LIPIcs – Leibniz International Proceedings in Informatics

LIPIcs is a series of high-quality conference proceedings across all fields in informatics. LIPIcs volumes are published according to the principle of Open Access, i.e., they are available online and free of charge.

RANDOM

Preface

This volume contains the papers presented at the 26th International Conference on Approximation Algorithms for Combinatorial Optimization Problems (APPROX 2023) and the 27th International Conference on Randomization and Computation (RANDOM 2023), which were organized at Georgia Institute of Technology, Atlanta, GA, USA, September 11-13, 2023. APPROX focuses on algorithmic and complexity issues surrounding the development of efficient approximate solutions to computationally-difficult problems, and the 2023 edition was the 26th in the series. RANDOM is concerned with applications of randomness to computational and combinatorial problems, and the 2023 edition was the 27th in the series. Prior to 2003, APPROX took place in Aalborg (1998), Berkeley (1999), Saarbruücken (2000), Berkeley (2001), and Rome (2002), while RANDOM took place in Bologna (1997), Barcelona (1998), Berkeley (1999), Geneva (2000), Berkeley (2001), and Harvard (2002). Since 2003, APPROX and RANDOM have been co-located, taking place in Princeton (2003), Cambridge (2004), Berkeley (2005), Barcelona (2006), Princeton (2007), Boston (2008), Berkeley (2009), Barcelona (2010), Princeton (2011), Boston (2012), Berkeley (2013), Barcelona (2014), Princeton (2015), Paris (2016), Berkeley (2017), Princeton (2018), and Boston (2019). In 2020, 2021, and 2022, the conferences were held online. We were delighted to return to an in-person event in 2023!

Topics of interest for APPROX include approximation algorithms, hardness of approximation, small space, sub-linear time and streaming algorithms, online algorithms, approaches that go beyond worst case analysis, distributed and parallel approximation, embeddings and metric-space methods, mathematical-programming methods, spectral methods, combinatorial optimization, algorithmic game theory, mechanism design and economics, computational-geometry problems, approximate learning. Those at RANDOM include the design and analysis of randomized algorithms, randomized complexity theory, pseudorandomness and derandomization, random combinatorial structures, random walks/Markov chains, expander graphs and randomness extractors, probabilistic proof systems, random projections and embeddings, error-correcting codes, average-case analysis, smoothed analysis, property testing, computational learning theory, and the role of (pseudo)randomness in other areas of computer science such as cryptography, data privacy, and quantum information.

The volume contains 28 contributed papers selected by the APPROX Program Committee out of 62 submissions, and 38 contributed papers selected by the RANDOM Program Committee out of 67 submissions. We would like to thank all the authors who submitted papers, the members of the program committees, and the external reviewers. We are grateful for the guidance of the steering committees: Jarosław Byrka, Samir Khuller, Monaldo Mastrolili, Laura Sanità, Chaitanya Swamy, László Végh, Virginia Vassilevska Williams, and David P. Williamson for APPROX, and Oded Goldreich, Raghu Meka, Cris Moore, Anup Rao, Omer Reingold, Dana Ron, Ronitt Rubinfeld, Amit Sahai, Ronen Shaltiel, Alistair Sinclair, and Paul Spirakis for RANDOM.

Abstract

We consider the classic 1-center problem: Given a set P of n points in a metric space find the point in P that minimizes the maximum distance to the other points of P. We study the complexity of this problem in d-dimensional ℓ_p-metrics and in edit and Ulam metrics over strings of length d. Our results for the 1-center problem may be classified based on d as follows.

- **Small *d*.** Assuming the hitting set conjecture (HSC), we show that when $d = \omega(\log n)$, no subquadratic algorithm can solve the 1-center problem in any of the ℓ_p-metrics, or in the edit or Ulam metrics.
- **Large *d*.** When $d = \Omega(n)$, we extend our conditional lower bound to rule out sub*quartic* algorithms for the 1-center problem in edit metric (assuming Quantified SETH). On the other hand, we give a $(1+\epsilon)$-approximation for 1-center in the Ulam metric with running time $\widetilde{O_\varepsilon}(nd + n^2\sqrt{d})$.

We also strengthen some of the above lower bounds by allowing approximation algorithms or by reducing the dimension d, but only against a weaker class of algorithms which list all requisite solutions. Moreover, we extend one of our hardness results to rule out subquartic algorithms for the well-studied 1-median problem in the edit metric, where given a set of n strings each of length n, the goal is to find a string in the set that minimizes the sum of the edit distances to the rest of the strings in the set.

2012 ACM Subject Classification Theory of computation → Computational geometry; Theory of computation → Facility location and clustering; Theory of computation → Problems, reductions and completeness; Theory of computation → Unsupervised learning and clustering

Keywords and phrases Center, Clustering, Edit metric, Ulam metric, Hamming metric, Fine-grained Complexity, Approximation

1 Introduction

Given a set of points P in a metric space, finding the point that "best" represents P is a fundamental question in both discrete and continuous optimization. Motivated by applications ranging from machine learning to computational biology, this question has naturally received a large amount of attention through the years.

The objective can be phrased in various ways: In the median problem, the goal is to find the point p that minimizes the sum of the distances to the points in P; in the mean problem, it is the point that minimizes the sum of distances squared; while in the center problem, it is the point p that minimizes the maximum distance from a point of P to p. When the metric is the ℓ_2 (Euclidean) metric, the question of computing the geometric median dates back to the 17th century, when Torricelli was looking for a solution for the case $|P| = 3$, and to whom Fermat described an explicit solution. More recently, the question of computing the center has also become central in applications arising, e.g., in machine learning [11], to compute the minimum enclosing ball of a set of points, or in computational biology, to find a good representative of a set of strings (representing molecular sequences) (e.g., [30]). This fundamental computational geometry problem which has applications to various domains, is the problem we consider in this paper.

Formally, in the (often referred to as the *discrete*) 1-center problem, the input is a set of points P in a metric space, and the goal is to find a point of P that minimizes the maximum distance to the points in P. When doing data summarization or compression, the discrete version often makes more sense: Given a set of, say n strings, taking the most representative string among the input strings, or at least in the set of grammatically (or semantically) meaningful strings is much more insightful than taking an arbitrary string as representative. This also applies more globally, outputting a data element that has been observed provides a better summary than a data element that has been forged by the algorithm and that may be unlikely to exist in the real-world. From a computational complexity standpoint, this problem can be easily solved in time $O(|P|^2 f(d))$ where $f(d)$ is the time required to compute the distance of two points. This can be done by enumerating all possible choices for the center; and for each choice computing the distance from each point in P; then outputting the best center. However, is this naïve algorithm the best we can do?

The computational geometry community has done extensive work on the above question since the 80s. For metrics such as ℓ_1 or ℓ_2, computing the center has received a large deal of attention. When the dimension is assumed to be a constant, there exist *barely subquadratic* algorithms for the ℓ_2 metric, while there exists near-linear time algorithms for the ℓ_1 case (for a discussion on this we refer the reader to [35]). For the case of string metrics, such as Ulam or Edit distance metrics, nothing better than the $O(|P|^2 f(d))$ (where d is the string length) "brute-force" algorithm is known.

Understanding how fast the 1-center problem can be solved in these different metrics is not only interesting from a computational complexity point of view, but also from the perspective of an improved understanding of the geometry of these metrics. For example, is the geometry of the ℓ_1 metric "more amenable" for designing algorithms than the ℓ_2 one? Is the Edit distance metric hard for such problems? We also believe that understanding the geometry of the Ulam and Edit distance metrics, which one may interpret as generalization of the Hamming metric, is not only a very basic computational geometry question, but also would likely lead to better algorithms for these widely-studied problems. We thus ask:

How fast can the 1-center problem be solved or approximated in ℓ_p-metrics and stringology metrics such as Ulam or Edit distance?

1.1 Our Results

In this paper, we take a step towards answering the above question by providing lower and upper bounds on solving the 1-center problem in ℓ_p, Ulam, and Edit distance metrics.

Assuming the Hitting Set Conjecture (HSC), we provide a strong conditional lower bound for the 1-center problem, in a pleathora of metrics.

▶ **Theorem 1** (see Theorem 9, Corollary 12, and Corollary 14 for formal statement). *Assuming* HSC*, no algorithm running in time $n^{2-o(1)}$ can given as input a set of points/strings P of dimension/length d solve the discrete 1-center problem in Edit/Ulam/ℓ_p metric, where $|P| = n$, $d = \widetilde{\Omega}(\log n)$, and $p \in \mathbb{R}_{\geq 1} \cup \{0\}$.*

Moreover, by assuming a stronger complexity theoretic assumption we can strengthen this lower bound in the case when $d = \text{poly}(n)$ for the Edit metric. For the sake of presentation, we state our result below when $d = n$.

▶ **Theorem 2** (see Theorem 15). *Assuming Quantified SETH, no algorithm running in time $n^{4-o(1)}$ can given as input a set of n strings of length $d := n$ each, solve the discrete 1-center problem in Edit metric.*

It's worth emphasizing that the above lower bound for the edit metric is a rare quartic lower bound in fine-grained complexity. It's true that, conceptually, it's not unexpected because there's a quadratic hardness from the 1-center problem and a quadratic hardness from edit distance, so we would expect the combined problem to be quartic. But we find it noteworthy that this actually works on the technical level because complexity theory is full of notorious examples where such "semi-stitching techniques" completely fail (for example KRW games [20]).

Note that we cannot expect such lower bounds for the 1-center problem in ℓ_p-metrics when $d = n$, as one can compute all pairwise distances within a point-set in subcubic time using fast matrix multiplication.

Next, we complement the lower bounds by the following subcubic approximation scheme for the 1-center in the Ulam metric.

▶ **Theorem 3.** *There exists a $1 + \epsilon$ approximation algorithm for the 1-center under Ulam metric that runs in time $\widetilde{O}_\epsilon(nd + n^2\sqrt{d})$.*

It is worth emphasizing here that for the (discrete) 1-center problem in any metric space, an arbitrary point in the input is a 2-approximate solution. Also note that exact 1-center in Ulam metric can be solved in $O(n^2 d)$ time. It remains an open problem to show a conditional lower bound of $n^{3-o(1)}$ for computing the 1-center in the Ulam metric for n strings each of length n.

Finally, we strengthen some of the lower bounds above, but against a weaker class of algorithms, specifically, against algorithms which list all requisite solutions. Using the ideas in [35, 10], assuming HSC, we rule out subquadratic algorithms that can list all optimal solutions to the 1-center problem in the Euclidean metric even for very low $d = o(\log n)$ dimensions. At a high level, this result contrasts with both ℓ_1 and ℓ_∞ metrics where the 1-center in $o(\log n)$ dimensions can be solved in $n^{1+o(1)}$ time.

▶ **Theorem 4** (see Theorem 20 for formal statement). *Assuming* HSC*, there is no $n^{2-o(1)}$-time algorithm listing all optimal solutions to the 1-center problem in $7^{\log^* n}$ dimensions in the Euclidean metric.*

In the same spirit as above, by applying the distributed PCP framework [2, 31] we extend the lower bound in Theorem 1 against approximation algorithms which list all approximately optimal 1-centers.

▶ **Theorem 5** (see Theorem 22 for formal statement). *Assuming* HSC*, there is some $\delta > 0$, such that no $n^{2-o(1)}$-time algorithm can given as input a set of points/strings P of dimension/length d, list all $(1+\delta)$-approximate solutions to the 1-center problem in the Edit/Ulam/ℓ_p metric, where $|P| = n$, $d = \widetilde{\Omega}(\log n)$, and $p \in \mathbb{R}_{\geq 1} \cup \{0\}$.*

One may compute all pairwise distances in $\widetilde{O}(n^2)$ time for the inputs in Theorems 4 and 5, and then obtain the list of all optimal and approximately optimal solutions efficiently. Our theorems above say that one cannot do much better. It remains an intriguing open problem to extend the above two conditional lower bounds but against standard decision algorithms. We note that this involves breaking some technical barriers and in particular, developing techniques that go beyond the dimensionality reduction techniques of [35, 10] and the distributed PCP framework [2, 31] respectively.

We close this subsection by a short discussion about the Discrete 1-median problem in ℓ_p-metrics and string metrics. For the case when $d = n$, we can prove a result similar to Theorem 2 (see Remark 18). On the other hand for ℓ_p-metrics, one cannot prove a result similar to Theorem 1 for the 1-median problem, because the 1-median problem in Hamming and ℓ_1-metrics admits a near linear time algorithm and for the Euclidean metric, it is even unclear if the problem is in NP! (see discussion in [18].) Also note that by subsampling coordinates, we can approximate 1-median in all ℓ_p-metrics to $(1+\varepsilon)$ factor, for any $\varepsilon > 0$ in near linear time.

1.2 Related Work

We now review the related work on the 1-center problem, and the related 1-median problem. Both problems may be considered in the *discrete* or *continuous* settings. The discrete[1] version asks the center or median to be picked from an input set of points, while in the continuous version, the "center" is an arbitrary element of the metric. See [13] for a discussion on these two settings.

Below, we mainly discuss 1-center problem in stringology metrics as the literature on related work in ℓ_p metrics is too vast to survey (but the interested reader may look at [12, 25, 23, 16] and the references therein).

Metrics arising in stringology

We now review results on the 1-center problem in metric spaces arising from stringology applications. Let Σ be an alphabet, often the binary alphabet $\{0,1\}$. Consider the set of strings $\Sigma^* = \Sigma^L$ of length L, with a metric distance $D : \Sigma^* \times \Sigma^* \mapsto \mathbb{R}$. Researchers have mainly considered the following metrics defined over this space:

- **Edit distance** (ED or Levenshtein distance): The minimum number of single-character insertions, deletions, and substitutions required to change one string to the other.
- **Hamming distance or ℓ_1 over binary alphabets** (HD): A special case of edit distance, where only substitutions are allowed.
- **Ulam distance** (UD): Same as edit distance with the restriction that the input strings may not contain any character more than once.

[1] Sometimes called the *medoid* problem in contrast to *median*, *generalized* median, or *Steiner* string.

For most of the above metrics, one need to incorporate into the running times obtained for simpler metric such as ℓ_1 or ℓ_2 the time it takes to compute the exact or approximate distance between any two points of the space. Naumovitz et al. [28] show how to approximate UD within factor $1+\varepsilon$ in time $\widetilde{O}(d/\eta+\sqrt{d})$ if the distance is η. This result is tight up to log factors.

Turning back to the 1-center and 1-median problem, note the *discrete* versions can be solved exactly via $O(n^2)$ distance computations, giving trivial $\widetilde{O}(n^2 d)$-time algorithms for the case of UD. In Section 4, we show that this can be improved to $\widetilde{O}(n^2\sqrt{d})$ for $1+\varepsilon$ approximation if we combine two algorithms [26, 28] for computations of UD. Note that a 2-approximation is trivial, as we can output any string as the hub in the case of 1-center or a random string in the case of 1-median.

Recently [9] made progress on obtaining better approximation algorithms for the continuous 1-Median problem in UD, where the median can be picked from anywhere in space, by presenting the first polynomial-time constant-factor approximation algorithm with approximation guarantee smaller than 2 as well as an exact algorithm for the case where the input contains *three* strings. They observe that if the average distance to median is $\Omega(d)$, picking the best string as the median already gives an approximation better than two. Now the problem is reduced to the above case if the total cost is mostly due to a small subset of characters. Otherwise, they argue that one can deduce the relative ordering of a good portion of the optimal median by looking at pairs of characters whose relative order is consistent in *most* input strings.

Note that in the continuous case, for constant d or constant n, the median and center problems are both solvable in polynomial time for string problems. De la Higuera and Casacuberta [15] prove that median and center are both NP-hard. Nicolas and Rivals [29] lift the restrictions and show that median and center are both NP-hard and $W[1]$-hard (when parameterized by n, the number of strings), even for binary alphabets. Prior to these works, NP-hardness of median was only known for ED when the substitutions have specific costs for each pair of characters [33]. Li et al. [24, 25] give a PTAS for the HD 1-center problem,[2] augmenting the LP-based PTAS for super-logarithmic d [5]. The HD 1-center problem is known to be NP-hard [16, 23].[3] Previously the best polynomial-time approximation ratio was $\frac{4}{3}+\varepsilon$ in general [23, 19], with an exact algorithm known for constant d (optimal value) [34].

1.3 Organization of the Paper

In Section 2, we provide the formal definition of 1-center problem and the various hypotheses used in the paper. In Section 3, we provide conditional lower bounds against exact algorithms that compute 1-center when $d=\omega(\log n)$. Next, in Section 4, we provide a subcubic approximation algorithm for 1-center in Ulam metric when $d=n$. Finally, in Section 5, we provide some hardness of approximation results (Theorem 5).

2 Preliminaries

▶ **Definition 6** (Discrete 1-center). *Let (X,Δ) be a metric space. Given a set of points $P\subseteq X$ in the metric space, find x in P which minimizes the maximum distance to every other point.*

[2] This is the *closest string* problem. They also give a PTAS for the *closest substring* problem, which assumes that the cost of deletions from the input strings (∞ for HD) is zero.

[3] Note that median is solvable exactly for HD.

Perhaps the most popular assumption for proving conditional lower bounds for polynomial time problems is the Orthogonal Vectors Hypothesis (OVH) that is implied by the Strong Exponential Time Hypothesis (SETH). Unfortunately, the logical structure of these problems makes reductions to our 1-center problems difficult. This was observed already by Abboud, Vassilevska Williams, and Wang [3] in the context of 1-center in *graphs* (known as the Graph Radius problem) and has lead them to introduce the hitting set conjecture (HSC): a stronger variant of OVH that facilitates reductions to problems with different structure. A formal barrier for establishing HSC (and similarly also any hardness results for 1-center) under SETH was presented by Carmosino et al. [8].

▶ **Definition 7** (HSC). *For every $\varepsilon > 0$ there exists $c > 1$ such that no algorithm running in time $n^{2-\varepsilon}$ can, given as input two collections of n-many subsets $\mathcal{A}$ and $\mathcal{B}$ of the universe $U := [c \log n]$, determine if there exists S in $\mathcal{A}$ which has non-empty intersection with every subset in $\mathcal{B}$.*

The difference between HSC and OVH is in the quantifiers: $\exists\forall$ versus $\exists\exists$. Studying the *polyline simplification* problem, Bringmann and Chaudhury [6] proposed a further strengthening with more quantifiers. Just like OVH is implied by SETH, an assumption about k-SAT, so too can HSC and its generalizations with more quantifiers be based on the hardness of a quantified version of k-SAT; an assumption called *Quantified-SETH*. Interestingly, the previous papers using Quantified-SETH [6, 1] only needed its special case where the quantifier structure is $\forall\exists$; whereas in this paper we benefit from a $\exists\forall\exists$ structure that has one more alternation.

The specific hardness assumption (implied by Quantified SETH) that we need is the following; we refer to [6, 1] for further discussion on Quantified-SETH and to [3, 36] for further discussion on HSC and on the need for assumptions with other quantifier structures.

▶ **Definition 8** ($\exists\forall\exists\exists$OVH). *For every $\varepsilon > 0$ there exists $c > 1$ such that no algorithm running in time $n^{4-\varepsilon}$ can, given as input four collections of n-many subsets $\mathcal{A}, \mathcal{B}, \mathcal{C}$, and $\mathcal{D}$ of the universe $U := [c \log n]$, determine if there exists S_A in $\mathcal{A}$ such that for all S_B in $\mathcal{B}$ there exist $S_C \in \mathcal{C}$ and $S_D \in \mathcal{D}$ such that the intersection $S_A \cap S_B \cap S_C \cap S_D = \emptyset$ is empty.*

3 Exact Lower Bounds for 1-center

In this section, we prove conditional lower bounds for the 1-center problem. We start with some high-level remarks about the reductions and our contributions.

Previous work (for example [31, 14]) has already designed reductions from SETH and OVH to *closest pair* kinds of questions for the metrics we consider, and our work can be viewed as lifting these results to the 1-center question. As discussed in Section 2 this requires a new starting assumption (either Quantified SETH or the Hitting Set Conjecture) that has a different structure. Thus, technically, the main contribution is to adapt the gadgetry of previous work into new reductions with a different structure. In some cases, fundamental difficulties arise and we can only resolve them by requiring that the algorithm lists all solutions.

In all our reductions, we first reduce to the *Discrete 1-center with Facilities*, where given a set of clients $C \subseteq X$ and a set of facilities $F \subseteq X$ in the metric space, the goal is to find x in F which minimizes the maximum distance to every point in C. We then reduce a hard instance (F, C) of the Discrete 1-center with Facilities problem to an instance P of the standard Discrete 1-center problem (without facilities) by adding a few additional coordinates to points in $F \cup C$ and then introducing a new point/string s such that it is far from every point in C (in comparison to its distance from the points/strings in F). Thus we ensured that the 1-center of $P := F \cup C \cup \{s\}$ must be from F. Nevertheless, for the sake of compactness, this two step reduction in the proofs of this section is sometimes written as a one step reduction.

This section is organized as follows. In Section 3.1, we show the conditional subquadratic time lower bounds for 1-center in various metrics (Theorem 1). Next, in Section 3.2, we show the conditional subquartic time lower bound for 1-center in edit metric (also Theorem 2) and explain how to adapt it for 1-median. Finally, in Section 3.3, we show that there are no subquadratic listing algorithms for Euclidean 1-center even in low dimensions (Theorem 4).

3.1 Subquadratic Lower Bounds for 1-center when $d = \omega(\log n)$ in String and ℓ_p-metrics

In this subsection, we show that subquadratic time algorithms for 1-center do not exist in ℓ_p-metrics, Ulam metic, and edit metric, when $d = \omega(\log n)$.

▶ **Theorem 9** (Subquadratic Hardness of 1-center in ℓ_p-metrics)**.** *Let $p \in \mathbb{R}_{\geq 1} \cup \{0\}$. Assuming* HSC*, for every $\varepsilon > 0$, there exists $c > 1$ such that no algorithm running in time $n^{2-\varepsilon}$ can, given as input a point-set $P \subseteq \{0,1\}^d$, solve the discrete 1-center problem in ℓ_p-metric, where $|P| = n$ and $d = c \log n$.*

Proof. Let $(\mathcal{A} := (S_1, \ldots, S_n), \mathcal{B} := (T_1, \ldots, T_n), U)$ be an instance arising from HSC. We construct a point-set $P \subseteq \{0,1\}^d$ where $|P| = 2n + 1$ and $d = 5 \cdot |U| + 2$. We build the two maps $\tau_{\mathcal{A}} : \mathcal{A} \to \{0,1\}^d, \tau_{\mathcal{B}} : \mathcal{B} \to \{0,1\}^d$ and a special point $s \in \{0,1\}^d$ and the point-set P is then simply defined to be the union of $\{s\}$ and the images (range) of $\tau_{\mathcal{A}}$ and $\tau_{\mathcal{B}}$, i.e.,

$$P := \{\tau_{\mathcal{A}}(S) \mid S \in \mathcal{A}\} \cup \{\tau_{\mathcal{B}}(T) \mid T \in \mathcal{B}\} \cup \{s\}.$$

Let $U := \{u_1, \ldots, u_m\}$. We define our special point s as follows:

$$\forall i \in [5m+2],\ s_i := \begin{cases} 0 & \text{if } 1 \leq i \leq 3m \\ 1 & \text{if } 3m+1 \leq i \leq 5m+2 \end{cases}$$

For any $S \in \mathcal{A}$ we define $\tau_{\mathcal{A}}(S)$ as follows:

$$\forall i \in [5m+2],\ \tau_{\mathcal{A}}(S)_i := \begin{cases} 1 & \text{if } u_i \in S \text{ and } 1 \leq i \leq m \\ 0 & \text{if } u_i \notin S \text{ and } 1 \leq i \leq m \\ 0 & \text{if } u_{i-m} \in S \text{ and } m+1 \leq i \leq 2m \\ 1 & \text{if } u_{i-m} \notin S \text{ and } m+1 \leq i \leq 2m \\ 0 & \text{if } 2m+1 \leq i \leq 4m+1 \\ 1 & \text{if } 4m+2 \leq i \leq 5m+2 \end{cases}$$

For any $T \in \mathcal{B}$ we define $\tau_{\mathcal{B}}(T)$ as follows:

$$\forall i \in [5m+2],\ \tau_{\mathcal{B}}(T)_i := \begin{cases} 1 & \text{if } u_i \in T \text{ and } 1 \leq i \leq m \\ 0 & \text{if } u_i \notin T \text{ and } 1 \leq i \leq m \\ 0 & \text{if } m+1 \leq i \leq 2m \\ 0 & \text{if } u_{i-2m} \in T \text{ and } 2m+1 \leq i \leq 3m \\ 1 & \text{if } u_{i-2m} \notin T \text{ and } 2m+1 \leq i \leq 3m \\ 0 & \text{if } 3m+1 \leq i \leq 5m+2 \end{cases}$$

Notice that for any S, S' in $\mathcal{A}$ and T in $\mathcal{B}$, we have

$$\begin{aligned}\|\tau_{\mathcal{A}}(S)-\tau_{\mathcal{B}}(T)\|_p &= (|S|+|T|-2\cdot|S\cap T|+m-|S|+m-|T|+m+1)^{1/p}\\ &= (3m+1-2\cdot|S\cap T|)^{1/p}\,.\end{aligned}$$

$$\|\tau_{\mathcal{A}}(S)-\tau_{\mathcal{A}}(S')\|_p \le (2m)^{1/p}\,.$$

$$\|\tau_{\mathcal{A}}(S)-s\|_p = (2m+1)^{1/p}\,.$$

$$\|\tau_{\mathcal{B}}(T)-s\|_p = (3m+2)^{1/p}\,.$$

Suppose there exists S in $\mathcal{A}$ such that it intersects with every subset T in $\mathcal{B}$ then $\tau_{\mathcal{A}}(S)$ has distance strictly less than $(3m+1)^{1/p}$ with $\tau_{\mathcal{B}}(T)$ for every T in $\mathcal{B}$. Additionally, $\tau_{\mathcal{A}}(S)$ has distance at most $(2m)^{1/p}$ with $\tau_{\mathcal{A}}(S')$ for any $S' \in \mathcal{A}$ and distance $(2m+1)^{1/p}$ with s. Therefore, $\tau_{\mathcal{A}}(S)$ is at distance at most $(3m)^{1/p}$ from every point in P.

On the other hand, if for every S in $\mathcal{A}$ there exists T in $\mathcal{B}$ such that S and T are disjoint, then we show that for any point x in P there is a point y in P such that $\|x-y\|_p \ge (3m+1)^{1/p}$. Suppose $x := \tau_{\mathcal{B}}(T)$ for some $T \in \mathcal{B}$ then we have x is at distance $(3m+2)^{1/p}$ from s. Similarly if $x := s$ then it is at distance $(3m+2)^{1/p}$ from every $\tau_{\mathcal{B}}(T)$ for all $T \in \mathcal{B}$. Finally, if $x := \tau_{\mathcal{A}}(S)$ for some $S \in \mathcal{A}$ then from the soundness assumption we have that there exists T in $\mathcal{B}$ such that S and T are disjoint. Thus, x is at distance $(3m+1)^{1/p}$ from $\tau_{\mathcal{B}}(T)$. ◀

▶ Remark 10. For the ℓ_∞-metric, we can solve Discrete 1-center problem in $O(nd^2)$ time as follows. Given input point-set P, for every coordinate $i \in [d]$, determine a farthest pair of points (a_i, b_i) in the point-set when restricted to that coordinate. Note that discrete 1-center cost of P is equal to the cost of the discrete 1-center of the point-set $\{a_1, ..., a_d, b_1, ..., b_d\}$ when the center can be picked anywhere in P. Thus we can solve discrete 1-center in the ℓ_∞-metric in $O(nd^2)$ time, which is near linear time as long as $d = n^{o(1)}$.

The quadratic lower bound for 1-center in Ulam metric follows from the below lemma.

▶ **Lemma 11.** *Let Π_d denote the set of all permutations over $[d]$. For every $d \in \mathbb{N}$, there is a function $\eta : \{0,1\}^d \to \Pi_{2d}$, such that for all $a, b \in \{0,1\}^d$ the following holds:*

$$\mathsf{ed}(\eta(a), \eta(b)) = 2\cdot\|a-b\|_0.$$

Moreover, for any $a \in \{0,1\}^d$, $\eta(a)$ can be computed in $O(d)$ time.

Proof. Let $a \in \{0,1\}^d$. We define $\eta(a)$ as follows:

$$\forall i \in [2d],\ \eta(a)[i] = \begin{cases} i & \text{if } i = 2k-1 \text{ and } a_k = 0 \text{ for some } k \in \mathbb{N}\\ i & \text{if } i = 2k \text{ and } a_k = 0 \text{ for some } k \in \mathbb{N}\\ i+1 & \text{if } i = 2k-1 \text{ and } a_k = 1 \text{ for some } k \in \mathbb{N}\\ i-1 & \text{if } i = 2k \text{ and } a_k = 1 \text{ for some } k \in \mathbb{N}\end{cases}$$

Fix some $k \in [d]$ and $a, b \in \{0,1\}^d$. If $a_k = b_k$ then notice that $\eta(a)[2k] = \eta(b)[2k]$ and $\eta(a)[2k-1] = \eta(b)[2k-1]$. If $a_k \ne b_k$ then $\eta(a)[2k] = \eta(b)[2k-1]$ and $\eta(a)[2k-1] = \eta(b)[2k]$. Since the characters do not repeat, we have that the optimal distance is obtained by swapping which amounts to two edit operations. ◀

▶ **Corollary 12** (Subquadratic Hardness of 1-center in Ulam metric). *Assuming* HSC*, for every $\varepsilon > 0$ there exists $c > 1$ such that no algorithm running in time $n^{2-\varepsilon}$ can given as input a set P of n many permutations of $[d]$, solve the discrete 1-center problem in Ulam metric, where $|P| = n$ and $d = c\log n$.*

The quadratic lower bound for 1-center in Edit metric follows from the below lemma.

▶ **Lemma 13.** *For every $d \in \mathbb{N}$, there is a function $\eta : \{0,1\}^d \to \{0,1\}^{d'}$, such that for all $a, b \in \{0,1\}^d$ the following holds:*

$$\mathsf{ed}(\eta(a), \eta(b)) = \|a - b\|_0.$$

Moreover, for any $a \in \{0,1\}^d$, $\eta(a)$ can be computed in $O(d \log d)$ time.

Proof. Let $l_1, l_2, \ldots, l_d$ be d strings of length $10 \log d$ each made by realizing $10 \log d$ 0/1 bits uniformly at random. It follows that with high probability, the hamming distance as well as the edit distance of each pair l_i, l_j $(i \neq j)$ is $\Omega(\log d)$ [22]. For a string a, we define $\eta(a)$ in the following way: we make a string of size $d(10 \log d + 1)$ which consists of d consecutive blocks. Each block i starts with a_i and is followed by l_i. By putting all the blocks next to each other we obtain a string of size $d(10 \log d + 1)$ which we denote by $\eta(a)$. We prove in the following that $\mathsf{ed}(\eta(a), \eta(b)) = \|a - b\|_0$ holds for each pair of strings a and b.

$\mathsf{ed}(\eta(a), \eta(b)) \leq \|a - b\|_0$ immediately follows from the fact that by only toggling the first characters of some block of $\eta(a)$ we can turn $\eta(a)$ into $\eta(b)$ and this transformation only costs $\|a - b\|_0$. Note that we only toggle the first characters of the blocks whose corresponding characters in a and b are not the same.

Now, assume for the sake of contradiction that $\mathsf{ed}(\eta(a), \eta(b)) < \|a - b\|_0$ holds. This implies that for at least $d - \|a - b\|_0 + 1$ many blocks of a, the transformation cost is 0. In other words, for each of these blocks, there is a substring of length $10 \log d + 1$ in $\eta(b)$ which is completely the same as that block. Since the blocks are generated randomly, this can only happen if for some i, the i'th block of $\eta(a)$ is transformed into the i'th block of $\eta(b)$ and $a_i = b_i$. Thus, this implies that for at least $d - \|a - b\|_0 + 1$ different values of i we have $a_i = b_i$ which is contradiction. ◀

▶ **Corollary 14** (Subquadratic Hardness of 1-center in Edit metric). *Assuming* HSC*, for every $\varepsilon > 0$ there exists $c > 1$ such that no algorithm running in time $n^{2-\varepsilon}$ can given as input a point-set $P \subseteq \{0,1\}^d$ solve the discrete 1-center problem in edit metric, where $|P| = n$ and $d = c \log n \log \log n$.*

Next we prove much higher lower bounds for the Edit metric when d is larger.

3.2 Subquartic Lower Bound for 1-center when $d = n$ in Edit metric

We now present our lower bound under Quantified SETH which offers a conceptual novelty since as discussed in Section 2 it is the first time (to our knowledge) that more than two quantifier alternations are utilized.

▶ **Theorem 15** (Subquartic Hardness of 1-center in Edit metric). *Assuming Quantified SETH, for every $\varepsilon > 0$ no algorithm running in time $n^{4-\varepsilon}$ can given as input a point-set $P \subseteq \{0,1\}^n$ solve the discrete 1-center problem in edit metric, where $|P| = n$.*

Proof. Let us first reduce to the 1-center problem with facilities where there are two sets of binary strings, a set of clients C and a set of facilities F and the goal is to decide if there is a string in F that has ED at most τ to all strings in C. Given an instance $\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D}$ of $\exists\forall\exists\exists$OVH we construct C and F as follows.

First we will use the following lemma that follows from the existing reductions from OVH to ED [4, 7] (the latter reference gets the alphabet size down to 2).

▶ **Lemma 16** ([7]). *There are two linear time algorithms such that: each algorithm takes a set (A or B) of n binary vectors of length d and constructs (independently of the other) a binary string (s_A or s_B) of length $O(nd)$ with the following property for a fixed value τ that only depends on n, d: $ED(s_A, s_B) < \tau$ if there is a pair of orthogonal vectors $v_A \in A, v_B \in B$ and $ED(s_A, s_B) \geq \tau$ otherwise.*

For a set $X \subseteq [d]$ let $v(X) \in \{0,1\}^d$ be the natural encoding of the set as a binary vector where $v(X)[i] = 1$ iff $i \in X$. Note that two vectors are orthogonal iff the two corresponding sets are disjoint.

Now, for each set $S_A \in \mathcal{A}$ define the set of n vectors $A = \{v(X) \mid S_C \in \mathcal{C}, X = S_A \cap S_C\}$ representing the n sets that result from intersecting S_A with any set in $\mathcal{C}$. Similarly, for each set $S_B \in \mathcal{B}$ define the set of n vectors $B = \{v(X) \mid S_D \in \mathcal{D}, X = S_B \cap S_D\}$.

It follows that there is an orthogonal pair $v_A \in A, v_B \in B$ iff there exist $S_C \in \mathcal{C}$ and $S_D \in \mathcal{D}$ such that $S_A \cap S_B \cap S_C \cap S_D = \emptyset$. Therefore, if we use the algorithms in the above lemma to encode each set A with a string s_A and add it to the set of facilities F, and also encode each set B with a string s_B and add it into the set of clients C we get the reduction we are after: By the definition of the ∃∀∃∃OVH problem, there is a string $s_A \in F$ such that for all strings $s_B \in C$ we have $ED(s_A, s_B) < \tau$ if and only if the given ∃∀∃∃OVH instance is a yes-instance.

Finally, we reduce to the basic 1-center problem (without facilities). Suppose that the strings in F, C have length m. We simply construct an instance $P \subseteq \{0,1\}^{4m}$ of 1-center as follows.

$$P := \{1^m \circ f \circ 0^{2m} \mid f \in F\} \cup \{1^m \circ c \circ 1^{2m} \mid c \in C\} \cup \{0^{4m}\}.$$

The following simple facts about the ED of the transformed strings show that the optimal center in P must be from $\{1^m \circ f \circ 0^{2m} \mid f \in F\}$ and its cost would be smaller than $2m + \tau$ iff the original ∃∀∃∃OVH instance is a yes-instance.

▷ Claim 17. Let x, y be two binary strings of length m with ED exactly t.

- $ED(1^m \circ x \circ 0^{2m}, 1^m \circ y \circ 0^{2m}) \leq m$.
- $ED(1^m \circ x \circ 0^{2m}, 0^{4m}) \leq 2m$.
- $ED(1^m \circ x \circ 0^{2m}, 1^m \circ y \circ 1^{2m}) = 2m + t$.
- $ED(1^m \circ x \circ 1^{2m}, 0^{4m}) \geq 3m$.

The first and second items follow from the straightforward alignment of the strings. The fourth item follows because $ED(0^\ell, 1^\ell) = \ell$. The third item requires a bit more care. First, to see that the ED is at most $2m + t$ consider the alignment that maps x to y optimally at cost t and then maps the other parts in the straightforward way at cost $2m$. Now suppose for contradiction that there was a better alignment. This alignment must match one of the new letters (from the transformation) to x or y; otherwise it would yield an alignment between x, y at cost smaller than t. But any alignment that matches the 1 letters on the left to x or y can be corrected so that the 1^m parts on the left are matched to each other, without affecting the cost. Similarly, any matching between the letters on the right to x or y can be corrected without increasing the cost. Suppose that a 0 from the right is matched to y. This implies that one of the 1's to the right of y must be deleted (because there are no longer enough 0's in the other string to get substituted with all of them), and a corrected alignment that instead substitutes the 0 with a 1 (reducing the number of such deletions by one) and leaves the mate in y unmatched does not have a higher cost. We refer the reader to [7] for more formal proofs of such claims. ◀

▶ Remark 18. The above reduction to Edit also work for the 1-median problem but with two key differences. The first and main difference is that, since we take the sum instead of the max, the cost in the objective may now be affected by non-orthogonal pairs and it is no longer sufficient to have gadgets that give distance $< \tau$ or $\geq \tau$ depending on the orthogonality. Instead, we need gadgets that guarantee that the distance is either $< \tau$ or exactly τ. Fortunately, such requirements can be accomplished, see e.g. Theorem 4 in [4]. The second difference is that we do not need the $\forall$ quantifier in the starting assumption; the sum is powerful enough to support the (standard) $\exists\exists\exists\exists$ structure type. Therefore, the lower bounds for 1-median can be based on the standard SETH rather than the Quantified-SETH.

3.3 Subquadratic Lower Bounds for 1-center in Low dimensional Euclidean space

In this subsection, we show that an algorithm with subquadratic running time does not exist in the low dimensional Euclidean metric for the 1-center problem. Our proof essentially adopts ideas developed in [35, 10]. We note that this result is surprising as there is a near linear time algorithm for 1-center in the low dimensional ℓ_1-metric.

▶ Remark 19. For the ℓ_1-metric, we can solve Discrete 1-center problem in $O(n2^{2d})$ time by using the isometric embedding of the ℓ_1-metric to the ℓ_∞-metric [27], and then noting Remark 10.

▶ **Theorem 20.** *Assuming* HSC*, there exists a constant $\eta > 1$ such that for every $\varepsilon > 0$, no algorithm running in time $n^{2-\varepsilon}$ can given as input a point-set $P \subseteq \mathbb{R}^d$ and a positive real α output all points in P whose 1-center cost in the Euclidean metric is at most α, where $|P| = n$, $d = \eta^{\log^* n}$, and representing each vector requires at most $\widetilde{O}(\log n)$ bits.*

Proof of Theorem 20. We prove the theorem statement by contradiction. Suppose for some $\varepsilon > 0$ there is an algorithm $\mathcal{T}$ running in time $n^{2-\varepsilon}$ that can given as input a point-set $P \subseteq \mathbb{R}^d$ and a positive real α output all points in P whose 1-center cost in the Euclidean metric is at most α, where $|P| = n$, $d = \eta^{\log^* n}$, and each vector is of at most $k \log n$ bit entries (for some constant integer k).

Let $(\mathcal{A} := (S_1, \ldots, S_n), \mathcal{B} := (T_1, \ldots, T_n), U)$ be an instance arising from HSC, where $|U| = c \log n$. We think of each set in $\mathcal{A}$ and $\mathcal{B}$ as its characteristic vector in $\{0,1\}^{c \log n}$. We show how we can decide this instance in $n^{2-\frac{\varepsilon}{2}}$ time using $\mathcal{T}$, thus contradicting HSC.

We need the following theorem from Chen [10].

▶ **Theorem 21** (Chen [10])**.** *Let b, ℓ be two sufficiently large integers. There is a reduction $\psi_{b,\ell} : \{0,1\}^{b\cdot\ell} \to \mathbb{Z}^\ell$ and a set $V_{b,\ell} \subseteq \mathbb{Z}$, such that for every $x, y \in \{0,1\}^{b\cdot\ell}$,*

$$x \cdot y = 0 \Leftrightarrow \psi_{b,\ell}(x) \cdot \psi_{b,\ell}(y) \in V_{b,\ell}$$

and

$$0 \leq \psi_{b,\ell}(x)_i < \ell^{6^{\log^*(b)}\cdot b}$$

for all possible x and $i \in [\ell]$. Moreover, the computation of $\psi_{b,\ell}(x)$ takes $\mathrm{poly}(b \cdot \ell)$ time, and the set $V_{b,\ell}$ can be constructed in $O\left(\ell^{O(6^{\log^*(b)}\cdot b)} \cdot \mathrm{poly}(b \cdot \ell)\right)$ time.

We use the above theorem with $\ell = 7^{\log^* n}$ and $b = |U|/\ell$. Note that if $\ell = 7^{\log^* n}$ then $\log\left(\ell^{6^{\log^*(b)}\cdot b}\right) = o(\log n)$. All of the below construction details appears in [35, 10] and we skip many of the calculations and claim proofs hereafter. Our contributions are mainly in using these previously known constructions in a new way to prove the theorem statement. In particular, for every $t \in V_{b,\ell}$ we create an instance $(P_t \subseteq \mathbb{R}^{(\ell+1)^2+3}, \alpha := \sqrt{2n^5-1})$ of 1-center as follows.

For every[4] $S_i \in \mathcal{A}$ (resp. $T_j \in \mathcal{B}$) we first define a point $p_i^t \in \mathbb{Z}^{\ell+1}$ (resp. $q_j^t \in \mathbb{Z}^{\ell+1}$) as follows:

$$p_i^t := (\psi_{b,\ell}(S_i), t) \text{ (resp. } q_j^t := (\psi_{b,\ell}(T_j), -1)).$$

It is then easy to verify that $S_i \cap T_j = \emptyset$ if and only if there exists some $t \in V_{b,\ell}$ such that $\langle p_i^t, q_j^t \rangle = 0$. Next for every $p_i^t \in \mathbb{Z}^{\ell+1}$ (resp. $q_j^t \in \mathbb{Z}^{\ell+1}$) we define $\widetilde{p}_i^t \in \mathbb{Z}^{(\ell+1)^2}$ (resp. $\widetilde{q}_j^t \in \mathbb{Z}^{(\ell+1)^2}$) as follows:

$$\forall a, b \in [\ell+1],\ \widetilde{p}_i^t(a,b) := p_i^t(a) \cdot p_i^t(b) \text{ (resp. } \widetilde{q}_j^t(a,b) := -q_j^t(a) \cdot q_j^t(b)).$$

It is then straightforward to verify that $\langle p_i^t, q_j^t \rangle = 0$ if and only if $\langle \widetilde{p}_i^t, \widetilde{q}_j^t \rangle \geq 0$.

Finally, we have our pointset $P_t \in \mathbb{R}^{(\ell+1)^2+3}$ defined as follows:

$$P_t := \underbrace{\left\{ \left(\widetilde{p}_i^t, \sqrt{n^5 - \|\widetilde{p}_i^t\|_2^2}, 0, 0 \right) \middle| S_i \in \mathcal{A} \right\}}_{P_t^{\mathcal{A}}} \bigcup \underbrace{\left\{ \left(-\widetilde{q}_j^t, 0, \sqrt{n^5 - \|\widetilde{q}_j^t\|_2^2}, \sqrt{n^5} \right) \middle| T_j \in \mathcal{B} \right\}}_{P_t^{\mathcal{B}}} \cup \{\vec{0}\},$$

where $\vec{0} = (0, 0, \ldots, 0)$.

It can then be verified that $\langle \widetilde{p}_i^t, \widetilde{q}_j^t \rangle \geq 0$ if and only if the distance between $\left(\widetilde{p}_i^t, \sqrt{n^5 - \|\widetilde{p}_i^t\|_2^2}, 0 \right)$ and $\left(-\widetilde{q}_j^t, 0, \sqrt{n^5 - \|\widetilde{q}_j^t\|_2^2} \right)$ is at least $\sqrt{2n^5}$; otherwise their distance is at most $\sqrt{2n^5-1}$. Also note that any pair of points in $P_t^{\mathcal{A}}$ or any pair of points in $P_t^{\mathcal{B}}$ are at distance at most $\sqrt{2n^5-1}$ from each other. Finallt, note that the distance between any point in $P_t^{\mathcal{B}}$ and $\vec{0}$ is exactly $\sqrt{2n^5}$ and the distance between any point in $P_t^{\mathcal{A}}$ and $\vec{0}$ is exactly $\sqrt{n^5}$.

We run $\mathcal{T}$ on $(P_t, \alpha := \sqrt{2n^5-1})$ for every $t \in V_{b,\ell}$. Let $\mathcal{O}_t \subseteq P_t$ be the output of running $\mathcal{T}$ on (P_t, α). In other words for every $t \in V_{b,\ell}$ and every $p \in \mathcal{O}_t$ we have that for every $p' \in P_t$, $\|p - p'\|_2 \leq \sqrt{2n^5-1}$.

We claim that there exists S in $\mathcal{A}$ such that it intersects with every subset T in $\mathcal{B}$ if and only if there exists $i \in [n]$ such that for all $t \in V_{b,\ell}$, we have $\left(\widetilde{p}_i^t, \sqrt{n^5 - \|\widetilde{p}_i^t\|_2^2}, 0 \right) \in \mathcal{O}_t$.

Suppose there exists S_{i^*} in $\mathcal{A}$ such that it intersects with every subset T in $\mathcal{B}$. Fix $t \in V_{b,\ell}$. We have that $\left(\widetilde{p}_{i^*}^t, \sqrt{n^5 - \|\widetilde{p}_{i^*}^t\|_2^2}, 0 \right)$ is at distance at most $\sqrt{2n^5-1}$ from every other point in $P_t^{\mathcal{A}}$ just from construction. Suppose there is $\left(-\widetilde{q}_j^t, 0, \sqrt{n^5 - \|\widetilde{q}_j^t\|_2^2} \right) \in P_t^{\mathcal{B}}$ such that their distance is greater than $\sqrt{2n^5-1}$ then from the construction, their distance must be $\sqrt{2n^5}$, which implies that $S_{i^*} \cap T_j = \emptyset$, a contradiction.

On the other hand, if for every S in $\mathcal{A}$ there exists T in $\mathcal{B}$ such that S and T are disjoint then we show that for any point $\left(\widetilde{p}_i^t, \sqrt{n^5 - \|\widetilde{p}_i^t\|_2^2}, 0 \right)$ there exists $t \in V_{b,\ell}$ such that $\left(\widetilde{p}_i^t, \sqrt{n^5 - \|\widetilde{p}_i^t\|_2^2}, 0 \right) \notin \mathcal{O}_t$. Fix $i \in [n]$. Let $T_j \in \mathcal{B}$ such that $S_i \cap T_j = \emptyset$. Let $t^* := \psi_{b,\ell}(S_i) \cdot \psi_{b,\ell}(T_j)$. From Theorem 21 we have that $t^* \in V_{b,\ell}$. Thus $\left(\widetilde{p}_i^{t^*}, \sqrt{n^5 - \|\widetilde{p}_i^{t^*}\|_2^2}, 0 \right)$ and $\left(-\widetilde{q}_j^{t^*}, 0, \sqrt{n^5 - \|\widetilde{q}_j^{t^*}\|_2^2} \right)$ in P_{t^*} are at distance at least $\sqrt{2n^5}$ and thus $\left(\widetilde{p}_i^{t^*}, \sqrt{n^5 - \|\widetilde{p}_i^{t^*}\|_2^2}, 0 \right) \notin \mathcal{O}_{t^*}$.

Finally, note that the total run time was $O(n^{2-\varepsilon} \cdot |V_{b,\ell}|) = O(n^{2-\varepsilon} \log n) < n^{2-\frac{\varepsilon}{2}}$. ◀

[4] Recall that we think of S_i and T_j through their characteristic vector.

4 An $n^{2.5}$ time $1+\epsilon$ Approximation Algorithm for 1-Center in Ulam Metric when $d = n$

In this section, we consider the 1-center problem under Ulam metric. More precisely, we consider a problem where n strings $s_1, s_2, \ldots, s_n$ are given as input and our goal is to find a string s_k such that the maximum distance of s_k from the rest of the strings is minimized. Our focus here is on the Ulam metric.

We assume throughout this section that the length of all strings is equal to d. Our algorithm for this case is two-fold. Let o be the value of the solution (i.e., the maximum distance of the center of the strings to the rest of the strings is exactly equal to o). If o is lower bounded by $\sqrt{d}$, previous work on Ulam distance gives us a $1+\epsilon$ approximate solution for center in the following way: We iterate over all pairs of strings and each time we estimate their Ulam distance via the algorithm of Naumovitz, Saks, and Seshadhri [28] for approximating the Ulam distance of each pair. When the Ulam distance of two strings is equal to u, their algorithm takes time $\widetilde{O}_\epsilon(d/u + \sqrt{d})$ to $1+\epsilon$ approximate the solution. Thus, we only run their algorithm up to a runtime of $\widetilde{O}_\epsilon(\sqrt{d})$ to either obtain a $1+\epsilon$ approximate solution for the Ulam distance or verify that the Ulam distance is smaller than $\sqrt{d}$. It follows that if $o \geq \sqrt{d}$ this information is enough for us to approximate the 1-center problem within a factor $1+\epsilon$ and the runtime of the algorithm is bounded by $\widetilde{O}_\epsilon(n^2\sqrt{d})$. Thus, it only remains to design an algorithm for the low-distance regime.

From here on, we assume that $o \leq \sqrt{d}$. In this case, we take an arbitrary string (say s_1) and compute the Ulam distance of that string to all the other strings. In addition to this, we also keep track of the changes that convert s_1 into all the strings. It follows that since $o \leq \sqrt{d}$, the distance of s_1 to all the strings is bounded by at most $2\sqrt{d}$. Thus, via the transformations we compute in this step, we would be able to make a transformation from any s_i to any s_j with at most $4\sqrt{d}$ operations (we can combine the transformation from s_1 to s_i and the transformation from s_1 to s_j). Using this information, we can determine the exact Ulam distance of every string s_i to every string s_j in the following way:

We start with the non-optimal transformation from s_i to s_j that uses at most $4\sqrt{d}$ operations. We then split the characters from $[1, \ldots, d]$ into buckets such that in each bucket all the characters are next to each other and they appear in the same order in the two strings. To be more precise, consider the following procedure: color each character of s_i and s_j which is touched in the transformation (deleted, added, or changed) in red and the rest blue. Each set of consecutive blue characters and each single red character makes a bucket. It follows that because there is a transformation from s_i to s_j with at most $4\sqrt{d}$ operations, the total number of buckets would be bounded by $O(\sqrt{d})$. Moreover, there exists an optimal transformation wherein either all characters of each buckets are deleted/inserted or all characters of each bucket remain intact. This implies that we can compress the two strings into smaller strings by replacing each bucket with a single character. The insertion and deletion of these special characters then has a cost proportional to the size of the bucket. This way, the size of the two strings would be bounded by $O(\sqrt{d})$ and thus we can compute the Ulam distance of the two strings in time $\widetilde{O}(\sqrt{d})$. Therefore, we can compute the center of the strings in time $\widetilde{O}_\epsilon(nd + n^2\sqrt{d})$.

▶ **Theorem 3.** *There exists a $1+\epsilon$ approximation algorithm for the 1-center under Ulam metric that runs in time $\widetilde{O}_\epsilon(nd + n^2\sqrt{d})$.*

Proof of Theorem 3. The outline of the algorithm along with its runtime analysis is given earlier. Here we prove that the approximation factor of the algorithm is bounded by $1+\epsilon$. In case $o \geq \sqrt{d}$, we use the $1+\epsilon$ approximation algorithm of Naumovitz, Saks, and Seshadhri [28]

Algorithm 1 1-center of n strings under Ulam metric.

```
Data: $s_1, s_2, \ldots, s_n$
Result: 1-center
$o \leftarrow \infty$;
for $i \leftarrow 1$ to $n$ do
    $mx \leftarrow -1$;
    for $j \leftarrow 1$ to $n$ do
        Run [28] on $s_i$ and $s_j$ up to $\widetilde{O}_\epsilon(\sqrt{d})$ steps;
        if the algorithm terminates then
            $mx \leftarrow \max\{mx, \text{the output of the algorithm}\}$;
        end
    end
    $o \leftarrow \min\{o, mx\}$;
end
if $o \neq -1$ then
    return o;
end
else
    $o \leftarrow \infty$;
    for $i \leftarrow 1$ to $n$ do
        $tr_i \leftarrow$ optimal transformation between $s_1$ and $s_i$;
    end
    for $i \leftarrow 1$ to $n$ do
        $mx \leftarrow -1$;
        for $j \leftarrow 1$ to $n$ do
            $(s_i^*, s_j^*) \leftarrow$ compressed versions of $(s_i, s_j)$ based on $tr_i$ and $tr_j$;
            $mx \leftarrow \max\{mx, \text{the Ulam distance of } s_i^* \text{ and } s_j^*\}$;
        end
        $o \leftarrow \min\{o, mx\}$;
    end
    return $o$;
end
```

for each pair of strings up to a runtime of $\widetilde{O}_\epsilon(\sqrt{d})$. If the algorithm gives an estimation before we terminate it, we take the value into account when determining the maximum distance for the strings involved. It follows that since $o \geq \sqrt{d}$, then for each string s_x, there is one string s_y whose distance to s_x is at least $\sqrt{d}$ and thus the maximum distance we determine for each string is a $1+\epsilon$ approximation of the optimal value.

Next, we show that in case $o \leq \sqrt{d}$, our algorithm determines the Ulam distance of each pair exactly and thus solves the 1-center problem correctly. In order to determine the Ulam distance between s_i and s_j, we begin with a transformation of size at most $4\sqrt{d}$ between the two strings. We then mark all the characters that are either deleted or inserted in this transformation and all the characters that are next to these characters. We then compress the two strings in the following way: each marked character becomes a single character with the same value. Each maximal interval of unmarked characters that are next to each other also become a single character whose value represents the entire interval. Therefore, the compressed strings have $O(\sqrt{d})$ characters each. It follows that the Ulam distance of the compressed strings is exactly equal to the Ulam distance of the original strings. Moreover, even though for the compressed strings the operations have arbitrary costs, we can still solve Ulam distance in time proportional to the length of the strings which results in an algorithm with runtime $\widetilde{O}(\sqrt{d})$ for computing Ulam distance between each pair. ◀

5 Hardness of Approximation of 1-center in String and ℓ_p-metrics

In this section, we prove hardness of approximation results for the 1-center problem. A background on error correcting codes is detailed in Appendix A.

▶ **Theorem 22** (Subquadratic Inapproximability of 1-center in ℓ_p-metrics)**.** *Let $p \in \mathbb{R}_{\geq 1} \cup \{0\}$. Assuming* HSC*, for every $\varepsilon > 0$ there exists $\delta > 0$ such that no algorithm running in time $n^{2-\varepsilon}$ can given as input a point-set $P \subseteq \{0,1\}^d$ and a positive real α output all points in P whose 1-center cost in the ℓ_p-metric is at most $\alpha \cdot (1+\delta)$, where $|P| = n$ and $d = O_\varepsilon(\log n)$.*

Proof. Fix $p \in \mathbb{R}_{\geq 1} \cup \{0\}$. We prove the theorem statement by contradiction. Suppose for some $\varepsilon > 0$ there is an algorithm $\mathcal{T}$ running in time $n^{2-\varepsilon}$ that can for every $\delta > 0$, given as input a point-set $P \subseteq \mathbb{R}^d$ and a positive real α output all points in P whose 1-center cost in the ℓ_p-metric is at most $\alpha \cdot (1+\delta)$, where $|P| = n$ and $d = O_\varepsilon(\log n)$ (dependency on ε will become clear later in the proof).

Let $(\mathcal{A} := (S_1, \ldots, S_n), \mathcal{B} := (T_1, \ldots, T_n), U)$ be an instance arising from HSC, where $|U| = c \log n$. We think of each set in $\mathcal{A}$ and $\mathcal{B}$ as its characteristic vector in $\{0,1\}^{c \log n}$. We show how we can decide this instance in $n^{2-\frac{\varepsilon}{2}}$ time using $\mathcal{T}$, thus contradicting HSC.

The construction below is exactly the same as the one suggested by Rubinstein [31]. We however, use this construction to fit our purposes of proving lower bound for the 1-center problem.

Algebrization. Fix $T = 2c/\varepsilon$. Let q be the smallest prime greater than T (i.e., $q < 2 \cdot T$). Let $m := c \log n$. Let $C^1_{m/T}$ and $C^2_{m/T}$ be the codes guaranteed in Theorem 26 over $\mathbb{F}_{q^2}$ with block length $\ell \leq \lambda m/T$.

Let $\widetilde{C} \subseteq C^2_{m/T}$ such that $\omega \in \widetilde{C}$ if and only if $\omega\ |_{[m/T]} = \vec{0}$ (i.e., ω has a zero entry in each of the first m/T coordinates). For every $\omega \in \widetilde{C}$ we define two functions $\tau^\omega_{\mathcal{A}}, \tau^\omega_{\mathcal{B}} : \{0,1\}^m \to \{0,1\}^r$, where $r := q^{4(T+2)} \times \ell$. We can thus index every $i \in [r]$ using elements in $\mathbb{F}^T_{q^2} \times \mathbb{F}^T_{q^2} \times [\ell]$.

Fix $x \in \{0,1\}^m$. Let $x = (x^1, \ldots, x^T) \in \{0,1\}^m$ where for all $i \in [T]$ we have $x^i \in \{0,1\}^{m/T}$. We define $\tau^\omega_{\mathcal{A}}(x)$ coordinate wise. Fix $\zeta \in [r]$ and we think of ζ as follows:

$$\zeta = \big((\mu^{\mathcal{A}}_1, \ldots, \mu^{\mathcal{A}}_{T+2}), (\mu^{\mathcal{B}}_1, \ldots, \mu^{\mathcal{B}}_{T+2}), j\big) \in \mathbb{F}^{T+2}_{q^2} \times \mathbb{F}^{T+2}_{q^2} \times [\ell]. \tag{1}$$

We define $\tau^\omega_{\mathcal{A}}(x)_\zeta$ to be 1 if and only if:

$$\sum_{i \in [T+2]} \mu^{\mathcal{A}}_i \cdot \mu^{\mathcal{B}}_i = \omega(j) \quad \text{and} \quad \forall i \in [T],\ \mu^{\mathcal{A}}_i = C^1_{m/T}(x^i)_j, \text{ and } \mu^{\mathcal{A}}_{T+1} = 0,\ \mu^{\mathcal{A}}_{T+2} = C^1_{m/T}(\mathbb{1}^{m/T})_j.$$

Similarly, we define $\tau^\omega_{\mathcal{B}}(x)$ coordinate wise. Fix $\zeta \in [r]$ and we think of ζ as in (1). We define $\tau^\omega_{\mathcal{B}}(x)_\zeta$ to be 1 if and only if:

$$\sum_{i \in [T+2]} \mu^{\mathcal{A}}_i \cdot \mu^{\mathcal{B}}_i = \omega(j) \quad \text{and} \quad \forall i \in [T],\ \mu^{\mathcal{B}}_i = C^1_{m/T}(x^i)_j \text{ and } \mu^{\mathcal{B}}_{T+1} = C^1_{m/T}(\mathbb{1}^{m/T})_j,\ \mu^{\mathcal{B}}_{T+2} = 0.$$

Construction. For every $S_i \in \mathcal{A}$, we define $s_i^\omega := \tau_{\mathcal{A}}^\omega(S_i)$. Further, we define $\widetilde{s}_i^\omega = (s_i^\omega, \mathbb{1}^r - s_i^\omega, \mathbb{1}^{2r}) \in \{0,1\}^{4r}$. For every $T_j \in \mathcal{B}$, we define $t_j^\omega := \tau_{\mathcal{B}}^\omega(T_j)$. Further, we define $\widetilde{t}_j^\omega = (\mathbb{1}^r - t_j^\omega, t_j^\omega, 0^{2r}) \in \{0,1\}^{4r}$.

We define the point-set P_ω to be $P_\omega^{\mathcal{A}} := \{\widetilde{s}_i^\omega \mid S_i \in \mathcal{A}\} \cup P_\omega^{\mathcal{B}} := \{\widetilde{t}_j^\omega \mid T_j \in \mathcal{B}\} \cup \{\mathbb{1}^{4r}\}$. Let $\alpha := (2q^{4(T+2)} - 4q^{2(T+1)}) \cdot \ell + 2r + \ell$. Let $\delta := 1/(4q^{4T} - 4q^{2T-2} + 1)$.

Analysis. We run $\mathcal{T}$ on (P_ω, α) for every $\omega \in \widetilde{C}$. Let $\mathcal{O}_\omega \subseteq P_\omega$ be the output of running $\mathcal{T}$ on (P_ω, α). In other words for every $\omega \in \widetilde{C}$ and every $s \in \mathcal{O}_t$ we have that for every $s' \in P_\omega$, $\|s - s'\|_p \leq (1+\delta)^{1/p} \cdot \alpha^{1/p}$.

We claim that there exists S in $\mathcal{A}$ such that it intersects with every subset T in $\mathcal{B}$ if and only if there exists $i \in [n]$ such that for all $\omega \in \widetilde{C}$, we have $\widetilde{s}_i^\omega \in \mathcal{O}_\omega$.

Suppose there exists S_{i^*} in $\mathcal{A}$ such that it intersects with every subset T in $\mathcal{B}$. Fix $\omega \in \widetilde{C}$. We have that $\widetilde{s}_{i^*}^\omega$ is at distance at most $(2r)^{1/p}$ from every other point in $P_\omega^{\mathcal{A}}$ just from construction. Suppose there is $\widetilde{t}_j^\omega \in P_\omega^{\mathcal{B}}$ such that their distance is greater than $\alpha^{1/p}$ then from the construction, their distance must be at least $(1+\delta)^{1/p} \cdot \alpha^{1/p}$, which implies that $S_{i^*} \cap T_j = \emptyset$, a contradiction.

On the other hand, if for every S in $\mathcal{A}$ there exists T in $\mathcal{B}$ such that S and T are disjoint then we show that for any point $\widetilde{s}_i^\omega$ there exists $\omega \in \widetilde{C}$ such that $\widetilde{s}_i^\omega \notin \mathcal{O}_\omega$. Fix $i \in [n]$. Let $T_j \in \mathcal{B}$ such that $S_i \cap T_j = \emptyset$. Let $\omega^* := \sum_{e \in [T]} C^1_{m/T}(S_i^e) \cdot C^1_{m/T}(T_j^e)$. From Theorem 26 we have that $\omega^* \in \widetilde{C}$. Thus $\widetilde{s}_i^{\omega^*}$ and $\widetilde{t}_j^{\omega^*}$ in P_{ω^*} are at distance at least $(1+\delta)^{1/p} \cdot \alpha^{1/p}$ and thus $\widetilde{s}_i^{\omega^*} \notin \mathcal{O}_{\omega^*}$. Also, note that for all $\omega \in \widetilde{C}$, we have that every point in $P_\omega^{\mathcal{B}}$ is at distance at least $(3r)^{1/p}$ from $\mathbb{1}^{4r}$.

Finally, note that the total run time was $O(n^{2-\varepsilon} \cdot |\widetilde{C}|) = O(n^{2-\varepsilon+\frac{c}{T}}) < n^{2-\frac{\varepsilon}{2}}$. ◀

We remark that the above construction is the same as the one in [31] albeit for a different problem (nearest neighbors problem).

Theorem 22 readily extend to the edit metric from the below statement and to the Ulam metric from Lemma 11.

▶ **Lemma 23** (Rubinstein [31]). *For large enough $d \in \mathbb{N}$, there is a function $\eta : \{0,1\}^d \to \{0,1\}^{d'}$, where $d' = O(d \log d)$, such that for all $a, b \in \{0,1\}^d$ the following holds for some constant $\lambda > 0$:*

$$|\mathsf{ed}(\eta(a), \eta(b)) - \lambda \cdot \log d \cdot \|a - b\|_0| = o(d').$$

Moreover, for any $a \in \{0,1\}^d$, $\eta(a)$ can be computed in $2^{o(d)}$ time.

A Error Correcting Codes

An error correcting code C over alphabet Σ is a function $C : \Sigma^m \to \Sigma^\ell$ where m and ℓ are positive integers which are referred to as the *message length* and *block length* of C respectively. Intuitively, the function C encodes an original message of length m to an encoded message of length ℓ. The *rate* of a code $\rho(C)$ is defined as the ratio between its message length and its block length, i.e., $\rho(C) = {}^m/_\ell$. The *relative distance* of a code, denoted by $\delta(C)$, is defined as $\min\limits_{x \neq y \in \Sigma^m} \delta(C(x), C(y))$ where $\delta(C(x), C(y))$ is the *relative Hamming distance* between $C(x)$ and $C(y)$, i.e., the fraction of coordinates on which $C(x)$ and $C(y)$ disagree.

In this paper, we require our codes to have some special algebraic properties which have been shown to be present in algebraic geometric codes [17]. First, we will introduce a couple of additional definitions.

▶ **Definition 24** (Systematicity). *Given $s \in \mathbb{N}$, a code $C : \Sigma^m \to \Sigma^\ell$ is* s-systematic *if there exists a size-s subset of $[\ell]$, which for convenience we identify with $[s]$, such that for every $x \in \Sigma^s$ there exists $w \in \Sigma^m$ in which $x = C(w)\mid_{[s]}$.*

▶ **Definition 25** (Degree-t Closure). *Let Σ be a finite field. Given two codes $C : \Sigma^m \to \Sigma^\ell, C' : \Sigma^{m'} \to \Sigma^\ell$ and positive integer t, we say that C' is a degree-t closure of C if, for every $w_1, \ldots, w_r \in \Sigma^m$ and $P \in \mathbb{F}[X_1, \ldots, X_r]$ of total degree at most t, it holds that $\omega := P(C(w_1), \ldots, C(w_r))$ is in the range of C', where $\omega \in \Sigma^\ell$ is defined coordinate-wise by the equation $\omega_i := P(C(w_1)_i, \ldots, C(w_r)_i)$.*

Below we provide a self-contained statement of the result we need; it follows from Theorem 7 of [32], which gives an efficient construction of the algebraic geometric codes based on [17]'s explicit towers of function fields.

▶ **Theorem 26** ([17, 32]). *There is a constant $\lambda > 0$ such that for any prime $q \geq 7$, there are two code families $\mathcal{C}^1 = \{C_n^1\}_{n\in\mathbb{N}}$, $\mathcal{C}^2 = \{C_n^2\}_{n\in\mathbb{N}}$ such that the following holds for all $n \in \mathbb{N}$,*

- *C_n^1 and C_n^2 are n-systematic code with alphabet $\mathbb{F}_{q^2}$,*
- *C_n^1 and C_n^2 have block length less than λn.*
- *C_n^2 has relative distance $\geq {}^1/_2$,*
- *C_n^2 is a degree-2 closure of C_n^1, and,*
- *Any codeword in C_n^1 or C_n^2 can be computed in poly(n) time.*

We point the interested reader to [21] for a proof sketch of the above theorem.

Probabilistic Metric Embedding via Metric Labeling

Abstract

We consider probabilistic embedding of metric spaces into ultra-metrics (or equivalently to a constant factor, into hierarchically separated trees) to minimize the expected distortion of any pairwise distance. Such embeddings have been widely used in network design and online algorithms. Our main result is a polynomial time algorithm that approximates the optimal distortion on any instance to within a constant factor. We achieve this via a novel LP formulation that reduces this problem to a probabilistic version of uniform metric labeling.

1 Introduction

Embedding a finite metric space into simpler spaces such as trees, ultrametrics, and Euclidean spaces (called "target metrics") has a wide range of applications, and has been widely studied. In such an embedding, the distance between any pair of points should be at least as large as in the original space, while being at most a factor of α larger, where α is termed the *distortion* of the embedding. The goal is to design an embedding into a given target metric whose distortion is as small as possible. We will denote by n the number of points in the metric space.

A lot of attention has focused on probabilistic embeddings, which construct a distribution over metrics from the target space, for instance, a distribution over trees or ultrametrics. The goal is now to bound the *expected distortion* for any pair of points relative to their distance in the original metric space. Probabilistic embeddings typically allow for much lower values of distortion. Indeed, when the target metric is a tree or an ultrametric, deterministic embeddings have distortion $\Omega(n)$ [2], while probabilistic embeddings have distortion $\alpha = O(\log n)$ [20].

In this paper, we consider the problem of embedding metrics into a distribution over ultrametrics, defined in Section 2. To within a constant factor on distortion, these metrics embed into *hierarchically separated trees* (HSTs), and such embeddings have found myriad uses in network design, data analysis and online algorithms. This is because most network design problems such as Steiner tree or facility location are NP-Hard in general metric spaces, but amenable to polynomial time algorithms on trees. If the objective function is a linear combination of distances, the solution on the distribution over HSTs yields a α approximation algorithm for the input metric space, where α is the distortion of the embedding. Indeed, recent breakthroughs in developing competitive algorithms for the celebrated randomized k-server problem proceed via probabilistic embedding into HSTs [16, 4]. Other applications include analysis of hierarchical clusterings [10, 31, 17], and approximation algorithms for group Steiner trees [21], buy-at-bulk network design [3], and metric labeling [27].

In this context, it is known that in the worst case over input metric spaces, the distortion of embedding into a distribution over ultrametrics is $\alpha = O(\log n)$ [20], and this bound is tight [25, 5]. However, these algorithms typically use fixed ball-growing procedures oblivious to the actual metric. It is conceivable that any given metric can be embedded with much lower distortion than such procedures imply. For instance, an entirely different algorithm can embed doubling metrics into ultrametrics with distortion $O(\log \Delta)$, where Δ is the spread[1] of the point set; this can be significantly better if $\Delta = o(n)$ or independent of n [26]. Further, many real-world social graphs have small diameter, often independent of the network size n [32, 30] and again, it is conceivable that specifically tailored algorithms can embed these better than what the worst case bounds imply.

In this paper, we therefore ask: *Can we achieve the best possible (in terms of distortion) probabilistic embedding of a given discrete metric space into ultrametrics in polynomial time?*

1.1 Result

Our main result is positive:

▶ **Theorem 1.** *Given any n-point metric space that can be embedded into a distribution over ultrametrics with optimal distortion α, there is an algorithm with expected polynomial running time*[2] *that can find an embedding of distortion $16 \cdot \alpha$.*

Prior to our work, the best published approximation factor was $O(\log n)$ [20], which is also the tight existence result. In contrast, we provide a nearly tight *computational* result, which also yields improved instance-dependent approximation factors for problems like metric labeling and buy-at-bulk network design, where the factor of $O(\log n)$ in the approximation ratio improves to $O(\alpha)$.

1.2 Technique

Our algorithm for proving Theorem 1 proceeds via constructing an LP relaxation. In this LP relaxation, the variables $\gamma^r_{jj'}$ represent the probability that j, j' are separated in the HST at radius (or level) r. This LP is our main non-trivial contribution. Note that though there are LP formulations that embed metrics into trees [11, 27], we do not know how to solve them to a $o(\log n)$ approximation factor.

We then use the randomized rounding technique for uniform metric labeling in [27] in decreasing order of radius to construct a distribution over centers and assignments, while relaxing $\gamma^r_{jj'}$ by a factor of 2. In the uniform metric labeling problem, the goal is to assign one of k labels to the vertices of a graph with edge weights so that the total weight of the edges whose end-points have different labels is minimized. In the algorithm of [27], they encode the probability that two endpoints of an edge are separated as a random variable

[1] Spread is the ratio of the largest to smallest distance in the metric space.

[2] For any $\delta > 0$, the algorithm can easily be converted to a $16 + \delta$ approximation in deterministic polynomial time, with the polynomial depending on n and $\log \frac{\Delta}{\delta}$, where Δ is the ratio of largest to smallest distance in the metric space.

in their LP, and then minimize an expected cost over these random variables. Our main idea is that the event whether two nodes belong to the same subtree in the HST can be similarly treated as a random variable in our LP. The expected "cost" of the labeling is the contribution of these variables to the distortion, and these variables can be randomly rounded via the same ideas as for metric labeling.

Note that the algorithm for general metric labeling [27] – where the labels lie in a metric space and the weight of the edge is multiplied by the distance between the corresponding labels – proceeds via embedding the metric over labels into an ultrametric. We effectively reduce in the reverse direction and show that metric embedding reduces to (uniform) metric labeling!

1.3 Related Work

The main technique for probabilistically embedding metrics into ultrametrics is low-diameter decompositions. These involve decomposing the input metric space into small diameter components via sampling radii from a suitable distribution and randomly partitioning based on these radii. Starting with a result of [5], a sequence of results showed improving bounds for such embeddings [6, 11, 20], culminating in the optimal distortion bound of $O(\log n)$. Better results are known for special types of metrics [26]. All these decompositions proceed by deriving absolute bounds on the probability that a pair of nodes end up in different partitions; in contrast, we encode this probability as variables in an LP formulation.

Trees are more general spaces than ultrametrics, and the seminal work of [2] initiated the study of embedding metrics into trees. Though the worst case bound for embedding into a distribution over trees remains $\Theta(\log n)$, better results are known for embedding specific classes of metrics such as the shortest path metrics of k-outerplanar or small pathwidth graphs [13, 23, 29]. The work of [11] provides an LP formulation for computing the optimal distortion for embedding into a distribution over trees; however, their separation oracle – the minimum communication cost spanning tree problem – is unlikely to admit a $o(\log n)$ approximation. Our LP for ultrametrics, in contrast, is inspired by stochastic optimization and metric labeling and shows a constant approximation.

The above works provide worst case guarantees on the distortion of the embedding, while we provide an approximation result. Though other prior work has considered such approximation guarantees [19, 24, 1, 15], these works focus on *deterministic* embeddings, while ours consider approximations for probabilistic embeddings. The work of [1] provides a polynomial time algorithm for optimally embedding a metric into a single ultrametric, and the work of [15] shows an improved running time for obtaining such an embedding. However, the optimal distortion for embedding into a single ultrametric might be $\Omega(n)$, while it is $O(\log n)$ for embedding into a distribution. This result motivates the need for algorithms that approximate the optimal probabilistic embedding. We note that the algorithm of [1] does not extend to probabilistic embeddings.

Our LP is also similar in spirit to those in [28]. They give a 2-approximation to separating decompositions (see [28] for formal definitions) by writing an LP using variables similar to our variables γ for the separation probabilities. The key observation we make is that unlike in their setting where there is a fixed separation probability, we need to optimize over the separation probabilities at all levels of the HST simultaneously.

Stochastic Optimization. Our algorithms involve rounding a linear programming relaxation to the optimal solution. This LP is inspired by similar LPs approximate stochastic optimization, particularly those for stochastic knapsack [18], multi-armed bandits [22], Bayesian auctions [9, 12, 8], and stochastic matching [14]. The novel aspects of our work is the formulation of probabilistic embeddings as a stochastic optimization problem, and viewing the uniform metric labeling algorithm as a stochastic rounding procedure [27].

2 Terminology

▶ **Definition 2** (Metric space). *A metric space (N, d) is a finite set of n points N endowed with a distance function $d : N \times N \to \mathbb{R}^+ \cup \{0\}$. This distance function has the following properties:*

- $d(x, x) = 0$ *for all* $x \in N$*;*
- $d(x, y) = d(y, x)$ *for all* $x, y \in N$*; and*
- $d(x, z) \leq d(y, z) + d(x, y)$ *for all* $x, y, z \in N$*.*

▶ **Definition 3** (Embedding). *Given two metric spaces (N, d) and (T, d_T), an embedding from N to T is a function $f : N \to T$.*

With an abuse of notation, for $x, y \in N$, we use $d_T(x, y)$ to refer to $d_T(f(x), f(y))$.

Our goal is to *embed* a given n point metric space into a probability distribution over ultrametrics. An ultrametric and probabilistic embedding are defined below.

▶ **Definition 4** (Ultrametric). *A metric space (N, d) is an* ultrametric *if for all points $x, y, z \in N$, we have $d(x, z) \leq \max(d(x, y), d(y, z))$.*

▶ **Definition 5** (Probabilistic embedding). *Given a metric space (N, d), an embedding is a distribution over ultrametrics (N, d_T), where ultrametric T is chosen with probability p_T. Let F denote this distribution and S denote its support. The embedding should be* non-contractive*, meaning that*

$$\forall x, y \in N, \quad \forall T \in S, \; d_T(x, y) \geq d(x, y).$$

Further, this embedding has distortion α (where $\alpha \geq 1$) if

$$\forall x, y \in N, \mathsf{E}_{T \sim F}[d_T(x, y)] \leq \alpha \cdot d(x, y).$$

Hierarchically Separated Trees. It is convenient to consider a specific type of ultrametric termed *hierarchically separated trees.* These are defined as follows.

▶ **Definition 6** (exact c-HST). *A metric (N, d) is an exact c-HST (for $c > 1$) if the elements of N are the leaves of a rooted tree T, all of whose leaves are at the same level. Each internal node v of T is associated with a number δ_v. These numbers increase by a factor of exactly c as we move up the tree, so that $\delta_v = c \cdot \delta_u$ whenever u is a child of v. Given leaves $x, y \in N$, let z be their least common ancestor in T. Then $d(x, y) = \delta_z$.*

The diameter of a c-HST with root r is δ_r. Note that a c-HST with diameter D decomposes into c-HSTs with diameter D/c, where points in different parts are separated by distance exactly D.

The following result shows that it suffices to consider embedding into exact c-HSTs.

▶ **Lemma 7** ([7]). *Given a metric space and its embedding into a distribution over ultrametrics with distortion α, there is an embedding into a distribution over exact c-HSTs with distortion $\alpha \cdot c$.*

3 Linear Programming Relaxation

The LP relaxation is not obvious, and we will present it in some detail. We are given a metric space (N, d) whose smallest distance is 1 and largest distance is Δ. We will use exact c-HSTs for $c = 2$; using any other value of c only yields a worse approximation factor, and our presentation is simplified without the parameter c. By losing a factor of 2, we assume that the optimal solution embeds this metric into a distribution over exact 2-HSTs. Let this embedding have distortion $q \le 2\alpha$ if the optimal distortion for probabilistically embedding into ultrametrics is α. Our goal therefore is to approximate q in polynomial time.

Given this optimal probabilistic embedding into 2-HSTs, let M denote the set of possible δ_z values in powers of 2. Note that $|M| = O(\log \Delta)$, since $1 \le \delta_r \le 2\Delta$ without loss of generality.[3]

Consider some 2-HST in the optimal embedding of (N, d) and some $r \in M$. For any sub-tree T' whose root z has $\delta_z = r$, all nodes in T' have distance in the 2-HST at most r from some node $i \in T'$. Since this embedding is non-contractive, we have $d(i, j) \le r$ for all $j \in T'$. We arbitrarily pick one i in this subtree as the "representative" of this subtree and "assign" all other nodes in the subtree to i. Therefore, each node j is assigned to one representative i at each level $r \in M$ in the tree and this satisfies $d(i, j) \le r$. Now we can define a graph $G_r(N, E_r)$ for each $r \in M$, where there is an edge $(i, j) \in E_r$ if and only if $d(i, j) \le r$. Let $B_i(r) = \{j \in N, d(i, j) \le r\}$.

For $(i, j) \in E_r$, define a variable x^r_{ij} as the probability that j's representative at level r is i. Similarly, let $z^r_{ijj'}$ be the probability that both j, j' have i as their level r representative, where we assume $(i, j) \in E_r$ and $(i, j') \in E_r$. Finally, let $\gamma^r_{jj'}$ be the probability that j and j' do not share a level r representative.

The LP relaxation with variables $x^r_{ij}, z^r_{ijj'}$, and $\gamma^r_{jj'}$, and is shown in Figure 1.

$$
\text{(LP1)}\qquad
\begin{aligned}
&\text{Minimize } q && (1)\\
\forall j, j', \quad & \sum_{r \in M} r \cdot \gamma^r_{jj'} \le q \cdot d(j, j') && (2)\\
\forall i, r, j, j' \in B_i(r) \quad & \min(x^r_{ij}, x^r_{ij'}) \ge z^r_{ijj'} && (3)\\
\forall j, j', r \quad & \sum_{i: j, j' \in B_i(r)} z^r_{ijj'} \ge 1 - \gamma^r_{jj'} && (4)\\
\forall j, r \quad & \sum_{i: j \in B_i(r)} x^r_{ij} = 1 && (5)\\
\forall j, j', r < d(j, j') \quad & \gamma^r_{jj'} = 1 && (6)\\
\forall i, j, j', r \quad & \gamma^r_{jj'}, x^r_{ij}, z^r_{ijj'} \ge 0. && (7)
\end{aligned}
$$

Figure 1 Linear program relaxation for embedding into 2-HSTs.

[3] To see this, consider any HST in the support of the optimal probabilistic embedding. We can contract all the internal nodes v of the HST with $\delta_v \ge 2\Delta$ into one node r with $\delta_r = 2\Delta$. Clearly, this preserves the non-contractivity property, since no pair of vertices are more than Δ far apart. Furthermore, this can only decrease the expected distortion of any edge.

▶ **Lemma 8.** *LP1 is feasible and is a 2-approximation to the distortion of the optimal probabilistic embedding into ultrametrics.*

Proof. Consider an optimal embedding of the input metric into 2-HSTs with distortion q. As mentioned before, since q is a factor 2 approximation to optimal distortion of embedding into ultrametrics, this means the objective is a 2-approximation. We only need to show that there is a feasible solution to the LP with objective at most q.

Now, consider any 2-HST in the support of the optimal embedding. We interpret the variables as described before. To interpret Equation (2), note that if (j, j') have least common level r, they are separated at levels $r/2, r/4, r/8$, and so on. Therefore, the contribution this 2-HST makes to the LHS of Equation (2) is $r/2 + r/4 + \cdots \leq r$. Taking expectation over all 2-HSTs in the optimal embedding, we have $\mathsf{E}[r] \leq q \cdot d(i, j)$, where q is the distortion of this embedding. This shows that the constraint holds.

Equation (6) captures that the embedding is non-contractive: If $d(j, j') < r$, then they are separated at level r. The remaining constraints are interpreted as follows. Equation (3) says j, j' are co-assigned to i implies they were both individually assigned to i; Equation (5) says each $j \in N$ has a representative at each level r; and Equation (4) says that the probabilities that j, j' are co-assigned and not co-assigned at level r sum to at least 1.

One feasible solution to the LP is to assign each node j to itself at all levels, so that $x^r_{jj} = 1$ for all $j \in N, r \in M$. Then $z^r_{ijj'} = 0$ and $\gamma^r_{jj'} = 1$ for all $j \neq j'$. This is feasible when $q = 2\Delta$. ◀

4 Rounding and HST Construction

We first present a procedure in Algorithm 1 that generates partitions separately for each level r. Essentially, our algorithm solves $|M|$ instances of metric labeling, one for each level r. This step adapts the rounding scheme in [27] for uniform metric labeling. Each "label" is a possible representative at level r. The expected cost of this metric labeling is then used to bound the expected distortion of the embedding.

To construct the HST itself, we inductively compute the tree in the following manner: At level 2Δ, every node is assigned the same representative. For every lower level r, the set of nodes assigned to the same representative at level $\frac{r}{2}$ belong to the same subtree. These nodes are then assigned new representatives at level r based on the metric labeling.

Algorithm 1 Rounding to Create Partitions.

```
for $r \in M$ in decreasing order do
    $S \leftarrow N$; $P^r_i = \emptyset$ for all $i \in N$
    while $S \neq \emptyset$ do
        Choose a center $i \in N$ uniformly at random independent of past choices.
        Choose $\ell^r_i \in [0, 1]$ uniformly at random independent of past choices.
        For each $j \in S \cap B_i(r)$, if $x^r_{ij} \geq \ell^r_i$, assign $j$ to $P^r_i$ and remove $j$ from $S$.
    end while
end for
```

We next combine these partitions into a 2-HST in Algorithm 2.

Analysis

We first consider Algorithm 1. The lemma below follows directly from the analysis of the rounding algorithm for uniform metric labeling in [27]. For completeness, we provide the proof here.

Algorithm 2 Combining Partitions and Constructing the 2-HST.

```
Place a root node $w$ at the highest level with $\delta_w = 2\Delta$ and set $S_w = N$.
for $r \in M$ in decreasing order do
    for each node $w$ at the previous (parent) level with set $S_w$ do
        for each $i$ with $P_i^r \cap S_w \neq \emptyset$ do
            Place a child node $v$ with set $S_v = P_i^r \cap S_w$ and $\delta_v = 2r$
        end for
    end for
end for
```

▶ **Lemma 9** (Lemma 3.2 in [27]). *Consider some pair j, j' with $d(j, j') = R$. Consider some level $r \geq R$. For any $(j, j') \in E(G)$,*

$$\Pr[j, j' \textit{ separated at level } r] \leq 2\gamma_{jj'}^r.$$

Proof. We assume $|C| = n \geq 2$; the result is trivial for $n = 1$. Since we fix a phase r, we will omit the superscript r from the proof below.

Suppose that both $j, j' \in S$ at some point in time. Then j is assigned to i with probability $\frac{x_{ij}}{n}$, where $\frac{1}{n}$ is the probability that i is chosen; conditioned on this, j is assigned to i if $\ell_i \leq x_{ij}$. Therefore, j is assigned to some center at this step with probability is $\sum_{i:j \in B_i} \frac{x_{ij}}{n} = \frac{1}{n}$.

Similarly, conditioned on both $j, j' \in S$, the probability with which they are assigned to center $i \in C$ is $\frac{\min(x_{ij}, x_{ij'})}{n} \geq \frac{z_{ijj'}}{n}$, so this pair is co-assigned with probability at least $\frac{\sum_i z_{ijj'}}{n} \geq \frac{1-\gamma_{jj'}}{n}$. This is therefore a lower bound on the probability with which both j and j' get assigned this step.

By the inclusion-exclusion principle on the pair (j, j'), conditioned on both $j, j' \in S$, the probability with which either j or j' gets assigned is:

$$\Pr[\text{Either } j \text{ or } j' \text{ assigned } | j, j' \in S] \leq \frac{1}{n} + \frac{1}{n} - \frac{1-\gamma_{jj'}}{n} = \frac{1+\gamma_{jj'}}{n}. \tag{8}$$

Since $n \geq 2$ and $\gamma_{jj'} \leq 1$, the RHS above is at most 1. Therefore, the probability that both $j, j' \in S$ at time t is at least $\left(1 - \frac{1+\gamma_{jj'}}{n}\right)^{t-1}$. Conditioned on this event, they are co-assigned at time step t with probability at least $\frac{1-\gamma_{jj'}}{n}$. Therefore, we have

$$\Pr[j, j' \text{ not separated }] \geq \sum_{t=1}^{\infty} \left(1 - \frac{1+\gamma_{jj'}}{n}\right)^{t-1} \cdot \frac{1-\gamma_{jj'}}{n} = \frac{1-\gamma_{jj'}}{1+\gamma_{jj'}}.$$

Noting that $\Pr[j, j' \text{ separated}] \leq 1 - \frac{1-\gamma_{jj'}}{1+\gamma_{jj'}} \leq 2\gamma_{jj'}$, this completes the proof. ◀

The following two lemmas will now complete the proof of Theorem 1.

▶ **Lemma 10.** *The construction in Algorithm 1 and Algorithm 2 is non-contractive.*

Proof. Suppose $d(j, j') = R$. Consider some level $r \in M \cap [R/4, R/2]$. For this value of r, there is no center i such that $j, j' \in B_i(r)$. Therefore, j, j' lie in different partitions at this level. Observing that Algorithm 2 sets $\delta_v = 2r$ for nodes v at level r, their common ancestor u must have $\delta_u \geq 4r \geq R$. Therefore, the embedding is non-contractive. ◀

▶ **Lemma 11.** *In the output of Algorithm 2, the expected distortion of any distance is at most $8q$. This implies a 16 approximation to the optimal embedding into a distribution over ultrametrics.*

Proof. Consider some pair j, j' with $d(j, j') = R$. Consider some level $r \geq R$. By Lemma 9,

$$\Pr[j, j' \text{ separated at level } r] \leq 2\gamma^r_{jj'}.$$

If $r < R$, note that $\gamma^r_{jj'} = 1$, so the above inequality trivially holds.

If r^* is the highest level at which j, j' are separated, the distance in the embedding is $4r^*$. As an upper bound, we simply add a distance of $4r$ for all levels r at which j, j' are cut. This yields:

$$\mathsf{E}[\text{ Distance in embedding between } (j, j')] \leq \sum_{r \in M} 4r \cdot 2\gamma^r_{jj'} \leq 8q \cdot d(j, j').$$

Since q itself is a 2 approximation to the optimal distortion of embedding into ultrametrics, this implies a 16 approximation to the distortion of embedding into a distribution over ultrametrics. ◀

Running Time. Since each j gets assigned with probability $1/n$ each step, the expected number of steps is $O(n \log n)$ per level, and there are $O(\log \Delta)$ levels. Suppose we stop the process after $c \cdot n \ln \frac{\Delta}{\delta}$ steps. Then for large constant c, the probability that at some level, all j have not been assigned is at most $\frac{\delta}{\Delta}$. In this event, we pretend the ultrametric distorts all distances to Δ. The expected distortion now becomes a $16 + \delta$ approximation. This completes the proof of Theorem 1.

5 Conclusion

We have in effect reduced probabilistic metric embeddings to metric labeling, performing the reverse of the reduction in [27] that reduces metric labeling to metric embedding. There are some open questions that arise from this work. First, is there an *exact* polynomial time algorithm for embedding into ultrametrics or even a PTAS? Second, can similar results be obtained for the more general problem of embedding into tree metrics?

Approximating Submodular k-Partition via Principal Partition Sequence

Karthekeyan Chandrasekaran
University of Illinois, Urbana-Champaign, IL, USA

Weihang Wang
University of Illinois, Urbana-Champaign, IL, USA

Abstract

In submodular k-partition, the input is a submodular function $f : 2^V \to \mathbb{R}_{\geq 0}$ (given by an evaluation oracle) along with a positive integer k and the goal is to find a partition of the ground set V into k non-empty parts $V_1, V_2, \ldots, V_k$ in order to minimize $\sum_{i=1}^{k} f(V_i)$. Narayanan, Roy, and Patkar [18] designed an algorithm for submodular k-partition based on the principal partition sequence and showed that the approximation factor of their algorithm is 2 for the special case of graph cut functions (which was subsequently rediscovered by Ravi and Sinha [22]). In this work, we study the approximation factor of their algorithm for three subfamilies of submodular functions – namely monotone, symmetric, and posimodular and show the following results:

1. The approximation factor of their algorithm for monotone submodular k-partition is $4/3$. This result improves on the 2-factor that was known to be achievable for monotone submodular k-partition via other algorithms. Moreover, our upper bound of $4/3$ matches the recently shown lower bound under polynomial number of function evaluation queries [23]. Our upper bound of $4/3$ is also the first improvement beyond 2 for a certain graph partitioning problem that is a special case of monotone submodular k-partition.
2. The approximation factor of their algorithm for symmetric submodular k-partition is 2. This result generalizes their approximation factor analysis beyond graph cut functions.
3. The approximation factor of their algorithm for posimodular submodular k-partition is 2.

We also construct an example to show that the approximation factor of their algorithm for arbitrary submodular functions is $\Omega(n/k)$.

1 Introduction

A set function $f : 2^V \to \mathbb{R}$ is submodular if $f(A) + f(B) \geq f(A \cap B) + f(A \cup B)$ for every $A, B \subseteq V$. An evaluation oracle for a function $f : 2^V \to \mathbb{R}$ takes a subset $A \subseteq V$ as input and returns $f(A)$. We consider the *submodular k-partition* problem defined as follows: The input consists of a non-negative submodular function $f : 2^V \to \mathbb{R}_{\geq 0}$ on a finite ground set V via an evaluation oracle and an integer $k \geq 2$. The goal is to find a partition $V_1, V_2, \ldots, V_k$ of V into k non-empty parts in order to minimize $\sum_{i=1}^{k} f(V_i)$. Namely, the goal is to compute

$$\min \left\{ \sum_{i \in [k]} f(V_i) : \; V_1, V_2, \ldots, V_k \text{ is a partition of } V, \; V_i \neq \emptyset \; \forall i \in [k] \right\}.$$

Throughout, we will assume that the input submodular function is non-negative and denote the size of the ground set V by n. If $k = 2$, then the problem reduces to the classic submodular minimization problem. We emphasize that our focus is on submodular k-partitioning when k is part of input (see [4] for a discussion of the problem for fixed constant k). Submodular k-partition formulates several interesting partitioning problems and we will discuss some of the special cases below. For arbitrary submodular functions, the problem is NP-hard [10], does not admit a $(2 - \epsilon)$-approximation assuming polynomial number of function evaluation queries [23], does not admit a $n^{1/(\log \log n)^c}$-approximation for every constant c assuming the Exponential Time Hypothesis [6], and the best approximation factor that is known is $O(k)$ [19,26].

In this work, we will be interested in the submodular k-partition problem for subfamilies of submodular functions – namely monotone, symmetric, and posimodular submodular functions. A set function $f : 2^V \to \mathbb{R}$ is

1. monotone if $f(B) \geq f(A)$ for every $A \subseteq B \subseteq V$,
2. symmetric if $f(A) = f(V - A)$ for every $A \subseteq V$, and
3. posimodular if $f(A) + f(B) \geq f(A - B) + f(B - A)$ for every $A, B \subseteq V$.

If the input submodular function is monotone/symmetric/posimodular, then we call the associated submodular k-partition problem as monotone/symmetric/posimodular submodular k-partition. We note that monotone submodular functions and symmetric submodular functions are also posimodular[1]. Hence, posimodular submodular k-partition problem generalizes both monotone submodular k-partition and symmetric submodular k-partition problems. We now discuss the approximation status of symmetric/monotone/posimodular submodular k-partition and some of their well-known special cases (see Table 1 for a summary of approximation factors of symmetric/monotone/posimodular submodular k-partition achieved by different approaches).

Monotone submodular k-partition. Special cases of monotone submodular k-partition problem include matroid k-partition and coverage k-partition – the submodular functions of interest here are matroid rank functions and coverage functions respectively. Matroid k-partition captures several interesting problems: e.g., (1) partition the columns of a given matrix into k non-empty parts to minimize the sum of the dimension of the subspace spanned by the parts and (2) partition the edges of a given graph into k non-empty parts to *maximize* the sum of the number of connected components formed by the parts. Coverage k-partition also captures several interesting problems: e.g., (3) partition the vertices of a given graph into k non-empty parts $V_1, V_2, \ldots, V_k$ in order to minimize $\sum_{i=1}^{k} f(V_i)$, where $f(P)$ is the number of edges incident to the vertex subset $P \subseteq V$. To gain a better understanding of the difficulty in solving/approximating monotone submodular k-partition, we encourage the reader to briefly think about the concrete special case of matrix column partitioning problem (i.e., problem (1) described above which is seemingly a linear algebra problem) before reading further.

[1] In fact, monotone functions are posimodular since $f(A) \geq f(A - B)$ and $f(B) \geq f(B - A)$ for every $A, B \subseteq V$. Symmetric submodular functions are posimodular: for every $A, B \subseteq V$, we have that $f(A) + f(B) = f(V - A) + f(B) \geq f((V - A) \cup B) + f((V - A) \cap B) = f(V - (A - B)) + f(B - A) = f(A - B) + f(B - A)$.

Monotone submodular k-partition is NP-hard [23]. Moreover, it admits a simple (and fast) $(2-1/k)$-approximation algorithm that will be denoted henceforth as the *cheapest singleton partitioning algorithm*: return the partition $V_1 := \{v_1\}, V_2 := \{v_2\}, \ldots, V_{k-1} := \{v_{k-1}\}, V_k := V - \{v_1, \ldots, v_{k-1}\})$, where the n elements of the ground set are ordered as $v_1, \ldots, v_n$ such that $f(\{v_1\}) \leq f(\{v_2\}) \leq \ldots \leq f(\{v_n\})$. Santiago [23] showed that this is a 2-approximation. His analysis can be extended to show that it is in fact a $(2-1/k)$-approximation[2] and this is the best possible approximation factor for this algorithm[3]. Alternatively, the greedy splitting algorithm presented in [26] achieves a $(2-2/k)$-approximation. On the inapproximability front, Santiago [23] showed that there does not exist an algorithm that makes polynomial number of function evaluation queries to obtain a $(4/3-\epsilon)$-approximation for every constant $\epsilon > 0$.

Symmetric submodular k-partition. Well-known special cases of symmetric submodular k-partition problem are graph k-cut and hypergraph k-partition – the submodular functions of interest here are the cut functions of an explicitly given graph and hypergraph respectively. Graph k-cut is NP-complete [10] and does not have a polynomial-time $(2-\epsilon)$-approximation for every constant $\epsilon > 0$ under the Small Set Expansion Hypothesis [12]. There are several known approaches to achieve a 2-approximation for graph k-cut – (i) greedy splitting approach [24], (ii) Gomory-Hu tree based approach [25], (iii) extreme sets based approach [13], (iv) principal partition sequence based approach [2, 18, 22], and (v) covering-LP based approach [7, 15, 21]. Greedy splitting, Gomory-Hu tree, and extreme sets based approaches lead to a $(2-2/k)$-approximation while the principal partition sequence and the covering-LP based approaches lead to a $(2-2/n)$-approximation for graph k-cut. The principal partition sequence and the covering-LP based approaches for graph k-cut have also been shown to be related to each other [7]. The principal partition sequence based approach is the main algorithm of interest to our work and we will discuss it in detail in Section 2.

For the more general problem of symmetric submodular k-partition, two of the approaches discussed in the previous paragraph for graph k-cut have been generalized to obtain 2-approximations – the greedy splitting approach [26] and the Gomory-Hu tree approach lead to a $(2-2/k)$-approximation. Analyzing the approximation factor of the principal partition sequence based approach for symmetric submodular k-partition was one of the driving motivations of our work. On the inapproximability front, Santiago [23] showed that there does not exist an algorithm that makes polynomial number of function evaluation queries to obtain a $(2-\epsilon)$-approximation for every constant $\epsilon > 0$.

[2] The cheapest singleton partitioning algorithm returns a solution whose cost is $f(V - V_k) + \sum_{i=1}^{k-1} f(\{v_i\}) \leq f(V) + \sum_{i=1}^{k-1} f(\{v_i\}) \leq f(V) + (1-1/k)\sum_{i=1}^{k} f(\{v_i\}) \leq (2-1/k)\max\{f(V), \sum_{i=1}^{k} f(\{v_i\})\}$ while the cost of an optimum k-partition is at least $\max\{f(V), \sum_{i=1}^{k} f(\{v_i\})\}$. The lower bound on the cost of the optimum k-partition $V_1^*, \ldots, V_k^*$ is because $\sum_{i=1}^{k} f(V_i^*) \geq f(V)$ by non-negativity and submodularity and moreover, if the optimum partition is indexed such that $\min\{j \in [n] : v_j \in V_i^*\} \leq \min\{j \in [n] : v_j \in V_{i+1}^*\}$ for all $i \in [k-1]$, then $f(V_i^*) \geq f(\{v_i\})$ by monotonicity and hence, $\sum_{i=1}^{k} f(V_i^*) \geq \sum_{i=1}^{k} f(\{v_i\})$.

[3] The best possible approximation factor for the cheapest singleton partitioning algorithm is $2-1/k$ as seen from this example: Let f be the rank function of a partition matroid on a k-partition $\{S_1, \ldots, S_k\}$ of the ground set S where $|S_i| \geq 2$ for all $i \in [k]$. Then, the algorithm may return $\{\{s_1\}, \{s_2\}, \ldots, \{s_{k-1}\}, S - \{s_1, \ldots, s_{k-1}\}\}$, where $s_i \in S_i$ for all $i \in [k-1]$ and this k-partition has objective value $2k-1$, whereas the partition $\{S_1, \ldots, S_k\}$ has objective value k.

Posimodular submodular k-partition. The only natural family of posimodular submodular functions that we are familiar with are symmetric submodular functions and monotone submodular functions as well as their positive linear combinations. As mentioned before, posimodular submodular k-partition is a unified generalization of symmetric submodular k-partition and monotone submodular k-partition. To the best of authors' knowledge, posimodular submodular k-partition has not been studied in the literature before and there are no specialized algorithms or approximation factor analysis of existing algorithms for posimodular submodular k-partition. A slight modification to the analysis of the greedy splitting algorithm presented in [26] shows that their algorithm achieves a $(3 - 2/k)$-approximation for posimodular submodular k-partition – we refrain from presenting this analysis in the interests of brevity. On the inapproximability front, since symmetric submodular functions are also posimodular submodular, the lower bound for symmetric submodular k-partition also holds for posimodular submodular k-partition, i.e., there does not exist an algorithm for posimodular submodular k-partition that makes polynomial number of function evaluation queries to obtain a $(2 - \epsilon)$-approximation for every constant $\epsilon > 0$.

1.1 Our Results

In this work, we investigate Narayanan, Roy, and Patkar's [18] principal partition sequence based algorithm for submodular k-partition. They showed that their algorithm achieves a 2-approximation for graph k-cut (which was subsequently rediscovered by Ravi and Sinha [22]). We show the following results:

1. Their algorithm achieves a 4/3-approximation for monotone submodular k-partition. This result improves on the 2-factor that is known to be achievable via two different algorithms: the cheapest singleton partitioning algorithm and the greedy splitting algorithm. Moreover, our upper bound of 4/3 matches the lower bound shown by Santiago [23]. We will discuss the significance of our upper bound result shortly.
2. Their algorithm achieves a 2-approximation for symmetric submodular k-partition. This factor matches the 2-factor that is known to be achievable via two other algorithms: the greedy splitting algorithm and the Gomory-Hu tree based algorithm, and also matches the lower bound [12, 23]. Our contribution here is generalizing the analysis of [18, 22] to beyond graph cut functions.
3. Their algorithm achieves a 2-approximation for posimodular submodular k-partition. This result improves on the 3-factor that is known to be achievable via the greedy splitting algorithm and matches the lower bound of 2 shown by Santiago [23].

See Table 1 for a comparison. Graph k-cut is the well-studied special case of symmetric submodular k-partition/posimodular submodular k-partition, so we include that as the last column in the table for comparison. Approximation factors in the row corresponding to principal partition sequence are the main results of this work. In the last row of the table, we include the known lower bounds on the approximation factor for comparison. The lower bound for graph cut function is assuming the Small Set Expansion Hypothesis [12] while the rest of the lower bounds are assuming polynomial number of function evaluation queries. Dashes in the table indicate that either the approach does not extend or there has been no analysis of the approximation factor of the approach for the subfamily.

We complement our upper bounds on the approximation factor of their algorithm with matching lower bound constructions for each subfamily of submodular functions. Our results show that the principal partition sequence based algorithm achieves the best possible approximation factor for broad subfamilies of submodular functions, thus illustrating the power and applicability of this algorithm. On the other hand, we show that the approximation factor of their algorithm for arbitrary submodular functions is $\Omega(n/k)$ via a lower bound construction. This construction shows that their principal partition sequence based algorithm cannot directly improve the approximation factor for submodular k-partition beyond the current best $O(k)$.

We briefly discuss the significance of our 4/3-approximation result for monotone submodular k-partition. Firstly, prior to our results, there were no known families of submodular functions for which the submodular k-partition problem could be approximated to a factor better than 2. Our result for monotone submodular functions breaks this 2-factor barrier for a broad family of submodular functions. Secondly, our result for monotone submodular k-partition leads to a new approximation result even for a graph partitioning problem that we describe now. For a graph $G = (V, E)$ with edge weights $w : E \to \mathbb{R}_+$, consider functions $d, f : 2^V \to \mathbb{R}_+$ defined by $d(S) := w(\delta(S))$ and $f(S) := w(E[S]) + w(\delta(S))$ for every $S \subseteq V$, where $\delta(S)$ denotes the set of edges with exactly one end-vertex in S, $E[S]$ denotes the set of edges with both end-vertices in S, and $w(F) := \sum_{e\in F} w(e)$ for every $F \subseteq E$. The function d is the cut function of the graph and is symmetric submodular. The function f is the coverage function of the graph and is monotone submodular. Submodular k-partition for the function d is known as graph k-cut and it is known that graph k-cut does not admit a $(2-\epsilon)$-approximation under the Small Set Expansion Hypothesis [12]. In contrast, our results show that coverage k-partition in graphs – i.e., submodular k-partition for the function f – admits a 4/3-approximation. We note that coverage k-partition in graphs is NP-hard [23] and its approximability is an intriguing open question.

Table 1 Approximation factors of symmetric/monotone/posimodular submodular k-partition using different approaches. Result in the first row marked with an asterisk follows by slight modifications to the known analysis of the approximation factor for symmetric submodular functions given in [26].

	Monotone Submodular Function	Symmetric Submodular Function	Posimodular Submodular Function	Graph Cut Function
Greedy splitting	$2-2/k$ [26]	$2-2/k$ [26]	$3-2/k$ [26]*	$2-2/k$ [24]
Extreme Sets	—	—	—	$2-2/k$ [13]
Gomory-Hu tree	—	$2-2/k$ [Folklore]	—	$2-2/k$ [25]
Covering-LP	—	—	—	$2-2/k$ [7, 15]
Cheapest Singleton Partitioning	$2-1/k$ [23]	—	—	—
Principal Partition Sequence	$4/3-4/(9n+3)$ (this work)	$2-2/n$ (this work)	$2-2/(n+1)$ (this work)	$2-2/n$ [18, 22]
Lower Bound	$4/3-\epsilon$ [23]	$2-\epsilon$ [23]	$2-\epsilon$ [23]	$\mathbf{2-\epsilon}$ [12]

Organization. We discuss the principal partition sequence based algorithm in Section 2. We analyze the approximation factor of the algorithm with matching lower bound constructions for monotone submodular k-partition in 3. Due to space limitations, we refer the reader to the full version of the work [5] for the analysis of the approximation factor of the constructionsalgorithm with matching lower bound constructions for symmetric submodular k-partition and posimodular submodular k-partition. We exhibit an instance of submodular k-partition where the algorithm achieves an approximation factor of $\Omega(n/k)$ in Section 4 and conclude with certain open questions in Section 5.

1.2 Related work

The principal partition sequence based algorithm for submodular k-partition was introduced by Narayanan, Roy, and Patkar [18]. We will formally define the principal partition sequence of a submodular function and describe their algorithm in Section 2. They analyzed the approximation factor of their algorithm for two variants of k-partitioning problems in hypergraphs. These two variants are not special cases of symmetric/monotone/posimodular submodular k-partition and are not of direct interest to our work. However, we describe these variants to highlight the versatility of the principal partition sequence based approach and also to shed light on the results of Narayanan, Roy, and Patkar's work which do not seem to be well-known in the literature. Given a hypergraph $H = (V, E)$, a hyperedge cost function $c : E \to \mathbb{R}_+$, and an integer k, the goal is to find a partition $\mathcal{P} := \{V_1, V_2, \ldots, V_k\}$ of V into k non-empty parts that minimizes an objective of interest:

1. If the objective is the sum of cost of hyperedges that intersect at least two parts of $\mathcal{P}$, then the problem is known as *hypergraph k-cut.*

2. If the objective is the sum of *cost of hyperedges relative to the partition* $\mathcal{P}$, where the cost of a hyperedge e relative to $\mathcal{P}$ is $c(e)(\ell - 1)$ with ℓ being the number of parts of $\mathcal{P}$ intersected by e, then the problem is known as *normalized coverage k-partition*[4].

Narayanan, Roy, and Patkar [18] showed that their principal partition sequence based algorithm achieves a $r(1 - 1/n)$-approximation for hypergraph k-cut, where r is the size of the largest hyperedge and n is the number of vertices in the input hypergraph, and achieves a $(2 - 2/n)$-approximation for normalized coverage k-partition. A consequence (of both of their results) is that the principal partition sequence based algorithm achieves a $(2 - 2/n)$-approximation for graph k-cut. Their principal partition sequence based algorithm for graph k-cut is equivalent to the Lagrangean relaxation approach suggested by Barahona [2]. The approximation factor of the principal partition sequence based algorithm for graph k-cut being at most 2 was rediscovered by Ravi and Sinha [22] and for hypergraph k-cut being at most r was rediscovered by Baïou and Barahona [1].

We mention that a slight modification to the analysis of the greedy splitting algorithm presented in [26] shows that the greedy splitting algorithm achieves a $(2-2/k)$-approximation for normalized coverage k-partition and hypergraph k-partition. We note that hypergraph k-partition is a special case of symmetric submodular k-partition and is different from hypergraph k-cut (for definition of hypergraph k-partition, see discussion of symmetric submodular k-partition at the beginning of the introduction). On the inapproximability front, it is known that hypergraph k-cut does not admit an approximation factor of $n^{1/(\log \log n)^c}$, where c is a constant, assuming the Exponential Time Hypothesis [6]. The best inapproximability result for the more general submodular k-partition problem (mentioned in the introduction) follows from this inapproximability for hypergraph k-cut.

[4] We introduce this nomenclature because the problem is equivalent to finding a partition $V_1, V_2, \ldots, V_k$ of the ground set V in order to minimize $\sum_{i=1}^{k} f(V_i) - f(V)$, where $f : 2^V \to \mathbb{R}_+$ is an explicitly given coverage function (every coverage function can be uniquely represented using a hypergraph [3]). We consider the subtraction of $f(V)$ as normalizing the objective since it is a trivial lower bound on the sum of the function values of the parts: $\sum_{i=1}^{k} f(V_i) \geq f(V)$ holds for every k-partition $V_1, V_2, \ldots, V_k$ since f is a coverage function.

2 Principal partition sequence based algorithm

In this section, we recall the principal partition sequence based algorithm for submodular k-partition designed by Narayanan, Roy, and Patkar [18]. We begin with some notation. Throughout this work, a *partition* of a set S is defined to be a collection of *nonempty* pairwise disjoint subsets of S whose union is S, and a *k-partition* of a set S is defined to be a partition of S with exactly k parts. For two distinct partitions $\mathcal{P}$ and $\mathcal{Q}$ of a set S, if every part of $\mathcal{Q}$ is completely contained in some part of $\mathcal{P}$ then we say that $\mathcal{Q}$ *refines* $\mathcal{P}$ (equivalently, $\mathcal{P}$ is a coarsening of $\mathcal{Q}$). For two distinct partitions $\mathcal{P}$ and $\mathcal{Q}$ of a set S, we will say that $\mathcal{Q}$ is obtained from $\mathcal{P}$ by refining only one part of $\mathcal{P}$ if there exists a part $P \in \mathcal{P}$ such that $P \notin \mathcal{Q}$ and every part $Q \in \mathcal{Q}$ satisfies either $Q \subsetneq P$ or $Q \in \mathcal{P}$ (i.e., either Q is a proper subset of the part P or Q is a part of the partition $\mathcal{P}$); we will denote such a part $P \in \mathcal{P}$ as the part refined by $\mathcal{Q}$.

Let $f : 2^V \to \mathbb{R}$ be a set function on ground set V. For a collection $\mathcal{P}$ of subsets of V, we write $f(\mathcal{P}) := \sum_{P\in\mathcal{P}} f(P)$. We will say that a partition $\mathcal{P} = \{P_1, \ldots, P_k\}$ is an optimal k-partition if $f(\mathcal{P}) \le f(\mathcal{Q})$ for every k-partition $\mathcal{Q}$ of V. We define the function $g_{f,\mathcal{P}} : \mathbb{R}_{\ge 0} \to \mathbb{R}$ for a partition $\mathcal{P}$ of the ground set V and the function $g_f : \mathbb{R}_{\ge 0} \to \mathbb{R}$ as follows:

$$\begin{aligned} g_{f,\mathcal{P}}(b) &:= f(\mathcal{P}) - b|\mathcal{P}| \text{ and} \\ g_f(b) &:= \min\{g_{f,\mathcal{P}}(b) : \mathcal{P} \text{ is a partition of } V\}. \end{aligned}$$

We drop the subscript f and instead write $g_{\mathcal{P}}$ and g respectively, if the function f is clear from context. By definition, the function g_f is piece-wise linear. It can be shown that g_f has at most $|V| - 1$ breakpoints. The next theorem shows that if the function $f : 2^V \to \mathbb{R}$ is submodular, then there exists a sequence of partitions achieving the g_f function values at the breakpoints that have a nice structure; moreover, the breakpoints and such a sequence of partitions can be computed in polynomial time given access to the evaluation oracle of the submodular function f. We emphasize that the theorem holds for arbitrary submodular functions (which may not be non-negative valued).

▶ **Theorem 1** ([16, 18]). *Let $f : 2^V \to \mathbb{R}$ be a submodular function on a ground set V. Then, there exists a sequence $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_r$ of partitions of V and values $b_1, b_2, \ldots, b_{r-1}$ such that*

1. *$\mathcal{P}_1 = \{V\}$ and $\mathcal{P}_r = \{\{v\} : v \in V\}$,*
2. *For each $j \in [r-1]$, the partition $\mathcal{P}_{j+1}$ is obtained from $\mathcal{P}_j$ by refining only one part of $\mathcal{P}_j$,*
3. *$b_1 < b_2 < \ldots < b_{r-1}$,*
4. *$g(b_j) = g_{\mathcal{P}_j}(b_j) = g_{\mathcal{P}_{j+1}}(b_j)$ for each $j \in [r-1]$ and*
5. *$g(b) = g_{\mathcal{P}_1}(b)$ for all $b \in (-\infty, b_1]$,*
   $g(b) = g_{\mathcal{P}_{j+1}}(b)$ for all $b \in [b_j, b_{j+1}]$ for each $j \in [r-2]$, and
   $g(b) = g_{\mathcal{P}_r}(b)$ for all $b \in [b_{r-1}, \infty)$.

Moreover, such a sequence $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_r$ of partitions of V and values $b_1, b_2, \ldots, b_{r-1}$ can be computed in polynomial time given access to the evaluation oracle of the submodular function f.

For a submodular function $f : 2^V \to \mathbb{R}$, we will denote a sequence of partitions $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_r$ and the sequence of values $b_1, b_2, \ldots, b_{r-1}$ satisfying the conditions given in Theorem 1 as a *principal partition sequence* and the *critical value sequence* of f, respectively. We note that this definition differs from those in [16, 18] owing to the reversed indexing order and the imposition of condition 2 – we note that the proofs given in those papers also show that condition 2 holds (also see [22]). The principal partition sequence of submodular functions is known in the literature as *principal lattice of partitions* of submodular functions since there exists a lattice structure associated with the sequence of partitions. We choose to call it as principal partition sequence in this work since the sequence suffices for our purpose. For more on principal lattice of partitions of submodular functions and their computation, we refer the reader to [2, 8, 9, 11, 14, 16–18, 20].

We now discuss the principal partition sequence based algorithm for submodular k-partition that was proposed by Narayanan, Roy, and Patkar [18]. This algorithm computes a principal partition sequence satisfying all conditions in Theorem 1. If the sequence contains a partition that has exactly k parts, then the algorithm returns this k-partition. Otherwise, the algorithm returns a k-partition obtained by refining the partition in the sequence that has the largest number of parts that is less than k. The refinement is based on the partition in the sequence that has the fewest number of parts that is more than k. The formal description of the refinement is given in Algorithm 1. Since the sequence $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_r$ satisfying the conditions of Theorem 1 can be computed in polynomial time, Algorithm 1 can indeed be implemented to run in polynomial time. By design, the algorithm returns a k-partition. The remainder of this work will focus on analyzing the approximation factor of the algorithm.

Algorithm 1 Principal partition sequence based algorithm for submodular k-partition.

```
Input: A submodular function $f : 2^V \to \mathbb{R}$ given by evaluation oracles and an integer $k \geq 2$.
Output: A $k$-partition $\mathcal{P}$ of $V$.
Use Theorem 1 to compute a principal partition sequence $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_r$ of the submodular function $f$ satisfying all conditions stated in that theorem.
if $|\mathcal{P}_j| = k$ for some $j \in [r]$ then
  Return $\mathcal{P} := \mathcal{P}_j$.
end if
Let $i \in \{2, 3, \ldots, r\}$ so that $|\mathcal{P}_{i-1}| < k < |\mathcal{P}_i|$.
Let $S \in \mathcal{P}_{i-1}$ be the part refined by $\mathcal{P}_i$ and $\mathcal{P}'$ be the parts of $\mathcal{P}_i$ contained in $S$.
Let $\mathcal{P}' = \{B_1, \ldots, B_{|\mathcal{P}'|}\}$ such that $f(B_1) \leq f(B_2) \leq \ldots \leq f(B_{|\mathcal{P}'|})$.
Return $\mathcal{P} := (\mathcal{P}_{i-1} \backslash \{S\}) \cup \left\{B_1, B_2, \ldots, B_{k-|\mathcal{P}_{i-1}|}\right\} \cup \left\{\bigcup_{j=k-|\mathcal{P}_{i-1}|+1}^{|\mathcal{P}'|} B_j\right\}$.
```

To construct examples that exhibit tight lower bound on the approximation factor of Algorithm 1, we will need the following proposition that identifies a special case under which the principal partition is unique and consists only of two partitions – namely, the partition into singletons and the partition that consists of only one part. We refer the reader to the full version of this work for the proof [5].

▶ **Proposition 2.** *Let $f : 2^V \to \mathbb{R}_{\geq 0}$ be a non-negative submodular function. Suppose that for every partition $\mathcal{P} \neq \mathcal{Q}, \{V\}$ where $\mathcal{Q} := \{\{v\} : v \in V\}$, the function f satisfies*

$$\frac{f(\mathcal{P}) - f(V)}{|\mathcal{P}| - 1} > \frac{f(\mathcal{Q}) - f(V)}{|V| - 1}.$$

Then, the principal partition sequence of f is $\{V\}, \mathcal{Q}$.

3 Approximation factor analysis

In this section, we analyze the approximation factor of Algorithm 1 for various subfamilies of submodular functions. We state and prove certain lemmas that will be useful for all submodular functions (Lemmas 3 and 4). We analyze the approximation factor of Algorithm 1 for monotone submodular functions in Section 3.1. We refer the reader to the full version of this work [5] for the analysis of the approximation factor of Algorithm 1 for symmetric submodular functions and for posimodular submodular functions.

Our first lemma identifies a special case in which Algorithm 1 returns an optimum k-partition. This special case was also identified by Narayanan, Roy, and Patkar. We note that the following lemma holds for arbitrary submodular functions (which may not be non-negative).

▶ **Lemma 3** ([18]). *Let $k \geq 2$ be an integer, $f : 2^V \to \mathbb{R}$ be a submodular function on a ground set V, and $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_r$ be a principal partition sequence of the submodular function f satisfying the conditions of Theorem 1. If there exists $j \in [r]$ such that $|\mathcal{P}_j| = k$, then $\mathcal{P}_j$ is an optimal k-partition.*

Proof. Let $\mathcal{P}^*$ be a k-partition of V that minimizes $f(\mathcal{P}^*)$ and let b_j be the value where $g(b_j) = g_{\mathcal{P}_j}(b_j)$. Then,

$$f(\mathcal{P}^*) - b_j \cdot k = g_{\mathcal{P}^*}(b_j) \geq g(b_j) = g_{\mathcal{P}_j}(b_j) = f(\mathcal{P}_j) - b_j|\mathcal{P}_j| = f(\mathcal{P}_j) - b_j \cdot k,$$

and hence, $f(\mathcal{P}^*) \geq f(\mathcal{P}_j)$. Therefore, $\mathcal{P}_j$ is indeed an optimal k-partition. ◀

In order to address the case where there is no $j \in [r]$ such that $|\mathcal{P}_j| = k$, we need the following lemma that shows two lower bounds on the optimum value. The first lower bound in the lemma holds for arbitrary submodular functions (which may not be non-negative) while the second lower bound holds for non-negative submodular functions.

▶ **Lemma 4.** *Let $k \geq 2$ be an integer, $f : 2^V \to \mathbb{R}$ be a submodular function on a ground set V, $\mathcal{P}^*$ be a k-partition of V that minimizes $f(\mathcal{P}^*)$, and $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_r$ be a principal partition sequence of the submodular function f satisfying the conditions of Theorem 1. Suppose $|\mathcal{P}_j| \neq k$ for all $j \in [r]$. Let $\mathcal{P}_{i-1}, \mathcal{P}_i$ be the partitions such that $|\mathcal{P}_{i-1}| < k < |\mathcal{P}_i|$. Then,*
(i) *$f(\mathcal{P}^*) \geq \frac{|\mathcal{P}_i|-k}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|} f(\mathcal{P}_{i-1}) + \frac{k-|\mathcal{P}_{i-1}|}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|} f(\mathcal{P}_i)$ and*
(ii) *$f(\mathcal{P}^*) \geq f(\mathcal{P}_{i-1})$ if f is non-negative.*

Proof. We prove the two lower bounds below.
(i) Let b_{i-1} be the value such that $g_{\mathcal{P}_{i-1}}(b_{i-1}) = g_{\mathcal{P}_i}(b_{i-1})$. Then, we have

$$f(\mathcal{P}_{i-1}) - b_{i-1}|\mathcal{P}_{i-1}| = f(\mathcal{P}_i) - b_{i-1}|\mathcal{P}_i| \implies b_{i-1} = \frac{f(\mathcal{P}_i) - f(\mathcal{P}_{i-1})}{|\mathcal{P}_i| - |\mathcal{P}_{i-1}|}. \tag{1}$$

By condition 4 of Theorem 1, we also have

$$\begin{aligned} f(\mathcal{P}^*) - b_{i-1} \cdot k = g_{\mathcal{P}^*}(b_{i-1}) \geq g(b_{i-1}) = g_{\mathcal{P}_i}(b_{i-1}) = f(\mathcal{P}_i) - b_{i-1}|\mathcal{P}_i| \\ \implies f(\mathcal{P}^*) \geq f(\mathcal{P}_i) + b_{i-1}(k - |\mathcal{P}_i|). \end{aligned} \tag{2}$$

Combining (1) and (2), we get

$$\begin{aligned} f(\mathcal{P}^*) &\geq f(\mathcal{P}_i) + \frac{f(\mathcal{P}_i) - f(\mathcal{P}_{i-1})}{|P_i| - |P_{i-1}|}(k - |\mathcal{P}_i|) \\ &= \frac{|\mathcal{P}_i| - k}{|\mathcal{P}_i| - |\mathcal{P}_{i-1}|} f(\mathcal{P}_{i-1}) + \frac{k - |\mathcal{P}_{i-1}|}{|\mathcal{P}_i| - |\mathcal{P}_{i-1}|} f(\mathcal{P}_i). \end{aligned}$$

(ii) Let $P_1^*, \ldots, P_k^*$ be the parts of $\mathcal{P}^*$ (in arbitrary order). Let $k' := |\mathcal{P}_{i-1}|$. We know that $k' < k$. Consider the k'-partition $\mathcal{Q}$ obtained as $Q_1 := P_1^*, Q_2 := P_2^*, \ldots, Q_{k'-1} := P_{k'-1}^*, Q_{k'} := \cup_{j=k'}^{k} P_j^*$. Then,

$$f(\mathcal{P}^*) = \sum_{i=1}^{k} f(P_i^*) \geq \left(\sum_{i=1}^{k'-1} f(P_i^*) \right) + f(\cup_{j=k'}^{k} P_j^*) = \sum_{i=1}^{k'} f(Q_i) = f(\mathcal{Q}).$$

The inequality above is due to submodularity and non-negativity. The partition $\mathcal{Q}$ is a k'-partition. By Lemma 3, the partition $\mathcal{P}_{i-1}$ is an optimal k'-partition. Hence,

$$f(\mathcal{Q}) \geq f(\mathcal{P}_{i-1}).$$

The above two inequalities together imply that $f(\mathcal{P}^*) \geq f(\mathcal{P}_{i-1})$. ◀

3.1 Monotone submodular functions

In this section, we bound the approximation factor of Algorithm 1 for monotone submodular k-partitioning. The following is the main theorem of this section.

▶ **Theorem 5.** *The approximation factor of Algorithm 1 for non-negative monotone submodular k-partitioning is $\frac{4}{3} - \frac{4}{9n+3}$, where n is the size of the ground set.*

The asymptotic approximation factor of 4/3 achieved by Algorithm 1 is the best possible for non-negative monotone submodular k-partition: for every constant $\epsilon > 0$, there does not exist an algorithm that achieves a $(4/3 - \epsilon)$-approximation using polynomial number of function evaluation queries [23]. We will also exhibit examples to show the tightness of the approximation factor for Algorithm 1 after proving the theorem. The proof of Theorem 5 follows from Lemma 3 and Lemma 6 shown below.

▶ **Lemma 6.** *Let $k \geq 2$ be an integer, $f : 2^V \to \mathbb{R}_{\geq 0}$ be a non-negative monotone submodular function on a ground set V of size n, $\mathcal{P}^*$ be a k-partition of V that minimizes $f(\mathcal{P}^*)$, and $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_r$ be a principal partition sequence of the submodular function f satisfying the conditions of Theorem 1. Suppose $|\mathcal{P}_j| \neq k$ for all $j \in [r]$. Then, the partition $\mathcal{P}$ returned by Algorithm 1 satisfies*

$$f(\mathcal{P}) \leq \left(\frac{4}{3} - \frac{4}{9n+3} \right) f(\mathcal{P}^*).$$

Proof. Let $\mathcal{P}_{i-1}, \mathcal{P}_i$ be the partitions such that $|\mathcal{P}_{i-1}| < k < |\mathcal{P}_i|$. Let S and $\mathcal{P}' = \{B_1, B_2, \ldots, B_{|\mathcal{P}'|}\}$ be as in Algorithm 1.

Firstly, since $\cup_{j=k-|\mathcal{P}_{i-1}|+1}^{|\mathcal{P}'|} B_j \subseteq S$ and f is monotone, we have that

$$f\left(\cup_{j=k-|\mathcal{P}_{i-1}|+1}^{|\mathcal{P}'|} B_j \right) \leq f(S).$$

Secondly, by our choice of $B_1, B_2, \ldots, B_{k-|\mathcal{P}_{i-1}|}$, we know that

$$\sum_{j=1}^{k-|\mathcal{P}_{i-1}|} f(B_j) \leq \frac{k - |\mathcal{P}_{i-1}|}{|\mathcal{P}'|} f(\mathcal{P}').$$

Hence,

$$\begin{aligned}
f(\mathcal{P}) &= f(\mathcal{P}_{i-1}) - f(S) + \sum_{j=1}^{k-|\mathcal{P}_{i-1}|} f(B_j) + f\left(\bigcup_{j=k-|\mathcal{P}_{i-1}|+1}^{|\mathcal{P}'|} B_j\right) \\
&\le f(\mathcal{P}_{i-1}) + \sum_{j=1}^{k-|\mathcal{P}_{i-1}|} f(B_j) \\
&\le f(\mathcal{P}_{i-1}) + \frac{k-|\mathcal{P}_{i-1}|}{|\mathcal{P}'|} f(\mathcal{P}') \\
&= f(\mathcal{P}_{i-1}) + \frac{k-|\mathcal{P}_{i-1}|}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|+1}(f(\mathcal{P}_i)+f(S)-f(\mathcal{P}_{i-1})),
\end{aligned}$$

where the last equality follows from the fact that $f(\mathcal{P}_{i-1}) - f(S) + f(\mathcal{P}') = f(\mathcal{P}_i)$ and $|\mathcal{P}'| = |\mathcal{P}_i| - |\mathcal{P}_{i-1}| + 1$. Rearranging, we have that

$$\begin{aligned}
f(\mathcal{P}) &\le \frac{f(\mathcal{P}_{i-1})}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|+1}(|\mathcal{P}_i|-k+1) + \frac{f(\mathcal{P}_i)}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|+1}(k-|\mathcal{P}_{i-1}|) \\
&\qquad + \frac{f(S)}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|+1}(k-|\mathcal{P}_{i-1}|) \\
&= \left(\frac{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|+1}\right)\left(\frac{f(\mathcal{P}_{i-1})}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|}(|\mathcal{P}_i|-k+1) + \frac{f(\mathcal{P}_i)+f(S)}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|}(k-|\mathcal{P}_{i-1}|)\right) \\
&\le \left(\frac{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|+1}\right)\left(f(\mathcal{P}^*) + \frac{f(\mathcal{P}_{i-1})}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|} + \frac{f(S)}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|}(k-|\mathcal{P}_{i-1}|)\right) \\
&\le \left(\frac{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|+1}\right)\left(f(\mathcal{P}^*) + \frac{f(\mathcal{P}_{i-1})}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|}(1+k-|\mathcal{P}_{i-1}|)\right). \qquad (3)
\end{aligned}$$

where the second inequality above is by by Lemma 4(i) and the third inequality above is because $f(S) \le f(\mathcal{P}_{i-1})$. Inequality (3) implies that

$$\begin{aligned}
f(\mathcal{P}) &\le \left(\frac{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|+1}\right)\left(f(\mathcal{P}^*) + f(\mathcal{P}_{i-1}) + \frac{f(\mathcal{P}_{i-1})}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|}(1+k-|\mathcal{P}_i|)\right) \\
&\le \left(1 - \frac{1}{|\mathcal{P}_i|-|\mathcal{P}_{i-1}|+1}\right)(f(\mathcal{P}^*)+f(\mathcal{P}_{i-1})) \quad \text{(since } k < |\mathcal{P}_i|\text{)} \\
&\le 2f(\mathcal{P}^*),
\end{aligned}$$

where the last inequality is because $f(\mathcal{P}_{i-1}) \le f(\mathcal{P}^*)$ by Lemma 4(ii). The above analysis shows that the approximation factor is at most 2. We tighten the analysis now. As a consequence of the above inequality, we may assume that $f(\mathcal{P}^*) \neq 0$ because if $f(\mathcal{P}^*) = 0$, then the returned k-partition $\mathcal{P}$ also satisfies $f(\mathcal{P}) = 0$ and thus, is optimal. Let $c := f(\mathcal{P}_{i-1})/f(\mathcal{P}^*)$. By Lemma 4(ii), we have that $f(\mathcal{P}_{i-1}) \le f(\mathcal{P}^*)$ and hence, $c \in [0,1]$. For convenience, we define $A := k - |\mathcal{P}_{i-1}|$ and $B := |\mathcal{P}_i| - k$ and note that $A, B \ge 1$. Using this notation, we may rewrite inequality (3) as

$$\begin{aligned}
f(\mathcal{P}) &\le \left(\frac{A+B}{A+B+1}\right)\left(f(\mathcal{P}^*) + \frac{1+A}{A+B} f(\mathcal{P}_{i-1})\right) \\
&= \left(\frac{A+B}{A+B+1}\right)\left(1 + \frac{1+A}{A+B}\cdot c\right) f(\mathcal{P}^*). \qquad (4)
\end{aligned}$$

By Lemma 4(i), we have

$$f(\mathcal{P}^*) \ge \left(\frac{B}{A+B}\right) f(\mathcal{P}_{i-1}) + \left(\frac{A}{A+B}\right) f(\mathcal{P}_i) = \left(\frac{B}{A+B}\right) c f(\mathcal{P}^*) + \left(\frac{A}{A+B}\right) f(\mathcal{P}_i).$$

Rearranging, we have

$$f(\mathcal{P}_i) \le \left(1 - \frac{B}{A+B} \cdot c\right)\left(\frac{A+B}{A}\right) f(\mathcal{P}^*) = \left(\frac{A+B}{A} - \frac{B}{A} \cdot c\right) f(\mathcal{P}^*).$$

Since $\mathcal{P}$ is obtained by coarsening $\mathcal{P}_i$, we have $f(\mathcal{P}) \le f(\mathcal{P}_i)$ by submodularity and non-negativity of f. This implies

$$f(\mathcal{P}) \le \left(\frac{A+B}{A} - \frac{B}{A} \cdot c\right) f(\mathcal{P}^*). \tag{5}$$

Combining inequalities (4) and (5), we have

$$\frac{f(\mathcal{P})}{f(\mathcal{P}^*)} \le \max_{c \in [0,1]} \min \left\{ \left(\frac{A+B}{A+B+1}\right)\left(1 + \frac{1+A}{A+B} \cdot c\right), \frac{A+B}{A} - \frac{B}{A} \cdot c \right\}. \tag{6}$$

Thus, in order to upper bound the approximation factor, it suffices to upper bound the right hand side of inequality (6). Since $\left(\frac{A+B}{A+B+1}\right)\left(1 + \frac{1+A}{A+B} \cdot c\right)$ and $\frac{A+B}{A} - \frac{B}{A} \cdot c$ are both linear in c, with the former increasing and the latter decreasing as a function of c, the value

$$\max_{c \in \mathbb{R}} \min \left\{ \left(\frac{A+B}{A+B+1}\right)\left(1 + \frac{1+A}{A+B} \cdot c\right), \frac{A+B}{A} - \frac{B}{A} \cdot c \right\}$$

is achieved when the two terms are equal. Setting $\left(\frac{A+B}{A+B+1}\right)\left(1 + \frac{1+A}{A+B} \cdot c^*\right) = \frac{A+B}{A} - \frac{B}{A} \cdot c^*$ and solving for c^*, we get

$$c^* = \frac{\frac{A+B}{A} - \frac{A+B}{A+B+1}}{\frac{1+A}{A+B+1} + \frac{B}{A}} = \frac{\frac{B}{A} + \frac{1}{A+B+1}}{\frac{1+A}{A+B+1} + \frac{B}{A}}.$$

Plugging $c = c^*$ into $\frac{A+B}{A} - \frac{B}{A} \cdot c$ yields

$$\begin{aligned}
\frac{f(\mathcal{P})}{f(\mathcal{P}^*)} &\le \max_{c \in [0,1]} \min \left\{ \frac{A+B}{A+B+1}\left(1 + \frac{1+A}{A+B} \cdot c\right), \frac{A+B}{A} - \frac{B}{A} \cdot c \right\} \\
&\le \frac{A+B}{A} - \frac{B}{A} \cdot c^* = 1 + \frac{B}{A}(1 - c^*) = 1 + \frac{B}{A}\left(1 - \frac{\frac{B}{A} + \frac{1}{A+B+1}}{\frac{1+A}{A+B+1} + \frac{B}{A}}\right) \\
&= 1 + \frac{AB}{A + A^2 + AB + B^2 + B} \\
&\le 1 + \frac{AB}{3AB + A + B} \quad (\text{since } A^2 + B^2 \ge 2AB) \\
&= \frac{4}{3} - \frac{1}{3} \cdot \frac{A+B}{3AB/2 + 3AB/2 + A + B} \\
&\le \frac{4}{3} - \frac{1}{3} \cdot \frac{A+B}{3AB/2 + 3(A^2 + B^2)/4 + A + B} \quad (\text{since } AB \le \frac{A^2 + B^2}{2}) \\
&= \frac{4}{3} - \frac{1}{3} \cdot \frac{1}{3(A+B)/4 + 1} \\
&\le \frac{4}{3} - \frac{4}{9n+3}.
\end{aligned}$$

The last inequality above is because $A + B = |\mathcal{P}_i| - |\mathcal{P}_{i-1}| \le n - 1$. ◀

▶ Remark 7. The approximation factor of Algorithm 1 for non-negative monotone submodular functions is at least $4/3 - 4/(9n+3)$. We show this for $n = 3$ using the following example: Let $V = \{a, b, c\}$, $k = 2$, and $f : 2^V \to \mathbb{R}_{\geq 0}$ be defined by

$$f(\emptyset) = 0,\ f(\{a\}) = 1,\ f(\{b\}) = f(\{c\}) = 1 + \epsilon,$$
$$f(\{a, b\}) = f(\{a, c\}) = \frac{3}{2} + \epsilon,\ f(\{b, c\}) = f(V) = 2 + 2\epsilon.$$

Submodularity and monotonicity of f can be verified by considering all possible subsets. Moreover, the principal partition sequence of this instance is $\{V\}, \{\{a\}, \{b\}, \{c\}\}$. Thus, Algorithm 1 returns the 2-partition $\{\{a\}, \{b, c\}\}$, whose objective value is $3+2\epsilon$. An optimum 2-partition is $\{\{c\}, \{a, b\}\}$, whose objective value is $5/2 + \epsilon$. Thus, the approximation factor is $\frac{3+2\epsilon}{5/2+\epsilon} \to \frac{6}{5}$ as $\epsilon \to 0$. We note that for $n = 3$, the approximation factor guaranteed by Theorem 5 is $\frac{4}{3} - \frac{4}{9n+3} = \frac{6}{5}$.

We conclude the section by showing that there exist monotone submodular functions for which the approximation factor of Algorithm 1 is at least 4/3 asymptotically (i.e., as $n \to \infty$).

▶ **Lemma 8.** *For every odd positive integer $n \geq 5$, there exists a function $k = k(n)$ (i.e., k is a function of n) and an instance of non-negative monotone submodular k-partition over an n-element ground set such that the approximation factor of Algorithm 1 on that instance is arbitrarily close to $4/3 - 4/(3n + 3)$.*

Proof. Let $n \geq 5$ be an arbitrary odd number, $k = \frac{n+1}{2}$, and let $V = \{v_1, \ldots, v_n\}$ be the ground set. Moreover, let $U := \{v_1, \ldots, v_{\frac{n-1}{2}}\}$ and $D := \{v_{\frac{n+1}{2}}, \ldots, v_n\}$ so that $V = U \uplus D$. Let $g : 2^U \to \mathbb{R}_{\geq 0}$ be a function over the ground set U defined by

$$g(S) = \begin{cases} \frac{1}{2} + \frac{1}{2} \cdot |S| & \text{if } \emptyset \neq S \subseteq U, \\ 0 & \text{if } S = \emptyset. \end{cases}$$

and $f : 2^V \to \mathbb{R}_{\geq 0}$ be defined by

$$f(S) := \min\left\{g(S \cap U) + (1 + \epsilon)|S \cap D|,\ \frac{n+1}{2}\right\}\ \forall\ S \subseteq V,$$

where $\epsilon > 0$ is infinitesimally small. The function f satisfies $f(\emptyset) = 0$, $f(V) = \frac{n+1}{2}$, $f(U) = \frac{n+1}{4}$, $f(D) = \frac{n+1}{2}$, $f(\{v\}) = 1$ for each $v \in U$, and $f(\{v\}) = 1 + \epsilon$ for each $u \in D$. We will use $\mathcal{Q}$ to denote the partition of V into n singleton sets. The following claims show properties about the function f. We refer the reader to the full version of this work for the proof [5].

▷ Claim 9. The function f is submodular and monotone.

▷ Claim 10. For every partition $\mathcal{P} \neq \mathcal{Q}, \{V\}$, the function f satisfies

$$\frac{f(\mathcal{P}) - f(V)}{|\mathcal{P}| - 1} > \frac{f(\mathcal{Q}) - f(V)}{n - 1}.$$

By Proposition 2, Algorithm 1 returns the partition $\{\{v_1\}, \ldots, \{v_{\frac{n-1}{2}}\}, D\}$ (because $\{v_1\}, \ldots, \{v_{\frac{n-1}{2}}\}$ are the $k - 1$ singleton sets that minimize the f values), whose objective is $\frac{n-1}{2} + \frac{n+1}{2} = n$. The partition $\{\{v_1, \ldots, v_{\frac{n+1}{2}}\}, \{v_{\frac{n+3}{2}}\}, \ldots, \{v_n\}\}$ has objective $\frac{n+1}{4} + (1 + \epsilon) + (1 + \epsilon)\frac{n-1}{2} = \frac{3n+3}{4} + \frac{(n+1)\epsilon}{2}$. The approximation factor is at least

$$\frac{n}{\frac{3n+3}{4} + \frac{(n+1)\epsilon}{2}} \to \frac{4}{3} - \frac{4}{3n + 3} \text{ (as } \epsilon \to 0).$$

This completes the proof of Lemma 8. ◀

4 Lower bound for arbitrary submodular functions

In this section, we present an instance of submodular k-partition where Algorithm 1 achieves an approximation factor of $\Omega(n/k)$. We emphasize that the submodular function in our instance is not symmetric/monotone/posimodular.

Let $V = \{v_0, v_1, \ldots, v_{n-1}\}$ be the ground set. We define a digraph $D = (V, E(D))$ and a hypergraph $H = (V, E(H))$ on the same vertex set V as follows (see Fig.1):

$$E(D) = \{v_0 v_i : i \in [n-1]\} \text{ and}$$
$$E(H) = \{\{v_1, v_2, \ldots, v_{n-1}\}\}.$$

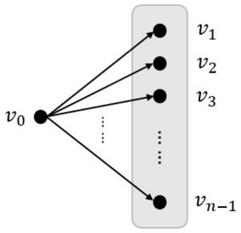

Figure 1 Example in Section 4. The arcs belong to the digraph D and the hyperedge $\{v_1, \ldots, v_{n-1}\}$ belongs to the hypergraph H.

For every subset $S \subseteq V$, we will use $d_D^{in}(S)$ to denote the number of arcs in D whose tails are in $\bar{S}$ and heads are in S. We will use $d_H(S)$ to denote the number of hyperedges in H that have at least one vertex in S and one vertex in $\bar{S}$. Next, we define a set function $f : 2^V \to \mathbb{R}_{\geq 0}$ by

$$f(S) := a \cdot d_D^{in}(S) + d_H(S) \quad \forall S \subseteq V,$$

where $a \gg 1$ is a large constant. We note that f is submodular because it is a positive linear combination of two submodular functions (and it is not monotone/symmetric/posimodular).

▷ Claim 11. The principal partition sequence of f is $\{V\}, \{\{v_i\} : i \in \{0, 1, \ldots, n-1\}\}$.

Proof. For convenience, we will use $\mathcal{Q}$ to denote the partition of V into singletons. By Proposition 2 and the fact that $f(V) = 0$, it suffices to prove that for every partition $\mathcal{P}$ of V such that $\mathcal{P}$ is not $\mathcal{Q}$ or $\{V\}$, we have that

$$\frac{f(\mathcal{P})}{|\mathcal{P}| - 1} > \frac{f(\mathcal{Q})}{n-1}. \tag{7}$$

Let $P_0 \in \mathcal{P}$ be the part that contains v_0. Then, we have that $f(P_0) \geq 1$ if $P_0 \neq \{v_0\}$ and $f(P_0) = 0$ otherwise. For each part $P \in \mathcal{P}$ that does not contain v_0, we have that $f(P) \geq 1+a$ if $|P| = 1$ and $f(P) \geq 2+a$ if $|P| \geq 2$. Since $\mathcal{P} \neq \mathcal{Q}$, we have that either $P_0 \neq \{v_0\}$ or at least one of the parts $P \in \mathcal{P} \backslash \{P_0\}$ has size $|P| \geq 2$. Thus, $f(\mathcal{P}) = \sum_{P \in \mathcal{P}} f(P) \geq (1+a)(|\mathcal{P}|-1)+1$. Moreover, we have $f(\mathcal{Q}) = (1+a)(n-1)$ and hence

$$\frac{f(\mathcal{P})}{|\mathcal{P}| - 1} \geq \frac{(1+a)(|\mathcal{P}|-1)+1}{|\mathcal{P}|-1} = 1 + a + \frac{1}{|\mathcal{P}|-1} > 1 + a = \frac{(1+a)(n-1)}{n-1} = \frac{f(\mathcal{Q})}{n-1}.$$

This proves inequality (7). ◁

▷ Claim 12. The approximation factor of Algorithm 1 on input (f, k) is $\Omega(n/k)$.

Proof. We note that $f(\{v_0\}) = 0$ and $f(\{v_i\}) = 1 + a$ for all $i \in [n-1]$. By Claim 11, on input (f, k), Algorithm 1 returns a partition $\mathcal{P}$ consisting of the $k-1$ singleton parts that minimizes f among all singleton sets and the complement of the union of these $k-1$ singleton parts. Therefore, the returned partition $\mathcal{P}$ contains $\{v_0\}$ as a part and thus

$$f(\mathcal{P}) = \sum_{P \in \mathcal{P}: P \neq \{v_0\}} f(P) \geq f(V - \{v_0\}) = a(n-1).$$

The second inequality follows from submodularity of the function f. Consider the k-partition $\{\{v_1\}, \{v_2\}, \ldots, \{v_{k-1}\}, V - \{v_1, \ldots, v_{k-1}\}\}$, which has objective $(1+a)(k-1)+1$. This implies that the optimum k-partition $\mathcal{P}^*$ satisfies $f(\mathcal{P}^*) \leq (1+a)(k-1)+1$. Thus, the approximation factor of the solution returned by Algorithm 1 is

$$\frac{f(\mathcal{P})}{f(\mathcal{P}^*)} \geq \frac{a(n-1)}{(1+a)(k-1)+1} \to \frac{n-1}{k-1} \text{ as } a \to \infty. \qquad \triangleleft$$

5 Conclusion

The principal partition sequence of submodular functions was shown to exist by Narayanan [16]. The principal partition sequence of submodular functions is known in the literature as *principal lattice of partitions* of submodular functions since there exists a lattice structure associated with the sequence of partitions [2, 8, 9, 11, 14, 17, 20]. We chose to call it as principal partition sequence in this work since the sequence suffices for our purpose. Narayanan, Roy, and Patkar [18] used the principal partition sequence to design an algorithm for submodular k-partition. They analyzed the approximation factor of their algorithm for certain subfamilies of submodular functions that arise from hypergraphs. In this work, we investigated the approximation factor of their algorithm for three broad subfamilies of submodular functions – namely monotone, symmetric, and posimodular submodular functions. Our results show that the principal partition sequence based algorithm achieves the best possible asymptotic approximation factor for all these three subfamilies. A novelty of our contributions is the improvement in the approximability of monotone submodular k-partition from 2 to 4/3, thus matching the inapproximability threshold. It would be interesting to pin down the approximability of special cases of monotone submodular k-partition – e.g., matroid k-partition and coverage k-partition which are interesting by themselves since they capture several interesting partitioning problems.

Abstract

We consider a general p-norm objective for experimental design problems that captures some well-studied objectives (D/A/E-design) as special cases. We prove that a randomized local search approach provides a unified algorithm to solve this problem for all nonnegative integer p. This provides the first approximation algorithm for the general p-norm objective, and a nice interpolation of the best known bounds of the special cases.

1 Introduction

In experimental design problems, we are given vectors $v_1, \ldots, v_n \in \mathbb{R}^d$ and a budget $k \geq d$, and the goal is to choose a subset S of k vectors so that $\sum_{i \in S} v_i v_i^\top$ optimizes some objective function that measures the "diversity" of the input data. The most popular and well-studied objective functions are:

- D-design: Maximizing $(\det(\sum_{i \in S} v_i v_i^\top))^{\frac{1}{d}}$.
- A-design: Minimizing $\frac{1}{d}\operatorname{tr}((\sum_{i \in S} v_i v_i)^{-1})$.
- E-design: Maximizing $\lambda_{\min}(\sum_{i \in S} v_i v_i^\top)$.

Experimental design problems have a long history and wide applications, from statistics to machine learning to numerical linear algebra to graph algorithms. For more information on these applications, we refer the reader to [13, 11, 1, 7, 6] and the references therein.

Although the objectives of D/A/E-design look quite different, we observe that there is a natural generalization using eigenvalues that captures all three objectives as special cases.

[1] Corresponding author

▶ **Definition 1** (p-Norm of Inverse Eigenvalues). *Given a d-dimensional real-symmetric matrix A with eigenvalues $\lambda_1, \ldots, \lambda_d > 0$ and a natural number $0 \leq p \leq \infty$, we define*

$$\Phi_p(A) := \left(\frac{1}{d} \operatorname{tr}\left(A^{-p}\right)\right)^{\frac{1}{p}} = \left(\frac{1}{d} \sum_{i=1}^{d} \lambda_i^{-p}\right)^{\frac{1}{p}}, \tag{1}$$

with $\Phi_0(A) := \lim_{p \to 0^+} \Phi_p(A)$ and $\Phi_\infty(A) := \lim_{p \to +\infty} \Phi_p(A)$.

Given $p \geq 0$, we refer to the experimental design problem with the objective function Φ_p as Φ_p-design. To see that Φ_p-design is a generalization of D/A/E-design, let $A = \sum_{i \in S} v_i v_i^T$ and note that:

- For $p = \infty$, $\Phi_\infty(A) = \lambda_{\max}(A^{-1}) = 1/\lambda_{\min}(A)$, which is the inverse of the E-design objective;
- For $p = 1$, $\Phi_1(A) = \frac{1}{d}\operatorname{tr}(A^{-1})$ is exactly the A-design objective;
- For $p = 0$, $\Phi_0(A)$ is the inverse of the D-design objective, as

$$\Phi_0(A) = \lim_{p \to 0^+} \left(\frac{1}{d} \sum_{i=1}^{d} \lambda_i^{-p}\right)^{1/p} = \left(\prod_{i=1}^{d} \lambda_i^{-1}\right)^{1/d} = \det(A)^{-1/d},$$

  where the second equality is a well-known fact (see, e.g., Exercise 28 in Chapter 5 of [16]).

It is known that $\Phi_p(A)$ is convex in A for any given $0 \leq p \leq \infty$, and so the following is a natural convex programming relaxation for Φ_p-design:

$$\begin{aligned} \underset{x \in \mathbb{R}^n}{\text{minimize}} \quad & \Phi_p\left(\sum_{i=1}^{n} x(i) \cdot v_i v_i^\top\right) \\ \text{subject to} \quad & \sum_{i=1}^{n} x(i) \leq k, \\ & 0 \leq x(i) \leq 1, \qquad \text{for } 1 \leq i \leq n. \end{aligned} \tag{2}$$

To the best of our knowledge, there are no known approximation algorithms for the general Φ_p-design problem, other than the special cases $p = 0, 1, \infty$ which we summarize as follows (the notation $x \gtrsim y$ denotes that $x \geq cy$ for some large enough constant c):

- There is a $(1+\varepsilon)$-approximation algorithm for Φ_0-design (D-design) when $k \gtrsim d/\varepsilon$ [13, 9, 11, 6].
- There is a $(1+\varepsilon)$-approximation algorithm for Φ_1-design (A-design) when $k \gtrsim d/\varepsilon$ [9, 11, 6].
- There is a $(1+\varepsilon)$-approximation algorithm for Φ_∞-design (E-design) when $k \gtrsim d/\varepsilon^2$ [1, 7].

These results are tight in the sense that they match the known integrality gap lower bound of the convex programming relaxation (2) (see [11] for integrality gap examples).

Note that there is a d/ε vs d/ε^2 gap between the relaxations for D/A-design ($p = 0, 1$) and for E-design ($p = \infty$). The main question that we study in this paper is: How does the integrality gap of the convex programming relaxation (2) change with varying value of p? In particular, where does the transition from d/ε to d/ε^2 happen?

1.1 Main Result

Our main result is that, when $k \gtrsim \min\{dp/\varepsilon, d/\varepsilon^2\}$, there is a $(1+\varepsilon)$-approximation algorithm for Φ_p-design.

▶ **Theorem 2.** *Given an integer $p \geq 1$, let $\mathsf{x} \in [0,1]^n$ be an optimal fractional solution to (2). For any $\varepsilon \in (0,1)$, let $\gamma = \max\{\varepsilon, 1/p\}$, if $k \gtrsim d/(\gamma\varepsilon)$, then there is a randomized polynomial time algorithm that returns an integral solution $Z = \sum_{i=1}^n z(i) \cdot v_i v_i^\top$ with $z(i) \in \{0,1\}$ for $1 \leq i \leq n$ such that*

$$\Phi_p\left(\sum_{i=1}^n z(i) \cdot v_i v_i^\top\right) \leq (1+\varepsilon) \cdot \Phi_p\left(\sum_{i=1}^n x(i) \cdot v_i v_i^\top\right) \quad \text{and} \quad \sum_{i=1}^n z(i) \leq k,$$

with probability at least $1 - O\left(\frac{(d^2+d/\gamma)^2}{\varepsilon^2 p^2} \cdot e^{-\Omega(\gamma\sqrt{d})}\right) - e^{-\Omega(\varepsilon d/\gamma)}$.

▶ Remark. Theorem 2 can be generalized to all real $p \geq 1$, see Remark 11 for more details. The $p = 0$ case can also be covered by Theorem 2, but with a different analysis from [6].

This is the first approximation algorithm for Φ_p-design for general p. Theorem 2 shows that Φ_p-design for constant p admits as good an approximation algorithm as for D/A-design, and there is a unifying algorithm to achieve this guarantee.

Note that, when $p \to +\infty$, Φ_p becomes the E-design objective and $\gamma = \max\{\varepsilon, 1/p\} = \varepsilon$. Thus, Theorem 2 provides a nice interpolation between the d/ε bound for D/A-design and the d/ε^2 bound for E-design.

We further remark that our results can be generalized to the weighted setting to handle multiple budget/knapsack constraints as in [6], but we omit the details to keep the presentation cleaner as they are the same as in [6].

The proof of Theorem 2 is built on the randomized local search approach in [7] and [6], but several new technical ideas are needed to handle higher moments that are introduced by the higher p-norm. In Section 2, we will review the background and previous work, present the algorithm and the overall structure of the analysis, and explain the new ideas in this work. Then, in Section 3, we will present the details of the Φ_p experimental design.

1.2 Discussions and Future Directions

Our proof of Theorem 2 does not address the range $p \in [0,1)$. However, with a similar analysis as in [6], exactly the same algorithm in this paper can achieve a $(1+\varepsilon)$-approximation for $p = 0$ (i.e., D-design) when $k \gtrsim d/\varepsilon$. It would be interesting to see whether the randomized local search approach can be extended to Φ_p-design with $p \in (0,1)$. An obstacle to the current analysis is that the Lieb-Thirring inequality used in the proof of Lemma 10 goes in the wrong direction for $p \in (0,1)$.

If we plot the minimum required k for achieving the $(1+\varepsilon)$-approximation for the Φ_p-design as a function of p, Theorem 2 has ruled out a sharp transition of the curve at $p = 1$, from d/ε to d/ε^2. However, we do not know whether Theorem 2 is tight or not, in particular, in the range of $p \geq 1/\varepsilon$ (see Figure 1 for a demonstration). It would be interesting to fully characterize the whole curve.

1.3 Related Work

In this paper, we focus on generalizing the D/A/E-design with the p-norm objective in (1). However, there are other different ways to extend D/A/E-design. For example, the Bayesian framework of experimental design [2] extends the problem by adding a fixed matrix B (which encodes some prior information, e.g., a multiple of identity) to the covariance matrix before applying the objective function. When $B = 0$, we recover classical experimental design problems. Tantipongpipat [14] provided an approximation algorithm for Bayesian A-design

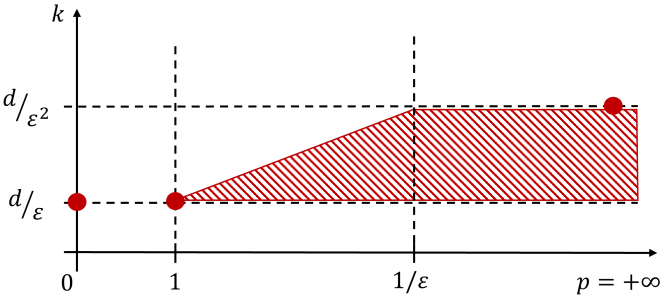

Figure 1 Known results on the minimum k required to achieve $(1+\varepsilon)$-approximation for the Φ_p-design (ignoring constant factors). The exact curve should lie within the shadowed area.

problem when B is a multiple of identity. Dereziński et. al. [3] studied approximation algorithms for Bayesian A/D-design (together with C/V-design, i.e., two other objectives) with a general PSD matrix B. Another example is using elementary symmetric polynomials to generalize A/D-design [10]. Nikolov et. al. [11] extended their approximation algorithm for A-design to tackle this family of generalized ratio objectives.

All these are interesting generalizations of D/A/E-design. It would be interesting to see whether the randomized local search approach in [7, 6] and this paper can be applied to these settings to obtain better results.

2 The Framework

In this section, we first review the randomized local search approach in Section 2.1. Then, we present the full algorithm in Section 2.2 and state the main technical theorem. Then, in Section 2.3, we provide the overall proof plan and the precise statements for analyzing the randomized exchange algorithm, and then put together the statements to prove the main technical theorem. Finally, we discuss the main difficulty and the new ideas needed to analyze the Φ_p objective in Section 3.

2.1 Randomized Local Search Approach

The proof of Theorem 2 is built on the randomized local search approach in [6], which is based on the regret minimization framework developed in [1] for experimental design problems and the randomized spectral rounding techniques in [7]. We review this approach in this subsection.

In [6], the first step is to solve (2) for D/A/E-design to obtain a solution $x \in \mathbb{R}^n$, and then to normalize the vectors v_i's so that $\sum_{i=1}^n x(i) \cdot v_i v_i^\top = I$ for using the regret minimization framework in [1]. Then, the rounding algorithm starts from a random initial solution set S_0 that is independently sampled according to x. Using the density matrix A_t maintained by the regret minimization framework at each step t, the algorithm randomly chooses a pair of vectors v_{i_t} and v_{j_t} with the following probability distributions:

$$\Pr(i_t = i) \propto \big(1 - x(i)\big) \cdot \Big(1 - \alpha\langle v_i v_i^\top, A_t^{1/2}\rangle\Big) \quad \text{and} \quad \Pr(j_t = j) \propto x(j) \cdot \Big(1 + \alpha\langle v_j v_j^\top, A_t^{1/2}\rangle\Big), \tag{3}$$

and set $S_{t+1} \leftarrow S_t - v_{i_t} + v_{j_t}$. Using the above randomized local search strategy, it can be shown that the size of the solution is expected to stay around k, while the potential function from the regret minimization framework [1] related to the minimum eigenvalue is expected to improve as long as the minimum eigenvalue is less than $1 - \varepsilon$. Freedman's martingale inequality and a new concentration inequality for non-martingales are used in [7] to prove that all these quantities are close to their expected values with high probability. This randomized local search algorithm provides a $(1 \pm \varepsilon)$-approximate solution for D/A/E-design when $k \gtrsim d/\varepsilon^2$.

The main contribution in [6] is to prove that the randomized local search algorithm can be adapted to achieve $(1 \pm \varepsilon)$-approximation for D/A-design when $k \gtrsim d/\varepsilon$, thus providing a unifying approach to achieve the optimal integrality gap for D/A/E-design. Essentially, the algorithm is the same as the one for E-design but only require that the solution to have minimum eigenvalue $3/4$ rather than $1 - \varepsilon$. For the analysis, the randomized local search algorithm is conceptually divided into two phases. In the first phase, the algorithm will find a solution with minimum eigenvalue at least $3/4$ with high probability when $k \gtrsim d/\varepsilon$. In the second phase, the minimum eigenvalue will maintain to be at least $1/4$ with high probability, and the objective value for D/A-design will improve to $(1 \pm \varepsilon)$ times the optimal objective value in polynomial time with high probability. The analysis of the first phase follows directly from earlier work on spectral rounding in [7]. The analysis of the second phase includes two main parts: (1) to show that, in expectation, the probability distributions in (3) for E-design are also good for making progress towards D/A-design objectives; (2) to show that the progress in the objective value is concentrated around the expectation with a martingale concentration argument. The condition that the minimum eigenvalue is at least $1/4$ is very important in both parts in the second phase, and the optimality conditions for the convex program (2) is crucially used in the second part in the second phase.

In this paper, we will extend the algorithm and the analysis described above and show that the randomized local search algorithm provides a unifying approach for Φ_p-design for all p.

2.2 The Algorithm

We present the full algorithm for Φ_p-design in this subsection.

Algorithm 1 Randomized Exchange Algorithm.

```
Input: $m$ vectors $u_1, \dots, u_m \in \mathbb{R}^d$, a budget $k \geq d$, an accuracy parameter $\varepsilon \in (0,1)$.

1. Solve the convex programming relaxation (2) and obtain an optimal solution $x \in [0,1]^m$ with at most $d^2 + 1$ fractional entries, i.e. $|\{i \in [m] \mid 0 < x(i) < 1\}| \leq d^2 + 1$. Let $X = \sum_{i=1}^m x(i) \cdot u_i u_i^\top$.
2. Preprocessing: Let $v_i \leftarrow X^{-1/2} u_i$ for all $i \in [m]$, so that $\sum_{i=1}^m x(i) \cdot v_i v_i^\top = I_d$.
3. Initialization: $t \leftarrow 1$, $S_0 \leftarrow \emptyset$, $\gamma = \max\{\frac{\varepsilon}{6}, \frac{1}{6p}\}$, $\kappa = \max\{\frac{\varepsilon}{2}, \frac{1}{2p}\}$, $M \leftarrow \frac{d}{\gamma} + d^2 + 1$, and $\alpha \leftarrow \frac{\sqrt{d}}{\gamma}$.
4. Add $i$ into $S_0$ independently with probability $x(i)$ for each $i \in [m]$. Let $Y_1 \leftarrow \sum_{i \in S_0} u_i u_i^\top$ and $Z_1 \leftarrow \sum_{i \in S_0} v_i v_i^\top$.
5. While the termination condition $(\mathrm{tr}(Y_t^{-p}))^{\frac{1}{p}} \leq (1+\varepsilon)(\mathrm{tr}(X^{-p}))^{\frac{1}{p}}$ is not satisfied and $t \leq \frac{2M}{\gamma} + \frac{2M}{\varepsilon p}$, do the following:
   a. $S_t \leftarrow \mathrm{Exchange}(S_{t-1})$.
   b. Set $Y_{t+1} \leftarrow \sum_{i \in S_t} u_i u_i^\top$, $Z_{t+1} \leftarrow \sum_{i \in S_t} v_i v_i^\top$ and $t \leftarrow t+1$.
6. Return $S_{t-1}$ as the solution.
```

The main algorithm is almost the same as the one in [6], but with two additional parameters γ, κ that will depend on the value of p. For A-design (when $p = 1$), the algorithm in [6] is just a special case of the randomized exchange algorithm with parameter $\gamma = \frac{1}{8}$ and $\kappa = 1$. In this paper, the parameter γ is used to adjust the learning rate α of the regret minimization framework and the parameter κ will be used in the exchange subroutine.

■ **Algorithm 2** Exchange Subroutine.

```
Input: the current solution set $S_{t-1}$.

1. Compute the action matrix $A_t := (\alpha Z_t - c_t I)^{-2}$, where $Z_t = \sum_{i \in S_{t-1}} v_i v_i^\top$ and $c_t$ is the
   unique scalar such that $A_t \succ 0$ and $\operatorname{tr}(A_t) = 1$.
2. Define $S'_t := \{ i \in S_{t-1} \mid \alpha \langle v_i v_i^\top, A_t^{1/2} \rangle \le \frac{1}{2}$ and $\langle v_i v_i^\top, Z_t^{-1} \rangle \le \kappa \}$.
3. Sample $j_t \in [m] \backslash S_{t-1}$ from the following probability distribution

     $\Pr(j_t = j) = \frac{x(j)}{M} \cdot \big(1 + \alpha \langle v_j v_j^\top, A_t^{1/2} \rangle\big)$, for $j \in [m] \backslash S_{t-1}$ and
     $\Pr(j_t = \emptyset) = 1 - \sum_{j \in [m] \backslash S_{t-1}} \frac{x(j)}{M} \cdot \big(1 + \alpha \langle v_j v_j^\top, A_t^{1/2} \rangle\big)$.

4. Sample $i_t \in S'_{t-1}$ from the following probability distribution

     $\Pr(i_t = i) = \frac{1 - x(i)}{M} \cdot \big(1 - \alpha \langle v_i v_i^\top, A_t^{1/2} \rangle\big)$, for $i \in S'_{t-1}$ and
     $\Pr(i_t = \emptyset) = 1 - \sum_{i \in S'_{t-1}} \frac{1 - x(i)}{M} \cdot \big(1 - \alpha \langle v_i v_i^\top, A_t^{1/2} \rangle\big)$.

5. Return $S_t := S_{t-1} \cup \{j_t\} \backslash \{i_t\}$.
```

The exchange subroutine is also almost the same as in [6]. The key difference is to use the new parameter κ to further restrict the set of vectors that are allowed to remove from the current solution.

