditional expectation. This is either the box tested positively for the threshold corresponding to the largest quantile, or any box (when all tested negative for $\tau_1$).

We consider the values of $q_j$ in the form $q_j = \alpha_j/n$ for some $\alpha_j \in (0, n)$, for all $j \in [k]$. In Table 1, we give example values of $\alpha_j$ and the resulting competitive ratios for different values of $k$. We obtained these values by numerical optimization over a bounded interval.

We use $F$ to denote the CDF, i.e., $F(x) = \Pr[X_i < x]$, for each $i \in [n]$ and $x \in [0,1]$. For the maximum over $n$ i.i.d. draws, we obtain the CDF $F_m(x) = (F(x))^n = (\Pr[X_i < x])^n = \prod_i (\Pr[X_i < x]) = \Pr[\max_i X_i < x]$. We denote the complementary CDF by $G(x) = \Pr[X_i \geq x] = 1 - F(x)$ and $G_m(x) = \Pr[\max_i X_i \geq x] = 1 - F_m(x)$. Since $F$ is continuous, threshold $\tau_j = G^{-1}(q_j) = F^{-1}(1 - q_j)$, i.e., $G(\tau_j) = q_j$ and $F(\tau_j) = 1 - q_j$. Similarly, $F_m(\tau_j) = (1 - q_j)^n$ and $G_m(\tau_j) = 1 - (1 - q_j)^n$. We here restrict attention to values of $\alpha_j \in o(n)$, we will assume these are constants throughout. This implies $\lim_{n\to\infty} G_m(\tau_j) = 1 - \mathsf{e}^{-\alpha_j}$.

Our analysis proceeds via stochastic dominance. For any given threshold $t \geq 0$ we compare the complementary CDF $G_m(t)$ to the complementary CDF of our algorithm. We denote the latter by $A(t) = \Pr[X_\sigma \geq t]$, where $\sigma$ is the box chosen by our algorithm. If $A(t) \geq c \cdot G_m(t)$ for all $t \geq 0$, then the algorithm is $c$-competitive by stochastic dominance.

For any given $t \in [0, \infty)$ let $q = G(t) = 1 - F(t)$ and $\alpha = n \cdot q$. We will conduct our analysis with respect to $\alpha \in [0, n]$ instead of $t \in [0, \infty)$. We split $[0, n]$ into intervals $I_j = [\alpha_{j+1}, \alpha_j]$ for $j = 0, \ldots, k$, where we use $\alpha_0 = n$ and $\alpha_{k+1} = 0$. Suppose we see a positive test for $\alpha_j$. Then, between the positive test for $\alpha_{j-1}$ and the one for $\alpha_j$, assume there are $\ell_j \geq 0$ negative tests.

**Two Thresholds.** We start by discussing an algorithm with $k = 2$ thresholds. Suppose $\alpha \in I_2$. First, let's assume we only have a positive test for $t_1$ but not for $t_2$. We call this event $\mathcal{E}_{10}$. It happens with probability

$$\begin{aligned}\Pr[\mathcal{E}_{10}] &= \sum_{\ell_1=0}^{n-1} (1-q_1)^{\ell_1} q_1 \cdot (1-q_2)^{n-1-\ell_1} = q_1 \cdot (1-q_2)^{n-1} \cdot \frac{1 - \left(\frac{1-q_1}{1-q_2}\right)^n}{1 - \frac{1-q_1}{1-q_2}} \\ &= q_1 \cdot \frac{(1-q_2)^n - (1-q_1)^n}{q_1 - q_2} \quad = \quad \alpha_1 \cdot \frac{\left(1 - \frac{\alpha_2}{n}\right)^n - \left(1 - \frac{\alpha_1}{n}\right)^n}{\alpha_1 - \alpha_2} \ .\end{aligned}$$

In this case, the algorithm selects the box that was tested positive for $\tau_1$. It has a value at least $t$ with probability $q/q_1 = \alpha/\alpha_1$.

Otherwise, we have a positive test for $\tau_1$ and $\tau_2$, which we call event $\mathcal{E}_{11}$. The event that we have a positive test for $\tau_1$ (irrespective of what happens for $\tau_2$) is called $\mathcal{E}_1$. Clearly,

$$\Pr[\mathcal{E}_{11}] = \Pr[\mathcal{E}_1] - \Pr[\mathcal{E}_{10}].$$

In case $\mathcal{E}_{11}$ happens, we select the box that tested positive for $\tau_2$. It has a value at least $t$ with probability $q/q_2 = \alpha/\alpha_2$.

Overall, for $\alpha \in I_2$ we see

$$\begin{aligned}A(\alpha) &= \frac{\alpha}{\alpha_1} \Pr[\mathcal{E}_{10}] + \frac{\alpha}{\alpha_2} \Pr[\mathcal{E}_{11}] = \alpha \cdot \left( \frac{\Pr[\mathcal{E}_{10}]}{\alpha_1} + \frac{\Pr[\mathcal{E}_1] - \Pr[\mathcal{E}_{10}]}{\alpha_2} \right) \\ &= \alpha \cdot \left( \frac{\Pr[\mathcal{E}_1]}{\alpha_2} - \frac{(\alpha_1 - \alpha_2) \Pr[\mathcal{E}_{10}]}{\alpha_1 \alpha_2} \right) = \frac{\alpha}{\alpha_2} \cdot \left(1 - \left(1 - \frac{\alpha_2}{n}\right)^n\right) \\ &= c_2(\alpha) \cdot \left(1 - \left(1 - \frac{\alpha}{n}\right)^n\right) = c_2(\alpha) \cdot G_m(\alpha) \ .\end{aligned}$$

Hence,

$$c_2(\alpha) = \frac{\alpha}{\alpha_2} \cdot \frac{1 - \left(1 - \frac{\alpha_2}{n}\right)^n}{1 - \left(1 - \frac{\alpha}{n}\right)^n} \geq \lim_{\alpha \to 0} c_2(\alpha) = \frac{1 - \left(1 - \frac{\alpha_2}{n}\right)}{\alpha_2} \geq \frac{1 - \mathsf{e}^{-\alpha_2}}{\alpha_2} \ ,$$

since for every given $n \geq 1$ and every $\alpha > 0$, the ratio $\alpha/(1 - (1 - \alpha/n)^n) > 1$, because $\alpha \geq 1 - (1 - \alpha/n)^n$ by concavity of the latter function.

Now for $\alpha \in I_1$, we consider the case with a positive test on $\tau_1$ but not on $\tau_2$. In this case, the box has a value of at least $t$ with probability $q/q_1 = \alpha/\alpha_1$. Alternatively, if we see a positive test for $\tau_1$ and $\tau_2$, the algorithms selects a box with a value of at least $t$ with probability 1. Overall, for $\alpha \in I_1$

$$A(\alpha) = \frac{\alpha}{\alpha_1} \cdot \Pr[\mathcal{E}_{10}] + \Pr[\mathcal{E}_{11}] \ = \ \Pr[\mathcal{E}_1] - \left( \frac{\alpha_1 - \alpha}{\alpha_1} \right) \cdot \Pr[\mathcal{E}_{10}]$$

$$= 1 - \left(1 - \frac{\alpha_1 - \alpha}{\alpha_1 - \alpha_2}\right)\left(1 - \frac{\alpha_1}{n}\right)^n - \frac{\alpha_1 - \alpha}{\alpha_1 - \alpha_2}\left(1 - \frac{\alpha_2}{n}\right)^n$$
$$= c_1(\alpha) \cdot \left(1 - \left(1 - \frac{\alpha}{n}\right)^n\right).$$

Since $\alpha \in [\alpha_2, \alpha_1]$ is a constant,

$$\lim_{n\to\infty} c_1(\alpha) = \frac{1}{1 - \mathsf{e}^{-\alpha}} \cdot \left(1 - \mathsf{e}^{-\alpha_1} - \frac{(\alpha_1 - \alpha)(\mathsf{e}^{-\alpha_2} - \mathsf{e}^{-\alpha_1})}{\alpha_1 - \alpha_2}\right).$$

Finally, for $\alpha \in I_0$, we see that

$$A(\alpha) = \frac{\alpha - \alpha_1}{n - \alpha_1}(1 - \Pr[\mathcal{E}_1]) + \Pr[\mathcal{E}_1] = \frac{\alpha - \alpha_1}{n - \alpha_1}\left(1 - \frac{\alpha_1}{n}\right)^n + \left(1 - \left(1 - \frac{\alpha_1}{n}\right)^n\right)$$
$$= c_0(\alpha) \cdot \left(1 - \left(1 - \frac{\alpha}{n}\right)^n\right).$$

Thus,

$$c_0(\alpha) \geq \frac{1 - \left(1 - \frac{\alpha_1}{n}\right)^n}{1 - \left(1 - \frac{\alpha}{n}\right)^n} \geq \frac{1 - \mathsf{e}^{-\alpha_1}}{1 - \mathsf{e}^{-\alpha}},$$

where the latter bound holds for any $n \geq 1$ and any constant $\alpha$. Indeed, when $\alpha \in \omega(1)$, we obtain a bound of $1 - \mathsf{e}^{-\alpha}$ in the limit for $n \to \infty$.

As a sanity check, observe that $c_1(\alpha_1) = c_0(\alpha_1) = 1$. Indeed, suppose we have a box with value $t \geq \tau_1$. Then either this box is tested positive for $\tau_1$, or some other box was tested positive for $\tau_1$ before. In either case, the algorithm indeed selects a box of value at least $\tau_1$. Similarly, observe that $c_2(\alpha_2) = 1$ as well. Indeed, suppose we have a box with value $t \geq \tau_2$. Suppose (1) this box is tested positive for $\tau_2$. Then it is selected. Suppose (2) the box is tested positive for $\tau_1$. Then it is selected, unless some later box is tested positive for $\tau_2$. Either way, we eventually obtain a value of at least $\tau_2$. Finally, suppose (3) the box is not tested at all. Then we have already selected a box of value at least $\tau_2$ before.

To obtain the best ratio, we strive to select constants $0 < \alpha_2 < \alpha_1$ in order to

$$\max_{\alpha_1,\alpha_2} \{\min_{\alpha\in I_2} c_2(\alpha), \min_{\alpha\in I_1} c_1(\alpha), \min_{\alpha\in I_0} c_0(\alpha)\}.$$

For $c_2(\alpha)$ and $c_0(\alpha)$ we obtain fairly clear lower bounds, which even hold pointwise for any $n$. It seems unpromising to obtain an insightful analytic formula for the minimum of $c_1(\alpha)$ as a function of $\alpha_1$ and $\alpha_2$. Instead, we numerically optimized parameters $\alpha_1, \alpha_2$ and used standard solver software to minimize $c_1(\alpha)$. The lower bounds for $c_2$ and $c_0$ then amount to $(1 - \mathsf{e}^{-0.35932})/0.35932 \geq 0.8400637\ldots$ and $1 - \mathsf{e}^{1.83298} \geq 0.8400564\ldots$. The minimum of $\lim_{n\to\infty} c_1(\alpha)$ is located roughly at $\alpha^* \approx 0.832961265\ldots$ with a value for $c_1(t) = 0.8400569\ldots$ For a plot of the ratios see Figure 1.

Along similar lines, we analyze the case with $k = 3$ thresholds in the full version, which yields a ratio of at least $0.869 - o(1)$ (see Table 1). Based on similar calculations, we also numerically optimized the case with $k = 4$, but we see only very slight improvements. Intuitively, the probability to reach a state with positive tests for all $k$ thresholds becomes extremely small. Increasing this probability requires to decrease the value to be tested for in the first $k - 1$ tests. However, the possibility to obtain an improvement in this way seems to vanish very quickly as $k$ grows larger. We conjecture that for all values of $k$, we cannot significantly improve the competitive ratio beyond 0.869 as $n \to \infty$. ◀

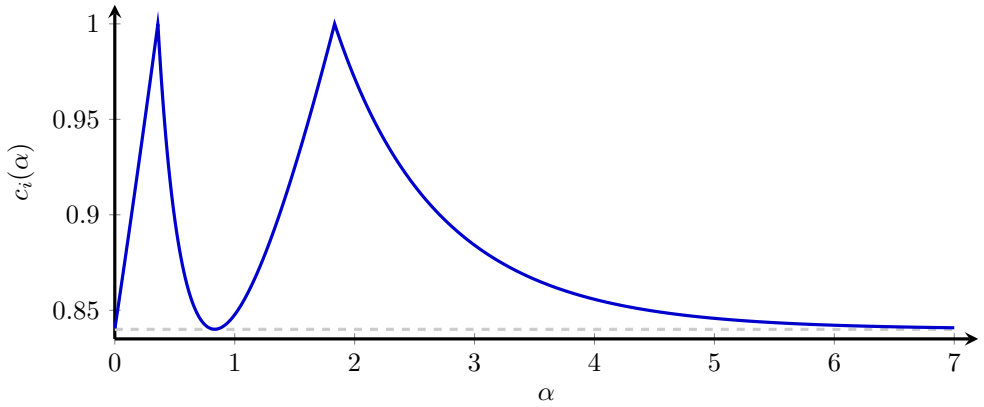

**Figure 1** Ratios $c_2$, $c_1$ and $c_0$ in the limit for $n \to \infty$ using $\alpha_1 = 1.83298$ and $\alpha_2 = 0.35932$.

Observe that the analysis of our algorithms is tight. Consider the value of $\alpha'$ that yields the minimum of all $c_i(\alpha)$ in the respective intervals $I_i$. For a "golden nugget"-distribution, where each $X_i$ has value 1 with probability $\alpha'/n$ and 0 otherwise, the above calculations become exact, and the analysis of the competitive ratio becomes tight. While, strictly speaking, this golden-nugget distribution is discrete, it is straightfoward to approximate it arbitrarily closely by a continuous distribution.

## 4 Discrete Distributions

Let us shift attention from a continuous distribution to a finite discrete distribution $F$. We assume $F$ is represented in straightforward form as a list of (value, probability) pairs. We denote by $m$ the number of distinct realizations, and we use $v_1 < v_2 < \ldots < v_m$ to denote the support of $F$.

Observe that w.l.o.g. we only need to test for these values $v_j$. If we test for a threshold $t$ in between two consecutive $v_j < t \leq v_{j+1}$, we obtain the same result by testing for $t = v_{j+1}$ instead. As such, we restrict to tests for values in the support.

### 4.1 Testing Algorithms

We first observe that an optimal testing algorithm can be computed in polynomial time. Moreover, we show that this algorithm yields a competitive ratio of $0.869 - o(1)$.

▶ **Theorem 5.** *For finite discrete distributions, an optimal testing algorithm can be computed by dynamic programming in polynomial time.*

**Proof.** We use backwards induction. Consider the last test of box $n$. Clearly, given the previously tested boxes $1, \ldots, n-1$, we can restrict attention to the one with the highest conditional expectation. We denote this value by $V^*_{n-1}$. Since each box is tested for exactly one of the $m$ realizations, there are $2m$ different possibilities for $V^*_{n-1}$. There are $m$ possible tests for box $n$. We can enumerate all the $2m^2$ combinations. For each value of $V^*_{n-1}$, the optimal test of box $n$ is the one leads to the highest expected value of the chosen item. Thus, to determine and describe the optimal decision for box $n$, we only need to consider $2m$ options of $V^*_{n-1}$, and for each option we record the best of the $m$ possible tests for box $n$.

For the induction, let $V^*_{i-1}$ and $V^*_i$ be the conditional expectation of the best tested box before and after testing box $i$, resp. Suppose that for each possible value of $V^*_i$, we have computed an optimal testing strategy for subsequent boxes $i+1, \ldots, n$, along with the

resulting expected value of $X_\sigma$. Now for box $i$, consider each of the $2m$ possible values for $V^*_{i-1}$. For each realization $v_k$, we can determine the effect when we test box $i$ for $v_k$ – i.e., the probability that $V^*_i = V^*_{i-1}$ (when the test on $i$ implies the conditional expectation of $i$ is at most $V^*_{i-1}$), as well as the probability that $V^*_i$ becomes any higher value (otherwise). For the resulting $V^*_i$, we inspect the value obtained by an optimal testing strategy for boxes $i+1, \dots, n$. This serves to find the test of box $i$ resulting in the optimal expected value.

Overall, to determine and describe the optimal decision for box $i$, we need to consider $2m$ options of $V^*_{i-1}$, and for each option we determine the best of the $m$ possible tests for box $i$ (using the results of the subsequent optimal testing strategy for boxes $i+1, \dots, n$). Finally, for box 1 $V^*_0$ is undefined. At this point, we only need to find the best of the $m$ possible tests for box 1 (using the results of the subsequent optimal testing strategy for boxes $2, \dots, n$). This concludes the backwards induction.

We record for each possible value $V^*_{i-1}$ the best threshold to test box $i$ along with the resulting expected value emerging from an optimal algorithm for boxes $i+1, \dots, n$. Hence, we can describe an optimal testing strategy using $2 \cdot (1 + (n-1) \cdot 2m))$ entries. This strategy can be computed in polynomial time via dynamic programming as described above. ◀

At this point, it is unclear how to apply our algorithm from the previous section to finite discrete distributions since $F^{-1}(1-q)$ may not be defined for the relevant values of $q$. In fact, we will show that the optimal algorithm in Theorem 5 achieves a competitive ratio of at least $0.869 - o(1)$ for finite discrete distributions.

We consider the following different model for testing discrete distributions, called *probability testing*. It can be viewed as the limit that emerges from approximating discrete with continuous distributions arbitrarily close. Here a test requires an input value $q \in [0,1]$. It then returns whether or not the value $v$ in the box lies in the top-$q$ fraction of probability mass of $F$. For a finite discrete distribution $F$, let $k$ be such that $\sum_{j=k+1}^{m} \Pr[v = v_j] < q \leq \sum_{j=k}^{m} \Pr[v = v_j]$. Then the test is positive for $v \in \{v_{k+1}, \dots, v_m\}$ and negative for $v \in \{v_1, \dots, v_{k-1}\}$. For $v = v_k$ it yields a randomized outcome, i.e., positive with probability $p_q = \left(q - \sum_{j=k+1}^{m} \Pr[v = v_j]\right) / \Pr[v = v_k]$ and negative otherwise. Hence, the overall probability that box $i$ is tested positive is exactly $q$.

Clearly, our algorithm from Section 3 can be implemented with probability testing and obtains a competitive ratio of $0.8969 - o(1)$. Probability and threshold testing are equivalent for continuous distributions, since there is a bijection between thresholds and values for $q$. For finite discrete distributions we observe in Proposition 6 that any algorithm for probability testing can be simulated using randomized threshold tests. We then show that randomized tests are not beneficial, i.e., for any algorithm with randomized threshold tests, there is one with *deterministic* tests performing at least as good. For a formal proof, see the full version.

▶ **Proposition 6.** *If there is a $c$-competitive algorithm for probability testing, then there is a $c$-competitive algorithm for threshold testing.*

▶ **Corollary 7.** *The optimal algorithm for finite discrete distributions is at least $(0.869 - o(1))$-competitive for threshold testing.*

## 4.2 Impossibility

Complementing our results in the previous subsection, we proceed to show a constant upper bound on the competitive ratio for $n \to \infty$.

▶ **Theorem 8.** *There exists no $(1 - o(1))$-competitive algorithm for threshold testing.*

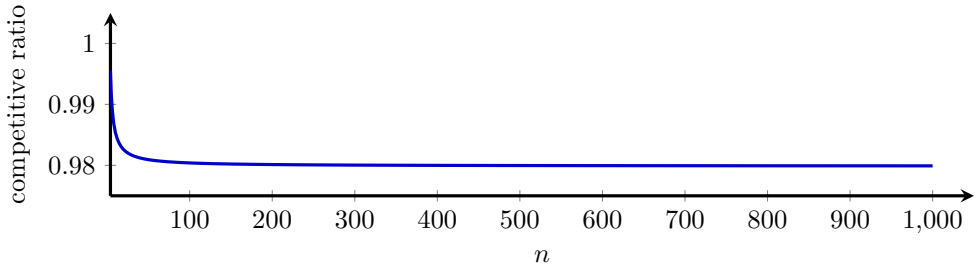

**Figure 2** The best-possible competitive ratio on the instance used in the proof of Theorem 8 as a function of $n$.

To prove the theorem, we are going to construct a counter example that is a discrete distribution, which carries over to the continuous case by the arguments given in Section 4. We first observe that such a distribution needs to depend on $n$: Otherwise, the top realization appears with constant probability in each box, and an algorithm simply testing for that realization finds it with probability $1 - o(1)$. Furthermore, such a distribution needs to have a support of cardinality at least 4: If the cardinality of the support is 3, it is w.l.o.g. exactly 3, and the algorithm can obtain $\max\{X_1, \dots, X_n\}$ by testing for the middle realization and, upon a positive test, testing for the top realization. If it finds a positive test on the top realization, it clearly obtains $\max\{X_1, \dots, X_n\}$ by choosing the corresponding box. If it finds a positive test on the middle realization, the corresponding box is the only one that can possibly contain the top realization, which the algorithm obtains by picking it, so it also obtains $\max\{X_1, \dots, X_n\}$. In the final case, $\max\{X_1, \dots, X_n\}$ is only the lowest realization, which the algorithm will also obtain by choosing any box.

We consider boxes that contain a realization 3, 2, or 1 with probability $1/n$ each and 0 otherwise. Intuitively, any algorithm that does not always test for the value 1 before encountering a positive test runs the risk of missing a value 1. Similarly, any algorithm that does not always test for the value 2 afterwards and before encountering another positive test runs the risk of missing a value 2. Such an algorithm, however, with constant probability, gets into a situation in which it has encountered precisely two positive tests, specifically, for the values 1 and 2. In that situation, it is clearly optimal to choose the box that has been positively tested for the value 2. With a constant probability, the value of this box is, however, equal to 2 while the one that has been tested positively for value 1 is equal to 3. The conclusion is that the algorithm, in any case, loses a constant fraction of $\mathbb{E}[\max\{X_1, \dots, X_n\}]$. In the full version, we present a formal version of this argument.

We have verified numerically (by solving the dynamic program from Theorem 5) that for this distribution the achievable competitive ratio decreases in $n$ in the interval $n = 2, \dots, 1000$. For $n = 1000$, the optimal competitive ratio is ca. 0.9799 (computed with full precision). See Figure 2 for the results.

## 5 Multiple Tests per Box

In this section, we consider a setting with $n$ boxes and a budget of $n$ threshold tests. Each box can be tested an arbitrary number of times with different thresholds[2] as long as there are still tests available. We again assume continuous distributions and show the following result.

[2] Recall that nature draws *initially a single* value $X_i \sim F$ inside each box $i$. All tests on the same box are evaluated accordingly. The results of multiple tests on the same box are all consistent with the single unknown $X_i$ drawn upfront.

▶ **Theorem 9.** *There is an efficient* $(1 - o(1))$*-competitive algorithm for threshold testing with multiple tests per box and a continuous distribution.*

**Proof.** In the first step, our algorithm discards the last $\lceil n^{2/3} \rceil$ boxes, losing only a $\lceil n^{2/3} \rceil / n$ fraction of the value. The remaining ones are tested for the threshold $F^{-1}(1 - n^{-1/3})$. Let $P$ be the set of boxes that were tested positively. For each box $i \in P$, the algorithm next searches the integers $\{0, \dots, \lfloor n^{2/3} \rfloor\}$ to find the largest $j$ such that the test for $F^{-1}(1 - n^{-1/3} + j/n)$ is negative. Then[3], $F^{-1}(1 - n^{-1/3} + j/n) < X_i \leq F^{-1}(1 - n^{-1/3} + (j+1)/n)$. Using a binary search, this requires at most $\lceil 2/3 \cdot \log n \rceil$ tests for each box $i \in P$. Using the result, we say that box $i$ is of type $j$. Since there are potentially up to $n$ boxes in $P$, the algorithm may well run out of tests during this process. Eventually, if the algorithm succeeds to determine the type of each box in $P$, it picks a box from $P$ with the highest type. If no such box exists, it is not unique, or the algorithm ran out of tests before determining the type of each box in $P$, it may choose an arbitrary box.

To analyze our algorithm, we fix any $v \in [F^{-1}(1 - n^{-1/3}), F^{-1}(1))$. We denote by $\mathcal{M}_v$ the event that $\max\{X_1, \dots, X_n\} = v$, and by $X_\sigma$ the value obtained by the algorithm. Our goal is to show that, whenever an optimal box has a high value $v$, the probability that we choose an optimal box is

$$\Pr[X_\sigma = v \mid \mathcal{M}_v] = 1 - o(1). \tag{1}$$

Now we see an optimal box with a high value with probability

$$\Pr[\max\{X_1, \dots, X_n\} \geq F^{-1}(1 - n^{-1/3})] = 1 - (1 - n^{-1/3})^n = 1 - o(1),$$

so proving Eq. (1) indeed suffices to prove the theorem. To show Eq. (1), we define two additional events:

- $\mathcal{E}_1$ is the event that $|P| \leq n^{1/2}$ (in particular, this implies that the algorithm does not run out of tests for large-enough $n$),
- $\mathcal{E}_2$ is the event that only a single box has the largest type.

Note that $\Pr[X_\sigma = v \mid \mathcal{M}_v] \geq \Pr[\mathcal{E}_1 \cap \mathcal{E}_2 \mid \mathcal{M}_v]$ since our algorithm chooses the box with the maximum value if both $\mathcal{E}_1$ and $\mathcal{E}_2$ occur. We finalize the argument by observing that

$$\begin{aligned}\Pr[\mathcal{E}_1 \cap \mathcal{E}_2 \mid \mathcal{M}_v] &= \Pr[\mathcal{E}_1 \mid \mathcal{M}_v] \cdot \Pr[\mathcal{E}_2 \mid \mathcal{M}_v \cap \mathcal{E}_1] \\ &\geq \left(1 - e^{-\frac{n^{1/3}}{3}}\right) \cdot \left(1 - \frac{n^{-2/3}}{1 - n^{-1/3}}\right)^{n^{1/2}} = 1 - o(1).\end{aligned}$$

For the inequality, we bound the first probability using a one-sided multiplicative Chernoff bound with $\mu = n^{1/3}$ and factor 2. We bound the second probability by observing that, conditioned on $\mathcal{M}_v$, the probability that a single box other than that with realization $v$ has the same type is at most $n^{-2/3}/(1 - n^{-1/3})$. Here, $n^{-2/3}$ is an upper bound on the probability of having the same type, and $1 - n^{-1/3}$ is a lower bound on the probability that an independently drawn value is below $v$ (using that $v$ is a high value). The additional condition on $\mathcal{E}_1$ does not increase the probability of $\mathcal{E}_2$. This shows Eq. (1) and thus completes the proof. ◀

It is rather straightforward to apply the insights from Sec. 4 to show similar results for testing with multiple tests per box and a finite discrete distribution. Our algorithm in the proof of Theorem 9 can be cast as a *sequential* testing algorithm: It tests boxes

[3] We use the convention $F^{-1}(x) = F^{-1}(1)$ for $x > 1$.

sequentially from box 1 to $n - \lceil n^{2/3} \rceil$. For each box $i$ it applies tests to determine whether $i \in P$ or not, and then binary search the type of $i$ (or aborts when it runs out of tests). For finite discrete distributions, we can optimize over such sequential testing algorithms using backwards induction, much like in the proof of Theorem 5. When considering box $i$, an optimal decision about the next test can be found by relying on three additional parameters. Apart from the best conditional expectation of a previous box $V^*_{i-1}$, we also consider the smallest realization for which we saw a positive test for $i$, the largest one for which we saw a negative test for $i$, as well as the number of tests we applied so far. These parameters sufficiently describe the current state of the system before applying the next test. Note that there is only a polynomial number of combinations of these parameters that need to be considered. Then the algorithm has up to $m$ possible options for the next test of box $i$ – or $m$ possible options for the first test of box $i+1$, thereby concluding the testing of box $i$. Hence, there are only polynomially many combinations that need to be considered to find the optimal decision for the current test (assuming that an optimal testing algorithm for the subsequent number of tests/boxes has already been computed via backwards induction).

We can also transfer the approximation guarantee for the algorithm from Theorem 9. We apply the algorithm in the model with probability tests and interpret them as randomized threshold tests. By applying the arguments of Proposition 6 to the sequential model with multiple tests per box, we see that for every randomized threshold testing algorithm there is a deterministic one that performs at least as good. Overall, this yields the following corollary.

▶ **Corollary 10.** *For finite discrete distributions, an optimal sequential testing algorithm for multiple tests per box can be computed by dynamic programming in polynomial time. It is at least* $(1 - o(1))$*-competitive for threshold testing with multiple tests per box.*

## 6 Conclusion

In this paper, we have initiated the study of threshold testing of i.i.d. random variables, a probing model with partial revelation and binary feedback. For non-adaptive algorithms, the model is essentially equivalent to the standard gambler's problem, and optimal performance is governed by the i.i.d. prophet inequality of approximately 0.745. For adaptive algorithms, we obtain a testing algorithm with competitive ratio of 0.869. This significantly outperforms 0.745, proves that there is a substantial adaptivity gap, and reveals the structural difference of the adaptive problem. Moreover, we show a constant upper bound on the ratio achievable by any adaptive testing algorithm. In contrast, when we can (adaptively) apply multiple tests to a single box, it is possible to achieve even a ratio of $1 - o(1)$.

There are many intriguing open problems arising from our work. Obviously, the current upper and lower bounds for the i.i.d. model are not tight. More generally, a simple argument similar to Observation 1 shows that free-order prophet inequalities [5] transfer directly to non-adaptive threshold testing, even for non-i.i.d. boxes. It is an intriguing open problem whether these guarantees can be strictly improved using an adaptive testing algorithm. Can we obtain a ratio strictly larger than 0.745 also for non-i.i.d. threshold testing?

In addition, there are many combinatorial versions of the problem that deserve attention, i.e., when the algorithm is allowed to select more than one box. Testing algorithms for, e.g., knapsack, matroid, or general downward-closed feasibility structures represent a natural and important direction for future research.

## Abstract

In the Minimum Bisection problem input is a graph $G$ and the goal is to partition the vertex set into two parts $A$ and $B$, such that $||A| - |B|| \leq 1$ and the number $k$ of edges between $A$ and $B$ is minimized. The problem is known to be NP-hard, and assuming the Unique Games Conjecture even NP-hard to approximate within a constant factor [Khot and Vishnoi, J.ACM'15]. On the other hand, a $\mathcal{O}(\log n)$-approximation algorithm [Räcke, STOC'08] and a parameterized algorithm [Cygan et al., ACM Transactions on Algorithms'20] running in time $k^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ is known.

The Minimum Bisection problem can be viewed as a clustering problem where edges represent similarity and the task is to partition the vertices into two equally sized clusters while minimizing the number of pairs of similar objects that end up in different clusters. Motivated by a number of egregious examples of unfair bias in AI systems, many fundamental clustering problems have been revisited and re-formulated to incorporate fairness constraints. In this paper we initiate the study of the Minimum Bisection problem with fairness constraints. Here the input is a graph $G$, positive integers $c$ and $k$, a function $\chi : V(G) \to \{1, \ldots, c\}$ that assigns a color $\chi(v)$ to each vertex $v$ in $G$, and $c$ integers $r_1, r_2, \cdots, r_c$. The goal is to partition the vertex set of $G$ into two almost-equal sized parts $A$ and $B$ with at most $k$ edges between them, such that for each color $i \in \{1, \ldots, c\}$, $A$ has exactly $r_i$ vertices of color $i$. Each color class corresponds to a group which we require the partition $(A, B)$ to treat fairly, and the constraints that $A$ has exactly $r_i$ vertices of color $i$ can be used to encode that no group is over- or under-represented in either of the two clusters.

We first show that introducing fairness constraints appears to make the Minimum Bisection problem qualitatively harder. Specifically we show that unless FPT=W[1] the problem admits no $f(c)n^{\mathcal{O}(1)}$ time algorithm even when $k = 0$. On the other hand, our main technical contribution shows that is that this hardness result is simply a consequence of the very strict requirement that each color class $i$ has *exactly* $r_i$ vertices in $A$. In particular we give an $f(k, c, \epsilon)n^{\mathcal{O}(1)}$ time algorithm that finds a balanced partition $(A, B)$ with at most $k$ edges between them, such that for each color $i \in [c]$, there are at most $(1 \pm \epsilon)r_i$ vertices of color $i$ in $A$.

Our approximation algorithm is best viewed as a proof of concept that the technique introduced by [Lampis, ICALP'18] for obtaining FPT-approximation algorithms for problems of bounded tree-width or clique-width can be efficiently exploited even on graphs of unbounded width. The key insight is that the technique of Lampis is applicable on tree decompositions with unbreakable bags (as introduced in [Cygan et al., SIAM Journal on Computing'14]). An important ingredient of our approximation scheme is a combinatorial result that may be of independent interest, namely that for every $k$, every graph $G$ admits a tree decomposition with adhesions of size at most $\mathcal{O}(k)$, unbreakable bags, and logarithmic depth.

## 1 Introduction

Clustering is one of the most fundamental problems in computer science. In a clustering problem, we are typically interested in dividing the given collection of data points into a group of *clusters*, such that the set of data points belonging to each cluster are more "similar" to each other, as compared to the points belonging to other clusters. Depending on the specific setting and application, there are a number of ways to model this abstract task of clustering as a concrete mathematical problem. We refer the reader to surveys such as [30, 27, 3] for a detailed background and literature on the topic.

In one such model of clustering, the input is represented as a simple, undirected graph, and the existence of an edge between a pair of vertices denotes that the two vertices are related to, or similar to, each other. For example, this is how one models social networks as graphs [25] – the set of vertices corresponds to people, and an edge represents that the two people are friends with each other. In this setting, the classical Minimum Bisection problem can be thought of as a clustering problem [31, 7] – we are interested in finding two size-balanced clusters of vertices, such that the number of edges going across the two clusters is minimized. More formally, in Minimum Bisection problem, we are given a graph $G = (V, E)$ on $n$ vertices, and a non-negative integer $k$, and the goal is to determine whether there exists a balanced edge cut $(A, B)$ of order $k$. Here, an *edge cut* $(A, B)$ is a partition of $V(G)$ into two non-empty subsets $A$ and $B$, an edge cut is *balanced* if $||A| - |B|| \leq 1$, and the *order* of the cut $(A, B)$ is the number of edges with one endpoint in $A$ and the other in $B$. The NP-completeness of Minimum Bisection has long been known [13], and it is extensively studied from the perspective of approximation and parameterized algorithms. Minimum Bisection admits a logarithmic approximation in polynomial time [26], and it is hard to approximate within any constant factor, assuming the Unique Games Conjecture [19]. In the realm of Parameterized Algorithms, one can solve the problem exactly in time $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$, i.e., it is Fixed-Parameter Tractable (FPT) parameterized by $k$ [10, 9].

More recently, the notion of *fairness* has gained prominence in the literature of clustering algorithms – and algorithm design in general. This is motivated from the fact that, often the real-life data reflects unconscious biases, and unless the algorithm is explicitly required to counteract these biases, the output of the algorithm may have real-life consequences that are *unfair* ((see, e.g., [15, 24, 11]). Researchers have proposed different models of fairness for the traditional center-based clustering problems, such as $k$-Median/Means/Center. These models of fairness can be broadly classified into two types – *individual fairness*, and *group fairness*. At a high level, individual fairness requires that the solution treats each of

the individuals (a point) in a fair way, e.g., every point has a cluster-center "nearby" [6]. On the other hand, in the group fairness setting, the set of points is typically divided into multiple colors, where each color represents, say a particular demographic (such as gender, ethnicity etc.). In this setting, the fairness constraints are represented in terms of the colors as a group. There are multiple notions of group fairness (see, e.g., [2, 6, 12, 22, 14, 18]), but to the specific interest to us is the *color-balanced clustering* model, studied in [28, 17, 1]. Roughly speaking, in this setting we want the "local proportions" of all colors in every cluster to be approximately equal to their "global proportions". Inspired from this *color-balanced* notion of fairness, study the following *fair* version of Minimum Bisection.

In this problem formulation the color classes $i \in \{1, \ldots, c\}$ are protected groups which are required to be treated fairly by the clustering algorithm. The imposed fairness constraint for group $i$ is that, in the edge cut $(A, B)$, the set $A$ contains precisely $r_i$ vertices colored $i$.

Fair Bisection
**Input:** An instance $(G, c, k, r^\circ, \chi)$, where
- $G$ is an unweighted graph
- $c$ and $k$ are positive integers
- $\chi : V(G) \to c$ is a coloring function on $V(G)$ using at most $c$ colors
- $r^\circ = (r_1, \cdots, r_c)$ is a $c$ length tuple of positive integers

**Question:** Does there exist an edge cut $(A, B)$ of $G$ of order at most $k$ having exactly $r_i$ vertices of color $i$ in $A$ for each $i \in [c]$.

We will say that an edge cut that satisfies the fairness constraints imposed by the tuple $r^\circ$ is $r^\circ$-*fair*.

Thus, when $r_i$ is set to be precisely half of the number $c_i$ of vertices colored $i$ an $r^\circ$-fair edge cut must evenly split each color class across the two sides $A$ and $B$.

## Our Results

It is quite easy to see that the existing parameterized algorithms [9, 10] for Minimum Bisection directly generalize to a $n^{\mathcal{O}(c)}k^{\mathcal{O}(k)}$ time algorithm for Fair Bisection[1]. Therefore, the first natural question is whether it is possible to eliminate the dependence on $c$ in the exponent of $n$ in the running time. Our first result (Theorem 20) is that, assuming $\mathsf{FPT} \neq \mathsf{W}[1]$, an $f(c)n^{\mathcal{O}(1)}$ time algorithm is not possible even when $k = 0$. In fact, this hardness result holds even in the special case where the vertices of each color are required to be evenly split across both partitions (in particular, when $2r_i = c_i$ for every $i$).

Our main technical contribution (Theorem 11) is to show that this hardness result is quite brittle. Indeed, the requirement that each color class $i$ have *exactly* $r_i$ vertices in $A$ is probably much too strong in the color-balanced fairness setting. We are satisfied even if the number of vertices of each color class is sufficiently close to the desired target number. We will say that an edge cut $(A, B)$ is $(\epsilon, r^\circ)$-*fair* if $A$ contains no more than $r_i(1 + \epsilon)$ of vertices colored $i$ and $B$ contains no more than $(c_i - r_i)(1 + \epsilon)$ vertices colored $i$. We show (in Theorem 11) that there exists an algorithm that takes as input an instance $(G, c, k, r^\circ, \chi)$, together with an $\epsilon > 0$, runs in time $f(\epsilon, k, c)n^{\mathcal{O}(1)}$, and if $G$ has a $r^\circ$-fair edge cut $(\hat{A}, \hat{B})$ of order at most $k$ then the algorithm produces a $(\epsilon, r^\circ)$-fair edge cut $(A, B)$ of order at most $k$.

[1] A formal proof of this claim is a corollary of our Theorem 11.

## Our Methods

The hardness result of Theorem 20 is a fairly straightforward parameterized reduction from Multi-Dimensional Subset Sum parameterized by the dimension[2], whose main purpose is to put the parameterized approximation scheme of Theorem 11 in context. We only discuss here the methods in the proof of of Theorem 11.

At a *very* high level the algorithm of Theorem 11 is the combination of two well-known techniques in parameterized algorithms: dynamic programming over tree decompositions with unbreakable bags (introduced by Cygan et al. [10]), and the geometric rounding technique of Lampis [20] for parameterized approximation schemes for problems on graphs of bounded tree-width or clique-width. The conceptual novelty in (and perhaps the most interesting technical aspect of) our work is to realize that Lampis' technique can be applied even to dynamic programming algorithms over tree decompositions with unbounded width to yield approximation schemes for parameterized problems on general graphs. Executing on this vision requires a few non-trivial technical insights, which we will shortly highlight. However, to describe these technical insights in more detail we first give a brief description of the two techniques that we combine.

### Lampis' Geometric Rounding Technique

We first discuss how the technique of Lampis [20] applies to tree decompositions of bounded width. A *tree decomposition* of a graph $G$ is a pair $(T, \beta)$ where $T$ is a tree and $\beta$ is a function that assigns to each vertex $t \in V(T)$ a vertex set $\beta(t) \subseteq V(G)$ (called a *bag*) in $G$. To be a tree decomposition the pair $(T, \beta)$ must satisfy the tree-decomposition axioms: *(i)* for every $v \in V(G)$ the set $\{t \in V(T) \ : \ v \in \beta(t)\}$ induces a non-empty and connected subgraph of $T$, and *(ii)* for every edge $uv \in E(G)$ there exists a $t \in V(T)$ such that $\{u, v\} \subseteq \beta(t)$. The *width* (or tree-width) of a decomposition $(T, \beta)$ is defined as $\max_{t \in V(T)} |\beta(t)| - 1$.

Roughly speaking, Lampis' technique considers dynamic programming (DP) algorithms over a tree decomposition $(T, \beta)$ of $G$ of width $k$. In such an algorithm there is a DP-table for every node $t$ of the decomposition tree, and suppose that the entries in these tables are indexed by vectors in $\{1, 2, \ldots, n\}^d$ (for some integer $d$), where $n$ is the number of vertices of $G$. To decrease the size of the DP tables and thereby also the running time of the algorithm, one "sparsifies" the DP table to only consider entries in $S^d$, where $S = \left\{\lfloor (1+\delta)^i \rfloor : i \geq 0\right\}$. This makes the size of the DP table upper bounded by $(\log_{1+\delta} n)^{\mathcal{O}(d)}$, at the cost of introducing a multiplicative error of $(1+\delta)$ in every round of the DP algorithm (since now vectors in $\{1, 2, \ldots, n\}^d$ are "approximated" by their closest vector in $S^d$). If the decomposition tree $T$ has depth $\mathcal{O}(\log n)$ the dynamic program only needs $\mathcal{O}(\log n)$ rounds, and so the total error of the algorithm is a multiplicative factor of $(1+\delta)^{\mathcal{O}(\log n)}$. Setting $\delta = \epsilon / \log^2 n$ gives the desired trade-off between DP table size (and therefore running time) and accuracy. Luckily, every tree decomposition of width $k$ can be turned into a tree decomposition of width at most $3k+2$ and depth $\mathcal{O}(\log n)$ [4] and so this approach works on all graphs of tree-width $k$.

### Tree Decompositions with Unbreakable Bags

We now turn to the technique of Cygan et al. [10] for Minimum Bisection, namely dynamic programming over tree decompositions with small adhesions and unbreakable bags. We again need to define a few technical terms. An *adhesion* of a tree decomposition $(T, \beta)$ of a graph

[2] The hardness of Multi-Dimensional Subset Sum parameterized by the dimension is folklore, but we were unable to find a reference, so for completeness we provide a proof.

$G$ is a set $\beta(u) \cap \beta(v)$ for an edge $uv \in E(T)$. The *adhesion size* of a tree-decomposition is just the maximum size of an adhesion of the decomposition. A tree decomposition $(T, \beta)$ is said to have $(q, k)$-*unbreakable bags* if for every bag $\beta(t)$ of the decomposition and every edge-cut $(A, B)$ of order at most $k$ in $G$ it holds that $\min(|A \cap \beta(t)|, |B \cap \beta(t)|) \leq q$.

The main engine behind the algorithm of Cygan et al. [10] (see also [9]) is a structural theorem that for every graph $G$ and integer $k$ there exists a tree decomposition $(T, \beta)$ of $G$ with adhesion size at most $k$ and $(k+1, k)$-unbreakable bags. This is coupled with an observation that even though this tree decomposition might have unbounded tree-width, we can still do dynamic programming over this tree decomposition, keeping a DP table for every *adhesion* of the tree decomposition, rather than for every bag. However, while tree-width based DP algorithms utilize a simple recurrence to calculate the DP table at a bag from the tables of its children, Cygan et al. [10] need to turn to a clever "randomized contraction" (see [8]) based algorithm to compute the DP table for an adhesion from the DP tables of its children.

### Combining Tree Decompositions with Unbreakable Bags and Geometric Rounding

As we mentioned eariler, the technique of Cygan et al. [10] for Minimum Bisection generalizes in a relatively straightforward way, to give a $f(k)n^{\mathcal{O}(c)}$ time algorithm for Fair Bisection. Here we do dynamic programming over the tree decomposition of $G$ with adhesions of size $k$ and $(k+1, k)$-unbreakable bags. We have a DP table for every adhesion that is indexed by a vector in $[n]^c$ (this vector describes partial solutions, where the $i^{th}$ element of the vector is the number of vertices of color $i$ that have so far been put on the $A$ side in this partial solution).

We want to apply Lampis' geometric rounding technique and "sparsify" the DP table to only consider entries in $S^c$, where $S = \left\{\lfloor (1+\delta)^i \rfloor : i \geq 0\right\}$. There are a few technical obstacles to realizing this plan, that we overcome. The most important one of them is that the depth reduction theorem of Bodlaender and Hagerup [4] only applies to tree decompositions of bounded width, therefore it is not immediate how to obtain a tree decomposition with small adhesions, unbreakable bags and logarithmic depth. A closer inspection of the proof sketch of Bodlaender and Hagerup [4] reveals that a tree decomposition with adhesions of size $k$ and $(k+1, k)$-unbreakable bags can be turned into a tree decomposition with adhesions of size $\mathcal{O}(k)$, and logarithmic depth, such that each bag of the new decomposition is the union of a constant number of bags of the old one (the bags in this new decomposition do *not* need to themselves be unbreakable). Nevertheless we prove that some careful modifications to this tree decomposition are sufficient to obtain a tree decomposition with adhesions of size $\mathcal{O}(k)$, logarithmic depth, and $(\mathcal{O}(k), k)$-unbreakable bags (see Theorem 9). We believe that Theorem 9 will be a useful tool for future applications of Lampis' geometric rounding technique to tree decompositions with unbreakable bags.

### Organization of the Paper

We begin by defining the basic notions on graphs and tree decompositions in Section 2. In Section 3, we prove Corollary 10 that shows how to obtain logarithmic-depth unbreakable tree decompositions. Then, in Section 4, we use such a tree decomposition to design our exact and approximate algorithms. In Section 5, we sketch the proof of our hardness result, which shows that Fair Bisection is W[1]-hard parameterized by $c$ even when $k = 0$. Finally, in Section 6, we give concluding remarks and future directions. Proofs marked with $*$ can be found in the full version of the paper.

## 2 Preliminaries

For an integer $k$, we denote the set $\{1, 2, \ldots, k\}$ by $[k]$. For a graph $G$, *an edge cut* is a pair $A, B \subseteq V(G)$ such that $A \cup B = V(G)$ and $A \cap B = \emptyset$. The order of an edge cut $(A, B)$ is $|E(A, B)|$, that is, the number of edges with one endpoint in $A$ and the other in $B$. For a subset $X \subseteq V(G)$, let $G \setminus X$ denote the graph $G[V(G) \setminus X]$. For an edge cut $(A, B)$, and a subset $X \subseteq V(G)$, the cut *induced* on $X$ by $(A, B)$ is $(A \cap X, B \cap X)$.

▶ **Definition 1** (unbreakability). *A set $X \subseteq V(G)$ is* $(q, s)$-edge-unbreakable *if every edge cut $(A, B)$ of order at most $s$ satisfies $|A \cap X| \leq q$ or $|B \cap X| \leq q$.*

For a rooted tree $T$ and vertex $t \in V(T)$, we denote by $T_t$ the subtree of $T$ rooted at $t$. For a rooted tree $T$ and a non-root vertex $t \in V(T)$, we denote the parent of $t$ by $\mathcal{P}(t)$. The depth of a tree $T_t$ is the maximum length of a $t$ to leaf path in $T_t$. For a node $t$, we denote $\mathsf{ht}_T(t)$ to be the the depth of the subtree $T_t$ rooted at $t$ in $T$.

Consider a tree decomposition $(T, \beta)$ of a graph $G$. For every $t \in V(T)$ a set $\beta(t) \subseteq V(G)$, is called a *bag*. We can extend the function $\beta$ to subsets of $V(T)$ in the natural way: for a subset $X \subseteq V(T)$, $\beta(X) := \bigcup_{x \in X} \beta(x)$. Another important notion that we need is of tree decomposition where bags are "highly connected", i.e., unbreakable. For a rooted tree $T$ and vertex $v \in V(T)$ we denote by $T_v$ the subtree of $T$ rooted at $v$. We refer to the vertices of $T$ as nodes.

For $s, t \in V(T)$ we say that *$s$ is a descendant of $t$* or that *$t$ is an ancestor of $s$* if $t$ lies on the unique path from $s$ to the root; note that a node is both an ancestor and a descendant of itself. By $\mathsf{child}(t)$, we denote the set of children of $t$ in $T$. For any $X \subseteq V(T)$, define $G_X := G[\cup_{t \in X} \beta(V(T_t))]$.