▶ Remark 3. Using the new analysis in this paper, the same algorithm in [6] (without changing the parameters γ and κ) can achieve $(1+\varepsilon)$-approximation for Φ_p-design when $k \gtrsim 2^{O(p)} d/\varepsilon$, with an exponential dependence on p in the budget requirement, much worse than $k \gtrsim \min\{dp/\varepsilon, d/\varepsilon^2\}$ in Theorem 2.

Main Technical Theorem

To prove Theorem 2, we will prove that the randomized exchange algorithm is a bicriteria approximation algorithm, such that it returns a solution that is $(1+\varepsilon)$-approximate in the Φ_p objective and the size of the solution is not much larger than k.

▶ **Theorem 4.** *Given $\varepsilon \in (0,1)$, if $k \gtrsim \frac{d}{\gamma\varepsilon}$, then the randomized exchange algorithm returns a solution set S within $\frac{2M}{\gamma} + \frac{2M}{\varepsilon p}$ iterations such that*

$$\left(\operatorname{tr} \left(\Big(\sum_{i \in S} u_i u_i^\top \Big)^{-p} \right) \right)^{\frac{1}{p}} \le (1+\varepsilon) \cdot \left(\operatorname{tr} \left(X^{-p} \right) \right)^{1/p}$$

with probability at least $1 - O\big(\frac{M^2}{\varepsilon^2 p^2} \cdot e^{-\Omega(\gamma\sqrt{d})}\big)$, where X is an optimal fractional solution to (2). Moreover, the solution set S satisfies $|S| \le (1+\varepsilon)k + O\big(\frac{d}{\gamma} + \frac{d}{\kappa}\big)$ with probability at least $1 - e^{-\Omega(\varepsilon d / \min\{\gamma,\kappa\})}$.

With Theorem 4, we can prove Theorem 2 by first noticing that both γ and κ are chosen in the order of $\Theta(\max\{\varepsilon, 1/p\})$ and then turning the bicriteria approximation result into a true approximation with a scaling argument as in [6]. We omit the standard proof and refer the readers to [6] for more details.

2.3 The Proof Plan

In this subsection, we provide the overall plan and the precise statements for analyzing the randomized exchange algorithm, and then put together the statements to obtain the main technical theorem.

2.3.1 Well-Defined Algorithm

First, we prove that the randomized exchange algorithm is well-defined. In particular, we need to show that a fractional optimal solution to the convex relaxation (2) with at most $O(d^2)$ fractional entries can be found in polynomial time, and also the probability distributions in the exchange subroutine are well-defined for $M = d^2 + \frac{d}{\gamma} + 1$. These can be established using the same arguments (with a different value for γ) as in Lemma 4.2 and Claim 4.4 in [6]. Note that the modified exchange subroutine does not affect these arguments.

The following simple observation (Observation 4.3 in [6]) will be useful in the analysis of the algorithm.

▶ **Observation 5.** *For any $t \geq 0$, it holds that $i \in S_t$ for all i with $x(i) = 1$ and $j \in [n] \backslash S_t$ for all j with $x(j) = 0$. This further implies that $\Pr(i_t = i) = 0$ for all i with $x(i) \in \{0, 1\}$ and $\Pr(j_t = j) = 0$ for all j with $x(j) \in \{0, 1\}$.*

2.3.2 Solution Size Bound

Then, we show that the algorithm returns a solution set S of size not much larger than k with high probability.

▶ **Theorem 6** (Variant of Theorem 3.12 of [7]). *Let $\alpha = \sqrt{d}/\gamma$ and κ be the parameters used in the randomized exchange algorithm. Suppose that the solution S_t of the randomized exchange algorithm satisfies $\lambda_{\min}\left(\sum_{i \in S_t} v_i v_i^\top\right) < 1$ for all $t \in [\tau]$. Then, for any given $\delta \in [0, 1]$,*

$$\Pr\left[|S_\tau| \leq (1+\delta) \cdot \sum_{i=1}^{n} x(i) + \left(\frac{12d}{\gamma} + \frac{2d}{\kappa}\right)\right] \geq 1 - \exp\left(-\Omega\left(\frac{\delta d}{\min\{\gamma, \kappa\}}\right)\right).$$

When $\kappa = 1$, the above theorem follows directly from the one-sided spectral rounding result in [7]. With smaller κ, we are restricting the set of vectors that can be swapped out from the current solution. This would increase the chance of not removing a vector, and thus increasing the size of the solution. Fortunately, we can show that the increase of the solution size can be bounded by an additive d/κ term. The proof idea is similar to the one in [7], and the main difference is a modified bound on the expected change of size. Please refer to the appendices of the full arxiv version [5] for more details.

2.3.3 Approximation Guarantee

The most technical part of the proof is to establish the approximation guarantee. We follow the analysis in [6] to conceptually divide the execution of the algorithm into two phases as described in Section 2.1.

In the first phase, we show that the minimum eigenvalue will reach $1 - 2\gamma$ in $O(M/\gamma)$ iterations with high probability, which follows from the spectral rounding result in [7].

▶ **Proposition 7** (Counterpart of Proposition 4.5 in [6]). *The probability that the randomized exchange algorithm has terminated successfully within $2M/\gamma$ iterations or there exists $\tau_1 \leq 2M/\gamma$ with $\lambda_{\min}(Z_{\tau_1}) \geq 1 - 2\gamma$ is at least $1 - \exp(-\Omega(\sqrt{d}))$.*

In the second phase, the minimum eigenvalue will be at least $1 - 5\gamma$ during the next $\Theta\left(\frac{M}{\varepsilon p}\right)$ iterations with good probability.

▶ **Proposition 8** (Counterpart of Proposition 4.6 in [6]). *Suppose $\lambda_{\min}(Z_{\tau_1}) \geq 1 - 2\gamma$ for some τ_1. In the randomized exchange algorithm, the probability that $\lambda_{\min}(Z_t) \geq 1 - 5\gamma$ for all $\tau_1 \leq t \leq \tau_1 + \frac{2M}{\varepsilon p}$ is at least $1 - \frac{4M^2}{\varepsilon^2 p^2} \cdot e^{-\Omega(\gamma\sqrt{d})}$.*

Both of the proofs of Proposition 7 and Proposition 8 follow same arguments in [6] (with a new parameter γ). We remark that the modified exchange subroutine with a restricted S'_t does not affect these arguments, as removing less vectors only helps to improve the minimum eigenvalue of the solution. We omit the proofs and refer the readers to [6].

The main technical contribution in this paper is to prove that the Φ_p objective will improve to at most $(1 + \varepsilon)$ times the optimal value during the second phase when the minimum eigenvalue is at least $1 - 5\gamma$.

▶ **Theorem 9.** *Given $\varepsilon \in (0, 1)$, if $p \leq 1/\varepsilon$ and $k \gtrsim \frac{pd}{\varepsilon}$ for some $\varepsilon \in (0, 1)$, then the probability that the following three events happen simultaneously during the execution of the randomized exchange algorithm is at most $\exp(-\Omega(\gamma\sqrt{d}))$.*

1. *$\lambda_{\min}(Z_{\tau_1}) \geq 1 - 2\gamma$ for some τ_1;*
2. *$\lambda_{\min}(Z_t) \geq 1 - 5\gamma$ for all $\tau_1 \leq t \leq \tau_1 + \frac{2M}{\varepsilon p}$;*
3. *the randomized exchange algorithm has not terminated by time $\tau_1 + \frac{2M}{\varepsilon p}$.*

2.3.4 Proof of Theorem 4

We put together the statements in this subsection to obtain Theorem 4.

Proof of Theorem 4. We start with analyzing the approximation guarantee in the theorem.

Firstly, consider the easier case $p \geq 1/\varepsilon$, which implies that $\gamma = \varepsilon/6$. By Proposition 7, there exists $\tau_1 \leq 2M/\gamma$ such that $\lambda_{\min}(Z_{\tau_1}) \geq (1 - \varepsilon/3)$ with probability $1 - \exp(-\Omega(\sqrt{d}))$. We note that $\lambda_{\min}(Z_{\tau_1}) \geq (1 - \varepsilon/3)$ is equivalent to $Y_{\tau_1} \succcurlyeq (1 - \varepsilon/3)X$, which is sufficient to establish

$$(\operatorname{tr}(Y_{\tau_1}^{-p}))^{1/p} \leq (1 + \varepsilon)(\operatorname{tr}(X^{-p}))^{1/p},$$

i.e., the approximation guarantee in the theorem. We remark that we do not need the assumption $k \gtrsim d/(\gamma\varepsilon)$ in the proof of this case.

Then, we consider the case of $p \leq 1/\varepsilon$ and define the bad events for the randomized exchange algorithm:

- B_1: the algorithm has not terminated successfully within $2M/\gamma$ iterations and $\tau_1 > 2M/\gamma$ where τ_1 is the first time such that $\lambda_{\min}(Z_{\tau_1}) \geq 1 - 2\gamma$.
- B_2: there exists some $\tau_1 \leq t \leq \tau_1 + \frac{2M}{\varepsilon p}$ such that $\lambda_{\min}(Z_t) < 1 - 5\gamma$.
- B_3: the termination condition $(\operatorname{tr}(Y_t^{-p}))^{\frac{1}{p}} \leq (1 + \varepsilon)(\operatorname{tr}(X^{-p}))^{\frac{1}{p}}$ is not satisfied for all $\tau_1 \leq t \leq \tau_1 + \frac{2M}{\varepsilon p}$.

If none of the bad events happens, then either the algorithm has terminated successfully within $2M/\gamma$ iterations or the termination condition will be satisfied at some time $t \leq \tau_1 + \frac{2M}{\varepsilon p} \leq \frac{2M}{\gamma} + \frac{2M}{\varepsilon p}$. So, the probability that the randomized exchange algorithm has not satisfied the termination condition within $\frac{2M}{\gamma} + \frac{2M}{\varepsilon p}$ iterations is upper bounded by

$$\begin{aligned}\Pr[B_1 \cup B_2 \cup B_3] &= \Pr[B_1] + \Pr[B_2 \cap \neg B_1] + \Pr[B_3 \cap \neg B_2 \cap \neg B_1] \\ &\leq O\left(e^{-\Omega(\sqrt{d})}\right) + O\left(\frac{M^2}{\varepsilon^2 p^2} \cdot e^{-\Omega(\gamma\sqrt{d})}\right) + O\left(e^{-\Omega(\gamma\sqrt{d})}\right) \\ &\leq O\left(\frac{M^2}{\varepsilon^2 p^2} \cdot e^{-\Omega(\gamma\sqrt{d})}\right),\end{aligned}$$

where $\Pr[B_1]$ is bounded in Proposition 7, $\Pr[B_2 \cap \neg B_1]$ is bounded in Proposition 8, and $\Pr[B_3 \cap \neg B_2 \cap \neg B_1]$ is bounded in Theorem 9 (note that we need the assumption $p \leq 1/\varepsilon$ and $k \gtrsim pd/\varepsilon$ here). The termination condition implies the approximation guarantee directly.

Finally, we consider the size of the returned solution. Note that if $\lambda_{\min}(Z_t) \geq 1$ then $Y_t \succcurlyeq X$, which further implies that the termination condition is met at time t. Hence, we can assume $\lambda_{\min}(Z_t) < 1$ before the algorithm terminates. Therefore, we can apply Theorem 6 to conclude that the returned solution S satisfies $|S| \leq (1+\varepsilon)k + O\big(\frac{d}{\gamma} + \frac{d}{\kappa}\big)$ with probability at least $1 - \exp(-\Omega(\frac{\varepsilon d}{\min\{\gamma,\kappa\}}))$. ◀

2.4 New Ideas

The key in proving Theorem 9 is to bound the change of the objective value after an exchange. For A-design ($p = 1$), there is a simple inequality bounding the change of the objective as

$$\operatorname{tr}\left(\left(Y - vv^\top + ww^\top\right)^{-1}\right) \leq \operatorname{tr}\left(Y^{-1}\right) + \underbrace{\frac{v^\top Y^{-2} v}{1 - \langle vv^\top, Y^{-1}\rangle} - \frac{w^\top Y^{-2} w}{1 + \langle ww^\top, Y^{-1}\rangle}}_{\text{progress}}.$$

For general Φ_p-design, the change of the Φ_p function under rank-two updates is considerably more complicated. Using Sherman-Morrison formula and Lieb-Thirring inequality, we can bound the change of the Φ_p objective (in fact, the p-th power of the Φ_p objective) as follows:

$$\begin{aligned}&\operatorname{tr}\left((Y + ww^\top - vv^\top)^{-p}\right) \\ &\quad\leq \operatorname{tr}(Y^{-p}) + \sum_{i=1}^{p} \binom{p}{i} \left((-1)^i \frac{(w^\top Y^{-1} w)^{i-1} \cdot w^\top Y^{-p-1} w}{(1 + w^\top Y^{-1} w)^i} + \frac{(v^\top Y^{-1} v)^{i-1} \cdot v^\top Y^{-p-1} v}{(1 - v^\top Y^{-1} v)^i}\right).\end{aligned}$$

There are many higher order terms introduced by the p-norm, and dealing with these is the main technical difficulty in this paper.

As discussed in Remark 3, if we use the same algorithm in [6], with some careful manipulations including applying Hölder's inequality appropriately, we can achieve $(1+\varepsilon)$-approximation but with the much worst requirement that $k \gtrsim 2^{O(p)} d/\varepsilon$. The reason is that removing some "influential" vectors (even with relatively small probability) from the current solution will blow up the expectation of the change of the objective function due to the higher order terms in the above inequality.

To overcome this issue, we introduce the parameter κ and modify the randomized exchange algorithm by restricting those vectors (in S_t') that are allowed to swap out of the current solution. This helps us to effectively bound those higher order terms in the above inequality about the change of the objective function. But, with smaller κ, we are restricting the set of vectors that can be swapped out from the current solution. This would increase the chance of not removing a vector, and thus increasing the size of the solution. Fortunately, we can show that the increase of the solution size can be bounded by an additive d/κ term as described in Theorem 6.

The analysis for A-design in [6] contains two parts: (1) bound the expected progress; (2) prove the concentration of the total progress. The condition that the minimum eigenvalue is at least 1/4 is very important in both parts, and the optimality conditions for the convex program (2) is crucially used in the concentration argument. Interestingly, the optimality condition of the convex program (2) is also crucial in bounding the expected progress for Φ_p objective with higher p. Much effort in this paper is used to get the expectations of the objective value right, while it was relatively easy for D/A-design (when $p = 0, 1$).

3 The Analysis of Φ_p Objective

The goal of this section is to prove Theorem 9. Since we are focusing on the case of $p \le 1/\varepsilon$ in Theorem 9, we can assume without loss of generality that

$$\gamma = \max\left\{\frac{\varepsilon}{6}, \frac{1}{6p}\right\} = \frac{1}{6p} \qquad \text{and} \qquad \kappa = \max\left\{\frac{\varepsilon}{2}, \frac{1}{2p}\right\} = \frac{1}{2p}$$

in the remaining of this section. For ease of notation, we also assume the start time of the second phase is $\tau_1 = 1$. To analyze progress of the algorithm in terms of the objective function, we upper bound the change of $\mathrm{tr}(Y_t^{-p})$ after a swap using the following lemma, for which we will provide a proof in Section 3.1.

▶ **Lemma 10.** *Let $Y \succ 0$ be a d-dimensional positive definite matrix and $p \ge 1$ be an integer. For any $w \in \mathbb{R}^d$ and $v \in \mathbb{R}^d$ such that $v^\top Y^{-1} v < 1$,*

$$\begin{aligned}
&\mathrm{tr}\left((Y + ww^\top - vv^\top)^{-p}\right) \\
&\quad \le \mathrm{tr}(Y^{-p}) + \sum_{i=1}^{p} \binom{p}{i} \left((-1)^i \frac{(w^\top Y^{-1} w)^{i-1} \cdot w^\top Y^{-p-1} w}{(1 + w^\top Y^{-1} w)^i} + \frac{(v^\top Y^{-1} v)^{i-1} \cdot v^\top Y^{-p-1} v}{(1 - v^\top Y^{-1} v)^i} \right).
\end{aligned}$$

In the randomized exchange algorithm, we swap vectors u_{i_t} and u_{j_t} in each iteration where u_{i_t} is in the current solution. Thus, $u_{i_t}^\top Y_t^{-1} u_{i_t} \le 1$ always holds, and in fact it will be clear later that $u_{i_t}^\top Y_t^{-1} u_{i_t}$ is strictly less than 1. Hence, Lemma 10 can be applied repeatedly to obtain that, for any $\tau \ge 1$,

$$\begin{aligned}
\mathrm{tr}(Y_{\tau+1}^{-p}) - \mathrm{tr}(Y_1^{-p}) \le \sum_{t=1}^{\tau} \Bigg(&\underbrace{\sum_{i=1}^{p} \binom{p}{i} \frac{(u_{i_t}^\top Y_t^{-1} u_{i_t})^{i-1} \cdot u_{i_t}^\top Y_t^{-p-1} u_{i_t}}{(1 - u_{i_t}^\top Y_t^{-1} u_{i_t})^i}}_{\text{loss}} \\
&- \underbrace{\sum_{i=1}^{p} \binom{p}{i} (-1)^{i+1} \frac{(u_{j_t}^\top Y_t^{-1} u_{j_t})^{i-1} \cdot u_{j_t}^\top Y_t^{-p-1} u_{j_t}}{(1 + u_{j_t}^\top Y_t^{-1} u_{j_t})^i}}_{\text{gain}} \Bigg).
\end{aligned} \tag{4}$$

We define gain g_t, loss l_t, and progress Γ_t in the t-th iteration as follows

$$\begin{aligned}
g_t &:= \sum_{i=1}^{p} \binom{p}{i} (-1)^{i+1} \frac{(u_{j_t}^\top Y_t^{-1} u_{j_t})^{i-1} \cdot u_{j_t}^\top Y_t^{-p-1} u_{j_t}}{(1 + u_{j_t}^\top Y_t^{-1} u_{j_t})^i}, \\
l_t &:= \sum_{i=1}^{p} \binom{p}{i} \frac{(u_{i_t}^\top Y_t^{-1} u_{i_t})^{i-1} \cdot u_{i_t}^\top Y_t^{-p-1} u_{i_t}}{(1 - u_{i_t}^\top Y_t^{-1} u_{i_t})^i}, \\
\Gamma_t &:= g_t - l_t.
\end{aligned}$$

In Section 3.2, we will prove that if x is a fractional optimal solution to (2) and Z_t has lower-bounded minimum eigenvalue and the objective value of the current solution is far from optimal, then the expected progress in the t-th iteration is large. Then, in Section 3.3, we will prove that the total progress is concentrated around its expectation. Finally, we complete the proof of Theorem 9 in Section 3.4.

3.1 Change of Objective Value in One Step

In [6], a rank-two update formula is used to compute the change of the objective value in one step when $p = 1$. For general Φ_p-design, the rank-two update formula becomes considerably more complicated, and instead we do the update in two smaller steps: We first use a rank-one update to add u_{j_t} to the current solution, then use another rank-one update to remove u_{i_t} from the current solution.

Proof of Lemma 10. Let $Y_1 = Y + ww^\top$. By Sherman-Morrison formula [12], it holds that

$$\operatorname{tr}(Y_1^{-p}) = \operatorname{tr}\left(\left(Y^{-1} - \frac{Y^{-1}ww^\top Y^{-1}}{1 + w^\top Y^{-1}w}\right)^p\right) = \operatorname{tr}\left(\left(Y^{-1/2}\left(I - \frac{Y^{-1/2}ww^\top Y^{-1/2}}{1 + w^\top Y^{-1}w}\right)Y^{-1/2}\right)^p\right).$$

Then, we can apply Lieb-Thirring inequality [8] to show that

$$\operatorname{tr}(Y_1^{-p}) \le \operatorname{tr}\left(Y^{-p/2}\left(I - \frac{Y^{-1/2}ww^\top Y^{-1/2}}{1 + w^\top Y^{-1}w}\right)^p Y^{-p/2}\right) = \operatorname{tr}\left(Y^{-p}\left(I - \frac{Y^{-1/2}ww^\top Y^{-1/2}}{1 + w^\top Y^{-1}w}\right)^p\right).$$

Expanding by the binomial theorem,

$$\begin{aligned}\operatorname{tr}(Y_1^{-p}) &\le \sum_{i=0}^{p}(-1)^i\binom{p}{i}\operatorname{tr}\left(Y^{-p}\left(\frac{Y^{-1/2}ww^\top Y^{-1/2}}{1 + w^\top Y^{-1}w}\right)^i\right)\\ &= \operatorname{tr}(Y^{-p}) + \sum_{i=1}^{p}(-1)^i\binom{p}{i}\frac{(w^\top Y^{-1}w)^{i-1}\cdot w^\top Y^{-p-1}w}{(1 + w^\top Y^{-1}w)^i}.\end{aligned} \tag{5}$$

For $Y_2 = Y_1 - vv^\top$, we can apply similar argument to show that

$$\operatorname{tr}(Y_2^{-p}) \le \operatorname{tr}(Y_1^{-p}) + \sum_{i=1}^{p}\binom{p}{i}\frac{(v^\top Y_1^{-1}v)^{i-1}\cdot v^\top Y_1^{-p-1}v}{(1 - v^\top Y_1^{-1}v)^i}.$$

Notice that $Y_1 = Y + ww^\top \succcurlyeq Y$ and $v^\top Y^{-1}v < 1$, thus it holds that

$$\operatorname{tr}(Y_2^{-p}) \le \operatorname{tr}(Y_1^{-p}) + \sum_{i=1}^{p}\binom{p}{i}\frac{(v^\top Y^{-1}v)^{i-1}\cdot v^\top Y^{-p-1}v}{(1 - v^\top Y^{-1}v)^i}. \tag{6}$$

The lemma follows by combining (5) and (6). ◀

▶ Remark 11. Lemma 10 can be generalized to all real $p \ge 1$ by invoking Newton's generalized binomial theorem in the proof. To guarantee the convergence of the generalized binomial theorem, we need to ensure a stronger condition $v^\top Y^{-1}v \le \frac{1}{2}$. This is not an issue for our application, as our algorithm always removes vectors from the restricted set S_t', which guarantees that $v^\top Y^{-1}v \le \frac{1}{2}$ is satisfied. Given the new version of Lemma 10 with real p, we can generalize the main result in this paper (i.e., Theorem 2) to all real $p \ge 1$ with essentially the same analysis.

3.2 Expected Progress

To analyze the expected progress, we need to use the following two lemmas. The first one is an implication of the lower-bounded minimum eigenvalue condition, which is an analog of Lemma 4.13 in [6], and we refer the readers to the appendices of the arxiv version of this paper [5] for a proof.

▶ **Lemma 12.** *For $\gamma \le \frac{1}{6}$, if $Z_t \succcurlyeq (1-5\gamma)I$, then*

$$\langle v_i v_i^\top, Z_t^{-1} \rangle \le \alpha \langle v_i v_i^\top, A_t^{\frac{1}{2}} \rangle \le \alpha \lambda_{\min}(Z_t) \langle v_i v_i^\top, Z_t^{-1} \rangle \qquad \forall i \in [n].$$

The other one is an implication of the optimality condition of (2). The proof of the lemma is similar to the one in [6] for A-design, see the appendices of the full arxiv version [5] for more details.

▶ **Lemma 13.** *Let $x \in [0,1]^n$ be an optimal fractional solution of the convex programming relaxation (2) for the p-norm problem. Then, for each $1 \le i \le n$ with $0 < x(i) < 1$,*

$$\langle X^{-p-1}, u_i u_i^\top \rangle \le \frac{1}{k} \cdot \operatorname{tr}(X^{-p}).$$

Now, we are ready to lower bound the expected progress. We will first handle the expected loss and expected gain separately in Lemma 14 and Lemma 15. Then, combine the two parts to lower bound the expected progress in Lemma 17. For simplicity, we denote $\mathbb{E}_t[\cdot]$ as the conditional expectation given what had happened up to time t, that is, $\mathbb{E}[\cdot \mid S_{t-1}]$.

3.2.1 Expected Loss

The minimum eigenvalue lower bound (Lemma 12), the optimality condition (Lemma 13), and the introduction of the new parameter κ in the randomized exchange algorithm are all crucial in the following lemma.

▶ **Lemma 14** (Expected Loss). *Let S_{t-1} be the solution set at time t and $Z_t = \sum_{i \in S_{t-1}} v_i v_i^\top$ for $1 \le t \le \tau$. Suppose x is an optimal solution of (2), $\lambda_{\min}(Z_t) \in [1-5\gamma, 1)$, $\gamma = 1/6p$, and $\kappa = 1/2p$. Then*

$$\mathbb{E}_t[l_t] \le \frac{p}{M}\Big(\operatorname{tr}(Y_t^{-p}) - \langle X_{S_{t-1}}, Y_t^{-p-1} \rangle\Big) + O\Big(\frac{p^2 d}{kM}\Big) \cdot \operatorname{tr}(X^{-p}),$$

where we denote $X_S := \sum_{i \in S} x(i) u_i u_i^\top$ for any set $S \subseteq [n]$.

Proof. There are p terms in the loss term l_t. We deal with the linear term and higher order terms separately. Consider the linear term:

$$\begin{aligned}\mathbb{E}_t\left[\frac{p \cdot u_{i_t}^\top Y_t^{-p-1} u_{i_t}}{1 - u_{i_t}^\top Y_t^{-1} u_{i_t}}\right] &= \sum_{i \in S'_{t-1}} \frac{1-x(i)}{M}\Big(1 - \alpha \langle v_i v_i^\top, A_t^{1/2} \rangle\Big) \cdot \frac{p \cdot u_i^\top Y_t^{-p-1} u_i}{1 - u_i^\top Y_t^{-1} u_i} \\ &= \sum_{i \in S'_{t-1}} \frac{1-x(i)}{M}\Big(1 - \alpha \langle v_i v_i^\top, A_t^{1/2} \rangle\Big) \cdot \frac{p \cdot u_i^\top Y_t^{-p-1} u_i}{1 - \langle v_i v_i^\top, Z_t^{-1} \rangle},\end{aligned}$$

where the second line follows by the definitions of Y_t and Z_t, which implies that

$$\langle v_i v_i^\top, Z_t^{-1} \rangle = u_i^\top Y_t^{-1} u_i. \tag{7}$$

Note that $\gamma = 1/6p \leq 1/6$. Thus, we can apply the first inequality in Lemma 12 and then relax S'_{t-1} to S_{t-1} to obtain that

$$\begin{aligned}\mathbb{E}_t\left[\frac{p \cdot u_{i_t}^\top Y_t^{-p-1} u_{i_t}}{1 - u_{i_t}^\top Y_t^{-1} u_{i_t}}\right] &\leq \frac{p}{M} \sum_{i \in S_{t-1}} (1 - x(i)) \cdot u_i^\top Y_t^{-p-1} u_i \\ &= \frac{p}{M}\Big(\operatorname{tr}(Y_t^{-p}) - \langle X_{S_{t-1}}, Y_t^{-p-1}\rangle\Big). \qquad (8)\end{aligned}$$

Then, we consider the remaining $p-1$ higher order loss terms.

$$\begin{aligned}&\underbrace{\mathbb{E}_t\left[\sum_{l=2}^{p} \binom{p}{l} \frac{(u_{i_t}^\top Y_t^{-1} u_{i_t})^{l-1} \cdot u_{i_t}^\top Y_t^{-p-1} u_{i_t}}{(1 - u_{i_t}^\top Y_t^{-1} u_{i_t})^l}\right]}_{\textcircled{1}} \\ &\qquad = \sum_{i \in S'_{t-1}} \frac{1 - x(i)}{M} \Big(1 - \alpha\langle v_i v_i^\top, A_t^{1/2}\rangle\Big) \sum_{l=2}^{p} \binom{p}{l} \frac{(u_i^\top Y_t^{-1} u_i)^{l-1} \cdot u_i^\top Y_t^{-p-1} u_i}{(1 - u_i^\top Y_t^{-1} u_i)^l}.\end{aligned}$$

Again, by applying Lemma 12, it holds that

$$\textcircled{1} \leq \sum_{i \in S'_{t-1}} \frac{1 - x(i)}{M} \cdot u_i^\top Y_t^{-p-1} u_i \cdot \sum_{l=2}^{p} \binom{p}{l} \frac{(u_i^\top Y_t^{-1} u_i)^{l-1}}{(1 - u_i^\top Y_t^{-1} u_i)^{l-1}}.$$

Notice that

$$\lambda_{\min}(Z_t) \geq 1 - 5\gamma \qquad \Longleftrightarrow \qquad Y_t \succcurlyeq (1 - 5\gamma)X. \qquad (9)$$

Thus, by the assumption $\lambda_{\min}(Z_t) \geq 1 - 5\gamma$, it follows that

$$\textcircled{1} \leq \frac{(1 - 5\gamma)^{-p-1}}{M} \sum_{i \in S'_{t-1}} (1 - x(i)) \cdot u_i^\top X^{-p-1} u_i \cdot \sum_{l=2}^{p} \binom{p}{l} \frac{(u_i^\top Y_t^{-1} u_i)^{l-1}}{(1 - u_i^\top Y_t^{-1} u_i)^{l-1}}.$$

Using the fact that x is a fractional optimal solution to (2) and then applying Lemma 13, it holds that

$$\begin{aligned}\textcircled{1} &\leq \frac{(1 - 5\gamma)^{-p-1}}{kM} \cdot \operatorname{tr}(X^{-p}) \sum_{i \in S'_{t-1}} (1 - x(i)) \cdot \sum_{l=2}^{p} \binom{p}{l} \frac{(u_i^\top Y_t^{-1} u_i)^{l-1}}{(1 - u_i^\top Y_t^{-1} u_i)^{l-1}} \\ &\leq \frac{(1 - 5\gamma)^{-p-1}}{kM} \cdot \operatorname{tr}(X^{-p}) \sum_{l=2}^{p} \binom{p}{l} \sum_{i \in S'_{t-1}} u_i^\top Y_t^{-1} u_i \cdot \frac{(u_i^\top Y_t^{-1} u_i)^{l-2}}{(1 - u_i^\top Y_t^{-1} u_i)^{l-1}}.\end{aligned}$$

Due to the definition of the set S'_{t-1} and (7), it holds that $u_i^\top Y_t^{-1} u_i \leq \kappa$ for all $i \in S'_{t-1}$. Thus,

$$\textcircled{1} \leq \frac{(1 - 5\gamma)^{-p-1}}{kM} \cdot \operatorname{tr}(X^{-p}) \sum_{l=2}^{p} \binom{p}{l} \sum_{i \in S'_{t-1}} u_i^\top Y_t^{-1} u_i \cdot \left(\frac{\kappa}{1 - \kappa}\right)^{l-2} \cdot \frac{1}{1 - \kappa}.$$

Since $\sum_{i \in S'_{t-1}} u_i^\top Y_t^{-1} u_i \leq \langle Y_t, Y_t^{-1}\rangle = d$, we can further upper bound the $\textcircled{1}$ term by

$$\begin{aligned}\textcircled{1} &\leq \frac{(1 - 5\gamma)^{-p-1} d}{kM} \cdot \operatorname{tr}(X^{-p}) \cdot \sum_{l=2}^{p} \binom{p}{l} \left(\frac{\kappa}{1 - \kappa}\right)^{l} \cdot \frac{1 - \kappa}{\kappa^2} \\ &= \frac{(1 - 5\gamma)^{-p-1} d}{kM} \cdot \operatorname{tr}(X^{-p}) \cdot \frac{1 - \kappa}{\kappa^2} \left(\frac{1}{(1 - \kappa)^p} - 1 - \frac{p\kappa}{1 - \kappa}\right) \\ &\leq \frac{(1 - 5\gamma)^{-p-1} d}{kM} \cdot \operatorname{tr}(X^{-p}) \cdot \frac{1}{\kappa^2} \cdot \frac{1}{(1 - \kappa)^p}. \qquad (10)\end{aligned}$$

Combining (8) and (10), the expected loss can be bounded by

$$\begin{aligned}\mathbb{E}_t[l_t] &\le \frac{p}{M}\Big(\operatorname{tr}(Y_t^{-p}) - \langle X_{S_{t-1}}, Y_t^{-p-1}\rangle\Big) + \frac{(1-5\gamma)^{-p-1}d}{\kappa^2(1-\kappa)^p kM}\cdot \operatorname{tr}(X^{-p})\\ &\le \frac{p}{M}\Big(\operatorname{tr}(Y_t^{-p}) - \langle X_{S_{t-1}}, Y_t^{-p-1}\rangle\Big) + O\Big(\frac{p^2 d}{kM}\Big)\cdot \operatorname{tr}(X^{-p}),\end{aligned}$$

where the last inequality follows by the choice of γ and κ. ◀

3.2.2 Expected Gain

The analysis of the expected gain is slightly more complicated since the sampling probability does not cancel out with the denominator term in g_t as nicely as in the analysis of loss l_t, and so we will divide into two cases and use different arguments. Again, the lower bound of the minimum eigenvalue (Lemma 12) and the optimality condition (Lemma 13) are crucial in the following lemma, the proof of which is deferred to Appendix A due to the space limit.

▶ **Lemma 15** (Expected Gain). *Let S_{t-1} be the solution set at time t and $Z_t = \sum_{i\in S_{t-1}} v_i v_i^\top$ for $1 \le t \le \tau$. Suppose x is an optimal solution to* (2)*, $\lambda_{\min}(Z_t) \in [1-5\gamma, 1)$, and $\gamma = 1/6p$. Then*

$$\mathbb{E}_t[g_t] \ge \frac{p}{M}\Big(\langle X, Y_t^{-p-1}\rangle - \langle X_{S_{t-1}}, Y_t^{-p-1}\rangle\Big) - O\Big(\frac{p^2 d}{kM}\Big)\cdot \operatorname{tr}(X^{-p}).$$

3.2.3 Expected Progress

Finally, we apply Hölder's inequality appropriately to compare the gain term and loss term.

▶ **Lemma 16.** *Given positive definite matrices $A, B \in \mathbb{S}^d_{++}$ and an integer $p \ge 1$, it holds that*

$$\langle A, B^{-p-1}\rangle \ge \left(\frac{\operatorname{tr}(B^{-p})}{\operatorname{tr}(A^{-p})}\right)^{1/p}\cdot \operatorname{tr}(B^{-p}).$$

Proof. Let $A = \sum_{i=1}^d a_i v_i v_i^\top$ be the eigendecomposition of A, and $B = \sum_{i=1}^d b_i w_i w_i^\top$ be the eigendecomposition of B. Then,

$$\begin{aligned}\operatorname{tr}(B^{-p}) = \sum_{i=1}^d \frac{1}{b_i^p} &= \sum_{1\le i,j\le d} \frac{1}{b_i^p}\langle v_i, w_j\rangle^2\\ &= \sum_{1\le i,j\le d} \frac{a_j^{p/(p+1)}}{b_i^p}\langle v_i, w_j\rangle^{2p/(p+1)}\cdot \frac{1}{a_j^{p/(p+1)}}\langle v_i, w_j\rangle^{2/(p+1)}\\ &\le \Big(\sum_{1\le i,j\le d} \frac{a_j}{b_i^{p+1}}\langle v_i, w_j\rangle^2\Big)^{p/(p+1)}\cdot \Big(\sum_{1\le i,j\le d}\frac{1}{a_j^p}\langle v_i, w_j\rangle^2\Big)^{1/(p+1)}\\ &= \langle A, B^{-p-1}\rangle^{p/(p+1)}\cdot \operatorname{tr}(A^{-p})^{1/(p+1)},\end{aligned}$$

where the inequality follows by Hölder's inequality. Then, the lemma follows by taking the $(p+1)/p$'s power of both sides and rearranging the terms. ◀

Now, we lower bound the expected progress by combining Lemma 14 and Lemma 15.

▶ **Lemma 17.** *Let S_{t-1} be the solution set at time t and $Z_t = \sum_{i \in S_{t-1}} v_i v_i^\top$ for $1 \leq t \leq \tau$. Suppose x is an fractional optimal solution to (2), and $\lambda_{\min}(Z_t) \in [1-5\gamma, 1)$, $(\mathrm{tr}(Y_t^{-2}))^{1/p} \geq \lambda \cdot (\mathrm{tr}\left(X^{-2}\right))^{1/p}$ for some $\lambda \geq 1$ and for $1 \leq t \leq \tau$. Then*

$$\mathbb{E}_t[\Gamma_t] \geq \left(\frac{p(\lambda-1)\lambda^p}{M} - O\Big(\frac{p^2 d}{kM}\Big)\right) \cdot \mathrm{tr}(X^{-p}).$$

In particular, when $\lambda > 1+\varepsilon$ and $k \gtrsim \frac{pd}{\varepsilon}$, the expected progress is positive.

Proof. Combining the expected loss Lemma 14 and the expected gain Lemma 15, it follows that

$$\mathbb{E}_t[\Gamma_t] \geq \frac{p}{M}\Big(\langle X, Y_t^{-p-1}\rangle - \mathrm{tr}(Y_t^{-p})\Big) - O\Big(\frac{p^2 d}{kM}\Big) \cdot \mathrm{tr}(X^{-p}).$$

Applying Lemma 16, we derive that

$$\mathbb{E}_t[\Gamma_t] \geq \frac{p}{M}\left(\left(\frac{\mathrm{tr}(Y_t^{-p})}{\mathrm{tr}(X^{-p})}\right)^{1/p} \cdot \mathrm{tr}(Y_t^{-p}) - \mathrm{tr}(Y_t^{-p})\right) - O\Big(\frac{p^2 d}{kM}\Big) \cdot \mathrm{tr}(X^{-p}).$$

By the assumption that $(\mathrm{tr}(Y_t^{-p}))^{1/p} \geq \lambda(\mathrm{tr}(X^{-p}))^{1/p}$, or equivalently $\mathrm{tr}(Y_t^{-p}) \geq \lambda^p \, \mathrm{tr}(X^{-p})$, we arrive at the final bound that

$$\mathbb{E}_t[\Gamma_t] \geq \frac{p(\lambda-1)}{M} \cdot \mathrm{tr}(Y_t^{-p}) - O\Big(\frac{p^2 d}{kM}\Big) \cdot \mathrm{tr}(X^{-p}) \geq \left(\frac{p(\lambda-1)\lambda^p}{M} - O\Big(\frac{p^2 d}{kM}\Big)\right) \cdot \mathrm{tr}(X^{-p}). ◀$$

3.3 Martingale Concentration Argument

In this subsection, we prove that the total progress is concentrated around the expectation. The proof uses the minimum eigenvalue assumption and the optimality characterization in Lemma 13 to bound the variance of the random process. The proof idea is similar to the one in [6], but we need some additional efforts to take care of the higher order terms that are introduced by higher p-norm. We defer the detailed proof to Appendix A.

▶ **Lemma 18.** *For any $\eta > 0$, it holds that*

$$\Pr\left[\sum_{t=1}^{\tau} \Gamma_t \leq \sum_{t=1}^{\tau} \mathbb{E}_t[\Gamma_t] - \eta \bigcap \min_{1 \leq t \leq \tau} \lambda_{\min}(Z_t) \geq 1-5\gamma\right] \leq \exp\left(-\Omega\left(\frac{\eta^2 kM}{\tau p^3 \sqrt{d}(\mathrm{tr}(X^{-p}))^2 + \eta p M \, \mathrm{tr}(X^{-p})}\right)\right).$$

3.4 Proof of Theorem 9

We are ready to prove Theorem 9. Let $\tau = \frac{2M}{\varepsilon p}$. We want to upper bound the probability that the following three events happen simultaneously:

- E_1: The randomized exchange algorithm entered the second phase, i.e., $\lambda_{\min}(Z_1) \geq 1-2\gamma$ using the notation in this subsection.
- E_2: $\min_{1 \leq t \leq \tau} \lambda_{\min}(Z_t) \geq 1-5\gamma$.
- E_3: The second phase of the algorithm has not terminated by time τ.

Suppose the event E_3 happens. Then $\lambda = \min_{1 \leq t \leq \tau+1} (\mathrm{tr}(Y_t^{-p}))^{1/p} / (\mathrm{tr}(X^{-p}))^{1/p} > (1+\varepsilon)$. If the event E_2 also happens, then Lemma 17 implies that

$$\begin{aligned}\sum_{t=1}^{\tau} \mathbb{E}_t\left[\Gamma_t\right] &\geq \tau \cdot \left(\frac{p(\lambda-1)\lambda^p}{M} - O\Big(\frac{p^2 d}{kM}\Big)\right) \cdot \mathrm{tr}(X^{-p}) \\ &\geq \frac{2M}{\varepsilon p} \cdot \left(\frac{\varepsilon p}{M} - \frac{\varepsilon p}{2M}\right) \cdot \mathrm{tr}(X^{-p}) \geq \mathrm{tr}\left(X^{-p}\right), \end{aligned} \tag{11}$$

where the second inequality holds for $k \gtrsim pd/\varepsilon$ with large enough constant.

On the other hand, the initial solution of the second phase satisfies $Z_1 \succcurlyeq (1-2\gamma)I$ (follows by E_1), which implies that $Y_1 \succcurlyeq (1-2\gamma)X$. Thus, $\operatorname{tr}(Y_1^{-p}) \leq (1-2\gamma)^{-p}\operatorname{tr}(X^{-p}) \leq (1-1/3p)^{-p}\operatorname{tr}(X^{-p}) \leq 3\operatorname{tr}(X^{-p})/2$, for $p \geq 1$. When the event E_2 happens, we know from Lemma 12 that $\langle v_{i_t} v_{i_t}^\top, Z_t^{-1}\rangle \leq \alpha \cdot \langle v_{i_t} v_{i_t}^\top, A_t^{\frac{1}{2}}\rangle < \frac{1}{2}$, and so we can apply (4) to deduce that

$$\operatorname{tr}(Y_{\tau+1}^{-p}) \leq \operatorname{tr}(Y_1^{-p}) - \sum_{t=1}^{\tau}\Gamma_t \leq \frac{3}{2}\cdot\operatorname{tr}\left(X^{-p}\right) - \sum_{t=1}^{\tau}\Gamma_t.$$

Since the algorithm has not terminated by time τ,

$$\operatorname{tr}(X^{-p}) \leq \operatorname{tr}(Y_{\tau+1}^{-p}) \quad\Longrightarrow\quad \sum_{t=1}^{\tau}\Gamma_t \leq \frac{1}{2}\cdot\operatorname{tr}\left(X^{-p}\right). \tag{12}$$

Combining (11) and (12), $E_1 \cap E_2 \cap E_3$ implies a large deviation of the progress from the expectation such that

$$\sum_{t=1}^{\tau}\Gamma_t - \sum_{t=1}^{\tau}\mathbb{E}_t[\Gamma_t] < -\frac{1}{2}\cdot\operatorname{tr}(X^{-p}).$$

Thus, we can apply Lemma 18 with $\eta = \frac{1}{2}\cdot\operatorname{tr}(X^{-p})$ and $\tau = \frac{2M}{\varepsilon p}$ to conclude that

$$\begin{aligned}
\Pr\left[E_1 \cap E_2 \cap E_3\right] &\leq \Pr\left[\sum_{t=1}^{\tau}\Gamma_t < \sum_{t=1}^{\tau}\mathbb{E}_t\left[\Gamma_t\right] - \frac{1}{2}\cdot\operatorname{tr}(X^{-p}) \bigcap E_2\right] \\
&\leq \exp\left(-\Omega\left(\frac{(\operatorname{tr}(X^{-p}))^2\cdot kM}{\left(\frac{2M}{\varepsilon p}\right)p^3\sqrt{d}\cdot(\operatorname{tr}(X^{-p}))^2 + pM\cdot(\operatorname{tr}(X^{-p}))^2}\right)\right) \\
&\leq \exp\left(-\Omega\left(\frac{\varepsilon k}{p^2\sqrt{d}}\right)\right) \leq \exp\left(-\Omega\left(\frac{\sqrt{d}}{p}\right)\right) = \exp\left(-\Omega\left(\gamma\sqrt{d}\right)\right),
\end{aligned}$$

where the last inequality holds by the assumption $k \gtrsim pd/\varepsilon$, and the last equality follows as $\gamma = 1/6p$.

A Omitted Proofs in Section 3

Proof of Lemma 15 (Expected Gain). We consider two separate cases:

$$
\begin{aligned}
&S_1 := \{j \in [m] \backslash S_{t-1} \mid \alpha \langle v_j v_j^\top, A_t^{1/2} \rangle \geq p \cdot u_j^\top Y_t^{-1} u_j\} \quad \text{and} \\
&S_2 := \{j \in [m] \backslash S_{t-1} \mid \alpha \langle v_j v_j^\top, A_t^{1/2} \rangle < p \cdot u_j^\top Y_t^{-1} u_j\}.
\end{aligned}
$$

Then, the expected gain can be written as

$$
\begin{aligned}
\mathbb{E}_t[g_t] = &\sum_{j \in S_1} \frac{x(j)}{M} \cdot \left(1 + \alpha \langle v_j v_j^\top, A_t^{1/2} \rangle\right) \cdot \sum_{l=1}^{p} \binom{p}{l} (-1)^{l+1} \frac{(u_j^\top Y_t^{-1} u_j)^{l-1} \cdot u_j^\top Y_t^{-p-1} u_j}{(1 + u_j^\top Y_t^{-1} u_j)^l} &(13)\\
&+ \sum_{j \in S_2} \frac{x(j)}{M} \cdot \left(1 + \alpha \langle v_j v_j^\top, A_t^{1/2} \rangle\right) \cdot \sum_{l=1}^{p} \binom{p}{l} (-1)^{l+1} \frac{(u_j^\top Y_t^{-1} u_j)^{l-1} \cdot u_j^\top Y_t^{-p-1} u_j}{(1 + u_j^\top Y_t^{-1} u_j)^l}. &(14)
\end{aligned}
$$

We analyze (13) and (14) separately. First, we consider (13) and rearrange the g_t term a bit, which will be easier for the analysis of (13).

$$\begin{aligned} g_t &= \frac{u_{j_t}^\top Y_t^{-p-1} u_{j_t}}{u_{j_t}^\top Y_t^{-1} u_{j_t}} \cdot \sum_{i=1}^{p} \binom{p}{i} (-1)^{i+1} \left(\frac{u_{j_t}^\top Y_t^{-1} u_{j_t}}{1 + u_{j_t}^\top Y_t^{-1} u_{j_t}} \right)^i \\ &= \frac{u_{j_t}^\top Y_t^{-p-1} u_{j_t}}{u_{j_t}^\top Y_t^{-1} u_{j_t}} \left(1 - \left(1 - \frac{u_{j_t}^\top Y_t^{-1} u_{j_t}}{1 + u_{j_t}^\top Y_t^{-1} u_{j_t}} \right)^p \right) \qquad (15) \\ &= \frac{u_{j_t}^\top Y_t^{-p-1} u_{j_t}}{u_{j_t}^\top Y_t^{-1} u_{j_t}} \left(1 - \frac{1}{(1 + u_{j_t}^\top Y_t^{-1} u_{j_t})^p} \right). \qquad (16) \end{aligned}$$

Thus, we can rewrite (13) as

$$(13) = \sum_{j \in S_1} \frac{x(j)}{M} \cdot \left(1 + \alpha \langle v_j v_j^\top, A_t^{1/2} \rangle \right) \cdot \frac{u_j^\top Y_t^{-p-1} u_j}{u_j^\top Y_t^{-1} u_j} \left(1 - \frac{1}{(1 + u_j^\top Y_t^{-1} u_j)^p} \right).$$

By the definition of S_1, it holds that

$$(13) \geq \sum_{j \in S_1} \frac{x(j)}{M} \cdot u_j^\top Y_t^{-p-1} u_j \cdot \frac{1 + p \cdot u_j^\top Y_t^{-1} u_j}{u_j^\top Y_t^{-1} u_j} \left(1 - \frac{1}{(1 + u_j^\top Y_t^{-1} u_j)^p} \right).$$

Let $x = u_j^\top Y_t^{-1} u_j > 0$ (as $Y_t \succ 0$). Then, it holds that

$$\frac{1 + px}{x} \cdot \left(1 - \frac{1}{(1+x)^p} \right) = \frac{1 + px}{x} \cdot \frac{(1+x)^p - 1}{(1+x)^p} = \frac{px(1+x)^p + (1+x)^p - 1 - px}{x(1+x)^p} \geq p.$$

Thus,

$$(13) \geq \frac{p}{M} \sum_{j \in S_1} x(j) \cdot u_j^\top Y_t^{-p-1} u_j. \qquad (17)$$

Then, we consider (14). As in the proof of Lemma 14, we separate (14) into two parts, ② concerning the linear term and ③ concerning the remaining $p - 1$ higher order terms.

$$\begin{aligned} (14) = & \underbrace{\sum_{j \in S_2} \frac{x(j)}{M} \cdot \left(1 + \alpha \langle v_j v_j^\top, A_t^{1/2} \rangle \right) \cdot \frac{p \cdot u_j^\top Y_t^{-p-1} u_j}{1 + u_j^\top Y_t^{-1} u_j}}_{\textcircled{2}} \\ & \underbrace{- \sum_{j \in S_2} \frac{x(j)}{M} \cdot \left(1 + \alpha \langle v_j v_j^\top, A_t^{1/2} \rangle \right) \cdot \sum_{l=2}^{p} \binom{p}{l} (-1)^l \frac{(u_j^\top Y_t^{-1} u_j)^{l-1} \cdot u_j^\top Y_t^{-p-1} u_j}{(1 + u_j^\top Y_t^{-1} u_j)^l}}_{\textcircled{3}} . \end{aligned}$$

The linear term ② is easy to bound, we can control it by Lemma 12 (combined with (7)) so that

$$\textcircled{2} \geq \frac{p}{M} \sum_{j \in S_2} x(j) \cdot u_j^\top Y_t^{-p-1} u_j. \qquad (18)$$

Then, we upper bound the higher order terms ③ (notice that ③ does not contain the minus sign). To upper bound ③, for each $j \in S_2$, we can assume $\sum_{l=2}^{p} \binom{p}{l} (-1)^l \frac{(u_j^\top Y_t^{-1} u_j)^{l-1} \cdot u_j^\top Y_t^{-p-1} u_j}{(1 + u_j^\top Y_t^{-1} u_j)^l} \geq 0$ without loss of generality, as otherwise we can simply ignore the j-th term. With this assumption and by the definition of S_2, it follows that

$$\begin{aligned}\textcircled{3} &\leq \frac{1}{M}\sum_{j\in S_2} x(j)(1+pu_j^\top Y_t^{-1}u_j)\sum_{l=2}^{p}\binom{p}{l}(-1)^l\frac{(u_j^\top Y_t^{-1}u_j)^{l-1}\cdot u_j^\top Y_t^{-p-1}u_j}{(1+u_j^\top Y_t^{-1}u_j)^l}\\ &= \frac{1}{M}\sum_{j\in S_2} x(j)u_j^\top Y_t^{-p-1}u_j\cdot(1+pu_j^\top Y_t^{-1}u_j)\sum_{l=2}^{p}\binom{p}{l}(-1)^l\frac{(u_j^\top Y_t^{-1}u_j)^{l-1}}{(1+u_j^\top Y_t^{-1}u_j)^l}.\end{aligned}$$

Using the assumption $\lambda_{\min}(Z_t)\geq 1-5\gamma$ and (9), it holds that

$$\textcircled{3} \leq \frac{(1-5\gamma)^{-p-1}}{M}\sum_{j\in S_2} x(j)u_j^\top X^{-p-1}u_j\cdot(1+pu_j^\top Y_t^{-1}u_j)\sum_{l=2}^{p}\binom{p}{l}(-1)^l\frac{(u_j^\top Y_t^{-1}u_j)^{l-1}}{(1+u_j^\top Y_t^{-1}.u_j)^l}.$$

Since x is an optimal solution to (2), we can apply Lemma 13 and derive that

$$\begin{aligned}\textcircled{3} &\leq \frac{(1-5\gamma)^{-p-1}}{kM}\cdot\operatorname{tr}(X^{-p})\sum_{j\in S_2} x(j)\cdot(1+pu_j^\top Y_t^{-1}u_j)\sum_{l=2}^{p}\binom{p}{l}(-1)^l\frac{(u_j^\top Y_t^{-1}u_j)^{l-1}}{(1+u_j^\top Y_t^{-1}u_j)^l}\\ &= \frac{(1-5\gamma)^{-p-1}}{kM}\cdot\operatorname{tr}(X^{-p})\cdot\\ &\qquad \sum_{j\in S_2} x(j)\cdot\frac{1+pu_j^\top Y_t^{-1}u_j}{u_j^\top Y_t^{-1}u_j}\left(\left(1-\frac{u_j^\top Y_t^{-1}u_j}{1+u_j^\top Y_t^{-1}u_j}\right)^p-1+\frac{pu_j^\top Y_t^{-1}u_j}{1+u_j^\top Y_t^{-1}u_j}\right).\end{aligned}$$

Let $x=u_j^\top Y_t^{-1}u_j$, we want to upper bound

$$\begin{aligned}&\frac{1+px}{x}\left(\left(1-\frac{x}{1+x}\right)^p-1+\frac{px}{1+x}\right)=\\ &\qquad\qquad \frac{1}{x}\left(\left(1-\frac{x}{1+x}\right)^p-1+\frac{px}{1+x}\right)+p\left(\left(1-\frac{x}{1+x}\right)^p-1+\frac{px}{1+x}\right).\end{aligned}$$

For any $y\in[0,1]$, it holds that $(1-y)^p\leq 1-py+\binom{p}{2}y^2$. Thus, it follows that

$$\begin{aligned}&\frac{1}{x}\left(\left(1-\frac{x}{1+x}\right)^p-1+\frac{px}{1+x}\right)+p\left(\left(1-\frac{x}{1+x}\right)^p-1+\frac{px}{1+x}\right)\\ &\leq \frac{1}{x}\cdot\binom{p}{2}\cdot\frac{x^2}{(1+x)^2}+p\cdot\frac{px}{1+x}=\binom{p}{2}\cdot\frac{x}{1+x}+\frac{p^2x}{1+x}\leq 2p^2x.\end{aligned}$$

Therefore, the $\textcircled{3}$ term can be further bounded by

$$\begin{aligned}\textcircled{3} &\leq \frac{2(1-5\gamma)^{-p-1}\cdot p^2}{kM}\cdot\operatorname{tr}(X^{-p})\sum_{j\in S_2} x(j)\cdot u_j^\top Y_t^{-1}u_j\\ &\leq \frac{2(1-5\gamma)^{-p-1}\cdot p^2}{kM}\cdot\operatorname{tr}(X^{-p})\langle X, Y_t^{-1}\rangle.\end{aligned}$$

Using (9), it holds that

$$\textcircled{3} \leq \frac{2(1-5\gamma)^{-p-2}\cdot p^2 d}{kM}\cdot\operatorname{tr}(X^{-p})\leq O\left(\frac{p^2d}{kM}\right)\cdot\operatorname{tr}(X^{-p}), \tag{19}$$

where the last inequality follows by the choice of γ.

Combining (17), (18) and (19), we can lower bound the expected gain by

$$\begin{aligned}\mathbb{E}_t[g_t] &\geq \frac{p}{M}\left(\sum_{j\in[m]\setminus S_{t-1}} x(j)u_j^\top Y_t^{-p-1}u_j\right)-O\left(\frac{p^2d}{kM}\right)\cdot\operatorname{tr}(X^{-p})\\ &= \frac{p}{M}\left(\langle X, Y_t^{-p-1}\rangle-\langle X_{S_{t-1}}, Y_t^{-p-1}\rangle\right)-O\left(\frac{p^2d}{kM}\right)\cdot\operatorname{tr}(X^{-p}).\end{aligned}$$ ◀

Proof of Lemma 18. We define two sequences of random variables $\{X_t\}_t$ and $\{Y_t\}_t$, where $X_t := \mathbb{E}_t[\Gamma_t] - \Gamma_t$ and $Y_t := \sum_{l=1}^{t} X_l$. It is easy to check that $\{Y_t\}_t$ is a martingale with respect to $\{S_t\}_t$. We will use Freedman's inequality (see, e.g., [4, 15]) to bound the probability $\Pr[Y_\tau \geq \eta \cap \min_{1\leq t\leq \tau} \lambda_{\min}(Z_t) \geq 1-5\gamma]$.

In the following, we first show that if the event $\min_{1\leq t\leq\tau}\lambda_{\min}(Z_t) \geq 1-5\gamma$ happens, then we can upper bound X_t and $\mathbb{E}_t[X_t^2]$ so that we can apply Freedman's inequality. To upper bound X_t, we first prove an upper bound on g_t and l_t.

Note that, if the event $\lambda_{\min}(Z_t) \geq 1-5\gamma$ happens, then $Y_t \succeq (1-5\gamma)X$, which implies

$$u_{i_t}^\top Y_t^{-p-1} u_{i_t} \leq (1-5\gamma)^{-p-1} u_{i_t}^\top X^{-p-1} u_{i_t} \quad \text{and} \quad u_{j_t}^\top Y_t^{-p-1} u_{j_t} \leq (1-5\gamma)^{-p-1} u_{j_t}^\top X^{-p-1} u_{j_t}.$$

By Observation 5, for all the exchange pairs i_t, j_t, it holds that $x(i_t), x(j_t) \in (0,1)$. Thus, we can apply Lemma 13 to show that $\langle X^{-p-1}, u_{i_t}u_{i_t}^\top\rangle \leq \frac{1}{k}\cdot \mathrm{tr}(X^{-p})$ and $\langle X^{-p-1}, u_{j_t}u_{j_t}^\top\rangle \leq \frac{1}{k}\cdot \mathrm{tr}(X^{-p})$. Therefore, since $\gamma = 1/6p$,

$$u_{i_t}^\top Y_t^{-p-1} u_{i_t} \leq O\Big(\frac{1}{k}\Big)\cdot \mathrm{tr}(X^{-p}) \quad \text{and} \quad u_{j_t}^\top Y_t^{-p-1} u_{j_t} \leq O\Big(\frac{1}{k}\Big)\cdot \mathrm{tr}(X^{-p}). \tag{20}$$

We first give a deterministic bound on g_t. Let $x = u_{j_t}^\top Y_t^{-p-1} u_{j_t}$, according to (15), the gain term g_t can be written as

$$g_t = u_{j_t}^\top Y_t^{-p-1} u_{j_t} \cdot \frac{1}{x} \cdot \Big(1 - \Big(1 - \frac{x}{1+x}\Big)^p\Big).$$

Since $(1-y)^p \geq 1 - py$ for $y \in [0,1]$ and $p \geq 1$, we can bound g_t by

$$0 \leq g_t \leq u_{j_t}^\top Y_t^{-p-1} u_{j_t} \cdot \frac{1}{x}\cdot\frac{px}{1+x} \leq p \cdot u_{j_t}^\top Y_t^{-p-1} u_{j_t} \leq O\Big(\frac{p}{k}\Big)\cdot \mathrm{tr}(X^{-p}),$$

where the last inequality follows from (20).

Then, we give an deterministic bound on l_t. By the definition of S'_{t-1} and (7), it holds that $0 < u_{i_t}^\top Y_t^{-1} u_{i_t} = \langle v_{i_t} v_{i_t}^\top, Z_t^{-1}\rangle \leq \kappa$. Thus, we can bound l_t by

$$\begin{aligned} 0 \leq l_t = \sum_{i=1}^{p} \binom{p}{i} \frac{(u_{i_t}^\top Y_t^{-1} u_{i_t})^{i-1} \cdot u_{i_t}^\top Y_t^{-p-1} u_{i_t}}{(1 - u_{i_t}^\top Y_t^{-1} u_{i_t})^i} &\leq u_{i_t}^\top Y_t^{-p-1} u_{i_t} \cdot \sum_{i=1}^{p} \binom{p}{i} \frac{\kappa^{i-1}}{(1-\kappa)^i} \\ &= u_{i_t}^\top Y_t^{-p-1} u_{i_t} \cdot \frac{1}{\kappa}\cdot\Big(\frac{1}{(1-\kappa)^p} - 1\Big). \end{aligned}$$

For $\kappa = \frac{1}{2p}$, we can control l_t such that

$$l_t \leq O(p)\cdot u_{i_t}^\top Y_t^{-p-1} u_{i_t} \leq O\Big(\frac{p}{k}\Big)\cdot \mathrm{tr}(X^{-p}),$$

where the last inequality follows from (20).

With the above bounds on g_t and l_t, we can control the size of the martingale increment by

$$|X_t| = |\mathbb{E}_t[\Gamma_t] - \Gamma_t| \leq g_t + l_t \leq O\Big(\frac{p}{k}\Big)\cdot \mathrm{tr}(X^{-p}).$$

Next, we upper bound $\mathbb{E}_t[X_t^2]$ by

$$\mathbb{E}_t[X_t^2] \leq |X_t|\cdot \mathbb{E}_t[|X_t|] \leq O\Big(\frac{p}{k}\Big)\cdot \mathrm{tr}(X^{-p})\cdot\Big(\mathbb{E}_t[g_t] + \mathbb{E}_t[l_t]\Big).$$

Using Lemma 14, we bound the expected loss term by

$$\begin{aligned}\mathbb{E}_t[l_t] &\le \frac{p}{M}\Big(\operatorname{tr}(Y_t^{-p}) - \langle X_{S_{t-1}}, Y_t^{-p-1}\rangle\Big) + O\Big(\frac{p^2 d}{kM}\Big)\cdot\operatorname{tr}(X^{-p})\\ &\le O\Big(\frac{p}{M}\Big)\cdot\operatorname{tr}(X^{-p}) + O\Big(\frac{p^2 d}{kM}\Big)\cdot\operatorname{tr}(X^{-p})\\ &\le O\Big(\frac{p}{M}\Big)\cdot\operatorname{tr}(X^{-p}),\end{aligned}$$

where the second inequality follows by the assumption that $\lambda_{\min}(Z_t) \ge 1 - 5\gamma$ happens (and (9)), the last inequality follows by the assumption on k.

Then, with the expression of g_t in (15), we write the expected gain as

$$\mathbb{E}_t[g_t] = \sum_{j\in[m]\setminus S_{t-1}} \frac{x(j)}{M}\cdot\Big(1+\alpha\langle v_j v_j^\top, A_t^{\frac{1}{2}}\rangle\Big)\cdot\frac{u_j^\top Y_t^{-p-1}u_j}{u_j^\top Y_t^{-1}u_j}\left(1-\left(1-\frac{u_j^\top Y_t^{-1}u_j}{1+u_j^\top Y_t^{-1}u_j}\right)^p\right).$$

Using the fact that $(1-y)^p \ge 1 - py$ for $y \in [0,1]$ and $p \ge 1$, the expected gain can be bounded by

$$\mathbb{E}_t[g_t] \le \sum_{j\in[m]\setminus S_{t-1}} \frac{p}{M}\cdot x(j)\cdot u_j^\top Y_t^{-p-1}u_j\cdot\frac{1+\alpha\langle v_j v_j^\top, A_t^{\frac{1}{2}}\rangle}{1+u_j^\top Y_t^{-1}u_j}.$$

By (7), $u_j^\top Y_t^{-1}u_j = \langle v_j v_j^\top, Z^{-1}\rangle$. Then, by the second inequality in Lemma 12, it holds that

$$\mathbb{E}_t[g_t] \le \frac{p}{M}\cdot\alpha\lambda_{\min}(Z_t)\cdot\sum_{j=1}^m x(j)\cdot u_j^\top Y_t^{-p-1}u_j \le \frac{p}{M}\cdot\alpha\cdot\langle X, Y_t^{-p-1}\rangle,$$

where the last inequality holds as $\lambda_{\min}(Z_t) < 1$ before the termination of the algorithm. By the assumption that $\lambda_{\min}(Z_t) \ge 1 - 5\gamma$ happens (and (9)) and the choice of $\alpha = \sqrt{d}/\gamma$ and $\gamma = 1/6p$, we obtain the bound that

$$\mathbb{E}_t[g_t] \le \frac{p\sqrt{d}}{\gamma(1-5\gamma)^{p+1}M}\cdot\operatorname{tr}(X^{-p}) \le O\Big(\frac{p^2\sqrt{d}}{M}\Big)\cdot\operatorname{tr}(X^{-p}).$$

Therefore,

$$\mathbb{E}_t[X_t^2] \le O\Big(\frac{p}{k}\Big)\cdot O\Big(\frac{p^2\sqrt{d}}{M}\Big)\cdot\big(\operatorname{tr}(X^{-p})\big)^2 = O\Big(\frac{p^3\sqrt{d}}{kM}\Big)\cdot\big(\operatorname{tr}(X^{-p})\big)^2,$$

which implies

$$W_t := \sum_{l=1}^t \mathbb{E}_l[X_l^2] \le O\Big(\frac{\tau p^3\sqrt{d}}{kM}\Big)\cdot\big(\operatorname{tr}(X^{-p})\big)^2, \quad \forall t\in[\tau].$$

Finally, we can apply Freedman's martingale inequality Theorem (see, e.g., [4, 15]) with

$$R = O\Big(\frac{p}{k}\Big)\cdot\operatorname{tr}(X^{-p}) \qquad\text{and}\qquad \sigma^2 = O\Big(\frac{p^3\sqrt{d}\tau}{kM}\Big)\cdot\big(\operatorname{tr}(X^{-p})\big)^2$$

to conclude that

$$\begin{aligned}&\Pr\left[Y_\tau \ge \eta \bigcap \min_{1\le t\le\tau}\lambda_{\min}(Z_t) \ge 1-5\gamma\right]\\ \le\ &\Pr[\exists t\in[\tau] : Y_t \ge \eta \cap W_t \le \sigma^2] \le \exp\left(-\frac{\eta^2/2}{\sigma^2 + R\eta/3}\right)\\ =\ &\exp\left(-\Omega\left(\frac{\eta^2 kM}{\tau p^3\sqrt{d}(\operatorname{tr}(X^{-p}))^2 + \eta pM\operatorname{tr}(X^{-p})}\right)\right).\end{aligned}$$

The lemma follows by noting that $\sum_{t=1}^{\tau}\Gamma_t \le \sum_{t=1}^{\tau}\mathbb{E}_t[\Gamma_t] - \eta$ is equivalent to $Y_\tau \ge \eta$. ◄

Approximation Algorithms for Maximum Weighted Throughput on Unrelated Machines

Abstract

We study the classic weighted maximum throughput problem on unrelated machines. We give a $(1 - 1/e - \varepsilon)$-approximation algorithm for the preemptive case. To our knowledge this is the first ever approximation result for this problem. It is an immediate consequence of a polynomial-time reduction we design, that uses any ρ-approximation algorithm for the single-machine problem to obtain an approximation factor of $(1 - 1/e)\rho - \varepsilon$ for the corresponding unrelated-machines problem, for any $\varepsilon > 0$. On a single machine we present a PTAS for the non-preemptive version of the problem for the special case of a constant number of distinct due dates or distinct release dates. By our reduction this yields an approximation factor of $(1 - 1/e) - \varepsilon$ for the non-preemptive problem on unrelated machines when there is a constant number of distinct due dates or release dates on each machine.

1 Introduction

We study the classic scheduling problem of maximizing weighted throughput. We are given a set $\mathcal{J}$ of n jobs, where job j has release date r_j, due date d_j and nonnegative weight w_j. The jobs are to be scheduled on a set $\mathcal{M}$ of m machines so that no two jobs are ever processed simultaneously on the same machine. Job j completes when it has been processed for an amount equal to its processing time. If *preemption* is allowed, the processing of a job may be interrupted and resumed later at no cost. The objective is to maximize the total weight of jobs that complete by their due dates. This basic problem has been studied for decades, but for most of its versions we have no tight approximability results.

We employ the standard 3-field notation $\alpha|\,\beta|\,\gamma$ of [18], where α stands for the machine environment, β for the job characteristics and γ for the objective function. When $\beta = pmtn$ preemption is allowed. When $\alpha = 1$ there is a single machine; $\alpha = P$ stands for m *identical* parallel machines: job j has processing time p_j on every machine i. When $\alpha = R$ the m machines are *unrelated:* job j has processing time p_{ij} on machine i. In this paper we focus on the most general machine environment of unrelated machines. The problem of maximizing weighted throughput on unrelated machines without preemption is denoted by $R|\,r_j|\,\sum w_j\bar{U}_j$.

We provide a polynomial-time reduction that shows that a ρ-approximation algorithm for the single-machine problem $1|\, r_j,\, \beta|\, \sum w_j \bar{U}_j$ yields a $((1-1/e)\rho - \varepsilon)$-approximation for $R|r_j, \beta| \sum w_j \bar{U}_j$, for any $\varepsilon > 0$ (cf. Theorem 2). For the preemptive version and using different ideas, Kalyanasundaram and Pruhs gave a 6-approximate reduction from $P|r_j, pmtn| \sum w_j \bar{U}_j$ to the single-machine problem [13]. Pruhs and Woeginger [19] designed an FPTAS for $1|\, r_j, pmtn|\, \sum w_j \bar{U}_j$, using a pseudopolynomial algorithm by Lawler [17]. Therefore, our framework produces a $(1 - 1/e - \varepsilon)$-approximation algorithm for $R|\, r_j,\, pmtn|\, \sum w_j \bar{U}_j$. To our knowledge this is the first approximation result for preemptive throughput maximization on unrelated machines (see also [7]). Our reduction is based on a simple idea. We write a Configuration LP for the parallel-machine setting and use the single-machine algorithm as an approximate separation oracle for the dual. Except for the definition of what constitutes a configuration, the LP and its dual are essentially the same as the ones in [8]. In the latter a Knapsack subroutine was used as a separation oracle. We round the fractional primal LP solution using the dependent rounding method of [21, 9]. Despite its simplicity, our reduction is powerful enough to allow machine-dependent release and due dates: on machine i, job j can be processed in the interval $[r_{ij}, d_{ij}]$. Moreover, for the preemptive case, our algorithm produces a schedule on the unrelated machines with the desirable property of no migrations: every job is processed in its entirety on a single machine. For the non-preemptive case, our approach shows the existence of a $((1-1/e)\rho_* - \varepsilon)$-approximation algorithm, where ρ_* is the approximability threshold of $1|\, r_j|\, \sum w_j \bar{U}_j$. Despite decades of research, the latter threshold is yet to be determined; we only know that $\rho_* \leq 1/2$ [4, 2]. The best known bound for the unweighted case (i.e., $w_j = 1, \forall j$) is 0.6448 [12]. Currently, our reduction does not improve on the best known non-preemptive algorithms for $R|\, r_j|\, \sum w_j \bar{U}_j$, which achieve a ratio of $1/2 - \varepsilon$ [2, 4]. Since the single-machine problem is far from well-understood, special cases have received considerable attention. Our method can translate all existing optimal algorithms or approximation schemes for special cases of the single-machine problem to an $(1 - 1/e - \varepsilon)$ guarantee on unrelated machines. See Corollary 1 for a list of results.

The unrelated machines setting can be further extended by adding constraints on the grouping of jobs. We provide one such extension. Every job j has a *type* t_j from a finite set T of types. Machines need to undergo preparation to accommodate different job types. For every machine i, we are thus given a set $E_i \subseteq 2^T$ that specifies the allowed combinations of types that may be processed on i in a feasible schedule. Denote this problem as $R|\, r_j,\, \text{types}\, |\, \sum_j w_j \bar{U}_j$. Using a ρ-approximate oracle for $1|\, r_j,\, \beta|\, \sum w_j \bar{U}_j$ we obtain a $((1-1/e)\rho - \varepsilon)$ guarantee for $R|\, r_j,\, \beta,\, \text{types}\, |\, \sum_j w_j \bar{U}_j$ in time polynomial in $\sum_{i \in \mathcal{M}} |E_i|$. To avoid clutter we present in Theorem 2 the result where all jobs have the same type and provide the details for the more general setting in the Appendix.

Our algorithm for $R|\, r_j, pmtn|\, \sum w_j \bar{U}_j$ uses the FPTAS of [17, 19] for the preemptive case on a single machine as a black box. For the single-machine non-preemptive case, the dynamic program of Lawler [17] can produce an FPTAS only for the case of *similarly ordered* release and due dates, i.e., $d_i < d_j$ implies $r_i \leq r_j$ for each pair of jobs i and j. The dynamic program in [17] yields thus an FPTAS for the non-preemptive version when all jobs have a common due date or a common release date. It takes significant effort and new ideas to overcome the restriction of similarly ordered release and due dates. We show how to do this and obtain a PTAS for the single-machine, non-preemptive version, when there is a constant number of distinct due dates (or release dates) (cf. Theorems 8 and 9). At a high level our PTAS combines the FPTAS of [17] with the ideas from the PTAS of Khan et al. [15] for the Generalized Assignment Problem with a constant number of bins. More specifically, our approach can be summarized as follows (we restrict our description to the case of a constant number of distinct due dates; the arguments are symmetric for the constant number of release dates). By guessing the jobs straddling the due dates, we split the schedule into

Table 1 Summary of our main results for weighted throughput on unrelated machines; ρ_* is the approximability threshold of $1|\,r_j|\,\sum w_j\bar{U}_j$.

Preemption	m	# distinct d_j	# distinct r_j	Previous	This work
$\surd$	any	any	any	–	$1-1/e-\varepsilon$ (Cor. 1)
–	any	any	any	$1/2-\varepsilon$ [2, 4]	$(1-1/e)\rho_*-\varepsilon$ (Thm. 2)
–	1	$O(1)$	any	$1/2-\varepsilon$ [2, 4]	PTAS (Thm. 8)
–	1	any	$O(1)$	$1/2-\varepsilon$ [2, 4]	PTAS (Thm. 9)
–	any	$O(1)$	any	$1/2-\varepsilon$ [2, 4]	$1-1/e-\varepsilon$ (Cor. 1)
–	any	any	$O(1)$	$1/2-\varepsilon$ [2, 4]	$1-1/e-\varepsilon$ (Cor. 1)

bins of two different kinds: (i) bins with jobs whose release dates occur before the bin, and (ii) bins with jobs whose release date may occur inside the bin. By partitioning the jobs of $\mathcal{J}$, we split the problem into a constant number of subproblems each defined on a disjoint subset of jobs and where each subproblem contains only one bin of the second kind. This allows us to apply the ideas of [17] on the bin of kind (ii), and the GAP ideas of [15] on the bins of kind (i) *simultaneously*. The combination of all "parallel" subproblems defines the dynamic programming state of our PTAS.

By the aforementioned reduction our PTAS yields a $(1-1/e-\varepsilon)$-approximation on unrelated machines when on every machine the number of distinct due dates or release dates is constant. Even for these special cases, we are not aware of any previous results that improve upon the $1/2-\varepsilon$ ratio of [2, 4]. We summarize our main results in Table 1.

Other related work. The single-machine problem without release dates $1|\,|\,\sum_j w_j\bar{U}_j$ is equivalent in optimality with the problem of minimizing the total weight of late jobs. The latter was one of Karp's 21 NP-complete problems [14]. Without release dates, preemption is of no use; therefore, $1|\,pmtn|\,\sum_j w_j\bar{U}_j$ is also NP-complete. Several versions of the unweighted problem are hard. $1|\,r_j|\,\sum_j \bar{U}_j$ is strongly NP-complete [10], and $R|\,r_j|\,\sum_j \bar{U}_j$ is MAX SNP-hard [3]. $P|\,pmtn|\,\sum \bar{U}_j$ is NP-complete [16]. Chuzhoy et al. [6] provide a $(1-1/e-\varepsilon)$-approximation algorithm for the Job Interval Selection Problem, in which for every job we are given an explicit list of allowed intervals and the intervals selected for all scheduled jobs must be disjoint. The objective is to maximize the number of scheduled jobs. Because of the explicit list requirement, the running time of the algorithm of [6] becomes pseudopolynomial when applied to $R|\,r_j|\,\sum_j \bar{U}_j$. Hyatt-Denesik et al. [11] provide a PTAS that works for unweighted jobs on identical machines, when m, the number of distinct release dates, and the number of distinct due dates, are all bounded by a constant. A number of further results for identical machines are given in [4, 12].

The paper is structured as follows. In Section 2 we provide the reduction from the unrelated machines to the single-machine problem and the improved approximation bounds that are obtained as a consequence. In Section 3 we present the PTAS for the single-machine case when the number of distinct due dates is fixed. In Section 4 we outline the necessary modifications to the algorithm from Section 3 in order to obtain a PTAS for the single-machine when the number of distinct release dates is fixed.

2 Reduction to the single-machine case

In this section we provide a polynomial-time approximation-preserving reduction from the problem with machine-dependent release and due dates, $R|\,r_{ij},\,d_{ij},\,\beta|\,\sum w_j\bar{U}_j$, to $1|\,r_j,\,\beta|\,\sum w_j\bar{U}_j$. We provide first a Configuration LP relaxation for $R|\,r_{ij},\,d_{ij},\,\beta|\,\sum w_j\bar{U}_j$.

For machine $i \in \mathcal{M}$ we define a set $\mathcal{C}(i)$ of configurations. A configuration $C \in \mathcal{C}(i)$ is a schedule of a subset $J \subseteq \mathcal{J}$ of jobs on machine i such that (i) all jobs in J respect their release and due dates on i (ii) there is no unnecessary idle time (iii) the β-constraints are met. $\mathcal{C}(i)$ is a finite set whose size can be naively bounded by $(n!)2^n$. We slightly abuse notation and we also view a configuration C as the set of jobs in the corresponding schedule. Without loss of generality we can assume that $\mathcal{C}(i) \cap \mathcal{C}(j) = \varnothing$ for $i, j \in \mathcal{M}$, $i \neq j$. The configuration LP, here denoted (CLP), is the formulation (1) of [8] and has a variable x_C for each machine i and configuration $C \in \mathcal{C}(i)$:

$$\max \sum_{j \in \mathcal{J}} w_j \left(\sum_{i \in \mathcal{M}} \sum_{C \in \mathcal{C}(i): j \in C} x_C \right) \tag{CLP}$$

$$\sum_{C \in \mathcal{C}(i)} x_C \leq 1 \qquad \forall i \in \mathcal{M} \tag{1}$$

$$\sum_{i \in \mathcal{M}} \sum_{C \in \mathcal{C}(i): j \in C} x_C \leq 1 \qquad \forall j \in \mathcal{J} \tag{2}$$

$$x_C \geq 0 \qquad \forall i \in \mathcal{M}, \forall C \in \mathcal{C}(i) \tag{3}$$

The set of constraints (1) ensures that to each machine is assigned at most one configuration. Constraints (2) ensure that each job is assigned at most once. Clearly, an integer solution to (CLP) corresponds to a feasible schedule for $R|\,\beta|\,\sum w_j \bar{U}_j$. For a configuration C, let $w(C) := \sum_{j \in C} w_j$. The dual of (CLP) is the following:

$$\min \sum_{i \in \mathcal{M}} y_i + \sum_{j \in \mathcal{J}} z_j \tag{D-CLP}$$

$$y_i + \sum_{j \in C} z_j \geq w(C) \qquad \forall i \in \mathcal{M}, \forall C \in \mathcal{C}(i) \tag{4}$$

$$y, z \geq 0 \tag{5}$$

In what follows, we will use the notion of a *ρ-approximate separation oracle* for (D-CLP) (see e.g., [8]), i.e., a polynomial-time algorithm that, given values y, z, either returns a violated constraint, or guarantees that values $y/\rho, z$ satisfy constraints (4)-(5). It is well-known (cf. Lemma 2.2 in [8]) that such an oracle, combined with binary search on the optimal value, implies a polynomial-time $(\rho - \delta)$-approximate algorithm for solving (D-CLP), and hence (CLP), for any constant $\delta > 0$ (without any constraint violations). The facet complexity ϕ of (D-CLP) is $O(n \log w_{\max})$, where $w_{\max} = \max_{j \in \mathcal{J}} w_j$. Since the coefficients of the objective function are all 1, by well-known arguments the optimal value of (D-CLP) can be represented by $O(n^2\phi)$ bits and hence binary search on the optimum runs in polynomial-time (see Corollary 10.2a in [20]). Our reduction is based on the following simple fact.

▶ **Lemma 1.** *If there is a polynomial-time ρ-approximation algorithm A_β for the problem* $1|\,r_j,\,\beta|\,\sum w_j \bar{U}_j$, *then there is a ρ-approximate separation oracle for* (D-CLP).

Proof. Given a candidate solution (y, z) to (D-CLP), the separation oracle has to solve $|M|$ instances of $1|\,\beta|\,\sum w_j \bar{U}_j$, one instance I_i for each $i \in \mathcal{M}$.

We define instance I_i. We have a single machine and the n jobs in $\mathcal{J}$ where job j has processing time p_{ij}, release date r_{ij}, due date d_{ij}. Job j has a (possibly negative) *value* $v_j := w_j - z_j$. There is a violated constraint (4) corresponding to machine i iff there is a feasible schedule for I_i where the total value of the on-time jobs exceeds y_i. Any such schedule can contain only jobs of positive value; therefore, we discard any job j with $v_j \leq 0$. If there are no jobs of positive value, then the constraint cannot be violated for any configuration in $\mathcal{C}(i)$ and we move to examine the next instance I_{i+1}.

We run algorithm A_β on instance I_i. A_β will return a feasible schedule whose value is at least ρ-times the maximum value, for $\rho \leq 1$. If this value exceeds y_i we have identified a violated constraint. Else the vectors $(y/\rho, z)$ satisfy all constraints (4) for machine i. ◀

▶ **Theorem 2.** *If there is a polynomial-time ρ-approximation algorithm A_β for the problem $1|\, r_j,\, \beta|\, \sum w_j \bar{U}_j$, then there is a $((1 - 1/e)\rho - \varepsilon)$-approximation algorithm for $R|\, r_{ij},\, d_{ij},\, \beta|\, \sum w_j \bar{U}_j$ where $\varepsilon > 0$ is any constant of our choice.*

Proof. By Lemma 1 and Lemma 2.2 in [8] the ρ-approximation algorithm A_β for $1|\beta|\sum w_j \bar{U}_j$, can be used to compute a $(\rho - \delta)$-approximate solution x^* to (CLP), for some $\delta > 0$. It remains to round the fractional solution x^* to an integer one. We use the dependent rounding method of [21, 9] in the setting where we have a collection of m star graphs, each corresponding to a machine $i \in M$ and the subset of configurations from $C(i)$ that have been assigned by a non-zero amount by x^* to i. We sample independently from m distributions, one for each star, to produce an integer assignment $\hat{x}$ of configurations to the machines. Each distribution and the corresponding sampling method are designed using the technique of [21], so that, with probability 1, each machine gets one configuration and the assignment of configurations to a machine respects negative correlation. Moreover, the expectation of $\hat{x}_C$ equals x^*_C. Adapting slightly the analysis for the maximum coverage problem in [21] we obtain that the expected total weight of the jobs that appear in at least one configuration in the support of $\hat{x}$ is at least $(1 - 1/e)$ the value of the x^* solution. For the sake of completeness we include in Appendix A the relevant details from [21]. Every configuration chosen by $\hat{x}$ corresponds to a feasible schedule on the corresponding machine. To obtain the final schedule, for every job j that appears in more that one configurations we arbitrarily delete all but one of its occurrences. Note that every machine gets exactly one configuration by $\hat{x}$, therefore the occurrences of j happen each on a different machine. Since x^* is $(\rho - \delta)$-approximate we obtain the theorem. ◀

The upcoming corollary collects applications of Theorem 2 to settings where an (F)PTAS exists for the single machine case. The *additive laxity* of a job j is defined as $d_j - p_j - r_j$. For each application we provide the reference for the single-machine result. Note that the algorithm in [1] finds an optimal solution.

▶ **Corollary 1.** *There is a polynomial-time $(1 - 1/e - \varepsilon)$-approximation algorithm for $R|\, r_{ij},\, d_{ij},\, \beta|\, \sum_j w_j \bar{U}_j$ where jobs have machine-dependent release and due dates and β can stand for the following:* (i) *preemption is allowed [17, 19]* (ii) *on every machine the number of distinct release dates or the number of distinct due dates is constant (Theorems 8, 9)* (iii) *on every machine the number of distinct processing times is constant and all jobs have unit weights [11]* (iv) *for every machine i and job j, $p_{ij} = p_i$, i.e., all jobs have the same processing time on machine i [1]* (v) *on every machine the jobs have equal additive laxity [5]* (vi) *on every machine release dates and due dates are similarly ordered [17, 19].*

In all the results of Corollary 1, we used as a lower bound for the optimum the value of (CLP), i.e., the value of a (fractional) schedule in which a job may be simultaneously executed on more than one machine. On the other hand the algorithm of Theorem 2 produces an integer solution where every scheduled job runs completely on one machine, i.e., in the preemptive case it produces a schedule with no migrations. The following is immediate.

▶ **Corollary 2.** *The approximation ratio of* $(1 - 1/e - \varepsilon)$ *for* $R|\, r_{ij},\, d_{ij},\, pmtn|\, \sum_j w_j \bar{U}_j$ *holds both for the problem version where a job may be simultaneously executed on two or more machines and for the version where this is not allowed.*

The above can be extended to the setting where jobs have different types, see Appendix B.

3 Constant number of distinct due dates

In this section we provide a PTAS for the setting where we have a single machine and the number of distinct due dates is constant.

3.1 Preliminaries

For a set of jobs S, we denote by $w(S) = \sum_{j \in S} w_j$ its total weight, $p(S) = \sum_{j \in S} p_j$ its total processing time. Wlog only jobs that meet their due dates are processed in a feasible schedule. Given a schedule σ in which a set S of jobs is processed we denote by $w(\sigma)$ the quantity $w(S)$. For a time interval B we denote its length by $|B|$. The jobs *scheduled in* B are jobs that start and finish in the interval. We slightly abuse notation and denote by $w(B)$ the total weight of the jobs scheduled in B if an associated schedule is clear from the context.

We assume that the due dates of the n jobs take a value out of k possible numbers $D_1 \leq D_2 \leq \ldots \leq D_k$. Let $D_0 := 0$. We assume that time 0 coincides with the earliest release date. Wlog the time horizon $T = D_k$. For an integer m, the notation $m \in (i, k]$ (resp. $m \in [i, k]$) stands for $m = i+1, \ldots, k$ (resp. $m = i, \ldots, k$). Similarly $m \in [i, k)$ is a shorthand for $m = i, \ldots, k-1$. We denote by R_i, $i \in [1, k]$, the set of jobs j s.t. $D_{i-1} \leq r_j < D_i$.

3.2 A structure lemma

In this section we devise structural properties of a near-optimal solution and show how to pre-compute in polynomial time some of its features.

Let OPT be an optimal solution for the problem $1|\, r_j|\, \sum w_j \bar{U}_j$. Wlog $w(OPT) \geq w_{\max}$. Let $\varepsilon_1 > 0$ be any constant. We apply the classic knapsack rounding in order to reduce the job weights within a polynomial range: by rounding all job weights down to the closest multiple of $\theta := \varepsilon_1 w_{\max}/n$, the total weight is still at least $(1 - \varepsilon_1)OPT$, but now all job weights are between 1 and $O(n/\varepsilon_1)$ in units of θ. In addition, we can impose the following special structure:

- We shift all scheduled jobs later, to start as late as possible: the schedule consists of contiguous (i.e., without idle time) blocks of jobs, each finishing at a due date (with the last block finishing at D_k).
- In every interval $[D_{i-1}, D_i)$, we can rearrange the jobs that start and finish within the interval to be scheduled in non-decreasing order of release dates. Note that any jobs from the set R_i that are scheduled in the interval, are scheduled last.

A job j *straddles* time t if j starts at or before t and finishes after t. Let $S_1, S_2, \ldots, S_{k-1}$ be the jobs straddling due dates $D_1, \ldots, D_{k-1}$, and let s_i, f_i be the starting and finishing times of straddler S_i. Note that due to the structure of OPT, some due dates may not have a straddler, just like D_0, D_k; in this case $S_i = \emptyset$. Wlog we may assume that no job straddles more than one due date. We will assume that we know the straddlers by enumerating all $O(n^k)$ possibilities.

Let $K_m = (f_{m-1}, s_m)$ be the interval between the end of S_{m-1} and the beginning of S_m, and $|K_m| \leq D_m - D_{m-1}$ its length. K_m is the concatenation of intervals $B_m^1, B_m^2, \ldots, B_m^m$ in this order, so that B_m^h contains only the jobs of R_h scheduled in K_m. We refer to these intervals as *bins.* Note that the jobs in each B_m^h are scheduled al late as possible, and each bin straddles only release dates. Figure 1 shows bins $B_m^1, \dots, B_m^{m-2}, B_m^{m-1}, B_m^m$ of K_m. The following lemma will allow us to enumerate the bin sizes in polynomial time for the PTAS.

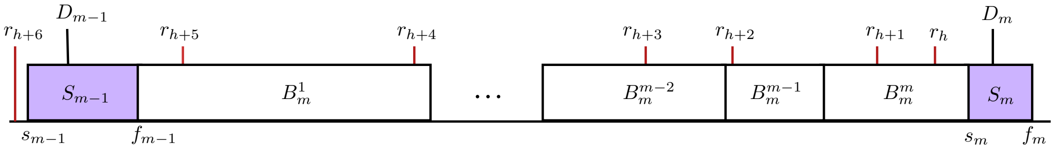

Figure 1 Bins $B_m^1, \dots, B_m^{m-2}, B_m^{m-1}, B_m^m$ of K_m. Bin B_m^m contains jobs in R_m, i.e., with release dates $r_h, r_{h+1}, \dots, r_{h+5}$. Jobs with release date r_{h+6} will be scheduled in B_m^{m-1}.

▶ **Lemma 3.** *Let $\varepsilon > 0$ be any given constant. Let be $J \subseteq \mathcal{J}$ be a set of jobs feasibly scheduled in an interval I without idle time where I does not contain a due date. Then there is $\hat{J} \subseteq J$, and a subinterval $\hat{I}$ of I s. t.* (i) *$\hat{I}$ has the same right endpoint as I,* (ii) *$w(\hat{J}) \geq (1-3\varepsilon)w(J)$ and $p(\hat{J}) \leq |\hat{I}| \leq |I|$,* (iii) *the jobs in $\hat{J}$ can be feasibly scheduled without idle time in $\hat{I}$, and* (iv) *$|\hat{I}|$ takes values from a set of size $O(n^{1/\varepsilon^2} \log_{1+\varepsilon} |I|)$.*

Proof. Let σ be the feasible schedule of the jobs of J in I. The set $\hat{J}$ and the corresponding feasible schedule $\hat{\sigma}$ are derived in two phases. We adapt the methods in [15] to account for the presence of release dates in I. In Phase 1, we apply Theorem 11 of [15] for a single bin that corresponds to interval I. We establish the existence of subsets X and Y of J. Define $J' = J - X - Y$. By Theorem 11, for every $j \in J'$, $p_j \leq \varepsilon(|I| - p(X))$. We produce a schedule σ' of $X \cup J'$ by deleting from σ the jobs of Y and replacing them by idle time. Schedule σ' executes in the same interval I as σ. By Theorem 11, $w(X \cup J') \geq (1-\varepsilon)w(J)$.

In Phase 2, we extend the trimming method of [15] to show that there is $R \subseteq J'$ s.t. $w(R) \leq (2\varepsilon/(1-\varepsilon))w(J')$ and there is an integer β s.t. $p(J'-R) \leq (1+\varepsilon)^\beta \leq |I| - p(X)$. See Appendix D.3. We set $\hat{J} = X \cup (J' - R)$. We have that $w(\hat{J}) \geq (1-\varepsilon)(1-2\varepsilon/(1-\varepsilon))w(J) = (1-3\varepsilon)w(J)$. The schedule $\hat{\sigma}$ results from σ' by deleting all jobs in R and shifting jobs as needed to the right to remove any idle time. This is feasible, since I doesn't contain any due dates. It suffices to set $\hat{I}$ to an interval that ends at the right endpoint of I such that $|\hat{I}|$ equals $p(\hat{J})$. By Theorem 11, there are $O(n^{1/\varepsilon^2})$ choices for the set X and accordingly that many choices for $p(X)$. The value $p(J'-R)$ can be upper-bounded by a number that takes $O(\log_{1+\varepsilon} |I|)$ many values. Therefore $|\hat{I}|$ takes values from a set of size $O(n^{1/\varepsilon^2} \log_{1+\varepsilon} |I|)$. ◀

We apply Lemma 3 with $\varepsilon := \varepsilon_2$ to the jobs scheduled in OPT in each of the $O(k^2)$ bins B_m^i, $m \in [1,k]$, $i \in [1,m]$. There are sets X_m^i and integers a_m^i such that there is a near-optimal feasible schedule that assigns to each bin B_m^i a set S_m^i of "small" jobs in addition to X_m^i so that $p(S_m^i) \leq (1+\varepsilon_2)^{a_m^i}$. By enumerating all $O(n^{O(k^2/\varepsilon_2^2)}(\log_{1+\varepsilon_2} D_k)^{k^2})$ possibilities, we can assume that we have determined all the X_m^i's and a_m^i's.

Let $\widehat{OPT}$ be the solution of value at least $(1-3\varepsilon_2)(1-\varepsilon_1)w(OPT)$ obtained from OPT by replacing each bin B_m^i by a (smaller) bin $\hat{B}_m^i$ with known size $|\hat{B}_m^i| = p(X_m^i) + (1+\varepsilon_2)^{a_m^i}$. By Lemma 3 $|\hat{B}_m^i| \leq |B_m^i|$. Then K_m has been replaced by a (smaller) $\hat{K}_m$ of size $\hat{K}_m = \sum_{i=1}^m |\hat{B}_m^i|$, and all scheduled jobs are shifted as late as possible, while maintaining $S_1, S_2, \dots, S_{k-1}$ as straddlers. Figure 2 shows $\widehat{OPT}$.

Expansion of X_m^i. Let $|\hat{B}_m^i|' := |\hat{B}_m^i| - p(X_m^i)$ be the bin space available for jobs other than X_m^i in $\widehat{OPT}$, i.e., job sets J_m^i s.t. $p(J_m^i) \leq |\hat{B}_m^i|'$. In order to be able to apply the techniques of [15] later, we need to keep in $\widehat{OPT}$ only jobs of J_m^i that satisfy a property

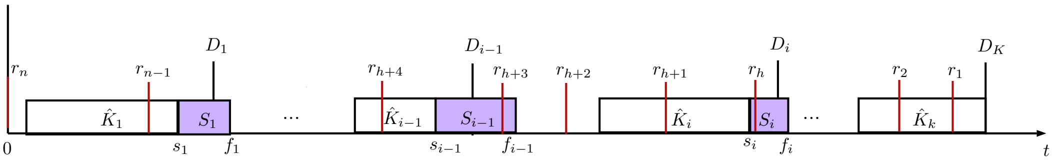

Figure 2 An approximate optimal schedule $\widehat{OPT}$. Note that the length of $\hat{K}_i$ is at most the length of the original K_i. Release dates are in non-increasing order. R_i contains all jobs with release dates $r_h, r_{h+1}, r_{h+2}, r_{h+3}$.

stronger than the property $p_j \le \varepsilon(|B^i_m| - p(X^i_m))$ guaranteed by Lemma 3 for all jobs of J^i_m. We apply the structure theorem of [15] (Theorem 11 in Appendix D) on each job set $J^i_{i+1}, J^i_{i+2}, \ldots, J^i_k$ for each $i \in [1, k)$, to define job sets W^i_m and U^i_m with $|W^i_m| = O(1/\varepsilon_3^2)$, such that $w(\cup_{i,m} U^i_m) \le \varepsilon_3 \widehat{OPT}$ and

$$p_j \le \varepsilon_3(|\hat{B}^i_m|' - p(W^i_m)),\ \forall j \in J^i_m - W^i_m - U^i_m.$$

Note that bins $B^i_i, i = 1, 2, \ldots, k$ do not participate in this process, and, therefore, $W^i_i := \emptyset$. We expand the sets X^i_m to include W^i_m, i.e., we reset $X^i_m := X^i_m \cup W^i_m$ for all i and m. The sets W^i_m can be enumerated in $O(n^{k^2/\varepsilon_3^2})$ time.

▶ **Definition 1.** *A job j is* large *if $j \in \bigcup_{i,m} X^i_m$.*

▶ **Definition 2.** *A job j is* small *for bin $\hat{B}^i_m$ if j is not large and $p_j \le \varepsilon_3(|\hat{B}^i_m|' - p(W^i_m))$.*

Since $|\cup_{i,m} X^i_m| = O(k^2/(\min\{\varepsilon_2, \varepsilon_3\})^2)$, for the rest of the paper we will assume that we have "guessed" all sets X^i_m of large jobs and their placement in bins. Keeping in $\widehat{OPT}$ only the large and small jobs, as defined in Definitions 1 and 2, $\widehat{OPT}$ still achieves total weight at least $(1 - \varepsilon_3)(1 - 3\varepsilon_2)(1 - \varepsilon_1)OPT$.

Calculation of times s_i, f_i. Since we can enumerate them in polynomial time, in what follows we will assume that we have "guessed" sizes $|\hat{K}_i|$, $i = 1, \ldots, k$. Starting from D_k, and going backwards in time, we use these sizes to calculate times $f_{k-1}, s_{k-1}, f_{k-2}, s_{k-2}, \ldots, f_1, s_1$. We should only be careful in case $s_i - |\hat{K}_i| - p(S_{i-1}) < D_i - D_{i-1}$, i.e., when the beginning of $\hat{K}_i$ is more than $p(S_{i-1})$ time units after D_{i-1}. In this case, we don't allow S_{i-1} to be scheduled after D_{i-1} (as a non-straddler), but we set $s_{i-1} := D_{i-1}$, and continue.

The following lemma summarizes the properties of $\widehat{OPT}$:

▶ **Lemma 4** (Structure Lemma). *There is a feasible schedule $\widehat{OPT}$ of weight at least $(1 - \varepsilon_3)(1 - 3\varepsilon_2)(1 - \varepsilon_1)OPT$, such that:*

- *Job weights are between 1 and $O(n/\varepsilon_1)$.*
- *There are k known straddlers S_i, with known starting and finishing times s_i, f_i, $i \in [1, k]$.*
- *Jobs are scheduled in intervals $\hat{K}_i \subseteq (f_{i-1}, s_i)$ contiguously as late as possible, and in Earliest Release Date (ERD) order. Each $\hat{K}_i$ is adjacent to S_i, and its size $|\hat{K}_i|$ is known.*
- *Only large and small jobs are scheduled; the large jobs can be computed in polynomial-time.*

3.3 A PTAS for $\widehat{OPT}$

We order the jobs in Latest Release Date (LRD) ordering, i.e., in non-increasing release date order $r_1 \ge r_2 \ge \ldots \ge r_n = 0$. The algorithm will schedule the jobs one at a time, and a job scheduled in some bin $\hat{B}^i_m$ of $\hat{K}_i$ is scheduled right *before* the jobs already scheduled in $\hat{B}^i_m$. There are at most k^2 different bins overall. Recall that all job weights are at most $O(n/\varepsilon_1)$, hence there are $O((n^2/\varepsilon_1^2)^{k^2})$ different combinations of total weights for the bins.

3.3.1 Intuition

When there is only one due date D_1, the DP of [17] for non-preemptive maximum throughput is applicable, because its requirement of similarly ordered release and due dates is met. Crucially, the correctness of the algorithm is based on DP subproblems computing the minimum total schedule time needed to achieve a total weight target (cf. Appendix C). Unfortunately, this approach cannot work with more than one due date, because for a given R_i, the notion of minimum total scheduling time is not well-defined for all its bins *simultaneously*.

For a different approach that allows for simultaneous scheduling across all $\hat{K}_m$'s, one may turn to [15], who give a very interesting PTAS for the Generalized Assignment Problem (GAP) with a *constant* number of bins (cf. Appendix D). When discretizing the state space of the dynamic program the algorithm of [15] augments bin capacities by a $(1+\varepsilon)$ factor. It then employs trimming (see Appendix D.2) to remove a low-weight contiguous set of jobs, which exists by the Pigeonhole Principle, so that the remaining jobs fit in the bins with the original capacities restored. In our case, increasing the bin capacities may entail that in some $\hat{K}_m$, jobs may end up scheduled to start *before* their release dates in (f_{m-1}, s_m). (We remind the reader that $f_{m-1} > D_{m-1}$ is the completion time of the $(m-1)$th straddler and $s_m \leq D_m$ is the start time of the mth straddler). Unfortunately, the trimming part of [15] may fail when applied to such a block of jobs: it can only work if the jobs removed are the latest ones in the block so that *all* the previous ones can be shifted later and meet their release date. On the other hand, if all release dates of the jobs in the block occur *before* D_{m-1}, then the whole procedure works as for GPA, without any problems. The two key observations for deriving a PTAS for our problem are the following:

Obs1 We can break the problem into a *constant* number of subproblems that schedule disjoint subsets of jobs: we are going to have one subproblem for each set $R_i, i = 1, 2, \ldots, k$.

Obs2 The subproblem for R_i consists of at most k bins $\hat{B}^i_i, \hat{B}^i_{i+1}, \ldots, \hat{B}^i_k$, each being a "slice" of $\hat{K}_i, \hat{K}_{i+1}, \ldots, \hat{K}_k$ (recall that in each $\hat{K}_m$, jobs in R_g are scheduled before jobs in R_h when $g < h$). Note that the release dates of jobs in R_i do not affect the scheduling of bins $\hat{B}^i_{i+1}, \ldots, \hat{B}^i_k$, since these release dates occur before D_i and all those intervals start after D_i; for these bins the PTAS of [15] for GAP is applicable, when the bin capacities $|\hat{B}^i_{i+1}|, \ldots, |\hat{B}^i_k|$ are given. This leaves bin $\hat{B}^i_i$, which is scheduled using the minimum total processing time idea of [17], while respecting the total processing time and weight targets of the rest of the bins and so that the release dates of R_i are respected.

Obs1 above together with the total processing times, $|\hat{B}^i_i|, \ldots, |\hat{B}^i_k|$, for the bins for each R_i, allows us to combine all "parallel" subproblems in a common DP state, computed by k "parallel" applications of Obs2.

3.3.2 Scheduling of the jobs

Recall that we have "guessed" the large jobs X^i_m that have already been slotted for each bin $\hat{B}^i_m$. We consider jobs one-by-one for scheduling in a Latest Release Date (LRD) ordering. If large and small jobs have the same release date, the large jobs are scheduled first. Recall that Lemma 3 allowed us to "guess" bin sizes $|\hat{B}^i_m|$. Let $|\hat{B}^i_m|' := |\hat{B}^i_m| - p(X^i_m)$ be the bin space available for jobs small for $\hat{B}^i_m$, as defined in Definition 2. Note that given the (guessed) $|\hat{B}^i_m|'$ and W^i_m the algorithm can determine whether a job j is small for bin $\hat{B}^i_m$.

Resource augmentation. We increase the bin capacities allocated to small jobs $|\hat{B}^i_m|'$ in each bin $\hat{B}^i_m, m > i$, and set $|\hat{B}^i_m|'' := (1+\varepsilon_3)|\hat{B}^i_m|'$, and round the job processing times according to the resource augmentation scheme of [15] (cf. Appendix D.1). The bin capacity allocated to the large jobs of the bin is not augmented. Now small jobs may have different processing times for different bins; let p_{mj} be the processing time of a small job $j \in R_i$ for bin $\hat{B}^i_m$ ($p_{mj} = \infty$ if j cannot be scheduled in $\hat{B}^i_m$, e.g., when it is not small for this bin, according to definition 2). Let $\widehat{OPT}_a$ be the maximum throughput schedule for the resource-augmented instance. The following lemma is a direct corollary of Lemma 1 in [15].

▶ **Lemma 5.** *Schedule $\widehat{OPT}$ is feasible for the resource-augmented instance, hence $w(\widehat{OPT}_a) \geq w(\widehat{OPT})$.*

DP states and state transitions. Recall that jobs are scheduled one by one, in LRD order. The DP table records whether a given state is feasible. It is initialized with value ∞, indicating infeasibility, everywhere except for base-case-state $(0, 0, \dots, 0)$ that is initialized to value 1, indicating feasibility. Table entries that cannot be reached by legitimate state transitions as described below will remain infeasible throughout the execution.

Assume that the first $j-1$ jobs have been considered, and we are now considering job $j \in R_i$. For brevity, we present the portion (substate) $\mathcal{S}^i(j-1)$ of the DP state $\mathcal{S}(j-1) = (\mathcal{S}^1(j-1), \mathcal{S}^2(j-1), \dots, \mathcal{S}^k(j-1))$ that corresponds to the i-th "parallel" subproblem, defined for jobs in R_i. It has the form of the following tuple:

$$\mathcal{S}^i(j-1) = (Z^{j-1}_i, W^{j-1}_i, Z^{j-1}_{i+1}, W^{j-1}_{i+1}, \dots, Z^{j-1}_k, W^{j-1}_k),$$

where Z^{j-1}_m is the processing time used by the jobs in $\{1, 2, \dots, j-1\} \cap R_i$ scheduled in $\hat{B}^i_m$, and W^{j-1}_m is their total weight. Scheduling job $j \in R_i$ produces the following transitions $\mathcal{S}(j-1) \to \mathcal{S}(j)$:

- Large job $j \in X^i_m$ is scheduled in $\hat{B}^i_m$, $m \geq i$: There is a transition to state $\mathcal{S}(j)$ with

  $$\mathcal{S}^i(j) = (Z^{j-1}_i, W^{j-1}_i, \dots, Z^{j-1}_m + p_{mj}, W^{j-1}_m + w_j, \dots, Z^{j-1}_k, W^{j-1}_k).$$

- Job j is scheduled as small in a $\hat{B}^i_m$, $m > i$: We check whether the following conditions hold: (i) d_j is not violated, (ii) large jobs in X^i_m with release dates smaller than r_j can still be feasibly scheduled in $\hat{B}^i_m$, (iii) $Z^{j-1}_m + p_{mj} \leq |\hat{B}^i_m|''$, and (iv) there isn't already a feasible state $\mathcal{T}(j-1)$ with

  $$\mathcal{T}^i(j-1) = (T, W^{j-1}_i, \dots, Z^{j-1}_m + p_{mj}, W^{j-1}_m + w_j, \dots, Z^{j-1}_k, W^{j-1}_k)$$

  such that $T < Z^{j-1}_i$. Note that large jobs with release dates at least r_j have already been scheduled before j, so given Z^i_m it is easy to check condition (iii) above. If all conditions hold, then there is a transition to state $\mathcal{S}(j)$ with

  $$\mathcal{S}^i(j) = (Z^{j-1}_i, W^{j-1}_i, \dots, Z^{j-1}_m + p_{mj}, W^{j-1}_m + w_j, \dots, Z^{j-1}_k, W^{j-1}_k),$$

  otherwise j is not scheduled in $\hat{B}^i_m$.

- Job j is scheduled as small in $\hat{B}^i_i$: We check whether the following conditions hold: (i) large jobs in X^i_i with release dates smaller than r_j can still be feasibly scheduled in LRD order in $\hat{B}^i_i$, (ii) $Z^{j-1}_i + p_{ij} \leq |\hat{B}^i_i|''$, and (iii) the scheduling of j doesn't violate r_j. If all conditions hold, then we consider the state $\mathcal{T}(j-1)$ with

  $$\mathcal{T}^i(j-1) = (Z, W^{j-1}_i + w_j, Z^{j-1}_{i+1}, W^{j-1}_{i+1}, \dots, Z^{j-1}_k, W^{j-1}_k)$$

  that, after scheduling the $j-1$ first jobs, achieves total weight $W^{j-1}_i + w_j$ in $\hat{B}^i_i$, while the rest of the state is the same as $\mathcal{S}(j-1)$. If state $\mathcal{T}(j-1)$ is not feasible, then we schedule

j in $\hat{B}_i^i$ as in the previous case. Otherwise, Z is well defined as a sum of processing times. Then there is a transition to state $\mathcal{S}(j)$ with

$$\mathcal{S}^i(j) = \begin{cases} (Z_i^{j-1} + p_{ij}, W_i^{j-1} + w_j, Z_{i+1}^{j-1}, W_{i+1}^{j-1}, \ldots, Z_k^{j-1}, W_k^{j-1}), & Z_i^{j-1} + p_{ij} < Z \\ \mathcal{T}^i(j-1), & Z_i^{j-1} + p_{ij} \geq Z. \end{cases} \tag{6}$$

- Job j is not scheduled: In this case $\mathcal{S}(j) = \mathcal{S}(j-1)$.

After the feasibility of all DP states $\mathcal{S}(j) = (\mathcal{S}^1(j), \mathcal{S}^2(j), \ldots, \mathcal{S}^k(j))$ has been computed for all j, we keep as a solution the feasible state $\mathcal{S}(n)$ with the maximum sum of total weights in all bins, as well as the schedule S that achieves it.

▶ **Lemma 6.** *The DP algorithm correctly outputs a feasible schedule S that is as good as $\widehat{OPT}_a$, if the latter exists.*

Proof. First note that $\widehat{OPT}_a$ complies with the structure of Lemma 4. Let $\widehat{OPT}_a(j)$ be the sub-schedule of $\widehat{OPT}_a$ containing only jobs $1, \ldots, j$ in the LRD order. Note that $\widehat{OPT}_a(j)$ continues to comply with the structure of Lemma 4. Let $\bar{Z}_m^i(j), \bar{W}_m^i(j)$ be the total processing time and total weight scheduled in $\hat{B}_m^i$ by $\widehat{OPT}_a(j)$.

▷ Claim 7. For $j = 0, 1, \ldots, n$, there is a feasible state $\mathcal{S}(j)$ with substates

$$\mathcal{S}^i(j) = (Z_i^i(j), W_i^i(j), Z_{i+1}^i(j), W_{i+1}^i(j), \ldots, Z_k^i(j), W_k^i(j)),\ i = 1, \ldots, k$$

corresponding to jobs in R_i, produced by the DP after considering jobs $1, 2, \ldots, j$, such that

$$Z_m^i(j) = \bar{Z}_m^i(j), W_m^i(j) = \bar{W}_m^i(j),\ \forall i, m : m > i, \ \text{ and } \ Z_i^i(j) \leq \bar{Z}_i^i(j), W_i^i(j) = \bar{W}_i^i(j),\ \forall i.$$

Proof. The proof is by induction on j. For the base case $j = 0$, the feasible DP state $\mathcal{S}(0) = (0, 0, \ldots, 0)$ proves the claim trivially true. We assume that the claim is true up to job $j-1$, and we consider the case $j \in R_i$. Let $\mathcal{S}(j-1)$ be the state which by the inductive hypothesis corresponds to $\widehat{OPT}_a(j-1)$. There are three cases to consider.

If j is not scheduled in the transition from $\widehat{OPT}_a(j-1)$ to $\widehat{OPT}_a(j)$ then setting $\mathcal{S}(j) = \mathcal{S}(j-1)$ satisfies the claim.

If $\widehat{OPT}_a(j)$ is obtained from $\widehat{OPT}_a(j-1)$ by scheduling j in $\hat{B}_m^i$ for some $m > i$, then the transition from the state $\mathcal{S}(j-1)$ to a state $\mathcal{S}(j)$ with the same placement of j as $\widehat{OPT}_a(j-1)$ is feasible, since it is feasible for $\widehat{OPT}_a(j)$, and $\mathcal{S}(j)$ satisfies the claim.

If $\widehat{OPT}_a(j)$ is obtained from $\widehat{OPT}_a(j-1)$ by scheduling j in $\hat{B}_i^i$, then the transition from state $\mathcal{S}(j-1)$ of the inductive hypothesis to a state $\mathcal{S}(j)$ when the same placement of j as in $\widehat{OPT}_a(j-1)$ is tried, can follow one of two possibilities: (i) If there is another feasible state $\mathcal{T}(j-1)$ with Z_i^i value T smaller than $Z_i^i(j-1) + p_j \leq \bar{Z}_i^i(j-1) + p_j$, W_i^i value U equal to $W_i^i(j-1) + w_j$, and all other values equal to the values of $\mathcal{S}(j-1)$, then the transition followed by the DP (bottom branch of (6)) sets $\mathcal{S}(j) = \mathcal{T}(j-1)$ (which means that j is not scheduled in $\mathcal{S}(j)$), and the claim is satisfied. (ii) If there is no such state $\mathcal{T}(j-1)$, then by the inductive hypothesis $Z_i^i(j-1) \leq \bar{Z}_i^i(j-1)$ which implies that $Z_i^i(j-1) + p_j \leq \bar{Z}_i^i(j-1) + p_j$. In addition, the transition of the DP for this case (top branch of (6)) is feasible, since it was feasible for $\widehat{OPT}_a(j-1)$, and the new state $\mathcal{S}(j)$ it produces again satisfies the claim. ◁

The claim proves that there is a path of feasible states of the DP that achieves the same total weight as $\widehat{OPT}_a(j)$ for all j, and, therefore, there is a feasible state $\mathcal{S}(n)$ of total weight equal to $w(\widehat{OPT}_a(n)) = w(\widehat{OPT}_a)$. ◀

Trimming. Schedule S corresponds to scheduling in a resource-augmented set of bins $\hat{B}^i_m, m > i$. Following [15], we apply trimming (cf. Appendix D.2) to each one of them with $\gamma := 1 + \varepsilon_3$, $\delta := \varepsilon_3, \varepsilon := \varepsilon_3$, for a total loss of at most $2\varepsilon_3\widehat{OPT}_a$ total weight. The resulting schedule is feasible for the original problem without speed-up, and its total weight is at least $(1 - \varepsilon)OPT$, where $\varepsilon \leq 1 - (1 - \varepsilon_1)(1 - 3\varepsilon_2)(1 - 3\varepsilon_3)$.

Running time. Let us focus first on the subproblem for a fixed R_i. There are $C := O(n^{O(k/\varepsilon^2)}(\log_{1+\varepsilon} D_k)^k)$ choices for all the large sets and the bin sizes. For each choice we run the DP for resource-augmented bin sizes, with rounded weight values, which gives a total of $O((n^2/\varepsilon^2)^k \cdot C)$ choices for the coordinates, except for the first one, of the substate $\mathcal{S}^i()$. By Claim 7, for every such combination of coordinates we keep one substate. To place job $j \in R_i$ we examine $O(k)$ transitions. Taking into account that there are k sets $R_1, \dots, R_k$, we obtain a total running time of $O((n \log D_k)^{O(k^2/\varepsilon^2)})$.

▶ **Theorem 8.** *There is a PTAS for the maximum weighted throughput problem on a single machine with a constant number of distinct due dates.*

Theorem 8 is used in part (ii) of Corollary 1.

4 Constant number of distinct release dates

The ideas behind Theorem 8 can easily be applied to provide a PTAS for the case of a constant number of release dates. Let $d_{\max} = \max_{j \in \mathcal{J}} d_j$. The role of due dates is now played by the k different release dates $0 = r_1 \leq r_2 \leq \ldots \leq r_k$, that define k intervals $[r_i, r_{i+1})$, $i \in [1, k-1]$, and $[r_k, d_{\max})$. Note that release dates are now ordered in non-decreasing order. Let S_i be the straddler of r_i, $i \in [2, k]$ and $S_1 = \emptyset$.

After the rounding of the job weights, we consider an optimal schedule OPT where jobs are now shifted as *early* as possible. Intervals $K_m = (f_m, s_{m+1})$ between straddlers S_m, S_{m+1} are defined as before, and Lemma 3 applies to show the existence of a subset of the scheduled jobs of K_m that can now be scheduled in (smaller) intervals $\hat{K}_m$ starting also at f_m and with polynomially many possible sizes. This is ensured by Lemma 3, modified to apply to bins straddling only due dates, and by scheduling jobs within the bins in Earliest Due Date (EDD) order and as early as possible. When empty space is created within a bin, we shift jobs to the left on the time axis as needed so as to eliminate idle time. The only additional change to Lemma 4 is that now jobs within each interval are scheduled in EDD order.

The PTAS description is virtually the same, with the role of R_i played by D_i, the set of jobs with due dates in $[r_i, r_{i+1})$. Bins $\hat{B}^i_m$, $i \in [m, k]$, of $\hat{K}_m$ are defined similarly to Section 3.3, where $\hat{B}^i_m$ contains jobs scheduled in $\hat{K}_m$ with due date in $\hat{K}_i$. These bins appear from left to right in $\hat{K}_m$, i.e., in order of increasing i. The DP transitions are also defined similarly, to always respect (i) the due dates, (ii) the bin capacities, and (iii) the invariant that the jobs from D_i that are scheduled in $\hat{B}^i_i$ occupy the minimum processing time, *given* the processing time target for bins $\hat{B}^i_m$, $m \in [1, i)$, and the total weight targets for bins $\hat{B}^i_m$, $m \in [1, i]$. By the latter invariant, Lemma 6 applies also to this case. Hence we have:

▶ **Theorem 9.** *There is a PTAS for the maximum weighted throughput problem on a single machine with a constant number of distinct release dates.*

Theorem 9 is used in part (ii) of Corollary 1.

A Technical details for the proof of Theorem 2

We explain how the dependent rounding method of [21, 9] is used in the proof of Theorem 2. The details in this section are a simple application of the work of Srinivasan [21] (see also [9]) and we provide them here for the sake of completeness. Let x^* be a $(\rho - \delta)$-approximate (fractional) solution of (CLP). Without loss of generality we can assume that $\sum_{C \in \mathcal{C}(i)} x^*_C = 1, \quad \forall i \in \mathcal{M}$.

Let $\bar{\mathcal{C}}(i)$ be the configurations in $\mathcal{C}(i)$ with nonzero value in x^*. We define $x^{(i)}$ to be the projection of the x^* vector to the coordinates that correspond to configurations in $\bar{\mathcal{C}}(i)$. Denote $|\bar{\mathcal{C}}(i)|$ by t_i. Srinivasan [21] defines a distribution $D(t_i, x^{(i)})$ over vectors in $\{0,1\}^{t_i}$ such that any vector X sampled from the distribution satisfies the following three properties:

(A1) *(probability preservation)* $\forall C \in \bar{\mathcal{C}}(i), \Pr[X_C = 1] = x^*_C$.

(A2) *(degree preservation)* $\Pr[|\{C \in \bar{\mathcal{C}}(i) \colon X_C = 1\}| = 1] = 1$.

(A3) *(negative correlation)* For all $S \subseteq \bar{\mathcal{C}}(i)$ we have $\Pr[(\bigwedge_{C \in S}(X_C = 0)] \leq \prod_{C \in S} \Pr[X_C = 0]$ and $\Pr[(\bigwedge_{C \in S}(X_C = 1)] \leq \prod_{C \in S} \Pr[X_C = 1]$.

The existence of the distribution is established algorithmically:

▶ **Theorem 10** ([21])**.** *Given the vector $x^{(i)}$ there is a linear-time algorithm that generates a sample from distribution $D(t_i, x^{(i)})$.*

The rounding algorithm follows. It takes as input the vector x^*.

Algorithm 1 DependentRounding.

```
For all $i \in \mathcal{M}$, do independently:
    1. Using the algorithm of Theorem 10, sample from $D(t_i; x^{(i)})$ to obtain vector
       $X^{(i)} \in \{0,1\}^{t_i}$. By Property (A2), $X^{(i)}$ has a unique entry equal to 1.
    2. Assign the configuration $C$ that corresponds to the nonzero entry of $X^{(i)}$ to
       machine $i$.
```

For every $i \in \mathcal{M}$ and $C \in \mathcal{C}(i)$ s.t. $X^{(i)} = 1$, we set $\hat{x}_C = 1$. The remaining entries of $\hat{x}$ are set to zero. The rest of the proof simply adapts the analysis of [21] for Maximum-Coverage-type problems. Since the sets $\bar{\mathcal{C}}(i)$ are pairwise disjoint we slightly abuse notation and omit the machine superscript from the vectors $X^{(i)}$. For $j \in \mathcal{J}$, let z_j be the random variable that takes value 1 if job j is assigned by Algorithm DependentRounding to at least one machine and 0 otherwise. Let $\mathcal{C}$ denote $\bigcup_{i \in \mathcal{M}} \mathcal{C}(i)$.

$$\begin{aligned} \Pr[z_j = 1] &= 1 - \Pr[\bigwedge_{C \in \mathcal{C}: C \ni j} (X_C = 0)] \\ &\geq 1 - \prod_{C \in \mathcal{C}: C \ni j} \Pr[X_C = 0] \qquad (7) \\ &= 1 - \prod_{C \in \mathcal{C}: C \ni j} (1 - x^*_C) \qquad (8) \end{aligned}$$

Inequality (7) follows from the negative correlation property (A3), and equality (8) from property (A1). Define $z^*_j := \sum_{C \in \mathcal{C}: C \ni j} x^*_C$. This is the fractional amount by which job j is scheduled, and the objective value of the solution x^* is equal to $\sum_{j \in \mathcal{J}} w_j z^*_j$. Observe that for every j, $z^*_j \leq 1$. Using calculus we obtain that the expression in (8) is greater than $(1 - 1/e) \cdot z^*_j$.

B Scheduling with job types

In this section we show how the proofs in Section 2 can be extended to accommodate job types. Only jobs with certain types can be scheduled together on each machine and the actual combination of types affects the job characteristics.

The extended problem is defined as follows. Every job j has a *type* t_j from a finite set T of types. For every machine i, we are given a set $E_i \subseteq 2^T$ that specifies the allowed combinations of types that may be processed on i in a feasible schedule. We assume from now that $\sum_{i\in\mathcal{M}}|E_i|$ is bounded by a polynomial in n and m. For machine i, let $E_i = \{e_i(1), \ldots, e_i(k_i)\}$ be the set of allowed combinations. In a feasible schedule, the set J_i assigned to machine i must meet the following two additional constraints. C(i): all jobs in J_i must have a type in $e_i(l)$ for some $e_i(l) \in E_i$. We call this type combination $e_i(l)$ *active* for machine i. C(ii): The jobs in J_i have processing times, release dates, and due dates that depend on the active type $e_i(l)$, and are denoted $p^l_{ij}, r^l_{ij}, d^l_{ij}$ respectively.

We denote by $R|\, r_{ij},\, d_{ij}$, types $|\sum_j w_j\bar{U}_j$ the problem of maximizing weighted throughput on unrelated machines under the additional constraints C(i) and C(ii). Using a ρ-approximate oracle for $1|\, r_j,\, \beta|\sum w_j\bar{U}_j$ we show how to obtain a $((1-1/e)\rho-\varepsilon)$ guarantee for $R|\, r_{ij},\, d_{ij}$,β, types $|\sum_j w_j\bar{U}_j$. We outline only the necessary modifications in the proofs of Section 2.

The definition of a configuration is now as follows. A configuration $C \in \mathcal{C}(i)$ is a schedule of a subset $J \subseteq \mathcal{J}$ of jobs on machine i such that (i) all jobs in J have types from some set $e_i(l) \in E_i$ (ii) job j in J has processing p^l_{ij} and it must be scheduled in the interval $[r^l_{ij}, d^l_{ij}]$ on i (iii) there is no unnecessary idle time (iv) the β-constraints are met.

In the proof of Lemma 1 instead of a single instance I_i for machine i we define k_i instances, one for every element of E_i. Instance $I_i(l)$ is defined on job set $J_i(l) = \{j \in \mathcal{J} \mid j \text{ has type in } e_i(l)\}$. Job j in $J_i(l)$ has processing time, release date, and due date $p^l_{ij}, r^l_{ij}, d^l_{ij}$ respectively. Running algorithm A_β on each instance $I_i(l)$, $l = 1, \ldots, k_i$, will detect whether there is a configuration C in $\mathcal{C}(i)$ with total value more than y_i/ρ.

The rounding algorithm in the proof of Theorem 2 will return on every machine a configuration C s.t. all jobs in C have a type from a set $e_i(l) \in E_i$. The rest of the proof holds as before, including the analogous extensions of Corollaries 1 and 2 to the setting with types.

C FPTAS for similarly ordered release and due dates [17]

When release and due dates are similarly ordered, Lawler ([17], Section 6) observed that there is a non-preemptive EDD (Earliest Due Date) optimal schedule, that can be computed by the following DP:

$$C_j(w) = \min\{C_{j-1}(w), \max\{r_j, C_{j-1}(w-w_j)\} + p_j\}, \tag{9}$$

where $C_j(w)$ is the minimum total scheduling time needed to achieve total weight at least w, by a feasible schedule of the first j jobs in an EDD order. If the right-hand side of (9) violates any d_i, then $C_j(w) = \infty$. While the running time of this DP is $O(n^2 w_{\max})$, it can be transformed into a FPTAS for maximum weighted throughput by rounding the job weights as in the classic knapsack problem.

The FPTAS can be adapted to work with the setting of Section 3, since there is also an optimal schedule that has all its jobs shifted as late as possible such that within each contiguous block of jobs that does not contain a due date, jobs appear in earliest release date order. The correctness of the algorithm is not affected if we construct the optimal schedule in a "towards the past" direction, starting at $d_{\max}$, and examining the jobs in a Latest Release Date (LRD) order.

For the setting of a constant number of distinct release dates (due dates), we exploit the fact that the algorithm of [17] computes the optimal solution when all jobs have a common due date (common release date).

D PTAS for GAP with a constant number of bins [15]

In the Generalized Assignment Problem (GAP), we are given m bins (machines in the terminology of [15]), with bin i having volume capacity B_i, and n jobs with weight w_j for job j, as well as processing time p_{ij} when scheduled in bin i (note that if job j cannot go to machine i, $p_{ij} = \infty$); the goal is to maximize the total weight of scheduled jobs. There are no release or due dates.

Khan et al. [15] presented a PTAS for the case of constant m. They split the jobs into "big" and small according to their processing times, by proving the following structural theorem for any feasible GAP solution:

▶ **Theorem 11** (Theorem 3 in [15]). *Let S be a feasible solution to GAP, and let $S_i \subseteq S$ be the jobs assigned to the i-th bin. Then for all $\varepsilon > 0$, there exist sets X and Y such that $|X| \leq m/\varepsilon^2$ and $w(Y) \leq \varepsilon w(S)$ and*

$$p_{ij} \leq \varepsilon \left(B_i - \sum_{j \in X \cap S_i} p_{ij} \right), \ \forall i, \ \forall j \in S_i - X - Y.$$

Having guessed the set X together with the assignment of its jobs to bins, [15] turn to the scheduling of the rest of the jobs that are small in the sense of Theorem 11. In order to recover total weight at least $(1-\varepsilon)w(S-X)$, the authors in [15] apply *resource augmentation* for processing times (Section D.1), followed by a DP-based PTAS for scheduling the jobs with their rounded processing times, and, lastly, *trimming* (Section D.2) is used in order to remove a lengthy enough set of cheap jobs so as to restore the bin volume capacities to their original values. We proceed to outline how resource augmentation and trimming are defined in [15] and under what conditions they can be used for the throughput problem.

D.1 Resource augmentation

For every bin i, define a scaling factor $\mu_i := \varepsilon B_i/n$. Also, define new bin volume capacity $B'_i := \lfloor B_i/\mu_i \rfloor + n$ and new job processing times $p'_{ij} := \lceil p_{ij}/\mu_i \rceil$. Then there is an optimal solution to maximum throughput that can be calculated by a PTAS, and the bin capacities used are $B'_j \leq (1+\varepsilon)B_j$. Obviously, this optimal solution is at least as good as the optimal solution that can be obtained with the original bin capacities. Khan et al. [15] show that if the items (jobs) have size at most εB_i after trimming the solution as in Section D.2 the bin capacities can be restored to their original values while losing only an ε-fraction of weight (profit).

Resource augmentation can be applied on a maximum throughput instance restricted to an interval I on the time axis only when there are no release or due dates contained in I.

D.2 Trimming

Khan et al. [15] designed the trimming method that follows for a knapsack instance. Suppose that in bin i, there is a schedule of a set S_i of jobs, without due dates or relase dates, s.t. $p(S_i) = \gamma B_i$, with $\gamma \leq 1 + \delta$ and with total weight $w(S_i)$. Moreover, $p_{ij} \in (0, \varepsilon B_i]$ for $j \in S_i$. Then for parameters δ, ε with $\delta \leq \varepsilon$, [15] show how to create empty space of length at least δB_i, without losing more than $((\delta + \varepsilon)/(\gamma - \varepsilon))w(S_j)$ weight, and the scheduling of the remaining jobs takes no more than B_i processing time.

This trimming technique of [15] can be extended to apply to a maximum throughput schedule with different release dates and a common due date (different due dates and a common release date). In this case, all jobs can be shifted as late (as early) as possible, to create a new schedule ending at the due date (starting at the release date) with no idle time. This can be achieved without violating any release (due) dates. We provide the details for the case of the common due date in our Lemma 3.

D.3 Proof of Lemma 3

We provide the missing details for the existence of set R. We adjust the trimming method of [15] in order to account for the existence in our setting of release dates and achieve the parameters we need in the statement of the lemma. In particular let σ' be the feasible schedule of the set $X \cup J'$ in the interval I where for every $j \in J'$, $p_j \leq \varepsilon(|I| - p(X))$. Let $B = |I| - p(X)$. We consider the set S of the subintervals of I that contain idle time or jobs from J'. Their length may vary and they may not be consecutive on the time axis as they may be intermingled with the jobs of X. Clearly the total length of these subintervals equals B. Let $k = \lfloor (1 - \varepsilon)/(2\varepsilon) \rfloor$. Put a blue marker to the leftmost endpoint of a subinterval in S. Moving to the right, sweep along the time axis within the subintervals of S only and put a red marker after length εB, a blue marker after the next length εB and so on. Therefore the markers alternate between red and blue. Proceed until you have placed $k + 1$ red markers and $k + 1$ blue markers. The last marker will be red. Since

$$(k + 1)\varepsilon B + k\varepsilon B = (\varepsilon + 2\varepsilon \lfloor (1 - \varepsilon)/(2\varepsilon) \rfloor)B \leq B$$

this is always possible. Number the markers from 0 to $2k + 1$ from left to right. Consider the set of jobs S_i, $i \in \{0, 1, \dots, k\}$ that are scheduled to a non-zero extent after blue marker $2i$ and up to red marker $2i + 1$. These sets are pairwise disjoint. Let $S_i^* = \arg\min_{i=0}^{k} w(S_i)$. It follows that $w(S_{i^*}) \leq \frac{1}{k+1} \sum_{i=0}^{k} w(S_i) \leq (2\varepsilon)/(1 - \varepsilon)w(J')$. Removing $R := S_{i^*}$ will leave empty space of εB. We have that $p(J' - R) \leq (1 - \varepsilon)B$. Define the integer $\beta \geq 0$ such that $(1 + \varepsilon)^{\beta} \leq B < (1 + \varepsilon)^{\beta + 1}$. Then $p(J' - R) \leq (1 - \varepsilon^2)(1 + \varepsilon)^{\beta}$.

Facility Location in the Sublinear Geometric Model

Morteza Monemizadeh ✉
Department of Mathematics and Computer Science, TU Eindhoven, The Netherlands

Abstract

In the *sublinear geometric model*, we are provided with an oracle access to a point set P of n points in a bounded discrete space $[\Delta]^2$, where $\Delta = n^{O(1)}$ is a polynomially bounded number in n. That is, we do not have direct access to the points, but we can make certain types of queries and there is an oracle that responds to our queries. The type of queries that we assume we can make in this paper, are range counting queries where ranges are axis-aligned rectangles (that are basic primitives in database [36, 11, 17], computational geometry [1, 2, 6, 5], and machine learning [35, 31, 29, 28]). The oracle then answers these queries by returning the number of points that are in queried ranges. Let Alg be an algorithm that (exactly or approximately) solves a problem $\mathcal{P}$ in the sublinear geometric model. The query complexity of Alg is measured in terms of the number of queries that Alg makes to solve $\mathcal{P}$. In this paper, we study the complexity of the (uniform) Euclidean facility location problem in the sublinear geometric model. We develop a randomized sublinear algorithm that with high probability, $(1+\epsilon)$-approximates the cost of the Euclidean facility location problem of the point set P in the sublinear geometric model using $\tilde{O}(\sqrt{n})$ range counting queries. We complement this result by showing that approximating the cost of the Euclidean facility location problem within $o(\log(n))$-factor in the sublinear geometric model using the sampling strategy that we propose for our sublinear algorithm needs $\tilde{\Omega}(n^{1/4})$ RangeCount queries. We leave it as an open problem whether such a polynomial lower bound on the number of RangeCount queries exists for any randomized sublinear algorithm that approximates the cost of the facility location problem within a constant factor.

1 Introduction

In the *sublinear query model*, we consider scenarios in which we do not have direct access to the underlying data, but there is an oracle or a prophet who provides us *metadata* about the data that we are interested in. An interesting real-world application of such scenarios is for retail or ride hailing companies that have millions of customers. Often these giant companies do outsourcing by hiring a party outside a company to perform temporary services to reduce costs or optimize customers buying experience. Due to privacy concerns[1], these companies do not want to provide accurate and detailed information of their customers to the outsourced companies. However, they can provide some sort of metadata (such as how many customers are in an area or a neighborhood or how often customers in a town purchase particular goods or use a service) that can help the outsourced company to perform its service.

[1] See "Threat to Security and Confidentiality" in `https://www.thebalancesmb.com/top-outsourcing-disadvantages-2533777` and "Security and Privacy Concerns" in `https://www.truppglobal.com/blog/top-10-outsourcing-problems-and-how-to-solve-them#5-security-and-privacy-concerns`

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

Leibniz International Proceedings in Informatics
Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

As a concrete example, let us consider a retail company that plans to open new stores or lockers to provide fast and responsive support for its customers. To this end, the company hires an (experienced) outsourced company to estimate the total cost of opening new stores or lockers. Due to privacy concerns, the company does not want to provide information about its customers, but it can provide aggregate data such as how many customers are in an area or a neighborhood. An interesting question is how many times these aggregate data should be provided so that the outsourced company can estimate a fairly accurate cost of opening new stores or lockers.

Motivated by these applications, we study the (uniform) Euclidean facility location in the *sublinear geometric model* which is a sublinear model suitable when the underlying data is a point set in a d-dimensional Euclidean space. In particular, we seek to design sublinear algorithms that approximate the cost of the Euclidean facility location problem when we do not have access to the underlying point set, but instead, we can make queries and there is an oracle who will respond and provide solutions to our queries. Next, we define the facility location problem formally.

▶ **Definition 1** ((uniform) Euclidean facility location)**.** *In the* (uniform) Euclidean facility location *problem, we are given a point set P of size n in a bounded discrete space $[\Delta]^2$, where $\Delta = n^{O(1)}$ is a polynomially bounded number in n and an opening cost $f > 0$, and the goal is to compute a set $F^* \subset [\Delta]^2$ of facilities that minimizes the cost function $cost_{FL}(P, F^*) = \sum_{p \in P} \operatorname{dist}(p, F^*) + f \cdot |F|$, where $dist(p, F^*) = \min_{q \in F^*} dist(p, q)$ is the Euclidean distance of p to its nearest facility in F^*. We denote the optimal facility location cost of the point set P by $OPT_{FL}(P, f)$.*

1.1 Sublinear geometric model

Let $P \subseteq [\Delta]^2$ be a point set of size n in a 2-dimensional discrete space $[\Delta]^2 = \{1, 2, 3, \cdots, \Delta\}^2$, where $\Delta = n^{O(1)}$ is a polynomially bounded number in n. For the simplicity of exposition, we assume that $\Delta = n$. This means that the space $[\Delta]^2$ is indeed, the space $[n]^2$. We also assume that every unit square (of side length one), can store at most one (weighted) point [2].

In the *sublinear geometric model*, we assume we do not have access to points of P directly, but instead, we have *query access* to points of P. That is, we can make certain queries with respect to point set P and there is an oracle that returns the solutions to our queries. The type of queries that we assume are provided in the sublinear geometric model are *range counting queries* where ranges are *axis-aligned rectangles* (that are basic primitives in database [36, 11, 17], computational geometry [1, 2, 6, 5], and machine learning [35, 31, 29, 28]). The oracle then answers these queries by returning the number of points in queried ranges.

Range counting queries. We assume that we have a query access to P where we query an axis-aligned rectangle $c \subseteq [n]^2$ and the oracle returns the number of points $n_c = |P \cap c|$ that are in rectangle c. We denote such a query by $\textsc{RangeCount}(c)$. Let $\textsc{Alg}$ be an algorithm that (exactly or approximately) solves a problem $\mathcal{P}$ in the sublinear geometric model. The query complexity of $\textsc{Alg}$ is measured in terms of the number of $\textsc{RangeCount}(c)$ queries that $\textsc{Alg}$ makes to solve $\mathcal{P}$. Assume that the input of problem $\mathcal{P}$ is a point set P of size n. If the number of $\textsc{RangeCount}(c)$ queries that we ask is $o(n)$, we say the query complexity of problem $\mathcal{P}$ is sublinear in terms of its input set.

[2] We make these explicit assumptions to simplify the notations in this paper.

1.2 Our Contribution

Here, we state our main result.

▶ **Theorem 2** (Facility location in sublinear geometric model). *Let P be a point set of size n in a discrete space $[n]^2$. Let $f > 0$ be the opening cost for the facility location problem and $0 < \epsilon \leq 1$ be the error parameter. Then, there exists a randomized sublinear algorithm that (w.h.p.) returns an $(1+\epsilon)$-estimator for the facility location cost of P in the sublinear geometric model using $\tilde{O}(\sqrt{n})$ RangeCount queries.*

We complement this result by showing that approximating the cost of the Euclidean facility location problem within $o(\log(n))$-factor in the sublinear geometric model using the sampling strategy that we propose for Theorem 2 needs $\tilde{\Omega}(n^{1/4})$ RangeCount queries. See Figure 2 in Section 4 for the illustration of the hard instance that we explain there. We leave it as an open problem whether such a polynomial lower bound on the number of RangeCount queries exists for any randomized sublinear algorithm that approximates the cost of the facility location problem within a constant factor.

▶ **Lemma 3** (Lower bound). *There exists a facility location instance for which the sublinear algorithm of Theorem 2 needs $\Omega(\frac{\sqrt[4]{n}}{\log n})$ RangeCount queries to estimate the cost of facility location within $o(\log n)$-factor in the sublinear geometric model.*

Outline of the proof of Theorem 2. Our starting point to prove this theorem is to choose a known polynomial-time approximation scheme (PTAS) for the Euclidean facility location problem in the plane. Our goal would be to simulate such a PTAS in sublinear time to obtain an estimator for the optimal cost of the facility location problem.

Known PTAS algorithms [7, 30, 15] are often based on partitioning the underlying space of a point set. Two such PTAS algorithms are known. The first one was proposed by Arora, Raghavan, and Rao [7] and later improved by Kolliopoulos and Rao [30] that partitions the space into regions and then combine solutions of small regions using the dynamic programming to obtain solutions for the bigger regions. The issue with extracting an estimator based on this PTAS is that simulating the dynamic programming in sublinear time seems to be hard.

The second PTAS for this problem was proposed by Czumaj, Lammersen, Monemizadeh, and Sohler [15] where they partition the underlying space $[n]^2$ of a point set P into a set Λ of cells in a way that they can solve the facility location instance inside each cell independent of the facility location instances of the other cells. The independency that is provided by this algorithm is a good choice for us. However, the problem with using this approach (in order to develop an estimator) in the geometric sublinear model is we do not have access to Λ.

Overall Idea: We develop a sublinear algorithm that randomly samples cells of a number of grids (of exponentially increasing granularity) that we impose on the discrete space $[n]^2$ and determines whether the sampled cells could be cells in the set Λ or not. For those sampled cells that are in fact, cells in Λ, we solve the facility location instance independently and compute a $(1+\epsilon)$-approximation of their facility location costs. We then multiply their costs with proper weights to $(1+\epsilon)$-estimate the optimal facility location cost $OPT_{FL}(P, f)$.

Next we briefly describe the space partitioning and the PTAS that are developed in [15] and then, we explain our sublinear algorithm in detail.

PTAS of [15]. Suppose we are given a point set $P \subset [n]^2$ of size n. We impose a (nested) grid set $\mathcal{G}_{\log(n)+1}, \mathcal{G}_{\log(n)}, \cdots, \mathcal{G}_1, \mathcal{G}_0$ on the space $[n]^2$ where the grid $\mathcal{G}_i$ consists of cells of side length 2^i. We then randomly shift the border lines of the grids $\mathcal{G}_{\log(n)+1}, \mathcal{G}_{\log(n)}, \cdots, \mathcal{G}_1, \mathcal{G}_0$ as follows. We choose two random real numbers $v_1, v_2 \in [0, n]$. Then, we shift every border line ℓ of every grid $\mathcal{G}_i$ using the random vector $v = (v_1, v_2)$. Observe that after this random shifting process, the point set P is enclosed in a rectangle of side length $[2n]^2$. In the sublinear geometric model, whenever we make range queries for ranges that are axis-aligned rectangles, we first shift these rectangles using v and then query them.

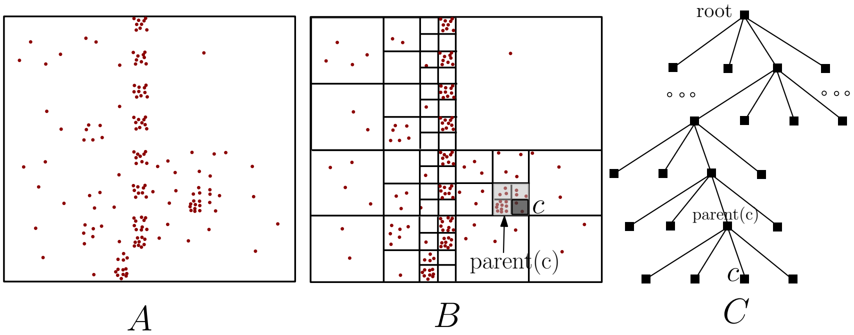

Figure 1 In the sub-figure A, a point set $P \subseteq [\Delta]^2$ is given. The sub-figure B illustrates the space partitioning Λ that is computed by the PTAS of [15]. A light cell c (dark gray square) that is in the partition set Λ and its parent *parent*(c) (gray square) are shown. In the sub-figure C, the nodes that correspond to c and *parent*(c) are also shown in the corresponding quadtree partitioning.

The PTAS [15] is based on partitioning heavy cells and detecting light cells, two notions that we define next. Let c be an arbitrary cell in a grid $\mathcal{G}_i$. We use the 3-approximation algorithm due to Jain and Vazirani [26] (who developed it for facility location) to determine if c is heavy or light. Let us call this algorithm $\textsc{Alg}^3_{FL}$. We say an arbitrary c in a grid $\mathcal{G}_i$ is a *heavy cell* if $\textsc{Alg}^3_{FL}(P \cap c)$ outputs that the facility location cost of $P \cap c$ is at least $\delta_{FL} \cdot f$ where $\delta_{FL} = O(\epsilon^{-2} \log^2 n)$. If the reported cost is less than $\delta_{FL} \cdot f$, c is a *light* cell.

Starting with the square $[2n]^2$, if a cell $c \in \mathcal{G}_i$ is heavy, we then split it into its 4 children c_1, c_2, c_3, c_4 (that are in the grid $\mathcal{G}_{i-1}$) of equal side length and recurse for those children that are heavy. At the end of this recursive algorithm, we let Λ be the set of all light cells that are constructed in this way. Interestingly, for every cell c, we can solve the facility location instance of the point subset $P \cap c$ independently. Later, we combine the solutions of these independent instances to obtain a $(1+\epsilon)$-approximate solution of the optimal facility location of P. See Figure 1 for an illustration of Λ.

Sublinear algorithm. Now, we outline our sublinear algorithm. This algorithm samples cells of the grids $\mathcal{G}_{\log(n)+1}, \mathcal{G}_{\log(n)}, \cdots, \mathcal{G}_1, \mathcal{G}_0$ randomly and determine whether the sampled cells can be in set Λ or not. If we sample enough cells from Λ uniformly at random, compute a $(1+\epsilon)$-approximation of their costs and multiply their costs with proper weights, we can approximate the optimal facility location cost $OPT_{FL}(P, f)$ within $(1+\epsilon)$-factor. However, this is not an easy task in the sublinear geometric model as we have the following challenges:

- **Query Access:** Given a cell c in a grid $\mathcal{G}_i$:
  - We need to determine if c is heavy or light using $\textsc{Alg}^3_{FL}(P \cap c)$.
  - If we know that we have sampled a cell $c \in \Lambda$, we need to compute a $(1+\epsilon)$-approximation of its cost using a PTAS algorithm, say [15].

  However, we do not have direct access to the points in $P \cap c$. We can only make range counting queries.
- **Many noisy empty cells:** In any grid $\mathcal{G}_i$ for $i \leq \frac{1}{2} \cdot \log(n)$, we have $\Omega(n)$ cells and plenty of them could be empty. Recall that $|P| = n$. Thus, a uniform random sampling may need to sample many cells to hit a cell from Λ.

We first develop a tester algorithm (so-called HeavyTester) that using $\mathrm{poly}(\epsilon^{-1} \cdot \log(n))$ RangeCount queries determines if a cell c in a grid $\mathcal{G}_i$ is a heavy or a light cell. In case that c is a light cell, the tester returns the facilities that $(1+\epsilon)$-approximates the optimal facility location cost of the cell c. This already resolves the first challenge. Next, we deal with the second challenge. We first develop a sublinear algorithm (so-called $\sqrt{n}$-Estimator) that using $\tilde{O}(\sqrt{n})$ RangeCount queries distinguishes between the following two cases:

- **Low cost instances:** The first case is if the optimal cost of P is upper-bounded by $O(\sqrt{n}f)$. If this is indeed the case, the algorithm $\sqrt{n}$-Estimator solves the facility location instance of P and returns $(1+\epsilon)$-approximate solution (not the cost) of P.
- **High cost instances:** The second case is if the optimal cost of P is $\Omega(\sqrt{n}f)$. For this case, the algorithm $\sqrt{n}$-Estimator outputs that the cost of P is $\Omega(\sqrt{n}f)$.

From now on, we assume that the optimal facility location cost of P is $\Omega(\sqrt{n}f)$.

We develop a **telescoping sampling** that samples any arbitrary cell c in a grid $\mathcal{G}_i$ with probability $\mathbf{Pr}[c] = \frac{n_{parent(c)}}{n}$, where $parent(c)$ is the parent of c in the grid $\mathcal{G}_{i+1}$ and $n_{parent(c)} = |parent(c) \cap P|$ is the number of points in $parent(c)$ (See Figure 1 for the illustration of a light cell and its parent.) The reason that we do the telescoping sampling based on $n_{parent(c)}$ not $n_c = |c \cap P|$ is that the cells in Λ are light, but their parents (and ancestors) are heavy, so heavy parents have a minimum number of points that helps us to use known concentration bounds [3, 32] to analyze the telescoping sampling.

For a grid $\mathcal{G}_i$, we implement the telescoping sampling as follows. We start with the unique cell c' in grid $\mathcal{G}_{\log(n)+1}$ and split it into 4 sub-cells c_1, c_2, c_3, c_4 and query the number of points inside each of them. Then, we sample the sub-cell c_j for $j \in [4]$ with probability $\frac{n_{c_j}}{n_{c'}}$. Suppose we sample c_1. We let $c' = c_1$ and recursively repeat the same process till we end up with the parent of a cell $c \in \mathcal{G}_i$. By the telescoping argument, a cell $c \in \mathcal{G}_i$ is sampled with probability $\mathbf{Pr}[c] = \frac{n_{parent(c)}}{n}$.

Once we sample a cell c in a grid $\mathcal{G}_i$ with probability $\mathbf{Pr}[c] = \frac{n_{parent(c)}}{n}$, we test if c is a heavy or a light cell using algorithm $\textsc{HeavyTester}(c)$. If c is heavy or both c and $parent(c)$ are light, we do not do anything. If c is a light cell and its parent is a heavy cell, the cell c must be in Λ. In this case, the tester returns set F_c of facilities that $(1+\epsilon)$-approximates the optimal facility location cost of the instance $c \cap P$. Let $\mathrm{cost}^{\epsilon}_{FL}(c, F_c, f) = \sum_{p \in P \cap c} \mathrm{dist}(p, F_c) + |F_c| \cdot f$ be the facility location cost of c with respect to facility set F_c.

Next, we would like to assign a weight to the sampled cell c that is in Λ. For that, one option would be to multiply $\mathrm{cost}^{\epsilon}_{FL}(c, F_c, f)$ by the term $\frac{n}{n_{parent(c)}}$. However, this may not be possible. The problem is $n_{parent(c)}$ might be very small and so, the weight $\frac{n}{n_{parent(c)}}$ may be $\Omega(n)$ which essentially means if we want to use known concentration bounds such as the Hoeffding bound [22], we need $\Omega(n)$ samples to approximate the optimal cost $OPT_{FL}(P, c)$.

We develop a novel sampling technique that samples (almost uniformly at random) those light cells in a grid $\mathcal{G}_i$ whose parents have roughly the same number of points. To this end, we first observe that from set Λ, we only need to consider those cells whose cost is at least

τf where $\tau = O(\frac{\epsilon}{\log(n)})$. We call these cells *significant light cells* and we let Ψ be the set of significant light cells of Λ. We show that in order to develop a $(1+\epsilon)$-estimator for facility location, we can safely ignore insignificant light cells (those with cost less than τf) of Λ.

We then partition Ψ into likelihood classes Ψ_i^j, where Ψ_i^j is the set of those significant light cells that are in the grid $\mathcal{G}_i$ and their parents have at least $(1+\epsilon)^j$ points and less than $(1+\epsilon)^{j+1}$. We consider only those likelihood classes Ψ_i^j whose size is $|\Psi_i^j| \geq \beta\sqrt{n}$ where $\beta = (\frac{\epsilon}{\log(n)})^{O(1)}$. We call these classes *contributing likelihood classes.* We show that non-contributing likelihood classes can be safely ignored.

We follow the steps below to show that if a likelihood class Ψ_i^j is contributing, we can approximate the facility location cost of it within $(1+\epsilon)$-factor.

- **Step 1:** We first show that if we sample any arbitrary cell $c \in \Psi_i^j$ with probability $\mathbf{Pr}[c] = \frac{n_{parent(c)}}{n}$, cell c is sampled almost uniformly at random from the set Ψ_i^j.
- **Step 2:** Next, we prove that with high probability, we sample at least $\text{poly}(\epsilon^{-1}\log(n))$ significant light cells from Ψ_i^j.
- **Step 3:** We finally develop an estimator that $(1+\epsilon)$-approximates the size of Ψ_i^j.

Putting everything together, we obtain an estimator that $(1+\epsilon)$-approximates the optimal cost $OPT_{FL}(P, f)$ in the sublinear geometric model using $\tilde{O}(\sqrt{n})$ range counting queries.

1.3 Related Work

Sublinear algorithms have been studied extensively for problems in metric spaces. Czumaj and Sohler [16] showed that we can $(1+\epsilon)$-approximate the weight of minimum spanning tree in metric space in time $\tilde{O}(n) = O(n\text{poly}(\epsilon^{-1}\log n))$. Badoiu, Czumaj, Indyk, and Sohler [8] showed that we can approximate the cost of facility location in metric space within constant factor in time $\tilde{O}(n)$, and Indyk [23] showed that we can return a constant factor approximation of the k-median problem in metric spaces in time $\tilde{O}(n)$. Interestingly, all sublinear algorithms that we are aware of in metric spaces have $\tilde{O}(n)$ running times. One may ask if there exists any sublinear algorithm that is truly sublinear in n?

For sparse graphs this is indeed possible. Chazelle, Rubinfeld, and Trevisan [12] in a seminal work showed that given a connected graph G (that is represented by adjacency lists) of average degree $\overline{d}$ with edge weights in the set $\{1, ..., w\}$, we can $(1+\epsilon)$-approximate the weight of the minimum spanning tree (MST) of G in time $O(\overline{d}w\epsilon^{-2}\log(\frac{\overline{d}w}{\epsilon}))$. Observe that a graph with average degree $\overline{d}$ is a sparse graph as it can have at most $O(n\overline{d})$ edges. Later, Nguyen and Onak [33] in another seminal work initiated the study of sublinear algorithms for Vertex Cover, Maximum Matching, Maximum Weight Matching, and Set Cover problems in bounded-degree graphs. As an example, for the problem of estimating the size of maximum matching, they showed how to approximate the size of the maximum matching up to an additive error ϵn in time $2^{d^{O(1/\epsilon)}}$, where d is the maximum degree of a vertex in the graph G. They obtained similar bounds for the aforementioned problems that approximate their size or cost up to an (ϵn)-additive term. Yoshida, Yamamoto, and Ito[38] and then Behnezhad [10] improve the running time (in fact, the query complexity) of Nguyen and Onak's algorithm for estimating the size of maximum matching and minimum vertex cover. As an example, Behnezhad showed that we can approximate the size of maximal matching (i.e., 2-approximate maximum matching) to within (ϵn)-additive error in time $\tilde{O}((\overline{d}+1)/\epsilon^2)$.

What do we know for Euclidean spaces? Interestingly, very few sublinear algorithms have been developed for optimization problems in Euclidean spaces. Indeed, we are aware of two sublinear algorithms for problems in Euclidean spaces. The first work is due to Czumaj, Ergün, Fortnow, Magen, Newman, Rubinfeld, and Sohler [14] who studied the problem of approximating the weight of Euclidean minimum spanning trees (EMST) in a sublinear time. The authors show that if we are provided with oracle access to basic data structures in the Euclidean space, we can estimate the weight of a EMST within $(1+\epsilon)$-factor.

In particular, they assume that we do not have access to a point set, but we can make queries and there is an oracle that answers our queries. The type of queries that they are allowed to make are *minimum bounding box* queries, *range* queries and *approximate nearest neighbor* queries. They show that in order to $(1+\epsilon)$-approximate the weight of the Euclidean minimum spanning tree in the plane (i.e., $\mathbb{R}^2$), we need to make $\tilde{O}(\sqrt{n})$ such queries.

The second sublinear algorithm that we are aware is for the minimum Euclidean bichromatic matching due to Indyk [25]. This algorithm is more of a linear-time constant factor approximation algorithm than a sublinear algorithm. Indyk assumed that we have access to points, but the main issue is solving the minimum Euclidean bichromatic matching problem using classical algorithms known for the maximum matching problem, say *Hungarian method* takes $O(n^3)$ time. (See [37]). He showed we can approximate the cost of minimum bichromatic matching within constant factor in near linear time and he showed that in time $\tilde{O}(n)$, we are able to do that. Later, Raghvendra and Agarwal [34] showed that in time $\tilde{O}(n)$ we can in fact, compute $(1+\epsilon)$-approximate Euclidean bichromatic matching.

The sublinear geometric model that we study in this paper is closely related to the dynamic geometric streaming model [24, 19] and the Massively Parallel Computations (MPC) model [27, 20]. In the the dynamic geometric streaming model [24, 19], Frahling and Sohler [19] in a groundbreaking work showed that given a (polynomially in n bounded) stream of insertions and deletions of points from an underlying space $[\Delta]^2$ (where $\Delta = n^{O(1)}$), we can compute a $(1+\epsilon)$-approximate solution for the k-median, k-means, MaxCut, maximum travelling salesperson, maximum spanning tree and average distance problems using $\text{poly}(k\epsilon^{-2}\log(n))$ space. Frahling, Indyk and Sohler [18] studied the problem of approximating the weight of the Euclidean minimum spanning tree within $(1+\epsilon)$ in the dynamic geometric streaming model. Later, Czumaj, Lammersen, Monemizadeh, and Sohler [15] developed a $(1+\epsilon)$-estimator for the cost of the Euclidean facility location using $\text{poly}(\epsilon^{-1}\log(n))$ space.

The Massively Parallel Computations (MPC) model was first introduced by Karloff, Suri, and Vassilvitskii [27] and later extended by [9, 20]. Andoni, Nikolov, Onak, Yaroslavtsev [4] studied the Euclidean minimum spanning tree and the minimum Euclidean bichromatic matching problems in the MPC model. They showed $O(1)$-round MPC $(1+\epsilon)$-algorithm for the Euclidean minimum spanning tree that uses $\tilde{O}(\sqrt{n})$ machines each one having local space $\tilde{O}(\sqrt{n})$. For the minimum Euclidean bichromatic matching problem, they showed that we can approximate the cost of minimum bichromatic matching within $(1+\epsilon)$-factor using similar number of communication rounds, number of machines, and the space per machine.

2 Preliminaries

Rounding notations. For the sake of simplicity, we assume that the logarithm of a number is always rounded down or up in an appropriate manner. As an example, if we want to use a range $[\lfloor\log(a)\rfloor, \cdots]$ or a range $[\cdots, \lceil\log(a)\rceil]$ where $a \in \mathbb{R}$, we write $[\log(a), \cdots]$ and $[\cdots, \log(a)]$ to simplify the notation, respectively.

Randomly shifted grids. Let $P \subseteq [n]^2$ be a point set of size n. We consider $\log(n)+1$ grids $\mathcal{G}_{\log(n)+1}, \mathcal{G}_{\log(n)}, \cdots, \mathcal{G}_1, \mathcal{G}_0$ where the grid $\mathcal{G}_i$ consists of cells of side length 2^i that we impose on the space $[n]^2$. We randomly shift the border lines of the grids as follows. We choose two random real numbers $v_1, v_2 \in [0, n]$ and we let $v = (v_1, v_2)$ be the random vector. Then, we shift every border line ℓ of every grid $\mathcal{G}_i$ using v. Observe that after this shift process, the point set P is enclosed in a rectangle of side length $[2n]^2$. In the sublinear geometric model, whenever we make range queries for ranges that are axis-aligned rectangles, we first shift these rectangles using v and then query them.

We let $\mathcal{G}_{\geq i} = \{\mathcal{G}_i, \mathcal{G}_{i+1}, \cdots, \mathcal{G}_{\log(n)}\}$ and $\mathcal{G}_{\leq i} = \{\mathcal{G}_i, \mathcal{G}_{i-1}, \cdots, \mathcal{G}_0\}$. Let $c \in \mathcal{G}_i$ be a cell in a grid $\mathcal{G}_i$. We denote by $c \cap P$ the subset of points that are inside the cell c or on the border lines of c. We denote the number of points in c by $n_c = |c \cap P|$. We let ℓ_c be the side length of c which is 2^i in the grid $\mathcal{G}_i$. We denote the parent of c which is in the grid $\mathcal{G}_{i+1}$ by *parent*(c). Let $c' \in \mathcal{G}_{\geq i}$ be a cell that contains c (i.e., $c \subseteq c'$). We say c' is an *ancestor* of c. We denote the ancestor of c at a grid $\mathcal{G}_{j \geq i}$ by ancestor(c, j). If $c' \in \mathcal{G}_{>i}$, we say that c' is a *proper ancestor* of c. Similarly, let $c' \in \mathcal{G}_{<i}$ be a cell that is contained in the cell c. We say c' is a *descendant* of c. We denote the descendant of c at a grid $\mathcal{G}_{j<i}$ by *descendant*(c, j).

2.1 Space partitioning and PTAS of [15]

Let $P \subseteq [2n]^2$ be a point set of size n and $f > 0$ be a positive real number. Let $0 < \epsilon \leq 1$ be the error parameter. As we explained in the introduction of this paper, Czumaj, Lammersen, Monemizadeh, and Sohler [15] show a construction for the facility location problem that partitions the space $[2n]^2$ into a set Λ of disjoint cells for which we can solve the facility location problem independently. We denote this algorithm by $\textsc{Alg}^{\epsilon}_{FL}(P)$ whose pseudocode is given below.

Algorithm 1 $\textsc{Alg}^{\epsilon}_{FL}$ - Czumaj, Lammersen, Monemizadeh, and Sohler [15].

```
Data: A point set $P \subseteq [n]^2$, an opening cost $f > 0$, and a parameter $0 < \epsilon \leq 1$.
Let $c$ be the square $[2n]^2$. Let $\Gamma = \{c\}$ and $\Lambda = \emptyset$;
while $\Gamma$ has a heavy cell $c$ do
    Let $\Gamma = \Gamma \backslash \{c\}$;
    Let $c_1, c_2, c_3, c_4$ be children of $c$ ; /* If $c \in \mathcal{G}_i$, its children are in $\mathcal{G}_{i-1}$ */
    for $c_i \in \{c_1, c_2, c_3, c_4\}$ do
        if $c_i$ is a heavy cell then
            $\Gamma = \Gamma \cup \{c_i\}$;
        else
            $\Lambda = \Lambda \cup \{c_i\}$ ;                /* $c_i$ is light */
for $c \in \Lambda$ do
    Let $F_c$ be the set of facilities returned by the PTAS [30] for the point set $P \cap c$;
    Let $\mathrm{cost}^{\epsilon}_{FL}(c, F_c, f) = \sum_{p \in P \cap c} \mathrm{dist}(p, F_c) + |F_c| \cdot f$ be the cost of $c \cap P$;
return Set $\Lambda$ and for every cell $c \in \Lambda$, set $F_c$ of opened facilities and $\mathrm{cost}^{\epsilon}_{FL}(c, F_c, f)$;
```

The PTAS [15] is based on partitioning heavy cells and detecting light cells, two notions that we define them next. Let c be an arbitrary cell in a grid $\mathcal{G}_i$. We use the 3-approximation algorithm due to Jain and Vazirani [26] to determine if c is heavy or light.

Heavy and light cells. Let c be a cell in a grid $\mathcal{G}_i$. Let $\delta_{FL} = 2^{20} \cdot (\frac{\log n}{\epsilon})^2$. Let F_c be the set of facilities returned by $\textsc{Alg}^{3}_{FL}(P \cap c)$. We say c is a *heavy cell* if $\mathrm{cost}^{3}_{FL}(c, F_c, f) = \sum_{p \in P \cap c} \mathrm{dist}(p, F_c) + |F_c| \cdot f \geq \delta_{FL} \cdot f$; otherwise it is a *light* cell.

▶ **Lemma 4** ([15]). *Let $P \subseteq [2n]^2$ be a point set of size n and $f \in \mathbb{R}^+$ be a positive real number. Let $0 < \epsilon \leq 1$ be the error parameter. For the output of $\textsc{Alg}^{\epsilon}_{FL}(P)$ we have*

- *For every cell $c \in \Lambda$, we have $cost^{\epsilon}_{FL}(c, F_c, f) \leq (1 + \epsilon) \cdot OPT_{FL}(P \cap c, f)$.*
- *$(1 - \epsilon) \cdot OPT_{FL}(P, f) \leq cost^{\epsilon}_{FL}(\Lambda, f) = \sum_{c \in \Lambda} cost^{\epsilon}_{FL}(c, F_c, f) \leq (1 + \epsilon) \cdot OPT_{FL}(P, f)$.*

3 Sublinear algorithm for facility location problem

In this section, we develop our sublinear algorithm for the facility location problem and prove Theorem 2. We break this algorithm into four steps as follows:

1. **Heavy tester:** We first develop a tester algorithm for heavy cells.
2. **Telescoping sampling:** Then, we explain the telescoping sampling.
3. **$O(\sqrt{n})$-estimator:** In the third step, we explain a $\sqrt{n}$-estimator for the Euclidean facility location problem in the sublinear geometric model.
4. **$(1+\epsilon)$-estimator:** In the final step, we describe our $(1+\epsilon)$-estimator in the sublinear geometric model and analyze it.

3.1 A tester algorithm for heavy cells

Here, we develop a tester algorithm in the sublinear geometric model that given an arbitrary cell c in a grid $\mathcal{G}_i$, makes $\text{poly}(\epsilon^{-1} \cdot \log(n))$ RangeCount queries to distinguish between the case that c is a heavy cell or a light one. The proof of the following lemma is in Appendix A.

▶ **Lemma 5** (Heavy Tester). *Let c be a cell in a grid $\mathcal{G}_i$. Then, there exists a deterministic tester algorithm that we call HeavyTester(c) so that*

- ***Testing heaviness:*** *It makes $O(\epsilon^{-8} \cdot \log^6(n))$ RangeCount queries to determine if the cell c is heavy or light.*
- ***Approximating a solution:*** *If c is a light cell in set Λ, then HeavyTester(c) returns a set F_c of facilities that $(1+\epsilon)$-approximates the optimal facility location cost of c.*

3.2 $O(\sqrt{n})$-approximate sublinear algorithm

Now, we explain an algorithm that distinguishes between the case that the facility location cost of P is at most $\sqrt{n} \cdot f$ or it is greater than $\sqrt{n} \cdot f$. For the former case, we return $(1+\epsilon)$-approximate solution and for the latter, we obtain a lower bound $\sqrt{n} \cdot f$ for the cost.

Algorithm 2 $\sqrt{n}$-Estimator.

```
Data: The discrete space $[2n]^2$, an opening cost $f > 0$, and an error parameter
      $0 < \epsilon \le 1$.
Result: A $\sqrt{n}$-estimator $\mathcal{Z}$ for the facility location cost of a point set $P \subseteq [2n]^2$.
Let $c$ be the square $[2n]^2$ and let $\Gamma$ be an empty set. Let $\mathcal{H} = \{c\}$;
At any time, let $\text{cost}^{\epsilon}_{FL}(\Gamma, f) = \sum_{c' \in \Gamma} \text{cost}^{\epsilon}_{FL}(c, F_c, f)$, where $F_c$ is the set of
  facilities that the randomized algorithm [15] $\text{Alg}^{\epsilon}_{FL}$ returns for each cell $c \in \Gamma$;
while $cost^{\epsilon}_{FL}(\Gamma, f) \le \sqrt{n} \cdot f$ and $\mathcal{H} \ne \emptyset$ do
    Take an arbitrary cell $c \in \mathcal{H}$ and delete it from $\mathcal{H}$;
    if HeavyTester$(c)$ returns that $c$ is a heavy cell then
        Let $C_c = \{c_1, c_2, c_3, c_4\}$ be the four children of $c$ in the grid $\mathcal{G}_{i-1}$;
        Let $\mathcal{H} = \mathcal{H} \cup C_c$;
    else
        Add $c$ to the set $\Gamma$;
Return $\Gamma$;
```

Lemma 6 is similar to Lemma 22 and we explain Lemma 22 in detail later.

▶ **Lemma 6.** *Let $P \subseteq [\Delta]^2$ be a point set of size n. Let $f > 0$ be the opening cost and $0 < \epsilon \leq 1$ be the error parameter. Then, the sublinear algorithm $\sqrt{n}$-*Estimator *uses $O(\epsilon^{-9} \log^7(n) \cdot \sqrt{n}))$* RangeCount *queries and distinguishes between the following cases:*

- *If the optimal facility location cost of P is $O(\sqrt{n} \cdot f)$, then this sublinear algorithm returns a set of facilities that $(1+\epsilon)$-approximates the optimal facility location cost of P.*
- *If the optimal facility location cost of P is $\Omega(\sqrt{n} \cdot f)$, then this sublinear algorithm $O(\sqrt{n})$-approximates the optimal facility location cost $OPT(P, f)$ of P. Moreover, it finds an $\Omega(\sqrt{n} \cdot f)$ lower-bound for the optimal facility location cost $OPT_{FL}(P, f)$ of P.*

3.3 Telescoping sampling

In this section we develop a sampling mechanism that samples a cell c with probability $p_c = \frac{n_c}{n}$. This will be used as a basic primitive that we later use for our $(1+\epsilon)$-estimator.

Algorithm 3 TelescopingSampling.

```
   Data: A grid $\mathcal{G}_i$
   Result: A sampled cell $c' \in \mathcal{G}_i$ such that the probability that any cell $c'' \in \mathcal{G}_i$ is $c'$ is
           $\mathbf{Pr}[c' = c''] = \frac{n_{c''}}{n}$.
1  Let $c$ be the cell in the grid $\mathcal{G}_{\log(n)}$ and let $j = \log(n)$ ;
2  while $j > i$ do
3      Split $c$ into its four sub-cells $c_1, c_2, c_3, c_4$ that are in the grid $\mathcal{G}_{j-1}$ and query the
         number of points inside each of them using the subroutine RangeCount;
4      Sample the sub-cell $c_i$ for $i \in [4]$ with probability $\frac{n_{c_i}}{n_c}$;
5      Let $c'$ be the cell that is sampled in Step 4;        // $c'$ is one of $c_1, c_2, c_3, c_4$.
6      Let $c = c'$ and $j = j - 1$;
7  Return $c$;
```

The proofs of the following lemmas are given in Appendix B.

▶ **Lemma 7.** *Assume that we invoke Subroutine* TelescopingSampling*($\mathcal{G}_i$). Then, a cell c that is returned by this subroutine is sampled with the probability that $\mathbf{Pr}[c] = \frac{n_c}{n}$.*

▶ **Lemma 8.** *Given a grid $\mathcal{G}_i$, the number of* RangeCount *queries that we make in Subroutine* TelescopingSampling*($\mathcal{G}_i$) is $O(\log n)$.*

3.4 $(1+\epsilon)$-approximate sublinear algorithm

In this section, we prove Theorem 2. We first give the pseudocode of our main sublinear algorithm. Next, we prove the correctness of our algorithm and analyze its query complexity.

3.5 Analysis

Let P be a point set of n points in discrete space $[2n]^2$. Now, for the sake of the analysis, assume that we run the following two processes.

- In the first process, for point set P, we run the quadtree construction (for the facility location problem) that we presented in Lemma 4 and it returns a set Λ of light cells.
- In the second process, given RangeCount query access to point set P, we invoke Algorithm 4 $(1+\epsilon)$-Estimator and it returns the estimator $\mathcal{Z} = \mathcal{A} + \mathcal{B}$.

Algorithm 4 $(1+\epsilon)$-Estimator.

```
Data: The discrete space $[2n]^2$, an opening cost $f > 0$, and an error parameter $0 < \epsilon$.
Result: A $(1+\epsilon)$-estimator $\mathcal{Z}$ for the facility location cost of a point set $P \subseteq [2n]^2$.
Let $\mathcal{Z} = 0$, $\mathcal{A} = 0$, and $\mathcal{B} = 0$ ;
for $i = \log(n) + 1$ down to $\frac{3}{4} \cdot \log(n)$ do
    for each cell $c \in \mathcal{G}_i$ do
        if HeavyTester$(c)$ returns that $c$ is a heavy cell then
            Let $C_c = \{c_1, c_2, c_3, c_4\}$ be the four children of $c$ in the grid $\mathcal{G}_{i-1}$;
            Invoke HeavyTester for the sub-cells $C_c$ to find out which ones are heavy;
            for each light sub-cell $c' \in C_c$ if there exists any light cell do
                Let $\mathrm{cost}^{\epsilon}_{FL}(c', F_{c'}, f)$ be the cost that the algorithm Alg$^{\epsilon}_{FL}(c')$ returns for $c$. Let $\mathcal{A} = \mathcal{A} + \mathrm{cost}^{\epsilon}_{FL}(c, F_{c'}, f)$;
for $i = \frac{3}{4} \cdot \log(n)$ down to 1 do
    Let $\mathcal{W}_{i-1} = 0$;
    Let $\mathcal{X}_{i-1}$ and $\mathcal{Y}_{i-1}$ be two vectors of length $\log_{1+\epsilon}(n)$ initialized to zero;
    for $\ell = 1$ to $z = 2^{14}\delta^2_{FL} \log^5(n)\epsilon^{-6} \cdot \sqrt{n}$ do
        Let $c$ be a cell sampled using Subroutine TelescopingSampling$(\mathcal{G}_i)$;
        if HeavyTester$(c)$ returns that $c$ is a heavy cell then
            Let $C_c = \{c_1, c_2, c_3, c_4\}$ be the four children of $c$ in the grid $\mathcal{G}_{i-1}$;
            Invoke HeavyTester for the sub-cells $C_c$ to find out which ones are heavy;
            if at least one of the sub-cells $C_c$ is a significant light cell then
                Let $j$ be the power of $(1+\epsilon)$ where $(1+\epsilon)^j \le n_c < (1+\epsilon)^{j+1}$;
                Let $C'_c$ be the sub-cells in $C_c$ that are significant light cells;
                Let $\mathcal{Y}_{i-1}[j] = \mathcal{Y}_{i-1}[j] + |C'_c|$;
                for each significant light sub-cell $c' \in C'_c$ do
                    Let $\mathrm{cost}^{\epsilon}_{FL}(c', , F_{c'}, f)$ be the cost that Algorithm Alg$^{\epsilon}_{FL}(c')$ returns for $c'$. Let $\mathcal{X}_{i-1}[j] = \mathcal{X}_{i-1}[j] + \mathrm{cost}^{\epsilon}_{FL}(c', F_{c'}, f)$;
    for $j = 1$ to $\log_{1+\epsilon}(n)$ do
        Let $w^j_i = \frac{n}{z(1+\epsilon)^j} \cdot \mathcal{Y}_{i-1}[j]$. Let $\mathcal{W}_{i-1} = \mathcal{W}_{i-1} + w^j_i \cdot \mathcal{X}_{i-1}[j]$;
    Let $\mathcal{B} = \mathcal{B} + \mathcal{W}_{i-1}$;
Return $\mathcal{Z} = \mathcal{A} + \mathcal{B}$;
```

Recall that for the quadtree construction in Lemma 4, we randomly shift the border lines of cells of the quadtree using a random vector v. In the sublinear geometric model, we randomly shift the border lines of axis-aligned rectangles (using v) that we use in RangeCount queries. Lemma 4 shows that $(1-\epsilon) \cdot OPT_{FL}(P, f) \le \sum_{c \in \Lambda} \mathrm{cost}^{\epsilon}_{FL}(c, F_c, f) \le (1+\epsilon) \cdot OPT_{FL}(P, f)$.

We further split the set Λ into two subsets $\Lambda_{\mathcal{A}}$ and $\Lambda_{\mathcal{B}}$. In particular, let $\Lambda_{\mathcal{A}}$ be the subset of light cells in Λ that are in the grids $\mathcal{G}_{\frac{3}{4} \cdot \log(n)}, \cdots, \mathcal{G}_{\log(n)+1}$. Let $\Lambda_{\mathcal{B}} = \Lambda \backslash \Lambda_{\mathcal{A}}$ be the subset of light cells in Λ that are in $\mathcal{G}_1, \cdots, \mathcal{G}_{\frac{3}{4} \cdot \log(n)-1}$. Our goal in this section is to show that with a probability greater than $1 - 1/n^5$, the following three claims are correct:

- The number of queries that Algorithm 4 $(1+\epsilon)$-Estimator makes is $\tilde{O}(\sqrt{n})$.
- The term $\mathcal{A}$ is the cost of light cells of the set $\Lambda_{\mathcal{A}}$. That is, $\mathcal{A} = \sum_{c \in \Lambda_{\mathcal{A}}} \mathrm{cost}^{\epsilon}_{FL}(c, F_c, f)$.

- The term $\mathcal{B}$ is an $(1+\epsilon)$-estimator for the cost of light cells of the set $\Lambda_{\mathcal{B}}$. That is, $(1-\epsilon)\cdot\sum_{c\in\Lambda_{\mathcal{B}}}\text{cost}^{\epsilon}_{FL}(c,F_c,f)\leq\mathcal{B}\leq(1+\epsilon)\cdot\sum_{c\in\Lambda_{\mathcal{B}}}\text{cost}^{\epsilon}_{FL}(c,F_c,f)$.

Once we prove these three claims, we have shown that $\mathcal{Z}$ is an $(1+\epsilon)$-estimator of the optimal facility location cost $OPT_{FL}(P,f)$ what proves Theorem 2.

3.5.1 The estimator term $\mathcal{A}$

The following two lemmas (whose proofs are given in Appendix C) show that (1) the number of RangeCount queries that we make to compute estimator $\mathcal{A}$ is $\tilde{O}(\sqrt{n})$, and (2) the term $\mathcal{A}$ approximates the facility location cost of light cells of set $\Lambda_{\mathcal{A}}$.

▶ **Lemma 9.** *Let $\Lambda_{\mathcal{A}}$ be the subset of light cells in Λ that are in the grids $\mathcal{G}_{\geq\frac{3}{4}\cdot\log(n)}$. Then,*

- *All light cells of $\Lambda_{\mathcal{A}}$ are detected by Algorithm 4 $(1+\epsilon)$-Estimator.*
- *To compute estimator $\mathcal{A}$, we make $O(\epsilon^{-8}\cdot\log^{6}(n)\cdot\sqrt{n})$ RangeCount queries.*

▶ **Lemma 10.** $\mathcal{A}=\sum_{c\in\Lambda_{\mathcal{A}}}cost^{\epsilon}_{FL}(c,F_c,f)$.

3.5.2 The estimator term $\mathcal{B}$

In this section, we prove that estimator $\mathcal{B}$ approximates the cost of light cells of $\Lambda_{\mathcal{B}}$ within $(1+\epsilon)$-factor. Let $c\in\Lambda$ be an arbitrary light cell in the set Λ. Suppose that c is in a grid $\mathcal{G}_i$. Then, the parent of c that we denote it by *parent*(c) is a heavy cell in grid $\mathcal{G}_{i+1}$.

▶ **Definition 11** (Significant Light Cells). *Let $\tau=\frac{\epsilon}{9\log(n)}$. We say a light cell $c\in\Lambda$ is a significant light cell if $cost^{\epsilon}_{FL}(c,F_c,f)\geq\tau f$; otherwise, we say c' is an insignificant light cell. We let $\Psi=\{c\in\Lambda:cost^{\epsilon}_{FL}(c,F_c,f)\geq\tau f\}$ be the set of light cells in Λ that are significant.*

We denote by $\Psi_i=\{c\in\Psi:c\in\mathcal{G}_i\}$ the set of significant light cells in the grid $\mathcal{G}_i$.

▶ **Definition 12** (Heavy Parents of Significant Light Cells). *We denote the set of heavy parents of significant light cells Ψ_i by $\Gamma(\Psi_i)=\{c'\in\mathcal{G}_{i+1}:\exists c\in\Psi_i$ such that c' is parent$(c)\}$.*

Note that up to 4 cells in Ψ_i can have the same heavy parent.

▶ **Definition 13** (Likelihood Classes). *We partition Ψ_i into $\epsilon^{-1}\log(n)$ likelihood classes Ψ_i^j where a cell $c\in\Psi_i^j$ if the number of points in its parent(c) is in the range $(1+\epsilon)^j\leq n_{parent(c)}<(1+\epsilon)^{j+1}$.*

We denote the set of heavy parents of significant light cells that are in the class Ψ_i^j by $\Gamma(\Psi_i^j)=\{c'\in\mathcal{G}_{i+1}:\exists c\in\Psi_i^j$ such that $c'=$ *parent*$(c)\}$.

▶ **Definition 14** (Contributing Likelihood Classes). *Let $\beta=\frac{\epsilon^2}{2\delta_{FL}\cdot\log^2(n)}$. We say a class Ψ_i^j is a contributing likelihood class if $|\Psi_i^j|\geq\beta\sqrt{n}$; otherwise, it is a non-contributing class.*

Roadmap of the proof of Theorem 2. We first prove (in Lemma 22) that the cost of significant light cells of $\Psi=\{c\in\Lambda:\text{cost}^{\epsilon}_{FL}(c,F_c,f)\geq\tau f\}$ is an $(1+\epsilon)$-approximation of $OPT_{FL}(P,f)$. Therefore, when we develop a $(1+\epsilon)$-estimator for the facility location problem, we can ignore insignificant light cells of Λ.

On the other hand, all significant light cells of Ψ are partitioned into likelihood classes Ψ_i^j. Now imagine we have the lower bound $OPT_{FL}(P,f)\geq\sqrt{n}\cdot f$ for $OPT_{FL}(P,f)$. Otherwise, the estimator $\sqrt{n}$-Estimator of Lemma 6 makes $O(\epsilon^{-9}\log^{7}(n)\cdot\sqrt{n}))$ RangeCount queries and returns a set of facilities that $(1+\epsilon)$-approximates the optimal facility location cost of P. Lemma 27 shows that we can safely ignore the contribution of the non-contributing likelihood classes Ψ_i^j. Let us fix a contributing likelihood classes Ψ_i^j.

- In Lemma 15 we show that with probability at least $1 - 2/n^5$, the estimator w_i^j in Algorithm 4 $(1+\epsilon)$-ESTIMATOR is a $(1+\epsilon)$-approximation of the size of Ψ_i^j.
- Lemma 16 shows that if we sample any arbitrary cell $c \in \Psi_i^j$ with probability $\mathbf{Pr}[c] = \frac{n_{parent(c)}}{n}$, the cell c is sampled almost uniformly at random from the set Ψ_i^j.
- Lemma 17 proves that with probability at least $1 - 1/n^{20}$, Algorithm 4 $(1+\epsilon)$-ESTIMATOR samples at least $\mathrm{poly}(\epsilon^{-1} \cdot \log(n))$ significant light cells from Ψ_i^j.

In Lemma 18, we use these three tools to show that if a likelihood class Ψ_i^j is contributing, we can approximate the facility location cost $\mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f)$ to within $(1+\epsilon)$-factor. Putting everything together, the estimator $\mathcal{Z}$ that is computed in Algorithm 4 $(1+\epsilon)$-ESTIMATOR is an $(1+\epsilon)$-approximation of $OPT_{FL}(P, f)$ what proves Theorem 2.

The statements of Lemmas 22 and 27, and their proofs are given in Appendix D.

Approximating the number of cells of a contributing class. In this section, we show that with high probability, the estimator w_i^j in Algorithm 4 $(1+\epsilon)$-ESTIMATOR is a $(1+\epsilon)$-approximation of the size of the contributing likelihood class Ψ_i^j.

▶ **Lemma 15.** *Let Ψ_i^j be a contributing class. Then, with probability at least $1 - 2/n^5$, the estimator w_i^j in Algorithm 4 $(1+\epsilon)$-*ESTIMATOR *is a $(1+\epsilon)$-approximation of $|\Psi_i^j|$. That is,* $\mathbf{Pr}\left[(1-\epsilon) \cdot |\Psi_i^j| \le w_i^j \le (1+\epsilon) \cdot |\Psi_i^j|\right] \ge 1 - 1/n^5$.

Proof. We define z runs $\mathcal{R}_1, \cdots, \mathcal{R}_z$ where during a run $\mathcal{R}_\ell$ we sample a cell $c \in \mathcal{G}_{i+1}$. We define a random variable Y_ℓ corresponding to the number of significant light sub-cells of a heavy cell $c \in \Gamma(\Psi_i^j)$ that is sampled in the run $\mathcal{R}_\ell$. Note that a heavy cell can have $0, 1, 2, 3, 4$ significant light sub-cells. If a heavy cell c from the set $\Gamma(\Psi_i^j)$ is sampled using Subroutine TELESCOPINGSAMPLING$(\mathcal{G}_{i+1})$, the random variable Y_ℓ will be the number of significant light sub-cells of c; otherwise Y_ℓ is zero. Then, we have $\mathbf{E}[Y_\ell] = \sum_{c \in \Gamma(\Psi_i^j)} \mathbf{Pr}[c] \cdot |C'_c|$, where C'_c is the set of significant light sub-cells of a heavy cell $c \in \Gamma(\Psi_i^j)$.

Recall that the likelihood class Ψ_i^j contains those cells $c \in \Psi_i$ for which $(1+\epsilon)^j \le n_{parent(c)} < (1+\epsilon)^{j+1}$. Then, $\frac{(1+\epsilon)^j}{n} \cdot \sum_{c \in \Gamma(\Psi_i^j)} |C_c| \le \mathbf{E}[Y_\ell] \le \frac{(1+\epsilon)^{j+1}}{n} \cdot \sum_{c \in \Gamma(\Psi_i^j)} |C_c|$.

Next, we define the random variable $Y = \frac{n}{z(1+\epsilon)^j} \cdot \sum_{\ell=1}^{z} Y_\ell$ for which we have $|\Psi_i^j| = \sum_{c \in \Gamma(\Psi_i^j)} |C_c| \le \mathbf{E}[Y] \le (1+\epsilon) \cdot \sum_{c \in \Gamma(\Psi_i^j)} |C_c| = (1+\epsilon) \cdot |\Psi_i^j|$.

Since the likelihood class Ψ_i^j is contributing, Lemma 28 tells us that for $\alpha = \frac{\epsilon^3}{18\delta_{FL} \log^3(n)}$ we have $\mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f) = \sum_{c \in \Psi_i^j} \mathrm{cost}_{FL}^{\epsilon}(c, F_c, f) \ge \alpha\sqrt{n} \cdot f$. All cells in the likelihood class Ψ_i^j are light which means that $\mathrm{cost}_{FL}^{\epsilon}(c, F_c, f) \le \delta_{FL} \cdot f$. This essentially means that $|\Psi_i^j| \ge \frac{\alpha\sqrt{n} \cdot f}{\delta_{FL} \cdot f} = \frac{\alpha}{\delta_{FL}} \cdot \sqrt{n}$. We can assume that $n \ge 2^{12}\epsilon^{-4}\log^2(n)(\frac{\delta_{FL}}{\alpha})^2$, otherwise the facility location instance of the point set P has at most $\mathrm{poly}(\epsilon^{-1}\log(n))$ points, that can be $(1+\epsilon)$-approximately solved using $\mathrm{poly}(\epsilon^{-1}\log(n))$ RANGECOUNT queries. Therefore, $\mathbf{E}[Y] \ge \frac{\alpha}{\delta_{FL}} \cdot \sqrt{n} \ge 60\epsilon^{-2}\log(n)$. Now, we use the Hoeffding bound [22] where we set $M = 4$ to obtain we have $\mathbf{Pr}\left[|w_i^j - |\Psi_i^j|| \ge \epsilon \cdot |\Psi_i^j|\right] = \mathbf{Pr}\left[|\mathbf{E}[Y] - Y|| \ge \epsilon \cdot \mathbf{E}[Y]\right] \le 2\exp(-(\frac{\epsilon^2 \cdot \mathbf{E}[Y]}{12})) \le 2/n^5$.

Thus, with probability at least $1 - 2/n^5$, the estimator w_i^j is within $(1+\epsilon)$-approximation of $|\Psi_i^j|$. This proves the lemma. ◀

Almost uniformly sampling from a contributing class. Let Ψ_i^j be a contributing likelihood class. Here we show that if we sample any arbitrary cell $c \in \Psi_i^j$ with probability $\mathbf{Pr}[c] = \frac{n_{parent(c)}}{n}$, the cell c is sampled almost uniformly at random. We later show that with high probability, Algorithm 4 $(1+\epsilon)$-ESTIMATOR samples significant light cells from each contributing likelihood class Ψ_i^j.

▶ **Lemma 16.** *Suppose we sample a cell $c \in \Psi_i^j$ with probability $\mathbf{Pr}[c] = \frac{n_{parent(c)}}{n}$. Then, the cells in Ψ_i^j are sampled almost uniformly at random. That is, the probability that we sample a cell $c \in \Psi_i^j$ is $(1-\epsilon) \cdot \frac{1}{|\Psi_i^j|} \le \mathbf{Pr}[c] \le (1+\epsilon) \cdot \frac{1}{|\Psi_i^j|}$.*

Proof. Recall that for every light cell $c \in \Psi_i^j$, we have $(1+\epsilon)^j \le n_{parent(c)} < (1+\epsilon)^{j+1}$. Thus $\frac{(1+\epsilon)^j}{n} \le \mathbf{Pr}[c] = \frac{n_{parent(c)}}{n} \le \frac{(1+\epsilon)^{j+1}}{n}$. We conclude that the probability of sampling light cells Ψ_i^j is within $(1+\epsilon)$ of $\frac{(1+\epsilon)^j}{n}$. ◀

▶ **Lemma 17.** *Let Ψ_i^j be a contributing class. Then, with probability at least $1 - 1/n^{20}$, a set of at least $x = 2^9 \delta_{FL} \epsilon^{-3} \log^2(n)$ heavy cells are sampled from the set $\Gamma(\Psi_i^j)$.*

Proof. Recall that $z = 2^{14} \delta_{FL}^2 \log^5(n) \epsilon^{-6} \cdot \sqrt{n}$. We define z runs $\mathcal{R}_1, \cdots, \mathcal{R}_z$ where during a run $\mathcal{R}_\ell$ we sample a cell $c \in \mathcal{G}_{i+1}$. Next we study the probability of sampling a heavy cell $c \in \Gamma(\Psi_i^j)$. We define an indicator random variable Y_ℓ corresponding to the run $\mathcal{R}_\ell$ which is one if a heavy cell $c \in \Gamma(\Psi_i^j)$ is sampled using Subroutine TelescopingSampling($\mathcal{G}_{i+1}$) in Line 14 (of Algorithm 4 $(1+\epsilon)$-Estimator) and zero otherwise. Then, we have $\mathbf{E}[Y_\ell] = \mathbf{Pr}[Y_\ell = 1] = \frac{1}{n} \cdot \sum_{c \in \Gamma(\Psi_i^j)} n_c$.

Based on Lemma 29, the number of points in the contributing likelihood class Ψ_i^j must be at least $n(\Psi_i^j) = \sum_{c \in \Psi_i^j} n_c \ge \frac{\alpha\sqrt{n}}{(1+\epsilon)}$, for $\alpha = \frac{\epsilon^3}{18\delta_{FL}\log^3(n)}$. Therefore, $\mathbf{E}[Y_\ell] = \frac{1}{n} \cdot \sum_{c \in \Gamma(\Psi_i^j)} n_c \ge \frac{\frac{\alpha\sqrt{n}}{(1+\epsilon)}}{n} \ge \frac{\alpha}{(1+\epsilon)} \cdot \frac{1}{\sqrt{n}}$. Next, we define the random variable $Y = \sum_{\ell=1}^{z} Y_\ell$ whose expectation is $\mathbf{E}[Y] = \sum_{\ell=1}^{z} \frac{1}{n} \cdot \sum_{c \in \Gamma(\Psi_i^j)} n_c \ge 2^{10} \delta_{FL} \epsilon^{-3} \log^2(n)$.

Using the Chernoff bound [13] and since $\delta_{FL} = 2^{20} \cdot (\frac{\log n}{\epsilon})^2$, we obtain

$$\mathbf{Pr}\left[\left|\mathbf{E}[Y] - Y\right| \ge \epsilon \cdot \mathbf{E}[Y]\right] \le 2\exp(-(\frac{\epsilon^2 \cdot 2^{10}\delta_{FL}\epsilon^{-3}\log^2(n)}{3})) \le 1/n^{20} .$$

Thus, with probability at least $1 - 1/n^{20}$, we sample at least $(1-\epsilon) \cdot 2^{10} \delta_{FL} \epsilon^{-3} \log^2(n) \ge 2^9 \delta_{FL} \epsilon^{-3} \log^2(n)$ heavy cells from the set $\Gamma(\Psi_i^j)$. Note that up to 4 cells in Λ_i^j can have the same heavy parent and they are sampled together. This proves this lemma. ◀

An unbiased estimator for contributing classes. Next, we prove that having an estimation of the size of a contributing likelihood class Ψ_i^j and assuming that we can sample cells in Ψ_i^j almost uniformly at random, we can then $(1+\epsilon)$-approximate the facility location cost of the contributing likelihood class Ψ_i^j.

▶ **Lemma 18** (Estimator for Contributing Classes). *Let Ψ_i^j be a contributing class. Suppose we can sample a cell from Ψ_i^j almost uniformly at random. That is, the probability that we sample a cell $c \in \Psi_i^j$ is $(1-\epsilon) \cdot \frac{1}{|\Psi_i^j|} \le \mathbf{Pr}[c] \le (1+\epsilon) \cdot \frac{1}{|\Psi_i^j|}$. Let S be a sampled set of $x \ge 2^9 \delta_{FL} \epsilon^{-3} \log^2(n)$ light cells $S = \{c_1, \cdots, c_x\} \subseteq \Psi_i^j$ that are sampled almost uniformly at random. Let y be an arbitrary number in the range $[\frac{|\Psi_i^j|}{(1-\epsilon)}, \frac{|\Psi_i^j|}{(1+\epsilon)}]$. Then, with probability at least $1 - 1/n^5$, we have $(1-\epsilon) \cdot \sum_{c \in \Psi_i^j} cost_{FL}^{\epsilon}(c, F_c, f) \le \frac{y}{x} \cdot \sum_{\ell=1}^{x} cost_{FL}^{\epsilon}(c_\ell, F_{c_\ell}, f) \le (1+\epsilon) \cdot \sum_{c' \in \Psi_i^j} cost_{FL}^{\epsilon}(c, F_c, f)$.*

Proof. We define x random variables $X_1, \cdots, X_x$ where X_ℓ corresponds to the cost of the light cell c_ℓ sampled from Ψ_i^j. Then, since $\mathbf{E}[X_\ell] = \sum_{c \in \Psi_i^j} \mathbf{Pr}[c] \cdot \mathrm{cost}_{FL}^{\epsilon}(c, F_c, f)$, we have $(1-\epsilon) \cdot \frac{1}{|\Psi_i^j|} \cdot \mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f) \le \mathbf{E}[X_\ell] \le (1+\epsilon) \cdot \frac{1}{|\Psi_i^j|} \cdot \mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f)$, where $\mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f) = \sum_{c \in \Psi_i^j} \mathrm{cost}_{FL}^{\epsilon}(c, F_c, f)$. By the linearity of expectation for the random variable $X = \sum_{\ell=1}^{x} X_\ell$, we obtain $(1-\epsilon)^2 \cdot \mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f) \le \frac{y}{x} \cdot \mathbf{E}[X] \le (1+\epsilon)^2 \cdot \mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f)$.

Recall that the minimum and the maximum facility location cost of a significant light cell $c \in \Psi_i^j$ are $\tau \cdot f$ and $\delta_{FL} \cdot f$, respectively, where $\tau = \frac{\epsilon}{9\log(n)}$ and $\delta_{FL} = 2^{20} \cdot (\frac{\log n}{\epsilon})^2$. Thus, $X_\ell \leq \delta_{FL} \cdot f$. Also, $\mathbf{E}[X_\ell] \geq (1-\epsilon) \cdot \frac{1}{|\Psi_i^j|} \cdot \mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f) \geq (1-\epsilon) \cdot \frac{1}{|\Psi_i^j|} \cdot \tau \cdot f |\Psi_i^j| = (1-\epsilon)\tau f$.

Therefore, $\mathbf{E}[X] \geq x(1-\epsilon)\tau f \geq 2^5 \delta_{FL}\epsilon^{-2}\log(n) \cdot f$. We use the Hoeffding bound [22] where we set $M = \delta_{FL} \cdot f$ and since $f > 0$ to obtain

$$\mathbf{Pr}\left[(1-\epsilon)^3 \cdot \mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f) \leq \frac{y}{x} \cdot \mathbf{E}[X] \leq (1+\epsilon)^3 \cdot \mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f)\right]$$
$$= \mathbf{Pr}\left[|X - \mathbf{E}[X]| \geq \epsilon \cdot \mathbf{E}[X]\right] \leq 2 \cdot \exp(-\frac{\mathbf{E}[X] \cdot \epsilon^2}{3 \cdot M}) \leq 2 \cdot \exp(-\frac{2^5 \delta_{FL}\epsilon^{-2}\log(n) \cdot f\epsilon^2}{3\delta_{FL} \cdot f}) \leq \frac{2}{n^5} \ .$$

We replace ϵ by $\epsilon/3$ to finish the proof of this lemma. ◀

Finishing Proof of Theorem 2. Now we are ready to finish the proof of Theorem 2. Lemma 18 shows that if a likelihood class Ψ_i^j is contributing, we can approximate the facility location cost $\mathrm{cost}_{FL}^{\epsilon}(\Psi_i^j, f)$ to within $(1+\epsilon)$-factor if (1) we can sample x significant light cells of Ψ_i^j almost uniformly at random, and (2) we can $(1+\epsilon)$-approximate the size $|\Psi_i^j|$.

Lemma 16 shows that if we sample any arbitrary cell $c \in \Psi_i^j$ with probability $\mathbf{Pr}[c] = \frac{n_{parent(c)}}{n}$, the cell c is sampled almost uniformly at random. Lemma 17 proves that with probability at least $1 - 1/n^{20}$, Algorithm 4 $(1+\epsilon)$-Estimator samples at least x significant light cells from each contributing likelihood class Ψ_i^j. Finally, Lemma 15, with probability at least $1 - 2/n^5$, the estimator w_i^j in Algorithm 4 $(1+\epsilon)$-Estimator is a $(1+\epsilon)$-approximation of the size of the contributing likelihood class Ψ_i^j.

Recall that in Lemma 22 we proved that the cost of significant light cells of $\Psi = \{c \in \Lambda : \mathrm{cost}_{FL}^{\epsilon}(c, F_c, f) \geq \tau f\}$ is an $(1+\epsilon)$-approximation of $OPT_{FL}(P, f)$. Therefore, we can ignore insignificant light cells of Λ. All significant light cells of Ψ are partitioned into likelihood classes Ψ_i^j. Using Lemma 27, we can safely ignore the contribution of the non-contributing likelihood classes Ψ_i^j. Putting everything together, the estimator $\mathcal{Z}$ that is computed in Algorithm 4 $(1+\epsilon)$-Estimator is an $(1+\epsilon)$-approximation of $OPT_{FL}(P, f)$.

As for the query complexity of Algorithm 4 $(1+\epsilon)$-Estimator. In Lemma 9, to compute the estimator $\mathcal{A}$ we use $O(\epsilon^{-8} \cdot \log^6(n) \cdot \sqrt{n})$ RangeCount queries. For the estimator $\mathcal{B}$, we sample $z = 2^{14}\delta_{FL}^2 \log^5(n)\epsilon^{-6} \cdot \sqrt{n}$ cells using Subroutine TelescopingSampling$(\mathcal{G}_i)$ for each grid $\mathcal{G}_{i \leq \frac{3}{4}\log(n)}$. Therefore, we invoke the tester HeavyTester for less than $5z\log(n)$ cells (z times for the sampled cells and $4z$ for their children) where each such a call makes $O(\epsilon^{-8} \cdot \log^6(n))$ RangeCount queries as is shown in Lemma 5. Therefore, in total, the query complexity of the $(1+\epsilon)$-estimator $\mathcal{Z}$ is $\tilde{O}(\sqrt{n})$. This finishes the proof of Theorem 2.

4 Hard instance for the sublinear geometric model

In this section, we prove Lemma 3. See Figure 2 for the illustration of the hard instance that we explain next.

Suppose the opening cost is $f = n^{3/4}$. In the grid $\mathcal{G}_{\frac{3}{4}\cdot\log(n)}$, we have $n^{1/2}$ cells each one having side length $n^{3/4}$. We choose a set $A \subset \mathcal{G}_{\frac{3}{4}\cdot\log(n)}$ of $n^{1/4}$ cells arbitrarily and assign $n^{3/4}$ points to each such a cell. Observe that the sparsity of the grid $\mathcal{G}_{\frac{3}{4}\cdot\log(n)}$ is $n^{1/4}$. That is in average from every $n^{1/4}$ cells in this grid, only one of them has $n^{3/4}$ points and the rest are empty. Note that every cell in A is heavy since it has at least $\frac{f}{n^{3/4}} = 1$ points.

At grids $\mathcal{G}_i$ and $\mathcal{G}_j$ for $i = \frac{\log(n)}{2}$ and $j = \frac{\log(n)}{4}$, a cell has side length $n^{1/2}$ and $n^{1/4}$. We sample a subset $B \subset A$ of $\log(n)$ cells uniformly at random. A cell $c \in B$ has a set $\mathcal{D}_c$ of $\sqrt{n}$ descendants in the grid $\mathcal{G}_{\frac{1}{2}\cdot\log(n)}$, each one having $n^{\frac{1}{4}}$ points equally distant (at distance

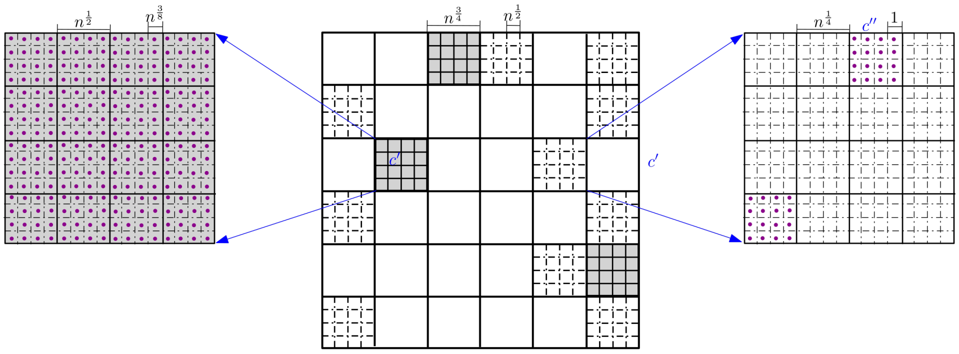

Figure 2 In this figure, cells of B are colored gray and cells in the set $A \backslash B$ are shown with a net of dash-dotted lines. The rest of cells that are shown as white cells are empty cells. The cell $c \in B$ has $\sqrt{n}$ descendants in the grid $\mathcal{G}_{\frac{1}{2}\cdot\log(n)}$ that are all heavy cells. The cell $c' \in A\backslash B$ has n descendants in the grid $\mathcal{G}_{\frac{1}{4}\cdot\log(n)}$ out of which $n^{1/4}$ of them are heavy and the rest are empty cells.

$n^{\frac{3}{8}}$) from its top, bottom, left and right points. Every cell in $\mathcal{D}_c$ has $n^{\frac{1}{4}} = \frac{f}{n^{1/2}}$ points, so it is a heavy cell in the grid $\mathcal{G}_{\frac{1}{2}\cdot\log(n)}$. In the optimal solution for the facility location problem, we must open at least one facility within distance $n^{1/2}$ of each heavy cell in the grid $\mathcal{G}_{\frac{1}{2}\cdot\log(n)}$. Thus, the optimal cost of the facility location problem for the cell set B is at least $\mathcal{L} = \log(n) \cdot \frac{n^{1/2}}{9} \cdot f$ where in the denominator we have 9 since the points inside at most 9 cells (i.e., a grid of 3×3) in the grid $\mathcal{G}_{\frac{1}{2}\cdot\log(n)}$ can be assigned to one open facility that we open in one of them, say the center one.

Each cell $c' \in A\backslash B$ has n descendants in the grid $\mathcal{G}_j$, but only $n^{1/4}$ of them that are chosen uniformly at random are heavy, i.e., has $\frac{f}{n^{1/4}} = n^{1/2}$ points and the rest are empty cells. Suppose that for each heavy descendant (in the grid $\mathcal{G}_j$) of each cell $c' \in A\backslash B$, we open at most one facility. The total cost of cells of the set $A\backslash B$ would be at most $\mathcal{U} \leq |A\backslash B| \cdot n^{1/4} \cdot \frac{f}{n^{1/4}} \cdot n^{1/4}\sqrt{2} \leq \sqrt{2}n^{1/2} \cdot f$

Now, observe that with respect to the grids $\mathcal{G}_{\geq \frac{3}{4}\cdot\log(n)}$, all the cells in the set A look exactly the same and they all have $n^{3/4}$ points each. Since $|B| = \log(n)$ and $|A| = n^{1/4}$, in expectation we need to sample $\frac{|A|}{|B|} = \frac{n^{1/4}}{\log(n)}$ cells so that we can have at least one cell from B in the sampled set; otherwise, we cannot estimate the number of cells and the cost of each cell in the set B and thus, we cannot approximate the cost of the facility location problem within a factor better than $\Omega(\frac{\mathcal{L}}{\mathcal{U}}) = \Omega(\log(n))$.

A Missing proof of Subsection 3.1

Proof of Lemma 5. Testing whether a cell c is a heavy or a light cell needs to find out if c has a facility location cost of at least $\delta_{FL} f$ or lower than this quantity. To this end, we first develop a deterministic sublinear algorithm for the k-median problem that using $O(k\epsilon^{-4}\log^2(n))$ RangeCount queries returns a $(1+\epsilon)$-approximate solution. We then show how we can use this sublinear algorithm to develop the tester algorithm HeavyTester.

What is interesting is the difference between the query complexity of the k-median and the facility location problems in the sublinear geometric model. For the k-median problem, we can report a $(1+\epsilon)$-approximate solution (not the cost) in the sublinear model using $O(k\epsilon^{-4}\log^2(n))$ RangeCount queries. However, for the facility location, Lemma 3 shows that we do not hope to $o(\log n)$-approximate the cost of the facility location problem in the sublinear geometric model using $\Omega(\frac{\sqrt[4]{n}}{\log n})$ RangeCount queries.

▶ **Definition 19** (k-median problem). *In the k-*median problem*, we are given a point set $P \subset [2n]^2$ of size n in a discrete space and a number $k \in \mathbb{N}$ of centers. The goal is to return a set $C^* \subset [2n]^2$ of k centers that minimizes the cost function $cost_{k\text{-}med}(P, C^*) = \sum_{p\in P} dist(p, C^*)$, where $dist(p, C^*) = \min_{c\in C^*} dist(p, c)$ is the Euclidean distance of p to its nearest center in C^*. We denote the optimal k-median cost of the point set P by $OPT_{k\text{-}med}(P, k)$.*

▶ **Lemma 20** (Sublinear algorithm for k-median). *Let P be a point set of size n in $[2n]^2$. Let $k > 0$ be the number of centers and $0 < \epsilon \leq 1$ be the error parameter. Then, there exists a deterministic sublinear algorithm that returns a $(1+\epsilon)$-approximate solution of the k-median problem for P in the sublinear geometric model using $O(k\epsilon^{-4}\log^2(n))$ RangeCount queries.*

Assume for a moment that this lemma is correct. We next explain the tester algorithm.

Algorithm HeavyTester(c). For every choice $k \in \{1, 2, \cdots, \delta_{FL} = 2^{20} \cdot (\frac{\log n}{\epsilon})^2\}$, we run the sublinear algorithm of Lemma 20 on the input set $P \cap c$ that reports a set C_k of k centers. We then compute the k-median cost of $P \cap c$ using the center set C_k and add the opening cost kf to the k-median cost to compute the facility location cost. Among all δ_{FL} runs, we find the one that has the lowest facility location cost. If the lowest facility location cost is less than δ_{FL}, we report that the cell c is a light cell, otherwise we report it as a heavy cell. This finishes the description of the algorithm HeavyTester(c).

Query complexity of HeavyTester(c). We invoke δ_{FL} parallel runs each choice $k \in [\delta_{FL}]$. Each such a run needs $O(k\epsilon^{-4}\log^2(n))$ RangeCount queries using Lemma 20. Thus, using $O(\delta_{FL}^2 \cdot \epsilon^{-4}\log^2(n)) = O(\epsilon^{-8} \cdot \log^6(n))$ RangeCount queries, we can detect if the cell c is a heavy cell or a light one. This finishes the proof of the first part of Lemma 5.

Now we prove the second part of this lemma. Imagine the case when c is a cell in the set Λ. Recall that $c \in \Lambda$ if c is a light cell and its *parent*(c) is a heavy cell. We run the tester HeavyTester for c and *parent*(c). This tester is a deterministic algorithm and so, it correctly reports c is a light cell and *parent*(c) is a heavy cell. Lemma 4 ensures that for the correct guess of the number of facilities in c, the set F_c of facilities that the tester HeavyTester(c) returns will satisfy the following what finishes the proof of Lemma 5. $\text{cost}^{\epsilon}_{FL}(c, F_c, f) = \sum_{p\in P\cap c} \text{dist}(p, F_c) + |F_c| \cdot f \leq (1+\epsilon) \cdot OPT_{FL}(P \cap c, f)$.

Proof of Lemma 20. We prove this lemma using a modification that we do to the quadtree construction that Frahling and Sohler [19] developed for the k-median problem. The quadtree construction in [19] is based on the notions of dense and sparse cells.

Dense and sparse cells: Let P be a point set of size n in $[2n]^2$. Let $0 < \epsilon \leq 1$ be an error parameter. Let $\delta_{k\text{-}med} = 2^{20} \cdot \frac{k\log(n)}{\epsilon^3}$. We say a cell $c \in \mathcal{G}_i$ of side length 2^i is *dense* if it contains $n_c \geq \delta_{k\text{-}med} \cdot \frac{OPT_{k\text{-}med}(P,k)}{2^i}$ points; otherwise it is a *sparse* cell.

Observe that for the definition of dense and sparse cells, we assume we know the optimal k-median cost $OPT_{k\text{-}med}(P,k)$. In general, we can $(1+\epsilon)$-approximate $OPT_{k\text{-}med}(P,k)$ using $\log_{(1+\epsilon)}(4n^2) = O(\epsilon^{-1}\log(n))$ guesses. To see this, observe that in the discrete space $[2n]^2$, the maximum pairwise distance between two points is at most $4n$ and the minimum distance is 1. The set P has n points, so the ratio between the maximum and the minimum k-median costs is at most $n \times 4n = 4n^2$. We then consider $t = \log_{(1+\epsilon)}(4n^2) = O(\epsilon^{-1}\log(n))$ parallel guesses $r_0, \cdots, r_t$ for the optimal k-median cost $OPT_{k\text{-}med}(P,k)$ where $r_j = (1+\epsilon)^j$. We must have an index $j \in [t]$ for which $(1+\epsilon)^j \leq OPT_{k\text{-}med}(P,k) < (1+\epsilon)^{j+1}$.

Sublinear algorithm for k-median based on quadtree construction of [19]. We run the following algorithm for all $O(\epsilon^{-1}\log(n))$ guesses of $OPT_{k\text{-}med}(P,k)$ in parallel. Let us consider the j^{th} guess $r_j = (1+\epsilon)^j$ for $OPT_{k\text{-}med}(P,k)$. We create a run j for the j^{th} guess for which we do the following.

Let $\mathcal{K}_j$ and $\mathcal{R}_j$ be two empty sets. Given the single square $c = [2n]^2$ in the grid $\mathcal{G}_{\log(n)+1}$, we build a tree similar to the quadtree as follows. In particular, suppose that we have a cell $c \in \mathcal{G}_i$. If c is sparse, we add c to $\mathcal{K}_j$ and stop; otherwise, (i.e., if c is dense), we split it into 4 equal sub-cells c_1, c_2, c_3, c_4 (they are in the grid G_{i-1}) of the same side length and recurse for those sub-cells that are dense. We add all **non-empty sparse cells** that are constructed in this way to $\mathcal{K}_j$. If during the run j, the size of $\mathcal{K}_j$ is more than $O(k\epsilon^{-3}\log(n))$, we immediately stop that run because that run corresponds to the guess $(1+\epsilon)^j$ that is much smaller than the optimal k-median cost $OPT_{k\text{-}med}(P,k)$. At the end of this recursive procedure, for each cell $c \in \mathcal{K}_j$, we consider the center of c as the representative point r_c of c and assign the weight $w(r_c) = n_c = |P \cap c|$ to r_c. Observe that for every cell $c \in \mathcal{K}_j$, we need one RangeCount query to find out $w(r_c) = n_c = |P \cap c|$. Let $\mathcal{R}_j$ be the set of weighted representative points that we compute in this way for the run j.

Next, we need to compute the k-median cost of the representative set $\mathcal{R}_j$. To this end, we use the deterministic $(1+\epsilon)$-approximation algorithm that Har-Peled and Mazumdar [21] develop for the k-median problem. The running time of this algorithm is

$O(n + 2^{O((1+1/\epsilon)}k^{O(1)}\log^{O(1)}(n))$. We denote this algorithm by $\textsc{Alg}^{\epsilon}_{k\text{-}med}$. For the weighted representative set $\mathcal{R}_j$, we then invoke the $\textsc{Alg}^{\epsilon}_{k\text{-}med}(\mathcal{R}_j)$ that returns a set C_j of k centers and its k-median cost $\Gamma_j = \mathrm{cost}_{k\text{-}med}(\mathcal{R}_j, C_j) = \sum_{r_c \in \mathcal{R}_j} w(r_c) \cdot \mathrm{dist}(p, C_j)$, where $\mathrm{dist}(p, C_j) = \min_{c \in C_j} \mathrm{dist}(p, c)$ is the distance of p to its nearest center in C_j.

Among all parallel guesses $r_0, \cdots, r_t$ where $[t = O(\epsilon^{-1}\log(n))]$, we choose the smallest guess $r_{j^*} = (1+\epsilon)^{j^*}$ for which we have $(1+\epsilon)^{j^*} \le \Gamma_{j^*} < (1+\epsilon)^{j^*+1}$. Let $\mathcal{K}_{j^*}$ and $\mathcal{R}_{j^*}$ be the set of non-empty sparse cells and the set of representative points that correspond to the guess $(1+\epsilon)^{j^*}$, respectively. We then have the following guarantee.

▶ **Lemma 21** ([19]). *Let $P \subseteq [2n]^2$ be a point set of size n and $k \in \mathbb{N}$ be a natural number. Let $0 < \epsilon \le 1$ be the error parameter. Then:*

- *The number of non-empty sparse cells in $\mathcal{K}_{j^*}$ (or, the number of representative points in $\mathcal{R}_{j^*}$) that are found using the above construction is $|\mathcal{K}_{j^*}| = |\mathcal{R}_{j^*}| = O(k\epsilon^{-3}\log(n))$.*
- *The output of Algorithm [21] $\textsc{Alg}^{\epsilon}_{k\text{-}med}$ on input set $\mathcal{R}_{j^*}$ is a set C_{j^*} of k centers such that $(1-\epsilon)OPT_{k\text{-}med}(P, k) \le \Gamma_{j^*} = cost_{k\text{-}med}(\mathcal{R}_{j^*}, C_{j^*}) \le (1+\epsilon)OPT_{k\text{-}med}(P, k)$.*

Query Complexity of sublinear algorithm for k-median. Let us consider a run j. Recall that if during the run j, the size of $\mathcal{K}_j$ is more than $O(k\epsilon^{-3}\log(n))$, we immediately stop this run. Observe that for every cell $c \in \mathcal{K}_j$, we need one $\textsc{RangeCount}$ query to find out its weight $w(r_c) = n_c = |P \cap c|$. Thus, the number of $\textsc{RangeCount}$ queries that we make to build the set $\mathcal{K}_j$ is $O(k\epsilon^{-3}\log(n))$. In addition, observe that the algorithm $\textsc{Alg}^{\epsilon}_{k\text{-}med}(\mathcal{R}_j)$ does not make any $\textsc{RangeCount}$ query. We have $t = O(\epsilon^{-1}\log(n))$ guesses for the optimal k-median cost $OPT_{k\text{-}med}(P, k)$. Thus, the number of $\textsc{RangeCount}$ queries that we make to develop our sublinear algorithm for the k-median problem is $O(k\epsilon^{-4}\log^2(n))$. This finishes the proof of Lemma 20. ◀

◀

B Missing proofs of Subsection 3.3

Proof of Lemma 7. Let us consider the ancestors $c_{i+1}, \cdots, c_j, \cdots, c_{\log(n)}$ where cell c_j for $i+1 \le j \le \log(n)$ is the ancestor of cell c in grid $\mathcal{G}_j$. Observe that the probability that we sample the cell c is $\mathbf{Pr}[c] = \mathbf{Pr}\left[c_{\log(n)-1} | c_{\log(n)}\right] \cdot \mathbf{Pr}\left[c_{\log(n)-2} | c_{\log(n)-1}\right] \cdots \mathbf{Pr}\left[c_{i+1} | c_{i+2}\right] \cdot \mathbf{Pr}\left[c | c_{i+1}\right] = \frac{n_{c_{\log(n)-1}}}{n} \cdot \frac{n_{c_{\log(n)-2}}}{n_{c_{\log(n)-1}}} \cdots \frac{n_{c_{i+1}}}{n_{c_{i+2}}} \cdot \frac{n_c}{n_{c_{i+1}}} = \frac{n_c}{n}$. ◀

C Missing proofs of Subsection 3.5.1

Proof of Lemma 9. Recall that the estimator $\mathcal{A}$ is for the contribution of those light cells in Λ that are in the grids $\mathcal{G}_{\frac{3}{4}\cdot\log(n) \le i \le \log(n)+1}$. Let S be the set of all cells in $\mathcal{G}_{\frac{3}{4}\cdot\log(n) \le i \le \log(n)+1}$. In total, all these grids have at most $|S| \le \frac{2n^2}{n^{6/4}} + \frac{1}{4} \cdot \frac{2n^2}{n^{6/4}} + \cdots + \frac{1}{4^i} \cdot \frac{2n^2}{n^{6/4}} + \cdots + 1 \le 4\sqrt{n}$ cells. For every heavy cell $c \in S$, its sub-cells c_1, c_2, c_3, c_4 are created and tested if they are heavy or light cell. Recall that we run the $\textsc{HeavyTester}$ algorithm for those sub-cells to determine which ones are heavy or light. Using Lemma 5, to detect if a cell c is heavy or light, the tester algorithm $\textsc{HeavyTester}(c)$ uses $O(\epsilon^{-8} \cdot \log^6(n))$ $\textsc{RangeCount}$ queries.

Let us consider an empty set T in the beginning. For each heavy cell $c \in S$, we add its light sub-cells to the set T. The first claim of this lemma is proven by observing that $|T| \le 4|S| = 16\sqrt{n}$. As for the second claim, we invoke the $\textsc{HeavyTester}$ algorithm for $|S| + |T| \le 20\sqrt{n}$ cells each one uses $O(\epsilon^{-8} \cdot \log^6(n))$ $\textsc{RangeCount}$ queries. ◀

Proof of Lemma 10. Based on Lemma 5, the tester algorithm HeavyTester is a deterministic algorithm that correctly detects if an arbitrary cell c is heavy or light. Thus, Algorithm 4 $(1+\epsilon)$-Estimator detects all light cells $\Lambda_{\mathcal{A}}$. For every light cell $c \in \Lambda_{\mathcal{A}}$, Lemma 5 shows that the Tester algorithm $(1+\epsilon)$-approximates the optimal cost $OPT^{\epsilon}_{FL}(P \cap c, f)$. Thus, the term $\mathcal{A}$ is a $(1+\epsilon)$-estimator for the cost of light cells of the set $\Lambda_{\mathcal{A}}$. ◀

D Missing proofs of Subsection 3.5.2

The following lemma shows that we can safely remove insignificant light cells from the set Λ and only consider significant light cells Ψ.

▶ **Lemma 22.** *Let $\tau = \frac{\epsilon}{9\log(n)}$. Let $\Psi = \{c \in \Lambda : cost^{\epsilon}_{FL}(c, F_c, f) \geq \tau f\}$ be the set of light cells in Λ that are significant. Then,*

$$OPT_{FL}(P, f) \leq cost^{\epsilon}_{FL}(\Psi, f) = \sum_{c \in \Psi} cost^{\epsilon}_{FL}(c, F_c, f) \leq (1+\epsilon) \cdot OPT_{FL}(P, f) \ .$$

Proof. In order to prove Lemma 22, we first define charging heavy cells. We prove that at most $3\log(n)$ insignificant light cells are created during the construction of any charging heavy cells. We can assign all these insignificant light cells to the charging heavy cell whose construction creates these cells. We show that the cost of a charging heavy c is at least $\Omega(\delta_{FL} \cdot f)$. On the other hand, overall the total facility location cost of the insignificant light cells that are assigned to c is at most $\epsilon \cdot f$ that can be charged to $\mathrm{cost}^{\epsilon}_{FL}(c, F_c, f)$.

▶ **Definition 23** (Charging heavy cell). *Let c be a heavy cell having children c_1, c_2, c_3, c_4. We say c is a charging heavy cell if all children c_1, c_2, c_3, c_4 are light.*

▶ **Lemma 24.** *Let c be a heavy cell. Then, either c is a charging heavy cell or at least one of its descendants is a charging heavy cell.*

Proof. For the sake of contradiction assume that c is not a charging heavy cell. As otherwise, we have nothing to prove. Let c' be a copy of c. Let c_1, c_2, c_3, c_4 be the four children of c'. Let $C^H_{c'}$ be the set of heavy children of c'. By our assumption, $|C^H_c| > 0$. Let us pick a heavy child of c' from C^H_c, say c_1 is heavy. We let $c' = c_1$. Recursively, either all children of c' are light or at least one of the children of c' is heavy for which we recurse. This recursion repeats for $O(\log n)$ times. At the end we either find a charging heavy cell or arrive at a cell $c \in \mathcal{G}_0$ that has side length one and can store only one point p_c. If that cell c is still heavy, we can open a facility at p_c of cost f which contradicts with the fact that the cost of c must be at least $\delta_{FL} \cdot f$. Thus, the recursion will end by outputting a charging heavy cell. ◀

Let us fix a charging heavy cell c at a grid $\mathcal{G}_i$. Let us consider the quadtree construction that we explained for the facility location problem in Section 2.1. Starting from the root of the quadtree that corresponds to the square $[2n]^2$ going down to the cell c, we see the ancestors of c. At any grid $\mathcal{G}_{j>i}$, the ancestor(c, j) of c creates 4 children. At most 3 of them are insignificant light cells and one is the ancestor$(c, j-1)$ of c at grid $\mathcal{G}_{j-1}$ which is a heavy cell. Suppose we assign all the insignificant light cells that ancestor(c, j) creates to c. If there are more than one heavy cell among the children of ancestor(c, j), we can arbitrarily assign the insignificant light children of ancestor(c, j) to either of them. Let $\mathcal{O}_c$ be the set of all insignificant light cells that are assigned to c. We have the following bound for $|\mathcal{O}_c|$.

▶ **Corollary 25.** *Let c be a charging heavy cell. Let $\mathcal{O}_c$ be the set of all insignificant light cells that are assigned to c. Then, $|\mathcal{O}_c| \leq 3\log(n)$.*

▶ **Corollary 26.** *Let c be a charging heavy cell. Let $\mathcal{O}_c$ be the set of all insignificant light cells that are assigned to c. Then, the total facility location cost of insignificant light cells $\mathcal{O}_c$ is $cost^{\epsilon}_{FL}(\mathcal{O}_c, f) = \sum_{c' \in \mathcal{O}_c} cost^{\epsilon}_{FL}(c', F_{c'}, f) \leq \frac{\epsilon}{3} \cdot f$.*

Now we finish the proof of Lemma 22. Recall that the charging heavy cell c has cost $\text{cost}^{\epsilon}_{FL}(c, F_c, f) \geq \delta_{FL} \cdot f$. On the other hand, the four children $C_c = \{c_1, c_2, c_3, c_4\}$ of c are light that are in the set Λ as we have seen in Lemma 4. This lemma shows that for each cell $c' \in C_c$ we must have $\text{cost}^{\epsilon}_{FL}(c', F_c, f) \leq (1+\epsilon) \cdot OPT_{FL}(P \cap c', f)$. However, $\sum_{c' \in C_c} \text{cost}^{\epsilon}_{FL}(c', F_c, f) \geq \frac{\delta_{FL} \cdot f}{4}$. Otherwise, we can upper bound $\text{cost}^{\epsilon}_{FL}(c, F_c, f)$ by $\sum_{c' \in C_c} \text{cost}^{\epsilon}_{FL}(c', F_c, f) \leq \frac{\delta_{FL} \cdot f}{4}$ which essentially means that c is light cell contradicting our assumption that c is a charging heavy cell. Thus, $\frac{\delta_{FL} \cdot f}{4(1+\epsilon)} \leq \frac{\sum_{c' \in C_c} \text{cost}^{\epsilon}_{FL}(c', F_c, f)}{(1+\epsilon)} \leq \min(\sum_{c' \in C_c} OPT_{FL}(P \cap c', f), OPT_{FL}(P \cap c', f))$. Using Corollary 26, for the set $\mathcal{O}_c$ of insignificant light cells that are assigned to c we have $\text{cost}^{\epsilon}_{FL}(\mathcal{O}_c, f) \leq \frac{\epsilon}{3} \cdot f$ which is less than ϵ-fraction of the optimal facility location cost $OPT_{FL}(c, f)$ of c. Therefore, the overall facility location cost of insignificant light cells in Λ is at most $\epsilon \cdot OPT_{FL}(P, f)$. Thus, for set $\Psi = \{c \in \Lambda : \text{cost}^{\epsilon}_{FL}(c, F_c, f) \geq \tau f\}$ of significant light cells we have $OPT_{FL}(P, f) \leq \text{cost}^{\epsilon}_{FL}(\Psi, f) = \sum_{c \in \Psi} \text{cost}^{\epsilon}_{FL}(c, F_c, f) \leq (1+\epsilon) \cdot OPT_{FL}(P, f)$. ◀

Next lemma shows that the cost of non-contributing classes Ψ^j_i is only $\frac{\epsilon}{2}$-fraction of the optimal facility location cost of point set P. Thus, when we develop a sublinear algorithm that $(1+\epsilon)$-approximates $OPT_{FL}(P, f)$, we can ignore the cost of non-contributing classes.

▶ **Lemma 27.** *Suppose we know that $OPT_{FL}(P, f) \geq \sqrt{n} \cdot f$. Let Ψ^j_i be a likelihood class that is non-contributing, i.e., $|\Psi^j_i| < \beta\sqrt{n}$, where $\beta = \frac{\epsilon^2}{2\delta_{FL} \cdot \log^2(n)}$. We can safely ignore the contribution of the class Ψ^j_i toward the optimal facility location cost of the point set P.*

Proof. Recall that the class Ψ^j_i consists of only light cells and that a cell c is light if $\text{cost}^{\epsilon}_{FL}(c, F_c, f) < \delta_{FL} \cdot f$. Recall that we test whether a cell is light or heavy using the tester algorithm HeavyTester of Lemma 5. Since $|\Psi^j_i| < \beta\sqrt{n}$, for $\beta = \frac{\epsilon^2}{2\delta_{FL} \cdot \log^2(n)}$, the overall cost of the class Ψ^j_i is upper-bounded by $\text{cost}^{\epsilon}_{FL}(\Psi^j_i, f) = \sum_{c \in \Psi^j_i} \text{cost}^{\epsilon}_{FL}(c, F_c, f) \leq \frac{\epsilon^2}{2\delta_{FL} \cdot \log^2(n)} \cdot \sqrt{n} \cdot \delta_{FL} \cdot f \leq \frac{\epsilon^2}{2\log^2 n} \cdot OPT_{FL}(P, f)$.

Note that based on Definition 13, we can have at most $\epsilon^{-1} \cdot \log(n)$ classes for every grid $\mathcal{G}_i$ and we have at $\log(n) + 1$ grids. Thus, the total cost of non-contributing classes is at most $\sum_{i=1}^{\log(n)+1} \sum_{j=1}^{\epsilon^{-1} \cdot \log(n)} \text{cost}^{\epsilon}_{FL}(\Psi^j_i, f) \leq \frac{\epsilon}{2} \cdot OPT_{FL}(P, f)$. Thus we can safely ignore the contribution of these grids toward the optimal facility location cost of the point set P. ◀

We first find a lower bound for the cost of contributing classes. Next, we obtain a lower bound for the minimum number of points in a contributing likelihood class.

▶ **Lemma 28.** *Let $\alpha = \frac{\epsilon^3}{18\delta_{FL} \log^3(n)}$ and $\beta = \frac{\epsilon^2}{2\delta_{FL} \cdot \log^2(n)}$. Let Ψ^j_i be a likelihood class that is contributing, i.e., $|\Psi^j_i| \geq \beta\sqrt{n}$. Then, $cost^{\epsilon}_{FL}(\Psi^j_i, f) = \sum_{c \in \Psi^j_i} cost^{\epsilon}_{FL}(c, F_c, f) \geq \alpha\sqrt{n} \cdot f$.*

Proof. A class Ψ^j_i is contributing if $|\Psi^j_i| \geq \beta\sqrt{n}$. Moreover, every class Ψ^j_i consists of light cells that are significant. A light cell $c \in \Lambda$ is significant if $\text{cost}^{\epsilon}_{FL}(c, F_c, f) \geq \tau f$, where $\tau = \frac{\epsilon}{9\log(n)}$. Thus, we have the following lower bound for the facility location cost of the class Ψ^j_i: $\text{cost}^{\epsilon}_{FL}(\Psi^j_i, f) = \sum_{c' \in \Psi^j_i} \text{cost}^{\epsilon}_{FL}(c', f) \geq |\Psi^j_i| \cdot \tau \cdot f \geq \frac{\epsilon^3}{18\delta_{FL} \log^3(n)} \cdot \sqrt{n} \cdot f$. ◀

Next, using the lower bound that we obtained for the cost of contributing classes, we find a lower-bound on the number of points in every contributing class. This will help us to prove that can sample cells of contributing classes almost uniformly at random.

▶ **Proposition 29.** *For a contributing likelihood class Ψ_i^j we have $n(\Psi_i^j) = \sum_{c \in \Psi_i^j} n_c \geq \frac{\alpha\sqrt{n}}{(1+\epsilon)}$.*

Proof. Let us consider a significant light cell $c \in \Psi_i^j$. Since Algorithm [15] $\textsc{Alg}_{FL}^{\epsilon}$ is a $(1+\epsilon)$-approximation algorithm for the facility location problem, we have $\text{cost}_{FL}^{\epsilon}(c', f) \leq (1+\epsilon) \cdot OPT_{FL}(P \cap c, f)$. This essentially means that $OPT_{FL}(P \cap c, f) \geq \frac{\text{cost}_{FL}^{\epsilon}(c',f)}{(1+\epsilon)} \geq \frac{\tau}{(1+\epsilon)} \cdot f$.

Now we take the sum over the cells of Ψ_i^j, apply Lemma 28, and let $\alpha = \frac{\epsilon^3}{18\delta_{FL}\log^3(n)}$ to obtain $\sum_{c \in \Psi_i^j} OPT_{FL}(P \cap c, f) \geq \sum_{c \in \Psi_i^j} \frac{\text{cost}_{FL}^{\epsilon}(c',f)}{(1+\epsilon)} \geq |\Psi_i^j| \cdot \frac{\tau}{(1+\epsilon)} \cdot f \geq \frac{\alpha\sqrt{n}}{(1+\epsilon)} \cdot f$.

We claim that $n(\Psi_i^j) = \sum_{c \in \Psi_i^j} n_c \geq \frac{\alpha\sqrt{n}}{(1+\epsilon)}$. As for the contradiction, suppose this claim is not correct. That is assume that $n(\Psi_i^j) < \frac{\alpha\sqrt{n}}{(1+\epsilon)}$. Then, imagine that we open one facility for each point in Ψ_i^j. Since we assume that $n(\Psi_i^j) \leq \frac{\alpha\sqrt{n}}{(1+\epsilon)}$, the overall opening cost (in fact, the facility location cost since the connection cost is zero) of Ψ_i^j is less than $\frac{\alpha\sqrt{n}}{(1+\epsilon)} \cdot f$ which can not be the case. Thus, overall the cells in Ψ_i^j must have at least $\frac{\alpha\sqrt{n}}{(1+\epsilon)}$ points. ◀

Bicriteria Approximation Algorithms for Priority Matroid Median

Abstract

Fairness considerations have motivated new clustering problems and algorithms in recent years. In this paper we consider the Priority Matroid Median problem which generalizes the Priority k-Median problem that has recently been studied. The input consists of a set of facilities $\mathcal{F}$ and a set of clients $\mathcal{C}$ that lie in a metric space $(\mathcal{F} \cup \mathcal{C}, d)$, and a matroid $\mathcal{M} = (\mathcal{F}, \mathcal{I})$ over the facilities. In addition, each client j has a specified radius $r_j \geq 0$ and each facility $i \in \mathcal{F}$ has an opening cost $f_i > 0$. The goal is to choose a subset $S \subseteq \mathcal{F}$ of facilities to minimize $\sum_{i \in \mathcal{F}} f_i + \sum_{j \in \mathcal{C}} d(j, S)$ subject to two constraints: (i) S is an independent set in $\mathcal{M}$ (that is $S \in \mathcal{I}$) and (ii) for each client j, its distance to an open facility is at most r_j (that is, $d(j, S) \leq r_j$). For this problem we describe the first bicriteria (c_1, c_2) approximations for fixed constants c_1, c_2: the radius constraints of the clients are violated by at most a factor of c_1 and the objective cost is at most c_2 times the optimum cost. We also improve the previously known bicriteria approximation for the uniform radius setting ($r_j := L \; \forall j \in \mathcal{C}$).

1 Introduction

Clustering and facility-location problems are widely studied in areas such as machine learning, operations research, and algorithm design. Among these, center-based clustering problems in metric spaces form a central topic and will be our focus. The input for these problems is a set of clients $\mathcal{C}$ and a set of facilities $\mathcal{F}$ from a metric space $(\mathcal{F} \cup \mathcal{C}, d)$. The goal is to select a subset of facilities $S \subseteq \mathcal{F}$ to open, subject to various constraints, so as to minimize an objective that depends on the distances of the clients to the chosen centers; we use $d(j, S)$ to denote the quantity $\min_{i \in S} d(j, i)$ which is the distance from j to S. Typical objectives are of the form $(\sum_{j \in \mathcal{C}} d(j, S)^p)^{1/p}$ for some parameter p (the ℓ_p norm of the distances). When the constraint on facilities is that at most k can be chosen (that is, $|S| \leq k$), we obtain several standard and well-studied problems such as k-Center ($p = \infty$), k-Median ($p = 1$), and k-Means ($p = 2$) problems. These problems are extensively studied from many perspectives [15, 25, 10, 2, 5, 19, 16]. These are also well-studied in the geometric setting when $\mathcal{F}$ is the continuous space $\mathbb{R}^\ell$ for some finite dimension ℓ. In this paper we restrict our attention to the discrete setting, and in particular, to the median objective ($p = 1$).

The Matroid Median problem is a generalization of the k-Median clustering problem. Here, the cardinality constraint k on S is replaced by specifying a matroid $\mathcal{M} = (\mathcal{F}, \mathcal{I})$ on the facility set $\mathcal{F}$ and requiring that $S \in \mathcal{I}$ (we refer a reader unfamiliar with matroids to

Section 2 formal definitions and details). The k-Median clustering problem can be written as an instance of Matroid Median where $\mathcal{M}$ is the uniform matroid of rank k. The Matroid Median problem was first introduced by Krishnaswamy et al. [21] as a generalization of k-Median and Red-Blue Median [14].

Motivated by the versatility of the Matroid Median problem, and several other considerations that we will discuss shortly, in this paper we study the Priority Matroid Median problem (PMatMed). Formally, in PMatMed we are given a set of clients $\mathcal{C}$ and facilities $\mathcal{F}$ from a metric space $(\mathcal{F} \cup \mathcal{C}, d)$ where each facility $i \in \mathcal{F}$ has a facility opening cost f_i, and each client $j \in \mathcal{C}$ has a radius value r_j. We are also given a matroid $\mathcal{M} = (\mathcal{F}, \mathcal{I})$ over the facilities. The goal is to select a subset of facilities S that is an independent set of the matroid $\mathcal{M}$ where the objective $\sum_{j \in \mathcal{C}} d(j, S) + \sum_{i \in S} f_i$ (i.e. the *cost* induced by selected facilities) is minimized, and the *radius* constraint $d(j, S) \leq r_j$ is satisfied for all clients $j \in \mathcal{C}$.

Most of the center-based clustering problems are NP-Hard even in very restricted settings. We focus on polynomial-time approximation algorithms which have an extensive history in center-based clustering. Moreover, due to the nature of the constraints in PMatMed, we can only obtain bicriteria approximation guarantees that violate both the objective and the radius constraints. An (α, β)-approximation algorithm for PMatMed is a polynomial-time algorithm that either correctly states that no feasible solution is possible or outputs a set of facilities $S \in \mathcal{I}$ (hence satisfies the matroid constraint) such that (i) $d(j, S) \leq \alpha r_j$ for all clients $j \in \mathcal{C}$ and (ii) the cost objective value of S is at most $\beta \cdot OPT$ where OPT is the cost of an optimum solution.

1.1 Motivation, Applications to Fair Clustering, and Related Work

Our study of PMatMed is motivated, at a high-level, by two considerations. First, there has been past work that combines the k-Median objective with that of the k-Center objective. Alamdari and Shmoys [3] considered the k-Median problem with the additional constraint that each client is served within a given uniform radius L and obtained a $(4, 8)$-approximation. Their work is partially motivated by the ordered median problem [24, 4, 8]. Kamiyama [18] studied a generalization of this uniform radius requirement on clients to the setting of Matroid Median and derived a $(11, 16)$-approximation algorithm. Note that this is a special case of PMatMed where $r_j = L$ for each j. We call this the UniPMatMed problem.

Another motivation for studying PMatMed is the recent interest in *fair clustering* in the broader context of algorithmic fairness. The goal is to capture and address social concerns in applications that rely on clustering procedures and algorithms. Various notions of fair clustering have been proposed. Chierchetti et al. [11] formulated the Fair k-Center problem: clients belong to one or more groups based on various attributes. The objective is to return a clustering of points where each chosen center services a representative number of clients from *every* group. This notion has since been classified as one that seeks to achieve *group* fairness. Several other group fair clustering problems have since been introduced and studied [7, 20, 1, 13]. Subsequently, clustering formulations that aimed to encapsulate *individual* fairness were explored which seek to ensure that each individual is treated fairly. One such formulation was introduced by Jung et al. [17]. This formulation is related to the well-studied k-Center clustering and is the following. Given n points in a metric space representing users, and an integer k, find a set of k centers S such that $d(j, S)$ is at most r_j where r_j denotes the smallest radius around j that contains n/k points. Such a clustering is fair to individual users since no user will be forced to travel outside their *neighborhood.* Jung et al. [17] showed that the problem is NP-Hard and described a simple greedy algorithm that finds k centers S such that $d(j, S) \leq 2r_j$ for all j. Jung et al.'s model can be related to an earlier model of Plesník who considered the Weighted k-Center problem [25]. In Plesník's version, each user j specifies an *arbitrary* radius $r_j > 0$ and the goal is to find k centers S to serve each user within their radius requirement. Plesník showed that a simple variant of a well-known algorithm for k-Center due to Hochbaum and Shmoys [15] yields a 2-approximation. Plesník's problem has been relabeled as the Priority k-Center problem in recent work [6].

Priority clustering. The model of Jung et al. motivated several variations and generalizations of the Priority k-Center problem. Bajpai et al. [6] defined, and provided constant factor approximations, for Priority k-Supplier (where facilities and clients are considered to be disjoint sets), as well as Priority Matroid and Knapsack Center, where facilities are subject to matroid and knapsack constraints, respectively. Mahabadi and Vakilian [23] explored and developed approximation algorithms for Priority k-Median and Priority k-Means problems; their motivation was to combine the individual fairness requirements in terms of radii proposed by Jung et al., with the traditional objectives of clustering. They obtained bicriteria approximation algorithms via local-search. The approximation bounds were later improved via LP-based techniques. Chakrabarty and Negahbani [9] obtained an $(8, 8)$-approximation for Priority k-Median and a $(8, 16)$-approximation for Priority k-Means. Vakilian and Yalcner [28] further improved these results via a nice black box reduction of Priority k-Median to the Matroid Median problem! Via their reduction they obtained $(3, 7.081 + \epsilon)$-approximation for the Priority k-Median problem (relying on the algorithm for Matroid Median from [22]). They extended the algorithmic ideas from Matroid Median to handle ℓ_p norm objectives and were thus able to derive algorithms for Priority k-Means as well. The advantage of the reduction to Matroid Median is the guarantee of 3 on the radius dilation. This is optimal even for the k-Supplier problem [15].

1.2 Results and Technical Contribution

In this paper, we define the PMatMed problem and derive the first (c_1, c_2)-bicriteria approximation algorithms where c_1, c_2 are both constants. There are different trade-offs between c_1 and c_2 that we can achieve. Since PMatMed simultaneously generalizes k-Supplier and Matroid Median, the best c_1 we can hope for is 3, and the best c_2 that we can hope for is ≈ 8, which comes from current algorithms for Matroid Median [22, 27]. We prove the following theorem which captures two results, one optimizing for the radius guarantee, and the other for the cost guarantee.

▶ **Theorem 1.** *There is a $(21, 12)$-approximation algorithm for the Priority Matroid Median Problem. There is also a $(36, 8)$-approximation algorithm.*

As we previously mentioned, [28], via their black box reduction to Matroid Median achieve a $(3, \alpha)$ approximation for Priority k-Median where α is the best approximation for Matroid Median. We conjecture that there is a $(3, O(1))$-approximation for PMatMed. This is interesting and open even for the special case with uniform radii under partition matroid constraint.

Our second set of results are for UniPMatMed. Recall that [18] obtained a $(11, 16)$-approximation for this problem. We prove the following theorem that strictly dominates the bound from [18]. In addition, we show that a tighter radius guarantee is achievable.

▶ **Theorem 2.** *There is a $(9, 8)$-approximation algorithm for the Uniform Priority Matroid Median Problem. For any fixed $\epsilon > 0$ there is a $(5 + 8\epsilon, 4 + \frac{2}{\epsilon})$-approximation.*

▶ Remark 3. We believe that we can extend the ideas from this paper to obtain bicriteria approximation algorithms for Priority Matroid objectives that involve the ℓ_p norm of distances (Priority Matroid Median is when $\ell_p := 1$). Such an approximation algorithm would result in a radius factor dependent on p. [28] already showed that Matroid Median can be extended to the p-norm objective.

Now, we give a brief overview of our technical approach. The reader may wonder about the reduction of Priority k-Median to Matroid Median [28]. Can we make use of this for PMatMed? Indeed one can employ the same reduction, however, the resulting instance is no longer an instance of Matroid Median but an instance of Matroid Intersection Median which is inapproximable [27]. The reduction works in the special case of Priority k-Median since the intersection of a matroid with a cardinality constraint yields another matroid. We therefore address PMatMed directly. Our approximation algorithms are based on a natural LP relaxation. It is not surprising that we need to build upon the techniques for Matroid Median since it is a special case. We build extensively on the LP-based 8-approximation for Matroid Median given by Swamy [27] which improved the first constant factor approximation algorithm of Krishnaswamy et al. [21]. Although the Matroid Median approximation has been improved to 7.081 [22], the approach in [22] seems more difficult to adapt to PMatMed.

Our main technical contribution is to handle the non-uniform radii constraints imposed in PMatMed in the overall approach for Matroid Median. We note that the rounding algorithms for Matroid Median are quite complex, and involve several non-trivial stages: filtering, finding half integral solutions via an auxiliary polytope, and finally rounding to an integral solution via matroid intersection [21, 27, 22]. Kamiyama adapted the ideas in [21] to UniPMatMed and his work involves four stages of reassigments that are difficult to follow. The non-uniform radii case introduces additional complexity. We explain the differences between the uniform radii case and the non-uniform radii case briefly. The LP relaxation opens fractional facilities and assigns each client j to fractionally open facilities. In the LP for PMatMed we write a natural constraint that j cannot be assigned to any facility i where $d(i, j) > r_j$. Let $\bar{C}_j$ denote the distance paid by j in the LP solution. The preceding constraint ensures that $\bar{C}_j \leq r_j$. For UniPMatMed, $r_j = L$ for all $j \in \mathcal{C}$. LP-based approximation algorithms for k-Median use filtering and other rounding steps by sorting clients in increasing order of $\bar{C}_j$ values since they are directly relevant to the objective. When one considers uniform radius constraint, one can still effectively work with $\bar{C}_j$ values since we have $\bar{C}_j \leq L$ for all j. However, when clients have non-uniform radii we can have the following situation; there can be clients j and k such that $\bar{C}_j \ll \bar{C}_k$ but $r_j \gg r_k$. Thus the radius requirements may not correspond to the fractional distances paid in the LP.

We handle the above mentioned complexity via two careful adaptations to Matroid Median rounding. One of these changes occurs in the second stage of Matroid Median rounding, where we construct a half-integral solution using an auxiliary polytope. We must take care to ensure that the half-integral solution constructed in this stage is one that will not violate the radius requirements for clients. To do so, we create additional constraints in the auxiliary polytope. These constraints ensure the half-integral solution satisfies certain properties that are crucial to obtain a constant factor radius guarantee.

The second change occurs in the first filtering stage and plays a role not only for adapting Matroid Median to PMatMed, but also for each of our other results. We first provide an abstract way to describe the filtering stage that allows us to specificy the order in which points are considered, and the distances each point can travel to be reassigned. For our first PMatMed result, the ordering and distances are based on both $\bar{C}_j$ and r_j. For UniPMatMed, we slightly alter the ordering and distances (using the above observations and some ideas from [18]). Our remaining results will also involve changes to the filtering stage. This seems to indicate that filtering plays a large role in the cost and radius trade-off.

Organization. In Section 2, we discuss preliminaries. In particular, we provide definitions and relevant information regarding matroids, define PMatMed and provide its LP relaxation, and discuss the generalized filtering procedure we will use in our algorithm. In Section 3 we present our algorithm for PMatMed and show that it can be used to obtain $(21, 12)$-approximate solutions for instances of PMatMed. In Section 4, we describe how to modify our algorithm for PMatMed to obtain a $(9, 8)$-approximate solution for instances of UniPMatMed, and the remaining results. We also provide some details for the remaining results, and $(36, 8)$-approximate solutions for instances of PMatMed. We defer the proofs of our results to the Appendix.

2 Preliminaries

2.1 Matroids, Matroid Intersection and Polyhedral Results

We assume some basic knowledge about matroids, but provide a few relevant definitions for sake of completeness; we refer the reader to [26] for more details. A matroid $\mathcal{M} = (S, \mathcal{I})$ consists of a finite ground set S and a collection of *independent* sets $\mathcal{I} \subseteq 2^S$ that satisfy the following axioms: (i) $\emptyset \in \mathcal{I}$ (non-emptiness of $\mathcal{I}$) (ii) $A \in \mathcal{I}$ and $B \subset A$ implies $B \in \mathcal{I}$ (downward closure) and (iii) $A, B \in \mathcal{I}$ with $|A| < |B|$ implies there is $i \in B \setminus A$ such that $A \cup \{i\} \in \mathcal{I}$ (exchange property). The rank function of a matroid, $r_{\mathcal{M}} : 2^S \to \mathbb{Z}^{\geq 0}$ assigns to each $X \subseteq S$ the cardinality of a maximum independent subset in X. It is known that $r_{\mathcal{M}}$ is a monotone submodular function. The matroid polytope for a matroid $\mathcal{M}$, denoted by $\mathcal{P}_{\mathcal{M}}$ is the convex hull of the characteristic vectors of the independent sets of $\mathcal{M}$. This can be characterized via the rank function:

$$\mathcal{P}_{\mathcal{M}} = \{v \in \mathbb{R}^S \mid \forall X \subseteq S : \ v(X) \leq r_M(X) \text{ and } \forall e \in S : \ v(e) \geq 0\}.$$

Assuming an independence oracle[1] or a rank function oracle for $\mathcal{M}$, one can optimize and separate over $\mathcal{P}_{\mathcal{M}}$ in polynomial time. A *partition matroid* $\mathcal{M} = (S, \mathcal{I})$ is a special type of matroid that is defined via a partition $S_1, S_2, \ldots, S_h$ of S and non-negative integers $k_1, \ldots, k_h$. A set $X \subseteq S$ is independent, that is $X \in \mathcal{I}$, iff $|X \cap S_i| \leq k_i$ for $1 \leq i \leq h$. A simple partition matroid is one in which $k_i = 1$ for each i.

Given two matroids $\mathcal{M} = (S, \mathcal{I}_1)$ and $\mathcal{N} = (S, \mathcal{I}_2)$, on the same ground set, their intersection is defined as $\mathcal{M} \cap \mathcal{N} := (S, \mathcal{I}_1 \cap \mathcal{I}_2)$ consisting of sets that are independent in both $\mathcal{M}$ and $\mathcal{N}$. Computing a maximum weight independent set in the intersection can be done efficiently. The convex hull of the characteristic vectors of the independent sets of $\mathcal{M} \cap \mathcal{N}$, denoted by $\mathcal{P}_{\mathcal{M},\mathcal{N}}$, is simply the intersection of $\mathcal{P}_{\mathcal{M}}$ and $\mathcal{P}_{\mathcal{N}}$! That is

$$\mathcal{P}_{M,N} = \{v \in \mathbb{R}_+^S \mid \forall X \subseteq S : \ v(X) \leq r_M(X), v(X) \leq r_{\mathcal{N}}(X)\}.$$

Thus, one can optimize over $\mathcal{P}_{\mathcal{M},\mathcal{N}}$ if one has independence or rank oracles for $\mathcal{M}$ and $\mathcal{N}$. We will need these results later in the paper. See [26] for these classical results.

The input matroid $\mathcal{M}$ for Priority Matroid Median has ground set $\mathcal{F}$ i.e. the set of facilities. Thus, an integer point of the polytope $v^* \in \mathcal{P}_{\mathcal{M}}$ will represent a subset of facilities that is an independent set of the matroid $\mathcal{M}$.

[1] An independence oracle returns whether $A \in \mathcal{I}$ for a given $A \subseteq S$.

2.2 Priority Matroid Median

We provide below a more general definition of Priority Matroid Median that includes a notion of client *demands.*

▶ **Definition 4** (PMatMed). *The input is a set of facilities $\mathcal{F}$ and clients $\mathcal{C}$ from a metric space $(\mathcal{F} \cup \mathcal{C}, d)$. Each $i \in \mathcal{F}$ has an opening cost $f_i \geq 0$. Each client $j \in \mathcal{C}$ has a radius value, $r_j \geq 0$ and a demand value $a_j \geq 0$. We are also given a matroid $\mathcal{M} = (\mathcal{F}, \mathcal{I})$. The goal is to choose a set $S \in \mathcal{I}$ to minimize $\sum_{i \in S} f_i + \sum_{j \in \mathcal{C}} a_j d(j, S))$ with the constraint that $d(j, S) \leq r_j$ for each $j \in \mathcal{C}$.*

A PMatMed instance $\mathscr{I}$ is the tuple $(\mathcal{F}, \mathcal{C}, d, \mathbf{f}, \mathbf{r}, \mathbf{a}, \mathcal{M})$, where $\mathbf{f} \in \mathbb{R}^{\mathcal{F}}$ and $\mathbf{r}, \mathbf{a} \in \mathbb{R}^{\mathcal{C}}$.

2.3 LP relaxation for PMatMed

Our algorithm is based on an LP relaxation for a PMatMed instance $\mathscr{I} = (\mathcal{F}, \mathcal{C}, d, \mathbf{f}, \mathbf{r}, \mathbf{a}, \mathcal{M})$ that we describe next. We use i to index facilities in $\mathcal{F}$, j to index clients in $\mathcal{C}$. Recall that $r_{\mathcal{M}}$ denotes the rank function of the matroid $\mathcal{M}$. The y_i variables denote the fractional amount a facility i is open, while the x_{ij} variables indicate the fractional amount a client j is assigned to facility i.

$$\min \quad \sum_{i \in \mathcal{F}} f_i y_i + \sum_j \sum_i a_j d(i,j) x_{ij} \tag{1a}$$

$$\text{s.t.} \quad \sum_{i \in \mathcal{F}} x_{ij} \geq 1 \qquad \forall j \in \mathcal{C} \tag{1b}$$

$$x_{ij} \leq y_i \qquad \forall i \in \mathcal{F}, j \in \mathcal{C} \tag{1c}$$

$$x_{ij} = 0 \qquad \forall i \in \mathcal{F}, j \in \mathcal{C} : d(i,j) > r_j \tag{1d}$$

$$y \in \mathcal{P}_{\mathcal{M}} \tag{1e}$$

$$x_{ij}, y_i \geq 0 \qquad \forall i \in \mathcal{F}, j \in C \tag{1f}$$

Constraint 1b states that each client must be fully assigned to facilities, and constraint 1c ensures that these facilities have indeed been opened enough to service clients. For integral y, constraint 1e mandates that the facilities come from an independent set of the matroid $\mathcal{M}$. Finally, constraint 1d ensures that no client is assigned to a center that is farther than its radius value.

We make a few basic observations about the LP relaxation. We assume that it is feasible for otherwise the algorithm can terminate reporting that there is no feasible integral solution. Indeed, the LP is solvable in polynomial time via the rank oracle for $\mathcal{M}$. First, some notation. For $X \subseteq \mathcal{F}$, we let $y(X)$ denote $\sum_{i \in X} y_i$. For client j and radius parameter R we let $B(j, R)$ denote the set $\{i \in \mathcal{F} \mid d(i,j) \leq R\}$ of facilities within R of j. Constraints 1b and 1d ensure the following simple fact.

▶ **Fact 5.** *Let (x, y) be a feasible solution to the PMatMed LP. Then $y(B(j, r_j)) \geq 1$ holds $\forall j \in \mathcal{C}$.*

Let $COST(x, y)$ denote the cost of the LP using solution (x, y). Going forward, we will assume that we are working with an optimum fractional solution to the LP relaxation for the given instance.

▶ Remark 6. We say that y is feasible if $y \in \mathcal{P}_{\mathcal{M}}$ and $y(B(j, r_j)) \geq 1$ for all $j \in C$. Given feasible y, a corresponding x satisfying the constraints and minimizing $COST(x, y)$ is determined by solving a min-cost assignment problem for each client $j \in C$ separately.

2.4 Filtering

Filtering is a standard step in several approximation algorithms for clustering and facility location wherein one identifies a subset of well-separated and representative clients. Each client is assigned to a chosen representative. In priority median problems there are two criteria that dictate the filtering process. One is the radius upper bound r_j for the client j. The other is the LP distance $\bar{C}_j = \sum_i d(i,j)x(i,j)$ paid by the client which is part of the objective. Balancing these two criteria is important. To facilitate different scenarios later we develop a slightly abstract filtering process. Building on a procedure introduced in [15, 25], Filter takes in the metric and demands from a PMatMed instance $\mathscr{I} = (\mathcal{F}, \mathcal{C}, d, \mathbf{f}, \mathbf{r}, \mathbf{a}, \mathcal{M})$, as well as functions $\phi, \lambda : \mathcal{C} \rightarrow \mathbb{R}_+$ that satisfy the following condition.

▶ **Definition 7** (compatibility). *Functions $\phi, \lambda : \mathcal{C} \rightarrow \mathbb{R}_+$ are compatible if for any ordering of clients $j_1, j_2, \ldots, j_n$ where $\phi(j_1) \leq \phi(j_2) \leq \ldots \leq \phi(j_n)$, it is the case that $\lambda(j_1) \leq \lambda(j_2) \leq \ldots \leq \lambda(j_n)$.*

▶ Remark 8. This condition trivially holds when ϕ and λ are identical. The filtering stages of many clustering approximation algorithms [6, 17, 9] utilize equal ϕ and λ functions. We use both identical and non-identical settings for ϕ and λ in this paper.

The function ϕ encodes an ordering of clients, while λ represents a client's coverage distance. Filter chooses cluster centers in order of increasing ϕ values, and then "covers" any remaining client k that is within distance $2 \cdot \lambda(k)$ from the newly added center j. The demand from the covered points is transferred to the center that first covered them. The new demand variables a' represent the aggregated demand for the chosen centers. Filter returns the set of cluster centers, the clusters assigned to each cluster center, and new demand assignments for all clients.

Algorithm 1 Filter.

```
Require: Metric $(\mathcal{F} \cup \mathcal{C}, d)$, demands $\mathbf{a}$, compatible functions $\phi, \lambda : \mathcal{C} \rightarrow \mathbb{R}_{>0}$
$U \leftarrow \mathcal{C}$                                        ▷ The set of uncovered clients
$C \leftarrow \emptyset$                                        ▷ The set of cluster centers
$\forall j \in \mathcal{C}$ set $a'_j := 0$                     ▷ Initialize new demand variables
while $U \neq \emptyset$ do
    $j \leftarrow \arg\min_{j \in U} \phi(j)$
    $C \leftarrow C \cup \{j\}$
    $D(j) \leftarrow \{k \in U : d(j,k) \leq 2 \cdot \lambda(k)\}$    ▷ Note: $D(j)$ includes $j$ itself
    $a'_j = \sum_{k \in D(j)} a_k$                             ▷ Accumulate all demands of $D(j)$ to $j$
    $U \leftarrow U \backslash D(j)$
end while
Return cluster centers $C$, $\{D(j) : j \in C\}$, updated demands $\mathbf{a}' \in \mathbb{R}^{\mathcal{C}}$
```

The resulting cluster centers $C \subseteq \mathcal{C}$, and the sets of clients relocated to each cluster center $\{D(j) \mid j \in C\}$ form a partition of the client set $\mathcal{C}$. When the given ϕ and λ are compatible, the returned clusters satisfy certain desirable properties, described in the following facts which are relatively easy to see, and standard in the literature. For this reason we omit formal proofs.

▶ **Fact 9.** *The following statements hold for the output of Filter: (a) $\forall j, j' \in C, d(j,j') > 2\max\{\lambda(j), \lambda(j')\}$. (b) $\{B(j, \lambda(j)) \mid j \in C\}$ are mutually disjoint. (c) $\{D(j) \mid j \in C\}$ partitions $\mathcal{C}$. (d) $\forall j \in C, \forall k \in D(j), \phi(j) \leq \phi(k)$ and $\lambda(j) \leq \lambda(k)$. (e) $\forall j \in C, \forall k \in D(j), d(j,k) \leq 2 \cdot \lambda(k)$*

Choosing ϕ and λ. As we remarked, the two criteria that influence the filtering process are r_j and $\bar{C}_j$. For the algorithm in Section 3 we choose $\phi(j) = \lambda(j) = \min\{r_j, 2\bar{C}_j\}$. There are other valid settings of compatible ϕ and λ that can be used in the filtering stage. Different settings of ϕ and λ will result in different approximation factors for cost and radius. We elaborate on this further in Section 4.

3 A $(21, 12)$-approximation for Priority Matroid Median

Our algorithm will follow the overall structure of the LP-based procedure used for approximating Matroid Median from [27], but will contain a few key alterations that allow us to be mindful of the radius objective of PMatMed. Stage 1 of our algorithm involves filtering the client set to construct an updated instance $\mathscr{I}'$ using the cluster centers and updated demands. We will show that a solution to $\mathscr{I}'$ can be converted to a solution for $\mathscr{I}$ while only incurring a small increase to the cost and radius. The focus then shifts to constructing a solution for $\mathscr{I}'$. In Stage 2, we obtain a half-integral solution for the LP-relaxation for $\mathscr{I}'$ by working with an auxiliary polytope. In Stage 3, this half-integral solution is converted to an integral solution for $\mathscr{I}'$. This is done via a reduction to matroid intersection. Finally, we will show that this solution yields a $(21, 12)$-approximation for the original instance $\mathscr{I}$. Algorithm 2 is given as a summary of the various stages of our algorithm. The omitted proofs from this section can be found in Appendix A.

Algorithm 2 Overview of bi-criteria approximation algorithm for PMatMed.

```
Input: PMatMed instance $\mathscr{I} = (\mathcal{F}, \mathcal{C}, d, \mathbf{f}, \mathbf{r}, \mathbf{a}, \mathcal{M})$.
Output: $(\alpha, \beta)$-approximate solution for $\mathscr{I}$.
0: Solve $LP$ for $\mathscr{I}$ and let $(x, y)$ denote the optimal fractional solution. Use $(x, y)$ and
   radius values $\mathbf{r}$ to help set $\phi$ and $\lambda$.
1: Stage 1 - Run Filter$((\mathcal{F} \cup \mathcal{C}, d), \mathbf{a}, \phi, \lambda)$ which returns cluster centers $C$, and updated
   client demands $\mathbf{a}'$. Create an updated instance $\mathscr{I}' = (\mathcal{F}, C, d, \mathbf{f}, \mathbf{r}, \mathbf{a}', \mathcal{M})$ (Section 3.1).
2: Stage 2 - Construct a half-integral solution $(\hat{x}, \hat{y})$ for $\mathscr{I}'$ by setting up a polytope $\mathcal{Q}$
   with half-integral extreme points (Section 3.2).
3: Stage 3 - Convert the half-integral solution to an integral solution $(\tilde{x}, \tilde{y})$ for $\mathscr{I}'$ by
   setting up an instance of matroid intersection between the input matroid $\mathcal{M}$, and a
   partition matroid $\mathcal{N}$ constructed with respect to the half-integral solution (Section 3.3).
4: Convert the integral solution for $\mathscr{I}'$ to one for $\mathscr{I}$ (Lemma 10).
```

3.1 Stage 1: Filtering Clients

In this stage, we create a new instance of PMatMed from the initial one by using the Filter process described in Section 2.4. Recall that Filter will return a set of cluster centers $C \subseteq \mathcal{C}$, and collections of clients that are relocated to each cluster center $\{D(j) \mid j \in C\}$. Filter also returns a set of updated demands for all clients, $\mathbf{a}'$. Now, using C and $\mathbf{a}'$, we construct a new instance of PMatMed $\mathscr{I}' = (\mathcal{F}, C, d, \mathbf{f}, \mathbf{r}, \mathbf{a}', \mathcal{M})$. Here, we overload notation and take $\mathbf{r}$ and $\mathbf{a}'$ to denote the vector of radius values and demands, respectively, for cluster centers (i.e. $\mathbf{r}, \mathbf{a}' \in \mathbb{R}^C$). Notice that we do not lose any information by restricting $\mathbf{a}'$ to C, since the updated demands for relocated points are set to 0. Furthermore, we will reconcile the radius objective for relocated points in the final solution at the end of the section.

The solution (x, y) for instance $\mathscr{I}$, when restricted to C, will still be a feasible solution for the LP for $\mathscr{I}'$, since the new LP is made up of a subset of constraints from the original LP. For updated instance $\mathscr{I}'$, we denote the cost of the LP solution (x, y) by $COST'(x, y)$.

$$COST'(x,y) = \sum_{i\in\mathcal{F}} f_i y_i + \sum_{j\in C} a'_j \sum_{i\in\mathcal{F}} d(i,j)x_{ij} = \sum_{i\in\mathcal{F}} f_i y_i + \sum_{j\in C} a'_j \bar{C}_j$$

The next lemma shows that an integral solution to $\mathscr{I}'$ can be translated to an integer solution for $\mathscr{I}$ by incurring a small additive increase to the cost objective. In subsequent sections we will address how the translated solution also ensures that all clients are served within a constant factor of their radius constraint.

▶ **Lemma 10.** *The following is true of $\mathscr{I}'$: (a) $COST'(x, y) \leq 2 \cdot COST(x, y)$. (b) Any integer solution (x', y') for $\mathscr{I}'$ can be converted to an integer solution for $\mathscr{I}$ that incurs an additional cost of at most $4 \cdot COST(x, y)$.*

The following lemma follows directly from Fact 9.

▶ **Lemma 11.** *Let $k \in \mathcal{C}$ be assigned to $j \in C$ after* Filter *(i.e. $k \in D(j)$). Then, $d(j, k) \leq 2\lambda(k) \leq 2r_k$.*

3.2 Stage 2: Constructing Half-Integral Solution $(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}})$

In the second stage the goal is to construct a half-integral solution to $\mathscr{I}'$. This means that each cluster center/client $j \in C$ will connect to at most two facilities. This is accomplished by constructing a specific polytope $\mathcal{Q}$ with only facility variables, and a proxy objective that also has only facility variables and arguing about the properties of $\mathcal{Q}$ and the objective function.

To describe $\mathcal{Q}$, we define, for each client $j \in C$, several facility sets that will play an important role. Let $F_j = \{i \in \mathcal{F} \mid d(i, j) = \min_{k\in C} d(i, k)\}$ denote the set of facilities i for which j is the closest client in C (ties are broken arbitrarily). Let $F'_j = \{i \in F_j \mid d(i, j) \leq \lambda(j)\} \subseteq F_j$. Let $\gamma_j := \min_{i\notin F_j} d(i, j)$ denote the distance between client $j \in C$ and the closest facility i not included in F_j. In other words, i in the definition of γ_j is the closest facility to j that has some other closest cluster center $j' \in C$ such that $j \neq j'$. Using γ_j, let $G_j = \{i \in F_j \mid d(i, j) \leq \gamma_j\}$. Finally, let ρ_j be the smallest distance such that $y(B(j, \rho_j)) \geq 1$, and $B_j := B(j, \rho_j)$.[2] See Figure 1.

We summarize some basic properties of the defined sets below.

▶ **Fact 12.** *The following hold for all $j \in C$: (a) If $j' \neq j$, $F_j \cap F_{j'} = \emptyset$; (b) F_j contains all the facilities i such that $d(i, j) \leq \lambda(j)$; (c) $\gamma_j > \lambda(j)$; (d) $F'_j \subseteq G_j$; (e) $\rho_j \leq r_j$, (f) $\sum_{i\in F'_j} x_{ij} \geq 1/2$ and when $\lambda(j) = r_j$, $\sum_{i\in F'_j} x_{ij} = 1$;*

Proof. (a) follows from definition of F_j, (b), (c), (d) follow from Fact 9(b) and definitions. (e) follows from the LP constraint. We now prove (f). If $\lambda(j) = r_j$, $F'_j = \{i \mid d(i, j) \leq r_j\}$, and by LP constraint $\sum_{i\in F'_j} x_{ij} = 1$. Otherwise $\lambda(j) = 2\bar{C}_j < r_j$. Note that $\bar{C}_j = \sum_i d(i, j)x_{ij}$. By averaging argument (Markov's inequality) we have $\sum_{i:d(i,j)\leq 2\bar{C}_j} x_{ij} \geq 1/2$. This gives the desired claim since $F'_j = \{i \mid d(i, j) \leq \lambda(j)\}$. ◀

[2] Note that though it may be the case that $y(B(j, \rho_j)) > 1$, we can split facilities and define B_j as the points of $B(j, \rho_j)$ such that $y(B_j) = 1$.

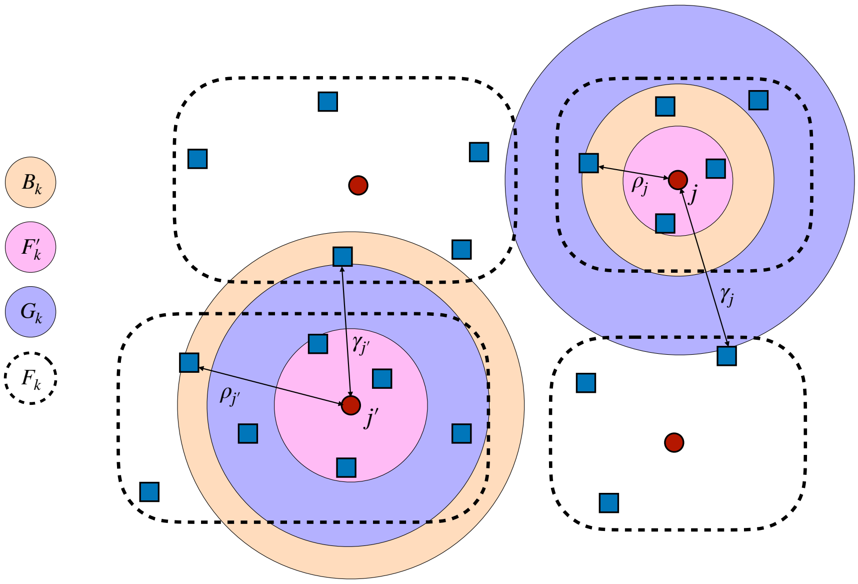

Figure 1 The F, F', G, and B sets for points $j \in C_s$ and $j' \in C_b$. Observe that for j, $\rho_j \leq \gamma_j$, hence $B_j \subseteq G_j$.

At this point in the algorithm, in a departure from the Matroid Median algorithm of [27], we need to be mindful of two cases. If $\rho_j \leq \gamma_j$, in order to satisfy the radius requirements of PMatMed, it is important to open one facility within radius ρ_j of j. If it is the case that $\rho_j > \gamma_j$, it is not necessary to do so. To distinguish these two cases, we partition C into $C_s = \{j \in C \mid \rho_j \leq \gamma_j\}$, and $C_b = \{j \in C \mid \rho_j > \gamma_j\}$. For $j \in C_s$, it should be clear that $B_j \subseteq G_j$. Using these sets, we define a polytope $\mathcal{Q}$ with facility variables $v_i, i \in \mathcal{F}$ as follows. It consists of the matroid constraints induced by $\mathcal{M}$ and a second set of constraints induced by C and C_s as defined above. In particular, we require that all points j in C has at least $1/2$ value assigned cumulatively to facilities within their F'_j balls. We require points of C_s to have exactly 1 assigned to facilities within B_j.

$$\mathcal{Q} = \Big\{ v \in \mathbb{R}^{\mathcal{F}}_{\geq 0} \;\mid\; \forall S \subseteq \mathcal{F} : v(S) \leq r_{\mathcal{M}}(S), \;\; \forall j \in C : \;\; v(F'_j) \geq 1/2 \text{ and } v(G_j) \leq 1, \\ \forall j \in C_s : v(B_j) = 1 \Big\}$$

▶ **Lemma 13.** *The extreme points of the polytope $\mathcal{Q}$, if non-empty, are half-integral.*

The proof of the preceding lemma is similar to those in previous works on Matroid Median [21, 27]. We give a proof (found in Appendix A) for the sake of completeness since the polytope we define is slightly different due to the separation of clients in C into C_s and C_b in order to enforce an additional constraint.

We will now define a vector y' that lies in $\mathcal{Q}$ which will prove that it is non-empty. Further, we also define a linear objective function $T(\cdot)$ over vectors in $\mathcal{Q}$ to serve as a proxy for the cost. Following the analysis for the improved bound in [27], we set up $T(\cdot)$ with some slack so that the slack can be exploited in the analysis of the next step in the algorithm.

We define $y' \in \mathbb{R}^{\mathcal{F}}_{\geq 0}$ as follows. For all $j \in C$ and $i \in G_j$, set $y'_i = x_{ij} \leq y_i$. For a facility $i \notin \cup_j G_j$ set $y'_i = 0$. From this definition it should be clear that $y'(G_j) \leq 1$ for all $j \in C$, since $\sum_{i \in G_j} x_{ij} \leq 1$. Also, from Fact 12, $y'(F'_j) \geq 1/2$. For $j \in C_s$, it will be the case that $y'(B_j) = 1$ since $\sum_{i \in B_j} x_{ij} = 1$; we also know that for these points, $y'(G_j) = y'(B_j)$.

To build up to the definition of T, we first state the following lemma, which we will prove in the proof of Lemma 17 (Appendix A).

▶ **Lemma 14.** *Consider some $j \in C$, and let i and j' be the facility and cluster used to define γ_j (i.e. $\gamma_j = d(i,j)$) where $i \in F_{j'}$ for some $j' \neq j$. For every $i' \in F'_{j'}$, $d(i',j) \leq 3\gamma_j$.*

Keeping the preceding lemma in mind, we can use as proxy for j's per-unit-demand cost a function written in terms of the facility vector v. When $y'(G_j) = 1$, the cost for j can be bounded by $\sum_{i\in G_j} d(i,j)y'_i \leq \bar{C}_j$. When $y'(G_j) < 1$, the preceding lemma indicates that we can upper bound the cost of the solution by $\sum_{i\in G_j} d(i,j)y'_i + 3\gamma_j(1 - y'(G_j)) \leq 3 \cdot \bar{C}_j$. Using these two bounds, we define $T(\cdot)$ for $v \in \mathcal{Q}$ as follows:

$$T(v) = \sum_{i\in\mathcal{F}} f_i v_i + \sum_{j\in C} a'_j \Big(2 \sum_{i\in G_j} d(i,j)v_i + 4\gamma_j(1 - v(G_j))\Big)$$

For v such that $v(F'_j) \geq 0.5$ and $v(G_j) \leq 1$ for all $j \in C$, the term $a'_j(2\sum_{i\in G_j} d(i,j)y'_i + 4\gamma_j(1-y'(G_j)))$ will upper bound j's assignment cost with respect to v via Lemma 14. When $v(G_j) = v(B_j) = 1$ for $j \in C_s$, j's assignment cost will be at most $a'_j(2\sum_{i\in B_j} d(i,j)v_i)$. Indeed $T(v)$ is an *overestimate* and we will use this in the next step.

We find an optimum half-integral solution $\hat{y}$ to $\mathcal{Q}$ with objective $T(v)$. It follows that $T(\hat{y}) \leq T(y')$. Now, we construct a half-integral solution $(\hat{x}, \hat{y})$ from $\hat{y} \in \mathcal{Q}$: For each cluster center $j \in C$, if $\hat{y}(G_j) = 1$, set $\sigma(j) = j$. Otherwise, set $\sigma(j) = \arg\min_{j'\in C:j'\neq j} d(j,j')$. Now, the *primary facility* for each cluster center is the closest facility $i \in \mathcal{F}$ such that $\hat{y}_i > 0$ (this will always be located in F'_j), is denoted by $i_1(j)$, and thus $\hat{x}_{i_1(j)j} = \hat{y}_{i_1(j)}$. A cluster center's *secondary* facility, denoted by $i_2(j)$, is the next option of facility for j to use, when it cannot be completely serviced by its primary facility. If $\hat{y}_{i_1(j)} = 1$, then j does not need a secondary facility, since $i_1(j)$ has been completely opened, and will remain completely opened. When $\hat{y}_{i_1(j)} < 1$ and $\hat{y}(G_j) = 1$, then set $i_2(j)$ to be the second closest partially opened facility to j (where $\hat{y}_{i_2(j)} > 0$). Otherwise, when $\hat{y}_{i_1(j)} < 1$ and $\hat{y}(G_j) < 1$, we now set $i_2(j) = i_1(\sigma(j))$ and $\hat{x}_{i_1(j)} = \hat{x}_{i_2(j)} = 1/2$. Note that if $j \in C_s$ then $\hat{y}(B_j) = 1$ which implies that j's primary and secondary facilities are both in B_j and $\sigma(j) = j$. The following two claims are easy to see.

▷ Claim 15. For all $j \in C$, $d(j, \sigma(j)) \leq 2\gamma_j$.

▷ Claim 16. For all $j \in C_s$, $\hat{y}(G_j) = 1$. If $\hat{y}(G_j) < 1$, it must be the case that $j \in C_b$.

By Fact 9(b), each j will have a unique primary facility that is at least partially opened in F'_j. For points $j \in C_s$, their secondary facility must be in B_j. However, for points in $j \in C_b$, $i_2(j)$ might not be in G_j or even F_j. As per Lemma 14, we know that j will be able to find a partially open facility to be serviced by that is within distance $3\gamma_j < 3\rho_j$. In the following lemma, we derive our bound for the cost of $(\hat{x}, \hat{y})$.

▶ **Lemma 17.** *$COST'(\hat{x}, \hat{y}) \leq T(\hat{y}) \leq T(y') \leq 4 \cdot COST'(x,y) \leq 8 \cdot COST(x,y)$.*

Before moving on to the final stage of the algorithm, we prove a few lemmas that will be relevant for our analysis of the radius dilation of the final solution. Lemma 18 allows us to relate the radius of cluster center j to that of a client k in the original instance that was relocated to j. We need such a lemma because even though we know that $\phi(j) = \min\{r_j, 2\bar{C}_j\}$ and $\phi(j) \leq \phi(k)$ for all $k \in D(j)$, we cannot assume that $r_j \leq r_k$.

▶ **Lemma 18.** *Suppose client $k \in \mathcal{C}$ is relocated to $j \in C$ after filtering ($k \in D(j)$). Then $\rho_j \leq 3r_k$.*

Proof. Note that $y(B(k, r_k)) \geq 1$ via the LP constraint. We have $d(j,k) \leq 2\lambda(k) \leq 2r_k$ since $\lambda(k) = \min\{r_k, 2\bar{C}_k\}$. Via triangle inequality, $B(k, r_k) \subseteq B(j, 3r_k)$. Thus $\rho_j \leq 3r_k$. ◀

Lemma 14 and Lemma 18 imply Lemma 19, which bounds the distance between relocated points and the primary and secondary facilities of the cluster center they are relocated to.

▶ **Lemma 19.** *Let $k \in \mathcal{C}$ and $k \in D(j)$ for a cluster center $j \in C$. Then, $d(j, i_1(j)) \leq \lambda(j) \leq \lambda(k) \leq r_k$. When $j \in C_s$, $d(j, i_2(j)) \leq \rho_j \leq 3r_k$. When $j \in C_b$, $d(j, i_2(j)) \leq d(j, \sigma(j)) + d(i_1(\sigma(j)), \sigma(j)) \leq 3\gamma_j \leq 3\rho_j \leq 9r_k$.*

▶ Remark 20. Notice that the $v(B_j) = 1$ constraint imposed for points $j \in C_s$ ultimately did not effect the cost analysis in Lemma 17. That is, we did not need to draw a distinction between points in C_s and points in C_b in order to obtain $COST'(\hat{x}, \hat{y}) \leq 4 \cdot COST'(x, y)$. The purpose of defining sets C_s and C_b and imposing an additional constraint for points in C_s is to ensure certain radius guarantees. In particular, Lemma 19 would not hold if the constraint $v(B_j) = 1$ for $j \in C_s$ was not enforced in $\mathcal{Q}$.

3.3 Stage 3: Converting to an Integral Solution

The procedure to convert the half-integral $(\hat{x}, \hat{y})$ to an integral solution involves setting up a matroid intersection instance consisting of the input matroid $\mathcal{M}$ and a partition matroid that is constructed using the primary and secondary facilities from $(\hat{x}, \hat{y})$ after another clustering step. The solution to this instance will be used to construct an integral solution $(\tilde{x}, \tilde{y})$ to $\mathscr{I}'$.

For $j \in C$ set $\hat{C}_j = (d(i_1(j), j) + d(j, \sigma(j)) + d(i_2(j), \sigma(j)))/2$. In cases where j has no secondary facility, let $i_2(j) = i_1(j)$. For each $j \in C$, define $S_j = \{i \mid \hat{x}_{ij} > 0\} = \{i_1(j), i_2(j)\}$. S_j has either one or two facilities. In addition, the following holds and will be relevant later.

▷ Claim 21. When $S_j \cap S_{j'} \neq \emptyset$, one of three cases can occur. (i) $S_j \cap S_{j'} = \{i_1(j), i_2(j)\}$, in which case $\sigma(j) = j'$ and $\sigma(j') = j$; (ii) $S_j \cap S_{j'} = \{i_1(j)\}$, and thus $\sigma(j') = j$ and $\sigma(j) \neq j'$ (a symmetric case occurs when switching j and j'); (iii) $S_j \cap S_{j'} = \{i_2(j)\}$ where $i_2(j) = i_2(j')$, hence $\sigma(j) = \sigma(j') = p$ and $p \neq j, j'$.

We construct a partition matroid $\mathcal{N}$ on ground set $\mathcal{F}$ via another clustering process to create a set $C' \subseteq C$. Repeat the following two steps until no clients in C are left to consider: (1) Pick $j \in C$ with the smallest $\hat{C}_j$ value and add j to the set C' then (2) remove every $j' \in C$ where $S_j \cap S_{j'} \neq \emptyset$, and have j be the center of j' (denoted by $\mathsf{ctr}(j') = j$). It is easy to see that the sets $S_j, j \in C'$ are mutually disjoint. Thus, a partition of $\mathcal{F}$ is induced by $\{S_j \mid j \in C'\}$, and the set $\mathcal{F} \setminus \cup_{j \in C'} S_j$. Set the capacity for each set of this partition to 1.

Now we consider the polytope that is intersection of the matroid polytopes of $\mathcal{M}$ and $\mathcal{N}$:

$$\mathcal{R} = \{z \in \mathbb{R}_+^{\mathcal{F}} \mid \forall S \subseteq \mathcal{F} : \ z(S) \leq r(S), \quad \forall j \in C' : \ z(S_j) \leq 1\}$$

The polytope $\mathcal{R}$ has integral extreme points via the classical result of Edmonds [12, 26].

The goal now is to figure out the set of facilities to open by optimizing a relevant objective over $\mathcal{R}$. First, we define a vector $\hat{y}' \in \mathbb{R}_+^{\mathcal{F}}$: if $i \in S_j$ for some $j \in C'$ we set $\hat{y}'_i = \hat{x}_{ij} \leq \hat{y}_i$, otherwise we set $\hat{y}'_i = \hat{y}_i$. Observe that $\hat{y}'$ is feasible for $\mathcal{R}$ and shows that $\mathcal{R}$ is not empty.

We now define a linear function $H(\cdot)$ over vectors in $\mathcal{R}$. We will optimize $H(\cdot)$ over $\mathcal{R}$ to obtain an integral extreme point $\tilde{y}$ and we will analyze its cost via $\hat{y}'$. For $z \in \mathbb{R}_+^{\mathcal{F}}$, define $H(z)$ as follows.

$$H(z) = \sum_i f_i z_i + \sum_{j \in C} L_j(z), \text{ where}$$

$$L_j(z) = \begin{cases} \sum_{i\in S_{\mathsf{ctr}(j)}} a'_j d(i,j) z_i & i_1(j) \in S_{\mathsf{ctr}(j)} \\ \sum_{i\in S_{\mathsf{ctr}(j)}} a'_j \Big(d(j,\sigma(j)) + d(\sigma(j),i)\Big) z_i & \\ \qquad +a'_j\Big(d(i_1(j),j) - d(j,\sigma(j)) - d(i_1(\sigma(j)),\sigma(j))\Big) z_{i_1(j)} & \text{otherwise} \end{cases}$$

Let $\tilde{y} \in \mathcal{R}$ be an integer extreme point such that $H(\tilde{y}) \leq H(\hat{y}')$. We use this to define an integral solution $(\tilde{x}, \tilde{y})$ to the modified instance by assigning each $j \in C'$ to the facility opened from S_j i.e. the facility $i \in S_j$ such that $\tilde{y}_i = 1$. For each $j' \in C \setminus C'$, assign j' to either $i_1(j')$ if it is open or the facility opened from $S_{\mathsf{ctr}(j')}$. $L_j(\tilde{y})$ serves as a proxy and upper bound for j's assignment cost. When $i_1(j) \notin S_{\mathsf{ctr}(j)}$, the second term of $L_j(\tilde{y})$ will adjust the distance j pays depending on whether $i_1(j)$ is opened or not. This adjustment is not needed when $i_1(j) \in S_j$ or when $i_1(j) \notin S_j$ is not opened, since in this case j must be assigned to the center opened from $S_{\mathsf{ctr}(j)}$. The following lemmas will show how the cost of $(\tilde{x}, \tilde{y})$ can be bounded by that of the half-integral solution $(\hat{x}, \hat{y})$ from the previous stage.

▶ **Lemma 22.** *$COST'(\tilde{x}, \tilde{y})$ is at most $H(\tilde{y}) \leq H(\hat{y}')$.*

▶ **Lemma 23.** *$H(\hat{y}') \leq T(\hat{y})$.*

▶ Remark 24. We do not lose a factor in the cost when converting the half-integral solution to an integral solution because the analysis in Stage 2 "overpays" for the half-integral solution. We follow the approach from [27].

3.4 Cost and Radius Analysis for PMatMed

Lemmas 10, 17, 22, and 23 together imply the following bound on the cost of $(\tilde{x}, \tilde{y})$ for instance $\mathscr{I}$ with respect to the cost of the LP solution (x, y).

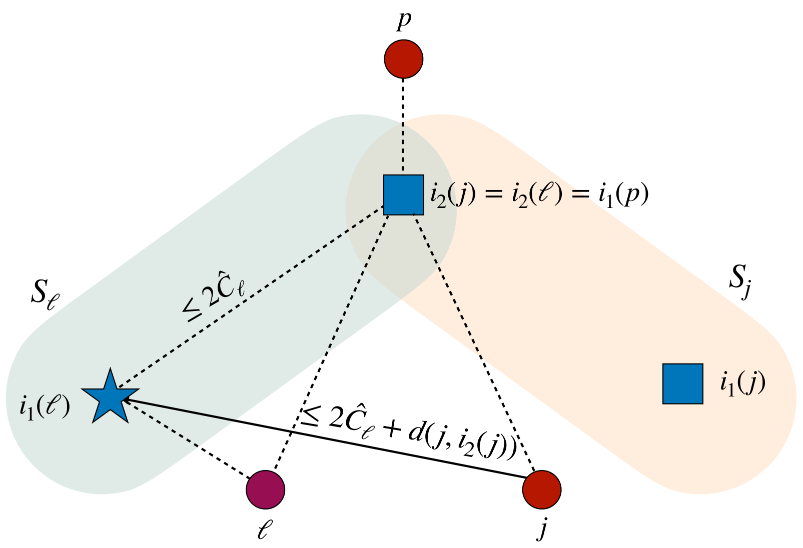
▶ **Theorem 25.** *$COST(\tilde{x}, \tilde{y}) \leq 12 \cdot COST(x, y)$.*

Proof. $COST'(\tilde{x}, \tilde{y})$ will be at most $T(\hat{y})$ (Lemmas 22 and 23), and $T(\hat{y})$ is at most $4 \cdot COST'(x, y) \leq 8 \cdot COST(x, y)$ (Lemma 17). Hence, $(\tilde{x}, \tilde{y})$ will give a solution to $\mathscr{I}'$ of cost at most $8 \cdot COST(x, y)$. Lemma 10 tells us that translating an integer solution for $\mathscr{I}'$ to an integer solution for $\mathscr{I}$ will incur an additional cost of at most $4 \cdot COST(x, y)$. All together, $COST(\tilde{x}, \tilde{y}) \leq COST'(\tilde{x}, \tilde{y}) + 4 \cdot COST(x, y) \leq 8 \cdot COST(x, y) + 4 \cdot COST(x, y) = 12 \cdot COST(x, y)$. ◀

To complete our analysis of the radius approximation factor, we must determine how far points will be made to travel once the final centers are chosen. In Lemma 19 we guaranteed that each cluster center j will not travel farther than $3\rho_j$ to reach its secondary facility. However, in this final stage, we are assigning some cluster centers to others, and cannot guarantee that their primary or secondary facility will be opened. We can still show that even if a cluster center j from C_s gets assigned to a cluster center ℓ from C_b (i.e. that $\mathsf{ctr}(j) = \ell$), j will still only travel a constant factor outside of ρ_j. Consequently, using Lemma 18 we can show that each client $k \in \mathcal{C}$ will travel only a constant factor times its radius value r_k.

▶ **Lemma 26.** *Let $k \in \mathcal{C}$, where $k \in D(j)$ for $j \in C$. The final solution will open a facility i such that $d(i, j) \leq 19 r_k$.*

Proof. There are several cases to consider but most of them are simple. We provide the analysis for the case that gives the 19 factor, and other notable cases.



p
$i_2(j) = i_2(\ell) = i_1(p)$
S_ℓ
S_j
$\leq 2\hat{C}_\ell$
$i_1(\ell)$
$i_1(j)$
$\leq 2\hat{C}_\ell + d(j, i_2(j))$
ℓ
j

Figure 2 The farthest a point $j \in C$ will be from an opened center occurs when $\mathsf{ctr}(j) = \ell$, $\sigma(j) = \sigma(\ell) = p$, and $i_1(\ell)$ is opened.

If $j \in C'$, then either $i_1(j)$ or $i_2(j)$ will be opened in the final solution. Lemma 19 indicates that j will be assigned to a center that is at most $9r_k$ away. If $j \notin C'$, it must be the case that $\mathsf{ctr}(j) = \ell$ where $S_\ell \cap S_j \neq \emptyset$, and $\hat{C}_\ell \leq \hat{C}_j$. We claim that $\hat{C}_j \leq \frac{1}{2}(d(i_1(j), j) + d(i_2(j), j)) \leq \frac{1}{2}(r_k + 9r_k) = 5r_k$ where we used Lemma 19 to bound $d(i_1(j), j)$ and $d(i_2(j), j)$).

The farthest that j would have to travel occurs when j and ℓ share secondary facilities, and ℓ's primary facility is opened (see Figure 2). More precisely, this is when $S_\ell \cap S_j = \{i_2(\ell)\} = \{i_2(j)\}$ and $\sigma(\ell) = \sigma(j) = p$ where p is not j or ℓ, and $i_1(\ell)$ is opened at the end of Stage 3. In this case, we have

$$\begin{aligned} d(i_1(\ell), j) &\leq d(i_1(\ell), i_2(\ell)) + d(i_2(\ell), j) \leq d(i_1(\ell), \ell) + d(i_2(\ell), \ell) + d(i_2(j), j) \\ &= 2\hat{C}_\ell + d(i_2(j), j) \leq 2\hat{C}_j + d(i_2(j), j) \leq 10r_k + 9r_k = 19r_k. \end{aligned}$$ ◀

▶ Remark 27. Notice that in the last step of our proof for Lemma 26, we bound the distance $d(i_1(\ell), j)$ by $d(i_1, j) + 2d(i_2(j), j)$, where $d(i_2(j), j) \leq 9r_k$. Hence, the majority of the distance that j is traveling, according to our analysis, is due to the distance between j and its secondary facility. If we could guarantee that cluster center j has a reasonably close secondary facility, we could improve this radius factor. We will explore this further in Section 4.3.

Using Lemmas 11 and 26, we have the following radius bound for the output of our algorithm.

▶ **Theorem 28.** *Let S be the output of the aforementioned approximation algorithm. For all $k \in \mathcal{C}$, $d(k, S) \leq 21r_k$.*

Theorems 25 and 28 together give us Theorem 1.

4 Exploring Cost and Radius Trade-offs

In this section, we will outline the remaining results for PMatMed and UniPMatMed. The algorithms for these results are nearly identical to the one in the previous section. The only change is in setting ϕ and λ (in the first step of Algorithm 2). These results suggest that filtering plays a non-trivial role in the cost and radius trade-offs, and that further improvements may be possible if one finds effective ways to filter points.

We begin with the $(9, 8)$-approximate solution for UniPMatMed. As we discussed in the introduction, having uniform radii allows us to rely only on $\bar{C}_j$ values obtained from the LP solution. We will then discuss how we can extend this approach to the non-uniform case to obtain a $(36, 8)$-approximate solution for PMatMed. Finally, we show how to further tighten the radius guarantee for UniPMatMed.

4.1 $(9, 8)$-approximation for UniPMatMed

First, observe that instances of UniPMatMed can be written as instances of PMatMed, where each $r_j := L$ for all $j \in \mathcal{C}$. As such, our algorithm to obtain a $(9, 8)$-approximation for UniPMatMed is the following: Run Algorithm 2 on UniPMatMed instance $\mathscr{J}$, but in Line 0, set $\phi(j) := \bar{C}_j$ and $\lambda(j) := \min\{r_j, 2\bar{C}_j\}$.

Notice that these assignments of ϕ and λ satisfy compatibility (Definition 7) only when r_j's are uniform. We explain this in more detail in Appendix B, and defer the analysis and proofs for this result to that section.

4.2 $(36, 8)$-approximation for PMatMed

Building off the result for UniPMatMed, which is able to optimize for the cost by changing $\phi(j)$, we show how to obtain a $(36, 8)$-approximate solution for PMatMed. To do so, we will keep the same setting for $\phi(j) := \bar{C}_j$ as UniPMatMed, but will instead choose a λ that is compatible for non-uniform radii. Our algorithm is as follows: Run Algorithm 2 on PMatMed instance $\mathscr{I}$, but in Line 0, set $\phi(j) := \bar{C}_j$ and $\lambda(j) := 2\bar{C}_j$.

Clearly, ϕ and λ are compatible. Furthermore, notice that this setting of ϕ is identical to that of our algorithm of UniPMatMed. Since cost analysis for the filtering stage only uses ϕ (and not λ), our analysis for cost will be identical to that of our analysis of UniPMatMed, therefore we will have a cost guarantee of 8.

To analyze the radius guarantee, notice that while λ does not explicitly use radius values, PMatMed LP has a constraint that ensures $\forall j \in \mathcal{C}$ $\bar{C}_j \leq r_j$. Therefore, $\lambda(j) = 2\bar{C}_j \leq 2r_j$. Our initial setting of λ ($\lambda(j) := \min\{r_j, 2\bar{C}_j\}$) made it so $\lambda(j) \leq r_j$. Hence, the new setting of λ will worsen the radius guarantee of the final solution. The analysis for this result can be found in Appendix C.

4.3 Tighter radius guarantee for UniPMatMed

In the previous result for UniPMatMed, we set $\phi(j) := \bar{C}_j$ and $\lambda := \min\{L, 2\bar{C}_j\}$. In the second result for PMatMed, we showed how setting $\lambda(j) := 2L$ would increase the radius guarantee. Thus, in order to tighten the radius guarantee for UniPMatMed, we will again change $\lambda(j)$, but this time in a way that will allow points to have tighter radius bounds.

To build up to our new setting for λ, we first partition points in the original client set into points that have relatively small, or *tiny* $\bar{C}_j$ values, $\mathcal{C}_T = \{j \in \mathcal{C} \mid \bar{C}_j \leq \epsilon L\}$ and points that have *large* $\bar{C}_j$ values, $\mathcal{C}_L = \{j \in \mathcal{C} \mid \bar{C}_j > \epsilon L\}$. Now, our algorithm is as follows: Run Algorithm 2 on PMatMed instance $\mathscr{I}$, but in Line 0, set $\phi(j) := \bar{C}_j$ and $\lambda(j)$ as defined below.

$$\lambda(j) = \begin{cases} 2\bar{C}_j & j \in \mathcal{C}_T \\ L & j \in \mathcal{C}_L \end{cases}$$

Note that ϕ and λ will satisfy compatibility. Furthermore, this setting of λ improves the radius bound of Section 4.1 since it forces cluster centers from $\mathcal{C}_L$ to open their own primary and secondary facilities (i.e. they will force $\sigma(j) = j$ for cluster centers j that are from $\mathcal{C}_L$). Any point j such that $\sigma(j) \neq j$ will be from $\mathcal{C}_T$, and furthermore $\sigma(j) \in \mathcal{C}_T$ for all of these points. Therefore, we are decreasing the distance between any point and its secondary facility, for both points in $\mathcal{C}_L$ and $\mathcal{C}_T$. As noted in Remark 27, this will help reduce the radius guarantee.

To achieve the $(5+8\epsilon, 4+2/\epsilon)$-approximation result, we also make a change to Section 2.4 of Filter. Details about this change, as well as the full analysis for this result can be found in the full version of this paper.

A Omitted Proofs

Proof of Lemma 10. We first prove that $COST'(x,y) \leq 2 \cdot COST(x,y)$. The fractional facility opening cost, $\sum_i f_i y_i$ is identical in both. The difference in the client connection cost is because the demands of clients in $\mathcal{C} \setminus C$ are relocated. Consider a client $k \in \mathcal{C} \setminus C$ that is relocated to its cluster center $j \in C$ (thus $k \in D(j)$). In $COST(x,y)$ client k pays $a_k \bar{C}_k$. In $COST'(x,y)$, the demand of k is moved to j and pays $a_k \bar{C}_j$. Thus, it suffices to prove that $\bar{C}_j \leq 2\bar{C}_k$. From Fact 9, $\phi(j) \leq \phi(k) \leq 2\bar{C}_k$. LP constraints 1d and 1c of the LP for $\mathscr{I}$ ensures that $\bar{C}_j \leq r_j$ for all $j \in \mathcal{C}$. Hence, if $\bar{C}_j > 2\bar{C}_k$ we would have $\phi(j) = \min\{r_j, 2\bar{C}_j\} > 2\bar{C}_k$ which would be a contradiction to $\phi(j) \leq \phi(k)$. This shows that $\bar{C}_j \leq 2\bar{C}_k$.

Now we consider the second part. From Fact 9, $d(j,k) \leq 2\lambda(k) \leq 2(2 \cdot \bar{C}_k)$. Suppose the cost of an integer solution to $\mathscr{I}'$ is α. We keep the same facilities for $\mathscr{I}$ and account for the increase in connection cost when considering the original client locations. Consider a client $k \in \mathcal{C} \setminus C$ that is relocated to center $j \in C$. If j connects to i in the integer solution for $\mathscr{I}'$, k can connect to i in the solution to $\mathscr{I}$, and its per unit connection cost increases by at most $d(j,k) \leq 4\bar{C}_k$. Thus the total increase in the connection cost when comparing to α is upper bounded by $\sum_{j \in C} \sum_{k \in D(j)} a_k \cdot 4\bar{C}_k \leq 4 \cdot COST(x,y)$. ◀

Proof of Lemma 13. Suppose $\mathcal{Q}$ is non-empty and v^* is any extreme point. Then v^* is the unique solution of a linear system $Av = b$ where A is a subset of the inequalities of $\mathcal{Q}$ with A having full row and column rank (in particular the rows of A are linearly independent vectors). A can be partitioned into A_1 and A_2 where A_1 is a subset of the inequalities coming from the matroid $\mathcal{M}$ (of the form $v(S) = r_{\mathcal{M}}(S)$), while A_2 is a subset of the remaining inequalities. Via the submodularity of the matroid rank function, it is known that one can choose A_1 such that the rows of A_1 correspond to a laminar family of subsets of $\mathcal{F}$ [26]. We observe that the non-matroidal system of inequalities in $\mathcal{Q}$ correspond to a laminar family of sets over $\mathcal{F}$: (a) the sets $G_j, j \in C$ are disjoint and $F'_j \subseteq G_j$ for each j and (b) for $j \in C_s$, we have $B_j \subseteq G_j$. See Figure 1.

Thus the rows of the matrix of A come from two laminar families of sets over $\mathcal{F}$, and it is known that such a matrix is totally uniodular [26]. Thus $v^* = A^{-1}b$ where A^{-1} is an integer matrix, and b is half-integral which implies that v^* is half-integral. ◀

Proof of Lemma 17. We first show that $T(y') \leq 4 \cdot COST'(x,y)$ (we already have $T(\hat{y}) \leq T(y')$). We know that $COST'(x,y)$ can be expressed as $\sum_i f_i y_i + \sum_j a'_j \cdot \bar{C}_j$. For any $j \in C$, observe that $\bar{C}_j = \sum_{i \in G_j} d(i,j)x_{ij} + \sum_{i \notin G_j} d(i,j)x_{ij}$ and hence $\bar{C}_j \geq \sum_{i \in G_j} d(i,j)x_{ij} + \gamma_j \sum_{i \notin G_j} x_{ij}$.

$$
\begin{aligned}
T(y') &\leq \sum_i f_i y_i + \sum_j a'_j \Big(2 \sum_{i \in G_j} d(i,j)x_{ij} + 4\gamma_j \Big(1 - \sum_{i \in G_j} x_{ij}\Big)\Big) \\
&\leq \sum_i f_i y_i + 4 \sum_j a'_j \cdot \bar{C}_j \leq 4 \cdot COST'(x,y)
\end{aligned}
$$

Next, we upper bound $COST'(\hat{x},\hat{y})$ by $T(\hat{y})$. It suffices to focus on the assignment cost. Consider $j \in C_s$. Its primary and secondary facilities are in B_j and it is easy to see that its connection cost is precisely $\sum_{i \in B_j} d(i,j)\hat{x}_{ij}$. Now consider $j \in C_b$. Recall that when $\hat{y}(G_j) = 1$, the total assignment cost of j is at most $\sum_{i \in G_j} d(i,j)\hat{y}_i$. When $\hat{y}(G_j) < 1$, j connects to primary facility in F'_j and a secondary facility. The second nearest facility will not be in its G_j ball, i.e. $i_2(j) \notin F_j$. Let $j' \neq j$ be client that defines γ_j. Via Lemma 14, we have $d(i_2(j), j) \leq 3\gamma_j$. Assuming this, when $\hat{y}(G_j) < 1$, the total assignment cost of j is at most $\sum_{i \in G_j} d(i,j)\hat{y}_i + 3\gamma_j(1 - \hat{y}(G_j))$. Based on these assignment cost upper bounds we see that $COST'(\hat{x},\hat{y}) \leq T(\hat{y})$.

Now we prove Lemma 14. From Fact 9 we have $2\max\{\lambda(j), \lambda(j')\} \leq d(j,j')$. Via triangle inequality $d(j,j') \leq d(j,i) + d(i,j') \leq 2\gamma_j$. Thus $2\lambda(j') \leq 2\gamma_j$ which implies that $\lambda(j') \leq \gamma_j$. Recall that $F'_{j'}$, from its definition, is contained in a ball of radius $\lambda(j')$ around j'. Thus, for any facility $i' \in F'_{j'}$, $d(i',j') \leq \lambda(j') \leq \gamma_j$, Therefore, $d(i',j) \leq d(j,j') + d(j',i') \leq 3\gamma_j$. This gives us the lemma.

Finally, using Lemma 10, we know that $COST'(x,y) \leq 2 \cdot COST(x,y)$, hence $4 \cdot COST'(x,y) \leq 8 \cdot COST(x,y)$. ◀

Proof of Lemma 22. Since the facility costs of $(\tilde{x}, \tilde{y})$ will remain as they are in $H(\tilde{y})$, it suffices to show that for all $j \in C$, the assignment cost of j is at most $L_j(\tilde{y})$. When $j \in C'$, $\mathsf{ctr}(j) = j$ and the assignment cost of j will be exactly $L_j(\tilde{y})$.

Now we consider two possibilities for $j' \in C \setminus C'$. Let $\mathsf{ctr}(j') = j$. If j' gets assigned to a center from S_j, there are two possible cases for the value of $L_{j'}(\tilde{y})$. If $i_1(j') \in S_j$ then the assignment cost for j' is exactly $L_{j'}(\tilde{y})$. Otherwise, $i_1(j') \notin S_j$ and $\tilde{y}_{i_1(j')} = 0$. In this case $L_{j'}(\tilde{y}) = \sum_{i \in S_j} a'_{j'}(d(j', \sigma(j)) + d(i, \sigma(j)))\tilde{y}_i$. By triangle inequality, $d(i, j') \leq d(i, \sigma(j')) + d(j, \sigma(j'))$, therefore the assignment cost of j' is at most $L_{j'}(\tilde{y})$.

If j' is assigned to a center that is not from S_j, it is because $\tilde{y}_{i_1(j')} = 1$ and $i_1(j') \notin S_j$. Here, the assignment cost of j' is $a'_{j'}d(i_1(j'), j')$. Let $i \in S_j$ be such that $\tilde{y}_i = 1$. The value of $L_{j'}(\tilde{y})$ is therefore

$$\begin{aligned}L_{j'}(\tilde{y}) &= a'_j\Big(d(j', \sigma(j')) + d(i, \sigma(j')) + d(i_1(j'), j) - d(j', \sigma(j')) - d(i_1(\sigma(j)), \sigma(j))\Big)\\ &= a'_j\Big(d(i, \sigma(j')) + d(i, i_1(j')) - d(i_1(\sigma(j)), \sigma(j))\Big)\end{aligned}$$

Since $i \in S_j$ cannot be closer to $\sigma(j')$ than the primary facility of $\sigma(j')$, we know that $d(i_1(\sigma(j)), \sigma(j)) \leq d(i, \sigma(j'))$. Thus, the assignment cost of j' is at most $L_{j'}(\tilde{y})$. ◀

Proof of Lemma 23. For notational ease, let $Q_j(\hat{y}) := 2\sum_{i \in G_j} d(i,j)\hat{y}_i + 4\gamma_j(1 - \sum_{i \in G_j} \hat{y}_i)$. Thus, $T(\hat{y}) = \sum_i f_i \hat{y}_i + \sum_{j \in C} a'_j Q_j(\hat{y})$. As in the proof of the previous lemma, we focus on just the assignment costs of clients, since clearly $\sum_i f_i \hat{y}'_i \leq \sum_i f_i \hat{y}_i$. Specifically, we will show that $L_j(\hat{y}') \leq a'_j Q_j(\hat{y})$ for all $j \in C$. For the remainder of the proof, we omit the term a'_j from both sides of this inequality, since it remains fixed throughout our analysis.

First, we show $\hat{C}_j \leq Q_j(\hat{y})$ for all $j \in C$. Recall that j has no secondary facility when $\hat{y}_{i_1(j)} = 1$, in which case $i_2(j) = i_1(j)$. When $\hat{y}(G_j) = 1$, $\sigma(j) = j$ and the primary and secondary facilities of j are the only facilities in G_j where $\hat{y}_i > 0$. Since $\hat{y}$ is half integral, we get $\hat{C}_j = (d(i_1(j), j) + d(i_2(j), j))/2 = \sum_{i \in G_j} d(i,j)\hat{y}_i \leq Q_j(\hat{y})$. When $\hat{y}(G_j) = 1/2$, $\sigma(j) = \ell \neq j$ and $i_2(j) = i_1(\ell)$. In this case $\hat{C}_j = (d(i_1(j), j) + d(j, \ell) + d(i_1(\ell), \ell))/2$. Using Claim 15 and definitions, $d(j, \ell) + d(\ell, i_1(\ell)) \leq 3\gamma_j$. Therefore $\hat{C}_j \leq \sum_{i \in G_j} d(i,j)\hat{y}_i + 3\gamma_j(1 - \hat{y}(G_j)) \leq Q_j(\hat{y})$. To prove $L_j(\hat{y}') \leq a'_j Q_j(\hat{y})$ we consider several cases.

1. $j \in C'$: we have $\mathsf{ctr}(j) = j$ and $i_1(j) \in S_j$.

$$\begin{aligned}L_j(\hat{y}') = \sum_{i \in S_j} d(i,j)\hat{y}'_i \leq \sum_{i \in S_j} d(i,j)\hat{y}_i &= \frac{1}{2}(\Big(d(i_1(j), j) + d(i_2(j), j)\Big)\\ &\leq \frac{1}{2}\Big(d(i_1(j), j) + d(i_1(j), \sigma(j)) + d(i_2(j), \sigma(j))\Big) \quad \text{(via triangle ineq.)}\\ &= \hat{C}_j \leq Q_j(\hat{y}).\end{aligned}$$

2. $j' \in C \setminus C'$. Let $\mathsf{ctr}(j') = j$. We have $\hat{C}_j \leq \hat{C}_{j'}$.
   a. $i_1(j') \in S_j$. Then $i_2(j) = i_1(j')$ hence $\sigma(j) = j'$.

$$\begin{aligned}L_{j'}(\hat{y}') &= \frac{1}{2}(d(i_1(j), j') + d(i_2(j), j'))\\ &\leq \frac{1}{2}(d(i_1(j), j) + d(j, j') + d(i_2(j), j')) \quad \text{(via triangle ineq.)}\\ &= \hat{C}_j \leq \hat{C}_{j'} \leq Q_{j'}(\hat{y}).\end{aligned}$$

   b. $i_1(j') \notin S_j$: Then $S_j \cap S_{j'}$ is either $\{i_1(j)\}$ or $\{i_2(j)\}$ (Claim 21). In both cases, $\sigma(j') = \ell \neq j'$ and therefore $\hat{y}(G_{j'}) = \hat{y}_{i_1(j')} = 1/2$. Hence

$$L_{j'}(\hat{y}') = \frac{1}{2} \cdot \Big(2d(j', \ell) + d(i_1(j), \ell) + d(i_2(j), \ell) + d(i_1(j'), j') - d(j', \ell) - d(i_1(\ell), \ell)\Big)$$

i. When $S_j \cap S_{j'} = \{i_1(j)\}$, $i_1(j) = i_2(j')$ thus $\ell = j$. Using the fact that $d(i_2(j), j) \leq 2\hat{C}_j - d(i_1(j), j)$, we have

$$\begin{aligned} L_{j'}(\hat{y}') &= \frac{1}{2}\Big(2d(j', j) + d(i_1(j), j) + d(i_2(j), j) + d(i_1(j'), j') - d(j', j) - d(i_1(j), j)\Big) \\ &= \frac{1}{2}\Big(d(j, j') + d(i_2(j), j) + d(i_1(j'), j')\Big) \\ &\leq \frac{1}{2}\Big(d(j, j') + 2\hat{C}_j - d(i_1(j), j) + d(i_1(j'), j')\Big) \\ &\leq \frac{1}{2}\Big(d(j, j') + 2\hat{C}_{j'} - d(i_1(j), j) + d(i_1(j'), j')\Big) \\ &= d(j, j') + d(i_1(j'), j'). \end{aligned}$$

ii. When $S_j \cap S_{j'} = \{i_2(j)\}$, $i_2(j) = i_2(j') = i_1(\ell)$ and so $\ell \neq j, j'$ and $\sigma(j) = \sigma(j') = \ell$. Since $2\hat{C}_j \leq 2\hat{C}_{j'}$, $d(i_1(j), j) + d(j, \ell) \leq d(i_1(j'), j') + d(j', \ell)$. Therefore,

$$\begin{aligned} L_{j'}(\hat{y}') &= \frac{1}{2}\Big(d(j', \ell) + d(i_1(j), \ell) + d(i_1(j'), j')\Big) \\ &\leq \frac{1}{2}\Big(d(j', \ell) + d(i_1(j), j) + d(j, \ell) + d(i_1(j'), j')\Big) \quad \text{(via triangle ineq.)} \\ &\leq \frac{1}{2}\Big(d(j', \ell) + d(i_1(j'), j') + d(j', \ell) + d(i_1(j'), j')\Big) \\ &\leq d(i_1(j'), j') + d(j', \ell). \end{aligned}$$

Thus, in both cases we have

$$\begin{aligned} L_{j'}(\hat{y}') &\leq d(i_1(j'), j') + d(j', \ell) \\ &\leq d(i_1(j'), j') + 2\gamma_{j'} \quad \text{(via Claim 15)} \\ &\leq 2\sum_{i \in G_{j'}} d(i, j')\hat{y}_i + 4\gamma_{j'}(1 - \sum_{i \in G_{j'}} \hat{y}_i) = Q_{j'}(\hat{y}) \quad \text{(since } \hat{y}(G_{j'}) = 1/2). \end{aligned}$$

This finishes the case analysis and the proof. ◀

B Uniform Priority Matroid Median

The UniPMatMed problem is a special case of the PMatMed problem in which all clients have the same radius value L. An instance $\mathscr{I}$ of the UniPMatMed problem can be described using the tuple $(\mathcal{F}, \mathcal{C}, d, \mathbf{f}, L, \mathbf{a}, \mathcal{M})$. We will abuse notation and interpret L as not only a single radius value, but also as a vector from $\mathbb{R}^{\mathcal{C}}$ where each entry is L; this will allow us to use our algorithm for PMatMed on instances of UniPMatMed.

In this section we show how we can take advantage of the uniform radius requirement to improve upon the $(21, 12)$-approximation for PMatMed. In particular, since we have $\bar{C}_j \leq L$ for all $j \in \mathcal{C}$, we can pick points in filtering in order of their $\bar{C}_j$ values and set $\phi(j) := \bar{C}_j$ for Filter. This setting of ϕ will be compatible with the setting of $\lambda(j) := \min\{L, 2\bar{C}_j\}$. Furthermore, Filter with these ϕ and λ functions is identical to the filtering step in Kamiyama's algorithm [18]. Notice that these same settings for PMatMed, i.e. $\phi(j) := \bar{C}_j$ and $\lambda := \min\{r_j, 2\bar{C}_j\}$, are not necessarily compatible. The uniform radius constraint also help us to derive tighter bounds throughout the radius analysis of the PMatMed algorithm.

Using the above observations, our algorithm for UniPMatMed is the following: Run Algorithm 2 on UniPMatMed instance $\mathscr{I}$, but in Line 0, set $\phi(j) := \bar{C}_j$ and $\lambda(j) := \min\{r_j, 2\bar{C}_j\}$. Thus, the only change in the algorithm is the filtering step. We argue that this algorithm yields a better approximation algorithm for UniPMatMed.

▶ **Theorem 29** (Theorem 2a). *There is a $(9, 8)$-approximation algorithm for UniPMatMed.*

B.1 Cost and Radius Analysis for UniPMatMed

Since our algorithm for UniPMatMed only slightly differs from the one in Section 3, we omit several proofs that would be identical. The only change to the cost analysis occurs in the filtering stage (Section 3.1). In particular, we can derive a tighter bound than in Lemma 10. This ultimately leads to the improved cost bound, shown in Theorem 31.

▶ **Lemma 30.** *The following is true of $\mathscr{J}'$. (a) $COST'(x,y) \leq COST(x,y)$. (b) Any integer solution (x',y') for $\mathscr{J}'$ can be converted to an integer solution for $\mathscr{J}$ that incurs an additional cost of at most $4 \cdot COST(x,y)$.*

Recall that $(\tilde{x},\tilde{y})$ is the final integeral solution output by the algorithm.

▶ **Theorem 31.** *$COST(\tilde{x},\tilde{y}) \leq 8 \cdot COST(x,y)$.*

We now analyze the radius guarantee and outline the changes in the analysis. First, we have the following lemma in place of Lemma 11 which also follows directly from Fact 9.

▶ **Lemma 32.** *Let $k \in \mathcal{C}$ be assigned to $j \in C$ after using the Filtering procedure (i.e. $k \in D(j)$). Then, $d(j,k) \leq 2\lambda(k) \leq 2L$.*

Since all radius values are equal, we do not need Lemma 18 to relate the radius values of different clients. We do need to update Lemma 19 and Lemma 26. These updated lemmas are given below.

▶ **Lemma 33.** *Let $k \in \mathcal{C}$ and $k \in D(j)$ for a cluster center $j \in C$. Then (a) $d(j,i_1(j)) \leq \lambda(j) \leq \lambda(k) \leq L$ and (b) when $j \in C_s$ $d(j,i_2(j)) \leq \rho_j \leq L$ and (c) when $j \in C_b$ $d(j,i_2(j)) \leq d(j,\sigma(j)) + d(i_1(\sigma(j)),\sigma(j)) \leq 3\gamma_j \leq 3\rho_j \leq 3L$.*

The reasoning for the preceding lemma is the same as Lemma 19, except L is used in place of r_j and r_k values. This results in the following update to Lemma 26

▶ **Lemma 34.** *Let $j \in C$. The final solution will open a facility i such that $d(i,j) \leq 7L$.*

Lemma 32 and Lemma 34 give us the following improved radius bound for the solution output by the algorithm. This, along with Theorem 31, proves Theorem 29.

▶ **Theorem 35.** *Let S be the output of the aforementioned approximation algorithm for UniPMatMed. For all $k \in \mathcal{C}$, $d(k,S) \leq 9L$.*

C Analysis for $(36,8)$-approximation for PMatMed

In this section we show how to obtain a $(36,8)$-approximate solution for PMatMed. Our algorithm is as follows: Run Algorithm 2 on PMatMed instance $\mathscr{I}$, but in Line 0, set $\phi(j) := \bar{C}_j$ and $\lambda(j) := 2\bar{C}_j$. Clearly, ϕ and λ are compatible. Furthermore, notice that this setting of ϕ is identical to that of our algorithm of UniPMatMed. Since cost analysis for the filtering stage of UniPMatMed only uses ϕ (and not λ), Lemma 30 and Theorem 31 hold in this case as well. This is the reason why the cost factor guarantee will be 8.

Though our setting for λ does not use radius values, from the PMatMed LP constraint, $\forall j \in \mathcal{C}$, $\bar{C}_j \leq r_j$ holds. Therefore, $\lambda(j) = 2\bar{C}_j \leq 2r_j$. Previous settings of λ (where $\lambda(j) := \min\{r_j, 2\bar{C}_j\}$) made it so $\lambda(j) \leq r_j$. Thus the new setting of λ can lead to a weakening of the radius guarantee. First, we formalize the above observation in Fact 36 which we will use to update the radius analysis of Section 3.

▶ **Fact 36.** *The following holds after* Filter *when $\phi(j) := \bar{C}_j$ and $\lambda(j) := 2\bar{C}_j$: (a) $\bar{C}_j \leq r_j$, and hence $\lambda(j) = 2\bar{C}_j \leq 2r_j$, (b) $\forall k \in D(j) \;\; d(j,k) \leq 2\lambda(k) \leq 4C_k \leq 4r_k$.*

The following updated lemmas now hold in place of their counterparts from Section 3. The proofs for these results are identical to those from Section 3 up to certain bounds that change due to the above fact and the subsequent lemmas. These changes occur whenever definitions of ϕ and λ are used in the analysis, and the following lemmas will be invoked in place of their counterparts from Section 3.

▶ **Lemma 37** (Updated Lemma 11). *Let $k \in \mathcal{C}$ be assigned to $j \in C$ after using the Filtering procedure (i.e. $k \in D(j)$). Then, $d(j,k) \leq 2\lambda(k) \leq 4r_k$.*

▶ **Lemma 38** (Updated Lemma 18). *For some $k \in \mathcal{C}$, where $k \in D(j)$, $\rho_j \leq 5r_k$.*

▶ **Lemma 39** (Updated Lemma 19). *Let $k \in \mathcal{C}$ where $k \in D(j)$ for $j \in C$. (a) $d(j, i_1(j)) \leq \lambda(j) \leq \lambda(k) \leq 2r_k$, (b) when $j \in C_s$, $d(j, i_2(j)) \leq \rho_j \leq 5r_k$, and (c) when $j \in C_b$, $d(j, i_2(j)) \leq d(j, \sigma(j)) + d(i_1(\sigma(j)), \sigma(j)) \leq 3\gamma_j \leq 3\rho_j \leq 15r_k$.*

▶ **Lemma 40** (Updated Lemma 26). *Let $k \in \mathcal{C}$, where $k \in D(j)$ for $j \in C$. The final solution will open a facility i such that $d(i,j) \leq 32r_k$.*

Finally, using Lemma 37 Lemma 40, along with Theorem 31, we get the following result.

▶ **Theorem 41** (Theorem 1(b)). *There is a $(36, 8)$-approximation algorithm for Priority Matroid Median.*

Approximation Algorithms for Directed Weighted Spanners

Abstract

In the *pairwise weighted spanner* problem, the input consists of a weighted directed graph on n vertices, where each edge is assigned both a *cost* and a *length*. Furthermore, we are given k terminal vertex pairs and a distance constraint for each pair. The goal is to find a minimum-cost subgraph in which the distance constraints are satisfied.

We study the weighted spanner problem, in which the edges have positive *integral* lengths of magnitudes that are *polynomial* in n, while the costs are *arbitrary* non-negative rational numbers. Our results include the following in the classical offline setting:

- An $\tilde{O}(n^{4/5+\varepsilon})$-approximation algorithm for the weighted pairwise spanner problem. When the edges have unit costs and lengths, the best previous algorithm gives an $\tilde{O}(n^{3/5+\varepsilon})$-approximation, due to Chlamtáč, Dinitz, Kortsarz, and Laekhanukit (Transactions on Algorithms, 2020).
- An $\tilde{O}(n^{1/2+\varepsilon})$-approximation algorithm for the weighted spanner problem when the terminal pairs consist of *all* vertex pairs and the distances must be preserved *exactly*. When the edges have unit costs and arbitrary positive lengths, the best previous algorithm gives an $\tilde{O}(n^{1/2})$-approximation for the all-pair spanner problem, due to Berman, Bhattacharyya, Makarychev, Raskhodnikova, and Yaroslavtsev (Information and Computation, 2013).

We also prove the first results for the weighted spanners in the *online* setting. Our results include the following:

- An $\tilde{O}(k^{1/2+\varepsilon})$-competitive algorithm for the online weighted pairwise spanner problem. The state-of-the-art results are an $\tilde{O}(n^{4/5})$-competitive algorithm when edges have unit costs and arbitrary positive lengths, and a $\min\{\tilde{O}(k^{1/2+\varepsilon}), \tilde{O}(n^{2/3+\varepsilon})\}$-competitive algorithm when edges have unit costs and lengths, due to Grigorescu, Lin, and Quanrud (APPROX, 2021).
- An $\tilde{O}(k^{\varepsilon})$-competitive algorithm for the online weighted single-source (or single-sink) spanner problem. Without distance constraints, this problem is equivalent to the online directed Steiner tree problem. The best previous algorithm for online directed Steiner trees is an $\tilde{O}(k^{\varepsilon})$-competitive algorithm, due to Chakrabarty, Ene, Krishnaswamy, and Panigrahi (SICOMP, 2018).

Our online results also imply efficient approximation algorithms for the corresponding offline problems. To the best of our knowledge, these are the first approximation (online) polynomial-time algorithms with sublinear approximation (competitive) ratios for the weighted spanner problems.

1 Introduction

We study a multi-commodity problem in directed graphs, which we call the *pairwise weighted spanner* problem. In this problem, we are given a directed simple graph $G = (V, E)$ with n vertices, and a set of k terminal pairs $D \subseteq V \times V$. Each edge $e \in E$ is associated with a *cost* given by the function $c : E \to \mathbb{R}_{\geq 0}$ and a *length* given by the function $\ell : E \to \mathbb{R}_{\geq 0}$. We say that the graph has unit lengths if $\ell(e) = 1$ (respectively, unit costs if $c(e) = 1$) for all $e \in E$. Each pair $(s, t) \in D$ is associated with a target distance given by a function $Dist : D \to \mathbb{R}_{\geq 0}$. Let $H = (V(H), E(H))$ be a subgraph of G and $d_H(s, t)$ denote the *distance* from s to t in H, i.e., the total length of a shortest $s \rightsquigarrow t$ path of edges in $E(H)$. The cost of H is $\sum_{e \in E(H)} c(e)$. The goal is to find a *minimum-cost subgraph* H of G such that the distance from s to t is at most $Dist(s, t)$, namely, $d_H(s, t) \leq Dist(s, t)$ for each $(s, t) \in D$.

The pairwise weighted spanner problem captures many network connectivity problems and is motivated by common scenarios, such as constructing an electricity or an internet network, which requires not only cost minimization but also a delivery time tolerance for the demands. Each edge is thus associated with two "weights" in this setting: the cost and the delivery time. This general formulation has been studied under many variants: when the edges have general lengths and unit costs, one may ask for sparse subgraphs that *exactly* maintain pairwise distances, i.e., *distance preservers*, or for sparse subgraphs that *approximately* maintain pairwise distances, i.e., *spanners*; when the edges have general costs and unit lengths, one may ask for cheap subgraphs that maintain pairwise connectivity, i.e., *Steiner forests*. Spanners and distance preservers are well-studied objects, which have found applicability in domains such as distributed computation [7,49], data structures [4,55], routing schemes [20,47,50,52], approximate shortest paths [8,24,25], distance oracles [8,17,48], and property testing [6,11]. Similarly, Steiner forests have been studied in the context of multicommodity network design [30,34], mechanism design and games [16,42,43,53], computational biology [40,51], and computational geometry [9,13].

A slightly more special case of the pairwise weighted spanner problem was originally proposed by Kortsarz [44] and Elkin and Peleg [27], where it was called the *weighted s-spanner* problem. The precise goal in [27,44] is to find a minimum-cost subgraph that connects *all* the pairs of vertices in G, and each $Dist(s, t) = s \cdot d_G(s, t)$ for some integer s called the *stretch* of the spanner. The work of [27] presents a comprehensive list of inapproximability results for different variants of sparse s-spanners. Even in the special case where edges have unit costs (i.e., the directed s-spanner problem defined below), the problem is hard to approximate within a factor of $O(2^{\log^{1-\varepsilon} n})$ unless $NP \subseteq DTIME(n^{\text{polylog}\, n})$.

In the case when the edges have unit costs, the weighted s-spanner problem is called the *directed s-spanner* problem. For low-stretch spanners, when $s = 2$, there is a tight $\Theta(\log n)$-approximate algorithm [26,44]; with unit lengths and costs, when $s = 3, 4$, there are $\tilde{O}(n^{1/3})$-approximation algorithms [10,23]. For $s > 4$ with general lengths, the best known approximation is $\tilde{O}(n^{1/2})$ [10].

The *pairwise spanner* problem considers graphs with unit edge costs, D can be any subset of $V \times V$, and the target distances are general. The state-of-the-art is $\tilde{O}(n^{4/5})$-approximate for general lengths [33] and $\min\{\tilde{O}(k^{1/2+\varepsilon}), \tilde{O}(n^{3/5+\varepsilon})\}$-approximation for unit lengths [19,33].

When the target distances are infinite and the edges have unit lengths, the pairwise weighted spanner problem captures the *directed Steiner forest* problem. For the directed Steiner forest problem, there is an $\min\{\tilde{O}(k^{1/2+\varepsilon}), \tilde{O}(n^{2/3+\varepsilon})\}$-approximate algorithm for general costs [10, 18] and an $\tilde{O}(n^{4/7})$-approximate algorithm for unit costs [1].

1.1 Our contributions

1.1.1 Pairwise weighted spanners

To the best of our knowledge, none of the variants studied in the literature gives efficient sublinear-factor approximation algorithms for the pairwise weighted spanner problem, even in the case of unit edge length. Our main result for pairwise weighted spanners is stated as follows and proved in Section 2.

▶ **Definition 1** (Pairwise Weighted Spanner).

Instance: *A directed graph $G = (V, E)$ with n vertices and edge costs $c : E \to \mathbb{Q}_{\geq 0}$, edge lengths $\ell : E \to \{1, 2, 3, ..., \mathsf{poly}(n)\}$, and a set $D \subseteq V \times V$ of vertex pairs and their corresponding pairwise distance bounds $Dist : D \to \mathbb{Q}_{\geq 0}$ (where $Dist(s, t) \geq d_G(s, t)$) for every terminal pair $(s, t) \in D$.*

Objective: *Find a min-cost subgraph H of G such that $d_H(s, t) \leq Dist(s, t)$ for all $(s, t) \in D$.*

▶ **Theorem 2.** *For any constant $\varepsilon > 0$, there is a polynomial-time randomized algorithm for Pairwise Weighted Spanner with approximation ratio $\tilde{O}(n^{4/5+\varepsilon})$, which succeeds in resolving all pairs in D with high probability.*[2]

The Pairwise Weighted Spanner problem is equivalent to the problem of finding a minimum-cost Steiner forest under pairwise distance constraints, and hence our result is the first polynomial-time $o(n)$-approximate algorithm for the directed Steiner forests with distance constraints. This problem is hard to approximate within a factor of $O(2^{\log^{1-\varepsilon} n})$ unless $NP \subseteq DTIME(n^{\text{polylog}\, n})$ even for the special case when all vertex pairs are required to be connected and the stretch $s \geq 5$ [44].

1.1.2 All-pair weighted distance preservers

When the target distances are the distances in the given graph G, the spanner problem captures the *distance preserver* problem. When edges have unit costs, there exists a distance preserver of cost $O(n)$ if the number of the source vertices is $O(n^{1/3})$ [12]. When edges have unit costs and lengths, the state-of-the-art result is $\tilde{O}(n^{3/5+\varepsilon})$-approximate [19]. We consider the case where the terminal set consists of *all* vertex pairs and the subgraph is required to preserve the distances of all vertex pairs. This problem is called All-pair Weighted Distance Preserver. We prove the following in Section 3.

▶ **Definition 3** (All-pair Weighted Distance Preserver).

Instance: *A directed graph $G = (V, E)$ with edge costs $c : E \to \mathbb{Q}_{\geq 0}$, edge lengths $\ell : E \to \{1, 2, 3, ..., \mathsf{poly}(n)\}$.*

Objective: *Find a min-cost subgraph H of G such that $d_H(s, t) = d_G(s, t)$, for all $(s, t) \in V \times V$.*

[2] Throughout our discussion, when we say high probability we mean probability at least $1 - 1/n$.

▶ **Theorem 4.** *For any constant $\varepsilon > 0$, there is a polynomial-time randomized algorithm for* All-pair Weighted Distance Preserver *with approximation ratio $\tilde{O}(n^{1/2+\varepsilon})$, which succeeds in resolving all pairs in $V \times V$ with high probability.*

Beside distance preservers, there are other previous special-case results for the all-pair weighted spanner problem. When edges have unit costs, the state-of-the-art is an $\tilde{O}(n^{1/2})$-approximation algorithm [10]. When there are no distance constraints, this problem is termed the *minimum strongly connected subgraph* problem and is equivalent to the all-pair Steiner forest problem. This problem is NP-hard and does not admit a polynomial-time approximation scheme if $NP \neq P$ [39]. The best algorithm is a 3/2-approximation [54].