We define an *adhesion* of an edge $e = (t, t_0) \in E(T)$ to be the set $\sigma(e) := \beta(t) \cap \beta(t_0)$, and an adhesion of $t \in V(T)$ to be $\sigma(t) := \sigma(t, \mathcal{P}(t))$, or $\sigma(t) = \emptyset$ if the parent of $t$ does not exist, i.e., when $t$ is the root of $T$. We define the following notation for convenience:

$$\gamma(t) := \bigcup_{s\text{: descendant of } t} \beta(s)$$

$$\alpha(t) := \gamma(t) \setminus \sigma(t), \qquad G_t := G[\gamma(t)] - E(G[\sigma(t)]).$$

We say that a rooted tree decomposition $(T, \beta)$ of $G$ is *compact* if for every node $t \in V(T)$ for which $\alpha(t) \neq \emptyset$ we have that $G[\alpha(t)]$ is connected and $N_G(\alpha(t)) = \sigma(t)$.

## 3 Obtaining a Low Depth Unbreakable Tree Decomposition

In this section we show that there exists a tree decomposition that has low (i.e., $\mathcal{O}(\log n)$) depth, small-size (i.e., $\mathcal{O}(k)$) adhesions, and $(\mathcal{O}(k), k)$-unbreakable bags. To this end, we design a polynomial-time algorithm that, given a tree decomposition with small adhesions and unbreakable bags, produces a tree decomposition with the aforementioned properties. In the next section, we design a dynamic programming algorithm over such a low depth decomposition to obtain an FPT approximation for Fair Bisection.

In our algorithm, we use the notion of a *tree partition* of a graph, which, informally, captures the "tree-likeness" of a graph. Tree partitions were introduced by [29, 16], and are easy to define.

▶ **Definition 2** (Tree Partition). *A tree partition of a graph $G$ is a pair $(\mathcal{T}, \tau)$ where $\mathcal{T}$ is a tree and $\tau : V(G) \to V(\mathcal{T})$ is a function from $V(G)$ to $V(\mathcal{T})$ such that for each $e = (u, v) \in E(G)$ either $\tau(u) = \tau(v)$ or $(\tau(u), \tau(v)) \in E(T)$. A rooted tree partition $(\mathcal{T}, \tau)$ with root $r$ is the tree partition $(\mathcal{T}, \tau)$ where the tree $\mathcal{T}$ is a rooted tree with root $r$.*

We remark that we use calligraphic font ($\mathcal{T}$) to denote trees corresponding to Tree Partitions to easily distinguish them from graphs that are trees. Observe that for a tree $T$, the pair $(\mathcal{T} = T, \tau)$ where $\tau(v) = v$ for each $v \in T$ is a trivial tree partition of $T$. For our result we only use tree partitions of trees. Given a tree decomposition $(T, \beta)$ with small adhesions and unbreakable bags, our goal in this section is to use $(T, \beta)$ to obtain a tree decomposition of bounded height without blowing up the adhesion size and unbreakability guarantees too much. For this we first find a tree partition $(\mathcal{T}, \tau)$ of $T$ that satisfies additional properties, such as logarithmic depth and for each $t \in V(\mathcal{T})$, it holds that $|\tau^{-1}(t)| \leq 4$. Using this tree partition, we obtain a tree decomposition $(\mathcal{T}, \beta_1)$ whose underlying tree is $\mathcal{T}$, and each bag $\beta_1(t)$, $t \in V(\mathcal{T})$ is a union of at most 4 bags of $(T, \beta)$; $\beta_1(t) = \bigcup_{x \in \tau^{-1}(t)} \beta(x)$. This tree decomposition already has bounded height, small adhesion size and each bag is a union of at most four unbreakable bags of $(T, \beta)$. From here with some extra work we obtain a tree decomposition with unbreakable bags as well. For this we use other properties of $(\mathcal{T}, \tau)$ to modify $(\mathcal{T}, \beta_1)$ to obtain our desired tree decomposition. As outlined above, for our result we need tree partitions of a tree satisfying some properties. We now define such tree partitions below and show how to find one in polynomial time.

▶ **Definition 3** (Nice Tree Partition). *A tree partition $(\mathcal{T}, \tau)$ of a tree $T$ is said to be a nice tree partition if it satisfies the following properties:*

1. *$\mathcal{T}$ has depth at most $\lceil \log_2 |V(T)| \rceil$*
2. *for each $t \in V(\mathcal{T})$, $1 < |\tau^{-1}(t)| \leq 4$.*
3. *for each $t \in V(\mathcal{T})$, $T[V_t]$ is a subtree of $T$, where $V_t = \bigcup_{x \in V(\mathcal{T}_t)} \tau^{-1}(x)$.*

We now show how to find a nice tree partition of a tree in polynomial time. For this we use a recursive procedure. The core idea in each recursive step is to map a balanced separator $b$ of the tree to the root of the tree partition. To ensure the connectivity properties of a tree partition, we have a set $M$ of marked vertices in the tree that are always mapped to the root of the tree partition in addition to $b$. Then for each connected component in the forest obtained by removing $M \cup \{b\}$ from the tree, we mark new vertices and recurse. We need some extra work to make sure that every node in the tree partition is mapped to by only a constant number of nodes in the tree. For this we ensure that in each recursive call we mark only a few ($\leq 2$) new vertices.

▶ **Lemma 4.** *Given a tree $T$ on $n$ vertices with root $r$, one can in polynomial time compute a rooted nice tree partition $(\mathcal{T}, \tau)$ of $T$ with root $r_{\mathcal{T}}$ such that $\tau(r) = r_{\mathcal{T}}$.*

**Proof.** We now design a procedure `FindBalancedTP` that takes as an argument a tree $T'$, and a non-empty set $M \subseteq V(T')$ of size at most 2, and returns a rooted nice tree partition $(\mathcal{T}', \tau')$ of $T'$ with root $r'$, such that $M \subseteq \tau'^{-1}(r')$. We will invoke this procedure on the input tree $T$ with $M = \{r\}$, where $r$ is the root of $T$ to obtain a rooted nice tree partition $(\mathcal{T}, \tau)$ of $T$.

In the procedure `FindBalancedTP`$(T', M)$ we carry out the following steps:

- We find a balanced bisector $b$ of $T'$ and initialize $M' = M \cup \{b\}$.
- If all vertices in $M'$ do not lie on a path in $T'$, we add an extra vertex $x$ to $M'$. Let $x$ be the last common vertex on the path from $m_1$ to $m_2$ and the path from $m_1$ to $b$ in $T$. Modify $M' = M' \cup \{x\}$.
- For each tree $H$ in the forest $T' \setminus M'$, we recursively call `FindBalancedTP`$(H, M_H)$ where $M_H = N_{T'}(M') \cap V(H)$ is the set of neighbors of vertices in $M'$ in $H$. Let $(\mathcal{H}, \tau_H)$ be the tree partition returned by this procedure call.

- We now construct a tree partition $(\mathcal{T}', \tau')$ with root $r'$. We assign $\tau'^{-1}(r') = M'$. Then for each tree $H$ in the forest $T' \setminus M'$, we make $\mathcal{H}$ a subtree of $\mathcal{T}'$ by attaching the root of $\mathcal{H}$ as a child to $r'$. Further for each $t \in V(\mathcal{H})$ we assign $\tau'^{-1}(t) = \tau_H(t)$.
- We return $(\mathcal{T}', \tau')$.

We now prove that for any tree $T'$ with root $r'$, and any non-empty subset $M \subseteq V(T')$ with $0 < |M| \leq 2$, the procedure `FindBalancedTP`$(T', M)$ returns a rooted nice tree partition $(\mathcal{T}', \tau')$ of $T'$ with root $r'$ such that $M \subseteq \tau'^{-1}(r')$. The proof is by induction.

*Base Case $|V(T')| = 1$ or $V(T') = M'$:* In this case $V(\mathcal{T}') = \{r'\}$ and $\tau(r') = M'$. Observe that $0 < |M'| \leq 4$. This is because the procedure is called with a non-empty set $M$ of size at most two. Then, the procedure initializes $M' = M$, and adds at most two other vertices ($b$ and $x$) in $V(T')$ to $M'$. Thus $(\mathcal{T}', \tau')$ is a nice tree partition with root $r'$ and $M \subseteq \tau'^{-1}(r')$.

Now we prove the *inductive case* where $V(T')$ has size $i$, $i > 1$ and $V(T') \neq M'$. For this we assume the inductive hypothesis that the procedure returns a tree partition with the desired properties for all trees $H$ having less than $i$ vertices and non-empty sets $M' \subseteq V(H)$ of size at most two.

Let $H$ be a tree in the forest $T' \setminus M'$. We now show that $|V(H)| \leq \lceil |V(T')|/2 \rceil$ and $1 < |M_H| \leq 2$. By construction $M'$ contains the vertex $b$, a balanced bisector of $T'$. Thus $V(H)$ has size at most $\lceil |V(T')|/2 \rceil$. $|M_H| > 1$ since $H$ contains at least one child of $M'$ since it is a tree in the forest $T' \setminus M'$. To show $|M_H| \leq 2$, we first show there is a vertex $s$ in $M'$ such that in the forest $T' \setminus \{s\}$ every vertex $s' \in M' \setminus \{s\}$ is contained in a different tree. If all vertices in $M \cup \{b\}$ do not lie on a path in $T'$, then $s$ is just the vertex $x$ we added to $M'$ in the second step of the procedure. If the vertices of $M \cup \{b\}$ lie on a path $P$ in $T'$ then $M' = M \cup \{b\}$. In this case if $|M'| \leq 2$, then $s$ is any vertex in $M'$. On the other hand if $|M'| = 3$, then $s$ is the second vertex from $M'$ in the path $P$. Due to the property of $s$, $H$ may contain a child of $s$ and a child of one other $s' \in M' \setminus \{s\}$. Thus $|M_H| \leq 2$.

Since $H$ is a tree with $|V(H)| \leq \lceil |V(T')|/2 \rceil$ and $1 < |M_H| \leq 2$, by induction the tree partition $(\mathcal{H}, \tau_H)$ returned by the call to the procedure `FindBalancedTP`$(H, M_H)$ is a nice tree partition with root $r_H$ and $M_H \subseteq \tau_H^{-1}(r_H)$.

We now show that $(\mathcal{T}, \tau')$ is a rooted tree partition of $T'$ with root $r'$. First we show that each vertex $v \in \mathcal{T}$ is mapped to exactly one vertex $t \in \mathcal{T}$ by $\tau'$. If $v \in M'$, then $\tau(v)$ is mapped to $r'$. If $v \in H$, $H \in T' \setminus M'$, then since $(\mathcal{H}, \tau_H)$ is a rooted tree partition of $H$, $\tau(v) = \tau_H(v)$ by construction. Next we show that each edge $(x, y) \in T'$ satisfies either $\tau'(x) = \tau'(y)$ or $(\tau'(x), \tau'(y)) \in E(\mathcal{T})$, by considering three cases. (i) If $x, y \in M'$, then this is trivially true. (ii) If $x, y \notin M'$ then $x, y$ must belong to some tree $H \in T' \setminus M'$ and thus by induction $(\tau'(x) = \tau_H(x), \tau'(y) = \tau_H(y)) \in E(\mathcal{T})$. (iii) If $x \in M'$ and $y \notin M'$, by construction, $\tau(x) = r'$ and $y \in M_H$ for some $H \in T' \setminus M'$. Since $M_H \subseteq \tau_H^{-1}(r_H)$ and $r_H$ is a child of $r'$ in $\mathcal{T}'$, $(\tau'(x) = r, \tau'(y) = r_H) \in E(\mathcal{T})$.

$M \subseteq \tau'^{-1}(r')$ just by construction. We now prove properties $(1) - (4)$ in Definition 3 to show that $(\mathcal{T}', \tau')$ is a nice tree partition. Recall that for each $H \in T' \setminus M'$, $H$ is a subtree of $T'$ with $r_H$ being a child of $r'$ in $\mathcal{T}'$. Then, since $|V(H)| \leq \frac{|V(T)|}{2}$, by inductive hypothesis, $\mathcal{H}$ has depth at most $\lceil \log_2(|V(T')|/2) \rceil = \lceil \log_2(|V(T')|) \rceil - 1$. Therefore, $\mathcal{T}'$ has depth $\lceil \log_2 |V(T')| \rceil$, since the addition of the root $r'$ increases the depth by 1. For each $t' \in V(\mathcal{T}')$, $1 < |\tau'^{-1}(t')| \leq 4$ since $1 < |\tau'^{-1}(r')| \leq 4$ and for each $H \in T' \setminus M'$ and for each $t \in V(\mathcal{H})$, $1 < |\tau_H^{-1}(t)| \leq 4$. For each $t' \in V(\mathcal{T}')$, $T'[V_{t'}]$ is a subtree of $T'$, where $V_{t'} = \bigcup_{x \in V(\mathcal{T}'_{t'})} \tau'^{-1}(x)$ because for each $H \in T' \setminus M'$ and $t \in V(\mathcal{H})$, $H[V_t]$ is a subtree of $H$, where $V_t = \bigcup_{x \in V(\mathcal{H}_t)} \tau_H^{-1}(x)$ and $H$ is subtree of $T'$. This completes the proof. ◀

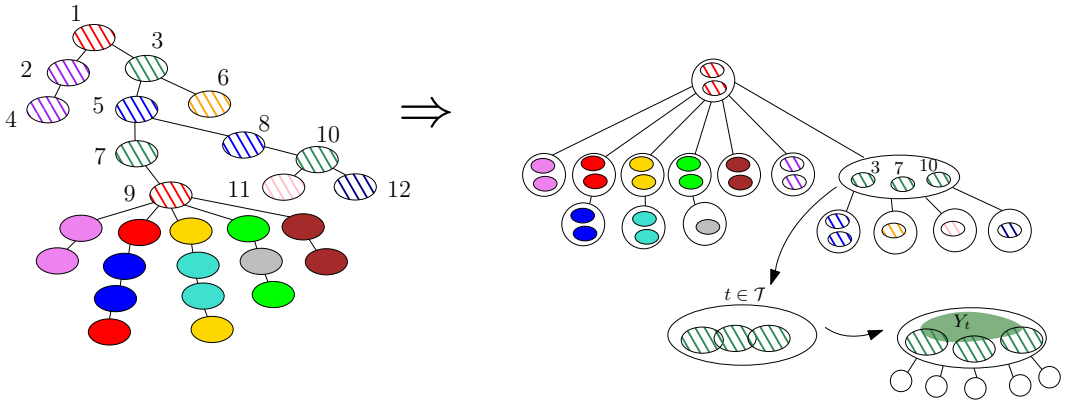

**Figure 1** Left: Tree decomposition $(T, \beta)$ with bags colored for easy understanding. Right: tree decomposition $(\mathcal{T}, \beta_1)$ that is constructed using a tree partition $(\mathcal{T}, \tau)$. The bags in $(T, \beta)$ are mapped according to $\tau$ to $(\mathcal{T}, \beta_1)$. The bags in $\tau^{-1}(t)$, $t \in \mathcal{T}$ can overlap as demonstrated by bags $3, 7, 10$ but their overlap is small and contained in $Y_T$.

Let $(T, \beta)$ be a rooted tree decomposition of a graph $G$ with root $r$, $(q, k)$-unbreakable bags and adhesions of size at most $k$. Further let $(\mathcal{T}, \tau)$ be a rooted nice tree partition of $T$ with root $r_{\mathcal{T}}$ as provided by Lemma 4. We now show that we can obtain a natural rooted tree decomposition $(\mathcal{T}, \beta_1)$ of $G$ where the tree in the decomposition is $\mathcal{T}$. Here $\beta_1 : V(\mathcal{T}) \to 2^{V(G)}$ and $\beta_1(t) = \bigcup_{x \in \tau^{-1}(t)} \beta(x)$. See Figure 1 for an example of $(\mathcal{T}, \beta_1)$.

From now on we fix $G, (T, \beta), (\mathcal{T}, \tau)$, and $\beta_1$ for the rest of the section. We remark that to prove $(\mathcal{T}, \beta_1)$ is a tree decomposition we will not need the *nice* properties of $(\mathcal{T}, \tau)$ nor the properties of the bags and adhesions in $(T, \beta)$. We will later use them to deduce some helpful structural properties of $(\mathcal{T}, \beta_1)$. Figure 1 is the accompanying figure for the proof of the following lemma.

▶ **Lemma 5** $(*)$**.** *The pair $(\mathcal{T}, \beta_1)$ is a tree decomposition of $G$.*

Observe that since $(\mathcal{T}, \tau)$ is a nice tree partition of $T$, the tree decomposition $(\mathcal{T}, \beta_1)$ has depth at most $\lceil \log_2 |V(G)| \rceil$ and each of its bags is a union of at most four bags of $(T, \beta)$. We now prove a few other useful properties of $(\mathcal{T}, \beta_1)$ that will help us design our desired tree decomposition.

▶ **Lemma 6.** *There exists a function $\gamma : V(\mathcal{T}) \to V(T)$, and a set $Y_t \subseteq \beta_1(t)$ for each node $t \in V(\mathcal{T})$, that satisfy, for each node $t \in V(\mathcal{T})$, the following properties:*

1. $|Y_t| \leq 8k$
2. *If $t$ is not the root $r_{\mathcal{T}}$ then $\beta_1(\mathcal{P}(t)) \cap \beta_1(t) \subseteq Y_t$*
3. *for each distinct $x, y \in \tau^{-1}(t)$, $\beta(x) \cap \beta(j) \subseteq Y_t$*
4. *for each child $t_c$ of $t$ in $\mathcal{T}$, it holds that $t = \tau(\gamma(t_c))$ and $\beta_1(t_c) \cap \beta_1(t) \subseteq Y_t \cup \beta(\gamma(t_c))$*

*Furthermore, $\gamma$ and the sets $Y_t$ for each $t \in V(\mathcal{T})$ can be computed in polynomial time.*

**Proof.** For $e = (x, x') \in E(T)$, let $\sigma(e) = \beta(x) \cap \beta(x')$ be the adhesion of edge $e$ in $(T, \beta)$.

For $r_{\mathcal{T}}$, let $T_{r_{\mathcal{T}}} = \bigcup_{x \in \tau^{-1}(r_{\mathcal{T}})} \sigma((x, \mathcal{P}(x)))$ and $\gamma(r_{\mathcal{T}}) = r$. For $t \in V(\mathcal{T})$, $t \neq r_{\mathcal{T}}$, let $E_t = \{e : e = (x, y) \in E(T), x \in \tau^{-1}(\mathcal{P}(t)), y \in \tau^{-1}(t)\}$. Then let $Y_t = \bigcup_{x \in \tau^{-1}(r_{\mathcal{T}})} \sigma((x, \mathcal{P}(x))) \cup \bigcup_{e \in E_T} \sigma(e)$.

For each $x$ in $\tau^{-1}(\mathcal{P}(t))$, there exists at most one $y \in \tau^{-1}(t)$ such that $(x, y) \in E(T)$. This is because $T[V_t]$ is connected, where $t = \bigcup_{x \in V(\mathcal{T}_t)} \tau^{-1}(x)$. If $x$ has an edge to two vertices in $\tau(t)$, then there would be a cycle in $T$. Thus, $|E_t| \leq 4$. Further since $\mathcal{T}$ is from a nice tree partition, $|\tau^{-1}(t)| \leq 4|$. Therefore $|Y_t| \leq 8k$ for each $t \in V(\mathcal{T})$.

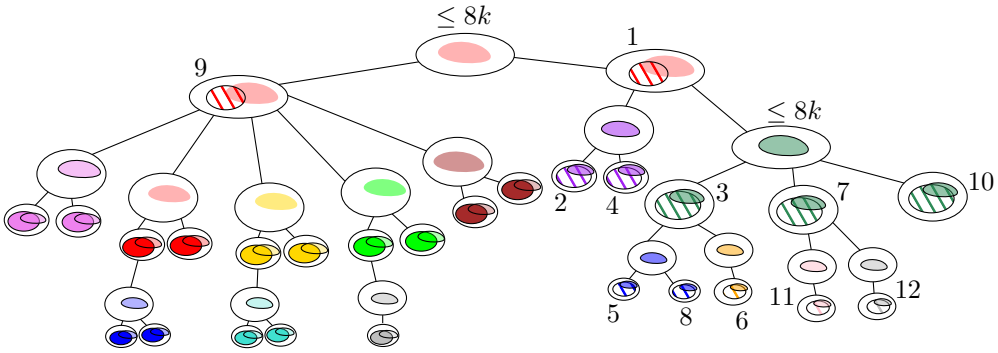

**Figure 2** This shows the final tree decomposition $(T^*, \beta^*)$ constructed using $(T, \beta)$ and $(\mathcal{T}, \beta_1)$ as shown in Fig 1. $(T^*, \beta^*)$ is our desired tree decomposition with low depth, unbreakable bags and small adhesions. Recall that, $V(T^*) = V(T) \cup V(\mathcal{T})$ and $E(T^*) = \{(\tau(x), x) : x \in T\} \cup \{(\gamma(t), t) : t \in \mathcal{T} \setminus \{r_{\mathcal{T}}\}\}$.

For $t \neq r_{\mathcal{T}}$, $t \in V(\mathcal{T})$. Since $(T, \beta)$ is a tree decomposition and $E_t$ are the only set of edges in $\mathcal{T}$ between vertices in $\tau^{-1}(t)$ and $\tau^{-1}(\mathcal{P}(t))$. Further since $(\mathcal{T}, \beta_1)$ is a tree decomposition with $\beta_1(t) = \bigcup_{x \in \tau^{-1}(t)} \beta(x)$, $\beta_1(\mathcal{P}(t)) \cap \beta_1(t) \subseteq Y_t$.

Recall that $(T, \beta)$ is a tree decomposition. Therefore, for any two nodes $x, y \in V(T)$, consider a vertex $v \in \beta(x) \cap \beta(y)$. Note that $v$ must belong to every bag of the node appearing on the unique $x$ to $y$ path in $T$. Let $z \in V(T)$ be the least common ancestor of $x$ and $y$ – note that $z$ may be equal to $x$ or $y$ or neither. Suppose $z \notin \{x, y\}$. Then, $v$ must appear in $\beta(x) \cap \beta(\mathcal{P}(x)) = \sigma(x, \mathcal{P}(x))$, as well as in $\sigma(y, \mathcal{P}(y))$. Otherwise, if $z = x$ (w.l.o.g.), then $v \in \sigma(y, \mathcal{P}(y))$. Since $Y_t \supseteq \sigma(x, \mathcal{P}(x)) \cup \sigma(y, \mathcal{P}(y))$, we get the third property.

Let $t_c \in V(\mathcal{T})$, $t_c \neq r_{\mathcal{T}}$. Further let $t = \mathcal{P}(t_c)$ in $\mathcal{T}$. We now show that for all but at most one vertex $x \in \tau^{-1}(t)$, $\beta_1(t_c) \cap \beta(x) \subseteq Y_t$. If for all $x \in \tau^{-1}$, $\beta_1(t_c) \cap \beta(x) \subseteq Y_t$ then we assign $\gamma(t_c) = y$ for some $y \in \tau^{-1}$. In this case, property 4 directly holds. Otherwise there is one vertex $x \in \tau^{-1}(t)$ such that $\beta_1(t_c) \cap \beta(x)$ is not a subset of $Y_t$, then we assign $\gamma(t_c) = x$. Here too, property 4 holds.

Now we show that for all but at most one vertex $x \in \tau^{-1}(t)$, $\beta_1(t_c) \cap \beta(x) \subseteq Y_t$. Since $\mathcal{T}$ is a nice tree partition, $T[V_{t_c}]$ is a subtree of $T$, where $V_{t_c} = \bigcup_{x \in V(\mathcal{T}_{t_c})} \tau^{-1}(x)$. Next $V_{t_c}$ does not contain $r_T$ because $t_c \neq r_{\mathcal{T}}$ and $\tau(r_t) = r_{\mathcal{T}}$. Further $V_{t_c}$ is tree in the forest $T \setminus \tau^{-1}(t)$. Every vertex in $\tau^{-1}(t)$ has at most one neighbor in $V_{t_c}$ otherwise it will form a cycle. Since $T$ is a rooted tree there is at most one node $x \in \tau^{-1}(t)$ whose neighbor in $V_{t_c}$ is not an ancestor (or a parent) of $x$. Thus for all others $\beta(x) \cap \beta_1(t_c) \subseteq \sigma(x, \mathcal{P}(x)) \subseteq Y_T$. ◀

Let $\gamma : V(\mathcal{T}) \to V(T)$ and $Y_t \subseteq \beta_1(t)$ for each node $t \in \mathcal{T}$ be function and sets given by Lemma 6. We now define a pair $(T^*, \beta^*)$ based on $T, \mathcal{T}, \gamma$ and $Y_t$ that we will prove to be a tree decomposition of $G$ having all our desired properties including unbreakable bags.

▶ **Definition 7** ($(T^*, \beta^*)$). *Let $T^*$ be a graph with $V(T^*) = V(T) \cup V(\mathcal{T})$ and $E(T^*) = \{(\tau(x), x) : x \in T\} \cup \{(\gamma(t), t) : t \in \mathcal{T} \setminus \{r_{\mathcal{T}}\}\}$. Also let $\beta^* : V(T^*) \to 2^{V(G)}$ be a function with $\beta^*(t) = Y_t$, for $t \in \mathcal{T}$ and $\beta^*(x) = Y_{\tau(x)} \cup \beta(x)$ for $x \in T$.*

In the following, we show that $(T^*, \beta^*)$ is a tree decomposition of $G$ (see Figure 2).

▶ **Lemma 8** ($*$). *$(T^*, \beta^*)$ is a rooted tree decomposition of $G$. Further $(T^*, \beta^*)$ satisfies the following properties:*

1. *every adhesion of $(T^*, \beta^*)$ is of size at most $8k$*
2. *every bag of $(T^*, \beta^*)$ is $(q + 8k, k)$-unbreakable in $G$.*
3. *$T^*$ has depth at most $2\lceil \log_2 |V(G)| \rceil$*

We are now ready to prove the main theorem of this section.

▶ **Theorem 9.** *There exists a polynomial-time algorithm that takes input an $n$-vertex graph $G$ and positive integers $k$ and $q$, and a rooted tree decomposition $(T, \beta)$ of $G$ satisfying the following properties:*
1. *every adhesion of $(T, \beta)$ is of size at most $k$*
2. *every bag of $(T, \beta)$ is $(q, k)$-unbreakable in $G$*

*and finds a compact tree decomposition $(T', \beta')$ of $G$ satisfying the following properties:*
1. *every adhesion of $(T', \beta')$ is of size at most $8k$*
2. *every bag of $(T', \beta')$ is $(q + 8k, k)$-unbreakable in $G$.*
3. *$T'$ has depth at most $2\lceil \log_2 n \rceil$.*

**Proof.** Let $(T, \beta)$ be the input tree decomposition of $G$. We first compute a nice tree partition $(\mathcal{T}, \tau)$ of $T$ using Lemma 4. Then we obtain the tree decomposition $(\mathcal{T}, \beta_1)$ of $G$ where $\beta_1 : V(G) \to V(\mathcal{T})$ and $\beta_1(t) = \bigcup_{x \in \tau^{-1}(t)} \beta(x)$ – it is a tree decomposition by Lemma 5.

Let $\beta^* : V(T^*) \to 2^{V(G)}$ be a function with $\beta^*(t) = Y_t$, for $t \in \mathcal{T}$ and $\beta^*(x) = Y_{\tau(x)} \cup \beta(x)$ for $x \in T$. We compute the tree decomposition $(T^*, \beta^*)$ with $V(T^*) = V(T) \cup V(\mathcal{T})$ and $E(T^*) = \{(\tau(x), x) : x \in T\} \cup \{(\gamma(t), t) : t \in \mathcal{T} \setminus \{r_{\mathcal{T}}\}\}$. By Lemma 8 it satisfies all our required properties except compactness. We can in polynomial time obtain a compact tree decomposition $(T', \beta')$ whose each bag is a subset of some bag of $(T^*, \beta^*)$ and whose height is the same as $\mathcal{T}^*$ [5]. Thus the tree decomposition $(T', \beta')$ will satisfy all our required properties. ◀

The following corollary directly follows from Theorem 9, and a known result ([9]) that outputs a tree decomposition of a graph satisfying the premise of Corollary 10 in time $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$.

▶ **Corollary 10.** *Given an $n$-vertex graph $G$ and an integer $k$, one can in time $2^{\mathcal{O}(k \log k)} n^{\mathcal{O}(1)}$ compute a rooted compact tree decomposition $(T, \beta)$ of $G$ such that:*
1. *Every adhesion of $(T, \beta)$ is of size at most $8k$*
2. *Every bag of $(T, \beta)$ is $(9k, k)$-unbreakable in $G$*
3. *$T$ has depth at most $2\lceil \log_2 n \rceil$*

## 4 Exact and Approximation algorithms

Let $(G, c, k, r^\circ, \chi)$ be an instance of Fair Bisection and let $n = |V(G)|$. We start by invoking the algorithm of Theorem 10 with $G$ and $k$ to obtain a rooted compact tree decomposition $(T, \beta)$ of $G$ with root $r$, having $(9k, k)$-edge-unbreakable bags and adhesions of size at most $8k$. This takes time $2^{\mathcal{O}(k \log k)} n^{\mathcal{O}(1)}$. Recall that an edge cut $(A, B)$ is $(\epsilon, r^\circ)$-*fair* if $A$ and $B$ contain no more than $r_i(1 + \epsilon)$ and $(c_i - r_i)(1 + \epsilon)$ vertices respectively.

▶ **Theorem 11.** *Given an instance $(G, c, k, r^\circ, \chi)$ of Fair Bisection and $\epsilon > 0$ there exists an algorithm that in time $2^{\mathcal{O}(k \log k)} \cdot \left(\frac{c}{\epsilon}\right)^{\mathcal{O}(c)} \cdot n^{\mathcal{O}(1)}$ finds an $(\epsilon, r^\circ)$-fair edge cut of $G$ if one exists, else returns no.*

Given a subset $S \subseteq V(G)$, we use $\chi^\circ(S)$ to denote the $c$ length tuple where the $i^{th}$ entry is the number of vertices $v$ in $S$ having color $i$, i.e. $\chi(v) = i$. We remark that we use $^\circ$ to denote tuples of integers of length $c$. Further we use operators such as $+, -$, scalar multiplication, and $\lceil\rceil$ on tuples, which perform the respective operations on each entry in the tuple(s).

For a node $t \in V(T)$ recall that $\gamma(t) = \bigcup_{s:\text{ descendant of } t} \beta(s)$, $\alpha(t) = \gamma(t) \backslash \sigma(t)$, $G_t = G[\gamma(t)] - E(G[\sigma(t)])$. We perform bottom-up dynamic programming on $(T, \beta)$. For each node $t \in V(T)$, we first define a Boolean function $f_t : \{0, \cdots, k\} \times 2^{\sigma(t)} \times \{0, \cdots, n\}^c \times \{0, \cdots, n\}^c \to \{\mathsf{True}, \mathsf{False}\}$. For each integer $w \in \{0, \cdots, k\}$, subset $A_t \subseteq \sigma(t)$, and $c$ length tuples $a^\circ$ and $b^\circ$ with $a^\circ, b^\circ \in \{0, \cdots, n\}^c$, we define the following.

▶ **Definition 12.** *$f_t(w, A_t, a^\circ, b^\circ) = \mathsf{True}$ if there exists an edge cut $(A, B)$ of $G_t$ that satisfies the following properties: (1) $(A, B)$ has order at most $w$, (2) $A \cap \sigma(t) = A_t$, (3) $\chi^\circ(A \cap \alpha(t)) = a^\circ$, and (4) $\chi^\circ(B \cap \alpha(t)) = b^\circ$. If such a cut does not exist, $f_t(w, A_t, a^\circ, b^\circ) = \mathsf{False}$. Further if $f_t(w, A_t, a^\circ, b^\circ) = \mathsf{True}$, we say an edge cut $(A, B)$ of $G_t$ that satisfies properties $1 - 4$ **realizes** $f_t(w, A_t, a^\circ, b^\circ)$.*

From the definition of $f_t$ one can make the following observation.

▶ **Observation 13.** *$(G, c, k, r^\circ, \chi)$ is a yes-instance to* Fair Bisection *if and only if for $f_r(k, \emptyset, r^\circ, c - r^\circ) = \mathsf{True}$, where $r$ is the root of $T$.*

In order to reduce the size of the domain of $f$ (and hence the running time), we work with the *reduced* domain $D = \left\{(1 + \delta)^i : i \geq 0\right\}$. This will approximate the number of vertices of each color at either side of the cut to the nearest power of $1 + \delta$, where $\delta > 0$ is a parameter whose value will be fixed later.

Let $\mathcal{C}_t$ be the set of all possible edge-cuts $(A, B)$ of $G_t$. To compute $f_t$ we have a *table* $M_t : \{0, \cdots, k\} \times 2^{\sigma(t)} \times D^c \times D^c \to \{\mathcal{C}_t \cup \perp\}$ that satisfies properties $M_t \to f_t$ and $f_t \to M_t$ (defined below in Definition 14 and 16). $M_t$ will help us to approximately obtain $f_t$. Let $z \geq 0$ be a sufficiently large constant; for example, $z = 10$ suffices. We have Definitions 14 and 16 that will be crucial towards proving the correctness of the approximation algorithm.

▶ **Definition 14** (Property $M_t \to f_t$)**.** *If $M_t(w, A_t, a^\circ, b^\circ) \neq \perp$ then $\exists\ x^\circ \in \{0, \cdots, n\}$ and $y^\circ \in \{0, \cdots, n\}$ such that:*

- *$f_t(w, A_t, x^\circ, y^\circ) = \mathsf{True}$ and $M_t(w, A_t, a^\circ, b^\circ)$ is an edge-cut that realizes $f_t(w, A_t, x^\circ, y^\circ)$*
- *$a^\circ \leq x^\circ \leq (1 + \delta)^{z \cdot \mathsf{ht}(t) \log^2 n} \cdot a^\circ$*
- *$b^\circ \leq y^\circ \leq (1 + \delta)^{z \cdot \mathsf{ht}(t) \log^2 n} \cdot b^\circ$*

▶ **Definition 15** (Global-feasible edge cut)**.** *An edge cut $(A, B)$ is global-feasible if there exists an edge cut $(A', B')$ of $G$ having order at most $k$ which induces the cut $(A, B)$ on $A \cup B$.*

▶ **Definition 16** (Property $f_t \to M_t$)**.** *If $f_t(w, A_t, x^\circ, y^\circ) = \mathsf{True}$ and there is a global-feasible edge cut $(A, B)$ of $G_t$ that realizes it then $\exists\ a^\circ \in D^c$ and $b^\circ \in D^c$ such that:*

- *$M_t(w, A_t, a^\circ, b^\circ) \neq \perp$*
- *$a^\circ \leq x^\circ \leq (1 + \delta)^{z \cdot \mathsf{ht}(t) \log^2 n} \cdot a^\circ$*
- *$b^\circ \leq y^\circ \leq (1 + \delta)^{z \cdot \mathsf{ht}(t) \log^2 n} \cdot b^\circ$*

▶ **Definition 17** (Good $M_t$)**.** *$M_t$ is* good *if it satisfies properties $M_t \to f_t$ and $f_t \to M_t$.*

▶ **Lemma 18.** *For each $\epsilon > 0$ and $\delta = \frac{\epsilon}{2z \log^3 n}$, if $f_r(k, \phi, r^\circ, c^\circ - r^\circ) = \mathsf{True}$ and $M_r$ is good, then $\exists\ a^\circ, b^\circ \in D^c$ such that $M_r(k, \phi, a^\circ, b^\circ)$ is a $(\epsilon, r^\circ)$-fair edge cut of $G$.*

**Proof.** We first note that, if $\delta \coloneqq \frac{\epsilon}{2z \log^3 n}$, then $(1+\delta)^{z \cdot \log^3 n} \leq 1+\epsilon$. This is because $\ln(1+\epsilon) \geq \frac{\epsilon}{1+\epsilon} \geq \frac{\epsilon}{2}$, since $\epsilon \in (0, 1)$, which implies that $(1 + \delta)^{z \cdot \log^3 n} \leq \exp\left(\frac{\epsilon}{2z \log^3 n} \cdot z \log^3 n\right) \leq \exp\left(\frac{\ln(1+\epsilon)}{z \log^3 n} \cdot z \log^3 n\right) = 1 + \epsilon$. Furthermore, $\log_{1+\delta} n = (\log n/\epsilon)^{\mathcal{O}(1)}$.

Let $f_r(k, \phi, r^\circ, c^\circ - r^\circ) = \mathsf{True}$ and $M_r$ satisfy properties $M_r \to f_r$ and $f_r \to M_r$. Since $ht(T) = \log n$, by the previous claim $(1+\delta)^{z \cdot \mathsf{ht}(t) \log^2 n} \leq 1 + \epsilon$. So by property $f_r \to M_r$, $\exists\ a^\circ, b^\circ \in D^c$ such that: (1) $M_r(k, \phi, a^\circ, b^\circ) \neq \perp$, (2) $a^\circ \leq r^\circ \leq (1+\epsilon) \cdot a^\circ$, and $b^\circ \leq c^\circ - r^\circ \leq (1+\epsilon) \cdot b^\circ$.

Further by property $M_r \to f_r$, since $M_r(k, \phi, a^\circ, b^\circ) \neq \perp$, $\exists\ x^\circ, y^\circ \in \{0, \cdots, n\}$ such that, (1) $f_r(k, \phi, x^\circ, y^\circ) = \mathsf{True}$ and $M_r(k, \phi, a^\circ, b^\circ)$ is an edge-cut that realizes $f_r(k, \phi, x^\circ, y^\circ)$, (2) $a^\circ \leq x^\circ \leq (1+\epsilon) \cdot a^\circ \leq (1+\epsilon) \cdot r^\circ$, and (3) $b^\circ \leq y^\circ \leq (1+\epsilon) \cdot b^\circ \leq (1+\epsilon) \cdot (r^\circ - c^\circ)$. Thus, $M_r(k, \phi, a^\circ, b^\circ)$ is a $(\epsilon, r^\circ)$-fair edge-cut of $G$. This completes our proof. ◀

Lemma 18 shows us that computing a good table $M$ efficiently is sufficient for obtaining our final approximation. We now state as a theorem that we can compute a good $M_t$ assuming a good $M_{t'}$ has been computed for each $t' \in \mathsf{child}(t)$.

▶ **Lemma 19** (∗). *There exists an algorithm that takes as input $t \in V(T)$, $\delta > 0$, $(T, \beta)$, and a good $M_{t'}$ for each $t' \in \mathsf{child}(t)$ and computes a good $M_t$ in time $2^{\mathcal{O}(k \log k)} (\log_{1+\delta} n)^{\mathcal{O}(c)} n^{\mathcal{O}(1)}$.*

Assuming Lemma 19 and Lemma 18, the correctness of our algorithm follows. Setting $\delta$ as in Lemma 18, we obtain our desired runtime thus proving Theorem 11.

**Proof of Theorem 11.** Let $\delta := \frac{\epsilon}{2z \log^3 n}$. In our algorithm we compute $M$ by computing good $M_t$ using Lemma 19 for each $t \in V(T)$, bottom up, starting from leaves of $T$ to root of $T$. We finally go over each $a^\circ, b^\circ \in D^c$ and output a cut $M_r(k, \phi, a^\circ, b^\circ)$ that is a $(\epsilon, r^\circ)$-fair edge cut of $G$ if one exists.

The correctness follows directly from the definition of $f$ and Lemma 18. The time taken by our algorithm is equal the size of domain of $M$ times the time taken to compute each entry in $M$. The size of the domain of $M$ is at most $2^{\mathcal{O}(k)} (\log_{1+\delta} n)^{\mathcal{O}(c)} n^{\mathcal{O}(1)}$ because $|D| \leq \log_{1+\delta} n$ and all adhesions in $(T, \beta)$ have size at most $8k$. The time taken to compute each entry in $M$ is $2^{\mathcal{O}(k \log k)} (\log_{1+\delta} n)^{\mathcal{O}(c)} n^{\mathcal{O}(1)}$ by Lemma 19.

Using $\log_{1+\delta} n = (\log n / \epsilon)^{\mathcal{O}(1)}$ and a standard case analysis on whether $c \leq \frac{\log n}{\log \log n}$, it follows that the total time taken is $2^{\mathcal{O}(k \log k)} (\log_{1+\delta} n)^{\mathcal{O}(c)} n^{\mathcal{O}(1)} \leq 2^{\mathcal{O}(k \log k)} \left(\frac{c}{\epsilon}\right)^{\mathcal{O}(c)} \cdot n^{\mathcal{O}(1)}$. ◀

## Computing $M_t$: A sketch of proof of Lemma 19

In particular, we design an algorithm that takes as input a graph $G$, the tree decomposition $(T, \beta)$ and a node $t$ of $T$, together with dynamic programming tables $M_{t'}$ for every child $t'$ of $t$, and outputs the appropriate dynamic programming table $M_t$ (which is good) for $t$. This algorithm is an adaptation of a similar step performed by Cygan et al. [10] in their algorithm for the Minimum Bisection problem. The algorithm of Cygan et al. [10] proceeds by a random coloring step, followed by a "knapsack"-like dynamic programming algorithm. Our algorithm proceeds in a similar manner, but faces the following key difficulty: in order to keep time and space bounded by $f(k, c, \epsilon) n^{O(1)}$ we can only store approximate values in the knapsack dynamic programming table (the table satisfies soundness and completeness properties similar to Definition 17). Therefore, after computing each entry of the table (from previous entries) we need to perform a rounding step that introduces a $(1 + (\frac{\epsilon}{\log n})^{\mathcal{O}(1)})$ multiplicative factor in the error bound. The standard way of solving Knapsack involves considering each item in the input one by one, however this would lead to the rounding error possibly accumulating and getting out of hand. We overcome this by organizing the dynamic program in a complete binary tree. That is, split the items in two equal sized groups, compute dynamic programming tables for the two groups recursively, and combine

the dynamic programming tables to the two halves to a dynamic programming for all the items. This ensures that the total error is upper bounded by a multiplicative factor of $(1+(\frac{\epsilon}{\log n})^{\mathcal{O}(1)})^{\mathcal{O}(\log^3 n)} = 1+\mathcal{O}(\epsilon)$.

## 5 Hardness

Here, we sketch the proof of our result that establishes W[1]-hardness of Fair Bisection. To this end, we first consider the following problem, called Multi-Dimensional Subset Sum. In this problem, we are given an instance $(\mathcal{V}, T)$, where $\mathcal{V} = \{V_1, \ldots, V_n\}$, such that each $V_i \in \mathcal{V}$ is a $d$-dimensional vector, i.e., $V_i \in \mathbb{Z}^d_{\geq 0}$; and $T \in \mathbb{Z}^d_{\geq 0}$ is the $d$-dimensional *target vector*. The task is to determine whether there exists a subset $U \subseteq \mathcal{V}$ such that $\sum_{V_i \in \mathcal{U}} V_i = T$?

Although it is folklore that Multi-Dimensional Subset Sum is W[1]-hard parameterized by the dimension $d$, we are unable to find a reference for this result. Thus, we give a reduction from Binary Constrainted Satisfaction Problem to MDSS; the W[1]-hardness of the former problem was established in [23, 21]. In fact, our reduction shows that MDSS is W[1]-hard even when the integer entries in each vector are bounded by a polynomial in $n$. As the first step of our reduction, given an instance $(\mathcal{V}, T)$ of MDSS, we reduce it to Multi-Dimensional Partition (MDP), where the target vector $T$ is exactly half of the sum of entries along each dimension. Now, for each vector $V_i \in \mathcal{V}$, we create a subset $U_i$ of vertices, which contains exactly $V_i(j)$ many vertices of color $1 \leq j \leq d$. Then, we arbitrarily choose a vertex in $U_i$ and connect the rest of the vertices in $U_i$ to it, making a connected component a star. Proceeding this way for each vector $V_i$, we obtain a graph $G$ that is a disjoint union of $n$ stars on $U_i$'s, with each $U_i$ containing at most polynomially many vertices of each color. It is straightforward to see the equivalence between the instance $(\mathcal{V}, T)$ of MDP, and the resulting instance of Fair Bisection, with the cut-size $k$ being zero. Thus, we conclude with the following theorem, whose formal proof can be found in the full version.

▶ **Theorem 20.** Fair Bisection *is* W[1]*-hard parameterized by the number of colors $c$, even when $k$, the cut-size is zero.*

## 6 Conclusion

In this paper, we initiated the study of Fair Bisection from the perspective of parameterized algorithms. We showed that the problem is W[1]-hard parameterized by the number of colors $c$, even when $k = 0$; thus, we cannot hope to generalize the FPT algorithm to Fair Bisection with a running time of the form $f(k, c) \cdot n^{\mathcal{O}(1)}$. On the other hand, the known $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$ algorithm for Minimum Bisection ([9, 10]) extends to Fair Bisection in a straightforward manner with running time $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(c)}$. Our main result is that Fair Bisection admits an FPT-approximation algorithm that finds an $(\epsilon, \mathsf{r})$-fair bisection in time $2^{\mathcal{O}(k \log k)} \cdot \left(\frac{c}{\epsilon}\right)^{\mathcal{O}(c)} \cdot n^{\mathcal{O}(1)}$. In fact, by setting $\epsilon = 1/(2n)$, we can obtain the previously mentioned exact algorithm as a corollary.

We note that our approximation algorithm also works in the setting where a vertex can belong to multiple color classes. Also, our technique can be extended to Fair $q$-section problem, where we want to partition the vertex set into $q$ parts such that (i) at most $k$ edges with endpoints in different parts, and (ii) each part has proportional representation from each color – here, the algorithm will have an XP dependence on $q$.

Our main conceptual contribution is the observation that it is possible to design parameterized approximation algorithms by applying the technique of Lampis [20] to design DP over tree decompositions with unbreakable bags. Towards this goal we designed an algorithm that

given a graph $G$ and integer $k$ computes a $(9k, k)$-unbreakable tree decomposition of $G$ with logaritmic depth and adhesions of size at most $8k$ in time $2^{\mathcal{O}(k \log k)} n^{\mathcal{O}(1)}$. We expect that this will be a useful tool for obtaining parameterized approximation algorithms for other problems by using Lampis [20]-style dynamic programming over tree decompositions with unbreakable bags.

# Improved Quantum Boosting

**Adam Izdebski**[1]

## Abstract

Boosting is a general method to convert a weak learner (which generates hypotheses that are just slightly better than random) into a strong learner (which generates hypotheses that are much better than random). Recently, Arunachalam and Maity [5] gave the first quantum improvement for boosting, by combining Freund and Schapire's AdaBoost algorithm with a quantum algorithm for approximate counting. Their booster is faster than classical boosting as a function of the VC-dimension of the weak learner's hypothesis class, but worse as a function of the quality of the weak learner. In this paper we give a substantially faster and simpler quantum boosting algorithm, based on Servedio's SmoothBoost algorithm [22].

## 1 Introduction

### 1.1 Boosting

There has been tremendous growth in machine learning research and applications, both in practice (applying all sorts of methods on all sorts of data and seeing what works well) and in theory (computational learning theory). However, not very many ideas generated in theoretical machine learning have had a large impact on machine learning practice. One of the exceptions is *boosting*, which is a simple, general, and widely applicable method to improve the generalization error of a given learning method, i.e., to convert a *weak* learner into a *strong* learner.

The set-up here is binary classification: we are trying to predict binary labels $y$ from points $x \in \mathcal{X}$. A typical case would be $\mathcal{X} = \{0,1\}^n$. We are given $m$ labeled examples $(x_1, y_1), \ldots, (x_m, y_m) \in \mathcal{X} \times \{-1, 1\}$ where the $x_i$s are independent and identically distributed (i.i.d.) according to some unknown distribution $\mathcal{D}$, and the binary labels are determined by some unknown *target function* $f : \mathcal{X} \to \{-1, 1\}$ that we are trying to learn, i.e., $y_i = f(x_i)$. A weak learner $\mathcal{W}$ is an algorithm that can be fed a number of examples according to a specified

[1] Work done while a student at the IILC of the University of Amsterdam.

distribution $D$ (not to be confused with the unknown data-generating distribution $\mathcal{D}$) over the $m$ examples of the given sample, and that is then promised to generate a hypothesis $h : \mathcal{X} \to \{-1, 1\}$ that is slightly better than random w.r.t. that $D$:

$$\Pr_{x\sim D}[h(x) \neq f(x)] \leq 1/2 - \gamma.$$

Here $\gamma \in (0, 1/2)$ is a small but positive number that gives the quality of the weak learner. We denote the "cost" (in time complexity or whatever measure the user likes) of one run of $\mathcal{W}$ by $W$, and use this number also as an upper bound on the number of examples (distributed according to $D$) that the weak learner uses.