1.1.3 Online weighted spanners

Next, we turn to online weighted spanners. In the online problem, the directed graph, the edge lengths, and the edge costs are given offline. The vertex pairs and the corresponding target distances arrive one at a time, in an online fashion, at each time stamp. The algorithm must irrevocably select edges at each time stamp and the goal is to minimize the cost, subject to the target distance constraints. We call this problem the Online Pairwise Weighted Spanner problem. For notation convenience, the vertex pair (s_i, t_i) denotes the i-th pair that arrives online.

▶ **Definition 5** (Online Pairwise Weighted Spanner).

Instance: *A directed graph $G = (V, E)$ with edge costs $c : E \to \mathbb{Q}_{\geq 0}$, edge lengths $\ell : E \to \{1, 2, 3, ..., \mathsf{poly}(n)\}$, and vertex pairs $D = \{(s_i, t_i) \in V \times V \mid i \in [k]\}$ (k is unknown) with their corresponding pairwise distance bounds $Dist(s_i, t_i) \in \mathbb{Q}_{\geq 0}$ (where $Dist(s_i, t_i) \geq d_G(s_i, t_i)$) arrive online one at a time.*

Objective: *Upon the arrival of (s_i, t_i) with $Dist(s_i, t_i)$, construct a min-cost subgraph H of G such that $d_H(s_i, t_i) \leq Dist(s_i, t_i)$ by irrevocably adding edges from E.*

The performance of an online algorithm is measured by its *competitive ratio*, namely the ratio between the cost of the online solution and that of an optimal offline solution. With unit edge costs, the best algorithm is $\tilde{O}(n^{4/5})$-competitive; with unit edge costs and lengths, the state-of-the-art is $\min\{\tilde{O}(k^{1/2+\varepsilon}), \tilde{O}(n^{2/3+\varepsilon})\}$-competitive [33]. Our result for Online Pairwise Weighted Spanner is stated as follows and proved in Section 4.

▶ **Theorem 6.** *For any constant $\varepsilon > 0$, there is a polynomial-time randomized online algorithm for* Online Pairwise Weighted Spanner *with competitive ratio $\tilde{O}(k^{1/2+\varepsilon})$, which succeeds in resolving all pairs in D with high probability.*

In a special case of Pairwise Weighted Spanner where the source vertex $s \in V$ is fixed, we call this problem Single-source Weighted Spanner. Without distance constraints, this problem is equivalent to the directed Steiner tree problem.[3] The best algorithm for the directed Steiner tree problem is $O(k^{\varepsilon})$-approximate [15].

▶ **Definition 7** (Single-source Weighted Spanner).

Instance: *A directed graph $G = (V, E)$ with edge costs $c : E \to \mathbb{Q}_{\geq 0}$, edge lengths $\ell : E \to \{1, 2, 3, ..., \mathsf{poly}(n)\}$, and a set $D \subseteq \{s\} \times V$ of vertex pairs and their corresponding pairwise distance bounds $Dist : D \to \mathbb{Q}_{\geq 0}$ (where $Dist(s, t) \geq d_G(s, t)$) for every terminal pair $(s, t) \in D$).*

Objective: *Find a min-cost subgraph H of G such that $d_H(s, t) \leq Dist(s, t)$ for all $(s, t) \in D$.*

[3] Throughout the paper, the term *without distance constraints* means that the target distances are infinity. This is equivalent to the connectivity problem.

When $D \subseteq \{s\} \times V$, a single-source weighted spanner connects s to the sinks. We say that s is the *root* of the single-source weighted spanner and the single-source weighted spanner is *rooted at* s. The definition for a single-sink weighted spanner where the terminal pairs share the same sink is defined similarly.

The online version of Single-source Weighted Spanner is termed Online Single-source Weighted Spanner. For notation convenience, the vertex pair (s, t_i) denotes the i-th pair that arrives online.

▶ **Definition 8** (Online Single-source Weighted Spanner).
Instance: *A directed graph $G = (V, E)$ with edge costs $c : E \to \mathbb{Q}_{\geq 0}$, edge lengths $\ell : E \to \{1, 2, 3, ..., \mathsf{poly}(n)\}$, and vertex pairs $D = \{(s, t_i) \mid t_i \in V, i \in [k]\}$ (k is unknown) with their corresponding pairwise distance bounds $Dist(s, t_i) \in \mathbb{Q}_{\geq 0}$ (where $Dist(s, t_i) \geq d_G(s, t_i)$) arrive online one at a time.*
Objective: *Upon the arrival of (s, t_i) with $Dist(s, t_i)$, construct a min-cost subgraph H of G such that $d_H(s, t_i) \leq Dist(s, t_i)$ by irrevocably selecting edges from E.*

The state-of-the-art result for online directed Steiner trees is $\tilde{O}(k^{\varepsilon})$-competitive implied by a more general online buy-at-bulk network design framework [14]. Our result is stated as follows and proved in Section 4.

▶ **Theorem 9.** *For any constant $\varepsilon > 0$, there is a polynomial-time randomized online algorithm for Online Single-source Weighted Spanner with approximation ratio $\tilde{O}(k^{\varepsilon})$, which succeeds in resolving all pairs in D with high probability.*

Our online framework essentially generalizes the online Steiner forest problem by allowing distance constraints when edge lengths are positive integers of magnitude $\mathsf{poly}(n)$. We note that the online algorithms also imply efficient algorithms for the corresponding offline problems with the same approximation ratios.

1.1.4 Summary

We summarize our main results for weighted spanners in Table 1 by listing the approximation (competitive) ratios and contrast them with the corresponding known approximation (competitive) ratios. We note that offline $\tilde{O}(k^{1/2+\varepsilon})$-approximate Pairwise Weighted Spanner and offline $\tilde{O}(k^{\varepsilon})$-approximate Single-source Weighted Spanner can be obtained by our online algorithms.

1.2 High-level technical overview

Most of the literature on approximation algorithms for *offline* spanner problems [10, 11, 19, 21, 28, 33] partition the terminal pairs into two types: thin or thick. A pair $(s, t) \in D$ is *thin* if the graph $G^{s,t}$ induced by feasible $s \rightsquigarrow t$ paths has a small number of vertices, and *thick* otherwise. To connect each thick terminal pair (s, t), it is sufficient to sample vertices from the graph G to hit $G^{s,t}$, and then add shortest-path in-and-out-arborescences rooted at the sampled vertices. To connect each thin terminal pair (s, t), one uses a flow-based linear program (LP) and then rounds the solution.

1.2.1 Pairwise Weighted Spanners

For this problem, the goal is to approximately minimize the total cost while maintaining the required distances between terminal pairs, so it turns out that the approach for directed Steiner forests [10, 28] is more amenable to this formulation. The approach for directed

Table 1 Summary of the approximation and competitive ratios. Here, n refers to the number of vertices and k refers to the number of terminal pairs. All edge lengths are positive integers in $\mathsf{poly}(n)$ and all edge costs are non-negative rational numbers. We note that Pairwise Weighted Spanner without distance constraints is equivalent to the directed Steiner forest problem. The all-pair weighted spanner problem without distance constraints is equivalent to the all-pair Steiner forest problem or the minimum strongly connected subgraph problem.

Problem	Our Results	Previous Results
Pairwise Weighted Spanner	$\tilde{O}(n^{4/5+\varepsilon})$ (Thm 2) $\tilde{O}(k^{1/2+\varepsilon})$ (Thm 6)	$\tilde{O}(n^{4/5})$ (unit edge costs) [33] $\tilde{O}(n^{3/5+\varepsilon})$ (unit edge costs and lengths) [19] $\min\{\tilde{O}(k^{1/2+\varepsilon}), \tilde{O}(n^{2/3+\varepsilon})\}$ (without distance constraints) [10, 18] $\tilde{O}(n^{4/7+\varepsilon})$ (unit edge costs and lengths, without distance constraints) [1]
All-pair Weighted Spanner	$\tilde{O}(n^{1/2+\varepsilon})$ (distance preservers, Thm 4)	$\tilde{O}(n^{1/2})$ (unit edge costs) [10] 3/2 (without distance constraints) [54]
Online Pairwise Weighted Spanner	$\tilde{O}(k^{1/2+\varepsilon})$ (Thm 6)	$\tilde{O}(n^{4/5})$ (unit edge costs) [33] $\min\{\tilde{O}(k^{1/2+\varepsilon}), \tilde{O}(n^{2/3+\varepsilon})\}$ (unit edge costs and lengths) [33] $\tilde{O}(k^{1/2+\varepsilon})$ (without distance constraints) [14]
Single-Source Weighted Spanner	$\tilde{O}(k^{\varepsilon})$ (also holds for online, Thm 9)	$O(k^{\varepsilon})$ (without distance constraints) [15] $\tilde{O}(k^{\varepsilon})$ (online, without distance constraints) [14]

Steiner forests [10, 28] is slightly different, namely, thick pairs are connected by adding cheap paths that contain at least one sampled vertex. In the Steiner forest algorithms, there are usually three cases for the terminal pairs: 1) pairs that are thick and have low-cost connecting paths, 2) the majority of the remaining pairs have high-cost connecting paths, and 3) the majority of the remaining pairs have low-cost connecting paths.

With distance constraints, we have to modify the analysis for *all* three cases. The actual implementation of the strategy requires several new ideas and it significantly departs from the analysis of [10, 28] in several aspects, as we describe below.

In our first case, we cannot simply add cheap paths because they might violate the distance requirement. Instead, we add *feasible* cheap paths that satisfy the distance requirements, in order to connect the terminal pairs. For this purpose, we use the restricted shortest path FPTAS from [37, 45] as our subroutine.

The remaining two cases are resolved by using an iterative greedy algorithm based on a *density* argument. In each iteration, the greedy algorithm constructs a partial solution $E' \subseteq E$ with low density. We define the density of E' to be the ratio of the total edge cost of E' to the number of pairs connected by E'. Iteratively adding low-density partial solutions leads to a global solution of approximately minimum cost.

In the second case, [10,28] use the low-density *junction trees* (the union of an in-arboresence and an out-arboresence rooted at the same vertex) from [18] in order to connect pairs with high-cost paths. However, the junction tree approximation in [18] cannot handle the distance constraints in our setting. Fortunately, with slight modifications, the junction tree approximation from [19] can be made to handle our distance requirements.

In the third case, [10, 28] formulate an LP where each edge has an indicator variable, then round the LP solution, and argue that with high probability, one can obtain a low-density partial solution that connects the terminal pairs with cheap paths. Two challenges arise in our setting. First, the LP formulation is different from the one in [10, 28] because we have to handle both distance and cost requirements. We resolve these constraints by using a different separation oracle from the previous literature [37, 45], namely we use the FPTAS for the *resource-constrained shortest path* problem from [38] (see Section A.1 for more details). Secondly, in order to round the LP solution, we can no longer use the analysis in [10]. This is because the LP rounding scheme uses a union bound that depends on the number of the minimal subset of edges whose removal disconnects the terminal pairs (i.e., anti-spanners). Since we have to handle both lengths and costs in the LP constraints, we consider all possible subsets of edges and this is sufficient to achieve the $\tilde{O}(n^{4/5+\varepsilon})$-approximation.

1.2.2 All-pair Weighted Distance Preservers

For this problem, the solution takes advantage of the requirement that we have to *exactly* preserve the *all-pair* distances. It turns out that the strategy for the spanner problems [10, 11, 19, 21, 33] is more amenable. Recall that terminal pairs are either thin or thick.

To settle thick terminal pairs, most of the previous work that considers graphs with unit edge cost samples vertices from the graph G to hit $G^{s,t}$, and then adds shortest-path in-and-out-arborescences rooted at the sampled vertices. Note that the cost of an in-arborescence or an out-arborescence is always $n-1$. However, with edge costs, it is not clear how the *cheapest* shortest-path in-and-out arborescences can be obtained. Instead, we add cheap *single-source and single-sink weighted distance preservers* rooted at the sampled vertices. This approach requires using the algorithm for Online Single-source Weighted Spanner described in details in Section 4. The key observation is that the terminal pairs of any single-source (single-sink) weighted distance preserver is a subset of all vertex pairs. This implies that any approximately optimal single-source (single-sink) weighted distance preserver must be cheap compared to the cost of the optimal all-pair weighted distance preserver.

The approach that settles the thin pairs closely follows the algorithm in [10], which rounds a fractional solution of the LP for all-pair spanners. Different from Pairwise Weighted Spanner, we only have to handle the lengths in the LP constraints, so the analysis follows [10] and we can get a better approximation ratio. Ultimately, the costs for settling thick and thin pairs are both at most an $\tilde{O}(n^{1/2+\varepsilon})$ factor of the optimal solution.

1.2.3 Online Weighted Spanners

The main challenge for the online pairwise weighted spanner problem is that the standard greedy approach, which iteratively extracts low-density greedy solutions partially connecting terminal pairs, is no longer applicable. Another challenge is to handle the distance constraints for the terminal pairs that arrive online. Fortunately, the online spanner framework from [33] already adapts both the approach introduced in [14], which constructs a *collection of junction trees* in an online fashion, and the approach of [19], which judiciously handles distance constraints when edges have unit lengths. Our online results are obtained by extending the framework of [33] from graphs with unit edge costs to general edge costs.

1.3 Organization

In Section 2, we present the $\tilde{O}(n^{4/5+\varepsilon})$-approximation algorithm for Pairwise Weighted Spanner. In Section 3, we present the $\tilde{O}(n^{1/2+\varepsilon})$-approximation algorithm for All-pair Weighted Distance Preserver. In Section 4, we present the $\tilde{O}(k^{1/2+\varepsilon})$-competitive algorithm for Online Pairwise Weighted Spanner and the $\tilde{O}(k^{\varepsilon})$-competitive algorithm for Online Single-source Weighted Spanner. We refer the reader to Appendix A for a detailed description of related work and Appendix C for the concluding remarks.

2 Pairwise Weighted Spanners

In this section, we prove Theorem 2. For ease of presentation, we assume that we have a guess for the cost of the optimal solution - OPT for that instance as in [10, 28]. Let τ denote the value of our guess. We set $\tau_0 = \min_{e \in E}\{c(e) \mid c(e) > 0\}$; then we carry out multiple iterations of our overall procedure setting τ to be equal to an element in $\{(\tau_0, 2 \cdot \tau_0, 4 \cdot \tau_0, \ldots, 2^i \cdot \tau, \ldots, \sum_{e \in E} c(e))\}$ for those iterations. Finally, we take the cheapest spanner from across all these iterations. Thus, it is sufficient to give the approximation guarantee for the iteration when $\mathsf{OPT} \leq \tau \leq 2 \cdot \mathsf{OPT}$. We can obtain this guess in $O(\log(\sum_{e \in E} c(e)/\tau_0))$ iterations, which is polynomial in the input size.

We define some notions commonly used in the spanner and Steiner forest literature. Fix some parameters $\beta = n^{3/5}$ and $L = \tau / n^{4/5}$. We say that a path $p(s,t)$ that connects a specific terminal pair (s,t) is *feasible* if $\sum_{e \in p(s,t)} \ell(e) \leq \mathit{Dist}(s,t)$. We say that $p(s,t)$ is *cheap* if the $\sum_{e \in p(s,t)} c(e) \leq L$. We say that a terminal pair $(s,t) \in D$ is *thick* if the *local graph* $G^{s,t} = (V^{s,t}, E^{s,t})$ induced by the vertices on feasible $s \leadsto t$ paths of cost at most L has at least n/β vertices; we say it is *thin* otherwise. We note that the definitions of thick and thin pairs are slightly different from how they are defined in [10, 28]. We say that a set $E' \subseteq E$ settles (or resolves) a pair $(s,t) \in D$ if the subgraph (V, E') contains a feasible $s \leadsto t$ path.

2.1 Resolving thick pairs

Let $S = \{s \mid \exists t : (s,t) \in D\}$ and $T = \{t \mid \exists s : (s,t) \in D\}$. We first settle the thick pairs with high probability. We do this by sampling some vertices using Algorithm 1 and then adding some incoming paths and outgoing paths from the samples to the vertices in S and T respectively using Algorithm 2. We ensure that any path we build is both feasible and cheap and we do that with the help of a black box for the Restricted Shortest Path problem.

Algorithm 1 Sample($G(V, E)$).

```
$R \leftarrow \phi$, $k \leftarrow 3\beta \ln n$.
Sample $k$ vertices independently and uniformly at random and store them in the set $R$.
return $R$.
```

▷ Claim 10. Algorithm 1 selects a set of samples R such that with high probability any given thick pair (s,t) has at least one vertex from its local graph in R.

In Algorithm 2, we call Algorithm 1 to get a set of samples R. For each $u \in R, s \in S, t \in T$, we try to add a shortest $s \leadsto u$ path and a shortest $u \leadsto v$ path each of cost at most L.

For this purpose, we use the restricted shortest path (bi-criteria path) problem from [45].

▶ **Definition 11** (Restricted Shortest Path).

Instance: *A directed graph $G = (V, E)$, edge lengths $\ell : E \to \mathbb{R}_{\geq 0}$, edge costs $c : E \to \mathbb{R}_{\geq 0}$, a vertex pair $(s,t) \in V \times V$, and a threshold $T \in \mathbb{R}_{>0}$.*

Objective: *Find a minimum cost $s \leadsto t$ path P such that $\sum_{e \in P} \ell(e) \leq T$.*

The following lemma from [37, 45] gives an FPTAS for Restricted Shortest Path.

▶ **Lemma 12** ([37, 45]). *There exists an FPTAS for Restricted Shortest Path that gives a $(1 + \varepsilon, 1)$ approximation, i.e., the path ensures that $\sum_{e \in P} \ell(e) \leq T$ and has a cost at most $1 + \varepsilon$ times the optimal.*

Using Lemma 12 as our black box, we binary search for a path of length between $\min_{e \in E}\{\ell(e)\}$ and $n \cdot \max_{e \in E}\{\ell(e)\}$ that will give us a cheap $s \rightsquigarrow u$ path. Since the edge lengths and thus the path lengths are all integers, this is possible in $O(\log(n \cdot \max_{e \in E}\{\ell(e)\}))$ iterations which is polynomial in the input size. It is possible that we never find an $s \rightsquigarrow u$ path of cost less than L, in which case we just ignore this (s, u) pair. We then do the same for all the (u, t) pairs. See the full details in Algorithm 2.

Algorithm 2 Thick pairs resolver $(G(V, E), \{\ell(e), c(e)\}_{e \in E})$.

```
R ← ϕ, G′ ← ϕ.
R ← Sample(G(V, E)).
for u ∈ R do
    for s ∈ S do
        Use RSP to find the shortest s ⇝ u path of cost at most L · (1 + ε) and add it to G′.
for u ∈ R do
    for t ∈ T do
        Use RSP to find the shortest u ⇝ t path of cost at most L · (1 + ε) and add it to G′.
return G′
```

▶ **Lemma 13.** *With high probability, the set of edges returned by Algorithm 2 resolves all thick pairs in D with a total cost $\tilde{O}(n^{4/5} \cdot \tau)$. Moreover, Algorithm 2 runs in polynomial time.*

Proof. If some $u \in R$ was originally in the local graph $G^{s,t}$, then Algorithm 2 would have added at least one $s \rightsquigarrow u \rightsquigarrow t$ path from $G^{s,t}$ that is feasible and has cost less than $2L(1+\varepsilon)$. This is because if u was in the local graph of (s, t), then there exists an $s \rightsquigarrow u$ path of cost less than L of some length $\ell \in [n \cdot \max_{e \in E}\{\ell(e)\}]$. Since we binary search over the possible values for ℓ and take the lowest possible one, we will find such a path with distance at most the minimum length of an $s \rightsquigarrow t$ path that is cheap. Note that we could have a smaller distance because we use a larger bound for cost for our path in comparison to the local graph. Using Claim 10, such a cheap and feasible path will exist with a high probability for all $(s, t) \in D$ that are thick for some samples $u \in R$.

Now we analyze the cost of Algorithm 2. The cost from all the edges we add in Algorithm 2 would be $O(n \cdot k \cdot L)$. This is because we pick k samples and each of them needs to add an incoming and outgoing path of cost $L(1 + \varepsilon)$ to at most n vertices. Plugging in the values for k and L, we can see that the total cost would be $\tilde{O}(n^{4/5} \cdot \tau)$. In addition, note that Algorithm 2 will run in polynomial time because our binary search only needs to search the integers in $[\min_{e \in E}\{\ell(e)\}, n \cdot \max_{e \in E}\{\ell(e)\}]$.[4] ◀

2.2 Resolving thin pairs

Now we focus on the thin pairs after removing the settled thick pairs from the set D. The *density* of a set of edges E' is the ratio of the total cost of E' to the number of pairs settled by E'. We first describe how to efficiently construct a subset K of edges with density $\tilde{O}(n^{4/5+\varepsilon})\tau/|D|$. Then we iteratively find edge sets with that density, remove the pairs, and repeat until we resolve all thin pairs. This gives a total cost of $\tilde{O}(n^{4/5+\varepsilon} \cdot \tau)$. We construct K by building two other sets K_1 and K_2 and picking the smaller density of them. Let H be

[4] Note that Algorithm 2 will still run in polynomial-time if we use an exhaustive search instead of a binary search since the edge lengths are in $\mathsf{poly}(n)$.

an optimal solution with cost τ. Let C be the set of demand pairs for which the minimum cost of a feasible $s \rightsquigarrow t$ path in H is at least L (note that the local graph for these pairs would be empty). We have two cases: 1) $|D|/2 \leq |C| \leq |D|$ and 2) $0 \leq |C| < |D|/2$.

2.2.1 When $|D|/2 \leq |C| \leq |D|$

We will use the notion of *junction tree* as a black box for resolving this case. Informally, junction trees are trees that satisfy significant demand at low cost. They have a root node r, a collection of paths into r, and paths out of r to satisfy some of this demand. In our case, we also need these paths to be cheap and short. The following is a formal definition of a junction tree variant that fits the needs of our problem.

▶ **Definition 14** (*Distance-preserving Weighted Junction Tree*)**.** *Let $G = (V, E)$ be a directed graph with edge lengths $\ell : E \to \mathbb{R}_{\geq 0}$, edge costs $c : E \to \mathbb{R}_{\geq 0}$, and a set $D \subseteq V \times V$ of ordered pairs and their corresponding pairwise distance bounds $Dist : D \to \mathbb{R}$ (where $Dist(s,t) \geq d_G(s,t)$ for every terminal pair $(s,t) \in D$), and a root $r \in V$. We define* distance-preserving weighted junction tree *to be a subgraph H of G that is a union of an in-arboresences and an out-arboresences both rooted at r containing an $s \rightsquigarrow t$ path going through the root r of length at most $Dist(s,t)$, for one or more $(s,t) \in D$.*

The *density* of a junction tree is defined as the ratio of the sum of costs of all edges in the junction tree to the number of pairs settled by the junction tree.

▷ Claim 15. If $|D|/2 \leq |C| \leq |D|$, then there exists a distance-preserving weighted junction tree of density $O\left(n^{4/5} \cdot \tau/|D|\right)$.

Proof. Let H be an optimal solution subgraph of G that connects all the costly thin pairs. Take the paths in H connecting the pairs in C. The sum of the costs of all such paths is at least $|C|L$. Now, let μ be the maximum number of these paths that any edge in G belongs to. The sum of the costs of the paths is at most $\mu \cdot \tau$ and thus there must exist an edge belonging to $\mu \geq |C|L/\tau$ paths. Pick such an arbitrary edge and call it the *heavy-enough edge*, and call its source as the *heavy-enough vertex*, denoted h_v. Now, consider a tree made by adding feasible paths from $s \in S$ to h_v and h_v to $t \in T$ that satisfies at least μ pairs. We do not add an edge if it is not in H. This ensures that the cost of this tree is less than τ. This tree would connect at least μ pairs, and thus it would have a density at most $\tau/\mu = \tau^2/(|C|L)$.

If $L = \tau/n^{4/5}$, then $\tau^2/(|C|L) = n^{4/5} \cdot \tau/|C|$. If $|D| > |C| > |D|/2$, we have $n^{4/5} \cdot \tau/|C| = O\left(n^{4/5} \cdot \tau/|D|\right)$. We have proved the existence of a junction tree of the required density. ◁

The following lemma is essentially from [19] (Theorem 5.1). But the small yet important modifications that we need are not covered in [19]. We refer the reader to the full version [32] for the complete proof.

▶ **Lemma 16.** *For any constant $\varepsilon > 0$, there is a polynomial-time approximation algorithm for the minimum density distance-preserving junction tree as long as the edge lengths are integral and polynomial in n. In other words, there is a polynomial time algorithm which, given a weighted directed n vertex graph $G = (V, E)$ where each edge $e \in E$ has a cost $c(e) \in \mathbb{R}_{\geq 0}$ and integral length $\ell(e) \in \{1, 2, ..., \mathsf{poly}(n)\}$, terminal pairs $P \subseteq V \times V$, and distance bounds $Dist : P \to \mathbb{N}$ (where $Dist(s,t) \geq d_G(s,t)$) for every terminal pair $(s,t) \in P$, approximates the following problem to within an $O(n^{\varepsilon})$ factor:*

- *Find a non-empty set of edges $F \subseteq E$ minimizing the ratio:*

$$\min_{r \in V} \frac{\sum_{e \in F} c(e)}{|\{(s,t) \in P | d_{F,r}(s,t) \leq Dist(s,t)\}|} \tag{1}$$

where $d_{F,r}(s,t)$ is the length of the shortest path using edges in F which connects s to t while going through r (if such a path exists).

▶ **Lemma 17.** *When $|D|/2 \leq |C| \leq |D|$, we can get a set of edges K_1 that has density at most $\tilde{O}(n^{4/5+\varepsilon} \cdot \tau/|D|)$*

Proof. From Claim 15, there exists a distance-preserving weighted junction tree of density at most $O(n^{4/5} \cdot \tau/|D|)$. We use Lemma 16 to get a distance-preserving weighted junction tree with density at most $\tilde{O}(n^{4/5+\varepsilon} \cdot \tau/|D|)$ and store the edges returned by it in K_1. ◀

2.2.2 When $0 \leq |C| < |D|/2$

To handle this case, we build a linear program (LP) that fits our problem's requirements, solve it approximately with the help of a separation oracle, and finally round it to get a set of edges with density $\tilde{O}(n^{4/5+\varepsilon}) \cdot \tau/|D|$. The linear program is quite similar to the one used in [10, 28], but it has a subtle distinction that significantly changes the tools and proof techniques we have to use. We will be referring to [28] quite frequently in this section because [10] does not directly present a way to solve the LP (it relies on [28] for this).

2.2.2.1 Building and solving the linear program

We will need the following definition in order to set up a relevant LP. For $(s,t) \in D$, let $\Pi(s,t)$ be the set of all *feasible* $s \rightsquigarrow t$ paths of cost at most L, and let $\Pi = \cup_{(s,t)\in D}\Pi(s,t)$. Each edge e has a capacity x_e, each path $p \in \Pi$ carries f_p units of flow, and $y_{s,t}$ is the total flow through all paths from s to t. Define a linear program as follows:

$$\begin{aligned}
\min \quad & \sum_{e \in E} c(e) \cdot x_e & & \\
\text{subject to} \quad & \sum_{(s,t)\in D} y_{s,t} \geq \frac{|D|}{2}, & & \\
& \sum_{\Pi(s,t) \ni p \ni e} f_p \leq x_e & & \forall (s,t) \in D, e \in E, \\
& \sum_{p \in \Pi(s,t)} f_p = y_{s,t} & & \forall (s,t) \in D, \\
& 0 \leq y_{s,t}, f_p, x_e \leq 1 & & \forall (s,t) \in D, p \in \Pi, e \in E.
\end{aligned} \tag{2}$$

LP (2) tries to connect at least $|D|/2$ pairs from D using paths of cost at most L while minimizing the total cost of the used edges. It is almost identical to the corresponding LP in [10, 28] for Steiner forests, except that we consider only *feasible* paths that are cheaper than L, while they consider all paths that are cheaper than L. The crucial part of our approach is the use of an FPTAS for the Restricted Shortest Path problem, which served as an approximate separation oracle for the dual program. The proof of the following lemma is provided in Appendix B.1.

▶ **Lemma 18.** *Let OPT be the optimal value of an instance of* Pairwise Weighted Spanner. *Then, the optimal value of LP (2) corresponding to that instance is at most OPT. In addition, a solution for LP (2) of value at most $(1+\varepsilon) \cdot OPT$ can be found in polynomial time.*

2.2.2.2 Rounding our solution

Now we need to round the solution of LP (2) appropriately to decide which edges we need to include in our final solution. The overall structure of our rounding procedure is similar to that of [10], but there are some important differences in the proof techniques we use here because the nature of our problem prevents us from using some of the techniques used by [10]. Let $\{\hat{x}_e\} \cup \{\hat{y}_{s,t}\}$ be a feasible approximate solution to LP (2). Let K_2 be the set of edges obtained by running Algorithm 3 on $\{\hat{x}_e\}$.

Algorithm 3 Thin pair rounding [LP rounding] (x_e).

```
$E'' \leftarrow \phi$ .
for $e \in E$ do
    Add $e$ to $K_2$ with probability $\min\{n^{4/5} \ln n \cdot x_e, 1\}$;
return $E''$
```

The following lemma is an adaptation of Claim 2.3 from [10].

▷ Claim 19. Let $A \subseteq E$. If Algorithm 3 receives a fractional vector $\{\hat{x}_e\}$ with nonnegative entries satisfying $\sum_{e \in A} \hat{x}_e \geq 2/5$, the probability that it outputs a set E'' disjoint from A is at most $\exp(-2n^{4/5} \cdot \ln n/5)$.

Proof. If A contains an edge e which has $\hat{x}_e \geq 1/(n^{4/5} \ln n)$, then e is definitely included in E''. Otherwise, the probability that no edge in A is included in E'' is

$$\prod_{e \in A} (1 - n^{4/5} \ln n \cdot \hat{x}_e) \leq \exp\left(-\sum_{e \in A} n^{4/5} \ln n \cdot \hat{x}_e\right) \leq \exp\left(-\frac{2}{5} n^{4/5} \ln n\right). \quad \triangleleft$$

Let us now define anti-spanners which serve as a useful tool to analyze the rounding algorithm for our LP. Our definition of anti-spanners is slightly different from Definition 2.4 in [10] to account for the fact we also have distance constraints.

▶ **Definition 20.** *A set $A \subseteq E$ is an anti-spanner for a terminal pair $(s,t) \in E$ if $(V, E \setminus A)$ contains no feasible path from s to t of cost at most L. If no proper subset of anti-spanner A for (s,t) is an anti-spanner for (s,t), then A is minimal. The set of all minimal anti-spanners for all thin edges is denoted by $\mathcal{A}$.*

The following lemma is an analogue of Claim 2.5 from [10].

▶ **Lemma 21.** *Let $\mathcal{A}$ be the set of all minimal anti-spanners for thin pairs. Then $|\mathcal{A}|$ is upper-bounded by $|D| \cdot 2^{(n/\beta)^2/2}$.*

Proof. Let $PS(s,t)$ be the power set of all edges in the local graph for a given thin pair (s,t). Since (s,t) is a thin pair we have at most n/β vertices and $(n/\beta)^2/2$ edges in the local graph, therefore $|PS(s,t)| \leq 2^{(n/\beta)^2/2}$ for any (s,t) that is a thin pair. Now, every anti-spanner for a specific demand pair $(s,t) \in D$ is a set of edges and therefore corresponds to an element in $PS(s,t)$. Let $PS_{\text{thin}} = \bigcup_{(s,t)} PS(s,t)$ where $(s,t) \in D$ are thin pairs. Every anti-spanner for a thin pair is a set of edges and therefore corresponds to an element in PS_{thin}. We have $|\mathcal{A}| \leq |PS_{\text{thin}}| \leq |D| \cdot 2^{(n/\beta)^2/2}$ which proves the lemma. ◀

The rest of this discussion is quite similar to [10] although the exact constants and the expressions involved are different because of the result in Lemma 21. Lemma 22 is similar to Lemma 5.2 from [10].

▶ **Lemma 22.** *With high probability set K_2 settles every thin pair (s,t) with $\hat{y}_{s,t} \geq 2/5$.*

Proof. For every thin pair $(s,t) \in D$ with $\hat{y}_{s,t} \geq 2/5$, if A is an anti-spanner for (s,t) then $\sum_{e\in A} \hat{x}_e \geq \sum_{P\in\Pi(s,t)} \hat{f}_p \geq 2/5$, where $\hat{f}_p$ is the value of the variable f_p in LP (2) that corresponds to the solution $\{\hat{x}_e\} \cup \{\hat{y}_{s,t}\}$.

By Claim 19, the probability that A is disjoint from K_2 is at most $\exp(-2n^{4/5} \cdot \ln n/5)$. Further using Lemma 21, we can bound the number of minimal anti-spanners for thin pairs and then if we apply union bound, we have the probability that K_2 is disjoint from any anti spanner for a thin pair is at most $\exp\left(-2n^{4/5} \cdot \ln n/5\right) \cdot |D| \cdot 2^{(n/\beta)^2/2}$. In the worst case, $|D|$ is n^2. Recall that $\beta = n^{3/5}$, we have $(n/\beta)^2 = n^{4/5}$, so

$$\exp\left(-\frac{2}{5} \cdot n^{4/5} \cdot \ln n + \ln\left(n^2 \cdot 2^{n^{4/5}/2}\right)\right) = \exp\left(-\Theta(n^{4/5} \ln n)\right).$$

Thus we have shown that the probability K_2 is disjoint from any anti-spanner for a thin pair is exponentially small when $\hat{y}_{s,t} \geq 2/5$. ◀

▶ **Lemma 23.** *When $0 \leq |C| < |D|/2$, with high probability, the density of K_2 is at most*

$$\tilde{O}(n^{4/5} \cdot \tau/|D|).$$

Proof. Firstly notice that the expected cost of K_2 would be at most $n^{4/5} \ln n \cdot \tau$. We also point out that the number of pairs $(s,t) \in D$ for which $\hat{y}_{s,t} < 2/5$ is at most $5|D|/6$ because otherwise the amount of flow between all pairs is strictly less than $|D|/2$ which violates a constraint of LP (2). Since with high probability all pairs for which $\hat{y}_{s,t} \geq 2/5$ are satisfied, this means that the expected density of K_2 is at most

$$\frac{n^{4/5} \ln n \cdot \tau}{|D|/6} = \frac{6n^{4/5} \ln n \cdot \tau}{|D|} = \frac{\tilde{O}(n^{4/5} \cdot \tau)}{|D|}.$$ ◀

Now we are ready to prove Theorem 2.

Proof of Theorem 2. Using Lemma 13 we can resolve all thick pairs with high probability with cost at most $\tilde{O}(n^{4/5+\varepsilon})$. Then, we can make two sets of edges K_1 and K_2 using a distance-preserving weighted junction tree and by rounding the approximate solution to LP (2) respectively. By Lemmas 17 and 23, we can see that at least one of them will have a density at most $\tilde{O}(n^{4/5} \cdot \tau/|D|)$. If we take the cheaper among them and keep iterating we can resolve all thin pairs with a high probability and with cost at most $\tilde{O}(n^{4/5+\varepsilon})$. ◀

3 All-pair Weighted Distance Preservers

In this section, we prove Theorem 4. Our proof structure for this subsection is very similar to that of [10] except for our use of single sink and single source spanners.

As in Section 2, we assume that we have a guess for the cost of the optimal solution - OPT for the given instance of All-pair Weighted Distance Preserver. Let τ denote the value of our guess. Let us set $\beta = n^{1/2}$. We say that a terminal pair $(s,t) \in D$ is *thick* if the *local graph* $G^{s,t} = (V^{s,t}, E^{s,t})$ induced by the vertices on feasible paths from s to t has at least n/β vertices; we say it is *thin* otherwise. We note that the definitions of thick and thin pairs are slightly different from how they are defined in Section 2 as we only care about the feasibility of a path, not its cost. We say that a set $E' \subseteq E$ settles (or resolves) a pair $(s,t) \in D$ if the subgraph (V, E') contains a feasible path from s to t.

3.1 Thick pairs

We first resolve the thick pairs by randomly sampling vertices and building single-source and single-sink spanners from the samples using Theorem 9. We then resolve thin pairs by building a linear program, solving it, and rounding as in [10]. As mentioned earlier, our definition of thick and thin pairs is different in this section when compared to Section 2, and this allows us to use a much simpler proof (although one that will be effective only in the case of weighted distance preservers as opposed to the more general weigthed spanners).

Algorithm 4 Thick pairs resolver - Distance preserver $(G(V, E), \{\ell(e), c(e)\}_{e\in E})$.

```
$R \leftarrow \phi$, $G' \leftarrow \phi$.
for $i = 1$ to $\beta \ln n$ do
    $v \leftarrow$ a uniformly random element of $V$.
    $S_v^{source} \leftarrow$ a single-source distance preserver rooted at $v$ with $D = \{v\} \times V$ .
    $S_v^{sink} \leftarrow$ a single-sink distance preserver rooted $v$ with $D = \{v\} \times V$.
    $G' \leftarrow G' \cup S_v^{source} \cup S_v^{sink}$, $R \leftarrow R \cup \{v\}$.
return $G'$
```

▶ **Lemma 24.** *Algorithm 4 resolves all thick pairs for* All-pair Weighted Distance Preserver *with high probability and cost* $\tilde{O}(n^{\varepsilon} \cdot \beta \cdot OPT) = \tilde{O}(n^{1/2+\varepsilon} \cdot OPT)$.

Proof. Let $\mathsf{OPT}(S_v^{source})$ be the optimal costs of a single-source distance preserver rooted at v with $D = \{v\} \times V$ and $\mathsf{OPT}(S_v^{sink})$ be the optimal costs of a single-sink distance preserver rooted at v with $D = \{v\} \times V$.

This theorem also gives an $\tilde{O}(k^{\delta})$-approximation for the offline problem Single-source Weighted Spanner for any constant $\delta > 0$. Single-sink distance preservers can be obtained by simply reversing the edges. The number of terminal pairs $k = \Theta(n^2)$. By setting $\delta = \varepsilon/2$ and the target distances to the exact distances in G for all vertex pairs, we observe that the cost due to one sample in Algorithm 4 is at most $\tilde{O}(n^{\varepsilon}(\mathsf{OPT}(S_v^{source}) + \mathsf{OPT}(S_v^{sink})))$. Note that a distance preserver for all pairs also serves as a distance preserver for any subset of the pairs and thus we have for any $v \in V$, $\mathsf{OPT}(S_v^{sink}) \le \mathsf{OPT}$ and $\mathsf{OPT}(S_v^{source}) \le \mathsf{OPT}$. Thus, using Theorem 9, the cost of the G' returned by Algorithm 4 is at most $|R| \cdot \tilde{O}(n^{\varepsilon} \cdot \mathsf{OPT}) \le \tilde{O}(n^{\varepsilon} \cdot \beta \cdot \mathsf{OPT})$.

Using a hitting set argument very similar to Claim 10, we can see that with high probability, there is at least one sample v such that there is a $s \leadsto v \leadsto t$ path for every $(s, t) \in V \times V$ where $d_{G'}(s, v) + d_{G'}(v, t) = d_G(s, t)$.

The single-sink distance preserver gives us a $s \leadsto v$ path of length $d_G(s, v)$ and the single-source distance preserver gives us a $v \leadsto t$ path of length $d_G(v, t)$. Thus, thick pairs are resolved with high probability by the edges in G'. ◀

3.2 Thin pairs

To resolve thin pairs, we start by redefining anti-spanners by ignoring the path costs in Definition 20.

▶ **Definition 25.** *A set $A \subseteq E$ is an anti-spanner for a demand pair $(s, t) \in E$ if $(V, E \setminus A)$ contains no feasible path from s to t. If no proper subset of anti-spanner A for (s, t) is an anti-spanner for (s, t), then A is minimal. The set of all minimal anti-spanners for all thin edges is denoted by $\mathcal{A}$.*

Consider the following LP which is a slightly modified version of a similar LP from [10].

$$\min \sum_{e\in E} c(e)\cdot x_e \quad \text{subject to} \sum_{e\in A} x_e \geq 1 \quad \forall A \in \mathcal{A} \text{ and } x_e \geq 0 \quad \forall e \in E. \tag{3}$$

Let OPT denote the optimal solution to the LP. We can obtain this in a way identical to [10] as we only change the objective (which does not affect the separation oracle). Now, if $\{\hat{x_e}\}$ denotes the vector of x_e's in the solution to LP (3), then add every edge $e \in E$ to G' with probability $\min\{\sqrt{n}\cdot \ln n \cdot \hat{x_e}, 1\}$. We now state the following claim from [10].

▷ Claim 26. Given a feasible solution to LP (3), the rounding procedure produces a set of edges E'' that settles all thin pairs with high probability and has size at most $2\mathsf{OPT}\cdot\sqrt{n}\cdot\ln n$.

▶ **Theorem 4.** *For any constant $\varepsilon > 0$, there is a polynomial-time randomized algorithm for* All-pair Weighted Distance Preserver *with approximation ratio $\tilde{O}(n^{1/2+\varepsilon})$, which succeeds in resolving all pairs in $V \times V$ with high probability.*

Proof of Theorem 4. Using Lemma 24 we can resolve all thick pairs with high probability with cost at most $\tilde{O}(n^{1/2+\varepsilon}\cdot\mathsf{OPT})$ by running Algorithm 4. Then, using Claim 26, we can solve and round LP (3) to resolve the thin pairs with high probability and cost $\tilde{O}(\mathsf{OPT}\cdot\sqrt{n})$. ◀

4 Online Weighted Spanners

This section is dedicated to proving Theorems 6 and 9. The proof outline is as follows.

1. We first show that there exists an α-approximate solution consisting of distance-preserving weighted junction trees (see Definition 14). Here, $\alpha = O(\sqrt{k})$ for Pairwise Weighted Spanner and $\alpha = 1$ for Single-source Weighted Spanner.
2. We slightly modify the online algorithm from [33] to find an online solution consisting of distance-preserving weighted junction trees by losing a factor of $\tilde{O}(k^{\varepsilon})$.

The main difference between the online approach and the offline approach in Section 2 is that we cannot greedily remove partial solutions to settle the terminal pairs in the online setting. Instead, we construct a distance-preserving weighted junction tree solution in an online fashion.

▶ **Definition 27.** *A* distance-preserving weighted junction tree solution *is a collection of distance-preserving weighted junction trees rooted at different vertices, that satisfies all the terminal distance constraints.*

We construct a distance-preserving weighted junction tree solution online and compare the online objective with the optimal distance-preserving weighted junction tree solution with objective value OPT_{junc}. The following theorem is essentially from [33] for the case when the edges have unit costs and lengths. However, the slight yet important modifications that we need when edges have arbitrary positive costs and integral lengths in $\mathsf{poly}(n)$ are not covered in [33]. We refer the reader to the full version [32] for the complete proof.

▶ **Theorem 28.** *For any constant $\varepsilon > 0$, there exists a polynomial-time randomized online algorithm for* Online Pairwise Weighted Spanner *that constructs a distance-preserving weighted junction tree solution online with a cost at most $\tilde{O}(k^{\varepsilon})OPT_{junc}$ with high probability.*

With this theorem, we are ready to prove Theorems 6 and 9.

Proof for Theorems 6 and 9. Let OPT denote the cost of the optimal solution and α denote the ratio between OPT_{junc} and OPT. It suffices to show that $\alpha = O(\sqrt{k})$ for Pairwise Weighted Spanner and $\alpha = 1$ for Single-source Weighted Spanner because Theorem 28 implies the existence of an $\tilde{O}(\alpha k^{\varepsilon})$-competitive online algorithm.

To show that $\alpha = 1$ for Single-source Weighted Spanner, let H be an optimal solution. We observe that H itself is a distance-preserving weighted junction tree rooted at the source s that is connected to all the k sinks, so $\alpha = 1$.

To show that $\alpha = O(\sqrt{k})$ for Pairwise Weighted Spanner, we use a density argument via a greedy procedure which implies an $O(\sqrt{k})$-approximate distance-preserving weighted junction tree solution. We recall the density notion in Section 2.2. The density of a distance-preserving weighted junction tree is its cost divided by the number of terminal pairs that it connects within the required distances.

Intuitively, we are interested in finding low-density distance-preserving weighted junction trees. We show that there always exists a distance-preserving weighted junction tree with density at most a $\sqrt{k}$ factor of the optimal density. The proof of Lemma 29 closely follows the one for the directed Steiner network problem in [18] and pairwise spanners [33] by considering whether there is a *heavy* vertex that lies in $s_i \rightsquigarrow t_i$ paths for distinct i or there is a simple path with low density. The case analysis also holds when there is a distance constraint for each (s_i, t_i). We refer the reader to Appendix B.2 for the complete proof.

▶ **Lemma 29.** *There exists a distance-preserving weighted junction tree J with density at most $\mathsf{OPT}/\sqrt{k}$.*

Consider the procedure that finds a minimum density distance-preserving weighted junction tree in each iteration, and continues on the remaining disconnected terminal pairs. Suppose there are t iterations, and after iteration $j \in [t]$, there are n_j disconnected terminal pairs. Let $n_0 = k$ and $n_t = 0$. After each iteration, the minimum cost for connecting the remaining terminal pairs in the remaining graph is at most OPT, so the total cost of this procedure is upper-bounded by

$$\sum_{j=1}^{t} \frac{(n_{j-1} - n_j)\mathsf{OPT}}{\sqrt{n_{j-1}}} \leq \sum_{i=1}^{k} \frac{\mathsf{OPT}}{\sqrt{i}} \leq \int_{1}^{k+1} \frac{\mathsf{OPT}}{\sqrt{x}} dx = 2\mathsf{OPT}(\sqrt{k+1} - 1) = O(\sqrt{k})\mathsf{OPT}$$

where the first inequality uses the upper bound by considering the worst case when only one terminal pair is removed in each iteration of the procedure. ◀

A Related work

A.1 Resource-constrained Shortest Path

In the resource-constrained shortest path problem [38] for directed networks, each edge is associated with r non-negative weights. Each type of weight $i \in [r-1]$ is associated with a budget. The r-th weight denotes the cost of the edge. The goal is to find a minimum-cost path that connects the single source to the single sink without violating the $r-1$ budgets. The results of [38] show that when r is a constant, there exists an FPTAS that finds a path with a cost at most the same as the feasible minimum-cost path by violating each budget by a factor of $1+\varepsilon$. When $r=2$, this problem is equivalent to the restricted shortest path problem [37, 45], which has been used extensively in the LP formulations for spanners and directed Steiner forests [10, 19, 21, 28, 33]. For our purpose, $r=3$ because the LP formulation implicitly considers whether there exists a feasible path between terminal pairs whose cost exceeds a given threshold.

A.2 Undirected Bi-criteria Network Design

A general class of undirected bi-criteria network problems was introduced by [46]. A more related problem to ours is the undirected Steiner tree problem. The goal is to connect a subset of vertices to a specified root vertex. In the bi-criteria problem, the distance from the root to a target vertex is required to be at most the given global threshold. [46] presented a bi-criteria algorithm for undirected Steiner trees that is $O(\log n)$-approximate and violates the distance constraints by a factor of $O(\log n)$. Following [46], [36] extends this result to a more general buy-at-bulk bi-criteria network design problem, where the objective is $\mathsf{polylog}(n)$-approximate and violates the distance constraints by a factor of $\mathsf{polylog}(n)$.

Recently, [29, 35] studied the tree embedding technique used for undirected network connectivity problems with *hop* constraints. For a positively weighted graph with a global parameter $h \in [n]$, the *hop distance* between vertices u and v is the minimum weight among the u-v-paths using at most h edges. Under the assumption that the ratio between the maximum edge weight and the minimum edge weight is $\mathsf{poly}(n)$, the tree embedding technique allows a $\mathsf{polylog}(n)$-approximation by relaxing the hop distance within a $\mathsf{polylog}(n)$ factor for a rich class of undirected network connectivity problems.

A.3 Other related directed network problems

The more related directed network problems are variants of spanners and Steiner problems, including directed Steiner trees [15, 56], directed Steiner network [18], fault-tolerance spanners [21, 22], and parameterized complexity analysis for directed s-spanners [31]. For a comprehensive account of the vast literature, we refer the reader to the excellent survey for spanners [2].

There is an extensive list of other related directed network problems, including distance preservers [12, 19], approximate distance preservers [41], reachability preservers [1], and buy-at-bulk network design [5]. One direction along this line of research is to study the extremal bounds for the optimal subgraph in terms of the input parameters, instead of comparing the costs of the approximate and optimal solution [1, 12, 41]. Another direction is to consider the online problem where terminal pairs arrive online and the goal is to irrevocably select edges so that the cost of the network is approximately minimized [3, 14, 33].

B Missing Proofs in Section 2

B.1 Proof for Lemma 18

▶ **Lemma 18.** *Let OPT be the optimal value of an instance of* Pairwise Weighted Spanner*. Then, the optimal value of LP* (2) *corresponding to that instance is at most OPT. In addition, a solution for LP* (2) *of value at most* $(1+\varepsilon)\cdot \mathsf{OPT}$ *can be found in polynomial time.*

Proof. We recall LP (2):

$$\begin{aligned}
\min \quad & \sum_{e \in E} c(e)\cdot x_e \\
\text{subject to} \quad & \sum_{(s,t)\in D} y_{s,t} \geq \frac{|D|}{2}, \\
& \sum_{\Pi(s,t)\ni p \ni e} f_p \leq x_e && \forall (s,t)\in D, e \in E, \\
& \sum_{p \in \Pi(s,t)} f_p = y_{s,t} && \forall (s,t) \in D, \\
& 0 \leq y_{s,t}, f_p, x_e \leq 1 && \forall (s,t)\in D, p \in \Pi, e \in E.
\end{aligned} \tag{2}$$

Let us consider the dual of LP (2).

$$\begin{aligned}
\max \quad & \sum_{e\in E} x_e + \sum_{(s,t)\in D} y_{s,t} - W \cdot \frac{|D|}{2} && && \text{(4a)}\\
\text{subject to} \quad & \sum_{(s,t)\in D} z_{(s,t),e} + c(e) \le x_e && \forall e \in E, && \text{(4b)}\\
& y_{s,t} + w_{s,t} \ge W && \forall (s,t) \in D, && \text{(4c)}\\
& w_{s,t} \le \sum_{e\in p} z_{(s,t),e} && \forall (s,t) \in D, p \in \Pi(s,t), && \text{(4d)}\\
& W, x_e, y_{s,t}, z_{(s,t),e} \ge 0 && \forall (s,t) \in D, e \in E. && \text{(4e)}
\end{aligned}$$

Our dual is slightly different from the dual in [10, 28]. Constraints in (4b), (4c), and (4e) are identical, but constraints in (4d) are slightly different because the set of paths Π we consider are different from the set of paths considered in [28]. As in [28], we could find violating constraints for (4b), (4c), and (4e) in polynomial time. The only constraints that require care are the constraints in (4d), which may be exponentially many.

When we consider a single (s,t) pair, [28] pointed out that their variant of constraints in (4d) are equivalent to Restricted Shortest Path which is NP-hard, see [37, 45]. [28] then uses an FPTAS [37, 45] for Restricted Shortest Path as an approximate separation oracle for those constraints. But we need a different separation oracle because the set of paths Π allowed in our LP have two restrictions (as opposed to [28] which has only one) in addition to an objective. We now define the Resource-constrained Shortest Path problem that is presented in [38].

▶ **Definition 30** (Resource-constrained Shortest Path (k-RCSP)).

Instance: *A directed graph $G = (V, E)$, with edge costs $c : E \to \mathbb{Q}_{\ge 0}$, and a pair (s,t). For each edge $e \in E$, we have a vector $r_e = (r_{1,e}, r_{2,e}, \ldots, r_{k,e})$ of size k where each $r_{i,e} \in \mathbb{Q}_{\ge 0}$ $\forall i \in [k]$.*

Objective: *Find a minimum cost $s \rightsquigarrow t$ path P such that $\sum_{e\in P} r_{i,e} \le R_i$, $\forall i \in [k]$.*

▷ Claim 31. 2-RCSP acts as a separation oracle for those constraints in equation (4d) that correspond to a specific $(s,t) \in D$.

Proof. We can use one of the resource constraints in 2-RCSP for ensuring that the distance constraints for (s,t) are satisfied and use the other resource constraint to ensure that $w_{s,t} > \sum_{e\in P} z_{(s,t),e}$. In other words, we use one resource to model the edge lengths and another to model the dual variable $z_{\{s,t\},e}$. We can now try to find a minimum cost $s \rightsquigarrow t$ path in this instance of 2-RCSP where costs for 2-RCSP are equivalent to the costs in our instance of Pairwise Weighted Spanner. If the minimum cost obtained when we meet these constraints is less than L, then we have a violating constraint and if not we do not have one. ◁

The Resource-constrained shortest path problem is NP-hard [38]. So, we instead get a separation oracle for an approximate variant of LP (4). Now, given resource constraints $R_1, R_2, \ldots, R_k$ for the Resource-constrained shortest path problem, let OPT_{RCSP} be the cost of the minimum cost $s \rightsquigarrow t$ path that satisfies the resource constraints. An $(1; 1+\varepsilon, \ldots, 1+\varepsilon)$-approximation scheme finds an $s \rightsquigarrow t$ path whose cost is at most OPT_{RCSP}, but the resource constraints are satisfied up to a factor of $1+\varepsilon$ for that path.

▶ **Lemma 32** (RCSP – [38]). *If k is a constant then there exists a fully polynomial time $(1; 1+\varepsilon, \dots, 1+\varepsilon)$-approximation scheme for the k-RCSP that runs in time polynomial in input size and $1/\varepsilon$.*

We have to be careful in our usage of Lemma 32. The FPTAS for the Restricted Shortest Path problem from [45] cleanly serves the requirements of [28] as it is a $(1+\varepsilon; 1)$ approximation and it can strictly satisfy the constraints. [28] then uses these constraints to ensure that the weight requirements are strictly met. But the FPTAS given by [38] does not strictly satisfy the constraints since we need both the length and weight constraints to be satisfied strictly.

We overcome this obstacle by re-purposing the objective to handle the edge weights and by carefully ensuring that any error in the path length caused by using the $1+\varepsilon$ approximation from [38] does not make us use an incorrect path. To ensure that we do not select an incorrect path, it is sufficient to ensure that the potential error from [38] is less than any error that is possible in our given input graph. Since the edge lengths are positive integers, observe that for any two $s \rightsquigarrow t$ paths with different lengths, the length difference is at least one. In addition, the path lengths are at most $n \cdot \max_{e\in E}\{\ell(e)\}$. Since all edge lengths are integral and of magnitude $\mathsf{poly}(n)$, it is sufficient to have $\varepsilon \le 1/(n \cdot \max_{e\in E}\{\ell(e)\})$. Thus, we can fix ε such that $1/\varepsilon = O(n \cdot \mathsf{poly}(n))$ to ensure that the running time will remain polynomial in input size and strictly satisfy the distance constraints.

Now, we take an approximate version of LP (4) which is the following LP

$$\begin{aligned}
\max \quad & \sum_{e\in E} x_e + \sum_{s,t} y_{s,t} - W \cdot \frac{|D|}{2} && \\
\text{subject to} \quad & \sum_{s,t} z_{(s,t),e} + c(e) \le x_e && \forall e \in E, \\
& y_{s,t} + w_{s,t} \ge W && \forall (s,t) \in D, \\
& (1+\varepsilon) \cdot w_{s,t} \le \sum_{e\in p} z_{(s,t),e} && \forall (s,t) \in D, p \in \Pi(s,t), \\
& W, x_e, y_{s,t}, z_{(s,t),e} \ge 0 && \forall (s,t) \in D, e \in E.
\end{aligned} \tag{5}$$

We can exactly solve LP (5) using [38] and thus we can also exactly solve the dual of LP (5) which would be:

$$\begin{aligned}
\min \quad & \sum_{e\in E} c(e) \cdot x_e && \\
\text{subject to} \quad & \sum_{(s,t)\in D} y_{s,t} \ge \frac{|D|}{2}, && \\
& \sum_{\Pi(s,t)\ni P\ni e} f_p \le x_e \cdot (1+\varepsilon) && \forall (s,t) \in D, e \in E, \\
& \sum_{P\in\Pi(s,t)} f_p = y_{s,t} && \forall (s,t) \in D, \\
& 0 \le y_{s,t}, f_p, x_e \le 1 && \forall (s,t) \in D, p \in \Pi, e \in E.
\end{aligned} \tag{6}$$

Let $\mathsf{OPT}(\varepsilon)$ and OPT be the optimal values to (6) and (2) respectively. Observe that $\mathsf{OPT}(\varepsilon) \le \mathsf{OPT}$ because the constraints in LP (6) are slacker than the constraints in (2) and both these LPs are minimization LPs. Also note that if $\hat{x}(\varepsilon)$ is a feasible solution to (6), then by replacing the value of every variable x_e in $\hat{x}(\varepsilon)$ by $\min(1, x_e \cdot (1+\varepsilon))$, we get a new solution $\hat{x}$ which is a feasible solution to (2). The value of the optimal solution then is at most $(1+\varepsilon) \cdot \mathsf{OPT}(\varepsilon) \le (1+\varepsilon) \cdot \mathsf{OPT}$. ◀

B.2 Missing proof for Lemma 29

▶ **Lemma 29.** *There exists a distance-preserving weighted junction tree J with density at most $\mathsf{OPT}/\sqrt{k}$.*

Proof. Let G^* (a subgraph of G) be the optimal pairwise weighted spanner solution with cost OPT. The proof proceeds by considering the following two cases: 1) there exists a vertex $r \in V$ that belongs to at least $\sqrt{k}$ $s_i \rightsquigarrow t_i$ paths of distance at most $Dist(s_i, t_i)$ in G^* for distinct i, and 2) there is no such vertex $r \in V$.

For the first case, we consider the union of the $s_i \rightsquigarrow t_i$ paths in G^*, each of distance at most $Dist(s_i, t_i)$, that passes through r. This subgraph in G^* contains an in-arborescence and an out-arborescence both rooted at r, whose union forms a distance-preserving weighted junction tree. This distance-preserving weighted junction tree has cost at most OPT and connects at least $\sqrt{k}$ terminal pairs, so its density is at most $\mathsf{OPT}/\sqrt{k}$.

For the second case, each vertex $r \in V$ appears in at most $\sqrt{k}$ $s_i \rightsquigarrow t_i$ paths in G^*. More specifically, each edge $e \in E$ also appears in at most $\sqrt{k}$ $s_i \rightsquigarrow t_i$ paths in G'. By creating $\sqrt{k}$ copies of each edge, all terminal pairs can be connected by edge-disjoint paths. Since the overall duplicate cost is at most $\sqrt{k} \cdot \mathsf{OPT}$, at least one of these paths has cost at most $\sqrt{k} \cdot \mathsf{OPT}/k$. This path constitutes a distance-preserving weighted junction tree whose density is at most $\mathsf{OPT}/\sqrt{k}$. ◀

C Conclusion

In this paper, we presented algorithms for a variant of directed spanners that could also handle costs on edges, in addition to the more standard setting of edge lengths. The proof strategy for Theorem 2 follows a high-level structure that is similar to other results for directed Steiner forests, but involves significant obstacles in each part of the proof due to the addition of distance constraints. We overcome these obstacles by using the proper approaches. For example, the Resource-constrained Shortest Path problem from [38] is carefully adapted for our specifics. We also needed to carefully adapt many other parts of the proof, such as the analysis of our junction-tree approximation and our rounding algorithm for the LPs, to fit the addition of distance constraints.

We also present online algorithms for Online Pairwise Weighted Spanner and Online Single-source Weighted Spanner. We use our result for Online Single-source Weighted Spanner to solve a special case of Pairwise Weighted Spanner, namely, All-pair Weighted Distance Preserver, and obtain a significantly better approximation for that case.

We propose the following directions for future work:

- Is it possible to get a better analysis for the rounding algorithm for Theorem 2 as in [10]? This should improve the overall approximation factor for Pairwise Weighted Spanner in Theorem 2.
- Is there a hardness bound for Pairwise Weighted Spanner that is greater than the existing hardness bounds for Steiner forests and unit-cost spanners?
- Is there a better approximation factor for all-pair weighted spanners, i.e., an instance of Pairwise Weighted Spanner where $D = V \times V$?
- Can we get a result for pairwise weighted distance preserver that is better than using the Pairwise Weighted Spanner results in Theorem 2?

Abstract

Graph Burning models information spreading in a given graph as a process such that in each step one node is infected (informed) and also the infection spreads to all neighbors of previously infected nodes. Formally, given a graph $G = (V, E)$, possibly with edge lengths, the burning number $b(G)$ is the minimum number g such that there exist nodes $v_0, \ldots, v_{g-1} \in V$ satisfying the property that for each $u \in V$ there exists $i \in \{0, \ldots, g-1\}$ so that the distance between u and v_i is at most i.

We present a randomized 2.314-approximation algorithm for computing the burning number of a general graph, even with arbitrary edge lengths. We complement this by an approximation lower bound of 2 for the case of equal length edges, and a lower bound of 4/3 for the case when edges are restricted to have length 1.

This improves on the previous 3-approximation algorithm and an APX-hardness result.

1 Introduction

Graph Burning was introduced by Bonato et al. [4] as a model of information spreading and, more specifically, as a model of contagion or influence in social networks. The idea is that "infecting" several nodes in the network and spreading information from them may reach the whole network very fast. Formally, it is defined as the following process, where *burned* nodes in a graph represent the infected part of the network.

At time $t = 0$, no node of the graph is burned. At time $t = 1$, we choose a node and burn it. At each time step $t > 1$, all neighbors of already burned nodes are also burned, and we may choose another node to burn. The process stops when all nodes are burned. We call the sequence of chosen nodes a burning schedule of the graph. The burning number $b(G)$ of a graph G is the minimum number of steps needed for all nodes of G to be burned.

For a burning schedule of length ℓ, the node selected at time t ensures that all nodes within distance $\ell - t$ from it will be burned. We can thus reformulate the Graph Burning problem as looking for the minimal g such that all nodes of the graph can be covered by some placement of g balls with unique radii from $g - 1$ to 0. Placing a ball with radius r at node v thus ensures the coverage of all nodes within the ball and represents selecting node v to be set on fire at time $g - r$ in the original formulation of the problem. This formulation also works naturally in the presence of arbitrary edge lengths.

The ball formulation emphasizes the relation of Graph Burning to the k-Center problem, where we try to cover the graph by k balls of equal radius, with the objective of minimizing the radius. In the non-uniform variant of the k-Center problem [7], different balls (centers) can have different radii, and in particular, the variant with a constant number of different radii is well-studied [11, 10]. Graph Burning can be viewed as an extreme version of the Non-Uniform k-Center problem, where neither the number of centers nor the number of distinct radii are fixed. This setting is challenging both for the design of efficient algorithms and for proving lower bounds. Thus studying Graph Burning can help to develop new techniques and insights that may be useful even for variants of k-Center and/or other facility location problems.

1.1 State of the art

Adapting a well-known greedy 2-approximation algorithm for the k-Center problem, Bonato and Kamali [5] gave a 3-approximation algorithm for Graph Burning. In fact, the approximation ratio of the algorithm is $3 - 2/b(G)$, which is a slight improvement if $b(G)$ is small; see also Appendix 3 for a review of this algorithm. Another $(3 - 2/b(G))$-approximation algorithm for arbitrary graphs was reported in [9]. In [5] it was stated as an open problem to find an improved algorithm, but no $(3 - \varepsilon)$-approximation algorithm for general graphs was known before our work.

In previous work approximation algorithms and approximation schemes were developed for trees [5] and other special graph classes [6], we refer to survey [3] for further references. This stream of research is now subsumed by [15], where it is shown that for graphs of small treewidth, a PTAS exists. The parameterized complexity of Graph Burning was studied in [12, 13, 14].

On the hardness side, it is known that computing the burning number of a graph is NP-complete even on simple classes of graphs such as trees or even disjoint unions of paths with unit edge lengths [2]. Answering an open question from [5], Mondal et al. [17, 18] have shown that Graph Burning is APX-hard, using a complex reduction from vertex cover in cubic graphs, but did not give an explicit lower bound on the approximation ratio.

1.2 Our results

In this paper, we present a randomized $(\alpha + \varepsilon)$-approximation algorithm for the Graph Burning problem on graphs with arbitrary edge lengths, where $\alpha = 2e^2/(e^2 - 1) < 2.314$ and $\varepsilon > 0$ is arbitrarily small. This is the first improvement of the previous easy 3-approximation algorithm based on k-Center results.

It has been speculated in [5] that an improved approximation algorithm will need to use a better lower bound on the burning number, presumably combinatorial. We do not use this line of attack. Instead, we use the power of randomization and analyze the following procedure: we greedily process the yet uncovered nodes and, on each such node, we put a center with radius chosen uniformly from a range $0, \dots, R$ for a carefully chosen R. This process is not easy to analyze, as the choices of nodes to be covered depend on the previous random choices. Nevertheless, we are able to show that it has a martingale property and use this to prove that the process succeeds with high probability.

On the hardness side, we give simple and explicit lower bounds on the approximation ratio for Graph Burning. We first prove a lower bound of 2 on the approximation ratio for graphs with edge lengths, which is close to our upper bound. This is an important insight since the methods we use in our algorithms but also other current approaches work even in the presence of arbitrary edge lengths, so they are all subject to this lower bound. We note that the lower bound works even if all the edge lengths are equal. We also prove a lower bound of 4/3 for graphs where all edges have length 1.

In [5] the authors note that known hardness results for related problems such as the k-Center or Dominating Set problems do not apply to Graph Burning. Indeed, they cannot be applied directly, as in approximations for Graph Burning we implicitly use both more centers and larger radii of the balls. Lower bounds for this kind of bicriteria approximations are naturally harder to show, which explains the slow progress on the inapproximability side.

We use a somewhat indirect reduction from the Dominating Set problem. For edges of length 1 the reduction is more complicated, as we need to subdivide the edges of the Dominating Set instance. As a consequence, when converting the dominating set to a Graph Burning solution, we have to use larger radii to cover the new vertices, which decreases the inapproximability bound. When other edge lengths are allowed, the subdivided edges can be replaced by long edges, which leads to the improved lower bound of 2. This is close to the performance of our algorithm.

Closing the remaining gap is an interesting open problem. We conjecture that the optimal approximation ratio is 2 at least for the version with arbitrary edge lengths.

1.3 Paper overview

In Section 2 we introduce some notations and conventions. In Section 3, we review the 3-approximation algorithm in our framework, which amounts to using the same radius for all centers. In Sections 4 and 5 we gradually introduce the building blocks of our algorithm. We examine the possibility of using a constant number of different radii, which leads to a deterministic algorithm for a logarithmic number of centers (Section 4). Then we examine the possibility of randomly choosing among two radii in Section 5. This leads to an approximation ratio below 3 and allows us to gently introduce the necessary probabilistic machinery, including the martingale approach. In Section 6 we apply all the ingredients and present the final 2.314-approximation algorithm. Finally, in Section 7 we present our lower bounds.

2 Preliminaries

We start with a formal definition of Graph Burning.

▶ **Definition 2.1.** *An instance of* Graph Burning *is an undirected graph $G = (V, E)$ with non-negative edge lengths. The* distance $d(u, v)$ *is defined as the length of the shortest path from u to v. We let $n = |V|$.*

A center *is a pair $c = (v, r)$ with $v \in V$ and r a non-negative integer; v denotes the node where the center is placed and r denotes the radius. Given a center c we denote its radius by $r(c)$. A solution of a Graph Burning instance is a set of centers $\{(v_0, 0), (v_1, 1), \dots, (v_{g-1}, g-1)\}$. It is feasible if for any node $w \in V$ there exists $i < g$ such that $d(w, v_i) \leq i$. The objective of the Graph Burning problem is to minimize g over all feasible solutions. The minimum g is called the* burning number *of G and is denoted $b(G)$.*

Conventions for the algorithms. When running our algorithms, we will be building up a set of centers ALG. We allow the set ALG not to use all the radii between 0 and the maximal radius. At the end of the algorithm, if needed, balls with the remaining radii can be placed arbitrarily completing a feasible solution without changing the maximal radius.

The set $\{(v_0, 0), \ldots, (v_{n-1}, n-1)\}$ is a *trivial* valid solution for any ordering of $V = \{v_0, \ldots, v_{n-1}\}$. Thus $b(G) \leq n$ even with arbitrary edge lengths. We assume that $V \neq \emptyset$ and thus $b(G) \geq 1$. For most of our algorithms, we will assume that the algorithm is given an integer g, presumably the burning number, and its goal is to find a feasible solution of size at most σg for some approximation ratio σ, or possibly fail if g is smaller than $b(G)$. We then try all n possible values of g in our final algorithm.

Notations for the optimum. In the analysis of our algorithms, we fix some optimal solution OPT using centers with unique radii from 0 to $b(G) - 1$. Furthermore, we assign each node $w \in V$ to a unique center $c_{\text{OPT}}(w) = (v, r) \in \text{OPT}$ that is covering it (i.e., $d(w, v) \leq r$), thus creating a partition of the set of nodes of the graph. For every $c_{\text{OPT}} \in \text{OPT}$ we denote the set of nodes assigned to it as $V(c_{\text{OPT}})$.

Good centers. For any center c_{OPT} in the optimal solution, if the computed solution ALG contains a center $c_{\text{ALG}} = (v, r)$ where $r \geq 2r(c_{\text{OPT}})$ and $v \in V(c_{\text{OPT}})$, then all nodes in $V(c_{\text{OPT}})$ are covered by c_{ALG}. If such a c_{ALG} exists, we say that c_{OPT} is made *good* by c_{ALG}.

▶ **Definition 2.2.** *A center $c_{\text{OPT}} \in \text{OPT}$ is* good *if there exists a $c_{\text{ALG}} = (v, r) \in \text{ALG}$ with $r \geq 2r(c_{\text{OPT}})$ and $v \in V(c_{\text{OPT}})$.*

Note that c_{OPT} being good is not a necessary condition for all of $V(c_{\text{OPT}})$ to be covered – a well-placed center of radius $r < 2r(c_{\text{OPT}})$, multiple smaller centers, and/or centers located outside of $V(c_{\text{OPT}})$ might cover all of $V(c_{\text{OPT}})$.

We design our algorithms so that the (expected) number of good centers increases in each step and rely on the fact that a solution ALG is feasible whenever it makes all centers of the optimum good. While it may happen that not all centers of OPT become good, eventually all nodes end up covered as the number of good centers is increasing and it cannot increase beyond the number of centers in the optimal solution.

Classes of centers. Most of our algorithms divide the radii at their disposal using a series of thresholds. The thresholds are given as a list $q_1, q_2, q_3, \ldots$ of increasing numbers (not necessarily integers). For a center $c_{\text{OPT}} \in \text{OPT}$, we define its *class* as the smallest i such that using q_i for $v \in V(c_{\text{OPT}})$ ensures that c_{OPT} becomes good:

▶ **Definition 2.3.** *For a center $c_{\text{OPT}} \in \text{OPT}$ we refer to the minimal i such that the threshold q_i is larger than or equal to $2r(c_{\text{OPT}})$ as the* class *of c_{OPT}.*

Procedure for selecting a radius. Whenever our algorithms need to use a radius to add a center to ALG, they call the procedure $\textsc{Select}(q)$, which takes a number q (typically a threshold) as its input. It then returns the minimal integer radius that has not yet been used by the algorithm and is at least q.

This procedure guarantees that our algorithms always use centers of distinct radii, at the cost of possibly increasing the largest radius and thus the size of the solution. In the analysis, we then need to prove that the maximal radius used is (with high probability) small enough.

Notations. We use $\exp(x)$ to denote e^x. We also use the convention that $x/yz = x/(yz)$.

3 Deterministic 3-approximation algorithm and overall approach

We revisit the 3-approximation algorithm from [4]. See Algorithm 1 for our formalization; recall that we assume that the algorithm is given g. We use a single threshold $q_1 = 2(g-1)$. This means that all centers c_{OPT} are class 1, as the optimum uses radii up to $g-1$, while our algorithm will use radii $2g-2$, $2g-1$ and so on.

Algorithm 1 The deterministic 3-approximation algorithm.

```
ALG ← ∅; $q_1 = 2g - 2$
while an uncovered node exists do
    Select an arbitrary uncovered node $v$
    $r = \textsc{Select}(q_1)$
    Add center $(v, r)$ to ALG and update the set of uncovered nodes
return ALG
```

Observe that whenever we select an uncovered node v, it is covered by some class 1 center $c_{\text{OPT}}(v)$ that is not good. Placing a center c_{ALG} with radius at least q_1 at v is guaranteed to make $c_{\text{OPT}}(v)$ good. Thus, once we place g centers c_{ALG} with radii at least q_1, all centers of OPT will be good and the algorithm finishes. Note that all nodes might be covered without all centers of OPT being good, making the algorithm finish sooner. Either way, we are guaranteed to never select a radius greater than $q_1 + g - 1 = 3g - 3$, making this a 3-approximation algorithm. More precisely, the algorithm uses $3g-2$ centers, as opposed to optimal $b(G) \leq g$. So the approximation ratio becomes $3 - 2/b(G)$, as mentioned in the introduction.

4 Deterministic algorithm for small burning number

Let us now explore an approach that uses z thresholds equally spaced between 0 and $2(g-1)$, for some constant z. This means, disregarding rounding, that the optimum centers are divided into z classes, where the class i has g/z centers of radii between $(i-1)g/z$ and ig/z. The algorithm will aim to cover the centers of class i using thresholds approximately $2ig/z$, each for g/z nodes. As a result the largest radius can be bounded by $2g + g/z$.

Similar to before, this algorithm will choose an uncovered node in each iteration as a center for the approximate solution. This would work easily if we knew in advance the class of the center c_{OPT} covering the chosen node, so that we could use the corresponding threshold in the algorithm. Instead, we try all the possible sequences of thresholds, using each threshold for at most $\lceil g/z \rceil$ nodes, matching the number of optimal centers of each class. The analysis is somewhat subtle, as the node to be processed depends on the previous choices of the algorithm, so the sequence of thresholds used in the optimum needs to be constructed based on the nodes chosen by the algorithm.

Formalizing this idea with some attention to rounding and also the fact that the optimum can use fewer than g centers, we obtain an algorithm that finds a Graph Burning solution with objective at most $(2 + 1/z)g$ in time $\mathcal{O}\left(z^g \text{poly}(n)\right)$ for any given integer z and $g \geq b(G)$; see Algorithm 2.

▶ **Theorem 4.1.** *If $g \geq b(G)$ then Algorithm 2 runs in $\mathcal{O}\left(z^g \text{poly}(n)\right)$-time and achieves an approximation ratio of $(2 + 1/z)$.*

For the full proof of Theorem 4.1 see Appendix A. (For $z \geq g$, the proof actually gives ratio $2 - 1/g$. We omit that in the statement, as in the relevant case z is small.)

Algorithm 2 Deterministic algorithm for small g.

```
if $z > g$ then $z \leftarrow g$
Order $V$ arbitrarily
$q_i \leftarrow 2gi/z - 2$ for $i \in \{1, \dots, z\}$
Let $\mathbb{S}$ be a set of all possible sequences $S = s_0, s_1, \dots, s_{g-1}$ with $s_t \in \{1, \dots, z\}$
  such that each value is used at most $\lceil g/z \rceil$ times
for $S \in \mathbb{S}$ do
    ALG $\leftarrow \emptyset$
    for $t \leftarrow 0, 1, \dots, g-1$ do
        Let $v$ be the first uncovered node; $r \leftarrow$ SELECT$(q_{s_t})$
        Add center $(v, r)$ to ALG and update the set of uncovered nodes
        if all nodes are covered then return ALG
return Fail
```

The running time is polynomial if $g \in \mathcal{O}(\log n)$ and $z \in \mathcal{O}(1)$, thus we get a deterministic $(2 + 1/z)$-approximation algorithm in this case. We will later use this result in our final algorithm with $z = 4$, ensuring an approximation ratio of $2 + 1/4 < 2.314$ for small $b(G)$.

5 Randomized approach with two classes of centers

As a warmup, in this section we introduce the main ideas of our techniques by considering a simpler setup. In particular, let us only use two thresholds $g - 1$ and $2(g - 1)$, and choose a radius randomly among the two values of the threshold; see Algorithm 3.

Algorithm 3 The randomized algorithm with two classes.

```
ALG $\leftarrow \emptyset$; $q_i \leftarrow i(g-1)$ for $i \in \{1, 2\}$
while an uncovered node exists do
    Select an arbitrary uncovered node $v$
    Let $k_v \in \{1, 2\}$ be chosen uniformly at random, independently from other choices
    $r \leftarrow$ SELECT$(q_{k_v})$
    Add center $(v, r)$ to ALG and update the set of uncovered nodes
return ALG
```

Note that, as the radii start with 0, the optimum has $\lceil g/2 \rceil$ class 1 centers and $\lfloor g/2 \rfloor$ class 2 centers. Observe that a class 1 center c_{OPT} becomes good whenever we select an uncovered node from $V(c_{\text{OPT}})$. A class 2 center c_{OPT} becomes good if we select an uncovered node from $V(c_{\text{OPT}})$ and then randomly decide to use threshold q_2. If we were to make all centers of OPT good, we would use in expectation one radius per class 1 center and two radii per class 2 center, evenly distributed between threshold q_1 and threshold q_2. Since each class of centers of OPT contains roughly $0.5g$ centers, we expect at most $1.5g$ total radii being needed. Of these, we expect half, i.e., $0.75g$, to be at least the threshold $q_2 \leq 2g$. This indicates that roughly a 2.75-approximation algorithm should be the result.

Using a detailed analysis it is indeed possible to prove that Algorithm 3 is a $(2.75 + \varepsilon)$-approximation algorithm, improving on the previously known 3-approximation. For simplicity and to introduce the key ideas for our main algorithm, we will however only prove that this is a 2.9-approximation algorithm for g divisible by 10 (to avoid rounding issues), and then move on to give our 2.314-approximation in the following section. We show that the following holds with high probability:

- less than $1.6g$ centers c_{ALG} are placed by Algorithm 3, and
- less than $0.9g$ centers c_{ALG} with radius at least q_2 are placed, conditioned on the previous event (i.e., that the algorithm uses less than $1.6g$ centers).

5.1 Total number of centers

We will use martingales to analyze the algorithm; see the textbooks [1, 16] for reference. For convenience, we use a slight modification of the one-sided Azuma inequality for supermartingales. This follows easily, as any supermartingale can be converted to a martingale by shifting (increasing) the random variables appropriately.

▶ **Definition 5.1.** *A sequence of random variables $X_0, X_1, X_2, \ldots$ is a supermartingale if and only if both $|\mathbb{E}[X_t]| < \infty$ and $\mathbb{E}[X_{t+1} \mid X_0, \ldots, X_t] \le X_t$ for all t.*

▶ **Theorem 5.2** (Azuma Inequality). *If $X_0, X_1, X_2, \ldots$ is a supermartingale with $|X_t - X_{t-1}| \le \delta$ for all t, the following inequality holds:*

$$\Pr[X_t - X_0 \ge \Delta] \le \exp\left(\frac{-\Delta^2}{2\delta^2 t}\right).$$

We will track the progress of our algorithm by defining a potential describing the difference between the algorithm's true and expected behaviour. Formally, let C_t be a random variable denoting the set of centers of OPT made good by the first t centers c_{ALG} placed by Algorithm 3. Let us define $f(c_{\text{OPT}})$ as the class of c_{OPT}. Finally, let the potential be

$$\Phi_t = t - \sum_{c_{\text{OPT}} \in C_t} f(c_{\text{OPT}}).$$

The value $f(c_{\text{OPT}})$ is chosen so that a center c_{OPT} is expected to become good after the algorithm selects $f(c_{\text{OPT}})$ centers from $V(c_{\text{OPT}})$. Thus, at a given moment, the sum in the potential denotes the number of centers the algorithm was expected to select to make all $c_{\text{OPT}} \in C_t$ good. If t, the actual number of centers of the algorithm, is smaller than the sum, the potential is negative and the algorithm is progressing better than expected. If t is smaller than the sum, the potential is positive and the algorithm is progressing worse than expected. Our goal is to show that the potential is unlikely to be positive and large.

The random choice of a threshold influences whether the current $c_{\text{OPT}}(v)$ enters C_t. Besides that, the random choices also possibly change the set of covered nodes, influencing the later choices of the algorithm. Thus the changes of the potential in different steps are not independent (even if the choices of thresholds are) and we need to analyze the process as a martingale.

Observe that $\Phi_0, \Phi_1, \ldots$ is a sequence of random variables with $\Phi_0 = 0$. When we select node v as the $(t+1)$-st node to cover, only $c_{\text{OPT}} = c_{\text{OPT}}(v)$ can become good. If center c_{OPT} is class 1, then $f(c_{\text{OPT}}) = 1$ and we make it good with probability 1, which guarantees $\Phi_{t+1} = \Phi_t$. If center c_{OPT} is class 2, $f(c_{\text{OPT}}) = 2$. We make it good with probability at least $1/2$ and in this case $\Phi_{t+1} = \Phi_t - 1$. Otherwise $\Phi_{t+1} = \Phi_t + 1$. Thus $\mathbb{E}[\Phi_{t+1} \mid \Phi_0, \ldots, \Phi_t] \le \Phi_t$ and $\Phi_0, \Phi_1, \ldots$ is a supermartingale with $\Phi_0 = 0$ and $\delta = 1$.

We have $\sum_{c_{\text{OPT}} \in \text{OPT}} f(c_{\text{OPT}}) \le 1.5g$, corresponding to the fact that the expected number of radii needed for the algorithm is $1.5g$. Thus, if the algorithm does not stop before placing $1.6g$ centers, we have $\Phi_{1.6g} = 1.6g - \sum_{c_{\text{OPT}} \in C_{1.6g}} f(c_{\text{OPT}}) \ge 0.1g$. We use Azuma's inequality to show that the probability of this happening is small, keeping in mind that $\Phi_0 = 0$ and $\delta = 1$:

$$\Pr[\Phi_{1.6g} \ge 0.1g] \le \exp\left(\frac{-0.01g^2}{3.2g}\right) = \exp\left(\frac{-g}{320}\right).$$

5.2 Number of large centers

To show that less than $0.9g$ centers c_{ALG} with radius at least q_2 are placed among the first $1.6g$ centers chosen by the algorithm, we use the standard Chernoff bound, see the textbooks [1, 16].

▶ **Theorem 5.3** (Chernoff bound). *Suppose $X_1, \dots, X_J \in \{0,1\}$ are independent random variables. Let $X = \sum X_j$ and $\mu = \mathbb{E}[X] = \sum \mathbb{E}[X_j]$. Then for any $\varepsilon \in (0,1]$,*

$$\Pr[X \geq (1+\varepsilon)\mu] \leq \exp\left(\frac{-\varepsilon^2\mu}{3}\right).$$

Suppose that the algorithm chooses J centers for some $J \leq 1.6g$. Let X_j, $j = 1, \dots, J$, be a 0-1 indicator variable equal to 1 if we use a threshold q_2 when choosing the j-th center in the algorithm. Since every X_j is equal to 1 with probability 1/2 we have $\mu = \mathbb{E}[\sum X_j] = J/2 \leq 0.8g$. By Chernoff's bound, the probability of using threshold 2 more than $0.9g$ times is at most

$$\Pr[X \geq (1+\tfrac{1}{8})\mu] \leq \exp\left(\frac{-(\frac{1}{8})^2\mu}{3}\right) \leq \exp\left(\frac{-g}{320}\right).$$

5.3 Final bound

▶ **Theorem 5.4.** *The probability that Algorithm 3 uses a radius larger than or equal to $2.9g$ is at most $2\exp(-g/320)$.*

Proof. Using the previous two estimates, the probability that the algorithm uses more than $1.6g$ centers in total or more than $0.9g$ times threshold q_2 is bounded by $2\exp(-g/320)$.

If none of these events happen, we distinguish two cases. Either the algorithm uses all the radii between q_1 and q_2; then we use the fact that the total number of centers is at most $1.6g$ and thus the largest radius is at most $q_1 + 1.6g < 2.6g$. Otherwise, radii q_2 and larger are used only when threshold q_2 is selected, which happens at most $0.9g$ times and thus the largest radius is less than $q_2 + 0.9g < 2.9g$. ◀

6 Main randomized algorithm

The performance of Algorithm 3 can be further improved by using more thresholds. Ultimately, this leads to using a range of integers as thresholds. In particular, for a given g we use all integers up to approximately αg where α is the desired approximation ratio given by the following definition.

▶ **Definition 6.1.** *We set $\alpha = 2e^2/(e^2-1) < 2.314$.*

Let us present and analyze Algorithm 4 which is the key part of the final algorithm. For any $\varepsilon > 0$, we shall show that its approximation ratio is at most $(1+\varepsilon)^4\alpha$. We assume that $\varepsilon < 1$ (as otherwise we could use the known 3-approximation), $\alpha g < |V|$ (as otherwise a trivial solution is an α-approximation), $g \geq b(G)$ (as we will later iterate over all g) and $g \geq 100/\varepsilon^3$ (as we will use Algorithm 2 otherwise).

6.1 Expected number of centers

Next we analyze the expected number of centers that the algorithm uses. This is the key part that determines the approximation ratio and our choice of α. In particular, we set α so that the expected number of centers used is αg. On one hand, the largest radius is

Algorithm 4 The randomized algorithm for large g.

```
$\textsc{alg} \leftarrow \emptyset$; $R \leftarrow (1+\varepsilon)^2\alpha g$
while an uncovered node exists do
    Select an arbitrary uncovered node $v$
    Let $k_v \in \{0, \ldots, \lfloor R \rfloor\}$, be chosen uniformly and independently at random
    $r \leftarrow \textsc{Select}(k_v)$
    Add center $(v, r)$ to $\textsc{alg}$ and update the set of uncovered nodes
return $\textsc{alg}$
```

necessarily at least the number of centers used, on the other hand, once the range of radii exceeds the expected number of centers by a small factor, we will be able to show that with high probability the largest radius used is not much larger than the expected number of centers. This eventually gives an approximation factor arbitrarily close to the chosen α.

Similar to Section 5, the value $f(c_{\textsc{opt}})$ is chosen so that a center $c_{\textsc{opt}}$ is expected to become good after the algorithm selects $f(c_{\textsc{opt}})$ centers from $V(c_{\textsc{opt}})$.

▶ **Definition 6.2.** *For any center $c_{\textsc{opt}}$ of the optimum, define*

$$f(c_{\textsc{opt}}) = \frac{\alpha g}{\alpha g - 2r(c_{\textsc{opt}})} = \frac{1}{1 - \frac{2r(c_{\textsc{opt}})}{\alpha g}} .$$

▶ **Lemma 6.3.** *For any given center $c_{\textsc{opt}}$, whenever Algorithm 4 selects a node in $V(c_{\textsc{opt}})$, the probability that $c_{\textsc{opt}}$ is made good is at least $1/f(c_{\textsc{opt}})$. The expected number of nodes in $V(c_{\textsc{opt}})$ selected by Algorithm 4 is bounded by $\mathbb{E}\left[|\textsc{alg} \cap V(c_{\textsc{opt}})|\right] \leq f(c_{\textsc{opt}})$.*

Proof. Every time the algorithm selects a node in $V(c_{\textsc{opt}})$, the number of possible values for uniformly random k_v is $1 + \lfloor R \rfloor \geq R \geq \alpha g$. Thus the algorithm selects a radius $r' \geq 2r(c_{\textsc{opt}})$ with probability at least $p = 1 - 2r(c_{\textsc{opt}})/\alpha g = 1/f(c_{\textsc{opt}})$ and this makes $c_{\textsc{opt}}$ good. Once $c_{\textsc{opt}}$ is made good, no more nodes in $V(c_{\textsc{opt}})$ are selected. Since the choices of k_v are independent, we get $\mathbb{E}\left[|\textsc{alg} \cap V(c_{\textsc{opt}})|\right] \leq 1/p = f(c_{\textsc{opt}})$. ◀

▶ **Lemma 6.4.** *The expected total number of radii used by Algorithm 4 is at most αg.*

Proof. Each node of G is in $V(c_{\textsc{opt}})$ for exactly one $c_{\textsc{opt}}$. Thus, by Lemma 6.3 and linearity of expectation,

$$\mathbb{E}\left[|\textsc{alg}|\right] = \mathbb{E}\left[\sum_{c_{\textsc{opt}} \in \textsc{opt}} |\textsc{alg} \cap V(c_{\textsc{opt}})|\right] = \sum_{c_{\textsc{opt}} \in \textsc{opt}} \mathbb{E}\left[|\textsc{alg} \cap V(c_{\textsc{opt}})|\right] \leq \sum_{c_{\textsc{opt}} \in \textsc{opt}} f(c_{\textsc{opt}}) .$$

We have, using $\alpha = 2e^2/(e^2-1)$ in the penultimate step,

$$\sum_{c_{\textsc{opt}} \in \textsc{opt}} f(c_{\textsc{opt}}) = \sum_{r=0}^{g-1} \frac{\alpha g}{\alpha g - 2r} < \int_0^g \frac{\alpha g}{\alpha g - 2r} dr = \left[-\frac{\alpha g}{2} \ln(\alpha g - 2r)\right]_0^g$$
$$= \frac{\alpha g}{2} \ln\left(\frac{\alpha g}{\alpha g - 2g}\right) = \frac{\alpha g}{2} \ln\left(\frac{\alpha}{\alpha - 2}\right) = \frac{\alpha g}{2} \ln\left(e^2\right) = \alpha g . \quad ◀$$

6.2 High-probability bound

Next, we need to prove that there is a low probability that Algorithm 4 will use significantly more radii than expected. Similar to Section 5 we define a potential Φ_t comparing the number of the algorithm's centers to the expected progress and use martingale bounds to show that the potential is unlikely to be large.

▶ **Definition 6.5.** *Let C_t be a random variable denoting the set of centers of* OPT *made good by the first t centers c_{ALG} placed by the algorithm and*

$$\Phi_t = t - \sum_{c_{\text{OPT}} \in C_t} f(c_{\text{OPT}})\,.$$

Observe that $\Phi_0 = 0$ and that $\Phi_0, \Phi_1, \ldots$ is a sequence of random variables, since C_t depends on the random choices of the values k_v in Algorithm 4. We now prove that the potential is a supermartingale and thus we can use Azuma's inequality to show that Algorithm 4 is unlikely to use more than $(1+\varepsilon)\alpha g$ radii.

▶ **Lemma 6.6.** *$\Phi_0, \Phi_1, \ldots$ is a supermartingale with $|\Phi_t - \Phi_{t-1}| \le 7$ for all t.*

Proof. Let v be the t-th selected node. Since v is not covered when it is selected, we have $c_{\text{OPT}}(v) \notin C_{t-1}$. Only $c_{\text{OPT}}(v)$ can be made good by a center c_{ALG} placed at v and thus Φ_t is equal to either $\Phi_{t-1} + 1 - f(c_{\text{OPT}}(v))$ or $\Phi_{t-1} + 1$. By Lemma 6.3, the probability p of center $c_{\text{OPT}}(v)$ being made good is at least $1/f(c_{\text{OPT}}(v))$, making $\mathbb{E}[\Phi_t | \Phi_0, \ldots, \Phi_{t-1}] = p(\Phi_{t-1} + 1 - f(c_{\text{OPT}}(v)) + (1-p)(\Phi_{t-1}+1) = \Phi_{t-1} + 1 - pf(c_{\text{OPT}}(v)) \le \Phi_{t-1}$ and thus $\Phi_0, \Phi_1, \ldots$ is a supermartingale.

As $\alpha = 2e^2/(e^2-1) > 16/7$ and $r(c_{\text{OPT}}) < g$, we get $f(c_{\text{OPT}}) < \alpha g/(\alpha g - 2g) < 8$. Thus $\Phi_t - \Phi_{t-1}$ is at least $1 - f(c_{\text{OPT}}) \ge -7$ and at most 1, meaning that $|\Phi_t - \Phi_{t-1}| \le 7$ for all t. ◀

▶ **Lemma 6.7.** *The probability that Algorithm 4 uses at least $(1+\varepsilon)\alpha g$ radii is at most $1/e$.*

Proof. We know that $\Phi_0 = 0$. By Lemma 6.4 we know that $\sum f(c_{\text{OPT}}) \le \alpha g$. Thus, if the process has not finished before using $T = \lceil (1+\varepsilon)\alpha g \rceil$ radii, the value of Φ_T is at least $\varepsilon \alpha g$. By Lemma 6.6 we know that $\Phi_0, \Phi_1, \ldots$ is a supermartingale with differences at most 7. From Azuma's inequality (Theorem 5.2) for $X_t = \Phi_t$, $\Delta = \varepsilon\alpha g$, $T = \lceil (1+\varepsilon)\alpha g \rceil$ and $\delta = 7$, using also the bounds $g \ge 100/\varepsilon^3$ and $\varepsilon < 1$ we get

$$\Pr[\Phi_T \ge \varepsilon \alpha g] \le \exp\left(\frac{-(\varepsilon\alpha g)^2}{2 \cdot 7^2 \cdot \lceil (1+\varepsilon)\alpha g \rceil}\right) < \exp\left(\frac{-\varepsilon^2 g}{100}\right) < \frac{1}{e}\,.$$ ◀

6.3 Bounding the maximum radius

The only possibility for Algorithm 4 to use a radius larger than R is due to the procedure Select in which case the larger radii are used one by one in increasing order. In particular, to use a radius larger than $R + b$, the algorithm must, for some x, generate at least $b + x$ values k_v that are at least $R - x$ and thus cause Select to pick a radius larger than R at least b times. Using Chernoff bounds, we now show that this event is unlikely for $b = \varepsilon R$.

▶ **Lemma 6.8.** *Conditioned on the event that Algorithm 4 uses no more than $(1+\varepsilon)\alpha g$ radii, Algorithm 4 uses a radius of value at least $(1+\varepsilon)^3\alpha g$ with probability at most $1/100$.*

Proof. Recall that $R = (1+\varepsilon)^2\alpha g$ and let $b = \varepsilon R = (1+\varepsilon)^2\varepsilon\alpha g$. Therefore, $(1+\varepsilon)^3\alpha g = (1+\varepsilon)R = R + b$. We proceed to show that the probability of Algorithm 4 using radius $\lceil R + b \rceil$ is small.

Let r_{min} be a random variable denoting the minimal radius such that all radii from $\{r_{min}, \ldots, \lceil R+b \rceil\}$ are used by Algorithm 4; if $\lceil R + b \rceil$ is not used, r_{min} is undefined. Algorithm 4 uses a radius at least $R + b$ if and only if r_{min} is defined.

Informally, the proof idea is as follows. We partition this event according to the value of r_{min}, grouping its possible values into blocks of size b (disregarding rounding) so that block i contains values in $(R - ib, R - (i-1)b]$ for $i \in \{1, \dots, \lceil 1/\varepsilon \rceil\}$. If r_{min} is in block 1, i.e., larger than $R - b$, it must be the case that k_v was chosen larger than $R - b$ at least b times. In general, for block i, k_v must have been chosen to be larger than $R - ib$ at least ib times. This probability decreases geometrically with i; this follows from Chernoff bounds, using also the conditioning in the lemma, which implies that the number of chosen radii is smaller than R by a constant factor $(1 + \varepsilon)$.

For a full version of the proof, please see Appendix B. ◀

6.4 Final algorithm

We combine the preceding algorithms to get the final Algorithm 5.

Algorithm 5 The final algorithm.

```
Input: Graph $G(V, E)$ and real number $\bar{\varepsilon} > 0$
Output: A burning schedule for $G$ of length at most $(\alpha + \bar{\varepsilon})b(G)$
$\varepsilon \leftarrow (1 + \bar{\varepsilon}/\alpha)^{1/4} - 1$; $\ell \leftarrow 100/\varepsilon^3$          ▷ Note that $\varepsilon \in \Theta(\bar{\varepsilon})$
for $g \leftarrow 1, \dots, \lfloor |V|/\alpha \rfloor$ do
    if $g \leq \ell$ then
        Use Algorithm 2 with $z = 4$ to get ALG or Fail
        if ALG was found then return ALG
    else
        Use Algorithm 4 to get ALG
        if ALG uses no radius greater than $(1 + \varepsilon)^3 \alpha g - 1$ then return ALG
return a trivial solution $\{(v_0, 0), \dots, (v_{n-1}, n-1)\}$ for $V = \{v_0, \dots, v_{n-1}\}$
```

▶ **Theorem 6.9.** *Algorithm 5 is an $(\alpha + \bar{\varepsilon})$-approximation algorithm for any given $\bar{\varepsilon} > 0$ and runs in time $2^{\mathcal{O}(1/\bar{\varepsilon}^3)}\text{poly}(n)$.*

Proof. By Theorem 4.1, Algorithm 2 is guaranteed to succeed if run with $g \geq b(G)$ and it never uses a radius greater than $2.25g - 1$. Thus, if $b(G) \leq \ell$, Algorithm 5 always finds a 2.25-approximation.

If $b(G) > \ell$, either Algorithm 2 succeeds with $g < b(G)$, or we run Algorithm 4 while increasing g. By Lemma 6.7, once $g \geq b(G)$, Algorithm 4 uses more than $(1 + \varepsilon)\alpha g$ radii with probability at most $1/e$. By Lemma 6.8, if Algorithm 4 uses at most $(1 + \varepsilon)\alpha g$ radii, it uses a radius greater than $(1 + \varepsilon)^3 \alpha g - 1$ with probability at most $1/100$. Thus it succeeds with probability at least $1/2$. This probability is independent and increasing for each successive iteration, ensuring that the expected number of failures is at most 2. Thus the expected maximum radius is at most $(1 + \varepsilon)^3 \alpha (b(G) + 2) - 1$. We get $(1 + \varepsilon)^3 \alpha (b(G) + 2) = (1+\varepsilon)^3 \alpha b(G) + 2(1+\varepsilon)^3 \alpha \leq (1+\varepsilon)^3 \alpha g + 50 \leq (1+\varepsilon)^4 \alpha b(G) - 1$, using the value of α for the first inequality and for the last one also the case condition $b(G) > \ell$ and $\ell \geq 100/\varepsilon \geq 51/\varepsilon(1+\varepsilon)^3 \alpha$. By the choice of ε in the algorithm, the approximation ratio is at most $(1 + \varepsilon)^4 \alpha = \alpha + \bar{\varepsilon}$.

Since Algorithm 5 iterating over the possible values of g multiplies the time complexity by at most n, the running time is dominated by Algorithm 2, and thus it is bounded by $2^{\mathcal{O}(\ell)}\text{poly}(n)$. Our choice of ε satisfies $\varepsilon = \Theta(\bar{\varepsilon})$ for a small $\bar{\varepsilon} > 0$ (using the fact that $(1 + \varepsilon)^4 \approx 1 + 4\varepsilon$), thus we get $\ell = 100/\varepsilon^3 = \mathcal{O}\left(1/\bar{\varepsilon}^3\right)$ and the bound in the theorem follows. ◀

We note that, instead of using Algorithm 2 for $g \leq \ell$, we can find an optimal solution by exhaustive search in time $n^{\mathcal{O}(g)}$, which is still polynomial. We prefer to use Algorithm 2 to achieve FPT-type running time dependency on ε.

7 Lower bounds for Graph Burning

In this section, we first prove a lower bound of 2 for the approximation ratio of the Graph Burning problem on a graph with edge lengths. We also prove a lower bound of 4/3 for graphs with unit edge lengths.

Both results rely on a reduction from the Dominating Set problem defined as follows.

▶ **Definition 7.1.** *A* dominating set *of an undirected graph $G = (V, E)$ is a set $D \subseteq V$ such that each vertex of G either is in D or has a neighbor in D. In an instance of the Dominating Set problem, we are given an undirected graph and our task is to find a dominating set of the lowest possible size.*

The hardness of approximation of Dominating Set is equivalent to that of Set Cover. After a long line of research in PCP theory, the ultimate result is the following one.

▶ **Theorem 7.2** (Dinur, Steurer [8])**.** *For any $\varepsilon > 0$, there exists no $(1-\varepsilon)\ln n$-approximation algorithm for Dominating Set or Set Cover problems unless $P = NP$.*

In the first reduction, we modify a Dominating Set instance by setting the length of all edges to k for some integer k. We use the fact that in the burning schedule, the centers with radii in $[k, 2k)$ cover exactly their neighbors (due to the edge lengths). Thus a dominating set of size t implies a burning schedule of length $t + k$ in the graph with edge lengths, and a graph burning schedule with length at most $2k$ implies a dominating set of size at most $2k$. By considering a carefully chosen k, this together with a $(2 - \varepsilon)$-approximation algorithm for Graph Burning gives an $\mathcal{O}(1)$-approximation algorithm for Dominating Set, contradicting Theorem 7.2.

Technically, we try all values of k and stop at the smallest k that yields a Graph Burning solution of size at most $2k$ and thus a Dominating Set approximation. The number of possible values of k is bounded by $|V|$. Testing only the chosen important values of k used in the proof (i.e., approximately $k = 2t/\varepsilon$ for testing size t Dominating Set) would be sufficient and slightly more efficient, but we prefer to keep the algorithm simple.

▶ **Theorem 7.3.** *For any constant $\varepsilon > 0$, there exists no $(2 - \varepsilon)$-approximation algorithm for the Graph Burning problem with arbitrary edge lengths unless $P = NP$. This holds even for the case when restricted to Graph Burning instances with all edge lengths equal.*

Proof. For a contradiction, assume that we have a $(2-\varepsilon)$-approximation algorithm for Graph Burning with arbitrary but equal edge lengths. Let $\sigma = \lceil 1/\varepsilon \rceil$. We give a reduction that results in an approximation algorithm for the Dominating Set problem with an approximation ratio of at most $4\sigma \in \mathcal{O}(1)$.

We use the reduction described above; see Algorithm 6 for a formal description.

First, we claim that the output D is always a dominating set. Indeed, if we stop at a feasible solution with $g \leq 2k$, any $w \in G$ is covered by some center (v_i, i) for $i < 2k$, i.e., the distance between w and v_i is less than $2k$. Since the lengths of the edges are set to k, this means that v_i is a neighbor of or equal to w. In the fallback case, $D = V$ is a dominating set.

Now assume that G has a dominating set $\{w_0, \ldots, w_{t-1}\}$ of size t. We claim that for any given k, the burning number of G with edge lengths is at most $k + t$. Indeed, the set of centers $\{(w_i, k + i) \mid i = 0, \ldots, t - 1\}$ augmented by arbitrary centers with radii smaller than k is a required feasible solution.

Algorithm 6 Reduction using edge lengths.

```
Input: Dominating Set instance $G = (V, E)$
for $k \leftarrow 1, \dots, \lfloor |V|/2 \rfloor$ do
    Set the length of each edge to $k$
    Run the $(2 - \varepsilon)$-approximation algorithm for Graph Burning on $G$,
        obtaining a feasible solution $\{(v_0, 0), (v_1, 1), \dots, (v_{g-1}, g - 1)\}$ for some $g$.
    if $g \le 2k$ then return the set $D = \{v_0, v_1, \dots, v_{g-1}\}$.
return the set $D = V$.
```

If $t < |V|/4\sigma$, consider $k = 2\sigma t \le |V|/2$. The choice of k implies that $\varepsilon k \ge 2t$ as $\sigma = \lceil 1/\varepsilon \rceil$. The assumed $(2 - \varepsilon)$-approximation algorithm for Graph Burning finds a feasible solution of size at most $(2 - \varepsilon)(k + t)$, which is bounded by $(2 - \varepsilon)(k + t) < 2k - \varepsilon k + 2t \le 2k$. Thus the algorithm stops for some $k' \le k$ with a dominating set D of size at most $2k = 4\sigma t$.

If $t \ge |V|/4\sigma$, the reduction trivially gives a 4σ-approximation. Overall we have obtained a 4σ-approximation for Dominating Set.

By Theorem 7.2, no $\mathcal{O}(1)$-approximation algorithm for the Dominating Set problem exists, unless $P = NP$. This yields the contradiction and the theorem. ◀

We can modify the previous reduction so that, instead of edges of length k, we subdivide them into paths of unit-length edges. As a consequence, when converting the dominating set to a Graph Burning solution, we have to use larger radii to cover the new vertices, which degrades the inapproximability bound. Also, when converting a burning schedule to a dominating set, we cannot use the subdivision points as elements of the dominating set. Instead, we substitute any subdivision point with the two closest original vertices, i.e., the endpoints of the subdivided edge.

▶ **Theorem 7.4.** *For any constant $\varepsilon > 0$, there exists no $(4/3 - \varepsilon)$-approximation algorithm for the Graph Burning problem with unit edge lengths, unless $P = NP$.*

Proof. For a contradiction, assume that we have a $(4/3 - \varepsilon)$-approximation algorithm for Graph Burning with unit-length edges. Let $\sigma = \lceil 1/\varepsilon \rceil$. We give a reduction that results in an algorithm for Dominating Set with an approximation ratio of at most $8\sigma \in \mathcal{O}(1)$. The reduction follows the outline given above; see Algorithm 7 for a formal description.

Graph G' is of polynomial size, and thus the whole reduction is polynomial. Furthermore, if $u, w \in V$ are vertices of the input graph G, then the distance between u and w in G' is a multiple of $2k$. In particular, if u and w are not equal, their distance in G' is equal to $2k$ if u and w are neighbors in G, and their distance is at least $4k$ otherwise.

We claim that the output D is always a dominating set. Indeed, if we stop at a feasible solution with $g \le 4k$, any $w \in V$ is covered by some center (v_i, i) for $i < 4k$, i.e., the distance between w and v_i is less than $4k$. The construction of D_i implies that the shortest path between w and v_i contains one of $u \in D_i$. Thus the distance between u and w in G' is less than $4k$ and u and w are neighbors in G. It follows that D is a dominating set. In the fallback case, $D = V$ is a dominating set as well.

Now assume that G has a dominating set $\{w_0, \dots, w_{t-1}\}$ of size t. We claim that for any given k, the burning number of G' is at most $3k + t$. Indeed, the set of centers $\{(w_i, 3k + i) \mid i = 0, \dots, t - 1\}$ augmented by $3k$ arbitrary centers with radii smaller than $3k$ is a required feasible solution. Each vertex v in G' has distance at most k to the closest vertex in G, which in turn has distance at most $2k$ to a vertex in the dominating set. Thus the balls of radius at least $3k$ at the vertices of the dominating set cover the whole G'.

Algorithm 7 Reduction for unit edge lengths.

```
Input: Dominating Set instance $G = (V, E)$
for $k = 1, \dots, |V|$ do
    Create $G'$ from $G$ by replacing each edge of $G$ by a path of $2k$ new edges
        with $2k - 1$ new internal vertices.
    Run the $(4/3 - \varepsilon)$-approximation algorithm for Graph Burning on $G'$,
        obtaining a feasible solution $\{(v_0, 0), (v_1, 1), \dots, (v_{g-1}, g - 1)\}$ for some $g$.
    if $g \leq 4k$ then
        for $i = 0, 1, \dots, g - 1$ do
            if $v_i \in V$ then                ▷ i.e., $v_i$ is a vertex of the input graph $G$
                $D_i \leftarrow \{v_i\}$
            else                ▷ i.e., $v_i$ is a new internal vertex on an added path
                $D_i \leftarrow \{u, u'\}$ where $u, u' \in V$ are such that $v_i$ is a new vertex
                    on the path in $G'$ that replaced the edge $uu'$ of $G$.
        return the set $D = D_0 \cup D_1 \cup \dots \cup D_{g-1}$.
return the set $D = V$.
```

If $t < |V|/\sigma$, consider $k = \sigma t \leq |V|$. The choice of k implies that $t \leq \varepsilon k$ as $\sigma = \lceil 1/\varepsilon \rceil$. The assumed $(4/3 - \varepsilon)$-approximation algorithm for Graph Burning finds a feasible solution of size at most $(4/3 - \varepsilon)(3k + t)$. We have

$$\left(\frac{4}{3} - \varepsilon\right)(3k + t) \leq 4k - 3\varepsilon k + \frac{4}{3}t \leq 4k - 3t + \frac{4}{3}t < 4k\,.$$

Thus the algorithm stops for some $k' \leq k$ with a dominating set D of size at most $2 \cdot 4k = 8\sigma t$, since each set D_i contains at most two vertices for each center v_i of the burning schedule.

If $t \geq |V|/\sigma$, the reduction trivially gives an σ-approximation. Altogether we have obtained an 8σ-approximation algorithm for Dominating Set.

By Theorem 7.2, no $\mathcal{O}(1)$-approximation algorithm for the dominating set problem exists, unless $P = NP$. This yields the contradiction and the theorem. ◀

A Proof of Theorem 4.1

We first prove the following lemma.

▶ **Lemma A.1.** *If $g \geq b(G)$ then Algorithm 2 always returns a solution.*

Proof. Let $v(S, t)$ be the t-th selected node while the algorithm is using sequence S. Observe that $v(S, t)$ only depends on the initial segment $s_1, \ldots, s_{t-1}$ of S. With this in mind, we show in the next paragraph that there exists $S^* \in \mathbb{S}$ such that s^*_t of S^* is the class of $c_{\text{OPT}}(v(S^*, t))$.

Formally, for $t = 1, 2, \ldots$ we define s_t^* as the class of $c_{\text{OPT}}(v(\bar{S}, t))$ for an arbitrary extension $\bar{S} \in \mathbb{S}$ of $s_1^*, \ldots, s_{t-1}^*$. Such an $\bar{S} \in \mathbb{S}$ exists, as the optimum solution OPT contains at most g centers with no more than $\lceil g/z \rceil$ centers of any given class. If $v(\bar{S}, t)$ is undefined (i.e., all nodes are covered at this point), we choose $s_t^* = \bar{s}_t$. As $v(\bar{S}, t)$ and thus s_t^* depends only on $s_1^*, \ldots, s_{t-1}^*$, which is the initial segment of $\bar{S}$, eventually S^* is the sequence of the classes of centers $c_{\text{OPT}}(v(S^*, t))$.

It follows that using this S^* in the loop makes all centers good, thus all nodes are covered and the algorithm stops with a valid solution. ◀

▶ **Theorem A.2** (Theorem 4.1). *If $g \geq b(G)$ then Algorithm 2 runs in $\mathcal{O}(z^g \text{poly}(n))$-time and achieves an approximation ratio of $(2 + 1/z)$.*

Proof. Lemma A.1 implies that the algorithm returns a solution covering all nodes. We first bound the maximal radius used and thus the approximation ratio. We distinguish two cases.

If $z \geq g$, the algorithm uses $z = g$. Each threshold is used at most once, making the maximal used radius at most $q_z = 2g - 2$, giving a solution with $2g - 1$ many centers, and thus approximation ratio of $2 - 1/g$.

If $z < g$ there are at least $\lfloor 2g/z \rfloor$ radii between any two consecutive thresholds as there are at least $\lfloor 2g/z \rfloor$ integers in $[q_i, q_{i+1})$. We use the same threshold at most $\lceil g/z \rceil$ times by the definition of $\mathbb{S}$. We have $\lceil g/z \rceil \leq \lfloor 2g/z \rfloor$, as $\lceil x \rceil \leq \lfloor 2x \rfloor$ for any $x \geq 1$, while we use the same threshold for at most $\lceil g/z \rceil$ nodes by the definition of $\mathbb{S}$. Thus the radii produced by using a given threshold q_i do not exceed the following threshold q_{i+1}. Furthermore no more than $\lceil g/z \rceil$ nodes use the last threshold $q_z = 2g - 2$, making the maximal used radius at most $2g - 2 + \lceil g/z \rceil \leq 2g + g/z - 1$. Thus the objective value is at most $2g + g/z$ and the ratio $2 + 1/z$.

The runtime bound follows since the number of sequences of length g with numbers from $\{1, \ldots, z\}$ is z^g, and this gives an upper bound on the size of $\mathbb{S}$. ◀

B Proof of Lemma 6.8

▶ **Lemma B.1** (Lemma 6.8). *Conditioned on the event that Algorithm 4 uses no more than $(1+\varepsilon)\alpha g$ radii, Algorithm 4 uses a radius of value at least $(1+\varepsilon)^3\alpha g$ with probability at most $1/100$.*

Proof. Recall that $R = (1+\varepsilon)^2\alpha g$ and let $b = \varepsilon R = (1+\varepsilon)^2\varepsilon\alpha g$. Therefore, $(1+\varepsilon)^3\alpha g = (1+\varepsilon)R = R + b$. We proceed to show that the probability of Algorithm 4 using radius $\lceil R + b \rceil$ is small.

Let r_{min} be a random variable denoting the minimal radius such that all radii from $\{r_{min}, \ldots, \lceil R + b \rceil\}$ are used by Algorithm 4; if $\lceil R + b \rceil$ is not used, r_{min} is undefined. Algorithm 4 uses a radius at least $R + b$ if and only if r_{min} is defined.

Informally, the proof idea is as follows. We partition this event according to the value of r_{min}, grouping its possible values into blocks of size b (disregarding rounding) so that block i contains values in $(R - ib, R - (i-1)b]$ for $i \in \{1, \ldots, \lceil 1/\varepsilon \rceil\}$. If r_{min} is in block 1, i.e., larger than $R - b$, it must be the case that k_v was chosen larger than $R - b$ at least b times. In general, for block i, k_v must have been chosen to be larger than $R - ib$ at least ib times. This probability decreases geometrically with i; this follows from Chernoff bounds, using also the conditioning in the lemma, which implies that the number of chosen radii is smaller than R by a constant factor $(1 + \varepsilon)$.

For $i \in \{1, \ldots, \lceil 1/\varepsilon \rceil\}$, we define A_i as the event that r_{min} is defined and i is the smallest integer such that $R - ib < r_{min}$. Exactly one of the events A_i occurs whenever r_{min} is defined. The event A_i implies that the algorithm randomly generated k_v greater than $R - ib$

at least ib times, as by definition of r_{min}, choosing $k_v < r_{min}$ does not allow SELECT to generate a radius equal to or larger than r_{min} and at the same time all at least ib radii between $r_{min} \leq R - (i-1)b$ and $\lceil R + b \rceil$ are used.

By the conditioning in the lemma, we assume that the algorithm uses no more than $(1+\varepsilon)\alpha g$ radii. Let p be the probability that upon processing v, the algorithm generates k_v larger than $R - ib$. We have $p \leq ib/R$, as out of $\lfloor R \rfloor + 1 > R$ options for k_v, there are at most ib values larger than $R - ib$. Consider X which is a sum of $J = \lfloor (1+\varepsilon)\alpha g \rfloor$ independent indicator random variables, each equal to 1 with probability ib/R. We have $Pr[A_i] \leq Pr[X \geq ib]$, as X overestimates the number of k_v larger than $R - ib$ in two ways: First, we possibly increase the number of trials and second, we increase the probability of the indicator variable to be 1 from p to ib/R.

Let $\mu = \mathbb{E}[X]$. We have $\mu = \lfloor (1+\varepsilon)\alpha g \rfloor \cdot ib/R \leq (1+\varepsilon)\alpha g ib/R = ib/(1+\varepsilon)$. As $g \geq 100/\varepsilon^3 \geq 100$, the rounding error is small, namely we have $\mu \geq \frac{99}{100}(1+\varepsilon)\alpha g \cdot ib/R = \frac{99}{100}\varepsilon(1+\varepsilon)i\alpha g$, using also $b = \varepsilon R$. Now we use Chernoff bound and get

$$\begin{aligned}\Pr[A_i] &\leq \Pr[X \geq ib] \leq \Pr[X \geq (1+\varepsilon)\mu] \leq \exp\left(\frac{-\varepsilon^2\mu}{3}\right) \leq \exp\left(\frac{-\frac{99}{100}\varepsilon^3(1+\varepsilon)i\alpha g}{3}\right) \\ &\leq \exp\left(-\frac{3}{4}\varepsilon^3 ig\right) \leq \exp(-75i)\ ,\end{aligned}$$

where we used $\frac{99}{100}(1+\varepsilon)\alpha/3 > 3/4$. We obtain that the probability of using radius at least $R + b$ is at most

$$\Pr\left[\bigcup_i A_i\right] \leq \sum_{i=1}^{\infty} \exp(-75i) \leq 1/100\,. \qquad \blacktriangleleft$$

The (Im)possibility of Simple Search-To-Decision Reductions for Approximation Problems

Abstract

We study the question of when an approximate search optimization problem is harder than the associated decision problem. Specifically, we study a natural and quite general model of black-box search-to-decision reductions, which we call *branch-and-bound reductions* (in analogy with branch-and-bound algorithms). In this model, an algorithm attempts to minimize (or maximize) a function $f : D \to \mathbb{R}_{\geq 0}$ by making oracle queries to $h_f : \mathcal{S} \to \mathbb{R}_{\geq 0}$ satisfying

$$\min_{x \in S} f(x) \leq h_f(S) \leq \gamma \cdot \min_{x \in S} f(x) \tag{1}$$

for some $\gamma \geq 1$ and any subset S in some allowed class of subsets $\mathcal{S}$ of the domain D. (When the goal is to maximize f, h_f instead yields an approximation to the maximal value of f over S.) We show tight upper and lower bounds on the number of queries q needed to find *even a γ'-approximate minimizer* (or maximizer) for quite large γ' in a number of interesting settings, as follows.

- For arbitrary functions $f : \{0,1\}^n \to \mathbb{R}_{\geq 0}$, where $\mathcal{S}$ contains all subsets of the domain, we show that no branch-and-bound reduction can achieve $\gamma' \lesssim \gamma^{n/\log q}$, while a simple greedy approach achieves essentially $\gamma^{n/\log q}$.
- For a large class of MAX-CSPs, where $\mathcal{S} := \{S_w\}$ contains each set of assignments to the variables induced by a partial assignment w, we show that no branch-and-bound reduction can do significantly better than essentially a random guess, even when the oracle h_f guarantees an approximation factor of $\gamma \approx 1 + \sqrt{\log(q)/n}$.
- For the Traveling Salesperson Problem (TSP), where $\mathcal{S} := \{S_p\}$ contains each set of tours extending a path p, we show that no branch-and-bound reduction can achieve $\gamma' \lesssim (\gamma - 1)n/\log q$. We also prove a nearly matching upper bound in our model.

These results show an oracle model in which approximate search and decision are strongly separated. (In particular, our result for TSP can be viewed as a negative answer to a question posed by Bellare and Goldwasser (SIAM J. Comput. 1994), though only in an oracle model.) We also note two alternative interpretations of our results. First, if we view h_f as a data structure, then our results unconditionally rule out black-box search-to-decision reductions for certain data structure problems. Second, if we view h_f as an efficiently computable heuristic, then our results show that any reasonably efficient branch-and-bound *algorithm* requires more guarantees from its heuristic than simply Eq. (1).

Behind our results is a "useless oracle lemma," which allows us to argue that under certain conditions the oracle h_f is "useless," and which might be of independent interest. See also the full version [7].

1 Introduction

We study *branch-and-bound search-to-decision* reductions for approximate optimization problems. These are algorithms that attempt to find an approximate minimizer (or maximizer) of a function $f : D \to \mathbb{R}_{\geq 0}$ by making oracle queries to an oracle h_f that yields an approximation to $\min_{x \in S} f(x)$ (or to $\max_{x \in S} f(x)$) for certain subsets $S \subseteq D$.[1] In the introduction, we will typically assume that $D = \{0, 1\}^n$.

1.1 Background and motivation

To explain our motivation, we first recall that any *exact* optimization problem comes in two flavors. The *decision* problem asks us to compute $\min_{x \in \{0,1\}^n} f(x)$ (or to compute the maximum) for some input objective function f.[2] The *search* problem asks us to find an $x \in \{0, 1\}^n$ that optimizes $f(x)$. In practice, for *many* problems of interest, search and decision seem to be more-or-less equally hard, in the sense that the fastest known algorithm for the decision problem effectively already solves the search problem. In other words, often it seems that the best way to determine whether something exists is to look for it. (Of course, this is certainly not always the case!)

One can try to formally explain this phenomenon by showing a *search-to-decision reduction*. In other words, to show that search and decision are essentially equivalent, we can prove that we can efficiently solve the search problem using an oracle for the decision problem.

Indeed, there is a well known and very elegant greedy approach to search-to-decision reductions that works for many *exact* optimization problems. Specifically, to minimize some function $f : \{0, 1\}^n \to \mathbb{R}_{\geq 0}$, one can define $f_{x_1} : \{0, 1\}^{n-1} \to \mathbb{R}_{\geq 0}$ for a bit $x_1 \in \{0, 1\}$ to be the function $f_{x_1}(x') := f(x_1, x')$, i.e., the function f with its first input bit set to x_1. One can then use a decision optimization oracle to find $V_{x_1} := \min_{x' \in \{0,1\}^{n-1}} f_{x_1}(x')$. (Here, we are assuming for simplicity that the decision problem is expressive enough to represent f_{x_1}. More generally, one can define f_0 and f_1 to be restrictions of f onto some sets S_0, S_1 that partition the domain.) Notice that $V_{x_1} \leq V_{1-x_1}$ if and only if there is an x that minimizes f

[1] The name "branch-and-bound reduction" comes from an analogy with *branch-and-bound algorithms* for optimization problems, which are ubiquitous in both theory and practice. (See, e.g., [14] and the references therein.) In the branch-and-bound literature, one typically uses some efficiently computable heuristic h_f to estimate $\min_{x \in S} f(x)$ in order to find an (exact or approximate) minimizer of f. See Section 1.4.

[2] Formally, to make this a true decision problem, we should include a threshold r in the input, and the problem should be to determine whether $\min_{x \in \{0,1\}^n} f(x) \leq r$. However, these two problems are essentially equivalent, as a simple binary-search-based reduction shows. We therefore ignore such subtleties.

and whose first bit is x_1. We can then repeat the process on f_{x_1} with x_1 chosen such that V_{x_1} is minimal, finding a second bit $x_2 \in \{0,1\}$ such that there exists a minimizer with first bit x_1 and second bit x_2, etc. Eventually, we will have found all of the bits of a minimizer x of f.[3]

This elegant and natural idea has many applications. Perhaps most importantly, this shows that if the decision problem of computing the minimal value of a function over subsets of the domain is solvable in time $T_D(n)$, then the search problem of *finding* a minimizer is solvable in time $T_S(n) \le O(n) \cdot T_D(n)$, so that the search and decision variants of this problem are equivalent in quite a strong sense. Indeed, this reduction even shows a type of "instance-wise equivalence," in the sense that it shows that the search problem of minimizing any *specific* function f is essentially equivalent to the problem of computing the minimal value of simple restrictions of f. Slight variants of this simple greedy reduction work for many *exact* optimization problems of interest, so that one can conclude that search and decision are essentially equivalent (and even instance-wise equivalent) for *many* important optimization problems. (However, Bellare and Goldwasser showed that this is not always the case by proving that there exist search problems that are not solvable in polynomial time but whose decision problems *are* solvable in polynomial time [2] (assuming a certain reasonable complexity-theoretic conjecture).)

It is then natural to ask what happens when we move to *approximate* optimization problems. Indeed, Feige first raised the question of whether *approximation* can be harder than *estimation* [5], and Feige and Jozeph later showed that there exist problems for which approximation is harder than estimation if and only if $\mathsf{FP} \neq \mathsf{TFNP}$ [6]. Here, we have adopted Feige's terminology, in which the task of *finding* $x \in \{0,1\}^n$ such that $f(x) \le \gamma \min_{x \in \{0,1\}^n} f(x)$ is called an *approximation problem*, while the task of determining $y \ge 0$ such that $\min_{x \in \{0,1\}^n} f(x) \le y \le \gamma \min_{x \in \{0,1\}^n} f(x)$ is called an *estimation problem*. In other words, approximation is the approximate search problem, and estimation is the approximate decision problem.

In fact, if the estimation problem is NP-complete for some approximation factor γ, then there is a certain rather weak sense in which approximation is provably equivalent to estimation (where both problems have the same approximation factor γ). For example, since such problems are polynomial-time equivalent to various exact optimization problems for which the above search-to-decision reduction works (e.g., MAX-3-SAT), one can simply combine reductions to and from such an exact optimization problem together with the search-to-decision reduction described above to reduce approximation to estimation for any NP-complete approximate optimization problem. However, this reduction is much less satisfying than the "greedy" search-to-decision reduction described above because, e.g., it can increase the size of the input instance by an arbitrary polynomial and will not in general preserve properties of the input instance (i.e., it will not prove instance-wise equivalence).[4]

[3] For a more concrete example, consider the maximization problem MAX-3-SAT. In this example, the reduction iteratively finds an assignment $(x_1, \dots, x_n) \in \{0,1\}^n$ that maximizes the number of satisfied clauses one bit at a time, using a decision MAX-3-SAT oracle. Specifically, it uses its decision oracle to determine x_1 such that such an assignment exists with first bit x_1, then to determine x_2 such that such an assignment exists with first two bits (x_1, x_2), etc.

[4] For example, the greedy reduction described above implies that $T_S(n) \le O(n) \cdot T_D(n)$, where $T_S(n)$ and $T_D(n)$ are "the fastest possible running times" for exact search and decision optimization problems. In contrast, the above NP-completeness-based reduction only guarantees that $T_{A,\gamma}(n) \le T_{E,\gamma}(n^C)$ where $T_{A,\gamma}(n)$ and $T_{E,\gamma}(n)$ are "the fastest possible running times" for approximation and estimation respectively for some fixed optimization problem for which γ-estimation is NP-complete (each with approximation factor γ), and C is an arbitrarily large constant. Since $T_{E,\gamma}(n)$ is superpolynomial in n (unless $\mathsf{P} = \mathsf{NP}$), this is not a very useful conclusion. E.g., it could be the case that $T_{E,\gamma}(n) = 2^n$, while $T_{A,\gamma}(n) = 2^{n^{100}}$. The fundamental issue is that this NP-completeness-based reduction can increase the instance size n by an arbitrary polynomial.

What we would really like is a *simple* reduction from approximation to estimation, that is, a reduction roughly like the "greedy" search-to-decision reduction for exact optimization described above. Such a reduction would ideally not increase the size n of the input instance. And, it would be even better if such a reduction only called its oracle on "subinstances" of the input instance, again in analogy with the simple greedy reduction. We might even be willing to sacrifice in the approximation factor in exchange for this simplicity – reducing γ'-approximation to γ-estimation for some $\gamma' > \gamma$.

Indeed, we originally arrived at this question in the context of lattice problems, in which preserving the size and structure of the input instance is often even more important than preserving the approximation factor. (See, e.g., [13, 15, 16].)

1.2 Our model

Our definition of branch-and-bound reductions can be viewed as one way of formalizing such "simple" reductions. Specifically, our model captures reductions that work via black-box access to an estimation oracle for "subinstances," i.e., an oracle h_f that estimates the optimal value of f up to a factor of γ over a subset S of the domain D.

In more detail, for an unknown objective function $f : D \to \mathbb{R}_{\geq 0}$ over a domain D (from some family of objective functions), such (possibly randomized) reductions have access to an oracle $h_f : \mathcal{S} \to \mathbb{R}_{\geq 0}$, where $\mathcal{S} \subseteq 2^D$ is a collection of subsets of the domain D. We assume that the oracle h_f satisfies

$$\min_{x \in S} f(x) \leq h_f(S) \leq \gamma \cdot \min_{x \in S} f(x)$$

for some not-too-large $\gamma \geq 1$, i.e., that h_f is a *γ-approximate estimation oracle* that solves the estimation problem on restrictions of f to various subsets. The goal of such a reduction is to find an explicit x such that $f(x) \leq \gamma' \min_{x \in D} f(x)$ for some not-too-large γ'.

We measure the running time of the reduction entirely in terms of the number of *queries* q made to this oracle. This makes our model quite strong in some sense. In particular, the lower bounds that we describe below are lower bounds on the number of queries, and therefore even rule out algorithms that perform a bounded number q of queries but otherwise perform arbitrary unbounded computation. (To be clear, queries may even be adaptive, i.e., the result of a previous query may be used to decide what to query next.) And, we study the best achievable approximation factor γ' for the problem of optimizing f that is achievable in this model, as a function of the number of queries q and the estimation approximation factor γ.

We stress that the *only* information that these reductions have about the function f comes from the oracle h_f. In particular, these reductions do *not* take as input a description of the function f. (Formally, the input to the reduction is actually empty.) This can be viewed as a weakness of our model. But, it does capture a wide class of reductions, and even more importantly, it is precisely this choice that will allow us to prove such strong *unconditional* lower bounds on the approximation factor γ' that is achievable after a certain number of oracle queries (without, e.g., requiring us to prove that $\mathsf{FP} \neq \mathsf{TFNP}$ along the way). Indeed, if we gave our reductions direct access to the input, then our model would actually be *stronger* than the standard model(!), and we would therefore have little hope of proving unconditional lower bounds in such a model.

We call reductions in our model *branch-and-bound reductions* in analogy with the paradigm of branch-and-bound algorithms. (See Section 1.4.) E.g., the simplest branch-and-bound reductions use a greedy approach like the one described above. In other words, they find

$x^* \in \{0,1\}^n$ that approximately minimizes $f : \{0,1\}^n \to \mathbb{R}_{\geq 0}$ as follows. The reduction first *branches*, i.e., it chooses subsets $S_1, \ldots, S_k \subseteq \{0,1\}^n$ that partition the input space $\{0,1\}^n$. It then uses h_f to compute values $h_f(S_1), \ldots, h_f(S_k)$ such that $h_f(S_i) \approx \min_{x \in S_i} f(x)$. It then chooses an i such that $h_f(S_i)$ is minimal and repeats the procedure on S_i – partitioning S_i into subsets $T_1, \ldots, T_k \subseteq S_i$, computing estimates $h_f(T_j)$, selecting T_j that minimizes this estimate, and so on. Eventually, the reduction is left with a single element $x^* \in \{0,1\}^n$, and we hope that $f(x^*)$ is relatively close to the optimal value $\min_{x \in \{0,1\}^n} f(x)$. It is not hard to see that this greedy reduction makes at most $q \leq k(n/\log k + 1)$ queries and outputs x^* with

$$f(x^*) \leq \gamma^{n/\log k+1} \min_{x \in \{0,1\}^n} f(x) \approx \gamma^{n/\log q} \min_{x \in \{0,1\}^n} f(x) \; .$$

(See Proposition 10 for a formal statement and proof.)

Even this quite large approximation factor $\gamma' \approx \gamma^{n/\log q}$ has proven to be quite useful in some rather specific contexts (e.g., [9, 16]). But, we of course would like to know if we can do better. I.e., is there a branch-and-bound reductions that makes at most q queries but achieves an approximation factor significantly better than $\gamma^{n/\log q}$? For example, a significant improvement to this approximation factor would resolve an important open problem in lattice-based cryptography [16]. (Indeed, this work originally arose from an effort to improve [16].)

1.3 Our results

Our first main result shows that the greedy reduction described above is essentially optimal in general. That is, there exist(s a distribution over) functions $f : \{0,1\}^n \to \mathbb{R}_{\geq 0}$ and a γ-approximate estimation oracle $h_f : 2^{\{0,1\}^n} \to \mathbb{R}_{\geq 0}$ such that no algorithm making significantly fewer than q queries to h_f can find $x^* \in \{0,1\}^n$ with $f(x^*) \ll \gamma^{n/\log q} \min_{x \in \{0,1\}^n} f(x)$. We use the notation $y \leftarrow \mathcal{A}^{h_f}()$ for sampling from the output distribution of the oracle algorithm $\mathcal{A}^{h_f}$, which formally takes no input.

▶ **Theorem 1** (Lower bound for arbitrary functions f. See Section 4). *For every $\gamma \geq 1$ and positive integer ℓ, there exists a distribution over functions $f : \{0,1\}^n \to \mathbb{R}_{\geq 0}$ and a γ-approximate estimation oracle $h_f : 2^{\{0,1\}^n} \to \mathbb{R}_{\geq 0}$ for f such that for any oracle algorithm $\mathcal{A}$ making at most q queries to h_f,*

$$\Pr[x^* \leftarrow \mathcal{A}^{h_f}() \;:\; f(x^*) \leq \gamma' \min_{x \in \{0,1\}^n} f(x)] \leq \varepsilon$$

where $\gamma' \approx \gamma^{n/\ell}$ and $\varepsilon \approx q2^{-\ell}$.

This shows that there is no branch-and-bound search-to-decision reduction that performs significantly better than the greedy reduction for *all* functions – even if it has an estimation oracle that works for arbitrary subsets S of the domain. So, if we want to do better than the generic greedy approach, we must place some restrictions on our objective function f. (In particular, this shows that we cannot improve upon the search-to-decision reductions in [9, 16] without using some specific properties of the relevant lattice-based objective functions f.)

We therefore turn our attention to specific classes of functions that have additional structure. Specifically, we study branch-and-bound search-to-decision reductions for Max-Constraint Satisfaction Problems (Max-CSPs), and the Traveling Salesperson Problem (TSP). These problems are natural in this context in part because both of these problems are often solved using branch-and-bound techniques in practice, for finding either exact solutions or approximate solutions. See, e.g., [3] for discussion of branch-and-bound algorithms for Max-CSPs (specifically MAX-k-SAT), and [4] for discussion of branch-and-bound algorithms for TSP.

In the case of Max-CSPs, we show a strong lower bound for any "reasonable" set of constraints $\mathcal{F}$. (See Section 6.) In this introduction, we discuss only the application of our more general result to MAX-3-SAT for simplicity.

Our result holds for *partial assignment queries.* That is, our oracle h_I for an instance I takes as input a partial assignment w to the n input variables and outputs a γ-approximation to the maximal number of constraints in the instance I satisfied by any assignment v that matches w.[5] This notion of a partial assignment arises naturally in this context (e.g., in practical branch-and-bound algorithms for MAX–CSP).

Before we state our result, we note that it is trivial to find an assignment to a MAX-3-SAT instance that satisfies roughly a $7/8 - o(1)$ fraction of the constraints. Indeed, a random assignment suffices with high probability. So, we can easily output an assignment that satisfies at least $7/8 - o(1)$ times as many clauses as an optimal assignment (with high probability, using an algorithm that is actually independent of the instance). Our lower bound shows that a branch-and-bound reduction cannot achieve an approximation factor of better than $7/8 + o(1)$, even with a very good estimation oracle with approximation factor $\beta = 1 - o(1)$. (Here, since we have switched from minimization to maximization, we have switched to oracles h satisfying

$$\beta \max_{x \in S} f(x) \le h_f(x) \le \max_{x \in S} f(x)$$

for some $\beta \le 1$.) In other words, no branch-and-bound reduction performs significantly better than the algorithm that simply outputs a uniformly random assignment, even if the estimation oracle is extremely powerful.

▶ **Theorem 2** (Lower bound for MAX-3-SAT. See Section 6 for a more general result.). *There exists a distribution over* MAX-3-SAT *instances I such that for every $\beta < 1$, there is a β-approximate estimation oracle h_I such that for any oracle algorithm $\mathcal{A}$ making at most q queries to h_I,*

$$\Pr[v^* \leftarrow \mathcal{A}^{h_f}() \ : \ \mathsf{SAT}_I(v^*) \ge \delta \max_{v \in \{0,1\}^n} \mathsf{SAT}_I(v)] \le \varepsilon$$

where $\delta = 7/8 + o(1)$ and $\varepsilon \approx q2^{-(1-\beta)^2 n}$.

Finally, we study (non-metric) TSP. Here, we consider a natural class of oracles that work for *subtour* queries. That is, they take as input a path $(v_1, \ldots, v_k)$ of (distinct) vertices in the input graph, and they output a γ-approximation to the minimal value of a tour that contains the path $(v_1, \ldots, v_k)$. This naturally captures branch-and-bound reductions that, e.g., "build a path one edge at a time." We prove the following lower bound.

▶ **Theorem 3** (Lower bound for TSP. See Section 5.). *For every $\gamma > 1$ and positive integer $\ell \ll n$, there exists a distribution G of TSP instances and a γ-approximate estimation oracle h_G such that for any oracle algorithm $\mathcal{A}$ making at most q oracle queries,*

$$\Pr[c^* \leftarrow \mathcal{A}^{h_G}() \ : \ w_G(c^*) \le \gamma' \cdot \min_c w_G(c)] \le \varepsilon \ ,$$

where $\gamma' \approx (\gamma - 1)n/\ell$, $\varepsilon \approx qe^{-\ell}$, and $w_G(c)$ is the weight of the tour c in G.

[5] To formally represent this in our model, consider the function $f : \{0,1\}^n \to \mathbb{R}_{\ge 0}$ such that $f(v)$ is the number of clauses satisfied by an assignment v. Then, h_f takes as input subsets $S_w \subseteq \{0,1\}^n$ consisting of all assignments v that match a partial assignment w. E.g., $\{v = (v_1, \ldots, v_n) \in \{0,1\}^n \ : \ v_1 = 0, v_{82} = 1\}$. Of course, it is far more natural to simply consider an oracle h_I that takes w as input directly.

We note in passing that this lower bound can be viewed as a partial answer to a question posed by Bellare and Goldwasser [2], who asked whether a search-to-decision reduction was possible for approximate TSP, and particularly one that preserves the approximation factor. Theorem 3 rules out a large class of such reductions, even those achieving a significantly worse approximation factor than what was considered in [2]. But, we only rule this out in an oracle model.

Our lower bound for TSP is in some sense quite strong. For example, it shows that a polynomial-time branch-and-bound reduction cannot achieve an approximation factor $\gamma' < o(n/\log n)$, even with an estimation oracle that achieves a constant approximation factor $\gamma = O(1)$. However, it is not immediately obvious whether there is a nearly matching upper bound. E.g., the natural greedy approach achieves an approximation factor of roughly $\gamma' = \gamma^{n/k}$ using roughly n^k queries, which is quite far from our lower bound. Perhaps our lower bound can be improved?

As it happens, there *is* a nearly matching upper bound (specifically, a reduction that uses roughly n^t queries and achieves an approximation factor of roughly $\gamma n/t$). So, our lower bound is essentially tight in our model. But, the reduction achieving this upper bound is inefficient and therefore rather unsatisfying. In other words, while the reduction uses relatively few oracle queries, it performs additional computation that requires superpolynomial time, as described in Theorem 14.[6]

1.4 Other interpretations of our model

Above, we have presented our model in terms of branch-and-bound reductions from approximation problems to associated estimation problems. However, we note that there are at least two different interpretations of our model (and results) that are perhaps just as interesting.

Branch-and-bound algorithms

We of course named our model of branch-and-bound reductions in analogy with branch-and-bound *algorithms.* Such algorithms are ubiquitous in the study of optimization problems. (See, e.g., [14] and the references therein.) To view our model in terms of branch-and-bound algorithms, one simply needs to view the estimation oracle h_f as some efficiently computable *heuristic.* In other words, a branch-and-bound algorithm works by using some heuristic h_f to estimate the optimal value of f on various subsets until it has found an approximate optimizer of f.

Though branch-and-bound algorithms are very natural, they seem to be quite difficult to understand from a theoretical perspective. E.g., Nemhauser said "I have always wanted to prove a lower bound about the behavior of branch and bound, but I never could" [11]. (See also the third proposed research direction in [14].) Of course, part of the difficulty in proving such lower bounds is simply coming up with a model that is sufficiently strong to capture a wide class of branch-and-bound algorithms but weak enough to allow for provable lower bounds.

[6] The reduction first calls the oracle on all n^k subpaths $V = (v_1, \ldots, v_k)$ of length k. It then finds (in superpolynomial time) a way to combine subpaths $V_1, \ldots, V_{n/k}$ together into a tour while minimizing $h_G(V_1) + \cdots + h_G(V_{n/k})$. It is not hard to show that such a reduction achieves an approximation factor of essentially $\gamma n/k$.

One can view our results as progress towards that goal. In particular, we prove lower bounds for branch-and-bound algorithms with arbitrary estimation heuristics h_f. That is, any branch-and-bound algorithm that beats our lower bounds must use some property of the heuristic h_f that is stronger than the approximation guarantee

$$\min_{x \in S} f(x) \leq h_f(S) \leq \gamma \min_{x \in S} f(x) .$$

Approximation vs. estimation for data structure problems

Yet another interpretation of our results is in terms of *data structures* for optimization problems. For this interpretation, we focus on the problem of optimizing an arbitrary function with arbitrary subset queries, as this is most natural in this context.

Specifically, consider the following very natural and simple data structure problem. We are first given as input a function $f : \{0,1\}^n \to \mathbb{R}_{\geq 0}$ (or, equivalently, a list of 2^n numbers) and allowed arbitrary time to preprocess it into some data structure H (with some constraint on the size of H). Then, we receive as input some subset $S \subseteq \{0,1\}^n$. In the estimation version of this problem, our goal is to estimate $\min_{x \in S} f(x)$ using as few queries to H as possible (i.e., reading as few bits or words from H as possible). In the approximation version, our goal is to find an $x^* \in S$ such that $f(x^*)$ is as small as possible, relative to $\min_{x \in S} f(x)$ (again, using as few queries to H as possible).

It is then natural to ask whether there is a *black-box data-structure reduction* from approximation to estimation in this setting. Here, a black-box reduction means an algorithm that solves the approximation problem using *only* the estimates obtained from the data structure for the estimation problem – i.e., a branch-and-bound algorithm. Notice in particular that, in the setting of data structures, the number of queries made by such a reduction is the natural complexity measure.

Our lower bound on branch-and-bound reductions extends immediately to black-box data-structure reductions as well. Specifically, no black-box data-structure reduction making q estimate queries can achieve an approximation factor significantly better than $\gamma' \approx \gamma^{\log |S| / \log q}$.

1.5 Our techniques

Our main technical tool is a "useless oracle lemma." The idea is that "an oracle cannot be useful if most of its answers are predictable." While this lemma is quite general, we focus below on how it applies to our setting. (Very similar ideas are used in a different context in the literature on submodular optimization. See, e.g., [18, 17].)

Suppose that we can construct a distribution over functions f together with a γ-approximate estimation oracle $h_f : \mathcal{S} \to \mathbb{R}_{\geq 0}$ such that for any fixed query $S \in \mathcal{S}$, $h_f(S) = g(S)$ with high probability over f, where g is some *fixed* function that does not depend on f. E.g., our hard instance for arbitrary optimization has this property with $g(S) \approx \gamma^{n - \log |S|}$. Then, the useless oracle lemma tells us that "an algorithm with oracle access to h_f is essentially no more powerful than an algorithm with no access to any oracle that depends on f at all." The specific statement is of course quantitative and depends on the number of oracle queries and the probability that $h_f(S) \neq g(S)$. (See Section 3. We do not claim that this idea is original, though we do not know of prior work using it.)

With this tool in hand, our goal becomes to construct distributions of functions f together with oracles h_f such that (1) the oracle is "useless" in the sense described above; and (2) for every fixed $x \in \{0,1\}^n$, $f(x) \geq \gamma' \min_{x' \in \{0,1\}^n} f(x')$ with high probability over f (i.e., there is no way to choose an x independently of f such that $f(x)$ is nearly optimal). This boils down to finding a distribution over functions f such that (1) the random variable $\min_{x\in S} f(x)$ is highly concentrated; and (2) this quantity tends to be much larger as $|S|$ becomes smaller. In particular, concentration of $\min_{x\in S} f(x)$ around some value $g(S)$ (independent of f) implies that we can set $h_f(S) \approx g(S)$. And, if $g(S)$ increases rapidly as $|S|$ becomes smaller, then the optimal value of f, $\min_{x\in\{0,1\}^n} f(x) \approx g(\{0,1\}^n)$ will in particular be much smaller than $g(\{x'\})$ for any fixed $x' \in \{0,1\}^n$, causing our final approximation factor to be large.

Below, we briefly describe the distributions that we use and some of the intuition behind them.

Arbitrary functions

For our lower bound against optimizing arbitrary functions (Theorem 1), we sample each value $f(x)$ independently (but not uniformly) from a distribution over the set $\{1, \gamma, \gamma^2 \ldots, \gamma^{n/\ell}\}$, where 2^ℓ is the number of queries made by the algorithm. We choose our distribution so that any subset $S \subseteq \{0,1\}^n$ of size roughly $2^{\ell k}$ (1) contains at least one element with value either $\gamma^{n/k-1}$ or $\gamma^{n/k}$ with probability significantly larger than $1 - 2^{-\ell}$; and (2) does not contain an element with value less than $\gamma^{n/k-2}$, except with probability significantly less than $2^{-\ell}$. We can then set $h_f(S) = \gamma^{n/k}$, and we see that with high probability "any 2^ℓ queries made by the algorithm will reveal no information about the function f with high probability."

TSP

For the Traveling Salesperson Problem, we sample the weight of each edge independently to be either 1 or essentially γn, with equal probabilities. We then use the theory of random graphs to argue that with high probability the value of an optimal tour containing any subpath of length ℓ is highly concentrated around a value of roughly $\gamma \ell n/2 + n - \ell/2$.

CSPs

For ("reasonable") k-CSPs, we construct "a random instance with a random planted satisfying assignment." That is, we first sample a uniformly random assignment $P \sim [c]^n$.[7] We then repeatedly sample a k-tuple $T = (t_1, \ldots, t_k) \in [n]^k$ and add to our CSP a random constraint on the variables $x_{t_1}, \ldots, x_{t_k}$ that is satisfied by our planted assignment $P_{t_1}, \ldots, P_{t_k}$. We do this $m = O(n)$ times to generate our CSP. (For simplicity, we are ignoring the possibility that there might not exist any such constraint. In Section 6, we handle this carefully.)

Then, for any partial assignment w, we study $\rho_w(P)$, which is the maximum over all assignments $v \in [c]^n$ extending w of the probability that v satisfies a constraint sampled as above. It is easy to see via the Chernoff-Hoeffding bound that, for a fixed planted assignment P, the maximum over all such v of the actual number of satisfied constraints in our instance will be heavily concentrated around $\rho_w(P) \cdot m$. The difficult step in our analysis is then to prove that $\rho_w(P)$ is itself highly concentrated around its expectation $\mathbb{E}_P[\rho_w(P)]$. This follows from a careful application of McDiarmid's inequality.

[7] Throughout this paper, for $x \in \mathbb{N}$, $[x]$ denotes the set $\{1, 2, \ldots, x\}$.

2 Preliminaries

Given an event E and a random variable X, we will write $\Pr[E \mid X]$ for the random variable whose value in case $X = x$ is $\Pr[E \mid X = x]$. We will need the following concentration inequalities.

▶ **Lemma 4** (Chernoff-Hoeffding bound [8]). *Suppose $X_1, \dots, X_n$ are independent random variables, and let $X := \sum_{i=1}^n X_i$. Then for any $0 < \delta < 1$,*

$$\Pr\left[|X - \mathbb{E}[X]| \ge \delta\, \mathbb{E}[X]\right] \le 2\exp(-\delta^2\, \mathbb{E}[X]/3).$$

▶ **Lemma 5** (McDiarmid's inequality [12]). *Suppose $X_1, \dots, X_n$ are independent random variables, $c_1, \dots, c_n$ are real numbers, and $f : \mathbb{R}^n \to \mathbb{R}$ is a function with the property that for all $i \in [n]$ and $x_i, x_i' \in \mathbb{R}$, $|f(x_1, \dots, x_i, \dots, x_n) - f(x_1, \dots, x_i', \dots, x_n)| \le c_i$. Then for all $t > 0$,*

$$\Pr\left[|f(X_1, \dots, X_n) - \mathbb{E}[f(X_1, \dots, X_n)]| \ge t\right] \le 2\exp\left(\frac{-t^2}{2\sum_{i=1}^n c_i^2}\right).$$

3 Useless Oracles

We now present the technical tool that we will use for all of our lower bounds, which we call the useless oracle lemma. (The authors do not claim that this result is original, though they do not know of any prior work using a similar idea.)

To understand the lemma and its relation to branch-and-bound algorithms, suppose that we sample the objective function $f : D \to \mathbb{R}_{\ge 0}$ that our algorithm is meant to optimize from some distribution, and then choose our heuristic h_f according to f. And, recall that such an algorithm's "only access to this objective function f" is via oracle access to this heuristic h_f, which satisfies $\min_{x \in S} f(x) \le h_f(S) \le \gamma \min_{x \in S} f(x)$ for every S in some collection of subsets $\mathcal{S}$ of the domain D.

Now, imagine that instead of giving our algorithm oracle access to h_f, we give it oracle access to some *other* function g, which is fixed (i.e., not a random variable) and therefore independent of our choice of f. Notice that this is a rather cruel thing to do, since now our algorithm cannot possibly hope to glean any information about f from its oracle queries. So, at least intuitively, it should be quite easy to prove lower bounds against such algorithms.

The useless oracle lemma provides conditions that allow us to effectively replace the oracle $\mathcal{O} = h_f$ with the "useless" oracle g. In particular, it says that if (1) h_f and g have the property that $\Pr[h_f(S) = g(S)]$ is large for all *fixed* S, and (2) our algorithm does not make too many oracle queries; then the output of our algorithm is nearly the same whether it is given access to h_f or to g.

▶ **Lemma 6** (The useless oracle lemma). *Let $g : \mathcal{S} \to R$ be a* fixed *function, and let $\mathcal{O} : \mathcal{S} \to R$ be a distribution over oracles such that for all $S \in \mathcal{S}$,*

$$\Pr[\mathcal{O}(S) \ne g(S)] \le p\,.$$

Then, for any oracle algorithm $\mathcal{A}^{\mathcal{O}}$ making at most q queries to $\mathcal{O}$, the statistical distance between $\mathcal{A}^{\mathcal{O}}()$ and $\mathcal{A}^{g}()$ is at most qp.

Proof. Let $S_1, \ldots, S_q \in \mathcal{S}$ be the sequence of oracle queries made by $\mathcal{A}^{\mathcal{O}}$. Notice that the S_i are random variables, and that S_i might depend on $\mathcal{O}(S_j)$ for $j < i$ (which is what makes the lemma non-trivial). Let E_i be the event that there exists a $j \le i$ such that $\mathcal{O}(S_j) \neq g(S_j)$. It suffices to prove that $\Pr[E_q] \le qp$ (because the two distributions are identical if we condition on $\neg E_q$).

Notice that

$$\Pr[E_q] = \Pr[E_{q-1}] + \Pr[\mathcal{O}(S_q) \neq g(S_q) \text{ and } \neg E_{q-1}] \; .$$

Let $S'_1, \ldots, S'_q$ be the sequence of oracle queries made by $\mathcal{A}^g$ (as opposed to $\mathcal{A}^{\mathcal{O}}$), and notice that S'_i is independent of $\mathcal{O}$ by definition. In particular, this implies that $\Pr[\mathcal{O}(S'_i) \neq g(S'_i)] \le p$. Therefore,

$$\Pr[\mathcal{O}(S_q) \neq g(S_q) \text{ and } \neg E_{q-1}] = \Pr[\mathcal{O}(S'_q) \neq g(S'_q) \text{ and } \neg E_{q-1}] \le \Pr[\mathcal{O}(S'_q) \neq g(S'_q)] \le p \; .$$

It follows that $\Pr[E_q] \le p + \Pr[E_{q-1}]$, which implies the result when combined with the trivial fact that $\Pr[E_1] \le p$. ◀

▶ **Corollary 7.** *Let $f \sim \mathcal{D}$ be sampled over some distribution of functions $f : D \to \mathbb{R}_{\ge 0}$, and let $\mathcal{S} \subseteq 2^D$ be a collection of subsets of D such that $D \in \mathcal{S}$ and $\{x\} \in \mathcal{S}$ for all $x \in D$. Suppose that there exists some fixed function $g : \mathcal{S} \to \mathbb{R}_{\ge 0}$ such that*

$$\Pr[g(S)/\gamma \le \min_{x \in S} f(x) \le g(S)] \ge 1 - p$$

for all $S \subseteq \mathcal{S}$ and some $p > 0$, $\gamma \ge 1$.

Then, there exists a γ-approximate heuristic $h_f : \mathcal{S} \to \mathbb{R}_{\ge 0}$ for f such that for any algorithm $\mathcal{A}$ making at most q oracle queries to h_f,

$$\Pr[x^* \leftarrow \mathcal{A}^{h_f}(), \; f(x^*) < \gamma' \min_{x \in D} f(x)] \le (q+2)p \; ,$$

where

$$\gamma' := \gamma^{-1} \cdot \min_{x \in D} \frac{g(\{x\})}{g(D)} \; .$$

Proof. We define

$$h_f(S) := \begin{cases} g(S) & g(S)/\gamma \le \min_{x \in S} f(x) \le g(S) \\ \min_{x \in S} f(x) & \text{otherwise.} \end{cases}$$

In other words, $h_f(S)$ is a γ-approximate heuristic that agrees with $g(S)$ whenever it is possible for a γ-approximate heuristic to do so (and when this is not possible, it simply outputs the exact minimal value).

Notice that by assumption

$$\Pr_{f \sim D}[h_f(S) \neq g(S)] \le p \; .$$

We may therefore apply the useless oracle lemma with $\mathcal{O} = h_f$ to show that $\mathcal{A}^{h_f}()$ is within statistical distance qp of $\mathcal{A}^g()$. So, it suffices to show that

$$\Pr_{f \sim \mathcal{D}}[x^* \leftarrow \mathcal{A}^g(), \; f(x^*) \le \gamma' \min_{x \in D} f(x)] \le 2p \; .$$

Indeed, since g is independent of f (as it is a fixed function), we have that for any $r \geq 0$,

$$\Pr_{f \sim \mathcal{D}}[x^* \leftarrow \mathcal{A}^g(),\ f(x^*) \leq r] = \sum_{x \in D} \Pr[x^* \leftarrow \mathcal{A}^g(),\ x^* = x] \cdot \Pr_{f \sim \mathcal{D}}[f(x) \leq r] \leq \max_{x \in D} \Pr_{f \sim \mathcal{D}}[f(x) \leq r] \ .$$

By assumption, for any $x \in D$,

$$\Pr[f(x) < \min_{x' \in D} g(\{x'\})/\gamma] \leq p \ ,$$

and similarly,

$$\Pr[\min_{x' \in D} f(x') > g(D)] \leq p \ .$$

Therefore, for any $x \in D$,

$$\Pr[f(x) < \gamma' \min_{x' \in D} f(x')] \leq \Pr[f(x) < \min_{x' \in D} g(\{x'\})/\gamma] + \Pr[\min_{x' \in D} f(x') > g(D)] \leq 2p \ ,$$

and the result follows. ◀

4 A Generic Optimization Problem

▶ **Theorem 8.** *For any n, any $\gamma \geq 1$, and any integer $1 \leq \alpha \leq n$, there exists a distribution over functions $f : \{0,1\}^n \to \mathbb{R}_{\geq 0}$ such that for any integer $1 \leq k \leq \alpha$ and any $S \subseteq \{0,1\}^n$ with $2^{(k-1)n/\alpha} \leq |S| \leq 2^{kn/\alpha}$,*

$$\Pr_f[\gamma^{\alpha-k+1} \leq \min_{x \in S} f(x) \leq \gamma^{\alpha-k+2}] \geq 1 - 4(n/\alpha)2^{-n/\alpha} \ .$$

Proof. For each $x \in \{0,1\}^n$ and integer $1 \leq i \leq \alpha$, we set $f(x) = \gamma^i$ independently with probability p_i, where $p_i := \delta \cdot 2^{in/\alpha - n}$ for $i = 1, \ldots, \alpha - 1$ and $p_\alpha := 1 - p_1 - p_2 - \cdots - p_{\alpha-1}$, with $\delta := n/\alpha \cdot 2^{-n/\alpha} < 1$.

Notice that

$$p_\alpha = 1 - \delta \cdot \sum_{i=1}^{\alpha-1} 2^{in/\alpha - n} \geq 1 - \delta \ .$$

In particular, this is non-negative, so that this is in fact a valid probability distribution. We have

$$\Pr_f[\gamma^{\alpha-k+1} \leq \min_{x \in S} f(x) \leq \gamma^{\alpha-k+2}] = 1 - \Pr[\min_{x \in S} f(x) < \gamma^{\alpha-k+1}] - \Pr[\min_{x \in S} f(x) > \gamma^{\alpha-k+2}] \ .$$

We wish to argue that each of the probabilities on the right-hand side are smaller than, say, 2δ. First, we see that, for the non-trivial case $k > 2$,

$$\Pr[\min_{x \in S} f(x) > \gamma^{\alpha-k+2}] \leq (1 - p_{\alpha-k+2})^{|S|} \leq \left(e^{-p_{\alpha-k+2}}\right)^{2^{(k-1)n/\alpha}} = e^{-\delta 2^{n/\alpha}} \leq \delta \ ,$$

where the second inequality uses the fact that $1 - x \leq e^{-x}$. Second,

$$\Pr[\min_{x \in S} f(x) < \gamma^{\alpha-k+1}] \leq |S| \cdot \Pr[f(x) \leq \gamma^{\alpha-k}] \leq 2^{kn/\alpha} \cdot \delta \cdot \sum_{i=1}^{\alpha-k} 2^{in/\alpha - n} \leq 2\delta \ ,$$

as needed. ◀

▶ **Corollary 9.** *For any integer n, any $1 \le \ell \le n/3$, and any $\gamma \ge 1$, there exists a distribution of functions $f : \{0,1\}^n \to \mathbb{R}_{\ge 0}$ and a γ-approximate heuristic $h_f : 2^{\{0,1\}^n} \to \mathbb{R}_{\ge 0}$ for f such that for any algorithm $\mathcal{A}^{h_f}$ making at most q oracle queries to h_f,*

$$\Pr[x^* \leftarrow \mathcal{A}^{h_f}(),\ f(x) < \gamma' \cdot \min_{x \in \{0,1\}^n} f(x)] \le (q+2) \cdot \ell 2^{-\ell+3}$$

where $\gamma' := \gamma^{\lfloor n/\ell \rfloor - 1}$.

Proof. We apply Corollary 7 to the choice of f from Theorem 8, with $g(S) := \gamma^{\alpha-k+2}$ for the unique integer $1 \le k \le \alpha$ satisfying $2^{(k-1)n/\alpha} \le |S| < 2^{kn/\alpha}$ where $\alpha := \lfloor n/\ell \rfloor$ and $g(\{0,1\}^n) := \gamma$. Notice in particular that $g(\{x\})/g(\{0,1\}^n) = \gamma^\alpha$. ◀

The following proposition shows that the lower bound of Corollary 9 is essentially tight.

▶ **Proposition 10.** *For all integers $n \ge \ell \ge 1$, there exists an algorithm $\mathcal{A}^h$ such that for all functions $f : \{0,1\}^n \to \mathbb{R}_{\ge 0}$, all $\gamma \ge 1$, and all γ-approximate heuristics $h : 2^{\{0,1\}^n} \to \mathbb{R}_{\ge 0}$ for f, $\mathcal{A}^h$ makes at most $\lceil n/\ell \rceil \cdot 2^\ell$ queries to h, and outputs x^* with $f(x^*) \le \gamma^{\lceil n/\ell \rceil} \min_{x \in S} f(x)$.*

Proof. The algorithm $\mathcal{A}^h$ is a natural greedy algorithm. It first partitions the domain $S^0 = \{0,1\}^n$ into $k := 2^\ell$ subsets $S^0_1, \ldots, S^0_k$ and queries h on each subset. It sets $S^1 = S^0_i$ for some S^0_i of minimum h value; that is, $h(S^0_i) = \min_{1 \le j \le k} h(S^0_j)$. It then repeats this process, partitioning S^1 itself into k subsets $S^1_1, \ldots, S^1_k$ of size $2^{n-2\ell}$, querying h on each one, setting S^2 to be any subset with minimum h value, and so on. After $\lceil n/\ell \rceil - 1$ iterations, it finds a subset $S^{\lceil n/\ell \rceil - 1}$ with fewer than k elements. It then queries h on each singleton subset of $S^{\lceil n/\ell \rceil - 1}$ to find a singleton subset $S^{\lceil n/\ell \rceil} =: \{x^*\}$ of minimum h value, and outputs x^*.

It is clear that $\mathcal{A}^h$ makes at most $\lceil n/\ell \rceil \cdot 2^\ell$ queries to h. Moreover, we trivially have $f(x^*) = \min_{x \in S^{\lceil n/\ell \rceil}} f(x)$. And for each i, by the fact that h is a γ-approximate heuristic for f, we have that

$$\begin{aligned}\min_{x \in S^{i+1}} f(x) \le h(S^{i+1})& \\ &= \min_{1 \le j \le k} h(S^i_j) \\ &\le \min_{1 \le j \le k} \gamma \cdot \min_{x \in S^i_j} f(x) \\ &\le \gamma \min_{x \in S^i} f(x).\end{aligned}$$

It is therefore clear by induction that the output x^* satisfies $f(x^*) \le \gamma^{\lceil n/\ell \rceil} \min_{x \in S} f(x)$. ◀

In particular, when $n = \mathrm{poly}(\ell)$, the greedy algorithm achieves $\gamma' = \gamma^{\tilde{O}(n/\log q)}$, and by Corollary 9, this is the best approximation factor achievable (up to lower-order terms) by any oracle algorithm that succeeds with constant probability.

5 The Traveling Salesperson Problem

We consider undirected weighted complete graphs on n vertices with no self-loops where all edge weights are non-negative. For an edge $e = \{i, j\}$ of a graph G, $w(e)$ and $w(i, j)$ denote the weight of e.

We write C_n for the set of all Hamiltonian cycles in a complete n-vertex graph G. The weight of a cycle c is the sum of the weights of its edges: $w(c) = \sum_{i=1}^n w(c_i, c_{i+1 \bmod n})$. For $0 \le k \le n-1$, let P^k_n be the set of all length-k simple paths on an n-vertex graph:

$$P^k_n = \{(v_0, \ldots, v_k) \mid v_0, \ldots, v_k \in [n], v_0, \ldots, v_k \text{ all distinct}\}.$$

By $\mathrm{OPT}(G)$ we denote the weight of an optimal traveling salesperson (TSP) cycle in G, and for a path $p \in P_n^k$ by $\mathrm{OPT}(G, p)$ we denote the minimum weight of a TSP cycle in G containing p.

We will use the following result that says that a random graph contains a Hamiltonian cycle with all but negligible probability.

▶ **Lemma 11** (E.g., [1]). *A uniform random undirected graph with n vertices contains a Hamiltonian cycle with probability $\geq 1 - 2^{-n+o(n)}$.*

We define a "useless oracle" for TSP in Theorem 12. Namely, for every approximation factor $\gamma > 1$ and every probability of error ($\approx e^{-t}$), we give a distribution of graphs such that with high probability, the weight of an optimal Hamiltonian cycle extending a path of length k essentially does not depend on the path, but only on its length k. Intuitively, an approximate TSP oracle is useless for this distribution of graphs because (with high probability) it reveals no information about the input graph.

▶ **Theorem 12** (TSP useless oracle). *For all $\gamma > 1$ and $1 \leq t \leq \delta n/2$ where $\delta = (\gamma - 1)/(\gamma + 1)$, there exists a distribution $\mathcal{G}$ over n-vertex graphs, and values $v_0, \ldots, v_{n-1}$ such that*

- *$v_0 \leq n/\gamma$ and $v_{n-1} \geq (\gamma - 1)n^2/(5t)$,*
- *for all $0 \leq k \leq n-1$ and all paths $p \in P_n^k$,*

$$\Pr_{G\sim\mathcal{G}}\left[\mathrm{OPT}(G, p) \in [v_k,\ \gamma v_k]\right] \geq 1 - O(e^{-\delta^2 t/30}).$$

For reasons of space, we defer the proofs of this and subsequent theorems to the appendix. They can also be found in the full version [7].

We are now ready to prove the main result of this section showing an essentially tight bound on search to decision reductions with an approximate TSP oracle.

▶ **Definition 13** (TSP oracle). *A function h_G is a γ-approximate TSP estimation oracle for $G \in \mathcal{G}_n$ if for all $0 \leq k \leq n-1$, for all $p \in P_n^k$,*

$$\mathrm{OPT}(G, p) \leq h_G(p) \leq \gamma\,\mathrm{OPT}(G, p).$$

▶ **Theorem 14** (TSP oracle bounds). *For every $\gamma > 1$ and positive integer $\ell \leq \delta^3 n/20$ for $\delta = (\gamma-1)/(\gamma+1)$, there exists a distribution $\mathcal{G}$ over n-vertex graphs G and a γ-approximate TSP estimation oracle h_G for G such that for any algorithm $\mathcal{A}^{h_G}$ making at most q queries to h_G,*

$$\Pr[c \leftarrow \mathcal{A}^{h_G}()\ :\ w(c) \leq \gamma' \cdot \mathrm{OPT}(G)] \leq \varepsilon,$$

where $\gamma' := (\gamma - 1)\delta^2 n/(150\ell)$ and $\varepsilon := O\big(q \cdot e^{-\ell}\big)$.

Furthermore, for every $\gamma \geq 1$ and positive integer ℓ, there exists an algorithm $\mathcal{A}^{h_G}$ making at most $\binom{n}{\ell} \cdot \ell! \leq n^\ell$ queries to a γ-approximate TSP estimation oracle h_G that computes a $\gamma n/(\ell - 1)$-approximation to TSP.

In particular, using q queries, one can achieve $\gamma' = \gamma n/(\log q - 1)$, but no algorithm that succeeds with constant probability can do better than $\gamma' = O((\gamma - 1)n/\log q)$.

6 Constraint Satisfaction Problems

Informally, a constraint satisfaction problem (CSP) consists of constraints applied to variables; the goal is to find an assignment of values to variables that satisfies all or most of the constraints. For example, graph coloring is a CSP, where each edge corresponds to the constraint that the endpoints have different colors.

A CSP is specified by a non-empty family of constraint functions $\mathcal{F}$. Each constraint function $f \in \mathcal{F}$ is a function $f : [c]^k \to \{0,1\}$, where the alphabet size c and arity k are fixed. An assignment assigns a value from $[c]$ to each of the n variables $x_1, \ldots, x_n$. Formally, we represent this by a function $v : [n] \to [c]$. An assignment v satisfies a constraint $C = (f, (j_1, \ldots, j_k))$, written $v \models C$, if $f(v(x_{j_1}), \ldots, v(x_{j_k})) = 1$. We write $\mathsf{CSP}(\mathcal{F})$ for the CSP specified by $\mathcal{F}$; an instance $I \in \mathsf{CSP}(\mathcal{F})$ is simply a collection of constraints. For simplicity, we allow duplicate constraints. As is standard, we say I is satisfiable if there is an assignment v that satisfies all constraints of I. For example, the classical 3-SAT problem is $\mathsf{CSP}(\mathcal{F}_{3-\mathrm{SAT}})$, where $\mathcal{F}_{3-\mathrm{SAT}}$ is the family of constraint functions defined by disjunctive clauses (e.g., $f(x_1, x_2, x_3) = \neg x_1 \vee x_2 \vee x_3$).

We are interested in an approximation version of the constraint satisfaction problem, namely $\mathsf{MAX–CSP}(\mathcal{F})$ [10]. $\mathsf{MAX–CSP}(\mathcal{F})$ is the computational problem whose instances I are collections of $m(I)$ constraints on variables $x_1, \ldots, x_n$, and the objective is to find an assignment v to these variables that maximizes the number of satisfied constraints.

A *partial assignment* assigns values to a subset of the n variables. Formally, a partial assignment is represented by a partial function $w : [n] \to [c]$. An assignment v *extends* w if v agrees with w on all variables to which w assigns a value. Define $\mathsf{SAT}(I)$ to be the maximum number of satisfied constraints over all assignments. Define $\mathsf{SAT}_I(w)$ in the same way, except the maximum is taken over only the assignments extending w. In the special case where w is a total assignment, this is simply the number of constraints satisfied (unsatisfied) by that assignment. Similar to before, for $\beta < 1$, we define a function h_I to be a β-heuristic if $\beta\,\mathsf{SAT}_I(w) \le h_I(w) \le \mathsf{SAT}_I(w)$.

To state our lower bound for Max-CSPs in full generality, we must first define the hard distribution $\mathcal{D}_s$ over instances $I \in \mathsf{CSP}(\mathcal{F})$. $\mathcal{D}_s$ is defined by the following sampling process. All sampling steps are done uniformly at random. First we sample a “planted” assignment P. Then, for each of s steps $i = 1, 2, \ldots, s$, we sample an ordered tuple $\left(x_{J_1^{(i)}}, \ldots, x_{J_k^{(i)}}\right)$ of k distinct variables, and sample a constraint function F_i that is satisfied by the input $\left(P\big(x_{J_1^{(i)}}\big), \ldots, P\big(x_{J_k^{(i)}}\big)\right)$. If there is no such $F_i \in \mathcal{F}$, we write $C_i = \mathsf{NULL}$ to indicate that we do not add a constraint; otherwise, C_i is the constraint $(F_i, (J_1^{(i)}, \ldots, J_k^{(i)}))$. The sampled instance $I \sim \mathcal{D}_s$ consists of all non-NULL constraints C_i. Given an assignment v, it will be convenient to write $v \models i$ to mean that $C_i \ne \mathsf{NULL}$ and $v \models C_i$.

Let $a(\mathcal{F}) := \liminf_{n\to\infty} \min_v \Pr[v \text{ does not satisfy } C_i \mid C_i \ne \mathsf{NULL}]$. That is, $a(\mathcal{F})$ is (close to, for sufficiently large n) the minimal achievable expected fraction of unsatisfied constraints (in an instance drawn from $\mathcal{D}_s$) over all fixed assignments v. Our lower bound roughly states that even for satisfiable instances, it is hard to satisfy much more than a $(1 - a(\mathcal{F}))$ fraction of constraints. Although the definition of $a(\mathcal{F})$ looks complicated, it is actually a fairly natural measure of the hardness of choosing a fixed assignment to satisfy a random constraint from $\mathcal{F}$. For example, it is not hard to see that $a(\mathcal{F}_{3-\mathrm{SAT}}) = 1/8$, and $a(\mathcal{F}_{\mathrm{k-LIN}}) = 1/2$. These are exactly the expected fraction of random constraints not satisfied by any fixed assignment. We will write a for $a(\mathcal{F})$ when $\mathcal{F}$ is clear from context.

Say that a constraint family $\mathcal{F}$ is *constant satisfiable* (resp. *constant unsatisfiable*) if there is $b \in [c]$ for which every $f \in \mathcal{F}$ has $f(b, \ldots, b) = 1$ (resp. $f(b, \ldots, b) = 0$).

▶ **Theorem 15.** *For all constraint families $\mathcal{F}$ that are not constant unsatisfiable, there is $r > 0$ such that for all $0 < \varepsilon < 1$, there are $(1-\varepsilon)$-approximate estimation oracles h_I such that for all oracle algorithms $\mathcal{A}^{h_I}$ making at most q queries to h_I, letting $I \sim \mathcal{D}_s$ and $v \leftarrow \mathcal{A}^{h_I}()$, for sufficiently large n,*

$$\Pr[\mathsf{SAT}_I(v)/\mathsf{SAT}_I \ge (1+\delta)(1-a)] \le q \exp(-(\delta^2 + \varepsilon^2) \cdot r \cdot n),$$

where $s = 1000k^2 \log(c) n/\varepsilon^2$.

In particular, for any small $\delta > 0$, for sufficiently large n, an arbitrary assignment satisfies a $1 - a - \delta$ fraction of constraints with overwhelming probability, but no algorithm can satisfy a $1 - a + \delta$ fraction of constraints unless it makes exponentially many queries.

A few additional remarks are in order. The theorem is vacuous for trivially satisfiable constraint families $\mathcal{F}$, since the assignment v mapping every variable to b satisfies all constraints, which implies $a(\mathcal{F}) = 0$. But by the same logic, no non-trivial lower bound on the approximation ratio is possible for such families. Fortunately, if $\mathcal{F}$ is not trivially satisfiable, $a(\mathcal{F})$ is strictly positive. To see this, fix an assignment v, and let b be the majority value of v. By assumption, there is $f^* \in \mathcal{F}$ such that $f^*(b, \ldots, b) = 0$. Sample a random constraint $(f, (j_1, \ldots, j_k))$. Independent of $(j_1, \ldots, j_k)$, over the random choice of P, we have that $f^*(P(x_{j_1}), \ldots, P(x_{j_k})) = 1$ with probability at least $1/c^k$. Conditional on this, f is chosen to be f^* with probability at least $1/2^{c^k}$. Hence f is chosen to be f^* with probability at least $1/c^k \cdot 1/2^{c^k}$. Suppose $n \geq ck$. For any assignment v, we have $v(x_{j_1}) = \cdots = v(x_{j_k}) = b$ with probability (over the random choice of $j_1, \ldots, j_k$ independent of P and f^*) at least $\Pi_{i=0}^{k-1}(n/c - i)/(n - i) \geq \Pi_{i=0}^{k-1}(k - i)/(ck - i)$ (the last expression corresponds to the case of $n = ck$ and balanced v). Thus, for $n \geq ck$, the random constraint is unsatisfied with probability at least $1/c^k \cdot 1/2^{c^k} \cdot \Pi_{i=0}^{k-1}(k - i)/(ck - i) > 0$; it follows $a(\mathcal{F}) > 0$.

The trivial unsatisfiability condition is slightly less natural; however, some similar condition is necessary for lower bounds. Consider the problem of 3-coloring a graph to maximize the number of edges with one green endpoint and one blue endpoint. This is clearly a CSP. Starting with all nodes colored red, one can color two nodes blue and green and use a heuristic to determine if there is an edge between them. Proceeding in this way, using $O(n^2)$ queries, one can recover the whole graph and (using unbounded computation) recover the optimal coloring. So, in our model, we cannot hope to rule out a branch-and-bound algorithm for such a CSP. This CSP is ruled out by trivial unsatisfiability, because coloring all nodes red makes the only constraint in the family (the blue-green constraint) output 0.

A Omitted Proofs

A.1 Proof of Theorem 12

Proof. $\mathcal{G}$ is defined by independently setting the weight of each edge e as follows:

$$w(e) = \begin{cases} 1 & \text{w.p. } 1/2\,, \\ \omega := 1 + (\gamma - 1)n/t & \text{w.p. } 1/2\,. \end{cases}$$

The following is the definition of v_k:

$$v_k = \begin{cases} n/\gamma & \text{if } k = 0\,, \\ n & \text{if } 1 \le k \le t\,, \\ k(\omega+1)/(\gamma+1) + n - k & \text{if } t < k < n - t\,, \\ \big(k/2 + n/(\gamma+1)\big)(\omega+1)/2 & \text{if } k \ge n - t\,. \end{cases}$$

The definitions of v_0 and v_{n-1} satisfy the first item of the theorem statement as $v_0 = n/\gamma$, and

$$v_{n-1} \ge (n-1)(\omega+1)/4 \ge (n-1)(\gamma-1)n/(4t) \ge (\gamma-1)n^2/(5t)\,.$$

It remains to bound from above $\Pr_{G\sim\mathcal{G}}\big[\mathrm{OPT}(G,p) \notin [v_k, \gamma v_k]\big]$ for every fixed $p \in P_n^k$. By the Chernoff-Hoeffding bound (Lemma 4), for every $\varepsilon \in (0,1)$, p contains from $(1-\varepsilon)k/2$ to $(1+\varepsilon)k/2$ edges of weight ω with probability at least $1 - 2e^{-\varepsilon^2 k/6}$. Therefore,

$$\Pr_{G\sim\mathcal{G}}\big[w(p) \in [(1-\varepsilon)k(\omega+1)/2,\ (1+\varepsilon)k(\omega+1)/2]\big] \ge 1 - O\big(e^{-\varepsilon^2 k/6}\big)\,. \qquad (2)$$

Let $G \sim \mathcal{G}$, and let G' be the graph consisting of the vertices of G not belonging to the path p, and the edges of G of weight 1. Note that G' is a uniformly random unweighted graph with $n-k-1$ vertices. By Lemma 11, G' contains a Hamiltonian cycle with probability $1 - 2^{-(n-k-1)(1-o(1))}$. With probability at least $1 - (3/4)^{n-k-1}$ the endpoints of p are connected by edges of weight 1 to a pair of consecutive points of the Hamiltonian cycle in G'. Thus, with probability at least $1 - O\big((3/4)^{n-k}\big)$, p can be extended to a TSP cycle in G by taking a Hamiltonian path in G', removing an edge from it, and connecting the two endpoints to the endpoints of p by edges of weight 1. Hence,

$$\Pr_{G\sim\mathcal{G}}[\mathrm{OPT}(G,p) = w(p) + n - k] \geq 1 - O\big((3/4)^{n-k}\big)\,. \tag{3}$$

Now we consider the following four cases.

- $k = 0$. For the distribution $\mathcal{G}$, Lemma 11 implies that for every $p \in P_n^0$, $\mathrm{OPT}(G,p) = \mathrm{OPT}(G) = n$ with probability $1 - 2^{-n+o(n)} \geq 1 - O(e^{-\delta^2 t/30})$.
- $1 \leq k \leq t$. For each path $p \in P_n^k$, $\mathrm{OPT}(G,p) \geq n = v_k$, and, by (3), with probability at least $1 - O\big((3/4)^{n-k}\big) \geq 1 - O\big((3/4)^{n/2}\big) \geq 1 - O(e^{-\delta^2 t/30})$, we have that

  $$\mathrm{OPT}(G,p) = w(p) + n - k \leq k\omega + n - k \leq \gamma n = \gamma v_k\,.$$

- $t < k < n - t$. From (3), with probability $1 - O\big((3/4)^t\big)$, $\mathrm{OPT}(G,p) = w(p) + n - k$. By setting $\varepsilon = \delta$, from (2), with probability at least $1 - O(e^{-\delta^2 t/6})$, $w(p) \in [k(\omega+1)/(\gamma+1),\ \gamma k(\omega+1)/(\gamma+1)]$. Together these bounds give us that

  $$\mathrm{OPT}(G,p) = w(p) + n - k \in [v_k, \gamma v_k]$$

  with probability at least $1 - O\big((3/4)^t\big) - O(e^{-\delta^2 t/6}) \geq 1 - O(e^{-\delta^2 t/30})$.
- $k \geq n - t$. From (2) with $\varepsilon = 1/2 - \frac{n}{k(\gamma+1)} \geq 1/2 - 2/(\gamma+3)$, with probability $1 - O(e^{-(1-4/(\gamma+3))^2 k/24}) \geq 1 - O(e^{-\delta^2 t/30})$ (where we used that $t \leq \delta n/2$ and $k \geq n(1-\delta/2)$), we have that

  $$\begin{aligned} w(p) &\in [(1-\varepsilon)k(\omega+1)/2,\ (1+\varepsilon)k(\omega+1)/2] \text{ and} \\ \mathrm{OPT}(G,p) &\in [w(p),\ w(p) + \omega(n-k)] \\ &\subseteq [(1-\varepsilon)k(\omega+1)/2,\ (\omega+1)(n-(1-\varepsilon)k/2)] \\ &= \big[\big(k/2 + n/(\gamma+1)\big)(\omega+1)/2,\ \big(2n - \big(k/2 + n/(\gamma+1)\big)\big)(\omega+1)/2\big] \\ &\subseteq [v_k, \gamma v_k] \end{aligned}$$

  for every $k \geq n - t \geq n(1-\delta) = 2n/(\gamma+1)$. ◀

A.2 Proof of Theorem 14

We prove the first part of the theorem using Corollary 7. For this, we first denote by $\mathcal{G}$ the distribution of graphs from Theorem 12, and by D the set of all cycles C_n. We define the distribution $\mathcal{D}$ of functions $f_G\colon D \to \mathbb{R}_{\geq 0}$ computing the length of a given cycle in $G \sim \mathcal{G}$. For a path $p \in P_n^k$, we denote by $S_p \subseteq C_n$ the set of cycles containing the path p, and we define

$$\mathcal{S} = \{S_p\colon p \in P_n^k,\ 0 \leq k \leq n-1\}\,.$$

It is easy to see that $C_n \in \mathcal{S}$ and for every cycle $c \in C_n$, $\{c\} \in \mathcal{S}$. Now for a set $S_p \in \mathcal{S}$ corresponding to a path $p \in P_n^k$, we define $g(S_p) = \gamma v_k$. By Theorem 12 with $t = 30\ell/\delta^2$, for each S_p, $\Pr[g(S_p)/\gamma \leq \min_{c\in S_p} f(c) \leq g(S_p)] \geq 1 - p$ for $p = O\big(e^{-\delta^2 t/30}\big) = O\big(e^{-\ell}\big)$. Now we apply Corollary 7 to our choices of f and g, and

$$\gamma' := \gamma^{-1} \cdot \min_{c\in D} \frac{g(\{c\})}{g(D)} \geq \gamma^{-1} \cdot v_{n-1}/v_0 \geq (\gamma-1)\delta^2 n/(150\ell)\,,$$

and have that

$$\Pr_{G\sim\mathcal{G}}[c \leftarrow \mathcal{A}^{h_G}(),\ w(c) \le \gamma' \operatorname{OPT}(G)] \le (q+2)\cdot O\big(e^{-\ell}\big) \le O\big(q\cdot e^{-\ell}\big)\,.$$

To prove the "furthermore" part, we consider the following algorithm. Let G be an input graph on n vertices, and let n be a multiple of $\ell-1$. The algorithm first queries $h_G(p)$ for each path $p\in P_n^{\ell-1}$ of length $\ell-1$. Then the algorithm returns a cycle $c=(c_0,\dots,c_{n-1})\in C_n$ that minimizes the sum

$$H(c) := h_G(c_0,\dots,c_{\ell-1}) + h_G(c_{\ell-1},\dots,c_{2(\ell-1)}) + \ldots + h_G(c_{n+1-\ell},\dots,c_{n-1},c_0)\,.$$

It is easy to see that the algorithm makes $|P_n^{\ell-1}| = \binom{n}{\ell}\cdot\ell!$ queries to h_G.

Since for every path $p\in P_n^{\ell-1}$, $w(p)\le h_G(p)$, the weight of the resulting cycle does not exceed $H(c)$. Now it remains to show that $\min_{x\in C_n} H(x) \le \gamma n \operatorname{OPT}(G)/(\ell-1)$. To this end, consider an optimal TSP cycle $c'\in C_n$ in G. Since for every subpath $p\in P_n^{\ell-1}$ of c', $h_G(p)\le\gamma\operatorname{OPT}(G)$, we have that

$$H(c) \le H(c') \le \gamma \operatorname{OPT}\cdot n/(\ell-1)\,.$$

A.3 Proof of Theorem 15

First, in the following lemma, we show that the "optimal satisfaction probability" $\rho_w(P)$ is concentrated as a function of P.

▶ **Lemma 16.**

$$\Pr\left[|\rho_w(P) - \mathbb{E}[\rho_w(P)]| \ge (\varepsilon/10)\,\mathbb{E}[\rho_w(P)]\right] \le 2\exp\Big(-n\varepsilon^2\,\mathbb{E}[\rho_w(P)]^2/(200k^2)\Big).$$

Proof. Notice that for all assignments v, P and indices $j\in[n]$, letting E be the event $(j=J_1^{(i)})\vee\cdots\vee(j=J_k^{(i)})$, we have

$$\rho_v(P) = \Pr[E]\cdot\Pr[v\models i \mid E, P] + \Pr[\overline{E}]\cdot\Pr[v\models i\mid \overline{E},P]$$

Observe that $\Pr[E]=k/n$, and $\Pr[v\models i\mid\overline{E},P]$ does not depend on $P(j)$. Thus, defining

$$v^{\oplus j} = \begin{cases}\neg v(x) & x=j\\ v(x) & x\ne j,\end{cases}$$

we have

$$|\rho_v(P) - \rho_v(P^{\oplus j})| \le k/n.$$

It follows that for all partial assignments w,

$$|\rho_w(P) - \rho_w(P^{\oplus j})| \le k/n.$$

Indeed, if no v improves by more than k/n in success probability, the maximum success probability over all v extending w cannot improve by more than k/n either. The desired result follows by McDiarmid's inequality (Lemma 5). ◀

It follows from the definition of $a=a(\mathcal{F})$ and the Chernoff-Hoeffding bound that there is a constant $r'>0$ such that for all assignments v:

$$\Pr_{I\sim\mathcal{D}}[\mathsf{SAT}_I(v)/\mathsf{SAT}_I \ge (1+\delta)(1-a)] = \Pr_{I\sim\mathcal{D}}[\mathsf{SAT}_I(v)\ge(1+\delta)(1-a)m(I)] \le \exp(-r'\cdot\delta^2\cdot n).$$

(Informally, any fixed assignment is unlikely to satisfy much more than a $1-a$ fraction of constraints.)

Notice that, for $x, y > 0$, if $x \in [(1-\varepsilon/3)y, (1+\varepsilon/3)y]$, then $x \in [(1-\varepsilon)z, z]$, where $z = (1+\varepsilon/3)y$. Thus, by the useless oracle corollary (Corollary 7), Theorem 15 will follow immediately from the claim below.

▷ Claim 17. Given a partial assignment w, let $\rho_w(P) = \max_{v:v \text{ extends } w} \Pr[v \models i \mid P]$. There is a constant $r > 0$ such that

$$\Pr_{I \sim \mathcal{D}_m}\left[|\mathsf{SAT}_I(w) - m\,\mathbb{E}[\rho_w(P)]| \geq (\varepsilon/3)m\,\mathbb{E}[\rho_w(P)]\right] \leq \exp(-r \cdot \varepsilon^2 \cdot n).$$

Proof. Fix a partial assignment w. We will argue that $\mathsf{SAT}_I(w)$ is concentrated conditional on P. Fixing P and an assignment v, $\mathsf{SAT}_I(v)$ is the sum of m independent coin tosses $\mathbb{1}(v \models i)$ with success probability $\rho_v(P)$. For the optimal v^* extending w, we have $\mathbb{E}[\mathsf{SAT}_I(v)] = m\rho_w(P)$, and the Chernoff-Hoeffding bound gives

$$\Pr\left[|\mathsf{SAT}_I(v^*) - m\rho_w(P)| \geq (\varepsilon/10)m\rho_w(P) \mid P\right] \leq 2\exp(-\varepsilon^2 m\rho_w(P)/600). \tag{4}$$

Moreover, for any v extending w, $\mathsf{SAT}_I(v)$ is the sum of m independent coin tosses with a smaller success probability $\rho_v(P) \leq \rho_w(P)$. Hence the upper bound of (4) holds, namely

$$\Pr[\mathsf{SAT}_I(v) \geq (1+\varepsilon/10)m\rho_w(P) \mid P] \leq \exp(-\varepsilon^2 m\rho_w(P)/600). \tag{5}$$

Recall that $\mathsf{SAT}_I(w)$ is the maximum over all v extending w of $\mathsf{SAT}_I(v)$. Inequality (4) is thus a high-probability lower bound on $\mathsf{SAT}_I(w)$, and (5) combined with a union bound over the (at most c^n) assignments v extending w gives a high-probability upper bound. Specifically, plugging in $m = \frac{1000k^2\log(c)n}{\varepsilon^2}$, we have

$$\begin{aligned}&\Pr\left[|\mathsf{SAT}_I(w) - m\rho_w(P)| \geq (\varepsilon/10)m\rho_w(P) \mid P\right]\\ &\leq (c^n+2)\exp(-\varepsilon^2 m\rho_w(P)/600)\\ &\leq \exp(-n\rho_w(P)/(100k^2)).\end{aligned} \tag{6}$$

Third, combining Inequality (6) with Lemma 16 yields

$$\Pr\left[|\mathsf{SAT}_I(w) - m\,\mathbb{E}[\rho_w(P)]| \leq (\varepsilon/3)m\,\mathbb{E}[\rho_w(P)]\right] \leq 2\exp(-n\varepsilon^2\,\mathbb{E}[\rho_w(P)]^2/(200k^2)), \tag{7}$$

where we have used $\mathbb{E}[\rho_w(P)] \leq 1 \Rightarrow \mathbb{E}[\rho_w(P)]^2 \leq \mathbb{E}[\rho_w(P)]$.

To finish the proof, we show that $\mathbb{E}[\rho_w(P)]$ is bounded below by a constant independent of n and w, if $n \geq ck$. Since $\mathcal{F}$ is not trivially unsatisfiable, for all $b \in [c]$, there is $f^* \in \mathcal{F}$ with $f(b, \ldots, b) = 1$. As we argued before with trivial satisfiability, when a random constraint is sampled, it is non-NULL and has constraint function f^* with probability at least $1/c^k \cdot 1/2^{c^k}$. Letting the variable indices in the constraint be $j_1, \ldots, j_k$, again for any assignment v (for $n \geq ck$) we have $v(x_{j_1}) = \cdots = v(x_{j_k}) = b$ with probability at least $\Pi_{i=0}^{k-1}(k-i)/(ck-i)$ (again, the last expression corresponds to the case of $n = ck$ and balanced v). Thus the constraint is satisfied with probability at least $1/c^k \cdot 1/2^{c^k} \cdot \Pi_{i=0}^{k-1}(k-i)/(ck-i)$, as needed. ◁

Approximating Red-Blue Set Cover and Minimum Monotone Satisfying Assignment

Abstract

We provide new approximation algorithms for the Red-Blue Set Cover and Circuit Minimum Monotone Satisfying Assignment (MMSA) problems. Our algorithm for Red-Blue Set Cover achieves $\tilde{O}(m^{1/3})$-approximation improving on the $\tilde{O}(m^{1/2})$-approximation due to Elkin and Peleg (where m is the number of sets). Our approximation algorithm for MMSA$_t$ (for circuits of depth t) gives an $\tilde{O}(N^{1-\delta})$ approximation for $\delta = \frac{1}{3}2^{3-\lceil t/2 \rceil}$, where N is the number of gates and variables. No non-trivial approximation algorithms for MMSA$_t$ with $t \geq 4$ were previously known.

We complement these results with lower bounds for these problems: For Red-Blue Set Cover, we provide a nearly approximation preserving reduction from Min k-Union that gives an $\tilde{\Omega}(m^{1/4-\varepsilon})$ hardness under the Dense-vs-Random conjecture, while for MMSA we sketch a proof that an SDP relaxation strengthened by Sherali–Adams has an integrality gap of $N^{1-\varepsilon}$ where $\varepsilon \to 0$ as the circuit depth $t \to \infty$.

1 Introduction

In this paper, we study two problems, *Red-Blue Set Cover* and its generalization *Circuit Minimum Monotone Satisfying Assignment.* Red-Blue Set Cover, a natural generalization of Set Cover, was introduced by Carr et al. [5]. Circuit Minimum Monotone Satisfying Assignment, a problem more closely related to Label Cover, was introduced by Alekhnovich et al. [2] and Goldwasser and Motwani [12].

▶ **Definition 1.** *In Red-Blue Set Cover, we are given a universe of $(k+n)$ elements U partitioned into disjoint sets of red elements (R) of size n and blue elements (B) of size k, that is $U = R \cup B$ and $R \cap B = \emptyset$, and a collection of sets $\mathcal{S} := \{S_1, \cdots, S_m\}$. The goal is to find a sub-collection of sets $\mathcal{F} \subseteq \mathcal{S}$ such that the union of the sets in $\mathcal{F}$ covers all blue elements while minimizing the number of covered red elements.*

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

Besides Red-Blue Set Cover, we consider the Partial Red-Blue Set Cover *problem in which we are additionally given a parameter $\hat{k}$, and the goal is cover at least $\hat{k}$ blue elements while minimizing the number of covered red elements.*

▶ **Definition 2.** *The Circuit Minimum Monotone Satisfying Assignment problem of depth t, denoted as $MMSA_t$, is as follows. We are given a circuit C of depth t over Boolean variables $x_1, \ldots, x_n$. Circuit C has AND and OR gates: all gates at even distances from the root (including the output gate at the root) are AND gates; all gates at odd distances are OR gates. The goal is to find a satisfying assignment with the minimum number of variables x_i set to 1 (true).*

Note that C computes a monotone function and the assignment of all ones is always a feasible solution. Though the definitions of the problems are quite different, Red-Blue Set Cover and MMSA_t are closely related. Namely, Red-Blue Set Cover is equivalent to MMSA_3.[1] The correspondence is as follows: variables $x_1, \ldots, x_n$ represent red elements; AND gates in the third layer represent sets $S_1, \ldots, S_m$; OR gates in the second layer represent blue elements. The gate for a set S_j is connected to OR gates representing blue elements of S_j and variables x_i representing red elements of S_j. It is easy to see that an assignment to $x_1, \ldots, x_n$ satisfies the circuit if and only if there exists a sub-family $\mathcal{F} \subseteq \mathcal{S}$ that covers all the blue elements, and only covers red elements corresponding to variables x_i which are assigned 1 (but not necessarily all of them).

Background. Red-Blue Set Cover and its variants are related to several well-known problems in combinatorial optimization including *group Steiner* and *directed Steiner* problems, *minimum monotone satisfying assignment* and *ymmetric minimum label cover.* Arguably, the interest to the general MMSA_t problem is mostly motivated by its connection to complexity and hardness of approximation.

The Red-Blue Set Cover has applications in various settings such as *anomaly detection, information retrieval* and notably in *learning of disjunctions* [5]. Learning of disjunctions over $\{0,1\}^m$ is one of the basic problems in the PAC model. In this problem, given an arbitrary distribution $\mathcal{D}$ over $\{0,1\}^m$ and a target function $h^* : \{0,1\}^m \to \{-1,+1\}$ which denotes the true labels of examples, the goal is to find the best disjunction $f^* : \{0,1\}^m \to \{-1,+1\}$ with respect to $\mathcal{D}$ and h^* (i.e., $f^*(x)$ computes a disjunction of a subset of coordinates of x). The problem of learning disjunctions can be formulated as an instance of the (Partial) Red-Blue Set Cover problem [4]: we can think of the positive examples as blue elements (i.e., $h^*(x) = 1$) and the negative examples as red elements (i.e., $h^*(x) = -1$). Then, we construct a set S_i corresponding to each coordinate i and the set S_i contains an example x if the i-th coordinate of x is equal to 1. Let $C \subset \{S_1, \cdots, S_m\}$. Then, the disjunction f_C corresponding to C, i.e., $f_C(x) := \bigvee_{S_i \in C} x_i$, outputs one on an example x if in the constructed Red-Blue Set Cover instance, the element corresponding to x is covered by sets in C.

As we observe in Section 5, Red-Blue Set Cover is also related to the Min k-Union problem which is a generalization of Densest k-Subgraph [8]. In Min k-Union, given a collection of m sets $\mathcal{S}$ and a target number of sets k, the goal is to pick k sets from $\mathcal{S}$ whose union has the minimum cardinality. Notably, under a hardness assumption, which is an extension of the "Dense vs Random" conjecture for Densest k-Subgraph to hypergraphs, Min k-Union

[1] Also observe that MMSA_2 is equivalent to Set Cover.

cannot be approximated better than $\tilde{\Omega}(m^{1/4-\varepsilon})$ [9]. In this paper, we prove a hardness of approximation result for Red-Blue Set Cover by constructing a reduction from Min k-Union to Red-Blue Set Cover.

1.1 Related work

Carr et al. [5] formulated the Red-Blue Set Cover problem and presented a $2\sqrt{m}$-approximation algorithm for the problem when every set contains only one blue element. Later, Elkin and Peleg [11] showed that it is possible to obtain a $2\sqrt{m\log(n+k)}$ approximation in the general case of the problem. This remained the best known upper bound for Red-Blue Set Cover prior to our work. No non-trivial algorithms for MMSA_t were previously known for any $t \geq 4$.

On the hardness side, Dinur and Safra [10] showed that MMSA_3 is hard to approximate within a factor of $O(2^{\log^{1-\epsilon} m})$ where $\epsilon = 1/\log\log^c m$ for any constant $c < 1/2$, if $P \neq NP$. As was observed by Carr et al. [5], this implies a factor of $O(2^{\log^{1-\epsilon} m})$ hardness for Red-Blue Set Cover as well. The hardness result holds even for the special case of the problem where every set contains only one blue and two red elements.

Finally, Charikar et al. [7] gave a lower bound on a variant of MMSA in which the circuit depth t is not fixed. Assuming a variant of the Dense-vs-Random conjecture, they showed that for every $\varepsilon > 0$, the problem does not admit an $O(n^{1/2-\varepsilon})$ approximation, where n is the number of variables, and an $O(N^{1/3-\varepsilon})$ approximation, where N is the total number of gates and variables in the circuit.

Learning of Disjunctions. While algorithms for Red-Blue Set Cover return a disjunction with no error on positive examples, i.e., it covers all "blue" elements, it is straightforward to make those algorithms work for the case with two-sided error. A variant of the problem with a two-sided error is formally defined as *Positive–Negative Partial Set Cover* [15] where the author showed that a $f(m,n)$-approximation for Red-Blue Set Cover implies a $f(m+n,n)$-approximation for Positive-Negative Partial Set Cover. Our result also holds for Partial Red-Blue Set Cover and a c-approximation for Partial Red-Blue Set Cover can be used to output a c-approximate solution of Positive-Negative Partial Set Cover.

Awasthi et al. [4] designed an $O(n^{1/3+\alpha})$-approximation for any constant $\alpha > 0$. While the proposed algorithm of Awasthi et al. is an *agnostic learning* of disjunctions (i.e., the solution is not of form of disjunctions), employing an approximation algorithm of Red-Blue Set Cover, produces a disjunction as its output (i.e., the algorithms for Red-Blue Set Cover are *proper* learners).

Geometric Red-Blue Set Cover. The problem has been studied extensively in geometric models. Chan and Hu [6] studied the setting in which R and B are sets of points in $\mathbb{R}^2$ and $\mathcal{S}$ is a collection of unit squares. They proved that the problem still remains NP-hard in this restricted instance and presented a PTAS for this problem. Madireddy and Mudgal [13] designed an $O(1)$-approximation algorithm for another geometric variant of the problem, in which sets are unit disks. The problem has also been studied in higher dimensions with hyperplanes and axis-parallel objects as the sets [3, 14, 1].

1.2 Our Results

In this paper, we present new approximation algorithms for Red-Blue Set Cover, MMSA_4, and general MMSA_t. Additionally, we offer a new conditional hardness of approximation result for Red-Blue Set Cover. We also discuss the integrality gap of a basic SDP relaxation of MMSA_t strengthened by Sherali–Adams when $t \to \infty$.

We start by describing our result for Red-Blue Set Cover.

▶ **Theorem 3.** *There exists an $O(m^{1/3} \log^{4/3} n \log k)$-approximation algorithm for Red-Blue Set Cover where m is the number of sets, n is the number of red elements, and k is the number of blue elements.*

As we demonstrate later, our algorithm also works for the Partial Red-Blue Set Cover. Our approach partitions the instance into subinstances in which all sets have a bounded number of red elements, say between r and $2r$, and each red element appears in a bounded number of sets. Utilizing the properties of this partition, we show that we can always find a small collection of sets that preserves the right ratio of red to blue elements in order to make progress towards an $\tilde{O}(m^{1/3})$-approximation algorithm.[2] Then, by applying the algorithm iteratively until all blue elements are covered, we obtain the guarantee of Theorem 3. In each iteration, our analysis guarantees the feasibility of a local LP relaxation for which a simple randomized rounding obtains the required ratio of blue to red vertices.

Now we describe our results for the MMSA problem.

▶ **Theorem 4.** *There exists an $\tilde{O}(N^{1/3})$-approximation algorithm for MMSA$_4$, where N is the total number of gates and variables in the input instance.*

Our algorithm for MMSA$_4$ is inspired by our algorithm for MMSA$_3$, though due to the complexities of the problem, the algorithm is significantly more involved. In particular, there does not seem to be a natural preprocessing step analogous to the partition we apply for Red-Blue Set Cover, and so we need to rely on a higher-moment LP relaxation and a careful LP-based partition which is built into the algorithm.

▶ **Theorem 5.** *Let $t \geq 4$. Define $\delta = \frac{1}{3} \cdot 2^{3-\lceil t/2 \rceil}$. There exists an $\tilde{O}(N^{1-\delta})$-approximation algorithm for MMSA$_t$ where N is the total number of gates and variables in the input instance.*

Our algorithm for general MMSA$_t$ applies a recursion on the depth t, with our algorithms for Red-Blue Set Cover and MMSA$_4$ as the basis of the recursion. Each recursive step relies on an initially naive LP relaxation to which we add constraints as calls to the algorithm for smaller depth MMSA reveal new violated constraints.

We complement our upper bound for Red-Blue Set Cover with a hardness of approximation result.

▶ **Theorem 6.** *Assuming the Hypergraph Dense-vs-Random Conjecture, for every $\varepsilon > 0$, no polynomial-time algorithm achieves better than $O(m^{1/4-\varepsilon}/\log^2 k)$ approximation for Red-Blue Set Cover where m is the number of sets and k is the number of blue elements.*

To show the hardness, we present a reduction from Min k-Union to Red-Blue Set Cover that preserves the approximation up to a factor of polylog(k). Then, the hardness follows from the standard conjectured hardness of Min k-Union [9]. In our reduction, all elements of the given instance of Min k-Union are considered as the red elements in the constructed instance for Red-Blue Set Cover and we further complement each set with a sample size of $O(\log k)$ (with replacement) from a ground set of blue elements of size k. We prove that this reduction is approximation-preserving up to a factor of polylog(k).

[2] Here, we abuse the $\tilde{O}$ notation to hide polylog factors of n, k.

Organization. In Section 2, we restate Red-Blue Set Cover and introduce some notation. In Section 3, we present our algorithm for Red-Blue Set Cover. We adapt this algorithm for Partial Red-Blue Set Cover in Appendix A. Then, in Section 4 we give the algorithm for MMSA_t with $t \geq 5$. This algorithm relies on the algorithm for MMSA_4, which we describe later in Section 6. We present a reduction from Min k-Union to Red-Blue Set Cover, which yields a hardness of approximation result for Red-Blue Set Cover, in Section 5. The discussion on hardness of the general MMSA_t problem is deferred to the full version of the paper.

2 Preliminaries

To simplify the description and analysis of our approximation algorithm for Red-Blue Set Cover, we restate the problem in graph-theoretic terms. Essentially we restate the problem as MMSA_3. Specifically, we think of a Red-Blue Set Cover instance as a tripartite graph (B, J, R, E) in which all edges (E) are incident on J and either B or R. The vertices in J represent the set indices, and their neighbors in B (resp. R) represent the blue (resp. red) elements in these sets. Thus, our goal is to find a subset of the vertices in J that is a dominating set for B and has a minimum total number of neighbors in R. For short, we will denote the cardinality of these different vertex sets by $k = |B|$, $m = |J|$, and $n = |R|$.

Similarly, we think of a MMSA_4 instance as a tuple (B, J, R, S, E). Here, B, J, and R represent gates in the second, third, and fourth layers of the circuit (where layer i consists of the gates at distance $i - 1$ from the root), respectively; S represents the variables; E represent edges between gates/variables. Combinatorially, the goal is to obtain a subset of J as above, along with a minimum dominating set in S for the red neighbors (in R) of our chosen subset of J.

Notation. We use $\Gamma(\cdot)$ to represent neighborhoods of vertices, and for a vertex set U, we use $\Gamma(U)$ to denote the union of neighborhoods of vertices in U, that is $\bigcup_{u\in U} \Gamma(u)$. We also consider restricted neighborhoods, which we denote by $\Gamma_T(u) := \Gamma(u) \cap T$ or $\Gamma_T(U) = \Gamma(U) \cap T$. We will refer to the cardinality of such a set, i.e. $|\Gamma_T(u)|$ as the *T-degree* of u.

▶ Remark 7. Note that, for every set index $j \in J$, the set $\Gamma(j)$ is simply the set S_j in the set system formulation of the problem, and the set $\Gamma_R(j)$ (resp. $\Gamma_B(j)$) is simply the subset of red (resp. blue) elements in the set with index j. Similarly, $\Gamma_J(i)$ consists of indices j representing those sets S_j that contain element i, for any $i \in R \cup B$.

For Red-Blue Set Cover algorithms, we introduce a natural notion of progress:

▶ **Definition 8.** *We say that an algorithm for Red-Blue Set Cover* makes progress towards an $O(A \cdot \log k)$-approximation *if, given an instance with an optimum solution containing* OPT *red elements, the algorithm finds a subset $\hat{J} \subseteq J$ such that* $\frac{|\Gamma_R(\hat{J})|}{|\Gamma_B(\hat{J})|} \leq A \cdot \frac{\text{OPT}}{|B|}$.

It is easy to see that if we have an algorithm which makes progress towards an A-approximation, then we can run this algorithm repeatedly (with decreasing $|B|$ parameter, where initially $|B| = k$) until we cover all blue elements and obtain an $O(A \cdot \log k)$-approximation. For brevity, all logarithms are implicitly base 2 unless otherwise specified, that is, we write $\log(\cdot) \equiv \log_2(\cdot)$.

3 Approximation Algorithm for Red-Blue Set Cover

We begin by excluding a small number of red elements, and binning the sets J into a small number of bins with uniform red-degree. For an $O(A)$-approximation, the goal will be to exclude at most $A \cdot \mathrm{OPT}$ red elements (we may guess the value of OPT by a simple linear or binary search). This is handled by the following lemma:

▶ **Lemma 9.** *There is a polynomial time algorithm, which, given an input (B, J, R, E) and parameter n_0, returns a set of at most $\log n$ pairs (J_α, R_α) with the following properties:*

- *The sets $J_\alpha \subseteq J$ partition the set J.*
- *The sets $R_\alpha \subseteq R$ form a nested collection of sets, and the smallest among them (i.e., their intersection) has cardinality at least $n - n_0$. That is, at most n_0 red elements are excluded by any of these sets.*
- *For every α there is some r_α such that every set $j \in J_\alpha$ has R_α-degree (or restricted red set size) $|\Gamma_{R_\alpha}(j)| \in [r_\alpha, 2r_\alpha]$,*
- *and for every α, every red element $i \in R_\alpha$ has J_α-degree at most (that is, the number of red sets in J_α that contain i) $|\Gamma_{J_\alpha}(i)| \leq \frac{2mr_\alpha \log n}{n_0}$.*

Proof. Consider the following algorithm:

- Let r be the maximum red-degree (i.e., $\max_{j \in J} \deg_R(j)$).
- Repeat the following while $J \neq \emptyset$:
  - Delete the top $n_0 / \log n$ J-degree red elements from R, along with their incident edges.
  - After this deletion, let $J' = \{j \in J \mid \deg_R(j) \in [r/2, r]\}$.
  - If J' is non-empty, add the current pair (J', R) to the list of output pairs (excluding all elements deleted from R so far).
  - Remove the sets in J' from J (along with incident edges) and let $r \leftarrow r/2$.

By the decrease in r, it is easy to see that this partitions J into at most $\log n$ sets (or more specifically, log of the initial maximum red set size, $\max_{j \in J} \deg_R(j)$). Also note that at the beginning of each iteration, all red sets have size at most r, and so there are at most mr edges to R, and the top $n_0 / \log n$ J-degree red elements will have average degree (and in particular minimum degree) at most $mr/(n_0/\log n)$. Thus, after removing these red elements, all remaining red elements will have J-degree (and in particular J'-degree) at most the required bound of $\frac{2mr_\alpha \log n}{n_0}$ where $r_\alpha = r/2$. Finally, since there at most $\log n$ iterations, the total number of red elements removed across all iterations is at most n_0. ◀

Our algorithm works in iterations, where at every iteration, some subset of blue elements is covered and removed from B. However, nothing is removed from J or R. Thus the above lemma applies throughout the algorithm. Note that for an optimum solution $J_{\mathrm{OPT}} \subseteq J$, for at least one of the subsets J_α in the above partition, the sets in $J_{\mathrm{OPT}} \cap J_\alpha$ must cover at least a $(1/\log n)$-fraction of B. Thus, to achieve an $O(A)$ approximation, it suffices to apply the above lemma with parameter $n_0 = \mathrm{OPT} \cdot A$, and repeatedly make progress towards an A-approximation within one of the subgraphs induced on (B, J_α, R_α). We will only pay at most another $\mathrm{OPT} \cdot A$ in the final analysis by restricting our attention to these subinstances.

Let us fix some optimum solution $J_{\mathrm{OPT}} \subseteq J$ in advance. For any α in the above partition, let $J^\alpha_{\mathrm{OPT}} = J_\alpha \cap J_{\mathrm{OPT}}$ be the collection of sets in J_α that also belong to our optimum solution, and let $B_\alpha = \Gamma_B(J^\alpha_{\mathrm{OPT}})$ be the blue elements covered by the sets in J^α_{OPT}. Note that every blue element must belong by the feasibility of J_{OPT} to at least one B_α. In this context we can show the following:

▶ **Lemma 10.** *For any α in the partition described in Lemma 9, there exists a red element $i_0 \in R_\alpha$ such that its optimum J_α-restricted neighbors $\Gamma_{J^\alpha_{\mathrm{OPT}}}(i_0)$ cover at least $|B_\alpha| r_\alpha/\mathrm{OPT}$ blue elements.*

Proof. Consider the following subgraph of $(B_\alpha, J^\alpha_{\mathrm{OPT}}, E(B_\alpha, J^\alpha_{\mathrm{OPT}}))$. For every blue element $\ell \in B_\alpha$, retain exactly one edge to J^α_{OPT}. Let $\hat{F}$ be this set of edges.

Thus the blue elements B_α have at least $|B_\alpha| r_\alpha$ paths through $\hat{F} \times E(J^\alpha_{\mathrm{OPT}}, R_\alpha)$ to the red neighbors of J^α_{OPT} in R_α. Since there are at most OPT such red neighbors, at least one of them, say $i_0 \in \Gamma_{R_\alpha}(J^\alpha_{\mathrm{OPT}})$, must be involved in at least a $1/\mathrm{OPT}$ fraction of these paths. That is, at least $|B_\alpha| r_\alpha/\mathrm{OPT}$ paths. Since the $\hat{F}$-neighborhoods of the vertices in J^α_{OPT} are disjoint (by construction), these paths end in distinct blue elements, thus, at least $|B_\alpha| r_\alpha/\mathrm{OPT}$ elements in B_α. ◀

Of course, we cannot know which red element will have this property, but the algorithm can try all elements and run the remainder of the algorithm on each one. Now, given a red element $i_0 \in R_\alpha$, our algorithm proceeds as follows: Begin by solving the following LP.

$$\max \sum_{\ell \in B} z_\ell \tag{1}$$

$$\sum_{i \in R_\alpha} y_i \le \mathrm{OPT} \tag{2}$$

$$0 \le z_\ell \le \min\{1, \sum_{j \in \Gamma_{J_\alpha}(i_0) \cap \Gamma_{J_\alpha}(\ell)} x_j\} \qquad \forall \ell \in B \tag{3}$$

$$0 \le x_j \le y_i \le 1 \qquad \forall j \in \Gamma_{J_\alpha}(i_0), i \in \Gamma_{R_\alpha}(j) \tag{4}$$

In the intended solution, x_j is the indicator for the event that $j \in \Gamma_{J^\alpha_{\mathrm{OPT}}}(i_0)$, y_i is the indicator variable for the event that red vertex i is in the union of red sets indexed by $\Gamma_{J^\alpha_{\mathrm{OPT}}}(i_0)$ (and therefore in the optimum solution), and z_ℓ is the indicator variable for the event that the blue vertex $\ell \in B$ is is covered by some set in $\Gamma_{J^\alpha_{\mathrm{OPT}}}(i_0)$. This LP is always feasible (say, by setting all variables to 0), though since there are at most $\log n$ subinstances in the partition, for at least one α we must have $|B_\alpha| \ge |B|/\log n$, and then by Lemma 10, there is also some choice of $i_0 \in R_\alpha$ for which the objective function satisfies

$$\sum_{\ell \in B} z_\ell \ge \frac{|B_\alpha| r_\alpha}{\mathrm{OPT}} \ge \frac{|B| r_\alpha}{\mathrm{OPT} \cdot \log n}. \tag{5}$$

The algorithm will choose α and i_0 that maximize the rescaled objective function $\sum_{\ell \in B} z_\ell / r_\alpha$, guaranteeing this bound. Finally, at this point, we perform a simple randomized rounding, choosing every set $j \in \Gamma_{J_\alpha}(i_0)$ independently with probability x_j. The entire algorithm is described in Algorithm 1.

Now let $J^* \subseteq J_\alpha$ be the collection of sets added by this step in the algorithm. Let us analyze the number of blue elements covered by J^* and the number of red elements added to the solution. First, noting that this LP acts as a max coverage relaxation for blue elements, the expected number of blue elements covered will be at least $(1 - 1/e)\frac{|B| r_\alpha}{\mathrm{OPT} \cdot \log n}$, by the standard analysis and the bound (5).

Now let us bound the number of red elements added. Let $J_+ = \left\{ j \in \Gamma_{J_\alpha}(i_0) \;\middle|\; x_j \ge \frac{\mathrm{OPT}}{r_\alpha \hat{A}} \right\}$ for a value of $\hat{A}$ to be determined later. By Constraint (4), every red neighbor $i \in \Gamma_{R_\alpha}(J_+)$ will also have $y_i \ge \mathrm{OPT}/(r_\alpha \hat{A})$, and so by Constraint (2), there can be at most $r_\alpha \hat{A}$ such neighbors. On the other hand, the expected number of red elements added by the remaining sets $j \in J^* \setminus J_+$ is bounded by

    let $J_{\text{ALG}} = J_{\text{ALG}} \cup J^*$
    let $B = B \setminus \Gamma_B(J^*)$
    remove edges incident to deleted vertices from $E$
end while
return $J_{\text{ALG}}$
```

$$\begin{aligned}
\mathbb{E}\left[\left|\bigcup_{j \in J^* \setminus J_+} \Gamma_{R_\alpha}(j)\right|\right] &\leq 2r_\alpha \mathbb{E}\left[|J^* \setminus J_+|\right] && \text{by } R_\alpha\text{-degree bounds for } j \in J_\alpha \\
&= 2r_\alpha \cdot \sum_{j \in \Gamma_{J_\alpha}(i_0) \setminus J_+} x_j \\
&\leq 2r_\alpha \cdot \frac{\text{OPT}}{r_\alpha \hat{A}} |\Gamma_{J_\alpha}(i_0) \setminus J_+| && \text{by definition of } J_+ \\
&\leq \frac{2\text{OPT}}{\hat{A}} \cdot \frac{2mr_\alpha \log n}{\text{OPT} \cdot \hat{A}} && \text{by } J_\alpha\text{-degree bounds for } i \in R_\alpha \\
&= \frac{4mr_\alpha \log n}{\hat{A}^2}
\end{aligned}$$

These two bounds are equal when $r_\alpha \hat{A} = 4mr_\alpha \log n/\hat{A}^2$, that is, when $\hat{A} = (4m \log n)^{1/3}$, giving us a total bound on the expected number of red elements added in this step of

$$\mathbb{E}[|\Gamma_{R_\alpha}(J^*)|] \leq 2r_\alpha(4m \log n)^{1/3} \leq \frac{2r_\alpha(4m \log n)^{1/3}}{(1 - 1/e)|B|r_\alpha/(\text{OPT} \cdot \log n)} \cdot \mathbb{E}[|\Gamma_B(J^*)|].$$

Thus, $\mathbb{E}[|\Gamma_{R_\alpha}(J^*)|] - \frac{2(4m \log^4 n)^{1/3}\text{OPT}}{(1-1/e)|B|} \cdot \mathbb{E}|\Gamma_B(J^*)| \leq 0$. Using the method of conditional expectations, we can derandomize the algorithm and find J^* with a non-empty blue neighbor set such that $\frac{|\Gamma_{R_\alpha}(J^*)|}{|\Gamma_B(J^*)|} \leq O(1) \cdot m^{1/3} \log^{4/3} n \cdot \frac{\text{OPT}}{|B|}$. Thus, we make progress (according to Definition 8) towards an approximation guarantee of $\tilde{A} \cdot k$ for $\tilde{A} = O\left(m^{1/3} \log^{4/3} n\right)$, which, as noted, ultimately gives us the same approximation guarantee for Red-Blue Set Cover, proving Theorem 3.

4 Approximating MMSA$_t$ for $t \geq 5$

We now turn to the general problem of approximating MMSA$_t$ for arbitrarily large (but fixed) t. We will build on our approximation algorithm for MMSA$_4$ (described in Section 6) by recursively calling approximation algorithms for the problem with smaller values of t, and using the result of this approximation as a separation oracle in certain cases.

We will denote the total size of our input by N, and we will denote our approximation factor for MMSA$_t$ by A_t. We will only describe an algorithm for even depth. There is a very slightly simpler but quite similar algorithm for odd depth, however the guarantee we are able to achieve for MMSA$_{2t-1}$ is nearly the same as for MMSA$_{2t}$ (up to an $O(\log N)$ factor). Since MMSA$_{2t-1}$ is essentially a special case of MMSA$_{2t}$, we focus only on even levels.

▶ **Lemma 11.** *For $t \geq 2$, if MMSA$_{2t}$ can be approximated to within a factor of A_{2t}, then we can approximate MMSA$_{2t+2}$ (and thus MMSA$_{2t+1}$) to within $O(\sqrt{N \cdot A_{2t}} \log N)$.*

Proof. Denote our input as a layered graph with vertex layers $V_1, \ldots, V_{2t+2}$. Ideally, we would like to discard any vertex $j \in V_{2t}$ such that covering its neighbors $\Gamma_{2t+1}(j)$ requires more than OPT vertices in V_{2t+2}, however, checking this precisely requires solving Set Cover. Instead, we discard any vertex $j \in V_{2t}$ for which the smallest *fractional* set cover[3] in V_{2t+2} of its neighbors $\Gamma_{V_{2t+1}}(j)$ has value greater than OPT. Such vertices cannot be included without incurring cost greater than OPT and so we know they do not participate in any optimum solution. We begin with the following basic LP:

$$\sum_{h \in V_{2t+2}} w_h \leq \text{OPT} \tag{6}$$

$$y_i \leq \sum_{h \in \Gamma_{2t+2}(i)} w_h \qquad \forall i \in V_{2t+1} \tag{7}$$

$$x_j \leq y_i \qquad \forall j \in V_{2t}, i \in \Gamma_{V_{2t+1}}(j) \tag{8}$$

$$x_j, y_i, w_h \in [0,1] \qquad \forall j \in V_{2t} \forall i \in V_{2t+1} \forall h \in V_{2t+2} \tag{9}$$

Note that, as stated, this LP is trivial. Indeed, in the absence of any additional constraints, the all-zero solution is feasible. However, we will add new violated constraints as the algorithm proceeds.

Given a solution to the above linear program, our algorithm for MMSA$_{2t+2}$ is as follows:

- Let $V_{2t}^+ = \{j \in V_{2t} \mid x_j \geq 2(1 + \ln N)/A_{2t+2}\}$. Add these vertices to the solution.
- Let $V_{2t+2}^+ = \Gamma_{V_{2t+2}}(\Gamma_{V_{2t+1}}(V_{2t}^+))$ be the neighbors-of-neighbors of V_{2t}^+.
- Apply a greedy $(1 + \ln N)$-approximation for Set Cover to obtain a set cover (in V_{2t+2}) for $\Gamma_{V_{2t+1}}(V_{2t}^+)$, and add this set cover to the solution as well.
- Create an instance of MMSA$_{2t}$ by removing layers V_{2t+1}, V_{2t+2}, all vertices in V_{2t}^+, as well as their neighbors in V_{2t-1}, that is, $\Gamma_{V_{2t-1}}(V_{2t}^+)$, as these are already covered by V_{2t}^+.
- Apply an A_{2t}-approximation algorithm for MMSA$_{2t}$ to this instance, and let $U_{\text{ALG}} \subseteq V_{2t} \setminus V_{2t}^+$ be the result (or at least the portion belonging to layer $2t$).
- If $|U_{\text{ALG}}| \leq A_{2t+2}/(2 + 2\ln N)$, add the vertices in U_{ALG} to the solution, as well as a greedy set cover (in V_{2t+2}) for the neighborhood $\Gamma_{V_{2t+1}}(U_{\text{ALG}})$.
- Otherwise (if $|U_{\text{ALG}}| > A_{2t+2}/(2 + 2\ln N)$), continue the Ellipsoid algorithm using the new violated constraint

$$\sum_{j \in V_{2t} \setminus V_{2t}^+} x_j \geq \left\lfloor \frac{A_{2t+2}}{2(1 + \ln N) A_{2t}} \right\rfloor + 1, \tag{10}$$

and restart the algorithm (discarding the previous solution) using the new LP solution.

[3] That is, $\min\left\{\sum_{h \in S} z_h \;\middle|\; \forall i \in \Gamma_{V_{2t+1}}(j) : \sum_{h \in \Gamma_{V_{2t+2}}(i)} z_h \geq 1;\ \forall h \in S : z_h \geq 0\right\}$.

Let us now analyze this algorithm. By (8), we know that all neighbors $i \in V_{2t+1}$ of V_{2t}^+ have LP value $y_i \geq 2(1+\ln N)/A_{2t+2}$. Thus, by (7), if for every vertex $h \in V_{2t+2}$ we define $w_h^+ = w_h \cdot A_{2t+2}/(2+2\ln N)$, then this is a fractional Set Cover for the V_{2t+1}-neighborhood $\Gamma_{V_{2t+1}}(V_{2t}^+)$, and by (6) it has total fractional value at most $\mathrm{OPT} \cdot A_{2t+2}/(2+2\ln N)$. Thus, the greedy Set Cover $(1+\ln N)$-approximation algorithm will cover this neighborhood using at most $\mathrm{OPT} \cdot A_{2t+2}/2$ vertices in V_{2t+2}. After this step, we may add at most $\mathrm{OPT} \cdot A_{2t+2}/2$ additional vertices in V_{2t+2} to our solution to obtain an A_{2t+2}-approximation.

Now, suppose our MMSA_{2t} approximation returns a set U_{ALG} of cardinality $|U_{\mathrm{ALG}}| \leq A_{2t+2}/(2+2\ln N)$. Clearly, adding to our solution the vertices of U_{ALG} and a V_{2t+2}-Set Cover for its neighborhood $\Gamma_{V_{2t+1}}(U_{\mathrm{ALG}})$ gives a feasible solution to our MMSA_{2t+2} instance. Moreover, since by our preprocessing, the neighborhood $\Gamma_{V_{2t+1}}(j)$ of every $j \in U_{\mathrm{ALG}}$ has a fractional Set Cover in V_{2t+2} of value at most OPT, it follows that the union of all these neighborhoods, that is $\Gamma_{V_{2t+1}}(U_{\mathrm{ALG}})$, has a fractional set cover in V_{2t+2} of value at most $\mathrm{OPT} \cdot |U_{\mathrm{ALG}}| \leq \mathrm{OPT} \cdot A_{2t+2}/(2+2\ln N)$. And so applying a greedy Set Cover algorithm for the neighborhood $\Gamma_{V_{2t+1}}(U_{\mathrm{ALG}})$ contributes at most an additional $\mathrm{OPT} \cdot A_{2t+2}/2$ vertices in V_{2t+2} to our solution, as required.

Finally, let us examine the validity of the final step (the separation oracle). If the A_{2t}-approximation for MMSA_{2t} was not able to find a solution of size at most $A_{2t+2}/(2+2\ln N)$, then by definition, the value of any solution to our MMSA_{2t} instance must be greater than $A_{2t+2}/((2+2\ln N)A_{2t})$. This is a subinstance of our original instance, so any solution to our original MMSA_{2t+2} instance must also contain more than $A_{2t+2}/((2+2\ln N)A_{2t})$ vertices in V_{2t}. Thus, Constraint (10) is valid for any optimum solution. But when is it violated?

By definition of V_{2t}^+, the current total LP value of $V_{2t} \setminus V_{2t}^+$ is at most $2(1+\ln N)N/A_{2t+2}$. And so the current LP solution violates (10) if

$$\frac{2(1+\ln N)N}{A_{2t+2}} \leq \frac{A_{2t+2}}{2(1+\ln N)A_{2t}} \qquad \Longleftrightarrow \qquad A_{2t+2} \geq 2(1+\ln N)\sqrt{N \cdot A_{2t}}.$$

Thus, we can obtain an approximation factor of $A_{2t+2} = O(\sqrt{N \cdot A_{2t}} \log N)$ as claimed. ◀

Thus, by induction on t, with the guarantee of Theorem 4 for MMSA_4 as the basis of the induction, and Lemma 11 for the inductive steps, we get a general approximation algorithm for MMSA_t with approximation ratio $O\left(N^{1-\frac{1}{3}2^{3-\lceil t/2 \rceil}} \cdot (\log N)^{2+O(2^{-t/2})}\right)$.

5 Reduction from Min k-Union to Red-Blue Set Cover

In this section, we first present a reduction from Min k-Union to Red-Blue Set Cover and then prove a hardness result for Red-Blue Set Cover. We start with formally defining the Min k-Union problem.

▶ **Definition 12** (Min k-Union). *In the Min k-Union problem, we are given a set X of size n, a family $\mathcal{S}$ of m sets $S_1, \ldots, S_m$, and an integer parameter $k \geq 1$. The goal is to choose k sets $S_{i_1}, \ldots, S_{i_k}$ so as to minimize the cost $\left|\bigcup_{t=1}^k S_{i_t}\right|$. We will denote the cost of the optimal solution by $\mathrm{OPT}_{MU}(X, \mathcal{S}, k)$.*

Note that Min k-Union resembles the Red-Blue Set Cover Cover problem: in both problems, the goal is to choose some subsets $S_{i_1}, \ldots, S_{i_r}$ from a given family $\mathcal{S}$ so as to minimize the number of elements or red elements in their union. Importantly, however, the feasibility requirements on the chosen subsets $S_{i_1}, \ldots, S_{i_r}$ are different in Red-Blue Set Cover Cover and Min k-Union; in the former, we require that the chosen sets cover all k blue points but in the latter, we simply require that the number of chosen sets be k. Despite this difference, we show that there is a simple reduction from Min k-Union to Red-Blue Set Cover.

▷ Claim 13. There is a randomized polynomial-time reduction from Min k-Union to Red-Blue Set Cover that given an instance $\mathcal{I} = (X, \mathcal{S}, k)$ of Min k-Union returns an instance $\mathcal{I}' = (R, B, \{S'_i\}_{i\in[m]})$ of Red-Blue Set Cover satisfying the following two properties:

1. If $S'_{j_1}, \dots, S'_{j_r}$ is a feasible solution for $\mathcal{I}'$ then $k' \le r$ and the cost of solution $S_{j_1}, \dots, S_{j_{k'}}$ for Min k'-Union where $k' = \lfloor k/\ell \rfloor$ and $\ell = \lceil \log_e k \rceil + 1$ does not exceed that of $S'_{j_1}, \dots, S'_{j_r}$ for Red-Blue Set Cover:
$$\mathrm{cost}_{MU}(S_{j_1}, \dots, S_{j_{k'}}) \equiv \left|\bigcup_{t=1}^{k'} S_{i_t}\right| \le \left|\bigcup_{t=1}^{r} (S'_{i_t} \cap R)\right| = \mathrm{cost}_{RB}(S'_{j_1}, \dots, S'_{j_r}).$$
This is true always no matter what random choices the reduction makes.
2. $\mathrm{OPT}_{RB}(R, B, \{S'_i\}_i) \le \mathrm{OPT}_{MU}(X, \mathcal{S}, k)$ with probability at least $1 - 1/e$.

Proof. We define instance $\mathcal{I}'$ as follows. Let $R = X$ and $B = [k]$. For every $i \in [m]$, let $R_i = S_i$; B_i be a set of ℓ elements randomly sampled from $[k]$ with replacement, and $S'_i = R_i \cup B_i$. All random choices are independent. Now we verify that this reduction satisfies the required properties.

Consider a feasible solution $S'_{j_1}, \dots, S'_{j_r}$ for $\mathcal{I}'$. Since this solution is feasible, $\cup_{t=1}^{r} B_t = B$. Now $|B_t| \le \ell$ and thus $r \ge |B|/\ell = k/\ell \ge k'$, as required. Further,
$$\mathrm{cost}_{MU}(S_{j_1}, \dots, S_{j_{k'}}) \equiv \left|\bigcup_{t=1}^{k'} S_{j_t}\right| = \left|\bigcup_{t=1}^{k'} R_{j_t}\right| \le \left|\bigcup_{t=1}^{r} R_{j_t}\right| \equiv \mathrm{cost}_{RB}(S'_{j_1}, \dots, S'_{j_r}).$$
We have verified that item 1 holds. Now, let $S_{i_1}, \dots, S_{i_k}$ be an optimal solution for $\mathcal{I}$. We claim that $S'_{i_1}, \dots, S'_{i_k}$ is a feasible solution for $\mathcal{I}'$ with probability at least $1 - 1/e$. To verify this claim, we need to lower bound the probability that $B_{i_1} \cup \dots \cup B_{i_k} = B$. Indeed, set $B_{i_1} \cup \dots \cup B_{i_k}$ consists of $k\ell$ elements sampled from B with replacement. The probability that a given element $b \in B$ is not in $B_{i_1} \cup \dots \cup B_{i_k}$ is at most $(1 - 1/k)^{k\ell} \le e^{-\ell} \le \frac{1}{ek}$. By the union bound, the probability that there is some $b \in B \setminus (B_{i_1} \cup \dots \cup B_{i_k})$ is at most $k \times \frac{1}{ek} = \frac{1}{e}$. Thus, there is no such b with probability at least $1 - 1/e$ and consequently $B_{i_1} \cup \dots \cup B_{i_k} = B$. In that case, the cost of solution $S'_{i_1}, \dots, S'_{i_k}$ for Red-Blue Set Cover equals $\left|\bigcup_{i=1}^{k} R'_{i_t}\right| = \left|\bigcup_{i=1}^{k} S_{i_t}\right|$, the cost of the optimal solution for Min k-Union. ◁

▶ **Corollary 14.** *Assume that there is an $\alpha(m, n)$ approximation algorithm $\mathcal{A}$ for Red-Blue Set Cover (where α is a non-decreasing function of m and n).Then there exists a randomized polynomial-time algorithm $\mathcal{B}$ for Min k-Union that finds k' sets $S_{i_1}, \dots, S_{i_{k'}}$ such that*
$$\left|\bigcup_{t=1}^{k'} S_{i_t}\right| \le \alpha(m, n)\mathrm{OPT}_{MU}(X, \mathcal{S}, k).$$
The failure probability is at most $1/n$.

Proof. We simply apply the reduction to the input instance of Min k-Union and then solve the obtained instance of Red-Blue Set Cover using algorithm $\mathcal{A}$. To make sure that the failure probability is at most $1/n$, we repeat this procedure $\lceil \log_e n \rceil$ times and output the best of the solutions we found. ◀

▶ **Theorem 15.** *Assume that there is an $\alpha(m,n)$ approximation algorithm $\mathcal{A}$ for Red-Blue Set Cover (where α is a non-decreasing function of m and n). Then there exists an $O(\log^2 k)\alpha(m,n)$ approximation algorithm for Min k-Union.*

Proof. Our algorithm iteratively uses algorithm $\mathcal{B}$ from the corollary to find an approximate solution. First, it runs $\mathcal{B}$ on the input instance and gets $k_1 = k'$ sets. Then it removes the sets it found from the instance and reduces the parameter k to $k - k_1$. Then the algorithm runs $\mathcal{B}$ on the obtained instance and gets k_2 sets. It again removes the obtained sets and reduces k to $k - k_1 - k_2$ (here k is the original value of k). It repeats these steps over and over until it finds k sets in total. That is, $k_1 + \cdots + k_T = k$ where T is the number of iterations the algorithm performs.

Observe that each of the instances of Min k-Union constructed in this process has cost at most $\mathrm{OPT}_{MU}(X, \mathcal{S}, k)$. Indeed, consider the subinstance $\mathcal{I}_{t+1}$ we solve at iteration $t+1$. Consider k sets that form an optimal solution for $(X, \mathcal{S}, k)$. At most $k_1 + \cdots + k_t$ of them have been removed from $\mathcal{I}_{t+1}$ and thus at least $k - k_1 - \cdots - k_t$ are still present in $\mathcal{I}_{t+1}$. Let us arbitrarily choose $k - k_1 - \cdots - k_t$ sets among them. The chosen sets form a feasible solution for $\mathcal{I}_{t+1}$ of cost at most $\mathrm{OPT}_{MU}(X, \mathcal{S}, k)$.

Thus, the cost of a partial solution we find at each iteration t is at most $\alpha(m,n) \cdot \mathrm{OPT}_{MU}(X, \mathcal{S}, k)$. The total cost is at most $\alpha(m,n) \cdot T \cdot \mathrm{OPT}_{MU}(X, \mathcal{S}, k)$. It remains to show that $T \leq O(\log^2 k)$. We observe that the value of k reduces by a factor at least $1 - 1/\ell$ in each iteration, thus after t iterations it is at most $(1 - 1/\ell)^t k$. We conclude that the total number of iterations T is at most $O(\ell \log k) = O(\log^2 k)$, as desired. ◀

Now we obtain a conditional hardness result for Reb-Blue Set Cover from a corollary from the Hypergraph Dense-vs-Random Conjecture.

▶ **Corollary 16** (Chlamtáč et al. [9]). *Assuming the Hypergraph Dense-vs-Random Conjecture, for every $\varepsilon > 0$, no polynomial-time algorithm for Min k-Union achieves better than $\Omega(m^{1/4-\varepsilon})$ approximation.*

Theorem 6 immediately follows.

6 Approximation Algorithm for MMSA$_4$

Consider an instance (B, J, R, S, E) of MMSA$_4$. As we did for Red-Blue Set Cover, we will focus on making progress towards a good approximation. Due to space constraints, we have omitted most proofs for statements in this section. Complete proofs can be found in the full version of the paper.

▶ **Definition 17.** *We say that an algorithm for MMSA$_4$* makes progress towards an $O(A)$-approximation *if, given an instance with an optimum solution containing at most* OPT *vertices in S, the algorithm finds a subset $\hat{J} \subseteq J$ and a subset $\hat{S} \subseteq S$ such that $\Gamma_R(\hat{J}) \subseteq \Gamma_R(\hat{S})$ (a valid partial solution) and $\frac{|\hat{S}|}{|\Gamma_B(\hat{J})|} \leq A \cdot \frac{\mathrm{OPT}}{|B|}$.*

As before, it is easy to see that given such an algorithm, we can run such an algorithm repeatedly to obtain an actual $\tilde{O}(A)$ approximation for MMSA$_4$. In fact, in the rest of this section we will *only* discuss an algorithm which makes progress towards an $O(A)$-approximation.

For the sake of formulating an LP relaxation with a high degree of uniformity, we will actually focus on a partial solution which covers a large fraction of blue elements in a uniform manner:

▶ **Lemma 18.** *For any cover $J_0 \subseteq J$ of the blue elements B, there exist subsets $J' \subseteq J_0$ and $B' \subseteq B$ and a parameter $\Delta > 0$ with the following properties:*

- *Every vertex $j \in J'$ has B'-degree in the range $\deg_{B'}(j) \in [\Delta, 2\Delta]$.*
- *Every blue element $\ell \in B'$ has at least one neighbor in J'_Δ and at most $2e\ln(2k)$ neighbors.*
- *We have the cardinality bound $|B'| \geq |B|/(\log k \log m)$.*

Simplifying Assumptions. We can make the following assumptions which will be useful in the analysis of our algorithm. First, we may assume that for every $j \in J$, the red neighborhood $\Gamma_R(j)$ has a fractional set cover in S of weight at most OPT. That is, the standard LP relaxation for covering $\Gamma_R(j)$ using S has optimum value at most OPT. If we have guessed the correct value of OPT, then we know that no $j \in J$ whose red neighborhood cannot be covered with cost OPT can participate in an optimum solution, and can therefore be discarded. We may also assume that for some $\varepsilon > 0$, the value Δ above is at most k/m^ε. The reason is that otherwise, the blue elements B' can be covered with at most $\tilde{O}(m^\varepsilon)$ vertices in J, and we know that for each of these, its red neighborhood can be covered by a set of size $\tilde{O}(\mathrm{OPT})$ in S, and thus we can make progress towards an $\tilde{O}(m^\varepsilon)$ approximation.

Guessing the value of $\Delta \in [k]$ above and the value of the optimum OPT, we can write the following LP relaxation:

$$\sum_{h\in S} w_h \leq \mathrm{OPT} \tag{11}$$

$$\sum_{\ell\in B} z_\ell \geq |B|/(\log k \log m) \tag{12}$$

$$z_\ell \leq \sum_{j\in\Gamma_J(\ell)} x_j^\ell \leq 2e\ln(2k) z_\ell \qquad \forall \ell \in B \tag{13}$$

$$\Delta x_j \leq \sum_{\ell\in\Gamma_B(j)} x_j^\ell \leq 2\Delta x_j \qquad \forall j \in J \tag{14}$$

$$0 \leq x_j^\ell \leq x_j, z_\ell \leq 1 \qquad \forall \ell \in B \forall j \in J \tag{15}$$

$$\sum_{h\in\Gamma_S(i)} w_h \geq y_i \qquad \forall i \in R \tag{16}$$

$$0 \leq x_j \leq y_i \qquad \forall (j,i) \in E(J,R) \tag{17}$$

We further strengthen this LP by partially lifting the above constraints. Specifically, for every $a \in J \cup S$, $j \in J$, $h \in S$, $i \in R$, and $\ell \in B$ we introduce variables $X_h^{(a)}, X_\ell^{(a)}, X_{\ell,j}^{(a)}, X_j^{(a)}, X_i^{(a)}$, and lift all the above constraints accordingly. For a precise definition, see Appendix B. For any $j \in J$ such that $x_j > 0$ or $h \in S$ such that $w_h > 0$, we will denote the "conditioned" variables by $\hat{w}_h^{(j)} = X_h^{(j)}/x_j$, $\hat{z}_\ell^{(h)} = X_\ell^{(h)}/w_h$, etc.

▶ Remark 19. The above linear program is a relaxation for the partial solution given by Lemma 18. Specifically, given an optimal solution $(J_{\mathrm{OPT}}, S_{\mathrm{OPT}})$, applying the lemma to $J_0 = J_{\mathrm{OPT}}$, we have the following feasible solution: Set the variables z_ℓ and x_j to be indicators for B' and J' as in the lemma, respectively, and the variables x_j^ℓ to be indicators for $J' \times B'$. Set the the variables w_h to be indicators for S_{OPT}, and the variables y_i to be indicators for the red neighbors $\Gamma_R(J')$ of J'.

Let us examine some useful properties of this relaxation. First of all, we note that it approximately determines the total LP value of J (since the LP assigns total LP value $\tilde{\Theta}(|B|)$ to B):

▷ Claim 20. Any solution satisfying constraints (13)-(15), has total LP weight in J bounded by $\frac{1}{2\Delta}\sum_{\ell\in B} z_\ell \le \sum_{j\in J} x_j \le \frac{2e\ln(2k)}{\Delta}\sum_{\ell\in B} z_\ell$.

These constraints also determine a useful combinatorial property: in any feasible solution, the number of blue neighbors a subset of J has is (at least) proportional to the LP value of that set.

▷ Claim 21. For any solution satisfying constraints (13)-(15), and any subset of vertices $\hat{J} \subseteq J$, the number of blue neighbors of $\hat{J}$ is bounded from below by:

$$|\Gamma_B(\hat{J})| \ge \frac{1}{4e\ln(2k)\log k \log m} \cdot \frac{x(\hat{J})}{x(J)} \cdot |B|.$$

A fractional variant of the above covering property for the blue vertices is the following:

▷ Claim 22. For any solution satisfying constraints (13)-(15), and any subset of vertices $\hat{J} \subseteq J$, at least $\varepsilon|B|$ vertices $\ell \in B$ satisfy $\sum_{j\in\Gamma_J(\ell)} x_j^\ell \ge \frac{1}{4\log k\log m} \cdot \frac{x(\hat{J})}{x(J)}$, where $\varepsilon = \frac{1}{8e\ln(2k)\log k\log m} \cdot \frac{x(\hat{J})}{x(J)}$.

Let us now analyze the approximation guarantee of Algorithm 2. We begin by stating simple lower bounds on the total LP value of the set J_0 as well as the vertices in the set.

▶ **Lemma 23.** *The set J_0 defined in Algorithm 2 has LP value at least $x(J)/(2\log m)$ and the lower bound on the individual LP values in the set is bounded by $x_0 \ge 1/m$.*

Next, we examine the bucketing of neighbors in S, and give a lower bound on the number of vertices in these bucketed sets.

▶ **Lemma 24.** *In Algorithm 2, for every vertex $j \in J_0$, and every red neighbor $i \in \Gamma_R(j)$, the bucketed set of neighbors $\hat{\Gamma}_j(i)$ of i has cardinality bounded from below by $|\hat{\Gamma}_j(i)| \ge 1/(6\beta_{ji}\log|S|\log(|S|^2 m))$.*

Proof. Fix vertices $j \in J_0$ and $i \in \Gamma_R(j)$. Let us begin by examining our choice of β_{ji}. Note that lifting Constraint 17, we get $x_j = X_j^{(j)} \le X_i^{(j)} (\le x_j)$, and so $\hat{y}^{(j)} = X_i^{(j)}/x_j = 1$. Lifting Constraint (16), we thus get $\sum_{h\in\Gamma_S(i)} \hat{w}_h^{(j)} \ge 1$. Note that the total LP weight of the set $S'_{ji} = \{h \in \Gamma_S(i) \mid \hat{w}_h^{(j)} \le 1/|S|^2\}$ is at most $1/|S| \le \hat{w}^{(j)}(\Gamma_S(i))/3$. Therefore, the total $\hat{w}^{(j)}$ LP weight of the bucketed sets S_s^{ji} for s such that $2^{-s} \ge 1/|S|^2$ is at least $\frac{2}{3}\hat{w}^{(j)}(\Gamma_S(i))$, and at least one of these bucketed sets has LP weight at least a $1/(2\log|S|)$-fraction of this, or at least $\hat{w}^{(j)}(\Gamma_S(i))/(3\log|S|) \ge 1/(3\log|S|)$. This gives a lower bound on the LP weight of the bucket which defines β_{ji}. Also, the heaviest bucket cannot be S_s^{ji} for s such that $2^{-s} \le 1/|S|^2$, since even the total weight of these buckets is at most $1/|S| = o(1/(3\log|S|))$. In particular, this means that $\beta_{ji} \ge 1/|S|^2$. Moreover, for s such that $2^{-s} = \beta_{ji}$, since the total conditional LP weight of S_s^{ji} is at least $1/(3\log|S|)$, and every vertex in the set has conditional LP value at most $2\beta_{ji}$, the cardinality of the set must be at least $1/(6\beta_{ji}\log|S|)$.

Now let us examine the second stage of bucketing. Note that for every $h \in \Gamma_S(i)$, we have $w_h \ge X_h^{(j)} = \hat{w}_h^{(j)} \cdot x_j \ge \beta_{ji}x_0 \ge 1/(|S|^2 m)$ (and, of course, $w_h \le 1$). Therefore, the number of non-empty buckets $\hat{S}_t^{ji}$ is at most $\log(|S|^2 m)$, and at least one of them must have cardinality at least $|S_s^{ji}|/\log(|S|^2 m)$, which, along with our lower bound on $|S_s^{ji}|$ above, gives us the required lower bound on $|\hat{\Gamma}_j(i)|$. ◀

Note that from the above proof, we also get upper-bounds on the number of values of β_{ji} and γ_{ji} that can produce non-empty buckets. In particular, we get the following bound:

▶ **Observation 25.** *The total number of possible values for β_{ji} is at most $2\log|S|$, and the total number of possible values for γ_{ji} is at most $\log(|S|^2m)$. Along with the range of values for D, the total number of triples $\langle\beta,\gamma,D\rangle$ for which $J^D_{\beta,\gamma}$ is non-empty is at most $2\log^2|S|\log(|S|^2m)$.*

The algorithm proceeds by separating the buckets corresponding to parameters for which the simple rounding (which samples a random subset of J of size $\tilde{\Omega}(J)$) makes progress towards an approximation guarantee of $\tilde{O}(A)$. If a large fraction of vertices in J_0 participate exclusively in such buckets, then the algorithm applies this rounding. The following lemma gives the analysis of the algorithm in this case.

▶ **Lemma 26.** *In Algorithm 2, if $|J_1| < |J_0|/2$, then with high probability the algorithm samples a subset $J_{\mathrm{ALG}} \subseteq J$ which covers an $\tilde{\Omega}(1)$-fraction of blue vertices, and a subset of S of size $\tilde{O}(A\cdot\mathrm{OPT})$ which covers all the red neighbors of J_{ALG}.*

Finally, we turn to the remaining case in Algorithm 2, when $|J_1| \le |J_0|/2$. The analysis of this case rests on a back-degree argument similar (though significantly more involved) to the argument in Lemma 10 for Red-Blue Set Cover. Indeed, we show the following:

▶ **Lemma 27.** *If $|J_1| \ge |J_0|/2$, then for β,γ,D,h_0 and the set J_{ALG} as defined by the algorithm in this case, we have $\sum_{j\in J_{\mathrm{ALG}}}\hat{x}_j^{(h_0)} \ge \frac{|J_0|Dx_0\beta}{\mathrm{OPT}}\cdot\frac{1}{4\log^2|S|\log(|S|^2m)\log m}$.*

Furthermore, for every vertex $j \in \tilde{J}$ (as defined by the algorithm), we have $\hat{x}_j^{h_0} \in [x_0\beta/(2\gamma), 4x_0\beta/\gamma]$.

We can now show that in this case, the algorithm makes progress towards an $\tilde{O}(m/A^2)$-approximation. Trading this off with the progress towards an $\tilde{O}(A)$-approximation as guaranteed by Lemma 26, we get an $\tilde{O}(m^{1/3})$-approximation by setting $A = m^{1/3}$.

▶ **Lemma 28.** *In Algorithm 2, if $|J_1| \ge |J_0|/2$, then with high probability, the algorithm makes progress towards an approximation guarantee of $\tilde{O}(m/A^2)$.*

Proof. Let us first bound the number of blue vertices covered by J_{ALG}. By Lemma 27, we have

$$\begin{aligned}
\hat{x}^{h_0}(J_{\mathrm{ALG}}) &\ge \frac{|J_0|x_0D\beta}{\mathrm{OPT}}\cdot\frac{1}{4\log^2|S|\log(|S|^2m)\log m} \\
&\ge \frac{x(J_0)D\beta}{\mathrm{OPT}}\cdot\frac{1}{4\log^2|S|\log(|S|^2m)\log m} && \text{since } \forall j\in J_0: 2x_0 \ge x_j \\
&\ge \frac{x(J)D\beta}{\mathrm{OPT}}\cdot\frac{1}{4\log^2|S|\log(|S|^2m)\log m} && \text{by Lemma 23} \\
&> x(J)\cdot\frac{A}{x(J_0)}\cdot\frac{1}{4\log^2|S|\log(|S|^2m)\log m}. && \text{since } \forall\langle\beta,\gamma,D\rangle\in P_1: \frac{\beta D}{\mathrm{OPT}} > \frac{A}{x(J_0)}
\end{aligned}$$

Thus, since the conditioned LP solution satisfies the basic LP, we can apply Claim 21 to this solution and get that the size of the blue neighborhood of J_{ALG} can be bounded by

$$\begin{aligned}
|\Gamma_B(J_{\mathrm{ALG}})| &\ge \frac{1}{4e\ln(2k)\log k\log m}\cdot\frac{A}{x(J_0)}\cdot\frac{1}{4\log^2|S|\log(|S|^2m)\log m}\cdot|B| \\
&= \frac{1}{16\ln(2k)\log k\log^2|S|\log(|S|^2m)\log^2 m}\cdot\frac{A}{x(J_0)}\cdot|B|.
\end{aligned}$$

Note that by the LP constraints and Lemma 27, for every red neighbor $i \in \Gamma_R(J_{\mathrm{ALG}})$, we have $\hat{y}_i^{h_0} \geq x_i^{h_0} \geq x_0\beta/(2\gamma)$, and so by (16), the rescaled solution $(\hat{w}_h^{h_0} \cdot 2\gamma/(x_0\beta))_{h\in S}$ is a fractional set cover for $\Gamma_R(J_{\mathrm{ALG}})$. Thus, sampling every $h \in S$ with probability $\min\{1, 2\ln n \cdot \hat{w}_h^{h_0} \cdot 2\gamma/(x_0\beta)\}$ produces a valid set cover with high probability. It remains to analyze the size of this set cover. Indeed, since $\hat{w}^{h_0}(S) \leq \mathrm{OPT}$, our sampling procedure produces a set of expected size

$$\begin{aligned}
\mathbb{E}[|S_{\mathrm{ALG}}|] &\leq \frac{4\gamma\ln n}{x_0\beta} \cdot \mathrm{OPT} \\
&\leq 8\ln n \cdot \frac{\gamma}{\beta} \cdot \frac{|J_0|}{x(J_0)} \cdot \mathrm{OPT} && \text{since } \forall j \in J_0 : x_j \leq 2x_0 \\
&\leq 8\ln n \cdot \frac{\gamma}{\beta} \cdot \frac{m}{x(J_0)} \cdot \mathrm{OPT} \\
&< 8\ln n \cdot \frac{1}{A} \cdot \frac{m}{x(J_0)} \cdot \mathrm{OPT}, && \text{since } \forall \langle \beta, \gamma, D\rangle \in P_1 : \frac{\beta}{\gamma} > A
\end{aligned}$$

and so with high probability we have $|S_{\mathrm{ALG}}| = O(\mathrm{OPT} \cdot m\log n/(A \cdot x(J_0)))$.

Putting our two bounds together, we get that in this case, the algorithm makes progress towards an approximation guarantee of

$$\frac{|B|}{|\Gamma_B(J_{\mathrm{ALG}})|} \cdot \frac{|S_{\mathrm{ALG}}|}{\mathrm{OPT}} = \tilde{O}(1) \cdot \frac{x(J_0)}{A} \cdot \frac{m}{A \cdot x(J_0)} = \tilde{O}(1) \cdot \frac{m}{A^2}. \qquad ◀$$

A Adapting and Applying our Algorithm to Partial Red-Blue Set Cover

Let us now consider the variation in which we are given a parameter $\hat{k}$, and are only required to cover at least $\hat{k}$ elements in a feasible solution. The algorithm and analysis work with almost no change other than the following.

In the algorithm, the stopping condition of the loop is of course no longer once we have covered all blue elements, but once we have covered at least $\hat{k}$ of them.

A slightly more subtle change involves the analysis of the LP rounding in the final iteration. The notion of progress towards a certain approximation guarantee may not be valid if the ratio of red elements to blue elements covered is still as small as required, but the number of blue elements added is far more than we need. Rather than derandomize the rounding, one can show that it succeeds (despite this issue) with high probability. Let us briefly sketch the argument here.

First, note that we can always preemptively discard any sets with more than OPT red elements, and so we may assume that $r_\alpha \leq \text{OPT}$. Suppose we need to cover an additional k^* elements in order to reach the target of $\hat{k}$ blue elements total. Since our bound on $\mathbb{E}[|\Gamma_{R_\alpha}(J^*)|]$ is a linear function of our bound on $\mathbb{E}[|J^* \setminus J_+|]$, by a Chernoff bound we have $|\Gamma_{R_\alpha}(J^*)| = \tilde{O}(r_\alpha A)$ with all but exponentially small probability. On the other hand, $|\Gamma_B(J^*)|$ is always at most $|B|$, so by Markov, we have

$$\text{Prob}\left[|\Gamma_B(J^*)| \leq \frac{\mathbb{E}[|\Gamma_B(J^*)|]}{2}\right] \leq \frac{|B| - \mathbb{E}[|\Gamma_B(J^*)|]}{|B| - \mathbb{E}[|\Gamma_B(J^*)|]/2} \leq 1 - \frac{1}{2|B|}.$$

Thus, repeating the rounding a polynomial number of times (in a given iteration), with all but exponentially small probability we can find a set $\hat{J} \subseteq J$ that satisfies both

$$|\Gamma_B(\hat{J})| \geq \frac{\mathbb{E}[|\Gamma_B(J^*)|]}{2} \qquad \text{and} \qquad |\Gamma_{R_\alpha}(\hat{J})|] = \tilde{O}(r_\alpha A).$$

Now if $\mathbb{E}[|\Gamma_B(J^*)|] \leq 2k^*$, then we have the required ratio and bound on the number of new red elements by the previous analysis. If $\mathbb{E}[|\Gamma_B(J^*)|] > 2k^*$, then this will be the last iteration, as we will cover at least the required k^* additional blue elements, and the number of red elements added at this final stage is at most $\tilde{O}(r_\alpha A) \leq \tilde{O}(A \cdot \mathrm{OPT})$, so we maintain the desired approximation ratio.

B Additional LP Constraints for MMSA$_4$

The following is a complete list of lifted constraints that we use in addition to the basic LP relaxation for MMSA$_4$:

$$\begin{aligned}
&X_j^{(h)} = X_h^{(j)} && \forall j \in J, \forall h \in S \\
&X_j^{(j)} = x_j && \forall j \in J \\
&\sum_{h \in \Gamma_S(i)} X_h^{(j)} \geq X_i^{(j)} && \forall j \in J \forall i \in R \\
&X_j^{(j)} \leq X_i^{(j)} && \forall j \in J \forall i \in \Gamma_R(j) \\
&0 \leq X_a^{(j)} \leq x_j && \forall j \in J \forall a \in \{j\} \cup R \cup S \\
&\sum_{h' \in S} w_{h'}^{(h)} \leq \mathrm{OPT} && \forall h \in S \\
&\sum_{\ell \in B} X_\ell^{(h)} \geq |B|/(\log k \log m) w_h && \forall h \in S \\
&X_\ell^{(h)} \leq \sum_{j \in \Gamma_J(\ell)} X_{\ell,j}^{(h)} \leq 2e \ln(2k) X_\ell^{(h)} && \forall h \in S \forall \ell \in B \\
&\Delta X_j^{(h)} \leq \sum_{\ell \in \Gamma_B(j)} X_{\ell,j}^{(h)} \leq 2\Delta X_j^{(h)} && \forall h \in S \forall j \in J \\
&0 \leq X_{\ell,j}^{(h)} \leq X_j^{(h)}, X_\ell^{(h)} \leq w_h && \forall h \in S \forall \ell \in B \forall j \in J \\
&\sum_{h' \in \Gamma_S(i)} X_{h'}^{(h)} \geq X_i^{(h)} && \forall h \in S \forall i \in R \\
&X_j^{(h)} \leq X_i^{(h)} && \forall h \in S \forall (j,i) \in E(J,R) \\
&0 \leq X_a^{(h)} \leq w_h && \forall h \in S \forall a \in B \cup J \cup R \cup S
\end{aligned}$$

Abstract

In this paper, we study the weighted k-server problem on the uniform metric in both the offline and online settings. We start with the offline setting. In contrast to the (unweighted) k-server problem which has a polynomial-time solution using min-cost flows, there are strong computational lower bounds for the weighted k-server problem, even on the uniform metric. Specifically, we show that assuming the unique games conjecture, there are no polynomial-time algorithms with a sub-polynomial approximation factor, even if we use c-resource augmentation for $c < 2$. Furthermore, if we consider the natural LP relaxation of the problem, then obtaining a bounded integrality gap requires us to use at least ℓ resource augmentation, where ℓ is the number of distinct server weights. We complement these results by obtaining a constant-approximation algorithm via LP rounding, with a resource augmentation of $(2 + \varepsilon)\ell$ for any constant $\varepsilon > 0$.

In the online setting, an $\exp(k)$ lower bound is known for the competitive ratio of any randomized algorithm for the weighted k-server problem on the uniform metric. In contrast, we show that 2ℓ-resource augmentation can bring the competitive ratio down by an exponential factor to only $O(\ell^2 \log \ell)$. Our online algorithm uses the two-stage approach of first obtaining a fractional solution using the online primal-dual framework, and then rounding it online.

1 Introduction

The k-Server problem is a foundational problem in online algorithms and has been extensively studied over the last 30 years [10]. In this problem, there are a set of k servers that must serve requests arriving online at the vertices of an n-point metric space. The goal is to minimize the total movement cost of the servers. The k-Server problem was defined by Manasse et al. [22], who also showed a lower bound of k on the competitive ratio of any deterministic algorithm for this problem. Koutsoupias and Papadimitriou [20] gave a $(2k-1)$-compeititive algorithm for k-Server. There has been much progress in the recent past on obtaining randomized algorithms with polylogarithmic (in k and n) competitive ratio [2, 13, 21, 14]. The Weighted k-Server version of this problem, introduced by Fiat and Ricklin [17], allows the servers to have non-uniform positive weights; the cost of moving a server is now scaled by its weight. In this paper, we consider the Weighted k-Server problem on a uniform metric, namely when all n points of the metric space are at unit

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

distance from each other, which means that the cost of moving a server between any two distinct points is simply the weight of the server. Note that the corresponding unweighted problem for the uniform metric is the extensively studied PAGING problem [10]. Indeed, one of the original motivations for studying the WEIGHTED k-SERVER problem came from a version of paging with non-uniform replacement costs for different cache slots [17]. In the rest of this paper, we will implicitly assume that the underlying metric space is a uniform metric.

The original paper of Fiat and Ricklin [17] introducing the WEIGHTED k-SERVER problem (on uniform metrics) gave a deterministic algorithm with a competitive ratio of about $2^{2^{2k}}$. They also showed a lower bound of $(k+1)!/2$ for deterministic algorithms. Chiplunkar and Viswanathan [15] improved this lower bound to $(k+1)!-1$, and gave a randomized algorithm that is 1.6^{2^k}-competitive against *adaptive* online adversaries; this also implies a deterministic competitive ratio of $2^{2^{k+1}}$ using the simulation technique of Ben-David et al. [8]. Bansal, Elias, and Koumutsos [6] showed that this competitive ratio is essentially tight for deterministic algorithms by showing a lower bound of $2^{2^{k-4}}$. They also gave a deterministic *work function algorithm* with a competitive ratio of $2^{2^{k+O(\log k)}}$. If the number of distinct server weights is ℓ and there are k_j servers of weight W_j, then the competitive ratio of their algorithm is $\exp(O(\ell k^3 \prod_{j=1}^{\ell}(k_j+1)))$, which is an exponential improvement over the general bound when ℓ is a constant. Unlike the k-SERVER and PAGING problems, it is unknown if randomization qualitatively improves the competitive ratio for WEIGHTED k-SERVER, although the best known lower bound for randomized algorithms against oblivious adversaries is only singly exponential in k [1] as against the doubly exponential lower bound for deterministic algorithms.

The above competitive ratios depend only on k, and are independent of the size n of metric space. Moreover, the hard instances are for metric spaces with the number of points n that are exponentially larger than the number of servers k. This is not a coincidence, since better algorithms exist for smaller values of n. Indeed, the WEIGHTED k-SERVER problem can be modeled as a metrical task system, where each state ω is a configuration (specifying the location of each of the k servers), and the distance between any two states ω, ω' is the cost to move between the configurations. Since there are $N = n^k$ states, one can obtain an n^k-competitive deterministic algorithm [11], and an $O(\text{poly}(k \log n))$-competitive randomized algorithm against *oblivious* adversaries [7, 3, 12, 16]; all these algorithms use $\text{poly}(n^k)$ time to explicitly maintain and manipulate the entire metric space, and hence are not efficient.

In this paper we ask: *is it possible to get efficient (randomized)* online *algorithms that have competitive ratios of the form* $\text{poly}(k \log n)$*, or even better? Is it possible to get such approximation ratios even in the* offline *setting?* We show that obtaining improved competitive or approximation ratios in polynomial time is possible, provided we allow for *resource augmentation* in the number of servers.

Resource augmentation in online algorithms has been widely studied in paging and scheduling settings (see e.g. [19, 23]). It is often a much needed assumption that allows for obtaining bounded or improved competitive ratios for such problems. Bansal et al. [5] studied the k-SERVER problem on trees under resource augmentation.

1.1 Our Results

Our first result establishes computational hardness of approximating the WEIGHTED k-SERVER problem in the offline setting. Unlike PAGING or k-SERVER, which are exactly solvable offline in polynomial time, we show that under the Unique Games conjecture, the WEIGHTED k-SERVER problem cannot be approximated to any subpolynomial factor even when we allow c-resource augmentation for any constant $c < 2$.

▶ **Theorem 1** (Hardness). *For any constant $\varepsilon > 0$, it is UG-hard to obtain an $N^{1/2-\varepsilon}$-approximation algorithm for* Weighted *k*-Server *with two weight classes, even when we are allowed c-resource augmentation for any constant $c < 2$. Here N represents the size of the input (including the request sequence length).*

Next, we show that the natural time indexed LP relaxation for Weighted k-Server (see LP) has a large integrality gap, unless we allow for a resource augmentation of almost ℓ, the number of distinct server weights.

▶ **Theorem 2** (Integrality Gap). *For any constant $\varepsilon > 0$, the integrality gap of the relaxation LP for* Weighted *k*-Server *is unbounded, even with $(\ell - \varepsilon)$-resource augmentation.*

It is worth noting that an optimal fractional solution to LP can be easily rounded to give an ℓ-approximation ratio with ℓ-resource augmentation. Indeed, we know that for each request, there exists a weight class which services this request to an extent of at least $1/\ell$. We can then scale this fractional solution by a factor ℓ and reduce this problem to ℓ instances of standard Paging problem. The integrality gap result shows that any rounding algorithm with bounded competitive ratio must incur almost ℓ-resource augmentation. We complement this integrality gap result with our main technical result, which gives an offline $O(1/\varepsilon)$-approximation with $(2+\varepsilon)\ell$-resource augmentation, for any $\varepsilon \in (0, 1)$.

▶ **Theorem 3** (Offline Algorithm). *Let $\mathcal{I}$ be an instance of* Weighted *k*-Server *with k_j servers of weight W_j for all $j \in [\ell]$. For any $\varepsilon \in (0, 1)$, there is a polynomial time algorithm for $\mathcal{I}$ that uses at most $2(1+\varepsilon)\ell \cdot k_j$ servers of weights W_j for each $j \in [\ell]$ and has server movement cost at most $O(1/\varepsilon)$ times the optimal cost of $\mathcal{I}$.*

Finally, we obtain an online algorithm for Weighted k-Server with 2ℓ-resource augmentation. The competitive ratio of the online algorithm is $O(\ell^2 \log \ell)$. (In constrast to the offline setting, it is no longer clear how to achieve an ℓ-competitive algorithm even if we augment the number of servers by a factor of ℓ.)

▶ **Theorem 4** (Online Algorithm). *Let $\mathcal{I}$ be an instance of* Weighted *k*-Server *with k_j servers of weight W_j for all $j \in [\ell]$. There is a randomized (polynomial time) online algorithm for $\mathcal{I}$ that uses at most $2\ell k_j$ servers of weights W_j for each $j \in [\ell]$ and has expected server movement cost at most $O(\ell^2 \log \ell)$ times the optimal cost of $\mathcal{I}$.*

Since $\ell \leq k$, the competitive ratio of the online algorithm is $O(k^2 \log k)$. This implies that an $O(\ell^2)$-resource augmentation achieves at least an exponential improvement in the competitive ratio of the Weighted k-Server problem. Moreover, by rounding the weights to powers of 2, we can assume that $\ell \leq O(\log W)$, where W is the aspect ratio of the server weights. Hence, the competitive ratio of the online algorithm is $O(\log^2 W \log\log W)$. Finally, note that for $\ell = O(1)$, the above theorem gives a $O(1)$-competitive online algorithm with $O(1)$-resource augmentation. This can be seen as a generalization of the classic result for the Paging problem that achieves a randomized competitive ratio of $O(\log \frac{k}{k-h+1})$ where the algorithm's cache has k slots while the adversary's has only $h < k$ slots [24].

1.2 Our Techniques

In this section, we give an overview of the main techniques in the paper. The UG hardness of Weighted k-Server is based on a reduction from the Vertex Cover problem. Given an instance of the vertex cover problem, the corresponding Weighted k-Server consists of one point in the uniform metric space for each vertex of the graph. The main observation is that if we know the minimum vertex cover size, we can keep one heavy weight server at each point corresponding to this vertex cover, which never change their positions. One can then generate an input sequence where the optimal solution pays a small cost, whereas an algorithm which does not cover an edge using heavy servers pays a much higher cost. The UG-hardness result for Vertex Cover translates to a corresponding resource augmentation lower bound for Weighted k-Server. Extending this approach to more than two weight classes (with stronger lower bounds on resource augmentation) turns out to be more challenging because the length of the input sequence becomes exponential in n. Instead, we show that the natural LP relaxation has a large integrality gap. The large gap instance consists of cycling through a sequence of subsets of the metric spaces with carefully varying frequency. The fractional solution is able to maintain a low cost by uniformly spreading servers over such cycles, but the integral solution is forced to service some of the cycles by small number of servers only.

Our main technical result shows how to round a solution to the LP relaxation. The relaxation has both covering and packing type constraints, and the rounding carefully addresses one set of constraints without violating the other. We first scale the LP by a factor of about 2ℓ, thus increasing both the resource augmentation and the cost. As a result, each request σ_t is covered to an extent of 2ℓ, and we can split this coverage across those weight classes which cover σ_t to an extent of at least 1. Now for a fixed weight class, we consider the requests which are covered by it to an extent of at least 1. We show how to integrally round this solution so that this coverage property is satisfied and yet, we do not violate any packing constraint. After this, we show that the packing constraints can be ignored. This allows to scale down the LP solution by a factor ℓ (which saves the cost by this factor) and uses total unimodularity of the constraint matrix to round it.

We extend our approximation algorithm to the online setting. The first step is to maintain an online fractional solution to the LP relaxation. Standard (weighted) paging algorithms for this problem rely on the fact that even the optimal offline algorithm needs to place a server at a requested location. But this turns out to be trickier here as we do not know the weight of the server which serves this location in the optimal solution. So we serve a request by ensuring that fractional mass from each weight classes is transferred at the same rate. The overall analysis proceeds by a careful accounting in the potential function. The online fractional solution satisfies the stronger guarantee that each request is served by servers of a particular weight class only. This allows us to reduce the rounding problem to independent instances of the Paging problem.

We now give an overview of the rest of the submission. In §2, we give details of the integrality gap construction; we defer the UG hardness proof to §A. The offline rounding of the LP relaxation is given in §3, and then we extend this algorithm to the online case in §4.

1.3 Preliminaries

In the Weighted k-Server problem on the uniform metric, we are given a set of n points $V = \{1, \ldots, n\}$, such that $d(v, v') = 1$ for each $v \neq v'$. There are k servers, labeled $1, \ldots, k$, with server i having weight $w_i \geq 0$. The input specifies a request sequence $(\sigma_1, \ldots, \sigma_T)$ of length T, with each request σ_t arriving at *time* t being a point in V. A solution $f : [k] \times \{0, \ldots, T\} \to V$ specifies the position of each server at each time $t \in [T]$ (where the initial positions $f(i, 0)$ are specified as part of the problem statement) such that for each time t there exists some server i_t such that $f(i_t, t) = \sigma_t$. The cost of the solution f is the total weighted distance travelled by the servers, i.e.,

$$1/2 \sum_{i=1}^{k} w_i \sum_{t=1}^{T} \mathbb{1}[f(i,t) \neq f(i,t-1)].$$

The goal is to find a solution with the minimum cost. We say that an instance has ℓ *weight classes* if the set $\{w_1, \ldots, w_k\}$ has cardinality ℓ. For an instance with ℓ different weight classes, we denote the distinct weights by $W_1, \ldots, W_\ell$, and let k_j denote the number of servers of weight W_j, with $\sum_j k_j = k$. For such an instance and a parameter $c \geq 1$, we say that the algorithm uses *c-resource augmentation* if it uses $\lfloor ck_j \rfloor$ servers of weight W_j for each $j = 1, \ldots, \ell$.

We now describe the natural LP relaxation for WEIGHTED k-SERVER. It has a variable $x(v, j, t)$ for each request time t, weight class $j \in [\ell]$ and vertex $v \in V$; it denotes the fractional mass of servers of weight W_j that are present at point v at time t. Let σ_t denote the vertex requested at time t. It is easy to verify that this is a valid relaxation.

$$\min {}^1\!/\!_2 \sum_{j\in[\ell]} W_j \sum_t \sum_{v\in V} |x_{v,j,t} - x_{v,j,t-1}| \tag{LP}$$

$$\sum_{v\in V} x_{v,j,t} \leq k_j \qquad \forall t, j \in [\ell] \tag{1}$$

$$\sum_{j\in[\ell]} x_{\sigma_t,j,t} \geq 1 \qquad \forall t \tag{2}$$

$$x_{v,j,t} \geq 0 \qquad \forall t, v \in V, j \in [\ell]$$

2 An Integrality Gap for the Natural Linear Program

In this section, we show that the relaxation LP for WEIGHTED k-SERVER has a large integrality gap, unless we allow for a resource augmentation of almost ℓ, the number of distinct server weights.

Recall that the ℓ weights are denoted $W_1 \gg \cdots \gg W_\ell$, and there are k_j servers of weight W_j. Our theorem is the following:

▶ **Theorem 2** (Integrality Gap). *For any constant $\varepsilon > 0$, the integrality gap of the relaxation LP for WEIGHTED k-SERVER is unbounded, even with $(\ell - \varepsilon)$-resource augmentation.*

An Instance for Two Classes. To gain some intuition, we first consider the special case of $\ell = 2$, and prove the result without giving any resource augmentation. There are $n/2$ servers of weight W and $n/4$ servers of weight 1, thereby giving a total of $k = 3n/4$ servers. The input is given in "phases". Each phase is specified by a distinct subset S of V, where $|S| = n/2$. During the phase corresponding to a subset S, we cycle through all subsets S' of S with $|S'| = |S|/2 = n/4$. Given such a subset S' of S, we send requests which cycle through the points in S' for L times, where L is large enough.

One fractional solution for such a sequence is defined as follows: we assign $1/2$ unit of weight-W server at each of the n locations. During the phase for a subset S, we assign $1/2$ unit of server of unit weight at each of the locations in S. The cost of the fractional solution is at most $Z := \binom{n}{n/2} \cdot n/4$ (not accounting for the initial movement of the servers). However, an integral solution either moves at least one heavy server, or else pays at least L during one of the phases, thereby must pay at least $\min(W, L)$. Assuming $W, L \gg Z$ gives an arbitrarily large integrality gap. (We can account for the initial movement of the fractional servers by repeating the process some M times: the integral solution would pay at least $\min(W, L)$ in each such iteration and the fractional solution would pay at most Z, so that the initial movement cost would get amortized away.)

The Instance for ℓ Classes. We extend this construction to larger values of ℓ by defining phases in a recursive manner on a nested sequence of subsets of V, with each phase containing several repetitions of the same sequence. Instead of decreasing by a factor 2, the number of servers of each weight class now goes down by a factor of $C \geq \ell$. This allows the integrality gap result to hold even when the integral solution is allowed a resource augmentation of nearly ℓ.

For some $r \leq \ell - 1$, we call a tuple $(S_0, \ldots, S_r)$ *valid* if (i) $S_0 = V$ and each $S_j \subseteq S_{j-1}$, and (ii) $|S_j| = |S_{j-1}|/C = n/C^j$. The request sequence is generated by calling Algorithm 1 with the trivial valid sequence $(S_0 = V)$. Given a valid tuple $(S_0, \ldots, S_r)$, the procedure cycles through all subsets $S \subseteq S_r$ of size $|S_r|/C$ and recursively calls $\mathsf{Generate}(S_0, \ldots, S_r, S)$; this process is repeated L_r times. Finally, in the base case when $r = \ell - 1$, it cycles through all the locations in S_ℓ for $L_{\ell-1}$ times. For a suitably large choice of M, we define for each $r \in [\ell]$:

$$L_r := M^r \qquad \text{and} \qquad W_r := M^{\ell - r}. \tag{3}$$

Finally, the number of servers of weight W_r is given by $k_r := \frac{n}{\ell C^{r-1}}$.

Algorithm 1 Procedure $\mathsf{Generate}(S_0, S_1, \ldots, S_r)$.

```
1.1 Input: A valid tuple $(S_0, S_1, \ldots, S_r)$
1.2 repeat
1.3     if $r$ is equal to $\ell - 1$ then
1.4         Send a request at each location in $S_{\ell-1}$.
1.5     else
1.6         for each subset $S$ of $S_r$ with $|S| = \frac{|S_r|}{C}$ do
1.7             // Move $1/\ell$ mass of servers of weight $W_{r+2}$ to $S$
1.8             Call Generate$(S_0, \ldots, S_r, S)$.
1.9 until $L_r$ iterations have occurred
```

Analyzing the Integrality Gap

We bound the cost of the optimal fractional solution for the above input sequence.

▶ **Lemma 5.** *There is a fractional solution of total cost $O(f(n)M^{\ell-2})$ for the input sequence constructed by Algorithm 1, where $f(n)$ is a function solely of n.*

Proof. Our fractional solution maintains the invariant: when the procedure $\mathsf{Generate}(S_0, \ldots, S_r)$ is called, we have $1/\ell$ fractional mass of servers of weight $W_1, \ldots, W_{r+1}$ respectively at each location in S_r. For the base case $r = 0$, we place $1/\ell$ server mass at each location in $S_0 = V$; recall that $k_1 = n/\ell$. For the inductive step, suppose this invariant is satisfied for a certain value of r where $0 \leq r < \ell - 1$; we need to show that it is satisfied for $r + 1$ as well. Indeed, the induction hypothesis implies that we have $1/\ell$ amount of server mass of weight $W_1, \ldots, W_{r+1}$ at each location in S_r, and hence at each location in S_{r+1}. Moreover, as line 1.7 indicates, we move $1/\ell$ fractional mass of servers of weight W_{r+2} to each location in S_{r+1} to satisfy the invariant condition. This costs $W_{r+2}\, k_{r+2}/\ell$; moreover, this is feasible because the total number of servers of weight W_{r+2} needed is $\frac{|S_{r+1}|}{\ell} = \frac{n}{\ell C^{r+1}} = k_{r+2}$. Finally, when $r = \ell - 1$, the invariant shows that 1 unit of server mass is present at each of the locations in S_ℓ, and hence the requests generated in line 1.4 can be served without any additional movement of servers.

We now account for the movement cost. The total server movement cost during $\mathsf{Generate}(S_0, \ldots, S_r)$ (not counting the movement costs in the recursive calls) is at most $O(L_r\, k_{r+1}\, W_{r+2}) = O(k_{r+1}\, M^{\ell-2})$. Since $k_{r+1} \le n$ and the number of calls to Generate is a function only of n, the overall movement cost can be expressed as $O(f(n) \cdot M^{\ell-2})$. (Again, by repeating the entire process multiple times we can amortize away the initial movement cost; we avoid this step for the sake of clarity.) ◀

The next lemma shows that any integral solution must have much higher cost.

▶ **Lemma 6.** *Let $\varepsilon > 0$ be a small enough constant. Assume that the integral solution is allowed $(\ell - \varepsilon)k_r$ servers of weight W_r for each $r \in [\ell]$. Any integral solution for the input sequence generated by Algorithm 1 (with $C = \ell/\varepsilon$) has movement cost at least $M^{\ell-1}$.*

We defer the proof to Appendix B; combining Lemma 5 and Lemma 6 proves Theorem 2.

3 An Offline Algorithm via LP Rounding

We now show an algorithm for the offline setting, that rounds any fractional solution to the LP relaxation (LP), and achieves the following guarantee:

▶ **Theorem 3** (Offline Algorithm). *Let $\mathcal{I}$ be an instance of Weighted k-Server with k_j servers of weight W_j for all $j \in [\ell]$. For any $\varepsilon \in (0,1)$, there is a polynomial time algorithm for $\mathcal{I}$ that uses at most $2(1+\varepsilon)\ell \cdot k_j$ servers of weights W_j for each $j \in [\ell]$ and has server movement cost at most $O(1/\varepsilon)$ times the optimal cost of $\mathcal{I}$.*

Instead of working with the relaxation (LP), we work with an equivalent relaxation which turns out to be easier to interpret. For each vertex $v \in V$, index $j \in [\ell]$ and time interval I, we have a variable $y_{v,j,I}$, which denotes the fractional mass of server of weight W_j residing at v during the entire time interval I. The variable $x_{v,j,t}$ used in (LP) can be expressed as follows:

$$x_{v,j,t} = \sum_{I: t \in I} y_{v,j,I}. \tag{4}$$

Let $\mathbf{I}$ denote the set of all intervals during the request timeline. The new linear program relaxation for Weighted k-Server is the following:

$$\begin{aligned}
&\min\ {}^1\!/_2 \sum_{j\in[\ell]} W_j \sum_{I\in\mathbf{I}} \sum_{v\in V} y_{v,j,I} && && \text{(LP2)}\\
&\text{s.t.}\ \sum_{j\in[\ell]} \sum_{I:t\in I} y_{\sigma_t,j,I} \ge 1 && \forall t && (5)\\
&\qquad \sum_{v\in V} \sum_{I:t\in I} y_{v,j,I} \le k_j && \forall t, j \in [\ell] && (6)\\
&\qquad\qquad y_{v,j,I} \ge 0 && \forall t, j \in [\ell], v \in V. &&
\end{aligned}$$

Note that the covering constraint (5) enforces having at least one unit of (fractional) server mass at the location σ_t requested for each time t. The packing constraint (6) enforces that the total (fractional) server mass of weight W_j used at any time t is at most the number of servers of this weight, namely k_j. Given a solution $y_{v,j,I}$ to LP2, the variables $x_{v,j,t}$ defined using (4) define a feasible solution to LP of the same cost.

Fix any constant $\varepsilon \in (0,1)$. We now prove Theorem 3 by rounding an optimal fractional solution $y_{v,j,I}$ to LP2. The rounding algorithm has two stages. The first stage scales and discretizes the LP variables to integers such that

Algorithm 2 Procedure $\mathsf{ScaleRound}(x, y, v, W_j)$.