A hypothesis with a generalization error that is just slightly better than random is not very useful by itself. The goal of boosting is to convert the weak learner into a strong learner, which is one that produces hypotheses not only with small empirical error (i.e., w.r.t. the uniform distribution over the $m$ examples), but even with small generalization error w.r.t. the unknown target function $f : \mathcal{X} \to \{-1, 1\}$ and the unknown distribution $\mathcal{D}$ that generated the examples:

$$\Pr_{x\sim \mathcal{D}}[h(x) \neq f(x)] \leq \varepsilon.$$

Here the desired upper bound $\varepsilon$ on the final generalization error is a parameter of the strong learner. Unsurprisingly, achieving smaller $\varepsilon$ requires a larger number of examples and larger runtime. For simplicity, in this introduction we focus on the case $\varepsilon = 1/3$ (in the body of the paper we cover the general case). Similarly, the smaller the initial advantage $\gamma$ is, the more work we will have to do find a hypothesis with small generalization error.[2]

The idea of boosting is to find a hypothesis with low empirical error by combining different runs of the weak learner on different distributions. Once we have a hypothesis with small empirical error on a sufficiently large set of examples, VC-theory implies that such a hypothesis will probably also have a small generalization error.

How can we find a hypothesis with small empirical error? Because empirical error is measured w.r.t. the uniform distribution over $\{x_1, \ldots, x_m\}$, that will be our first distribution $D^1$. We run the weak learner on $D^1$, and receive a hypothesis $h_1$ that is slightly better than random w.r.t. the uniform distribution. The next iteration then biases the distribution away from the examples that are already well-classified, by increasing the probability of misclassified examples, yielding a new distribution $D^2$. We then run the weak learner again, to generate a hypothesis $h_2$ that is slightly better than random w.r.t. this new distribution, and hence hopefully better than $h_1$ on the examples that were misclassified by $h_1$. Then we bias the distribution further towards the still-misclassified examples, and so on. The intuition here is that the distributions $D^t$ "zoom in" on the hardest examples, the ones that are most difficult to classify correctly. After some $T$ iterations, the $T$ different weak hypotheses are combined into one hypothesis $h$, typically by defining the latter as the sign of a linear combination $\sum_{t=1}^{T} \alpha_t h_t$ of the $T$ weak hypotheses $h_1, \ldots, h_T$. Surprisingly, already after a relatively small number of iterations, the resulting hypothesis will have small empirical error! Thus boosting converts the ability to generate weak hypotheses w.r.t. chosen distributions over the examples, into the ability to generate strong hypotheses, which have small error w.r.t. both the uniform distribution over the examples, and w.r.t the unknown target function $f$ and distribution $\mathcal{D}$ that generated our $m$ examples.

[2] For simplicity we will assume this $\gamma$ is known to the strong learner we are trying to design, but this is not necessary: if it doesn't know $\gamma$, the strong learner can try exponentially decreasing guesses for $\gamma$ until it finds a hypothesis with small empirical error.

A number of classical boosting algorithms exist that instantiate this meta-algorithm in different ways. The most famous of these is probably Freund and Schapire's AdaBoost [13, 14, 19] (short for "adaptive boosting"), which biases the new distribution $D^{t+1}$ based on the error $\varepsilon_t$ that $h_t$ made. It drives the empirical error all the way down to 0 (note that as soon as this error is $< 1/m$ it must actually be 0). AdaBoost uses $T = O(\log(m)/\gamma^2)$ iterations. Each iteration takes time $\tilde{O}(m)$ to compute the error $\varepsilon_t$ of $h_t$ and to update the distribution over the $m$ examples[3] and runs the weak learner $\mathcal{W}$ once, at cost $W$. This gives overall complexity

$$\tilde{O}\left(\frac{W+m}{\gamma^2}\right).$$

How large should $m$ be in order to make the inference from low empirical error to low generalization error? This depends on the hypothesis space $\mathcal{H}_{weak}$ of the weak learner, in particular on its *VC-dimension* $d$ (defined in Section 2.1). The hypothesis space $\mathcal{H}_{strong}$ of the boosting algorithm consists of all signs of linear combinations of up to $T$ elements of $\mathcal{H}_{weak}$. One can show that the VC-dimension of $\mathcal{H}_{strong}$ is $D = \tilde{O}(dT)$. VC-theory implies that (for constant $\varepsilon$) $m \approx D \approx dT \approx d/\gamma^2$ examples suffice to end up with generalization error $\leq \varepsilon$ (with high probability over the choice of the sample). Accordingly, when re-expressed as a function of $d$ rather than $m$, the complexity of AdaBoost is

$$\tilde{O}\left(\frac{W}{\gamma^2}+\frac{d}{\gamma^4}\right). \tag{1}$$

## 1.2 Quantum boosting

In the last few years there has been a surge in interest in possible ways in which *quantum* computers might help improve machine learning (see [9] for a survey of several algorithmic approaches and [6] for quantum learning theory).

Recently, Arunachalam and Maity [5] gave the first speed-up for boosting on a quantum computer. Here the given sample is still the same classical sequence of $m$ labeled examples $(x_1, y_1), \ldots, (x_m, y_m) \in \mathcal{X} \times \{-1, 1\}$, but these are now stored in a quantum-accessible classical memory, which means a quantum learner can query multiple examples in superposition.

The key insight of [5] is that the error $\varepsilon_t$ of the base classifier in the $t$-th iteration of AdaBoost can be approximated faster (in time $o(m)$) using a quantum counting algorithm; this approximation is subtle because it involves both multiplicative and additive error, in different regimes for $\varepsilon_t$. Their method works not only for boosting classical weak learners, but also for boosting *quantum* weak learners. These are fed quantum examples w.r.t. the distribution $D$:

$$\sum_{i=1}^{m} \sqrt{D(x_i)}|x_i, y_i\rangle. \tag{2}$$

If the quantum weak learner $\mathcal{W}$ expects to receive $W$ such examples, the quantum booster will have to prepare $W$ copies of this state to feed into $\mathcal{W}$.[4]

[3] The notation $\tilde{O}(f)$ means $O(f \cdot \text{polylog}(f))$.

[4] The classical boosting literature [19] distinguishes "boosting by resampling" and "boosting by reweighting". Like Arunachalam and Maity [5], we follow "boosting by resampling" and explicitly prepare the $W$ quantum or classical examples (w.r.t. $D^t$) that the weak learner needs, rather than just modifying $D^t$.

The quantum version of AdaBoost of [5] uses the same number of iterations as classical AdaBoost, but improves the complexity of each iteration (at least as a function of $m$ or $d$). Their main complexity upper bound is:

$$\tilde{O}\left(\frac{W^{1.5}\sqrt{d}}{\gamma^{11}}\right). \tag{3}$$

Comparing with the complexity of classical AdaBoost Eq. (1), this gives a speed-up over classical boosting in terms of the dependence on the VC-dimension $d$ of the weak learner's hypothesis class, but at the expense of a significant deterioration in terms of the dependence on the quality of the weak learner $\gamma$ and a milder deterioration in terms of the weak learner's cost $W$.

## 1.3 Our results

In this paper we give a simpler and faster quantum boosting algorithm. Instead of AdaBoost, our starting point will be Servedio's SmoothBoost algorithm [22], which we explain in Section 3. Servedio's motivation for smooth boosting was to deal with malicious noise (at a rate that depends on $\gamma$) in the sample better than AdaBoost. However, SmoothBoost is also very suitable for "quantization" thanks to the following advantages that it has over AdaBoost:

- SmoothBoost doesn't need to calculate or approximate the error $\varepsilon_t$ of $h_t$ on the $m$ examples, which means we don't need to apply approximate quantum counting for this.
- The distributions $D^t$ that it generates are "smooth" (whence its name), in the sense that no example has probability much bigger than the uniform probability $1/m$. Generating quantum examples as in Eq. (2) is cheaper when none of the probabilities is big.
- The weights $\alpha_t$ in the final linear combination $\sum_t \alpha_t h_t$ are all equal to 1 in SmoothBoost. In contrast, AdaBoost uses $\alpha_t = \frac{1}{2}\ln((1-\varepsilon_t)/\varepsilon_t)$, hence the quantum algorithm's approximation errors in $\varepsilon_t$ lead to approximation errors in $\alpha_t$ that need to be kept under control.

In addition to exploiting these "classical" advantages in order to obtain a simpler and faster quantum booster, we also give an improved procedure to generate quantum examples over the $m$ examples from $S$. This procedure assumes access to a non-normalized version of $D^t$ and doesn't have to worry about the normalizing factor. As explained in Section 4.1, in a way quantum mechanics will take care of the proper normalization for us.[5]

We obtain the following upper bound on the complexity of our Quantum SmoothBoost:[6]

$$\tilde{O}\left(\frac{W}{\gamma^4}+\frac{\sqrt{d}}{\gamma^5}\right). \tag{4}$$

[5] We also generate the quantum examples exactly, while [5] only generate them approximately and hence has to deal with the way the errors in this process affect the other parts of their boosting procedure. Our example-generating procedure could also be used to improve the bounds of quantum AdaBoost [5], though the result won't be as efficient as our quantum SmoothBoost. Note that if we want to use Quantum SmoothBoost with a classical weak learner $\mathcal{W}$, we can just measure the $W$ quantum examples in the computational basis to obtain the $W$ classical examples distributed according to $D^t$ that such a $\mathcal{W}$ needs as input. This still gives a speed-up in terms of the desired generalization error $\varepsilon$ compared to classically generating those $W$ examples.

[6] This bound is when we aim at constant generalization error $\varepsilon = 1/3$. We also make explicit the complexity for much smaller $\varepsilon$ (see Theorem 14).

This improves over the complexity of the booster of [5] (as given in Eq. (3)) in terms of the parameters $W$ and (especially) $\gamma$. The $\gamma$-dependence is still worse than classical AdaBoost (as given in Eq. (1)), but not by large powers anymore. It is an interesting open question whether this $\gamma$-dependence can be improved further.

### 1.4 Related work

Our main sources of inspiration for this paper were the quantum AdaBoost of Arunachalam and Maity [5] and classical SmoothBoost of Servedio [22], and we have tried in this paper to combine the best elements of both.

Here we mention a number of related quantum papers. Wang et al. [24] (which preceded [5]) give a quantum speed-up for a specific subtask of AdaBoost, namely to compute the coefficients $\alpha_t = \frac{1}{2}\ln((1-\varepsilon_t)/\varepsilon_t)$ that combine given base classifiers $h_1, \ldots, h_T$ into a good hypothesis $h = sign(\sum_t \alpha_t h_t)$. These weights $\alpha_t$ are approximated more efficiently than is possible classically using a version of approximate quantum counting. This, however, assumes the base classifiers have already been generated and sidesteps the most important aspect of AdaBoost, which is to generate the $h_t$'s adaptively by running the weak learner on a distribution $D^t$ that depends on $h_1, \ldots, h_{t-1}$. The even earlier paper by Schuld and Petruccione [21] considers quantum ensembles of classifiers (rather than the linear combinations used in boosting) and runs AdaBoost as a subroutine, but does not give a quantum boosting algorithm.

AdaBoost may be viewed as an instance of the multiplicative weights update method, see for instance the presentation in [4, Section 3.6]. There have been several quantum speed-ups for multiplicative weights methods in other contexts, particularly the quantum SDP-solvers of Brandão et al. [11, 3, 10, 2], and the very recent quantum version of the Hedge algorithm of Rebentrost et al. [18]. However, none of those speed-ups for versions of multiplicative weights seems directly applicable to our boosting setting.

## 2 Preliminaries

### 2.1 PAC learning

In this section we give a brief introduction to the PAC learning framework, which provides theoretical guarantees on learnability. The textbook by Shalev-Shwartz and Ben-David [23] provides an excellent and detailed introduction to the topic of classical PAC learning.

To formally introduce the PAC learning framework, let $\mathcal{D}$ denote a probability distribution over the set of *points* $\mathcal{X}$. We want to learn an unknown *target function* $f : \mathcal{X} \to \mathcal{Y}$. We will assume here that the set of labels $\mathcal{Y}$ is just $\{-1, 1\}$, so we are dealing with binary classification. A typical situation to keep in mind is the important special case of learning Boolean functions, where $\mathcal{X} = \{0,1\}^n$, or $\mathcal{X} = \cup_{n\geq 1}\{0,1\}^n$.

Learning begins by choosing a learning algorithm (a "learner") with an associated *hypothesis class* $\mathcal{H}$ of functions $h : \mathcal{X} \to \{-1, 1\}$. This hypothesis class could be any set of functions, but good examples to keep in mind are cases where $\mathcal{X} = \{0,1\}^n$ and $\mathcal{H}$ consists of objects with bounded computational power, for instance all Boolean circuits of at most a certain size, all neural networks with a specific depth and number of nodes, or all decision trees of at most a certain depth. We will assume that each $h \in \mathcal{H}$ has a succinct description and that we can efficiently evaluate a given $h$ on a given $x \in \mathcal{X}$. For simplicity we assume such an evaluation has unit cost.

The learner is given access to a *sample* $S = ((x_1, y_1), \ldots, (x_m, y_m))$, which is the training data. The points $x_i$ are i.i.d. generated according to an unknown distribution $\mathcal{D}$ on $\mathcal{X}$, and the labels $y_i = f(x_i)$ are determined by the target function $f$ that we are trying to learn. The learner's goal is to find an $h \in \mathcal{H}$ that fits well with the given training data, in the hope that this $h$ will generalize well to points that were not part of the data, in the sense of mostly giving the same labels as the target function. The PAC learning framework is a distribution-free setting, so we would like to design a learner that works well for every $\mathcal{D}$, in the sense of outputting a hypothesis with low generalization error.

▶ **Definition 1.** *The generalization error of $h : \mathcal{X} \to \mathcal{Y}$ w.r.t. target function $f : \mathcal{X} \to \mathcal{Y}$ under distribution $\mathcal{D}$ is*

$$err(h, f, \mathcal{D}) = \Pr_{x \sim \mathcal{D}}[h(x) \neq f(x)].$$

Generalization error is often referred to as the *true* error; it is the quantity the learner is really trying to minimize over the class $\mathcal{H}$ of available hypotheses.

As the distribution $\mathcal{D}$ is anyway unknown, the generalization error of a hypothesis $h$ cannot be calculated and the learner uses the *empirical* error of a hypothesis $h$ (the fraction of the sample that $h$ mislabels) to measure its performance, as a proxy for the generalization error.

▶ **Definition 2.** *The empirical error of $h : \mathcal{X} \to \mathcal{Y}$ w.r.t. sample $S = ((x_1, y_1), \ldots, (x_m, y_m))$ is*

$$\hat{err}(h, S) = \Pr_{i \in_R [m]}[h(x_i) \neq y_i],$$

*where $i \in_R [m]$ means that $i$ is taken uniformly at random from $[m] = \{1, \ldots, m\}$.*

▶ **Definition 3.** *An $(\varepsilon, \delta)$-PAC learner for a concept class $\mathcal{C}$ with hypothesis class $\mathcal{H}$ and sample complexity $m$, is an algorithm $\mathcal{A}$ such that the following holds for all target functions $f \in \mathcal{C}$ and all distributions $\mathcal{D}$ on $\mathcal{X}$:*

- *$\mathcal{A}$ takes as input $m$ examples $(x_1, f(x_1)), \ldots, (x_m, f(x_m))$ where the $x_i$ are i.i.d. according to $\mathcal{D}$.*
- *$\mathcal{A}$ outputs an $h \in \mathcal{H}$ which is "Probably Approximately Correct" in the sense that*

$$\Pr[err(h, f, \mathcal{D}) \leq \varepsilon] \geq 1 - \delta,$$

*where the probability is taken over the sample and over the learner's internal randomness.*

The end goal is to find a learner with small sample complexity $m$, small error probability $\delta$, and (most important of all) small generalization error $\varepsilon$. Often we will start, however, with a "weak" learner, one whose generalization error is only slightly better than random. Since we restricted to binary labels ($\mathcal{Y} = \{-1, 1\}$), generalization error $\varepsilon = 1/2$ is no better than random guessing. A weak learner is a learner that does slightly better than that:

▶ **Definition 4** (Weak learning)**.** *A $\gamma$-weak learner $\mathcal{W}$ for concept class $\mathcal{C}$ with hypothesis class $\mathcal{H}_{weak}$ is a $(1/2 - \gamma, 0)$-PAC learner. Hypotheses returned by a weak learner are called* base classifiers.

Following Servedio [22], we assume the weak learner $\mathcal{W}$ has error probability $\delta = 0$, so it always outputs a hypothesis with generalization error $\leq 1/2 - \gamma$. If instead we start with a $\mathcal{W}$ that has non-zero error probability, say $1/3$, then we can reduce this error probability

to small $\delta > 0$ as follows. Run $\mathcal{W}$ a total number of $r = \lceil \log_3(1/\delta) \rceil$ times, each time with fresh independent examples. Then, except with probability $\leq (1/3)^r \leq \delta$, at least one of the returned hypotheses $h_1, \ldots, h_r \in \mathcal{H}_{weak}$ will have generalization error $\leq 1/2 - \gamma$. However, finding (with success probability $\geq 1 - \delta$) among these $r$ hypotheses one with such low error has a cost. Deciding (with success probability $\geq 2/3$) for a given hypothesis $h$ whether it has error $\leq 1/2 - \gamma$ under a given distribution can be done by sampling $O(1/\gamma^2)$ examples according to that distribution and estimating the fraction of examples where $h$ predicts the label correctly. Searching over the $r$ hypotheses to find a good one adds a factor of $O(r)$ to the classical cost, and reducing the overall error probability from $1/3$ to $\delta$ adds another factor of $O(\log(1/\delta))$.[7]

Suppose we ideally want to run an errorless weak learner $T$ times, namely once in each of $T$ iterations. But instead we start with a weak learner with error probability $1/3$. Reducing $1/3$ to $\delta \ll 1/T$ allows us to take a union bound over all $T$ iterations, and conclude that with high probability each of the $T$ iterations produces a base classifier with generalization error $\leq 1/2 - \gamma$ (w.r.t. the distribution $D^t$ of that iteration). Because here we assumed our weak learner has no error probability from the start, we do not have to factor in the additional cost for this error reduction, but it anyway doesn't significantly affect the complexities of classical or quantum boosting (Eqs. (1) and (4) respectively).

## 2.2 How many examples suffice to ensure small generalization error?

The number of examples that are necessary and sufficient for learning is governed by the VC-dimension of the relevant hypothesis class and by the desired generalization error, as follows. A set $S \subseteq \mathcal{X}$ of $d$ points is said to be *shattered* by $\mathcal{H}$ if for each of the $2^d$ labelings $\ell : S \to \{0,1\}$, there exists an $h \in \mathcal{H}$ that agrees with $\ell$ on the points in $S$. The *VC-dimension* of a hypothesis class $\mathcal{H}$ is the size of a largest $S$ that is shattered by $\mathcal{H}$. Intuitively, if the VC-dimension of $\mathcal{H}$ is small, then it should be relatively simple to find a good hypothesis in it, i.e., one that minimizes empirical error.

The following theorem implies that for sufficiently large $m$, *every* $h \in \mathcal{H}$ has a generalization error that is only slightly worse than its empirical error. Such a result means it suffices to look for a hypothesis with small empirical error.

▶ **Theorem 5** (Theorem 2.5 in [19]). *Let $\mathcal{H}$ be a hypothesis class of finite VC-dimension $d$. Assume that a sample $S$ of size $m$ is chosen for some target function $f$, i.i.d. according to some distribution $\mathcal{D}$. Then for every $\eta > 0$ it holds that*

$$\Pr[\exists h \in \mathcal{H} : err(h, f, \mathcal{D}) > \hat{err}(h, S) + \eta] \leq 8\Big(\frac{em}{d}\Big)^d \exp\Big\{\frac{-m\eta^2}{32}\Big\}.$$

If we set $\eta = \varepsilon/2$ and

$$m = O\left(\frac{d\log(d/(\delta\varepsilon)) + \log(1/\delta)}{\varepsilon^2}\right),$$

with a sufficiently large constant in the $O(\cdot)$, then (except with probability $\delta$), each $h \in \mathcal{H}$ has a generalization error that is at most $\varepsilon/2$ bigger than its empirical error. Accordingly, if a learner now outputs any hypothesis $h \in \mathcal{H}$ whose empirical error is $\leq \varepsilon/2$, then its generalization error will be $\leq \varepsilon$, as desired.

[7] In the quantum case the $O(1/\gamma^2)$ can be replaced by $O(1/\gamma)$ using quantum approximate counting (Theorem 7 below), and the $O(r)$ can be replaced by $O(\sqrt{r})$ using Grover's algorithm [15].

## 2.3 Quantum PAC learning and helpful quantum subroutines

In order to introduce the quantum boosting algorithm in Section 4, we explain the query model that the quantum algorithm works with. We say that an algorithm has *query access* to a string $z \in Z_a^N$ over alphabet $Z_a = \{0, \ldots, a-1\}$ if it can apply a unitary $O_z$ such that

$$O_z : |i, b\rangle \mapsto |i, b \oplus z_i\rangle,$$

where $i \in \{0,1\}^{\lceil \log N \rceil}$, $b \in Z_a$, and $\oplus$ denotes addition modulo $a$. Naturally, a quantum algorithm can apply $O_z$ on a superposition of distinct inputs $i$.

In the classical setting we assumed a learner is given a sample $S = ((x_1, y_1), \ldots, (x_m, y_m))$ of $m$ labeled examples. Here points $x_i \in \mathcal{X}$ are independently drawn from an unknown distribution $\mathcal{D}$, and labeled $y_i = f(x_i)$ according to an unknown target function $f$. Such a classical sample will still be the starting point of our quantum boosting algorithm; we assume the learner has query access to the sample (viewed as a string $z \in (\mathcal{X} \times \{-1, 1\})^m$). One may think of the sample as being stored in a quantum-accessible classical memory, sometimes called QRAM, which may be queried throughout the algorithm (incl. by the weak learner). However, our setting also encompassed the case of *synthetic* data, where we would have an efficient procedure which, on input $i$, computes the example $(x_i, y_i)$.

Even though the initially given sample is classical, like Arunachalam and Maity [5] we will set up our quantum booster so that it can work to improve a classical weak learner but also to improve a *quantum* weak learner. The latter is given *quantum examples* w.r.t. distribution $D$:

$$\sum_{x \in \mathcal{X}} \sqrt{D(x)} |x, f(x)\rangle.$$

One can think of a quantum example as the coherent version of a random example $(x, f(x))$ where $x \sim D$. A quantum learner is given access to several copies of the quantum example and performs a POVM measurement, where each outcome is associated with a hypothesis $h$ in its hypothesis class. It won't matter for the purposes of this paper, but [7] proved that in the general PAC and agnostic learning settings, the required number of classical and quantum examples are the same up to contant factor.

In the case of boosting, the weak learner will be fed quantum examples w.r.t. a distribution $D$ that only has support on the $m$ given examples. Since our initially given sample is classical, our boosting algorithm will itself have to prepare the quantum examples that it wants to feed into the weak learner in each iteration, and we have to (and will) account for the cost of this.

We also assume that we can evaluate a given $h$ (in the weak learner's hypothesis class $\mathcal{H}_{weak}$) in superposition, meaning we can apply a unitary that maps $|h\rangle|x\rangle|b\rangle \mapsto |h\rangle|x\rangle|h(x) \cdot b\rangle$; here the basis states of the first space are the names of the $h \in \mathcal{H}_{weak}$, the basis states of the second space are the elements of $\mathcal{X}$, and the basis states of the third space are the labels in $\mathcal{Y} = \{-1, 1\}$.

The definitions of PAC learning and weak learning straightforwardly generalize to the quantum setting. We refer to the survey [6] for more on this model. The following basic quantum subroutines can be derived from Brassard et al. [12] (or from [1] if one wants to avoid use of the quantum Fourier transform):

▶ **Theorem 6** (Amplitude amplification). *Suppose we have an $m$-qubit unitary $U$ such that*

$$U|0^m\rangle = \sqrt{a}|\phi_0\rangle|0\rangle + \sqrt{1-a}|\phi_1\rangle|1\rangle,$$

*and we know a lower bound $a'$ on $a$. Then there exists a quantum algorithm $V$ using $O(1/\sqrt{a'})$ applications of $U$ and $U^\dagger$, and $\tilde{O}(1/\sqrt{a'})$ other gates, such that*

$$V|0^m\rangle = \sqrt{b}|\phi_0\rangle|0\rangle + \sqrt{1-b}|\phi_1\rangle|1\rangle,$$

*where $b \in [1/2, 1]$.*

▶ **Theorem 7** (Approximate counting). *Suppose we have query access to a string $z \in [0,1]^N$, with sum $s = \sum_{i=1}^N z_i \geq 1$. There exists a quantum algorithm that uses $O(\frac{1}{\varepsilon}\sqrt{N}\log(1/\delta))$ queries and $\tilde{O}(\frac{1}{\varepsilon}\sqrt{N}\log(1/\delta))$ other operations, and that outputs (except with probability $\leq \delta$) an $\tilde{s}$ such that $(1-\varepsilon)s \leq \tilde{s} \leq (1+\varepsilon)s$.*

## 3 SmoothBoost

We first consider the classical SmoothBoost algorithm of Servedio [22]. It generates only smooth distributions, in the sense that none of the examples get too much weight. In the next section we will introduce a quantum version of SmoothBoost.

We give the pseudocode of SmoothBoost in Algorithm 1. There are a few cosmetic changes compared to the pseudocode of [22] that will make it easier for us to quantize it later. The algorithm takes four inputs. First, a $\gamma$-weak learner $\mathcal{W}$ with associated hypothesis class $\mathcal{H}_{weak}$ and cost and sample complexity $W$. Second, a sample $S = ((x_1, y_1), (x_2, y_2), \ldots, (x_m, y_m)) \in (\mathcal{X} \times \{-1, 1\})^m$, for some sample size $m$ that we will choose later. Lastly, a parameter $\kappa \in (0, 1)$ which controls the empirical error of SmoothBoost and a parameter $\theta \in [0, \frac{1}{2})$ which controls the desired margin of the output hypothesis $h$. The goal of SmoothBoost is to output a hypothesis $h : \mathcal{X} \to \{-1, 1\}$ with small empirical error (and as we shall see later, for sufficiently large $m$, this $h$ will also have large generalization error). The final $h$ is going to be the sign of a sum of elements of $\mathcal{H}_{weak}$, so the strong learner's hypothesis class is larger than that of the weak learner.

The central objects in this algorithm are the vectors $M^1, M^2, \ldots, M^T \in [0, 1]^m$, which are unnormalized distributions over the $m$ examples. The distribution $D^t$ is the normalized version of $M^t$. SmoothBoost starts by initializing weights to $N_i^0 = 0$ and $M_i^1 = 1$, for all $i \in [m]$, so $D^1$ is uniform. In each iteration, Step 6 checks whether the sum of $M_i^t$ is below $\kappa m$, and if so it terminates. Otherwise it runs the weak learner on $W$ i.i.d. examples sampled (from $S$) according to $D^t$, producing a base classifier $h_t : \mathcal{X} \to \{-1, 1\}$. Step 9 updates $N^{t-1}$ to $N^t$ and $M^t$ to $M^{t+1}$. For each $i \in [m]$, $N_i^t$ is the cumulative amount by which hypotheses $h_1, \ldots, h_t$ beat the desired margin $\theta$. If $x_i$ got correctly classified by $h_t$, then it will get higher weight $N_i^t$, which results in smaller weight $M_i^{t+1}$ and smaller probability $D_i^{t+1}$ in the next round of boosting. This mechanism forces the next run of the weak learner $\mathcal{W}$ to "zoom in" (i.e., assign higher probabilities) to systematically misclassified instances. The procedure terminates if the sum of all weights $\sum_{i\in[m]} M_i^t$ gets sufficiently small, as controlled by the parameter $\kappa$.

We now state three results from Servedio [22] that show, respectively, that the intermediate distributions are smooth, that SmoothBoost terminates after a small number of iterations, and that it returns a hypothesis with low empirical error.

▷ Claim 8 (Lemma 1 of [22]). For each $1 \leq t \leq T$, it holds that $\max_{i\in m} |D_i^t| \leq \frac{1}{\kappa m}$.

Proof. This follows from the condition of Step 6: before termination we have $\sum_{i=1}^m M_i^t \geq \kappa m$ and $M_i^t \in [0, 1]$, hence $D_i^t = M_i^t / \sum_{i\in[m]} M_i^t \leq 1/\kappa m$ for all $i \in [m]$. ◁

**Algorithm 1** SmoothBoost.

**Input:** A $\gamma$-weak learner $\mathcal{W}$ with complexity $W$.
A sample $S = ((x_1, y_1), \ldots, (x_m, y_m)) \in (\mathcal{X} \times \{-1, 1\})^m$.
Parameters $\kappa \in (0, 1), \theta \in [0, \frac{1}{2})$.

**Output:** Hypothesis $h : \mathcal{X} \to \{-1, 1\}$.

**function** SmoothBoost($\mathcal{W}$, $S$, $\kappa$, $\theta$)
  For all $i \in [m]$ initialize: $N_i^0 \leftarrow 0$, $M_i^1 \leftarrow 1$.
  $t \leftarrow 1$
  **while** true **do**
    Compute $s = \sum_{i=1}^m M_i^t$.
    If $s < \kappa m$ then $T \leftarrow t - 1$, **return** $h \leftarrow sign(\sum_{t=1}^T h_t)$, and **terminate**.
    Prepare $W$ i.i.d. examples w.r.t. distribution $D^t = M^t / \sum_i M_i^t$ (see Footnote 8).
    Feed those $W$ examples into the weak learner $\mathcal{W}$ to obtain base classifier $h_t$.
    For all $i \in [m]$ set

$$N_i^t \leftarrow N_i^{t-1} + h_t(x_i) y_i - \theta$$

and

$$M_i^{t+1} \leftarrow \begin{cases} 1 & \text{for } N_i^t < 0 \\ (1-\gamma)^{\frac{N_i^t}{2}} & \text{for } N_i^t \geq 0 \end{cases}$$

    $t \leftarrow t + 1$.

▷ Claim 9 (Theorem 3 of [22]). If $\theta = \frac{\gamma}{2+\gamma}$ and for all $t$ it holds that $\Pr_{i \sim D^t}[h_t(x_i) \neq y_i] \leq \frac{1}{2} - \gamma$, then SmoothBoost terminates with $T < \frac{2}{\kappa \gamma^2 \sqrt{1-\gamma}}$ iterations.

Proof. [22, Lemmas 4 and 5] imply $\frac{2m}{\gamma\sqrt{1-\gamma}} > \gamma \sum_{t=1}^T \sum_{i=1}^m M_i^t$ (this is the hard part of Servedio's correctness proof of SmoothBoost). We have $\sum_{i=1}^m M_i^t \geq \kappa m$ for all $t$ until termination. Hence $\frac{2m}{\gamma\sqrt{1-\gamma}} > \gamma T \kappa m$, which implies the claim. ◁

▷ Claim 10 (Theorem 2 of [22]). After $t$ iterations of SmoothBoost, the hypothesis $h = sign(\sum_{t=1}^t h_t)$ has empirical error $\hat{err}(h) \leq \sum_{i=1}^m M_i^{t+1}/m$.

Proof. Note that $N_i^T = \sum_{t=1}^T (h_t(x_i) y_i - \theta)$. Hence if $i$ is such that $\sum_{t=1}^T h_t(x_i) y_i < \theta T$, then $N_i^T < 0$ and $M_i^{T+1} = 1$. The final hypothesis $h$ errs on the $i$th example iff $\sum_{t=1}^T h_t(x_i) y_i < 0$. We upper bound the number of $i \in [m]$ for which this happens:

$$\left| \left\{ i \mid \sum_{t=1}^T h_t(x_i) y_i < 0 \right\} \right| \leq \left| \left\{ i \mid \sum_{t=1}^T h_t(x_i) y_i < \theta T \right\} \right| = \sum_{i : \sum_{t=1}^T h_t(x_i) y_i < \theta T} M_i^{T+1} \leq \sum_{i=1}^m M_i^{T+1}.$$

◁

Since SmoothBoost terminates if $\sum_{i=1}^m M_i^{T+1} < \kappa m$, Claim 10 implies that the empirical error of the final hypothesis is $< \kappa$.

Combining the previous two claims, we see that the empirical error decreases like $O(1/(T\gamma^2))$. This contrasts with AdaBoost, where the empirical error goes down exponentially fast in $T$ and hence can be driven down to $< 1/m$ (and hence to 0) quite cheaply.

SmoothBoost does not drive the empirical error down all the way to 0, because that would require setting $\kappa < 1/m$ which implies a very large number of iterations, $T = O(m/\gamma^2)$. However, small but non-zero empirical error is good enough for our purposes, because (with sufficiently large sample size $m$) that already implies small generalization error.

We will choose $\kappa$ to be $\varepsilon/2$, which sets the above upper bound on the empirical error of the final hypothesis $h$ to half of the allowed generalization error. By the discussion following Theorem 5, if the sample size $m$ is large enough, the final hypothesis will have generalization error $\leq \varepsilon$, as desired. The required $m$ depends on the VC-dimension of the hypothesis class $\mathcal{H}_{strong}$ of SmoothBoost, which consists of signs of sums of $T$ elements of the hypothesis class $\mathcal{H}_{weak}$ of the weak learner. The VC-dimensions of these two classes are related as follows:

▷ Claim 11 (Shalev-Shwartz & Ben-David, p. 109 [23]). Let $\mathcal{H}_{weak}$ be a hypothesis class of VC-dimension $d$ and $\mathcal{H}_{strong} = \{sign(\sum_{i=1}^{T} h_i) \mid h_1, \ldots, h_T \in \mathcal{H}_{weak}\}$. Then the VC-dimension of $\mathcal{H}_{strong}$ is $D = O(Td\log(Td))$.

By Theorem 5 and the fact that $T = O(\frac{1}{\varepsilon\gamma^2})$ it thus suffices to take

$$m = O\left(\frac{D\log(D/(\delta\varepsilon)) + \log(1/\delta)}{\varepsilon^2}\right) = O\left(\frac{d\log(d/(\delta\varepsilon\gamma))^2}{\varepsilon^3\gamma^2} + \frac{\log(1/\delta)}{\varepsilon^2}\right) \tag{5}$$

examples in order to be able to infer (with success probability $\geq 1-\delta$) generalization error $\leq \varepsilon$ from empirical error $\leq \varepsilon/2$.

Finally, let us determine the complexity of SmoothBoost, in terms of the overall number of elementary operations and queries to the sample and to the $h_t$. There are $T = O(\frac{1}{\varepsilon\gamma^2})$ iterations. Each iteration involves one application of the weak learner $\mathcal{W}$, and $\tilde{O}(m)$ other operations. The weak learner needs to be fed $W$ examples sampled according to distribution $D^t$. Using rejection sampling, we can generate $W$ such examples at cost $O(W/\kappa) = O(W/\varepsilon)$.[8]

▶ **Theorem 12.** *Let $\mathcal{W}$ be a $\gamma$-weak learner of complexity $W$ for concept class $\mathcal{C}$, with hypothesis class $\mathcal{H}_{weak}$ of VC-dimension $d$. Then given $m$ examples according to Eq. (5), SmoothBoost is an $(\varepsilon,\delta)$-PAC learner for $\mathcal{C}$, with hypothesis class $\mathcal{H}_{strong}$. It runs the weak learner $O(\frac{1}{\varepsilon\gamma^2})$ times and uses*

$$\tilde{O}(T(W/\varepsilon + m)) = \tilde{O}\left(\frac{W}{\varepsilon^2\gamma^2} + \frac{m}{\varepsilon\gamma^2}\right) = \tilde{O}\left(\frac{W}{\varepsilon^2\gamma^2} + \frac{d}{\varepsilon^4\gamma^4}\right)$$

*other operations (elementary computational steps, queries to the sample, and evaluations of base classifiers).*

## 4 Quantum Smooth Boosting

In this section we introduce our quantum version of SmoothBoost. The algorithm is given query access to a quantum (or classical) weak learner $\mathcal{W}$ with sample complexity $W$, and to a sample $S$ of size $m$. The quantum weak learner needs to be fed *quantum* examples according to the distribution $D^t$ obtained by normalizing the weight-vector $M^t$. We will start with that.

[8] Specifically, Step 7 of SmoothBoost can be implemented as follows. Sample $i \in [m]$ uniformly. With probability $M_i^t$ output $(x_i, y_i)$, and otherwise repeat. Since the probability to output $(x_i, y_i)$ is proportional to $M_i^t$, the example (if we indeed output an example) is sampled according to the desired probability distribution $D^t$. Note that the probability that we output an example in one try is $\frac{1}{m}\sum_i M_i^t \geq \kappa$, because of the condition of Step 6. Hence the expected number of repetitions before we output an example is $\leq 1/\kappa$.

## 4.1 Preparing quantum examples

Here we show how we can efficiently prepare quantum examples w.r.t. the distribution $D^t$ induced by the non-normalized $M^t$, thanks to its smoothness. This may be viewed as a quantum analogue of the classical rejection sampling sketched in Footnote 8.

▶ **Theorem 13.** *Suppose we have query access to the $m$ numbers $M_1, \ldots, M_m \in [0,1]$. Let $s = \sum_{i=1}^m M_i$ be their (unknown) sum, which has a known lower bound of $\kappa m$. Define a probability distribution $D$ on $[m]$ by $D_i = M_i/s$. Then using an expected number of $O(1/\sqrt{\kappa})$ queries and $\tilde{O}(1/\sqrt{\kappa})$ other gates, we can prepare the state*

$$\sum_{i=1}^m \sqrt{D_i}|i\rangle.$$

**Proof.** Start by preparing the uniform state

$$\frac{1}{\sqrt{m}}\sum_{i=1}^m |i\rangle|0\rangle.$$

Using two queries (the second to uncompute the value $M_i$), and a few other gates to implement a conditional rotation by angle $\arcsin\left(\sqrt{M_i}\right)$, prepare

$$\frac{1}{\sqrt{m}}\sum_{i=1}^m |i\rangle(\sqrt{M_i}|0\rangle + \sqrt{1-M_i}|1\rangle).$$

The squared norm of the part of the state ending in $|0\rangle$ is $s/m \geq \kappa$. Now use $O(1/\sqrt{\kappa})$ rounds of amplitude amplification (Theorem 6) to increase that squared norm to $\geq 1/2$. This costs $O(1/\sqrt{\kappa})$ queries and $\tilde{O}(1/\sqrt{\kappa})$ other gates.

If we measure the last qubit of the resulting state, then we obtain outcome 0 with probability $\geq 1/2$ and the state collapses to the state that we want to prepare (with an extra $|0\rangle$-qubit that we can remove). Note that we know when we succeed to produce the desired state. Since the probability of success is $\geq 1/2$, the expected number of repetitions before success is $\leq 2$. ◀

Once we have produced a copy of the state

$$\sum_{i=1}^m \sqrt{D_i}|i\rangle,$$

we can easily convert this into a quantum example

$$\sum_{i=1}^m \sqrt{D_i}|x_i, y_i\rangle$$

by querying the sample $S$.

## 4.2 Quantizing SmoothBoost

The pseudocode of Quantum Smooth Boosting is given in Algorithm 2. The algorithm receives as input a weak quantum learner $\mathcal{W}$ with sample complexity $W$, and query access to a sample $S$ of $m$ examples. Additionally, it receives two parameters $\kappa, \theta$.

The algorithm looks a bit different from classical SmoothBoost because it doesn't update the $m$-dimensional vectors $N_i^t$ and $M_i^t$ explicitly anymore; the $O(m)$ that this costs is more than we are willing to spend in the quantum case. Instead, we will store the earlier base

classifiers $h_1, \ldots, h_t$. Queries to these classifiers together with queries to the sample $S$ allow us to calculate each entry $N_i^t$ and $M_i^t$ on demand in time $\tilde{O}(t)$, via the formulas of Step 9 of SmoothBoost.

The algorithm begins by initializing $N^0$, $M^1$ and by setting $t = 1$. Like in the classical case, we iterate until the sum of the weights $\sum_{i\in[m]} M_i^t$ becomes small enough. In contrast to the classical case, we do not have the time to sum these $m$ numbers exactly, so we will instead estimate the sum with small approximation error using quantum counting (Theorem 7).

**Algorithm 2** Quantum SmoothBoost.

**Input:** A $\gamma$-weak quantum learner $\mathcal{W}$ with complexity $W$.
A sample $S = ((x_1, y_1), \ldots, (x_m, y_m)) \in (\mathcal{X} \times \{-1, 1\})^m$.
Parameters $\kappa \in (0, 1), \theta \in [0, \frac{1}{2})$.

**Output:** Hypothesis $h : \mathcal{X} \to \{-1, 1\}$.

1: **function** QuantumSmoothBoost($\mathcal{W}$, $S$, $\kappa$, $\theta$)
2: $t \leftarrow 1$
3: **while** true **do**
4: Compute an estimate $\tilde{s}$ of $s = \sum_{i=1}^m M_i^t$ with multiplicative error 1.1 (using Theorem 7), where the $M_i^t$ are as defined in Step 9 of SmoothBoost (and only computed on demand).
5: If $\tilde{s} < \kappa m$ then $T \leftarrow t - 1$, **return** $h \leftarrow sign(\sum_{t=1}^T h_t)$, and **terminate**.
6: Prepare $W$ copies of example $|D^t\rangle$ w.r.t. distribution $D_i^t = \frac{M_i^t}{\sum_{i\in[m]} M_i^t}$ (using Theorem 13).
7: Feed those $W$ examples into the weak learner $\mathcal{W}$ to obtain base classifier $h_t$.
8: $t \leftarrow t + 1$.

Quantum Smoothboost runs $O(TW)$ quantum subroutines that each have some error probability. By setting this error probability to be $\ll 1/TW$, the union bound implies that the probability that at least one of them will fail, is very small. The extra cost-factor $\log(TW)$ that this error-reduction incurs will be absorbed by our $\tilde{O}(\cdot)$ notation.

If we condition on the very-high-probability event that the various quantum subroutines involved all succeed, then the weights $N^t$ and $M^t$ are just equal to the weights as they would be in classical SmoothBoost with the same number of iterations. Because our approximation $\tilde{s}$ of $s$ for the stopping criterion has small multiplicative error, the smoothness of the intermediate distributions $D^t$ before termination can be marginally worse than in classical SmoothBoost (Claim 8): For each $1 \le t \le T$, it holds that $\max_{i\in m} |D_i^t| \le \frac{1.1}{\kappa m}$.

Quantum SmoothBoost terminates if $\tilde{s} < \kappa m$. Because $\tilde{s}$ might underestimate the true $s$ by at most a factor 1.1, upon termination we have $s < 1.1\kappa m$ and hence Claim 10 implies empirical error $e\hat{r}r(h) < 1.1\kappa$. We set $\kappa = \varepsilon/2.2$ in order to ensure $e\hat{r}r(h) \le \varepsilon/2$. Like before, we choose the sample size $m$ given by Eq. (5) to ensure generalization error $\le \varepsilon$.

The total number of iterations is still $O(\frac{1}{\varepsilon\gamma^2})$.[9] It remains to determine the complexity of one iteration. The most costly steps in one iteration are Steps 4 and 6. As a subroutine these will use the fact that we can compute $M_i^t$ and $N_i^t$ using $O(t) = O(T)$ calls to the earlier base classifiers and the sample $S$.

[9] There is one small change in the proof of Claim 9: since we condition on all runs of quantum counting in Step 4 giving an estimate of $\sum_i M_i^t$ up to multiplicative error 1.1, we now have $\sum_{i=1}^m M_i^t \ge \kappa m/1.1$ for all $t$ until termination.

- Step 4. The approximation of $s = \sum_{i=1}^{m} M_i^t$ up to multiplicative error 1.1 using Theorem 7 costs $\tilde{O}(T\sqrt{m})$ (for simplicity assume $\varepsilon \gg 1/m$ to ensure the condition $s \geq 1$ in Theorem 7 holds.)
- Step 6. Preparing one copy of $|D^t\rangle$ costs $\tilde{O}(T/\sqrt{\varepsilon})$ by Section 4.1 (using our setting of $\kappa = \varepsilon/2.2$), so overall this step costs $\tilde{O}(WT/\sqrt{\varepsilon})$.

Adding these costs shows that one iteration costs $\tilde{O}(T(W/\sqrt{\varepsilon}+\sqrt{m}))$. Plugging in $T = O(\frac{1}{\varepsilon\gamma^2})$, and the same sample size $m = \tilde{O}(d/\varepsilon^3\gamma^2)$ as for classical SmoothBoost (from Eq. (5)), gives our main result:

▶ **Theorem 14.** *Let $\mathcal{W}$ be a $\gamma$-weak quantum learner of complexity $W$ for concept class $\mathcal{C}$, with hypothesis class $\mathcal{H}_{weak}$ of VC-dimension $d$. Then given $m$ examples according to Eq. (5), QuantumSmoothBoost is an $(\varepsilon, \delta)$-PAC learner for $\mathcal{C}$, with hypothesis class $\mathcal{H}_{strong}$. It runs the weak learner $O(\frac{1}{\varepsilon\gamma^2})$ times and uses*

$$\tilde{O}(T^2(W/\sqrt{\varepsilon}+\sqrt{m})) = \tilde{O}\left(\frac{W}{\varepsilon^{2.5}\gamma^4} + \frac{\sqrt{m}}{\varepsilon^2\gamma^4}\right) = \tilde{O}\left(\frac{W}{\varepsilon^{2.5}\gamma^4} + \frac{\sqrt{d}}{\varepsilon^{3.5}\gamma^5}\right)$$

*other operations (elementary computational steps, queries to the sample, and evaluations of base classifiers).*

For direct comparison with the quantum boosting result of Arunachalam and Maity [5], we instantiate this by setting $\varepsilon = \delta = 1/3$, in which case the complexity of Quantum SmoothBoost is

$$\tilde{O}\left(\frac{W}{\gamma^4} + \frac{\sqrt{d}}{\gamma^5}\right).$$

This polynomially improves over the time complexity $\tilde{O}\left(\frac{W^{1.5}\sqrt{d}}{\gamma^{11}}\right)$ of the quantum version of AdaBoost of [5], in the $W$-dependence but especially in the $\gamma$-dependence.

## 5 Future work

This work leaves open many questions for future work:

- The $\gamma$-dependence of Quantum Smoothboost is still slightly worse than in classical boosting ($1/\gamma^5$ vs $1/\gamma^4$). Is there a way to improve this further, or can we prove a lower bound on the $\gamma$-dependence for every quantum boosting algorithm that has $\sqrt{d}$-dependence on the VC-dimension of the weak learner's hypothesis class?
- Our quantum version of SmoothBoost improves the cost per iteration but not the number of iterations, which remains $T = O(1/\varepsilon\gamma^2)$. Can we reduce the number of iterations by quantizing SmoothBoost differently, or by quantizing some other boosting approach? There are classical boosting-type algorithms with fewer iterations than SmoothBoost, for instance [8], but it's not clear there how to significantly reduce the cost per iteration on a quantum computer.
- Boosting has many applications in theory and practice. Can we find applications where quantum Smoothboost is particularly suitable – some problem where the weak learner has relatively large advantage $\gamma$ and large VC-dimension $d$, so that the square-root improvement in $d$ dominates the worse dependence on $1/\gamma$?
- Can we do boosting for *agnostic* learning, where the label $y$ of an example $(x, y)$ is not determined by $x$ but $(x, y)$ is jointly generated by some distribution $\mathcal{D}$ on $\mathcal{X} \times \mathcal{Y}$?

- What about learning with various kinds of noise in the sample: random classification noise, or Massart noise, or Tsybakov noise, or malicious noise? Servedio [22] designed SmoothBoost motivated by its ability to deal with malicious noise on the labels of the sample: if 1/100 of the $m$ given examples have their label flipped, then a distribution that puts probability $\leq c/m$ on each $i$ only puts total probability $\leq c/100$ on the erroneous examples. Servedio used this to give a learning algorithm for linear threshold functions that is robust against small, $\gamma$-dependent amounts of malicious noise (see [17] and references therein for follow-up work). This result straightforwardly carries over to the quantum case using our Quantum SmoothBoost (we omit the details), but we don't know much more about quantum learning with malicious noise.
- What about learning functions that have a larger range than just $\{-1, 1\}$?
- Our booster relies on a VC-dimension-based analysis of boosting. However, there are non-VC-based analyses of boosting [20], which to some extent can explain why boosting avoids overfitting even when the VC-dimension of the booster's hypothesis class gets large (i.e., when $T$ gets large). We might use this to give an alternative analysis of quantum boosters.

## Abstract

We study the parameterized complexity of two classic problems on directed graphs: Hamiltonian Cycle and its generalization Longest Cycle. Since 2008, it is known that Hamiltonian Cycle is W[1]-hard when parameterized by *directed treewidth* [Lampis et al., ISSAC'08]. By now, the question of whether it is FPT parameterized by the *directed feedback vertex set* (DFVS) number has become a longstanding open problem. In particular, the DFVS number is the largest natural directed width measure studied in the literature. In this paper, we provide a negative answer to the question, showing that even for the DFVS number, the problem remains W[1]-hard. As a consequence, we also obtain that Longest Cycle is W[1]-hard on directed graphs when parameterized multiplicatively above girth, in contrast to the undirected case. This resolves an open question posed by Fomin et al. [ACM ToCT'21] and Gutin and Mnich [arXiv:2207.12278]. Our hardness results apply to the path versions of the problems as well. On the positive side, we show that Longest Path parameterized multiplicatively above girth belongs to the class XP.