```
Input: A fractional solution $(y_{v,j,I}, x_{v,j,t})$ to LP2, a location $v$ and a weight $W_j$
Initialize variables $\bar{y}_{v,j,I}$ to 0 for all intervals $I$.
(Scale): Define $\widetilde{y}_{v,j,I} = (2 + \varepsilon/2)\,\ell \cdot y_{v,j,I}$ and therefore,
    $\widetilde{x}_{v,j,t} = \sum_{I:t\in I} \widetilde{y}_{v,j,I} = (2 + \varepsilon/2)\,\ell \cdot x_{v,j,t}$ for each $I \in \mathbf{I}$.
(Round): for $h = 1, 2, \ldots, \ell$ do
    Initialize LastEvent = DOWN, LastTime = 0.
    repeat
        if LastEvent = UP then
            Let $t$ be the first DOWN after LastEvent
            Update LastEvent = DOWN, LastTime = $t$.
        else
            (LastEvent = DOWN) Let $t$ be the first UP after LastEvent
            Add $I = [\mathsf{LastTime}, t)$ to $\mathbf{I}_{v,j}(h)$ and increase $\bar{y}_{v,j,I}$ by 1.
            Update LastEvent = DOWN, LastTime = $t$.
    until we have reached the end of the timeline $[0, T]$
```

1. the packing constraints are satisfied up to a factor of $(2 + \varepsilon)\ell$,
2. the covering constraints are satisfied with a scaled covering requirement of ℓ instead of 1, i.e., $\sum_j \sum_{I:t\in I} y_{\sigma_t,j,I} \geq \ell$, for all times t, and
3. the cost of the fractional solution increases by a factor of $O(\ell/\varepsilon)$.

In the second stage, we remove the packing constraints from the LP; this results in the resulting interval covering LP being integral. Next, we scale the solution from the first stage down by ℓ, getting a feasible fractional solution to the standard LP relaxation for the interval covering problem. Finally, we use the integrality of the interval covering LP relaxation to obtain an integral solution for LP2. We present these two stages in the next two sections.

3.1 Stage I: Scaling and Discretization

The first stage of the rounding algorithm operates independently on each location $v \in V$ and for each server weight W_j; the formal algorithm $\mathsf{ScaleRound}(x, y, v, W_j)$ is given in Algorithm 2. We work with both the $y_{v,j,I}$ variables and the equivalent $x_{v,j,t}$ variables defined in (4); this representational flexibility makes it convenient to explain the algorithm. To begin, we scale the LP variables $y_{v,j,I}$ by a factor $(2 + \varepsilon/2)\ell$ to obtain $\widetilde{y}_{v,j,I}$ (we also define the auxiliary variables $\widetilde{x}_{v,j,t}$ by scaling $x_{v,j,t}$ similarly).

Discretization. Next we discretize the scaled variables $\widetilde{y}_{v,j,I}$ and $\widetilde{x}_{v,j,t}$ to nonnegative integers $\bar{y}_{v,j,I}$ and $\bar{x}_{v,j,t}$ respectively. To start, let us describe the discretization of $\widetilde{x}_{v,j,t}$ to obtain $\bar{x}_{v,j,t}$. Intuitively, we would like to define $\bar{x}_{v,j,t}$ as $\lfloor \widetilde{x}_{v,j,t} \rfloor$, i.e., the largest step function with unit step sizes entirely contained in $\widetilde{x}_{v,j,t}$, but this can amplify small fluctuations around integer values, and hence may increases the cost. To avoid this, we introduce *hysteresis* in our discretization, by setting different thresholds for increasing and decreasing the value of $\widetilde{x}_{v,j,t}$. We view $\widetilde{x}_{v,j,t}$ as a time-varying profile and define horizontal *slabs* in it corresponding to the restriction of the range of $\widetilde{x}_{v,j,t}$ to $[h, h + 1)$ for some integer h. For each such slab, we identify intervals I of width at most 1 and at least $1/2$ and set the increase the corresponding

$\bar{y}_{v,j,I}$ value by 1. In more detail, for each such level h, we identify a subset $\mathbf{I}_{v,j}(h)$ of intervals for which the corresponding $\bar{y}_{v,j,I}$ variable is to be increased by 1. We identify an alternating sequence of *up* and *down* events in the timeline $[0, T]$ as follows:

- UP event: At time t, there is an UP event at level h if $\widetilde{x}_{v,j,t^-} < h$ and $\widetilde{x}_{v,j,t} \geq h$, and the previous event at level h was a DOWN event.
- DOWN event: At time t, there is a DOWN event at level h if the previous event at level h was an UP, and $\widetilde{x}_{v,j,t^-} > h - \varepsilon/2$ and $\widetilde{x}_{v,j,t} \leq h - \varepsilon/2$, or $t = T$, the end of the timeline. (The reader should think of $\varepsilon/2$ as the "hysteresis gap" between the up and down events at any level.)

To make the definition complete, we set $\widetilde{x}_{v,j,t}$ to 0 at $t = 0^-$ and at $t = T^+$, and start with a DOWN at time 0. Finally, we add intervals stretching from each UP to the next DOWN to the set $\mathbf{I}_{v,j}(h)$ of intervals. By construction, these intervals are mutually disjoint. Finally, whenever an interval I is added to such a set $\mathbf{I}_{v,j}(h)$, we increment the corresponding variable $\bar{y}_{v,j,I}$. Thus we have:

$$\bar{y}_{v,j,I} = |\{h : I \in \mathbf{I}_{v,j}(h)\}|, \text{ and correspondingly, } \bar{x}_{v,j,t} = \sum_{I:t\in I} \bar{y}_{v,j,I}.$$

The next lemma shows that $\bar{x}_{v,j,t}$ can be thought of as a discretized form of $\widetilde{x}_{v,j,t}$:

▶ **Lemma 7.** *The following holds for variables $\bar{x}_{v,j,t}$:*

$$\widetilde{x}_{v,j,t} - 1 < \bar{x}_{v,j,t} < \widetilde{x}_{v,j,t} + \varepsilon/2. \tag{7}$$

Proof. Suppose $\widetilde{x}_{v,j,t} \in [r, r+1)$. Consider the **for** loop in line 2.4 in Algorithm 2 for a value $h \leq r$. We claim that at time t, the value of the variable LastEvent must be UP. Suppose not. Let t' be the value of LastTime at time t (i.e., t' is the last time before and including t when an UP or a DOWN occurred). Since a DOWN event happened at time t', $\widetilde{x}_{v,j,t'} < h$. Since $\widetilde{x}_{v,j,t} \geq h$, an UP event must occur during $(t', t]$, a contradiction. Therefore must have added an interval containing time t to $\mathbf{I}_{v,j}(h)$. Thus, $\bar{x}_{v,j,t}$ gets increased during each such iteration, i.e., $\bar{x}_{v,j,t} \geq r > \widetilde{x}_{v,j,t} - 1$. This proves the first inequality in (7).

We now prove the second inequality. Let h be an integer satisfying $h \geq \widetilde{x}_{v,j,t} + \varepsilon/2$. Consider the iteration of the **for loop** in Algorithm 2 for this particular value of h. We claim that the value of the variable LastEvent at time t must be DOWN. Suppose not, and let t' denote the value of the variable LastTime. Then an UP happened at time t' and so $\widetilde{x}_{v,j,t'} \geq h$. Since $\widetilde{x}_{v,j,t} \leq h - \varepsilon/2$, a DOWN event must have happened during $(t', t]$, a contradiction. Hence, we do not add any interval containing time t to the set $\mathbf{I}_{v,j}(h)$. Therefore, $\bar{x}_{v,j,t} < \widetilde{x}_{v,j,t} + \varepsilon/2$, which proves the second inequality in (7). ◀

The next lemma establishes the key properties of the variables $\bar{y}_{v,j,I}$ and $\bar{x}_{v,j,t}$.

▶ **Lemma 8.** *The following properties hold the for the variables $\bar{y}_{v,j,I}$:*

(i) *(Cost) The LP cost increases by at most $O(\ell/\varepsilon)$ when the original variables $y_{v,j,I}$ are replaced by the new variables $\bar{y}_{v,j,I}$:*

$$\sum_{v,j,I} W_j \cdot \bar{y}_{v,j,I} \leq O(\ell/\varepsilon) \cdot \sum_{v,j,I} W_j \cdot y_{v,j,I}.$$

(ii) *(Covering) The variables $\bar{y}_{v,j,I}$ satisfy the scaled covering constraints of* (LP2)

$$\sum_{j,I:t\in I} \bar{y}_{v,j,I} \geq \ell \quad \forall t.$$

(iii) *(Packing) The variables $\bar{y}_{v,j,I}$ approximately satisfy the packing constraints of* (LP2)*:*

$$\sum_{v,I:t\in I} \bar{y}_{v,j,I} \le (2+\varepsilon)\ell k_j \quad \forall j \in [\ell], t.$$

Proof. We first prove the cost bound: the cost of the solution $\bar{y}_{v,j,I}$ is the weight of all intervals added to the sets $\mathbf{I}_{v,j}(h)$ for all v, j, h. I.e.,

$$\sum_{v,j,I} W_j \cdot \bar{y}_{v,j,I} = \sum_{v,j} W_j \cdot \sum_{h\in[\ell]} |\mathbf{I}_{v,j}(h)|. \tag{8}$$

Fix a vertex v and indices j, h. For a non-negative number x, and non-negative integer h, define the *h-level truncation* of x to be $\mathsf{trunc}_h(x) := \min(1, (x-h)^+)$, where $(a)^+ := \max(a, 0)$ for any real a. Observe that $x = \sum_{h\ge 0} \mathsf{trunc}_h(x)$. In fact, for any two non-negative integers x and y:

$$|x-y| = \sum_{h'\ge 0} |\mathsf{trunc}_{h'}(x) - \mathsf{trunc}_{h'}(y)|. \tag{9}$$

Now let $I_1 = [s_1, t_1), \ldots, I_u = [s_u, t_u)$ be the intervals added to $\mathbf{I}_{v,j}(h)$ (in left to right order). Define $t_0 = 0$. We know that for any $i \in [u]$, an UP happens at s_u and a DOWN happens at t_u. Therefore, $\mathsf{trunc}_h(\widetilde{x}_{v,j,s_u}) - \mathsf{trunc}_h(\widetilde{x}_{v,j,t_{u-1}}) \ge \varepsilon/2$. Hence,

$$\begin{aligned}\varepsilon W_j/2 \cdot |\mathbf{I}_{v,j}(h)| &\le W_J \cdot \sum_{i=1}^{u} |\mathsf{trunc}_h(\widetilde{x}_{v,j,s_u}) - \mathsf{trunc}_h(\widetilde{x}_{v,j,t_{u-1}})| \\ &\le W_j \cdot \sum_{t'=1}^{T} |\mathsf{trunc}_h(\widetilde{x}_{v,j,t-1}) - \mathsf{trunc}_h(\widetilde{x}_{v,j,t})|,\end{aligned}$$

where the last inequality follows from triangle inequality. Summing over all h and using (9), we get

$$\varepsilon W_j/2 \cdot \bar{y}_{v,j,I} \le W_j \cdot \sum_{t'=1}^{T} |\widetilde{x}_{v,j,t-1}) - \widetilde{x}_{v,j,t}|.$$

Summing over all vertices v and indices $j \in [\ell]$, we see that the cost of the solution $\bar{y}_{v,j,I}$ is at most $2/\varepsilon$ times that of $\widetilde{y}_{v,j,I}$. Finally, the fact that $\widetilde{y}_{v,j,I}$ are obtained by scaling $y_{v,j,I}$ by a factor $(2+\varepsilon/2)\ell$, we get the desired bound on the cost of $\bar{y}_{v,j,I}$ solution.

Next, we prove the covering property. Since $x_{v,j,t}$ is a feasible solution to LP2, we have for any time t:

$$\sum_j x_{\sigma_t,j,t} \ge 1, \text{ and therefore, } \sum_j \widetilde{x}_{\sigma_t,j,t} \ge (2+\varepsilon/2)\ell.$$

Using Lemma 7, we have $\widetilde{x}_{\sigma_t,j,t} < \bar{x}_{\sigma_t,j,t} + 1$, so

$$\sum_{j\in\ell} (\bar{x}_{\sigma_t,j,t} + 1) > (2+\varepsilon/2)\ell, \text{ and therefore, } \sum_j \bar{x}_{\sigma_t,j,t} > \ell.$$

Finally, we prove the packing property. Since $x_{v,j,t}$ is a feasible solution to the LP, we have for any $j \in [\ell]$ and time t,

$$\sum_v x_{v,j,t} \le k_j, \text{ and therefore, } \sum_v \widetilde{x}_{v,j,t} \le (2+\varepsilon/2)\ell k_j.$$

Again Lemma 7 gives $\widetilde{x}_{v,j,t} > \bar{x}_{v,j,t} - \varepsilon/2$, which implies

$$\sum_j (\bar{x}_{v,j,t} - \varepsilon/2)^+ < (2 + \varepsilon/2)\ell k_j. \tag{10}$$

Since $\bar{x}_{v,j,t}$ is a nonnegative integer,

$$\bar{x}_{v,j,t} > 0 \implies \bar{x}_{v,j,t} \geq 1 \overset{\text{Lemma 7}}{\implies} \widetilde{x}_{v,j,t} > \bar{x}_{v,j,t} - \varepsilon/2 \geq 1 - \varepsilon/2.$$

Since $\sum_v \widetilde{x}_{v,j,t} \leq k_j$, it follows that the number of locations v for which $\bar{x}_{v,j,t} > 0$ is at most $\frac{k_j}{1-\varepsilon/2} < 2k_j$, if $\varepsilon < 1$. Using this fact in Equation (10), we get

$$\begin{aligned}\sum_v \bar{x}_{v,j,t} &= \sum_{v:\bar{x}_{v,j,t}>0} \bar{x}_{v,j,t} = \sum_{v:\bar{x}_{v,j,t}>0} (\bar{x}_{v,j,t} - \varepsilon/2) + \sum_{v:\bar{x}_{v,j,t}>0} \varepsilon/2 \\ &\leq \sum_v (\bar{x}_{v,j,t} - \varepsilon/2)^+ + 2k_j \cdot \varepsilon/2 \leq (2 + \varepsilon/2)\ell k_j + \varepsilon k_j.\end{aligned}$$

Since $\ell \geq 2$ (otherwise, we have the unweighted problem), we get

$$\sum_v \bar{x}_{v,j,t} \leq (2 + \varepsilon)\ell k_j.$$ ◀

3.2 Stage II: Weighted Interval Cover

In the second stage of the rounding algorithm, we first scale the (integer-valued) variables $\bar{y}_{v,j,I}$ down by a factor of ℓ to obtain new variables $y^*_{v,j,I}$:

$$y^*_{v,j,I} := \bar{y}_{v,j,I}/\ell \text{ and therefore, } x^*_{v,j,t} = \sum_{I:t\in I} y^*_{v,j,I} = \bar{x}_{v,j,t}/\ell. \tag{11}$$

Our goal is to round the fractional variables $y^*_{v,j,I}$ to $\{0,1\}$ values. In fact, our rounding will ensure that if the rounded value equals 1 then $y^*_{v,j,I} > 0$. Since $\bar{y}_{v,j,I}$ is integral, the packing property in Lemma 8 implies that for any time t, vertex v, and index $j \in [\ell]$, there are at most $(2+\varepsilon)\ell k_j$ intervals $I \ni t$ for which $\bar{y}_{v,j,I} > 0$. The rounding property of our algorithm will ensure that the final integral solution, which lies in the support of $y^*_{v,j,I}$, will also satisfy that there are at most $(2+\varepsilon)\ell k_j$ intervals containing any time t. Since we are allowed a resource augmentation of $(2+\varepsilon)\ell$ factor in the number of servers of weight W_j, we can serve the requests with the set of available servers. Henceforth, we can ignore the packing constraint (6) for our rounded solution. As a result, the relaxation LP2 decouples into n independent relaxations, one for each location $v \in V$.

In this decoupled instance, we get the following LP relaxation for each location v, where for each class $j \in [\ell]$, we define $\mathbf{I}_{v,j} := \{I \mid y^*_{v,j,I} > 0\}$ as the set of intervals I with a nonzero value of $y^*_{v,j,I}$ and $\mathcal{R}(v)$ as the set of times t when v is requested:

$$\begin{aligned} &\min 1/2 \sum_{j\in[\ell]} W_j \cdot \sum_{I\in\mathbf{I}_{v,j}} y_{v,j,I} && \text{(LP}_v\text{)} \\ &\text{s.t.} \sum_j \sum_{I\in\mathbf{I}_{v,j}:t\in I} y_{v,j,I} \geq 1 \qquad \forall t \in \mathcal{R}_v \\ &\qquad\qquad y_{v,j,I} \geq 0. \end{aligned}$$

By the covering property of Lemma 8, the variables $y^*_{v,j,I}$ defined in (11) are feasible solutions for (LP$_v$) for all locations v. Furthermore, by the lemma's cost property (and the scaling down by ℓ), the total cost $\sum_v \sum_j W_j \cdot \sum_I y^*_{v,j,I}$ is at most $O(1/\varepsilon)$ times the optimal cost of (LP2).

Finally, the constraint matrix for (LP_v) satisfies the consecutive-ones property: if the constraints are ordered chronologically, then a variable $y_{v,j,I}$ appears in the constraints corresponding to times $t \in I$ where $\sigma_t = v$, which is a contiguous subsequence of all times t where $\sigma_v = j$. Constraint matrices with this property are totally unimodular (see, e.g., [18]). Therefore, each of the solutions $\{y^*_{v,j,I} : j \in [\ell], I \in \mathbf{I}_{v,j}\}$ for LP_v can be rounded to a feasible integral solution without any increase in cost, which proves Theorem 3.

4 Online Algorithm

In this section, we describe an efficient online algorithm for Weighted k-Server and prove the following result:

▶ **Theorem 4** (Online Algorithm). *Let $\mathcal{I}$ be an instance of* Weighted k-Server *with k_j servers of weight W_j for all $j \in [\ell]$. There is a randomized (polynomial time) online algorithm for $\mathcal{I}$ that uses at most $2\ell k_j$ servers of weights W_j for each $j \in [\ell]$ and has expected server movement cost at most $O(\ell^2 \log \ell)$ times the optimal cost of $\mathcal{I}$.*

We begin by re-writing the LP relaxation (LP2) in terms of the "anti-page" variables, as in [4]. Recall that (LP2) has variables $y_{v,j,I}$ representing the (fractional) weight W_j server mass present at location v during the interval I; instead we first rewrite it in terms of the "page" variables $x_{v,j,t}$, which denote the total amount of weight W_j server mass at location v at time t, as given in (4). The objective of this LP in terms of $x_{v,j,t}$ is:

$$\sum_{v,j,I} W_j \cdot y_{v,j,I} = \sum_{v,j,I} W_j \cdot (x_{v,j,t} - x_{v,j,t^-})^+.$$

We can constrain any algorithm to values $x_{v,j,t} \in [0,1]$ for all v, j, t (since having multiple servers at a location is not beneficial). This allows us to work with non-negative *anti-page* variables $z_{v,j,t} := 1 - x_{v,j,t}$. The objective, now rewritten in terms of these new variables $z_{v,j,t}$, becomes:

$$\sum_{v,j,I} W_j \cdot (x_{v,j,t} - x_{v,j,t^-})^+ = \sum_{v,j,I} W_j \cdot (z_{v,j,t^-} - z_{v,j,t})^+. \tag{12}$$

We shall also maintain the following invariant for each server weight W_j and time t:

$$\sum_v x_{v,j,t} = k_j \qquad \Longleftrightarrow \qquad \sum_v z_{v,j,t} = n - k_j \quad \forall j, t. \tag{13}$$

We write the covering constraint (5) (or equivalently (2)) in terms of $z_{v,j,t}$ as:

$$\sum_j z_{\sigma_t,j,t} \le \ell - 1 \tag{14}$$

The algorithm follows the standard relax-and-round paradigm in the online setting. The first step is to compute a feasible fractional solution to an LP consisting of objective (12) and constraints (13) and (14), in an online setting. We show in §4.1 that we can find a fractional solution that uses $O(\ell k_j)$ servers of weight W_j for each class j, and has a competitive ratio of $O(\ell^2)$. The second step is to give an online rounding algorithm to convert this fractional solution to an integral solution: our rounding algorithm given in §4.2 uses the standard online rounding algorithm for the paging problem and increases the cost of the solution by a constant factor.

4.1 Online Fractional Algorithm

In this section, we give an online algorithm for maintaining a fractional solution to the LP involving $z_{v,j,t}$ variables. We obtain the following result:

▶ **Theorem 9.** *There is a deterministic (polynomial time) online fractional algorithm that maintains the condition that for every request time t, there exists an index $j \in [\ell]$ such that there is unit server mass of weight W_j at location σ_t at time t. The algorithm uses $2\ell k_j$ servers of weight W_j for each $j \in [\ell]$, and whose cost is at most $O(\ell^2 \log \ell)$ times that of an optimal fractional solution.*

Note that the condition in the theorem is stronger than (14), the feasibility condition for (LP2), because we are using server from a single weight class to service this request.

Consider a time t, and the request arriving at location σ_t. We first set $z_{v,j,t} = z_{v,j,t^-}$ for all $v \in V, j \in \ell$. Now the algorithm moves fractional server mass to σ_t until a relaxed version of the covering constraint (14) for time t gets satisfied. The relaxed constraint is given by

$$\exists j \in [\ell] \text{ such that } z_{\sigma_t,j,t} \leq 1 - \frac{1}{2\ell}. \tag{15}$$

Indeed, if the constraint is violated, then for each vertex $v \neq \sigma_t$ and each $j \in [\ell]$, if v has non-zero server mass of weight W_j (i.e., $z_{v,j,t} < 1$), then the algorithm moves server mass of weight W_j from v to σ_t using the following differential equation. (The derivative is with respect to a variable s which starts from 0 and increases at uniform rate.)

$$\dot{z}_{v,j,t} = \frac{1}{W_j |S_j|} \cdot (z_{v,j,t} + \delta) \qquad \forall j \in [\ell], \forall v \in S_j. \tag{16}$$

Here, $S_j \subseteq V$ denotes the instantaneous set of locations (i.e., at the current value of the variable s) that have $z_{v,j,t} < 1$, not including the location σ_t, and $\delta > 0$ is a parameter that we shall fix later. Correspondingly, we reduce $z_{\sigma_t,j,t}$ by the total amount of server mass of weight W_j entering σ_t:

$$\dot{z}_{\sigma_t,j,t} = -\frac{1}{W_j |S_j|} \cdot \sum_{v \in S_j} (z_{v,j,t} + \delta) \qquad \forall j \in [\ell]. \tag{17}$$

Note that server mass is moved away other locations and into location σ_t only if $z_{\sigma_t,j,t} > 1 - \frac{1}{2\ell}$ for all j. Since $z_{\sigma_t,j,t} \leq 1$ for all j, it follows that $z_{v,j,t} \in [1 - \frac{1}{2\ell}, 1]$ for all j, t. Hence,

$$z_{v,j,t} \geq 1 - \frac{1}{2\ell} \text{ for all } j,t \quad \Longrightarrow \quad |S_j| \geq 2\ell k_j - 1 \geq \frac{3\ell k_j}{2} \geq 3 \text{ for all } j,t, \tag{18}$$

since $\ell \geq 2, k_j \geq 1$.

To analyze the algorithm, we use a potential function Φ. The potential function depends on the offline (integral) optimal solution – let us call it $\mathcal{O}$, and let $\text{opt}_{v,j,t}$ be the indicator variable for the location v containing a server of weight W_j at time t. The potential at time t is defined as follows:

$$\Phi(t) := \sum_{v,j:\text{opt}_{v,j,t}=0} W_j \cdot \ln\left(\frac{1+\delta}{z_{v,j,t}+\delta}\right).$$

Let $\mathsf{cost}(t)$ denote the algorithm's server movement cost at time t and $\mathsf{cost}^{\mathcal{O}}(t)$ denote the corresponding quantity for the optimum solution $\mathcal{O}$. Our goal is to show that:

$$\frac{\mathsf{cost}(t)}{4\ell} + \Phi(t+1) - \Phi(t) \leq \ln(1 + 1/\delta) \cdot \mathsf{cost}^{\mathcal{O}}(t). \tag{19}$$

The following properties of $\Phi(t)$ can verified easily:

- **Nonnegativity:** Φ is always nonnegative, since $z_{v,j,t} \le 1$.
- **Lipschitzness property:** When the optimal solution moves a server of weight W_j from one location to another, the increase in Φ is at most $W_j \cdot \ln(1 + 1/\delta)$.

The Lipschitzness property implies that (19) holds when $\mathcal{O}$ serves the request at σ_t. It remains the analyze the cost and change in potential when the algorithm changes its solution. Consider the process when we transfer server mass to σ_t.

We first bound the online algorithm's cost. Since all the weight classes incur the same server movement cost while transferring to σ_t, the movement cost is ℓ times the movement cost incurred while transferring servers of a fixed class, say $j^\star$. The latter is at most

$$W_{j^\star} \sum_{v \in S_{j^\star}} \dot{z}_{v,j^\star,t} \overset{(16)}{=} \frac{1}{|S_{j^\star}|} \sum_{v \in S_{j^\star}} (z_{v,j^\star,t} + \delta) \quad = \frac{|S_{j^\star}| + 1 - k_{j^\star} + \delta |S_{j^\star}|}{|S_{j^\star}|} \le 1 + \delta. \tag{20}$$

Thus, the upper bound on the $\frac{\mathsf{cost}(t)}{4\ell}$ term in the LHS of (19) is at most $\frac{1+\delta}{4} \le 1/3$ provided $\delta \le 1/3$.

Next, we lower bound the rate of decrease of potential Φ. We begin by bounding the rate of decrease in potential due to because of server mass leaving all locations except σ_t:

$$\begin{aligned}\Delta^- &= - \sum_{j \in [\ell], v \neq \sigma_t : \mathrm{opt}_{v,j,t} = 0} \frac{W_j}{z_{v,j,t} + \delta} \cdot \dot{z}_{v,j,t} \quad \overset{(16)}{=} - \sum_{j, v \in S_j : \mathrm{opt}_{v,j,t} = 0} \frac{1}{z_{v,j,t} + \delta} \cdot \frac{z_{v,j,t} + \delta}{|S_j|} \\ &= - \sum_j \frac{|\{v \in S_j : \mathrm{opt}_{v,j,t} = 0\}|}{|S_j|} \quad \overset{(18)}{\le} - \sum_j \frac{|S_j| - k_j}{|S_j|} \le -\ell \left(1 - \frac{2}{3\ell}\right) = -\ell + 2/3.\end{aligned} \tag{21}$$

Next, we bound the rate of increase in potential due to server classes $j \neq j^*$ because of server mass entering σ_t:

$$\begin{aligned}\Delta^+ &= \sum_{j \neq j^*} \frac{W_j}{z_{\sigma_t,j,t} + \delta} \cdot \dot{z}_{\sigma_t,j,t} \quad \overset{(16)}{=} \sum_{j \neq j^*, v \in S_j} \frac{W_j}{z_{\sigma_t,j,t} + \delta} \cdot \frac{z_{v,j,t} + \delta}{|S_j| W_j} \\ &= \sum_{j \neq j^*} \frac{\sum_{v \in S_j} (z_{v,j,t} + \delta)}{|S_j| (z_{\sigma_t,j,t} + \delta)} \quad = \sum_{j \neq j^*} \frac{(|S_j| - k_j + (1 - z_{\sigma_t,j,t})) + \delta \cdot |S_j|}{|S_j| (z_{\sigma_t,j,t} + \delta)} \\ &\overset{(18)}{\le} \sum_{j \neq j^*} \frac{(|S_j| - k_j + 1/2\ell) + \delta \cdot |S_j|}{|S_j| (1 - 1/2\ell + \delta)} \quad \overset{(18)}{\le} \sum_{j \neq j^\star} \frac{1 - 2/3\ell + 1/6\ell + \delta}{1 - 1/2\ell + \delta} \quad \le \ell - 1,\end{aligned}$$

provided $\delta = 1/2\ell$. Combining with (21), we see that the overall change in potential is $\Delta^- + \Delta^+ \le -1/3$. Consequently, we get that the change in potential pays for the increase in the algorithm's cost (divided by 4ℓ) – which shows (19) – when the fractional solution changes.

This implies that we have an algorithm for maintaining $z_{v,j,t}$ that satisfies (15). In terms of the competitive ratio, the algorithm loses 4ℓ in (19) and $\ln(1 + 1/\delta) = O(\log \ell)$ in the Lipschitzness of the potential function. Note that (15) implies that for all t, there exists j such that $x_{\sigma_t,j,t} \ge \frac{1}{2\ell}$. We scale the fractional variables to obtain $\widetilde{x}_{v,j,t} := \min(2\ell x_{v,j,t}, 1)$; then, for all t, there exists j such that $\widetilde{x}_{\sigma_t,j,t} = 1$. Note that this satisfies the condition in Theorem 9. Equivalently, the corresponding "anti-page" variables $\widetilde{z}_{v,j,t} := 1 - \widetilde{x}_{v,j,t}$ satisfy the following condition for all t:

$$\exists j \text{ such that } \widetilde{z}_{\sigma_t,j,t} = 0. \tag{22}$$

The last scaling step creates a resource augmentation of 2ℓ, and increases the competitive ratio to $O(\ell^2 \log \ell)$. This completes the proof of Theorem 9.

4.2 Rounding the Fractional Solution Online

We round the fractional solution for each weight class j separately. Let T_j represent the request times t when (22) is satisfied by weight class j. Note that the solution $\widetilde{z}_{v,j,t}$ for weight class j represents a feasible fractional solution for an instance of the paging problem with $2\ell k_j$ cache slots, where there is a page request for each time $t \in T_j$ at location σ_t.

We now invoke the following known online rounding algorithm for the paging problem separately in each weight class j to complete the proof of Theorem 4.

▶ **Lemma 10** ([9]). *There is a randomized (polynomial time) online algorithm that converts any feasible fractional solution for an instance of the* Paging *problem to an integral solution using the same number of cache slots, and incurs constant times the cost of the fractional solution.*

5 Discussion

In this work, we have given the first efficient offline and online algorithms with non-trivial guarantees for Weighted k-Server. Several interesting problems remains open:

1. For the case of two distinct weight classes, we show in Appendix A that it is UG-Hard to obtain an $\Omega(N^c)$-approximation algorithm for some constant $c > 0$, even with $(2-\varepsilon)$-resource augmentation. Can we extend such a hardness result to more weight classes? For example, can we show that for three distinct weight classes, it is UG-Hard to obtain a C-approximation algorithm for any *constant* C, even with $(3-\varepsilon)$-resource augmentation? The principal reason why our hardness proof for $\ell = 2$ does not extend here is because one needs to recursively cycle through all subsets (of a certain size) of V to create an integrality gap instance for the natural LP relaxation. If the size of these subsets is large, then the length of the input becomes very large. If the size of these subsets is small, then it is not clear how to extend this to a hardness proof.
2. In Section 3, we give an offline constant approximation algorithm which requires slightly more than 2ℓ-resource augmentation. Can we get a constant approximation algorithm (or even an optimal algorithm) with exactly ℓ-resource augmentation? We conjecture that the integrality gap of LP is constant (or even 1) if the integral solution is allowed ℓ-resource augmentation.
3. In the online case, we give a $O(\ell^2 \log \ell)$-competitive algorithm with 2ℓ-resource augmentation in Section 4. Can we get a constant-competitive algorithm with $O(\ell)$-resource augmentation, i.e., a result in the same vein as our offline algorithm?

A The Unique Games Hardness

In this section, we consider the special case of Weighted k-Server when there are only two weight classes. Assume wlog that the two distinct weights are 1 and W, where $W \gg 1$. Our first main result shows that getting a good approximation algorithm with $(2-\varepsilon)$-resource augmentation for any constant $\varepsilon > 0$ is as hard as getting a better-than-two approximation for the vertex cover problem.

▶ **Theorem 1** (Hardness). *For any constant $\varepsilon > 0$, it is UG-hard to obtain an $N^{1/2-\varepsilon}$-approximation algorithm for Weighted k-Server with two weight classes, even when we are allowed c-resource augmentation for any constant $c < 2$. Here N represents the size of the input (including the request sequence length).*

Proof. We give a reduction from the Vertex Cover problem. Let $d = d(\varepsilon)$ be a constant to be fixed later, and let $c < 2$ be a constant as in the statement of the theorem. Let $\mathcal{I} = (G = (V, E), t)$ be an instance of the Vertex Cover problem on n vertices. We know that it is UG-hard to distinguish between the following two cases: (i) G has a vertex cover of size at most t, or (ii) every vertex cover of G must have size strictly larger than ct.

We map $\mathcal{I}$ to an instance $\mathcal{I}'$ of Weighted k-Server as follows: the set of points in $\mathcal{I}'$ is given by $V \cup \{v_0\}$, where v_0 is a special vertex. There are t servers of weight $W = n^d$ and one server of unit weight. Let the edges in E be $e_1, \ldots, e_m$. A subsequence of the request sequence consists of m *phases*, where we have a phase for each edge e_i. During phase i corresponding to edge $e_i = (u_i, v_i)$, the request sequence toggles between u_i and v_i for W times. Finally, the subsequence is repeated W times. In other words, it is the following sequence

$$\Big(\underbrace{u_1, v_1, u_1, v_1, \ldots, u_1, v_1}_{W \text{ times}}, \ldots, \underbrace{u_m, v_m, u_m, v_m, \ldots, u_m, v_m}_{W \text{ times}}\Big)^W.$$

We also have to specify the initial location of the servers. Assume that all servers are at location v_0 in the beginning. This completes the description of the instance $\mathcal{I}'$. Observe that N, the number of requests in instance $\mathcal{I}'$ is $O(m \cdot n^{2d})$.

▷ Claim 11. Suppose G has a vertex cover of size at most t. Then the cost of the optimal solution for $\mathcal{I}'$ is at most $2mW$.

Proof. Let $V' \subseteq V$ be a vertex cover of size t. Consider the following solution: we move the t heavy servers from v_0 to V' at the beginning. From now on, the heavy servers will not move at all. During a phase corresponding to an edge $e_i = (u_i, v_i)$, we know that at least one of these vertices will be occupied by a heavy server. If the other end-point, say v_i, is not occupied by a heavy server, we move the server of weight 1 to v_i. Now we have two servers occupying u_i and v_i respectively until the end of this phase. The total movement cost is incurred either at the beginning (which is tW overall), or at the beginning of each phase (when the cost is 1). Since there are mW phases, the overall cost is at most $tW + mW \leq 2mW$. ◁

▷ Claim 12. Suppose every vertex cover in G has size strictly larger than ct. Then cost of the optimal solution for $\mathcal{I}'$, even with c-resource augmentation, is at least W^2.

Proof. Consider any solution for $\mathcal{I}'$. Recall that the input consists of W subsequences, call these $S_1, \ldots, S_W$, where each subsequence S_j consists of m phases, one for each edge of G. We claim that during each such subsequence S_j, the solution must pay movement cost of at least W. Indeed, consider a subsequence S_j. If the solution moves a heavy server during S_j, then the claim follows directly. Else observe that the size of any vertex cover is strictly larger than the number of heavy servers ct, so there is some edge $e_i = (u_i, v_i)$ not covered by the heavy servers during S_j. Now the phase for e_i in S_j would require the unit weight server to toggle between u_i and v_i for W times. In either case, the cost of each subsequence is at least W, and the overall cost of the solution is at least W^2. ◁

The above two results along with the UG-hardness result for Vertex Cover impliy that it is UG-hard to obtain a $\frac{W^2}{2mW}$-approximation for Weighted k-Server with two weight classes. This ratio is equal to $\frac{W}{2m} \geq n^{d-2} \geq N^{1/2-\varepsilon}$, assuming d is $\Omega(1/\varepsilon)$, which proves Theorem 1. ◀

B Missing proofs from §2

▶ **Lemma 6.** *Let $\varepsilon > 0$ be a small enough constant. Assume that the integral solution is allowed $(\ell - \varepsilon)k_r$ servers of weight W_r for each $r \in [\ell]$. Any integral solution for the input sequence generated by Algorithm 1 (with $C = \ell/\varepsilon$) has movement cost at least $M^{\ell-1}$.*

Proof of Lemma 6. We prove the following more general statement by reverse induction on r: any integral solution for the sequence generated by Generate$(S_0, \ldots, S_r)$ for a valid tuple $(S_0, \ldots, S_r)$ which does not use any server of weight class $W_1, \ldots, W_r$ (at any location in S_r) has cost at least $M^{\ell-1}$. It suffices to prove this statement, because the case when $r = 0$ implies the lemma.

Consider the base case when $r = \ell - 1$. Consider the sequence generated by such a procedure Generate$(S_0, \ldots, S_r)$ such that no server of weight $W_1, \ldots, W_{\ell-1}$ is used for serving the requests at $S_{\ell-1}$. Thus all requests generated by this procedure must be served by servers of weight W_ℓ. Now, $|S_{\ell-1}| = \frac{n}{C^{\ell-1}}$, whereas the number of weight W_ℓ servers available to the algorithm is $(\ell - \varepsilon)k_\ell < \frac{n}{C^{\ell-1}}$. Therefore, during each iteration of the **repeat-until** loop in lines 1.2–1.8 in Algorithm 1, at least one server of weight W_ℓ must move. So the overall movement cost during this input sub-sequence is at least $W_\ell \cdot L_{\ell-1} = M^{\ell-1}$. This proves the base case.

The inductive case is proved in an analogous manner. Suppose the statement is true for $r+1$, and now consider the sub-sequence generated by $Gen(S_0, \ldots, S_r)$ for some valid tuple $(S_0, \ldots, S_r)$. Assume that no server of weight $W_1, \ldots, W_r$ is present at any node in S_r during this time. We claim that the algorithm must incur movement cost of at least W_{r+1} during each iteration of the **repeat-until** loop. Indeed, fix such an iteration. Two cases arise: (a) The algorithm moves a server of weight W_{r+1} then the claim follows trivially, or (b) No server of weight W_{r+1} is moved during this period. Now observe that $|S_r| = \frac{n}{C^r}$, and the number of weight W_{r+1} servers available to the algorithm is $(\ell - \varepsilon)k_{r+1} = |S_r| - \varepsilon k_{r+1} = |S_r| \left(1 - \frac{1}{C}\right)$. Thus, there is a subset S_{r+1} of S of size $\frac{|S_r|}{C} = \frac{n}{C^{r+1}}$ where no server of weight W_{r+1} appears during this input sub-sequence. Consider the recursive call Generate$(S_0, \ldots, S_r, S_{r+1})$ in line 1.8. The induction hypothesis implies that the movement cost during this recursive call is at least $M^{\ell-1} \geq W_{r+1}$.

Thus, we have shown that the movement cost during each iteration of the **repeat-until** loop during Generate$(S_0, \ldots, S_r)$ is at least W_{r+1}. Since there are L_r such iterations, the overall movement cost is at least $W_{r+1} \cdot L_r = M^{\ell-1}$. This completes the proof of the induction hypothesis, and implies the lemma. ◀

A Constant-Factor Approximation for Quasi-Bipartite Directed Steiner Tree on Minor-Free Graphs

Zachary Friggstad ✉

Ramin Mousavi ✉
Department of Computing Science, University of Alberta, Canada

Abstract

We give the first constant-factor approximation algorithm for quasi-bipartite instances of Directed Steiner Tree on graphs that exclude fixed minors. In particular, for K_r-minor-free graphs our approximation guarantee is $O(r \cdot \sqrt{\log r})$ and, further, for planar graphs our approximation guarantee is 20.

Our algorithm uses the primal-dual scheme. We employ a more involved method of determining when to buy an edge while raising dual variables since, as we show, the natural primal-dual scheme fails to raise enough dual value to pay for the purchased solution. As a consequence, we also demonstrate integrality gap upper bounds on the standard cut-based linear programming relaxation for the Directed Steiner Tree instances we consider.

1 Introduction

In the Directed Steiner Tree (DST) problem, we are given a directed graph $G = (V, E)$ with edge costs $c(e) \geq 0$ for all $e \in E$, a root node $r \in V$, and a collection of terminals $X \subseteq V \setminus \{r\}$. The nodes in $V \setminus (X \cup \{r\})$ are called *Steiner* nodes. The goal is to find a minimum cost subset $F \subseteq E$ such that there is an $r - t$ path using only edges in F for every terminal $t \in X$. Note any feasible solution that is inclusion-wise minimal must be an arborescence rooted at r. Throughout, we let n denote $|V|$.

One key aspect of DST lies in the fact that it generalizes many other important problems, e.g. Set Cover, (non-metric, multilevel) Facility Location, and Group Steiner Tree. Halperin and Krauthgamer [23] showed Group Steiner Tree cannot be approximated within $O(\log^{2-\epsilon} n)$ for any $\epsilon > 0$ unless NP $\subseteq$ ZTIME $(n^{\text{polylog}\,(n)})$ and therefore the same result holds for DST.

Building on a height-reduction technique of Calinescu and Zelikovsky [5, 36], Charikar et al. give the best approximation for DST which is an $O(|X|^\epsilon)$-approximation for any constant $\epsilon > 0$ [8] and also an $O(\log^3 |X|)$-approximation in $O(n^{\text{polylog}(|X|)})$ time (quasi-polynomial time). More recently, Grandoni, Laekhanukit, and Li [21] obtained a quasi-polynomial time $O(\frac{\log^2 |X|}{\log \log |X|})$-approximation factor for Directed Steiner Tree which is the best possible for quasi-polynomial time algorithms, assuming both the Projection Game Conjecture

and NP $\not\subseteq \bigcap_{0<\delta<1}$ ZTIME(2^{n^δ}). Ghuge and Nagarajan [18] studied a variant of DST called the Directed Tree Orienteering problem and presented an $O(\frac{\log |X|}{\log\log |X|})$-approximation in quasi-polynomial time which yields the same approximation guarantee as in [21] for DST.

Methods based on linear programming have been less successful. Zosin and Khuller [38] showed the integrality gap of a natural flow-based LP relaxation is $\Omega(\sqrt{|X|})$ but n, the number of vertices, in this example is exponential in terms of $|X|$. More recently, Li and Laekhanukit [27] provided an example showing the integrality gap of this LP is at least polynomial in n. On the positive side, [33] shows for ℓ-layered instances of DST that applying $O(\ell)$ rounds of the Lasserre hierarchy to a slight variant of the natural flow-based LP relaxation yields a relaxation with integrality gap $O(\ell \cdot \log |X|)$. This was extended to the LP-based Sherali-Adams and Lovász-Schrijver hierarchies by [14].

We consider the cut-based relaxation (**Primal-LP**) for DST, which is equivalent to the flow-based relaxation considered in [38, 27]; the flow-based relaxation is an extended formulation of (**Primal-LP**). Let $\delta^{in}(S)$ be the set of directed edges entering a set $S \subseteq V$,

$$\begin{aligned} \text{minimize:} \quad & \sum_{e\in E} c(e)\cdot x_e && \textbf{(Primal-LP)} \\ \text{subject to:} \quad & x(\delta^{in}(S)) \geq 1 \quad \forall S \subseteq V \setminus \{r\},\ S \cap X \neq \emptyset && (1) \\ & x \geq 0 \end{aligned}$$

It is useful to note that if $|X| = 1$ (the shortest $s-t$ path problem) or $X \cup \{r\} = V$ (the minimum cost arborescence problem), the extreme points of (**Primal-LP**) are integral, see [29] and [11] respectively.

The undirected variant of Steiner Tree has seen more activity[1]. A series of papers steadily improved over the simple 2-approximation [37, 25, 30, 32] culminating in a $\ln 4 + \epsilon$ for any constant $\epsilon > 0$ [4]. Bern and Plassmann [2] showed that unless P = NP there is no approximation factor better than $\frac{96}{95}$ for Steiner Tree. However, there is a PTAS for Steiner Tree on planar graphs [3] and more generally [1] obtains a PTAS for Steiner Forest on graphs of bounded-genus.

Another well-studied restriction of Steiner Tree is to quasi-bipartite graphs. These are the instances where no two Steiner nodes are connected by an edge (i.e., $V \setminus (X \cup \{r\})$ is an independent set). Quasi-bipartite instances were first studied by Rajagopalan and Vazirani [31] in order to study the bidirected-cut relaxation of the Steiner Tree problem: this is exactly (**Primal-LP**) where we regard both directions of an undirected edge as separate entities. Feldmann et al. [13] studied Steiner Tree on graphs that do not have an edge-induced claw on Steiner vertices, i.e., no Steiner vertex with three Steiner neighbours, and presented a faster ln(4)-approximation than the algorithm of [4]. Currently, the best approximation in quasi-bipartite instances of Steiner Tree is $\frac{73}{60}$-approximation [19].

A natural question is to study the complexity of DST on these restricted instances. Hibi and Fujito [24] presented an $O(\log |X|)$-approximation algorithm for this case. Assuming P $\neq$ NP, this result asymptotically matches the lower bound $(1 - o(1)) \cdot \ln |X|$ for any $\epsilon > 0$; this lower bound comes from the hardness of Set Cover [12, 10] and the fact that the quasi-bipartite DST problem generalizes the Set Cover problem. Friggstad, Könemann, and Shadravan [15] showed that the integrality gap of (**Primal-LP**) is also $O(\log |X|)$ by a primal-dual algorithm and again this matches the lower bound on the integrality gap of this

[1] One usually does not specify the root node in Steiner Tree, the goal is simply to ensure all terminals are connected.

LP up to a constant. Chan et al. [7] studied the k-connected DST problem on quasi-bipartite instances in which the goal is to find a minimum cost subgraph H such that there are k edge-disjoint paths (in H) from r to each terminal in X. They gave an upper bound of $O(\log |X| \cdot \log k)$ on the integrality gap of the standard cut-based LP (put k instead of 1 in the RHS of the constraints in (**Primal-LP**)) by presenting a polynomial time randomized rounding algorithm.

Very recently, [17] show a combinatorial $O(\log |X|)$-approximation algorithm for DST on planar graphs based on shortest path separators in planar graph by Thorup [35]. It is also worth noting that Demaine, Hajiaghayi, and Klein [9] show that if one takes a standard flow-based relaxation for DST in planar graphs and further constraints the flows to be "non-crossing", then the solution can be rounded to a feasible DST solution while losing only a constant factor in the cost. To date, we do not know how to compute a low-cost, non-crossing flow in polynomial time for DST instances on planar graphs.

It remains an open question whether DST on planar graphs admits a constant factor approximation or even a PTAS, or not. We make some progress on this question. We show quasi-bipartite DST on planar graphs and more generally graphs excluding a fixed minor admit a constant factor approximation. In contrast to the approach in [17], our algorithm is LP-based and bounds the integrality gap of the natural cut-based LP. Our algorithm also works in the more general setting of minor-free graphs, whereas the DST approximation in [17] is specific only to planar graphs.

1.1 Primal-Dual Approximations for Steiner Tree Problems

Consider the Node-Weighted Steiner Tree (NWST) problem which is similar to undirected Steiner Tree except the weight function is on the Steiner vertices instead of edges and can also be viewed as a special case of DST. Guha et al. [22] presented a primal-dual algorithm with guarantee of $O(\ln n)$ which is asymptotically tight since NWST also generalizes set cover. Könemann, Sadeghian, and Sanità [26] give an $O(\log n)$-approximation using the primal-dual framework for a generalization of NWST called Node-Weighted Prize Collecting Steiner Tree[2].

Demaine, Hajiaghayi, and Klein [9] considered a generalization of NWST called Node-Weighted Steiner Forest (NWSF) on planar graphs and using the generic primal-dual framework of Goemans and Williamson [20] they showed a 6-approximation and further they extended their result to minor-free graphs. Later Moldenhauer [28] simplified their analysis and showed an approximation guarantee of 3 for NWSF on planar graphs.

An interesting, non-standard use of the primal-dual scheme is in the work of Chakrabarty, Devanur, and Vazirani [6] for undirected, quasi-bipartite instances of Steiner Tree. They introduce a new "simplex-embedding" LP relaxation and their primal-dual scheme raises dual variables with different rates. It is worth noting that although they also obtain upper bound for the integrality gap of the so-called *bidirected cut relaxation* (BCR) of quasi-bipartite instances of Steiner Tree, the algorithm and the simplex-embedding LP relaxation itself are valid only in the undirected setting.

[2] A key aspect of their algorithm is that it is also *Lagrangian multiplier preserving*.

1.2 Our contributions

We present a primal-dual algorithm for quasi-bipartite DST on minor-free graphs.

Generally, it is difficult to effectively utilize primal-dual algorithms in directed network design problems. This is true in our setting as well: we begin by showing a standard primal-dual algorithm (similar to the primal-dual algorithm for the minimum-cost arborescence problem) does not grow sufficiently-large dual to pay for the set of edges it purchases within any constant factor.

We overcome this difficulty by highlighting different roles for edges in connecting the terminals to the root. For some edges, we maintain two slacks: while raising dual variables these two slacks for an edge may be filled at different rates (depending on the edge's role for the various dual variables being raised) and we purchase the edge when one of its slacks is exhausted. Furthermore, unlike the analysis of standard primal-dual algorithms where the charging scheme is usually more local (i.e., charging the cost of purchased edges to the dual variables that are "close by"), we need to employ a more global charging scheme. Our approach also provides an $O(1)$ upper bound on the integrality gap of the natural cut-based relaxation (**Primal-LP**) for graphs that exclude a fixed minor.

We summarize our results here.

▶ **Theorem 1.** *There is an $O(r \cdot \sqrt{\log r})$-approximation algorithm for* Directed Steiner Tree *on quasi-bipartite, K_r-minor free graphs. Moreover, the algorithm gives an upper bound of $O(r \cdot \sqrt{\log r})$ on the integrality gap of* (**Primal-LP**) *for DST instances on such graphs.*

▶ Remark 2. The running time of our algorithm is $O(|V|^c)$ where c is a fixed constant that is independent of r. Also, we only require that every (simple) minor of the graph has bounded average degree to establish our approximation guarantee. In particular, if every minor of the input (quasi-bipartite) graph has degree at most d, then the approximation factor will be $O(d)$.

▶ **Theorem 3.** *There is a 20-approximation algorithm for* Directed Steiner Tree *on quasi-bipartite, planar graphs. Moreover, the algorithm gives an upper bound of 20 on the integrality gap of* (**Primal-LP**) *for* Directed Steiner Tree *instances on such graphs.*

We also verify that Steiner Tree (and, thus, Directed Steiner Tree) remains NP-hard even when restricted to quasi-bipartite, planar instances. Similar results are known, but we prove this one explicitly since we were not able to find this precise hardness statement in any previous work.

▶ **Theorem 4.** *Steiner Tree instances on bipartite planar graphs where the terminals are on one side and the Steiner nodes are on the other side is* NP*-hard.*

The above hardness result shows DST instances on quasi-bipartite, planar graphs is NP-hard as well.

1.3 Organization of the paper

In Section 2, we state some definition and notation where we use throughout the paper. In Section 3 we present an example that shows the most natural primal-dual algorithm fails to prove our approximation results, this helps the reader understand the key difficulty we need to overcome to make a primal-dual algorithm work and motivates our more refined approach. In Section 4 we present our primal-dual algorithm and in Section 5 we present the analysis.

The analysis contains three main subsections where in each section we present a charging scheme. The first two charging schemes are straightforward but the last one requires some novelty. Finally, we put all these charging schemes together in Subsection 5.4 and prove Theorems 1 & 3. The proof of the hardness result (Theorem 4) is deferred to the full version of the paper [16].

2 Preliminaries

In this paper, graphs are simple directed graphs unless stated otherwise. By simple we mean there are no parallel edges[3]. Note that we can simply keep the cheapest edge in a group of parallel edges if the input graph is not simple; the optimal value for DST problem does not change.

Throughout this paper, we fix a directed graph $G = (V, E)$, a cost function $c : E \rightarrow \mathbb{R}_{\geq 0}$, a root r, a set of terminals $X \subseteq V \setminus \{r\}$, and no edge between any two Steiner nodes, as the input to the DST problem. We denote the optimal value for DST instance by OPT.

Given a subgraph G' of G we define $\delta^{in}_{G'}(S) = \{e = (u, v) \in E(G') : \ u \in V \setminus S, \ v \in S\}$ (i.e., the set of edges in G' entering S) we might drop the subscript if the underlying subgraph is G itself. For an edge $e = (u, v)$, we call u the **tail** and v the **head** of e. By a **dipath** we mean a directed path in the graph. By **SCCs** of $F \subseteq E$ we mean the strongly connected components of (V, F) that contains either the root node or at least one terminal node. So for example, if a Steiner node is a singleton strongly connected component of (V, F) then we do not refer to it as an SCC of F. Due to the quasi-bipartite property, these are the only possible strongly connected components in the traditional sense of (V, F) that we will not call SCCs. Observe F is a feasible DST solution if and only if each SCC is reachable from r.

An *arborescence* $T = (V, E)$ rooted at $r \in V$ is a directed tree oriented away from the root such that every vertex in V is reachable from r. By *height* of a vertex u in T we mean the number of edges between r (the root) and u in the dipath from r to u in T. We let T_u denotes the subtree of T rooted at u.

Our discussions, algorithm, and the analysis rely on the concept of *active sets*, so we define them here.

▶ **Definition 5** (Violated set). *Given a DST instance and a subset $F \subseteq E$, we say $S \subseteq V \setminus \{r\}$ where $S \cap X \neq \emptyset$ is a* violated *set with respect to F if $\delta^{in}_F(S) = \emptyset$.*

▶ **Definition 6** (Active set). *Given a DST instance and a subset $F \subseteq E$, we call a minimal violated set (no proper subset of it, is violated) an* active *set (or active moat) with respect to F.*

We use the following definition throughout our analysis and (implicitly) in the algorithm.

▶ **Definition 7** (F-path). *We say a dipath P is a F-path if all the edges of P belong to $F \subseteq E$. We say there is a F-path from a subset of vertices to another if there is a F-path from a vertex of the first set to a vertex of the second set.*

In quasi-biparitite graphs, active moat have a rather "simple" structure, our algorithm will leverage the following properties.

▶ **Lemma 8.** *Consider a subset of edges F and let A be an active set with respect to F. Then, A consists of exactly one SCC C_A of F, and any remaining in $A \setminus C_A$ are Steiner nodes. Furthermore, for every Steiner node in $A \setminus C_A$ there are edges in F that are oriented from the Steiner node to C_A.*

[3] Two edges are parallel if their endpoints are the same and have the same orientation.

Proof. By definition of violated sets, A does not contain r. If A contains only one terminal, then the first statement holds trivially. So consider two terminals t and t' in A. We show there is a F-path from t to t' and vice versa. Suppose not and wlog assume there is no F-path from t' to t. Let $B := \{v \in A : \exists F - path\ from\ v\ to\ t\}$. Note that B is a violated set and $B \subsetneq A \setminus \{t'\}$ which violates the fact that A is a minimal violated set. Therefore, exactly one SCC of F is in A.

Next we prove the second statement. Let s be a Steiner node (if exists) in $A \setminus C_A$. If there is no edge in F oriented from s to C_A, then $A \setminus \{s\}$ is a violated set, because the graph is quasi-bipartite and the fact that A is a violated set itself, contradicting the fact that A is a minimal violated set. ◀

Note that the above lemma limits the interaction between two active moats. More precisely, two active moats can only share Steiner nodes that lie outside of the SCCs in the moats.

▶ **Definition 9** (The SCC part of active moats). *Given a set of edges F and an active set A (with respect to F), we denote by C_A the SCC (with respect to F) inside A.*

We use C_A rather than C_A^F because the set F will always be clear from the context.

Finally we recall bounds on the size of K_r-minor free graphs that we use at the end of our analysis.

▶ **Theorem 10** (Thomason 2001 [34]). *Let $G = (V, E)$ be a K_r-minor free graph with no parallel edges. Then, $|E| \leq O(r \cdot \sqrt{\log r})|V|$ and this bound is asymptotically tight. The constant in the O-notation in the above theorem is at most 3 for large enough r.*

Bipartite planar graphs are K_5-minor free, but we know of explicit bounds sizes. The following is the consequence of Euler's formula that will be useful in our tighter analysis for quasi-bipartite, planar graphs.

▶ **Lemma 11.** *Let $G = (V, E)$ be a bipartite planar graph with no parallel edges. Then, $|E| \leq 2 \cdot |V|$.*

3 Standard primal-dual algorithm and a bad example

Given a DST instance with $G = (V, E)$, $r \in V$ as the root, and $X \subseteq V - \{r\}$ as the terminal set, we define $\mathcal{S} := \{S \subsetneq V : r \notin S,\ and\ S \cap X \neq \emptyset\}$. We consider the dual of (**Primal-LP**).

$$\text{maximize:} \quad \sum_{S \in \mathcal{S}} y_S \qquad \textbf{(Dual-LP)}$$

$$\text{subject to:} \quad \sum_{\substack{S \in \mathcal{S}: \\ e \in \delta^{in}(S)}} y_S \leq c(e) \quad \forall e \in E \qquad (2)$$

$$y \geq 0$$

As we discussed in the introduction, a standard primal-dual algorithm solves arborescence problem on any directed graph [11]. Naturally, our starting point was to investigate this primal-dual algorithm for DST instances. We briefly explain this algorithm here. At the beginning we let $F := \emptyset$. Uniformly increase the dual constraints corresponding to active moats and if a dual constraint goes tight, we add the corresponding edge to F. Update the active sets based on F (see Definition 6) and repeat this procedure. At the end, we do a reverse delete, i.e., we go over the edges in F in the reverse order they have been added to F and remove it if the feasibility is preserved. Unfortunately, for DST instances in quasi-bipartite planar graphs, there is a bad example (see Figure 1), that shows the total growth of the dual variables is $2 + k \cdot \epsilon$ while the optimal solution costs $2 + k + k \cdot \epsilon$ for arbitrarily large k. So the dual objective is not enough to pay for the cost of the edges in F (i.e., we have to multiply the dual objective by $O(k)$ to be able to pay for the edges in F).

What is the issue and how can we fix it? One way to get an $O(1)$-approximation is to ensure at each iteration the number of edges (in the final solution) whose dual constraints are losing slack at this iteration is proportioned to the number of active moats. In the bad example (Figure 1), when the bottom moat is paying toward the downward blue edges, there are only two active moats but there are k downward blue edges that are currently being paid for by the growing dual variables.

To avoid this issue, we consider the following idea: once the bottom active moat grew enough so that the dual constraints corresponding to all the downward blue edges are tight we purchase an arbitrary one of them, say (r, z_k) for our discussion here. Once the top active moat reaches z_1 instead of skipping the payment for this edge (since the dual constraint for (w_2, z_1) is tight), we let the active moat pay towards this edge again by ignoring previous payments to the edge, and then we purchase it once it goes tight. Note that now we violated the dual constraint for (w_2, z_1) by a multiplicative factor of 2. Do the same for all the other downward blue edges (except (r, z_k) that was purchased by the bottom moat). Now it is easy to see that we grew enough dual objective to approximately pay for the edges that we purchased. We make this notion precise by defining different roles for downward blue edges in the next section. In general, each edge can serve up to two roles and has two "buckets" in which it receives payment: each moat pays towards the appropriate bucket depending on the role that edge serves for that moat. An edge is only purchased if one of its buckets is filled and some tiebreaking criteria we mention below is satisfied.

4 Our primal-dual algorithm

As we discussed in the last section, we let the algorithm violate the dual constraint corresponding to an edge by a factor of 2 and hence we work with the following modified Dual-LP:

$$\begin{aligned}
\text{maximize:} \quad & \sum_{S \in \mathcal{S}} y_S && \textbf{(Dual-LP-Modified)} \\
\text{subject to:} \quad & \sum_{\substack{S \in \mathcal{S}: \\ e \in \delta^{in}(S)}} y_S \leq 2 \cdot c(e) \quad \forall e \in E && (3) \\
& y \geq 0
\end{aligned}$$

Note that the optimal value of (**Dual-LP-Modified**) is at most twice the optimal value of (**Dual-LP**) because consider a feasible solution y for the former LP then $\frac{y}{2}$ is feasible for the latter LP.

Let us define the different buckets for each edge that are required for our algorithm.

Antenna, expansion and killer buckets. We say edge $e = (u, v)$ is an *antenna* edge if $u \notin X \cup \{r\}$ and $v \in X$, in other words, if the tail of e is a Steiner node and the head of e is a terminal. For every antenna edge we associate an antenna bucket with size $c(e)$. For every non-antenna edge e, we associate two buckets, namely *expansion* and *killer* buckets, each of size $c(e)$. The semantics of these labels will be introduced below.

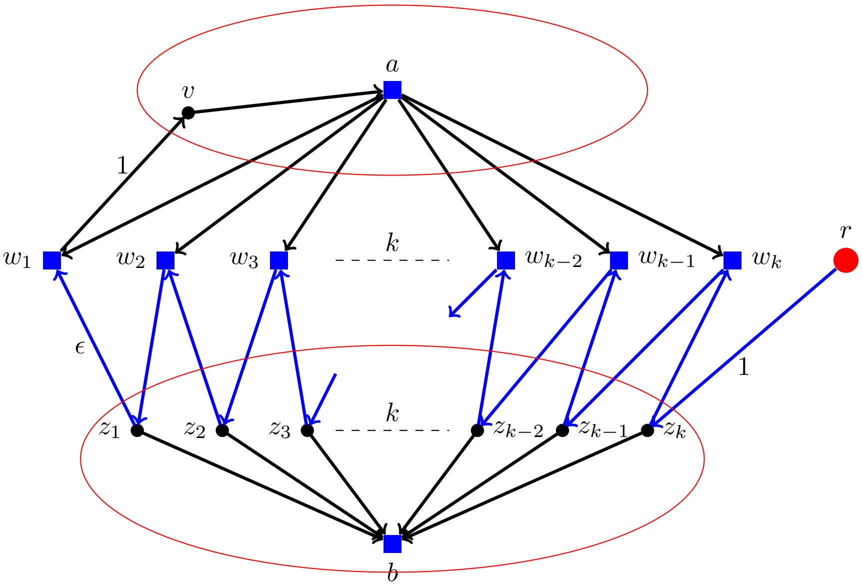

Figure 1 This is an example to show why a standard primal-dual algorithm fails. The square vertices are terminals. The downward blue edges (i.e., (w_i, z_{i-1})'s for $2 \leq i \leq k$) have cost 1, the upward blue edges (i.e., (z_i, w_i)'s for $1 \leq i \leq k$) have cost ϵ. The cost of the black edges are 0 except (w_1, v) who has cost 1. Note any feasible solution contains all the blue edges and the cost of an optimal solution is $k + k \cdot \epsilon + 1$. However, it is easy to see the total dual variables that are grown using a standard primal-dual algorithm is $2 + k \cdot \epsilon$.

Now we, informally, describe our algorithm, see Algorithm 1 for the detailed description. Recall the definition of active moats (Definition 6).

Growth phase. At the beginning of the algorithm we set $F := \emptyset$ and every singleton terminal is an active moat. As long as there is an active moat with respect to F do the following: uniformly increase the dual variables corresponding to the active moats. Let $e \notin F$ be an antenna edge with its head in an active moat, then the active moat pays towards the antenna bucket of e. Now suppose $e = (u, v) \notin F$ is a non-antenna edge, so $u \in X \cup \{r\}$. For every active moat A that contains v, if C_A (see Definition 9) is a subset of an active set A' with respect to $F \cup \{e\}$, then A pays toward the expansion bucket of e and otherwise A pays towards the killer bucket of e.

Uniformly increase the dual variables corresponding to active moats until a bucket for an edge e becomes full (antenna bucket in case e is an antenna edge, and expansion or killer bucket if e is a non-antenna edge), add e to F. Update the set of active moats $\mathcal{A}$ according to set F.

Pruning. Finally, we do the standard reverse delete meaning we go over the edges in F in the reverse order they have been added and if the resulting subgraph after removing an edge is still feasible for the DST instance, remove the edge and continue.

The following formalizes the different roles of a non-antenna edge that we discussed above.

▶ **Definition 12** (Relation between non-antenna edges and active moats). *Given a subset of edges $F \subseteq E$, let $\mathcal{A}$ be the set of all active moats with respect to F. Consider a non-antenna edge $e = (u, v)$ (so $u \in X \cup \{r\}$). Suppose $v \in A$ where $A \in \mathcal{A}$. Then,*

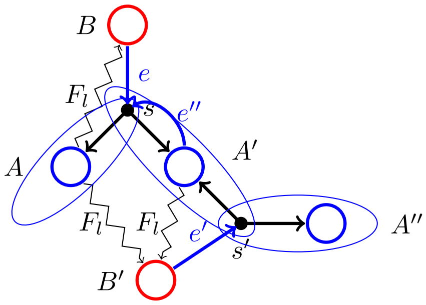

Figure 2 Above is a part of a graph at the beginning of iteration l in the algorithm. F_l denotes the set F at this iteration. The circles are SCCs in (V, F_l). Blue circles are inside some active moats shown with ellipses. The black dots s and s' are Steiner nodes. The black edges and the zigzag paths are in F_l. The edges e, e', and e'' have not been purchased yet (i.e., $e, e', e'' \notin F_l$). Since C_A is a subset of an active moat namely $A \cup B \cup \{s\}$ with respect to $F_l \cup \{e\}$, e is an expansion edge with respect to A. However, e is a killer edge with respect to A' and e'' is a killer edge with respect to A. Finally, e' is a killer edge with respect to A' (and A'') because there is a $F_l \cup \{e'\}$-path from C_A to $C_{A'}$ (and $C_{A''}$), therefore $C_{A'}$ (and $C_{A''}$) cannot be inside an active moat with respect to $F_l \cup \{e'\}$.

- *we say e is an expansion edge with respect to A under F if there is a subset of vertices A' that is active with respect to $F \cup \{e\}$ such that $C_A \subsetneq A'$,*
- *otherwise we say e is a killer edge with respect to A.*

For example, all exiting edges from r that are not in F is a killer edge with respect to any active moat (under F) it enters. See Figure 2 for an illustration of the above definition.

Intuition behind this definition. A non-antenna edge $e = (u, v)$ is a killer edge with respect to an active moat A, if and only if, there is a dipath in $F \cup \{e\}$ from r or $C_{A'}$ to C_A where $A' \neq A$ is an active moat with respect to F. Note that adding e to F will make the dual variable corresponding to A stop growing and that is why we call e a killer edge with respect to A. For example, in Figure 2, both e and e' are killer edges with respect to A'. On the other hand, if $e = (u, v)$ is an expansion edge with respect to A, then C_A will be a part of a "bigger" active moat with respect to $F \cup \{e\}$ and hence the name expansion edge for e. For example, in Figure 2, e is an expansion edge with respect to A because in $F \cup \{e\}$, $A \cup B \cup \{s\}$ is an active moat whose SCC contains C_A.

The complete description of the algorithm is given in Appendix A. Note that the purchased edge e_l at iteration l enters some active moat at iteration l.

After the algorithm finishes, then we label non-antenna edges by expansion/killer as determined by the following rule:

▶ **Definition 13** (Killer and expansion edges)**.** *Consider iteration l of the algorithm where we added a non-antenna edge e_l to F. We label e_l as expansion (killer) if the expansion (killer) bucket of e becomes full at iteration l, break ties arbitrarily.*

Following remark helps to understand the above definition better.

▶ Remark 14. It is possible that one bucket becomes full for an edge yet we do not purchase the edge with that bucket label (killer or expansion) due to tiebreaking when multiple buckets become full. For example, this would happen in our bad example for the downward blue edges: their killer buckets are full yet all but one are purchased as expansion edges.

Let us explain the growth phase of Algorithm 1 on the bad example in Figure 1. Since the early iterations of the algorithm on this example are straightforward, we start our explanation from the iteration where the active moats are $A = \{b, z_1, z_2, ..., z_k\}$ and $A' = \{a, v\}$.

Every (w_i, z_{i-1}) for $2 \leq i \leq k$ is a killer edge with respect to A so A pays toward the killer buckets of these edges. At the same iteration, (w_1, v) is an expansion edge with respect to A' so A' pays toward the expansion bucket of this edge. Now the respected buckets for all mentioned edges are full. Arbitrarily, we pick one of these edges, let us say (w_k, z_{k-1}), and add it to F. Then, A stops growing. In the next iteration, we only have one active moat A'. Since (w_1, v) is still expansion edge with respect to A' and its (expansion) bucket is full, in this iteration we add (w_1, v) to F and after updating the active moats, again we only have one active moat $\{a, v, w_1\}$ which by abuse of notation we denote it by A'. Next iteration we buy the antenna edge (z_1, w_1) and the active moat now is $A' = \{a, v, w_1, z_1\}$. In the next iteration, the crucial observation is that the killer bucket of (w_2, z_1) is full (recall the A payed toward the killer bucket of (w_2, z_1)); however, (w_2, z_1) is an expansion edge with respect to A' so A' will pay towards its expansion bucket and then purchases it. Similarly, the algorithm buys (w_i, z_{i-1})'s except (w_k, z_{k-1}) because this edge is in F already (recall we bought this edge with A). Finally, (r, z_k) is a killer edge with respect to the active moat in the last iteration and we purchase it.

5 The analysis

Because of the space constraints, we defer most of the proofs to the full version of the paper [16] and defer to the full version.

The general framework for analyzing primal-dual algorithms is to use the dual constraints to relate the cost of purchased edges and the dual variables. However, here we do not use the dual constraints and rather we use the buckets we created for each edge. Recall $\overline{F}$ is the solution output by Algorithm 1. We define $\overline{F}_{\text{Killer}}$ to be the set of edges in $\overline{F}$ that was purchased as killer edge (recall definition 13). Similarly define $\overline{F}_{\text{Exp}}$ and $\overline{F}_{\text{Ant}}$. For each iteration l, we denote by F_l the set F at this iteration, $\mathcal{A}_l$ denotes the set of active moats with respect to F_l, and ϵ_l is the amount we increased the dual variables (corresponding to active moats) with at iteration l. Finally, Let y^* be the dual solution for (**Dual-LP-Modified**) constructed in the course of the algorithm. We use the following notation throughout the analysis.

▶ **Definition 15.** *Fix an iteration l. For any $A \in \mathcal{A}_l$, let*

$$\Delta^l_{\text{Killer}}(A) := \{e \in \overline{F}_{\text{Killer}} : \ e \textit{ is killer with respect to } A \textit{ under } \ F_l\},$$

in other words, $\Delta^l_{\text{Killer}}(A)$ is the set of all killer edges in $\overline{F}$ such that they are killer edge with respect to A at iteration l. Similarly define $\Delta^l_{\text{Exp}}(A)$.

Let $\Delta^l_{\text{Ant}}(A) := \{e \in \overline{F}_{\text{Ant}} : \ e \in \delta^{in}(A)\}$. Finally, we define

$$\Delta^l(A) := \Delta^l_{\text{Killer}}(A) \cup \Delta^l_{\text{Exp}}(A) \cup \Delta^l_{\text{Ant}}(A).$$

Note $\Delta^l_{\text{Killer}}(A)$, $\Delta^l_{\text{Exp}}(A)$, and $\Delta^l_{\text{Ant}}(A)$ are pairwise disjoint for any $A \in \mathcal{A}_l$.

Suppose we want to show that the performance guarantee of Algorithm 1 is $2 \cdot \alpha$ for some $\alpha \geq 1$, it suffices to show the following: for any iteration l we have

$$\sum_{S \in \mathcal{A}_l} |\Delta^l(S)| \leq \alpha \cdot |\mathcal{A}_l|. \tag{4}$$

Once we have (4), then the $(2 \cdot \alpha)$-approximation follows easily:

$$
\begin{aligned}
\sum_{e \in \overline{F}} c(e) &= \sum_{e \in \overline{F}_{\text{Killer}}} \sum_{l} \sum_{\substack{S \in \mathcal{A}_l: \\ e \in \Delta^l_{\text{Killer}}(S)}} \epsilon_l + \sum_{e \in \overline{F}_{\text{Exp}}} \sum_{l} \sum_{\substack{S \in \mathcal{A}_l: \\ e \in \Delta^l_{\text{Exp}}(S)}} \epsilon_l + \sum_{e \in \overline{F}_{\text{Ant}}} \sum_{l} \sum_{\substack{S \in \mathcal{A}_l: \\ e \in \Delta^l_{\text{Ant}}(S)}} \epsilon_l && (5)\\
&= \sum_{l} \epsilon_l \cdot \sum_{S \in \mathcal{A}_l} |\Delta^l(S)| && (6)\\
&\leq \alpha \cdot \sum_{l} |\mathcal{A}_l| \epsilon_l && (7)\\
&= \alpha \cdot \sum_{S \subseteq V \setminus \{r\}} y^*_S && (8)\\
&\leq \alpha \cdot \big(2 \cdot \mathrm{OPT}(\mathbf{Dual-LP})\big) && (9)\\
&= 2 \cdot \alpha \cdot \mathrm{OPT}(\mathbf{Primal-LP}) && (10)\\
&\leq 2 \cdot \alpha \cdot \mathrm{OPT}, && (11)
\end{aligned}
$$

where the first equality follows from the algorithm, the second equality is just an algebraic manipulation, (7) follows from (4). Equality (8) follows from the fact we uniformly increased the dual variables corresponding to active moats by ϵ_l at iteration l, (9) follows from feasibility of $\frac{y^*}{2}$ for (**Dual-LP**), and (10) follows from strong duality theorem for linear programming.

It remains to show (4) holds. Consider iteration l. Using the bound on the total degree of nodes in G (using minor-free properties) to show (4), it suffices to bound the number of edges in $\bar{F}_{\text{Ant}} \cup \bar{F}_{\text{Killer}} \cup \bar{F}_{\text{Exp}}$ that are being paid by some active moat at iteration l, by $O(|\mathcal{A}_l|)$. We provide charging schemes for each type of edges, separately. Since G is quasi-bipartite, it is easy to show that for each active moat $A \in \mathcal{A}_l$, there is at most one antenna edge in $\bar{F}$ that enters A, this is proved in Section 5.1. The charging scheme for killer edges is also simple as one can charge a killer edge to an active moat that it kills; this will be formalized in Section 5.2. However, the charging scheme for expansion edges requires more care and novelty. The difficulty comes from the case that an expansion edge is not pruned because it would disconnect some terminals that are not part of any active moat that e is entering this iteration.

Our charging scheme for expansion edges is more global. In a two-stage process, we construct an auxiliary tree that encodes some information about which nodes can be reached from SCCs using edges in F_l (which is the information we used in the definition of expansion edge). Then using a token argument, we leverage properties of our construction to show the number of expansion edges is at most twice the number of active moats in any iteration. These details are presented in 5.3. Finally, in Section 5.4 we put all the bounds we obtained together and derive our approximation factors.

5.1 Counting the number of antenna edges in an iteration

Fix an iteration l. Recall F_l denotes the set F at iteration l, and $\mathcal{A}_l$ denotes the set of active moats with respect to F_l. It is easy to bound the number of antenna edges in $\overline{F}$ against $|\mathcal{A}_l|$. We do this in the next lemma.

▶ **Lemma 16.** *At the beginning of each iteration l, we have* $\sum\limits_{A \in \mathcal{A}_l} |\Delta^l_{\text{Ant}}(A)| \leq |\mathcal{A}_l|$.

5.2 Counting the number of killer edges in an iteration

We introduce a notion called *alive* terminal which helps us to bound the number of killer edges at a fixed iteration against the number of active moats in that iteration. Also this notion explains the name killer edge. Throughout the algorithm, we show every active moat contains exactly one alive terminal and every alive terminal is in an active moat.

We consider how terminals can be "killed" in the algorithm by associating active moats with terminals that have not yet been part of a moat that was killed. At the beginning of the algorithm, we mark every terminal alive, note that every singleton terminal set is initially an active moat as well. Let $e_l = (u, v)$ be the edge that was added to F_l at iteration l. If $e_l = (u, v)$ is a non-antenna edge, then for every active set A such that e_l is a killer edge with respect to A under F_l, mark the alive terminal in A as *dead*[4]. If $e_l = (u, v)$ is an antenna edge, then for every active moat A such that $e_l \in \delta^{in}(A)$ and C_A is **not** in any active moat with respect to $F_l \cup \{e_l\}$, then mark the alive terminal in A as dead[5].

The important observation here is that by definition, if e_l is a killer edge, then there must be an active set that satisfies the above condition, hence there is at least one alive terminal that will be marked dead because of e_l. In the case that e_l is bought as killer edge, arbitrarily pick an alive terminal t_{e_l} that dies because of e_l and assign e_l to t_{e_l}. Note that t_{e_l} was alive until e_l was added to F_l.

▶ **Definition 17.** *Fix an iteration l. We define*

$$\overline{F}^{l}_{\text{Killer}} := \bigcup_{A \in \mathcal{A}_l} \Delta^{l}_{\text{Killer}}(A),$$

in other words, $\overline{F}^{l}_{\text{Killer}}$ is the set of all killer edges in $\overline{F}$ such that some active moat(s) is paying toward their killer bucket at iteration l.

Now we can state the main lemma of this section.

▶ **Lemma 18.** *At the beginning of each iteration l, we have $|\overline{F}^{l}_{\text{Killer}}| \leq |\mathcal{A}_l|$.*

Note that the above lemma does not readily bound $\sum_{A \in \mathcal{A}_l} |\Delta^{l}_{\text{Killer}}(A)|$ against $|\mathcal{A}_l|$ which is required to prove inequality (4). We need the properties of minor-free graphs to do so. In the next section we prove a similar result for expansion edges and then using the properties of the underlying graph, we demonstrate our approximation guarantee.

5.3 Counting the number of expansion edges in an iteration

The high level idea to bound the number of expansion edges is to look at the graph $\overline{F} \cup F_l$ and contract all SCCs[6] of (V, F_l). Then, we construct an auxiliary tree that highlights the role of expansion edges to the connectivity of active moats. Finally, using this tree we provide our charging scheme and show the number of edges in $\overline{F}_{\text{Exp}}$ that are being paid by some active moats at iteration l is at most twice the number of active moats.

[4] It is possible, e_l is bought as an expansion edge but kills some alive terminals. For example, in Figure 2 suppose e is being added to F_l at iteration l as an expansion edge (note that A pays toward the expansion bucket of e). Then, we mark the alive terminal in A' as dead because e is a killer edge with respect to A' under F_l.

[5] For example, suppose the antenna edge $e_l = (u, v) \in \delta^{in}(A)$ is being added to F_l and u is in $C_{A'}$ for some active moat A'. Then, after adding e_l to F_l, we mark the alive terminal in A as dead.

[6] Recall that we do NOT call a Steiner node that is a singleton strongly connected component of (V, F_l) an SCC. So every SCC in (V, F_l) is either $\{r\}$ or contains at least one terminal node.

We fix an iteration l for this section. First let us recall some notation and definition that we use extensively in this section. (i) $\overline{F}$ is the output solution of the algorithm. (ii) $F_l \subseteq E$ is the set of purchased edges in the growing phase up to the beginning of iteration l (i.e., set F in the algorithm at iteration l). (iii) $\mathcal{A}_l$ is the set of active moats with respect to F_l (see Definition 6). Recall each $A \in \mathcal{A}_l$ is consists of an SCC (with respect to edges in F_l) and bunch of Steiner nodes. Denote by C_A the SCC part of A.

We define an analogous of Definition 17 for expansion edges.

▶ **Definition 19.** *Fix an iteration l. Then, we define*

$$\overline{F}^l_{\mathrm{Exp}} := \bigcup_{A \in \mathcal{A}_l} \Delta^l_{\mathrm{Exp}}(A),$$

in other words, $\overline{F}^l_{\mathrm{Exp}}$ is the set of all expansion edges in $\overline{F} \setminus F_l$ such that some active moat(s) is paying toward their expansion bucket at iteration l.

This section is devoted to prove the following inequality.

▶ **Lemma 20.** *At the beginning of each iteration l of the algorithm, we have $|\overline{F}^l_{\mathrm{Exp}}| \leq 2 \cdot |\mathcal{A}_l|$.*

Sketch of the proof. We start by giving a sketch of the proof of Lemma 20. Consider the subgraph $F_l \cup \overline{F}$ of G. Contract every SCC of (V, F_l) and denote the resulting subgraph by H (keeping all copies of parallel edges that may result). For every non-root, non-Steiner node $v \in V(H)$, we call v active if it is a contraction of an SCC that is a subset of an active moat in $\mathcal{A}_l$, otherwise we call v inactive. Note that r is a singleton SCC in (V, F_l) and therefore $r \in V(H)$. We call an edge in $E(H)$ an expansion edge, if its corresponding edge is in $\overline{F}^l_{\mathrm{Exp}}$. Note that every non root vertex in $V(H)$ is either labeled active/inactive, or it is a Steiner node. Lemma 20 follows if we show the number of expansion edges in H is at most twice the number of active vertices in H. As we stated at the beginning of this section, we use an arborescence that highlights the role of expansion edges to the connectivity of active vertices in H. A bit more formally, we show if every expansion edge is "good" with respect to the arborescence, which is formalized below, then every expansion edge is "close" to an active vertex in H and we use this in our charging scheme.

Given an arborescence T, define $\mathrm{Elevel}_T(v)$ to be the expansion level of v with respect to T, i.e., the number of expansion edges on the dipath from r to v in T.

▶ **Definition 21.** *Given an arborescence T and an expansion edge $e = (u, v)$, we say e is a* good *expansion edge with respect to T if one of the following cases happens:*

- *Type 1: If u has an active ancestor w such that* $\mathrm{Elevel}_T(w) = \mathrm{Elevel}_T(u)$.
- *Type 2: If e is not of type 1 and the subtree rooted at u has an active vertex w such that* $\mathrm{Elevel}_T(w) \leq \mathrm{Elevel}_T(u) + 1$.

Every expansion edge that is not of type 1 or type 2, is called a bad *expansion edge with respect to T.*

A starting point for an arborescence that every expansions edge is good, is a shortest path arborescence rooted at r in H where each expansion edge has cost 1 and the rest of the edges have cost 0. However, as Figure 3 shows, there could be some *bad* expansion edges in this arborescence. For example, e is a *bad* expansion edge with respect to the arborescence in Figure 3 (b). Since B_2, the tail of e, is an inactive vertex, there must be an active vertex, namely A_3, that has a dipath from A_3 to B_2 in F_ℓ. Then, we can "cut" the subtree rooted at B_2 and "paste" it under A_3 as shown in Figure 3(c). It is easy to verify that now every expansion edge is good with respect to the arborescence in Figure 3(c). We formalize this

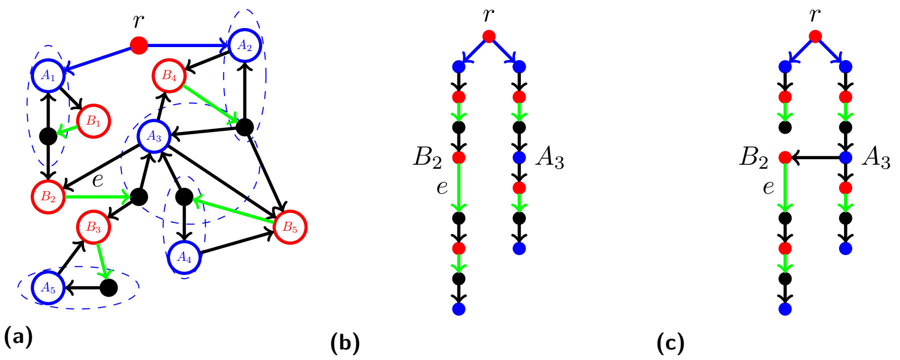

Figure 3 (a) shows subgraph $F_l \cup \bar{F}$ of G, in particular, the SCCs of (V, F_l) are shown with circles but the nodes inside SCCs are not shown for simplicity. The blue SCCs are inside some active moats shown with dashed ellipses. Contracting all the SCCs result in the graph H discussed before. Black edges are in F_l, blue edges are in $\bar{F} \setminus F_l$, and green edges are in $\bar{F}^l_{\text{Exp}}$. In (b), we have a shortest path arborescence rooted at r in H where the cost of edges is one if it is green and zero otherwise. Recall the definition of H at the beginning of this sketched proof. Note that e is a bad expansion edge with respect to this arborescence. In (c), we show how to construct an arborescence using cut-and-paste procedure so that every expansion edge is a good expansion edge in the resulting arborescence.

“cut and paste” procedures in Algorithm 2 in the full version of the paper and prove the output of the algorithm is an arborescence with the property that every expansion edge is good. Given an arborescence that every expansion edge is good, we show there is a rather natural charging scheme that proves Lemma 20.

Charging scheme. At the beginning we label every token **unused**. We process all the vertices with height l. For each expansion edge whose tail has height l we assign an unused token to it and change the label of the assigned token to **used**. Then we move to height $l-1$ and repeat the process. Fix height l. We do the following for every vertex u with this height: if there is no expansion edge whose tail is u then mark u as processed. Otherwise let $(u, v_1), \ldots, (u, v_k)$ be all the expansion edges whose tail is u. Note that by definition of type 1 and 2, either (i) all (u, v_i)'s are type 1 or (ii) all are type 2. Base on these two cases we do the following:

(i) Let $(u, v_1), \ldots, (u, v_k)$ be the expansion edges of type 1. For each $1 \leq i \leq k$ there is at least one unused token in $T^*_{v_i}$. Pick one such unused token and assign it to (u, v_i) and change its label to used. Mark u as processed.

(ii) Let $(u, v_1), \ldots, (u, v_k)$ be the expansion edges of type 2. For each $1 \leq i \leq k$ there is at least one unused token in $T^*_{v_i}$. Pick one such unused token and assign it to (u, v_i) and change its label to used. Furthermore, after this there is at least one more unused token in T^*_u. Mark u as processed.

The proof of correctness of this charging scheme is based on induction on the height l. ◀

5.4 Putting everything together

Fix an iteration l. We use Lemmas 18 & 20 and the properties of graph G to bound $\sum_{A \in \mathcal{A}_l} |\Delta^l_{\text{Killer}}(A) \cup \Delta^l_{\text{Exp}}(A)|$. Consider an active moat A and its SCC C_A. We show there is at most one killer/expansion edge that enters C_A. So the remaining killer/expansion edges must enter some Steiner node in $A \setminus C_A$. We use this fact later.

▷ Claim 22. Fix an iteration l and an active moat $A \in \mathcal{A}_l$. There is at most one edge in $\Delta^l_{\text{Killer}}(A) \cup \Delta^l_{\text{Exp}}(A)$ whose head is in C_A.

Consider the graph $F_l \cup \overline{F}$. Remove all vertices that are not in an active moat at this iteration. For each active moat A, remove all Steiner nodes in $A \setminus C_A$ that are not the head of any edge in $\overline{F}^l_{\text{Killer}} \cup \overline{F}^l_{\text{Exp}}$. Then, for each $A \in \mathcal{A}_l$ contract C_A to a single vertex and call the contracted vertex by C_A. Finally, if there are parallel edges, arbitrarily keep one of them and remove the rest[7]. Call the resulting graph G'.

Now we relate the sum we are interested in to bound with the sum of the indegree of vertices in G'.

▷ Claim 23. For each active moat $A \in \mathcal{A}_l$, we have

$$|\Delta^l_{\text{Killer}}(A) \cup \Delta^l_{\text{Exp}}(A)| \le |\delta^{in}_{G'}(C_A)| + 1. \tag{12}$$

Next, using Lemmas 18 & 20 we bound the number of vertices in G'.

▷ Claim 24. Fix an iteration l. Then, $|V(G')| \le 4 \cdot |\mathcal{A}_l|$.

Finally, we prove Theorems 1 & 3.

Proof of Theorem 1. Since G is K_r-minor free so does G'. So we can write

$$\begin{aligned}\sum_{A \in \mathcal{A}_l} \left|\Delta^l_{\text{Killer}}(A) \cup \Delta^l_{\text{Exp}}(A)\right| &\le \sum_{A \in \mathcal{A}_l} \left(|\delta^{in}_{G'}(C_A)| + 1\right) \\ &= |E(G')| + |\mathcal{A}_l| \\ &\le O(r \cdot \sqrt{\log r}) \cdot 4 \cdot |\mathcal{A}_l| + |\mathcal{A}_l| \\ &= O(r \cdot \sqrt{\log r})|\mathcal{A}_l|,\end{aligned} \tag{13}$$

where the inequality follows from Claim 23 and the second inequality follows from Claim 24 together with Theorem 10.

Next we show (4) holds for $\alpha = O(r \cdot \sqrt{\log r})$.

$$\begin{aligned}\sum_{A \in \mathcal{A}_l} |\Delta^l(A)| &= \sum_{A \in \mathcal{A}_l} |\Delta^l_{\text{Killer}}(A) \cup \Delta^l_{\text{Exp}}(A)| + \sum_{A \in \mathcal{A}_l} |\Delta^l_{\text{Ant}}(A)| \\ &\le O(r \cdot \sqrt{\log r})|\mathcal{A}_l| + |\mathcal{A}_l| \\ &= O(r \cdot \sqrt{\log r})|\mathcal{A}_l|,\end{aligned}$$

where inequality follows from inequality (13) and Lemma 16.

As we discussed at the beginning of Section 5 that if (4) holds for α then we have a $(2 \cdot \alpha)$-approximation algorithm. Hence, Algorithm 1 is an $O(r \cdot \sqrt{\log r})$-approximation for DST on quasi-bipartite, K_r-minor free graphs. ◀

Proof of Theorem 3. The proof is exactly the same as proof of Theorem 1 except instead of $O(r \cdot \sqrt{\log r})$ in (13) we have 2 because G' is a bipartite planar graph, see Lemma 11. Now we can write $\sum_{A \in \mathcal{A}_l} \left|\Delta^l_{\text{Killer}}(A) \cup \Delta^l_{\text{Exp}}(A)\right| \le 9 \cdot |\mathcal{A}_l|$ and $\sum_{A \in \mathcal{A}_l} |\Delta^l(A)| \le 10 \cdot |\mathcal{A}_l|$. Therefore, (4) holds for $\alpha = 10$ and hence we have a 20-approximation algorithm, as desired. ◀

[7] Note that all the parallel edges are antenna edges and so removing them does not affect the quantity $\sum_{A \in \mathcal{A}_l} |\Delta^l_{\text{Killer}}(A) \cup \Delta^l_{\text{Exp}}(A)|$ we are trying to bound.

Abstract

The k-Steiner-2NCS problem is as follows: Given a constant (positive integer) k, and an undirected connected graph $G = (V, E)$, non-negative costs c on the edges, and a partition $(T, V \setminus T)$ of V into a set of terminals, T, and a set of non-terminals (or, Steiner nodes), where $|T| = k$, find a min-cost two-node connected subgraph that contains the terminals. The k-Steiner-2ECS problem has the same inputs; the algorithmic goal is to find a min-cost two-edge connected subgraph that contains the terminals.

We present a randomized polynomial-time algorithm for the unweighted k-Steiner-2NCS problem, and a randomized FPTAS for the weighted k-Steiner-2NCS problem. We obtain similar results for a capacitated generalization of the k-Steiner-2ECS problem.

Our methods build on results by Björklund, Husfeldt, and Taslaman (SODA 2012) that give a randomized polynomial-time algorithm for the unweighted k-Steiner-cycle problem; this problem has the same inputs as the unweighted k-Steiner-2NCS problem, and the algorithmic goal is to find a min-cost simple cycle C that contains the terminals (C may contain any number of Steiner nodes).

1 Introduction

The k-Steiner-cycle problem is as follows: Given a constant k, and an undirected connected graph $G = (V, E)$, non-negative costs c on the edges, and a partition $(T, V \setminus T)$ of V into a set of terminals, T, and a set of non-terminals (or, Steiner nodes), where $|T| = k$, find a minimum-cost simple cycle C that contains all the terminals (and any subset of Steiner nodes). Note that this is an optimization problem and not a search problem. To the best of our knowledge,

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

no polynomial-time (deterministic or randomized) algorithm is known for finding an optimal solution of the (weighted) k-Steiner-cycle problem, even for $k = 3$; this problem has been open for several decades, see [7]. Björklund, Husfeldt, and Taslaman (SODA 2012) [3] give a randomized polynomial-time algorithm for the unweighted k-Steiner-cycle problem; also, see Taslaman's thesis [26]. Further research on the same problem is presented by Wahlström [27], and by Fafianie and Kratsch [10]. The algorithm of [3] extends easily to a randomized FPTAS for the weighted k-Steiner-cycle problem, by using techniques from Ibarra & Kim [15] and Hochbaum & Shmoys [14], see Proposition 6. All the results in our paper are based on the key result of Björklund et al. [3]. Below, in the section on related work, we discuss several papers that pertain to the k-Steiner-cycle problem, but we stress that the methods and techniques of these papers have no direct implications for the k-Steiner-cycle problem.

Network design encompasses a wide class of problems that find applications in sectors like transportation, facility location, information security, resource connectivity, etc. Due to its wide scope and usefulness, the area of network design has been studied for decades and it has spawned major algorithmic innovations. Most of the problems in network design are NP-Hard, and researchers in the area have focused on designing good approximation algorithms. The nodes of a network are designated as terminals (i.e., "essential" nodes) or non-terminals (i.e., Steiner nodes or "optional" nodes). A well-known goal of network design is to construct cheap networks that can survive the failure of one element (i.e., one edge or one node); "surviving" means that all the (remaining) terminals stay connected even after the deletion of one element, that is, there exists a path between every pair of (remaining) terminals after deleting one element.

In the *Steiner-2ECS* problem, the input is an undirected graph $G = (V, E)$, a set of terminals $T \subseteq V$, and non-negative costs c on the edges. The goal is to find a minimum-cost 2-edge-connected subgraph containing all the terminals. The *Steiner-2NCS* problem is defined similarly, where the goal is to find a minimum-cost 2-node-connected subgraph containing all the terminals. Both these problems are NP-Hard. The best known approximation algorithms achieve an approximation ratio of two, see [29].

Another paradigm to address NP-Hard problems is to develop parameterized algorithms. In this setting, a parameter of the input is chosen (e.g., the number of terminals, or the size of an optimal solution) and the goal is to develop algorithms whose running time depends on the input size and the parameter.

Feldmann, Mukherjee and van Leeuwen [11] presented parametrized algorithms for the Steiner-2ECS and Steiner-2NCS problems (among others) where the parameter is the optimal solution size, which is denoted by ℓ. They showed that if ℓ is bounded by a constant, then these problems can be solved in polynomial time. In particular, they present a *fixed parameter tractable* (FPT) algorithm that runs in time $n^{O(1)} f(\ell)$ and computes an optimal solution, where $f(\cdot)$ denotes some computable function.

Feldmann et al. [11] recently high-lighted the following open question in the area of network design: Is there a polynomial-time algorithm for the Steiner-2NCS problem, where the number of terminals is a constant? We use the term k-Steiner-2NCS problem (respectively, k-Steiner-2ECS problem) to refer to the special case of the Steiner-2NCS problem (respectively, Steiner-2ECS problem) with k terminals. Usually, we assume that the number of terminals is a constant, i.e., $k = O(1)$. We present a randomized polynomial-time algorithm for the unweighted k-Steiner-2NCS problem. We also consider the weighted k-Steiner-2NCS problem, and we provide a randomized fully polynomial time approximation scheme (FPTAS) for this problem.

We obtain similar results for the following generalization of the k-Steiner-2ECS problem: In the k-Flexible Steiner Tree (k-FST) problem, the input consists of an undirected graph $G = (V, E)$, a partition of the edge-set E into a set $\mathcal{S}$ of *safe edges* and a set $\mathcal{U}$ of *unsafe edges*, a set of terminals $T \subseteq V$ with $|T| = k$, and non-negative costs c on the edges. The goal is to find a minimum-cost connected subgraph $H = (U, F)$ such that $T \subseteq U$ and for any unsafe edge $e \in F$, the graph $H - e$ is connected. This problem is equivalent to the capacitated k-Steiner-2ECS problem, where the input is the same as that of the k-FST problem, except that there is a a positive integral capacity u on the edges (instead of the partition $E = \mathcal{S} \bigcup \mathcal{U}$); the goal is to find a minimum-cost connected subgraph $H = (U, F)$ such that $T \subseteq U$ and for any unit-capacity edge $e \in F$, the graph $H - e$ is connected. (The two problems are equivalent because the unsafe edges of the k-FST problem correspond to the unit-capacity edges of the latter problem, and the safe edges of the k-FST problem correspond to edges of capacity at least two of the latter problem.) We present a randomized polynomial-time algorithm for the unweighted k-FST problem; this easily extends to a randomized FPTAS for the weighted k-FST problem.

1.1 Our Results and Techniques

We prove that the k-Steiner-2NCS problem can be solved in randomized slicewise polynomial time, and hence it is in the complexity class randomized **XP**.

▶ **Theorem 1.** *For any $\eta > 0$, $\epsilon > 0$ and constant k,*

(i) *there exists a randomized algorithm for the unweighted* k-Steiner-2NCS *problem that outputs an optimal solution with probability $1 - \eta$ in time $O(\binom{n}{2k} \cdot B(3k) \cdot \binom{3k}{2}^k \cdot 2^{3k} \cdot n^{O(1)} \cdot \log \frac{k}{\eta}) = O\left(n^{O(k)} \cdot \log \frac{1}{\eta}\right)$, where $B(i)$ denotes the ith ordered Bell number.*

(ii) *there exists a randomized algorithm for the weighted* k-Steiner-2NCS *problem that runs in time $O(n^{O(k)} \cdot (1/\epsilon)^{O(k)} \cdot \log(1/\eta))$ such that, with probability at least $1 - \eta$, the solution returned by the algorithm costs at most $(1 + \epsilon)$ times the cost of an optimal solution.*

Our methods build on results by Björklund, Husfeldt, and Taslaman (SODA 2012) [3] that give a randomized polynomial-time algorithm for the unweighted k-Steiner-cycle problem. Given an instance of the k-Steiner-2NCS problem, we guess an ear decomposition of an optimal solution by enumeration, and repeatedly use the algorithm in [3] to construct an optimal subgraph. It can be seen that naively attaching new ears does not lead to an optimal solution. Hence, we also keep track of the high degree nodes in the optimal subgraph. Subsequently, we obtain our randomized FPTAS for the weighted k-Steiner-2NCS problem, by using the scaling techniques from Ibarra & Kim [15] and Hochbaum & Shmoys [14]. We present similar results for the k-FST problem.

▶ **Theorem 2.** *For any $\eta > 0$, $\epsilon > 0$ and constant k,*

(i) *there exists a randomized algorithm for the unweighted* k-FST *problem that outputs an optimal solution with probability $1 - \eta$ in time $O\left(n^{O(k)} \cdot \log \frac{1}{\eta}\right)$.*

(ii) *there exists a randomized algorithm for the weighted* k-FST *problem that runs in time $O(n^{O(k)} \cdot (1/\epsilon)^{O(k)} \cdot \log(1/\eta))$ such that, with probability at least $1 - \eta$, the solution returned by the algorithm costs at most $(1 + \epsilon)$ times the cost of an optimal solution.*

Our methods here rely on the block decomposition of an optimal solution, in conjunction with our results on the k-Steiner-2NCS problem. We use Theorem 1 to find the individual blocks optimally, and then paste these blocks together using the results by Adjiashvili, Hommelsheim, Mühlenthaler, and Schaudt [1] who give a polynomial-time algorithm for finding an optimal solution to the 2-FST problem; see Proposition 1 and Theorem 5 of [1]. As a corollary, we obtain the same results for the capacitated k-Steiner-2ECS problem.

▶ **Corollary 3.**

(i) *The capacitated* k-Steiner-2ECS *problem can be solved in slicewise polynomial time with high probability, hence, it is in randomized* $\mathbf{XP}$.

(ii) *There exists a randomized FPTAS for the weighted capacitated* k-Steiner-2ECS *problem.*

1.2 Related Work

1.2.1 k-Steiner-cycle problem

One of the key applications of the Graph Minors theory of Roberston and Seymour [23] is a polynomial-time algorithm for the decision/search version of the k disjoints paths problem for constant k. In this problem, we are given an undirected graph $G = (V, E)$ and k source-sink pairs s_i, t_i, and the goal is to decide (or, find) if there exist k node-disjoint paths P_i where the end-nodes of P_i are s_i and t_i. The Graph Minors theory (as of now) cannot address the optimization version of this problem.

There are many papers on the k disjoint paths problem, and a few on problems related to the k-Steiner-cycle problem. Kawarabayashi [19] presented improved algorithms for the search version of the latter problem, by improving on the methods from Graph Minors theory. There are a few other relevant results from the last few decades; for example, Fleischner and Woeginger present results for the unweighted 3-Steiner-cycle problem, see [13].

Recently, Lochet [21] and Bentert et al. [2] presented interesting algorithms for the so-called k disjoint shortest paths problem, i.e., each of the paths P_i (of the disjoint paths problem) is required to be a *shortest* path between s_i and t_i; this problem is *not* directly related to the optimization problems of interest to us.

1.2.2 k-Steiner-2NCS problem and k-Steiner-2ECS problem

Network design problems involving finding a cheapest subgraph subject to connectivity requirements have been studied for decades. One of the simplest such problems is the *minimum spanning tree* problem which is known to have polynomial-time algorithms. However, increasing the connectivity requirements makes these problems intractable. The 2-edge-connected spanning subgraph (2-ECSS) problem is Max-SNP-Hard, see [6]. In the weighted setting, the best known approximation algorithm achieves an approximation ratio of two, see Khuller and Vishkin [20]. The best known approximation ratio for the minimum-cost 2-node-connected spanning subgraph (2-NCSS) problem is two, see the survey by Nutov [22].

The analogous problems with Steiner nodes are usually harder. For instance, the minimum-cost Steiner tree problem is already NP-Hard [18]. The best known approximation ratio for this problem is ≈ 1.39, due to Byrka et al. [5]. The best known approximation ratios for the (weighted) Steiner-2ECS/Steiner-2NCS problem is two, see [29, 16, 12].

In the context of parameterized algorithms, Dreyfus and Wagner [9] showed that the Steiner tree problem can be solved in FPT time where the parameter is the number of terminals. Feldmann et al. [11] showed that the Steiner-2ECS and Steiner-2NCS problems can be solved in FPT time where the parameter is the size of an optimal solution.

Sami [24], in his master's thesis, has some results related to our paper. He notes that there is a reduction from the k-Steiner-2ECS problem to the k-Steiner-2NCS problem. $\big($We can "inflate" each node v of the graph G of the k-Steiner-2ECS problem to a complete graph, i.e., clique, C_v on $\deg_G(v)$ nodes with edges of cost zero, and replace the edges incident to v in G by edges incident to distinct nodes of C_v while preserving the edge costs.) Moreover, he shows that the FPT (in the solution size parameter ℓ) algorithm of [11] for the k-Steiner-2ECS problem can be combined with a result of Jordan [17] to give an FPT (in parameter $k = |T|$) algorithm for the k-Steiner-2ECM problem where the solution subgraph may pick multiple copies of any edge (and incurs cost c_e for each copy of e).

Borradaile and Klein [4] presented a PTAS for the planar case of the Steiner-2ECM problem (i.e., the multi-edge variant of the Steiner-2ECS problem).

2 Preliminaries

This section has definitions and preliminary results. Our notation and terms are consistent with [8], and readers are referred to that text for further information.

Let $G = (V, E)$ be a loopless multi-graph with non-negative costs $c \in \mathbb{R}^E_{\geq 0}$ on the edges. We take G to be the input graph, and we use n to denote $|V(G)|$. For a set of edges $F \subseteq E(G)$, $c(F) := \sum_{e \in F} c(e)$, and for a subgraph G' of G, $c(G') := \sum_{e \in E(G')} c(e)$.

For a positive integer k, we use $[k]$ to denote the set $\{1, \ldots, k\}$.

For a graph H and a set of nodes $S \subseteq V(H)$, $\Gamma_H(S) := \{w \in V(H) \setminus S \ : \ v \in S, vw \in E(H)\}$, thus, $\Gamma_H(S)$ denotes the set of neighbours of S.

For a graph H and a set of nodes $S \subseteq V(H)$, $\delta_H(S)$ denotes the set of edges that have one end node in S and one end node in $V(H) \setminus S$; moreover, $H[S]$ denotes the subgraph of H induced by S, and $H - S$ denotes the subgraph of H induced by $V(H) \setminus S$. For a graph H and a set of edges $F \subseteq E(H)$, $H - F$ denotes the graph $(V(H),\ E(H) \setminus F)$. We may use relaxed notation for singleton sets, e.g., we may use $\delta_H(v)$ instead of $\delta_H(\{v\})$, and we may use $H - v$ instead of $H - \{v\}$, etc.

We may not distinguish between a subgraph and its node set; for example, given a graph H and a set S of its nodes, we use $E(S)$ to denote the edge set of the subgraph of H induced by S.

2.1 2EC, 2NC and related notions

A multi-graph H is called k-edge connected if $|V(H)| \geq 2$ and for every $F \subseteq E(H)$ of size $< k$, $H - F$ is connected. Thus, H is 2-edge connected if it has ≥ 2 nodes and the deletion of any one edge results in a connected graph. A multi-graph H is called k-node connected if $|V(H)| > k$ and for every $S \subseteq V(H)$ of size $< k$, $H - S$ is connected. We use the abbreviations *2EC* for “2-edge connected,” and *2NC* for “2-node connected.”

For any instance H, we use $\textsc{opt}(H)$ to denote the minimum cost of a feasible subgraph (i.e., a subgraph that satisfies the requirements of the problem). When there is no danger of ambiguity, we use $\textsc{opt}$ rather than $\textsc{opt}(H)$.

By a *bridge* we mean an edge of a connected (sub)graph whose removal results in two connected components, and by a *cut-node* we mean a node of a connected (sub)graph whose deletion results in two or more connected components. A maximal connected subgraph without a cut-node is called a *block*. Thus, every block of a given graph G is either a maximal 2NC subgraph, or a bridge (and its incident nodes), or an isolated node. For any node v of G, let $\Gamma^{blocks}_G(v)$ denote the set of 2NC blocks of G that contain v.

2.2 Ear decompositions

An *ear decomposition* of a graph is a partition of the edge set into paths or cycles, $P_0, P_1, \ldots, P_\ell$, such that P_0 is the trivial path with one node, and each P_i $(1 \leq i \leq \ell)$ is either (1) a path that has both end nodes in $V_{i-1} = V(P_0) \cup V(P_1) \cup \ldots \cup V(P_{i-1})$ but has no internal nodes in V_{i-1}, or (2) a cycle that has exactly one node in V_{i-1}. For an ear P_i, let $\mathrm{int}(P_i)$ denote the set of nodes $V(P_i) \setminus V_{i-1}$. Each of $P_1, \ldots, P_\ell$ is called an *ear*; note that P_0 is not regarded as an ear. We call $P_i, i \in \{1, \ldots, \ell\}$, an *open ear* if it is a path, and we call it a *closed ear* if it is a cycle. An *open* ear decomposition $P_0, P_1, \ldots, P_\ell$ is one such that all the ears $P_2, \ldots, P_\ell$ are open. (The ear P_1 is always closed.)

▶ **Proposition 4** (Whitney [28]).

(i) *A graph is 2EC $\iff$ it has an ear decomposition.*

(ii) *A graph is 2NC $\iff$ it has an open ear decomposition.*

2.3 Algorithms for basic computations

There are well-known polynomial-time algorithms for implementing all of the basic computations in this paper, see [25]. We state this explicitly in all relevant results, but we do not elaborate on this elsewhere.

3 FPTAS for k-Steiner-cycle

Björklund, Husfeldt, and Taslaman [3] presented a randomized algorithm for finding a min-cost simple cycle that contains a given set of terminals T of an unweighted, undirected graph $G = (V, E)$ with a running time of $2^k n^{O(1)}$, where $k = |T|$ and $n = |V|$. In other words, they present a randomized **FPT**-algorithm for the unweighted k-Steiner-cycle problem.

▶ **Theorem 5.** *Consider a graph $G = (V, E)$ and a set of terminals $T \subseteq V$ of size k. Let $\eta > 0$ be a parameter. A minimum-size* k-Steiner-cycle *can be found, if one exists, by a randomized algorithm in time $2^k n^{O(1)} \log \frac{1}{\eta}$ with probability at least $1 - \eta$.*

We present a simple (randomized) FPTAS for the weighted k-Steiner-cycle problem, based on the algorithm of [3].

▶ **Proposition 6.** *Consider a graph $G = (V, E)$ with nonnegative costs $c \in \mathbb{R}^E_{\geq 0}$ on the edges, and a set of k terminals $T \subseteq V$. Let $\varepsilon, \eta > 0$ be some parameters. There is a randomized algorithm that finds a $(1 + \varepsilon)$-approximate* k-Steiner-cycle*, if one exists, with probability at least $1 - \eta$. The running time of the algorithm is $O\Big(2^k \cdot n^{O(1)} \cdot \big(\frac{1}{\varepsilon}\big)^{O(1)} \cdot \log \frac{1}{\eta}\Big)$.*

Proof. Let $E = \{e_1, e_2, \ldots, e_m\}$ where $c_{e_1} \leq c_{e_2} \leq \cdots \leq c_{e_m}$. Let $\eta' := \eta/2$. Let $j \in [m]$ denote the smallest index such that the graph $(V, \{e_1, \ldots, e_j\})$ contains a k-Steiner-cycle. Note that if G does not have a k-Steiner-cycle, then the weighted-version of the problem is trivially infeasible. Using at most m applications of Theorem 5 with the η-parameter set to η', we can find the index j with probability at least $1 - \eta/2$. Suppose that we have the correct index j. Let $\beta := c(e_j)$. Let Q^* denote an optimal k-Steiner-cycle in G, and $\textsc{opt} := c(Q^*)$ denote the optimal cost. By the definition of j, $\beta \leq \textsc{opt} \leq n\beta$. In particular, every edge in Q^* has cost at most $n\beta$. We now describe our randomized algorithm for obtaining a k-Steiner-cycle with cost at most $(1 + \varepsilon)\textsc{opt}$. First, we discard all edges e of G with cost $c_e > n\beta$. Let $\mu := \varepsilon\beta/n$; this is our "scaling parameter". For each edge e, define $\tilde{c}_e := \mu \cdot \max(1, \lceil c_e/\mu \rceil)$. Note that $\tilde{c}_e = \mu$ if $c_e = 0$. $\big($Observe that this rounding introduces errors, but the total error incurred on any cycle is $\le n\,\mu \le \epsilon\beta \le \epsilon\textsc{opt}$.) Consider the graph $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ obtained from G by replacing each edge e by a path of $\tilde{c}_e/\mu$ edges (of unit cost). Note that $|\widetilde{V}| \le |V| + |E| \cdot (n\beta)/\mu = O(mn^2/\varepsilon)$. Using a single application of Theorem 5, we can obtain a minimum-size k-Steiner-cycle $\widetilde{Q} \subseteq \widetilde{E}$ with probability at least $1 - \eta/2$ in $O\Big(2^k \cdot (\frac{n^2 m}{\varepsilon})^{O(1)} \cdot \log\frac{1}{\eta}\Big)$ time. Let Q denote the k-Steiner-cycle in G corresponding to $\widetilde{Q}$. By our choice of $\tilde{c}$, we have $c(Q) \le \tilde{c}(Q) \le \mu \cdot |\widetilde{Q}|$. Since the optimal k-Steiner-cycle Q^* consists of at most n edges each with cost at most $n\beta$, the (unweighted) k-Steiner-cycle $\widetilde{Q}^*$ in $\widetilde{G}$ corresponding to Q^* satisfies $\mu|\widetilde{Q}^*| \le \tilde{c}(Q^*) \le c(Q^*) + n\mu \le \textsc{opt}(1+\varepsilon)$. By the above discussion, we can obtain a k-Steiner-cycle Q satisfying $c(Q) \le \mu|\widetilde{Q}| \le \mu|\widetilde{Q}^*| \le (1+\varepsilon)\textsc{opt}$ with probability at least $1-\eta$. Clearly, the overall running time is $O\Big(2^k \cdot n^{O(1)} \cdot (\frac{1}{\varepsilon})^{O(1)} \cdot \log\frac{1}{\eta}\Big)$. ◀

4 Algorithms for k-Steiner-2NCS

In this section, we consider the k-Steiner-2NCS problem. First, we present a randomized polynomial-time algorithm for finding an optimal subgraph for the special case of unweighted k-Steiner-2NCS; then, using the method from Section 3 we extend our algorithm to a (randomized) FPTAS for weighted k-Steiner-2NCS.

We denote an instance of the k-Steiner-2NCS problem by $(G = (V, E),\ c \in \mathbb{R}^E_{\ge 0},\ T \subseteq V)$; G is the input graph with non-negative edge costs c, and T is the set of terminals, $|T| \ge 3$ (we skip the easy case of $|T| = 2$). We assume (w.l.o.g.) that G is a feasible subgraph, that is, all terminals are contained in one block of G.

For any graph H, let $D_3(H)$ denote the set of nodes that have degree ≥ 3 in H.

▶ **Lemma 7.** *Let $H = (V', E')$ be an (edge) minimal 2NC subgraph that contains T. Then H has an open ear decomposition $P_0, P_1, \ldots, P_\ell$ such that*

(i) *each of the ears P_i ($i \in [\ell]$) contains a terminal as an internal node (i.e., $\mathrm{int}(P_i) \cap T \neq \emptyset$), and P_0 contains a terminal,*

(ii) *$|D_3(H)| \le 2(|T| - 2)$.*

Proof.

(i) Pick any terminal to be P_0. Suppose we have constructed open ears $P_1, \ldots, P_{i-1}$ and that each $\mathrm{int}(P_j)(j \in [i-1])$ contains a terminal. Let $F = \cup_{j=1}^{i-1} E(P_j)$. Let t be a terminal in $T \setminus V(F)$ (we have the required ear decomposition, if $T \subseteq V(F)$). Suppose $i = 1$; then, G has two openly disjoint paths between t and P_0, and we take P_1 to be the edge-set of these two paths. Suppose $i \ge 2$; then, G has a two-fan P between t and $V(F)$ (i.e., P is the union of two paths between t and $V(F)$ that have only the node t in common); we take P_i to be P.

(ii) Clearly, $\ell \le |T| - 1$ for the ear decomposition of part (i), and each of the ears $P_2, \ldots, P_\ell$ contributes at most 2 (new) nodes to $D_3(H)$. ◀

The next lemma states an extension of Proposition 4.

▶ **Lemma 8.** *Let $G = (V, E)$ be a graph, and let $H = (V', E')$ be a 2NC subgraph of G. Let P be a path of G that has both end nodes in V'. Then, $H \cup P = (V' \cup V(P), E' \cup E(P))$ is a 2NC subgraph of G.*

Each set $S \subseteq V$ of size $\le 2|T| - 4$ is a candidate for $D_3(H)$ for a 2NC subgraph H that contains T, and we call $T \cup S$ the set of *marker* nodes.

Our algorithm has several nested loops. The outer-most loop picks a set $S \subseteq V$ of size $\leq 2|T| - 4$, and then applies the following main loop. Each iteration of the main loop attempts to construct a 2NC subgraph that contains the set of marker nodes $T \cup S$, by iterating over all ordered partitions $(\widetilde{T}_1, \widetilde{T}_2, \ldots, \widetilde{T}_r)$ of $T \cup S$ such that $|\widetilde{T}_1| \geq 2$ and the number of sets in the partition, r, is a positive integer, $r \leq k = |T|$.

Consider one of these ordered partitions $(\widetilde{T}_1, \widetilde{T}_2, \ldots, \widetilde{T}_r)$. We attempt to find a min-cost Steiner-cycle C_1 that contains $\widetilde{T}_1$ using the algorithm of [3]; if G has no Steiner-cycle that contains $\widetilde{T}_1$, then this iteration has failed, otherwise, we take C_1 to be the first (closed) ear of an open ear decomposition of our candidate 2NC subgraph that contains $T \cup S$. Then, for $i = 1, \ldots, r-1$, we pick a pair of nodes $s_i, t_i \in \widetilde{T}_1 \cup \cdots \cup \widetilde{T}_i$, and attempt to find a min-cost Steiner-path P_{i+1} between s_i and t_i that contains $\widetilde{T}_{i+1}$; if G has no such Steiner-path, then this iteration has failed, otherwise, we augment the current subgraph $H := C_1 \cup P_2 \cup \cdots \cup P_i$ by P_{i+1}.

The algorithm maintains an edge-set $\hat{F}$; initially, $\hat{F} = E$, and, at termination, $\hat{F}$ is the edge-set of a min-cost 2NC subgraph that contains T.

Pseudo-code for the algorithm is presented below.

We use $\mathcal{A}_{\text{BHT-cycle}}(G,\ \widetilde{T}_1,\ \eta)$ to denote a call to the Steiner-cycle algorithm of [3] where the inputs are the graph G, the terminal set $\widetilde{T}_1 \subseteq V(G)$, and the desired probability of failure η. With probability at least $1-\eta$, this call either returns the edge-set of a minimum-size cycle of G that contains all nodes of $\widetilde{T}_1$ or reports an error if G has no such cycle.

We use $\mathcal{A}_{\text{BHT-path}}(G,\ \widetilde{T}_1,\ s,\ t,\ \eta)$ to denote a call to the following subroutine that attempts to find an s,t-path of G that contains all nodes of $\widetilde{T}_1$. First, construct an auxiliary graph G' from G by adding a node u' and two edges $u's, u't$. Then call $\mathcal{A}_{\text{BHT-cycle}}(G',\ \widetilde{T}_1 \cup \{u', s, t\},\ \eta)$; report an error if the call returns an error, and, otherwise, return the path obtained by deleting the node u' (and its two incident edges) from the cycle returned by the call.

Algorithm 1 $\mathcal{A}_{2NC}(G, T, \eta)$ for the unweighted k-Steiner-2NCS problem.

```
$\eta' \leftarrow \eta/k$
$\hat{F} \leftarrow E$
for $S \subseteq V$ such that $|S| \leq 2k$ do
    for $r = 1, \ldots, k$ do
        for Ordered partitions $(\widetilde{T}_1, \ldots, \widetilde{T}_r)$ of $T \cup S$ such that $|\widetilde{T}_1| \geq 2$ do
            for $i = 1, \ldots, r-1$ and node pairs $(s_i, t_i) \in \cup_{j=1}^{i} \widetilde{T}_i$, where $s_i \neq t_i$ do
                $H \leftarrow \mathcal{A}_{\text{BHT-cycle}}(G, \widetilde{T}_1,\ \eta') \quad \bigcup_{i=1}^{r-1} \mathcal{A}_{\text{BHT-path}}(G, \widetilde{T}_{i+1}, s_i, t_i,\ \eta')$
                continue the loop if any call to any subroutine reports an error
                if $|E(H)| < |\hat{F}|$ then
                    $\hat{F} \leftarrow E(H)$
                end if
            end for
        end for
    end for
end for
return $\hat{F}$
```

▶ **Lemma 9.** *Let $H^* = (V^*, E^*)$ be an optimal subgraph for k-*Steiner-2NCS*. Assume that each of the calls to the subroutines (namely, $\mathcal{A}_{\textit{BHT-cycle}}, \mathcal{A}_{\textit{BHT-path}}$) returns a valid subgraph whenever one exists. Let $H = (U, \hat{F})$ denote the output of the above algorithm. Then H is a 2NC subgraph, $U \supseteq T$, and $|\hat{F}| \leq |E^*| = \text{OPT}$.*

Proof. By Lemma 7, H^* has an open ear decomposition $P_1, P_2, \dots, P_{r^*}$ such that each of the ears P_i contains at least one terminal as an internal node; hence, $r^* \leq k = |T|$. Let $S^* = D_3(H^*)$ be the set of nodes of degree ≥ 3 of H^*; clearly, $|S^*| \leq 2r^* \leq 2k$.

For $i = 1, \dots, r^*$, let $T_i^* = P_i \cap (T \cup S^*)$. For $i = 1, \dots, r^* - 1$, let (s_i^*, t_i^*) denote the end nodes of the ear P_{i+1}; clearly, $(s_i^*, t_i^*) \in \cup_{j=1}^{i}(T_i^*)$.

Now consider the loop in the algorithm where $S = S^*$, $r = r^*$, $\widetilde{T}_i = T_i^*$ for $i = 1, \dots, r^*$ and $(s_i, t_i) = (s_i^*, t_i^*)$ for $i = 1, \dots, r^* - 1$. Observe that the calls to the subroutines $\mathcal{A}_{\text{BHT-cycle}}$ and $\mathcal{A}_{\text{BHT-path}}$ return minimum-size subgraphs, hence, $|\mathcal{A}_{\text{BHT-cycle}}(G, \widetilde{T}_1)| \leq |P_1|$ and $|\mathcal{A}_{\text{BHT-path}}(G, \widetilde{T}_{i+1}, s_i, t_i)| \leq |P_{i+1}|$ for $i = 1, \dots, r^* - 1$. Since $|E^*| = \sum_{i=1}^{r^*} |P_i|$, we conclude that the 2NC subgraph H found by this iteration satisfies $|E(H)| \leq |E^*|$. Thus, the algorithm outputs an optimal 2NC subgraph that contains T. ◀

4.1 Proof of Theorem 1

Proof. As seen in the proof of Lemma 9, if the subroutines $\mathcal{A}_{\text{BHT-cycle}}$ and $\mathcal{A}_{\text{BHT-path}}$ run correctly when $S = S^*$, $r = r^*$, $\widetilde{T}_i = T_i^*$ for $i = 1, \dots, r^*$ and $(s_i, t_i) = (s_i^*, t_i^*)$ for $i = 1, \dots, r^* - 1$ corresponding to an ear decomposition of an optimal solution H^*, then the above algorithm outputs an optimal solution. During this loop, there are at most $r^* \leq k = |T|$ calls to the subroutines $\mathcal{A}_{\text{BHT-cycle}}$ and $\mathcal{A}_{\text{BHT-path}}$. Hence, with probability at least $(1 - \eta')^k \geq 1 - \eta$, Algorithm $\mathcal{A}_{2NC}$ outputs an optimal solution.

The running time is analyzed as follows: the term $2k \cdot \binom{n}{2k} = O(\binom{n}{2k})$ comes from choosing $S \subseteq V$, $|S| \leq 2k$ (in the outer-most loop), the term $B(3k)$ comes from choosing ordered partitions of $S \cup T$, the term $\binom{3k}{2}^k$ comes from choosing the node pairs (s_i, t_i) for the $r - 1 (\leq k)$ calls to $\mathcal{A}_{\text{BHT-path}}$, and the term $2^{3k} n^{O(1)} \log \frac{k}{\eta}$ comes from the running time of the algorithm of [3] for the Steiner-cycle problem, with error probability $\frac{\eta}{k}$.

Having solved the unweighted k-Steiner-2NCS problem, we can directly use the methods from Section 3 to obtain an FPTAS for the weighted k-Steiner-2NCS problem. ◀

5 FPTAS for k-FST and k-Steiner-2ECS

In this section we present a randomized polynomial-time algorithm for finding an optimal subgraph for the special case of unweighted k-FST; then, using the method from Section 3, we extend our algorithm to a (randomized) FPTAS for weighted k-FST. We assume that $k = |T| \geq 3$ is a positive integer. Note that the capacitated k-Steiner-2ECS problem can be reduced to the k-FST problem by defining the set of safe edges to be the set of edges with capacity at least 2 and defining the set of unsafe edges to be the set of edges with capacity exactly 1. Hence the results in this section can also be applied to the capacitated k-Steiner-2ECS problem.

Adjiashvili, Hommelsheim, Mühlenthaler, and Schaudt [1] give a polynomial-time algorithm for finding an optimal solution to the 2-FST problem; see Proposition 1 and Theorem 5 of [1]. We refer to their 2-FST algorithm as $\mathcal{A}_{\text{2-FST}}$. We refer to (inclusion-wise) minimal feasible solutions to a 2-FST problem on G as *1-protected paths*.

Informally speaking, our randomized polynomial-time algorithm for k-FST represents minimal feasible solutions as 2NC blocks connected together using 1-protected paths. To simplify our presentation, we first modify the k-FST instance $G = (V, \mathcal{S} \sqcup \mathcal{U}, T)$ as follows. For each terminal $v \in T$, we create a new node v' and a new safe edge vv'. Let T' denote the set of these new nodes and let E' denote the set of the new safe edges. Consider the modified instance $G' = (V \cup T', (\mathcal{S} \cup E') \sqcup \mathcal{U}, T')$. Observe that (U, F) is a feasible solution to the original instance if and only if $(U \cup T', F \cup E')$ is a feasible solution to the modified instance.

▶ **Definition 10** (Block-Tree). *A block-tree of a graph G is a tree $B(G)$ with the following properties:*

1. *The nodes of $B(G)$ are in one-to-one correspondence with the 2NC blocks of G.*
2. *If two 2NC blocks are connected by a bridge in G, then the two corresponding nodes in $B(G)$ are adjacent.*
3. *For each cut-node v of G, the subgraph of $B(G)$ induced by $\Gamma_G^{blocks}(v)$ is connected ($\Gamma_G^{blocks}(v)$ is the set of 2NC blocks of G that contain v). In other words, the unique path of $B(G)$ between any two nodes of $\Gamma_G^{blocks}(v)$ has all its internal nodes in $\Gamma_G^{blocks}(v)$.*

Informally speaking, a block-tree of a graph G represents how the 2NC blocks of G are connected together. Each edge of the block-tree either represents a bridge of G or connects a pair of 2NC blocks of G that share a common cut-node. Let H be a minimal feasible k-FST solution. Due to the modification above, we may assume that every leaf of $B(H)$ corresponds to a block of H that contains exactly one terminal. Then any path in $B(H)$ corresponds to a 1-protected path of H that connects either (i) two cut-nodes, or (ii) a cut-node and a terminal, or (iii) two terminals.

For our algorithmic application, nodes of $B(H)$ of degree two are redundant, and this motivates the notion of a "non-redundant" block-tree.

▶ **Definition 11** (Condensed Block-Tree). *A condensed block-tree of a graph G is a tree $\hat{B}(G)$ obtained from a block-tree $B(G)$ with the following properties:*

1. *The nodes of $\hat{B}(G)$ are nodes b of $B(G)$ such that $\deg_{B(G)}(b) \neq 2$.*
2. *Two nodes b_1 and b_2 are adjacent in $\hat{B}(G)$ if and only if every internal node in the path connecting b_1 and b_2 in $B(G)$ has degree two.*

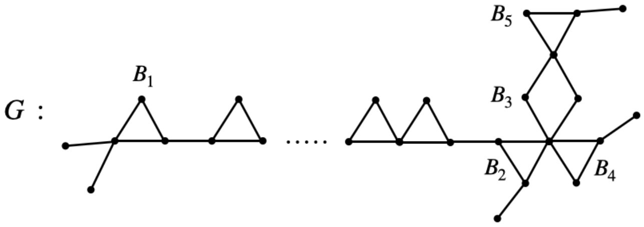

Figure 1 The original graph G.

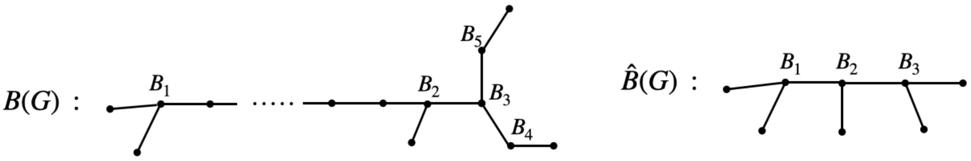

Figure 2 A block tree $B(G)$ and the corresponding condensed block tree $\hat{B}(G)$.

For any minimal feasible solution H of k-FST and a condensed block-tree $\hat{B}(H)$, we refer to the 2NC blocks of H that correspond to internal nodes of $\hat{B}(H)$ as *high-degree blocks.* The leaves of $\hat{B}(H)$ correspond to the terminals. Edges of $\hat{B}(H)$ correspond to 1-protected paths in H that connect either (i) two high-degree blocks, or (ii) a high-degree block and a terminal, or (iii) two terminals. The end-points of these 1-protected paths are either cut-nodes of H or terminals. Note that some of these 1-protected paths could be trivial paths corresponding to cut-nodes that are common to two high-degree blocks. We now state some useful lemmas that follow from the handshaking lemma applied to $\hat{B}(H)$.

▶ **Lemma 12.** *The number of internal nodes (i.e., non-leaf nodes) of $\hat{B}(H)$ is at most $k-2$ where k is the number of terminals.*

▶ **Lemma 13.** *The total number of cut-nodes (with repetitions) in high-degree blocks of H is at most $3k-6$ where k is the number of terminals.*

Now, we describe our algorithm for unweighted k-FST. We guess (via enumeration) the high-degree blocks of an optimal solution OPTSOLN corresponding to some condensed block-tree $\hat{B}(\text{OPTSOLN})$. The guess would include the number of high-degree blocks and the cut-nodes in each of these high-degree blocks. This is done by picking $3k-6$ nodes of V with replacement and then picking a partition $\widehat{\mathcal{P}}$ of these $3k-6$ nodes into at most $k-2$ sets. Let $r \leq k-2$ be the number of sets in the partition $\widehat{\mathcal{P}}$. Thus, $\widehat{\mathcal{P}} = (X_1, X_2, \ldots, X_r)$. For each set X_i, we use algorithm $\mathcal{A}_{2NC}$ to find B_i, a minimum size 2NC subgraph of G containing the specified cut-nodes in X_i, possibly, with some additional Steiner nodes. Finally, we construct a tree that connects these 2NC subgraphs and terminals via 1-protected paths using the following subroutine.

First, for every pair of nodes $(u, v) \in V' \times V'$, we use algorithm $\mathcal{A}_{\text{2-FST}}$ to find $G^{\min}_{uv}$, the minimum size 1-protected path connecting u and v in G'. We then construct a complete graph $K(X_1, \ldots, X_r)$ with $r+k$ nodes that has one node for each set X_i and one node corresponding to each terminal $\{t\}$. The cost of an edge between two nodes of K corresponding to node sets V_1 and V_2 is given by $\min\{|E(G^{\min}_{uv})| : u \in V_1, v \in V_2\}$. Note that if there is no 1-protected path connecting a node in V_1 to a node in V_2, then we fix the cost of the edge to be infinity. Thus an edge $\bar{e}$ of K corresponds to a subgraph $G^{\min}_{\bar{e}}$ in G' which is the minimum size 1-protected path whose end points are in V_1 and V_2 respectively. We then find a minimum spanning tree $\bar{T}$ in K. Note that if $\bar{T}$ has infinite cost, then we output an error. Else, we output the subgraph of G' defined by $G^{\min}(X_1, \ldots, X_r) := \cup_{\bar{e} \in \bar{T}} G^{\min}_{\bar{e}}$.

Algorithm 2 $\mathcal{A}_{\text{k-FST}}(G', T', \eta)$ for the unweighted k-FST problem.

```
$\eta' \leftarrow \eta/k$
$H \leftarrow G'$
for $S = (v_1, \ldots, v_{3k-6}) \in V^{3k-6}$ do
    for $r = 1, \ldots, k-2$ do
        for partitions $(X_1, \ldots, X_r)$ of $S$ do
            $\hat{H} \leftarrow G^{\min}(X_1, \ldots, X_r) \cup_{i=1}^{r} \mathcal{A}_{2NC}(G, X_i,\ \eta')$
            continue the loop if any call to any subroutine reports an error
            if $|E(\hat{H})| < |EH|$ then
                $H \leftarrow \hat{H}$
            end if
        end for
    end for
end for
return H
```

▶ **Lemma 14.** *Let $H^* = (V^*, E^*)$ be an optimal subgraph for k-FST. Assume that each of the calls to the subroutine $\mathcal{A}_{2NC}(G, X_i, \eta')$ returns a valid subgraph $2NC(G, X_i)$ whenever one exists. Let $H = (U, F)$ denote the output of the above algorithm. Then, H is a feasible k-FST solution and $|F| \le |E^*| = \text{OPT}$.*

Proof. We argue that the subgraph $\hat{H}$ in any iteration of the algorithm is a feasible k-FST solution. This holds because the algorithm finds 2NC subgraphs $2NC(G, X_i)$ and then connects them to one another and to the terminals using the 1-protected paths in $G^{\min}(X_1, \dots, X_r)$. Thus, $T \subseteq V(\hat{H})$ and any unsafe edge $e \in E(\hat{H})$ either lies in a 2NC subgraph of $\hat{H}$ or a 1-protected path in $\hat{H}$, hence, $\hat{H} - e$ is connected.

Now consider a condensed block-tree $\hat{B}(H^*)$. Let $B_1^*, \dots, B_{r^*}^*$ be the high-degree blocks of H^* and let X_i^* be the set of cut-nodes in B_i^*. By Lemma 13, the total number of cut-nodes in all the high-degree blocks B_i^* is at most $3k - 6$. We may assume that it is exactly $3k - 6$ by duplicating a cut-node $v \in X_1^*$ multiple times. Consider the iteration of the algorithm where $r = r^*$ and $X_i = X_i^*$ for $i = 1, \dots, r^*$. Then,

$$|E(2NC(G, X_i))| \le |E(B_i^*)| \qquad \forall i = 1, \dots, r.$$

Recall that the nodes of $\hat{B}(H^*)$ correspond to the high-degree blocks B_i^* (and hence to the node sets X_i^*) or to the terminals $\{t\}$. Also an edge $\bar{e}$ of $\hat{B}(H^*)$ between nodes corresponding to node sets V_1 and V_2 represents a 1-protected path $H_{\bar{e}}^*$ in H^* whose end-points lie in V_1 and V_2 respectively. Hence $\hat{B}(H^*)$ may be viewed as a subgraph of $K(X_1, \dots, X_r)$. Furthermore, since any two nodes in H^* have a 1-protected path between them, $\hat{B}(H^*)$ must be connected. Finally, by construction of K, $|E(H_{\bar{e}}^*)| \ge c(\bar{e})$ where $c(\bar{e})$ is the cost of the edge $\bar{e}$ in K. This implies that the cost of the minimum spanning tree in K is at most $\sum_{\bar{e} \in \hat{B}(H^*)} |E(H_{\bar{e}}^*)|$. Hence,

$$|E(G^{\min}(X_1, \dots, X_r))| \le \sum_{\bar{e} \in \hat{B}(H^*)} |E(H_{\bar{e}}^*)|.$$

Combining the two inequalities above we obtain

$$\begin{aligned}
|E(\hat{H})| &= |E(G^{\min}(X_1, \dots, X_r) \cup_{i=1}^{r} 2NC(G, X_i))| \\
&\le |E(G^{\min}(X_1, \dots, X_r))| + \sum_{i=1}^{r} |E(2NC(G, X_i))| \\
&\le \sum_{\bar{e} \in \hat{B}(H^*)} |E(H_{\bar{e}}^*)| + \sum_{i=1}^{r} |E(B_i^*)| \\
&= |E^*|
\end{aligned}$$

The last equation holds because E^* partitions into the edge-sets of the high-degree blocks B_i^* and the edge-sets of the 1-protected paths $H_{\bar{e}}^*$. This completes the proof of the lemma. ◀

5.1 Proof of Theorem 2

Lemma 14 proves that algorithm $\mathcal{A}_{\text{k-FST}}$ outputs an optimal solution to the k-FST problem with high probability. Let α denote the running time of the algorithm $\mathcal{A}_{\text{2-FST}}$ and let β denote the running time of the algorithm $\mathcal{A}_{\text{2NC}}$. Then, the running time of the algorithm $\mathcal{A}_{\text{k-FST}}$ is bounded by

$$O(n^2\alpha \cdot n^{3k-6} 2^k n^2 \beta \cdot k^2 \log k) = O\left(\alpha \cdot \beta \cdot n^{3k}\right).$$

Since $\mathcal{A}_{\text{2-FST}}$ has runtime $n^{O(1)}$ and $\mathcal{A}_{2\text{NC}}$ has runtime $n^{O(k)}$, we can conclude that the running time of the algorithm $\mathcal{A}_{\text{k-FST}}$ is $O\left(n^{O(k)} \cdot \log \frac{1}{\eta}\right)$.

Having solved the unweighted k-FST problem, we can directly use the methods from Section 3 to obtain an FPTAS for the weighted k-FST problem.

Oblivious Algorithms for the Max-kAND Problem

Noah G. Singer

Department of Computer Science, Carnegie Mellon University, Pittsburgh, PA, USA

Abstract

Motivated by recent works on streaming algorithms for constraint satisfaction problems (CSPs), we define and analyze *oblivious algorithms* for the Max-kAND problem. This is a class of simple, combinatorial algorithms which round each variable with probability depending only on a quantity called the variable's *bias*. Our definition generalizes a class of algorithms defined by Feige and Jozeph (Algorithmica '15) for Max-DICUT, a special case of Max-2AND.

For each oblivious algorithm, we design a so-called *factor-revealing* linear program (LP) which captures its worst-case instance, generalizing one of Feige and Jozeph for Max-DICUT. Then, departing from their work, we perform a fully explicit analysis of these (infinitely many!) LPs. In particular, we show that for all k, oblivious algorithms for Max-kAND provably outperform a special subclass of algorithms we call "superoblivious" algorithms.

Our result has implications for streaming algorithms: Generalizing the result for Max-DICUT of Saxena, Singer, Sudan, and Velusamy (SODA'23), we prove that certain separation results hold between streaming models for *infinitely many* CSPs: for *every* k, $O(\log n)$-space sketching algorithms for Max-kAND known to be optimal in $o(\sqrt{n})$-space can be beaten in (a) $O(\log n)$-space under a random-ordering assumption, and (b) $O(n^{1-1/k}D^{1/k})$ space under a maximum-degree-D assumption. Even in the previously-known case of Max-DICUT, our analytic proof gives a fuller, computer-free picture of these separation results.

1 Introduction

In this work, we study a restricted but natural class of randomized algorithms called *oblivious algorithms* for a family of *constraint satisfaction problems (CSPs)* called Max-kAND for $k \geq 2$. In the Max-kAND problem, an algorithm is presented with a list of m constraints on

n Boolean variables; each constraint is a disjunction on k literals (e.g., $x_1 \wedge \neg x_4 \wedge \neg x_5$ for the case of Max-3AND); and the goal is to satisfy the highest possible fraction of constraints. We begin by introducing these problems and algorithms informally and discussing the context and motivation for our work.

1.1 Background

Context on Max-kAND

Constraints of Max-kAND are maximally "precise" among all Boolean CSPs: each constraint specifies *exactly* what its k variables must be assigned to in order for that constraint to be satisfied.[1] Numerous works have developed algorithms for Max-kAND [43, 22, 23, 8] as well as NP-hardness-of-approximation results [44, 42, 34, 15, 35]; we now know that $\Theta(k/2^k)$-approximations are the best achievable in polynomial time assuming $\mathsf{P} \neq \mathsf{NP}$ [8, 35].

Further attention has been devoted to important special cases of Max-kAND. One particularly important example is the Max-DICUT problem, a special case of Max-2AND where each constraint is of the form "$x \wedge \neg y$". Max-DICUT can be viewed alternatively as a directed graph optimization problem, where the goal is to find a directed cut (S, T) maximizing the number of edges (s, t) such that $s \in S$ and $t \in T$. Approximation algorithms for Max-DICUT (and sometimes Max-2AND) were developed in [18, 16, 33, 30], and its hardness-of-approximation was studied in [24]. Max-3AND was studied in [47, 45].

The importance of Max-kAND, the extensive work on its polynomial-time approximability, and the "preciseness" of its constraints have inspired significant study on its approximability in restricted algorithmic settings. For instance, Trevisan [43] showed that the natural linear programming (LP) relaxation for Max-kAND beats the trivial (uniformly random rounding) algorithm's approximation ratio by a factor of 2, and that this LP's "nice" structure allows it to be solved (approximately) by distributed algorithms. Max-DICUT in particular has been studied extensively in various restrictive algorithmic frameworks and models, including "combinatorial" algorithms [21], spectral partitioning algorithms [46], local search algorithms [1, 2], parallel algorithms [6], near-linear time algorithms [40], and online algorithms [5].

Oblivious algorithms for Max-kAND

In this paper, we define a restricted class of algorithms for Max-kAND called *oblivious algorithms* (which were previously studied in the case of Max-DICUT by Feige and Jozeph [17]). Oblivious algorithms fall into the paradigm of *probabilistic rounding* algorithms. These algorithms somehow choose, for each variable v, a probability $p_v \in [0, 1]$, and then assign x_v to 1 w.p. p_v and 0 w.p. $1 - p_v$ (independently of all other variables); the goal is then to choose these probabilities efficiently while ensuring that the resulting assignment satisfies many of the constraints in expectation.

Informally, oblivious algorithms are probabilistic rounding algorithms which choose rounding probabilities for each variable v in a "very local" way. It is simplest to define these algorithms, as in [17], in the case of (the graph-theoretic view of) Max-DICUT. In this context, oblivious algorithms choose a rounding probability for each vertex depending only its *bias*. In a directed graph G, the bias of a vertex v is a real number in the interval $[-1, +1]$,

[1] In particular, as observed by Trevisan [43], an *arbitrary* Boolean predicate ϕ of arity k with r satisfying assignments can be converted to r "disjoint" applications of Max-kAND constraints; this transformation makes an instance of Max-CSP(ϕ) into an instance of Max-kAND and drops the value by a factor exactly r. In turn, this means that algorithms for Max-kAND can approximate the acceptance probability of k-bit probabalistically checkable proofs (PCP) verifiers.

and is defined as the difference between v's in- and out-degrees divided by its total degree. (Note that the in- and out-degrees of a vertex completely describe what the vertex can "see" about the graph around it by exploring paths of length 1.) The natural generalization of bias to a variable in Max-kAND is the difference between its number of positive and negative appearances in the instance, divided by the total number of appearances,[2] and oblivious algorithms again are those which round each variable depending only on its bias.

In this paper, we also define a class of algorithms called *superoblivious algorithms*. These are a subclass of oblivious algorithms which round each variable depending only on the *sign* of the bias (i.e., positive, negative, or zero) and not the magnitude; for instance, they ignore the distinction between variables of bias $+0.9$ (95% of appearances are positive) and bias $+0.1$ (55% of appearances are positive). A principal focus of this paper is showing that for all k, oblivious algorithms can achieve strictly better approximation ratios vs. superoblivious algorithms for Max-kAND, and we motivate this focus in the following section.

Max-kAND and streaming algorithms

Max-kAND and its special case Max-DICUT have recently received heavy attention in one particular family of models, namely, those of *streaming algorithms* [20, 14, 7, 37, 36].[3] In these models, the algorithm has highly bounded space (relative to n, the number of variables in the instance) and takes one or more passes over the list of constraints in the instance before outputting an estimate for the value of the instance. It turns out that certain separation results established between streaming models in [36, 37] are closely related to the distinction between oblivious and superoblivious algorithms described in the previous subsection, and to illuminate this connection, we pause to give a quick recap of these works on streaming algorithms for CSPs.

Chou, Golovnev, and Velusamy [14] designed a $O(\log n)$-space streaming algorithm which (arbitrarily-close-to-)4/9-approximates the value of instances of Max-DICUT, and showed that this algorithm is optimal in $o(\sqrt{n})$ space. Chou, Golovnev, Sudan, and Velusamy [12, 13] vastly generalized this "dichotomy" result to hold for all CSPs (even over non-Boolean alphabets): They showed that for every CSP predicate ϕ, there is a ratio α^*, below which there are $O(\log n)$-space approximation algorithms, and above which there are no $o(\sqrt{n})$-space algorithms.[4]

The recent works of Saxena, Singer, Sudan, and Velusamy [37, 36] demonstrated that Max-DICUT exhibits a streaming-complexity-theoretic phenomenon previously unbeknownst to any CSP: It admits approximation algorithms in certain streaming regimes which beat the optimal $o(\sqrt{n})$-space approximation ratio of 4/9 [14]. Specifically, better-than-4/9-approximations are achievable either by (i) using $\widetilde{O}(\sqrt{n})$ space or (ii) assuming that the input stream of constraints is randomly ordered. These works relied heavily on the investigation by Feige and Jozeph [17] of oblivious algorithms for Max-DICUT. Indeed, Feige and Jozeph [17] constructed a $0.483 > 4/9$-approximation oblivious algorithm for Max-DICUT, and the main thrust of [37, 36] is to use stronger streaming models to "implement" the [17] algorithm by sampling random edges and calculating the biases of their endpoints, thereby beating the 4/9-approximation of [14].

[2] Or, more generally in weighted instances, the total weight of the clauses in which it appears positively vs. those in which it appears negatively.

[3] Other works in the broader area of approximation algorithms for CSPs in streaming models include [3, 4, 29, 26, 27, 9, 10, 11, 19, 27, 28, 39]. See also Sudan's survey [41] and the author's undergraduate thesis [38].

[4] Technical note: The lower bounds in [12, 13] only hold in general for a special class of streaming algorithms called sketching algorithms; we ignore this point in the exposition.

The principal motivation for the current work is extending the results of [37, 36] to Max-kAND for all k: That is, showing that tweaking the streaming model can lead to improved approximations vs. the model studied in the dichotomy theorem of [12]. It is not difficult to show that oblivious algorithms can be "implemented" in these modified streaming settings, analogously to the Max-DICUT case. Thus, letting α_k^* denote the $O(\log n)$-vs.-$\Omega(\sqrt{n})$-space dichotomy threshold for Max-kAND, the goal becomes to show that oblivious algorithms beat the ratio α_k^*. A recent work of Boyland, Hwang, Prasad, Singer, and Velusamy [7] studied exactly this ratio, and showed that for each k, the optimal algorithm for Max-kAND essentially "implements" a superoblivious algorithm. (Note that *a priori* one cannot simulate a superoblivious algorithm in $O(\log n)$ space; the algorithm in [7] instead measures some quantitative properties of the input instance which turn out to relate to the behavior of a certain superoblivious algorithm.) In particular, the threshold ratio α_k^* equals the ratio achieved by *some* superoblivious algorithm. Thus, to prove the separation results, it suffices to show that oblivious algorithms strictly outperform superoblivious algorithms (for all k); as mentioned above, this is the main focus of the current work.

Linear programming as a tool for analyzing approximation algorithms

The key technical ingredient in the current work is the definition and analysis of a so-called *factor-revealing linear program (LP).* In such an LP, feasible solutions encode instances of the problem at hand (i.e., Max-kAND); when we fix an algorithm in the designated class (i.e., an oblivious algorithm), the objective function "reveals" the approximation ratio the algorithm achieves on any given instance. Similar programs were first studied in depth for facility location problems by Jain, Mahdian, Markakis, Saberi, and Vazirani [25], and have been examined in other contexts such as online bipartite matching [31]. Our LP is a generalization of the one developed by Feige and Jozeph [17] for Max-DICUT.

To show that there is a 0.483-approximation oblivious algorithm for Max-DICUT, Feige and Jozeph [17] used computer analysis of their LP; as mentioned above, the fact that $0.483 > 4/9$ – that is, oblivious algorithms outperform superoblivious algorithms for Max-DICUT – in turn powered the works of [37, 36] in establishing that there are improved approximations in stronger streaming models. However, this result of [17] was used as a black box. We believe that our approach, which contrasts between "superoblivious" and more general "oblivious" algorithms and attacks the corresponding LPs from an analytical perspective, gives a more natural and systematic explanation for why Max-DICUT admits these improved approximations – and implies that Max-kAND does as well, for all k.

1.2 Results

Next, we turn to statements of our results. In our notation, an oblivious algorithm for Max-kAND is denoted $\texttt{Obl}_k^{\mathbf{t},\mathbf{p}}$, where $\mathbf{t}$ and $\mathbf{p}$ are, respectively, a *bias partition* which splits the space of possible biases (i.e., the interval $[-1,+1]$) into discrete intervals, and a *rounding vector* $\mathbf{p}$ specifying a probability with which to round variables for each of these intervals. We denote by $\alpha(\texttt{Obl}_k^{\mathbf{t},\mathbf{p}})$ the approximation ratio achieved by this algorithm. (See Section 2 below for formal definitions of these objects.)

To state the theorems properly, we first define some relevant quantities which first arose in the context of small-space sketching algorithms for Max-kAND in the work of Boyland *et al.* [7]. We define

$$\gamma_k \overset{\text{def}}{=} \begin{cases} \frac{1}{k} & k \text{ odd} \\ \frac{1}{k+1} & k \text{ even,} \end{cases} \tag{1}$$

and

$$p_k^* \stackrel{\text{def}}{=} \frac{1}{2}(1+\gamma_k) \tag{2}$$

and

$$\alpha_k^* \stackrel{\text{def}}{=} 2 \cdot (p_k^*(1-p_k^*))^{\lfloor k/2 \rfloor}. \tag{3}$$

That is, for even k, $\alpha_k^* = 2^{-(k-1)}(1-1/(k+1))^{k/2}(1+1/(k+1))^{k/2}$, and for odd k, $\alpha_k^* = 2^{-(k-1)}(1-1/k)^{(k-1)/2}(1+1/k)^{(k-1)/2}$. In particular, at $k=2$, we have $p_k^* = 2/3$ and $\alpha_k^* = 4/9$.

Our first theorem states that the optimal superoblivious algorithm for Max-kAND achieves ratio α_k^*, and that this algorithm rounds with probability p_k^*:

▶ **Theorem 1** (Characterization for superoblivious algorithms). *For every $k \geq 2$, there is a unique superoblivious algorithm $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}$ achieving ratio $\alpha(\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}) = \alpha_k^*$, and all other superoblivious perform strictly worse. (In particular, for $\mathbf{t} = (0,1)$, every rounding vector $\mathbf{p} = (p)$ satisfies $\alpha(\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}) \leq \alpha_k^*$, with equality if and only if $p = p_k^*$.)*

Our main theorem then states that one can improve over these superoblivious algorithms using other oblivious algorithms, and indeed, it suffices to consider only slight "perturbations" of the optimal superoblivious algorithms:

▶ **Theorem 2** (Main theorem: Better oblivious algorithms). *For every $k \geq 2$, there exists a bias partition $\mathbf{t}$ and a rounding vector $\mathbf{p}$ such that the oblivious algorithm $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}$ achieves $\alpha(\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}) \gneq \alpha_k^*$. (In particular, there exists $\epsilon^* > 0$ such that for all $0 < \epsilon \leq \epsilon^*$, there exists $0 < \delta < 1$ such that $\mathbf{t} = (\delta, 1)$ and $\mathbf{p} = (p_k^* + \epsilon)$ satisfy $\alpha(\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}) \gneq \alpha_k^*$.)*

These theorems are both proven by analyzing the dual of a certain natural "factor-revealing" linear program. Arguably, this "dual" perspective systematizes the *ad hoc* analyses of small-space sketching algorithms for Max-DICUT in [14] and for Max-kAND in [7]. Indeed, the analysis in those paper examined certain systems of linear inequalities using "elementary" reasoning (i.e., taking nonnegative linear combinations), and it is exactly this type of reasoning which is captured by the technology of dual linear programs. Our perspective also sheds direct light on why oblivious algorithms outperform the 4/9 ratio for Max-2AND was key to the streaming separations established for Max-DICUT by Saxena *et al.* [37, 36].

Indeed, our results also have the following implications for streaming algorithms, generalizing connections established by Saxena, Singer, Sudan, and Velusamy [37] for the special case of Max-DICUT. We say an instance Ψ of Max-kAND is in *input form* if it is unweighted (i.e., the weight of every clause is 1), though multiple copies of the same clause are allowed. These instances will be the input to our algorithms though this is essentially without loss of generality as general instances can be "rounded" to such instances via standard arguments.

▶ **Theorem 3** (Random-order streaming algorithm). *For all $k \geq 2$, there exists $\alpha > \alpha_k^*$ such that for all $\epsilon > 0$, the following holds. There is an $O(\log n)$-space streaming algorithm which, for every instance Ψ of* Max-kAND *in input form with n variables and* $\mathrm{poly}(n)$ *clauses, given as input Ψ's clauses in a* randomly-ordered *stream, outputs an $(\alpha - \epsilon)$-approximation to the* Max-kAND *value of Ψ with probability* 99/100.

▶ **Theorem 4** (Bounded-degree streaming algorithm). *For all $k \geq 2$, there exists $\alpha > \alpha_k^*$ such that for all $\epsilon > 0$, the following holds: For all $D \geq 2$, there is an $O(D^{1/k} n^{1-1/k} \log n / \epsilon^{2/k})$-space streaming algorithm which, for every instance Ψ of input form with n variables and* maximum degree *$\leq D$ (i.e., every variable is contained in $\leq D$ clauses), given as input Ψ's clauses in an* adversarially-ordered *stream, outputs an $(\alpha_k^* + \epsilon)$-approximation to the* Max-kAND *value of Ψ with probability* 99/100.

Table 1 The table below displays concrete approximation ratio for Max-kAND, for $k \in \{2, \dots, 5\}$. In the second column, we write the trivial upper bound of $2^{-(k-1)}$ on the approximation ratio of all oblivious algorithms (and more generally all "local" algorithms) for Max-kAND (see Observation 7 below). In the third column, we write α_k^*, the approximation ratio achieved by the best superoblivious algorithm (and also by the best $o(\sqrt{n})$-space sketching algorithm [7]). In the fourth column, we highlight that the only previously known CSP for which oblivious algorithms outperformed superoblivious algorithms was Max-2AND (from [17]). In the fifth, we include approximation ratios from our "perturbed superoblivious" algorithms, as in Theorem 2 with $\delta = 0.01$ and $\epsilon = 0.001$. Finally, in the sixth column, we report ratios achieved by much more complex algorithms which we constructed. These algorithms are parametrized by triples (ℓ, x, y), where ℓ specifies the number of bias classes, and x, y specify a rounding vector. ℓ is chosen such that the number of variables, which is roughly $(2\ell)^k$ (see Section 3.1 below), is in at most the hundreds of thousands, in order for the LP solver to run in a reasonable amount of time. The bias partition is a uniform partition of $[0, 1]$ into ℓ intervals and, imitating the algorithm in [17, Proof of Theorem 1.3], our rounding vector are "two-piece piecewise-linear functions": the first part of the vector, up to bias x, interpolates linearly between probability $\frac{1}{2}$ and y, and the second part interpolates linearly between probability y and 1. The values in the last two columns were calculated with a Python script and the LP solver `glpk`; the code is available online at `https://github.com/singerng/oblivious-csps`. For the final column, the parameters (x, y) were chosen using a grid search; solving the final LPs took 1 hour, 56 minutes on a 2021 Macbook Pro.

k	**Upper bound**	**Superobl.**	**Prev.**	**New, pert.**	**New, piecewise lin.**
2	$1/2 = 0.5$	$4/9 \approx 0.4444$	0.4835 [17]	0.4457	0.4844 @ $(200, 0.5, 1.0)$
3	$1/4 = 0.25$	$2/9 \approx 0.2222$		0.2226	0.2417 @ $(30, 0.7, 1.0)$
4	$1/8 = 0.125$	$72/625 = 0.1152$		0.1157	0.1188 @ $(11, 0.8, 0.8)$
5	$1/16 = 0.0625$	$36/625 \approx 0.0576$		0.0578	0.0589 @ $(7, 0.95, 0.8)$

Both of these results are interesting because, as shown by Boyland *et al.* [7] (analyzing families of algorithms and lower bounds due to Chou *et al.* [12]), there are $O(\log n)$-space streaming algorithms which output (arbitrarily close to) α_k^*-approximations for adversarially-ordered streams, and this is the best achievable ratio in $o(\sqrt{n})$ space.[5] Therefore, our results show that by relaxing either the adversarial-ordering assumption or the space bound, one can achieve better algorithms (the latter under a bounded-degree assumption). Analogous results to Theorems 3 and 4 were obtained for Max-DICUT by Saxena, Singer, Sudan, and Velusamy [36] for the special case of Max-DICUT, there contrasting with algorithms and lower bounds due to Chou, Golovnev, and Velusamy [14].

We also include some explicit improved approximation ratios calculated using computer search and LP solvers in Table 1.

1.3 Technical overview

The first main technical step in the paper is to develop, for each oblivious algorithm $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}$ (defined by a bias partition $\mathbf{t}$ and a rounding vector $\mathbf{p}$), a linear program (LP) which characterizes the approximation ratio of $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}$; this LP is contained in Lemma 11 below, and is a generalization of the LP developed for oblivious algorithms in Max-DICUT in [17]. The LP has a simple structure: Each feasible solution corresponds to a certain family of instances of Max-kAND on which $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}$ produces the same approximation to the Max-kAND

[5] Again, this lower bound is currently only known to hold for a subclass of streaming algorithms called *sketching* algorithms, but the algorithm in Theorem 4 appears to be such an algorithm.

value, and the objective equals this approximation value. In particular, we will assign to each clause in an instance Ψ of Max-kAND a "pattern" based on the biases of and negations on the variables, and use the observation that the probability that any particular clause is satisfied depends only on its pattern.

Next, we formulate the dual LP for this original "primal" LP (see Lemma 12 below). Here is where we benefit massively from the fact that the performance of oblivious algorithms is captured by a linear program, because by the magic of LP duality, it is possible to constructively show that oblivious algorithms perform *well*: While feasible solutions to the *primal* LP *upper-bound* the ratio achieved by an oblivious algorithm $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}$, feasible solutions to the *dual* LP *lower-bound* the ratio! In other words, to prove that an oblivious algorithm performs well on *all* instances, it suffices to construct a *single* feasible dual solution.

To prove Theorem 2, we now want to compare the dual LP for superoblivious algorithms and their "perturbations", and show that we can get "improved" feasible solutions in the latter case. It turns out that in this setting, the primal LP has $O(k^5)$ variables and only 7 inequality constraints; therefore the dual LP has 7 variables and $O(k^5)$ inequality constraints. We make the crucial observation that in the superoblivious case there is an optimal dual solution which is *sparse*: It is supported on only 3 variables. Since this dual solution is so simple, we can analytically prove its feasibility for all k. The statement of the kind of dual solution we are seeking is in Lemma 13 below.

And moreover, this inequality will show that in the superoblivious case, when we plug in our special solution, all but 6 of the $O(k^5)$ dual constraints have slack! Thus, for very small values of δ, it will be sufficient to slightly perturb this special solution in a way that makes these 6 "core" constraints strictly satisfied. This involves careful analysis based on certain elementary inequalities, using simple inequalities such as that $\frac{1-\epsilon}{1-k\epsilon} > \frac{1+\epsilon}{1+k\epsilon}$ for all $\epsilon > 0$ and $k > 1$. The analysis outlined in this paragraph is omitted from this version of the paper; see the full version.

1.4 Future questions

Streaming algorithms

We hypothesize that the bounded-degree assumption in Theorem 4 can be relaxed to give an $\widetilde{O}(n^{1-1/k})$-space algorithm for *all* instances (in input form with poly(n) clauses). Specifically, Saxena, Singer, Sudan, and Velusamy [36] developed sketching techniques enabling such a guarantee for Max-DICUT, the bounded-degree counterpart being provided by their earlier work [37]; perhaps these ideas can be extended to Max-kAND.

More CSPs

It would also be interesting to extend the framework in this paper to more CSPs, both other Boolean CSPs and to CSPs over larger alphabets. To the best of our knowledge, it is even plausible that every CSP which admits nontrivial $O(\log n)$-space sketching algorithms (as analyzed in [13]) also admits "oblivious-style" approximation algorithms, which in turn yield better sublinear-space streaming algorithms. A good starting point here would be to analyze symmetric Boolean CSPs, since in that setting we know that all CSPs which do not support one-wise distributions of satisfying assignments admit such nontrivial sketching algorithms (see [12, Proposition 2.10]); this class includes Max-kAND, for which we developed such results in this paper, but we could hope for improved "oblivious-style" algorithms for other such CSPs, e.g. symmetric threshold functions.

"Uniform" hard instances

In the special case of Max-DICUT, Feige and Jozeph [17] constructed what might be called a *uniformly hard* instance of Max-DICUT: For this single instance, *every* oblivious algorithm achieves a ratio less than than 0.49. (This strengthens the $\frac{1}{2}$ bound from a "trivial" instance, a single bidirected edge; see also Observation 7 below.) It would be interesting to construct similar instances for Max-kAND, $k \geq 3$, especially if such this construction could be made analytic. We note that such an object corresponds to a feasible solution to the linear program in Lemma 11 for which *every* choice of rounding vector has objective strictly less than $\frac{1}{2}$, and therefore for Max-kAND, any proof would require certifying that a certain degree-k polynomial is bounded below $\frac{1}{2}$ over $p \in [0, 1]$.

An optimal rounding curve?

To construct an 0.483-approximate oblivious algorithm for Max-DICUT, Feige and Jozeph [17] rounded vertices using (a discretization of) a sigmoid-shaped piecewise-linear function: This function rounds vertices with bias $b \in (0, 1]$ to 1 with probability

$$p(b) = \begin{cases} \frac{1}{2} + b & 0 \leq b \leq \frac{1}{2} \\ 1 & \frac{1}{2} \leq b \leq 1 \end{cases}.$$

But is it possible to analytically calculate the optimal rounding function (and is it unique)? Given any discretization of biases into intervals, one could in principle enumerate all basic feasible solutions to the LP, and then calculate the best rounding vector; that is, each rounding vector will induce an objective function for the LP, and the best rounding vector maximizes the minimum objective over all basic feasible solution. Towards this, it might be helpful to get a handle on the vertices of this LP's polytope, and whether there is some simple way to enumerate them.

Outline

We define Max-kAND and oblivious algorithms formally in Section 2 and develop the linear-programming characterization for the approximation ratio of oblivious algorithms, and some other basic tools, in Section 3. We begin analyzing the dual LP to prove Theorem 2 in Section 4. The remainder of the proof of Theorem 2, and the proofs of the remaining theorems, are omitted; see the full version.

2 Definitions: Max-kAND and oblivious algorithms

We now give formal definitions for the Max-kAND problem and for oblivious algorithms.

The Max-kAND problem

For the remainder of the paper, we adopt a (nonstandard) convention which views variables in Max-kAND as taking $\{-1, +1\}$ values (as opposed to $\{0, 1\}$); this is for notational convenience in defining bias and similar concepts.

▶ **Definition 5** (Max-kAND). *An* instance *of the* Max-kAND *problem on n variables is given by a sequence of constraints $C_1, \ldots, C_m$, with $C_j = (V_j^+, V_j^-, w_j)$, consisting of "positive variables" $V_j^+ \subseteq [n]$ and "negative variables" $V_j^- \subseteq [n]$ with $V_j^+ \cap V_j^- = \emptyset$ and $|V_j^+ \cup V_j^-| = k$, and a weight $w_j \geq 0$. An* assignment *for this problem is given by $(\mathbf{x}) = (x_1, \ldots, x_n) \in \{\pm 1\}^n$, and the* value *of this assignment is*

$$\mathsf{val}_\Psi(\mathbf{x}) \overset{\text{def}}{=} \frac{\sum_{j=1}^m \mathbb{1}[x_v = +1\ \forall v \in V_j^+ \wedge x_v = -1\ \forall v \in V_j^-] \cdot w_j}{\sum_{j=1}^m w_j}.$$

The value *of the instance* Ψ *is*

$$\mathsf{val}_\Psi \overset{\text{def}}{=} \max_{\mathbf{x}\in\{\pm1\}^n} \mathsf{val}_\Psi(\mathbf{x}).$$

Next, towards defining the bias of a variable in an instance, for any variable $v \in [n]$, we define its *positive* and *negative weight*:

$$w_\Psi^+(v) \overset{\text{def}}{=} \sum_{j=1}^m \mathbb{1}[v \in V_j^+] \cdot w_j \text{ and } w_\Psi^-(v) \overset{\text{def}}{=} \sum_{j=1}^m \mathbb{1}[v \in V_j^-] \cdot w_j. \tag{4}$$

Bias

Then, we define the *bias* of a variable as:[6]

$$\mathsf{bias}_\Psi(v) \overset{\text{def}}{=} \frac{w_\Psi^+(v) - w_\Psi^-(v)}{w_\Psi^+(v) + w_\Psi^-(v)}. \tag{5}$$

Bias partitions

Next, we define notations for a partition of the space of possible biases $[-1,+1]$ into $L = 2\ell+1$ intervals labeled by $\{-\ell,\ldots,+\ell\}$. The data of such a partition is a "bias partition" vector $\mathbf{t} = (t_0,\ldots,t_\ell)$ with $0 \le t_0 < \cdots < t_{+\ell} = 1$. Each such vector $\mathbf{t}$ defines a set of intervals $\mathsf{Int}^{\mathbf{t}}_{-\ell},\ldots,\mathsf{Int}^{\mathbf{t}}_{+\ell}$ such that each real number in $[-1,+1]$ belongs to exactly one interval. Specifically, we define:

- $\mathsf{Int}^{\mathbf{t}}_0 := [-t_0,+t_0]$, and
- $\mathsf{Int}^{\mathbf{t}}_{-i} := [-t_i,-t_{i-1})$ and $\mathsf{Int}^{\mathbf{t}}_{+i} := (+t_{i-1},t_i]$ for each $i \in \{1,\ldots,\ell\}$.

Our choice of which ends of these intervals are open and which are closed is an arbitrary convention; the only important property of the decomposition of $[-1,+1]$ into intervals is that it is *symmetric*.

We also let t_i^+ and t_i^- denote the upper and lower bounds on $\mathsf{Int}^{\mathbf{t}}_i$, respectively, i.e., $t_i^+ = \sup \mathsf{Int}^{\mathbf{t}}_i$ and $t_i^- = \inf \mathsf{Int}^{\mathbf{t}}_i$, so that e.g., $t_i^+ = t_i$ for $i \ge 0$, whereas $t_i^+ = t_{-(i+1)}$ for $i < 0$.

Oblivious algorithms

Given a partition of $[-1,+1]$ into bias class intervals (defined by some vector $\mathbf{t}$ as in the previous paragraph), we now define an algorithm which randomly rounds each variable of an Max-kAND instance according to which interval its bias falls into. The data of such a rounding scheme is a *rounding vector* $\mathbf{p} = (p_1,\ldots,p_\ell)$ of probabilities; given this vector, a vertex with bias in $\mathsf{Int}^{\mathbf{t}}_{+i}$ is rounded to 1 with probability p_i.

More precisely, we define an oblivious algorithm as follows:

[6] Throughout the paper, we assume every variable appears in at least one constraint, and therefore that $w_\Psi^+(v) + w_\Psi^-(v) > 0$. (This is WLOG, since variables appearing in no constraints can be ignored for the purposes of Max-kAND.)

▶ **Definition 6** (Oblivious algorithm for Max-kAND). *Let $L = 2\ell + 1 \geq 3$ be an odd integer. Let $\mathbf{t} = (t_0, \dots, t_\ell)$ be a bias partition and $\mathbf{p} = (p_1, \dots, p_\ell)$ a rounding vector. For any $k \geq 2$, the oblivious algorithm $\texttt{Obl}_k^{\mathbf{t},\mathbf{p}}$ for* Max-kAND *behaves as follows: Given an instance Ψ, for each variable $v \in \{1, \dots, n\}$ independently:*

- *If $\mathsf{bias}_\Psi(v) \in \mathsf{Int}_0^{\mathbf{t}}$, assign $x_v \mapsto 1$ w.p. $\frac{1}{2}$, $x_v \mapsto -1$ w.p. $\frac{1}{2}$.*
- *If $\mathsf{bias}_\Psi(v) \in \mathsf{Int}_{+i}^{\mathbf{t}}$ for $i \in \{1, \dots, \ell\}$, assign $x_v \mapsto 1$ w.p. p_i, $x_v \mapsto -1$ w.p. $1 - p_i$.*
- *If $\mathsf{bias}_\Psi(v) \in \mathsf{Int}_{-i}^{\mathbf{t}}$ for $i \in \{1, \dots, \ell\}$, assign $x_v \mapsto 1$ w.p. $1 - p_i$, $x_v \mapsto -1$ w.p. p_i.*

We denote by $\texttt{Obl}_k^{\mathbf{t},\mathbf{p}}(\Psi)$ the expected value of the assignment produced by this algorithm,[7] *and by*

$$\alpha(\texttt{Obl}_k^{\mathbf{t},\mathbf{p}}) \stackrel{\text{def}}{=} \inf_{\Psi} \frac{\texttt{Obl}_k^{\mathbf{t},\mathbf{p}}(\Psi)}{\mathsf{val}_\Psi}$$

the approximation ratio achieved by this algorithm.

In the simplest interesting case, we have $\ell = 1$, $\mathbf{t} = (0, 1)$, and $\mathbf{p} = (p)$. These algorithms, which we call *superoblivious* algorithms, ignore the *magnitude* of the bias of each variable, rounding only based on sign: E.g., negatively-biased variables are rounded to 1 w.p. $1 - p$.

▶ **Observation 7** (A "symmetric" hard instance). *There is a simple lower-bound construction which shows that* no *oblivious algorithm for* Max-kAND *can achieve a ratio better than $2^{-(k-1)}$. (Note that the constant α_k^* defined above, which according to Theorem 1 is the optimal ratio of superoblivious algorithms, equals this upper bound times a "discounting" factor.) Consider any k and the instance with two equally weighted constraints $C^+ = (+1, \dots, +1), (1, \dots, k)$ and $C^- = (-1, \dots, -1), (1, \dots, k)$; that is, the two constraints want $x_1, \dots, x_k$ to be all-$(+1)$'s and all-(-1)'s, respectively. Every variable has bias zero so it will be rounded uniformly by every oblivious algorithm, yielding value 2^{-k}, while the "greedy" all-$(+1)$'s (or all-(-1)'s) assignment achieves value $\frac{1}{2}$. (Indeed, this "lower bound" holds for any class of algorithms which cannot "break the symmetry" between these two greedy assignments.) Thus, for* every *oblivious algorithm $\texttt{Obl}_k^{\mathbf{t},\mathbf{p}}$, $\alpha(\texttt{Obl}_k^{\mathbf{t},\mathbf{p}}) \leq 2^{-(k-1)}$.*

▶ **Observation 8** (Generalizing oblivious algorithms). *There are a few natural ways to generalize our definition of oblivious algorithms:*

- *We could consider rounding functions which are not "antisymmetric". That is, we could round variables with bias $+b$ and variables with bias $-b$ with probabilities which are not complementary. In particular, for $b = 0$, we could round bias-0 variables to 1 with probability $p \neq \frac{1}{2}$. However, on the instance described in the previous observation, such an algorithm outputs an assignment of value $\frac{1}{2}p^k + \frac{1}{2}(1-p)^k$, and this value is uniquely maximized at $p = \frac{1}{2}$.*
- *We could use "general rounding functions", that is, arbitrary functions mapping each bias value to a rounding probability, to round each vertex. Under this "rounding functions" view, the above definition via intervals corresponds to "step fucntions" where the domain is broken up into finitely many intervals on which the function is constant. However, the focus of the current work is analyzing the approximation ratio of oblivious algorithms via linear programming, and such "continuous" algorithms would not be (directly) amenable to analysis via linear programming.*

[7] We abuse this notation and often think of $\texttt{Obl}_k^{\mathbf{t},\mathbf{p}}(\Psi)$ as the *output* of the oblivious algorithm, i.e., we think of the oblivious algorithm's goal as outputting a (scalar) estimate of the value of the instance; this holds especially in the context of streaming algorithms.

- *We could use a "max" algorithm, taking an ensemble of oblivious algorithms and outputting the best assignment produced by any of them.*

For Max-2AND*, Feige and Jozeph [17] showed that even allowing all these generalizations simultaneously stills fall short of achieving the ultimate goal of a $\frac{1}{2}$-approximation, and they described a specific instance witnessing this.*

3 The linear-programming framework for oblivious algorithms

In this section, we develop a linear program which captures the "worst-case instance" for any oblivious algorithm, and therefore can be used to calculate the approximation ratio (Lemma 11), as well as the corresponding dual linear program (Lemma 12). These will be applied to bound the approximation ratios of certain oblivious algorithms in the following sections.

3.1 Clause patterns

Let Ptn_k^L denote the set of vectors $\mathbf{c} = (\mathbf{c}^+, \mathbf{c}^-) = (c^+_{-\ell}, \dots, c^+_{+\ell}, c^-_{-\ell}, \dots, c^-_{-\ell})$ whose entries are natural numbers and sum to k. These are useful because they describe each particular clause from the perspective of an L-class oblivious algorithms. In particular, given a clause C, we denote its *pattern* $\mathsf{ptn}^{\mathbf{t}}(C) = (c^+_{-\ell}, \dots, c^+_{+\ell}, c^-_{-\ell}, \dots, c^-_{-\ell}) \in \mathsf{Ptn}_k^L$ where c_i^+ and c_i^- denote the number of positive and negative literals in C whose variables have bias class i, respectively, for each $i \in \{-\ell, \dots, +\ell\}$. That is, e.g.,

$$c_i^+ = |\{v \in V_j^+ : \mathsf{bias}_\Psi(v) \in \mathsf{Int}_i^{\mathbf{t}}\}|.$$

Now, for any rounding vector $\mathbf{p} = (p_1, \dots, p_\ell)$, we define

$$\mathsf{prob}^{\mathbf{p}}(\mathbf{c}) = 2^{-(c_0^+ + c_0^-)} \prod_{i=1}^{\ell} p_i^{c^+_{+i} + c^-_{-i}} (1 - p_i)^{c^-_{+i} + c^+_{-i}} \tag{6}$$

for each $\mathbf{c} \in \mathsf{Ptn}_k^L$.[8] Then we have:

▷ Claim 9. Let Ψ be an instance of Max-kAND with clauses $C_1, \dots, C_m$ with weights $w_1, \dots, w_m$, respectively. Then

$$\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}(\Psi) = \frac{\sum_{j=1}^m \mathsf{prob}^{\mathbf{p}}(\mathsf{ptn}^{\mathbf{t}}(C_j)) \cdot w_j}{\sum_{j=1}^m w_j}.$$

Proof. By linearity of expectation, it suffices to show that each clause C_j is satisfied w.p. $\mathsf{prob}^{\mathbf{p}}(\mathsf{ptn}^{\mathbf{t}}(C_j))$. We can rewrite

$$\mathsf{prob}^{\mathbf{p}}(\mathbf{c}) = 2^{-c_0^+} 2^{-c_0^-} \prod_{i=1}^{\ell} p_i^{c^+_{+i}} p_i^{c^-_{-i}} (1 - p_i)^{c^-_{+i}} (1 - p_i)^{c^+_{-i}}.$$

Recalling that each variable is assigned independently, and the clause is satisfied iff each literal is, the above expression precisely represents the probability that the clause is satisfied. (E.g., if there is a negative literal whose variable has bias class $+i$, this literal is satisfied with probability $1 - p_i$; the number of such factors in the probability is c^-_{+i}.) ◁

We observe that $|\mathsf{Ptn}_k^L| = \binom{k+2L-1}{2L-1}$ by the "stars-and-bars" formula. For instance, if $L = 3$ (as will be the case in the explicit analysis in the following sections), we have $|\mathsf{Ptn}_k^L| = O(k^5)$.

[8] In this expression we adopt the convention $0^0 = 1$, i.e., if $p_i = 0$ but $c^-_{+i} + c^+_{-i} = 0$ then we ignore the factor 0.

3.2 The factor-revealing linear program

We denote by $\mathsf{PosPtn}_k^L \subseteq \mathsf{Ptn}_k^L$ the space of clause patterns without negations, i.e., $\mathbf{c}$ such that $c_{-\ell}^- = \cdots = c_{+\ell}^- = 0$. For two vectors $\mathbf{x} = (x_1, \ldots, x_n), \mathbf{y} = (y_1, \ldots, y_n) \in \mathbb{R}^n$, let $\mathbf{x} \odot \mathbf{y} = (x_1 y_1, \ldots, x_n y_n)$ denote their entrywise product. To design the linear program, we will need the following useful proposition:

▶ **Proposition 10** (Flipping). *Let Ψ be an instance of* Max-kAND*, and for any assignment $\mathbf{y} = (y_1, \ldots, y_n) \in \{\pm 1\}^n$, let $\mathsf{flip}^{\mathbf{y}}(\Psi)$ denote the instance of* Max-kAND *where we "flip" the variables v with $y_v = -1$; that is, each clause $C_j = (V_j^+, V_j^-, w_j)$ in Ψ becomes a clause $D_j = (U_j^+, U_j^-, w_j)$ where $U_j^+ = \{v \in V_j^+ : y_v = +1\} \cup \{v \in V_j^- : y_v = -1\}$ and $U_j^- = \{v \in V_j^+ : y_v = -1\} \cup \{v \in V_j^- : y_v = +1\}$. Then:*

- *For every assignment $\mathbf{x} \in \{\pm 1\}^n$, $\mathsf{val}_\Psi(\mathbf{x}) = \mathsf{val}_{\mathsf{flip}^{\mathbf{y}}(\Psi)}(\mathbf{x} \odot \mathbf{y})$.*
- *In particular, if $\mathbf{x}$ is an optimal assignment to Ψ, then $\mathbf{x} \odot \mathbf{y}$ is an optimal assignment to $\mathsf{flip}^{\mathbf{y}}(\Psi)$.*
- $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}(\Psi) = \mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}(\mathsf{flip}^{\mathbf{y}}(\Psi))$.

Proof. Follows immediately from definitions. ◀

▶ **Lemma 11** (Primal characterization). *For every bias partition $\mathbf{t} = (t_0, \ldots, t_\ell)$ and rounding vector $\mathbf{p} = (p_1, \ldots, p_\ell)$, the approximation ratio $\alpha(\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}})$ achieved by $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}$ equals the value of the following linear program:*

$$\begin{cases} \text{minimize} & \displaystyle\sum_{\mathbf{c} \in \mathsf{Ptn}_k^L} \mathsf{prob}^{\mathbf{p}}(\mathbf{c}) \cdot W(\mathbf{c}) & \\ \text{s.t.} & W(\mathbf{c}) \geq 0 & \forall \mathbf{c} \in \mathsf{Ptn}_k^L \\ & \displaystyle\sum_{\mathbf{c} \in \mathsf{PosPtn}_k^L} W(\mathbf{c}) = 1 & \\ & t_i^-(W^+(i) + W^-(i)) \leq W^+(i) - W^-(i) & \forall i \in \{-\ell, \ldots, +\ell\} \\ & W^+(i) - W^-(i) \leq t_i^+(W^+(i) + W^-(i)) & \forall i \in \{-\ell, \ldots, +\ell\} \end{cases}$$

where we define the linear functions

$$W^+(i) = \sum_{\mathbf{c} \in \mathsf{Ptn}_k^L} c_i^+ W(\mathbf{c}) \text{ and } W^-(i) = \sum_{\mathbf{c} \in \mathsf{Ptn}_k^L} c_i^- W(\mathbf{c}).$$

Proof. Let α_{alg} denote the approximation ratio of $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}$, and α_{LP} the minimum value of the linear program. This proof generalizes [17, Proof of Theorem 1.2].

$\boldsymbol{\alpha_{\text{LP}} \leq \alpha_{\text{alg}}}$. We show that for every instance Ψ of Max-kAND, there is a feasible LP solution $\{W(\mathbf{c})\}_{\mathbf{c} \in \mathsf{Ptn}_k^L}$ of objective value $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}(\Psi)/\mathsf{val}_\Psi$.

Towards this claim, by Proposition 10, we can assume WLOG that the all-(+1)'s assignment is optimal for Ψ. Also, we assume WLOG by rescaling that Ψ has total weight $\frac{1}{\mathsf{val}_\Psi}$, i.e., $\sum_{j=1}^m w_j = \frac{1}{\mathsf{val}_\Psi}$. Now, let $C_1, \ldots, C_m$ denote the constraints of Ψ, and let $W(\mathbf{c}) := \sum_{j=1}^m \mathbb{1}[\mathsf{ptn}^{\mathbf{t}}(C_j) = \mathbf{c}] w_j$. We claim that $\{W(\mathbf{c})\}_{\mathbf{c} \in \mathsf{Ptn}_k^L}$ is feasible and has objective value $\sum_{\mathbf{c} \in \mathsf{Ptn}_k^L} \mathsf{prob}^{\mathbf{p}}(\mathbf{c}) W(\mathbf{c}) = \mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}(\Psi)/\mathsf{val}_\Psi$.

First, we check feasibility. Clearly all $W(\mathbf{c})$'s are nonnegative. Next, we have

$$\begin{aligned}
\mathsf{val}_\Psi &= \mathsf{val}_\Psi(+\mathbf{1}) && \text{(all-(+1)'s is optimal)}\\
&= \frac{\sum_{j=1}^m w_j \mathbb{1}[|V_j^-| = 0]}{\sum_{j=1}^m w_j} && \text{(def. of } \mathsf{val}_\Psi(+\mathbf{1})\text{)}\\
&= \frac{\sum_{\mathbf{c}\in\mathsf{PosPtn}_k^L} W(\mathbf{c})}{1/\mathsf{val}_\Psi} && \text{(def. of } \mathsf{PosPtn}_k^L \text{ and total weight assumption)}
\end{aligned}$$

which rearranges to $\sum_{\mathbf{c}\in\mathsf{PosPtn}_k^L} W(\mathbf{c}) = 1$.

Now, recall the definitions of $\mathsf{bias}_\Psi, w_\Psi^+, w_\Psi^-$ from Section 2. Fix a bias class $i \in \{-\ell, \dots, +\ell\}$. For any variable v with bias class i, we have $\mathsf{bias}_\Psi(v) \in \mathsf{Int}_i^{\mathbf{t}}$, so $t_i^- \leq \mathsf{bias}_\Psi(v) \leq t_i^+$, so multiplying through by $w_\Psi^+(v) + w_\Psi^-(v)$, we get

$$t_i^-(w_\Psi^+(v) + w_\Psi^-(v)) \leq w_\Psi^+(v) - w_\Psi^-(v) \leq t_i^+(w_\Psi^+(v) + w_\Psi^-(v)).$$

Letting $\mathcal{V}_i$ denote the set of all variables in Ψ with bias class i, we can sum over these equations to get

$$t_i^- \sum_{v\in\mathcal{V}_i}(w_\Psi^+(v) + w_\Psi^-(v)) \leq \sum_{v\in\mathcal{V}_i}(w_\Psi^+(v) - w_\Psi^-(v)) \leq t_i^+ \sum_{v\in\mathcal{V}_i}(w_\Psi^+(v) + w_\Psi^-(v)).$$

We claim that

$$W^+(i) = \sum_{v\in\mathcal{V}} w_\Psi^+(v),$$

and similarly $W^-(i) = \sum_{v\in\mathcal{V}} w_\Psi^-(v)$. These equalities imply that $W(\cdot)$ satisfies the feasibility constraints, and it remains to prove them. Now recall $w_\Psi^+(v) = \sum_{j=1}^m \mathbb{1}[v \in V_j^+]w_j$; therefore,

$$\sum_{v\in\mathcal{V}} w_\Psi^+(v) = \sum_{j=1}^m \sum_{v\in V_j^+} \mathbb{1}[\mathsf{bias}_\Psi(v) \in \mathsf{Int}_i^{\mathbf{t}}]w_j,$$

and j-th term in this sum is precisely c_i^+ where $\mathbf{c} = (\mathbf{c}^+, \mathbf{c}^-) = \mathsf{ptn}^{\mathbf{t}}(C_j)$. The proof for $W^-(i)$ is similar.

Finally, by Claim 9 and our assumption $\sum_{j=1}^m w_j = 1/\mathsf{val}_\Psi$, we have

$$\mathtt{Obl}_k^{\mathbf{t},\mathbf{P}}(\Psi) = \frac{\sum_{j=1}^m w_j \mathsf{prob}^{\mathbf{P}}(\mathsf{ptn}^{\mathbf{t}}(C_j))}{\sum_{j=1}^m w_j} = \frac{\sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} W(\mathbf{c}) \cdot \mathsf{prob}^{\mathbf{P}}(\mathbf{c})}{1/\mathsf{val}_\Psi},$$

which rearranges to $\mathtt{Obl}_k^{\mathbf{t},\mathbf{P}}(\Psi)/\mathsf{val}_\Psi = \sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} W(\mathbf{c}) \cdot \mathsf{prob}^{\mathbf{P}}(\mathbf{c})$, as desired.

$\alpha_{\mathrm{LP}} \geq \alpha_{\mathrm{alg}}$. This argument is essentially converse to the former argument, but there are two technical issues: (i) the linear program does not encode strict inequality constraints, while an oblivious algorithm needs to (in the sense that e.g., if $t_0 = 0$, then the algorithm rounds vertices with bias 0 and bias $+\epsilon$ differently), and (ii) since an Max-kAND constraint cannot use a variable twice, we might need many variables with the same bias in the instance we create. We omit the proof here; see the full version. ◀

▶ **Lemma 12** (Dual characterization). *For every bias partition* $\mathbf{t} = (t_0, \dots, t_\ell)$ *and rounding vector* $\mathbf{p} = (p_1, \dots, p_\ell)$*, the approximation ratio* $\alpha(\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}})$ *achieved by* $\mathtt{Obl}_k^{\mathbf{t},\mathbf{p}}$ *equals the value of the following linear program:*

$$\begin{cases} \max & z \\ \text{s.t.} & \mathbb{1}[\mathbf{c} \in \mathsf{PosPtn}_k^L] \cdot z \\ & \quad + \sum_{i=-\ell}^{+\ell} \left(((1-t_i^-)c_i^+ - (t_i^- + 1)c_i^-)y_i^- + ((t_i^+ - 1)c_i^+ + (1 + t_i^+)c_i^-)y_i^+\right) \le \mathsf{prob}^{\mathbf{P}}(\mathbf{c}) & \forall \mathbf{c} \in \mathsf{Ptn}_k^L \\ & y_i^- \ge 0 & \forall i \in \{-\ell, \dots, +\ell\} \\ & y_i^+ \ge 0 & \forall i \in \{-\ell, \dots, +\ell\} \end{cases}$$

Proof. To place the primal LP (from Lemma 11) in a more standard form, we rewrite the primal inequality $t_i^-(W^+(i)+W^-(i)) \le W^+(i)-W^-(i)$ as $(t_i^- -1)W^+(i)+(t_i^- +1)W^-(i) \le 0$; expanding the definitions of $W^+(i)$ and $W^-(i)$, this is equivalent to $(t_i^- -1)\sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} c_i^+ W(\mathbf{c}) + (t_i^- +1)\sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} c_i^- W(\mathbf{c}) \le 0$. Similarly, the inequality $W^+(i)-W^-(i) \le t_i^+(W^+(i)+W^-(i))$ becomes $(1-t_i^+)\sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} c_i^+ W(\mathbf{c}) - (1+t_i^+)\sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} c_i^- W(\mathbf{c}) \le 0$. Therefore, the primal LP is equivalent to the following standard-form LP:

$$\begin{cases} \text{minimize} & \sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} \mathsf{prob}^{\mathbf{P}}(\mathbf{c}) \cdot W(\mathbf{c}) \\ \text{s.t.} & W(\mathbf{c}) \ge 0 & \forall \mathbf{c} \in \mathsf{Ptn}_k^L \\ & \sum_{\mathbf{c}\in\mathsf{PosPtn}_k^L} W(\mathbf{c}) = 1 \\ & (1-t_i^+) \sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} c_i^+ W(\mathbf{c}) - (1+t_i^+) \sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} c_i^- W(\mathbf{c}) \le 0 & \forall i \in \{-\ell, \dots, +\ell\} \\ & (t_i^- - 1) \sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} c_i^+ W(\mathbf{c}) + (t_i^- + 1) \sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} c_i^- W(\mathbf{c}) \le 0 & \forall i \in \{-\ell, \dots, +\ell\} \end{cases}$$

By LP duality, the above LP has the same value as its dual LP, which is the LP in the hypothesis.[9] ◀

4 Proving Theorem 2 by analyzing "dual slack"

In this section, we outline the first step towards proving Theorem 2 by constructing dual solutions which witness lower bounds on the approximation ratio of oblivious algorithms. This first step is the following lemma, which gives a clean sufficient condition for a lower bound on the approximation ratio by constructing a certain sparse dual solution and applying the dual program (Lemma 12):

[9] See e.g. [32, p. 85]). One has to be careful with the signs, since our primal LP is a *minimization* LP. Instead, we can consider the LP which maximizes $-\sum_{\mathbf{c}\in\mathsf{Ptn}_k^L} \mathsf{prob}^{\mathbf{P}}(\mathbf{c}) \cdot W(\mathbf{c})$ (whose output is the negation of our desired output).
Applying duality to this LP gives one which minimizes z' such that $\mathbb{1}[\mathbf{c} \in \mathsf{PosPtn}_k^L] \cdot z' + \sum_{i=-\ell}^{\ell} \left(((1-t_i^-)c_i^+ - (t_i^- + 1)c_i^-)y_i^- + ((t_i^+ - 1)c_i^+ + (1 + t_i^+)c_i^-)y_i^+\right) \ge -\mathsf{prob}^{\mathbf{P}}(\mathbf{c})$. Transforming to a maximization problem equivalent to our original LP (since we had a negation!), we maximize $-z'$ such that $\mathbb{1}[\mathbf{c} \in \mathsf{PosPtn}_k^L] \cdot z' + \sum_{i=-\ell}^{\ell} \left(((1-t_i^-)c_i^+ - (t_i^- + 1)c_i^-)y_i^- + ((t_i^+ - 1)c_i^+ + (1 + t_i^+)c_i^-)y_i^+\right) \ge -\mathsf{prob}^{\mathbf{P}}(\mathbf{c})$. Finally, we negate both sides of this inequality, and use the bijective transformation $z = -z'$.

▶ **Lemma 13** (Sufficient conditions for good approximations). *For every $k \geq 2 \in \mathbb{N}$, $0 \leq \gamma, \delta \leq 1$, let $\mathbf{t} = (\delta, 1)$ and $\mathbf{p} = (\frac{1}{2}(1+\gamma))$. The algorithm $\texttt{Obl}_k^{\mathbf{t},\mathbf{p}}$ has approximation ratio $\alpha(\texttt{Obl}_k^{\mathbf{t},\mathbf{p}}) \geq 2^{-(k-1)}\beta$ if the following statement holds: There exist $X, Y \geq 0$ such that:*

$$\begin{cases} (1+\delta)\left(1 - \dfrac{i+j}{k}\right)Y + (1-\delta)\dfrac{j}{k}X \leq \beta^{-1}(1-\gamma)^i(1+\gamma)^j & \forall i, j \in \mathbb{N}, i+j \leq k \\ 2 - (1-\delta)\left(1 - \dfrac{i+j}{k}\right)Y - (1+\delta)\dfrac{i}{k}X \leq \beta^{-1}(1-\gamma)^i(1+\gamma)^j & \forall i, j \in \mathbb{N}, i+j \leq k \end{cases}$$

Proof. Consider applying the dual characterization of the approximation ratio (Lemma 12) with the solution $z = 2\beta/2^k$, $y^+_{-1} = X\beta/(k2^k)$, $y^+_0 = Y\beta/(k2^k)$, and $y^+_{+1} = y^-_{-1} = y^-_0 = y^-_{+1} = 0$; it is sufficient to show that this solution is feasible. Note that $t^+_{-1} = -\delta$ and $t^+_0 = \delta$. Thus, the feasibility constraints in Lemma 12 become

$$\frac{\beta}{2^k}\left(\mathbb{1}[\mathbf{c} \in \mathsf{PosPtn}^L_k] \cdot 2 + ((-\delta - 1)c^+_{-1} + (1-\delta)c^-_{-1})\frac{X}{k} + ((\delta - 1)c^+_0 + (1+\delta)c^-_0)\frac{Y}{k}\right) \leq \mathsf{prob}^{\mathbf{P}}(\mathbf{c}) \quad \forall \mathbf{c} \in \mathsf{Ptn}^L_k. \quad (7)$$

By Equation (6), and since $c^+_{-1} + c^+_0 + c^+_{+1} + c^-_{-1} + c^-_0 + c^-_{+1} = k$, we have

$$\mathsf{prob}^{\mathbf{P}}(\mathbf{c}) = \left(\frac{1}{2} - \frac{\gamma}{2}\right)^{c^+_{-1}+c^-_{+1}}\left(\frac{1}{2}\right)^{c^+_0+c^-_0}\left(\frac{1}{2} + \frac{\gamma}{2}\right)^{c^+_{+1}+c^-_{-1}} = 2^{-k}(1-\gamma)^{c^+_{-1}+c^-_{+1}}(1+\gamma)^{c^+_{+1}+c^-_{-1}}.$$

Thus, dividing through by $\beta/2^k$, Equation (7) becomes

$$\mathbb{1}[\mathbf{c} \in \mathsf{PosPtn}^L_k] \cdot 2 + ((1-\delta)c^-_{-1} - (1+\delta)c^+_{-1})\frac{X}{k} + ((1+\delta)c^-_0 - (1-\delta)c^+_0)\frac{Y}{k} \leq \beta^{-1}(1-\gamma)^{c^+_{-1}+c^-_{+1}}(1+\gamma)^{c^+_{+1}+c^-_{-1}} \quad \forall \mathbf{c} \in \mathsf{Ptn}^L_k. \quad (8)$$

Finally, we claim that Equation (8) is implied by the hypothesis. Indeed, we consider two cases. First, if $\mathbf{c} \in \mathsf{PosPtn}^L_k$, then $c^-_{-1} = c^-_0 = c^-_{+1} = 0$ and $c^+_0 = k - c^+_{-1} - c^+_{+1}$, so Equation (8) becomes

$$2 - (1+\delta)\frac{c^+_{-1}}{k}X - (1-\delta)\frac{k - c^+_{-1} - c^+_{+1}}{k}Y \leq \beta^{-1}(1-\gamma)^{c^+_{-1}}(1+\gamma)^{c^+_{+1}}.$$

This is precisely the second hypothesized inequality, for $c^+_{-1} = i, c^+_{+1} = j$. On the other hand, if $\mathbf{c} \notin \mathsf{PosPtn}^L_k$, then we observe that replacing $(c^+_{-1}, c^+_0, c^+_{+1}, c^-_{-1}, c^-_0, c^-_{+1}) \mapsto (0, 0, 0, c^-_{-1} + c^+_{-1}, c^-_0 + c^+_0, c^-_{+1} + c^+_{+1})$ fixes the RHS of Equation (8), while only increasing the LHS; thus, it suffices to prove Equation (8) only in this extreme case. Hence, we can assume $c^-_0 = k - c^-_{-1} - c^-_{+1}$, so Equation (8) becomes

$$(1-\delta)\frac{c^-_{-1}}{k}X + (1+\delta)\frac{k - c^-_{-1} - c^-_{+1}}{k}Y \leq \beta^{-1}(1-\gamma)^{c^-_{+1}}(1+\gamma)^{c^-_{-1}},$$

which is precisely the first assumed condition for $c^-_{-1} = j, c^-_{+1} = i$. ◀

▶ Remark 14. We chose the specific family of dual solutions used in the proof of Lemma 13 by inspecting an LP solver's output for $k = 2$ and $k = 3$. Our investigation also suggests that this solution is unique in a certain sense: In the simplest case of $k = 2$ and $\delta = \gamma = 0$, it appears that *every* optimal feasible solution requires $y^+_{-1} = 2/9$, and further, the only solution with only two nonzero y entries sets $y^+_0 = 1/9$.

A 10/7-Approximation for Discrete Bamboo Garden Trimming and Continuous Trimming on Star Graphs

Felix Höhne ✉

Rob van Stee ✉
University of Siegen, Germany

Abstract

In the discrete bamboo garden trimming problem we are given n bamboo that grow at rates $v_1, \dots, v_n$ per day. Each day a robotic gardener cuts down one bamboo to height 0. The goal is to find a schedule that minimizes the height of the tallest bamboo that ever exists.

We present a 10/7-approximation algorithm that is based on a reduction to the pinwheel problem. This is consistent with the approach of earlier algorithms, but some new techniques are used that lead to a better approximation ratio.

We also consider the continuous version of the problem where the gardener travels in a metric space between plants and cuts down a plant each time he reaches one. We show that on the star graph the previously proposed algorithm *Reduce-Fastest* is a 6-approximation and the known *Deadline-Driven Strategy* is a $(3 + 2\sqrt{2})$-approximation. The Deadline-Driven Strategy is also a $(9 + 2\sqrt{5})$-approximation on star graphs with multiple plants on each branch.

1 Introduction

In the discrete bamboo garden trimming problem (BGT), first introduced by Gasieniec et al. [8] we are given a set of n bamboo that grow at rates $v_1, \dots, v_n$ per day, i.e. the height of bamboo i extends by v_i each day. We assume that these growth rates are arranged such that $v_1 \geq v_2 \geq \dots \geq v_n$. Initially the height is set to zero. Each day a robotic gardener cuts down one bamboo to height zero. The goal is to design a trimming schedule such that the height of the tallest bamboo is minimized. Gasieniec et al. [8] gave a 2-approximation for discrete BGT which has been improved by van Ee [14] to a $\frac{12}{7}$-approximation.

Both results are obtained by reducing BGT to the pinwheel scheduling problem. The pinwheel scheduling problem is motivated by the communication between a satellite and its ground station. The ground station wants to receive messages from n satellites. Time is slotted and a satellite i sends a message for p_i consecutive timeslots before switching to a different message. Each timeslot the ground station receives a message from a single satellite. This means in order to guarantee that no message is missed we need to find a schedule that allocates at least one timeslot to satellite i in any interval of p_i units of time. We discuss the literature on pinwheel scheduling in Section 2.

If a BGT algorithm maintains a height of K then each bamboo i must be visited at least once in a period of $p_i^* := \lfloor \frac{K}{v_i} \rfloor$ time steps. That is, there is a BGT schedule that maintains height K for the input $(v_1, \ldots, v_n)$ if and only if the pinwheel problem $(p_1^*, \ldots, p_n^*)$ is schedulable.

There are also a number of results that do not use the connection to the pinwheel problem, using various greedy-type algorithms. The *Deadline-Driven Strategy* always cuts the bamboo with the earliest deadline provided that the height of this bamboo has reached a certain threshold. The deadline of a bamboo is the time it reaches the height the algorithm wants to maintain. This algorithm has already been considered for discrete BGT and there it is a 2-approximation as shown by J. Kuszmaul [12].

A second simple algorithm is *Reduce-Fastest* which is a 2.62-approximation for discrete BGT as shown by Bilò et al. [2] This algorithm always cuts the fastest plant which has reached a certain threshold. A similar algorithm is *Reduce-Max* that always cuts the highest bamboo and is a 4-approximation. Both of these algorithms are online algorithms based on simple queries. This means they are flexible and can easily adapt to changes in the input (the set of growth rates).

In the first part of this paper we present an algorithm based on a pinweel reduction that improves the approximation ratio for discrete BGT to $\frac{10}{7}$. This algorithm combines a binary search with the known technique of porous schedules for pinwheel scheduling. This marks the first time that porous schedules are used to approximate the BGT problem.

In the second part, we consider the continuous version of the BGT problem, also introduced by Gasieniec et al. [8]. In this version the bamboo are located in some metric space and the gardener needs to travel between the bamboo to cut them. Cutting is done instantly and the goal is to find a route that minimizes the maximum height of the bamboos. Gasieniec et al. give a $O(\log n)$-approximation algorithm that works in any metric space.

We consider the case where the underlying metric is a star graph. In this context we study some of the simple algorithms above (compared to the relative complicatedness of a pinwheel schedule) that achieve constant approximation ratios for this case.

1.1 Our results

For discrete BGT we propose a 10/7-approximation algorithm that is based on a reduction to the pinwheel-problem. Previous work used only the sum of the speeds H as a lower bound on the optimum value. We improve on this by using binary search in the interval $[H, 2H]$ and by planning to lose a certain factor in advance. By this we mean that all periods are multiplied by our goal ratio after calculating them from the speeds, making it easier to find a pinwheel schedule. We can show that our algorithm always finds a schedule of height at most $10K/7$ if a schedule of height K exists. This is achieved by using the technique of porous schedules which we will discuss in Section 2. Thus, the binary search is used to essentially find the best possible lower bound for the optimal value within this framework.

The result can be improved to $\frac{7}{5}$ using a computer-assisted proof. Unfortunately the proof is too long to fit into the appendix but can be found under the link `https://github.com/Felixhhne/bamboo`

In the continuous version of the problem we consider a star graph. We show that the 2.62-approximate algorithm Reduce-Fastest for discrete BGT, which can be seen as a special instance of a star graph, still works on arbitrary star graphs with one bamboo on each branch and we show that it is a 6-approximation in this case.

Furthermore the deadline driven algorithm gives us a $(3+2\sqrt{2})$-approximation on the star. This result can be extended to the case where there are multiple bamboo on each branch of the star. Here we pay a price in the approximation ratio and achieve a $(9+2\sqrt{5})$-approximation.

1.2 Related work

Both the discrete and continuous version of BGT were first introduced by Gasieniec et al. [8]. They provide a variety of results. The first algorithm they present is Reduce-Fastest, which in each step cuts the fastest growing bamboo above a certain height treshhold. This algorithm is a 2.62-approximation as shown by Bilò el al. [2]. A similar algorithm is Reduce-Max that always cuts the highest bamboo and is a 4-approximation. The final algorithm in this set of algorithms based on simple queries is the Deadline-Driven Strategy which is a 2-approximation. The results for Reduce-Max as well as the Deadline-Driven Strategy are from J. Kuszmaul [12].

Gasieniec et al. also give a fully offline 2-approximation algorithm that preprocesses the input and reduces the problem to a pinwheel-instance. This approach has been improved by van Ee [14] to a $\frac{12}{7}$-approximation.

There are other problems where the goal is to minimize the maximum height or backlog reached on a machine. One example is the Minimum Backlog Problem [3, 1, 13] where an adversary distributes water among a set of cups and the player may empty one or more cups on their turn.

In the problem of Buffer minimization with conflicts [5] there is a set of machines on a graph and load may arrive on these machines at any time. The algorithm runs machines to decrease their load but machines that are adjacent to each other on the graph may not run at the same time.

2 Pinwheel problems

We represent an instance of the pinwheel scheduling problem by the vector $p = (p_1, \ldots, p_n)$ of periods with which each plant should be cut (or: each machine should be scheduled).

▶ **Definition 1.** *The* density *of a pinwheel scheduling instance $p = (p_1, \ldots, p_n)$ is $d(p) = \sum_{i=1}^{n} \frac{1}{p_i}$.*

For example, the instance $(2, 3)$ has density $\frac{5}{6}$ and can be scheduled by repeating the sequence 12. Because 121212 . . . is the *only* feasible schedule, the instance $(2, 3, p_3)$ can not be scheduled regardless of the value of p_3.

The pinwheel problem was first introduced by Holte et al. [11] and then picked up by Chan and Chin [4]. They conjecture that any pinwheel instance with density up to 5/6 can be scheduled. The above example shows that a better guarantee is not possible. This conjecture is supported by a variety of works, including Fishburn and Lagarias [7] who show that any instance with $p_1 = 2$ and density up to 5/6 can be scheduled. Dei Wing [6] shows that the claim also holds for low-dimensional vectors with dimension up to 5 and more recently Gasieniec et al. [9] improve this result further by proving the claim for instances with up to 12 elements. Additionally they give a set of schedules that solve all schedulable instances with at most 5 tasks.

Without loss of generality, the elements of the pinwheel instance are in nondecreasing order. An obvious requirement for schedulability is $d(p) \leq 1$. Hence, aside from the instance (1) an instance can only be scheduled if $p_1 \geq 2$. Consequently we assume $2 \leq p_1 \leq p_2 \leq \cdots \leq p_n$.

Given a pinwheel instance $p = (p_1, \ldots, p_n)$, a successful schedule for p is an infinite sequence over $\{1, \ldots, n\}$ such that any subsequence of length p_i contains at least one i. An important consideration for pinwheel scheduling and BGT is the representation of a solution. This is because in general an explicit representation of the schedule may take exponential space. The solutions for pinwheel scheduling provided by Fishburn and Lagarias as well as

Chan and Chin come in the form of *fast online schedulers*. These are algorithms that can decide whether they can schedule an instance in polynomial time and then generate each symbol of the schedule in constant time.

Porous schedules

Fishburn and Lagarias introduced the concept of porous schedules [7] as a useful tool in the construction of pinwheel schedules.

Let $p = (p_1, \ldots, p_n)$. Let $\mathcal{S}$ be a subset of $\{1, \ldots, n\}$ and define $\mathcal{U} = \{1, \ldots, n\} \setminus \mathcal{S}$. A *porous schedule* for $\mathcal{S}$ (the set of *scheduled* tasks) is a schedule that allocates a slot for plant $i \in \mathcal{S}$ at least once every p_i positions, but also contains slots that are not allocated to any plant. When writing out the schedule the first type of slot is denoted by i and the second type, which we also call a hole, is denoted by _. In this paper we will only consider schedules that consist of infinite repeats of finite lists, and describe such a schedule by giving only that list. Even that part may have exponential size as a function of the size of the input.

Let

$$D_{\mathcal{U}} = 1 - \sum_{k \notin \mathcal{U}} \frac{1}{p_k^*}$$

be the maximum possible density of the unscheduled machines.

For example, given the instance (2,4,8,9), we could set $\mathcal{U} = \{3, 4\}$, which corresponds to the (unscheduled) plants with speed 8 and 9, and $\mathcal{S} = \{1, 2\}$, which corresponds to the plants with speed 2 and 4. The schedule 12_ (meaning 12_12_12_...) is a porous schedule for the scheduled tasks $\mathcal{S}$, while $\mathcal{U}$ is the set of leftover plants that still need to be scheduled.

▶ **Definition 2.** *Let $p = (p_1, \ldots, p_n)$ be a pinwheel instance and let f be a porous schedule for $\mathcal{S} \subseteq \{1, \ldots, n\}$. Then for $i \in \mathcal{U} = \{1, \ldots, n\} \setminus \mathcal{S}$, we define h_i as the minimum number of holes in p_i consecutive positions of f.*

Sometimes we also write the function $h(x)$ to represent the minimum number of holes in x consecutive positions. The set $h = \{h_i | i \in \mathcal{U}\}$ is again a pinwheel instance unless there exists an i with $h_i = 0$. Of course, in general h might not be schedulable. Lemma 2 of [7] explains how solving the pinwheel problem h can lead to a solution of p. A version of it is given below.

▶ **Lemma 3.** *Consider a pinwheel instance p and let a porous schedule f for a subset $\mathcal{S}$ of the tasks. Let $\mathcal{U} := \{1, \ldots, n\} \setminus \mathcal{S}$. If $h = \{h_i | i \in \mathcal{U}\}$ is a schedulable pinwheel instance, then p is schedulable.*

Proof. By assumption, there is a schedule $g : \mathbb{Z} \to \mathcal{U}$ (that we can enumerate using a fast online scheduler) for the input h. Let β be an order preserving map from the set of holes in f to $\mathbb{Z}$. Let $f' = f$ except for the holes in f where $f'(k) = g(\beta(k))$. Then f' is a schedule for p. ◀

Let $b \in [0, 1]$. We say that b is a *density guarantee* for the pinwheel problem if all instances p with $d(p) \leq b$ can be scheduled. This is always taken to mean that there exists a schedule for p and we can efficiently find a fast online scheduler to generate the sequence. Our results rely on the following theorem.

▶ **Theorem 4** ([7]). *The value $3/4$ is a density guarantee for the pinwheel problem. For instances with $p_1 = 2$, the density guarantee is $5/6$. In both instances, schedules can be found in time $O(n^3)$.*

Note that solving or scheduling a pinwheel instance for our purposes means finding a fast online scheduler but does not include explicitly writing out the schedule (not even just the finite part that repeats). Chan and Chin give an algorithm that runs in time $O(n^3)$ and schedules any instance with density at most $\frac{7}{10}$. Their algorithm achieves the following guarantees based on p_1:

p_1	2	3	4	5	6	7	8	≥ 9
guarantee	0.75	0.70	0.708	0.721	0.733	0.738	0.744	> 0.75

In particular this means any instance with $p_1 \geq 9$ and density at most 0.75 can be scheduled in time $O(n^3)$. Fishburn and Lagarias find schedules for the remaining cases with small values for p_1 and density up to 0.75 based on the following idea.

They find a porous schedule for the first few elements and they extend this schedule using the results from Chan and Chin and Lemma 3 to find a schedule for the remaining machines that fits into the holes. For example for the instance $(3, 4, p_3, \dots)$ we can create a porous schedule 12_ as discussed above which has a hole at every third position. The remaining machines after removing machines 1 and 2 have density at most $\frac{3}{4} - \frac{1}{3} - \frac{1}{4} = \frac{1}{6}$, thus $p_i \geq 6$ for $i \geq 3$. For this pattern of holes we get the values for h_i by dividing the remaining periods by 3. For $p_3 = 6, 7, 8$ we get $h_3 = 2$ which increases the density by a factor of not more than 4, thus the density of the resulting instance is at most $\frac{1}{6} \cdot 4 < \frac{3}{4}$ with the first element of the new instance being 2. By the table of Chan and Chin this is schedulable. A similar argument holds for $p_3 \geq 9$ with the density of the new schedule being not more than $\frac{7}{10}$. They further refine this approach in the paper.

3 A 10/7-approximation for discrete BGT

We claim that $H = \sum_{i=1}^{n} v_i$ is a lower bound on the optimal value. As long as all bamboo have height at most $H' < H$ the sum of all bamboo heights increases by at least $H - H' > 0$ each step until it eventually exceeds nH'. Then there must be a bamboo with height more than H'. On the other hand, there is an algorithm that produces a schedule of height $2H$ [8]. Thus, the optimal value is indeed somewhere in the interval $[H, 2H]$.

Our algorithm is based on the following key result.

▶ **Lemma 5.** *Consider a pinwheel instance p and a porous schedule f for a subset $\mathcal{S}$ of the tasks. Let $\mathcal{U} := \{1, \dots, n\} \setminus \mathcal{S}$. If $\frac{h_i}{p_i} \geq D_{\mathcal{U}}$ for each $i \in \mathcal{U}$ in a porous schedule for $\mathcal{S}$ and $\frac{1}{p_i} \leq \frac{3}{4p_i^*}$ for all $i \in \mathcal{U}$, then $(p_1, \dots, p_n)$ is schedulable for* Alg.

Proof. If $\frac{h_i}{p_i} \geq D_{\mathcal{U}}$ then

$$\sum_{i \in \mathcal{U}} \frac{1}{h_i} \leq \frac{1}{D_{\mathcal{U}}} \sum_{i \in \mathcal{U}} \frac{1}{p_i} \leq \frac{1}{D_{\mathcal{U}}} \frac{3}{4} D_{\mathcal{U}} = \frac{3}{4}.$$

Thus the instance is schedulable by Lemma 3 and by Theorem 4. ◀

Our algorithm begins by defining periods for the pinwheel problem based on the growth speeds. These periods are then multiplied by a certain factor to get an instance that is easier to schedule. It would be easiest if we could multiply all periods by 4/3. That way we would get an instance with density at most 3/4 which is therefore schedulable by Theorem 4. However, the input for the pinwheel problem must be a set of natural numbers. This means that we must round down after scaling the periods. Even when choosing a scaling factor larger than 4/3 (in our case, 10/7), after rounding down there can still be some periods that become too small, resulting in a density that is too high. This means that we cannot rely on the previous work as a black box. Typically, there will be a few difficult periods remaining. For instance, the period 4 becomes $\lfloor \frac{10}{7} \cdot 4 \rfloor = 5$ after scaling, and 5 becomes 7. Typically, longer periods are easier to handle as the condition $\lfloor \frac{10}{7} p^* \rfloor \geq \frac{4}{3} p^*$ is often satisfied.

We overcome this difficulty by finding a porous schedule for the few difficult periods by hand and then showing that the remaining periods can be scheduled in the holes. To do this we need to consider some inputs for the pinwheel problem that were not considered in previous works, since (as discussed) the overall density of the instance may still be above 3/4 at this point. Thus we need to find a porous schedule for the cases not covered by the table of Chan and Chin and a schedule for the remaining machines.

Algorithm 1 Binary Search for BGT.