## 1 Introduction

**Hamiltonian Cycle (Path) Parameterized by DFVS.** In Hamiltonian Cycle (Path), we are given a (directed or undirected) graph $G = (V, E)$, and the objective is to determine whether $G$ contains a simple cycle (path) of length $n = |V(G)|$, called a *Hamiltonian cycle (path)*. Hamiltonian Cycle[1] has been widely studied, from various algorithmic (see, e.g., [7, 9–12, 15, 16, 28, 29, 37]) and structural (see, e.g., the survey [50]) points of view. This problem is among the first problems known to be NP-complete [60], and it remains NP-complete on various restricted graph classes (see, e.g., [2, 20, 46]). Nevertheless, a longest path can be found easily in polynomial-time on the large class of directed acyclic graphs (DAGs) using dynamic programming.[2] Thus, it is natural to ask – can we solve Hamiltonian Cycle efficiently on wider classes of directed graphs that resemble DAGs to some extent?

[1] Throughout the following paragraphs, we refer only to the cycle variant of the problem, but the same statements also hold for the path variant.

[2] For example, see the lecture notes at https://people.csail.mit.edu/virgi/6.s078/lecture17.pdf.

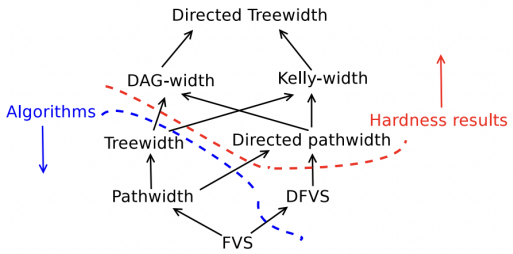

**Figure 1** Figure 3 in [59]. Caption (verbatim): *"The ecology of digraph widths. Undirected measures refer to the underlying undirected graph. Arrows denote generalizations (for example small treewidth implies small kelly-width). The dashed lines indicate rough borders of known tractability and intractability for most studied problems (including* Hamiltonian Cycle*)."*

In the undirected realm, the class of acyclic graphs (i.e., forests) can be generalized to graphs of bounded treewidth [27]. The celebrated Courcelle's theorem [24] states that a wide range of problems, including Hamiltonian Cycle, are *fixed-parameter tractable* (FPT)[3] when parameterized by treewidth. Historically, the notion of *directed treewidth* (Definition 4) was introduced by Johnson et al. [58] as a generalization of the undirected notion contrived to solving linkage problems such as Hamiltonian Cycle; see also [70]. Since then, directed treewidth has been intensively studied (see, e.g., [1, 47, 48, 52, 61, 76]). Over the years, various other width measures for directed graphs have been proposed and studied as well, where the most prominent ones are the DFVS number (which is the minimum number of vertices to remove to make the graph acyclic), *directed pathwidth* (defined similarly to directed treewidth, where we replace trees by paths), *DAG-width* [69] and *Kelly-width* [55]. Notably, DFVS is the largest among them (see Fig. 1). Johnson et al. [58] and Hunter et al. [55] proved that Hamiltonian Cycle (as well as Longest Cycle, defined later) is *slice-wise polynomial* (XP) parameterized by directed treewidth. Later, Lampis et al. [64] (originally in 2008 [63]) showed that, here, this is the "right" form of the time complexity: they proved that Hamiltonian Cycle parameterized by directed pathwidth is W[1]-hard (in fact, even W[2]-hard), implying that the problem is unlikely to be FPT.

Thus, since 2008, it has remained open whether Hamiltonian Cycle parameterized by DFVS is FPT or W[1]-hard (see Fig. 1). As a follow-up to their result, Kaouri et al. [59] wrote: *"Treewidth occupies a sweet spot in the map of width parameters: restrictive enough to be efficient and general enough to be useful. What is the right analogue which occupies a similar sweet spot (if it exists) for digraphs? One direction is to keep searching for the right width that generalizes DAGs, that is searching the area around (and probably above) DFVS. ... The other possibility is that widths which generalize DAGs, such as DFVS and all the currently known widths, may not necessarily be the right path to follow. ... The search is on!"*

Our main contribution is, essentially, the finish line for this search for Hamiltonian Cycle. We prove that, unfortunately, already for DFVS number itself, the problem is W[1]-hard. Formally, Hamiltonian Cycle (Path) By DFVS is defined as follows: Given a directed graph $G = (V, E)$ and a subset $X \subseteq V(G)$ such that $G - X$ is acyclic, determine whether $G$ contains a Hamiltonian cycle (path). Here, the parameter is $|X|$. Note that $X$ need not be given as input – the computation of a minimum-size vertex set whose removal makes a given directed graph acyclic is in FPT [23], so, given a directed graph $G$, we can simply run the corresponding algorithm to attain $X$ whose size is the DFVS number of $G$.

[3] A problem is FPT (resp. XP) if it is solvable in time $f(k) \cdot n^{O(1)}$ (resp. $n^{f(k)}$) for some computable function $f$ of the parameter $k$, where $n$ is the size of the input.

▶ **Theorem 1.** Hamiltonian Cycle By DFVS *is* W[1]*-hard.*

We also obtain the same hardness result for Hamiltonian Path By DFVS. Notice that Hamiltonian Cycle (Path) By DFVS is in XP, since, as mentioned earlier, it is already known to be in XP even when parameterized by the smaller parameter directed treewidth [58]. So, the classification of this problem is resolved.

Lastly, we remark that the choice of the larger directed feedback arc set (DFAS) number is also futile, as it also yields W[1]-hardness. Indeed, there is a simple reduction that shows this: Replace each vertex $v$ in $S$ by two vertices, $v_{\mathsf{in}}$ and $v_{\mathsf{out}}$, so that all vertices that were in-neighbors (out-neighbors) of $v$ become in-neighbors (out-neighbors) of $v_{\mathsf{in}}$ ($v_{\mathsf{out}}$), and add the arc $(v_{\mathsf{in}}, v_{\mathsf{out}})$. It is immediate that the original instance is a Yes-instance of Hamiltonian Cycle if and only if the new instance is, and that the DFVS number of the original graph equals the DFAS number of the new graph.

**Longest Cycle (Path) Above Girth.** In the Longest Cycle (Path) problem, also known as $k$-Long Cycle ($k$-Path), we are given a (directed or undirected) graph $G$ and a non-negative integer $k$, and the objective is to determine whether $G$ contains a simple cycle (path) of length at least $k$. Clearly, Longest Cycle is a generalization of Hamiltonian Cycle as the latter is the special case of the former when $k = n$. Over the past four decades, Longest Cycle and Longest Path have been intensively studied from the viewpoint of parameterized complexity. There has been a long race to achieve the best known running time on general (directed and undirected) graphs for the parameter is $k$ [5, 14, 17, 19, 22, 40, 44, 54, 62, 67, 72, 74, 77–79], where the current winners for directed graphs have time complexity $4^k \cdot n^{O(1)}$ [79] for Longest Cycle and $2^k \cdot n^{O(1)}$ [77] for Longest Path. Moreover, the parameterized complexity of the problems was analyzed with respect to structural parameterizations (see, e.g., [7, 28, 29, 33, 37, 45, 49]), on special graph classes (see, e.g., [32, 41, 42, 66, 68, 80]), and when counting replaces decision [3, 4, 6, 13, 18, 25, 26, 34, 65, 75]. In fact, Longest Path is widely considered to be one of the most well studied in the field, being, perhaps, second only to Vertex Cover [27].

We consider the "multiplicative above guarantee" parameterization for Longest Path where the guarantee is girth[4], called Longest Cycle (Path) Above Girth, which is defined as follows (for directed graphs): Given a directed graph $G = (V, E)$ with girth $g$ and a positive integer $k$, determine whether $G$ contains a cycle (path) of length at least $g \cdot k$. Here, the parameter is $k$. This parameterization of Longest Cycle (Path) was considered by Fomin et al. [36], who proved that on undirected graphs the problem is in FPT. They posed the following open question: *"For problems on directed graphs, parameterization multiplicatively above girth (which is now the length of a shortest directed cycle) may also make sense. For example, what is the parameterized complexity of* Directed Long Cycle *under this parameterization?"* This question was also posed by Gutin et al. [51] as Open Question 9. As our second contribution, we resolve this question – in sharp contrast to the undirected case, the answer is negative:

▶ **Theorem 2.** Longest Cycle Above Girth *is* W[1]*-hard.*

Again, we can transfer the hardness also to the longest path setting. On the positive side, we give a deterministic XP algorithm for the path variant of the problem.

▶ **Theorem 3.** Longest Path Above Girth *is in* XP*.*

[4] The girth of a graph is the length of its shortest cycle, and it is easily computable in polynomial time.

Therefore, the classification of this problem is resolved as well. Notice that this theorem also easily implies that when we ask for a path of length at least $g + k$, the problem is in FPT (in fact, solvable in time $2^{O(k)} \cdot n^{O(1)}$) as follows. If $k \geq g$, then we can simply run some known $2^{O(k)} \cdot n^{O(1)}$-time algorithm for Longest Path parameterized by the solution size. Otherwise, when $k < g$, we create $n$ instances of Longest Path Above Girth with parameter 2 (thus, solvable in polynomial time by our theorem), one for each vertex $v$: Replace $v$ by a path of length $g - k$ whose start vertex has all in-neighbors of $v$ as its in-neighbors and whose end vertex has all out-neighbors of $v$ as its out-neighbors, and take the disjoint union of the resulting graph and a cycle of length $g$; it is easy to see that we should return Yes if and only if the answer to at least one of these $n$ instances is Yes.

Other above/below guarantee versions of Longest Cycle (Path) were also considered in the literature; see [8,35,38,39,51,53,56,57]. Remarkably, while the parameterized complexity of all of these versions is quite well understood for undirected graphs, the resolution of the parameterized complexity of most of these versions has been (sometimes repeatedly) asked as an open question for directed graphs, where only little is known. It is conceivable that our contributions will shed light on these open questions as well in future works.

## 1.1 Techniques

**Hamiltonian Cycle By DFVS.** Before describing the ideas behind our reduction, we provide some background about the related Disjoint Paths problem. Here, we are given a graph with $k$ vertex pairs $(s_i, t_i)$ and the goal is to determine whether there exists $k$ vertex-disjoint[5] paths such that the $i$-th path connects $s_i$ to $t_i$. While Disjoint Paths is famously known to be FPT (parameterized by $k$) on undirected graphs [71], the problem becomes NP-hard on directed graphs already for $k = 2$ [43]. What is interesting for us is that when the input is restricted to be a DAG, then Disjoint Paths can be solved by an XP algorithm [43], but it is unlikely to admit an FPT algorithm as the problem is W[1]-hard [73].

The latter result suggests a starting point for extending the hardness to our problem. A simple idea to design a reduction from Disjoint Paths on DAGs is to just insert edges $t_1 \to s_2, t_2 \to s_3, \ldots, t_k \to s_1$. Then the set $\{s_1, \ldots, s_k\}$ becomes a DFVS and the existence of $k$ disjoint $(s_i, t_i)$-paths implies the existence of a long cycle. There is a catch, though. This construction might turn a No-instance into an instance with a long cycle because the cycle might traverse the vertices $s_i, t_i$ in a different order, corresponding to a family of disjoint paths which does not form a solution to the original instance. To circumvent this, we open the black box and give a reduction directly from the basic W[1]-complete problem – Multicolored Clique – while adapting some ideas from the hardness proof for Disjoint Paths on DAGs by Slivkins [73].

The construction by Slivkins uses two kinds of gadgets. First, for each $i = 1, \ldots, k$ one needs a *choice gadget* comprising two long directed paths with some arcs from the first path to the second one. The solution path corresponding to the $i$-th choice gadget must choose one of these arcs to "change the lane"; the location of this change encodes the choice of the $i$-th vertex in the clique. Next, for each pair $(i, j)$, where $1 \leq i < j \leq k$, one needs a *verification gadget* to check whether the $i$-th and $j$-th chosen vertices are adjacent. The corresponding solution path must traverse the $i$-th and $j$-th choice gadgets around the locations of their transitions. The arcs between the choice gadgets are placed in such a way that both these locations can be visited only when the corresponding edge exists in the original graph.

[5] Another studied variant involves finding edge-disjoint paths. While these two problems behave differently in some settings, this is not the case in our context.

Our reduction relies on a similar mechanism of choice gadgets, formed by $k$ directed paths, corresponding to $k$ colors in the Multicolored Clique instance. The $i$-th path is divided into blocks corresponding to the vertices of color $i$. We enforce that a Hamiltonian cycle must omit exactly one block when following such a path, thus encoding a choice of $k$ vertices. The arcs between blocks from different paths encode the adjacency matrix of the original graph. We would like to guarantee that any Hamiltonian cycle $C$ visits each omitted block $k-1$ times, utilizing the arcs mentioned above. To ensure this, we need to allow $C$ to "make a step backward" on the directed path during such a visit. On the other hand, we cannot afford to create too many disjoint cycles because DFVS should have size bounded in terms of $k$. As a remedy, we attach $k-1$ long cycles to each choice gadget, which are connected to every block in a certain way (see Figure 3 on page 8). Using the fact that every vertex in the gadget must be visited by $C$ at some point, we prove that each long cycle is entered exactly once and each choice gadget is entered exactly $k$ times in total, imposing a rigid structure on a solution. As a result, we get rid of the flaw occurring in the naive construction and obtain an equivalent instance with DFVS number $\mathcal{O}(k^2)$.

**Longest Cycle (Path) Above Girth.** Having established our main hardness result, it is easy to extend it to Longest Cycle (Path) Above Girth. We replace each vertex $v$ in the DFVS by two vertices $v_{in}$ and $v_{out}$, splitting the in- and out-going arcs of $v$ between them, and insert a long path from $v_{in}$ to $v_{out}$. This path is set sufficiently long to make the girth $g$ of the graph comparable to its size. Consequently, the original graph $G$ is Hamiltonian if and only if the second one has a cycle of length $g \cdot (\mathsf{dfvs}(G)+1)$. So, this problem is also W[1]-hard.

To design an XP algorithm for Longest Path Above Girth, we follow the win-win approach employed by the FPT algorithm for the undirected case [36], which relies on a certain version of the Grid Minor Theorem. In general, the theorem states that either a graph contains a $k \times k$-grid as a minor, or its treewidth is bounded by $f(k)$, for some (in fact, polynomial) function $f$. In the first scenario, a sufficiently long path always exists, whereas in the second scenario, the problem is solved via dynamic programming on the tree decomposition.

We take advantage of the directed counterpart of the Grid Minor Theorem: either a digraph contains a subgraph isomorphic to a subdivision of the order-$\mathcal{O}(k)$ cylindrical wall or its directed treewidth is bounded by $f(k)$, for some function $f$ [61]. We prove that in the first scenario again a sufficiently long path always exists (so we obtain a Yes-instance), while in the second scenario we can utilize the known algorithm to compute the longest path in XP time with the help of the directed tree decomposition. Finally, let us remark that this argument does not extend to Longest Cycle Above Girth because we cannot guarantee the existence of a sufficiently long cycle in a subdivision of a cylindrical wall. We leave it open whether this problem belongs to XP as well.

## 2 Preliminaries

**General Notation.** For an integer $r$, let $[r] = \{1, \ldots, r\}$, and for integers $r_1, r_2$, let $[r_1, r_2] = \{r_1, r_1+1, \ldots, r_2\}$. We refer to [27] for standard definitions in Parameterized Complexity.

**Directed Graphs.** We use standard graph theoretic terminology from Diestel's book [31]. We work with simple directed graphs (digraphs) where the edges are given by a set $E$ of ordered pairs of vertices. For an edge $e = (u, v)$ in a digraph $G$, we say that $u$ is an *in-neighbor* of $v$ and $v$ is an *out-neighbor* of $u$. We refer to $e$ as an *incoming edge of* $v$ and an *outgoing* edge of $u$. For a vertex set $S \subseteq V(G)$ we define $\partial^{out}(S) = \{(u, v) \in E(G) \colon u \in S\}$,

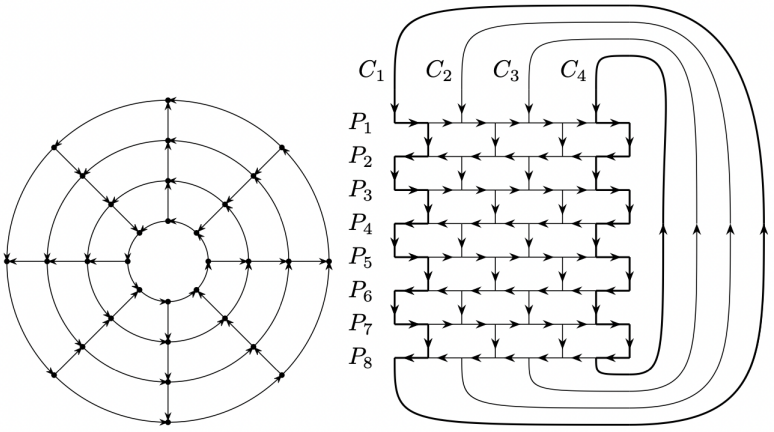

**Figure 2** A cylindrical grid and a cylindrical wall of order 4. The figure is taken from [61].

$\partial^{in}(S) = \{(u,v) \in E(G) \colon v \in S\}$, and $\partial(S) = \partial^{out}(S) \cup \partial^{in}(S)$. For two vertex sets $A, B \subseteq V(G)$ we write $E(A,B)$ for $\partial(A) \cap \partial(B)$, that is, the set of edges with one endpoint in $A$ and the other in $B$. We use this notation only when the digraph $G$ is clear from the context. When $C$ is a subgraph of $G$ we abbreviate $\partial(C) = \partial(V(C))$ and likewise for the remaining notation. A digraph $G$ is *isomorphic* to a digraph $H$ if there is a bijection $f : V(G) \to V(H)$ such that for any $u, v \in V(G)$ we have $(u,v) \in E(G)$ if and only if $(f(u), f(v)) \in E(H)$. The *length* of a path (or a cycle) $P$ is the number of edges in $P$. When the first and last vertices of a path $P$ are $s$ and $t$, respectively, we call it an *$(s,t)$-path*. A cycle in $G$ is called *Hamiltonian* if it visits all the vertices of $G$. The *girth* of a digraph $G$ is the shortest length of a cycle in $G$. For a rooted tree $T$ and a node $t \in V(T)$, $T_t$ denotes the subtree of $T$ rooted at $t$. By orienting each edge in a rooted tree from a parent to its child we obtain an *arborescence*.

**Directed Treewidth.** We move on to the directed counterparts of treewidth and grids.

▶ **Definition 4** (Directed Tree Decomposition [61]). *A* directed tree decomposition *of a directed graph $G$ is a triple $(T, \beta, \gamma)$, where $T$ is an arborescence, and $\beta : V(T) \to 2^{V(G)}$ and $\gamma : E(T) \to 2^{V(G)}$ are functions such that*

1. *$\{\beta(t) : t \in V(T)\}$ is a partition of $V(G)$ into (possibly empty) sets, and*
2. *if $e = (s,t) \in E(T)$, $A = \bigcup\{\beta(t') : t' \in V(T_t)\}$ and $B = V(G) \setminus A$, then there is no closed (directed) walk in $G - \gamma(e)$ containing a vertex in $A$ and a vertex in $B$.*

*For $t \in V(T)$, define $\Gamma(t) := \beta(t) \cup \bigcup\{\gamma(e) : e \text{ is incident with } t\}$. Moreover, define $\beta(T) := \bigcup\{\beta(t') : t' \in V(T)\}$.*

*The* width *of $(T, \beta, \gamma)$ is the least integer $w$ such that $|\Gamma(t)| \leq w+1$ for all $t \in V(T)$. The* directed treewidth *of $G$ is the least integer $w$ such that $G$ has a directed tree decomposition of width $w$.*

▶ **Definition 5** (Subdivision). *For a directed graph $G$, the* edge subdivision *of $(u,v) \in E(G)$ is the operation that removes $(u,v)$ from $G$ and inserts two edges $(u,w)$ and $(w,v)$ with the new vertex $w$. A graph derived from $G$ by a sequence of edge subdivisions is a* subdivision *of $G$.*

We now define special graphs called cylindrical grids and cylindrical walls (see Fig. 2).

▶ **Definition 6** (Cylindrical Grid and Cylindrical Wall [21]). *A* cylindrical grid of order $k$, *for some $k \geq 1$, is the directed graph $G_k$ consisting of $k$ pairwise vertex disjoint directed cycles $C_1, \ldots, C_k$, together with $2k$ pairwise vertex disjoint directed paths $P_1 \ldots, P_{2k}$ such that:*

- *for* $i \in [k]$, $V(C_i) = \{v_{i,1}, v_{i,2}, \ldots, v_{i,2k}\}$ *and* $E(C_i) = \{(v_{i,j}, v_{i,j+1}) |\ j \in [2k-1]\} \cup \{(v_{i,2k}, v_{i,1})\}$
- *for* $i \in \{1, 3, 5, \ldots, 2k-1\}$, $E(P_i) = \{(v_{1,i}, v_{2,i}), (v_{2,i}, v_{3,i}), \ldots, (v_{k-1,i}, v_{k,i})\}$, *and*
- *for* $i \in \{2, 4, 6, \ldots, 2k\}$, $E(P_i) = \{(v_{k,i}, v_{k-1,i}), (v_{k-1,i}, v_{k-2,i}), \ldots, (v_{2,i}, v_{1,i})\}$.

*A* cylindrical wall of order $k$ *is the directed graph* $W_k$ *obtained from the cylindrical grid* $G_k$ *by splitting each vertex of degree* 4 *as follows: we replace* $v$ *by two new vertices* $v_{in}, v_{out}$ *and an edge* $(v_{in}, v_{out})$ *so that every edge* $(u, v) \in E(G_k)$ *is replaced by an edge* $(u, v_{in})$ *and every edge* $(v, u) \in E(G_k)$ *is replaced by an edge* $(v_{out}, u)$.

Note that in the cylindrical grid $G_k$, the path $P_i$ is oriented from the first cycle to the last one if $i$ is odd, and from the last cycle to the first if $i$ is even (see Figure 2). We have the following theorem for directed graphs, which will be helpful in designing our algorithm in Section 4 using a win/win approach.

▶ **Theorem 7** (Directed Grid Theorem [61]). *There is a function* $f : \mathbb{N} \to \mathbb{N}$ *such that for every fixed* $k \in \mathbb{N}$*, when given a directed graph* $G$*, in polynomial time we can compute either:*

1. *a subgraph of* $G$ *that is isomorphic to a subdivision*[6] *of* $W_k$ *or*
2. *a directed tree decomposition of* $G$ *of width at most* $f(k)$.

## 3 Hardness of Hamiltonian Cycle By DFVS

This section is devoted to the proof of Theorem 1. It is based on a parameterized reduction from Multicolored Clique, defined as follows.

Multicolored Clique
**Input:** A graph $G = (V, E)$, an integer $k$, and a partition $(V^1, V^2, \ldots, V^k)$ of $V$.
**Parameter:** $k$
**Question:** Is there a clique of size $k$ with a vertex from each $V^i$, $i \in [k]$?

This problem is well-known to be W[1]-hard [27, Theorem 13.7]. For an instance $(G, (V^1, V^2, \ldots, V^k))$ of Multicolored Clique, we construct an instance $(G', X)$ of Hamiltonian Cycle By DFVS as follows.

**Construction of $G'$.** For $i \in [k]$ we construct a directed path $P^i$ corresponding to $V^i$ as follows. Let us fix an arbitrary ordering $<_i$ of the vertices in $V^i$, and accordingly, denote $V^i = \{v_1, v_2, \ldots v_{|V_i|}\}$. To each vertex $v \in V^i$ we associate a directed path $P_v$ on $2k$ vertices. We let $v^{left}$ and $v^{right}$ denote the first and last vertices of $P_v$, respectively. We refer to the $2(k-1)$ internal vertices of $P_v$ as $v^{1,out}, v^{1,in}, v^{2,out}, \ldots, v^{i-1,out}, v^{i-1,in}, v^{i+1,out}, v^{i+1,in}, \ldots, v^{k,out}, v^{k,in}$ (note that the index $i$ is avoided). The directed path $P^i$ is the concatenation of these paths: $P_{v_1} \to P_{v_2} \to, \ldots, \to P_{v_{|V^i|}}$.

For every $i \in [k]$ we create a "universal" vertex $u^i$ and insert edges $(u_i, v^{left})$, $(u_i, v^{right})$, $(v^{left}, u_i)$, $(v^{right}, u^i)$ for all $v \in V^i$. Next, we create $k-1$ cycles $C^{i \to j}$ for $j \in [k] \setminus \{i\}$, each of length $2 \cdot |V^i|$. The vertices of $C^{i \to j}$ are $c^{i \to j,out}_{v_1}, c^{i \to j,in}_{v_1}, c^{i \to j,out}_{v_2}, c^{i \to j,in}_{v_2}, \ldots, c^{i \to j,out}_{v_{|V_i|}}, c^{i \to j,in}_{v_{|V_i|}}$. We insert edges from $c^{i \to j,out}_v$ to $v^{j,out}$ and from $v^{j,in}$ to $c^{i \to j,in}_v$ for all $v \in V^i$. See Figure 3 for an illustration.

[6] The theorem in [61] states that the cylindrical wall of order $k$ is obtained as a topological minor of $G$. For any topological minor $H$ of $G$, there exists a subdivision of $H$ isomorphic to a subgraph of $G$.

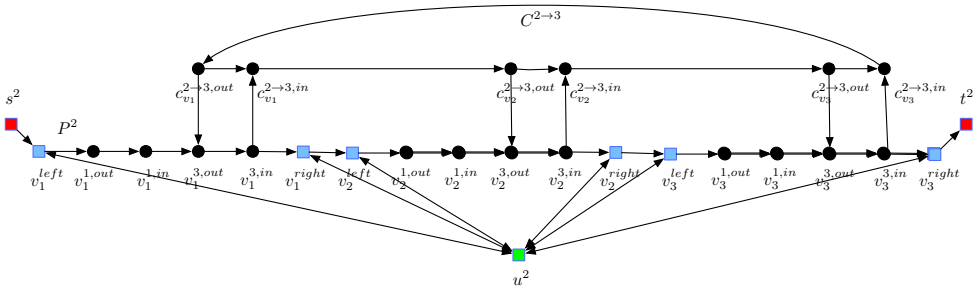

**Figure 3** Fragment of the graph $G'$: the path $P^2$ (comprising subpaths $P_{v_1}, P_{v_2}, P_{v_3}$) and the cycle $C^{2\to3}$.

We add two sets of $k$ "terminal" vertices: $S = \{s^1, s^2, \ldots, s^k\}$ and $T = \{t^1, t^2, \ldots, t^k\}$. For $i \in [k]$ we insert edges from $s^i, i \in [k]$, to $v_1^{left}$ (being the first vertex of the path $P^i$). We also add edges from $v_{|V^i|}^{right}$ (being the last vertex of the path $P^i$) to $t^i$.

We also create two additional sets of $\binom{k}{2}$ terminal vertices each: $\widehat{S} = \{\widehat{s}^{i\to j} : 1 \le 1 < j \le k\}$ and $\widehat{T} = \{\widehat{t}^{i\to j} : 1 \le 1 < j \le k\}$. For $i, j \in [k], i < j$, and $v \in V^i$, we insert an edge from $\widehat{s}^{i\to j}$ to $v^{j,\mathsf{in}}$ (which belongs to $P_v$ and hence to $P^i$) and for $v \in V^j$, we insert an edge from $v^{i,\mathsf{out}}$ to $\widehat{t}^{i\to j}$. Furthermore, we add edges from every $t \in T \cup \widehat{T}$ to every $s \in S \cup \widehat{S}$.

Finally we encode the adjacency matrix of $G$: for each edge $uv$ in $E(G)$ with $u \in V^i$ and $v \in V^j$ with $i < j$, we insert an edge from $u^{j,\mathsf{out}}$ to $v^{i,\mathsf{in}}$. See Figure 4 for an example.

This concludes the construction of $G'$. Clearly, the graph $G'$ can be computed in polynomial time when given $(G, (V^1, \ldots, V^k))$. We begin the analysis of $G'$ by showing that it has a DFVS of size $\mathcal{O}(k^2)$.

▶ **Lemma 8.** *There exists a subset $X \subseteq V(G')$ such that $G' - X$ is a DAG and $|X| = k(k-1) + 2k + \binom{k}{2}$.*

**Proof.** Let $Y$ be the set of vertices $\{c_{v^i}^{i\to j,\mathsf{out}} : i, j \in [k], i \ne j\}$ where $v^i$ stands for the first vertex in $V^i$. We set $X = Y \cup T \cup \widehat{T} \cup \{u^1, \ldots u^k\}$ and claim that $G' - X$ is a directed acyclic graph. First observe that for each $i \in [k]$ the graph $L^i := P^i \cup \bigcup_{j\ne i} C^{i\to j} - X$ is acyclic because it can be drawn with each edge being either vertical or horizontal facing right (see Figure 3). The remaining edges in $G' - X$ either start at $S \cup \widehat{S}$ (these vertices have no incoming edges) or go from $L^i$ to $L^j$ for $i < j$. Thus $G' - X$ is a DAG. Finally we check that $|X| = |Y| + |T| + |\widehat{T}| + k = k(k-1) + 2k + \binom{k}{2}$. ◀

**Correctness.** We first show that if $(G, (V^1, V^2, \ldots, V^k))$ is a Yes-instance then there exists a Hamiltonian cycle in $G'$. In the following lemmas, we refer to the directed feedback vertex set $X$ from Lemma 8.

▶ **Lemma 9.** *If $(G, (V^1, V^2, \ldots, V^k))$ is a Yes-instance of* Multicolored Clique *then $(G', X)$ is a Yes-instance of* Hamiltonian Cycle By DFVS.

**Proof.** Let $\{v_1, \ldots, v_k\}$ be a clique in $G$ with $v_i \in V^i$ for $i \in k$. For $i \in [k]$ we define the path $Z^i$ that starts at $s^i$, follows $P^i$ until $v_i^{left}$, visits $u^i$, and then follows $P^i$ from $v_i^{right}$ to $t^i$. Next, for $i < j$ we construct the path $Q^{i\to j}$ as $\widehat{s}^{i\to j} \to v_i^{j,\mathsf{in}} \to C^{i\to j} \to v_i^{j,\mathsf{out}} \to v_j^{i,\mathsf{in}} \to C^{j\to i} \to v_j^{i,\mathsf{out}} \to \widehat{t}^{i\to j}$. Note that one can traverse the entire cycle $C^{i\to j}$ after entering it from $v_i^{j,\mathsf{in}}$ and leave towards $v_i^{j,\mathsf{out}}$. The edge $(v_i^{j,\mathsf{out}}, v_j^{i,\mathsf{in}})$ is present in $G'$ due to the encoding of the adjacency matrix of $G$. The union of all these paths covers the entire vertex set of $G'$. It suffices to observe that these paths can be combined into a single cycle using the edges from $T \cup \widehat{T}$ to $S \cup \widehat{S}$. ◀

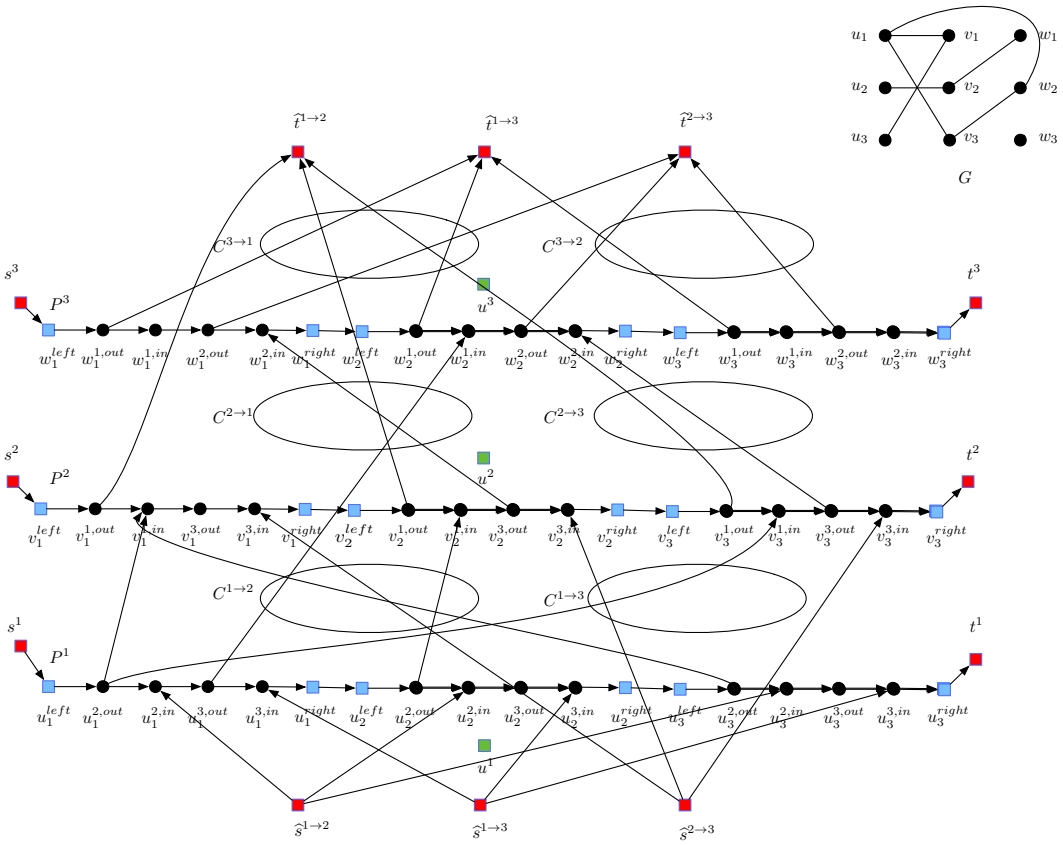

**Figure 4** Graph $G$ (top right) with a clique $\{u_1, v_3, w_2\}$ and the graph $G'$ encoding $G$. For the sake of legibility, several groups of edges are omitted in this picture: edges incident to $u^i$ or the cycles $C^{i\to j}$ and edges going from $T \cup \widehat{T}$ to $S \cup \widehat{S}$.

Proving the converse of Lemma 9 is more challenging. We will reveal the structure of a potential Hamiltonian cycle $H$ in $G'$ gradually. First, we show that if $H$ enters the cycle $C^{i\to j}$ through an incoming edge corresponding to a certain vertex $v \in V^i$, then it must also leave it through an outgoing edge related to $v$, and vice versa. A priori, there might be multiple vertices $v \in V^i$ for which this happens.

For $v \in V^i$ we denote the edge from $c_v^{i\to j,out}$ to $v^{j,out}$ by $e_v^{i\to j,out}$. Similarly, let the edge from $v^{j,in}$ to $c_v^{i\to j,in}$ be $e_v^{i\to j,in}$.

▶ **Lemma 10.** *Let $H$ be a Hamiltonian cycle in $G'$ and $1 \le i < j \le k$. Then $E(H) \cap \partial(C^{i\to j})$ is of the form $\bigcup_{v\in U}\{e_v^{i\to j,out}, e_v^{i\to j,in}\}$ where $U$ is some subset of $V^i$.*

**Proof.** Note that $\partial(C^{i\to j}) = \{e_{v_1}^{i\to j,out}, e_{v_1}^{i\to j,in}, e_{v_2}^{i\to j,out}, e_{v_2}^{i\to j,in}, \dots e_{v_{|V_i|}}^{i\to j,out}, e_{v_{|V_i|}}^{i\to j,in}\}$. First suppose that for some $v \in V^i$, we have $e_v^{i\to j,in} \in E(H)$. Since $H$ is a Hamiltonian cycle in $G'$, it has to visit the vertex $c_v^{i\to j,out}$. Thus $H$ contains an outgoing edge of $c_v^{i\to j,out}$. The only two outgoing edges of $c_v^{i\to j,out}$ are $e_v^{i\to j,out}$ and $(c_v^{i\to j,out}, c_v^{i\to j,in})$. Since $e_v^{i\to j,in} \in E(H)$ is an incoming edge of $c_v^{i\to j,in}$, the edge $(c_v^{i\to j,out}, c_v^{i\to j,in})$ cannot belong to $E(H)$. The only other candidate for the outgoing edge of $c_v^{i\to j,out}$ is $e_v^{i\to j,out}$, so $e_v^{i\to j,out} \in E(H)$.

The proof of implication in the other direction is analogous. Hence for each $v \in V^i$ we have $e_v^{i\to j,out} \in E(H) \Leftrightarrow e_v^{i\to j,in} \in E(H)$. ◀

As the next step, we show that when $v \in V^i$ and a Hamiltonian cycle enters some cycle $C^{i\to j}$ adjacent to $P^i$ through a vertex from $P_v$, then it must enter all the $k-1$ cycles adjacent to $P^i$ through $P_v$. Again, we cannot yet exclude a scenario that this would happen for multiple vertices $v \in V^i$.

▶ **Lemma 11.** *For any Hamiltonian cycle $H$ in $G'$ and $i \in [k]$, there exists a subset $U \subseteq V^i$ for which we have $E(H) \cap E(P^i, \bigcup_{j\neq i} C^{i\to j}) = \bigcup_{v\in U} E(P_v, \bigcup_{j\neq i} C^{i\to j})$.*

**Proof.** Targeting a contradiction, suppose there exists a vertex $v \in V^i$ such that at least one edge of $E(P_v, \bigcup_{j\neq i} C^{i\to j})$ is in $E(H)$ and at least one edge of $E(P_v, \bigcup_{j\neq i} C^{i\to j})$ is not in $E(H)$. From Lemma 10 we know that $E(H) \cap E(P_v, \bigcup_{j\neq i} C^{i\to j})$ is a union of pairs of the form $\{e_v^{i\to j,\mathsf{out}}, e_v^{i\to j,\mathsf{in}}\}$ for some $j \in [k] \setminus \{i\}$. Hence there indices $p, j \in [k] \setminus \{i\}$ so that $(v^{p,\mathsf{in}}, v^{j,\mathsf{out}}) \in E(P^i)$, one of the sets $E(B_v, C^{i\to p})$, $E(B_v, C^{i\to j})$ has empty intersection with $E(H)$ and the other one is contained in $E(H)$. We can assume w.l.o.g. that $j = p+1$ and the first of these sets is empty.

We arrive at the following scenario: $p \in [k] \setminus \{i\}$, $e_v^{i\to p,\mathsf{out}}, e_v^{i\to p,\mathsf{in}} \notin E(H)$ and $e_v^{i\to p+1,\mathsf{out}}, e_v^{i\to p+1,\mathsf{in}} \in E(H)$. Since $H$ is a Hamiltonian cycle, it has to visit the vertex $v^{p,\mathsf{in}}$. Thus, it has to traverse an outgoing edge of $v^{p,\mathsf{in}}$. The only outgoing edges of $v^{p,\mathsf{in}}$ are the edges $e_v^{i\to p,\mathsf{in}}$ and $(v^{p,\mathsf{in}}, v^{p+1,\mathsf{out}})$. By the assumption, $e_v^{i\to p,\mathsf{in}} \notin E(H)$ so $(v^{p,\mathsf{in}}, v^{p+1,\mathsf{out}}) \in E(H)$. On the other hand, since $e_v^{i\to p+1,\mathsf{out}} \in E(H)$ is an incoming edge of $v^{p+1,\mathsf{out}}$, we have $(v^{p,\mathsf{in}}, v^{p+1,\mathsf{out}}) \notin E(H)$ as it is also an incoming edge to $v^{p+1,\mathsf{out}}$. This yields a contradiction. ◀

We want to argue now that in fact the set $U$ in Lemma 11 is a singleton, that is, for fixed $i \in [k]$ each cycle $C^{i\to j}$ is being entered exactly once and from the same subpath $P_v$ of $P^i$. To this end, we take advantage of the universal vertices $u^i$.

▶ **Lemma 12.** *For any Hamiltonian cycle $H$ in $G'$ and $i \in [k]$ there exists $v \in V^i$ such that $E(H) \cap E(P^i, \bigcup_{j\neq i} C^{i\to j})$ is $E(P_v, \bigcup_{j\neq i} C^{i\to j})$.*

**Proof.** Let $U$ be the set from Lemma 11. Targeting a contradiction, suppose that there exist two distinct $v, w \in U$. That is, $E(H) \cap E(P^i, \bigcup_{j\neq i} C^{i\to j}) \supseteq E(P_v, \bigcup_{j\neq i} C^{i\to j}) \cup E(P_w, \bigcup_{j\neq i} C^{i\to j})$.

The Hamiltonian cycle $H$ must contain an outgoing edge of $v^{left}$, which is the first vertex on the path $P_v$. The only out-neighbors of $v^{left}$ are $u^i$ and $v^{p,\mathsf{out}}$ where $p = 1$ when $i \neq 1$ or $p = 2$ when $i = 1$. Recall that the $e_v^{i\to p,\mathsf{out}}$ is present in $E(B_v^i, \bigcup_{j\neq i} C^{i\to j})$ and thereby in $E(H)$ by the assumption. Also, since the edge $e_v^{i\to p,\mathsf{out}}$ is an incoming edge of $v^{p,\mathsf{out}}$ , the edge $(v^{left}, v^{p,\mathsf{out}})$ cannot be in $E(H)$. Thus the outgoing edge of $v^{left}$ in $H$ is $(v^{left}, u^i)$.

Now consider the vertex $w^{left}$, which is the first one of the path $P_w$. By the same argument as above, we have $(w^{left}, u^i) \in E(H)$. This implies that $u^i$ has two in-neighbors in $H$, a contradiction.

It is also impossible that $U = \emptyset$ because then $E(H) \cap \partial(C^{i\to j}) = \emptyset$ for each $j \neq i$ implying that $H$ is disconnected. Consequently, $U$ contains exactly one element. ◀

We can summarize the arguments given so far as follows: for a Hamiltonian cycle $H$ in $G'$ and $i \in [k]$, there exists $v_i \in V^i$, such that, for all $j \neq i$, it holds that $E(H) \cap \partial(C^{i\to j}) = E(P_{v_i}, C^{i\to j}) = \{e_{v_i}^{i\to j,\mathsf{out}}, e_{v_i}^{i\to j,\mathsf{in}}\}$. We make note of a simple implication of this fact.

▶ **Lemma 13.** *Let $H$ be a Hamiltonian cycle in $G'$ and $i, j \in [k]$. Let $v \in V^i$ satisfy $E(H) \cap \partial(C^{i\to j}) = \{e_v^{i\to j,\mathsf{out}}, e_v^{i\to j,\mathsf{in}}\}$. Then $e = (v^{j,\mathsf{out}}, v^{j,\mathsf{in}})$ does not belong to $E(H)$.*

**Proof.** Since $E(H) \cap \partial(C^{i \to j})$ comprises exactly two edges, we infer that $H$ contains the path $Q = v^{j,\text{in}} \to c_v^{i \to j,\text{in}} \to \ldots \to c_v^{i \to j,\text{out}} \to v^{j,\text{out}}$ with all internal vertices from $V(C^{i \to j})$. If $H$ traversed the edge $e = (v^{j,\text{out}}, v^{j,\text{in}})$, then it would contain the cycle $C$ formed by $Q$ and $e$. This would imply $H = C$, which contradicts that $H$ is Hamiltonian. ◀

We are going to show that $H$ can include only one edge that goes from $V(P^i)$ to $V(P^j)$; it will follow that this edge must be $(v_i^{j,\text{out}}, v_j^{i,\text{out}})$.

▶ **Lemma 14.** *Let $H$ be a Hamiltonian cycle in $G'$. For each pair $i, j \in [k]$ with $i < j$ we have $|E(H) \cap E(P^i, P^j)| \leq 1$.*

**Proof.** Suppose that $|E(H) \cap E(P^i, P^j)| \geq 2$. Then there exist $u, w \in V^j$ and $e_u \in \partial^{\text{in}}(u^{i,\text{in}}) \cap \partial^{\text{out}}(P^i)$, $e_w \in \partial^{\text{in}}(w^{i,\text{in}}) \cap \partial^{\text{out}}(P^i)$ such that $e_u, e_w \in E(H)$. This implies that the edges $(u^{i,\text{out}}, u^{i,\text{in}})$, $(w^{i,\text{out}}, w^{i,\text{in}}) \in E(P^j)$ cannot be used by $H$. Since $i < j$, the vertex $u^{i,\text{out}}$ has only one out-neighbor different than $u^{i,\text{in}}$: the terminal $\widehat{t}^{i \to j}$. Hence $(u^{i,\text{out}}, \widehat{t}^{i \to j}) \in E(H)$. But the same argument applies to $w^{i,\text{out}}$. As a consequence, two incoming edges of $\widehat{t}^{i \to j}$ are being used by $H$ and so we arrive at a contradiction. ◀

Finally, we prove the second implication in the correctness proof of the reduction.

▶ **Lemma 15.** *If $(G', X)$ is a Yes-instance of* Hamiltonian Cycle By DFVS *then $(G, (V^1, V^2, \ldots, V^k))$ is a Yes-instance of* Multicolored Clique.

**Proof.** Let $H$ be a Hamiltonian cycle in $G'$ and $v_i \in V^i$ be the vertex given by Lemma 12 for $i \in [k]$. Fix a pair of indices $i < j$. By Lemma 13 we know that the edge $(v_i^{j,\text{out}}, v_i^{j,\text{in}})$ does not belong to $E(H)$. The remaining outgoing edges of $v_i^{j,\text{out}}$ belong to $E(P^i, P^j)$ and $H$ must utilize one of them. By the same argument, $H$ must traverse one of the incoming edges of $v_j^{i,\text{in}}$ that belongs to $E(P^i, P^j)$. Due to Lemma 14, the Hamiltonian cycle $H$ can use at most one edge from $E(P^i, P^j)$. Consequently, we obtain that $(v_i^{j,\text{out}}, v_j^{i,\text{in}}) \in E(H)$. In particular, this means that $(v_i^{j,\text{out}}, v_j^{i,\text{in}})$ is present in $E(G')$ and, by the construction of $G'$, implies that $v_i v_j \in E(G)$. Therefore, $\{v_1, v_2, \ldots, v_k\}$ forms a clique in $G$. ◀

Lemmas 9 and 15 constitute that the instances $(G, (V^1, V^2, \ldots, V^k))$ and $(G', X)$ are equivalent while Lemma 8 ensures that $|X| = \mathcal{O}(k^2)$. We have thus obtained a parameterized reduction from Multicolored Clique to Hamiltonian Cycle By DFVS, proving Theorem 1.

Due to space constraints, the W[1]-hardness proofs for Longest Cycle Above Girth and the path variants of both problems are provided in the full version.

## 4 XP Algorithm for Longest Path Above Girth

Johnson et al. [58] proved that Hamiltonian Path is in XP parameterized by directed treewidth. This result was later extended by de Oliveira Oliveira [30] to capture a wider range of problems expressible in Monadic Second Order (MSO) logic with counting constraints. As a special case of this theorem, we have the following.

▶ **Theorem 16** ([30]). Longest Path *on directed graphs is in* XP *when parameterized by directed treewidth.*

We will use the Directed Grid Theorem (Theorem 7), which either returns a cylindrical wall of order $\mathcal{O}(k)$ in $G$ or concludes that the directed treewidth of $G$ is bounded in terms of $k$. In the former case, we prove that a path of length $g \cdot k$ always exists in $G$. In the latter case, we use Theorem 16 to solve the problem optimally by an XP algorithm.

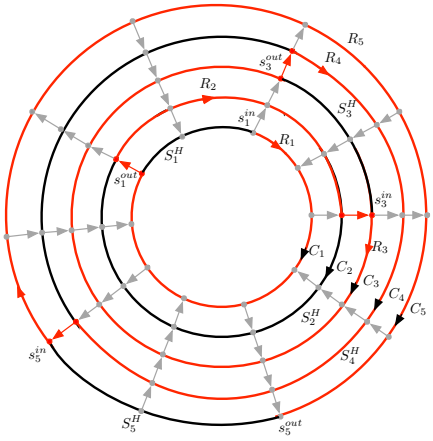

**Figure 5** The path $R$ (colored in red) in a subdivision of $W_5$, described in Lemma 20.

Throughout this section we abbreviate $W = W_{2k+1}$ (the cylindrical wall of order $2k+1$). In order to establish correctness of the algorithm, we need to argue that any subdivision $H$ of $W$ admits a path $k$ times longer than the girth of $H$.

We denote the $2k+1$ vertex disjoint cycles in $W$ by $C_1^W, C_2^W, \ldots C_{2k+1}^W$ counting from the innermost one. For a subdivision $H$ of $W$ we denote the counterpart of $C_i^W$ in $H$ as $C_i^H$. We refer to the girth of $H$ as $g$. Note that $g$ lower bounds the length of each cycle $C_i^H$.

▶ **Definition 17.** *A subpath in $C_i^W$ is called a* segment *of $C_i^W$ if its endpoints have out-neighbors in $C_{i+1}^W$ and none of its internal vertices has out-neighbors in $C_{i+1}^W$. A subpath in $C_i^H$ is a* segment *of $C_i^H$ if it is a subdivision of a segment in $C_i^W$.*

We make note of a few properties of segments.

▶ **Observation 18.** *For every $i \in [2k+1]$ the following hold.*

1. *Each cycle $C_i^W$ is a cyclic concatenation of $k+1$ segments of length 4.*
2. *Each cycle $C_i^H$ is a cyclic concatenation of $k+1$ segments.*
3. *If $i > 1$ then each segment of $C_i^W$ has a unique internal vertex with an in-neighbor in $C_{i-1}^W$.*

We show that in every cycle $C_i^H$ we can choose a segment $S$ so that the path obtained by traversing all vertices in $C_i^H$ that are not internal vertices of $S$ is almost as long as $C_i^H$.

▶ **Lemma 19.** *For a segment $S$ of $C_i^H$, let $\widehat{S}$ be the subpath of $C_i^H$ that starts at the end of $S$ and ends at the start of $S$. Then there exists a segment $S_i^H$ of $C_i^H$ such that $\widehat{S}_i^H$ has length at least $g - \frac{g}{k+1}$.*

**Proof.** By Observation 18 we know that $C_i^H$ can be partitioned into $k+1$ segments. By a counting argument, there exist a segment $S_i^H$ of size at most $\frac{|E(C_i^H)|}{k+1}$. Thus, for the path $\widehat{S}_i^H$ complementing $S_i^H$, we have $|E(\widehat{S}_i^H)| \geq |E(C_i^H)| \cdot (1 - \frac{1}{k+1}) \geq g \cdot (1 - \frac{1}{k+1})$. ◀

Let $s_i^{out}$ denote the first vertex on $S_i^H$. If $i > 1$, we define $s_i^{in}$ to be the unique internal vertex of $S_i^H$ corresponding to a vertex in $C_i^W$ with an in-neighbor in $C_{i-1}^W$. If $i = 1$, we define $s_i^{in}$ to be the last vertex on $S_i^H$.

▶ **Lemma 20.** *Let $H$ be a subdivision of $W_{2k+1}$ and $g$ be the girth of $H$. Then there exists a path of length at least $g \cdot k$ in $H$.*

**Proof.** For $i \in [2k+1]$ we define path $R_i$ in $C_i$ as follows. If $i$ is odd, we set $R_i$ to be the subpath of $C_i$ from $s_i^{in}$ to $s_i^{\circ out}$. If $i$ is even, the path $R_i$ begins at the unique vertex in $C_i^H$ that can be reached via a subdivided edge from $s_{i-1}^{\circ out}$ and $R_i$ ends at the unique vertex in $C_i^H$ from which $s_{i+1}^{in}$ is reachable by via a subdivided edge. Note that the first and last indices in $[2k+1]$ are odd, so the paths $R_i$ are well-defined. We can now concatenate $R_1, R_2, \ldots, R_{2k+1}$ using the subdivided edges between the cycles to obtain a path $R$ in $H$; see Figure 5.

We argue that $R$ is sufficiently long. There are $k+1$ odd indices in $[2k+1]$, and, for each of them, $R_i$ contains the path $\widehat{S}_i^H$ (from Lemma 19) of length at least $g - \frac{g}{k+1}$. Since these form vertex disjoint subpaths of $R$, we conclude that $E(R) \geq (g - \frac{g}{k+1})(k+1) = g(k+1) - g = g \cdot k$. ◀

We are ready to summarize the entire algorithm.

▶ **Theorem 3.** Longest Path Above Girth *is in* XP.

**Proof.** We first execute the algorithm from Theorem 7, which returns either a directed tree decomposition of width $f(k)$, for some computable function $f$, or a subgraph $H$ of $G$ that is a subdivision of $W_{2k+1}$. Note that the girth of $H$ is at least the girth of $G$. In the first case, we apply the algorithm from Theorem 16 to find the longest path in $G$ in polynomial time for fixed $k$. In the latter case, Lemma 20 asserts that $H$ contains a path of length at least $k$ times the girth of $H$, so we can report that $(G, k)$ a Yes-instance. ◀

## Abstract

The notion of $\mathcal{H}$-treewidth, where $\mathcal{H}$ is a hereditary graph class, was recently introduced as a generalization of the treewidth of an undirected graph. Roughly speaking, a graph of $\mathcal{H}$-treewidth at most $k$ can be decomposed into (arbitrarily large) $\mathcal{H}$-subgraphs which interact only through vertex sets of size $\mathcal{O}(k)$ which can be organized in a tree-like fashion. $\mathcal{H}$-treewidth can be used as a hybrid parameterization to develop fixed-parameter tractable algorithms for $\mathcal{H}$-DELETION problems, which ask to find a minimum vertex set whose removal from a given graph $G$ turns it into a member of $\mathcal{H}$. The bottleneck in the current parameterized algorithms lies in the computation of suitable tree $\mathcal{H}$-decompositions.

We present FPT-approximation algorithms to compute tree $\mathcal{H}$-decompositions for hereditary and union-closed graph classes $\mathcal{H}$. Given a graph of $\mathcal{H}$-treewidth $k$, we can compute a 5-approximate tree $\mathcal{H}$-decomposition in time $f(\mathcal{O}(k)) \cdot n^{\mathcal{O}(1)}$ whenever $\mathcal{H}$-DELETION parameterized by solution size can be solved in time $f(k) \cdot n^{\mathcal{O}(1)}$ for some function $f(k) \geq 2^k$. The current-best algorithms either achieve an approximation factor of $k^{\mathcal{O}(1)}$ or construct optimal decompositions while suffering from non-uniformity with unknown parameter dependence. Using these decompositions, we obtain algorithms solving ODD CYCLE TRANSVERSAL in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ parameterized by bipartite-treewidth and VERTEX PLANARIZATION in time $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$ parameterized by planar-treewidth, showing that these can be as fast as the solution-size parameterizations and giving the first ETH-tight algorithms for parameterizations by hybrid width measures.

## 1 Introduction

**Background and motivation.** Treewidth (see [7, 19] [16, §7]) is a width measure for graphs that is ubiquitous in algorithmic graph theory. It features prominently in the Graph Minors series [47] and frequently pops up unexpectedly [38] in the parameterized complexity [16, 20, 23] analysis of NP-hard graph problems on undirected graphs. The notion of treewidth captures how tree-like a graph is in a certain sense; it is defined as the width of an optimal tree decomposition for the graph. Unfortunately, computing an optimal tree decomposition is NP-hard [3]. As many of the algorithmic applications of treewidth

require a tree decomposition to be able to work, there has been long record of algorithms computing optimal [3, 6, 9, 43] or near-optimal [4, 8, 35] tree decompositions with no end in sight [36], as well as a long series of experimental work on heuristically computing good tree decompositions [10, 11, 17, 18]. In this paper, we present a new fixed-parameter tractable approximation algorithm for the notion of $\mathcal{H}$-treewidth, a generalization of treewidth which has recently attracted significant attention [1, 21, 29, 30]. Before describing our contributions for $\mathcal{H}$-treewidth, we summarize the most important background to motivate the problem.

The popularity of treewidth as a graph parameter can be attributed to the fact that it has very good algorithmic properties (by Courcelle's theorem, any problem that can be formulated in Counting Monadic Second-Order ($\mathrm{CMSO}_2$) logic can be solved in linear time on graphs of bounded treewidth [15]), while also having a very elegant mathematical structure theory. Unfortunately, simple substructures like grids or cliques in a graph can already make its treewidth large. This means that for many input graphs of interest, the treewidth is too large for an approach based on treewidth to be efficient: the running times of many treewidth-based algorithms are of the form $f(k) \cdot n^{\mathcal{O}(1)}$, where $f$ is an exponential function in the treewidth $k$ and $n$ is the total number of vertices of the graph.

Several approaches have been taken to cope with the fact that treewidth is large on graphs with large cliques or large induced grid subgraphs. One approach lies in generalized width measures like cliquewidth or rankwidth [41], by essentially replacing the use of separations of small order (which are encoded in tree decompositions), by separations of large order but in which the interactions between the two sides is well-structured. Unfortunately this generality comes at a price in terms of algorithmic applications [24, 25, 26].

This has recently led Eiben, Ganian, Hamm, and Kwon [21] to enrich the notion of treewidth in a different way. Consider a hereditary class $\mathcal{H}$ of graphs, such as bipartite graphs. The notion of $\mathcal{H}$-treewidth aims to capture how well a graph $G$ can be decomposed into subgraphs belonging to $\mathcal{H}$ which only interact with the rest of the graph via small vertex sets which are organized in a tree-like manner. While we defer formal definitions of $\mathcal{H}$-treewidth to Section 2, an intuitive way to think of the concept is the following: a graph $G$ has $\mathcal{H}$-treewidth at most $k$ if and only if it can be obtained from a graph $G_0$ with a tree decomposition of width at most $k$ by the following process: repeatedly insert a subgraph $H_i$ belonging to graph class $\mathcal{H}$, such that the neighbors of $H_i$ in the rest of the graph are all contained in a single bag of the tree decomposition of $G_0$. The $\mathcal{H}$-subgraphs $H_i$ inserted during this process are called *base components* and their neighborhoods have size at most $k+1$. When $\mathcal{H}$ is a graph class of unbounded treewidth, like bipartite graphs, the $\mathcal{H}$-treewidth of a graph can be arbitrarily much smaller than its treewidth. This prompted an investigation of the algorithmic applications of $\mathcal{H}$-treewidth.

In recent works [1, 21, 30], the notion of $\mathcal{H}$-treewidth was used to develop new algorithms to solve vertex-deletion problems. Many classic NP-hard problems in algorithmic graph theory can be phrased in the framework of $\mathcal{H}$-deletion: find a minimum vertex-subset $S$ of the input graph $G$ such that $G - S$ belongs to a prescribed graph class $\mathcal{H}$. Examples include Vertex Cover (where $\mathcal{H}$ is the class of edgeless graphs), Odd Cycle Transversal (bipartite graphs), and Vertex Planarization (planar graphs). All these problems are known to be fixed-parameter tractable [14, 33, 34, 39, 44] when parameterized by the size of a desired solution: there are algorithms that, given an $n$-vertex graph $G$ and integer $k$, run in time $f(k) \cdot n^{\mathcal{O}(1)}$ and output a vertex set $S \subseteq V(G)$ of size at most $k$ for which $G - S \in \mathcal{H}$, if such a set exists. These algorithms show that large instances whose optimal solutions are small, can still be solved efficiently. Alternatively, since the mentioned graph classes $\mathcal{H}$ can be defined in $\mathrm{CMSO}_2$, these vertex-deletion problems can be solved in time $f(w) \cdot n$

parameterized by the treewidth $w$ of the input graph via Courcelle's theorem, which shows that instances of small treewidth (but whose optimal solutions may be large) can be solved efficiently.

The notion of $\mathcal{H}$-treewidth (abbreviated as $\mathbf{tw}_{\mathcal{H}}$ from now on) can be used to combine the best of both worlds. It is not difficult to show that if a graph $G$ has a vertex set $S$ of size $k$ for which $G - S \in \mathcal{H}$ (we call such a set an $\mathcal{H}$-deletion set), then the $\mathcal{H}$-treewidth of $G$ is at most $k$: simply take a trivial tree decomposition consisting of a single bag of size $k$ for the graph $G_0 := G[S]$, so that afterwards the graph $G$ can be obtained from $G_0$ by inserting the graph $H = G - S$, which belongs to $\mathcal{H}$ and has all its neighbors in a single bag. Since the $\mathcal{H}$-treewidth of $G$ is also never larger than its standard treewidth, the *hybrid* (cf. [2]) parameterization by $\mathcal{H}$-treewidth dominates both the parameterizations by the solution size and the treewidth of the graph. This raises the question whether existing fixed-parameter tractability results for parameterizations of $\mathcal{H}$-DELETION by treewidth or solution size, can be extended to $\mathbf{tw}_{\mathcal{H}}$.

It was recently shown [1] that when it comes to *non-uniform* fixed-parameter tractability characterizations, the answer to this question is positive. If $\mathcal{H}$ satisfies certain mild conditions, which is the case for all graph classes mentioned so far, then for each value of $k$ there exists an algorithm $\mathcal{A}_{\mathcal{H},k}$ that, given a graph $G$ with $\mathbf{tw}_{\mathcal{H}}(G) \leq k$ and target value $t$, decides whether or not $G$ has an $\mathcal{H}$-deletion set of size at most $t$. There is a constant $c_{\mathcal{H}}$ such that each algorithm $\mathcal{A}_{\mathcal{H},k}$ runs in time $\mathcal{O}(n^{c_{\mathcal{H}}})$, so that the overall running time can be bounded by $f(k) \cdot n^{c_{\mathcal{H}}}$; however, no bounds on the function $f$ are given and in general it is unknown how to construct the algorithms whose existence is proven. Another recent paper [29] gave concrete FPT algorithms to solve $\mathcal{H}$-DELETION parameterized by $\mathbf{tw}_{\mathcal{H}}$ for certain cases of $\mathcal{H}$, including the three mentioned ones. For example, it presents an algorithm that solves ODD CYCLE TRANSVERSAL in time $2^{\mathcal{O}(k^3)} \cdot n^{\mathcal{O}(1)}$, parameterized by bipartite-treewidth. The bottleneck in the latter approach lies in the computation of a suitable tree $\mathcal{H}$-decomposition: on a graph of $\mathbf{tw}_{\mathcal{H}}(G) \leq k$, the algorithm runs in $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$ time to compute a tree $\mathcal{H}$-decomposition of width $w \in \mathcal{O}(k^3)$, and then optimally solves ODD CYCLE TRANSVERSAL on the decomposition of width $w$ in time $2^{\mathcal{O}(w)} \cdot n^{\mathcal{O}(1)} \leq 2^{\mathcal{O}(k^3)} \cdot n^{\mathcal{O}(1)}$. Note that the parameter dependence of this algorithm is much worse than for the parameterizations by solution size and by treewidth, both of which can be solved in single-exponential time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ [44, 37]. To improve the running times of algorithms for $\mathcal{H}$-DELETION based on hybrid parameterizations, improved algorithms are therefore required to compute approximate tree $\mathcal{H}$-decompositions. These form the subject of our work.

**Our contribution: $\mathcal{H}$-treewidth.** We develop generic FPT algorithms to approximate $\mathcal{H}$-treewidth, for graph classes $\mathcal{H}$ which are hereditary and closed under taking the disjoint union of graphs. To approximate $\mathcal{H}$-treewidth, all our algorithm needs is access to an oracle for solving $\mathcal{H}$-DELETION parameterized by solution size. The values of the solution size for which the oracle is invoked, will be at most twice as large as the $\mathcal{H}$-treewidth of the graph we are decomposing. Hence existing algorithms for solution-size parameterizations of $\mathcal{H}$-DELETION can be used as a black box to form the oracle. Aside from the oracle calls, our algorithm only takes $8^k \cdot kn(n+m)$ time on an $n$-vertex graph with $m$ edges. So whenever the solution-size parameterization can be solved in single-exponential time, an approximate tree $\mathcal{H}$-decomposition can be found in single-exponential time. The approximation factor of the algorithm is 5, which is a significant improvement over earlier poly(opt) approximations running in superexponential time. The formal statement of our main result is the following.

▶ **Theorem 1.** *Let $\mathcal{H}$ be a hereditary and union-closed class of graphs. There is an algorithm that, using oracle-access to an algorithm $\mathcal{A}$ for $\mathcal{H}$-DELETION, takes as input an $n$-vertex $m$-edge graph $G$, integer $k$, and either computes a tree $\mathcal{H}$-decomposition of $G$ of width at*

*most $5k+5$ consisting of $\mathcal{O}(n)$ nodes, or correctly concludes that $\boldsymbol{tw}_{\mathcal{H}}(G) > k$. The algorithm runs in time $\mathcal{O}(8^k \cdot kn(n+m))$, polynomial space, and makes $\mathcal{O}(8^k n)$ calls to $\mathcal{A}$ on induced subgraphs of $G$ and parameter $2k+2$.*

Theorem 1 yields the first constant-factor approximation algorithms for $\mathbf{tw}_{\mathcal{H}}$ that run in single-exponential time. For example, for $\mathcal{H}$ the class of bipartite graphs the running time becomes $\mathcal{O}(72^k \cdot n^2(n+m))$, and for interval graphs we obtain $\mathcal{O}(8^{3k} \cdot n(n+m))$ (the full version [31] gives results for more classes $\mathcal{H}$). Combining these approximate decompositions with existing algorithms that solve $\mathcal{H}$-DELETION on a given tree $\mathcal{H}$-decomposition, we obtain ETH-tight algorithms as a consequence. ODD CYCLE TRANSVERSAL can be solved in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$, and VERTEX PLANARIZATION can be solved in time $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$ when parameterized by $\mathbf{tw}_{\mathcal{H}}$ for $\mathcal{H}$ the class of bipartite and planar graphs, respectively, without having to supply a decomposition in the input. For VERTEX PLANARIZATION, the previous-best bound [32] was $2^{\mathcal{O}(k^5 \log k)} \cdot n^{\mathcal{O}(1)}$. Note that for the planarization problem, a parameter dependence of $2^{o(k \log k)}$ is impossible assuming the Exponential Time Hypothesis; this already holds for the larger parameterization by treewidth [42]. For ODD CYCLE TRANSVERSAL, an algorithm running in time $2^{o(n)}$ would violate the Exponential Time Hypothesis, which follows by a simple reduction from VERTEX COVER for which such a lower bound is known [16, Theorem 14.6]. This implies that the solution size parameterization cannot be solved in subexponential time.

Compared to existing algorithms to approximate treewidth, the main obstacle we have to overcome in Theorem 1 is identifying the base components of an approximate decomposition in a suitable way. The earlier FPT $\mathsf{poly}(\mathsf{opt})$-approximation for $\mathbf{tw}_{\mathcal{H}}$ effectively reduced the input graph $G$ to a graph $G'$ by repeatedly extracting large $\mathcal{H}$-subgraphs with small neighborhoods, in such a way that the treewidth of $G'$ can be bounded in terms of $\mathbf{tw}_{\mathcal{H}}(G)$, while a tree decomposition of $G'$ can be lifted into an approximate tree $\mathcal{H}$-decomposition of $G$. Several steps in this process led to losses in the approximation factor. To obtain our 5-approximation, we avoid the translation between $G$ and $G'$, and work directly on decomposing the input graph $G$.

Our recursive decomposition algorithm works similarly as the Robertson-Seymour 4-approximation algorithm for treewidth [45] (cf. [16, §7.6]). When given a graph $G$ and integer $k$ with $\mathbf{tw}_{\mathcal{H}}(G) \leq k$, the algorithm maintains a vertex set $S$ of size $3k+4$ which forms the boundary between the part of the graph that has already been decomposed and the part that still needs to be processed. If $S$ has a $\frac{2}{3}$-balanced separator $R$ of size $k+1$, we can proceed in the usual way: we split the graph based on $R$, recursively decompose the resulting parts, and combine these decompositions by adding a bag containing $R \cup S$ as the root. If $S$ does not have a balanced separator of size $k+1$, then we show (modulo some technical details) that for any optimal tree $\mathcal{H}$-decomposition, there is a subset $S' \subseteq S$ of $2k+3$ vertices which belong to a single base component $H_0$. Our main insight is that such a set $S'$ can be used in a win/win approach, by maintaining an $\mathcal{H}$-deletion set $X$ during the decomposition process that initially contains all vertices. To make progress in the recursion, we would like to split off a base component containing $S'$ via a separator $U$ of size at most $2k+2$, while adding $U$ to the boundary of the remainder of the graph to be decomposed. To identify an induced $\mathcal{H}$-subgraph with small neighborhood that can serve as a base component, we compute a minimum $(S', X)$-separator $U$ (we allow $U$ to intersect the sets $S', X$). Any connected component $H$ of $G - U$ that contains a vertex from $S'$ does not contain any vertex of the $\mathcal{H}$-deletion set $X$, so $H$ is an induced subgraph of $G - X$ which implies $H \in \mathcal{H}$ for hereditary $\mathcal{H}$. Hence if there is an $(S', X)$-separator $U$ of size at most $2k+2$, we can use it to split off base components neighboring $U$ that eliminate $2k+3$ vertices from $S$ from the boundary, thereby making room to insert $U$ into the boundary without blowing up its size.

Of course, it may be that all $(S', X)$-separators are larger than $2k + 2$; by Menger's theorem, this happens exactly when there is a family $\mathcal{P}$ of $2k+3$ vertex-disjoint $(S', X)$-paths. Only $k + 1$ paths in $\mathcal{P}$ can *escape* the base component $H_0$ covering $S'$ since its neighborhood has size at most $k + 1$, so that $k + 2$ of them end in a vertex of the deletion set $X$ that lies in $H_0$. The key point is now that this situation implies that $X$ is redundant in a technical sense: if we let $X'$ denote the endpoints of $k + 2$ $(S', X)$-paths starting and ending in $H_0$, we can obtain a smaller $\mathcal{H}$-deletion set by replacing $X'$ by the neighborhood of $H_0$, which has size at most $k + 1$. This replacement is valid as long as $\mathcal{H}$ is hereditary and union-closed. Using an oracle for $\mathcal{H}$-DELETION parameterized by solution size, we can therefore efficiently find a smaller $\mathcal{H}$-deletion set when we know $X'$. While the algorithm does not know $X'$ in general, this type of argument leads to the win/win: either there is a small $(S', X)$-separator which we can use to split off a base component, or there is a large family of vertex-disjoint $(S', X)$-paths which allows the $\mathcal{H}$-deletion set to be improved. As the latter can only happen $|V(G)|$ times, we must eventually identify a base component to split off, allowing the recursion to proceed.

**Our contribution: $\mathcal{H}$-elimination distance.** The $\mathcal{H}$-elimination distance $\mathbf{ed}_{\mathcal{H}}(G)$ of a graph $G$ is a parameter [12, 13] that extends treedepth [40] similarly to how $\mathcal{H}$-treewidth extends treewidth. For hereditary and union-closed classes $\mathcal{H}$, the $\mathcal{H}$-elimination distance of a graph $G$ is the minimum number of rounds needed to turn $G$ into a member of $\mathcal{H}$, when a round consists of removing one vertex from each connected component. Such an elimination process can be represented by a tree structure called *$\mathcal{H}$-elimination forest*. Aside from the fact that computing the $\mathcal{H}$-elimination distance may reveal interesting properties of a graph $G$, a second motivation for studying this parameter is that it can facilitate *polynomial-space* algorithms for solving $\mathcal{H}$-DELETION, while the parameterization by $\mathbf{tw}_{\mathcal{H}}$ (which is never larger) typically gives rise to exponential-space algorithms. At a high level, the state of the art for computing $\mathbf{ed}_{\mathcal{H}}$ is similar as for $\mathbf{tw}_{\mathcal{H}}$: there is an exact non-uniform FPT algorithm with unspecified parameter dependence that works as long as $\mathcal{H}$ satisfies some mild conditions [1], while uniform $\mathsf{poly}(\mathsf{opt})$-approximation algorithms running in time $2^{k^{\mathcal{O}(1)}} \cdot n^{\mathcal{O}(1)}$ are known for several concrete graph classes $\mathcal{H}$ [30].

By leveraging similar ideas as for Theorem 1, we also obtain improved FPT-approximation algorithms for $\mathbf{ed}_{\mathcal{H}}$. The following theorem gives algorithms for two settings: one for an algorithm using polynomial space whenever the algorithm $\mathcal{A}$ for $\mathcal{H}$-DELETION does, which is the case for most of the considered graph classes, and one for an exponential-space algorithm with a better approximation ratio.

▶ **Theorem 2.** *Let $\mathcal{H}$ be a hereditary and union-closed class of graphs. There exists an algorithm that, using oracle-access to an algorithm $\mathcal{A}$ for $\mathcal{H}$-DELETION, takes as input an $n$-vertex graph $G$ and integer $k$, runs in time $n^{\mathcal{O}(1)}$, makes $n^{\mathcal{O}(1)}$ calls to $\mathcal{A}$ on induced subgraphs of $G$ and parameter $2k$, and either concludes that $\mathbf{ed}_{\mathcal{H}}(G) > k$ or outputs an $\mathcal{H}$-elimination forest of depth $\mathcal{O}(k^3 \log^{3/2} k)$.*

*Under the same assumptions, there is an algorithm that runs in time $2^{\mathcal{O}(k^2)} \cdot n^{\mathcal{O}(1)}$, makes $n^{\mathcal{O}(1)}$ calls to $\mathcal{A}$ on induced subgraphs of $G$ and parameter $2k$, and either concludes that $\mathbf{ed}_{\mathcal{H}}(G) > k$ or outputs an $\mathcal{H}$-elimination forest of depth $\mathcal{O}(k^2)$.*

In the previous work [30, 32] such a dependence on $k$ was possible only in two cases: when $\mathcal{H}$ is the class of bipartite graphs or when $\mathcal{H}$ is defined by a finite family of forbidden induced subgraphs. In the general case, our result effectively shaves off a single $k$-factor in the depth of the returned decomposition and in the exponent of the running time, compared to the previously known approximations. Theorem 2 entails better approximation algorithms for $\mathcal{H}$-elimination distance for classes of e.g. chordal, interval, planar, bipartite permutation, or distance-hereditary graphs.

**Organization.** The remainder of the paper is organized as follows. We continue by presenting formal preliminaries in Section 2. In Section 3 we treat $\mathcal{H}$-treewidth, developing the theory and subroutines needed to prove Theorem 1. Due to space limitations, the resulting proof of Theorem 1 is deferred to the full version [31], which also provides a list of applications for concrete graph classes. The proof of Theorem 2 can also be found in the full version. We conclude in Section 4.

## 2 Preliminaries

**Graphs and graph classes.** We consider finite, simple, undirected graphs. We denote the vertex and edge sets of a graph $G$ by $V(G)$ and $E(G)$ respectively, with $|V(G)| = n$ and $|E(G)| = m$. For a set of vertices $S \subseteq V(G)$, by $G[S]$ we denote the graph induced by $S$. We use shorthand $G - v$ and $G - S$ for $G[V(G) \setminus \{v\}]$ and $G[V(G) \setminus S]$, respectively. The open neighborhood $N_G(v)$ of $v \in V(G)$ is defined as $\{u \in V(G) \mid uv \in E(G)\}$. The closed neighborhood of $v$ is $N_G[v] = N_G(v) \cup \{v\}$. For $S \subseteq V(G)$, we have $N_G[S] = \bigcup_{v \in S} N_G[v]$ and $N_G(S) = N_G[S] \setminus S$. We define the boundary $\partial_G(S)$ of the vertex set $S$ as $N_G(V(G) \setminus S)$, i.e., those vertices of $S$ which have a neighbor outside $S$.

A class of graphs $\mathcal{H}$ is called *hereditary* if for any $G \in \mathcal{H}$, every induced subgraph of $G$ also belongs to $\mathcal{H}$. Furthermore, $\mathcal{H}$ is *union-closed* if for any $G_1, G_2 \in \mathcal{H}$ the disjoint union of $G_1$ and $G_2$ also belongs to $\mathcal{H}$. For a graph class $\mathcal{H}$ and a graph $G$, a set $X \subseteq V(G)$ is called an $\mathcal{H}$-deletion set in $G$ if $G - X \in \mathcal{H}$. For a graph class $\mathcal{H}$, the parameterized problem $\mathcal{H}$-DELETION takes a graph $G$ and parameter $k$ as input, and either outputs a minimum-size $\mathcal{H}$-deletion set in $G$ or reports that there is no such set of size at most $k$.

**Separators.** For two (not necessarily disjoint) sets $X, Y \subseteq V(G)$ in a graph $G$, a set $P \subseteq V(G)$ is an $(X, Y)$-separator if no connected component of $G - P$ contains a vertex from both $X \setminus P$ and $Y \setminus P$. Such a separator may intersect $X \cup Y$. Equivalently, $P$ is an $(X, Y)$-separator if each $(X, Y)$-path contains a vertex of $P$. The minimum cardinality of such a separator is denoted $\lambda_G(X, Y)$. By Menger's theorem, $\lambda_G(X, Y)$ is equal to the maximum cardinality of a set of pairwise vertex-disjoint $(X, Y)$-paths. A pair $(A, B)$ of subsets of $V(G)$ is a *separation* in $G$ if $A \cup B = V(G)$ and $G$ has no edges between $A \setminus B$ and $B \setminus A$. Its order is defined as $|A \cap B|$.

▶ **Observation 3.** *For two sets $X, Y \subseteq V(G)$, it holds that $\lambda_G(X, Y) \leq k$ if and only if there exists a separation $(A, B)$ in $V(G)$ such that $X \subseteq A$, $Y \subseteq B$, and $|A \cap B| \leq k$.*

The following theorem summarizes how, given vertex sets $X, Y \subseteq V(G)$ and a bound $k$, we can algorithmically find a small-order separation or a large system of vertex-disjoint paths. The statement follows from the analysis of the Ford-Fulkerson algorithm for maximum $(X, Y)$-flow in which each vertex has a capacity of 1. If the algorithm has not terminated within $k$ iterations, then the flow of value $k + 1$ yields $k + 1$ vertex-disjoint paths. If it terminates earlier, a suitable separation can be identified based on reachability in the residual network of the last iteration.

▶ **Theorem 4** (Ford-Fulkerson, see [16, Thm. 8.2] and [49, §9.2])**.** *There is an algorithm that, given an $n$-vertex $m$-edge graph $G$, sets $X, Y \subseteq V(G)$, and integer $k$, runs in time $\mathcal{O}(k(n + m))$ and determines whether $\lambda_G(X, Y) \leq k$. If so, the algorithm also returns a separation $(A, B)$ in $G$ with $X \subseteq A$, $Y \subseteq B$, and $|A \cap B| \leq k$. Otherwise, the algorithm returns a family of $k + 1$ vertex-disjoint $(X, Y)$-paths.*

**$\mathcal{H}$-treewidth.** We continue by giving a formal definition of a tree $\mathcal{H}$-decomposition.

▶ **Definition 5.** *For a graph class $\mathcal{H}$, a tree $\mathcal{H}$-decomposition of graph $G$ is a triple $(T, \chi, L)$ where $L \subseteq V(G)$, $T$ is a rooted tree, and $\chi \colon V(T) \to 2^{V(G)}$, such that:*

1. *For each $v \in V(G)$ the nodes $\{t \mid v \in \chi(t)\}$ form a non-empty connected subtree of $T$.*
2. *For each edge $uv \in E(G)$ there is a node $t \in V(T)$ with $\{u, v\} \subseteq \chi(t)$.*
3. *For each vertex $v \in L$, there is a unique $t \in V(T)$ with $v \in \chi(t)$, and $t$ is a leaf of $T$.*
4. *For each node $t \in V(T)$, the graph $G[\chi(t) \cap L]$ belongs to $\mathcal{H}$.*

*The* width *of a tree $\mathcal{H}$-decomposition is defined as $\max(0, \max_{t \in V(T)} |\chi(t) \setminus L| - 1)$. The $\mathcal{H}$-treewidth of a graph $G$, denoted $\boldsymbol{tw}_{\mathcal{H}}(G)$, is the minimum width of a tree $\mathcal{H}$-decomposition of $G$. The connected components of $G[L]$ are called base components.*

*A pair $(T, \chi)$ is a (standard)* tree decomposition *if $(T, \chi, \emptyset)$ satisfies all conditions of an $\mathcal{H}$-decomposition; the choice of $\mathcal{H}$ is irrelevant.*

For a rooted tree decomposition $(T, \chi)$, $T_t$ denotes the subtree of $T$ rooted at $t \in V(T)$, while $\chi(T_t) = \bigcup_{x \in V(T_t)} \chi(x)$. Similarly as treewidth, $\mathcal{H}$-treewidth is a monotone parameter with respect to taking induced subgraphs.

▶ **Observation 6.** *Let $\mathcal{H}$ be a hereditary class of graphs, $G$ be a graph, and $H$ be an induced subgraph of $G$. Then $\boldsymbol{tw}_{\mathcal{H}}(H) \leq \boldsymbol{tw}_{\mathcal{H}}(G)$.*

## 3 Approximating $\mathcal{H}$-treewidth

We make preparations for the proof of Theorem 1. First, we formalize the concept of a potential base component using the notion of an $(\mathcal{H}, \ell)$-separation and relate it to *redundant* subsets in a solution to $\mathcal{H}$-DELETION. Next, we prove a counterpart of the balanced-separation property for graphs of bounded $\mathcal{H}$-treewidth and explain how it allows us to apply a win/win approach in a single step of the decomposition algorithm.

### 3.1 Redundancy and $(\mathcal{H}, \ell)$-separations

We summon the following concept from the previous work on $\mathcal{H}$-treewidth [30] to capture $\mathcal{H}$-subgraphs with small neighborhoods.

▶ **Definition 7.** *For disjoint $C, S \subseteq V(G)$, the pair $(C, S)$ is called an $(\mathcal{H}, \ell)$-separation in $G$ if (1) $G[C] \in \mathcal{H}$, (2) $|S| \leq \ell$, and (3) $N_G(C) \subseteq S$.*

This notion is tightly connected to the base components of tree $\mathcal{H}$-decompositions. For any tree $\mathcal{H}$-decomposition $(T, \chi, L)$ of width $k$ of a graph $G$, for any node $t \in T$, the graph $G[\chi(t) \cap L]$ belongs to $\mathcal{H}$ so that $C := \chi(t) \cap L$ satisfies Definition 7. The open neighborhood of $\chi(t) \cap L$ is a subset of $S := \chi(t) \setminus L$, which follows from the fact that vertices of $L$ only occur in a single bag, while each edge has both endpoints covered by a single bag. Since $|S| \leq k + 1$ by definition of the width of a tree $\mathcal{H}$-decomposition, this leads to the following observation.

▶ **Observation 8.** *Let $(T, \chi, L)$ be a tree $\mathcal{H}$-decomposition of a graph $G$ of width $k$. For each node $t \in V(T)$, the pair $(\chi(t) \cap L, \chi(t) \setminus L)$ is an $(\mathcal{H}, k+1)$-separation in $G$.*

The following concept will be useful when working with $(\mathcal{H}, \ell)$-separations.

▶ **Definition 9.** *For an $(\mathcal{H}, k)$-separation $(C, S)$ and set $Z \subseteq V(G)$, we say that $(C, S)$ covers $Z$ if $Z \subseteq C$, or weakly covers $Z$ if $Z \subseteq C \cup S$. Set $Z \subseteq V(G)$ is called (weakly) $(\mathcal{H}, \ell)$-separable if there exists an $(\mathcal{H}, \ell)$-separation that (weakly) covers $Z$.*

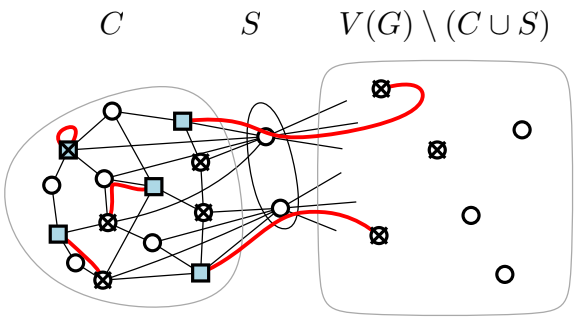

**Figure 1** Illustration for Lemma 12: an $(\mathcal{H}, \ell)$-separation $(C, S)$ in a graph $G$ where $\mathcal{H}$ is the class of triangle-free graphs and $\ell = 2$. Vertices marked with a cross form an $\mathcal{H}$-deletion set $X$ in $G$, while the set $Z$ of size $2\ell + 1 = 5$ marked with blue squares is weakly $(\mathcal{H}, \ell)$-separable. A set of $2\ell+1$ vertex-disjoint $(Z, X)$-paths $\mathcal{P}$ is highlighted, witnessing $\lambda_G(Z, X) = |Z|$. Since $|X \cap C| > \ell$, the set $X$ is not a minimum $\mathcal{H}$-deletion set in $G$: it can be improved by replacing $X \cap C$ with $S$. When $(C, S)$ weakly covering $Z$ exists but is unknown to the algorithm, we can still improve $X$ since the set of $X$-endpoints of $\mathcal{P}$ also form a redundant set in $X$.

We introduce both notions to keep consistency with the earlier work [30] but in fact we will be interested only in weak coverings. Following the example above, the set $Z = \chi(t)$ is weakly $(\mathcal{H}, k + 1)$-separable but not necessarily $(\mathcal{H}, k + 1)$-separable.

Next, we introduce the notion of redundancy for solutions to $\mathcal{H}$-DELETION.

▶ **Definition 10.** *For an $\mathcal{H}$-deletion set $X$ in $G$ we say that a subset $X' \subseteq X$ is* redundant *in $X$ if there exists a set $X'' \subseteq V(G)$ smaller than $|X'|$ such that $(X \setminus X') \cup X''$ is also an $\mathcal{H}$-deletion set in $G$.*

We remark that redundancy has been studied in the context of local-search strategies (cf. [27, 28]). It is known that for VERTEX COVER finding a redundant subset $X'$ in a solution $X$ is FPT in graphs of bounded local treewidth but W[1]-hard in general, when parameterized by the size of $|X'|$ [22]. However, when $X'$ is given, one can easily check whether it is redundant using an algorithm for $\mathcal{H}$-DELETION parameterized by the solution size, due to the following observation.

▶ **Observation 11.** *Let $X$ be an $\mathcal{H}$-deletion set in a graph $G$. A subset $X' \subseteq X$ is redundant in $X$ if and only if the graph $G - (X \setminus X')$ has an $\mathcal{H}$-deletion set smaller than $|X'|$.*

An important observation is that when $X' \subseteq X$ of size at least $\ell + 1$ is weakly $(\mathcal{H}, \ell)$-separable, then it is redundant in $X$ by a simple exchange argument. This fact has been already leveraged in previous work [1, 30] when analyzing the structure of minimum-size $\mathcal{H}$-deletion sets, which clearly cannot contain any redundant subsets. We exploit it in a different context, to prove that if there is a large flow between an $\mathcal{H}$-deletion set $X$ and a weakly $(\mathcal{H}, \ell)$-separable set $Z$, then $X$ has a redundant subset. Subsequently, we will show that this redundant subset can efficiently be detected.

▶ **Lemma 12.** *Let $\mathcal{H}$ be a hereditary and union-closed class of graphs. Consider a graph $G$, an $\mathcal{H}$-deletion set $X$ in $G$, and a weakly $(\mathcal{H}, \ell)$-separable set $Z \subseteq V(G)$. Suppose that there exists a subset $X' \subseteq X$ of size $2\ell + 1$ such that $\lambda_G(Z, X') = 2\ell + 1$. Then $X'$ is redundant in $X$.*

**Proof.** Let $(C, S)$ be an $(\mathcal{H}, \ell)$ separation in $G$ with $Z \subseteq C \cup S$. From the definition of an $(\mathcal{H}, \ell)$-separation, we have $G[C] \in \mathcal{H}$ while $N_G(C) \subseteq S$ and $|S| \leq \ell$.

By Menger's theorem, the cardinality of a maximum packing of vertex-disjoint $(Z, X')$-paths equals $\lambda_G(Z, X')$. Hence there exists a family $\mathcal{P} = \{P_1, \ldots, P_{2\ell+1}\}$ of vertex-disjoint paths, each of which connects a unique vertex $z_i \in Z$ to a unique vertex $x_i \in X'$ (possibly $x_i = z_i$). At most $|S|$ of these paths intersect the separator $S$ of the $(\mathcal{H}, \ell)$-separation (see Figure 1). Let $X'' = \{x_i \mid P_i \cap S = \emptyset\}$ denote the $X'$-endpoints of those paths not intersecting $S$, and let $\mathcal{P}'$ be the corresponding paths. Each path $P_i$ in $\mathcal{P}'$ is disjoint from $S$ and has an endpoint $z_i \in Z$. Since $Z \subseteq C \cup S$, the $z_i$ endpoint belongs to $C$. As $N_G(C) \subseteq S$ and $P_i$ does not intersect $S$, the other endpoint $x_i$ also belongs to $C$. Hence all vertices of $X''$ belong to $C$, and there are at least $2\ell + 1 - \ell = \ell + 1$ of them.

Let $X^* := (X \setminus X'') \cup S$, and observe that $|X^*| < |X|$ since $|X''| \geq \ell + 1$ while $|S| \leq \ell$. We prove that $G - X^* \in \mathcal{H}$, by showing that $S$ is an $\mathcal{H}$-deletion set in $G - (X \setminus X'')$. Since $\mathcal{H}$ is union-closed, it suffices to argue that each connected component $H$ of $G - ((X \setminus X'') \cup S)$ belongs to $\mathcal{H}$. If $H$ contains no vertex of $X''$, then $H$ is an induced subgraph of $G - X \in \mathcal{H}$ and therefore $H \in \mathcal{H}$ since the graph class is hereditary. If $H$ contains a vertex of $X'' \subseteq C$, then the component $H$ is an induced subgraph of $G[C]$ since $N_G(C) \subseteq S$ is part of the set $X^*$. Hence $H$ is an induced subgraph of $G[C] \in \mathcal{H}$, which implies $H \in \mathcal{H}$ as $\mathcal{H}$ is hereditary. This shows that $X^*$ is indeed an $\mathcal{H}$-deletion set.

Since $(X \setminus X'') \cup S$ is an $\mathcal{H}$-deletion set smaller than $X$, the set $X''$ is redundant in $X$. As $X' \supseteq X''$, it follows that $X'$ is redundant as well. ◀

## 3.2 The win/win strategy

The classic 4-approximation algorithm for computing a (standard) tree decomposition is based on the existence of balanced separators in graphs of bounded treewidth. In a graph $G$ of treewidth $\leq k$, any set $S$ of $3k + 4$ vertices can by partitioned into $S = S_A \cup S_B$ in such a way that $|S_A|, |S_B| \leq 2k + 2$ and $\lambda_G(S_A, S_B) \leq k + 1$ [16, Corollary 7.21]. This is not always possible if we only have a bound on $\mathcal{H}$-treewidth $\mathbf{tw}_{\mathcal{H}}(G) \leq k$ because a large subset $S'$ of $S$ might lie in a single well-connected base component of a tree $\mathcal{H}$-decomposition, i.e., a base component whose standard treewidth is large. But then $S'$ is weakly $(\mathcal{H}, k + 1)$-separable, which can also be exploited when constructing a decomposition. We show that this is in fact the only scenario in which we cannot split $S$ in a balanced way.

▶ **Lemma 13.** *Let $\mathcal{H}$ be a hereditary and union-closed class of graphs. Let $G$ be a graph with $\boldsymbol{tw}_{\mathcal{H}}(G) \leq k$. For any set $S \subseteq V(G)$ of size $3k + 4$, at least one of the following holds.*

1. *There is a partition $S = S_A \cup S_B$ such that $|S_A|, |S_B| \leq 2k + 2$ and $\lambda_G(S_A, S_B) \leq k + 1$.*
2. *There is a set $S' \subseteq S$ of size $2k + 3$ which is weakly $(\mathcal{H}, k + 1)$-separable.*

**Proof.** Consider an optimal tree $\mathcal{H}$-decomposition $(T, \chi, L)$ of $G$, so that $|\chi(t) \setminus L| \leq k + 1$ for each $t \in V(T)$. Let $r \in V(T)$ be its root. We start by showing that (2) holds if some leaf bag of the decomposition contains $2k + 3$ vertices from $S$.

So suppose there exists a leaf $t \in V(T)$ with $|\chi(t) \cap S| \geq 2k + 3$, and let $S' \subseteq \chi(t) \cap S$ be an arbitrary subset of size exactly $2k + 3$. Observation 8 ensures that $(C^* := \chi(t) \cap L, S^* := \chi(t) \setminus L)$ is an $(\mathcal{H}, k + 1)$-separation, which weakly covers $\chi(t)$ and therefore $S'$. Hence (2) holds.

In the remainder, it suffices to show that (1) holds when there is no leaf $t \in V(T)$ with $|\chi(t) \cap S| \geq 2k + 3$. Pick a deepest node $t^*$ in the rooted tree $T$ for which $|S \cap \chi(T_{t^*})| \geq 2k + 3$. Then $t^*$ is not a leaf since the previous case did not apply, so by definition of tree $\mathcal{H}$-decomposition we have $\chi(t^*) \cap L = \emptyset$. Let $D_1, \ldots, D_p$ be the connected components of $G - \chi(t^*)$. Since the pair $(T, \chi)$ satisfies all properties of a standard tree decomposition, the bag $\chi(t^*)$ is a separator in $G$ so that for each component $D_i$, there is a single tree $T^i$ in the unrooted forest $T - t^*$ such that $T^i$ contains all nodes whose bags contain some $v \in V(D_i)$; see for example [46, (2.3)].

The choice of $t^*$ ensures that $|V(D_i) \cap S| < 2k+3$ for all $i \in [p]$: when vertices of $D_i$ are contained in bags of a tree rooted at a child of $t^*$ this follows from the fact that $t^*$ is a deepest node for which $|S \cap \chi(T_{t^*})| \geq 2k+3$; when vertices of $D_i$ are contained in the tree $T^i$ of $T - t^*$ having the parent of $t^*$, this follows from the fact that $\chi(T_{t^*})$ contains at least $2k+3$ vertices from $S$, none of which appear in $D_i$ since a vertex occurring in $\chi(T_{t^*})$ and in a bag outside $T_{t^*}$, is contained in $\chi(t^*)$ and therefore part of the separator $\chi(t^*)$ used to obtain the component $D_i$. Hence none of the vertices of $S \cap \chi(t^*)$ can appear in $D_i$, which means there are at most $|S| - (2k+3) \leq k+1$ vertices in $V(D_i) \cap S$.

Since $|S| = 3k+4$ and no component $D_i$ contains at least $2k+3$ vertices from $S$, the components can be partitioned into two parts $\mathcal{D}_1, \mathcal{D}_2$ such that $\sum_{D_i \in \mathcal{D}_j} |V(D_i) \cap S| \leq 2k+2$ for each $j \in \{1,2\}$. If some component contains at least $k+2$ vertices from $S$, then that component is a part by itself, ensuring the remainder has at most $3k+4-(k+2) \leq 2k+2$ vertices from $S$; if no component contains at least $k+2$ vertices from $S$, then any inclusion-minimal subset of components having at least $k+2$ vertices from $S$ has at most $2k+2$ of them.

Define $S'_A := \bigcup_{D_i \in \mathcal{D}_1} V(D_i) \cap S$ and $S'_B := \bigcup_{D_i \in \mathcal{D}_2} V(D_i) \cap S$, and assume without loss of generality that $|S'_A| \geq |S'_B|$. Note that $|S'_A \cup S'_B| = |S \setminus \chi(t^*)| \geq 2k+3$, so that the larger side $S'_A$ contains at least $k+2$ vertices. To turn $S'_A, S'_B$ into the desired partition of $S$, it suffices to take $S_A = S'_A$ and $S_B = S'_B \cup (\chi(t^*) \cap S) = S \setminus S_A$. It is clear that $|S_A| = |S'_A| \geq k+2$, while $|S_B| = |S| - |S_A| \geq 3k+4-(2k+2) \geq k+2$. The fact that $|S_A|, |S_B| \geq k+2$ while they partition $S$ with $|S| = 3k+4$ implies $|S_A|, |S_B| \leq 2k+2$ as desired. Since $\chi(t^*)$ separates $S'_A$ from $S'_B$, it separates $S_A$ from $S_B$ and we have $\lambda_G(S_A, S_B) \leq |\chi(t^*)| = |\chi(t^*) \setminus L| \leq k+1$. ◀

We can now translate the last two lemmas into an algorithmic statement, which will be used as a subroutine in the main algorithm. When $\mathbf{tw}_{\mathcal{H}}(G) \leq k$ and $S \subseteq V(G)$ is of size $3k+4$, then we can either split it in a balanced way, split off a base component, or detect a redundancy in a given $\mathcal{H}$-deletion set and reduce its size. Each of these outcomes will guarantee some progress for the task of constructing a tree $\mathcal{H}$-decomposition.

▶ **Lemma 14.** *Let $\mathcal{H}$ be a hereditary and union-closed class of graphs. There is an algorithm that, using oracle-access to an algorithm $\mathcal{A}$ for $\mathcal{H}$-DELETION, takes as input an $n$-vertex $m$-edge graph $G$, integer $k$, $\mathcal{H}$-deletion set $X$ in $G$, and a set $S \subseteq V(G)$ of size $3k+4$, runs in time $\mathcal{O}(8^k \cdot k(n+m))$ and polynomial space, makes $\mathcal{O}(8^k)$ calls to $\mathcal{A}$ on induced subgraphs of $G$ and parameter $2k+2$, and terminates with one of the following outcomes.*

1. *A partition $S = S_A \cup S_B$ and a separation $(A, B)$ in $G$ are returned, such that $S_A \subseteq A$, $S_B \subseteq B$, $|S_A| \leq 2k+2$, $|S_B| \leq 2k+2$, and $|A \cap B| \leq k+1$.*
2. *A subset $S' \subseteq S$ and a separation $(A, B)$ in $G$ are returned, such that $S' \subseteq A$, $X \subseteq B$, $|S'| = 2k+3$, and $|A \cap B| \leq 2k+2$. (This implies that $G[A \setminus B] \in \mathcal{H}$.)*
3. *An $\mathcal{H}$-deletion set $X'$ in $G$ is returned, that is smaller than $X$.*
4. *The algorithm correctly concludes that $\boldsymbol{tw}_{\mathcal{H}}(G) > k$.*

**Proof.** The algorithm starts by trying to reach the first outcome. For each partition $S_A \cup S_B$ of $S$ in which both parts have at most $2k+2$ vertices, it performs at most $k+2$ iterations of the Fold-Fulkerson algorithm to test whether $\lambda_G(S_A, S_B) \leq k+1$. If so, then the algorithm outputs a corresponding separation $(A, B)$ in $G$ with $S_A \subseteq A$, $S_B \subseteq B$, and $|A \cap B| = \lambda_G(S_A, S_B) \leq k+1$. By Theorem 4, this can be done in time $\mathcal{O}(k(n+m))$.