```
Let $H = \sum_{i=1}^{n} v_i$ and $R = \frac{10}{7}$. Using binary search in the interval $[H, 2H]$ find the
  smallest $K$ such that the following procedure returns a valid schedule and return
  this schedule.
1. Given $K$ define $p_i^* = \lfloor \frac{K}{v_i} \rfloor$ and $p_i = \lfloor R p_i^* \rfloor$.
2. Solve the pinwheel problem $(p_1, \ldots, p_n)$.
```

In order to analyze Algorithm 1, we first show that whenever there exists a schedule for the pinwheel problem p^*, then the algorithm can find a schedule for p.

Assume that there exists a schedule for p^*. Then $d(p^*) \leq 1$. Whenever $\frac{p_i^*}{p_i} \leq \frac{3}{4}$ for all i we have $d(p) \leq \frac{3}{4}$ which means p is schedulable.

We can find schedules for cases that contain i with $\frac{p_i}{p_i^*} > \frac{3}{4}$ by assigning those periods to the subset $\mathcal{S}$ and applying Lemma 5. We create a porous schedule for $\mathcal{S}$ and define h_i for $i \in \mathcal{U} := \{1, \ldots, n\} \setminus \mathcal{S}$ as the minimum number of holes in p_i consecutive positions of the porous schedule. In some cases, the porous schedule is completely regular, with holes in every k-th location (and only there). In that case we get

$$\frac{h_i}{p_i} = \frac{\lfloor \frac{1}{k} \lfloor \frac{10}{7} p_i^* \rfloor \rfloor}{\lfloor \frac{10}{7} p_i^* \rfloor}$$

and for Lemma 5 we need to show that $h_i / p_i \geq D_{\mathcal{U}}$. If we write $p_i^* = 7a + b$ for some values a, b then this means showing that

$$\frac{5a + \lfloor \frac{1}{k} \lfloor \frac{10}{7} b \rfloor \rfloor}{10a + \lfloor \frac{10}{7} b \rfloor} \geq D_{\mathcal{U}}.$$

▶ **Lemma 6.** *If there is a schedule of height K then the procedure in Algorithm 1 finds a schedule of height at most $\frac{10}{7}K$.*

Proof. Let $p_i^* = \lfloor \frac{K}{v_i} \rfloor$. Assume there is a schedule of height K. Then there is a solution to the pinwheel problem $p^* = (p_1^*, \ldots, p_n^*)$ and thus $\sum_{i=1}^{n} \frac{1}{p_i^*} \leq 1$. If $p_1^* = 1$ then there is only one plant and the schedule is trivial. Thus we consider $p_1^* \geq 2$. The algorithm calculates the periods $p_i = \lfloor \frac{10 p_i^*}{7} \rfloor$ and solves the resulting pinwheel problem. Because of the definition of p_i^* the resulting schedule has height at most $\frac{10K}{7}$.

We show that if a schedule of height K exists, there is always a schedule for the pinwheel problem of Alg. If $p_i^* \geq 11$ then $\frac{1}{p_i}$ is smaller then $\frac{1}{p_i^*}$ by a factor of at least $\frac{3}{4}$ since

$$\frac{1}{p_i} = \frac{1}{\lfloor 10/7 p_i^* \rfloor} \leq \frac{1}{(10/7 p_i^* - 1)} \leq \frac{3}{4} \frac{1}{p_i^*} \text{ for } p_i^* \geq 11.$$

The same is true for every other value of p_i^* except $p_i^* = 2$ and $p_i^* = 4$ which can easily be verified. Thus if there is no p_i^* with value 2 or 4 the density of the pinwheel problem is at most 3/4 and it can be scheduled. We now consider all cases where these values do occur and use Lemma 5 to show that the pinwheel problem can be solved.

We denote these cases by listing the initial values of the instance p^*. For example, the notation 4,4,5 means that we are considering the case where $p_1^* = p_2^* = 4$ and $p_3^* = 5$. In that case $p = (5, 5, 7, \dots)$ with zero or more plants after the first three.

For each case, we create a porous schedule for a subset $\mathcal{S}$ of periods in p. We then need to show that $\frac{h_i}{p_i} \geq D_{\mathcal{U}}$ as well as $\frac{1}{p_i} \leq \frac{3}{4p_i^*}$ holds for all periods $\mathcal{U}$ that are not yet scheduled by the porous schedule. If that is the case, then p is schedulable by Lemma 5.

2 We have $p_i/p_i^* \geq 6/5$ for all p_i. This can easily be verified for $p_i^* = 2$ and $p_i^* = 4$ and it holds for all other periods because for those periods we have $p_i/p_i^* \geq 4/3$. This means the density in the pinwheel problem of Alg is at most 5/6. Since $p_1 = 2$ this problem can be solved.

$3, 3, 4$ and $3, 4, 4$ In this case there are only three plants and the schedule is 123.

$3, 4, p_3^* \geq 5$ Then $p = (4, 5, p_3 \geq 7, \dots)$. Alg schedules plants 1 and 2 using the schedule 1_2_. Then $D_{\mathcal{U}} = 5/12$ and $\frac{h_i}{p_i} = \frac{\lfloor \frac{1}{2} \lfloor \frac{10}{7} p_i^* \rfloor \rfloor}{\lfloor \frac{10}{7} p_i^* \rfloor}$. Let $p^* = 7a + b$. Then $\frac{h_i}{p_i} = \frac{5a + \lfloor \frac{1}{2} \lfloor \frac{10}{7} b \rfloor \rfloor}{10a + \lfloor \frac{10}{7} b \rfloor}$.

If $\frac{5a + \lfloor \frac{1}{2} \lfloor \frac{10}{7} b \rfloor \rfloor}{10a + \lfloor \frac{10}{7} b \rfloor} \geq D_{\mathcal{U}}$ then $\frac{5(a+1) + \lfloor \frac{1}{2} \lfloor \frac{10}{7} b \rfloor \rfloor}{10(a+1) + \lfloor \frac{10}{7} b \rfloor} \geq D_{\mathcal{U}}$ since $\frac{5}{10} > D_{\mathcal{U}}$.

Therefore if the inequality holds for a particular p_i^*, then it also holds for all subsequent p_i^* that have the same remainder after division by 7. In particular, this means that if there are 7 consecutive periods p_i^* with $h_i/p_i \geq D_{\mathcal{U}}$ then $h_i/p_i \geq D_{\mathcal{U}}$ also holds for all subsequent periods p_i^*.

We can determine that $h_i/p_i \geq D_{\mathcal{U}}$ holds for $p_i^* \geq 5$ by looking at enough periods (in this case periods 5 to 11). This argument is repeated in many of the subsequent cases. Appendix A contains tables that show the values for each case.

Furthermore $\frac{1}{p_i} \leq \frac{3}{4p_i^*}$ holds for $p_i^* \geq 5$. This means we can schedule this case.

$4, 4$ Then $p = (5, 5, \dots)$. Alg schedules plants 1 and 2 using the schedule 1_2__. Then $D_{\mathcal{U}} = 1/2$. For $p^* = 7a + b$ we get $\frac{h_i}{p_i} = \frac{6a + h(\lfloor \frac{10}{7} b \rfloor)}{10a + \lfloor \frac{10}{7} b \rfloor}$. By looking at 7 periods we can determine that $h_i/p_i \geq D_{\mathcal{U}}$ holds for $p_i^* \geq 4$.

Since $\frac{1}{p_i} \leq \frac{3}{4p_i^*}$ holds for $p_i^* \geq 5$ but not $p_i^* = 4$ we still need to consider the case where $p_1^* = p_2^* = p_3^* = 4$ but we can schedule this case for $p_3^* \geq 5$.

$4, 4, 4$ Then $p = (5, 5, 5, \dots)$. Alg schedules plants 1 to 3 using the schedule 123__. Then $D_{\mathcal{U}} = 1/4$. Using the same approach as in the previous case we can determine that $h_i/p_i \geq D_{\mathcal{U}}$ holds for $p_i^* \geq 4$. As in the previous case this means we can schedule all cases except the case where $p_1^* = \dots = p_4^* = 4$ since in this case $\frac{1}{p_i} \leq \frac{3}{4p_i^*}$ is not guaranteed. However in this case there are only four plants and therefore this case can be scheduled as well.

In all subsequent cases, all periods except the first are greater than 4. This means $\frac{1}{p_i} \leq \frac{3}{4p_i^*}$ holds for all periods after the first and we only need to verify $h_i/p_i \geq D_{\mathcal{U}}$. We get the following results.

◀

▶ **Theorem 7.** *Algorithm 1 is a polynomial-time $\frac{10}{7}$-approximation.*

Proof. The approximation ratio follows directly from Lemma 6. Since any height K that is at least the optimal height is schedulable, the procedure in algorithm 1 finds a valid schedule of height $\frac{10}{7}K$ for any height that is at least OPT. This means the binary search settles on a value that is at most OPT (since it is integer) and the algorithm returns a schedule of height at most $\frac{10}{7}$ times that value.

The porous schedules are given in the paper of Fishburn and Lagarias (in particular see table 1 of [7]) and are thus available in $O(1)$. Then the algorithm in [4] with runtime $O(n^3)$ is used to schedule the remaining machines. This means pinwheel instances with density at most 0.75 can be solved in time $O(n^3)$. In addition, as mentioned above Fishburn and Lagarias show that instances with $p_1 = 2$ and density up to $\frac{5}{6}$ can also be solved in time $O(n^3)$. ◀

4 Continuous BGT on a star

We now examine the continuous case of the BGT-problem. For this problem Gasieniec et al. propose a $O(\log n)$-approximation algorithm that works in any metric space. We consider the star graph and show that many of the constant approximation factor algorithms for discrete BGT can be extended to this case with only small losses in the approximation ratio.

4.1 Notation

Plants $1, \ldots, n$ grow at the end of each of n branches on a star graph. We define d_i as the time it takes the server to travel to plant i cut it and return to the center. The growth rate of plant i is denoted by h_i. Each *round* the server visits a plant and returns back to the center.

A *schedule* for continuous BGT on a star graph, is an infinite sequence over $\{1,\ldots,n\}$, that describes the order plants are visited in. While BGT is an infinite problem, it is sufficient to consider cyclic schedules. This is because any schedule that maintains a finite maximum height of a must visit each plant i at least once in $\frac{a}{h_i b}$ rounds, where b is the minimum distance needed to visit a plant. This means a schedule for BGT (on a star) solves the pinwheel problem with periods $\frac{a}{h_i b}$. Since any pinwheel schedule is cyclic (see Theorem 2.1 in [10]) the same is true for BGT schedules.

4.2 A lower bound for the star

Consider a cyclic schedule of length L. Let m_i be the amount of times plant i is visited in a segment of length L. Then $\frac{L}{m_i}$ is the average period between visits of i.

▶ **Lemma 8.** *The average height of p after a cut is $h_p(d_p + \sum_{i\neq p} \frac{m_i}{m_p} d_i)$.*

Proof. Consider a plant p. Let $\lambda_1,\ldots,\lambda_{m_p}$ be the heights plant p reaches in the schedule. The sum of all heights is the same as the sum of all distances that are traversed times the speed of the plant, i.e. $\sum_{k=1}^{m_p} \lambda_k = h_p \sum_{i=1}^{n} d_i m_i$. The average height is

$$\frac{1}{m_p}\sum_{k=1}^{m_p}\lambda_k = \frac{1}{m_p} h_p \sum_{i=1}^{n} d_i m_i = h_p(d_p + \sum_{i\neq p}\frac{m_i}{m_p} d_i).$$ ◀

Naturally the average height of p is a lower bound on the maximum height of p. This inspires the following model: The algorithm may visit each plant i at a certain fixed period f_i. These periods do not need to match a feasible schedule and may even be fractional. We only require that $\sum_{i=1}^{n} \frac{1}{f_i} = 1$ which means that the frequencies add up to one plant visited per round. The height a plant p reaches in this model is defined as $h_p(d_p + \sum_{i\neq p} \frac{f_p}{f_i} d_i)$.

By setting $f_i = \frac{L}{m_i}$ we get a solution for the new model with a height that is equal to the average height of a schedule in the original model and not more than the maximum height. This means a lower bound on the height in the new model is also a lower bound on the average as well as maximum height for continuous BGT on a star graph.

▶ **Lemma 9.** *$R \coloneqq \sum_{i=1}^{n} h_i d_i$ is a lower bound on the optimal height for continuous BGT on a star graph.*

Proof. Consider the new model. We set $K = \sum_{i=1}^{n} h_i$ and $f_i = \frac{K}{h_i}$. Then $\sum_{i=1}^{n} \frac{1}{f_i} = 1$ and this is a valid solution to the new model. Then the height of plant p is $h_p(d_p + \sum_{i\neq p} \frac{f_p}{f_i} d_i) = h_p(d_p + \sum_{i\neq p} \frac{h_i}{h_p} d_i) = \sum_{i=1}^{n} h_i d_i = R$.

It follows that all plants reach a height of R. Because of the requirement $\sum_{i=1}^{n} \frac{1}{f_i} = 1$ it is not possible to reach a maximum height lower than R, since visiting one plant more often would mean visiting other plants less often. This means R is a lower bound on the maximum height in the new model and therefore also a lower bound on the maximum height for continuous BGT on a star graph. ◀

4.3 Algorithms on the star

The algorithm Reduce-Fastest(x), introduced by Gasieniec et al. [8], cuts the next fastest growing bamboo among those with height at least $x \cdot R$. The proof of the following lemma is structured in a way similar to the proof by J. Kuszmaul for discrete BGT [13]; see the appendix.

▶ **Lemma 10.** *Reduce-Fastest*$(2(R + Dh_{max}))$ *is a 6-approximation on the star.*

Proof. Assume that at some point there is a bamboo b_i that reaches height $3(R + Dh_{max})$. Let t_1 be the most recent time b_i reaches height $2(R + Dh_{max})$ and t_3 the time it reaches height $3(R + Dh_{max})$. Furthermore let t_2 be the first time in between t_1 and t_2 where the gardener visits the center. Since it takes at most distance D to visit a plant and return to the center the height of b_i is at most $2R + 3Dh_{max}$ at this time. We consider the set S of bamboo that are cut at least once during the time interval $[t_2, t_3)$. For bamboo $j \in S$, let m_j be the number of times the bamboo is cut in the interval $[t_2, t_3)$.

Since b_i already has height at least $2(R + Dh_{max})$ when the algorithm decides to cut j we have $h_j \geq h_i$ for all $j \in S$.

For $m_j \geq 2$ we have $h_j(t_3 - t_2) > 2(R + Dh_{max})(m_j - 1)$ or $\frac{h_j(t_3-t_2)}{2(m_j-1)} > R + Dh_{max}$ because bamboo b_j needs to grow to height $2(R+Dh_{max})$ at least $m_j - 1$ times in the interval in order to be cut m_j times. Meanwhile bamboo b_i grows by at most $R + Dh_{max}$ during this interval and therefore $R + Dh_{max} > h_i(t_3 - t_2)$. It follows that $h_j > 2(m_j - 1)h_i \geq m_j h_i$.

During the interval the algorithm visits each plant $b_j \in S$ a total of m_j times and travels distance d_j each time. Additionally distance $\frac{d_i}{2}$ is traversed to reach plant b_i.

$$\begin{aligned} t_3 - t_2 &= \sum_{b_j \in S} m_j d_j + \frac{d_i}{2} \\ &< \sum_{b_j \in S} \frac{h_j d_j}{h_i} + \frac{d_i}{2} = \frac{1}{h_i} \sum_{b_j \in S} h_j d_j + \frac{d_i}{2} \\ &\leq \frac{1}{h_i}(R - h_i d_i) + \frac{d_i}{2} = \frac{R}{h_i} - \frac{d_i}{2} \end{aligned}$$

This however means that the inverval is too short for plant b_i to grow by height R since this takes time $\frac{R}{h_i}$. This is a contradiction and thus no plant can reach height $3(R + Dh_{max}) \leq 6L$. ◀

Define $L = \max(R, Dh_1)$, where D is the diameter of the star and h_1 is the growth rate of the fastest bamboo. This is a lower bound on Opt.

The Deadline-Driven algorithm always cuts the bamboo with the earliest deadline among those with height at least L where the deadline is determined by some height the algorithm wants to maintain. This means that in each round the algorithm chooses the plant with the earliest deadline, travels towards this plant and cuts it before returning to the center. The algorithm does not turn around when a more urgent plant reaches height L.

We say a plant is *requested* when it reaches height $(1 + \sqrt{2})L$ and before that this request is *initialized* at the time the plant has height 0. This happens either after a cut or at the beginning of the process. We choose the *deadline* as the time a bamboo reaches height $(3 + 2\sqrt{2})L$.

This means each request to cut a plant consists of an initialization time, a request time and a deadline.

▶ **Lemma 11.** *The Deadline-Driven algorithm maintains a height of* $(3 + 2\sqrt{2})L$.

Proof. Assume plant i reaches height $(3 + \sqrt{2})L$ at time T and is not cut. We scale the time (and distance) such that $L/h_i = 1$ which means plant i grows by L in one timestep. This is possible because whenever we scale the length of all edges by a factor then the heights of all plants reached in any schedule is scaled by the same factor. This holds for both Alg and Opt which means the approximation ratio is unaffected. We can also see this as changing the timescale using L/h_i as our unit of time.

Let t_1 be the last time the algorithm is idle or busy processing a request with deadline after T. Let time 0 be the most recent time before t_1 where plant i has height 0.

This means between time t_1 and T the algorithm is only processing requests with deadlines at or before T and it is not idle. Let the set of these requests be S and let v be the earliest request time among all request in S. We have $i \in S$, so $v \leq 1 + \sqrt{2}$ and $t_1 \geq v$.

We further divide the set S into old requests S_0 which are initialised before v and new requests S_1 which are initialised after v. The time required to process S_0 is $\sum_{j \in S_0} d_j$ because any bamboo with an old request must be visited once to fulfill the request. Afterwards the bamboo either has a deadline after T and is not visited again or becomes part of the bamboo with new requests. We next show that all bamboo with new requests also have an old request. Consider the earliest new request for a bamboo. This new request gets initialized inbetween v and T. This means there was a previous request for that bamboo with a deadline between v and T. This request is an old request.

The time required to process S_1 is $\sum_{j \in S_1} m_j d_j$ where m_j is the number of new requests of bamboo j which are requests with initialization time after v and a deadline before or at T. (Here $j \in S$ means there is a request for bamboo j in the set of requests S. We may also see S as a multi-set of bamboo instead.)

It is possible that just before v a request with a deadline after T arrives and is processed by the algorithm. The algorithm traverses a distance of r to serve this request if it exists, otherwise $r = 0$. This means $t_1 \leq v + r$.

We now show that $\sum_{j \in S_0} d_j + \sum_{j \in S_1} m_j d_j + v + r < T$ which contradicts the assumption that plant i is not cut before time T.

We begin by finding upper bounds on the time required to process the requests in S.

A bamboo with an old request must grow by at least $(2 + \sqrt{2})L$ in time at most $T - v$ to have a deadline before T which means $h_j(T - v) \geq (2 + \sqrt{2})L$. Meanwhile plant i grows by $(T - v)L$ in time $(T - v)$, that is $h_i(T - v) = (T - v)L$. It follows that

$$\frac{h_j}{h_i} \geq \frac{2 + \sqrt{2}}{T - v} \text{ for } j \in S_0 \tag{1}$$

A bamboo with new requests must reach the threshold $(1 + \sqrt{2})L$ exactly m_j times in time at most $T - v$ in order to be requested m_j times before T. Then $h_j(T - v) \geq m_j(1 + \sqrt{2})$. It follows that

$$\frac{h_j}{h_i} \geq m_j \frac{1 + \sqrt{2}}{T - v} \text{ for } j \in S_1 \tag{2}$$

We can now find upper bounds for the processing times of the requests in S. We first get

$$\sum_{j \in S_0} d_j \overset{(1)}{\leq} \frac{1}{h_i} \frac{T - v}{2 + \sqrt{2}} \sum_{j \in S_0} d_j h_j < \frac{T - v}{2 + \sqrt{2}} \frac{R}{h_i}$$

and then

$$\sum_{j \in S_1} m_j d_j \overset{(2)}{\leq} \frac{1}{h_i} \frac{T - v}{1 + \sqrt{2}} \sum_{j \in S_0} d_j h_j < \frac{T - v}{1 + \sqrt{2}} \frac{R}{h_i}$$

Given the timescale and because $R \leq L$ it takes time less than $\frac{T-v}{2+\sqrt{2}}$ to process the old requests and less than $\frac{T-v}{1+\sqrt{2}}$ to process the new requests.

It remains to show $\frac{T-v}{2+\sqrt{2}} + \frac{T-v}{1+\sqrt{2}} + v + r \leq T$.

We have $r \leq L/h_1 \leq L/h_i = 1$ where the first inequality holds because otherwise plant 1 would grow by more than L in the time it takes to travel distance r and the second follows from the ordering of the plants by their growth rate. Furthermore since $v < 1 + \sqrt{2}$ and the earliest deadline of i is $3 + 2\sqrt{2}$ we have $T - v \geq (2 + \sqrt{2})$.

It follows

$$r \leq 1 = \left(\frac{1}{2+\sqrt{2}}\right)\left(2+\sqrt{2}\right) \leq \left(\frac{1}{2+\sqrt{2}}\right)(T-v)$$

and then

$$\begin{aligned}
& r \leq \left(\frac{1}{2+\sqrt{2}}\right)(T-v) \\
& \Rightarrow \left(\frac{1}{2+\sqrt{2}}\right) v + r \leq \left(\frac{1}{2+\sqrt{2}}\right) T \\
& \Rightarrow \left(\frac{1}{2+\sqrt{2}}\right) v + r \leq \left(\frac{1}{2+\sqrt{2}}\right) T + \left(1 - \frac{1}{2+\sqrt{2}}\right) T - \left(1 - \frac{1}{2+\sqrt{2}}\right) T \\
& \Rightarrow \left(1 - \frac{1}{2+\sqrt{2}}\right) T + \left(\frac{1}{2+\sqrt{2}}\right) v + r \leq T \\
& \Rightarrow \left(1 - \frac{1}{2+\sqrt{2}}\right) T - \left(1 - \frac{1}{2+\sqrt{2}}\right) v + v + r \leq T \\
& \Rightarrow \frac{T-v}{2+\sqrt{2}} + \frac{T-v}{1+\sqrt{2}} + v + r \leq T
\end{aligned}$$

This means we can process all requests (including the request for b_i with deadline at time T) before time T and plant i does not grow above height $(3 + 2\sqrt{2})L$. ◀

4.4 Extending the star graph

It is also possible to extend some of these results to an extended version of a star graph, where several plants are placed on each branch at different distances from the center. We again number the plants from 1 to n and the definition of h_i and d_i remains the same.

This means that d_i is the time it takes the server to travel the path leading up to node i from the center two times (once in both directions). Additionally we denote with δ_i the time it takes the server to travel the singular edge, connected to node i from direction of the center, two times (once in both directions). The definitions of d_i and δ_i are visualized in Figure 1.

We assume that the speeds are decreasing on each branch. (If there is a plant a that is further away than plant b on a branch and has the same speed or more, then plant b gets visited whenever plant a is visited.)

For the star graph with multiple plants on each branch, there is more than one possibility to accurately represent the schedule. One possibility is to list each visit to a plant, but it is also possible to omit plants that are visited by the server in passing, as it travels to a plant further on the branch. The representation we will be using, lists all plants that are visited in a round, but omits the second visit, where the server passes the plant again on its way to the center.

▶ **Lemma 12.** *The value $\frac{1}{2}R$ with $R = \sum_{i=1}^{n} h_i\delta_i$ is a lower bound on the optimal height for continuous BGT on a star graph with multiple plants on each branch.*

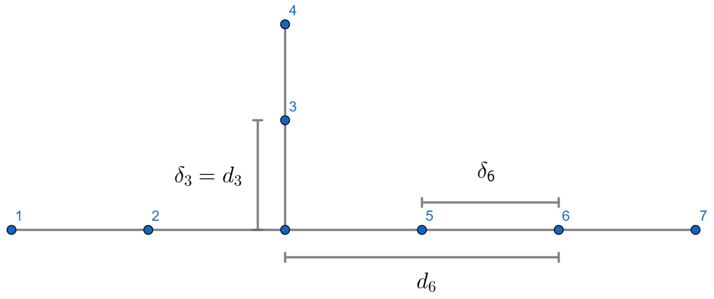

Figure 1 Multiple plants on each branch: example for values d_i and δ_i.

For the star with multiple plants on each branch we use the Deadline-Driven algorithm with a small modification. Whenever the algorithm visits a bamboo b_j on a branch it walks double the distance and cuts all additional bamboo it encounters. These bamboo can be removed from the graph since they are always cut together with b_j. Then the distance between b_j and the next bamboo b_i (i.e δ_i) on the branch is at least as much as the distance from b_j to the center (i.e. $d_i - \delta_i$). In particular it follows that $\delta_i \geq d_i - \delta_i$ and thus $d_i \leq 2\delta_i$.

Furthermore for the bamboo with multiple plants our lower bound is $\frac{1}{2}R$ with $R := \sum_{i=1}^{n} h_i\delta_i$ and therefore we define $L = \max(\frac{1}{2}R, Dh_1)$ to get a lower bound on OPT. For the star with multiple plants on each branch the deadline is the point in time a plant reaches height $(9+2\sqrt{5})L$ and it gets requested at height $(4+2\sqrt{5})L$. The initialization time remains the same.

▶ **Lemma 13.** *The modified Deadline-Driven algorithm maintains a height of* $(9+2\sqrt{5})L$*.*

5 Conclusions

It is possible to achieve a better approximation ratio by setting R in algorithm 1 to a lower value but this requires a much larger case analysis. This is because the periods p_i will be smaller. Using some computer assistance it is for example possible to achieve a ratio of $\frac{7}{5}$ but the length of the proof encourages finding new ideas. Using more cases, we could potentially get even closer to the ratio 4/3, but we could never reach it as long as we can only rely on pinwheel instances with density at most 3/4 being schedulable.

It should be noted that the pinwheel instances that our algorithm encounters are not general ones. For instance, the 10/7-approximation never encounters the period 6. It is conceivable that for the limited set of pinwheel instances that need to be considered, the density guarantee could be improved. Finally, of course the conjecture by Chan and Chin that all instances with density at most 5/6 are schedulable is still open. If that were proved, we could potentially get close to 6/5 (instead of only to 4/3). An approximation scheme currently seems out of reach.

B Multiple plants on each branch

We now find a lower bound for continuous BGT on a star graph with multiple plants on each branch. In this scenario, we make a distinction between cuts where the server comes from the center, and cuts where the server comes from the direction opposite the center. For both types of cuts, we find a lower bound on the maximum height a plant reaches in a particular schedule.

Consider plant p, and let A be the set of plants that are on the same branch but further from the center, and B the set of plants that are closer to the center on the same branch or on another branch.

Since the algorithm needs to visit the end of the branch at some point, p reaches a height of at least $h_p \sum_{i \in A} \delta_i$. This happens as the server is coming from the direction opposite the center and this is a lower bound on the maximum height.

Next, we develop a lower bound based on the cuts where the server comes from the direction of the center. Consider a cyclic schedule of length L, where only the first cut of each round, where the server comes from the center, is listed in this schedule. Each round the algorithm visits a branch and possibly multiple plants. We define m_i as the amount of rounds plant i is visited in. Then $\frac{L}{m_i}$ is the average period between visits of plant i, but only counting the first cut each round where the server comes from the direction of the center.

▶ **Lemma 14.** *The average height of p after a cut, with the server coming from the direction of the center, is $h_p(\delta_p + \sum_{i \in B} \frac{m_i}{m_p} \delta_i)$.*

Proof. Consider a plant p. Let $\lambda_1, \ldots, \lambda_{m_p}$ be the heights plant p reaches in the schedule, while only considering cuts coming from the center. The sum of these heights is the same as the sum of all distances travelled to visit plants in set $B \cup \{p\}$ multiplied by the speed of the plant. This means $\sum_{k=1}^{m_p} \lambda_k = h_p \sum_{i \in B \cup \{p\}} \delta_i m_i$. The average height is

$$\frac{1}{m_p} \sum_{k=1}^{m_p} \lambda_k = \frac{1}{m_p} h_p \sum_{i \in B \cup \{p\}} \delta_i m_i = h_p(\delta_p + \sum_{i \in B} \frac{m_i}{m_p} \delta_i) \qquad ◀$$

We now adapt our model. The algorithm may visit each plant i at a certain fixed period f_i. Let C be the set of all plants, that are closest to the center on their branch. We require $\sum_{i \in C} \frac{1}{f_i} = 1$, which means that the frequencies add up to one branch visited each round. Furthermore, the periods of plants on the same branch should be non decreasing as distance to the center increases. We define the height of a plant p as $\max(h_p(\sum_{i \in A} \delta_i, h_p(\delta_p + \sum_{i \in B} \frac{f_p}{f_i} \delta_i))$.

By setting $f_i = \frac{L}{m_i}$ we get a solution for the new model with a height that is equal to the average height of a schedule in the original model and not more than the maximum height. A lower bound on the maximum height in this new model is then a lower bound on the maximum height for continuous BGT on a star graph with multiple plants on each branch.

▶ **Lemma 12.** *The value $\frac{1}{2}R$ with $R = \sum_{i=1}^{n} h_i \delta_i$ is a lower bound on the optimal height for continuous BGT on a star graph with multiple plants on each branch.*

Proof. Consider the new model. We set $K = \sum_{i \in C}^{n} h_i$ and $f_i = \frac{K}{h_i}$. Let H_p be the maximum height that plant p reaches in the new model. By the definition of height we get $H_p \geq h_p \sum_{i \in A} \delta_i$ as well as $H_p \geq h_p(d_p + \sum_{i \in B} \frac{f_p}{f_i} d_i)$. Then

$$2H_p \geq h_p \sum_{i \in A} \delta_i + h_p(d_p + \sum_{i \in B} \frac{f_p}{f_i} \delta_i) = \sum_{i \in A} h_p \delta_i + h_p \delta_p + \sum_{i \in B} h_i \delta_i \geq \sum_{i=1}^{n} h_i \delta_i$$

The last inequality follows from the fact that the speeds are decreasing with distance to the center and therefore $h_p \geq h_i$ for $i \in A$. It follows that all plants reach a height of at least $\frac{1}{2}R$ and again it is not possible to achieve a lower height on all plants, since visiting one plant more often increases the height on other plants. ◀

▶ **Lemma 13.** *The modified deadline driven algorithm maintains a height of $(9 + 4\sqrt{5})L$.*

Proof. Assume plant i reaches height $(9 + 4\sqrt{5})L$ at time T. We scale the time (and distance) such that $L/h_i = 1$ which means plant i grows by L in one timestep. The old and new requests S_0 and S_1 as well as v and r are defined analogously to the proof for the star.

The time required to process S_0 is at most $\sum_{j\in S_0} d_j$ because any bamboo with an old request must be visited once to fulfill the request and in the worst case we start from the center traversing distance d_j to fulfill the request. It is possible that the algorithm is more efficient whenever plants with consecutive deadlines lie behind each other on the same branch.

Similarly the time required to process S_1 is at most $\sum_{j\in S_1} m_j d_j$ where m_j is the number of new requests on plant b_j.

Therefore in order to arrive at a contradiction we again need to show $\sum_{j\in S_0} d_j + \sum_{j\in S_1} m_j d_j + v + r < T$ which means plant i can be cut before time T.

Again we find upper bounds on the time required to process the old and new requests. These bounds are slightly different due to the changes in the algorithm as well as the lower bound.

A bamboo with an old request must grow by at least $(5+2\sqrt{5})L$ in time at most $T-v$ to have a deadline before T which means $h_j(T-v) \geq (5+2\sqrt{5})L$. Meanwhile plant i grows by $(T-v)L$ in time $(T-v)$, that is $h_i(T-v) = (T-v)L$. It follows that

$$\frac{h_j}{h_i} \geq \frac{5+2\sqrt{5}}{T-v} \text{ for } j \in S_0 \tag{3}$$

A bamboo with new requests must grow by $(4+2\sqrt{5})L$ exactly m_j times in time at most $T-v$ in order to have m_j deadlines before T. Then $h_j(T-v) \geq m_j(4+2\sqrt{5})$. It follows that

$$\frac{h_j}{h_i} \geq m_j\frac{4+2\sqrt{5}}{T-v} \text{ for } j \in S_1 \tag{4}$$

We now get

$$\sum_{j\in S_0} d_j \overset{(3)}{\leq} \frac{1}{h_i}\frac{T-v}{5+2\sqrt{5}}\sum_{j\in S_0} d_j h_j \leq \frac{1}{h_i}\frac{T-v}{5+2\sqrt{5}}\sum_{j\in S_0} 2\delta_j h_j < \frac{T-v}{5+2\sqrt{5}}\frac{2R}{h_i} \leq \frac{T-v}{5+2\sqrt{5}}\frac{4L}{h_i}$$

where we are using $d_i \leq 2\delta_i$ in the second inequality and $R \leq 2L$ in the last inequality. Analogously the following holds for the time required to process the new requests

$$\sum_{j\in S_1} m_j d_j \overset{(4)}{\leq} \frac{1}{h_i}\frac{T-v}{4+2\sqrt{5}}\sum_{j\in S_0} d_j h_j \leq \frac{1}{h_i}\frac{T-v}{4+2\sqrt{5}}\sum_{j\in S_0} 2\delta_j h_j < \frac{T-v}{4+2\sqrt{5}}\frac{2R}{h_i} \leq \frac{T-v}{4+2\sqrt{5}}\frac{4L}{h_i}$$

Given the timescale this means it takes time at most $4\frac{T-v}{5+2\sqrt{5}}$ to process the old requests and at most $4\frac{T-v}{4+2\sqrt{5}}$ to process the new requests. Furthermore since $v < 4+2\sqrt{5}$ and the earliest deadline of i is $9+4\sqrt{5}$ we have $T-v \geq (5+2\sqrt{5})$. It follows

$$\begin{aligned}
&r \leq 1 = \left(\frac{1}{5+2\sqrt{5}}\right)(5+2\sqrt{5}) \leq \left(\frac{1}{5+2\sqrt{5}}\right)(T-v) \\
&\Rightarrow \left(\frac{1}{5+2\sqrt{5}}\right)v + r \leq \left(\frac{1}{5+2\sqrt{5}}\right)T \\
&\Rightarrow \left(\frac{1}{5+2\sqrt{5}}\right)v + r \leq \left(\frac{1}{5+2\sqrt{5}}\right)T + \left(1-\frac{1}{5+2\sqrt{5}}\right)T - \left(1-\frac{1}{5+2\sqrt{5}}\right)T \\
&\Rightarrow \left(1-\frac{1}{5+2\sqrt{5}}\right)T + \left(\frac{1}{5+2\sqrt{5}}\right)v + r \leq T \\
&\Rightarrow \left(1-\frac{1}{5+2\sqrt{5}}\right)T - \left(1-\frac{1}{5+2\sqrt{5}}\right)v + v + r \leq T \\
&\Rightarrow 4\frac{T-v}{5+2\sqrt{5}} + 4\frac{T-v}{4+2\sqrt{5}} + v + r \leq T
\end{aligned}$$

This means we can process all requests (including the request for b_i with deadline at time T) before time T and plant i does not grow above height $(9+4\sqrt{5})L$. ◀

Online Matching with Set and Concave Delays

Abstract

We initiate the study of online problems with *set delay*, where the delay cost at any given time is an arbitrary function of the set of pending requests. In particular, we study the online min-cost perfect matching with set delay (MPMD-Set) problem, which generalises the online min-cost perfect matching with delay (MPMD) problem introduced by Emek et al. (STOC 2016). In MPMD, m requests arrive over time in a metric space of n points. When a request arrives the algorithm must choose to either match or delay the request. The goal is to create a perfect matching of all requests while minimising the sum of distances between matched requests, and the total delay costs incurred by each of the requests. In contrast to previous work we study MPMD-Set in the *non-clairvoyant* setting, where the algorithm does not know the future delay costs. We first show no algorithm is competitive in n or m. We then study the natural special case of *size-based* delay where the delay is a non-decreasing function of the number of unmatched requests. Our main result is the first non-clairvoyant algorithms for online min-cost perfect matching with size-based delay that are competitive in terms of m. In fact, these are the first non-clairvoyant algorithms for any variant of MPMD. A key technical ingredient is an analog of the symmetric difference of matchings that may be useful for other special classes of set delay. Furthermore, we prove a lower bound of $\Omega(n)$ for any deterministic algorithm and $\Omega(\log n)$ for any randomised algorithm. These lower bounds also hold for clairvoyant algorithms. Finally, we also give an m-competitive deterministic algorithm for uniform concave delays in the clairvoyant setting.

1 Introduction

Studying online problems with delay is a line of work that has recently gained traction in online algorithms (e.g. [4, 19, 21, 23]). In such problems, request arrive over time requiring service. Delaying the service of a request accumulates a delay cost given by a delay function associated with the request. The total cost of a solution is the cost of servicing all requests plus the sum of all delay costs incurred by each request.

We initiate the study of online problems with *set delay*. In this model, we generalize the notion of delay to one where the instantaneous delay cost at any point in time is determined by an arbitrary monotone non-decreasing function of the set of pending requests, rather than the sum of individual delay functions associated with each request. In particular, we study the online min-cost perfect matching with set delay (MPMD-Set) problem, which generalizes of the min-cost perfect matching with delays (MPMD) problem introduced by Emek et al. [19].

In MPMD, m requests arrive over time in a metric space of n points. Upon arrival of a request the algorithm must choose to either match the request, incurring a cost equal to the distance between the two requests, or to delay the request, incurring a cost given by a delay function associated with the request. Prior results for MPMD have mostly focused on each request sharing the same delay function (in particular, linear, concave, and convex) and achieve competitive ratios that solely depend either on n or m. Moreover, existing algorithms rely on clairvoyance, where the algorithm has full knowledge of future delay costs. Furthermore, existing randomised algorithms rely on metric embeddings which require knowledge of the metric space in advance.

In this paper, our main contribution is to study the more general MPMD-Set in the least restrictive setting where the algorithm does not know the metric space in advance and has no knowledge of future delay costs. We begin by showing that, in contrast to prior results, the MPMD-Set problem does not admit a deterministic competitive ratio that solely depends on n or m.

▶ **Theorem 1.** *Every deterministic algorithm for MPMD-Set has competitive ratio $\Omega(\Phi)$, where Φ is the aspect ratio of the metric space.*

Our lower bound holds even for simple instances where n and m are constants. Thus, we restrict our attention to designing a competitive solution for the MPMD-Set problem where the instantaneous delay cost at any point in time is a monotone non-decreasing function of the number of unmatched requests at that time. We call such a delay cost function *size-based* (See Section 2 for a formal definition). MPMD-Set with size-based delay (MPMD-Size) has natural applications in practical settings with service-level agreements such as cloud computing.[1]

Our main result is the first competitive algorithms for MPMD-Size, where the competitive ratio is a function of the number of requests. At the core of our result is a reduction from MPMD-Size to the well-known Metrical Task System (MTS) problem (defined in Section 1.1).

▶ **Theorem 2.** *For any $f(N)$-competitive algorithm for MTS with N states, there is an $f(2^m)$-competitive algorithm for MPMD-Size.*

We obtain our main result by applying state-of-the-art algorithms for MTS with some modifications.

▶ **Corollary 3.** *For MPMD-Size, there is an $O(2^m)$-competitive deterministic algorithm and an $O(m^4)$-competitive randomised algorithm.*

We emphasise that our algorithms are non-clairvoyant and do not need to know the metric space in advance. To the best of our knowledge, this is the first non-clairvoyant online algorithm for this problem. Non-clairvoyant algorithms nevertheless have been designed for other online problems such as the Set Cover problem [4], the k-server problem [25], and multi-level aggregation [26]. We also remark that every deterministic algorithm for known variants of online matching with delays has a competitive ratio that depends on m.

We complement Corollary 3 with the following lower bounds.

▶ **Theorem 4.** *Every deterministic algorithm for MPMD-Size has competitive ratio $\Omega(n)$.*

▶ **Theorem 5.** *Every randomised algorithm for MPMD-Size has competitive ratio $\Omega(\log n)$.*

[1] In these settings, the service level agreement requires the cloud provider to provide a certain level of service and the provider incurs penalties if the level is not met.

Finally, we consider MPMD with uniform concave delay in the clairvoyant setting and give the first deterministic algorithm for it. In this problem, we are given a non-negative, non-decreasing concave function f. The delay cost incurred by a request r is $f(w_r)$ where w_r is the time between r's arrival and when it was matched. The total delay cost is the sum of the delay cost of each request.

▶ **Theorem 6.** *There exists an $O(m)$-competitive deterministic algorithm for MPMD with concave delay.*

The correctness and competitiveness of our algorithm only relies on the fact that the time-augmented space satisfies the properties of a metric space. Similar to previous deterministic solutions for uniform linear delay, our algorithm does not need the metric space to be finite, and does not need to know it in advance.

The proofs of theorems 4, 5 and 6 can be found in the full version.

1.1 Our Techniques

Our main technical contribution is an online reduction from the MPMD-Set problem to MTS, which constitutes the proof of Theorem 2. The Metrical Task System (MTS) problem, introduced by Borodin et al. [15], is a cost minimisation problem defined by a set of states $S = \{s_1, s_2, ..., s_k\}$ and a cost matrix c that defines the cost of moving between states. The input consists of an initial state S_0 and a sequence of tasks $T = (t_1, ..., t_\ell)$. Each task t_j is associated with a k-dimensional cost vector C_j whose i-th coordinate defines the cost of servicing task t_j in state s_i. For a given input task sequence T, a solution is a sequence of states (called a *schedule*) $\sigma = (S_1, S_2, ..., S_\ell)$, where S_j is the state that task j is processed in. The total cost of a schedule consists of the costs associated with moving states (*transition cost*), as well as the cost of processing the tasks (*processing cost*).The aim is to produce a schedule of minimum cost.

We briefly outline the three main parts of the reduction below.

Step 1: MPMD-Set to MTS. The first part of the reduction transforms an instance of MPMD-Set into an instance of MTS. A natural approach at a reduction to MTS is to use the set of all possible matchings of requests as the set of states for the MTS instance. The transition cost between two states is then the total length of the edges in the symmetric difference of the corresponding matchings. Finally, there is a task for each timestep in the matching problem and the cost of processing the task in a state is the instantaneous delay incurred by the set of unmatched requests. Unfortunately, the number of states is equal to the number of possible matchings between the requests which is $\sim (\frac{m}{e})^{m/2} \frac{e^{\sqrt{m}}}{(4e)^{1/4}}$ for m requests.

Instead, we use the set of all possible even-sized subsets of the requests as the set of MTS states. Each state represents a set of requests that are matched. The set of input states thus develops over time as more requests arrive. The initial state is the empty set.

We now define the transition costs of the MTS. We define a *transition graph* $G(V, E)$ where V is the set of even-sized subsets of requests. The transition graph G has an edge between two states S and S' if $S \subset S'$ and $|S'| = |S| + 2$. In other words, S_2 consists of the same requests as S_1 with 2 additional requests, say p, q. The cost of the edge between the two states is $d(p, q)$, the distance between p and q in the original MPMD-Set instance. The transition cost between any two states in the MTS instance is defined to be the minimum cost path between the two corresponding nodes in G. The delay cost is translated into the vector costs associated with serving tasks: for any timestep t, the cost of servicing a task in state is simply the instantaneous delay cost accumulated by the set of requests that have arrived so far in the original MPMD-Set instance, that are not in that state.

Henceforth, we refer to an instance of MTS that is reduced from MPMD-Set as *MPMD-Set-MTS*, and an MTS instance that is reduced from MPMD-Set with size-based delay as *MPMD-Size-MTS*.

▶ **Definition 7** (Monotone). *A schedule $\sigma = (S_1, \ldots, S_\ell)$ is* monotone *if every transition only adds requests to the current state, i.e. $S_{i-1} \subseteq S_i$ for every i. In other words, the path never involves moving to a strictly smaller state. An algorithm for MPMD-Set-MTS is* monotone *if it always produces a* monotone *schedule.*

It is easy to see that a monotone schedule can be converted into a solution for the MPMD-Set instance without any increase in cost: when the schedule adds a set of requests S' to its current state, we add a min-cost perfect matching on S' to our matching. However, when we run existing MTS algorithms on the MPMD-Set-MTS instance, there is no guarantee that they will return a monotone schedule.

Step 2: Converting to Monotone. Fortunately, it is possible to convert, in an online manner, an arbitrary MPMD-Size-MTS solution to a monotone solution at no extra cost. We do this by designing an online algorithm which, given an online sequence of states $\sigma = (S_1, \ldots, S_\ell)$, produces for each state S_i a corresponding state S_i' such that the resulting schedule produced by the algorithm is *monotone*. We refer to an algorithm that *transforms* a given state as a *state conversion algorithm*.

Since the instantaneous delay in the MPMD-Size instance is a non-increasing function of currently matched requests, for every task in the MPMD-Size-MTS instance created by the reduction, the processing cost is a monotone non-increasing function of the state size. Our algorithm will exploit this by maintaining the invariant that our state is always at least large as that of σ. The technical crux here is to show that when our state is smaller, we can augment our state in a cost-efficient manner. If the MTS states were matchings, we can consider augmenting paths in the symmetric difference of our matching and that of σ. Motivated by this, we define analogs of the symmetric difference and augmenting paths to augment our state. We believe these ideas are useful for other interesting special classes of set delay functions.

Step 3: Applying MTS algorithms. There are two issues that prevent us from applying existing MTS algorithms directly. First, the cost bounds of all known algorithms for MTS have an additive term that is equal to the diameter of the MTS state space, and the MTS instance created by our reduction has state space with diameter much larger than the optimal. The second issue is that our reduction creates an MTS instance whose state space is constructed online, i.e. the states arrive over time. At a high level, the first issue can be overcome by a guess-and-double approach. The second issue is a problem for randomised MTS algorithms that rely on embedding the state space into a tree as a pre-processing step. This is overcome by using the online embedding of [10]. See Section 4.3 for a more detailed discussion.

Designing a deterministic algorithm for MPMD with Concave Delay. We use the (offline) moat-growing framework (generally used for constrained connectivity problems) by Goemans and Williamson [22], to design an online deterministic linear programming-based algorithm for MPMD with uniform concave delay. Our algorithm is a modification of an existing linear programming-based algorithm due to Bienkowski et al. [12], who give a deterministic competitive algorithm for MPMD with uniform linear delay. Their algorithm heavily relies on the fact that, when the delay function is linear, requests accumulate delay cost at the same rate at all times, regardless of their arrival time. The main challenge in applying the framework to concave delay is that, unlike in the case of linear delay, the requests can accumulate delay at different rates at any point in time, depending on their arrival time. See the full version of the paper on ArXiv for a detailed discussion.

1.2 Related Work

MPMD was introduced by Emek et al. [19] where the delay functions associated with each request are uniform linear. They designed a randomised algorithm that achieves a competitive ratio of $O(\log^2 n + \log \Delta)$, where n is the number of points in the metric space and Δ is its aspect ratio. Azar et al. [3] used a randomised HST embedding to provide a $O(\log n)$-competitive almost-deterministic algorithm, improving Emek et al.'s bound and removing the dependency on the aspect ratio of the metric space. Furthermore, they provided a lower bound of $\Omega(\sqrt{\log n})$ for any randomised algorithm in the case of linear delay. Ashlagi et al. [1] improved this lower bound to $\Omega(\frac{\log n}{\log \log n})$ and $\Omega(\sqrt{\frac{\log n}{\log \log n}})$ for the bipartite case, which are the best known so far. Liu et al. furthermore adapted the algorithm by Azar et al. to the bipartite setting and improved the analysis of Emek et al.'s algorithm to $O(\log n)$. The next deterministic algorithm for simple metrics was by Emek et al. [20] who proved a competitive ratio of 3 for the simple metric space of 2 points. The first deterministic algorithm for general metric spaces was by Bienkowski et al. [13] and their analysis resulted in a competitive ratio of $O(m^{2.46})$. Bienkowski et al. [12] and Azar et al. [6] concurrently and independently improved this bound to $O(m)$ and $O(m^{0.59})$ respectively, introducing the first linear and sub-linear deterministic solutions to the problem. The algorithms above assumed the delay cost to be given by a uniform linear delay function associated with each individual request.

Liu et al. [27] was the first to consider convex delay functions and demonstrated an interesting gap between the solutions for the case with linear delay and convex delay on a uniform metric space by giving a deterministic asymptotically optimal $O(m)$-competitive algorithm for the uniform metric space.

Azar et al. [8] subsequently considered the problem with concave delay and achieved an $O(1)$-competitive deterministic algorithm for the single point metric space and an $O(\log n)$ randomised algorithm for general metric spaces.

The above algorithms assumed all requests incurred delay in accordance with uniform delay functions and regarded the delay function to be associated with each individual request. Furthermore, all prior solutions to MPMD assumed clairvoyance. To the best of our knowledge, no one has considered the non-clairvoyant generalisation of the problem where the delay function depends on the set of unmatched requests.

Non-clairvoyant algorithms nevertheless have been designed for other online problems such as the Set Cover problem [4, 26], the k-server problem [25], and multi-level aggregation [26].

The notion of introducing delay to online problems originated well before it was applied to online metric matching and finds applications in amongst others aggregating messages in computer networks, aggregating orders in supply-chain management, and operating systems. See [4, 5, 7, 9, 11, 14, 17, 18, 21, 23, 26, 28] for further reading. All problems above define the cost of delay as a function associated with each request. To the best of our knowledge, no online problems with delay have so far defined the cost of delay as an arbitrary function of the set of unmatched requests.

2 Preliminaries

In this section we introduce our notation and give formal definitions for set delay and size-based delay functions, as well as MPMD-Set.

2.1 Min-cost Perfect Matching with Delay

The min-cost perfect matching with delays (MPMD) problem, introduced by Emek et. al [19] is defined on a metric space (V, d), which consists of a set of points V and distance function $d : V \times V \to \mathbb{R}^+$. An online input instance over (V, d) is a sequence of requests $R = (r_1, ..., r_m)$ that arrive at points in the metric space over time. Each $r_k \in R$ has an associated position and arrival time. We assume, without loss of generality, that time is divided into discrete timesteps.

Upon the arrival of a request, the algorithm must choose to either match the request, incurring a cost equal to the distance between the two requests in the metric space, or to delay the request, incurring a cost given by a delay function associated with the request, in the hope of finding a more suitable match in the near future.

A solution produced by an online matching algorithm is a sequence of matchings $\mathbb{M} = (M_0...M_{final})$, where M_i is the matching associated with the ith timestep. Note that we assume that requests only arrive at the start of a timestep. A solution $\mathbb{M}$ must satisfy the following properties:

- $M_0 = \emptyset$
- M_{final} is a perfect matching
- For all i, $M_i \subseteq M_{i+1}$

We refer to the third property as *monotonicity*. The cost associated with a solution $\mathbb{M}$ consists of the sum of the distances between matched requests in M_{final} plus the sum of the delay costs incurred by all requests. The aim of an online matching algorithm is to produce a sequence of matchings that satisfies the above properties with minimal cost.

In the original MPMD problem, the delay cost incurred by a request is the time between its arrival and when it was matched. In MPMD-Set, the instantaneous delay incurred at a timestep t can be an arbitrary function of the set of currently unmatched requests U_t. The total delay cost is the sum over timesteps t of $f_t(U_t)$ where f_t is a set delay function as defined below.

▶ **Definition 8** (Set delay function). *Let U be a set of requests. We define a delay function $f_t : 2^U \to \mathbb{R}^{\geq 0}$, for any timestep t, to be a* set delay *function if it satisfies the following properties:*

- $f_t(\emptyset) = 0$
- $A \subseteq B \Rightarrow f_t(A) \leq f_t(B)$
- *For all $\emptyset \neq U \in 2^V$, we have $\sum_{t=0}^{\infty} f_t(U) = \infty$*

The last property implies that all requests must eventually be matched.

In MPMD-Size, the set delay function is a size-based delay function, as defined below.

▶ **Definition 9** (Size-based delay function). *We define a delay function $f_t : 2^U \to \mathbb{R}^{\geq 0}$ to be* size-based *if, for any timestep t, it satisfies all properties of a set delay function and is monotone non-decreasing as a function of the size of the set of requests U.*

3 A Lower Bound for MPMD-Set

In this section, we prove Theorem 1.

Proof of Theorem 1. Consider a four-point metric space (as depicted in figure 1) with three points at distance ϵ from one another, and the fourth point (p_4) at distance D from the other points, where D is the diameter of the metric space.

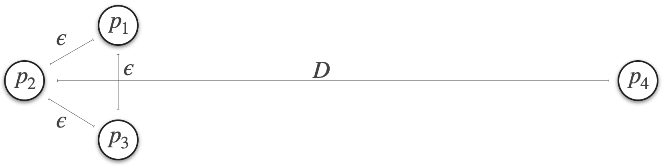

Figure 1 A visualisation of the four-point metric space.

We define a request sequence of six requests $R = (r_1, r_2, r_3, r_4, r_5, r_6)$ where the first four requests arrive at time $t = 0$ and the latter two arrive at time $t = 2$. For each $i \in \{1...4\}$, we place request r_i on point p_i. At $t = 2$, we then place request r_5 on p_3 and r_6 on p_4. In terms of delay, we are working with the special case of deadline functions. A *deadline function* is a delay function that is 0 up until some time d, called the deadline, and ∞ afterwards. When the deadline of a request is reached, the algorithm must ensure that the request is matched.

At $t = 0$, request r_1 reaches its deadline and hence the algorithm will need to match two requests. Since the algorithm is non-clairvoyant, the algorithm has no knowledge of the deadlines of future requests. We therefore assume without loss of generality that it matches r_1 to r_3 and pays a distance cost of ϵ. At $t = 1$, r_2 reaches its deadline and the algorithm is forced to match it to r_4 at a distance cost of D. At $t = 2$, the final two requests will arrive and instantly reach their deadline. The algorithm will consequently need to match r_5 to r_6 at a distance cost of D. The total cost of ALG is $2D + \epsilon$.

The optimal offline solution OPT is to match r_1 to r_2 and match locally at $t = 2$ on points p_3 and p_4. The total cost of OPT is therefore ϵ. The competitive ratio of the algorithm is $\Omega(D/\epsilon)$ and D/ϵ is the aspect ratio of the metric space, as desired. ◀

4 An Online Reduction from MPMD-Set to MTS

In this section, we prove Theorem 2 by defining a reduction from MPMD-Set to MTS. We start by translating an arbitrary instance of MPMD-Set into an instance of MTS in Section 4.1. In Section 4.2, we show that we can transform an arbitrary MPMD-Size-MTS solution into a monotone solution of the same or less cost. As observed in the Introduction, a monotone schedule directly corresponds to a solution for the online matching with delay problem of equal cost. This completes the proof of Theorem 2. We finish this section with a proof of Corollary 3.

4.1 Translating an instance of MPMD-Set into and instance of MTS

We define the set of internal states of the MTS instance to be the set of all possible subsets of the requests that have arrived so far in the MPMD-Set instance. In order to define the transition cost associated with moving between states, we define the following graph.

▶ **Definition 10** (Transition graph G). *The nodes of G are the states of the MPMD-Set-MTS instance. We define an undirected edge $(S, S') \in E$ between states S and S' if $S = S' \cup \{r, r'\}$ and define its cost $c(S, S')$ to be $d(r, r')$. Paths in the transition graph are called* transition paths.

We define the transition cost $c(S, S')$ of moving between arbitrary states S and S' in the MTS instance to be the cost of the shortest path between them in the transition graph G. Note that a path in G between states S, S' corresponds to a sequence of transitions from S to S', where each edge in the path corresponds to a transition that either adds two requests or removes two requests. Also, note that any schedule σ, produced by an online MTS algorithm, corresponds to a path in the metric completion of G and the total transition cost incurred by σ is simply the total cost of the path. Each task in the MTS instance is associated with a given timestep in the MPMD-Set problem. The cost vector associated with each task is, for every state S, the instantaneous delay cost accumulated by the set of requests not in S.

▶ **Definition 11** (R_i). *We define R_i to be the set of requests that have arrived up to and including timestep i in the original MPMD-Set instance.*

The total cost of a schedule $\sigma = (S_0, ..., S_T)$ can be expressed as follows.

$$\text{cost}(\sigma) = \sum_{i=0}^{T-1} c(S_i, S_{i+1}) + f_i(R_i \setminus S_i).$$

By construction, the cost associated with processing the tasks represent the delay cost incurred by the requests, while the distance cost is represented by the transition costs associated with moving between states.

4.2 Size-based delay functions admit monotone scheduling algorithms

In this subsection, we prove the existence of an online algorithm that converts an arbitrary MPMD-Size-MTS solution into a monotone solution, without incurring any extra cost.

▶ **Lemma 12.** *There exists an online algorithm that converts an arbitrary MPMD-Size-MTS solution into a monotone solution of the same or less cost.*

Proof. To prove Lemma 12, we define an online *state conversion algorithm* (Sensible-ALG) which, for every state S_i in a schedule σ, produced by an *arbitrary* online scheduling algorithm (OSA), produces a state S'_i such that the cost of the schedule $\sigma' = (S'_0, \ldots, S'_{|\sigma|})$ is at most the cost of the original schedule σ, and σ' is monotone.

The state conversion algorithm aims to maintain the invariant that $|S'_i| \geq |S_i|$ and the main property of a monotone schedule, which is that $S'_{i-1} \subseteq S'_i$ for every i. At a high level, it does this by adding requests to its current state when the invariant is violated that allows it to also move closer to the current state of σ. The algorithm Sensible-ALG uses the following analog of the symmetric difference of two matchings to augment its current state in a cost-efficient manner.

▶ **Definition 13** ((A, B)-difference graph). *Let H be a (multi-)graph with vertex set R, and A, B be states. The graph H is an (A, B)-*difference graph *if it is a T-join with $T = A \triangle B$: for every $r \in R$, the degree of r in H is odd if and only if $r \in A \triangle B$.*

For example, one way to obtain an (A, B)-difference graph is by taking a perfect matching M_A on A and a perfect matching M_B on B and then taking the symmetric difference of M_A and M_B.

▶ **Definition 14** (P-difference graph and realisable difference graphs)**.** *Let A, B be states and P be a transition path between A and B. The P-*difference graph $\mathrm{diff}(P)$ *is a (multi-)graph on vertex set R where the multiplicity of the edge (p, q) is equal to the number of transitions along the path P that adds or removes the $\{p, q\}$. An (A, B)-difference graph H is* realisable *if it is the P-difference graph for a transition path P between A, B.*

Note that if P is a transition path between states A, B, then a P-difference graph is an (A, B)-difference graph. Moreover, if P is a shortest path between S and S', then the total cost of the edges in $\mathrm{diff}(P)$ is exactly equal to $c(S, S')$. We also note that not all difference graphs are realisable[2]

We now characterise the structure of difference graphs that correspond to shortest paths in the transition graph.

▶ **Definition 15** (Canonical difference graphs)**.** *Let H be an (A, B)-difference graph. We say that H is* canonical *if it can be decomposed into a collection of $\ell := |A \triangle B|/2$ edge-disjoint paths $Q_1, \ldots, Q_\ell$ between disjoint pairs (p_i, q_i) of $A \triangle B$ such that for each i, Q_i consists of a single edge (p_i, q_i) if either both p, q are in $A \setminus B$ or both in $B \setminus A$, and Q_i consists of two edges $(p, s), (s, q)$ for some other request s if exactly one of p, q is in $A \setminus B$ and the other in $B \setminus A$.*

▶ **Proposition 16.** *If H is a canonical (A, B)-difference graph, then H is realisable.*

Proof. We show by induction on $\ell = |A \triangle B|/2$ that there is a transition path P from A to B. Consider the base case $\ell = 1$. Suppose Q_1 consists of a single edge (p, q). If $p, q \in A \setminus B$, then we can transition directly from A to B by removing p, q; otherwise, we add p, q. Next, suppose that Q_1 consists of two edges $(p, s), (s, q)$. Consider the case that $p \in A \setminus B$ and $q \in B \setminus A$. If $s \in A \cap B$, then we can transition from A to B by first removing p, s and then adding s, q; otherwise we first add s, q and then remove p, s. The case when $q \in A \setminus B$ and $p \in B \setminus A$ follows similarly. In all of these cases, we have that H is exactly the P-difference graph where P is the transition path corresponding to the sequence of transitions used.

Suppose the statement is true for ℓ up to $k - 1$ and let H be a canonical difference graph with k edge-disjoint paths. Let A' be the state after executing the above procedure on Q_1 and P_1 be the transition path corresponding to the sequence of transitions from A to A'. As argued above, Q_1 is the P_1-difference graph. Since $H \setminus Q_1$ is a canonical (A', B)-difference graph with $k - 1$ edge-disjoint paths, we can apply induction to get a transition path P_2 from A' to B such that $H \setminus Q_1$ is the P_2-difference graph. By concatenating P_1 and P_2, we get a transition path P from A to B. Moreover, H is the P-difference graph, as desired. ◀

▶ **Lemma 17.** *Let A, B be states. There exists a shortest path P in the transition graph between A, B such that* $\mathrm{diff}(P)$ *is canonical.*

Proof. Since $\mathrm{diff}(P)$ is an $(A \triangle B)$-join, it contains a collection of $\ell := |A \triangle B|/2$ edge-disjoint paths $Q_1, \ldots, Q_\ell$ connecting disjoint pairs of requests $p_i, q_i \in A \triangle B$.

We now shortcut these paths to produce a canonical (A, B)-difference graph H. In particular, for each i, if $p_i, q_i \in A \setminus B$ or $p_i, q_i \in B \setminus A$, add the edge (p_i, q_i) to H; otherwise, $p_i \in A \setminus B$ and $q_i \in B \setminus A$ (or vice versa), there must be an intermediate node s_i on the path

[2] For example, consider the difference graph H consisting of requests p, q, r and edges (p, q) and (q, r). Observe that H is an $(\{p, r\}, \emptyset)$-difference graph but there is no transition path P from $\{p, r\}$ to $\emptyset$ such that $\mathrm{diff}(P) = H$.

Q_i and we add the edges $(p_i, s_i), (s_i, q_i)$. The existence of s_i is because if Q_i only consists of a single edge (p_i, q_i) then p_i and q_i must be both in $A \setminus B$ or $B \setminus A$, otherwise the transition in P that adds or removes p_i, q_i is invalid.

By triangle inequality, the total cost of the edges in H is at most that of $Q_1 \cup \cdots \cup Q_\ell$ which in turn is contained in $\mathrm{diff}(P)$. Since H is a canonical (A, B)-difference graph, there exists a transition path P' with $\mathrm{diff}(P') = H$. Since $c(P')$ is equal to the total cost of the edges in $\mathrm{diff}(P') = H$, we get the lemma. ◀

▶ **Proposition 18.** *Let A, B be states such that $|A| = |B| + 2$. Let P be a shortest path in the transition graph between A, B such that $\mathrm{diff}(P)$ is canonical and $Q_1, \ldots, Q_\ell$ be the corresponding collection of $|A \triangle B|/2$ edge-disjoint paths connecting disjoint pairs of $A \triangle B$. Then, one such path Q_i is a single edge (p, q) with $p, q \in A \setminus B$.*

This proposition follows from the fact that $|A \setminus B| = |B \setminus A| + 2$ and so there must be a path Q_i connecting $p, q \in A \setminus B$. By definition of canonical difference graphs, Q_i is a single edge (p, q).

We are now ready to formally define Sensible-ALG.

Description of Sensible-ALG. Our online algorithm takes as input a sequence of states $\sigma = (S_1, \ldots, S_{|\sigma|})$ produced by an online scheduling algorithm. We assume that σ satisfies that for all $0 \leq i < |\sigma| - 1$, S_i and S_{i+1} are neighbours in G. This is without loss of generality: if the input schedule does not satisfy these properties then we can add intermediate timesteps and all states on the shortest path between S_i and S_{i+1} such that it satisfies the above property, and the cost remains the same. When a new state S_i arrives, if $|S_i| \leq |S'_{i-1}|$, the algorithm sets $S'_i = S'_{i-1}$; otherwise, it computes a shortest transition path P between S_i and S'_{i-1} such that $\mathrm{diff}(P)$ is canonical, and sets $S'_i = S'_{i-1} \cup \{p, q\}$ where $p, q \in S_i \setminus S'_{i-1}$ and (p, q) is a path in the path decomposition of $\mathrm{diff}(P)$.

Since Sensible-ALG always transitions to a state that is a superset of its previous state, its solution σ' is monotone.

Next, we analyse the transition cost of σ'.

▶ **Lemma 19.** $\sum_{i=0}^{|\sigma|-1} c(S'_{i-1}, S'_i) \leq \sum_{i=0}^{|\sigma|-1} c(S_{i-1}, S_i)$.

Proof. We prove this lemma by introducing the potential $\phi_i = c(S_i, S'_i)$.

We claim that in each iteration i, the transition cost of σ' is at most the transition cost of σ plus the decrease in the potential.

▷ Claim 20. For all i, we have $c(S'_{i-1}, S'_i) \leq c(S_{i-1}, S_i) - (\phi_i - \phi_{i-1})$.

Proof of Claim 20. By triangle inequality, we have

$$c(S_i, S'_{i-1}) \leq c(S_{i-1}, S_i) + c(S_{i-1}, S'_{i-1}). \tag{1}$$

Next, we will show that

$$c(S'_{i-1}, S'_i) \leq c(S_i, S'_{i-1}) - c(S_i, S'_i). \tag{2}$$

Combining these two inequalities yields the claim.

Observe that Inequality (2) holds when $S'_i = S'_{i-1}$. Suppose $S'_i \neq S'_{i-1}$. In this case, the algorithm computes the shortest path P between S_i and S'_{i-1} that is canonical and set $S'_i = S'_{i-1} \cup \{p, q\}$ where $p, q \in S_i \setminus S'_{i-1}$ and (p, q) is a path in the path decomposition of $\mathrm{diff}(P)$. We have that $\mathrm{diff}(P) \setminus (p, q)$ is a canonical (S_i, S'_i)-difference graph and thus, by

Proposition 16, corresponds to a transition path between S_i, S'_i with length $c(S_i, S'_{i-1}) - c(p,q) = c(S_i, S'_{i-1}) - c(S'_{i-1}, S'_i)$. Thus, $c(S_i, S'_i) \leq c(S_i, S'_{i-1}) - c(S'_{i-1}, S'_i)$. Rearranging this inequality yields Inequality (2). This completes the proof of the claim. ◁

Using Claim 20, we determine the total transition cost incurred by σ' as follows.

$$\begin{aligned}\sum_{i=1}^{|\sigma|} c(S'_{i-1}, S'_i) &\leq \sum_{i=1}^{|\sigma|} c(S_{i-1}, S_i) - \sum_{i=1}^{|\sigma|}(\phi_i - \phi_{i-1})\\ &= \sum_{i=1}^{|\sigma|} c(S_{i-1}, S_i) - \phi_{|\sigma|} + \phi_0\\ &\leq \sum_{i=1}^{|\sigma|} c(S_{i-1}, S_i).\end{aligned}$$

The last inequality holds because $\phi_0 = 0$ and the potential is non-negative. ◀

The cost of an MPMD-Set-MTS solution consists of the transitions cost, as well as the processing cost. Since in every iteration i, we have $|S'_i| \geq |S_i|$ and the processing cost of a state is a monotone non-increasing function of the size of the state, we get that the total processing cost of σ' is at most that of σ. Together with Lemma 19, we get that the total cost of σ' is at most that of σ. This concludes the proof of Lemma 12. ◀

4.3 Applying MTS Algorithms to MPMD-Set-MTS

In this section, we prove Corollary 3. Consider an instance of MPMD-Set with m requests in a metric space of n points and the instance of MPMD-Set-MTS created by applying Theorem 2. Let N be the number of states of the MPMD-Set-MTS instance.

There are two issues that arise when applying MTS algorithms to MPMD-Set-MTS directly.

4.3.1 Eliminating the Diameter

The first issue is that all known MTS algorithms have a cost bound of the form $f(N) \cdot cost(OPT) + D$ where OPT is the optimal MTS solution and D is the diameter of the MTS state space. Observe that D is at least the distance between the empty matching and the max-cost perfect matching, i.e. the cost of the max-cost perfect matching. Unfortunately, the cost of the max-cost perfect matching can be much larger than that of the optimal solution. To overcome this, one could restrict the MTS solution to only use states whose distance from the initial state is at most $cost(OPT)$. This can be achieved by setting the costs of the other states to be infinite. This effectively reduces the diameter of the state space to at most $2 \cdot cost(OPT)$, and would give us a cost bound of $O(f(N)) \cdot cost(OPT) + 2 \cdot cost(OPT)$. The issue is that, since the MTS tasks arrive in an online fashion, the optimal solution remains unknown until all tasks have arrived. To address this issue we use the Guess-and-Double Method, which, maintains a guess of the value of the optimal solution as the tasks are processed. This guess is used to determine the diameter of the state space used by the algorithm. When the guess becomes too small, the value of the guess is increased and the algorithm is simulated on the input that has already been processed, only this time on the larger state space, to determine the state it would now be in, and processes the new tasks accordingly. For the benefit of the reader, we give a high level overview of the method below.

The Guess-and-Double Method. Let $R = [r_1, r_2, ...r_T]$ be the sequence of tasks given by the MTS problem. Let OPT_t be the cost of the optimal solution for processing the tasks that have arrived up to and including time t. At any time t we maintain a *guess* j such that

$$2^{j-1} < OPT_t \leq 2^j. \tag{3}$$

When our guess j no longer satisfies (3) we increase it's value (thus doubling the radius of the metric space) until it is back within our bounds. Each new guess instantiates a new *phase*. At the start of each phase, we *restart* the MTS algorithm with a superset of the previous state space, which now consists of all states within distance 2^j from the original start state. Note that by *restart* we mean that we simulate the MTS algorithm with the new diameter on all tasks that have arrived so far, and process the new tasks in accordance with the decisions made by the algorithm with the new diameter.

Our initial guess j satisfies $2^{j-1} < OPT_1 \leq 2^j$. We define MTS_j to be the MTS algorithm that operates on the given state space with diameter 2^j. Let $R_t = [r_1, ..., r_t]$ be the sequence of tasks that have arrived up to and including timestep t. We define $MTS_j(R_t)$ to be the state MTS_j would end up in after processing R_t. The Guess-and-Double method, for every timestep t, maintains a guess j that satisfies (3), and moves to $MTS_j(R_t)$.

Algorithm 1 Updating the guess and splitting the tasks into phases.

```
Initialise the first phase.
Choose $j$ such that $2^{j-1} < OPT_1 \leq 2^j$.
for Every timestep $t$ do
    if $2^{j-1} < OPT_t \leq 2^j$ then
        Move to state $MTS_j(R_t)$
    end
    else
        End the previous phase and initialise a new phase.
        Update the value of $j$ such that $2^{j-1} < OPT_t \leq 2^j$.
        Move to state $MTS_j(R_t)$
    end
end
```

Note that each time we update the value of our guess, the value of the optimal solution has at least doubled since we made our last guess.

To analyse the total cost of the resulting schedule we look at two separate costs. The first is the cost incurred within each phase. This includes the transition costs incurred during the phase (from moving between states), plus the cost associated with servicing all tasks that arrived during the phase in the states the algorithm moved through during the phase. We refer to this cost as the *internal* phase cost. The second cost consist of the transition costs incurred in moving between the last state of a phase i, and the first state of the consecutive phase $i+1$. We refer to this cost as the *external* phase cost.

We start by bounding the internal phase cost. Let $cost(MTS_j)$ denote the internal phase cost of the phase associated with guess j. Because $cost(MTS_j)$ can be upper bounded by the cost the algorithm would have incurred for processing all tasks that arrived prior to and during the phase associated with guess j, we can bound $cost(MTS_j)$ as follows:

$$cost(MTS_j) \leq (O(f(N)) + 2) \cdot cost(OPT_j).$$

Therefore, the total internal phase cost incurred over all k phases is

$$\begin{aligned}\sum_{i=1}^{k} ALG_i &\leq (O(f(N)) + 2) \cdot \sum_{i=1}^{k} cost(OPT_i)\\ &\leq 2 \cdot (O(f(N)) + 2) \cdot cost(OPT_k).\end{aligned}$$

Next, we bound the external phase cost. Let S_i be the last state of a given phase i, associated with a guess j, and let S'_{i+1} be the first state of phase $i+1$, associated with the next guess j'. We bound $c(S_i, S'_{i+1})$[3] as follows:

Let S_0 be the empty start state.

$$c(S_i, S'_{i+1}) \leq c(S_i, S_0) + c(S'_{i+1}, S_0).$$

For all consecutive phases i and $i+1$, associated with guesses j and j' respectively, it holds that

$$c(S_i, S_0) \leq (O(f(N)) + 2) \cdot cost(OPT_i)$$

and

$$c(S'_{i+1}, S_0) \leq (O(f(N)) + 2) \cdot cost(OPT_{i+1}).$$

We thus bound the cost over all $k-1$ phase transitions as follows

$$\begin{aligned}\sum_{i=1}^{k-1} c(S_i, S'_{i+1}) &\leq 2 \cdot \sum_{i=1}^{k-1} (O(f(N)) + 2) \cdot cost(OPT_{i+1})\\ &\leq 4 \cdot (O(f(N)) + 2) \cdot cost(OPT_k).\end{aligned}$$

The total cost of the solution produced by the Guess-and-Double method can thus be bounded by $6 \cdot (O(f(N)) + 2) \cdot cost(OPT_k)$.

We can now use the $O(N)$-competitive deterministic algorithm of [15] to obtain our deterministic algorithm for MPMD-Size.

4.3.2 The Need for an Online Embedding

The second issue stems from the fact that the reduction in Theorem 2 creates an MTS instance where the states are arriving over time. This is because the states correspond to matchings of requests and the requests are arriving online. This does not pose a problem for the deterministic $O(N)$-competitive Work Function Algorithm of [15]. However, we cannot directly apply the current-best randomised algorithm for MTS of [16] as it pre-computes a probabilistic embedding of the MTS metric space into a hierarchically separated tree (HST). Instead, we need to use a probabilistic online embedding into a HST together with the $O(\log N)$-competitive randomized algorithm for MTS on HSTs of [16]. Using the online embedding of [24] adds a factor of $O(\log N \log \Phi)$ where Φ is the ratio of the largest distance to the smallest distance in the MTS state space, i.e. the aspect ratio. However, Φ can be arbitrarily large. We deal with this by proving that the Abstract Network Design Framework of [10] can be extended to apply to MTS. For the benefit of the reader, we give a short overview of the Abstract Network Design Framework.

[3] Recall that we denote the transition cost of going from state S_i to S'_{i+1} by $c(S_i, S'_{i+1})$.

The Abstract Network Design Framework. In an instance of abstract network design, the algorithm is given a connected graph $G(V, E)$ with edge lengths $d : E \rightarrow \mathbb{R}_+$. At each timestep i, a requests that consists of a set of points in the graph, called *terminals*, arrive in an online fashion. The algorithm provides a response $R_i = (G_i, C_i)$, which consists of a subgraph $G_i \subseteq E$, and a connectivity list C_i, which is an ordered subset of terminal pairs from the terminals that have arrived so far, and determines what will become (and remain) connected from this timestep onwards. The algorithm is given, at each timestep, a feasibility function $F_i : (C_1, ..., C_i) \rightarrow \{0, 1\}$ that maps a sequence of connectivity lists to either 0 (infeasible) or 1 (feasible). A solution S_i, which consists of a sequence of responses for every time step up to and including timestep i, is feasible if $F_i(C_1, ..., C_i) = 1$ and all pairs in C_j are connected in all G_i for all $i \geq j$. To determine the cost of a solution to the first i requests S_i, the framework uses a load function $\rho_i : 2^{\{1,...,i\}} \rightarrow \mathbb{R}_+$, which takes as input the sequence of timesteps in which the edge was used, and outputs a corresponding multiplier to the cost of an edge $d(e)$. It aims to model how the cost of using an edge grows as the edge is used multiple times. The function must be subadditive, monotone non-decreasing, and satisfy $\rho_i(I) = 0$ if and only if $I = \emptyset$. The total cost of a solution S_i is defined as follows.

$$cost(S_i) = \sum_{e \in E} d(e) \cdot \rho(\{j \leq i : e \in G_j\})$$

Extending the Abstract Network Design Framework. Though we can express the transition cost of an instance of general MTS using this framework, we cannot express the cost vectors associated with processing the tasks in MTS in the current state of the framework. In order to address this issue, we propose the following alterations to generalise the framework.

We replace the feasibility function with a function $F'_i : (C_1, ..., C_i) \rightarrow \mathbb{R}_+$, where $F'_i(C_1, ..., C_i)$ is the processing cost of the algorithm during timestep i if the solution $S_i = ((G_1, C_1), \ldots, (G_i, C_i))$ is feasible, and ∞ otherwise.

We now re-define the cost of a solution to the first i requests S_i to incorporate the total processing cost incurred by the algorithm.

$$cost(S_i) = \sum_{e \in E} d(e) \cdot \rho(\{j \leq i : e \in G_j\} + \sum_{l=1}^{i} F'(C_1, \ldots, C_l)$$

Since the processing cost provided to the algorithm is independent of the metric space, it follows that the processing cost remains unaffected by the online embedding. It therefore does not affect the overhead due to the online embedding.

Note that the extension of this framework means it can now be used to model online problems with delay, where the delay cost can be modelled as the processing cost.

Expressing MTS in the Abstract Network Design Framework. It remains to formulate the general MTS problem in the Extended Abstract Network Design Framework defined above.

We define the terminal set of the ith request to be the set of states that have arrived so far. We define the cost of an edge $d((u, v))$ to be the transition cost between states u, v. Let $\mathbb{T}_i$ be the cost vector associated with processing task i, and $T_i(w)$ be the cost of processing task i in state w. Let v be the last terminal in C_i. The extended feasibility function F_i is defined by $F_i(C_1, \ldots, C_i) = T_i(v)$ if there is only a single ordered pair in each C_j for all $j \leq i$ and the sequence of $(C_1, \ldots, C_i)$ is a valid path. The load function is simply the cardinality function because we pay the transition cost associated with the edge each time we transition to a different state.

Min-operator. Bartal et al. [10] show that if the problem can be captured by the Abstract Network Design Framework and admits a *min-operator*, it is possible to reduce the overhead due to the online embedding to $O(\log^3 N)$.

▶ **Definition 21** (Min-operator). *An algorithm admits a min-operator with factor $\mu \geq 1$ if there exists a competitive algorithm*[4] *for the problem, and for any two deterministic online algorithms A and B*[5]*, there exists a third online deterministic algorithm C such that the cost of C satisfies $cost(C) \leq \mu \cdot \min\{cost(A), cost(B)\}$, where $cost(A)$ and $cost(B)$ are the respective costs of algorithms A and B. If either algorithms A or B are randomised, the expected cost of C must satisfy $E[cost(C)] \leq \mu \cdot \min\{E[cost(A)], E[cost(B)]\}$.*

We have shown that the results by Bartal et al. [10] also hold for the extended Abstract Network Design Framework. Since the MTS problem in general admits a min-operator [2], using the framework of [10] allows us to reduce the overhead due to the online embedding to $O(\log^3 N)$ for an overall competitive ratio of $O(\log^4 N)$.

An Approximation Algorithm for the Exact Matching Problem in Bipartite Graphs

Lasse Wulf
Institute of Discrete Mathematics, TU Graz, Austria

Abstract

In 1982 Papadimitriou and Yannakakis introduced the Exact Matching problem, in which given a red and blue edge-colored graph G and an integer k one has to decide whether there exists a perfect matching in G with exactly k red edges. Even though a randomized polynomial-time algorithm for this problem was quickly found a few years later, it is still unknown today whether a deterministic polynomial-time algorithm exists. This makes the Exact Matching problem an important candidate to test the **RP**=**P** hypothesis.

In this paper we focus on approximating Exact Matching. While there exists a simple algorithm that computes in deterministic polynomial-time an *almost* perfect matching with exactly k red edges, not a lot of work focuses on computing perfect matchings with *almost* k red edges. In fact such an algorithm for bipartite graphs running in deterministic polynomial-time was published only recently (STACS'23). It outputs a perfect matching with k' red edges with the guarantee that $0.5k \leq k' \leq 1.5k$. In the present paper we aim at approximating the number of red edges without exceeding the limit of k red edges. We construct a deterministic polynomial-time algorithm, which on bipartite graphs computes a perfect matching with k' red edges such that $\frac{k}{3} \leq k' \leq k$.

1 Introduction

In the Exact Matching problem (denoted as EM) one is given a graph G whose edges are colored in red or blue and an integer k and has to decide whether there exists a perfect matching M in G containing exactly k red edges. This problem was first introduced in 1982 by Papadimitriou and Yannakakis [20] who conjectured it to be **NP**-complete. However a few years later, Mulmuley et al. [19] showed that the problem can be solved in randomized polynomial-time, making it a member of the class **RP**. This makes it unlikely to be **NP**-hard. In fact, while it is commonly believed that **RP**=**P**, the proof of this statement is a major open problem in complexity theory. Since EM is contained in **RP** but a deterministic polynomial-time algorithm for it is not known, the problem is a good candidate for testing the **RP**=**P** hypothesis. Actually Mulmuley et al. [19] even showed that EM is contained in **RNC**, which is the class of decision problems that can be solved by a polylogarithmic-time algorithm using polynomially many parallel processors while having access to randomness. As studied in [22], derandomizing the perfect matching problem from this complexity class is also a big open problem. This makes EM even more intriguing as randomness allows it to be efficiently parallelizable but we don't even know how to solve it sequentially without randomness.

Due to this, numerous works cite EM as an open problem. This includes the above mentioned seminal work on the parallel computation complexity of the matching problem [22], planarizing gadgets for perfect matchings [14], multicriteria optimization [13], matroid intersection [5], DNA sequencing [4], binary linear equation systems with small hamming weight [2], recoverable robust assignment [10] as well as more general constrained matching problems [3, 17, 21, 18]. Progress in finding deterministic algorithms for EM has only been made for very restricted classes of graphs, thus illustrating the difficulty of the problem. There exists a deterministic polynomial-time algorithm for EM in planar graphs and more generally in $K_{3,3}$-minor free graphs [25], as well as for graphs of bounded genus [11]. Additionally, standard dynamic programming techniques on the tree decomposition of the graph can be used to solve EM on graphs of bounded treewidth [7, 23]. Contrary to those classes of sparse graphs, EM on dense graphs seems to be harder to solve. At least 4 articles study solely complete and complete bipartite graphs [16, 12, 24, 15]. More recently those results were generalized in [8] with a polynomial-time algorithm solving EM for constant independence number[1] α and constant bipartite independence number[2] β. These algorithm have **XP**-time, i.e. they run in time $O(g(\alpha)n^{f(\alpha)})$ and $O(g(\beta)n^{f(\beta)})$. This was further improved for bipartite graphs in [9] where the authors showed an FPT algorithm parameterized by the bipartite independence number β solving EM on bipartite graphs.

Approximating EM

Given the unknown complexity status of EM, it is natural to try approximating it. In order to approximate EM, we need to allow for non-optimal solutions. Here two directions can be taken: either we consider non-perfect matchings, or we consider perfect matchings with not exactly k red edges. Yuster [25] took the first approach and showed an algorithm that computes an *almost perfect exact matching* (a matching with exactly k red edges and either $\frac{n}{2}$ or $\frac{n}{2} - 1$ total edges[3]). This is as close as possible for this type of approximation. However, there are two things to consider with Yuster's algorithm: First, the algorithm itself is very simple. Secondly, as long as a trivial condition on k is met, such an almost perfect exact matching always exists. It is surprising that this approximation is achieved by such simple methods in such generality. For the closely related *budgeted matching* problem, more sophisticated methods have been used recently to achieve a PTAS [3] and efficient PTAS [1]. These methods also do not guarantee to return a perfect matching.

The alternative is to find approximations which always return a perfect matching, but with possibly the wrong number of red edges. These kinds of approximations seem considerably more difficult to tackle. It is puzzling how little is known about this type of approximation, while the other type of approximation admits much stronger results. Very recently, El

[1] The independence number of a graph G is defined as the largest number α such that G contains an independent set of size α.

[2] The bipartite independence number of a bipartite graph G is defined as the largest number β such that G contains a balanced independent set of size 2β, i.e. an independent set using exactly β vertices from each partition.

[3] n is the number of vertices in the graph.

Maalouly [7] presented a polynomial-time algorithm which for bipartite graphs outputs a perfect matching containing k' red edges with $0.5k \leq k' \leq 1.5k$. To the best of our knowledge, this is the only result in this direction, despite the original EM problem being from 1982. Moreover, note that this algorithm can return both a perfect matching with too many or too few red edges. Hence El Maalouly's algorithm is not an approximation algorithm in the classical sense, as it only guarantees a two-sided, but not a one-sided, approximation.

Our contribution

We consider the problem of approximating EM, such that a perfect matching is always returned, and such that the approximation is one-sided. We show the first positive result of this kind. Formally, we consider the following optimization variant of EM:

Exact Matching Optimization (EM-opt)
Input: A graph G whose edges are colored red or blue; and an integer k.
Task: Maximize $|R(M)|$ subject to the constraint that M is a perfect matching in G and $|R(M)| \leq k$, where $R(M)$ is the set of red edges in M.

We consider bipartite graphs and prove:

▶ **Theorem 1.** *There exists a deterministic polynomial-time 3-approximation for EM-opt in bipartite graphs.*

We remark that there are three kinds of input instances to EM-opt : First, instances which are also YES-instances of EM, i.e. a perfect matching with k red edges exists. For those instances, our algorithm returns a perfect matching with k' red edges and $\frac{1}{3}k \leq k' \leq k$. Second, there are instances, where EM-opt is infeasible, in the sense that all perfect matchings have $k+1$ or more red edges. For such instances, our algorithm returns "infeasible". Finally, there are instances which are feasible, but the optimal solution to EM-opt has k^* red edges with $k^* < k$. For such instances, our algorithm returns a perfect matching with k' red edges and $\frac{1}{3}k^* \leq k' \leq k^*$.

The main idea behind our approximation algorithm is to start with an initial perfect matching, and then repeatedly try a small improvement step using dynamic programming. Whenever a small improvement step is not possible, we prove that the graph is "rigid" in a certain sense. We can prove that as a result of this rigidity, it is a good idea to guess a single edge e and to enforce that this edge e is contained in the solution matching. This paper contains concepts and lemmas, which make these ideas formal and may help for the development of future approximation algorithms. Our new ideas are based on a geometric intuition about the cycles appearing in such a "rigid" graph.

2 Preliminaries

2.1 Definitions and notations

All graphs considered are simple. Given a graph $G = (V, E)$, a perfect matching M of G is a subset of E such that every vertex in V is adjacent to exactly one edge in M. We introduce two tools related to M: the weight function w_M and the weighted directed graph G_M. These tools were first introduced in [8, 7]. They can be used to reason about EM, as is explained further below.

▶ **Definition** (Weight function w_M). *Given a graph $G = (V, E)$ whose edges are colored red or blue and a perfect matching M on G, we define the weight function w_M on the edges of G as follows:*

$$w_M(e) = \begin{cases} 0 & \textit{if } e \textit{ is a blue edge} \\ -1 & \textit{if } e \in M \textit{ is a red edge} \\ +1 & \textit{if } e \notin M \textit{ is a red edge} \end{cases}$$

▶ **Definition** (Oriented and edge-weighted graph G_M). *Given a bipartite graph $G = (A \sqcup B, E)$ whose edges are colored red or blue and a perfect matching M on G, the graph G_M is the oriented and edge-weighted graph such that:*

- *the vertex set of G_M is the vertex set $A \sqcup B$ of G;*
- *the edge set of G_M is the edge set of G such that edges in M are oriented from A to B and edges not in M are oriented from B to A;*
- *edges in G_M are weighted according to the weight function w_M.*

For ease of notation, we identify subgraphs of G and G_M with their edge sets. Any reference to their vertices will be made explicit. Since every edge in G_M has an undirected unweighted version in G, every subgraph H_M in G_M can be associated to the subgraph H in G of corresponding undirected and unweighted edge set, and vice versa. With a slight abuse of notation, we therefore sometimes do not differentiate H of H_M and denote them by the same object. If E_1 and E_2 are two edge sets, then we denote by $E_1 \Delta E_2 := (E_1 \setminus E_2) \cup (E_2 \setminus E_1)$ their symmetric difference. Let H be a subgraph of G_M. We use the following notations:

- $R(H)$ denotes the set of red edges in H.
- $E^+(H)$ denotes the set of positive edges in H (i.e. the red edges in H not contained in M).
- $E^-(H)$ denotes the set of negative edges in H (i.e. the red edges in H contained in M).
- $w_M(H)$ is the weight of H with respect to the edge weight function w_M, i.e. $w_M(H) = |E^+(H)| - |E^-(H)|$.

Unless stated otherwise, all considered cycles and paths in G_M are directed. Finally if C is a directed cycle in G_M, and $P_1 \subseteq C$ and $P_2 \subseteq C$ are sub-paths on C, we denote by $C[P_1, P_2]$ (respectively $C(P_1, P_2)$) the sub-path in C from P_1 to P_2 included (resp. excluded). If $w_M(C) > 0$ then we call C a *positive* cycle and if $w_M(C) \leq 0$ we call C a *non-positive* cycle. A *walk* in a directed graph is a sequence of edges $(e_1, \dots, e_t)$ such that the end vertex of e_i is the start vertex of e_{i+1} for $i = 1, \dots, t-1$. In contrast to a path, a walk may visit vertices and edges twice. A walk is *closed*, if its start and end vertex are equal.

2.2 Observations on G_M

In this subsection, we explain some simple observations, which we use later to reason about our approximation algorithm. Let G be a bipartite graph and M be a perfect matching of G. A cycle in G is said to be *M-alternating* if for any two adjacent edges in the cycle, one of them is in M and the other is not. It is a well-known fact that if M and M' are two perfect matchings, then $M \Delta M'$ is a set of vertex-disjoint cycles that are both M-alternating and M'-alternating. We now make the following important observations on the bipartite graphs G and G_M and the weight function w_M.

▶ **Observation 2.** *A cycle C in G is M-alternating if and only if the corresponding cycle C_M in G_M is directed.*

Proof. This follows directly from the definition of G_M. ◀

▶ **Observation 3.** *Let C be a directed cycle in G_M. Then $M' := M \Delta C$ is a perfect matching whose number of red edges is $|R(M')| = |R(M)| + w_M(C)$.*

Proof. Since C is M-alternating, it is a well-known fact that M' is again a perfect matching. The equation $|R(M')| = |R(M)| + w_M(C)$, follows directly from the definition of w_M. If an edge in C is blue, it does not change the amount of red edges of M. If an edge in C is red, it changes the number of red edges of M by ±1, depending on whether or not it is in M. ◀

▶ **Observation 4.** *Let C_1 and C_2 be two directed cycles in G_M that intersect at a vertex v. Then C_1 and C_2 also intersect on an edge adjacent to v.*

Proof. By Observation 2, C_1 and C_2 are M-alternating so they both contain exactly one adjacent edge to v that is also contained in M. Since M is a perfect matching, there exists a single adjacent edge to v in M. Thus C_1 and C_2 both contain this edge. ◀

2.3 Previous ideas

The first part of our algorithm for Theorem 1 presented in Section 3 is strongly inspired by the algorithm in [7, Theorem 1] that computes a perfect matching with between $0.5k$ and $1.5k$ red edges. We summarize the main ideas here.

One can compute a perfect matching of minimum number of red edges in polynomial time by using a maximum weight perfect matching algorithm (e.g. [6]) on the graph G where red edges have weight 0 and blue edges have weight +1. The idea in [7] is to start with a perfect matching of minimum number of red edges M. If $0.5k \leq |R(M)| \leq 1.5k$ then we are already done and can output M. Otherwise $|R(M)| < 0.5k$ (it cannot have more than k red edges by minimality). In that case the algorithm iteratively improves M using positive cycles. Indeed, assume for a moment that we could find a directed cycle C in G_M such that both $w_M(C) > 0$ and $|E^+(C)| \leq k$, then the perfect matching $M' := M \Delta C$ is such that

$$\begin{aligned} |R(M)| < |R(M')| &= |R(M)| + w_M(C) \\ &\leq |R(M)| + |E^+(C)| < 0.5k + k = 1.5k. \end{aligned}$$

Thus we can iteratively compute such cycles C and replace M by $M \Delta C$. We make true progress every time until $0.5k \leq |R(M)| \leq 1.5k$.

An important observation proven in [7] is that we can determine in polynomial time if such a cycle exists. We recall this result in Proposition 5.

▶ **Proposition 5** (Adapted from [7, Proposition 11]). *Let $G := (V, E)$ be an edge-weighted directed graph and $t \in \mathbb{N}$ be a parameter. There exists a deterministic polynomial-time algorithm that, given G, determines whether or not there exists a directed cycle C in G with $w(C) > 0$ and $|E^+(C)| \leq t$. If such a cycle C exists then the algorithm also outputs a cycle C' with the same properties as C (i.e. $w(C') > 0$ and $|E^+(C')| \leq t$).*

The idea of Proposition 5 is to flip the sign of all weights so that we are looking for a negative cycle. Those can be found by shortest path algorithms: for example the Bellman-Ford algorithm which relies on a dynamic program (DP). Each entry of this DP contains the shortest distance between two vertices. The DP can be adapted so that it contains an additional budget constraint corresponding to the number of negative edges (i.e. positive before we flip the sign of the weight) a path is allowed to use. We also add in the entry of the DP the last edge used in the path. This way, when looking at the entries corresponding to the shortest path from a vertex v to the same vertex v we are able to determine whether or not there exists a negative cycle that uses no more than t negative edges (i.e. positive before we flip the sign of the weight). If it is the case then the algorithm can output such a cycle. We redirect the reader for a detailed proof of Proposition 11 in [7, Section 3.1]. We finally remark that the proof in [7] is completed by showing that as long as M does not have between $0.5k$ and $1.5k$ red edges, a cycle C with $w_M(C) > 0$ and $|E^+(C)| \leq k$ always exists. However, to get a one-sided approximation, we need to guarantee the existence of a cycle C with $w_M(C) > 0$ and $|E^+(C)| \leq k - |R(M)|$. This might not be possible for certain graphs if $|R(M)| > 0$. This means that the above result is not enough for our purpose, as it only leads to a two-sided approximation.

2.4 Assumptions

In order to reduce the technical details needed to present our 3-approximation algorithm of EM-OPT, we show in this subsection that several simplifying assumptions can be made about the input instance.

▷ Claim 6. We can assume without loss of generality that the input instance to EM-OPT is also a YES-instance of EM, i.e. there exists a perfect matching with exactly k red edges.

Proof. Fix an instance $\langle G, k\rangle$ of EM-OPT. If the instance is feasible, let $k^* \leq k$ be the number of red edges in an optimal solution of EM-OPT. Suppose $\mathcal{A}$ is an algorithm for EM-OPT, which given an instance $\langle G, k\rangle$ returns a 3-approximate solution to EM-OPT if $k = k^*$, and returns some arbitrary perfect matching otherwise. We devise an algorithm $\mathcal{A}'$, which is a 3-approximation of EM-OPT for the input $\langle G, k\rangle$. First, $\mathcal{A}'$ computes in polynomial time the perfect matchings $M_{\min}$ and $M_{\max}$ with the minimum and maximum number of red edges. If it is not the case that $|R(M_{\min})| \leq k \leq |R(M_{\max})|$, then $\mathcal{A}'$ returns "infeasible". Afterwards, $\mathcal{A}'$ calls $\mathcal{A}$ as a subroutine for all $k' \in \{|R(M_{\min})|, \dots, k\}$ and receives a perfect matching $M_{k'}$ each time. Finally, $\mathcal{A}'$ returns the best among all the matchings $M_{k'}$ that are feasible for EM-OPT. It is easy to see that $\mathcal{A}'$ is a correct 3-approximation, since there will be an iteration with $k' = k^*$. If $\mathcal{A}$ has running time $O(f)$, then $\mathcal{A}'$ has running time $O(nf + f_{\text{Mat}})$, where f_{Mat} denotes the time to deterministically compute a maximum weight perfect matching. ◁

▷ Claim 7. We can assume without loss of generality that for every edge $e \in E$ there exists a perfect matching of G containing e.

Proof. If an edge is not contained in any perfect matching, it is irrelevant and it can be deleted. We can therefore pre-process the graph and check for each edge in time $O(f'_{\text{Mat}})$ if it is irrelevant. Here f'_{Mat} denotes the time to deterministically check if a graph has a perfect matching, e.g. by running a maximum weight perfect matching algorithm. ◁

3 A 3-approximation of Exact Matching

In this section we are proving our main result, Theorem 1. Let $G = (A \sqcup B, E)$ be a red-blue edge-colored bipartite graph and k be an integer, such that they together form an instance of EM-OPT. We work under the assumptions of Section 2.4. In Algorithm 1 we show an algorithm that given G and k outputs a perfect matching containing between $\frac{1}{3}k$ and k red edges. Let us discuss the general ideas before formally analysing the algorithm.

We reuse the idea from [7] to iteratively improve a perfect matching M by a small amount until it has the right amount of red edges. This improvement is done by finding positive cycles in G_M with no more than $\frac{2}{3}k$ positive edges (using the algorithm of Proposition 5). As

Algorithm 1 The 3-approximation algorithm for EM-OPT of Theorem 1.

```
Input: A bipartite graph $G = (A \sqcup B, E)$ and an integer $k \geq 0$, such that they fulfill
       the assumptions from Section 2.4.
Output: $M$, a perfect matching such that $\frac{1}{3}k \leq |R(M)| \leq k$.
1 Compute a perfect matching $M$ of minimal number of red edges.
2 If $|R(M)| \geq \frac{1}{3}k$ then output $M$.
3 Otherwise compute a cycle $C$ in $G_M$ with $w_M(C) > 0$ and $|E^+(C)| \leq \frac{2}{3}k$, or
    determine that no such cycle exists.
4 If such a cycle $C$ exists, set $M \leftarrow M \Delta C$ and go to Step 2.
5 Otherwise there are no positive cycles with $|E^+(C)| \leq \frac{2}{3}k$ in $G_M$. For every red edge
    $e \in R(G)$ do the following:
6     Compute the perfect matching $M^e$ containing $e$ of minimal number of red edges.
7     If $\frac{1}{3}k \leq |R(M^e)| \leq k$ then output $M^e$.
8 Output $\perp$
```

opposed to the algorithm in [7], we do not want to "overshoot" the number of red edges, i.e. the obtained perfect matching cannot have more than k red edges. We therefore constrain the cycle to have $|E^+(C)| \leq \frac{2}{3}k$. This implies $|R(M \Delta C)| \leq k$. However the issue with that approach is that unlike in [7], we cannot guarantee that such a cycle always exists. So what do we do if we are not able find a good cycle? The answer to this question turns out to be the key insight behind our algorithm. For every edge e we define

$$M^e \in \arg\min\{|R(M)| : M \text{ is a perfect matching with } e \in M\}$$

to be a perfect matching of G containing e with minimal number of red edges. Note that by Claim 7, M^e is properly defined. We also note that M^e can be computed in polynomial time.

We claim that in the case that no good cycle is found, the set of matchings M^e "magically" fixes our problems. Specifically, we claim that at least one of the matchings M^e is a sufficient approximation. The rough intuition behind this is the following. The fact that no good cycle exists means that the graph does not contain small substructures, which can be used to modify the current solution M towards a better approximation. In a sense, the graph is rigid. This rigidity means that maybe there could exist some edge e in the optimal solution M^*, such that every perfect matching including e is already quite similar to M^*. Our approximation algorithm simply tries to guess this edge e. After proving Lemma 8, the remaining part of the paper is devoted to quantify and prove this structural statement.

▶ **Lemma 8.** *Algorithm 1 runs in polynomial time and either outputs $\perp$ or a correct 3-approximation of EM-OPT.*

Proof. Note that the first inner loop is executed at most $O(|V|)$ times, since $w_M(C) > 0$ in each iteration, thus $|R(M)|$ is monotonously increasing. Furthermore, every iteration of the loop is executed in polynomial time due to Proposition 5. The second loop is executed at most $O(|E|)$ times. The matching in *Step 1*, as well as the matchings M^e can be computed in polynomial time using a minimum weight perfect matching algorithm. In total, this takes polynomial time. If the algorithm does not output $\perp$, then it outputs either in *Step 7* (which is obviously a 3-approximation), or in *Step 2*, which is a 3-approximation because $k/3 \leq |R(M \Delta C)| = |R(M)| + w_M(C) \leq |R(M)| + |E^+(C)| \leq k$. ◀

All it remains to prove is that Algorithm 1 never outputs $\perp$. This happens if the conditions in *Step 2* and in *Step 7* are not satisfied. In that regard, define the following *critical tuple*.

▶ **Definition** (Critical tuple). *Let (G, k, M^*, M) be such that G is a bipartite graph whose edges are colored red or blue, $k \geq 0$ is an integer and M^* and M are perfect matchings of G. The tuple (G, k, M^*, M) is said to be* critical *if:*

- *All the assumptions in Section 2.4 hold.*
- *M^* is a perfect matching of G with exactly k red edges.*
- *$|R(M)| < \frac{1}{3}k$.*
- *If C is a directed cycle in G_M such that $w_M(C) > 0$ then $|E^+(C)| > \frac{2}{3}k$.*
- *For every edge $e \in R(M^* \setminus M)$ we have $|R(M^e)| < \frac{1}{3}k$.*

Note that if Algorithm 1 outputs $\perp$, we must have a critcal tuple. Indeed, for every edge $e \in R(M^* \setminus M)$, by minimality of M^e, we have $|R(M^e)| \leq k$. So if the algorithm returns $\perp$, then it must be the case that $|R(M^e)| < k/3$ for all $e \in R(G)$ so in particular also for all $e \in R(M^* \setminus M)$. We will prove the following: critical tuples do not exist. This means that Algorithm 1 never outputs $\perp$ and is therefore a correct 3-approximation algorithm.

▶ **Lemma 9.** *A tuple (G, k, M^*, M) can never be critical.*

3.1 Overview of the main proof

In this section, we explain the idea behind the proof of our main lemma, Lemma 9. From this point onward, consider a fixed tuple (G, k, M^*, M). We prove Lemma 9 by contradiction and therefore assume that (G, k, M^*, M) is a critical tuple. The main strategy of the proof is to find a set of cycles with contradictory properties. Such a set of cycles is called a *target set*. We first introduce a special cycle, which we call the cycle C^+.

▶ **Definition** (Cycle C^+). *C^+ is the positive cycle in G_M such that $C^+ \subseteq M\Delta M^*$.*

We claim that C^+ is well-defined and unique. Indeed, since $|R(M)| < |R(M^*)|$, the set of cycles $M\Delta M^*$ has to contain at least one positive cycle. Furthermore, there are at most $k = |R(M^*)|$ positive edges in $M\Delta M^*$ and by the definition of a critical tuple, every positive cycle contains at least $\frac{2}{3}k$ of them. Hence there is no second positive cycle in $M\Delta M^*$.

We list the following simple observations. The last two state that there only exist two different types of cycles in a critical tuple. These two types can be distinguished by examining the number of positive edges in a cycle C. We will repeatedly make use of this key observation.

▶ **Observation 10.** *Let (G, k, M^*, M) be a critical tuple. Then the following properties hold.*

1. *$|E^-(G_M)| < \frac{1}{3}k$.*
2. *$\frac{2}{3}k < |E^+(C^+)| \leq k$*
3. *If C is a directed cycle in G_M then $w_M(C) > 0$ if and only if $|E^+(C)| > \frac{2}{3}k$.*
4. *If C is a directed cycle in G_M then $w_M(C) \leq 0$ if and only if $|E^+(C)| < \frac{1}{3}k$.*

Proof. (G, k, M^*, M) is a critical tuple so in particular $|R(M)| < \frac{1}{3}k$, thus the graph G_M contains at most $\frac{1}{3}k$ negative edges. As a consequence, if C is a non-positive cycle then $|E^+(C)| \leq |E^-(C)|$ and thus $|E^+(C)| < \frac{1}{3}k$. Furthermore, in a critical tuple every positive cycle contains at least $\frac{2}{3}k$ positive edges, hence the third observation follows directly. In particular, since C^+ is a positive cycle, we have $\frac{2}{3}k < |E^+(C^+)|$. Finally the upper bound on $|E^+(C^+)|$ comes from the fact that positive edges in $M\Delta M^*$ are red edges in M^*, hence $M\Delta M^*$ contains at most $k = |R(M^*)|$ positive edges. In particualr $|E^+(C^+)| \leq k$. ◀

▶ **Definition** (Target set). *We call a set $\mathcal{C}$ of non-positive cycles in G_M a* target set *if:*

1. *$\forall e \in E^+(C^+)$ there exists a cycle in $\mathcal{C}$ containing e. (Condition 1)*
2. *$\forall C \in \mathcal{C}$, $C \cap C^+$ is a single path. (Condition 2)*
3. *$\forall e \in E^-(G_M)$ there are at most two cycles in $\mathcal{C}$ containing e. (Condition 3)*

The following Lemma 11 shows that in order to prove our main lemma, Lemma 9, it suffices to find a target set.

▶ **Lemma 11.** *Let (G, k, M^*, M) be a critical tuple and $\mathcal{C}$ be a target set in G_M. Then a contradiction arises.*

Proof. We can lower bound the sum of the weights of cycles in $\mathcal{C}$.

$$\begin{aligned}\sum_{C\in\mathcal{C}} w_M(C) &\geq 1\cdot|E^+(C^+)| - 2\cdot|E^-(G_M)| \\ &> \frac{2}{3}k - 2\cdot\frac{1}{3}k && \text{(by Observation 10)} \\ &= 0\end{aligned}$$

However $\sum_{C\in\mathcal{C}} w_M(C) \leq 0$ since all cycles $C \in \mathcal{C}$ have non-positive weight $w_M(C) \leq 0$, so this is a contradiction. ◀

Note that Condition 2 is not needed in the proof of Lemma 11. However Condition 2 will be useful to achieve Condition 3.

The rest of the paper is structured as follows: First, we construct a set $\mathcal{C}$ of non-positive cycles satisfying only Condition 1. This is explained in Section 3.2. After that, we explain in Section 3.3 how to modify the initial set to additionally satisfy Condition 2. In Section 3.4 we show how to modify this set again to also satisfy Condition 3. Finally, the proof of Lemma 9 is summarized in Section 3.5. To help visualize the reasonings on G_M we provide various illustrations. We focus only on the orientation of paths and cycles and not on actual vertices and edges of G_M so we omit them and draw paths and cycles using simple lines whose orientation is indicated by an arrow. Individual edges and vertices will be indicated in red.

3.2 Obtaining an initial set of cycles satisfying Condition 1

We explain how to obtain an initial set of non-positive cycles in G_M which satisfies only Condition 1. To this end, for a fixed critical tuple (G, k, M^*, M) consider the following definition:

▶ **Definition** (Cycle C_e)**.** *Let $e \in E^+(C^+)$. We define $C_e \subseteq M\Delta M^e$ as the unique directed cycle in $M\Delta M^e$ which contains the edge e.*

Observe that C_e is well-defined, since $e \in M\Delta M^e$. We claim that for all possible $e \in E^+(C^+)$ we have $w_M(C_e) \leq 0$. Indeed, positive edges in $M\Delta M^e$ are red edges in M^e. By the definition of a critical tuple and $E^+(C^+) \subseteq R(M^* \setminus M)$, we have $|R(M^e)| < \frac{1}{3}k$, thus $|E^+(C_e)| < \frac{1}{3}k$. Hence by Observation 10, C_e has non-positive weight in G_M. As a direct consequence, the set of cycles $\{C_e : e \in E^+(C^+)\}$ is a set of non-positive cycles satisfying Condition 1.

3.3 Modifying the set to satisfy Condition 2

We now show how to modify the initial set $\{C_e : e \in E^+(C^+)\}$ into a set of non-positive cycles such that both Conditions 1 and 2 hold. Consider a fixed critical tuple (G, k, M^*, M). If every cycle C_e intersects C^+ in a single path, then we would directly have Condition 2. However, in reality the interaction between C_e and C^+ can be a great amount more complicated. One example is depicted in Figure 1. In order to analyse the interaction between these two cycles, we define multiple notions around them. First, we decompose the cycle C_e into *jumps* and *interjumps* where jumps are the sub-paths of C_e outside of C^+ and interjumps are the sub-paths of C_e intersecting C^+ between jumps.

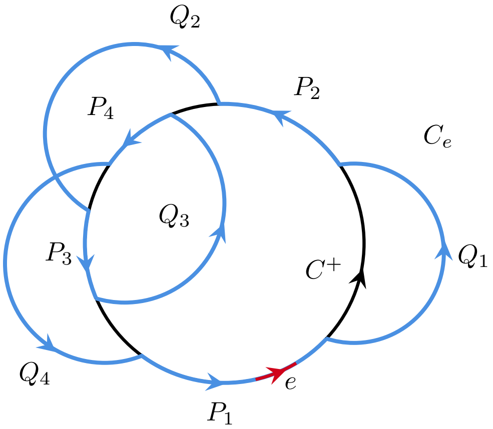

Figure 1 Decomposition of the cycle C_e (in blue) into 4 jumps Q_1, Q_2, Q_3, Q_4 and 4 interjumps P_1, P_2, P_3, P_4. The first interjump P_1 contains the edge e.

▶ **Definition** (Jumps and interjumps). *Let $e \in E^+(C^+)$. A jump of C_e is a sub-path $Q \subseteq C_e$ such that its endpoints are vertices of C^+ but none of its inner vertices are in C^+. Note that $Q \subseteq G_M \setminus C^+$. An interjump of C_e is a sub-path of $P \subseteq C_e$ contained in C^+ such that its endpoints are the endpoints of jumps of C_e. Note that $P \subseteq C^+$.*

▶ **Definition** (Decomposition of C_e into alternating jumps and interjumps). *Let $e \in E^+(C^+)$. Decompose C_e into jumps $Q_1, \ldots, Q_\ell$ and interjumps $P_1, \ldots P_\ell$ such that $e \in P_1$ and C_e is the concatenation of alternating jumps and interjumps:*

$$C_e = P_1 Q_1 \ldots P_j Q_j \ldots P_\ell Q_\ell$$

Let $\mathcal{J}_e = \{Q_1, Q_2, \ldots, Q_\ell\}$ be the set of jumps in C_e and $\mathcal{I}_e = \{P_1, P_2, \ldots, P_\ell\}$ be the set of interjumps in C_e.

Note that every jump in C_e must be followed by an interjump since all cycles considered are M-alternating cycles which cannot intersect in a single vertex (by Observation 4). Figure 1 shows a cycle C_e and its decomposition into jumps and interjumps.

To understand the interplay between C_e and C^+, we introduce the notion of forward and backward motion based on a visual intuition. Consider the directed cycle C^+ and take the convention of always drawing it with an anticlockwise orientation. We say that moving along C^+ in the direction of its directed edges equals to an *anticlockwise* or *forward* motion, while moving on the cycle C^+ against the direction of its directed edges equals to a *clockwise* or *backward* motion. We also want to interpret the direction a jump $Q \in \mathcal{J}_e$ is taking. However since Q is not a path in C^+ there is no obvious rule whether it should be seen as moving forward or backward. In fact, Figure 2 shows that the same jump can in principle be interpreted either as following a forward or a backward motion. We introduce the following rule which classifies all jumps as either a forward or a backward jump. We follow the convention to draw forward jumps outside of C^+, while we draw backward jumps inside of C^+. With this interpretation, in Figure 1 the jumps Q_1, Q_2 and Q_4 are forward and the jump Q_3 is backward.

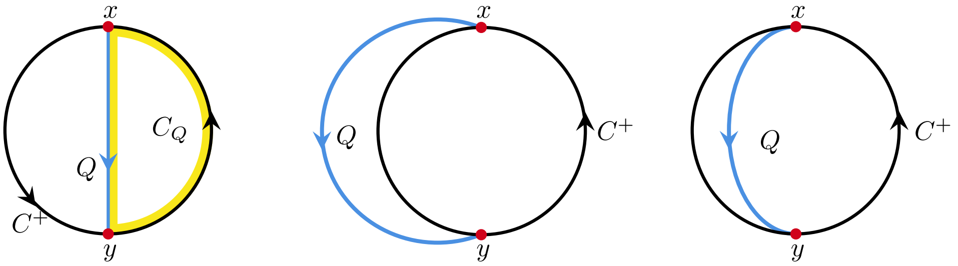

Figure 2 Consider a jump Q (blue) from the vertex x to the vertex y in C^+. Depending on the weight of C_Q (yellow highlight), the jump Q is either interpreted as following a forward (middle) or a backward (right) motion.

▶ **Definition** (Cycle C_Q and forward/backward jump). *Let $e \in E^+(C^+)$ and let Q be a jump of C_e. We define C_Q to be the unique directed cycle in the graph $C^+ \cup Q$ containing Q. Then:*

- *if $w_M(C_Q) > 0$, we call Q a* forward *jump;*
- *if $w_M(C_Q) \leq 0$, we call Q a* backward *jump.*

Let $\mathcal{J}_e^f$ be the set of forward jumps in C_e and $\mathcal{J}_e^b$ the set of backward jumps in C_e.

Observe that this is a valid definition, since the cycle C_Q is unique and independent of whether Q is a forward or a backward jump. We give a short informal explanation of why we use the weight of C_Q to distinguish between forward and backward jumps. A positive cycle must contain a large number of positive edges (at least $\frac{2}{3}k$ many, by Observation 10) and most of the positive edges of C_Q are contained in C^+ (since C_e has at most $\frac{1}{3}k$ positive edges). So for a forward jump Q_f, the cycle C_{Q_f} must have a large intersection with C^+ to be positive, i.e. Q_f only skips a small portion of the cycle. Similarly, for a backward jump Q_b, the cycle C_{Q_b} must be a non-positive cycle so it cannot contain too many positive edges and therefore cannot intersect a large part of C^+.

Finally, we introduce the notion of the *reach* of a jump Q, which is intuitively the sub-path of C^+ the jump Q is "jumping over". Figure 3 illustrates the reach of a forward jump and a backward jump. We say that the jump Q *covers* the edges in the reach of Q.

▶ **Definition** (Reach of a jump). *Let $e \in E^+(C^+)$ and let Q be a jump of C_e.*

- *If Q is a forward jump: the reach of Q is the sub-path of C^+ defined as $r(Q) := C^+ \setminus C_Q$.*
- *If Q is a backward jump: the reach of Q is the sub-path of C^+ defined as $r(Q) := C_Q \setminus Q$.*

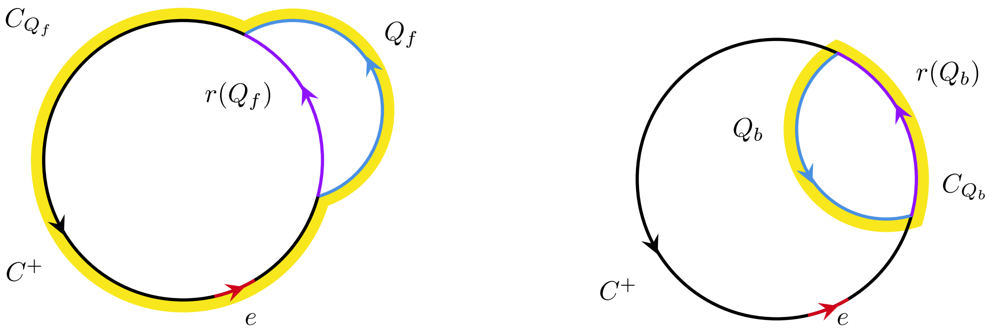

Figure 3 A forward jump Q_f and a backward jump Q_b (in blue). The respective reaches $r(Q_f)$ and $r(Q_b)$ of the jumps are colored in purple and the cycles C_{Q_f} and C_{Q_b} are highlighted in yellow.

We also extend the definition of the reach of a jump to the reach of C_e. Intuitively the reach of C_e is the union of sub-paths of C^+ the cycle C_e is jumping over. Here we differentiate between the sub-paths that are jumped over using *forward motions* (forward jumps or interjumps) and *backward motions* (backward jumps).

▶ **Definition** (Reach of C_e). *Let $e \in E^+(C^+)$. The forward reach $r_f(C_e)$ of C_e is defined as the union of every interjump of C_e and the reach of every forward jump of C_e.*

$$r_f(C_e) := \bigcup_{Q \in \mathcal{J}_e^f} r(Q) \cup \bigcup_{P \in \mathcal{I}_e} P$$

The backward reach $r_b(C_e)$ of C_e is defined as the union of the reaches of every backward jump of C_e.

$$r_b(C_e) := \bigcup_{Q \in \mathcal{J}_e^b} r(Q)$$

The reach $r(C_e)$ of C_e is defined as the union of the forward reach and the backward reach of C_e.

$$r(C_e) := r_f(C_e) \cup r_b(C_e)$$

All above definitions still hold when replacing C_e by a sub-path $\mathcal{P}$ of C_e. Since the reach of a truncated jump is undefined, we will only consider sub-paths which endpoints are vertices of C^+. If $\mathcal{P}$ contains a sub-path of an interjump then the forward reach of $\mathcal{P}$ contains this sub-path and not the entire interjump.

With those newly defined notions, we note that to achieve Condition 2, it suffices to prove the following Lemma 12. Due to space contraints, we leave the proof to Appendix A.

▶ **Lemma 12.** *Let (G, k, M^*, M) be a critical tuple. Every edge $e \in E^+(C^+)$ is contained in the backward reach of C_e, i.e. $\forall e \in E^+(C^+) : e \in r_b(C_e)$.*

Indeed, we can then construct a set of non-positive cycles satisfying Conditions 1 and 2 as explained in Lemma 13.

▶ **Lemma 13.** *Let (G, k, M^*, M) be a critical tuple. There exists a set $\mathcal{C}$ of non-positive cycles in G_M satisfying Conditions 1 and 2, i.e. such that the following holds:*

- *$\forall e \in E^+(C^+)$ there exists a cycle in $\mathcal{C}$ containing e.*
- *$\forall C \in \mathcal{C}$, $C \cap C^+$ is a single path.*

Proof. By Lemma 12, for each edge $e \in E^+(C^+)$ there exists a backward jump Q_e in C_e that covers e. Since it is a backward jump, the cycle C_{Q_e} formed by Q_e and its reach is a non-positive cycle. It also contains e and intersects C^+ in a single path $r(Q_e)$. Hence the set $\mathcal{C} := \{C_{Q_e} : e \in E^+(C^+), Q_e \in \mathcal{J}_e^b, e \in r(Q_e)\}$ satisfies Conditions 1 and 2. ◀

3.4 Modifying the set to satisfy Condition 3

In the previous section we obtained a set $\mathcal{C}$ of non-positive cycles satisfying Conditions 1 and 2. To additionally satisfy Condition 3, which is that for every negative edge $e \in E^-(G_M)$ there exist at most two cycles in $\mathcal{C}$ containing e, we proceed in two steps. First we focus in Lemma 15 on bounding the number of cycles containing a negative edge on the cycle C^+. Then we prove in Lemma 16 how to bound the number of cycles containing a negative edge outside the cycle C^+.

Observation 14 shows with a simple argument that if a set of paths in C^+ covers the whole cycle C^+, then it is enough to keep at most two paths covering the same edge in C^+. This is the key idea behind Lemma 15.

▶ **Observation 14.** *If $\mathcal{P}'$ is a set of paths in C^+, then there exists a subset $\mathcal{P} \subseteq \mathcal{P}'$ such that $\bigcup_{P' \in \mathcal{P}'} P' = \bigcup_{P \in \mathcal{P}} P$ and every $e \in C^+$ is contained in at most two paths of $\mathcal{P}$.*

Proof. Let $X = \bigcup_{P' \in \mathcal{P}'} P'$. Take $\mathcal{P}$ to be a minimal subset of $\mathcal{P}'$ such that $\bigcup_{P \in \mathcal{P}} P = X$. Suppose there exists an edge $e \in C^+$ such that $\exists P_1, P_2, P_3 \in \mathcal{P}$ with $e \in P_1 \cap P_2 \cap P_3$. W.l.o.g. suppose P_1 contains an edge that is furthest before e on C^+ among all edges of P_1, P_2 and P_3, and P_2 contains an edge furthest after e. Then $P_3 \subseteq P_1 \cup P_2$, which contradicts the minimality of $\mathcal{P}$. So every edge is contained in at most two paths from $\mathcal{P}$. ◀

▶ **Lemma 15.** *Let (G, k, M^*, M) be a critical tuple and $\mathcal{C}$ be a set of non-positive cycles in G_M satisfying Conditions 1 and 2, i.e. such that:*

- *$\forall e \in E^+(C^+)$ there exists a cycle in $\mathcal{C}$ containing e.*
- *$\forall C \in \mathcal{C}$, $C \cap C^+$ is a single path.*

Then there exists a set $\mathcal{C}' \subseteq \mathcal{C}$ of non-positive cycles satisfying the above Conditions 1 and 2 as well as the following property:

- *$\forall e \in E^-(C^+)$ there are at most two cycles in $\mathcal{C}$ containing e.*

Proof. By Condition 2, we can associate to each cycle C of $\mathcal{C}$ the sub-path $P_C := C \cap C^+$ intersecting with C^+. Let $\mathcal{P} := \{P_C : C \in \mathcal{C}\}$ be the set of such intersecting paths. By Condition 1 for every edge $e \in E^+(C^+)$ there exists a path $P \in \mathcal{P}$ containing e. We can thus apply Observation 14 to $\mathcal{P}$ and get a set $\mathcal{P}' \subseteq \mathcal{P}$ such that for every edge $e \in E^+(C^+)$ there exists a path $P \in \mathcal{P}'$ containing e and every $e \in C^+$ is contained in at most two paths from $\mathcal{P}'$. Let $\mathcal{C}' := \{C : P_C \in \mathcal{P}'\}$ be the set of cycles associated to each path in $\mathcal{P}'$. Then $\mathcal{C}' \subseteq \mathcal{C}$ still satisfies Conditions 1 and 2 and additionally for every edge $e \in C^+$ at most two cycles in $\mathcal{C}'$ contain e. ◀

▶ **Lemma 16.** *Let (G, k, M^*, M) be a critical tuple and $\mathcal{C}$ be a set of non-positive cycles in G_M satisfying Conditions 1 and 2, i.e. such that:*

- *$\forall e \in E^+(C^+)$ there exists a cycle in $\mathcal{C}$ containing e.*
- *$\forall C \in \mathcal{C}$, $C \cap C^+$ is a single path.*

Then there exists a set $\mathcal{C}' \subseteq \mathcal{C}$ of non-positive cycles satisfying the above Conditions 1 and 2 as well as the following property:

- *$\forall e \in E^-(G_M \setminus C^+)$ there are at most two cycles in $\mathcal{C}$ containing e.*

Proof. We show how to reduce three non-positive cycles of $\mathcal{C}$ containing an edge $e \in E^-(G_M \setminus C^+)$ into two non-positive cycles such that, when replacing the three cycles by the two new cycles, Conditions 1 and 2 still hold. By repeating this transformation, the number of cycles containing a negative edge $e \in E^-(G_M \setminus C^+)$ decreases until eventually at most two cycles in $\mathcal{C}$ contain e.

Fix an edge $e \in E^-(G_M \setminus C^+)$ and three non-positive cycles C_{Q_1}, C_{Q_2} and C_{Q_3} in $\mathcal{C}$ all containing e. For $i \in \{1, 2, 3\}$, by Condition 2, C_{Q_i} intersects C^+ in a single path. Hence let $r(Q_i) = C_{Q_i} \cap C^+$ be this path and let $Q_i := C_{Q_i} \setminus C^+$ be the remaining path of C_{Q_i} not intersecting C^+. Let also s_i and f_i be the first and last edge of Q_i. We can assume w.l.o.g. that the first edge of $r(Q_i)$ appears anti-clockwise on C^+ in the order $1, 2, 3$.

For $(i, j) \in \{(1, 2), (2, 3), (3, 1)\}$ consider the walk $W_{ij} = Q_j[s_j, e] \cup Q_i(e, f_i]$ that goes from s_j to f_i. This is a valid walk since $e \in Q_1 \cap Q_2 \cap Q_3$. W_{ij} can use edges multiple times so we identify W_{ij} to its multi-edge set. As illustrated in Figure 4, we can extract a simple

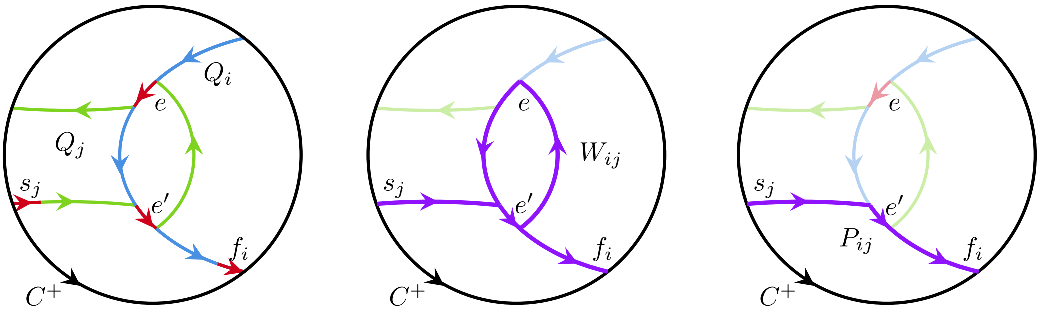

Figure 4 Possible configuration appearing in the proof of Lemma 16. Two jumps Q_i (blue) and Q_j (green) intersect in two different edges $e \in Q_1 \cap Q_2 \cap Q_3$ and $e' \in Q_i \cap Q_j$. The first edge of Q_j is denoted s_j and the last edge of Q_i is denoted f_i (red). The walk W_{ij} (purple, middle) from s_j to f_i is defined as $W_{ij} = Q_j[s_j, e] \cup Q_i(e, f_i]$ and uses the edge e' twice. The simple path P_{ij} (purple, right) is the simple sub-path from W_{ij} starting at s_j and ending at f_i.

path $P_{ij} \subseteq W_{ij}$ that goes from s_j to f_i. Let $C_{ij} = P_{ij} \cup C^+[r(Q_i), r(Q_j)]$. C_{ij} is a simple directed cycle since P_{ij} is a simple path from s_j to f_i outside of C^+ and $C^+[r(Q_i), r(Q_j)]$ is a simple path on C^+ from the endpoint of f_i on C^+ to the endpoint of s_j on C^+. An example of this construction is shown in Figure 5. If C_{ij} is a non-positive cycle, then we can replace C_{Q_i} and C_{Q_j} by C_{ij} in $\mathcal{C}$ and Conditions 1 and 2 would still hold. Indeed, by construction C_{ij} intersects C^+ on the single path $C^+[r(Q_i), r(Q_j)]$ so Condition 2 holds. Condition 1 holds because every edge $e \in E^+(C^+)$ that is contained in C_{Q_i} or C_{Q_j} is in fact in $r(Q_i)$ or $r(Q_j)$, which are both contained in C_{ij}. Hence it remains to show that there exists a pair $(i, j) \in \{(1, 2), (2, 3), (3, 1)\}$ such that C_{ij} is a non-positive cycle.

Suppose there exists a pair $(i, j) \in \{(1, 2), (2, 3), (3, 1)\}$ such that $r(Q_i)$ and $r(Q_j)$ are intersecting. Then we have:

$$\begin{aligned}
|E^+(C_{ij})| &= |E^+(P_{ij})| + |E^+(C^+[r(Q_i), r(Q_j)])| \\
&= |E^+(P_{ij})| + |E^+(r(Q_i) \cup r(Q_j))| \\
&\leq |E^+(W_{ij})| + |E^+(r(Q_i))| + |E^+(r(Q_j))| && \text{(because } P_{ij} \subseteq W_{ij}\text{)} \\
&= |E^+(Q_j[s_j, e])| + |E^+(Q_i(e, f_i])| + |E^+(r(Q_i))| + |E^+(r(Q_j))| \\
&\leq |E^+(Q_j)| + |E^+(Q_i)| + |E^+(r(Q_i))| + |E^+(r(Q_j))| \\
&= |E^+(C_{Q_i})| + |E^+(C_{Q_j})| \\
&< 2 \cdot \frac{1}{3}k && \text{(by Observation 10)}
\end{aligned}$$

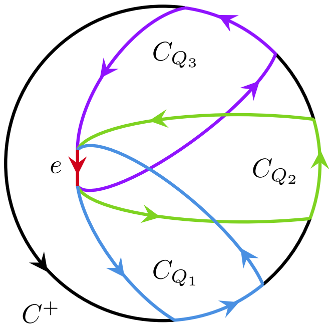
where the second equality follows from $C^+[r(Q_i), r(Q_j)] \subseteq r(Q_i) \cup r(Q_j)$. By Observation 10, C_{ij} cannot be positive and hence is a non-positive cycle, so we get the desired result.

If none of the paths $r(Q_1), r(Q_2), r(Q_3)$ are intersecting then assume for the sake of contradiction that C_{12}, C_{23} and C_{31} are all positive. By Observation 10 this means that

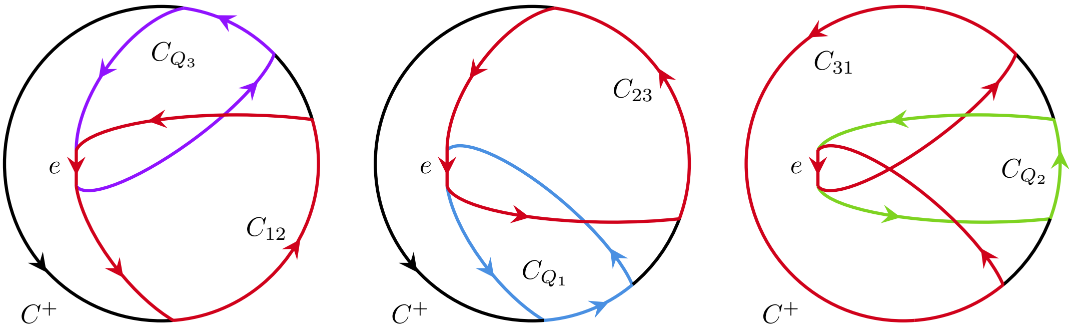
$$|E^+(C_{12})| + |E^+(C_{23})| + |E^+(C_{31})| > 3 \cdot \frac{2}{3}k = 2k.$$

However we also have for any pair $(i, j) \in \{(1, 2), (2, 3), (3, 1)\}$ that

$$\begin{aligned}
|E^+(C_{ij})| &= |E^+(P_{ij})| + |E^+(C^+[r(Q_i), r(Q_j)])| \\
&\leq |E^+(W_{ij})| + |E^+(C^+[r(Q_i), r(Q_j)])| && \text{(because } P_{ij} \subseteq W_{ij}\text{)} \\
&= |E^+(Q_j[s_j, e])| + |E^+(Q_i(e, f_i])| + |E^+(C^+[r(Q_i), r(Q_j)])|
\end{aligned}$$



(a) Three non-positive cycles C_{Q_1} (blue) C_{Q_2} (green) and C_{Q_3} (purple) intersecting in a single negative edge $e \notin C^+$.



(b) The newly constructed cycles C_{12}, C_{23} and C_{31} (in red from left to right). To construct C_{12} we combine the two cycles C_{Q_1} and C_{Q_2}.

Figure 5 Construction of three cycles C_{12}, C_{23} and C_{31} as done in the proof of Lemma 16. Note that this is a simplified configuration where the pairwise intersection of two non-positive cycles corresponds to the intersection of the three non-positive cycles C_{Q_1}, C_{Q_2} and C_{Q_3}.

Hence the total number of positive edges in the three cycles is:

$$\begin{aligned}
&|E^+(C_{12})| + |E^+(C_{23})| + |E^+(C_{31})| \\
&\quad \le |E^+(Q_2[s_2, e])| + |E^+(Q_1(e, f_1])| + |E^+(C^+[r(Q_1), r(Q_2)])| \\
&\qquad + |E^+(Q_3[s_3, e])| + |E^+(Q_2(e, f_2])| + |E^+(C^+[r(Q_2), r(Q_3)])| \\
&\qquad + |E^+(Q_1[s_1, e])| + |E^+(Q_3(e, f_3])| + |E^+(C^+[r(Q_3), r(Q_1)])| \\
&\quad = |E^+(Q_1)| + |E^+(Q_2)| + |E^+(Q_3)| \\
&\qquad + |E^+(C^+)| + |E^+(r(Q_1))| + |E^+(r(Q_2))| + |E^+(r(Q_3))| \\
&\quad = |E^+(C^+)| + |E^+(C_{Q_1})| + |E^+(C_{Q_2})| + |E^+(C_{Q_3})| \\
&\quad < k + 3 \cdot \frac{1}{3}k = 2k \qquad\qquad \text{(by Observation 10)}
\end{aligned}$$

where we can apply Observation 10 because C_{Q_i} is non-positive for any $i \in \{1, 2, 3\}$. Hence there has to exists a pair $(i, j) \in \{(1, 2), (2, 3), (3, 1)\}$ such that C_{ij} is non-positive. ◀

3.5 Constructing a target set

We can now prove Lemma 9.

Proof of Lemma 9. For the sake of contradiction let (G, k, M^*, M) be a critical tuple. Apply Lemmas 13, 16 and 15 in that order consecutively and get a target set $\mathcal{C}$. By Lemma 11, this leads to a contradiction. Thus (G, k, M^*, M) cannot be a critical tuple. ◀

As a consequence, Lemmas 8 and 9 together show that Algorithm 1 is a polynomial-time algorithm that always outputs a perfect matching M containing between $\frac{1}{3}k$ and k red edges. This completes the proof of Theorem 1.

4 Conclusion

In this paper we formally define EM-OPT, an optimization variant of the EXACT MATCHING problem and show a deterministic polynomial-time approximation algorithm for EM-OPT which achieves an approximation ratio of 3 on bipartite graphs. Although the algorithm is fairly simple to present, the proof of its correctness is more complex. In the second part of the algorithm we iterate over all edges e and compute a perfect matching of minimum number of red edges containing e. Most of our work is put into proving that there exists such a matching that approximates the optimal solution of EM-OPT by a factor 3. As our calculations are tight for an approximation ratio of 3, a natural continuation of our work would be to improve this ratio, e.g. to 2. We speculate that the algorithm could be improved by iterating over larger subsets of edges (of constant size) instead of one edge at a time and that such an algorithm could give a better approximation and maybe even a PTAS. The analysis of such an algorithm, however, remains quite challenging and new techniques and insights might be needed. Another open problem is to find an approximation algorithm for general graphs.

A Proof of Lemma 12

This section is devoted to the proof of Lemma 12. The proof technique is a combination of reasonings about forward and backward motion, shown in Lemmas 17 and 18, and an interpolation argument.

Let's start with a basic fact about sub-paths of C_e. Let e_s, e_f be two distinct edges on C^+. The following lemma captures the intuitive fact that any path from e_s to e_f must go either in a clockwise motion, or in an anticlockwise motion. While doing so, it must traverse all the edges between e_s and e_f in that direction.

▶ **Lemma 17.** *Let (G, k, M^*, M) be a critical tuple and fix an edge $e \in E^+(C^+)$. If e_s, e_f are distinct edges in C^+ and $\mathcal{P} = C_e[e_s, e_f]$ is a sub-path of C_e from e_s to e_f, then either $C^+[e_s, e_f] \subseteq r_f(\mathcal{P})$ or $C^+[e_f, e_s] \subseteq r_b(\mathcal{P})$.*

Proof. As a helpful tool, we consider the following definition of *shadow*. Let Q be a jump of C_e from x to y, where x and y are vertices in C^+. If Q is a forward jump, then the shadow $s(Q)$ of Q is the walk in C^+, which starts at x and goes anticlockwise, until it encounters y. If Q is a backward jump, then $s(Q)$ is the walk in C^+, which starts at x and goes clockwise, until it encounters y. We remark that formally, since $s(Q)$ can travel edges in reverse direction, $s(Q)$ is a walk in the undirected analogue of C^+ in G. For an interjump P from vertex x to y, the shadow of P is defined to be the path P itself. For a sub-path $\mathcal{P} \subseteq C_e$ consisting of the concatenation of alternating jumps and interjumps the shadow $s(\mathcal{P})$ of $\mathcal{P}$ is the concatenation of the corresponding shadows of jumps and interjumps in the same order.

By definition, the following basic observations hold. For any sub-path $\mathcal{P} \subseteq C_e$, its shadow $s(\mathcal{P})$ is a walk contained in C^+ such that it has the same start and end vertex as $\mathcal{P}$. Furthermore, the walk $s(\mathcal{P})$ can be thought of as a sequence of steps, where every step traverses one single edge of C^+ either clockwise or anticlockwise. The set $r_f(\mathcal{P})$ is exactly the set of edges which are traveled by the walk $s(\mathcal{P})$ with an anticlockwise step. The set $r_b(\mathcal{P})$ is exactly the set of edges which are traveled by the walk $s(\mathcal{P})$ with a clockwise step. The set $r(\mathcal{P})$ is exactly the set of edges which are traveled by the walk $s(\mathcal{P})$.

Now return to the statement of the lemma. The walk $s(\mathcal{P})$ is a walk contained in C^+, starting with the edge e_s and ending with the edge e_f. It is obvious that $s(\mathcal{P})$ must either traverse all of $C^+[e_s, e_f]$ with anticlockwise steps, or all of $C^+[e_f, e_s]$ with clockwise steps. This implies that either $C^+[e_s, e_f] \subseteq r_f(\mathcal{P})$ or $C^+[e_f, e_s] \subseteq r_b(\mathcal{P})$. ◀

In the proof of Lemma 12, we will consider a set of forward jumps and interjumps in C_e that cover all the cycle C^+. However we want to avoid forward jumps covering the edge e. The following Lemma 18 shows that this is possible under certain assumptions. Intuitively, since e is already contained in an interjump of C_e, there is no need to include a forward jump covering e in the set of forward jumps and interjumps covering C^+. However one needs to carefully select the forward jumps of the set, which explains the technicallity of the proof below.

▶ **Lemma 18.** *Let (G, k, M^*, M) be a critical tuple and fix an edge $e \in E^+(C^+)$. If $e \notin r_b(C_e)$, then there exists a set of forward jumps $\mathcal{Q} \subseteq \mathcal{J}_e^f$ such that*

$$C^+ = \bigcup_{Q \in \mathcal{Q}} r(Q) \cup \bigcup_{P \in \mathcal{I}_e} P$$

and $\nexists Q_f \in \mathcal{Q}$ with $e \in r(Q_f)$.

Proof. We prove the statement by constructing a tuple $(\mathcal{P}, \mathcal{R}, e')$, where $e' \in C^+$ is an edge of C^+, $\mathcal{P} = C_e[e, e']$ is a sub-path of C_e and $\mathcal{R}$ is a set of jumps and interjumps of C_e. We want $(\mathcal{P}, \mathcal{R}, e')$ to satisfy the following invariant.

▶ **Invariant.** *A tuple $(\mathcal{P}, \mathcal{R}, e')$ satisfies the invariant if the following properties hold:*

1. *There is no forward jump Q in $\mathcal{R}$ such that $e \in r(Q)$.*
2. *$C^+[e, e'] \subseteq r_f(\mathcal{P})$.*
3. *$C^+(e', e) \subseteq r_f(\mathcal{R})$*

We also want to ensure that there is no forward jump Q in $\mathcal{P}$ with $e \in r(Q)$. Indeed, in that case, define $\mathcal{Q}$ to be the set of forward jumps in $\mathcal{P} \cup \mathcal{R}$. Then by Invariant 1, $\mathcal{Q}$ doesn't contain any forward jump Q with $e \in r(Q)$. Also, by Invariants 2 and 3 of $(\mathcal{P}, \mathcal{R}, e')$:

$$\begin{aligned} C^+ &= C^+[e, e'] \cup C^+(e', e) \\ &\subseteq r_f(\mathcal{P}) \cup r_f(\mathcal{R}) \\ &\subseteq \bigcup_{Q \in \mathcal{Q}} r(Q) \cup \bigcup_{P \in \mathcal{I}_e} P \end{aligned}$$

which is the conclusion of Lemma 18.

We start with a tuple $(\mathcal{P}, \mathcal{R}, e')$ satisfying the invariant properties and then iteratively modify the tuple in order to achieve the additional property that no forward jump in $\mathcal{P}$ covers e. At first, e' is the edge before e in C_e. Note that $e' \in C^+$ because $e \notin M$ and C_e is M-alternating so $e' \in M$, and since C^+ is also M-alternating, edges of M adjacent to e must be in C^+. Let $\mathcal{P} = C_e[e, e']$ be a path starting in e and covering all edges of C_e and let $\mathcal{R} = \emptyset$ be an empty set. Clearly Invariants 1 and 3 holds for $(\mathcal{P}, \mathcal{R}, e')$. By Lemma 17 applied on $\mathcal{P}$, either $C^+[e, e'] \subseteq r_f(\mathcal{P})$ or $C^+[e', e] \subseteq r_b(\mathcal{P})$. However $e \notin r_b(C_e)$ so the latter is not possible. Hence $(\mathcal{P}, \mathcal{R}, e')$ satisfies all invariant properties. Let t be the number of forward jumps Q in $\mathcal{P}$ with $e \in r(Q)$. If $t = 0$, we are done.

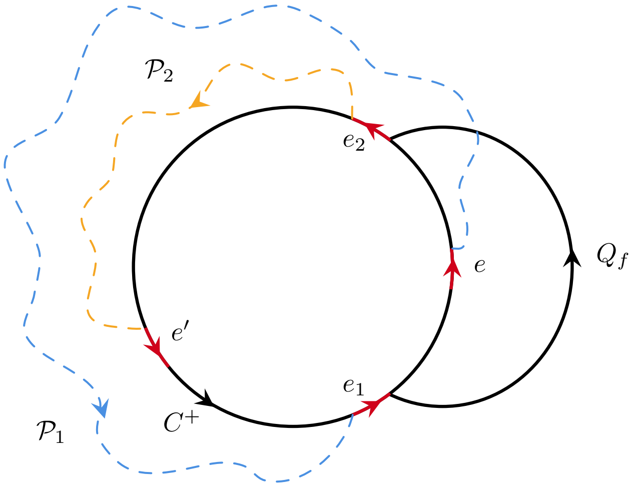

Figure 6 To prove Lemma 18 we consider a path $\mathcal{P} = C_e[e, e']$ that contains a jump Q_f with $e \in r(Q_f)$. e_1 and e_2 are the edges before and after the jump Q_f. We split $\mathcal{P}$ into two paths $\mathcal{P}_1$ (blue) and $\mathcal{P}_2$ (orange) that are respectively before and after the jump Q_f.

If $t > 0$, we replace $(\mathcal{P}, \mathcal{R}, e')$ by another tuple $(\mathcal{P}', \mathcal{R}', e_1)$ where $\mathcal{P}'$ contains $t - 1$ forward jumps covering e. We ensure that $(\mathcal{P}', \mathcal{R}', e_1)$ also satisfies the invariant properties, so that we can repeat the process until $t = 0$. Let Q_f be the last forward jump in $\mathcal{P}$ covering e

and let e_1 and e_2 be the first edges in C^+ before and after Q_f (see Figure 6). Consider the sub-paths $\mathcal{P}_1 = C_e[e, e_1]$ and $\mathcal{P}_2 = C_e[e_2, e']$ and define $\mathcal{P}' := \mathcal{P}_1$ and $\mathcal{R}' := \mathcal{R} \cup \mathcal{P}_2$. By definition, $\mathcal{P}'$ is the sub-path of $\mathcal{P}$ before Q_f (excluded), hence it contains $t-1$ forward jumps covering e. It remains to show that $(\mathcal{P}', \mathcal{R}', e_1)$ satisfies the invariant. By definition of Q_f, there is no forward jump in $\mathcal{P}_2$ covering e. Thus, since $(\mathcal{P}, \mathcal{R}, e')$ satisfies Invariant 1, $(\mathcal{P}', \mathcal{R}', e_1)$ also satisfies Invariant 1. We can apply Lemma 17 on $\mathcal{P}_1$ and get that either $C^+[e, e_1] \subseteq r_f(\mathcal{P}_1)$ or $C^+[e_1, e] \subseteq r_b(\mathcal{P}_1)$. However $e \notin r_b(C_e)$ so the latter case is not possible, hence $(\mathcal{P}', \mathcal{R}', e_1)$ satisfies Invariant 2. Finally, to prove that $C^+(e_1, e) \subseteq r_f(\mathcal{R}')$, consider two cases. If $C^+(e_1, e) \subseteq C^+(e', e)$ (as in Figure 6) then $C^+(e_1, e) \subseteq r_f(\mathcal{R}) \subseteq r_f(\mathcal{R}')$ by Invariant 3 of $(\mathcal{P}, \mathcal{R}, e')$. Otherwise if $C^+(e', e) \subseteq C^+(e_1, e)$, then the edges e_2, e_1, e', e appear in that order on C^+. We can thus write $C^+(e_1, e) = C^+(e_1, e'] \cup C^+(e', e)$. By Invariant 3 of $(\mathcal{P}, \mathcal{R}, e')$, we know that $C^+(e', e) \subseteq r_f(\mathcal{R})$. Note that $C^+(e_1, e'] \subseteq C^+[e_2, e']$. Applying Lemma 17 on $\mathcal{P}_2$ we get that either $C^+[e_2, e'] \subseteq r_f(\mathcal{P}_2)$ or $C^+[e', e_2] \subseteq r_b(\mathcal{P}_2)$. But $e \in C^+[e', e_2]$ and $e \notin r_b(C_e)$ so the latter case is not possible. Hence $C^+(e_1, e'] \subseteq \mathcal{P}_2$ and we thus have $C^+(e_1, e) \subseteq r_f(\mathcal{P}_2) \cup r_f(\mathcal{R}) = r_f(\mathcal{R}')$. So in both cases Invariant 3 holds for $(\mathcal{P}', \mathcal{R}', e_1)$. Therefore, we can safely replace $(\mathcal{P}, \mathcal{R}, e')$ by $(\mathcal{P}', \mathcal{R}', e_1)$ and maintain the invariant. ◀

We now have collected all the ingredients to prove the main result of this subsection. While the previous lemmas were proven using an intuition on forward and backward motion, Lemma 12 is proven using an interpolation argument.

Proof of Lemma 12. For the sake of contradiction, assume that there exists an edge $e \in E^+(C^+)$ such that $e \notin r_b(C_e)$. Apply Lemma 18 and let $\mathcal{Q}'$ be the resulting set of forward jumps. By identifying every jump in $\mathcal{Q}'$ with its reach, we can apply Observation 14 and get the resulting set $\mathcal{Q} \subseteq \mathcal{Q}'$. Consequently, $C^+ = \bigcup_{Q \in \mathcal{Q}} r(Q) \cup \bigcup_{P \in \mathcal{I}_e} P$, there is no jump $Q \in \mathcal{Q}$ covering e and every edge $e' \in C^+$ is contained in the reach of at most two jumps of $\mathcal{Q}$. Order the jumps in $\mathcal{Q}$ by the distance between e and their reach and write $\mathcal{Q} = \{Q_1, Q_2, \dots, Q_t\}$. Define $\mathcal{Q}_{odd} = \{Q_1, Q_3, \dots\}$ and $\mathcal{Q}_{even} = \{Q_2, Q_4, \dots\}$ to be the set of jumps of respectively odd and even index. Since there is no forward jump in $\mathcal{Q}$ covering e, the first and the last jump in $\mathcal{Q}$ are non-intersecting (otherwise the reach of one of them would contain e). Additionally, the reach of a jump Q_i can only intersect the reach of Q_{i-1} and Q_{i+1} (by the property obtained by Observation 14). Hence the reach of any two jumps in $\mathcal{Q}_{odd}$ as well as the reach of any two jumps in $\mathcal{Q}_{even}$ are not intersecting.

We can thus define two cycles $C^+_{odd} = C^+ \cup \mathcal{Q}_{odd} \setminus \{r(Q_1), r(Q_3), \dots\}$ and $C^+_{even} = C^+ \cup \mathcal{Q}_{even} \setminus \{r(Q_2), r(Q_4), \dots\}$. We show that at least one of them is non-positive using Observation 10. Indeed, the number of positive edges in C^+_{odd} is

$$\begin{aligned}|E^+(C^+_{odd})| &= |E^+(C^+)| + \sum_{Q \in \mathcal{Q}_{odd}} |E^+(Q)| - \sum_{Q \in \mathcal{Q}_{odd}} |E^+(r(Q))| \\ &= |E^+(C^+)| - \sum_{Q \in \mathcal{Q}_{odd}} m_Q\end{aligned}$$

where we define $m_Q := |E^+(r(Q))| - |E^+(Q)|$. Assume for now that $\sum\limits_{Q \in \mathcal{Q}_{odd}} m_Q \geq \sum\limits_{Q \in \mathcal{Q}_{even}} m_Q$ so that $\sum\limits_{Q \in \mathcal{Q}} m_Q = \sum\limits_{Q \in \mathcal{Q}_{odd}} m_Q + \sum\limits_{Q \in \mathcal{Q}_{even}} m_Q \leq 2 \sum\limits_{Q \in \mathcal{Q}_{odd}} m_Q$. So we get

$$|E^+(C^+_{odd})| \leq |E^+(C^+)| - \frac{1}{2} \sum_{Q \in \mathcal{Q}} m_Q$$

and we also have

$$\begin{aligned}\sum_{Q\in\mathcal{Q}} m_Q &= \sum_{Q\in\mathcal{Q}} |E^+(r(Q))| - \sum_{Q\in\mathcal{Q}} |E^+(Q)| \\ &= \left(\sum_{Q\in\mathcal{Q}} |E^+(r(Q))| + \sum_{P\in\mathcal{I}_e} |E^+(P)|\right) - \left(\sum_{P\in\mathcal{I}_e} |E^+(P)| + \sum_{Q\in\mathcal{Q}} |E^+(Q)|\right) \\ &\geq |E^+(C^+)| - \left(\sum_{P\in\mathcal{I}_e} |E^+(P)| + \sum_{Q\in\mathcal{Q}} |E^+(Q)|\right) \qquad \text{(by the construction of } \mathcal{Q}) \\ &\geq |E^+(C^+)| - |E^+(C_e)|\end{aligned}$$

where the last inequality comes from the fact that C_e can contain jumps outside of $\mathcal{Q}$. We finally get the following bound on the number of positive edges in C^+_{odd}.

$$\begin{aligned}|E^+(C^+_{odd})| &\leq |E^+(C^+)| - \frac{1}{2}(|E^+(C^+)| - |E^+(C_e)|) \\ &= \frac{1}{2}|E^+(C^+)| + \frac{1}{2}|E^+(C_e)| \\ &< \frac{1}{2}k + \frac{1}{2}\cdot\frac{1}{3}k \qquad \text{(by Observation 10)} \\ &= \frac{2}{3}k\end{aligned}$$

By Observation 10, we can conclude that C^+_{odd} is a non-positive cycle. If $\sum_{Q\in\mathcal{Q}_{odd}} m_Q \leq \sum_{Q\in\mathcal{Q}_{even}} m_Q$ then the same argument on C^+_{even} shows that C^+_{even} is a non-positive cycle. In the following we assume that C^+_{odd} is a non-positive cycle, but the reasoning can be adapted for the case that C^+_{even} is non-positive by interchanging *odd* by *even*.

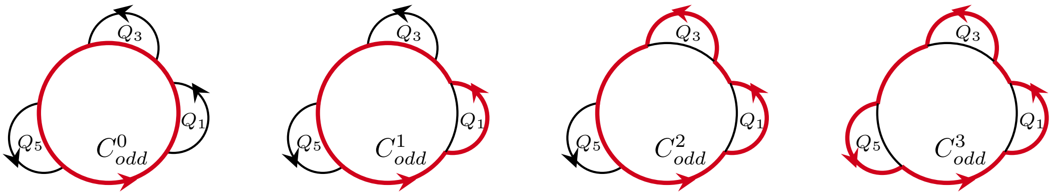

Figure 7 A sequence of cycles $C^0_{odd}, C^1_{odd}, C^2_{odd}, C^3_{odd}$ (in red from left to right) defined by sequentially adding the jumps in $\mathcal{Q}_{odd} = \{Q_1, Q_3, Q_5\}$ to the cycle C^+ and removing the corresponding reach, as done in the proof of Lemma 12. Note that $C^0_{odd} = C^+$.

Define a sequence of cycles $C^{i+1}_{odd} := C^i_{odd} \cup Q_{2i+1} \setminus r(Q_{2i+1})$ for $i \in |\mathcal{Q}_{odd}|$ starting at $C^0_{odd} := C^+$ and ending at C^+_{odd}. See Figure 7 for an example. The constructed C^i_{odd}'s are simple cycles since the reaches in $\mathcal{Q}_{odd}$ are non-intersecting. The sequence starts with a positive cycle C^+ and ends with a non-positive cycle C^+_{odd} so there must exists an index i such that C^i_{odd} is positive and C^{i+1}_{odd} is non-positive. However the number of positive edges in the non-positive cycle C^{i+1}_{odd} is

$$\begin{aligned}|E^+(C^{i+1}_{odd})| &= |E^+(C^i_{odd})| + |E^+(Q_{2i+1})| - |E^+(r(Q_{2i+1})| \\ &= |E^+(C^i_{odd})| + |E^+(C_{Q_{2i+1}})| - |E^+(C^+)| \\ &> \frac{2}{3}k + \frac{2}{3}k - k \qquad \text{(by Observation 10)} \\ &= \frac{1}{3}k\end{aligned}$$

By Observation 10, this implies that C^{i+1}_{odd} is positive, but we previously argued that it is non-positive. Hence it is not possible that $e \notin r_b(C_e)$. ◀

Tighter Approximation for the Uniform Cost-Distance Steiner Tree Problem

Abstract

Uniform cost-distance Steiner trees minimize the sum of the total length and weighted path lengths from a dedicated root to the other terminals. They are applied when the tree is intended for signal transmission, e.g. in chip design or telecommunication networks. They are a special case of general cost-distance Steiner trees, where different distance functions are used for total length and path lengths.

We improve the best published approximation factor for the uniform cost-distance Steiner tree problem from 2.39 [15] to 2.05. If we can approximate the minimum-length Steiner tree problem arbitrarily well, our algorithm achieves an approximation factor arbitrarily close to $1 + \frac{1}{\sqrt{2}}$. This bound is tight in the following sense. We also prove the gap $1 + \frac{1}{\sqrt{2}}$ between optimum solutions and the lower bound which we and all previous approximation algorithms for this problem use.

Similarly to previous approaches, we start with an approximate minimum-length Steiner tree and split it into subtrees that are later re-connected. To improve the approximation factor, we split it into components more carefully, taking the cost structure into account, and we significantly enhance the analysis.

1 Introduction

Steiner trees can be found in numerous applications, in particular in chip design and telecommunications. In these applications, both the total tree length and the signal speed are important. We consider Steiner trees that do not only minimize the total cost, but also the weighted path lengths from a dedicated root r to the other terminals. Formally, the problem is defined as follows.

An instance (M, c, T, r, p, w) consists of a metric space (M, c), a root r, a finite set T of sinks, a map $p : T\dot{\cup}\{r\} \to M$, and sink delay weights $w\colon T \to \mathbb{R}_{\geq 0}$. The task is to compute a Steiner tree A for $T \cup \{r\}$ with an extension $p : V(A) \setminus (T \cup \{r\}) \to M$ minimizing

$$\sum_{\{x,y\}\in E(A)} c(p(x),p(y)) + \sum_{t\in T}\left(w(t)\sum_{\{x,y\}\in E(A_{[r,t]})} c(p(x),p(y))\right), \tag{1}$$

where $A_{[r,t]}$ is the unique r-t-path in A. We call (1) the **(total) cost** of (A,p).

Given a Steiner tree A, we call

$$\sum_{\{x,y\}\in E(A)} c(p(x),p(y)) \quad \text{and} \quad \sum_{t\in T}\left(w(t)\sum_{\{x,y\}\in E(A_{[r,t]})} c(p(x),p(y))\right)$$

its **connection cost** and its **delay cost**.

Usually the position p of vertices is clear from the context. Then, we simply write $c(x,y)$ instead of $c(p(x),p(y))$ and $c(e)$ instead of $c(x,y)$ for edges $e=\{x,y\}$. To shorten the notation, we often also omit the underlying metric space from the notation and write only (T,r,w) to denote an instance. A simple lower bound for the objective function, is given by

$$C_{SMT}(T\cup\{r\}) + D(T,r,w), \tag{2}$$

where $C_{SMT}(T\cup\{r\})$ is the connection cost of a minimum-length Steiner tree for $T\cup\{r\}$, i.e. a Steiner tree A for $T\cup\{r\}$ minimizing $\sum_{e\in E(A)} c(e)$, and $D(T,r,w) := \sum_{t\in T} w(t)c(r,t)$ is the sum of weighted root-sink distances.

The Uniform Cost-Distance Steiner Tree Problem was first mentioned by [17], who considered the (general) cost-distance Steiner tree problem, where the connection cost may be unrelated to the delay cost. Cost-distance Steiner trees are heavily used in VLSI routing and interconnect optimization [11, 7]. Here, the weights arise as Lagrangean multipliers when optimizing global signal delay constraints on an integrated circuit [11]. Uniform cost-distance Steiner trees are computed as a first step of a Steiner tree oracle in global routing [11, 7].

The general cost-distance Steiner tree problem does not permit an approximation factor better than $\Omega(\log\log|T|)$ unless NP $\subseteq$ DTIME$(|T|^{\mathcal{O}(\log\log\log|T|)})$ [6], while a randomized $\mathcal{O}(\log|T|)$-factor approximation algorithm was given by [17] and [4]. Meyerson, Munagala and Plotkin [17] observed that a constant factor approximation algorithm for the Uniform Cost-Distance Steiner Tree Problem can be obtained using the shallow-light spanning tree algorithm from [16]. The resulting factor is 3.57. Using shallow-light Steiner trees [12] instead of spanning trees, the factor was improved to 2.87 independently by [10] and [18]. The first algorithm using the delay weights algorithmically was given by Khazraei and Held [15]. They achieve an approximation factor of $1+\beta$, where β is the approximation factor for computing a minimum-length Steiner tree. All these approaches compare against the lower bound in (2).

Similarly to algorithms for shallow-light trees, the algorithm in [15] starts from an approximately minimum Steiner tree, which is cut into a forest whose components are connected to the root r individually. While [16] cut the tree whenever the path length is too large, [15] cut off a subtree if its delay weight exceeds a certain threshold. Each cut-off tree is later re-connected through a direct connection from the root through one of its terminals, minimizing the resulting objective function.

The special case where we require a spanning tree instead of a Steiner tree and $w(t)$ is identical for all $t\in T$ is known as the *cable-trench problem.* It does not permit a PTAS unless P = NP [2].

The Uniform Cost-Distance Steiner Tree Problem is related to the *single-sink buy-at-bulk problem* where a set of demands needs to be routed from a set of sources to a single sink using a pipe network that has to be constructed from a finite set of possible pipe types with different costs and capacities [9, 19, 14]. The best known approximation factor for this problem is 40.82 due to [8], who also achieve a factor of 20.41 for the splittable case. If there is only one pipe type this problem is equivalent to the Uniform Cost-Distance Steiner Tree Problem. In fact, the threshold-based tree cutting used in the proof of [15] is similar to the algorithm in [9], but the re-connect to the root/sink differs.

1.1 Our contribution

In this paper, we improve the approximation algorithm in [15] for the Uniform Cost-Distance Steiner Tree Problem.

▶ **Theorem 1.** *The Uniform Cost-Distance Steiner Tree Problem can be approximated in polynomial time with an approximation factor of*

$$\beta + \frac{\beta}{\sqrt{\beta^2+1}+\beta-1},$$

where $\beta \geq 1$ is the approximation guarantee for the minimum-length Steiner tree problem.

With the best known approximation factor for the minimum Steiner tree problem $\beta = \ln(4)+\epsilon$ [3, 20], this results in an approximation factor < 2.05 and for $\beta = 1$ this gives the factor $1 + \frac{1}{\sqrt{2}} < 1.71$, clearly improving upon the previously best factors 2.39 and 2.0 in [15]. The polynomial-time approximation scheme by [1] allows choosing β arbitrarily close to one in the Euclidean and the Manhattan planes. However, general metric spaces do not allow $\beta \leq \frac{96}{95}$ unless $\mathrm{P} = \mathrm{NP}$ [5].

Assuming an ideal Steiner tree approximation factor of $\beta = 1$, our new approximation factor is tight with respect to the lower bound (2). We prove the following result

▶ **Theorem 2.**

$$\sup_{T,c,w} \frac{\mathrm{OPT}(T,r,w)}{C_{SMT}(T\cup\{r\}) + D(T,r,w)} = 1 + \frac{1}{\sqrt{2}},$$

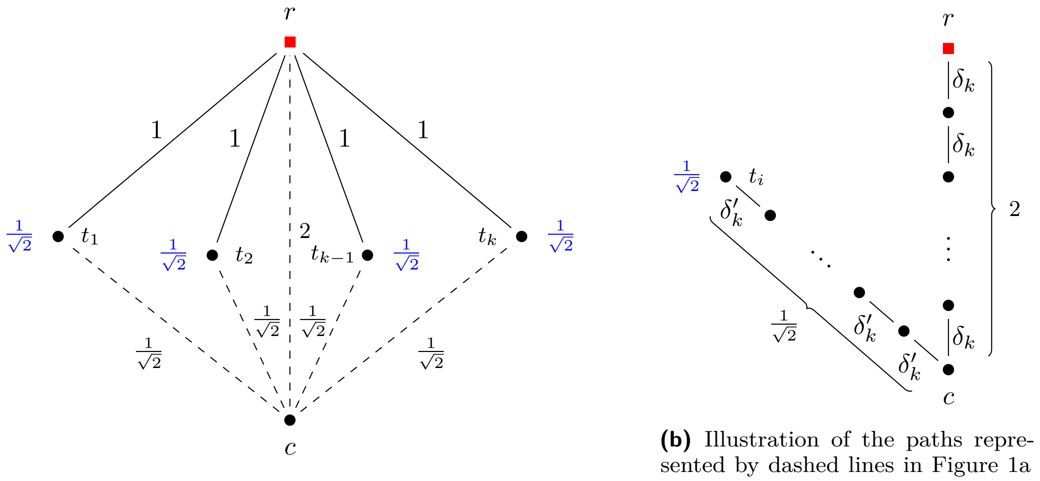
where $\mathrm{OPT}(T,r,w)$ denotes the optimum solution value for (T,r,w).

The algorithm in [15] starts from a short Steiner tree and iteratively splits off subtrees whose delay weight exceeds a given threshold. We proceed similarly, but we also take the structure of the subtrees into account and split off subtrees once they can be reconnected efficiently.

While [15] obtain a running time of $\mathcal{O}(\Lambda + |T|^2)$, where Λ is the time to compute an initial β-approximate minimum Steiner tree, our running time is $\mathcal{O}(\Lambda + |T|)$ (assuming that the metric c can be evaluated in constant time). Thus, it is very fast and applicable for large chip design instances.

We would like to mention that in a preliminary unpublished paper we achieved worse factors of 2.15 ($\beta = \ln(4)$) and 1.80 ($\beta = 1$) [13] using a more complicated algorithm and analysis. That paper also shows that the factor $1+\beta$ in [15] is tight for that algorithm.

The remainder of this paper is structured as follows. In Section 2, we show that the supremum in Theorem 2 is at least $1 + \frac{1}{\sqrt{2}}$. Then, in Section 3 we will briefly summarize the algorithm and proof from [15], as our work enhances it.



(a) Illustration of the complete instance.

(b) Illustration of the paths represented by dashed lines in Figure 1a by a single t_i.

Figure 1 Instance defined in the proof of Theorem 3. Solid lines represent edges, each dashed line represents a path. Black figures denote edge/path lengths, blue figures denote terminal weights.

Our improved splitting algorithm and analysis is presented in Section 4. The proof of Theorem 1 is presented in Section 4.2. It also shows that the supremum in Theorem 2 is at most $1 + \frac{1}{\sqrt{2}}$. We finish with conclusions in Section 5.

2 Optimality Gap of Lower Bound

In this section, we will show that the gap between an optimum solution and the lower bound in (2) can be as large as $1+\frac{1}{\sqrt{2}}$. Together with the approximation factor of our new algorithm for $\beta = 1$ (Theorem 1), the gap is asymptotically $1 + \frac{1}{\sqrt{2}}$.

▶ **Theorem 3.** *There are instances $I^{(k)}_{k\in\mathbb{N}}$ with $I^{(k)} = (T^{(k)}, r^{(k)}, w^{(k)})$ ($k \in \mathbb{N}$) for the uniform cost-distance Steiner tree problem such that*

$$\lim_{k\to\infty} \frac{\mathrm{OPT}^{(k)}}{C^{(k)} + D^{(k)}} = 1 + \frac{1}{\sqrt{2}},$$

where $\mathrm{OPT}^{(k)}$ is the optimum value for the instance $I^{(k)}$, while $C^{(k)} = C_{SMT}(T^{(k)} \cup \{r\})$, $D^{(k)} := D(T^{(k)}, r^{(k)}, w^{(k)})$ denote minimum possible connection cost and the minimum possible delay cost of $I^{(k)}$.

Proof. We will construct instances with underlying graph metrics induced by graphs indicated in Figure 1a. For $k \in \mathbb{N}$, we define the graph $G^{(k)} = (V^{(k)}, E^{(k)})$ by

$$V^{(k)} = \{r^{(k)}, c^{(k)}, t_1^{(k)}, \dots, t_k^{(k)}, v_1^{(k)}, \dots, v_q^{(k)}\}$$
$$\text{and } E^{(k)} = E_{r,c}^{(k)} \,\dot\cup\, E_{c,t}^{(k)} \,\dot\cup\, E_{r,t}^{(k)},$$

where q is chosen sufficiently large to provide sufficiently many inner path vertices $v_i^{(k)}$ ($1 \le i \le q$) in the following definitions of $E_{r,c}^{(k)}$, $E_{c,t}^{(k)}$ and $E_{r,t}^{(k)}$: For $0 < \delta_k < \delta'_k < \frac{1}{k}$, $E_{r,c}^{(k)}$ contains edges of length δ_k forming a path of total length 2 between $r^{(k)}$ and $c^{(k)}$, and $E_{c,t}^{(k)}$ contains edges of length δ'_k, forming paths of length $\frac{1}{\sqrt{2}}$ between $c^{(k)}$ and each $t_i^{(k)}$. Lastly,

$$E_{r,t}^{(k)} = \{\{r^{(k)}, t_i^{(k)}\} \mid i = 1, \dots, k\}$$

connects each $t_i^{(k)}$ directly to $r^{(k)}$ with an edge of length 1. The terminals are given by $T^{(k)} = V^{(k)} \setminus \{r^{(k)}\}$, and the delay weights $w^{(k)} \colon T^{(k)} \to \mathbb{R}_{\geq 0}$ are defined as

$$w^{(k)}(t) = \begin{cases} \frac{1}{\sqrt{2}} & \text{if } t \in \{t_1^{(k)}, \dots, t_k^{(k)}\} \\ 0 & \text{else.} \end{cases}$$

Now, the lower bound becomes:

$$C^{(k)} + D^{(k)} = 2 + \frac{k}{\sqrt{2}} + \sum_{i=1}^{k} \frac{1}{\sqrt{2}} \operatorname{dist}_{G^{(k)}}(r^{(k)}, t_i^{(k)}) = 2 + 2\,\frac{k}{\sqrt{2}} = 2 + \sqrt{2}\,k. \tag{3}$$

We claim that every optimum solution contains all edges of the form $\{r^{(k)}, t_i^{(k)}\}$. Additionally, we claim that all optimum solutions contain all edges of length δ_k and all but k edges of length δ'_k. This determines the structure of an optimum solution up to the choice of the k ommitted edges. The length of an optimum solution is $(1 + \frac{1}{\sqrt{2}})k + 2 - \delta'_k\ k$, and its objective is

$$\mathrm{OPT}^{(k)} = \left(1 + \frac{1}{\sqrt{2}}\right) k + 2 - \delta'_k k + \frac{k}{\sqrt{2}} = (1 + \sqrt{2})k + 2 - \delta'_k k. \tag{4}$$

Combining (3) and (4), we see that

$$\lim_{k\to\infty} \frac{\mathrm{OPT}^{(k)}}{C^{(k)} + D^{(k)}} = \lim_{k\to\infty} \frac{(1 + \sqrt{2})k + 2 - \delta'_k k}{2 + \sqrt{2}\ k} = \frac{1 + \sqrt{2}}{\sqrt{2}} = 1 + \frac{1}{\sqrt{2}}$$

as stated in the theorem.

To prove the first claim, assume there is an optimum solution Y^* not containing an edge $\{r^{(k)}, t_i^{(k)}\}$ for some $i \in \{1, \dots, k\}$. First, observe that any path from $r^{(k)}$ to $t_i^{(k)}$ not using the edge $\{r^{(k)}, t_i^{(k)}\}$ contains c, so we have

$$\operatorname{dist}_{Y^*}(r^{(k)}, t_i^{(k)}) \geq \operatorname{dist}_{G^{(k)}}(r^{(k)}, c^{(k)}) + \operatorname{dist}_{G^{(k)}}(c^{(k)}, t_i^{(k)}) = 1 + \frac{1}{\sqrt{2}} + \frac{1}{\sqrt{2}} = 1 + \sqrt{2}.$$

Let e be the edge of length δ'_k adjacent to $t_i^{(k)}$. Then $e \in E(Y^*)$, as otherwise $t_i^{(k)}$ would be isolated in Y^*. Now define Y' from Y^* by adding $\{r^{(k)}, t_i^{(k)}\}$ and removing e. This increases the connection cost by $1 - \delta'_k$. The delay cost decreases by at least

$$w(t_i^{(k)}) \left(\operatorname{dist}_{Y^*}(r^{(k)}, t_i^{(k)}) - \operatorname{dist}_{Y'}(r^{(k)}, t_i^{(k)})\right) \geq \frac{1 + \sqrt{2} - 1}{\sqrt{2}} = 1,$$

where we use $\operatorname{dist}_{Y'}(r^{(k)}, t_j^{(k)}) \leq \operatorname{dist}_{Y^*}(r^{(k)}, t_j^{(k)})$ for $j \neq i$. Thus, the total cost decreases by at least $1 - (1 - \delta'_k) = \delta'_k$, a contradiction to the optimality of Y^*.

Now we prove the second claim: By the first claim all optimum solutions have the same delay cost $\frac{k}{\sqrt{2}}$. Hence, only the connection cost for the remaining terminals is relevant. From each maximal path ending in c consisting only of short edges of length either δ_k or δ'_k, any solution must contain either all edges or all but one. Furthermore, there must be such a path from which the solution contains all edges, otherwise there would be no r-c-path. Since $\delta_k < \delta'_k$, the shortest such configuration is to take all edges of length δ_k and all but k edges of length δ'_k (namely all but one from each path). ◀

Algorithm 1 $(1+\beta)$-approximation algorithm by [15] using a parameter $\mu > 0$.

Step 1 (initial arborescence):
First, compute a β-approximate minimum cost Steiner r-arborescence A_0 for $T \cup \{r\}$ with outdegree 0 at all sinks in T and outdegree 2 at all Steiner vertices in $V(A_0) \setminus (T \cup \{r\})$.

Step 2 (split into branching):
Traverse A_0 bottom-up. For each traversed edge $(x,y) \in E(A_0)$, if $W_{(A_0)_y} > \mu$, remove the edge (x,y) creating a new arborescence $(A_0)_y$ in the branching.

Let $\mathcal{A}$ denote the set of all arborescences that were cut off from A_0 this way.

Step 3 (Re-connect arborescences):
Re-connect each sub-arborescence A' that was cut off in Step 2 as follows: Select a vertex $t \in T' := T_{A'}$ that minimizes the cost for serving the sinks in T' through the r-arborescence $A' + (r,t)$, i.e. select a vertex $t \in T'$ as a **port** for T' that minimizes

$$c(r,t) + C_{A'} + \sum_{t' \in T'} w(t') \cdot (c(r,t) + c(E(A'_{[t,t']}))).$$

Let $t_1, \ldots, t_{|\mathcal{A}|} \in T$ be the set of selected port vertices. Return the union of the final branching and the port connections $A_0 + \{(r,t_i) : i \in \{1,\ldots,|\mathcal{A}|\}\ \}$.

3 The $(1+\beta)$-approximation algorithm

For shorter formulas, we will use the following notation in the remainder of this paper. Let A be an arborescence. By A_v we denote the sub-arborescence rooted at v. Furthermore, $T_A := V(A) \cap T$ is the set of terminals in A, $W_A := w(T_A)$ is the sum of delay weights in A, $C_A := c(E(A))$ is the **connection cost** of A and $D_A := D_{T_A} := \sum_{t \in T_A} w(t)c(r,t)$ the **minimum possible delay cost** for connecting the sinks in T_A (independent of the structure of A).

Recall that $\beta \geq 1$ is the approximation guarantee for the minimum-length Steiner tree problem. The algorithm in [15] is described in Algorithm 1. After orienting its edges, we can consider any solution A as an r-arborescence. We use arborescences instead of trees to simplify the algorithmic notation.

3.1 Essential steps for a $1+\beta$ approximation

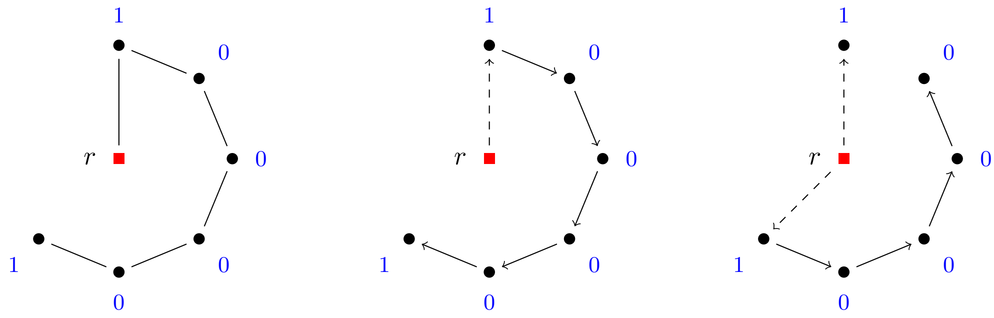
We quickly recap the essential steps in the analysis of [15], which we will use in our analysis. The cost to connect an arborescence $A' \in \mathcal{A}$ to the root r can be estimated as follows:

▶ **Lemma 4** (Khazraei and Held [15], Lemma 1). *Let $A' \in \mathcal{A}$ with corresponding terminal set T'. By the choice of the port $t \in T'$, the r-arborescence $(A' + \{r,t\})$ has a total cost at most*

$$C_{A'} + \sum_{e=(x,y) \in E(A')} \frac{2W_{A'_y}(W_{A'} - W_{A'_y})}{W_{A'}} c(e) + \left(1 + \frac{1}{W_{A'}}\right) D_{T'} \tag{5}$$

$$\leq \left(1 + \frac{W_{A'}}{2}\right) C_{A'} + \left(1 + \frac{1}{W_{A'}}\right) D_{T'} \tag{6}$$

$$\leq (1+\mu)\, C_{A'} + \left(1 + \frac{1}{\mu}\right) D_{T'}. \tag{7}$$



(a) Minimum-length Steiner tree. **(b)** Cost: $6 + (1 + 6) = 13$. **(c)** Cost: $6 + (1 + 1) = 8$.

Figure 2 Weakness of Algorithm 1: (M, c) is induced by a complete graph with seven vertices and unit weights. Delay weights are indicated by the blue node labels and $\mu = 1$. Algorithm 1 might start with the minimum-length Steiner tree on the left. Then the algorithm will cut the edge incident to r and reconnect the sub-arborescence resulting possibly in the solution in the middle. On the right a better splitting is shown.

We sketch the proof in Appendix A, because we use an inequality that was not stated explicitly in [15], Lemma 1. Note (from the proof) that only the bound (7) uses how the arborescences $A' \in \mathcal{A}$ were cut off during Step 2. In particular the bounds (5)-(6) will also apply for our improvement.

A similar cost bound can be shown easily for the arborescence A_r containing the root r after Step 2. Summing up the resulting cost bounds and choosing $\mu = \frac{1}{\beta}$, [15] obtain the approximation factor $(1 + \beta)$.

4 Improving the approximation ratio

Algorithm 1 suffers from the following weakness. Assume that after splitting we are given a sub-arborescence $A' \in \mathcal{A}$ with a high delay weight $W_{A'}$, a high connection cost $C_{A'}$, but a low minimum possible delay cost $D_{A'}$, e.g. as shown in Figure 2.

In this section, we propose a refined splitting criterion that provides a better approximation ratio. Instead of using a fixed threshold μ, we allow to split off sub-arborescences earlier if their expected re-connection cost (5) is sufficiently cheap. The precise criterion is specified in (8) (inside Algorithm 2). Observe that (8) provides cheaper solutions than (7), as one occurrence of μ is replaced by $\frac{\mu}{2}$.

Then we show in Lemma 8 that every sub-arborescence of the remaining root component has delay weight at most μ. This allows us to prove a similar improved cost bound for the root component in Lemma 9.

In Section 4.2, we simply combine all sub-arborescences and choose μ to prove Theorem 1. Theorem 2 follows as an immediate consequence.

4.1 Improving the splitting routine

Algorithm 2 shows our improved splitting step, which cuts off a sub-arborescence if we can re-connect it cheaply, i.e. if (8) holds. With Lemma 4 we immediately get the following result for the cut-off sub-arborescences:

Algorithm 2 Modifying Step 2 of Algorithm 1.

Step 2 (split into branching):
Traverse A_0 bottom-up. For each traversed edge $(v,z) \in E(A_0)$ consider $A_z := (A_0)_z$:
If $W_{A_z} > 0$ and

$$\sum_{e=(p,q)\in E(A_z)} \frac{2W_{(A_z)_q}(W_{A_z} - W_{(A_z)_q})}{W_{A_z}} c(e) + \frac{D_{A_z}}{W_{A_z}} \leq \frac{\mu}{2}\left(C_{A_z} + c(v,z)\right) + \frac{D_{A_z}}{\mu}, \quad (8)$$

remove (v,z) creating a new arborescence A_z.

▶ **Lemma 5.** *Let $A' \in \mathcal{A}$ be an arborescence that was cut off in Algorithm 2 and let $e_{A'}$ be the incoming edge in the root of the arborescence A' which was deleted during this step. Then the corresponding terminals in $T_{A'}$ can be connected to the root r with total cost at most*

$$\left(1 + \frac{\mu}{2}\right)\left(C_{A'} + c(e_{A'})\right) + \left(1 + \frac{1}{\mu}\right) D_{A'}.$$

After the original Step 2 of Algorithm 1, it is clear that for all edges $(r,x) \in \delta^+_{A_0}(r)$ of the root component the total delay weight $W_{(A_0)_x}$ is at most μ. We show that this also holds after the modified Step 2 in Algorithm 2. However, the analysis is more complicated and uses the following two functions.

▶ **Definition 6.** *Let $\mu > 0$ and $X^\mu := \{(a,b,c) \in (\mu, 2\mu) \times (0,\mu)^2 : c \leq a - b < \mu\}$. We define the functions $f, g\colon X^\mu \to \mathbb{R}$ as*

$$f(a,b,c) := \frac{2(a-c)c}{a} - \frac{\mu}{2} + \left(\frac{1}{a} - \frac{1}{\mu}\right) \cdot \frac{1}{\frac{1}{a-b} - \frac{1}{\mu}} \cdot \left(\frac{\mu}{2} - \frac{2((a-b)-c)c}{a-b}\right)$$

$$g(a,b,c) := \frac{2(a-c)c}{a} - \frac{\mu}{2} + \left(\frac{1}{a} - \frac{1}{\mu}\right) \cdot \frac{1}{\frac{1}{a-b} - \frac{1}{\mu}} \cdot \frac{\mu}{2}.$$

▶ **Lemma 7.** *For all $(a,b,c) \in X^\mu$, $f(a,b,c) \leq 0$ and $g(a,b,c) \leq 0$.*

A proof of Lemma 7 based on algebraic transformations can be found in Appendix B.

▶ **Lemma 8.** *After cutting off sub-arborescences with Algorithm 2, every child $x \in \Gamma^+_{A_r}(r)$ of r in the remaining root component $A_r := (A_0)_r$ satisfies $W_{(A_r)_x} \leq \mu$.*

Proof. Assume the opposite would be true. Let z be a vertex in $A_r - r$ such that the weight of the sub-arborescence $A_z := (A_r)_z$ exceeds μ and the weight of every child arborescence $(A_z)_x$ is at most μ for all edges $(z,x) \in \delta^+_{A_z}(z)$. We distinguish between two cases:

Case 1. z is a terminal. Then z is also a leaf and the left-hand side of (8) simplifies to

$$\frac{1}{W_{A_z}} D_{A_z} \leq \frac{1}{\mu} D_{A_z}$$

since A_z does not contain any edges. But then A_z would have been cut-off in Step 2, a contradiction.

Case 2. z is a Steiner vertex. Then z has two outgoing edges $e_x := (z,x), e_y := (z,y) \in \delta^+_{A_z}(z)$ as shown in Figure 3. A single outgoing edge would contradict the choice of z. With $A_x := (A_z)_x$ or $A_y := (A_z)_y$ this implies $0 < W_{A_x}, W_{A_y} \leq \mu$. If $W_{A_x} = \mu$, Lemma 4, (6)

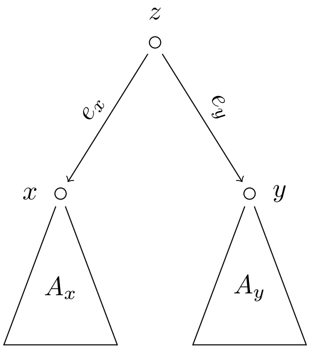


Figure 3 Setting in the proof of Lemma 8 if z is not a terminal.

shows that A_x satisfied the bound (8) when it was considered in Step 2 and would have been cut off. Analogously, $W_{A_y} \neq \mu$. Thus, $W_{A_x}, W_{A_y} < \mu$. Since (8) does not hold for A_x, we get (by transforming its negation)

$$\underbrace{\left(\frac{1}{W_{A_x}} - \frac{1}{\mu}\right)}_{>0} D_{A_x} > \sum_{e=(u,v)\in E(A_x)} \left(\frac{\mu}{2} - \frac{2(W_{A_x} - W_{(A_x)_v})W_{(A_x)_v}}{W_{A_x}}\right) c(e) + \frac{\mu}{2} c(e_x)$$

Combining this with the analogue inequality for A_y and using $D_{A_z} = D_{A_x} + D_{A_y}$, we get

$$\begin{aligned}
&\underbrace{\left(\frac{1}{W_{A_z}} - \frac{1}{\mu}\right)}_{<0} D_{A_z} \\
&\quad < \left(\frac{1}{W_{A_z}} - \frac{1}{\mu}\right) \Bigg(\sum_{e=(u,v)\in E(A_x)} \frac{1}{\frac{1}{W_{A_x}} - \frac{1}{\mu}} \left(\frac{\mu}{2} - \frac{2(W_{A_x} - W_{(A_x)_v})W_{(A_x)_v}}{W_{A_x}}\right) c(e) \\
&\qquad\qquad + \frac{\frac{\mu}{2}}{\frac{1}{W_{A_x}} - \frac{1}{\mu}} c(e_x) \\
&\qquad\qquad + \sum_{e=(u,v)\in E(A_y)} \frac{1}{\frac{1}{W_{A_y}} - \frac{1}{\mu}} \left(\frac{\mu}{2} - \frac{2(W_{A_y} - W_{(A_y)_v})W_{(A_y)_v}}{W_{A_y}}\right) c(e) \\
&\qquad\qquad + \frac{\frac{\mu}{2}}{\frac{1}{W_{A_y}} - \frac{1}{\mu}} c(e_y) \Bigg).
\end{aligned}$$

This inequality together with

$$\begin{aligned}
&\sum_{e=(u,v)\in E(A_z)} \left(\frac{2(W_{A_z} - W_{(A_z)_v})W_{(A_z)_v}}{W_{A_z}} - \frac{\mu}{2}\right) c(e) \\
&= \sum_{e=(u,v)\in E(A_x)} \left(\frac{2(W_{A_z} - W_{(A_z)_v})W_{(A_z)_v}}{W_{A_z}} - \frac{\mu}{2}\right) c(e) \\
&\quad + \left(\frac{2(W_{A_z} - W_{(A_z)_x})W_{(A_z)_x}}{W_{A_z}} - \frac{\mu}{2}\right) c(e_x) \\
&\quad + \sum_{e=(u,v)\in E(A_y)} \left(\frac{2(W_{A_z} - W_{(A_z)_v})W_{(A_z)_v}}{W_{A_z}} - \frac{\mu}{2}\right) c(e) \\
&\quad + \left(\frac{2(W_{A_z} - W_{(A_z)_y})W_{(A_z)_y}}{W_{A_z}} - \frac{\mu}{2}\right) c(e_y)
\end{aligned}$$

yields

$$\begin{aligned}
&\sum_{e=(u,v)\in E(A_z)} \left(\frac{2(W_{A_z} - W_{(A_z)_v})W_{(A_z)_v}}{W_{A_z}} - \frac{\mu}{2}\right) c(e) + \left(\frac{1}{W_{A_z}} - \frac{1}{\mu}\right) D_{A_z} \\
&\quad < \sum_{e=(u,v)\in E(A_x)} f(W_{A_z}, W_{A_y}, W_{(A_z)_v})c(e) + \sum_{e=(u,v)\in E(A_y)} f(W_{A_z}, W_{A_x}, W_{(A_z)_v})c(e) \\
&\quad + g(W_{A_z}, W_{A_y}, W_{(A_z)_v})c(e_x) + g(W_{A_z}, W_{A_x}, W_{(A_z)_v})c(e_y).
\end{aligned}$$

By Lemma 7 and $0 < W_{A_x}, W_{A_y} < \mu$, the last term is non-positive. Therefore A_z satisfied the bound (8) when it was considered in Step 2 and would have been cut off, a contradiction. ◀

In [15] the final root arborescence A_r, which was not cut off in Step 2 of Algorithm 1, was kept unaltered. Using Lemma 8, we show how to connect it in a better way.

▶ **Lemma 9.** *Let A_r be the sub-arborescence of A_0 rooted at r after the modified Step 2 of Algorithm 1. The terminal set T_{A_r} can be connected to the root r with total cost at most*

$$\left(1 + \frac{\mu}{2}\right) C_{A_r} + \left(1 + \frac{1}{\mu}\right) D_{A_r}.$$

Proof. Let $(r, x) \in \delta^+_{A_r}(r)$ be arbitrary and A_x the arborescence of $A_r - r$ rooted at x. We show that the terminal set T_{A_x} can be connected to the root r with total cost at most

$$\left(1 + \frac{\mu}{2}\right) (C_{A_x} + c(r, x)) + \left(1 + \frac{1}{\mu}\right) D_{A_x}.$$

Adding this cost for all edges in $\delta^+_{A_r}(r)$, we obtain the claim.

We distinguish between two cases:

Case 1.

$$W_{A_x}(C_{A_x} + c(r, x)) \le \frac{\mu}{2}(C_{A_x} + c(r, x)) + \frac{1}{\mu} D_{A_x}.$$

By keeping the arborescence A_x connected through (r, x), the connection cost is $C_{A_x} + c(r, x)$. In particular, for each terminal $t \in T_{A_x}$, the r-t-path in $A_x + (r, x)$ has a length of at most $C_{A_x} + c(r, x)$. We therefore obtain a total cost of at most

$$(1 + W_{A_x})(C_{A_x} + c(r, x)) \le \left(1 + \frac{\mu}{2}\right) (C_{A_x} + c(r, x)) + \frac{1}{\mu} D_{A_x}.$$

Case 2.

$$W_{A_x}(C_{A_x} + c(r, x)) > \frac{\mu}{2}(C_{A_x} + c(r, x)) + \frac{1}{\mu} D_{A_x}. \tag{9}$$

Therefore we have $W_{A_x} > 0$ and obtain from (9) an upper bound on the minimum possible delay cost of A_x

$$D_{A_x} < \left(W_{A_x} - \frac{\mu}{2}\right) \mu (C_{A_x} + c(r, x)). \tag{10}$$

We remove the edge (r, x) and connect the arborescence A_x to the root r. By Lemma 8, $W_{A_x} \leq \mu$. As in Lemma 4 we obtain total cost of at most

$$\begin{aligned}
&\left(1+\frac{W_{A_x}}{2}\right)C_{A_x}+\left(1+\frac{1}{W_{A_x}}\right)D_{A_x}\\
&=\left(1+\frac{W_{A_x}}{2}\right)C_{A_x}+\left(1+\frac{1}{\mu}\right)D_{A_x}+\underbrace{\frac{\mu-W_{A_x}}{\mu W_{A_x}}}_{\geq 0}D_{A_x}\\
&\overset{(10)}{\leq}\left(1+\frac{W_{A_x}}{2}\right)C_{A_x}+\left(1+\frac{1}{\mu}\right)D_{A_x}+\frac{\mu-W_{A_x}}{\mu W_{A_x}}\left(W_{A_x}-\frac{\mu}{2}\right)\mu(C_{A_x}+c(r,x))\\
&\leq\left(1-\frac{W_{A_x}}{2}+\frac{3}{2}\mu-\frac{\mu^2}{2W_{A_x}}\right)(C_{A_x}+c(r,x))+\left(1+\frac{1}{\mu}\right)D_{A_x}.
\end{aligned}$$

With the following estimation we obtain the claimed bound

$$-\frac{W_{A_x}}{2}+\frac{3}{2}\mu-\frac{\mu^2}{2W_{A_x}}=\frac{\mu}{2}-\frac{1}{2}\left(\sqrt{W_{A_x}}-\frac{\mu}{\sqrt{W_{A_x}}}\right)^2\leq\frac{\mu}{2}.$$ ◀

▶ **Theorem 10.** *Algorithm 2 and the re-connect in Step 3 as well as of the root component can be implemented to run in time $\mathcal{O}(|T|)$.*

Proof. A naïve implementation would immediately result in a quadratic running time. We can achieve a linear running time by computing all relevant information incrementally in constant time per node during the bottom-up traversal. Details can be found in Appendix C. ◀

4.2 Proving Theorem 1 and Theorem 2

We start by analyzing the combination of all sub-arborescences.

▶ **Theorem 11.** *Given an instance (T, r, w) of the Uniform Cost-Distance Steiner Tree Problem, we can compute in $\mathcal{O}(\Lambda + |T|)$ time a Steiner tree with objective value at most*

$$\left(1+\frac{\mu}{2}\right)C+\left(1+\frac{1}{\mu}\right)D, \tag{11}$$

where C is the cost of a β-approximate minimum-length Steiner tree and $D := D(T, r, w)$. Here, Λ is the running time for computing a β-approximate minimum Steiner tree for $T \cup \{r\}$.

Proof. We run Algorithm 1 with two modifications:

1. The cut-off routine (Step 2) is modified according to Algorithm 2.
2. The arborescence A_r containing the root r after Step 2 may be re-connected to the root r according to Lemma 9.

The total cost of the computed solution is upper bounded by the sum of the cost bounds for these r-arborescences, which is (11). For the running time analysis, we consider the individual steps of the algorithm:

In Step 1, a β-approximate minimum Steiner tree for $T \cup \{r\}$ is computed in time $\mathcal{O}(\Lambda)$ and transformed into the arborescence A_0 obeying the degree constraints in linear time as in [15]. The linear running time of Step 2 and Step 3 follows from Theorem 10. ◀

Finally, we choose the threshold μ based on the quantities C and D to prove Theorem 1:

Table 1 Comparison of approximation factors for the Uniform Cost-Distance Steiner Tree Problem with different approximation factors β for the minimum-length Steiner tree problem.

Parameter β	1	$\ln(4)+\epsilon$	$\frac{3}{2}$	2
Algorithm 1 [15]	2.00000	2.38630	2.50000	3.00000
Theorem 1	1.70711	2.04782	2.15139	2.61804

Proof of Theorem 1. We make the following modification of the algorithm in Theorem 11:

If $C = c(E(A_0)) = 0$, each r-t-path, $t \in T$, has length 0 in A_0. So this is already an optimal solution and we just return A_0.

Otherwise, set $\mu := \sqrt{\frac{2D}{C}}$ and the algorithm from Theorem 11 provides us with a solution with total cost at most

$$C + D + \sqrt{2}\sqrt{CD} \leq \beta C_{SMT}(T \cup \{r\}) + D + \sqrt{2}\sqrt{\beta C_{SMT}(T \cup \{r\}) \cdot D}.$$

We divide this by the lower bound $C_{SMT}(T \cup \{r\}) + D$ in (2). Now, the approximation factor is at most the maximum of the function $h\colon \mathbb{R}_{>0} \times \mathbb{R}_{\geq 0} \to \mathbb{R}$ given by

$$h(x,y) := \frac{\beta x + y + \sqrt{2}\sqrt{\beta x y}}{x+y}.$$

As we proof in Appendix D using algebraic reformulations,

$$h(x,y) \leq \beta + \frac{\beta}{\sqrt{\beta^2+1}+\beta-1},$$

proving the claimed approximation ratio. ◀

Using Theorem 1 we obtain the approximation factors shown in Table 1 (rounded to five decimal digits) for some interesting values of β in Table 1.

Proof of Theorem 2. This is a direct consequence of Theorem 3 and Theorem 1 for $\beta = 1$. ◀

5 Conclusion

We significantly improve the approximation factor for the Uniform Cost-Distance Steiner Tree Problem. For the lower bound (2) it is best possible if the minimum-length Steiner tree problem can be solved optimally.

This is achieved by an enhancement of the cut-off routine, where we do not simply cut off by delay weight, but take the (cost) structure of the sub-arborescences into account. Furthermore, the root component will be reconnected in a smarter way.

Our algorithm is very fast. After computing an approximate minimum-length Steiner tree, the remaining cutting and re-assembling takes linear time, which previously took a quadratic running time.

Based on the lower bound gap result, further attempts to improve the approximation ratio should rather focus on improving the lower bound. However, this does not appear to be easy.

A Proof of Lemma 4

Proof (Lemma 4). Note that Lemma 1 in [15] states only the bound (7). The bounds (5) and (6) follow immediately from their proof, which we will briefly sketch: We choose a terminal $t \in T'$ randomly with probability $p_t := \frac{w(t)}{W_{A'}}$ as the "port" vertex (only for the analysis). Then we obtain:

- The expected cost of (r,t) is $\mathbb{E}(c(r,t)) = \sum_{t \in T'} p_t c(r,t) = \frac{1}{W_{A'}} D_{T'}$.
- The (deterministic) connection cost within A' is $C_{A'}$.
- The expected effective delay cost of (r,t) is
$$\mathbb{E}(W_{A'} \cdot c(r,t)) = W_{A'} \cdot \sum_{t \in T'} p_t c(r,t) = D_{T'}.$$
- The expected delay weight served by an edge $(x,y) \in E(A')$ is
$$\frac{W_{A'_y}}{W_{A'}} \cdot (W_{A'} - W_{A'_y}) + \frac{W_{A'} - W_{A'_y}}{W_{A'}} \cdot W_{A'_y} = \frac{2W_{A'_y}(W_{A'} - W_{A'_y})}{W_{A'}} \le \frac{W_{A'}}{2},$$
where A'_y is the sub-arborescence of $A' - (x,y)$ containing y. The formula reflects the expected component of $(A' - (x,y))$ in which the port vertex is located. Summation over all edges in A' yields the following expected delay cost contribution of $E(A')$:
$$\sum_{e=(x,y) \in E(A')} \frac{2W_{A'_y}(W_{A'} - W_{A'_y})}{W_{A'}} c(e) \le \frac{W_{A'}}{2} C_{A'}.$$

The addition of these four terms gives the expected total cost of connecting A' to the root r, and provides the bound in (5). The bounds (6)-(7) follow as (5) is maximized for $W_{A'_y} = \frac{1}{2} W_{A'}$ and $W_{A'} \le 2\mu$ or A' is a (heavy) singleton. The deterministic best choice of the "port" vertex in Algorithm 1 cannot be more expensive. ◀

B Proof of Lemma 7

Proof. Note that the functions f and g differ only in the last factor. Actually, because of $\frac{1}{a} - \frac{1}{\mu} < 0$, $\frac{1}{\frac{1}{a-b} - \frac{1}{\mu}} > 0$ and $\frac{\mu}{2} - \frac{2((a-b)-c)c}{a-b} \le \frac{\mu}{2}$ we get $f(a,b,c) \ge g(a,b,c)$ for all $(a,b,c) \in X^\mu$, so it is sufficient to show $f(a,b,c) \le 0$.

We have

$$\begin{aligned} f(a,b,c) &= \frac{4ca - 4c^2 - \mu a}{2a} + \frac{(\mu - a)(a-b)}{a(\mu + b - a)} \left(\frac{\mu(a-b) - 4c(a-b-c)}{2(a-b)} \right) \\ &= \frac{(\mu - a)(4ca - 4c^2 - \mu a) + b(4ca - 4c^2 - \mu a)}{2a(\mu + b - a)} \\ &\quad + \frac{(\mu - a)\left(\mu(a-b) - 4c(a-b-c)\right)}{2a(\mu + b - a)} \\ &= \frac{b(4ca - 4c^2 - \mu a) + b(\mu - a)(4c - \mu)}{2a(\mu + b - a)} \\ &= \frac{b(4ca - 4c^2 - \mu a + 4\mu c - \mu^2 - 4ca + \mu a)}{2a(\mu + b - a)} \\ &= -\frac{b(2c - \mu)^2}{2a(\mu + b - a)} \\ &\le 0, \end{aligned}$$

where $\mu + b - a > 0$ by $(a,b,c) \in X^\mu$. ◀

C Detailed Proof of Theorem 10

Proof (Theorem 10). We will proof two claims:

1. Checking whether a branch should be cut off at the traversed vertex can be done in $\mathcal{O}(1)$ time.
2. Choosing the ports can be done in linear time.

Then, we just observe that Step 2 traverses the initial tree once, which also needs linear time.

Proof of Claim 1. We keep track of five values for each node v and its corresponding sub-arborescence $A_v := (A_0)_v$: $W_v := W_{A_v}$, the weight inside A_v, $D_v := D_{A_v}$, the minimum possible delay cost of A_v, $C_v := C_{A_v}$, the connection cost of A_v, $S_v^1 := \sum_{e=(p,q)\in E(A_v)} W_q(W_v - W_q)c(e)$ and $S_v^2 := \sum_{e=(p,q)\in E(A_v)} W_q c(e)$.

For leaves, we can compute these in constant time. For a node v with only one child x (because the other has been cut off), we can compute the values as follows: $W_v = W_x$, $D_v = D_x$, $C_v = C_x + c(v,x)$, $S_v^1 = S_x^1$, and $S_v^2 = S_x^2 + W_x c(v,x)$.

Whenever we consider a node v with children x and y, and $A_x := (A_v)_x$ and $A_y := (A_v)_y$, we can compute the values for v like so: $W_v = W_x + W_y$, $D_v = D_x + D_y$, $C_v = C_x + c(v,x) + C_y + c(v,y)$,

and

$$\begin{aligned}
S_v^1 &= \sum_{e=(p,q)\in E(A_v)} W_q(W_v - W_q)c(e)\\
&= \left(\sum_{e=(p,q)\in E(A_x)} W_q(W_v - W_q)c(e)\right) + W_x(W_v - W_x)c(v,x)\\
&\quad + \left(\sum_{e=(p,q)\in E(A_y)} W_q(W_v - W_q)c(e)\right) + W_y(W_v - W_y)c(v,y)\\
&= \left(\sum_{e=(p,q)\in E(A_x)} W_q(W_x - W_q)c(e)\right) + \left(\sum_{e=(p,q)\in E(A_x)} W_q W_y c(e)\right)\\
&\quad + W_x(W_v - W_x)c(v,x)\\
&\quad + \left(\sum_{e=(p,q)\in E(A_y)} W_q(W_y - W_q)c(e)\right) + \left(\sum_{e=(p,q)\in E(A_y)} W_q W_x c(e)\right)\\
&\quad + W_y(W_v - W_y)c(v,y)\\
&= S_x^1 + W_y S_x^2 + W_x(W_v - W_x)c(v,x) + S_y^1 + W_x S_y^2 + W_y(W_v - W_y)c(v,y)
\end{aligned}$$

and

$$S_v^2 = S_x^2 + W_x c(v,x) + S_y^2 + W_y c(v,y).$$

Proof of Claim 2. For each node $v \in V(A')$, the cost when using v as the port is

$$\text{cost}_v = c(r,v) + C_{A'} + \sum_{t\in T_{A'}} w(t)\cdot(c(r,v) + c(E(A'_{[v,t]}))).$$

So for an edge $e = (x, y) \in E(A')$ we have

$$\begin{aligned}\mathrm{cost}_x - \mathrm{cost}_y &= c(r,x) - c(r,y) + \sum_{t\in T_{A'}} w(t)(c(r,x) - c(r,y)) + \sum_{t\in T_{A'_y}} w(t)c(e)\\ &\quad - \sum_{t\in T_{A'}\setminus T_{A'_y}} w(t)c(e)\\ &= (c(r,x) - c(r,y))(1 + W_{A'}) + c(e)W_{A'_y} - c(e)(W_{A'} - W_{A'_y}).\end{aligned}$$

This allows us to compute in constant time the cost for choosing y as the port from the cost for choosing its parent x as the port. We take advantage of this property and first compute the cost for using the root of A' as the port in $\mathcal{O}(|E(A')| + |T_{A'}|)$. Then, we find the find the best "port" vertex in a top-down traversal in the claimed linear time. ◀

D Upper Bound on $h(x, y)$

We prove that for $\beta \geq 1$, $x, y \geq 0, x + y > 0$

$$\begin{aligned}h(x,y) &:= \frac{\beta x + y + \sqrt{2}\sqrt{\beta x y}}{x+y}\\ &= \beta + \frac{(1-\beta)y + \sqrt{2}\sqrt{\beta x y}}{x+y}\\ &\leq \beta + \frac{\beta}{\sqrt{\beta^2+1}+\beta-1}.\end{aligned}$$

Proof. For shorter notation, we set

$$a := \frac{\beta}{\sqrt{\beta^2+1}+\beta-1} > 0$$

and get

$$\begin{aligned}\frac{\beta}{2a} + 1 - \beta - a &= \frac{1}{2}\sqrt{\beta^2+1} - \frac{1}{2}(\beta-1) - \frac{\beta}{\sqrt{\beta^2+1}+\beta-1}\\ &= \frac{(\sqrt{\beta^2+1} - (\beta-1))(\sqrt{\beta^2+1} + (\beta-1)) - 2\beta}{2(\sqrt{\beta^2+1}+\beta-1)}\\ &= 0.\end{aligned}$$

Therefore,

$$\begin{aligned}h(x,y) &= \beta + \frac{(1-\beta)y + \sqrt{2}\sqrt{\beta x y}}{x+y} - \frac{\left(\frac{\beta}{2a} + 1 - \beta - a\right)y}{x+y}\\ &= \beta + \frac{\sqrt{2}\sqrt{\beta x y}}{x+y} - \frac{\left(\frac{\beta}{2a} - a\right)y}{x+y}\\ &= \beta + a - \frac{ax}{x+y} + \frac{\sqrt{2}\sqrt{\beta x y}}{x+y} - \frac{\frac{\beta}{2a}y}{x+y}\\ &= \beta + a - \frac{a}{x+y}\left(\sqrt{x} - \frac{\sqrt{\beta}}{\sqrt{2}a}\sqrt{y}\right)^2.\end{aligned}$$

As $a > 0$, we obtain

$$h(x,y) \leq \beta + a = \beta + \frac{\beta}{\sqrt{\beta^2+1}+\beta-1}.$$ ◀

Round and Bipartize for Vertex Cover Approximation

Danish Kashaev

ILLC, University of Amsterdam, The Netherlands

Abstract

The vertex cover problem is a fundamental and widely studied combinatorial optimization problem. It is known that its standard linear programming relaxation is integral for bipartite graphs and half-integral for general graphs. As a consequence, the natural rounding algorithm based on this relaxation computes an optimal solution for bipartite graphs and a 2-approximation for general graphs. This raises the question of whether one can interpolate the rounding curve of the standard linear programming relaxation in a beyond the worst-case manner, depending on how close the graph is to being bipartite. In this paper, we consider a round-and-bipartize algorithm that exploits the knowledge of an induced bipartite subgraph to attain improved approximation ratios. Equivalently, we suppose that we work with a pair $(\mathcal{G}, S)$, consisting of a graph with an odd cycle transversal.

If S is a stable set, we prove a tight approximation ratio of $1 + 1/\rho$, where $2\rho - 1$ denotes the odd girth (i.e., length of the shortest odd cycle) of the contracted graph $\tilde{\mathcal{G}} := \mathcal{G}/S$ and satisfies $\rho \in [2, \infty]$, with $\rho = \infty$ corresponding to the bipartite case. If S is an arbitrary set, we prove a tight approximation ratio of $(1 + 1/\rho)(1 - \alpha) + 2\alpha$, where $\alpha \in [0, 1]$ is a natural parameter measuring the quality of the set S. The technique used to prove tight improved approximation ratios relies on a structural analysis of the contracted graph $\tilde{\mathcal{G}}$, in combination with an understanding of the weight space where the fully half-integral solution is optimal. Tightness is shown by constructing classes of weight functions matching the obtained upper bounds. As a byproduct of the structural analysis, we also obtain improved tight bounds on the integrality gap and the fractional chromatic number of 3-colorable graphs. We also discuss algorithmic applications in order to find good odd cycle transversals, connecting to the MinUncut and Colouring problems. Finally, we show that our analysis is optimal in the following sense: the worst case bounds for ρ and α, which are $\rho = 2$ and $\alpha = 1 - 4/n$, recover the integrality gap of $2 - 2/n$ of the standard linear programming relaxation, where n is the number of vertices of the graph.

1 Introduction

In the vertex cover problem we are given a weighted graph $\mathcal{G} = (V, E, w)$, where $w : V \mapsto \mathbb{R}_+$ is a non-negative weight function on the vertices, and the goal is to find the minimal weight subset of vertices $U \subset V$ that covers every edge of the graph, i.e.,

$$\min\{w(U) \mid U \subset V,\ |U \cap \{i, j\}| \geq 1\ \forall (i, j) \in E\}.$$

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

We denote by OPT an optimal subset of vertices for this problem, and by $w(OPT)$ the total weight of that solution. The vertex cover problem is known to be NP-complete [27] and APX-complete [38]. Moreover, it was shown to be NP-hard to approximate within a factor of 7/6 in [23], a factor later improved to 1.36 in [16]. It is in fact NP-hard to approximate within a factor of $2-\varepsilon$ for any fixed $\varepsilon > 0$ if the unique games conjecture is true [28].

A natural linear programming relaxation, as well as its dual, is given by:

$$\begin{aligned} &\min \sum_{v\in V} w_v x_v &\qquad& \max \sum_{e\in E} y_e \\ &x_u + x_v \geq 1 \quad \forall (u,v)\in E && y(\delta(v)) \leq w_v \quad \forall v \in V \\ &x_v \geq 0 \quad \forall v \in V && y_e \geq 0 \quad \forall e \in E \end{aligned}$$

For a given graph $\mathcal{G}$, we denote the primal linear program by $P(\mathcal{G})$ and the dual by $D(\mathcal{G})$. The integrality gap of the standard linear relaxation $P(\mathcal{G})$ on a graph of n vertices is upper bounded by $2-2/n$, a bound which is attained on the complete graph. In fact, a more fine-grained analysis shows that it is equal to $2-2/\chi^f(\mathcal{G})$, where $\chi^f(\mathcal{G})$ is the fractional chromatic number of the graph [45]. An integrality gap of $2-\varepsilon$ is proved for a large class of linear programs in [4]. It is also known that any linear program which approximates vertex cover within a factor of $2-\varepsilon$ requires super-polynomially many inequalities [10].

An important property of $P(\mathcal{G})$ is the fact that any extreme point solution x^* is half-integral, i.e., $x^*_v \in \{0, \frac{1}{2}, 1\}$ for any vertex $v \in V$ [35]. This gives rise to a straightforward rounding algorithm by solving $P(\mathcal{G})$ and outputting all vertices whose LP variable is at least a half, i.e., $U := \{v \in V \mid x^*_v \geq \frac{1}{2}\}$. It is easy to see that this a 2-approximation, because $w(U) \leq 2w(OPT)$, see [24]. Moreover, it is known that $P(\mathcal{G})$ is integral for any bipartite graph [30]. As a consequence, the rounding algorithm returns an optimal solution if the graph is bipartite. This raises the question of whether we can interpolate the rounding curve of the standard linear program, depending on how close the graph is to being bipartite.

Set-up and algorithm

We consider the following setup. We are given a weighted non-bipartite graph $\mathcal{G} = (V, E, w)$ and an optimal solution $x^* \in \{0, \frac{1}{2}, 1\}$ to $P(\mathcal{G})$. We denote by $V_\alpha := \{v \in V \mid x^*_v = \alpha\}$ the vertices taking value α and by $\mathcal{G}_\alpha = \mathcal{G}[V_\alpha]$ the subgraph of $\mathcal{G}$ induced by the vertices V_α for any $\alpha \in \{0, \frac{1}{2}, 1\}$. By a standard preprocessing step, we may assume that we only work on the graph $\mathcal{G}_{1/2}$, since any c-approximate solution on this reduced graph can be lifted to a c-approximate solution on the original graph by adding the nodes V_1 to the solution [35]. In addition, we suppose that we have knowledge of an odd cycle transversal S of $\mathcal{G}_{1/2}$, meaning that $\mathcal{G}_{1/2} \setminus S$ is a bipartite graph. Equivalently, S intersects every odd cycle of $\mathcal{G}_{1/2}$. The question of finding a good such odd cycle transversal is also tackled later in the paper.

We consider the following simple round and bipartize algorithm, detailed in Algorithm 1. It first solves $P(\mathcal{G})$, takes the vertices assigned value one by the linear program to the solution and removes all the integral nodes from the graph to arrive at $\mathcal{G}_{1/2}$. The algorithm then takes all the vertices in the set S to the solution, removes them from the graph and solves another (now integral) linear program to get the optimal solution on the bipartite remainder. These vertices are then also added to the solution.

The question studied is the following. What is the worst-case approximation ratio of the algorithm and which weight functions are attaining it? Our motivation to study this question comes from the structural difference between the polyhedron of $P(\mathcal{G})$ for bipartite and non-bipartite graphs. In particular, we are interested in identifying parameters of the

Algorithm 1 Round and bipartize.