Next, the algorithm attempts to reach the second outcome. For each subset $S' \subseteq S$ of size $2k+3$, it performs at most $2k+3$ iterations of the Ford-Fulkerson algorithm to test whether $\lambda_G(S', X) \leq 2k+2$. If so, the algorithm extracts a corresponding separation $(A, B)$ with $S' \subseteq A$, $X \subseteq B$, and $|A \cap B| \leq 2k+2$, and outputs it.

If the algorithm has not terminated so far, it will reach the third or fourth outcome. It proceeds as follows.

1. For each subset $S' \subseteq S$ of size $2k+3$, we have $\lambda_G(S', X) > 2k+2$ since we could not reach the second outcome. As $|S'| = 2k+3$ this implies $\lambda_G(S', X) = 2k+3$. By Menger's theorem, there is a packing $\mathcal{P}_{S'}$ of $2k+3$ vertex-disjoint $(S', X)$-paths, and such a packing can be extracted from the final stage of the Ford-Fulkerson computation.
2. Let $X'_{S'} \subseteq X$ be the endpoints in the set $X$ of the paths $\mathcal{P}_{S'}$, so that $|X'_{S'}| = |S'| = 2k+3$.
3. We invoke algorithm $\mathcal{A}$ on the graph $G - (X \setminus X'_{S'})$ and parameter value $2k+2$, to find a minimum-size $\mathcal{H}$-deletion set in $G - (X \setminus X'_{S'})$ or conclude that such a set has size more than $2k+2$. If $\mathcal{A}$ returns a solution $Y$ of size at most $2k+2$, then $(X \setminus X'_{S'}) \cup Y$ is an $\mathcal{H}$-deletion set in $G$ smaller than $X$ and we return it as the third outcome.

If none of the preceding steps for any $S' \subseteq S$ of size $2k+3$ caused the algorithm to give an output, then we conclude that $\mathbf{tw}_{\mathcal{H}}(G) > k$ and terminate.

**Correctness.** We proceed to argue for correctness of the algorithm. It is clear that if the algorithm terminates with one of the first three outcomes, then its output is correct. We proceed to show that if $\mathbf{tw}_{\mathcal{H}}(G) \leq k$, then it will indeed terminate in one of those outcomes. So assume $\mathbf{tw}_{\mathcal{H}}(G) \leq k$, which means we may apply Lemma 13 to $S$ and $G$. If Case 1 of Lemma 13 holds, then the algorithm will detect the corresponding separation in the first phase of the algorithm and terminate with a suitable separation. So assume Case 2 holds, so that there is a set $S' \subseteq S$ of size $2k+3$ which is weakly $(\mathcal{H}, k+1)$-separable. Since the set $S'$ is a candidate for reaching the second outcome, if that outcome is not reached we have $\lambda_G(S', X) > 2k+2$ and hence $\lambda_G(S', X) = 2k+3 = |S'|$. Consider the family of $(S', X)$-paths $\mathcal{P}_{S'}$ constructed by the algorithm for this choice of $S'$ and let $X'_{S'}$ be their endpoints in $X$. The paths $\mathcal{P}_{S'}$ show that $\lambda_G(S', X'_{S'}) = |S'| = |X'_{S'}| = 2k+3$. Now we can apply Lemma 12 for $\ell = k+1$ to infer that $X'_{S'}$ is redundant in $X$, which implies that $G - (X \setminus X'_{S'})$ has an $\mathcal{H}$-deletion set smaller than $|X'_{S'}| = 2k+3$. Hence algorithm $\mathcal{A}$ outputs an $\mathcal{H}$-deletion set smaller than $|X'_{S'}|$ and the algorithm terminates with the third outcome.

Since the algorithm reaches one the first three outcomes when $\mathbf{tw}_{\mathcal{H}}(G) \leq k$, the algorithm is correct when it reaches the last outcome.

**Running time and oracle calls.** Each of the three phases of the algorithm consist of enumerating subsets $S' \subseteq S$, of which there are $2^{|S|} \leq 2^{3k+4} = \mathcal{O}(8^k)$. For each such set $S'$, the algorithm performs $\mathcal{O}(k)$ rounds of the Ford-Fulkerson algorithm in time $\mathcal{O}(k(n+m))$. In the last phase, the algorithm additionally invokes $\mathcal{A}$ on an induced subgraph of $G$ for each $S'$ to find an $\mathcal{H}$-deletion set of size at most $2k+2$ if one exists. It follows that the running time of the algorithm (not accounting for the time spent by $\mathcal{A}$) is $\mathcal{O}(8^k \cdot k(n+m))$. The space usage is easily seen to be polynomial in the input size since the algorithm is iterative. This concludes the proof of Lemma 14. ◀

## 3.3 The decomposition algorithm

We retrace the proof of [16, Theorem 7.18] which gives the classic algorithm for approximating (standard) treewidth. Consider sets $S \subseteq W \subseteq V(G)$ such that $\partial_G(W) \subseteq S$ and $|S| = 3k+4$; we aim to construct a tree decomposition of $G[W]$ which contains $S$ in its root bag. We can consider all ways to partition $S$ into $S_A \cup S_B$ such that $|S_A|, |S_B| \leq 2k+2$ and compute a minimum $(S_A, S_B)$-separator. Since $|S| = 3k+4$, there are $2^{3k+4} = \mathcal{O}(8^k)$ such partitions.

When $\mathbf{tw}(G) \leq k$, we are guaranteed that for some partition $S = S_A \cup S_B$ we will find a separator in $G[W]$ of size $\leq k+1$ which yields the separation $(A_W, B_W)$ in $G[W]$ satisfying $S_A \subseteq A_W$, $S_B \subseteq B_W$, and $|A_W \cap B_W| \leq k+1$. Then the boundary $\partial_G(A_W)$ is contained in $S_A \cup (A_W \cap B_W)$, and similarly $\partial_G(B_W) \subseteq S_B \cup (A_W \cap B_W)$. We create instances $(A_W, S_A \cup (A_W \cap B_W))$ and $(B_W, S_B \cup (A_W \cap B_W))$ to be solved recursively, analogously as $(W, S)$. Note that each of the sets $S_A \cup (A_W \cap B_W)$, $S_B \cup (A_W \cap B_W)$ has less than $3k+4$ vertices, so we can augment each of them with one more vertex before making the recursive call while preserving the size invariant. This step ensures that the recursion tree has at most $|V(G)|$ nodes. After computing tree decompositions for $G[A]$ and $G[B]$ we merge them by creating a new root with a bag $S \cup (A_W \cap B_W)$ of size at most $4k+5$. Hence, we are able to construct a tree decomposition of width $4k+4$ assuming that one of width $k$ exists.

There are two differences between the outlined algorithm and ours, while the recursive scheme stays the same. First, due to scenario (2) in Lemma 14 we need to handle the cases where we can directly create a base component containing at least $2k+3$ vertices from $S$. The lower bound $2k+3$ is greater than the separator size $2k+2$ so we will move on to a subproblem where $S$ is significantly smaller. We need to include the separator of size $2k+2$ in the root bag, together with $S$, so we obtain a slightly weaker bound on the maximum bag size, that is $5k+6$. Next, due to scenario (3) we might not make direct progress in the recursive scheme but instead we reduce the size of an $\mathcal{H}$-deletion set $X$ that we maintain (which initially contains all vertices). This situation can happen at most $|V(G)|$ many times, so eventually we will reach outcome (1) or (2).

The approach sketched above leads to a proof of Theorem 1. The details are deferred to the full version [31] due to space restrictions. Apart from carefully combining the ingredients collected so far, in the proof we take care to optimize the number of calls to the $\mathcal{H}$-DELETION oracle, leading to the clean bound of $\mathcal{O}(8^k n)$ oracle calls advocated in the introduction.

## 4 Conclusion

We contributed to the algorithmic theory of hybrid graph parameterizations, by showing how a 5-approximation to $\mathbf{tw}_{\mathcal{H}}$ can be obtained using an algorithm for the solution-size parameterization of $\mathcal{H}$-DELETION as a black box. This makes the step of computing a tree $\mathcal{H}$-decomposition now essentially as fast as that of solving $\mathcal{H}$-DELETION parameterized by solution size. Our new decomposition algorithm combines with existing algorithms to solve $\mathcal{H}$-DELETION on a given tree $\mathcal{H}$-decomposition, to deliver algorithms that solve $\mathcal{H}$-DELETION parameterized by $\mathbf{tw}_{\mathcal{H}}$. For Odd Cycle Transversal and Vertex Planarization, the parameter dependence of the resulting algorithm is equal to the worst of the parameter dependencies of the solution-size and treewidth-parameterizations. We believe that this is not a coincidence, and offer the following conjecture.

▶ **Conjecture 15.** *Let $\mathcal{H}$ be a hereditary and union-closed graph class. If $\mathcal{H}$-DELETION can be solved in time $f(s) \cdot n^{\mathcal{O}(1)}$ parameterized by solution size $s$, and in time $h(w) \cdot n^{\mathcal{O}(1)}$ parameterized by treewidth $w$, then $\mathcal{H}$-DELETION can be solved in time $(f(\mathcal{O}(k)) + h(\mathcal{O}(k))) \cdot n^{\mathcal{O}(1)}$ parameterized by $\mathcal{H}$-treewidth $k$.*

The conjecture is a significant strengthening of the equivalence, with respect to non-uniform fixed-parameter tractability, between solving $\mathcal{H}$-DELETION parameterized by solution size and computing $\mathbf{tw}_{\mathcal{H}}$ given by Agrawal et al. [1]. It essentially states that there is no *price of generality* to pay for using the hybrid parameterization by $\mathbf{tw}_{\mathcal{H}}$. After three decades in which the field of parameterized complexity has focused on parameterizations by solution size, this would lead to a substantial shift of perspective. We believe Theorem 1 is an important ingredient in this direction.

To understand the relative power of the parameterizations by solution size, treewidth, and $\mathcal{H}$-treewidth, the remaining bottleneck lies in using the tree $\mathcal{H}$-decomposition to compute a minimum $\mathcal{H}$-deletion set. Can the latter be done as efficiently when using a tree $\mathcal{H}$-decomposition as when using a standard tree decomposition? For problems like Odd Cycle Transversal and Vertex Planarization, this is indeed the case. But when the current-best dynamic-programming algorithm over a tree decomposition uses advanced techniques, it is currently not clear how to lift such an algorithm to work on a tree $\mathcal{H}$-decomposition. Can $\mathcal{H}$-deletion for $\mathcal{H}$ the class of interval graphs be solved in time $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$ parameterized by $\mathbf{tw}_{\mathcal{H}}$? Such a running time can be obtained for the parameterization by treewidth by adapting the approach of Saitoh, Yoshinaka, and Bodlaender [48].

While we have not touched on the subject here, we expect our ideas to also be applicable when $\mathcal{H}$ is a *scattered graph class*, i.e., when $\mathcal{H}$ consists of graphs where each connected component is contained in one of a finite number of graph classes $\mathcal{H}_1, \ldots, \mathcal{H}_t$. It is known [30] that, when Vertex Cover can be solved in polynomial time on each graph class $\mathcal{H}_i$, then Vertex Cover is FPT parameterized by the width of a given tree $\mathcal{H}$-decomposition. We expect that Theorem 1 can be generalized to work with scattered graph classes $\mathcal{H}$, as long as there is an oracle to solve $\mathcal{H}_i$-deletion parameterized by solution size for each individual class $\mathcal{H}_i$. To accommodate this setting, the algorithm maintains an $\mathcal{H}_i$-deletion set $X_i$ for *each* graph class $\mathcal{H}_i$. A step of the decomposition algorithm then either consists of finding a balanced separation of $S$, splitting off a base component, or improving *one of the* deletion sets $X_i$ (which can occur only $t \cdot |V(G)|$ times).

The decomposition algorithm we presented has an approximation factor of 5. It may be possible to obtain a smaller approximation ratio at the expense of a worse base of the exponent, by repeatedly splitting large bags [5, 35, 36]. For obtaining single-exponential $\mathcal{H}$-deletion algorithms, the advantage of the improved approximation factor would be immediately lost due to the increased running time and therefore we did not pursue this direction.

A final direction for future work concerns the optimization of the polynomial part of the running time. For standard treewidth, a 2-approximation can be computed in time $2^{\mathcal{O}(k)} \cdot n$ [35], which was obtained after a long series of improvements (cf. [8, Table 1]) on both the approximation factor and dependence on $n$. Can a constant-factor approximation to $\mathcal{H}$-treewidth be computed in time $2^{\mathcal{O}(k)} \cdot (n+m)$ for graph classes $\mathcal{H}$ like bipartite graphs?

## Abstract

We study the reverse shortest path problem on disk graphs in the plane. In this problem we consider the proximity graph of a set of $n$ disks in the plane of arbitrary radii: In this graph two disks are connected if the distance between them is at most some threshold parameter $r$. The case of intersection graphs is a special case with $r = 0$. We give an algorithm that, given a target length $k$, computes the smallest value of $r$ for which there is a path of length at most $k$ between some given pair of disks in the proximity graph. Our algorithm runs in $O^*(n^{5/4})$ randomized expected time, which improves to $O^*(n^{6/5})$ for unit disk graphs, where all the disks have the same radius.[1] Our technique is robust and can be applied to many variants of the problem. One significant variant is the case of weighted proximity graphs, where edges are assigned real weights equal to the distance between the disks or between their centers, and $k$ is replaced by a target weight $w$. In other variants, we want to optimize a parameter different from $r$, such as a scale factor of the radii of the disks.

The main technique for the decision version of the problem (determining whether the graph with a given $r$ has the desired property) is based on efficient implementations of BFS (for the unweighted case) and of Dijkstra's algorithm (for the weighted case), using efficient data structures for maintaining the bichromatic closest pair for certain bicliques and several distance functions. The optimization problem is then solved by combining the resulting decision procedure with enhanced variants of the interval shrinking and bifurcation technique of [4].

## 1 Introduction

In this paper we study the *reverse shortest path problem* (RSP for short) on graphs defined by disks in the plane.

[1] In this paper the $O^*(\cdot)$ notation hides subpolynomial factors.

In the simplest variant of this problem, we are given a set $P$ of $n$ points in the plane, two designated points $s, t \in P$, a real parameter $r > 0$ and an integer $k < n$. Define $G_r$ to be the graph $(P, E_r)$, where the edges of $E_r$ are all the pairs $(p, q)$ such that $\|p - q\| \leq 2r$. This is also the intersection graph of the disks of radius $r$ centered at the points of $P$. In the decision version of the RSP problem we want to determine whether $G_r$ contains a path from $s$ to $t$ with at most $k$ edges. In the optimization version, which is the reverse shortest path problem itself, we wish to find the smallest value $r^*$ for which $G_{r^*}$ has this property. Both versions (decision and optimization) of this problem have received considerable attention during the past decade [5, 7, 14].

**Our contributions.** We give an algorithm for this problem that runs in $O^*(n^{6/5})$ randomized expected time (where the $O^*(\cdot)$ notation hides subpolynomial factors). This improves the recent $O^*(n^{5/4})$-time solution of Wang and Zhao [14]. In fact we study the RSP problem in a much more general context that involves a variety of intersection or proximity graphs on a finite set of arbitrary disks in the plane, for which nontrivial bounds were not known prior to this work.

We first consider unweighted disk graphs in Section 3. In this setup, we have a set $\mathcal{D}$ of $n$ disks in the plane of arbitrary radii. Each disk $D \in \mathcal{D}$ is specified by its center $c_D$ and radius $\rho_D$. For a given parameter $r \geq 0$ we define the *proximity graph* $G_r$ by adding an edge between disks $D$ and $D'$ if the distance between them, $\mathsf{dist}(D, D') = \|c_D - c_{D'}\| - \rho_D - \rho_{D'}$, is at most $r$. The case $r = 0$ is of special interest and gives the intersection graph of the disks.[2]

For the decision version of this RSP problem we obtain an algorithm that runs in $O(n \log^4 n)$ time, and for the optimization version an algorithm that runs in $O^*(n^{5/4})$ randomized expected time. Our technique generalizes to other versions of the optimization problem. For example, we can consider the intersection graph of the disks ($r = 0$) and ask for the smallest scaling factor of the radii of all disks, either by a common additive term or by a common multiplicative factor, that would make the graph contain a path of at most $k$ edges between a designated pair of source and target disks $D_s$ and $D_t$.

In Section 4 we generalize our results further to weighted versions of the proximity graph $G_r$. We consider two natural weight functions for the edges. The first sets the weight of an edge $(D, D')$ to be the distance $\|c_D - c_{D'}\|$ between the centers of the disks, and the second sets the weight to be the distance $\mathsf{dist}(D, D') = \|c_D - c_{D'}\| - \rho_D - \rho_{D'}$ between the disks. We solve the decision problem on such weighted disk graphs, in which we want to determine whether the shortest path in $G_r$ from $D_s$ to $D_t$ is of length at most $w$, for some specified real threshold $w$, by a careful implementation of Dijkstra's algorithm (using a dynamic bichromatic closest pair structure, see below) in $O(n \log^4 n)$ or $O(n \log^6 n)$ time, depending on the type of edge weights. The optimization RSP problem is then solved in $O^*(n^{5/4})$ randomized expected time. For weighted unit disk graphs we still get the better bound of $O^*(n^{6/5})$ time for the optimization problem.

Our decision algorithms rely on rather complex dynamic data structures (see below), which should be avoided, if possible, from a practical point of view. Indeed, for unit disk graphs, there exist simpler and slightly more efficient implementations of BFS and Dijkstra's algorithm, in the unweighted and weighted cases, respectively [5, 7, 13]. However, as explained in the remarks following Theorems 2 and 7, we cannot use them in conjunction with our optimization technique, for certain technical reasons. We thus present in the full version of this paper alternative implementations, based on the known grid-based techniques, which satisfy our requirements and are arguably somewhat simpler.

[2] One technical difference is that when considering proximity graphs, it is customary, although not obligatory, to assume that the disks are pairwise disjoint, which is certainly not an assumption that one would make for intersection graphs.

**Our techniques.** We achieve our results by carefully combining three main technical ingredients. The first is an efficient "serial" implementation of parametric search, using what we call *interval shrinking* and *bifurcation* procedures. This technique was first used by Ben Avraham et al. [4] for solving problems involving the discrete and semi-discrete Fréchet distance with shortcuts. Here we apply a somewhat modified variant of it in the rather different context of our RSP problem, exposing its potential to be useful for a wide range of other problems as well.

We remark, that using this technique requires that the decision procedure access the parameter $r$ to be optimized via comparisons only, whose outcome depends on the relation between the optimal $r^*$ and certain critical values (which in our case turn out to be additively weighted inter-point distances between the centers of the disks), on which we can apply the interval shrinking procedure in an efficient manner. We review this technique in Section 2.

The second ingredient is a dynamic nearest neighbor and a dynamic bichromatic closest pair data structures for additively weighted Euclidean distances. Such structures with polylogarithmic time per update and access were recently developed by Kaplan et al. [8] and Liu [11].

The third ingredient that we use for the weighted versions of the problem is a technique that combines nearest neighbor data structures for two different distance functions. Specifically, given a (dynamic) nearest neighbor data structure for a distance function $d_1$, and a (dynamic) nearest neighbor data structure for a distance function $d_2$, we show how we can get a (dynamic) data structure that can answer constrained nearest neighbor queries of the form: find the closest point to a query $q$ according to the distance function $d_1$ among all points whose distance to $q$ according to $d_2$ is at most some threshold $r$ (which is part of the query).

**Previous work.** The decision problem in the unweighted variants can be solved by running a BFS from $s$ (or from $D_s$) in the underlying graph. Similarly, the decision problem in the weighted variants can be solved by running Dijkstra's shortest-path algorithm in the graph. However, the challenge is to do it efficiently, since the graph might have up to a quadratic number of edges. For unit-disk graphs, Cabello and Jejčič [5] presented an $O(n \log n)$ implementation of BFS, and subsequently Chan and Skrepetos [7] presented an alternative $O(n)$ implementation (after pre-sorting the points by their $x$- and $y$-coordinates). Moreover, Cabello and Jejčič [5] also described an $O(n^{1+\varepsilon})$ implementation of Dijkstra's algorithm for weighted unit-disk graphs, which was followed by a more efficient $O(n \log^2 n)$ implementation described by Wang and Xue [13]; see also [8].

The RSP problem in the context of unweighted unit-disk graphs was posed by Cabello and Jejčič [5], who observed that it can be solved conceptually easily in $O^*(n^{4/3})$ time, by running a binary search through the $O(n^2)$ inter-point distances (using an efficient distance selection algorithm). Recently, Wang and Zhao [14] managed to improve this bound, obtaining an algorithm that solves the problem in $O^*(n^{5/4})$ time. In the context of weighted unit-disk graphs, the situation is similar. The RSP problem can be solved easily in $O^*(n^{4/3})$ time, but Wang and Zhao [15] were able to obtain an improved $O^*(n^{5/4})$-time solution for that version too. [3]

As far as we know, both the decision and optimization problems have not been studied in the context of general disk graphs.

[3] The $O^*(n^{6/5})$ bound for the RSP problem in both unweighted and weighted unit disk graphs was already claimed in an unpublished manuscript [9], which appeared shortly after the first RSP paper of Wang and Zhao. However, this manuscript overlooks an issue that may arise when using an off-the-shelf decision problem, see the full version of this paper.

## 2 Preliminaries

In this section we provide necessary background on the serial parametric search technique of Ben Avraham et al. [4].

In its basic form, the technique is applicable when the threshold parameter $r^*$ is the distance between a pair of input points. There are $O(n^2)$ such distances, and the most naïve algorithm simply finds $r^*$ by running a binary search through them, guided by the decision procedure at each comparison. A basic improvement is to implement the binary search using an efficient procedure for distance selection, such as the one in [2] or [10], which runs in $O^*(n^{4/3})$ time. Up to an additional logarithmic factor, this dominates the cost of the whole procedure (assuming that the decision procedure is more efficient; as we show, this is indeed the case in all the RSP problems studied in this paper).

The technique of [4] is a combination of two subprocedures, referred to as the *interval shrinking* and the *bifurcation* procedures. The interval shrinking procedure receives an integer parameter $L \ll \binom{n}{2}$, and computes an interval $I \subset \mathbb{R}$ that contains $r^*$ and at most $L$ *critical values*, namely inter-point distances. As shown in [4], this can be done in $O^*(n^{4/3}/L^{1/3})$ expected time.

We then run the bifurcation procedure, which simulates the execution of the decision procedure at the (unknown) threshold $r^*$, as in the standard parametric search technique [12]. When the simulation reaches a comparison of $r^*$ with some concrete value $r$, we know the answer to the comparison when $r$ lies outside $I$. However, when $r \in I$ we bifurcate, following both possibilities $r^* > r$ and $r^* < r$ (the case $r^* = r$ will be handled too; see below). This produces a *bifurcation tree* $T$, which we expand until we either collect sufficiently many bifurcations, or until we reach a sufficiently large uniform depth of $T$. In either case we stop this simulation phase, resolve all collected comparisons by a binary search through them, using the (unsimulated) decision procedure to guide the search, and start a new bifurcation phase from the unique leaf of $T$ whose associated (shrunk) interval of critical values contains $r^*$. The binary search will also identify $r^*$ when it is one of the critical values through which it searches, and then terminate the entire procedure right away. In the worst case this will happen by the time when the entire decision procedure has been simulated.

We comment that this method is viable when the decision procedure is not known to have a parallel version of small depth, which is required in the standard parametric search technique. If such a parallel version were available, we could apply standard parametric search, and obtain a significantly faster algorithm. The RSP problem seems to be inherently sequential, as it seeks a path in a graph, and is indeed amenable to the technique of [4].

As shown in [4], the bifurcation procedure can be implemented to run in $O^*(L^{1/2}D(n))$ time, where $D(n)$ is the cost of the decision procedure. A suitable choice of $L$ yields an overall (randomized expected) running time $O^*(n^{6/5})$, for (suitable) decision procedures that run in nearly linear time, as do the decision procedures for all the variants of the RSP problem considered in this paper.

## 3 Reverse shortest paths for unweighted disk graphs

Here we are given a set $\mathcal{D}$ of $n$ disks in the plane, of arbitrary radii, each parameterized by its center $c_D$ and radius $\rho_D$. We consider the *intersection graph* $G^\times = (\mathcal{D}, E)$, where the edges of $G^\times$ are the intersecting pairs of disks. Formally, $E$ consists of all pairs $(D, D')$ for which $\|c_D - c_{D'}\| \leq \rho_D + \rho_{D'}$.

In the decision problem, we are given two designated disks $D_s$ and $D_t$, and an integer parameter $k$, and the goal is to determine whether $G^\times$ contains a path of at most $k$ edges from $D_s$ to $D_t$.

In the optimization problem we scale the radii of the disks (without changing their centers), either by an additive term or by a multiplicative factor, and seek the smallest scaling parameter that makes $G^\times$ have the desired $s$-$t$ path.

Towards the end of the section, we consider the special and important case of unit disk graphs, for which we obtain a better bound.

## 3.1 The decision procedure

We run BFS on $G^\times$ from $D_s$. Suppose that we have already discovered all disks at some level $i$ of the BFS. We expand the BFS to level $i+1$ as follows. We consider each disk $D$ at level $i$ in turn, and look for its nearest neighbor among the disks that have not yet been discovered. To do so, we maintain a dynamic additively-weighted Voronoi diagram $\mathrm{Vor}(\mathcal{U})$ of the set $\mathcal{U}$ of all the disks that the BFS has not yet reached, where the additive weight of a disk $D$ is $-\rho_D$. Initially, we are at level 0 of the BFS, which includes only $D_s$, and we set $\mathcal{U} = \mathcal{D} \setminus \{D_s\}$.

We search for the nearest neighbor $D'$ of $D$ in $\mathrm{Vor}(\mathcal{U})$. If the weighted distance between $D$ and $D'$ is at most $\rho_D$, that is, if $\|c_D - c_{D'}\| - \rho_{D'} \leq \rho_D$, we conclude that $\|c_D - c_{D'}\| \leq \rho_D + \rho_{D'}$, so we add $D'$ to level $i+1$, delete it from $\mathcal{U}$, and query the updated Voronoi diagram for the new nearest neighbor of $D$ again. We continue querying the updated $\mathrm{Vor}(\mathcal{U})$ with $D$ until the distance between $D$ and its nearest neighbor is larger than $\rho_D$. When this happens we replace $D$ by the next disk at level $i$ and repeat this process. When we finish processing in this manner all disks of level $i$, we have discovered all disks at level $i+1$, and we move on to level $i+1$.

Consider a sequence of queries to the Voronoi diagram with a disk $D$ at some level of the BFS. We can charge each of these queries but the last, to a new disk that we add, following this query, to the BFS tree. Therefore the running time of this decision procedure is dominated by the cost of $O(n)$ queries and $n$ deletions from $\mathrm{Vor}(\mathcal{U})$. The most efficient implementation of such a structure, with running time $O(n \log^4 n)$, is due to Liu [11]; see also the earlier study [8], with a worse polylogarithmic factor.

In summary, we have shown:

▶ **Theorem 1.** *Given $\mathcal{D}$, $D_s$, $D_t$, and $k$ as above, we can determine whether there exists a path of at most $k$ edges from $D_s$ to $D_t$ in the intersection graph $G^\times$ associated with $\mathcal{D}$, in $O(n \log^4 n)$ time.*

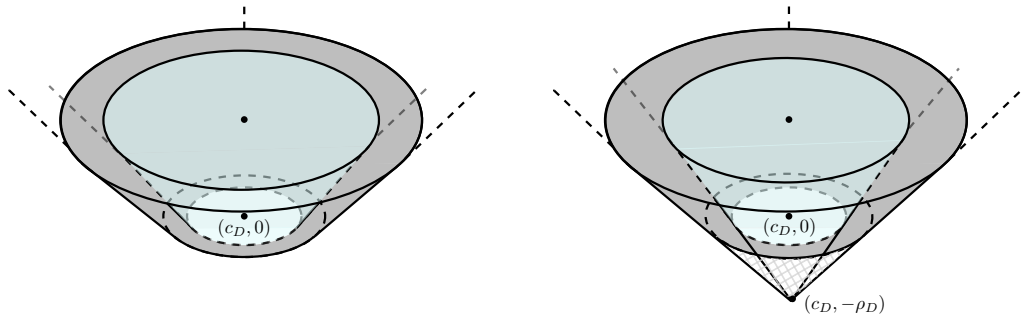
## 3.2 The optimization procedure

Each disk $D \in \mathcal{D}$ is assigned the radius $\rho_D + \alpha$, for some common additive parameter $\alpha$, and we want to find the minimum value $\alpha^*$ of $\alpha$ for which the intersection graph of the modified disks, now denoted by $G^\times_\alpha$, has the desired $s$-$t$ path. In principle $\alpha$ could also be negative, as long as no radius becomes negative, but for simplicity we only consider the case $\alpha > 0$.

We simulate the decision procedure at the unknown optimal value $\alpha^*$ by using a bifurcation procedure. Before starting the simulation, though, we perform an interval-shrinking step, as described in the introduction.

**Interval shrinking.** Recall that this step, as introduced in [4], receives an integer threshold parameter $L$ and produces an interval $I_0 \subset \mathbb{R}$ that contains $\alpha^*$ and at most $L$ other critical values, where a value $\alpha$ is critical if the outcome of a comparison changes as we go past $\alpha$. In the original formulation, the critical values were inter-point distances in the plane, and the resulting algorithm ran in $O^*(n^{4/3}/L^{1/3})$ randomized expected time.

Here the setup is different. The comparisons that the decision procedure performs are tests whether expressions of the form $\|c_D - c_{D'}\| - \rho_D - \rho_{D'} - 2\alpha$ are positive or negative. The critical values of the parameter $\alpha$ are thus of the form $\frac{1}{2}\left(\|c_D - c_{D'}\| - \rho_D - \rho_{D'}\right)$. The original mechanism of [4] is based on distance selection. We need a variant in which the basic step is to bound the number of these new critical values in a given interval $(\alpha_1, \alpha_2)$. We turn this problem into a range searching problem, where the disks of $\mathcal{D}$ serve as both data and query objects. Specifically, each disk $D$ is mapped to the point $(c_D, \rho_D)$ in $\mathbb{R}^3$, and also to the range $\sigma_D = \{D' \mid 2\alpha_1 \leq \|c_D - c_{D'}\| - \rho_D - \rho_{D'} \leq 2\alpha_2\}$, which is a conical shell in 3-space (see Figure 1(a)). Note that the ranges have three degrees of freedom, and that the problem is symmetric, so that ranges can be represented as points in $\mathbb{R}^3$ and points as ranges. In other words, we have a symmetric batched range searching problem in $\mathbb{R}^3$, involving $n$ points and $n$ semi-algebraic ranges. Using standard, cutting-based decomposition techniques in $\mathbb{R}^3$, such as in [1, 3], we can implement the range searching step to run in randomized expected time $O^*(n^{3/2})$. Combining this with parametric search, as in the standard distance selection procedure [2], we can implement the distance selection procedure to also run in randomized expected time $O^*(n^{3/2})$.



(a) (b)

**Figure 1** The range $\sigma_D$ (in grey) when scaling by an additive term (a) and by a multiplicative factor (b). The inner and outer radii of the annulus centered at $(c_D, 0)$ are $\rho_D + 2\alpha_1$ and $\rho_D + 2\alpha_2$, respectively, in (a) and $\rho_D\lambda_1$ and $\rho_D\lambda_2$, respectively, in (b).

Extending the machinery in [4], we can convert this distance selection technique to an interval-shrinking procedure that receives a parameter $L \ll \binom{n}{2}$ and yields an interval $I = (\alpha_1, \alpha_2)$ that contains the optimum value $\alpha^*$ and at most $L$ critical values. A suitable modification of the analysis in [4] shows that the algorithm runs in $O^*(n^{3/2}/L^{1/2})$ randomized expected time.

**Bifurcation.** We now present the basic bifurcation procedure. This procedure, sometimes with a few enhancements and modifications, is used in all our algorithms for the various variants of the RSP problem. We refer the reader to [4] where a similar procedure has been used.

Our simulation proceeds in *phases*, where in each phase we construct a bifurcation tree $T$ that represents some portion of the execution of the BFS, simultaneously for all values of $\alpha$ in some interval $I$. Initially $I = I_0$, but it will keep on shrinking as the simulation proceeds. Each node $b$ of $T$ is associated with an interval $I^b = (\alpha_1, \alpha_2) \subseteq I$, such that, up to the state of simulation represented by $b$, the BFS proceeds in an identical manner for all values $\alpha \in I^b$. We continue to simulate the BFS at $b$. At each comparison of (the unknown) $\alpha^*$ with some concrete value $\alpha$, we either resolve the comparison in a unique manner when $\alpha \notin I^b$, or

else bifurcate, meaning that we create two children $u$ and $v$ of $b$, assign $I^u := (\alpha_1, \alpha)$ and $I^v := (\alpha, \alpha_2)$, and continue to expand $T$ at $u$ and at $v$, at each of which we know the outcome of the above procedure (the possibility that $\alpha^* = \alpha$ will be tested later).

For each node $b$, let $y_b$ denote the amount of work performed at $b$ so far by the simulation (including comparisons that were fully resolved), and let $y_b^-$ denote the sum of the quantities $y_a$ over all proper ancestors $a$ of $b$, *excluding the root*. We refer to the cost at the root as the *initialization cost* of the tree, and denote it as $C_0(T)$.

We stop the expansion of $T$ at a node $b$ when $y_b^- + y_b = Y$, where $Y$ is a threshold parameter that will be determined later. That is, we stop the simulation at node $b$ as soon as $y_b^-$ plus the work done so far at $b$ becomes $Y$. We refer to such nodes $b$ as *incomplete leaves* of $T$. We then continue the expansion of $T$ at other nodes.

A subtle issue, that we will address later in more detail, is that when we back up from an incomplete node $b$ to explore other branches of $T$, we need to restore the state of execution at the suitable ancestors of $b$. See below for details.

We stop the entire construction of $T$ as soon as one of the following two conditions occurs:

- **(i)** We collect $X$ bifurcations, for another threshold parameter $X$ that will be determined later.
- **(ii)** All the leaves of $T$ are incomplete.

When this happens, we take all the (at most $X$) critical values of the bifurcations at the inner nodes of $T$, and run a binary search through them, using the unsimulated decision procedure to guide the search. This takes $O(D(n) \log n)$ time, and yields the leaf $w$ whose range $I^w$ contains $r^*$. It is also possible that the binary search will detect that one of the critical values it searches through is $r^*$ itself. In this case the entire procedure is terminated, and $r^*$ is output. Otherwise, this ends a phase of the simulation. We start a new phase (if the simulation has not already ended) with $w$ as the root of the tree, and with $I^w$ as the critical interval. Note that this will cause the work already done at $w$ to be repeated, and it is possible that the cost of this work is much larger than $Y$. However, by charging the incomplete work at $w$ to the initialization cost $C_0(T')$ of the next tree $T'$, we at most double this cost, so this will not affect the overall asymptotic bound on the performance of the procedure; see below for details.

**Restoring the execution state.** The issue of restoring the state at nodes we back up to, as mentioned earlier, is more acute in our specific application, because part of this state includes the Voronoi diagram that our procedure maintains dynamically. Although there are persistence-based techniques that can efficiently maintain all versions of the diagram, they are fairly involved, and we opt not to use them. Instead, we use the following simple approach, which also takes care of all aspects of restoring the state.

Specifically, we expand the bifurcation tree in a depth-first manner, so that at each node we first recursively construct the subtree of its left child and only then the subtree of its right child. We thus first expand the leftmost path of $T$, and slowly proceed to the right, backing from a node to its parent, and then proceed to the right child, or further up to the grandparent. When we back up from a node $w$ to its parent $v$, we simply undo the operations performed at $w$, including the updates that were done to the diagram, in reverse order, replacing each deletion of a disk by the corresponding reinsertion. This requires us to maintain a log of the updates performed at each node, as well as a log of the other operations, but is otherwise a reasonably simple procedure, which does not affect the asymptotic running time and storage bounds.

## 3.3 Analysis

By construction, a single phase produces a tree $T$ that has at most $X$ binary nodes, and the cost of producing each path of $T$ is at most $Y$, ignoring the initialization cost $C_0(T)$. This is easily seen to imply that the cost of generating $T$ is $O(XY + C_0(T))$. Indeed, the cost at each node of $T$, other than the root, is certainly at most $Y$, and there are $O(X)$ such nodes The cost of the subsequent binary search through the critical values is $O(D(n) \log n)$. Hence the overall cost of a single phase is $O(XY + C_0(T) + D(n) \log n)$. The number of phases is estimated as follows. If the phase terminates because of Condition (i), it has discovered $X$ critical values among those in the current critical interval, which are outside the new critical interval $I^w$. Hence the number of such phases is at most $L/X$.[4]

A phase that terminates because of Condition (ii) consumes $Y$ of the total cost of the decision procedure: when we pass to the next phase we follow a single path of the current $T$, but all paths use at least $Y$ of the cost, excluding the work done at the root. Note that, by construction, the part of the simulation performed along a path of the tree in one phase, excluding the work performed at the root, is disjoint from the part performed along a path of the tree in a different phase. This is easily seen to imply that the number of phases of type (ii) is at most $D(n)/Y$.

The sum $\sum_T C_0(T)$ of the initialization costs of all the trees is at most $D(n)$, because these initializations perform pairwise disjoint portions of the decision procedure. (Observe that execution at a root is always completed, no matter how expensive it is.)

We set our parameters so that $\frac{L}{X} = \frac{D(n)}{Y}$ and $XY = D(n) \log n$. That is, we choose $X = L^{1/2} \log^{1/2} n$ and $Y = D(n) \log^{1/2} n / L^{1/2}$, and obtain that the overall cost of the simulation is $O(L^{1/2} D(n) \log^{1/2} n)$ (this clearly also subsumes the cost $\sum_T C_0(T)$).

In total, the cost of the optimization procedure is

$$O^*\left(\frac{n^{3/2}}{L^{1/2}} + L^{1/2} D(n)\right) = O^*\left(\frac{n^{3/2}}{L^{1/2}} + L^{1/2} n\right).$$

We balance these two terms by choosing $L = n^{1/2}$, and obtain a total cost of $O^*(n^{5/4})$. This result is part of the summary in Theorem 2 (which also includes other variants of the problem), given below.

## 3.4 Other variants and unit disks

**Scaling by a multiplicative factor.** Consider first the case of intersection graphs where the radii are scaled by a common multiplicative factor $\lambda > 0$. In this case the critical value induced by a pair of disks $D$, $D'$ satisfies $\|c_D - c_{D'}\| - \lambda\rho_D - \lambda\rho_{D'} = 0$, or $\lambda = \dfrac{\|c_D - c_{D'}\|}{\rho_D + \rho_{D'}}$. As above, the algorithm requires a procedure that computes the number of critical values in an interval $(\lambda_1, \lambda_2)$. So we convert this task to batched range searching in three dimensions, where the ranges are now

$$\sigma_D = \{D' \mid \lambda_1(\rho_D + \rho_{D'}) \le \|c_D - c_{D'}\| \le \lambda_2(\rho_D + \rho_{D'})\}.$$

[4] This is a rather weak aspect of the analysis. For the bound $L/X$ to materialize, the $X$ critical values of each phase must form a prefix or a suffix of the sequence of critical values in the current interval $I$. In general, when these critical values are more uniformly spread within $I$, the number of such phases should be much smaller. It is a challenging open problem to turn this intuition into an improved procedure, if possible.

These too are conical shells, but here the bounding cones have a common apex and different opening angles (see Figure 1(b)). Other than this new type of ranges, the preceding machinery proceeds verbatim. The interval shrinking runs in $O^*(n^{3/2}/L^{1/2})$ expected time and the bifurcation procedure runs in $O^*(L^{1/2}n)$. With a proper choice of $L$, the overall cost is $O^*(n^{5/4})$ expected time.

**Proximity graphs.** Next, consider the case of proximity graphs. In this case, we assume that the disks of $\mathcal{D}$ are pairwise disjoint, and we are given an additional parameter $r > 0$. (For $r = 0$ we get the intersection graph $G^\times$.) The set of edges of the proximity graph $G_r$ consists of all pairs of disks $(D, D')$ for which $\mathsf{dist}(D, D') = \|c_D - c_{D'}\| - \rho_D - \rho_{D'} \leq r$. In the RSP problem for proximity graphs, we seek the smallest value of $r$ for which $G_r$ has the desired $s$-$t$ path. It is easy to see that this problem can be reduced to the (additive version of the) corresponding problem for intersection graphs, by simply adding $r/2$ to the radius of each of the disks. In the optimization procedure, the critical values are of the form $\|c_D - c_{D'}\| - \rho_D - \rho_{D'}$. Thus, except for the factor $\frac{1}{2}$ used earlier, the procedure is essentially identical to the earlier one.

**Unit disks.** Finally, consider the special case of unit disks, i.e., where all the radii are equal, and consider the intersection graph of the disks. In this case, we get a better bound, since the critical values are merely (one half of the) inter-point distances, and hence the interval shrinking step can be performed in $O^*(n^{4/3}/L^{1/3})$ randomized expected time, as in [4]. Modifying the expression for the overall running time accordingly, we get $O^*\left(\frac{n^{4/3}}{L^{1/3}} + L^{1/2}n\right)$ randomized expected time. We now balance these two terms by choosing $L = n^{2/5}$, and obtain a total cost of $O^*(n^{6/5})$. In summary, we have shown:

▶ **Theorem 2.** *The reverse shortest path problem for unweighted intersection or proximity graphs of arbitrary disks in the plane can be solved in $O^*(n^{5/4})$ randomized expected time. This bound applies to all the variants of the problem listed above. In the case of unit disks, where all radii are equal, the problem can be solved in $O^*(n^{6/5})$ randomized expected time.*

**Remark.** In the case of unit disks, the decision procedure itself can be implemented to run faster than $O(n \log^4 n)$. Chan and Skrepetos [7] even present an algorithm that runs in linear time (after a preliminary sorting step); see also [5]. However, the critical values produced by their procedure are not all inter-point distances, which affects the running time of the optimization procedure. To avoid the use of complex dynamic data structures, we modify the algorithm of Chan and Skrepetos, so that it can be combined with the optimization procedure, see the full version of this paper.

## 4 Reverse shortest paths for weighted disk graphs

Recall that, for a set $\mathcal{D}$ of $n$ disks in the plane and an additional parameter $r \geq 0$, the proximity graph $G_r$ of $\mathcal{D}$ has an edge between every pair of disks such that

$$\mathsf{dist}(D, D') := \|c_D - c_{D'}\| - \rho_D - \rho_{D'} \leq r. \tag{1}$$

The intersection graph $G^\times$ of $\mathcal{D}$ is the proximity graph of $\mathcal{D}$ for $r = 0$, except that in proximity graphs we usually assume that the disks are pairwise disjoint.

We next assign weights to the edges. There are two natural choices for these weights. One is to define the weight of an edge $(D, D')$ as the distance $\|c_D - c_{D'}\|$ between the centers. The other is to define the weight of $(D, D')$ to be $\mathsf{dist}(D, D')$ if $\mathsf{dist}(D, D') \geq 0$ and 0 otherwise (that is 0 if the disks intersect). Note that for intersection graphs only the first choice gives a reasonable weight function.

The case of weighted unit disk graphs is a special case of the problem for intersection graphs $G^{\times}$ with weights equal to the distances between the centers. In this case we have $\|c_D - c_{D'}\| = \mathsf{dist}(D, D') + 2$.

## 4.1 The decision procedure

We are given two disks $D_s$, $D_t$ of $\mathcal{D}$, and the proximity graph $G_r$ of $\mathcal{D}$ for some $r \geq 0$, weighted by one of the weight functions above. We want to compute the (length of the) shortest path $\pi(D_s, D_t)$ in $G$ from $D_s$ to $D_t$. We solve this by a clever implementation of Dijkstra's algorithm. The required sophistication of the implementation depends on the type of the weight function we use. We start with the simpler case in which the weight of $(D, D')$ is $\mathsf{dist}(D, D')$ (or 0 if the disks intersect). Specifically, the same function that defines the graph via the threshold $r$ (Equation (1)) is also used to define the weights.

The high-level approach is similar to that proposed by Cabello and Jejčič [5], although their original algorithm was given only for intersection graphs of unit disks. We briefly recall this technique, adapted to our context.

We maintain a decomposition of $\mathcal{D}$ into three disjoint subsets $\mathcal{R}$, $\mathcal{K}$ and $\mathcal{U}$, where $\mathcal{R} \cup \mathcal{K}$ is the set of disks $D$ for which we already have the correct distance label $\delta(D)$ (the length of the shortest path from $D_s$), and $\mathcal{U}$ is the remainder of $\mathcal{D}$, consisting of disks whose distance labels have not yet been determined. $\mathcal{R}$ (resp., $\mathcal{K}$) is the set of *active* (resp., *dead*) disks of $\mathcal{R} \cup \mathcal{K}$, meaning that the disks of $\mathcal{R}$ still have outgoing edges in $G_r$ to disks of $\mathcal{U}$, while disks of $\mathcal{K}$ have no such edges. Initially, $\mathcal{R} = \{D_s\}$, $\mathcal{K} = \emptyset$, and $\mathcal{U} = \mathcal{D} \setminus \{D_s\}$.

A single step of our implementation of Dijkstra's algorithm, a so-called *Dijkstra step*, picks the closest pair $(D, D')$ in $\mathcal{R} \times \mathcal{U}$, where the modified distance between $D$ and $D'$ is defined as

$$\mathsf{d}(D, D') = \delta(D) + \mathsf{dist}(D, D'). \tag{2}$$

Then we need to verify that $(D, D')$ is indeed an edge of $G_r$. If this is not the case, i.e., $\mathsf{dist}(D, D') > r$, we move $D$ from $\mathcal{R}$ to $\mathcal{K}$, and never process $D$ again. This action is justified by the following variant of [5, Lemma 6]:

▶ **Lemma 3.** *Let $D$ and $D'$ be as above, and assume that $\mathsf{dist}(D, D') > r$. Then $\mathsf{dist}(D, D'') > r$ for every disk $D'' \in \mathcal{U}$.*

**Proof.** By assumption, and since $(D, D')$ is the closest pair in $\mathcal{R} \times \mathcal{U}$, we have, for each $D'' \in \mathcal{U}$, $\delta(D) + r < \delta(D) + \mathsf{dist}(D, D') \leq \delta(D) + \mathsf{dist}(D, D'')$, so $\mathsf{dist}(D, D'') > r$, as asserted. ◀

Note that Lemma 3 also applies to weighted unit disk graphs (with weight $\|c_D - c_{D'}\|$ for edge $(D, D')$.)

Assume then that $\mathsf{dist}(D, D') \leq r$. We move $D'$ from $\mathcal{U}$ to $\mathcal{R}$, assign to it the distance label $\delta(D') = \delta(D) + \mathsf{dist}(D, D')$, and set $\mathsf{prev}(D') = D$, namely $D$ is the disk preceding $D'$ along the shortest path to $D'$. We then repeat the entire step with the new sets $\mathcal{R}$ and $\mathcal{U}$, and continue until $\mathcal{R}$ empties out. Upon termination, $\mathcal{U}$ is the set of disks that are unreachable from $D_s$ in $G_r$, and $\mathcal{K}$ is the set of reachable disks, each with its correct distance label and its predecessor.

The correctness of this procedure is argued exactly as in [5], even though the distance function is different. An efficient implementation is obtained by applying the efficient dynamic bichromatic closest-pair data structure of Kaplan et al. [8] and of Liu [11] to $\mathcal{R} \times \mathcal{U}$, under the distance function given in (2) and under deletions from $\mathcal{U}$ and insertions into and deletions from $\mathcal{R}$. The technique requires the following two properties.

- **(i)** The Voronoi diagram $\mathrm{Vor}_1(\mathcal{U})$ of $\mathcal{U}$, under the distance function $\mathsf{d}_1(q, D') = \|q - c_{D'}\| - \rho_{D'}$, for $D' \in \mathcal{U}$, where $c_{D'}$ and $\rho_{D'}$ are the respective center and radius of $D'$, has linear complexity.
- **(ii)** The Voronoi diagram $\mathrm{Vor}_2(\mathcal{R})$ of $\mathcal{R}$, under the distance function $\mathsf{d}_2(q, D) = \delta(D) + \|q - c_D\| - \rho_D$, for $D \in \mathcal{R}$, also has linear complexity.

Both properties indeed hold, as each diagram is an additively-weighted Voronoi diagram of the set of centers of the disks of $\mathcal{U}$ or of $\mathcal{R}$. Both diagrams need to be maintained dynamically, and the techniques of [8, 11] do that, with a polylogarithmic cost for each update and query operation. In the more efficient implementation of [11], the amortized cost of an update is $O(\log^4 n)$.

In summary, we have shown:

▶ **Theorem 4.** *The shortest-path tree from some starting disk in the proximity graph of $n$ disks (of arbitrary radii) in the plane, under the weights of inter-disk distances, can be constructed in $O(n \log^4 n)$ time.*

Next we address the more challenging weighted case when the edge weights are the distances between the centers.

**The edge weights are the distances between the centers.** In this case we need to maintain a dynamic bichromatic closest pair structure under the distance $\lambda(D, D') = \delta(D) + \|c_D - c_{D'}\|$, for $D \in \mathcal{R}$ and $D' \in \mathcal{U}$. But then Lemma 3 does not hold anymore, because it is then possible that the closest pair $(D, D') \in \mathcal{R} \times \mathcal{U}$ satisfies $\mathsf{dist}(D, D') > r$ but there could be other pairs $(D, D'')$ with $\mathsf{dist}(D, D'') \leq r$, so $D$ cannot be removed from $\mathcal{R}$ yet.

To overcome this difficulty we obtain a *bichromatic closest pair* (BCP for short) data structure by applying a black-box reduction of Chan [6] to two novel nearest-neighbor data structures that we now describe.

Our new data structures find for $D \in \mathcal{R}$ a nearest neighbor $D' \in \mathcal{U}$ according to the distance function $\lambda$ but only among disks $D'$ such that $dist(D, D') \leq r$, and similarly for $D \in \mathcal{U}$.

We then run the Dijkstra steps, using the BCP data structure, as long as there are still neighbors in $\mathcal{R} \times \mathcal{U}$. Upon termination, $\mathcal{U}$ is the set of disks that are unreachable from $D_s$ in $G_r$, and $\mathcal{R}$ is the set of reachable disks, each with its correct distance label and its predecessor.

Our nearest-neighbor data structure consists of two balanced search trees $T_{\mathcal{U}}$ and $T_{\mathcal{R}}$. The tree $T_{\mathcal{U}}$ ($T_{\mathcal{R}}$ is handled in a similar manner; see below) stores the disks $D' \in \mathcal{U}$ at its leaves, sorted in increasing order of the values $\rho_{D'}$. For each node $v$ of $T_{\mathcal{U}}$, we maintain an additively-weighted Voronoi diagram $\mathrm{Vor}_1(\mathcal{U}_v)$ on the set $\mathcal{U}_v$ of the disks of $\mathcal{U}$ stored at the leaves of the subtree rooted at $v$, where the weight of a disk $D'$ is $-\rho_{D'}$. We also maintain a second standard (unweighted) Voronoi diagram $\mathrm{Vor}_2(\mathcal{U}_v)$ for $\mathcal{U}_v$.

Querying $T_{\mathcal{U}}$ with a disk $D \in \mathcal{R}$ is performed as follows. We find the leftmost leaf $w_0$ of $T_{\mathcal{U}}$ whose disk $D'_0$ satisfies $\mathsf{dist}(D, D'_0) = \|c_D - c_{D'_0}\| - \rho_D - \rho_{D'_0} \leq r$. To find $w_0$, we search in $T_{\mathcal{U}}$ starting at the root. At each node $u$ that we reach, with a left child $v$ and a right child

$w$, we search with $D$ in $\mathrm{Vor}_1(\mathcal{U}_v)$, and obtain its nearest neighbor $D'$ in the corresponding subset of disks. If $\|c_D - c_{D'}\| - \rho_{D'} \leq \rho_D + r$, or, equivalently, $\mathsf{dist}(D, D') \leq r$, then we continue the search at the left child $v$. Otherwise we continue the search with the right child $w$. At the root we first search in $\mathrm{Vor}_1(\mathcal{U}_{\mathrm{root}} = \mathcal{U})$. If the nearest neighbor $D'$ satisfies $\|c_D - c_{D'}\| - \rho_{D'} > \rho_D + r$, that is, $\mathsf{dist}(D, D') > r$, we conclude that $D$ has no neighbor in $\mathcal{U}$.

Let $w_0$ be the leaf that the search reaches. Note that if a disk $D'$ is stored at a leaf to the left of $w_0$ then, by construction, $\mathsf{dist}(D, D') > r$. That is, only disks stored to the right of $w_0$, including $w_0$, need to be considered.

The search for $w_0$ provides us with a representation of the set $\mathcal{U}^+_{w_0}$ of the disks to the right of $w_0$ as the union of $O(\log n)$ pairwise disjoint canonical sets, each being the set of disks stored at the root of some subtree of $T_{\mathcal{U}}$. We query with $D$ in each of the $O(\log n)$ diagrams $\mathrm{Vor}_2(\mathcal{U}_v)$ that correspond to these subtrees, and return the disk that is nearest to $D$, i.e., with the minimum distance between their centers, among all the resulting nearest neighbors. The correctness of this procedure is a consequence of the following lemma.

▶ **Lemma 5.** *In the above procedure, the output disk $D'$ satisfies $\mathsf{dist}(D, D') \leq r$.*

**Proof.** Let $D'_0$ be the disk at the leaf $w_0$. By construction, we have

$$\rho_{D'_0} \leq \rho_{D'}. \tag{3}$$

By construction, $D'$ is the disk in $\mathcal{U}^+_{w_0}$ nearest to $D$ in the inter-center distance. That is,

$$\|c_D - c_{D'}\| \leq \|c_D - c_{D'_0}\|. \tag{4}$$

Assume by contradiction that $\mathsf{dist}(D, D') > r$. Then, by construction,

$$\|c_D - c_{D'_0}\| - \rho_{D'_0} - \rho_D = \mathsf{dist}(D, D'_0) \leq r < \mathsf{dist}(D, D') = \|c_D - c_{D'}\| - \rho_{D'} - \rho_D.$$

That is,

$$\|c_D - c_{D'_0}\| - \rho_{D'_0} < \|c_D - c_{D'}\| - \rho_{D'}. \tag{5}$$

Adding (3) and (5), we get a contradiction to (4). This establishes the lemma. ◀

The tree $T_{\mathcal{R}}$ is defined in an analogous manner for the disks of $\mathcal{R}$, except that (a) the leaves are sorted in increasing order of $\delta(D) + \rho_D$, and (b) the Voronoi diagram $\mathrm{Vor}_2(\mathcal{R}_v)$ at a node $v$ of $T_{\mathcal{R}}$, where $\mathcal{R}_v$ is the set of disks stored at the root of the subtree rooted at $v$, is the additively-weighted diagram on $\mathcal{R}_v$, where the additive weight of a disk $D$ is $\delta(D)$.

The first kind of Voronoi diagrams $\mathrm{Vor}_1(\mathcal{R}_v)$ are defined exactly as in the case of $T_{\mathcal{U}}$, with the additive weight being $-\rho_D$.

Here too, when we query $T_{\mathcal{R}}$ with a disk $D'$ of $\mathcal{U}$, we search in the tree to find the leftmost leaf $w_0$ of $T_{\mathcal{R}}$ whose disk $D_0$ satisfies $\mathsf{dist}(D_0, D') = \|c_{D_0} - c_{D'}\| - \rho_{D_0} - \rho_{D'} \leq r$. This is performed as follows. We first search for the leftmost leaf $w_0$ whose associated disk $D_0$ satisfies $\mathsf{dist}(D_0, D') \leq r$, using the same technique as in the previous search in $T_{\mathcal{U}}$, in which we query various Voronoi diagrams $\mathrm{Vor}_1(\mathcal{R}_v)$ along the search path to $w_0$. We then obtain the set $\mathcal{R}^+_{w_0}$ of all disks stored at the leaves to the right of $w_0$, including $w_0$, as the disjoint union of $O(\log n)$ subtrees. We query each of the diagrams $\mathrm{Vor}_2(\mathcal{R}_v)$ associated with these subtrees, and return the disk $D$ that is the nearest neighbor to $D'$ over all these diagrams.

The correctness of this procedure is a consequence of the following "sister" lemma to Lemma 5.

▶ **Lemma 6.** *In the above procedure, the output disk $D$ satisfies* $\mathsf{dist}(D, D') \leq r$.

**Proof.** Let $D_0$ be the disk at the leaf $w_0$. By construction, we have

$$\delta(D_0) + \rho_{D_0} \leq \delta(D) + \rho_D. \tag{6}$$

By construction, $D$ is the disk in $\mathcal{U}^+_{w_0}$ nearest to $D'$ in the inter-center distance with the additive weight $\delta$. That is,

$$\delta(D) + \|c_D - c_{D'}\| \leq \delta(D_0) + \|c_{D_0} - c_{D'}\|. \tag{7}$$

Assume by contradiction that $\mathsf{dist}(D, D') > r$. Then, by construction,

$$\|c_{D_0} - c_{D'}\| - \rho_{D_0} - \rho_{D'} = \mathsf{dist}(D_0, D') \leq r < \mathsf{dist}(D, D') = \|c_D - c_{D'}\| - \rho_D - \rho_{D'}.$$

That is,

$$\|c_{D_0} - c_{D'}\| - \rho_{D_0} < \|c_D - c_{D'}\| - \rho_D. \tag{8}$$

Adding (6) and (8), we get

$$\delta(D_0) + \|c_{D_0} - c_{D'}\| < \delta(D) + \|c_D - c_{D'}\|,$$

which is a contradiction to (7). This establishes the lemma. ◀

We make these nearest-neighbor data structures dynamic by maintaining the various Voronoi diagrams $\mathrm{Vor}_1(\mathcal{U}_v)$, $\mathrm{Vor}_2(\mathcal{U}_v)$, $\mathrm{Vor}_1(\mathcal{R}_v)$, $\mathrm{Vor}_2(\mathcal{R}_v)$, dynamically, using the technique of [8, 11], in which the update time of each diagram is $O(\log^4 n)$. An update of either of the trees $T_{\mathcal{U}}$, $T_{\mathcal{R}}$ requires updating $O(\log n)$ data structures along the path to the leaf containing the inserted or deleted element, and therefore takes $O(\log^5 n)$ time. The transformation of Chan [6] from the two nearest-neighbor structures to a BCP data structure incurs an additional logarithmic overhead. Overall we get

▶ **Theorem 7.** *The shortest-path tree from some starting disk in the proximity graph of $n$ disks (of arbitrary radii) in the plane, under the weights of inter-center distances, can be constructed in $O(n \log^6 n)$ time.*

**Remark.** As in the unweighted version, in the case of unit disks, the decision procedure itself can be implemented to run faster than $O(n \log^6 n)$. For example, Wang and Xue [13] present an algorithm that runs in $O(n \log^2 n)$ time, but this algorithm is not suitable for our optimization procedure, since its comparisons generate critical values that are determined by more than two disks. We thus replace its "problematic" components by new ones, to obtain a (somewhat simpler) algorithm that is suitable for the optimization procedure, see the full version of this paper.

## 4.2 The optimization procedure

The most natural reverse shortest path question is to find the smallest value of $r$ such that the length of the shortest path in $G_r$ from $D_s$ to $D_t$ is smaller than some given real parameter $w$.

This optimization procedure is implemented as in the unweighted case, using the same combination of the interval shrinking and bifurcation procedures. The critical values are the same as in the case for the unweighted proximity graph.

In summary, we have shown:

▶ **Theorem 8.** *The reverse shortest path problem for weighted intersection or proximity graphs of arbitrary disks in the plane can be solved in $O^*(n^{5/4})$ randomized expected time. This bound applies to all the variants of the problem listed above. In the case of unit disks, where all radii are equal, the problem can be solved in $O^*(n^{6/5})$ randomized expected time.*

**Remark.** The machinery developed in this section seems to be more broadly applicable to other optimization questions that involve shortest paths in weighted proximity or intersection graphs, of disks or of more general geometric objects. Simple extensions could involve different definitions of proximity or the use of other weight functions. Other extensions could involve different problems, such as computing all-pairs shortest paths, computing shortest paths with negative edge weights, computing the diameter of the graph, etc.

## Abstract

We consider maintaining strongly connected components (SCCs) of a directed graph subject to edge insertions and deletions. For this problem, we show a randomized algebraic data structure with conditionally tight $O(n^{1.529})$ worst-case update time. The only previously described subquadratic update bound for this problem [Karczmarz, Mukherjee, and Sankowski, STOC'22] holds exclusively in the amortized sense.

For the less general dynamic strong connectivity problem, where one is only interested in maintaining whether the graph is strongly connected, we give an efficient deterministic black-box reduction to (arbitrary-pair) dynamic reachability. Consequently, for dynamic strong connectivity we match the best-known $O(n^{1.407})$ worst-case upper bound for dynamic reachability [van den Brand, Nanongkai, and Saranurak FOCS'19]. This is also conditionally optimal and improves upon the previous $O(n^{1.529})$ bound. Our reduction also yields the first fully dynamic algorithms for maintaining the minimum strong connectivity augmentation of a digraph.

## 1 Introduction

Two vertices of a directed graph $G = (V, E)$ are *strongly connected* if they can reach each other via a path in $G$. Pairwise strong connectivity is an equivalence relation and the *strongly connected components* of $G$ are the equivalence classes of that relation. The graph $G$ is called *strongly connected* if it has a single strongly connected component, or, equivalently, the transitive closure of $G$ is a complete digraph. Testing strong connectivity and computing strongly connected components (SCCs) are among the most fundamental algorithmic problems on digraphs. Tarjan [24] famously showed a DFS-based linear-time algorithm for finding SCCs, which now, along with later alternatives [11, 23], is often taught in basic algorithms courses and appears in textbooks [9].

We study maintaining strong connectivity and strongly connected components in dynamic setting. A dynamic graph data structure is called *incremental* if it can handle edge insertions only, *decremental* if it can handle edge deletions only, and *fully dynamic* if it can handle both. When designing dynamic graph data structures, one is typically interested in optimizing both the (amortized or worst-case) update time of the data structure, and the query time. In the partially dynamic settings (i.e., incremental or decremental) one usually optimizes the total update time, i.e., the time needed to process the entire sequence of updates. In the following, let $n = |V|$ and $m = |E|$.

In this paper, we focus on the fully dynamic setting with single-edge updates. We are interested in maintaining the information about the *global* structure of SCCs of $G$, as opposed to supporting pairwise strong-connectivity queries. The information of interest may be either:

**(a)** a single bit indicating whether $G$ is strongly connected (let us call this variant *SC*),
**(b)** the number of SCCs of $G$ (*#SCC*),
**(c)** a representation of the SCCs allowing very efficient access to the individual SCCs, that is, computing the size in $O(\text{polylog}\, n)$ time, or reporting the elements in $O(\text{polylog}\, n)$ time per element (*SCCs*).

In particular, (c) can be achieved by maintaining an explicit $\Theta(n)$-sized partition of $V$ into SCCs, which also allows for $O(1)$-time pairwise strong connectivity queries. On the other hand, using pairwise strong connectivity queries cannot easily provide any of the considered global information. In the following, for simplicity, we assume the desired information is explicitly recomputed after each update so that there is no need to consider query time. Thus, our sole goal is to optimize the *worst-case* update time.

**Lower bounds.** Note that if one is required to maintain the SCCs of a fully dynamic graph explicitly, then a single update can cause quite dramatic $\Omega(n)$-sized change in the set of SCCs (consider a directed cycle). Abboud and Vassilevska Williams [1] showed that even for maintaining a single-bit information whether $G$ has more than two SCCs (the *SC2* problem), a data structure with $O(n^{1-\epsilon})$ amortized time[1] is unlikely, as it would break the Orthogonal Vectors conjecture, which is implied by SETH [15, 27]. The SETH-hardness of [1] does not seem to extend to *SC* though, which suggests that #SCC (or even SC2) might be a computationally harder problem.

The more recent OMv conjecture [14] implies that one cannot achieve $O(n^{1-\epsilon})$ update time even for SC. This suggests that for sparse graphs with $m = \widetilde{O}(n)$ the trivial recompute-from-scratch approach might be the best possible approach for SC and SCCs.

van den Brand, Nanongkai, and Saranurak [26] developed a few extensions of the OMv conjecture and proved, based on those, that fully dynamic $s,t$-reachability (where $s,t \in V$ are fixed) currently requires $\Omega(n^{1.406})$ amortized update time, and fully dynamic single-source reachability (with only the source $s$ fixed) currently requires $\Omega(n^{1.528})$ time per update.[2] This means that the state-of-the-art data structures [26, 20] for the respective variants are near-optimal. By known reductions (see, e.g., [1]), one obtains that SC requires $\Omega(n^{1.406})$ update time, whereas SCCs require $\Omega(n^{1.528})$ update time.

**Upper bounds.** Abboud and Vassilevska Williams [1] showed that in order to have $\widetilde{O}(n^{2-\epsilon})$ amortized update time for SC using fast matrix multiplication (FMM) is essential, thus ruling out non-trivial combinatorial approaches. And indeed, FMM-based algebraic dynamic reachability algorithms [20, 26] allow breaking the quadratic update bound. This is because

[1] Abboud and Vassilevska Williams[1] actually write that $\Omega(m^{1-o(1)})$ is the best bound one can hope for. However, since this bound is a function of $m$ exclusively, it is required to hold only for *some* density regime, e.g., sparse graphs.

[2] More specifically, based on their OMv conjecture variants, van den Brand, Nanongkai, and Saranurak [26] proved, for any $\epsilon > 0$, an $\Omega(\min_{a,b\in[0,1]}(n^{a+b} + n^{\omega(1,a,1)-a} + n^{\omega(1,a,b)-b}) \cdot n^{-\epsilon})$ lower bound for dynamic $s,t$-reachability, and an $\Omega(n^{1+\rho-\epsilon})$ lower bound for dynamic single-source reachability (SSR), where $\rho < 0.529$ satisfies $1 + 2\rho = \omega(1,\rho,1)$. Here $O(n^{\omega(a,b,c)})$ denotes the time needed to multiply an $n^a \times n^b$ boolean matrix by an $n^b \times n^c$ boolean matrix. These two conditional lower bounds become $\Omega(n^{1.406})$ and $\Omega(n^{1.528})$, respectively, assuming the current exponents of rectangular matrix multiplication. Furthermore, they become $\Omega(n^{1+1/4-\epsilon})$ and $\Omega(n^{1+1/2-\epsilon})$, respectively, assuming $\omega = 2$.

SC easily reduces to maintaining reachability to and from an arbitrary single vertex [26]. As a result, $O(n^{1.529})$ worst-case update time is possible in this case. This state-of-the-art bound does not match the $O(n^{1.406})$ lower bound [26], though. More generally, since the fully dynamic data structure of Sankowski [20] allows relatively cheap $O(n^{0.529})$-time arbitrary-pair reachability queries[3] at the cost of $O(n^{1.529})$ update time, this approach generalizes to maintaining some *at most* $k$ distinct SCCs of $G$ in $O(kn^{1.529})$ worst-case time per update. In particular, for $k = 2$ this trivially yields a solution to SC2 with $O(n^{1.529})$ worst-case update time. This matches the best known upper bound for SC. Consequently, the state-of-the-art bound for SC does not reflect the intuition of [1] that SC2 might be a harder problem.

The described approach, however, does not easily allow recomputing *all* SCCs of $G$, or even counting them, within subquadratic update time. In fact, the more general #SCC and SCCs problems do not seem to reduce to inspecting some $O(n^{2-\epsilon})$-sized subset of the reachability matrix of $G$. Nevertheless, Karczmarz, Mukherjee, and Sankowski [17] recently showed that SCCs (and thus #SCC) can be maintained in $O(n^{1.529})$ *amortized* time per update. Their approach is a mix of combinatorial and algebraic methods and critically depends on the efficiency of a *decremental SCCs* data structure. Bernstein, Probst Gutenberg, and Wulff-Nilsen [7] gave a near-optimal data structure maintaining SCCs *explicitly* under edge deletions with $\widetilde{O}(m)$ total update time. Although the $O(n^{1.529})$ amortized bound is near-optimal, the worst-case update time of the data structure of [7] might be $\Theta(n^2)$, and thus the worst-case update time of the fully dynamic SCCs data structure [17] may be as much as $\Theta(n^2)$ as well. To the best of our knowledge, no non-trivial worst-case bound for either #SCC or SCCs under fully dynamic edge updates has been described to date.

## 1.1 Our results

First of all, we close the gaps between the best known lower- and upper (worst-case) bounds for both fully dynamic strong connectivity (SC) and fully dynamic strongly connected components (SCC) in general directed graphs. See also Table 1. We achieve that by showing novel combinatorial reductions to the known fully dynamic arbitrary-pair reachability data structures [26, 20].

**Fully dynamic strongly connected components.** For fully dynamic SCCs we prove:

▶ **Theorem 1.** *Let $G$ be a digraph. Suppose there is a fully dynamic reachability data structure $\mathcal{D}$ processing single-edge updates and arbitrary-pair queries on $G$ in $U(n)$ and $Q(n)$ time respectively. Suppose the answers produced by $\mathcal{D}$ are correct with high probability*[4]*.*

*Then one can explicitly maintain the SCCs of $G$ subject to single-edge insertions and deletions in $\widetilde{O}(U(n) + n \cdot Q(n))$ time per update (worst-case if the bounds $U(n), Q(n)$ are worst-case). The obtained data structure is Monte Carlo randomized. The answers produced are correct with high probability.*

It is worth noting that the data structure trivially works against an adaptive adversary[5] since the revealed information, the SCCs, depend only on the current graph $G$. As far as the adversarial model of the assumed data structure $\mathcal{D}$ is concerned, no special requirements

[3] Throughout, we use the term *arbitrary-pair reachability* to refer to the situation when the endpoints $s, t$ of a reachability pair of interest are a part of a query and may vary for different queries. The output of a query is a single bit indicating whether $s$ can reach $t$ in the (current) graph.

[4] That is, with probability at least $1 - 1/n^c$, where the constant $c \geq 1$ can be set arbitrarily.

[5] That can only see the output of the data structure, and not the random bits used by the data structure internally.

beyond high-probability correctness are needed. Indeed, the query interface of $\mathcal{D}$ does not leak any information about the potential random choices made by $\mathcal{D}$ internally (unless $\mathcal{D}$ errs, which we treat as a low-probability failure anyway) since the correct answers are uniquely determined by the graph maintained in $\mathcal{D}$.

Sankowski [20] showed a Monte Carlo randomized data structure with $U(n) = O(n^{1+\rho})$ and $Q(n) = O(n^{\rho})$ (both worst-case), where $\rho < 0.529$ is such that $1 + 2\rho = \omega(1, \rho, 1)$. As a result, Theorem 1 implies a data structure with $O(n^{1.529})$ worst-case update bound for fully dynamic SCCs. To the best of our knowledge, we are the first to achieve a non-trivial $O(n^{2-\epsilon})$ *worst-case* update time for SCCs and even #SCC. Moreover, via a folklore[6] reduction from fully dynamic single-source reachability and the conditional lower bound of [26], the obtained $O(n^{1.529})$ bound is tight for SCCs. Hence, our data structure constitutes the final answer to the problem (up to polylog factors), unless the *Mv-hinted Mv* variant of the OMv conjecture of [26, Conjecture 5.7] fails. That being said, it is not clear whether our bound is tight for the counting variant #SCC whose output is a single number, as opposed to $n$ bits in SSR.

The worst-case update time guarantee allows applying Theorem 1 in the fault-tolerant model, where the goal is to recompute a graph property for a query set of at most $k$ failed edges or vertices. Georgiadis, Italiano, and Parotsidis [12] showed that after optimal linear preprocessing, one can compute the SCCs of $G$ after removing any single vertex/edge in optimal $O(n)$ time. Baswana, Choudhary, and Roditty [2] showed that after polynomial preprocessing, one can find the SCCs of $G$ after removing $k$ vertices/edges in $\widetilde{O}(2^k \cdot n)$ time. Thus, the known results could only handle at most $\log n$ failures faster than recompute-from-scratch, for any density of $G$. Our result implies that for $m = \Omega(n^{1.53})$ one can recompute SCCs faster than from scratch even under *polynomially* many (that is, $k = O(m/n^{1.529})$) vertex/edge failures[7]. That being said, the purely combinatorial data structures [2, 12] are significantly faster if, e.g., $k$ is constant.

It is worth noting that a reduction of computing SCCs to a reachability problem has been known in the parallel setting [21]. That static reduction does not seem to be applicable in the dynamic setting using algebraic techniques, though. More specifically, Schudy [21] reduces computing SCCs of $G$ to a number of adaptively generated instances of *multi-source reachability* (which in turn reduces to the single-source case by adding a super-source) on induced subgraphs of $G$ of total size $\widetilde{O}(m)$. In the dynamic setting, spending time linear in $m$ per update is prohibitive, and furthermore it is not clear how to efficiently simulate adaptively generated multi-source reachability queries for the following reasons. First, using the super-source trick would either require performing possibly $\Omega(n)$ edge updates (which are very costly, i.e., super-linear using algebraic methods) in the reachability data structure. If we wanted to avoid that, i.e., handle each source separately, we would possibly end up performing $\Omega(n^2)$ single-pair reachability queries. Our reduction for dynamic SCCs relies on being able to query $\widetilde{O}(n)$ arbitrary reachability pairs after each update. Crucially, these pairs cannot be grouped into, e.g., polylog$(n)$ multi-source queries. Such an $n$-arbitrary-pairs reachability problem looks much more difficult even in the static setting and does not seem to be solvable in linear time like multi-source reachability. In fact, we believe no static bound beyond $O(\min(nm, n^{\omega}))$ is known.

---

[6] It is enough to maintain a graph $G'$ obtained from $G$ by adding a super-sink $t$ and edges $vt$ for all $v \in V$. Then for a query source $s$, vertices reachable from $s$ in $G$ are those in the SCC of $s$ in $G' + ts$.

[7] Vertex failures can be easily simulated by splitting each $v \in V$ into $v_{\text{in}}, v_{\text{out}}$, that inherit the incoming and outgoing edges of $v$, resp, and introducing an edge $e_v = v_{\text{in}}v_{\text{out}}$. Then the failure of $v$ is equivalent to the failure of $e_v$.

**Strong connectivity.** For the less general dynamic strong connectivity (SC), we give an even more efficient and *deterministic* black-box reduction to dynamic arbitrary-pair reachability.

▶ **Theorem 2.** *Let $G$ be a digraph. Suppose there is a fully dynamic reachability data structure processing single-edge updates and arbitrary-pair reachability queries on $G$ in at most $T(n)$ time. Then one can maintain whether $G$ is strongly connected subject to single-edge insertions and deletions in $O(T(n)\log n)$ time per update (worst-case if the $T(n)$ bound is worst-case).*

van den Brand, Nanongkai, and Saranurak [26] showed a Monte Carlo randomized fully dynamic arbitrary-pair reachability data structure with $O(n^{1.407})$ worst-case update and query time. Therefore, Theorem 2 implies $O(n^{1.407})$ worst-case update bound for fully dynamic strong connectivity. This improves upon the known $O(n^{1.529})$ bound following from the trivial reduction to dynamic single-source reachability. By the conditional lower bound of [26], we essentially close the complexity of fully dynamic strong connectivity (up to polylogarithmic factors), unless the uMv-hinted uMv conjecture of [26, Conjecture 5.12] fails.

Whereas the obtained $O(n^{1.407})$ update bound is Monte Carlo randomized, this is only caused by the Schwartz-Zippel-lemma-style randomization inside the used reachability data structure. Obtaining a deterministic subquadratic fully dynamic reachability data structure would immediately imply a deterministic subquadaratic bound for SC.

Interestingly, our reduction *does not* seem to generalize to maintaining whether $G$ has more than two SCCs (SC2), which was the case for the trivial reduction. As a result, $O(n^{1.529})$ currently remains the sharpest update bound for SC2. At the same time the tightest conditional lower bound we have for SC2 is $\Omega(n^{1.407})$ because SC2 does not seem to be easily reducible from dynamic single-source reachability, which was the case for dynamic SCCs. This is a consequence of the fact that the output in the SCC problem is $n$ numbers, whereas in SC2 it is just a single bit. Obtaining a faster dynamic algorithm for SC2 or coming up with a plausible lower bound beyond $O(n^{1.407})$ is an interesting next step.

**Table 1** Comparison of state-of-the art conditional lower- and upper bounds for the problems SC, SC2, #SCC, and SCC, and new upper bounds obtained via our reductions. Each problem in the table generalizes the preceding one. For SC and SCC, our obtained upper bounds are tight.

<table>

<tr><td>SCC</td><td>$\Omega(n^{1.528})$<br>[26] via SSR</td></tr>
</table>

**Generalizations.** The reduction of Theorem 2 does generalize in two different ways. First, within the same update bound (see Theorem 11) we can actually maintain the exact size $\chi(G)$ of the *minimum strong connectivity augmentation* [10] of $G$. The minimum strong connectivity augmentation is a smallest possible set of edges that one needs to add to $G$ to make it strongly connected. $\chi(G)$ can be seen as an alternative and "orthogonal" (to the number of SCCs) measure of how much $G$ *is not* strongly connected. As shown by Eswaran and Tarjan [10], in the static setting, the value $\chi(G)$ and some minimum strong connectivity augmentation can be computed in linear time.

As is typical for algebraic data structures[8], maintaining an *object* – some minimum strong augmentation in our case – is trickier than maintaining only the optimal *value* $\chi(G)$. Our algorithm can be nevertheless extended to maintain some $\chi(G)$-sized augmentation $Y$ within the same $O(n^{1.407})$ worst-case bound and against an adaptive adversary, as long as $\chi(G) = O(n^{0.703})$. On the other hand, for larger $\chi(G)$, e.g., $\chi(G) = \Theta(n)$, some minimum augmentation $Y$ can be maintained in $O(n^{1.529})$ worst-case time per update.

Interestingly, the weighted version of the minimum strong connectivity augmentation problem, where the costs of different potential edges to be added vary, is NP-hard [10].

Moreover, the reduction behind Theorem 2 enables *universal* reachability queries, even if $G$ is not strongly connected. That is, in $O(n^{1.407})$ time, we can decide whether a query vertex $v$ can reach all vertices in $G$, or find some vertex that $v$ cannot reach. See Theorem 14. The $O(n^{1.529})$ query time follows trivially (simply issue all the $n$ possible reachability queries from $v$) from the fully dynamic single-source reachability data structure [20].

## 1.2 Further related work

Since the known lower bounds [1, 14] imply that fully dynamic (or partially dynamic with worst-case bounds) SCCs data structures are possible only for sufficiently dense graphs and using algebraic methods, most of the previous work regarding maintaining SCCs dealt with partially dynamic settings with the goal of optimizing total update time.

Maintaining SCCs has been studied in the incremental setting [5, 3, 13]. The current best known randomized solution for sparse graphs [5] has $\widetilde{O}(m^{4/3})$ total update time, whereas the best known deterministic data structure [3] has $O(m^{3/2})$ total update time. For denser graphs, Bender et al. [3] gave a near-optimal deterministic data structure with $\widetilde{O}(n^2)$ total update time. All these data structures maintain SCCs explicitly.

Decremental SCCs maintenance has been studied even more extensively [6, 7, 8, 18, 19]. Bernstein, Probst Gutenberg, and Wulff-Nilsen [7] gave a randomized data structure with near-optimal $\widetilde{O}(m)$ total update time. The current best known deterministic total update time bound of $\widetilde{O}(mn^{2/3})$ for general digraphs is due to Bernstein, Probst Gutenberg, and Saranurak [6]. For planar graphs, the near-optimal $\widetilde{O}(n)$ total update time can be achieved deterministically [16].

In the case of (global) strong connectivity, incremental graph search from/to an arbitrary single source yields optimal $O(m)$ total update time. It is not clear if decremental strong connectivity is easier, in any sense, than decremental SCCs, and no specialized data structures beyond those for SCCs maintenance [7, 6] are known for decremental strong connectivity.

# 2 Preliminaries

In this paper we deal with *directed* graphs. We write $V(G)$ and $E(G)$ to denote the sets of vertices and edges of $G$, respectively. We omit $G$ when the graph in consideration is clear from the context. A graph $H$ is a *subgraph* of $G$, which we denote by $H \subseteq G$, if and only if $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. We write $e = uv \in E(G)$ when referring to edges of $G$. By $G^{\mathrm{R}}$ we denote $G$ with edges reversed.

A sequence of vertices $P = v_1 \dots v_k$, where $k \geq 1$ is called an $s \to t$ path in $G$ if $s = v_1$, $v_k = t$ and there is an edge $v_i v_{i+1}$ in $G$ for each $i = 1, \dots, k-1$. We sometimes view a path $P$ as a subgraph of $G$ with vertices $\{v_1, \dots, v_k\}$ and (possibly zero) edges $\{v_1 v_2, \dots, v_{k-1} v_k\}$.

[8] For example, for dynamic reachability and exact distances, the known algebraic data structures [25, 26, 20] are polynomially faster than the known solutions to their respective path-reporting variants [4, 17].

For convenience, we sometimes consider a single edge $uv$ a path. If $P_1$ is a $u \to v$ path and $P_2$ is a $v \to w$ path, we denote by $P_1 \cdot P_2$ (or simply $P_1P_2$) a path obtained by concatenating $P_1$ with $P_2$. A vertex $t \in V(G)$ is *reachable* from $s \in V(G)$ if there is an $s \to t$ path in $G$.

## 3 Fully dynamic strongly connected components

In this section we describe our fully dynamic strongly connected components data structure.

Suppose there exists a reachability data structure maintaining an $n$-vertex digraph subject to single-edge insertions and deletions and answering arbitrary-pair reachability queries. Denote by $U(n)$ and $Q(n)$ the update and query (resp.) time bounds of the assumed data structure.

We start by proving the following key observation, that tracking the vertices $v \in V$ strongly connected to *some* vertex $t$ out of a chosen subset $T \subseteq V$ can be reduced to maintaining some $n$ cells of the transitive closure matrix (reachability pairs) of a certain auxiliary graph $G_T$.

▶ **Lemma 3.** *Let $G = (V, E)$ be a digraph, and let $T \subseteq V$. Let $G'$ be a graph with vertices $V' = \{v' : v \in V\}$, and edges $E' = \{u'v' : uv \in E\}$, i.e., $G'$ is a copy of $G$ with vertices primed. Consider a graph $G_T$ obtained from $G \cup G'$ by adding edges $tt'$ for each $t \in T$. Then, for any $v \in V$, $v$ is strongly connected with* some *$t \in T$ in $G$ if and only if there is a path $v \to v'$ in $G_T$.*

**Proof.** Suppose that $v$ is strongly connected with some $t \in T$ in $G$. Then, there exists a path $P = v \to t$ in $G$, and a path $Q = t \to v$ in $G$. As a result, there is a corresponding path $Q' = t' \to v'$ in $G'$. Since $tt' \in E(G_T)$, we conclude there is a $v \to v'$ path $P \cdot tt' \cdot Q'$ in $G_T$.

Now suppose there is a $v \to v'$ path in $G_T$. Note that a path $R$ starting in the $G$-part of $G_T$ can only depart from $G$ for $G'$ through an edge $tt'$, $t \in T$, and it cannot go back to $G$. As a result, $R$ can be expressed as $R_1 \cdot (tt') \cdot R'_2$, where $R_1 = v \to t$ is a path in $G$, and $R'_2$ is a $t' \to v'$ path in $G'$. But $R'_2$ has a corresponding path $R_2 = t \to v$ in $G$. The paths $R_1, R_2$ certify that $v$ and $t$ are strongly connected. Consequently, $v$ is strongly connected to some vertex of $T$ in $G$. ◀

To make use of Lemma 3 we will employ the *unique witness trick* (usually attributed to [22]) that have been used for computing witnesses of various matrix products, also in the dynamic setting [4]. However, in our case, we will use this technique with a conceptually very different purpose: to *select* a certain *root* of every SCC that ever appears in $G$ throughout edge updates.

▶ **Lemma 4.** [22] *Let $X \subseteq V$ be a subset with $n/2^{k+1} \le |X| \le n/2^k$ for an integer $k \ge 0$. Let $S \subseteq V$ be a subset obtained by sampling $2^k$ elements of $V$ uniformly at random and independently (with replacement). Then, with probability at least $1/6$, $|X \cap S| = 1$.*

**Proof.** The probability that only the $i$-th sampled vertex is a unique element of $X \cap S$ is

$$\frac{|X|}{n} \cdot \left(1 - \frac{|X|}{n}\right)^{2^k - 1} \ge \frac{1}{2^{k+1}} \cdot \left(1 - \frac{1}{2^k}\right)^{2^k - 1} \ge \frac{1}{2^{k+1}e}.$$

The probability that $|X \cap S| = 1$ is at least the probability of one of the above disjoint events happening, i.e., at least $2^k \cdot \frac{1}{2^{k+1}e} = \frac{1}{2e} \ge 1/6$. ◀

Let $\ell = (\gamma + 2) \cdot \log_{6/5} n$ for a constant $\gamma > 0$ that can be adjusted to control the error probability. Let $B$ be the smallest integer such that $n < 2^B$, so that $B = O(\log n)$. For a non-negative integer $m$, put $[m] := \{0, \ldots, m\}$. Let us identify $V$ with the $B$-bit numbers $\{1, \ldots, n\}$. Moreover, let

$$\mathcal{T} = \{T_{k,l,b} : k \in [B-1], l \in [\ell - 1], b \in [B-1]\}$$

be a family of subsets of $V$ obtained as follows. For $k \in [B-1], l \in [\ell - 1]$ let $T_{k,l}$ be a subset of $V$ obtained by sampling $2^k$ elements of $V$ uniformly at random and independently, with replacement. Then, set $T_{k,l,b}$ to be a subset of numbers $v \in T_{k,l}$ such that the $b$-th (0-based) bit of $v$ in the binary equals 1. Clearly, the family $\mathcal{T}$ has $O(\log^3 n)$ subsets.

First of all, we maintain the graph $G$ itself in the assumed fully dynamic reachability data structure $\mathcal{D}$. For each $T \in \mathcal{T}$, we set up another assumed data structure $\mathcal{D}_T$ maintaining the graph $G_T$, as defined in Lemma 3. Note that each edge update to the graph $G$ is reflected using just two edge updates to each graph $G_T$ since $G_T$ consists of two copies of $G$. As a result, every edge update can be processed in $O(U(n) \cdot |\mathcal{T}|) = \widetilde{O}(U(n))$ time (worst-case if the bound $U(n)$ is worst-case).

We now describe how the SCCs of $G$ are recomputed after an update. We build an auxiliary graph $H$ whose construction follows. For each $v \in V$, $k \in [B-1]$, and $l \in [\ell - 1]$, we do the following. For every $b \in [B-1]$, we query the data structure $D_{T_{k,l,b}}$ whether there exists a path $v \to v'$ in $G_{T_{k,l,b}}$. Let $s_{v,k,l}$ be a number (vertex) such that the $b$-th bit is set to 1 if and only if the corresponding path in $G_{T_{k,l,b}}$ exists. If $s_{v,k,l} \in \{1, \ldots, n\}$ (so that $s_{v,k,l}$ is indeed a vertex of $G$) and $v$ *is strongly connected with* $s_{v,k,l}$ (which can be tested using two queries to $\mathcal{D}$), we add an undirected edge $\{v, s_{v,k,l}\}$ to $H$.

Observe that the graph $H$ is constructed by performing $\widetilde{O}(n)$ queries to the assumed data structures $\mathcal{D}$ and $\mathcal{D}_T$, $T \in \mathcal{T}$. The cost of these queries is $\widetilde{O}(n \cdot Q(n))$ (worst-case if $Q(n)$ is worst-case).

Having constructed the undirected graph $H$, we output its connected components as the SCCs of $G$. Since $H$ has $\widetilde{O}(n)$ edges, this can be done in $\widetilde{O}(n)$ additional worst-case time.

▶ **Lemma 5.** *With probability at least $1 - 1/n^\gamma$, the connected components of $H$ and the strongly connected components of $G$ are equal.*

**Proof.** By the construction, if two vertices $u, v \in V$ are connected by an edge (or more generally, a path) in $H$, then they are strongly connected in $G$. Hence, we only need to prove that if $u, v \in V$ are strongly connected in $G$, then they are connected in $H$ as well.

Let $C$ be the SCC of $G$ containing both $u$ and $v$. Let $z \in [B-1]$ be such an integer that we have $n/2^{z+1} \leq |C| \leq n/2^z$. By Lemma 4, for each $l \in [\ell - 1]$, $T_{z,l}$ satisfies $|T_{z,l} \cap C| = 1$ with probability at least $1/6$. As a result, with probability at least $1 - (5/6)^\ell \geq 1 - 1/n^{\gamma+2}$, at least one of the sets $T_{z,l}$, say $T_{z,y}$, satisfies $|T_{z,y} \cap C| = 1$. Let $s$ be the unique element of $T_{z,y} \cap C$. Observe that for $b \in [B-1]$, we have $T_{z,y,b} \cap C = \{s\}$ if the $b$-th bit of $s$ equals 1 and $T_{z,y,b} \cap C = \emptyset$ otherwise. As a result, by Lemma 3, for both $u$ and $v$ the query to the data structure $\mathcal{D}_{T_{z,y,b}}$ will return true if and only if the $b$-th bit of $s$ is 1. Equivalently, we will have $s = s_{v,k,l} = s_{u,k,l} \neq 0$. Since both edges $\{v, s\}$ and $\{u, s\}$ are added to $H$, $u$ and $v$ are indeed connected in $H$.

As there are at most $n^2$ pairs $(u, v)$, the implications hold with probability at least $1 - n^2 \cdot (1/n^{\gamma+2}) = 1 - 1/n^\gamma$. ◀

Note that the above lemma holds for any version of $G$ since, unless the algorithm makes a mistake (which happens with low probability), we do not reveal any random bits to the adversary as the output is always unique. To summarize, we obtain the following.

▶ **Theorem 1.** *Let $G$ be a digraph. Suppose there is a fully dynamic reachability data structure $\mathcal{D}$ processing single-edge updates and arbitrary-pair queries on $G$ in $U(n)$ and $Q(n)$ time respectively. Suppose the answers produced by $\mathcal{D}$ are correct with high probability.*

*Then one can explicitly maintain the SCCs of $G$ subject to single-edge insertions and deletions in $\widetilde{O}(U(n) + n \cdot Q(n))$ time per update (worst-case if the bounds $U(n), Q(n)$ are worst-case). The obtained data structure is Monte Carlo randomized. The answers produced are correct with high probability.*

Sankowski [20] showed that there exists a fully dynamic reachability data structure with $U(n) = \widetilde{O}(n^{1+\rho})$ worst-case update time and $Q(n) = \widetilde{O}(n^{\rho})$ query time, where $\rho < 0.529$ is such that $1 + 2\rho = \omega(1, \rho, 1)$. By Theorem 1 it follows that there exists a fully dynamic data structure maintaining SCCs explicitly with $\widetilde{O}(n^{1+\rho}) = O(n^{1.529})$ worst-case update time.

## 4 Reducing dynamic strong connectivity to dynamic reachability

In this section we show how to maintain whether the graph $G$ is strongly connected subject to edge insertions and deletions using a fully dynamic reachability data structure supporting single-edge updates and arbitrary-pair reachability queries. Our reduction is deterministic and incurs only polylogarithmic overhead. Again, assume that $n < 2^B$ for an integer $B = O(\log n)$. The vertices are numbered 1 through $n$ and thus can be seen as $B$-bit numbers.

Let us define a *source strongly connected component* of $G$ to be an SCC of $G$ with no incoming edges from other SCCs of $G$. Clearly, if $G$ is strongly connected, it has precisely one source SCC. The main idea is to maintain a *source set* $\mathcal{Z} \subseteq V$ such that $\mathcal{Z}$ contains *precisely one* vertex $z$ of every source SCC of $G$. For example, if $G$ is strongly connected, then $\mathcal{Z}$ can be any single-element subset of $V$. We also have the following simple property.

▶ **Observation 6.** *For every vertex $v \in V(G)$ there exists some source SCC $S$ of $G$ such that $v$ is reachable from every $s \in S$.*

**Proof.** Let $C$ be the SCC of $v$ in $G$. Let $G^*$ be the *condensation* of $G$ obtained from $G$ by contracting the SCCs. Then, $G^*$ is a DAG. In a DAG, every vertex is reachable from a source (that is, a vertex with no incoming edges). In particular, $C$ is reachable from some source $S$ of $G^*$. Consequently, any vertex $s \in S$ can reach $v$ in $G$ by construction of $G^*$. ◀

The following lemma shows how a data structure maintaining some source set of $G$ can be used to maintain strong connectivity of $G$.

▶ **Lemma 7.** *Let $G^R$ be the reverse of $G$. Let $\mathcal{Z}$ be some source set of $G$ and let $\mathcal{Z}^R$ be some source set of $G^R$. Then $G$ is strongly connected if and only if $|\mathcal{Z}| = |\mathcal{Z}^R| = 1$ and $t \in \mathcal{Z}^R$ can reach $s \in \mathcal{Z}$ in $G$.*

**Proof.** Clearly, if $G$ is strongly connected, then $\mathcal{Z} = \{s\}$, $\mathcal{Z}^{\mathrm{R}} = \{t\}$ for some $s, t \in V$. Moreover, $t$ can reach $s$ in $G$.

Now suppose $\mathcal{Z} = \{s\}$ and $\mathcal{Z}^{\mathrm{R}} = \{t\}$. Consider any $x, y \in V$. By Observation 6, $y$ is reachable from $s$. Similarly, by Observation 6 applied to $G^{\mathrm{R}}$, $x$ is reachable from $t$ in $G^{\mathrm{R}}$, i.e., $t$ is reachable from $x$ in $G$. By the assumption, $t$ can reach $s$ in $G$. Thus, there exist a path $x \to t \to s \to y$ in $G$. Since the pair $x, y$ was arbitrary, $G$ is indeed strongly connected. ◀

By Lemma 7, we can maintain strong connectivity using a fully dynamic source set data structure built on $G$, a fully dynamic source set data structure built on $G^{\mathrm{R}}$, and a fully dynamic reachability data structure built on $G$. Every edge update translates to a single edge update in the three data structures, and a single query to the reachability data structure.

Let us now focus on maintaining a source set $\mathcal{Z}$ of $G$ subject to edge updates. We have:

▶ **Lemma 8.** *For any $w \in V$, there exists at most one $z \in \mathcal{Z}$ such that $w$ can reach $z$ in $G$. Moreover, $w$ is in a source SCC (containing $z$) if and only if such a $z \in \mathcal{Z}$ exists.*

**Proof.** Let $z \in \mathcal{Z}$ and let $C$ be the source SCC of $G$ with $z \in C$. By the definition of a source SCC, the only vertices of $V$ that can reach $z$ are those in $C$. As a result, if $w$ can reach $z$, then $w \in C$. Therefore, $w \notin C'$ for other source SCCs $C' \neq C$, and thus $w$ cannot reach any other $z' \in \mathcal{Z}$, $z' \neq z$. On the other hand, if $w \in C$ for some source SCC $C$, then $w$ can clearly reach the unique element of $\mathcal{Z} \cap C$. ◀

**Maintained data structures.** First of all, let $\bar{G}$ be the graph $G$ extended with a super source $s \notin V(G)$ and edges $sz$ for all $z \in \mathcal{Z}$. We store $\bar{G}$ in a fully dynamic reachability data structure $\mathcal{D}$. Note that using a single reachability query to $\mathcal{D}$ we can check whether some query vertex $v \in V$ is reachable from $\mathcal{Z}$ in $\bar{G}$. Since $G \subseteq \bar{G}$ and $s$ has no incoming edges, the data structure $\mathcal{D}$ can also handle usual reachability queries in $G$.

For $b \in [B-1]$, let $G_b$ be the graph $G$ extended with a super sink $t \notin V(G)$, and edges $zt$ for all $z \in \mathcal{Z}$ such that the $b$-th bit of the number $z$ equals 1. We store the $O(\log n)$ graphs $G_b$ in fully dynamic reachability data structures $\mathcal{D}_0, \ldots, \mathcal{D}_{B-1}$. Note that since every $v \in V$ has at least one bit set, $\bigcup_{i=0}^{B-1} G_b$ contains edges $zt$ for all $z \in \mathcal{Z}$. As a result, a vertex $w \in V$ can reach some vertex of $\mathcal{Z}$ if and only if $w$ can reach $t$ in $\bigcup_{i=0}^{B-1} G_b$. Moreover, by Lemma 8, if $w$ can reach some vertex of $\mathcal{Z}$, then it can reach precisely one such $z \in \mathcal{Z}$. The individual data structures $G_b$ can be used to find that $z$: observe that $w$ can reach $t$ (equivalently, reach $z$) in $G_b$ precisely if and only if $z$ has the $b$-th bit set. As a result, we have the following.

▶ **Lemma 9.** *For any $w \in V$ one can find the unique $z \in \mathcal{Z}$ that $w$ can reach in $G$ (if one exists) using $O(\log n)$ queries to the fully dynamic reachability data structures $\mathcal{D}_0, \ldots, \mathcal{D}_{B-1}$.*

Whenever the graph $G$ is updated or the set $\mathcal{Z}$ undergoes an update, the update is passed to all the $O(\log n)$ relevant data structures $\mathcal{D}$ and $\mathcal{D}_0, \ldots, \mathcal{D}_{B-1}$ so that they reflect the current graphs $\bar{G}$ and $G_0, \ldots, G_{B-1}$ respectively.

We now proceed with describing how the updates are processed. In the following, denote by $G'$ the graph $G$ after the edge update, whereas $G$ denotes the graph before the edge update considered.

**Edge insertions.** First consider an insertion of edge $uv$. If there exists a path $u \to v$ in $G$ (a single query to $\mathcal{D}$), the SCCs of $G$ do not change due to the insertion. No source SCC gets an incoming edge from another SCC. Therefore, $\mathcal{Z}$ remains a valid source set.

Let us thus assume that there is no $u \to v$ path in $G$. In particular, $u$ and $v$ are not strongly connected in $G$. Let us denote by $S_v$ the SCC containing $v$ in $G$. Inserting $uv$ cannot break any of the existing SCCs of $G$, but might cause some SCCs of $G$ (in particular $S_v$) merge in $G'$. Let $S^*$ denote the SCC of $v$ in $G'$. We have $S_v \subseteq S^*$, but potentially $S^* = S_v$.

Let us now argue that $S_v$ is the only SCC of $G$ that might lose the status of a source SCC due to the insertion. Indeed, if $S_v \neq S^*$, then every other SCC $S' \neq S_v$ of $G$, such that $S' \subset S^*$, is reachable from $S_v$ since the insertion of $uv$ makes $S_v$ and $S'$ strongly connected. As a result, $S'$ is not a source SCC of $G$. Moreover, the respective sets of incoming inter-SCC edges of other SCCs $S''$ of $G$ such that $S'' \cap S^* = \emptyset$ do not change, so such $S''$ is a source SCC of $G'$ if and only if $S''$ is a source SCC of $G$.

By Lemmas 8 and 9 we can test whether $S_v$ is a source SCC (and possibly find the unique $z \in S_v \cap \mathcal{Z}$) by performing $O(\log n)$ queries to the data structures $\mathcal{D}_0, \ldots, \mathcal{D}_{B-1}$. The next step is to remove $z$ (if it exists) from $\mathcal{Z}$, and update all the data structures $\mathcal{D}, \mathcal{D}_0, \ldots, \mathcal{D}_b$ accordingly. Next, we apply the insertion of $uv$ to all these data structures so that they store

(supergraphs) of the updated graph $G'$. Observe that at this point the set $\mathcal{Z}$ might miss at most one element, if $S^*$ turns out to be a source SCCs of $G'$. In order to detect whether this is the case we check whether $v \in S^*$ can be reached from $\mathcal{Z}$ in $G'$. Recall that this amounts to a single query to $\mathcal{D}$ about the existence of a path from $s$ to $u$ in $\bar{G}$. If so, $S^*$ is reachable from some other SCC, and thus is not a source SCC. Otherwise, $S^*$ is indeed a source SCC and thus we add to $\mathcal{Z}$ an arbitrary element of $S^*$, e.g., the vertex $v$, so that $\mathcal{Z}$ again becomes a valid source set of $G'$.

**Edge deletions.** Edge deletions can be handled essentially symmetrically to edge insertions. Suppose an edge $uv \in E(G)$ is deleted. Again, if the deletion does not make $v$ unreachable from $u$ (which can be tested by performing a single update and query on $\mathcal{D}$), neither the SCCs of $G$ nor the source SCCs of $G$ change. So suppose $u$ cannot reach $v$ after the deletion.

Let $S'_v$ be the SCC containing $v$ in $G'$ and let $S^*$ be the SCC containing $v$ in $G$. We have $S'_v \subseteq S^*$ and potentially $S'_v = S^*$. If $S^*$ is a source SCC in $G$, we can find $z \in S^* \cap \mathcal{Z}$ using $O(\log n)$ reachability queries from $v$ to $t$ in $\mathcal{D}_0, \ldots, \mathcal{D}_{B-1}$ by Lemmas 8 and 9.

Observe that $S'_v$ is the only SCC contained in $S^*$ that might potentially be a source SCC of $G'$: if $S' \neq S'_v$ is an SCC of $G'$, and $S' \subset S^*$, then $S'$ is surely reachable from $S'_v$ in $G'$ and thus $S'$ is not a source SCC of $G'$. Similarly as we did when processing an insertion, we remove $z$ (if exists) from $\mathcal{Z}$. At this point, $\mathcal{Z}$ might need inserting at most one element in order to become a valid source set of $G'$. This is the case precisely when $S'_v$ is a source SCC of $G'$. We can check that, again, by issuing a single $s \to v$ reachability query to $\mathcal{D}$ after the deletion is reflected in $\mathcal{D}$. If $S'_v$ happens to be a source SCC of $G'$, we add $v \in S'_v$ to $\mathcal{Z}$.

Note that processing an edge update causes at most two element updates to the set $\mathcal{Z}$. Each of these updates, and also the edge update itself, is reflected in $O(\log n)$ fully dynamic reachability data structures $\mathcal{D}, \mathcal{D}_0, \ldots, \mathcal{D}_{B-1}$. Moreover, only $O(\log n)$ reachability queries are performed on these data structures. Consequently, we obtain the following.

▶ **Lemma 10.** *Suppose there is a fully dynamic reachability data structure processing single-edge updates and arbitrary-pair reachability queries on $G$ in at most $T(n)$ time. Then one can maintain a source set $\mathcal{Z}$ of $G$ explicitly subject to single-edge insertions and deletions in $O(T(n) \log n)$ time per update (worst-case if the $T(n)$ bound is worst-case).*

By Lemma 10 and the discussion after Lemma 7, we obtain:

▶ **Theorem 2.** *Let $G$ be a digraph. Suppose there is a fully dynamic reachability data structure processing single-edge updates and arbitrary-pair reachability queries on $G$ in at most $T(n)$ time. Then one can maintain whether $G$ is strongly connected subject to single-edge insertions and deletions in $O(T(n) \log n)$ time per update (worst-case if the $T(n)$ bound is worst-case).*

The currently best known bound on the maximum of query time and update time of a fully dynamic arbitrary-pair reachability data structure is $T(n) = O(n^{1.407})$ worst-case (Monte Carlo randomized) due to [26]. Consequently, Theorem 2 combined with [26] yields $O(n^{1.407})$ worst-case update time for fully dynamic strong connectivity.

**Strong connectivity augmentation.** Due to a result of Eswaran and Tarjan [10], using Lemma 10 we can actually prove a more general result.

▶ **Theorem 11.** *Let $G$ be a digraph. Let $T(n)$ be defined as in Theorem 2. Then one can maintain the size $\chi(G)$ of a minimum strong connectivity augmentation of $G$ subject to single-edge insertions and deletions in $O(T(n) \log n)$ time per update. (worst-case if the $T(n)$ bound is worst-case).*

**Proof.** Let $\mathcal{Z}$ and $\mathcal{Z}^{\mathrm{R}}$ be source sets of $G$ and $G^{\mathrm{R}}$ respectively. Define a *sink SCC* to be an SCC of $G$ that is a source SCC in $G^{\mathrm{R}}$. Eswaran and Tarjan [10] prove that if $G$ is not strongly connected, then $\chi(G)$ equals $\max(s,t)+q$, where $s$ denotes the number of source SCCs that are not sink SCCs, $t$ denotes the number of sink SCCs that are not source SCCs, and $q$ denotes the number of "isolated SCCs" that are both source and sink SCCs. If $G$ is strongly connected then $\chi(G)=0$ holds trivially.

Note that with $s,t,q$ defined like this, we have $|\mathcal{Z}|=s+q$ and $|\mathcal{Z}^{\mathrm{R}}|=t+q$. Hence, if $G$ is not strongly connected, then $\max(|\mathcal{Z}|,|\mathcal{Z}^{\mathrm{R}}|)=\max(s,t)+q=\chi(G)$. As a result, it is enough to maintain some sets $\mathcal{Z}$ and $\mathcal{Z}^{\mathrm{R}}$, and test whether $G$ is strongly connected using Lemmas 10 and 7. Clearly, we need only $O(T(n)\log n)$ time for this. ◀

Again, by combining Theorem 11 with [26], we obtain that the size $\chi(G)$ of a minimum strong connectivity augmentation can be maintained in $O(n^{1.407})$ worst-case time per update.

Theorem 11 does not immediately yield any actual set $Y$ of edges such that $|Y|=\chi(G)$ and $G+Y$ is strongly connected. We now discuss how such an augmentation $Y$ can be maintained. To this end we now sketch the method [10] of obtaining an augmentation with $\max(|\mathcal{Z}|,|\mathcal{Z}^R|)$ edges in case $G$ is not strongly connected. Observe that in such a case, the quantity $\max(|\mathcal{Z}|,|\mathcal{Z}^R|)$ is clearly a lower bound on the size of $Y$.

Suppose wlog. that $|\mathcal{Z}|\geq|\mathcal{Z}^R|$. For each $z\in\mathcal{Z}$, let $t_z\in\mathcal{Z}^R$ be arbitrary such that $z$ can reach $t_z$ in $G$; note that at least one such $t_z$ always exists. Similarly, for each $z'\in\mathcal{Z}^R$, let $s_{z'}\in\mathcal{Z}$ be arbitrary such that $z'$ is reachable from $s_{z'}$ in $G$.

Consider a set of edges $F=\{zt_z : z\in\mathcal{Z}\}\cup\{s_{z'}z' : z'\in\mathcal{Z}^R\}$. Let $M$ be a maximal matching in $F$ (possibly allowing self-loops), that is, a maximal subset $\{y_1y'_1,\ldots,y_ky'_k\}\subseteq F$ such that all $y_1,\ldots,y_k$ are distinct and all $y'_1,\ldots,y'_k$ are distinct.

Put $A:=\{y_1,\ldots,y_k\}$, and $B=\{y'_1,\ldots,y'_k\}$. Moreover, put $\mathcal{Z}\setminus A=\{z_1,\ldots,z_p\}$ and $\mathcal{Z}'\setminus B=\{z'_1,\ldots,z'_q\}$, where $p\geq q$. By the maximality of $M$, we have that for all $z\in\mathcal{Z}\setminus A$, $t_z\in B$, that is, $z$ can reach some vertex from $B$ in $G$. Similarly, for all $z'\in\mathcal{Z}^R\setminus B$, $z'$ is reachable from a vertex of $A$.

Put $y_{k+1}:=y_1$. Consider an augmentation:

$$Y=\{y'_iy_{i+1} : i=1,\ldots,k\}\cup\{z'_{\max(i,q)}z_i : i=1,\ldots,p\}.$$

We have $|Y|=k+p=|\mathcal{Z}|=\max(|\mathcal{Z}|,|\mathcal{Z}^R|)$. Eswaran and Tarjan [10] argue rather easily that $G+Y$ is strongly connected: (1) the source and sink vertices in $A\cup B$ are pairwise strongly connected since they are arranged in a cycle, (2) every vertex in $\mathcal{Z}^R\setminus B$ can reach $A\cup B$ via $\mathcal{Z}\setminus A$ and the edges in $Y$, and (3) every vertex in $\mathcal{Z}\setminus A$ can be reached from $A\cup B$ via $\mathcal{Z}^R\setminus B$ and the edges in $Y$.

The above construction reduces, in $O(n)$ time, the problem of maintaining an optimal $Y$ to maintaining:

**(1)** for each vertex $z\in\mathcal{Z}$, an arbitrary vertex $t_z\in\mathcal{Z}^R$ reachable from $z$ in $G$,
**(2)** for each vertex $z'\in\mathcal{Z}^R$, an arbitrary vertex $s_{z'}\in\mathcal{Z}$ that can reach $z'$ in $G$.

If $\chi(G)=\max(|\mathcal{Z}|,|\mathcal{Z}^R|)$ is small enough, we can achieve the above by simply maintaining the $(\mathcal{Z}\cup\mathcal{Z}^R)\times(\mathcal{Z}\cup\mathcal{Z}^R)$ submatrix of the transitive closure of $G$. van den Brand, Forster, and Nazari [25] showed the following.

▶ **Theorem 12.** [25] *Let $G$ be a directed graph. Let $S$ be a dynamic subset of $V$ be such that $|S|=O(n^{0.85})$ at all times. There exists a data structure explicitly maintaining reachability between all-pairs of vertices in $S$ subject to fully dynamic single-edge updates to $G$ and single-element additions/deletions to $S$ in $O(n^{1.407}+|S|^2)$ worst-case time per update.*

Recall that if $G$ is subject to fully dynamic single-edge updates, then $\mathcal{Z}$ and $\mathcal{Z}^R$ undergo at most two element updates per update to $G$. As a result, by putting $S = \mathcal{Z} \cup \mathcal{Z}^R$ in the above theorem and combining with Lemma 10, we can maintain a minimum strong connectivity augmentation $Y$ in $O(n^{1.407})$ time as long as $\chi(G)^2 = O(n^{1.407})$.

If $\chi(G) = \Theta(n)$, however, the above method would have quadratic update time. We now argue that if we expect $\chi(G)$ to be large, then some desired sets $\{t_z \in \mathcal{Z}^R : z \in \mathcal{Z}\}$, and $\{s_{z'} \in \mathcal{Z} : z' \in \mathcal{Z}^R\}$ can be maintained in $O(n^{1.529})$ worst-case time per update anyway. This is possible using the below simple *existential reachability* data structure.

▶ **Lemma 13.** *Let $G$ be a directed graph. Suppose there is a fully dynamic reachability data structure processing single-edge updates and arbitrary-pair reachability queries on $G$ in $U(n) = \mathrm{poly}(n)$ and $Q(n) = \mathrm{poly}(n)$ time respectively.*

*Let $X \subseteq V$ be a dynamic subset. There is a data structure maintaining $G$ subject to fully dynamic edge updates and $X$ subject to single-element insertions and deletions with $\widetilde{O}(U(n))$ update time supporting the following queries in $\widetilde{O}(Q(n))$-time. Given a query vertex $s \in V$, find some vertex $x \in X$ that $s$ can reach in $G$ (if such an $x$ exists).*

**Proof sketch.** Suppose wlog. that the vertices of $G$ are identified with $\{1, \ldots, n\}$ and $n$ is a power of two. Let $G'$ be obtained from $G$ as follows. First, we augment $G$ with an auxiliary full binary tree $\mathcal{T}$ with $n$ leaves labeled $l_1, \ldots, l_n$ from left to right, so that $V(\mathcal{T}) \cap V(G) = \emptyset$. The edges in $\mathcal{T}$ are directed from children to their parents. Second, for every $x \in X$, we add an edge $xl_x$ to $G'$. Note that the graph $G'$ has at most $3n$ vertices.

We maintain the graph $G'$ using the assumed reachability data structure $\mathcal{D}$. Whenever $G$ is subject to an edge insertion or deletion, that update is also applied to $G'$. Similarly, if an element $x$ is inserted/deleted from $X$, this is reflected in $G'$ by adding/deleting the edge $xl_x$.

The binary tree $\mathcal{T}$ allows locating some (or even the minimum-label) vertex of $X$ that a query vertex $s$ can reach within $O(\log n)$ queries to $\mathcal{D}$. Indeed, note that $s$ can reach a vertex $w \in V(\mathcal{T})$ in $G'$ if and only if $s$ can reach in $G$ some vertex $x \in X$ such that $w$ is an ancestor of the leaf $l_x \in V(\mathcal{T})$. In particular, $s$ can reach $X$ in $G$ if and only if $s$ can reach the root of $\mathcal{T}$ in $G'$. If this is the case, the search starts in the root of $\mathcal{T}$ and descends down the tree maintaining the invariant that one of the leaves in the current subtree is reachable from $s$ in $G'$. Once we reach a leaf $l_x$, we report $x \in X$ as reachable from $s$. ◀

With Lemma 13 in hand (applied twice, to the graph $G$ with $X := \mathcal{Z}^R$ and to the graph $G^R$ with set $X := \mathcal{Z}$), using fully dynamic reachability data structure of [20] with $O(n^{1.529})$ worst-case update time and $O(n^{0.529})$ query time, we can find the desired sets by issuing $O(n)$ existential reachability queries. Recall that the sets $\mathcal{Z}$ and $\mathcal{Z}^R$ undergo $O(1)$ updates per edge update to $G$, so the worst-case update time is $O(n^{1.529})$.

Finally, we note that the described algorithms for maintaining the minimum strong connectivity augmentation $Y$ work against an adaptive adversary. Indeed, they are deterministic if provided with the required reachability information about $G$. That in turn is uniquely defined and maintained correctly with high probability by the data structures of [25, 20].

**Universal reachability.** By maintaining the source set $\mathcal{Z}$, we can also achieve the following.

▶ **Theorem 14.** *Let $G$ be a digraph. Let $T(n)$ be defined as in Theorem 2. There exists a data structure maintaining $G$ under single-edge insertions and deletions and answering queries whether a given vertex $v$ can reach all vertices in $G$ (and if not, providing an example of an unreachable vertex) with $\widetilde{O}(T(n))$ update and query time.*

**Proof.** Let $\mathcal{Z}$ be again a source set of $G$. Clearly, if $|\mathcal{Z}| > 1$, then no vertex of $G$ can reach all other vertices. Otherwise, if $|\mathcal{Z}| = 1$, then some $v$ can reach all of $V$ if and only if $v$ can reach (or, equivalently, is strongly connected to) the only element $z \in \mathcal{Z}$. As a result, given $\mathcal{Z}$ and the data structure $\mathcal{D}$, we can check whether $v$ can reach all vertices in $G$ by issuing a $v \to z$ query to $\mathcal{D}$ in $\widetilde{O}(T(n))$ time. If $v$ cannot reach some vertex of $G$, then it cannot reach some $z' \in \mathcal{Z}$. Since there is at most one $z \in \mathcal{Z}$ that $v$ can reach, to find some unreachable $z' \in \mathcal{Z}$, it is enough to issue two queries to $\mathcal{D}$. ◀

## Abstract

We consider the Max-3-Section problem, where we are given an undirected graph $G = (V, E)$ equipped with non-negative edge weights $w : E \to \mathbb{R}_+$ and the goal is to find a partition of $V$ into three equisized parts while maximizing the total weight of edges crossing between different parts. Max-3-Section is closely related to other well-studied graph partitioning problems, e.g., Max-Cut, Max-3-Cut, and Max-Bisection. We present a polynomial time algorithm achieving an approximation of 0.795, that improves upon the previous best known approximation of 0.673. The requirement of multiple parts that have equal sizes renders Max-3-Section much harder to cope with compared to, e.g., Max-Bisection. We show a new algorithm that combines the existing approach of Lassere hierarchy along with a random cut strategy that suffices to give our result.

## 1 Introduction

In this paper we study the Max-3-Section problem: given an undirected graph $G = (V, E)$ equipped with non-negative edge weights $w : E \to \mathbb{R}_+$ the goal is to partition the vertex set $V$ into three equisized parts while maximizing the total weight of edges that cross between different parts. Max-3-Section is closely related to other classic graph partitioning problems, where given the same input as in Max-3-Section the goal is to output a partition of the vertex set $V$ (possibly given some problem specific constraint) while maximizing the total weight of edges that cross between different parts. Perhaps the most famous of these problems is Max-Cut, whose constraint is that the partition contains only two parts with no restriction on the size of these parts. Max-Cut is one of Karp's 21 NP-hard problems [11]

and in their seminal work Goemans and Williamson [9] presented an approximation of 0.8786 using semi-definite programming and random hyperplane rounding. It is known that the latter result is tight, assuming the unique games conjecture, as proved by Khot, Kindler, Mossel, and O'Donnell [12].

A natural problem that generalizes Max-Cut is Max-$k$-Cut, whose constraint is that the partition contains $k$ parts with no restriction on the size of these parts. A simple algorithm that returns a uniform random solution, i.e., every vertex is assigned independently and uniformly to one of the $k$ parts, achieves an approximation of $1 - 1/k$. Several works aimed at improving the guarantee of this simple algorithm, e.g., [6, 8, 4, 14]. For example, a notable case that attracted much attention is the Max-3-Cut problem [6, 8, 4, 14], whose best approximation is 0.836 and was given by Goemans and Williamson [8]. Interestingly, the latter guarantee is worse than the approximation known for Max-Cut. For general values of $k$, it was shown by Frieze and Jerrum [6] that an approximation of $1 - 1/k + \Theta(\ln k/k^2)$ can be achieved. Further improvements for the approximation guarantee were presented by de Klerk, Pasechnik and Warners [4].

Adding a single global constraint to Max-Cut that requires both parts to be of equal size leads to the classic problem of Max-Bisection. Max-Bisection was extensively studied throughout the years, e.g., [6, 16, 10, 5, 15, 2]. This sequence of works currently culminates with the works of Raghavendra and Tan [15], who present an approximation of 0.85 that is based on rounding a Lasserre hierarchy semi-definite program, which was subsequently improved to 0.877 by Austrin, Benabbas, and Georgiou [2] who improved the former rounding. The question whether one can obtain for Max-Bisection the same approximation guarantee that is known for Max-Cut remains a tantalizing open problem.

Both Max-3-Section and Max-Bisection are captured by the Max-$k$-Section problem [1, 7, 13, 3], which falls in the above broad family of graph partitioning problems and whose constraint is that the partition contains $k$ equisized parts. Similarly to Max-$k$-Cut, it is known that the simple algorithm that returns a uniform random solution achieves an approximation of $1 - 1/k$. Thus, it is no surprise that the goal of past research, e.g., [1, 7, 13], was to improve upon this guarantee. For the special case of Max-3-Section, Ling [13] presented an approximation of 0.6733 that is based on rounding a semi-definite programming relaxation similarly to Max-3-Cut [8]. For general values of $k$, Andersson [1] presented an approximation of $1 - 1/k + \Theta(1/k^3)$, again by rounding a suitable semi-definite program relaxation. Additionally, Gaur, Krishnamurti, and Kohli [7] presented a local search algorithm for a more general problem in which each part has a (possibly different) limit on its size.

The main focus of this work is the Max-3-Section problem. For $k = 2$, the best known approximation for Max-Bisection (which is essentially Max-Cut with a single global constraint on the size of the first part in the partition) equals 0.877 and is (almost) identical to the best possible approximation of 0.878 for Max-Cut. However, when $k = 3$, the best known approximation for Max-3-Section (which is essentially Max-3-Cut with two global constraints on the size of the first two pieces in the partition) equals 0.6733 and is far from the best known approximation of 0.836 for Max-3-Cut. Moreover, the former approximation guarantee of 0.6733 for Max-3-Section only slightly improves upon the $2/3$ approximation guarantee of the trivial algorithm that simply returns a uniform random solution. Thus, we aim to understand and minimize the gap that exists for $k = 3$.

## 1.1 Our Results and Techniques

We present the following main algorithmic result for the Max-3-Section problem:

▶ **Theorem 1.** *There is a polynomial time algorithm for Max-3-Section that achieves an approximation guarantee of at least* 0.795.

It is important to note that the approximation guarantee of the above theorem improves upon the previous best known algorithm for Max-3-Section [13] that achieves an approximation of 0.6773. As proving the exact approximation guarantee of our algorithm is an involved task (for reasons that will be clear soon), we also present the following conjecture that is based on numerical evidence:

▶ **Conjecture 2.** *The algorithm presented to prove Theorem 1 achieves an approximation of* 0.8192 *for Max-3-Section.*

We further show how the algorithm we present for proving Theorem 1 can be extended to general values of $k$. First, we prove that the algorithm, alongside its analysis, cannot provide an improved approximation as $k$ increases (when compared to its approximation for the case of $k = 3$). Second, using numeric evidence we conjecture that the approximation of the algorithm remains 0.8192 for $k$ ranging from 3 up to 6. Hence, the above gives rise to the following extended conjecture:

▶ **Conjecture 3.** *There is a polynomial time algorithm achieving an approximation of* 0.8192 *for Max-k-Section for* $k = 3, 4, 5$.

The above conjecture provides, for $k = 4, 5$, an improved approximation when compared to the previous best known result. The current best is a small improvement over the trivial randomized approximation algorithm by Andersson [1] which achieves an approximation of $1 - 1/k + \Theta(k^{-3})$.

When considering our approach to Max-3-Section we focus on two of its closely related problems: Max-3-Cut and Max-Bisection and examine the approaches used to design and analyze algorithms for both. Let us start with Max-3-Cut. The approach used to obtain the current best known algorithms for Max-3-Cut, e.g., [8, 4, 14], is based on the random hyperplane rounding method due to Goemans and Williamson [9] (as well as extensions of this method) of a semi-definite programming relaxation. This approach, when applied to Max-3-Section, suffers a significant drawback since it does not preserve marginal values (a marginal value is the likelihood the relaxation assigns to the event that vertex $u$ belongs to part $i$). Specifically, the expected number of vertices assigned to every part by the rounding algorithm might be incomparable to $n/3$ and therefore applying these ideas as was done by Ling [13] leads only to a minor improvement over the random solution algorithm. It is worth noting that this drawback is already present when considering Max-Bisection.

Let us now consider Max-Bisection, and specifically we focus on the approach of Raghavendra and Tan [15] (as well as Austrin, Benabbas, and Georgiou [2] who build upon [15]). First, a Lasserre hierarchy of a natural semi-definite programming relaxation for Max-Bisection is solved. Second, a rounding procedure that preserves the marginal values is applied to obtain a subset $C_1 \subseteq V$ of vertices such that: (1) there are sufficiently many edges crossing the cut $C_1$ defines; and (2) $C_1$ contains (roughly) $n/2$ vertices. Third, the solution is re-balanced to obtain a perfect bisection, i.e., ensuring that $|C_1| = n/2$ without a significant loss in the number of edges crossing between $C_1$ and $C_2 = V \setminus C_1$.

There are two main difficulties when considering this approach in the context of Max-3-Section. The first difficulty stems from the fact that we have three parts in Max-3-Section, whereas in Max-Bisection there are only two parts. Therefore, if we use the above rounding procedure to find $C_1 \subseteq V$ of size (roughly) $n/3$ with sufficiently many edges crossing the cut $C_1$ defines, it is not clear how to recurse and further partition $V \setminus C_1$. We note that in Max-Bisection no recursion is needed since $C_2$ is chosen to be $V \setminus C_1$. However, in Max-3-Section $V \setminus C_1$ still needs to be partitioned into $C_2$ and $C_3$. Our solution to this

difficulty is to *condition* the marginal values of vertices remaining in $V \setminus C_1$ on the fact that each remaining vertex was not chosen to $C_1$. Such a conditioning, intuitively, ensures that we preserve marginal values overall while recursing on $V \setminus C_1$.

The second difficulty in applying this apporach arises from the following observation: we can show that if one first creates part $C_1$, and then creates part $C_2$ (and part $C_3$ is all remaining vertices), then if the analysis is performed edge-by-edge (as is the case in both [15, 2]) no approximation better than 0.7192 can be achieved. Specifically, we present a configuration of the vectors that correspond to the endpoints of an edge that satisfy: (1) the vectors are feasible for the semi-definite programming relaxation; and (2) the ratio between the probability of this edge being separated by the rounding algorithm and the contribution of its vectors to the objective function of the relaxation is at most 0.7192 (refer to Section 4 for a formal definition of a configuration and to Observation 35 in the full version of the paper). An approximation of 0.7192, if possible given the above approach, improves the current best known approximation of 0.6733 [13]. However, we aim for a much larger improvement. Our solution to this difficulty is to *uniformly permute* the order in which the parts are generated. Since the approach based on [15, 2] preserves marginals, this permutation allows us to better cope with problematic configurations. It is important to note that a permutation is meaningless for Max-Bisection, since whether a vertex belongs to $C_1$ immediately implies whether it belongs to $C_2$ and vice versa. In Max-3-Section this is obviously not the case.

Thus, following the above discussion, our approach builds upon the approach for Max-Bisection with two added ingredients. The first is altering the marginal values the semi-definite programming relaxation provides via appropriate conditioning when recursing. The second is uniformly permuting the order in which the rounding algorithm generates the parts. We note that these two added ingredients introduce two main additional obstacles. The first obstacle relates to the last re-balancing step. In both [15, 2] the re-balancing succeeds since it is proved that with a high probability each part by itself is close to being the desired size. The method this is proved is by bounding the variance of the size of each part alone. However, in our approach for Max-3-Section the bound on the variance of the size of a given part depends on the other parts as well. This introduces technical issues and hence bounding of the variance requires much care. The second obstacle relates to the computer assisted proof via *branch and bound* method we employ in order to lower bound the performance ratio of our algorithm. The expression of the separation probability of an edge by the rounding algorithm is involved, as both marginal values are altered when recursing and we employ a random permutation over the order in which the parts are generated. Moreover, a configuration describing how the semi-definite programming relaxation encodes an edge involves 7 different vectors (see Sections 3 and 4). Thus, we had to incorporate many technical ingredients, e.g., analytically bounding the gradient of the separation probability and restricting the search to specific type of configurations while analytically bounding the error this incurs, to make the computer assisted proof terminate faster. This results in about $150,000$ hours of CPU, which is roughly 20 CPU years, to prove Theorem 1.

## 1.2 Additional Related Work

The Max-Bisection problem has a long and rich history. Frieze and Jerrum [6] presented an approximation of 0.6514 based on rounding a semi-definite program. Later on, Ye [16], Halperin and Zwick [10], and Feige and Langberg [5] further improved the approximation guarantee to 0.699, 0.7016, and 0.7027, respectively. They achieved the above by strengthening the semi-definite programming relaxation, e.g., by adding triangle inequality constraints,

and presenting better rounding methods. The next leap in approximating Max-Bisection came with the work of Raghavendra and Tan [15]. They utilized a higher-level Lasserre hierarchy semi-definite program, together with an elegant rounding algorithm, and obtained a 0.85-approximation. Later on, Austrin, Benabbas, and Georgiou [2] showed an improved rounding algorithm, pushing the approximation guarantee up to 0.877. It should be noted that the latter is very close to the best possibloe approximation of 0.878 for Max-Cut.

Focusing on Max-$k$-Cut, Frieze and Jerrum [6] presented an approximation algorithm with better guarantee than the naive random algorithm. They utilized a semi-definite program relaxation alongside an elegant rounding algorithm that samples $k$ random vectors and assigns every vertex $v \in V$ to the cluster of the random vector that is closest to $v$'s vector in the relaxation. Goemans and Williamson [8] presented an improved approximation of 0.836 for Max-3-Cut by using a complex semi-definite program. In [4], de Klerk, Pasechnik, and Warners presented further improved bounds for Max-$k$-Cut. Please refer to Table 1 by Newman [14] for a summary of approximation guarantees.

## 1.3 Paper Organization

We start by presenting preliminary definitions in Section 2. Next, in Section 3 we present our semi-definite program for Max-3-Section and show that it can be strengthened to obtain a solution which is globally uncorrelated. In Section 4 we present our rounding algorithm and its analysis. To obtain a bound on the approximation guarantee of our rounding algorithm, we present an analysis which is based on a computer-assisted proof in Section 5. Furthermore, we discuss the generalization of our algorithm, and its numerical estimation, in Section 6. Missing proofs appear in the full version of the paper.

# 2 Preliminaries

We denote by $\Phi : \mathbb{R} \to [0,1]$ the cumulative distribution function of the normal gaussian distribution and by $\Phi^{-1} : [0,1] \to \mathbb{R}$ its inverse. Specifically, if $R \sim N[0,1]$ then: (1) $\forall x \in \mathbb{R}$: $\Pr[R \leq x] = \Phi(x)$ (or equivalently $\Pr[R \geq x] = 1 - \Phi(x)$); and (2) $\forall x \in [0,1]$: $\Pr[R \leq \Phi^{-1}(x)] = x$ (or equivalently $\Pr[R \geq \Phi^{-1}(x)] = 1 - x$). Moreover, we say that a vector $\mathbf{g}$ is a *random gaussian vector* if its coordinates are i.i.d standard gaussian $N(0,1)$ random variables.

We denote by $\Gamma_t : [0,1]^2 \to [0,1]$ the probability that a standard bi-variate gaussian distribution with correlation $t$ has both its coordinates at most the given quantiles, i.e.,

$$\forall q_1, q_2 \in [0,1] : \ \Gamma_t(q_1, q_2) \triangleq \Pr[X \leq \Phi^{-1}(q_1), Y \leq \Phi^{-1}(q_2)], \ \begin{pmatrix} X \\ Y \end{pmatrix} \sim N\left( \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & t \\ t & 1 \end{pmatrix} \right).$$

We define the mutual information between two random variables.

▶ **Definition 4.** *Let $X, Y$ be jointly distributed random variables taking values in $[q]$. The mutual information of $X$ and $Y$ is defined as*

$$I(X,Y) \triangleq \sum_{i,j \in [q]} \Pr(X = i, Y = j) \log \left( \frac{\Pr(X = i, Y = j)}{\Pr(X = i) \Pr(X = j)} \right).$$

For any two disjoint subsets of vertices $A, B \subseteq V$, we denote by $\delta(A,B)$ the collection of edges having one endpoint in $A$ and another endpoint in $B$. Hence, $|\delta(A,B)|$ denotes the number of edges crossing between $A$ and $B$.[1]

[1] For simplicity of presentation, we assume from this point onward that the graph is unweighted. All of our results apply to graphs equipped with non-negative edge weights, in which case one should substitute $|\delta(A,B)|$ with the total weight of edges crossing between $A$ and $B$.

## 3 The SDP Relaxation for Max-3-Section

In this section, we present a semi-definite programming (SDP) formulation and prove that it is a relaxation for the Max-3-Section problem. Similarly to previous works on Max-Bisection, e.g., [2, 15], we strengthen this formulation and obtain additional properties that will be useful to our rounding algorithm. We define the following SDP formulation for Max-3-Section:

$$\text{(SDP)} \qquad \text{maximize} \quad \sum_{e=(u,v)\in E} \left(1 - \sum_{i=1}^{3} \mathbf{y}_u^i \cdot \mathbf{y}_v^i\right) \tag{1}$$

$$\text{s.t.} \quad \|\mathbf{y}_\emptyset\|^2 = 1 \tag{2}$$

$$\|\mathbf{y}_v^i\|^2 = \mathbf{y}_\emptyset \cdot \mathbf{y}_v^i \qquad \forall v \in V, \forall i = 1,2,3 \tag{3}$$

$$\|\mathbf{y}_v^1\|^2 + \|\mathbf{y}_v^2\|^2 + \|\mathbf{y}_v^3\|^2 = 1 \qquad \forall v \in V \tag{4}$$

$$\mathbf{y}_v^i \cdot \mathbf{y}_v^j = 0 \qquad \forall v \in V, i \neq j \tag{5}$$

$$\mathbf{y}_u^i \cdot \mathbf{y}_v^j \geq 0 \qquad \forall u,v \in V, \forall i,j = 1,2,3 \tag{6}$$

$$\sum_{v\in V} \|\mathbf{y}_v^i\|^2 = n/3 \qquad \forall i = 1,2,3 \tag{7}$$

We note that in the above and what follows, for every vector $\mathbf{y}$ a square norm of a vector $\|\mathbf{y}\|^2$ is with respect to the $\ell_2$ (Euclidean) norm and equals $\mathbf{y} \cdot \mathbf{y}$. Next, we prove that the formulation is a relaxation for our problem. Intuitively, for every vertex $v \in V$ the formulation SDP assigns a distribution over the three clusters via the vectors $\mathbf{y}_v^1$, $\mathbf{y}_v^2$, and $\mathbf{y}_v^3$. Specifically, $\mathbf{y}_\emptyset$ is a unit vectors (Constraint (2)) that denotes *true* whereas the zero vector (that does not appear explicitly in SDP) denotes *false*. Each vector $\mathbf{y}_v^i$ indicates how much vertex $v$ is likely to be assigned to the $i^{\text{th}}$ cluster by SDP. Hence, $\|\mathbf{y}_v^i\|^2$, or equivalently $\mathbf{y}_v^i \cdot \mathbf{y}_\emptyset$ (see Constraint (3)), denotes the marginal probability of assigning vertex $v$ to the $i^{\text{th}}$ cluster by SDP. For every vertex $v \in V$, the sum of these marginal probabilities needs to sum up to one (Constraint 4). Since every vertex $v \in V$ can be assigned to a single cluster in any integral solution, SDP enforces that the vectors $\mathbf{y}_v^i$ and $\mathbf{y}_v^j$ for $i \neq j$ are orthogonal (Constraint (5)). Intuitively, the joint probability SDP assigns for vertices $u$ and $v$ to belong to the $i^{\text{th}}$ and $j^{\text{th}}$ clusters, respectively, is non-negative (Constraint (6)). Finally, since the three clusters are required to be of size $n/3$ each Constraint (7) is added to SDP. When focusing on the objective of SDP (see (1)), for every edge $(u,v) \in E$ the inner product $\mathbf{y}_u^i \cdot \mathbf{y}_v^i$ intuitively indicates the joint probability of both $u$ and $v$ to be assigned to the $i^{\text{th}}$ cluster by SDP. Therefore, intuitively $1 - \mathbf{y}_u^1 \cdot \mathbf{y}_v^1 - \mathbf{y}_u^2 \cdot \mathbf{y}_v^2 - \mathbf{y}_u^3 \cdot \mathbf{y}_v^3$ indicates the likelihood of separating an edge $(u,v)$ by SDP. Thus, this is the objective of SDP.

The following lemma proves that SDP is a relaxation to the Max-3-Section problem, i.e., the value of an optimal solution $\text{OPT}_{\text{SDP}}$ to SDP is an upper bound on the value of an integral optimal solution OPT.

▶ **Lemma 5.** *Given an instance of Max-3-Section let* $\text{OPT}_{\text{SDP}}$ *be the value of an optimal solution of* SDP *(1) and* OPT *be the value of an optimal integral solution. Then,* $\text{OPT}_{\text{SDP}} \geq \text{OPT}$.

**Proof.** Let $\{C_1^*, C_2^*, C_3^*\}$ be an optimal solution for the given instance of Max-3-Section whose value is OPT. Construct the following vector solution to SDP. First, fix an arbitrary unit vector $\mathbf{y}_\emptyset$. Second, for every $v \in V$ define $\mathbf{y}_v^i$ to be the zero vector if $v \notin C_i^*$ and $\mathbf{y}_v^i = \mathbf{y}_\emptyset$ if $v \in C_i^*$. One may notice that all the constraints hold for this solution and the value of the objective of SDP equals the value of the optimal solution $\{C_1^*, C_2^*, C_3^*\}$. Hence, $\text{OPT}_{\text{SDP}} \geq \text{OPT}$. ◀

For simplicity of presentation, we denote by $Y$ a solution to SDP. Thus, $Y$ consists of $\{\mathbf{y}_u^i\}_{u\in V,i=1,2,3}$ and $\mathbf{y}_\emptyset$. A useful property that any feasible solution $Y$ to SDP satisfies is that $\mathbf{y}_u^1+\mathbf{y}_u^2+\mathbf{y}_u^3$ always equals the vector $\mathbf{y}_\emptyset$. This is summarized in the following lemma.

▶ **Lemma 6.** *Let $Y$ be a feasible solution to* SDP*. Then, for every vertex $u \in V$: $\mathbf{y}_u^1+\mathbf{y}_u^2+\mathbf{y}_u^3 = \mathbf{y}_\emptyset$.*

An immediate corollary of the above lemma is that for every pair of vertices $u, v \in V$: $\mathbf{y}_u^i \cdot (\mathbf{y}_v^1+\mathbf{y}_v^2+\mathbf{y}_v^3) = \|\mathbf{y}_u^i\|^2$ (via Constraint (3)).

## 3.1 Globally Uncorrelated Solution

Next we define when a solution $Y$ to SDP is globally uncorrelated following the framework of [15]. Global uncorrelation implies that our rounding algorithm returns a solution that has close to $\frac{n}{3}$ vertices in each part with high probability (see Lemma 15). The sizes then can be corrected with a minor loss in approximation ratio by randomly shifting the imbalanced vertices (see Lemma 16).

A simple fact about any SDP solution is the following: given any two vertices $u, v$, there exists a *local* probability distribution $\mu_{u,v}$ on $\{1,2,3\}^2$ such that $\Pr_{\mu_{u,v}}[X_u = i, X_v = j] = \langle \mathbf{y}_u^i, \mathbf{y}_v^j \rangle$ for every $i, j \in \{1,2,3\}$ and $\Pr_{\mu_{u,v}}[X_u = i] = \|\mathbf{y}_u^i\|^2$ for every $i \in \{1,2,3\}$. The distribution implies that, at least, locally the semi-definite program is a distribution over integral solutions that satisfy correct correlations. The last property states that the distributions are consistent on their intersection which can be at most one vertex.

▶ **Definition 7.** *A solution $Y$ to* SDP *is $\varepsilon$-independent if $\mathbb{E}_{u,v}[I_{\mu_{u,v}}(X_u, X_v)] \leq \varepsilon$ where $\mu_{u,v}$ is the local probability distribution associated with vertices $u$ and $v$.*

The following lemma is an application of Theorem 4.6 from [15] to our SDP for Max-3-Section and it shows how to obtain a $\varepsilon$-independent solution. The algorithm proving Lemma 8 follows from solving the $\Theta(t^2)$-level Lasserre hierarchy semi-definite program for SDP and then inductively conditioning on variables.

▶ **Lemma 8.** *There is an algorithm which, given an integer $t > 0$ and an instance of Max-3-Section, runs in time $n^{O(poly(t))}$ and outputs a set of vectors $Y$ consisting of $\{\mathbf{y}_v^i\}_{v\in V,i=1,2,3}$ and $\mathbf{y}_\emptyset$ such that:*

1. *$Y$ is a feasible solution to* SDP*.*
2. *The objective value of* SDP *(1) when plugging in $Y$ is at least $\mathrm{OPT}_{\mathrm{SDP}} - \frac{1}{t}$.*
3. *$Y$ is $\frac{1}{t}$-independent.*

# 4 The Rounding Algorithm

In this section we present our rounding algorithm for SDP, which appears in Algorithm 1. The algorithm receives as input a solution to SDP and outputs a partition $\{C_1, C_2, C_3\}$ of $V$ that: (1) has high value compared to the SDP value of the input solution; and (2) is (nearly) balanced, i.e., for every $i = 1, 2, 3$: $|C_i|$ is close to $n/3$. We will conclude the analysis by proving that one can re-balance the partition without a significant loss in the value of the solution.

In order to state the algorithm, we require the following definition. For every vertex $u \in V$ and $i = 1, 2, 3$ we denote by $\mathbf{z}_u^i$ the normalized component of $\mathbf{y}_u^i$ that is orthogonal to $\mathbf{y}_\emptyset$, i.e., $\mathbf{y}_u^i = \|\mathbf{y}_u^i\|^2 \mathbf{y}_\emptyset + \sqrt{\|\mathbf{y}_i^i\|^2 - \|\mathbf{y}_u^i\|^4}\mathbf{z}_u^i$. Equivalently,

$$\mathbf{z}_u^i \triangleq \frac{\mathbf{y}_u^i - \|\mathbf{y}_u^i\|^2 \mathbf{y}_\emptyset}{\sqrt{\|\mathbf{y}_u^i\|^2 - \|\mathbf{y}_u^i\|^4}}. \tag{8}$$

Clearly, $\mathbf{z}_u^i$ is a unit vector that is orthogonal to $\mathbf{y}_\emptyset$. We note that if the marginal of vertex $u$ and cluster $i$ is integral, i.e., $\|\mathbf{y}_u^i\|^2 \in \{0, 1\}$, then $\mathbf{z}_u^i$ is not defined. In this case one can simply choose an arbitrary unit vector in the space orthogonal to $\mathbf{y}_\emptyset$ to be $\mathbf{z}_u^i$.

**Algorithm 1** Max-3-Section Rounding Algorithm.

**Input:** solution $\{\mathbf{y}_u^i\}_{u \in V, i=1,2,3}$ and $\mathbf{y}_\emptyset$ to SDP.
**Output:** a partition of $V$ into three parts.

1 Draw uniformly at random a permutation $\pi \in \mathcal{S}_3$.
2 Draw independently two random Gaussian vectors $\mathbf{g}_1$ and $\mathbf{g}_2$.
3 Define the following sets:

$$S_{\pi(1)} \triangleq \left\{ u \in V : \mathbf{z}_u^{\pi(1)} \cdot \mathbf{g}_1 \geq \Phi^{-1}\left(1 - \|\mathbf{y}_u^{\pi(1)}\|^2\right) \right\},$$
$$S_{\pi(2)} \triangleq \left\{ u \in V : \mathbf{z}_u^{\pi(2)} \cdot \mathbf{g}_2 \geq \Phi^{-1}\left(1 - \|\mathbf{y}_u^{\pi(2)}\|^2 / (1 - \|\mathbf{y}_u^{\pi(1)}\|^2)\right) \right\}.$$

4 Return $\{C_1, C_2, C_3\}$ where: $C_{\pi(1)} \triangleq S_{\pi(1)}$, $C_{\pi(2)} \triangleq S_{\pi(2)} \setminus S_{\pi(1)}$, $C_{\pi(3)} \triangleq V \setminus (S_{\pi(1)} \cup S_{\pi(2)})$.

We first prove that Algorithm 1 preserves the marginal probabilities of SDP, i.e., $\|\mathbf{y}_u^i\|^2$ is the probability vertex $u$ is assigned to cluster $C_i$. This is summarized in the following lemma.

▶ **Lemma 9.** *For every $u \in V$ and $i = 1, 2, 3$, it holds that* $\Pr[u \in C_i] = \|\mathbf{y}_u^i\|^2$.

**Proof.** Fix a permutation $\pi \in \mathcal{S}_3$, and let us calculate the probability that $u \in C_i$ conditioned on the event that $\pi$ was chosen in the first step of Algorithm 1. Hence, the following holds for $C_{\pi(1)}$:

$$\Pr\left[u \in C_{\pi(1)} | \pi\right] = \Pr\left[u \in S_{\pi(1)} | \pi\right] = \Pr\left[\mathbf{z}_u^{\pi(1)} \cdot \mathbf{g}_1 \geq \left(1 - \Phi^{-1}\left(1 - \|\mathbf{y}_u^{\pi(1)}\|^2\right)\right) | \pi\right] = \|\mathbf{y}_u^{\pi(1)}\|^2.$$

We observe that the sets $S_{\pi(1)}$ and $S_{\pi(2)}$ are constructed with independent vectors $\mathbf{g}_1$ and $\mathbf{g}_2$. Therefore, similarly to the above, the following holds for $C_{\pi(2)}$:

$$\begin{aligned}
\Pr\left[u \in C_{\pi(2)} | \pi\right] &= \Pr\left[u \notin S_{\pi(1)} \wedge u \in S_{\pi(2)} | \pi\right] \\
&= \Pr\left[u \notin S_{\pi(1)} | \pi\right] \cdot \Pr\left[u \in S_{\pi(2)} | \pi\right] \\
&= \left(1 - \|\mathbf{y}_u^{\pi(1)}\|^2\right) \cdot \Pr\left[\mathbf{z}_u^{\pi(2)} \cdot \mathbf{g}_2 \geq \left(1 - \Phi^{-1}\left(1 - \frac{\|\mathbf{y}_u^{\pi(2)}\|^2}{(1 - \|\mathbf{y}_u^{\pi(1)}\|^2)}\right)\right) \middle| \pi\right] \\
&= \left(1 - \|\mathbf{y}_u^{\pi(1)}\|^2\right) \cdot \frac{\|\mathbf{y}_u^{\pi(2)}\|^2}{(1 - \|\mathbf{y}_u^{\pi(1)}\|^2)} \\
&= \|\mathbf{y}_u^{\pi(2)}\|^2.
\end{aligned}$$

Finally, since the events $\{u \in C_{\pi(1)} | \pi\}$, $\{u \in C_{\pi(2)} | \pi\}$, and $\{u \in C_{\pi(3)} | \pi\}$ are disjoint and exactly one of them occurs, i.e., every vertex $u \in V$ belongs to exactly one cluster in the output, we can conclude that:

$$\Pr\left[u \in C_{\pi(3)} | \pi\right] = 1 - \Pr\left[u \in C_{\pi(1)} | \pi\right] - \Pr\left[u \in C_{\pi(2)} | \pi\right] = 1 - \|\mathbf{y}_u^{\pi(1)}\|^2 - \|\mathbf{y}_u^{\pi(2)}\|^2 = \|\mathbf{y}_u^{\pi(3)}\|^2.$$