```
Input: Weighted graph $\mathcal{G} = (V, E, w)$, odd cycle transversal $S \subset V_{1/2}$
Output: Vertex cover $U \subset V$
Solve the linear program $P(\mathcal{G})$ to get $V_0$ , $V_{1/2}$ and $V_1$
Solve the integral linear program $P(\mathcal{G}_{1/2} \setminus S)$ to get $W \subset V_{1/2}$
return $V_1 \cup S \cup W$
```

problem that enable us to derive more fine-grained bounds determining the approximation ratio of the algorithm, and allow to interpolate the rounding curve of the standard linear program from 1 to 2, depending on how far the graph is from being bipartite. As it turns out, the *odd girth*, i.e., the length of the shortest odd cycle, is a key parameter determining tight bounds on the approximation ratio. It is also a natural parameter, since a graph is bipartite if and only if it does contain an odd cycle. The larger the odd girth, the closer the graph is to being bipartite. It is also shown in [21] that graphs with a large odd girth admit a small cardinality odd cycle transversal.

Contributions and high-level view

We first do a pre-processing step and show that we may without loss of generality focus on weighted graphs $\mathcal{G} = (V, E, w)$ where the weights come from a certain weight space Q^W. Each edge has a dual weight $y_e \geq 0$ with a total sum of $y(E) = 1$, and the weight on each node is then determined by $w_v = y(\delta(v))$. This follows from the Nemhauser-Trotter theorem, complementary slackness and an appropriate normalization.

We then do the analysis under the assumption that S is a stable set, highlighting the main ideas of the analysis and the proof techniques. We show that the approximation ratio is upper bounded by $1 + 1/\rho$, where $2\rho - 1$ denotes the odd girth of the graph $\tilde{\mathcal{G}} := \mathcal{G}/S$, where all the vertices in S are contracted into a single node. Note that the parameter range is $\rho \in [2, \infty]$, with $\rho = \infty$ naturally corresponding to the case where $\tilde{\mathcal{G}}$ is bipartite. The proof technique involves a key concept, that we call *pairwise edge-separate* feasible vertex covers. Constructing k such covers allows to bound the approximation ratio by $1 + 1/k$. The construction of ρ such covers to get the result follows from a structural understanding of the contracted graph $\tilde{\mathcal{G}}$. As a byproduct, this structural understanding also allows to get improved bounds on the integrality gap and the fractional chromatic number of 3-colorable graphs. In particular, it even manages to compute an exact formula, depending on the odd girth, for the integrality gap and the fractional chromatic number of the contracted graph $\tilde{\mathcal{G}}$.

We then construct a class of weight functions $\mathcal{W} \subset Q^W$ where this upper bound holds with equality, thus showing that this proof technique obtains tight bounds and might have additional applications. This result can then be lifted to the case where S is a general set, by introducing an additional parameter α counting the total dual sum of the weights on the edges inside S, i.e. $\alpha = y(E[S])$. This then leads to an approximation ratio interpolating the rounding curve of the standard linear program with a tight bound of $(1 + 1/\rho)(1 - \alpha) + 2\alpha$ for any values of $\rho \in [2, \infty]$ and $\alpha \in [0, 1]$.

We then discuss algorithmic applications to find good such sets S, connecting to the MinUnCut and Colouring problems. Finally, we show that our analysis is optimal in the following sense: the worst case bounds for ρ and α, which are $\rho = 2$ and $\alpha = 1 - 4/n$, recover the integrality gap of $2 - 2/n$ of the standard linear programming relaxation for a graph on n vertices.

Implications and related work

Our analysis falls into the framework of beyond the worst-case analysis [41]. In particular, note that an odd cycle transversal always exists: we may simply take $S = V_{1/2}$, which recovers the standard 2-approximation algorithm for vertex cover. Depending on how S is chosen, our algorithm can however admit significantly better approximation ratios.

Our algorithm also connects to *learning-augmented algorithms*, which have access to some prediction in their input (e.g., obtained for instance through machine learning). This prediction is assumed to come without any worst-case guarantees, and the goal is then to take advantage of it by making the algorithm perform better when this prediction is good, while still keeping robust worst-case guarantees when it is off [7, 33, 39, 31, 2, 3]. In our case, assuming a prediction on the set S, robustness is guaranteed since we are never worse than a 2-approximation. In fact, even if the predicted set is not an odd cycle transversal, one may simply greedily add vertices to it until it becomes one, while still guaranteeing a 2-approximation. Otherwise, our results provide a precise understanding of how the approximation ratio improves depending on the predicted set S. In addition, once such a set S is found, the parameters α and ρ can easily be computed to see the improved guarantee on the approximation ratio. One may thus re-run the machine learning algorithm if the parameters give a bound very close to the worst-case of 2.

The odd cycle transversal number $\operatorname{oct}(\mathcal{G})$ is defined as the minimum number of vertices needed to be removed in order to make the graph bipartite. The minimum odd cycle transversal problem has been studied in terms of fixed-parameter tractability [40, 29]. In particular, it is the first problem where the iterated compression technique has been applied [40], now a classical tool in the design of fixed-parameter tractable algorithms. The best known approximation algorithm for it has a ratio of $O(\sqrt{\log(n)})$ [1]. Another relevant concept is the *odd cycle packing number* $\operatorname{ocp}(\mathcal{G})$, defined as the maximum number of vertex-disjoint odd cycles of $\mathcal{G}$ and satisfying $\operatorname{ocp}(\mathcal{G}) \leq \operatorname{oct}(\mathcal{G})$. The related maximum stable set problem has been studied in terms of $\operatorname{ocp}(\mathcal{G})$ in [11, 5, 15, 19].

A key property implying the integrality of a polyhedron is the *total unimodularity* (TU) of the constraint matrix describing the underlying problem, meaning that all the square subdeterminants of the matrix are required to lie in $\{-1, 0, 1\}$ (see for instance [43, 44]). In general we believe it is an interesting question to study whether one may exploit the knowledge of a TU substructure in an integer program to obtain improved approximation guarantees through rounding algorithms. In our case, the knowledge of an odd cycle transveral S is equivalent to the knowledge of an induced bipartite subgraph $\mathcal{G}' = \mathcal{G} \setminus S$, for which $P(\mathcal{G}')$ is TU. We hope the techniques introduced for the pair $(\mathcal{G}, S)$ can help tackle other problems.

One technique which might also benefit from our analysis is iterative rounding, which requires solving a linear program at each iteration [32]. Having a better analysis for the case where the linear program becomes integral could potentially be used to reduce the number of iterations and allow for better guarantees, since iterative rounding can terminate at this step without losing solution quality.

Several different algorithms achieving approximation ratios of $2 - o(1)$ have been found for the weighted and unweighted versions of the vertex cover problem: [26, 22, 9, 34, 8, 25]. Another large body of work is interested in exact fixed parameter tractable algorithms for the decision version: [12, 6, 13, 14, 17, 36, 37, 46, 18].

2 Preliminaries

We define $\mathbb{R}_+$ to be the non-negative real numbers and $[k] := \{1, \dots, k\}$ to be the natural numbers up to $k \in \mathbb{N}$. For a vector $x \in \mathbb{R}^n$, we denote the sum of the coordinates on a subset by $x(A) := \sum_{i \in A} x_i$. A key property of $P(\mathcal{G})$ was introduced by Nemhauser and Trotter in [35]. It essentially allows to reduce an optimal solution $x^* \in \{0, \frac{1}{2}, 1\}^V$ to a fully half-integral solution by looking at the subgraph induced by the half-integral vertices. As before, we denote by $V_\alpha := \{v \in V \mid x^*_v = \alpha\}$ the vertices taking value α and by $\mathcal{G}_\alpha = \mathcal{G}[V_\alpha]$ the subgraph induced by the vertices V_α.

▶ **Theorem 1** (Nemhauser, Trotter [35]). *Let $x^* \in \{0, \frac{1}{2}, 1\}^V$ be an optimal extreme point solution to $P(\mathcal{G})$. Then, $w(OPT(\mathcal{G}_{1/2})) = w(OPT(\mathcal{G})) - w(V_1)$.*

▶ **Corollary 2.** *Let $x^* \in \{0, \frac{1}{2}, 1\}^V$ be an optimal solution to $P(\mathcal{G})$. If $S \subset V_{1/2}$ is a feasible vertex cover on $\mathcal{G}_{1/2}$ with approximation ratio at most ϕ, i.e., $w(S) \leq \phi\, w(OPT(\mathcal{G}_{1/2}))$, then $w(S) + w(V_1) \leq \phi\, w(OPT(\mathcal{G}))$.*

The previous corollary thus implies that we may restrict our attention to the graph $\mathcal{G}_{1/2}$, since any ϕ-approximate solution on this reduced instance can be lifted to a ϕ-approximate solution on the original graph by adding V_1 to the solution. Note that on the weighted graph $\mathcal{G}_{1/2}$, the solution $(\frac{1}{2}, \dots, \frac{1}{2})$ is optimal.

For a given set $S \subset V$, we define $\mathcal{G}' := \mathcal{G} \setminus S = (V', E')$ to be the graph obtained by removing the set S and all the incident edges to it. Hence, $E = E' \cup \delta(S) \cup E[S]$ where $\delta(S) = \{(u, v) \in E \mid u \in S, v \notin S\}$ and $E[S] := \{(u, v) \in E \mid u \in S, v \in S\}$. We also denote by $\tilde{\mathcal{G}} := \mathcal{G}/S = (\tilde{V}, \tilde{E})$ the graph obtained by contracting all the vertices in S into a single new node $v^S \in \tilde{V}$. We allow for multiple edges, but no self-loops. The only edges present in E but not in $\tilde{E}$ are thus the ones with both endpoints in S, i.e., $E[S]$.

3 Weight Space

By Corollary 2, we may assume that every weighted graph $\mathcal{G}$ we work with has the property that the fully half-integral solution $x = (\frac{1}{2}, \dots, \frac{1}{2})$ is an optimal solution to the linear program $P(\mathcal{G})$. In this section, we characterize the weight functions satisfying this assumption. The following lemma is a simple application of complementary slackness and the proof is omitted.

▶ **Lemma 3.** *Let $\mathcal{G} = (V, E)$ be a graph and let $w : V \to \mathbb{R}_+$ be a weight function. The feasible solution $(\frac{1}{2}, \dots, \frac{1}{2})$ to the linear program $P(\mathcal{G})$ is optimal if and only if there exists $y \in \mathbb{R}^E_+$ satisfying $y(\delta(v)) = w_v$ for every $v \in V$.*

Such instances have been called *edge-induced* in [15, 19], in the sense that the dual values on the edges are free parameters, and the weights on the nodes are determined once the dual values are fixed. Such instances also satisfy:

$$w(V) = \sum_{v \in V} w_v = \sum_{v \in V} y(\delta(v)) = \sum_{v \in V} \sum_{e \in E} y_e\, 1_{\{e \in \delta(v)\}} = \sum_{e \in E} y_e \sum_{v \in V} 1_{\{e \in \delta(v)\}} = 2\, y(E).$$

Observe that the approximation ratio of a feasible solution $U \subset V$ is defined as $w(U)/w(OPT(\mathcal{G}))$ and is invariant under scaling of the weights. We thus make a normalization ensuring that the optimal LP solution has objective value one, i.e., $w(V)/2 = y(E) = 1$, to get the following weight space polytope:

$$Q^W := \left\{ w \in \mathbb{R}^V_+ \mid \exists y \in [0, 1]^E \text{ such that } y(E) = 1 \text{ and } w_v = y(\delta(v)) \quad \forall v \in V \right\}.$$

We end this section by showing that this normalization of the weight space allows us to get a convenient lower bound on $w(OPT(\mathcal{G}))$.

▶ **Lemma 4.** *Let $\mathcal{G} = (V, E)$ be a graph. For any $w \in Q^W$, $w(OPT(\mathcal{G})) \geq 1$.*

Proof. Since $w \in Q^W$, we know that the fully half-integral solution is an optimal linear programming solution, showing $1 = w(V)/2 \leq w(OPT(\mathcal{G}))$, by feasibility of $OPT(\mathcal{G})$. ◀

4 Round and Bipartize

4.1 Algorithm

This section is devoted to the analysis of the approximation ratio of the algorithm and is the main contribution of the paper. We assume that we are given as input a pair $(\mathcal{G}, S)$ consisting of a weighted graph and an odd cycle transversal $S \subset V$. By Corollary 2, we may assume that the weight function satisfies $w \in Q^W$. By the previous section, there are dual edge weights $y_e \geq 0$ such that $w_v = y(\delta(v))$ for every $v \in V$ and which satisfy $\sum_{e \in E} y_e = 1$.

The algorithm is now very simple. First, take the vertices in $S \subset V$ to the cover and remove them from the graph. Then solve the integral linear program $P(\mathcal{G} \setminus S)$ and take the vertices having LP value one to the cover. The *approximation ratio*, given a weight function w, is thus defined as

$$R(w) := \frac{w(S) + w(OPT(\mathcal{G} \setminus S))}{w(OPT(\mathcal{G}))}. \tag{1}$$

For simplicity of notation, we omit the dependence on w of $OPT(\mathcal{G})$ and $OPT(\mathcal{G} \setminus S)$. As a reminder, the bipartite graph $\mathcal{G} \setminus S$ is denoted by $\mathcal{G}' = (V', E')$. The vertex contracted graph $\mathcal{G}/S$ is denoted by $\tilde{\mathcal{G}} = (\tilde{V}, \tilde{E})$ and the contracted node is denoted by v_S.

4.2 Stable Set to Bipartite

We assume in this section that S is a stable set. We will then generalize the results obtained here in a natural way to the most general setting of an arbitrary set S. We now state our main theorem of this section.

▶ **Theorem 5.** *Let $(\mathcal{G}, S)$ be the input to the rounding algorithm, with S being a stable set. For any $w \in Q^W$, the approximation ratio satisfies $R(w) \leq 1 + 1/\rho$, where $2\rho - 1$ is the odd girth of the contracted graph $\tilde{\mathcal{G}}$ and satisfies $\rho \in [2, \infty]$. Moreover, this bound is tight and is attained for a class of weight functions $\mathcal{W} \subset Q^W$.*

▶ Remark 6. We define the odd girth of a bipartite graph as being ∞.

▶ **Definition 7.** *Let $(\mathcal{G}, S)$ be a pair consisting of a graph with an odd cycle transversal S. For a feasible vertex cover $U \subset V \setminus S$ of the bipartite graph $\mathcal{G}' = \mathcal{G} \setminus S$, we define*

$$E_U := \Big\{(u, v) \in E \;\Big|\; u \in U,\ v \in U \text{ or } u \in U,\ v \in S\Big\}.$$

In words, these are the edges with either both endpoints in the cover U, or with one endpoint in U and one in S.

▶ **Definition 8.** *Let $(\mathcal{G}, S)$ be a pair consisting of a graph with an odd cycle transversal S. Feasible vertex covers $U_1, \ldots, U_k$ of the bipartite graph $\mathcal{G}' = \mathcal{G} \setminus S$ are defined to be* pairwise edge-separate *if the edge sets $\{E_{U_1}, \ldots, E_{U_k}\}$ are pairwise disjoint.*

▶ Remark 9. We will often say that covers are pairwise edge-separate for the pair $(\mathcal{G}, S)$. It is however worth emphasizing that these covers are defined on the bipartite graph $\mathcal{G}' = \mathcal{G} \setminus S$.

This definition turns out to be the key concept for us in order to prove improved bounds on the approximation ratio of the algorithm, as shown by the next lemma.

▶ **Lemma 10.** *Let $(\mathcal{G}, S)$ be the input to the rounding algorithm, with S being a stable set. If there exists k pairwise edge-separate feasible vertex covers of the bipartite graph $\mathcal{G}' = \mathcal{G} \setminus S$, then, for every $w \in Q^W$, the approximation ratio of the algorithm satisfies $R(w) \leq 1 + 1/k$.*

Proof. Let $w \in Q^W$ and let $y \in \mathbb{R}_+^E$ be the corresponding dual solution satisfying $w_v = y(\delta(v))$ and $y(E) = 1$. We denote by $\{U_1, \ldots, U_k\}$ the pairwise edge-separate covers of $\mathcal{G}' = (V', E')$. We can now write down the weights of S and every feasible cover U_i with the help of the dual variables:

$$\begin{aligned} w(S) &= \sum_{v \in S} w_v = \sum_{v \in S} y(\delta(v)) = y(\delta(S)) \\ w(U_i) &= \sum_{v \in U_i} w_v = \sum_{v \in U_i} y(\delta(v)) = y(E') + y(E_{U_i}) \qquad \forall i \in [k] \end{aligned}$$

The first equality holds because S is a stable set and thus only has edges crossing the set. The second equality holds because every U_i counts the dual value y_e of every $e \in E'$ at least once, by feasibility of the cover, and thus giving a contribution of $y(E')$. The edges in E_{U_i} then give an additional contribution of $y(E_{U_i})$.

By Lemma 4, the approximation ratio satisfies:

$$\begin{aligned} R(w) &= \frac{w(S) + w(OPT(\mathcal{G} \setminus S))}{w(OPT(\mathcal{G}))} \leq w(S) + w(OPT(\mathcal{G}')) \leq w(S) + \min_{i \in [k]} w(U_i) \\ &= y(\delta(S)) + y(E') + \min_{i \in [k]} y(E_{U_i}) = 1 + \min_{i \in [k]} y(E_{U_i}) \leq 1 + \frac{1}{k}. \end{aligned}$$

The last equality follows from the fact that $E = E' \cup \delta(S)$ and $y(E) = 1$. The last inequality follows from the fact that the edge sets $\{E_{U_i}\}_{i \in [k]}$ are pairwise disjoint and have a dual sum of at most one, since the total sum of the edges of the graph is $y(E) = 1$. This minimum can thus be upper bounded by $1/k$. ◀

In order to prove the upper bound in Theorem 5, we thus need to construct ρ pairwise edge-separate covers of $\mathcal{G}' = \mathcal{G} \setminus S$. The key for being able to do that is to analyze the structure of the contracted graph $\tilde{\mathcal{G}} = \mathcal{G}/S$, where S is contracted into a single node v_S.

▶ **Lemma 11.** *Let $(\mathcal{G}, S)$ be a graph with an odd cycle transversal S. If the contracted graph $\tilde{\mathcal{G}}$ contains an odd cycle, then there exists ρ edge-separate feasible covers for the pair $(\tilde{\mathcal{G}}, v_S)$, where $2\rho - 1$ is the odd girth of $\tilde{\mathcal{G}}$.*

Proof. We now dive deeper into the structure of the bipartite graph $\mathcal{G} \setminus S = \tilde{\mathcal{G}} \setminus v_S$. By assumption, this graph admits a bipartition $A \cup B$ of the vertices. Let us assume that it has k connected components $A_1 \cup B_1, \ldots, A_k \cup B_k$, all of which are bipartite as well, where $A = \bigcup_i A_i$ and $B = \bigcup_i B_i$. We now fix an arbitrary such component $A_j \cup B_j$.

- If v_S has an incident edge to both A_j and B_j, then this component contains (if including v_S) an odd cycle of $\tilde{\mathcal{G}}$. This holds since any path between a node in A_j and a node in B_j has odd length.
- If v_S has incident edges with only one side, we assume without loss of generality that this side is A_j. One could simply switch both sides in the other case while still keeping a valid bipartition of the graph $\tilde{\mathcal{G}} \setminus v_S$.

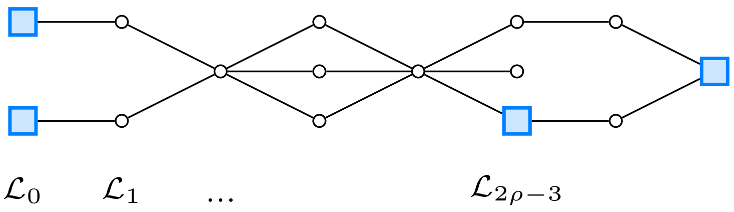

Figure 1 The layers of a bipartite graph $\tilde{\mathcal{G}} \setminus v_S = (A \cup B, E')$ with $\rho = 4$. The blue square vertices correspond to $N(v_S)$, where the two left ones are $\mathcal{L}_0 = N_A(v_S)$ and the two right ones are $N_B(v_S)$.

- If v_S does not have incident edges with either of the two sides, then $A_j \cup B_j$ is a connected component of $\tilde{\mathcal{G}}$. We call such components *dummy* components and denote by $A_d \cup B_d$ the bipartite graph formed by taking the union of all the dummy components.

We denote $N_A(v_S) = N(v_S) \cap A$ and $N_B(v_S) = N(v_S) \cap B$. We now split the graph into layers, where each layer corresponds to the nodes at the same shortest path distance from $N_A(v_S)$. More precisely, we define

$$\mathcal{L}_i := \Big\{ v \in A \cup B \mid d(N_A(v_S), v) = i \Big\} \quad \text{for } i \in \{0, \dots, q\} \tag{2}$$

where $d(N_A(v_S), v)$ represents the unweighted shortest path distance between v and a vertex in $N_A(v_S)$. The parameter q is defined to be the maximal finite distance from $N_A(v_S)$ in the graph $\tilde{\mathcal{G}}$. An important observation is the fact that these layers are alternatingly included in one side of the bipartition, see Figure 1 for an illustration of the construction.

If the graph $\tilde{\mathcal{G}}$ is not connected, note that $d(N_A(v_S), v) = \infty$ for the vertices v lying in dummy components. In order to add the dummy components to the layers and keep alternation between the two sides of the bipartition, we define the last two layers to either be $\{\mathcal{L}_{q+1} := A_d,\ \mathcal{L}_{q+2} := B_d\}$ or $\{\mathcal{L}_{q+1} := B_d,\ \mathcal{L}_{q+2} := A_d\}$, depending on which side of the bipartition the last connected layer $\mathcal{L}_q$ lies. We now have that $\mathcal{L}_i \subset A$ if i is even, and $\mathcal{L}_i \subset B$ if i is odd. In fact,

$$A = \bigcup_{i=0}^{\lfloor l/2 \rfloor} \mathcal{L}_{2i} \quad \text{and} \quad B = \bigcup_{i=1}^{\lceil l/2 \rceil} \mathcal{L}_{2i-1},$$

where the parameter $l \in \mathbb{N}$ represents the index of the last layer: if $\tilde{\mathcal{G}}$ is connected, then $l = q$, otherwise $l = q + 2$. Notice also that $\mathcal{L}_0 = N_A(v_S)$. However, $N_B(v_S)$ may now have several different vertices in different layers, see Figure 1.

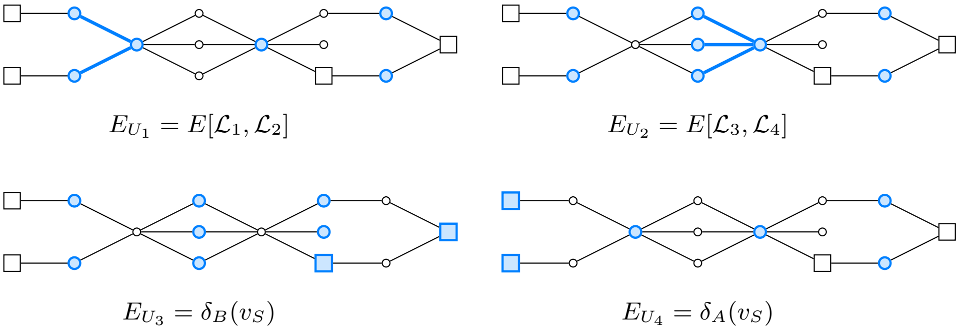
Let $C \subset V$ be an arbitrary odd cycle of $\tilde{\mathcal{G}}$. Notice that this cycle contains v_S, a vertex from $N_A(v_S)$ and a vertex from $N_B(v_S)$, since $\tilde{\mathcal{G}} \setminus v_S$ is bipartite and therefore does not contain an odd cycle. Any odd cycle C in $\tilde{\mathcal{G}}$ thus corresponds to an odd path between a vertex in $N_A(v_S) = \mathcal{L}_0$ and a vertex in $N_B(v_S)$. By the assumption that the shortest odd cycle length of $\tilde{\mathcal{G}}$ is $2\rho - 1$, the first layer having a non-empty intersection with $N_B(v_S)$ is $\mathcal{L}_{2\rho-3}$. A shortest odd cycle of length $2\rho - 1$ therefore corresponds to an odd path of length $2\rho - 3$ between $\mathcal{L}_0$ and a vertex in $\mathcal{L}_{2\rho-3} \cap N_B(v_S)$, see Figure 1 for an illustration. We now define edges connecting two consecutive layers $\mathcal{L}_i$ and $\mathcal{L}_{i+1}$ as follows:

$$E[\mathcal{L}_i, \mathcal{L}_{i+1}] := \{(u, v) \in E' \mid u \in \mathcal{L}_i, v \in \mathcal{L}_{i+1}\} \qquad \forall i \in \{0, \dots, l-1\}.$$

We also denote by

$$\delta_A(v_S) = \{(v_S, u) \in \tilde{E} \mid u \in A\}, \qquad \delta_B(v_S) = \{(v_S, u) \in \tilde{E} \mid u \in B\}$$

the incident edges to v_S respectively connecting to A and B.



$E_{U_1} = E[\mathcal{L}_1, \mathcal{L}_2]$

$E_{U_2} = E[\mathcal{L}_3, \mathcal{L}_4]$

$E_{U_3} = \delta_B(v_S)$

$E_{U_4} = \delta_A(v_S)$

Figure 2 The ρ feasible covers of $\mathcal{G}'$ constructed in the proof of Lemma 11.

We are now ready to construct our desired ρ pairwise edge-separate covers of $\tilde{\mathcal{G}} \setminus v_S$, that we denote by $U_1, \dots, U_\rho$ and illustrated in Figure 2. Firstly, notice that taking one side of the bipartition is a feasible vertex cover. We thus define $U_\rho = A$ and $U_{\rho-1} = B$. Observe that we then have $E_{U_\rho} = \delta_A(v_S)$ and $E_{U_{\rho-1}} = \delta_B(v_S)$. We now construct $\rho - 2$ additional covers with the help of the layers. If $\rho \neq 2$, fix a $j \in [\rho - 2]$, and start the cover U_j by taking the two consecutive layers $\mathcal{L}_{2j-1}$ and $\mathcal{L}_{2j}$. Complete this cover by taking remaining layers alternatingly (hence always skipping one) until covering every edge of the graph. Notice that this cover has an empty intersection with $N(v_S)$. We then have that

$$E_{U_\rho} = \delta_A(v_S), \qquad E_{U_{\rho-1}} = \delta_B(v_S), \qquad E_{U_j} = E[\mathcal{L}_{2j-1}, \mathcal{L}_{2j}] \quad \forall j \in [\rho - 2],$$

which are all pairwise disjoint edge sets, finishing the proof. ◀

We now have all the tools to prove the upper bound of Theorem 5.

Proof. Asume first that $\rho < \infty$, meaning that $\tilde{\mathcal{G}}$ contains an odd cycle. By Lemma 11, there exists ρ pairwise edge-separate covers for the pair $(\tilde{\mathcal{G}}, v_S)$. These covers are then still edge-separate for the pair $(\mathcal{G}, S)$, since the bipartite graph is the same in both cases, i.e. $\mathcal{G}' = \tilde{\mathcal{G}} \setminus v_S = \mathcal{G} \setminus S$. This finishes the proof by Lemma 10.

If $\rho = \infty$, then $\tilde{\mathcal{G}}$ is bipartite, with a bipartition $\tilde{A} \cup \tilde{B}$. Assume without loss of generality that $v^S \in \tilde{A}$. Note that $\tilde{E} = E' \cup \delta(v^S)$ and thus $1 = y(\tilde{E}) = y(E') + y(\delta(v^S))$. Any feasible cover of $\mathcal{G}' = \mathcal{G} \setminus S$ needs to count the dual value of every edge in E' at least once. Taking the cover $\tilde{A} \setminus v^S$ counts every edge in E' exactly once, showing that $w(OPT(\mathcal{G} \setminus S)) = y(E')$. Hence, $R(w) \leq w(S) + w(OPT(\mathcal{G} \setminus S)) = y(\delta(v_S)) + y(E') = 1$. ◀

We now show that this bound is tight and is attained for a class of weight functions $w \in \mathcal{W}$ for any such graph $\mathcal{G}$ and stable set S. For the case where $\rho = \infty$, it is clear that the approximation ratio always satisfies $R(w) \geq 1$, showing that the bound in Theorem 5 is tight for any $w \in Q^W$. We thus assume that $\rho < \infty$. Let $\mathcal{C}$ be all the shortest odd cycles (of length $2\rho - 1$) of the graph $\tilde{\mathcal{G}}$, each of which is containing v_S. For every such cycle $C \in \mathcal{C}$, we define the following dual function on the edges $y^C : \tilde{E} \to \mathbb{R}_+$: set both dual edges incident to v_S to $1/\rho$ and then alternatingly set the dual edges to 0 and $1/\rho$ along the odd cycle. For any edge outside of C, set its dual value to 0. Such a solution clearly satisfies $y^C(\tilde{E}) = 1$. We now take the convex hull of all these functions:

$$\mathcal{Y} := \Big\{ y : \tilde{E} \to \mathbb{R}_+ \mid y = \sum_{C \in \mathcal{C}} \lambda^C y^C, \quad \sum_{C \in \mathcal{C}} \lambda^C = 1, \quad \lambda^C \geq 0 \quad \forall C \in \mathcal{C} \Big\}.$$

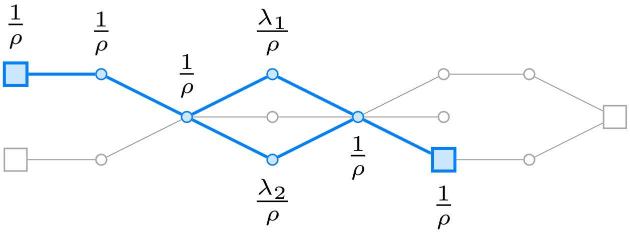


Figure 3 An example of a weight function $w \in \mathcal{W}$ obtained by a convex combination of two basic weight functions of shortest odd cycles.

Because of the one-to-one correspondence between the edge sets $\tilde{E}$ and E, due to the fact that S is a stable set, we can naturally define a weight function on the original vertex set once we fix a $y \in \mathcal{Y}$ by setting $w_v := y(\delta(v))$ for every $v \in V$. We define the space of all such weight functions as $\mathcal{W} := \{w : V \to \mathbb{R}_+ \mid w_v = y(\delta(v)) \ \forall v \in V, \ y \in \mathcal{Y}\}$.

▶ **Theorem 12.** *For any weight function $w \in \mathcal{W}$, the approximation ratio satisfies $R(w) = 1 + 1/\rho$, where $2\rho - 1$ is the odd girth of $\tilde{\mathcal{G}}$ and satisfies $\rho \in [2, \infty)$.*

Proof. Let $\mathcal{C}$ be the set of all the shortest odd cycles (of length $2\rho - 1$) of the graph $\tilde{\mathcal{G}}$ and let $w \in \mathcal{W}$ with the corresponding $y = \sum_{C \in \mathcal{C}} \lambda^C y^C$. Notice that, for any subset of vertices $U \subset V'$ of the bipartite graph $\mathcal{G}'$, we can count its weight as

$$w(U) = \sum_{v \in U} w_v = \sum_{v \in U} y(\delta(v)) = \sum_{v \in U} \sum_{C \in \mathcal{C}} \lambda^C y^C(\delta(v))$$
$$= \sum_{v \in U} \sum_{C \in \mathcal{C}} \frac{\lambda^C}{\rho} 1_{\{v \in C\}} = \frac{1}{\rho} \sum_{C \in \mathcal{C}} \lambda^C \sum_{v \in U} 1_{\{v \in C\}} = \frac{1}{\rho} \sum_{C \in \mathcal{C}} \lambda^C |U \cap C|. \tag{3}$$

The end of the proof now heavily uses the decomposition of $\tilde{\mathcal{G}}$ into layers described in (2). Notice that every odd cycle $C \in \mathcal{C}$ intersects each layer $\mathcal{L}_i$ for $i \in \{0, \dots, 2\rho - 3\}$ exactly once. Therefore, by (3), $w(\mathcal{L}_i) = 1/\rho$ for every $i \in \{0, \dots, 2\rho - 3\}$. We now claim that

$$w(OPT(\mathcal{G})) = 1, \quad w(OPT(\mathcal{G}')) = \frac{\rho - 1}{\rho} \quad \text{and} \quad w(S) = \frac{2}{\rho}.$$

The fact that $w(OPT(\mathcal{G})) \geq 1$ follows from Lemma 4. For the reverse inequality, notice that it is possible to take a feasible cover by taking exactly ρ layers in addition to the zero weight vertices, for instance $\mathcal{L}_0 \cup \mathcal{L}_2 \cup \mathcal{L}_3 \cup \mathcal{L}_5 \cdots \cup \mathcal{L}_{2\rho-3}$, showing $w(OPT(\mathcal{G})) \leq 1$.

Observe now that $w(OPT(\mathcal{G}')) = w(OPT(\mathcal{G} \setminus S)) = w(OPT(\tilde{\mathcal{G}} \setminus v_S))$. After removal of v_S, every cycle $C \in \mathcal{C}$ becomes a path of length $2\rho - 3$ (and thus consisting of $2\rho - 2$ vertices), with one vertex in each layer $\mathcal{L}_i$ for $i \in \{0, \dots, 2\rho - 3\}$. By feasibility, $OPT(\mathcal{G}')$ has to contain at least $\rho - 1$ vertices for every such path. Using (3), we infer $w(OPT(\mathcal{G}')) \geq (\rho - 1)/\rho$. For the reverse inequality, taking $\rho - 1$ layers alternatively, such as $\mathcal{L}_0 \cup \mathcal{L}_2 \cup \mathcal{L}_4 \cdots \cup \mathcal{L}_{2\rho-4}$, as well as the zero weight vertices, builds a feasible cover of weight exactly $(\rho - 1)/\rho$.

Finally, notice that $w(S) = w(v_S) = 2/\rho$ because every $C \in \mathcal{C}$ contains v_S. By combining the three equalities, we get the desired result $R(w) = 1 + 1/\rho$. ◀

Integrality gap and fractional chromatic number

Observe that the graphs we work with in this section have chromatic number $\chi(\mathcal{G}) = 3$. We focus now on the integrality gap and show again that the odd girth plays a key role. A result that we use here is given by Singh in [45], which relates the integrality gap with the fractional chromatic number of a graph: $IG(\mathcal{G}) = 2 - 2/\chi^f(\mathcal{G})$.

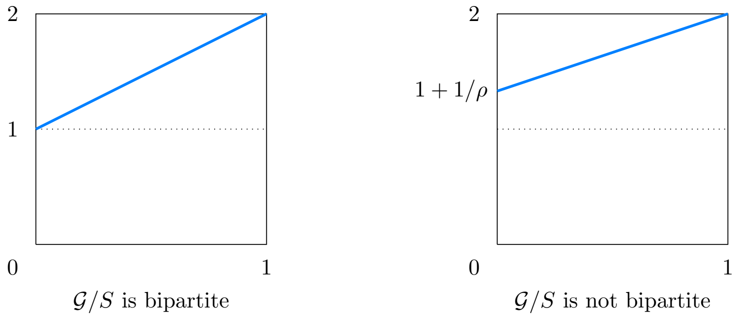

Figure 4 The plot of the approximation ratio $R(w)$ with respect to the parameter $\alpha \in [0,1]$.

▶ **Theorem 13.** *Let $\mathcal{G}$ be a 3-colorable graph with color classes $V = V_1 \cup V_2 \cup V_3$.*

$$\chi^f(\mathcal{G}) \leq 2 + \min_{i\in\{1,2,3\}} \frac{1}{\rho_i - 1}, \quad IG(\mathcal{G}) \leq 1 + \min_{i\in\{1,2,3\}} \frac{1}{2\rho_i - 1}$$

where $2\rho_i - 1$ is the odd girth of the contracted graph $\mathcal{G}/V_i$ for each $i \in \{1,2,3\}$. Moreover, equality holds if one color class only contains one vertex.

In particular, we manage to compute exact formulas of

$$\chi^f(\tilde{\mathcal{G}}) = 2 + \frac{1}{\rho - 1}, \quad IG(\tilde{\mathcal{G}}) = 1 + \frac{1}{2\rho - 1}$$

for the contracted graph $\tilde{\mathcal{G}}$. These statements generalize a result shown for the (odd) cycle graph in [4, 42]. The proofs are left to the appendix due to space constraints and heavily use the structural decomposition of the contracted graph $\tilde{\mathcal{G}}$ into the layers (2), implying that it may have further applications.

4.3 Arbitrary Set to Bipartite

We now consider the setting where S is now an arbitrary set. Our guarantee on the approximation ratio will now also depend on the total sum of the dual variables on the edges inside of the set S. We denote this sum by $\alpha := y(E[S]) \in [0,1]$.

▶ **Theorem 14.** *For any $w \in Q^W$, the approximation ratio satisfies*

$$R(w) \leq \left(1 + \frac{1}{\rho}\right)(1-\alpha) + 2\alpha \qquad \text{with } \alpha \in [0,1] \text{ and } \rho \in [2,\infty]$$

where $2\rho - 1$ denotes the odd girth of the contracted graph $\tilde{\mathcal{G}}$. Moreover, these bounds are tight and are attained for any $\alpha \in [0,1]$ and any $\rho \in [2,\infty]$.

Proof. We only prove here the upper bound with $\rho < \infty$ and leave the remaining statements to the appendix. The proof essentially follows the same arguments as the one of Lemma 10 with the α parameter incorporated, and we thus only highlight the main differences. We decompose the weight of the set S with respect to the dual variables. The edges in $E[S]$ are counted twice, whereas the edges in $\delta(S)$ are counted once:

$$w(S) = 2\alpha + y(\delta(S)). \tag{4}$$

Consider the contracted graph $\tilde{\mathcal{G}} = \mathcal{G}/S = (\tilde{V}, \tilde{E})$ and denote by v^S the contracted node. The edge set of this graph is now $\tilde{E} = \delta(S) \cup E'$, since the edges in $E[S]$ have been collapsed. By Lemma 11, we can construct ρ edge-separate covers $U_1, \dots, U_\rho \subset \tilde{V} \setminus v^S$ for the pair $(\tilde{\mathcal{G}}, v_S)$. These covers are still edge-separate for the pair $(\mathcal{G}, S)$, implying

$$w(OPT(\mathcal{G} \setminus S)) \leq \min_{i \in [\rho]} w(U_i) = y(E') + \min_{i \in [\rho]} y(E_{U_i}) \leq y(E') + \frac{1-\alpha}{\rho}. \tag{5}$$

The first inequality holds since every U_i is a feasible cover of $\mathcal{G} \setminus S$. The second equality holds by counting the weight of a cover U_i in terms of the dual edges. The last inequality holds because the edge sets $\{E_{U_i}\}_{i \in [\rho]}$ are pairwise disjoint, and their total dual sum is at most $1 - \alpha$. Combining Lemma 4, (4) and (5),

$$R(w) \leq 2\alpha + y(\delta(S)) + y(E') + \frac{1-\alpha}{\rho} = 1 + \alpha + \frac{1-\alpha}{\rho} = \left(1 + \frac{1}{\rho}\right)(1-\alpha) + 2\alpha. \qquad \blacktriangleleft$$

5 Algorithmic applications

We focus in this section on efficient ways to find odd cycle transversals with a low value for the α parameter. In fact, once such a set S is found, there can also be freedom in the choice of the dual solution in order to optimize the α parameter. This motivates the following definition.

▶ **Definition 15.** *Let $(\mathcal{G}, S, y, w)$ be a graph with an odd cycle transversal $S \subset V$, weights $w \in Q^W$ and a dual solution $y \in \mathbb{R}_+^E$. A tuple $(\mathcal{G}', S', y', w')$ is* approximation preserving *if*

$$w(S) + w(OPT(\mathcal{G} \setminus S)) \leq w'(S') + w'(OPT(\mathcal{G}' \setminus S')).$$

Moreover, we say that $\alpha \in [0,1]$ is valid *for the pair $(\mathcal{G}, S)$ if there exists an approximation preserving $(\mathcal{G}', S', y', w')$ such that $\alpha = y'(E[S'])$.*

Finding a valid $\alpha \in [0,1]$ would directly allow us to use it in the bound of Theorem 14, where the ρ parameter would correspond to the one of the approximation preserving graph. We present here an application if a coloring of a graph can be found efficiently.

▶ **Theorem 16.** *Let $\mathcal{G} = (V, E)$ be a graph with weights $w \in Q^W$ that can be k-colored in polynomial time for $k \geq 4$. There exists an efficiently findable set $S \subset V$ bipartizing the graph and a valid α such that $\alpha \leq 1 - 4/k$, leading to an approximation ratio of*

$$R(w) \leq 2 - \frac{4}{k}\left(1 - \frac{1}{\rho}\right)$$

Proof. Let us denote by $V_1, \dots, V_k$ the k independent sets defining the color classes of the graph $\mathcal{G}$. We assume without loss of generality that they are ordered by weight $w(V_1) \leq w(V_2) \cdots \leq w(V_k)$. Since $w(V) = 2$, the two color classes with the largest weights satisfy $w(V_{k-1}) + w(V_k) \geq 4/k$. We define the bipartizing set to be the remaining color classes: $S := V_1 \cup \cdots \cup V_{k-2}$. We denote by $y \in \mathbb{R}_+^E$ the dual solution satisfying complementary slackness and $y(E) = 1$.

We now define an approximation preserving $(\mathcal{G}', S', y', w')$ in the following way. Let $\mathcal{G}' = K_k$ be the complete graph on k vertices, denoted by $\{v_1, \dots, v_k\}$. The weights are defined to be

$$w'(v_i) := w(V_i) \quad \text{and} \quad y'(v_i, v_j) := y(E[V_i, V_j])$$

for every $i, j \in [k]$. These clearly satisfy the complementary slackness condition $y'(\delta(v_i)) = w'(v_i)$ for every $i \in [k]$. The bipartizing set is defined to be $S' := \{v_1, \dots, v_{k-2}\}$. This tuple is approximation preserving since $w(S) = w'(S')$ and $w(OPT(\mathcal{G} \setminus S)) \le w'(OPT(\mathcal{G}' \setminus S'))$. In order to prove the theorem, we still need to tweak the dual solution y' to ensure $\alpha := y'(E[S']) \le 1 - 4/k$. Observe that $w'(v_{k-1}) + w'(v_k) \ge 4/k$.

(i) If $y'(v_{k-1}, v_k) = 0$, then the result follows since in that case $y'(\delta(S')) \ge 4/k$ and thus $y'(E[S']) \le 1 - 4/k$.
(ii) If $y'(E[S']) = 0$, then the result trivially follows as well.

Suppose thus that $y'(E[S']) > 0$ and $y'(v_{k-1}, v_k) > 0$. Pick an arbitrary edge $(v_i, v_j) \in E[S']$ satisfying $y'(v_i, v_j) > 0$ and consider the 4-cycle (v_i, v_j, v_{k-1}, v_k). Notice that alternatively increasing and decreasing the dual values on the edges of this cycle by a small amount $\epsilon > 0$ gives another feasible dual solution satisfying the complementary slackness condition. More formally, we set $\epsilon := \min\{y'(v_i, v_j), y'(v_{k-1}, v_k)\}$, decrease $y'(v_i, v_j)$ and $y'(v_{k-1}, v_k)$ by ϵ, while increasing $y'(v_j, v_{k-1})$ and $y'(v_k, v_i)$ by the same amount. Observe that this leads to either (v_i, v_j) or (v_{k-1}, v_k) dropping to dual value zero. We can repeat this procedure until either $y'(E[S']) = 0$ or $y'(v_{k-1}, v_k) = 0$, finishing the proof of the theorem. ◀

We now claim that this result is optimal in the following sense. Consider an n-vertex graph. It is known that the integrality gap of the standard linear programming relaxation for vertex cover is upper bounded by $2 - 2/n$, a bound which is attained on the complete graph. This implies that any approximation algorithm lower bounding $w(OPT)$ by comparing it to the optimal LP solution, as we do in Lemma 4, cannot do better than $2 - 2/n$ in the worst case. Setting $\rho = 2$ in Theorem 16, which corresponds to the worst case since $\rho \in [2, \infty]$, recovers this bound and a result of Hochbaum in [25].

We now make another connection with the MinUncut problem, which is defined on a graph $\mathcal{G} = (V, E)$ with weights y_e for every edge $e \in E$. The goal of the problem is to find a cut of the graph which minimizes the total weight of uncut edges. This problem is NP-hard and admits a $O(\sqrt{\log(n)})$ approximation [1]. We call a MinUncut instance *light* if its optimal solution is bounded above by $y(E)/\Omega(\log(n))$.

▶ **Theorem 17.** *For any light MinUncut instance, combining the $O(\sqrt{\log(n)})$ approximation in [1] with Algorithm 1 outputs a vertex cover with approximation ratio at most $R(w) \le 1 + 1/\rho + o(1)$, where $2\rho - 1$ is the odd girth of the contracted graph $\tilde{\mathcal{G}}$ and satisfies $\rho \in [2, \infty]$.*

Proof. The key observation is that any feasible solution to the MinUncut problem of value α gives an odd cycle transversal S satisfying $y(E[S]) = \alpha$. Indeed, let $(C, V \setminus C)$ be a feasible solution, where the total weight of uncut edges is α. Observe that removing all the uncut edges makes C and $V \setminus C$ become stable sets, implying that the remaining graph is bipartite. We then define $S \subset V$ to be all the nodes incident to the uncut edges. Since removing all the nodes in S also removes all the uncut edges, the remaining graph is bipartite. Moreover, $y(E[S]) = \alpha$.

By the lightness assumption and the weight space normalization, the optimal solution α^* satisfies $\alpha^* \le y(E)/\Omega(\log(n)) = 1/\Omega(\log(n))$. Running the $O(\sqrt{\log(n)})$ approximation algorithm then outputs a solution with value $\alpha \le O(\sqrt{\log(n)})\ \alpha^* \le 1/\Omega(\sqrt{\log(n)}) = o(1)$. This therefore leads to an approximation guarantee of

$$R(w) = \left(1 + \frac{1}{\rho}\right)(1 - \alpha) + 2\alpha = 1 + \frac{1}{\rho} + \alpha\left(1 - \frac{1}{\rho}\right) \le 1 + \frac{1}{\rho} + o(1).$$ ◀

A Integrality Gap and Fractional Chromatic Number

We focus in this section on proving tight bounds for the integrality gap of 3-colorable graphs. A key result that we use in this section is given by Singh in [45], which relates the integrality gap with the fractional chromatic number of a graph. The latter is denoted as $\chi^f(\mathcal{G})$ and is defined as the optimal solution of the following primal-dual linear programming pair. We denote by $\mathcal{I} \subset 2^V$ the set of all independent sets of the graph $\mathcal{G}$. Solving these linear programs is however NP-hard because of the possible exponential number of independent sets.

$$\begin{aligned} \min \sum_{I\in\mathcal{I}} y_I & \\ \sum_{I\in\mathcal{I}, v\in I} y_I \geq 1 & \quad \forall v \in V \\ y_I \geq 0 & \quad \forall I \in \mathcal{I} \end{aligned} \qquad\qquad \begin{aligned} \max \sum_{v\in V} z_v & \\ \sum_{v\in I} z_v \leq 1 & \quad \forall I \in \mathcal{I} \\ z_v \geq 0 & \quad \forall v \in V \end{aligned}$$

Note that $\chi^f(\mathcal{G}) = 2$ if and only if $\mathcal{G}$ is bipartite.

▶ **Theorem 18** (Singh, [45]). *Let $\mathcal{G} = (V, E)$ be a graph. The integrality gap of the vertex cover linear programming relaxation $P(\mathcal{G})$ is:*

$$IG(\mathcal{G}) = 2 - \frac{2}{\chi^f(\mathcal{G})},$$

where $\chi^f(\mathcal{G})$ is the fractional chromatic number of the graph $\mathcal{G}$.

We first focus on graphs with the existence of a single vertex whose removal produces a bipartite graph. The following theorem generalizes the result given for the cycle graph in [4, 42] and turns out to be the same formula as for series-parallel graphs [20].

▶ **Theorem 19.** *Let $\mathcal{G} = (V, E)$ be a non-bipartite graph and $v_p \in V$ such that $\mathcal{G} \setminus v_p = (A \cup B, E')$ is bipartite. Then,*

$$\chi^f(\mathcal{G}) = 2 + \frac{1}{\rho - 1},$$

where $2\rho - 1$ is the odd girth of $\mathcal{G}$.

Proof of Theorem 19. We prove this theorem by constructing feasible primal and dual solutions of objective value $2 + 1/(\rho - 1)$. By strong duality, these two solutions are then optimal for their respective linear programs, hence proving the theorem.

We first construct the dual solution. Let $\mathcal{C}$ be the set of all the shortest odd cycles of $\mathcal{G}$. For any such cycle $C \in \mathcal{C}$, define the dual solution $z^C \in \mathbb{R}^V$ by

$$z_v^C = \begin{cases} 1/(\rho - 1) & \text{if } v \in C \\ 0 & \text{if } v \in V \setminus C \end{cases}$$

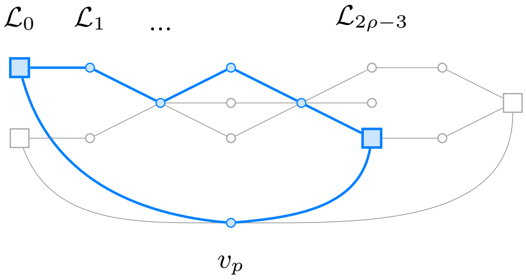

Figure 5 An optimal dual solution constructed in the proof of Theorem 19. Each node on a shortest odd cycle is assigned a fractional value of $1/(\rho-1)$.

This solution is feasible since any independent set in an odd cycle of length $2\rho-1$ has size at most $\rho-1$. Indeed, fix an independent set $I \in \mathcal{I}$, then:

$$\sum_{v\in I} z_v^C = \sum_{v\in I\cap C} \frac{1}{\rho-1} = \frac{|I\cap C|}{\rho-1} \leq 1.$$

Moreover, the objective value of this solution is:

$$\sum_{v\in V} z_v^C = \sum_{v\in C} \frac{1}{\rho-1} = \frac{2\rho-1}{\rho-1} = 2 + \frac{1}{\rho-1}.$$

Let us now construct the primal solution. We will do so by constructing $2\rho-1$ independent sets $I_k \in \mathcal{I}$ and assigning to each of them a fractional value of $y(I_k) = 1/(\rho-1)$. All the other independent sets are assigned value zero. We split the bipartite graph $\mathcal{G} \setminus v_p$ into the layers

$$\mathcal{L}_i := \{v \in A \cup B \mid d(N_A(v_p), v) = i\} \quad \text{for } i \in \{0, \dots, l\}.$$

as explained in (2). As a reminder, any shortest odd cycle corresponds to a path between $\mathcal{L}_0 = N_A(v_p)$ and $\mathcal{L}_{2\rho-3} \cap N_B(v_p)$. The original vertex set V is thus decomposed into $\{v_p\} \cup \mathcal{L}_0 \cup \cdots \cup \mathcal{L}_l$, where each layer is an independent set and only has edges going out to v_p or its two neighbouring layers.

Let us first focus on the subgraph consisting of the vertices in $\{v_p\} \cup \bigcup_{i=0}^{2\rho-3} \mathcal{L}_i$, where any shortest odd cycle has exactly one vertex per layer (per abuse of notation, we say that $\{v_p\}$ is also a layer in this situation). For convenience of indexing, we rename these layers as $\tilde{\mathcal{L}}_1, \dots, \tilde{\mathcal{L}}_{2\rho-1}$ where $\tilde{\mathcal{L}}_1 = v_p$ and $\tilde{\mathcal{L}}_i = \mathcal{L}_{i-2}$ for $i > 1$. We now create $2\rho-1$ independent sets on this subgraph in the following way. The first independent set is defined as $U_1 = \tilde{\mathcal{L}}_1 \cup \tilde{\mathcal{L}}_4 \cup \tilde{\mathcal{L}}_6 \ \cdots \cup \tilde{\mathcal{L}}_{2\rho-2}$, where we take the first layer $\tilde{\mathcal{L}}_1$, skip two before taking the next one and then continue by taking the remaining layers alternatingly (hence always skipping one), see Figure 6. Note that the layer following $\tilde{\mathcal{L}}_{2\rho-1}$ is assumed to be $\tilde{\mathcal{L}}_1$. This procedure generates in fact a distinct independent set by starting at $\tilde{\mathcal{L}}_k$ for any $k \in [2\rho-1]$ and we denote the corresponding independent set by U_k. Notice that each layer is contained in exactly $\rho-1$ of the constructed independent sets $\{U_k \mid k \in [2\rho-1]\}$.

We now focus on the subgraph consisting of the vertices in $\bigcup_{i>2\rho-3} \mathcal{L}_i$. We can construct two different independent sets there by taking either the odd or even indexed layers, i.e.

$$R_1 := \bigcup_{i \text{ odd},\, i>2\rho-3} \mathcal{L}_i \quad \text{and} \quad R_2 := \bigcup_{i \text{ even},\, i>2\rho-3} \mathcal{L}_i.$$

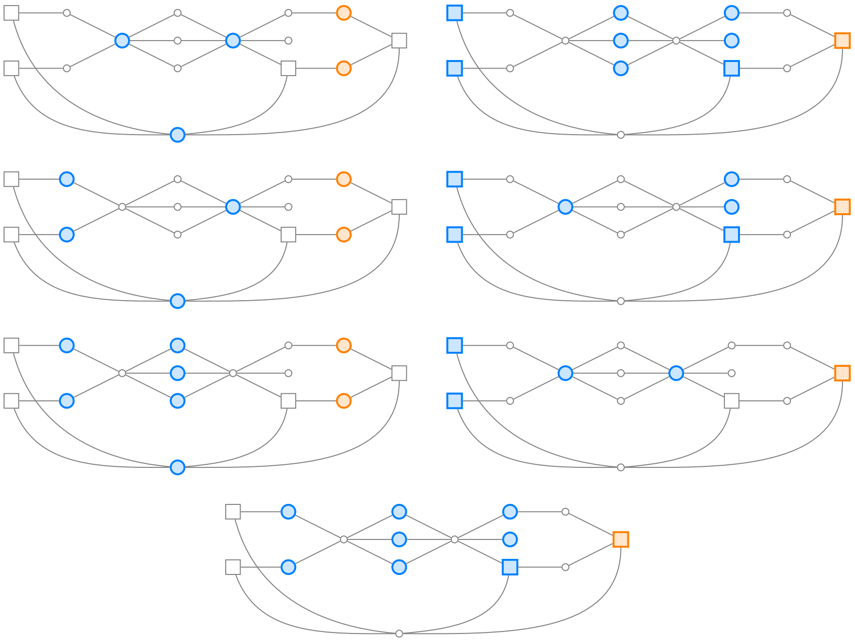

Figure 6 The $2\rho - 1$ independent sets I_k constructed in the optimal primal solution. The blue nodes correspond to $\{U_k \mid k \in [2\rho - 1]\}$, whereas the orange nodes correspond to $\{R_1, R_2\}$.

We now define our final $2\rho - 1$ independent sets on the full graph as:

$$I_k := \begin{cases} U_k \cup R_1 & \text{if } v_p \notin U_k \\ U_k \cup R_2 & \text{if } v_p \in U_k \end{cases} \qquad \forall k \in [2\rho - 1].$$

These are in fact independent sets: in the first case, the first layer in R_1 is $\mathcal{L}_{2\rho-1}$ whereas the last layer in U_k has index at most $2\rho - 3$, meaning that there are no two neighbouring layers. In the second case, since $v_p \in U_k$, we have that $\mathcal{L}_{2\rho-3} \notin U_k$, by construction of U_k. The last layer in U_k thus has index at most $2\rho - 4$, whereas the first layer in R_2 is $\mathcal{L}_{2\rho-2}$, meaning again that there are no two neighbouring layers. In addition, there is no edge between v_p and R_2, because the only even indexed layer having edges sent to v_p is $\mathcal{L}_0 = N_A(v_p)$.

We now define our primal solution as

$$y(I_k) = \frac{1}{\rho - 1} \qquad \forall k \in [2\rho - 1],$$

and $y(I) = 0$ for every other independent set $I \in \mathcal{I}$. We now show this is a feasible solution, i.e. that every vertex $v \in V$ belongs to at least $\rho - 1$ independent sets in $\{I_k \mid k \in [2\rho - 1]\}$. For $v \in \{v_p\} \cup \bigcup_{i=0}^{2\rho-3} \mathcal{L}_i$, such a vertex lies by construction in exactly $\rho - 1$ independent sets $\{U_k \mid k \in [2\rho - 1]\}$, and thus also of $\{I_k \mid k \in [2\rho - 1]\}$. For $v \in \bigcup_{i > 2\rho-3} \mathcal{L}_i$, if v belongs to an even indexed layer, then it is contained in $\rho - 1$ of the desired independent sets. If it belongs to an odd indexed layer, then it is contained in ρ of them. Therefore,

$$\sum_{I \in \mathcal{I}, v \in I} y_I = \sum_{k=1}^{2\rho-1} y(I_k)\, 1_{\{v \in I_k\}} = \frac{1}{\rho - 1} \sum_{k=1}^{2\rho-1} 1_{\{v \in I_k\}} \geq 1.$$

The objective value of this primal solution is clearly $2 + 1/(\rho - 1)$. We have constructed feasible primal and dual solutions with the same objective value. By strong duality, this finishes the proof of the theorem. ◀

We now consider the case where $\mathcal{G} = (V, E)$ is a graph with chromatic number $\chi(\mathcal{G}) = 3$.

▶ **Theorem 20.** *Let $\mathcal{G} = (V, E)$ be a 3-colorable graph with color classes $V = V_1 \cup V_2 \cup V_3$. Then,*

$$\chi^f(\mathcal{G}) \le 2 + \min_{i \in \{1,2,3\}} \frac{1}{\rho_i - 1}$$

where $2\rho_i - 1$ is the odd girth of the contracted graph $\mathcal{G}/V_i$ for each $i \in \{1, 2, 3\}$. Moreover, equality holds if one color class only contains one vertex.

Proof. We prove this theorem by constructing three feasible solutions of value $2 + 1/(\rho_i - 1)$ for each $i \in \{1, 2, 3\}$ to the primal linear program of the fractional chromatic number on the graph $\mathcal{G}$.

Fix an $i \in \{1, 2, 3\}$ and consider the graph $\tilde{\mathcal{G}} := \mathcal{G}/V_i = (\tilde{V}, \tilde{E})$ with odd girth $2\rho_i - 1$. We denote the contracted node by $\tilde{v} \in \tilde{V}$. Since this graph is bipartite if we were to remove $\tilde{v}$, we know that its fractional chromatic number is equal to $2 + 1/(\rho_i - 1)$ by Theorem 19. Let $\{\tilde{I}_k, k \in [2\rho_i - 1]\}$ be the independent sets in the support of the optimal primal solution of the graph $\tilde{\mathcal{G}}$ constructed in the proof of this theorem. For each of these independent sets, we extend them to the original graph in the following way:

$$I_k = \begin{cases} \tilde{I}_k & \text{if } \tilde{v} \notin \tilde{I}_k \\ (\tilde{I}_k \setminus \tilde{v}) \cup V_i & \text{if } \tilde{v} \in \tilde{I}_k. \end{cases}$$

In words, if $\tilde{v}$ happens to belong to $\tilde{I}_k$, we replace it by V_i to get a valid independent set in the original graph. Assigning fractional value $y(I_k) = 1/(\rho_i - 1)$ for every $k \in [2\rho_i - 1]$ yields a feasible primal solution with objective value $2 + 1/(\rho_i - 1)$. Since we can do this for every $i \in \{1, 2, 3\}$, and the optimal minimum value of the primal linear program is at most the objective value of any of these feasible solutions, the proof is finished.

Moreover, this upper bound is in fact tight, since it holds with equality when one of the color classes only contains one vertex by Theorem 19. ◀

B Arbitrary Set to Bipartite: Omitted Proofs

▶ **Theorem 21.** *Let $\mathcal{G} = (V, E)$ be a graph and $S \subset V$ such that $\mathcal{G} \setminus S = (A \cup B, E')$ is bipartite. For any $w \in Q^W$, the approximation ratio satisfies*

$$R(w) \le 1 + \alpha \qquad \textit{with } \alpha \in [0, 1]$$

if the contracted graph $\mathcal{G}/S$ is bipartite.

Proof. The only change with respect to the previous proof is the bound on $w(OPT(\mathcal{G} \setminus S))$ in (5). We denote the contracted graph by $\tilde{\mathcal{G}} = \mathcal{G}/S$ and by v^S the contracted vertex. Suppose $\tilde{\mathcal{G}}$ admits the bipartition $(\tilde{A} \cup \tilde{B}, \tilde{E})$ and assume without loss of generality that $v^S \in \tilde{A}$. Note that $\tilde{E} = E' \cup \delta(v^S)$.

Any feasible cover of $\mathcal{G} \setminus S$ needs to count the dual value of every edge in E' at least once. Taking the cover $\tilde{A} \setminus v^S$ counts every edge in E' exactly once, showing that $w(OPT(\mathcal{G} \setminus S)) = y(E')$. Hence, using $y(E) = \alpha + y(\delta(S)) + y(E') = 1$, we get

$$R(w) \le 2\alpha + y(\delta(S)) + y(E') = 1 + \alpha.$$ ◀

▶ **Theorem 22.** *Let $\alpha \in [0,1]$ and let $\rho \geq 2$. There exists a non-bipartite graph $\mathcal{G} = (V, E)$, with weights $(y, w) \in Q^{Y,W}$, and a set $S \subset V$ with $y(E[S]) = \alpha$, where $\mathcal{G}/S$ has odd girth $2\rho - 1$ and which satisfies*

$$R(w) = \left(1 + \frac{1}{\rho}\right)(1 - \alpha) + 2\alpha.$$

Proof. An example of such a graph can be constructed as follows. We first construct $\mathcal{G}/S$: take an odd cycle of length $2\rho - 1$ with a distinguished node v^S and assign dual value $(1-\alpha)/\rho$ to both edges incident to it. Alternatively assign dual values 0 and $(1-\alpha)/\rho$ along the odd cycle for the remaining edges. In order to construct $\mathcal{G}$, replace v^S by a triangle S with dual edges set to $\alpha, 0$ and 0, where the two previous incident edges to v^S are adjacent to the endpoints of the edge with value α. Note that we replace it with a triangle instead of a single edge in order to avoid $\mathcal{G}$ becoming bipartite. Similarly to the proof of Theorem 12, one can check that

$$w(S) = 2\alpha + \frac{2\,(1-\alpha)}{\rho}; \quad w(OPT(\mathcal{G} \setminus S)) = \frac{(1-\alpha)(\rho-1)}{\rho}; \quad w(OPT(\mathcal{G})) = 1.$$

Therefore,

$$R(w) = 2\alpha + \frac{2\,(1-\alpha)}{\rho} + \frac{(1-\alpha)(\rho-1)}{\rho} = \left(1 + \frac{1}{\rho}\right)(1 - \alpha) + 2\alpha.$$ ◀

▶ **Theorem 23.** *Let $\alpha \in [0,1]$. There exists a non-bipartite graph $\mathcal{G} = (V, E)$, with weights $(y, w) \in Q^{Y,W}$, and a set $S \subset V$ with $y(E[S]) = \alpha$, where $\mathcal{G}/S$ is bipartite and which satisfies*

$$R(w) = 1 + \alpha.$$

Proof. Let $\mathcal{G}$ be an arbitrary odd cycle. Consider an arbitrary edge $(u, v) \in E$ and assign it dual value α. The set S is defined to be $S = \{u, v\}$. Assign dual value zero to the edge $(u, w) \in E$, where w is the second neighbour of u in the cycle. For the remaining edges, arbitrarily assign dual values, while ensuring that they sum up to $1 - \alpha$. The fact that one edge is equal to zero is necessary in order to get the exact formula $w(OPT(\mathcal{G})) = 1$, a feasible cover showing $w(OPT(\mathcal{G})) \leq 1$ being the following: take both endpoints of the edge (u, w) and take remaining vertices alternatively (hence always skipping one) along the odd cycle. All the edges are counted once, except for (u, w), which is counted twice but has value zero. Moreover, $w(S) = 2\alpha + y(\delta(S))$ and $w(OPT(\mathcal{G} \setminus S)) = y(E')$, where E' is the edge set of the bipartite graph $\mathcal{G} \setminus S$. Therefore,

$$R(w) = 2\alpha + y(\delta(S)) + y(E') = 1 + \alpha.$$ ◀

On Minimizing Generalized Makespan on Unrelated Machines

Abstract

We consider the *Generalized Makespan Problem* (GMP) on unrelated machines, where we are given n jobs and m machines and each job j has arbitrary processing time p_{ij} on machine i. Additionally, there is a general symmetric monotone norm ψ_i for each machine i, that determines the load on machine i as a function of the sizes of jobs assigned to it. The goal is to assign the jobs to minimize the maximum machine load.

Recently, Deng, Li, and Rabani [8] gave a 3 approximation for GMP when the ψ_i are top-k norms, and they ask the question whether an $O(1)$ approximation exists for general norms ψ? We answer this negatively and show that, under natural complexity assumptions, there is some fixed constant $\delta > 0$, such that GMP is $\Omega(\log^{\delta} n)$ hard to approximate. We also give an $\Omega(\log^{1/2} n)$ integrality gap for the natural configuration LP.

1 Introduction

We consider a question by Deng, Li and Rabani [8] about scheduling jobs to minimize makespan on unrelated machines in the setting of more general norms. Recall that in the unrelated machines setting, we are given n jobs and m machines where each job $j \in [n]$ has some arbitrary processing time p_{ij} on machine $i \in [m]$. Given an assignment of jobs to machines, the load on a machine is the sum of the processing times of all the jobs assigned to it. In a seminal result, Lenstra, Shmoys and Tardos [14] gave a 2-approximation for minimizing the makespan (the maximum machine load). These results were later extended to the problem of minimizing the ℓ_p-norm of the machine loads [1, 4, 13, 16].

In a breakthrough work [5], Chakrabarty and Swamy introduced a substantial generalization of the problem to general symmetric monotone norms. Recall that a function $\phi : \mathbb{R}^m \to \mathbb{R}_{\geq 0}$ is a norm if it satisfies (i) $\phi(u) = 0$ iff $u = 0^n$, (ii) $\phi(\alpha u) = |\alpha| u$ for all u and $\alpha \in R$ and, (iii) $\phi(u + v) \leq \phi(u) + \phi(v)$. We say that ϕ is *symmetric* if $\phi(u) = \phi(u')$ where u' is some permutation of u, and it is monotone if $\psi(u) \leq \psi(v)$ for all u, v satisfying $0 \leq u(i) \leq v(i)$ for all $i \in [m]$.

Surprisingly, they showed that for any arbitrary symmetric monotone norm $\phi : \mathbb{R}^m \to \mathbb{R}_{\geq 0}$, that determines the overall objective as a function of the individual machine loads, there is an $O(1)$ approximation. The approximation ratio was subsequently improved to $4 + \epsilon$ [6]

and more recently to $2+\epsilon$ [11], which remarkably almost matches the bound for makespan. These results introduce several new ideas to handle general norms by relating them to the special class of top-k norms[1], and algorithmic techniques to work with them.

General inner and outer norms. An even further generalization was considered by Deng, Li and Rabani [8], which we refer to as the generalized load-balancing (GLB) problem. Here, additionally, each machine i also has an arbitrary symmetric monotone norm $\psi_i : \mathbb{R}^n \to \mathbb{R}_{\geq 0}$ referred to as the *inner-norm*, that determines the machine's load as a function of the sizes of the jobs assigned to it (note that all the results described previously have inner norm ℓ_1). Formally, given an assignment $\rho : [n] \to [m]$ of jobs to machines, the load on machine i is $\mathsf{load}(i) = \psi_i(p_i^\rho)$ where p_i^ρ is the vector of sizes of jobs assigned to i, i.e., $p_i^\rho(j) = p_{ij}$ if $\rho(j) = i$ and 0 otherwise. The overall objective is $\phi(\mathsf{load})$, where $\mathsf{load} = (\mathsf{load}(1), \dots, \mathsf{load}(m))$ is the vector of machine loads (where $\phi : \mathbb{R}^m \to \mathbb{R}_{\geq 0}$ is the norm as in [5]). We shall refer to ϕ as the *outer-norm.* Throughout this paper a general norm always means a symmetric monotone norm.

In its full generality (when the ψ_i and ϕ are general), GLB becomes $\Omega(\log n)$ hard to approximate, as it generalizes[2] the Set Cover problem when $\psi = \ell_\infty$ and $\phi = \ell_1$. Interestingly, [8] gave a matching $O(\log n)$ approximation for general ψ and ϕ, based on solving and rounding a novel configuration LP.

Generalized Makespan Problem (GMP). Given the $\Omega(\log n)$ hardness for the general case, [8] also consider the interesting and natural special case where the outer-norm ℓ_∞, but the inner norm is general (i.e., the goal is to minimize makespan but where the machine loads are given by general inner-norms ψ_i). We refer to this problem as the *Generalized Makepsan Problem* (GMP). In a sense, this problem can be considered as a "dual" of the problem considered by Chakrabarty and Swamy (where the inner-norm is ℓ_1, but the outer-norm is general).

For GMP, Deng, Li and Rabani gave a 3-approximation for the special case when each ψ_i is a top-k norm. The main open question they ask is whether an $O(1)$ approximation is achievable for general inner-norms. Apriori this seems quite plausible as there is close connection between top-k norms and general norms (see e.g. [5, 6]). Moreover, the $O(1)$ approximation of Chakrabarty and Swamy [5] for the "dual" problem, also suggests that GMP may have an $O(1)$ approximation.

Our Results

Our main result is that GMP does not admit an $O(1)$-approximation under standard complexity-theoretic assumptions, answering the main open problem in [8].

Our starting point is an integrality gap instance for the natural configuration LP for GMP.

▶ **Theorem 1.** *There is an instance of GMP with a symmetric monotone norm ψ, for which the natural configuration LP has an integrality gap of $\Omega((\log n)^{1/2})$.*

[1] The top-k norm of a non-negative vector v is the sum of its largest k entries.

[2] Given subsets $S_1, \dots, S_m$ of $[n]$, consider the scheduling instance on m machines (one per set) and n jobs (one per element), with $p_{ij} = 1$ iff element $j \in S_i$ and $p_{ij} = \infty$ otherwise. That is, only jobs in S_i can be assigned to i. The point is that as $\psi = \ell_\infty$, we have $\mathsf{load}(i) = 0$ if no job is assigned to i, and exactly 1 otherwise (even if all jobs in S_i are assigned to i). As $\phi = \ell_1$, the objective is exactly the number of machines (sets) needed to cover all the jobs.

The gap instance is based on a probabilistic construction and a key idea is to work with a suitably chosen norm ψ, defined as the sum of top-k norms at various different scales, that interacts nicely with properties of random set cover instances. This construction is described in Section 3, and it forms a key gadget in our following hardness result.

▶ **Theorem 2.** *There is a universal constant $\delta > 0$, such that any polynomial-time approximation algorithm for GMP has approximation ratio $\Omega(\log^{\delta} n)$ provided that* $\mathsf{NP} \not\subseteq \mathsf{ZTIME}(n^{O(\log\log n)})$.

Our construction for this hardness result builds on the ideas of Lund and Yannakakis [15], who showed the $\Omega(\log n)$ hardness of Set Cover by a gap reduction from the Label Cover problem. However, we require some additional ideas as reducing the Label Cover problem to a scheduling instance and exploiting the properties of the norm ψ requires much more care. Specifically, even though our gadget in Theorem 1 has the $\Omega((\log n)^{1/2})$ gap, embedding it into Label Cover imposes extra constraints on the number of labels in the Label Cover instance, and only leads to an $\Omega(\log^{\delta} n)$ hardness, for some constant $\delta > 0$. Interestingly, this constant δ depends on the soundness parameter of label cover as a function of the number of labels, based on Raz's parallel repetition theorem [18] and its subsequent improvements [10, 17].

▶ Remark. The constant δ can be computed explicitly, but we do not attempt to do this here. This construction is described in Section 4. We remark that there are extensive work on improving the soundness in PCP constructions as a function of the number of labels. The best known result in this direction is due to Chan [7] that achieves soundness roughly $L^{-1/2}$ for L labels. However, Chan's result does not have perfect completeness and hence cannot be used in our constructions. Roughly speaking, this is because each job must be assigned to some machine (this is similar to the reason that one requires perfect completeness in reducing label cover to set cover, as each element must be covered).

▶ Remark. In personal communication, Amey Bhangale has pointed out that in an unpublished manuscript, they can show that assuming the 2-to-2 conjecture with perfect completeness, there is a label cover instance with L labels that has perfect completeness and soundness $L^{-1/2}$. Using a such a label cover, our construction in Section 4 would imply a hardness of $\Omega(\log^{1/8} n)$ in Theorem 2. We note that currently, proving the 2-to-2 conjecture with perfect completeness remains open, and in particular the breakthrough results of Khot, Minzer and Safra [12] on the 2-to-2 conjecture assume imperfect completeness.

2 Preliminaries

2.1 (n, m, ℓ, β) Set-System

The constructions of the integrality gap instance in Section 3 and the reduction from label cover to GMP presented in Section 4 both use the following set system as a building block.

▶ **Definition 3** ((n, m, ℓ, β) Set-system). *Let n, m, ℓ be positive integers, $\beta \in (0, 1)$, U be a set with $|U| = n$, and $A_1, \dots, A_m$ be subsets of U. The sets $(U; A_1, \dots, A_m)$ form an (n, m, ℓ, β) set-system if for every set I of at most ℓ indices from $[m]$, $|\cup_{i\in I} B_i| \leq (1 - \beta)|U|$, where B_i is either A_i or $\overline{A}_i$.*

Intuitively, an (n, m, ℓ, β) set-system has the property that any set cover which uses at most ℓ subsets necessarily uses a complementary pair of subsets A_i and $\overline{A}_i$. Moreover, any collection of at most ℓ subsets that do not contain any complementary pair can cover at most a $(1-\beta)$ fraction of the elements in U. The following lemma shows that for a particular choice of parameters n, m, ℓ, and β, there is a simple and efficient randomized construction of an (n, m, ℓ, β) set-system.

▶ **Lemma 4.** *For a sufficiently large positive integer n and a positive integer $m \in [\sqrt{\log n}, 2\sqrt{\log n}]$ there exists an (n, m, ℓ, β) set-system $(U; A_1, \ldots, A_m)$ with $\ell = m/10$ and $\beta = \exp(-m) = \exp(-O(\sqrt{\log n}))$. There is a polynomial-time algorithm that constructs such a set system with high probability.*

Proof. Let U be a set of n elements, and initialize m empty sets $A_1, \ldots, A_m$. For each element $e \in U$, sample a random index set $J \subset [m]$ of size exactly $m/2$ and add e to sets A_j for $j \in J$.

We show that this construction gives an (n, m, ℓ, β) set-system with high probability. Consider an index set $I \subset [m]$ with $|I| = \ell$ and a collection of sets B_i for $i \in I$ such that each B_i is either A_i or $\overline{A_i}$. For a fixed $e \in U$, let p denote the probability that e is not contained in $\cup_{i\in I} B_i$, i.e., $p = \Pr[e \notin \cup_{i\in I} B_i]$. We have,

$$p \geq \binom{m-\ell}{m/2} \Big/ \binom{m}{m/2} \geq \left(\frac{m-\ell}{m/2}\right)^{m/2} \Big/ \left(\frac{em}{m/2}\right)^{m/2} \geq \left(\frac{m-\ell}{em}\right)^{m/2} \geq \exp(-0.6m),$$

where the second inequality uses that $\left(\frac{n}{k}\right)^k \leq \binom{n}{k} \leq \left(\frac{en}{k}\right)^k$.

The probability that $\cup_{i\in I} B_i$ contains a fixed subset of cardinality greater than or equal to $(1-\beta)n$ is at most $(1-p)^{(1-\beta)n}$. By a union bound over at most $\binom{n}{\beta n} n$ possible subsets with cardinality at least $(1-\beta)n$,

$$\begin{aligned}\Pr\left[|\cup_{i\in I} B_i| \geq (1-\beta)n\right] &\leq \binom{n}{\beta n} n \cdot (1-p)^{(1-\beta)n} \leq (e/\beta)^{\beta n}\, n \cdot e^{-(1-\beta)np} \\ &\leq \exp\left(3n\beta \log(1/\beta) - np/2\right) \leq \exp(-np/4) \leq \exp(-n^{0.9}),\end{aligned}$$

where in the second to last inequality we use that $3\beta \log(1/\beta) < p/4$.

A union bound over the at most $2^\ell \cdot \binom{m}{\ell} \leq \exp(\sqrt{\log n})$ possible choices to pick the ℓ sets B_i, gives that with high probability, the union of any ℓ sets B_i has cardinality less than $(1-\beta)n$. ◀

2.2 Label Cover

In Section 4, we prove the hardness of approximation of GMP via a reduction from the standard label cover problem as defined below.

▶ **Definition 5.** *A* label cover *instance $\mathcal{L}$ is defined by a tuple $((U, V, E), L, \Pi)$. Here (U, V, E) is a bipartite graph with vertices $U \cup V$ and edges $E \subseteq U \times V$; L is a positive integer and Π is a set of functions one for each edge $e \in E$ i.e., $\Pi = \{\pi_e : [L] \to [L] \mid e \in E\}$. A labeling of the vertices $\sigma : U \cup V \to [L]$ is said to satisfy an edge $e = (u, v)$ if $\pi_e(\sigma(u)) = \sigma(v)$. Given $\mathcal{L}$, the goal of the label cover problem is to find a labeling σ^* that satisfies the maximum number of edges in E. We use $OPT(\mathcal{L})$ to denote the fraction of the edges in E satisfied by σ^*.*

As we will need the explicit dependence between the number of labels and the soundness, for completeness we sketch below the precise gap version of the label cover problem that we will use.

▶ **Lemma 6** (Hardness of Gap Label Cover)**.** *Given a label cover instance $\mathcal{L} = ((U, V, E), L, \Pi)$ satisfying:*

(i) $|U| = |V| = N$
(ii) *The degree of every vertex in* $U \cup V$ *is* $d = O((\log N)^{c_1})$ *for some constant* c_1.
(iii) $L = \sqrt{\log N}$

There is some constant $c > 0$*, for which there is no polynomial-time algorithm to decide if* $OPT(\mathcal{L}) = 1$ *or* $OPT(\mathcal{L}) \leq (\log N)^{-c}$ *provided that* $\mathsf{NP} \not\subseteq \mathsf{DTIME}(N^{O(\log\log N)})$.

Proof. Using a standard argument (see for ex., [9, 2]) one can obtain a reduction from a 3SAT-5 instance ϕ with t variables to a Label Cover instance $\mathcal{L}_1 = ((U_1, V_1, E_1), 8, \Pi)$, where $|U_1| = |V_1| = O(t)$ and the graph (U_1, V_1, E) is 15-regular. The instance $\mathcal{L}_1$ has the following property: if ϕ has a satisfying assignment then $OPT(\mathcal{L}_1) = 1$; else if any assignment satisfies at most $(1 - \epsilon)$ fraction of clauses in ϕ, then $OPT(\mathcal{L}_1) \leq (1 - \Theta(\epsilon))$. By the PCP-theorem [3] it follows that, for some constant $\epsilon_0 > 0$, deciding if $OPT(\mathcal{L}_1) = 1$ or $OPT(\mathcal{L}_1) \leq 1 - \epsilon_0$ is NP-hard.

The following well-known construction [2] gives stronger inapproximability results for label cover. We define the kth power of the label cover instance $\mathcal{L}_k = ((U_k, V_k, E_k), 8^k, \Pi^k)$, where U_k, V_k are k-tuples of vertices in U_1, V_1 respectively, E_k is the set of all k-tuples of edges in E_1. The resulting graph has $N = t^{O(k)}$ vertices and is $(15)^k$-regular. The new set of labels[3] consist of k-tuples of $\{1, \dots, 8\}$. For an edge $e = (e_1, \dots, e_k) \in E_k$, we define the function $\pi_e^k(a_1, \dots, a_k) = (\pi_{e_1}(a_1), \dots, \pi_{e_k}(a_k))$. Raz's Parallel Repetition Theorem [18], shows that for the label cover instance constructed above, there exists a constant α such that $OPT(\mathcal{L}_k) \leq (OPT(\mathcal{L}_1))^{\alpha k}$.

We now pick k so that $L = \sqrt{\log N}$. Since $L = 8^k$ and $N = t^{O(k)}$, this gives $k = \Theta(\log\log t)$. This choice of k ensures that $d = (15)^k = (\log N)^{c_1}$ for some constant c_1. Moreover, if $OPT(\mathcal{L}_1) \leq (1 - \epsilon_0)$, then $OPT(\mathcal{L}_k) \leq (1 - \epsilon_0)^{\alpha k} \leq (\log t)^{-c'} \leq (\log N)^{-c}$ for some positive constants c, c'. ◀

3 Integrality Gap for Configuration LP

We begin by describing the configuration LP for GMP. We then explain the high-level ideas behind the gap construction and the properties we need from the norm ψ. We then describe the norm ψ and the integrality gap instance formally and then prove Theorem 1. As mentioned earlier, this gap instance and the norm ψ form the key gadget in our hardness construction in Section 4.1, and understanding it is crucial to the results in Section 4.

Configuration LP. The most natural LP relaxation of GMP is to consider assignment variables $x_{ij} \in [0, 1]$ that determine the fraction of job j assigned to machine i, and impose natural constraints. However, simple examples show that such an LP is too weak to handle general norms ψ. A stronger relaxation is the configuration LP, where we have exponentially many variables $x_{i,C}$, one for each machine i, and a possible subset of jobs C that can be feasibly assigned to machine i.

Let J denote the set of jobs, and $M = [m]$ be the set of machines. For a machine $i \in M$, and subset $C \subseteq J$, let $p_i[C] = (p_{ij} \cdot \mathbb{1}[j \in C])_{j \in J}$ denote the vector of sizes of jobs in C. Let T be a guess on the optimum makespan (we can do a binary search on T). Call a configuration C *valid* for machine i if the load $\psi_i(p_i[C])$ of C on i is at most T. We will slightly abuse notation and denote $\psi_i(p_i[C])$ by $\psi_i(C)$. Consider the following feasibility LP.

[3] The labels are essentially numbers from 1 to 8^k.

$$\sum_{C \subseteq J} x_{i,C} \leq 1 \qquad \forall i \in M \tag{1a}$$

$$\sum_{i \in M, C: j \in C} x_{i,C} = 1 \qquad \forall j \in J \tag{1b}$$

$$x_{i,C} = 0 \qquad \text{if } \psi_i(C) > T \tag{1c}$$

The first constraint says that each machine has at most one configuration. The second constraint says that each job is assigned to a machine, and the last constraint ensures that only valid configurations are considered and hence the generalized makespan on any machine is at most T. This LP can be solved efficiently for any desired accuracy $\epsilon > 0$ (so the configurations satisfy $\psi_i(C) \leq (1+\epsilon)T$), see e.g., [8].

The main idea. We start with a simple instructive example, that motivates our choice of the norm and the choice of parameters that lead to the $\Omega(\sqrt{\log n})$ integrality gap. Consider a random set system on a universe U of n elements and m sets $A_1, \ldots, A_m$ where each element independently lies in $m/2$ randomly chosen sets. We will set $m \ll \log n$. Create an unrelated machine (in fact restricted assignment) scheduling instance I with m machines, where only the jobs in A_i can be assigned to machine i (all other jobs have infinite size on i). As each element lies in $m/2$ sets, the LP solution that picks the configuration A_i on each machine i with $x_{i,A_i} = 2/m$ is feasible, and uses only 2 machines in total.

However, in any integral solution, we claim that several machines must pick a non-trivial fraction of jobs from their sets A_i. Roughly, this is because the union of any $\ell \ll m$ sets A_i still leaves about $2^{-\ell}|U|$ uncovered (as each element lies in a set with probability 1/2). Hence in any feasible integral solution, for any $\ell > 0$, at least ℓ machines must be assigned at least $2^{-\ell}|U|/m$ jobs.

To exploit this, suppose we define ψ as the top-k norm with $k \approx \Omega(2^{-\ell}n/m)$, so that any machine with $\geq k$ jobs incurs the same load, say T. Then in any integral solution, at least ℓ machines have load T, while fractionally at most 2 machines (in total) have load T. By creating $m/2$ disjoint copies $I^{(1)}, \ldots, I^{(m/2)}$ of these set-cover instances, one would then expect that fractionally each machine has load T, while integrally the average load becomes $\Omega(\ell)$.

Unfortunately, this does not quite work as stated above, because once there are several instances $I^{(1)}, \ldots, I^{(m/2)}$, as these jobs share the same machines, an algorithm can find a low makespan even if it cannot figure out the good underlying set cover solution. In fact, this is provably so, as [8] gave a 3-approximation when ψ is a Top_k norm.

However, our key observation is that this idea can still be made to work by choosing the instances $I^{(1)}, \ldots, I^{(m/2)}$ at different scales (of the number of jobs and processing times) and defining the norm ψ as a suitable mixture of the top-k norms at these different scales. Roughly, this norm ψ still behaves as a top-k norm at each individual scale, but when jobs from different scales are combined, it takes on a large value, which be used to create a large gap in the reduction above.

Implementing this idea requires separating every two scales by $\Omega(2^\ell)$. So the ℓ scales leads to instances with size about 2^{ℓ^2} leading to the choice of $\ell = \Theta(\sqrt{\log n})$ to produce the $\Omega(\ell)$ gap. We now give the details.

The Instance. The instance will have n jobs and $m = \sqrt{\log n}$ machines. We first create $h = m/8$ disjoint set-cover instances $I^{(1)}, \ldots, I^{(h)}$, where $I^{(s)} = (U(s); A_1(s), A_2(s), \ldots, A_m(s))$ forms an (n_s, m, ℓ, β) set-system with $\ell = m/10, \beta = \exp(-m)$ and $n_s = (\sqrt{n}/2) \cdot \exp(4ms) = (\sqrt{n}/2)\beta^{-4s}$. Note that n_s increases as β^{-4s} with s, and $n_1 \geq \sqrt{n}$ and $n_h = n/2$, and it is easily checked that parameters for each $I^{(s)}$ satisfy the condition in Lemma 4.

For each $s \in [h]$, the elements in $U(s)$ correspond to jobs with size $p^{(s)} = \beta^{s-1}$ (or infinite if the job cannot be assigned to a machine). Each job j in $U(s)$ has size $p_{ij} = p^{(s)}$ on machine i iff $j \in A_i(s)$ and $p_{ij} = \infty$ otherwise. We abuse the notation slightly to refer to the resulting scheduling instance also as $I^{(s)}$. As the instances $I^{(1)}, \dots, I^{(h)}$ are at different scales in terms of the number of jobs and processing times, we refer to jobs in $I^{(s)}$ as being in the s-th *size class* [4].

We define the inner norm $\psi = \sum_{s\in[h]} \psi^{(s)}$, where each $\psi^{(s)}$ is a scaled top-k norm given by

$$\psi^{(s)}(\mathbf{v}) = \frac{\mathsf{Top}_{\beta^2 n_s}(\mathbf{v})}{(\beta^2 n_s p^{(s)})}. \tag{2}$$

Each machine i will have the same inner norm $\psi_i = \psi$. Informally, ψ has the following key property: for any subset C of $A_i(s)$ with at least $\beta^2 n_s$ jobs, $\psi_i^{(s)}(C) = 1$ and $\psi_i^{(s')}(C) \approx 0$ for $s' \neq s$. This in particular implies that $\psi_i(A_i(s)) \approx 1$ for any class s. Moreover, if C is an arbitrary subset of jobs with at least a β^2 fraction of jobs from r distinct sets among $A_i(1), A_i(2), \cdots, A_i(h)$, then $\psi_i(C) \approx r$ (roughly, each such size-class s affects a different term $\psi^{(s)}$ of the norm). This property motivates the following definition.

▶ **Definition 7** (Heavy Size Class)**.** *Given an assignment of jobs $\rho : J \to M$, we say that size class $s \in [h]$ is heavy on machine $i \in M$, if at least $\beta^2 n_s$ jobs from $A_i(s)$ are assigned to machine i.*

We now formally state and prove the property of the norm described above.

▶ **Lemma 8.** *For any $s \in [h]$ and $i \in M$, $\psi_i(A_i(s)) = 1 + o(1)$. Furthermore, for an assignment $\rho : J \to M$, if C is the set of jobs assigned to machine i, then $\psi_i(C)$ is at least the number of heavy size classes $s \in [h]$ on machine i.*

Proof. We first show that $\psi_i(A_i(s)) = 1 + o(1)$ by computing the value of $\psi^{(s')}$ for different s'. By the definition of $\psi^{(s')}$,

$$\psi_i^{(s')}(A_i(s)) = \frac{\mathsf{Top}_{\beta^2 n_{s'}}(p_i[A_i(s)])}{(\beta^2 n_{s'} p^{(s')})} = \frac{\min\{\beta^2 n_{s'}, |A_i(s)|\} \cdot p^{(s)}}{(\beta^2 n_{s'} p^{(s')})} = \left(\min\left\{1, \frac{|A_i(s)|}{\beta^2 n_{s'}}\right\}\right) \frac{p^{(s)}}{p^{(s')}}$$

For $s = s'$, this exactly equals 1 (as $\beta \ll 1$ and $|A_i(s)| \approx \frac{n_s}{2}$).
For $s' < s$, we have $\psi_i^{(s')}(A_i(s)) \leq \frac{p^{(s)}}{p^{(s')}} = \beta^{(s-s')} \leq \beta$.
Finally, for $s' > s$, we have

$$\psi_i^{(s')}(A_i(s)) \leq \frac{|A_i(s)|}{\beta^2 n_{s'}} \cdot \frac{p^{(s)}}{p^{(s')}} \leq \frac{n_s}{\beta^2 n_{s'}} \cdot \frac{p^{(s)}}{p^{(s')}} = \beta^{3(s'-s)-2} \leq \beta.$$

Let us now consider an arbitrary set of jobs C assigned to machine i. By the monotonicity of the norm,

$$\psi_i^{(s)}(C) \geq \psi_i^{(s)}(C \cap A_i(s)) = \min\left\{1, \frac{|C \cap A_i(s)|}{\beta^2 n_s}\right\} \geq \mathbb{1}[s \text{ is heavy on } i].$$

As $\psi_i(C) = \sum\limits_{s\in[h]} \psi_i^{(s)}(C)$, it follows that $\psi_i(C)$ is at least the number of heavy size classes on i. ◀

[4] The total number of jobs in the h instances is $\sum_{i=1}^{h} n_s \approx n/2$. To make the total number of jobs n, we add dummy jobs that have processing time 0 on all machines.

Fractional Solution. We claim that the following solution is feasible for the configuration LP Equation (1) with $T = 2$: for each machine $i \in M$, set $x_{i,A_i(s)} = 2/m$ for each $s \in [h]$.

Clearly, Equation (1a) is satisfied for each $i \in M$ as there are $h < m/2$ sets of jobs $A_i(1), A_i(2), \ldots, A_i(h)$, each with value $2/m$. Equation (1b) is satisfied as each job $j \in U(s)$, for each $s \in [h]$, lies in $m/2$ sets in $A_1(s), A_2(s), \ldots, A_m(s)$. Equation (1c) is also satisfied as $\psi_i(A_i(s)) = 1 + o(1) < 2 = T$ by Lemma 8.

Integral Solution. We now show that any integral solution has generalized makespan $\Omega(\sqrt{\log n})$.

▶ **Lemma 9.** *For any assignment $\rho : J \to M$, there is some machine with load $\Omega(\sqrt{\log n})$.*

Proof. We first show that each size class is heavy on at least $\ell = \sqrt{\log n}/10$ machines. Suppose this is not true for some size class $s \in [h]$. Let $H \subseteq M$ be the set of machines on which s is heavy, and so $|H| < \ell$. As $I^{(s)}$ forms an (n_s, m, ℓ, β) set-system, by Definition 3, $| \cup_{i \in H} A_i(s)| \le (1 - \beta)n_s$, and hence at least βn_s jobs from $U(s)$ are assigned to machines $i \notin H$. However, as any machine $i \notin H$ can have at most $\beta^2 n_s$ jobs from $A_i(s)$, the machines in $i \notin H$ can have is at most $m \cdot \beta^2 n_s < \beta n_s$, contradicting that each job in $U(s)$ was assigned to some machine.

By averaging over machines, there exists a machine i on which at least $(h\ell/m) = \Omega(\sqrt{\log n})$ size classes are heavy. By Lemma 8, this implies that $\psi_i = \Omega(\sqrt{\log n})$. ◀

This concludes the proof of Theorem 1.

4 Reduction from Label-Cover

We now prove Theorem 2 by reducing Label Cover to a GMP instance.

Overview. Our construction builds on the ideas used by Lund and Yannakakis [15] to show the $\Omega(\log n)$ hardness of set cover, using a gadget based on a natural $\Omega(\log n)$ integrality gap instance. We first give a rough sketch of their idea (see e.g. [2] for an excellent exposition), and then explain the additional steps needed in our setting and why we only get a $\log^{\delta} n$ hardness for some small $\delta > 0$, despite the $\Omega(\log^{1/2} n)$ integrality gap instance above.

Consider a label cover instance $\mathcal{L} = ((U, V, E), L, \Pi)$, as defined in Definition 5, with label set $[L]$ and vertex sets U and V. The main idea in [15] is the following. For each edge $e = (u, v) \in E$, one associates a (n, m, ℓ, β)-system $I^e = (U^e; A_1^e \ldots, A_m^e)$ (with disjoint universes for each edge). The sets will be associated with labels for vertices (so that $L = m$) and we associate the set $A^e_{\pi_e(a)}$ with label a for u and $\overline{A_b^e}$ with label b for vertex v. The point is that in the completeness case, where the labels a' and b' for u and v satisfy e (i.e., $\pi_e(a') = b'$), U^e can be covered by just the two corresponding sets $A^e_{\pi_e(a')}$ and $\overline{A^e_{b'}}$. Conversely, in the soundness case, if U^e is covered using less than ℓ sets, there must be a pair of sets that are complements of each other, which can be used to produce a good labeling for $\mathcal{L}$.

To adapt this to our setting, suppose we create a job for each element in U^e, and m machines per vertex, one for each label in $[L]$. Also suppose that for labels a, b, we set the processing times of jobs in the set $A^e_{\pi_e(a)}$ to be finite on the a-th machine of vertex u and the processing times of jobs in set $\overline{A_b^e}$ to be finite on the b-th machine of vertex v. In the completeness case, any perfect labeling gives an assignment where jobs are assigned to exactly one out of the m machines per vertex (similar to the value of the LP solution in the gap example in Section 3). However, the soundness argument fails, as a low makespan assignment can spread jobs from U^e on multiple machines, and not give any information to recover a good labeling (this is similar to the reason we needed multiple size classes in the gap example in Section 3).

To get around this, for each e, we will use h different set systems $I^{e,1}, \ldots, I^{e,h}$ (of geometrically increasing sizes) where the s-th set system is the following $I^{e,s} = (U^e(s); A_1^e(s), \ldots, A_m^e(s))$. Each vertex will have m machines, one for each label. The intended solution is that if vertex u is assigned label a, then we pick the sets $A^e_{\pi_e(a)}(1), \ldots, A^e_{\pi_e(a)}(h)$, and assign the corresponding jobs to the m machines for u with small makespan (this requires some care so that for any label a, jobs from different classes s can be assigned to different machines, but we ignore this issue here).

Using the properties of the norm ψ and the arguments in Section 3 for the integrality gap, one can show that if $h = \Omega(m)$, then given any schedule with low makespan, one can construct a good labeling thereby proving soundness. A key new idea here beyond [15] is to show that there is some fixed size class s^*, such that the assignment of jobs in class s^* gives a small set of good candidate labels for a large fraction of edges. However, as the hardness of Label-Cover is only $\Omega(L^c)$ for some small constant c as a function of the number of labels, our resulting hardness is only $\Omega(\log^{c'} n)$ for some small $c' > 0$, instead of $\Omega(\log^{1/2} n)$.

4.1 The Reduction

Suppose that we are given a label cover instance, $\mathcal{L} = ((U, V, E), L, \Pi)$ satisfying the properties of Lemma 6, i.e., the number of vertices $|U| = |V| = N$, the degree of every vertex is $d = O((\log N)^{c_1})$ and the number of labels $L = \sqrt{\log N}$. We now describe a polynomial-time (randomized) reduction from $\mathcal{L}$ to a GMP instance $\mathcal{I}$ with machines M, jobs J and assign processing times for each machine $i \in M$ and job $j \in J$.

Machines. For each vertex $w \in U \cup V$, we create $m = L = \sqrt{\log N}$ machines. We denote the set of machines corresponding to vertex w by $M_w = \{w_1, \ldots, w_m\}$. We denote the set of all machines by $M = \bigcup_{w \in U \cup V} M_w$. In total, we have $2N\sqrt{\log N}$ machines.

Jobs. For each edge $e \in E$, we create $O(N)$ jobs and partition them into $h = m/8$ size-classes $U^e(1), U^e(2), \ldots, U^e(h)$ of geometrically increasing size. More precisely, we pick the number of jobs in the s-th set to be $|U^e(s)| = \sqrt{N} \cdot \exp(4s\sqrt{\log N})$ which is always $O(N)$ since $s \leq \sqrt{\log N}/8$. Therefore, the total number n of jobs created is poly(N). We also remark that these sets can be constructed efficiently by the randomized procedure described in Lemma 4 and that this is the only randomized step of the reduction.

Processing times. To assign processing times, for each edge $e \in E$ and $s \in [h]$, we construct a $(|U^e(s)|, m, \ell, \beta)$ set system $I^{e,s} = (U^e(s); A_1^e(s), \ldots, A_m^e(s))$ with $\ell = m/10$ and $\beta = \exp(-m)$. For every vertex $u \in U$, label $a \in [L]$ and $s \in [h]$, define the set

$$S_{u,a,s} = \bigcup_{e \in \delta(u)} A^e_{\pi_e(a)}(s). \tag{3}$$

Similarly for every vertex $v \in V$, label $b \in [L]$ and $s \in [h]$, define the set

$$S_{v,b,s} = \bigcup_{e \in \delta(v)} \overline{A^e_b}(s). \tag{4}$$

For every vertex $w \in U \cup V$, label $a \in [L]$ and size class $s \in [h]$, we choose the processing times of all the jobs in $S_{w,a,s}$ to be $p^{(s)} = \beta^{s-1}$ on the machine w_i if the index i satisfies $i \equiv (a+s) \pmod m$. This way of assigning processing times ensures that for a fixed machine w_i and a label a, there is at most one set of jobs among $S_{w,a,1}, S_{w,a,2}, \ldots, S_{w,a,h}$ that have finite processing time on w_i. This is a useful property to have when we prove the completeness of our reduction.

Norm. Define the norm $\psi = \sum_{s\in[h]} \psi^{(s)}$, where each $\psi^{(s)}$ is a scaled top-k norm given by

$$\psi^{(s)}(\mathbf{v}) = \frac{\mathsf{Top}_{\beta^2 n_s}(\mathbf{v})}{(\beta^2 n_s p^{(s)})} \tag{5}$$

where $n_s = \left|\bigcup_{e\in\delta(w)} U^e(s)\right|$ is the number of jobs of size class s contained in edges incident to any vertex. Note that since the graph is d-regular this number is the same for each vertex.

The above reduction takes poly(N) time because there are only polynomially many jobs, machines and the (n, m, ℓ, β) set systems required can be constructed efficiently by Lemma 4.

4.2 Analysis

The set of jobs $S_{w,a,s}$ for any vertex w, label a and size class s, only contribute to the s-th top-k term of ψ on machine w_i. Similar to Definition 7, we define heavy and light size classes and state a lemma whose proof is analogous to that of Lemma 8.

▶ **Definition 10** (Heavy Size Class). *For a vertex w, label a and size class s, consider the set $S_{w,a,s}$ of jobs and the machine w_i satisfying $i \equiv (a+s) \pmod m$. For an assignment $\rho : J \to M$, we say that size class s is heavy on machine w_i, if ρ assigns at least $\beta^2 n_s$ jobs from $S_{w,a,s}$ to machine w_i; otherwise, we say the size class s is light on machine w_i.*

▶ **Lemma 11.** *For any vertex w, label a, size class s, and a machine w_i satisfying $i \equiv a + s \pmod m$, the norm $\psi_{w_i}(S_{w,a,s}) = 1 + o(1)$. Furthermore, for an assignment $\rho : J \to M$, let S be the set of jobs assigned to machine w_i. Then $\psi_{w_i}(S)$ is at least the number of heavy size classes heavy on w_i.*

4.2.1 Completeness

Given a labeling σ for the label cover instance $\mathcal{L}$ which satisfies all the edges, we use it to construct an assignment of jobs ρ with a low makespan.

▶ **Lemma 12.** *If the label cover instance $\mathcal{L}$ satisfies $OPT(\mathcal{L}) = 1$, the instance $\mathcal{I}$ has an assignment $\rho : J \to M$ with makespan less than 2.*

Proof. Let σ be the labeling of vertices that satisfies all edges in the label cover instance $\mathcal{L}$. Consider the assignment ρ of jobs to machines constructed using σ in the following way: for every vertex $w \in U \cup V$, and size class $s \in [h]$, assign the jobs in $S_{w,\sigma(w),s}$ to machine w_i where the index i satisfies $i \equiv \sigma(w) + s \pmod m$.

For an edge $e = (u, v) \in E$ we first show that each job in the sets $U^e(1), U^e(2), \ldots, U^e(h)$ is assigned to some machine. For a size class $s \in [h]$, the jobs in $S_{u,\sigma(u),s}$ are assigned to a machine in M_u, and similarly, the jobs in $S_{v,\sigma(v),s}$ are assigned to a machine in M_v. Since $\pi_e(\sigma(u)) = \sigma(v)$, we infer that $A^e_{\sigma(v)}(s) = A^e_{\pi_e(\sigma(u))}(s) \subseteq S_{u,\sigma(u),s}$ and $\overline{A^e_{\sigma(v)}}(s) \subseteq S_{v,\sigma(v),s}$. It follows that each job in $U^e(s)$ is assigned to some machine.

We now bound the makespan of the assignment by showing that each machine is assigned jobs from at most one size class. For a vertex w and $i \in [m]$ consider the machine w_i. Since $h < m$, there is at most one $s \in [h]$ for which $\sigma(w) + s \equiv i \pmod m$. Therefore, w_i is assigned jobs from at most one of the sets $S_{w,\sigma(w),1}, S_{w,\sigma(w),2}, \cdots, S_{w,\sigma(w),h}$. Therefore, by Lemma 11 its norm is at most $1 + o(1) < 2$. ◀

4.2.2 Soundness

Next, we show that if the instance $\mathcal{I}$ has a makespan much less than ℓ, then $OPT(\mathcal{L})$ is large. Towards this end, we first prove some useful lemmas. Consider an assignment ρ with makespan $T \leq \ell/100$. Call a size class s to be *good* for a vertex w if it is heavy on at most $32T$ of the machines $w_1, \ldots, w_m$; if not define it to be bad. We first show that a large fraction of size classes are good for any vertex.

▶ **Lemma 13.** *There are at least $3h/4$ good size classes for each vertex.*

Proof. Let b be the number of bad size classes for some vertex w. By averaging over the m machines on vertex w, there is a machine w_i for which at least $(32Tb)/m$ size classes are heavy. By Lemma 11, w_i has norm at least $(32Tb)/m$. As any machine has norm at most T, we get $b \leq m/32 = h/4$ and hence the claim follows. ◀

Call a size class *good* for an edge (u, v) if it is good for both u and v. By Lemma 13 each edge e has at least $h/2$ good size classes. By averaging over the edges $e \in E$, there must exist a size class $s^* \in [h]$ which is good for at least $|E|/2$ edges.

We will fix the class s^* henceforth, and use it to construct a good label cover solution by assigning a suitable label to each vertex. These labels will only depend on the class s^*.

Constructing a good labeling. For each vertex $w \in U \cup V$, we define $L(w)$ to be the set of all labels a such that size-class s^* is heavy on w_i where $i \equiv (a + s) \pmod m$. If no such label exists, add an arbitrary label to $L(w)$.

▶ **Lemma 14.** *Let $e = (u, v)$ be an edge for which s^* is good. There exists $a \in L(u)$ and $b \in L(v)$ such that $\pi_e(a) = b$.*

Proof. Assume there are no such labels $a \in L(u)$ and $b \in L(v)$ for which $\pi_e(a) = b$. Since $|L(u)| + |L(v)| \leq 64T < \ell$, then the union of all the sets $A^e_{\pi_e(a)}(s^*)$ and $\overline{A^e_b}(s^*)$ such that $a \in L(u)$ and $b \in L(v)$ covers at most $(1 - \beta)|U^e(s^*)|$ from Definition 3.

From the definition of a light size class, for all labels $a \notin L(u)$ (resp. $b \notin L(v)$), at most $\beta^2 n_{s^*} = \beta^2(|U^e(s^*)| \cdot d)$ jobs from the sets $A^e_{\pi_e(a)}(s^*)$ (resp. $\overline{A^e_b}(s^*)$) are assigned to some machines on vertex u (resp. v) . Notice that the degree of the graph (U, V, E) is $d = O((\log N)^{c_1})$. So, the union of all the jobs assigned from the sets $A^e_{\pi_e(a)}(s^*)$ (resp. $\overline{A^e_b}(s^*)$) such that $a \notin L(u)$ (resp. $b \notin L(v)$) has at most $(2m \cdot \beta^2 \cdot |U^e(s^*)| \cdot d) < \beta|U^e(s^*)|$ jobs which is a contradiction. ◀

For each vertex w, set $\sigma(w)$ to be a label selected uniformly at random from $L(w)$. We show that σ satisfies a large fraction of edges of $\mathcal{L}$ completing the proof of soundness.

▶ **Lemma 15.** *If the instance $\mathcal{I}$ has an assignment $\rho : J \rightarrow M$ with makespan $T \leq \ell/100$, then $OPT(\mathcal{L}) \geq 1/(2048T^2)$.*

Proof. Consider an edge $e = (u, v)$ for which size class s^* is good. In this case, we have $|L(u)| \leq 32T$ and $|L(v)| \leq 32T$. Also, by Lemma 14 there exists $a \in L(u)$ and $b \in L(w)$ for which $\pi_e(a) = b$. Therefore, $\pi_e(\sigma(u)) = \sigma(v)$ with probability at least $1/(32T)^2$. We have by the analysis above that the number of edges for which s^* is good is at least $|E|/2$. Therefore, the expected number of edges satisfied by σ is at least $|E|/(2(32)^2T^2) = |E|/(2048T^2)$ and the lemma follows. ◀

▶ **Theorem 2.** *There is a universal constant $\delta > 0$, such that any polynomial-time approximation algorithm for GMP has approximation ratio $\Omega(\log^\delta n)$ provided that* $\mathsf{NP} \not\subseteq \mathsf{ZTIME}(n^{O(\log \log n)})$.

Proof. Suppose that we have an algorithm that in polynomial time can decide if the *GMP* instance constructed has a makespan of at least T or at most 2. By the reduction above, from Lemmas 12 and 15 this algorithm can also distinguish between label cover instances that have value 1 and those that have value at most $1/2048T^2$. Due to the hardness of label cover (Lemma 6), this is not possible if $1/2048T^2 \geq 1/(\log N)^c$, i.e., if $T \leq O((\log N)^{c/2}) = O((\log n)^{c/2})$ since the number of jobs $n = \text{poly}(N)$. This, in particular, implies that any approximation algorithm for GMP has an approximation ratio of at least $\Omega((\log n)^{c/2})$ provided that $\mathsf{NP} \not\subseteq \mathsf{ZTIME}(n^{O(\log \log n)})$. ◀

5 Concluding Remarks

We conjecture that GMP admits an $O(\sqrt{\log n})$ approximation, based on suitably rounding the configuration LP. However, we are unable to prove any $o(\log n)$ approximation even in the restricted assignment case (note that the integrality gap and hardness instances in this paper only use restricted assignment). Finding a $o(\log n)$ approximation algorithm for any of these variants would be extremely interesting.

Abstract

We consider the Bin Packing problem with a partition matroid constraint. The input is a set of items of sizes in $[0,1]$, and a partition matroid over the items. The goal is to pack the items in a minimum number of unit-size bins, such that each bin forms an independent set in the matroid. This variant of classic Bin Packing has natural applications in secure storage on the Cloud, as well as in equitable scheduling and clustering with fairness constraints.

Our main result is an *asymptotic* fully *polynomial-time approximation scheme (AFPTAS)* for Bin Packing with a partition matroid constraint. This scheme generalizes the known AFPTAS for Bin Packing with Cardinality Constraints and improves the existing *asymptotic polynomial-time approximation scheme (APTAS)* for Group Bin Packing, which are both special cases of Bin Packing with partition matroid. We derive the scheme via a new method for rounding a (fractional) solution for a configuration-LP. Our method uses this solution to obtain *prototypes*, in which items are interpreted as placeholders for other items, and applies *fractional grouping* to modify a fractional solution (prototype) into one having desired integrality properties.

1 Introduction

The *bin packing (BP)* problem involves packing a set of items in a minimum number of containers (bins) of the same (unit) size. Bin Packing is one of the most studied problems in combinatorial optimization. Indeed, in many real-life scenarios, a solution for BP is essential for optimizing the allocation of resources. In this paper, we consider the Bin Packing problem with a partition matroid constraint. The input is a set of items of sizes in $[0,1]$, and a partition matroid over the items. The goal is to pack all the items in a minimum number of unit-size bins, such that each bin forms an independent set in the matroid.

Formally, a *bin packing with partition matroid (BPP)* instance is a tuple $\mathcal{I} = (I, \mathcal{G}, s, k)$, where I is a set of items, $\mathcal{G}$ is a partition of I into groups, $s : I \to [0,1]$ gives the item sizes, and $k : \mathcal{G} \to \mathbb{N}_{>0}$ sets a cardinality constraint for each group. The *instance matroid* of $\mathcal{I}$ is the partition matroid $\mathcal{M} = (I, \mathcal{S})$ where $\mathcal{S} = \{S \subseteq I \mid \forall G \in \mathcal{G} : \; |S \cap G| \leq k(G)\}$.

A *configuration* of the instance $\mathcal{I}$ is a subset of items $C \subseteq I$ such that $\sum_{\ell \in C} s(\ell) \leq 1$ and $C \in \mathcal{S}$. That is, the total size of items in C is at most one, and for each *group* $G \in \mathcal{G}$ the configuration C contains at most $k(G)$ items from G. A *packing* of $\mathcal{I}$ is a partition of I into m subsets called *bins* $(A_1, \ldots, A_m)$ such that A_b is a configuration for all $b \in [m]$.[1] The objective is to find a packing of all items in a minimal number of bins. Indeed, the special case where each group consists of a *single* item and $k(G) = 1$ for all $G \in \mathcal{G}$ is the classic Bin Packing problem.

Bin Packing with Partition Matroid has natural application in secure storage of project data in the Cloud. Computational projects of large data scale often rely on cloud computing. Commonly, the project data is also stored in the cloud. In this setting, a main concern is that a malicious entity might gain access to confidential data [13]. To strengthen security, data is dispersed among multiple cloud storage devices [24]. Projects are fragmented into critical tasks, so that access to several tasks cannot reveal substantial information about the entire project. To this end, at most $n(P)$ tasks of each project P can be stored on a single storage device. Viewing a cloud storage device as a *bin* and each project as a *group* containing a collection of critical tasks (*items*), the problem of storing a set of projects on a minimal number of (identical) storage devices yields an instance of BPP.

BPP arises also in machine scheduling. Consider the following variant of *equitable scheduling* on a single machine [25]. The input is a set of n clients, each having a collection of jobs with arbitrary processing times, and a single machine that is available at any day for a limited amount of time. To ensure fairness, at most k jobs of the same client can be processed in a single day, for some $k \geq 1$. The objective is to complete processing all the jobs in a minimum number of days, subject to the equitability constraints. An instance of the problem can be cast as an instance of BPP, where days are the bins, jobs are the items, and the set of jobs of each client forms a group.

Another application of BPP comes from clustering problems with fairness constraints, where we have a set of items, each belongs to certain *category*, and we seek a partition of the items into clusters (or, groups) with restriction on the number of items from each category selected to each cluster, to ensure fairness. One real-life example is grouping students for educational activities, in which there is some cost associated with each participating student, and an overall budget for each group. The goal is to partition the students into a minimal number of working groups subject to the budget constraints, such that each group is balanced in terms of protected attributes like gender or race (since studies indicate that students might learn better in a diverse group). This variant of the *multi-fair capacitated grouping problem* [39] yields an instance of BPP.

Let $\text{OPT} = \text{OPT}(\mathcal{I})$ be the value of an optimal solution for an instance $\mathcal{I}$ of a minimization problem $\mathcal{P}$. As in the Bin Packing problem, we distinguish between *absolute* and *asymptotic* approximation. For $\alpha \geq 1$, we say that $\mathcal{A}$ is an absolute α-approximation algorithm for $\mathcal{P}$ if for any instance $\mathcal{I}$ of $\mathcal{P}$ it holds that $\mathcal{A}(\mathcal{I})/\text{OPT}(\mathcal{I}) \leq \alpha$, where $\mathcal{A}(\mathcal{I})$ is the value of the solution returned by $\mathcal{A}$. Algorithm $\mathcal{A}$ is an *asymptotic* α-approximation algorithm if $\mathcal{A}(\mathcal{I}) \leq \alpha\text{OPT}(\mathcal{I}) + o(\text{OPT}(\mathcal{I}))$ for any instance $\mathcal{I}$ of $\mathcal{P}$. An *asymptotic polynomial-time approximation scheme (APTAS)* is a family of algorithms $(\mathcal{A}_\varepsilon)_{\varepsilon>0}$ such that, for every $\varepsilon > 0$, $\mathcal{A}_\varepsilon$ is a polynomial-time asymptotic $(1+\varepsilon)$-approximation algorithm for $\mathcal{P}$. An *asymptotic* fully *polynomial-time approximation scheme (AFPTAS)* is an APTAS $(\mathcal{A}_\varepsilon)_{\varepsilon>0}$ such that $\mathcal{A}_\varepsilon(\mathcal{I})$ runs in time $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$, where $|\mathcal{I}|$ is the encoding length of the instance $\mathcal{I}$; that is, there is a bivariate polynomial p such that $\mathcal{A}_\varepsilon(\mathcal{I})$ runs in time $p(|\mathcal{I}|, \frac{1}{\varepsilon})$ or less.

[1] For any $n \in \mathbb{N}$ we denote by $[n]$ the set $\{1, 2, \ldots, n\}$.

By known results for the special case of Bin Packing [20], BP cannot be approximated within (absolute) ratio better than $\frac{3}{2}$, unless P=NP. Thus, we focus in this paper on deriving better *asymptotic* approximation ratio for BPP. Given that classic BP admits an AFPTAS [32, 26], it is natural to ask whether the same holds for the problem with the added partition matroid constraint. We answer this question affirmatively.

▶ **Theorem 1.** *There is an* AFPTAS *for* BPP.

As a special case, our scheme improves upon the recent APTAS of Doron-Arad et al. [8] for *group bin packing (GBP)*, where the cardinality constraint of all groups is equal to one (i.e., $k(G) = 1 \; \forall G \in \mathcal{G}$). This problem has been studied since the mid-1990's [37, 31].[2] Theorem 1 also generalizes the AFTPASs of [15, 30] for *bin packing with cardinality constraints (BPCC)*, the special case of BPP where all items belong to a single group (i.e., $\mathcal{G} = \{I\}$).[3]

1.1 Our Technique

We derive our scheme via a new technique for rounding a (fractional) *configuration* LP (c-LP) solution. Our technique interprets the standard c-LP solution as a prototype for a solution which is then modified via a sequence of rounding steps; a polytope associated with the prototype is used to ensure the prototype represents a valid solution following each of the rounding steps.

High Level Approach

To obtain a packing of the input BPP instance $\mathcal{I}$, our scheme partitions the set of items I into subsets $I_1, \ldots, I_r$; for each subset of items I_j it generates a packing $A'_1, \ldots, A'_m$ of the *large* items $L_j \subseteq I_j$ (of sizes at least δ), and extends the packing (in the *packing phase*) to include the *small* items $S_j = I_j \setminus L_j$ using a greedy algorithm (see Section 2). For this procedure to work, the following crucial properties must be satisfied.

1. The size $s(\ell) \leq \delta$ of a small item $\ell \in S_j$ is much smaller than the free space $\delta \ll 1 - s(A'_b)$ in a bin A'_b.
2. There is an upper bound $k_{j,G}$ on the number of large items from each group $G \in \mathcal{G}$ in any bin A'_b.
3. For each group $G \in \mathcal{G}$, there cannot be "too many" small items from G in S_j.

Figure 1 illustrates the packing of items in I_j. By the above properties, a main part of our scheme deals with generation of a partition of I into $I_1, \ldots, I_r$ and the corresponding partial packings.[4]

Let $\mathcal{C}$ denote the set of configurations of a BPP instance $\mathcal{I} = (I, \mathcal{G}, s, k)$. Our rounding technique interprets the vectors $\bar{x} \in \mathbb{R}^{\mathcal{C}}_{\geq 0}$ (i.e., vectors having a non-negative entry for each configuration $C \in \mathcal{C}$) as *prototypes*. The prototype $\bar{x} \in \mathbb{R}^{\mathcal{C}}_{\geq 0}$ serves as a blueprint for a (fractional) packing. Within the context of prototypes, each item $\ell \in C$ of a configuration C is interpreted as a placeholder (or, "slot") for items which can replace it. Also, some items may be added, thus utilizing the available capacity of the configuration C (given by $1 - s(C)$), while the items replacing the slots utilize the capacity $s(C)$ of the configuration. The value $\bar{x}_C$ represents a solution in which $\bar{x}_C$ configurations match the blueprint corresponding to C.

[2] See Table 1 for a summary of known results for GBP.
[3] An outline of the organization of this paper is given in Section 1.3.
[4] See the details in Section 3.

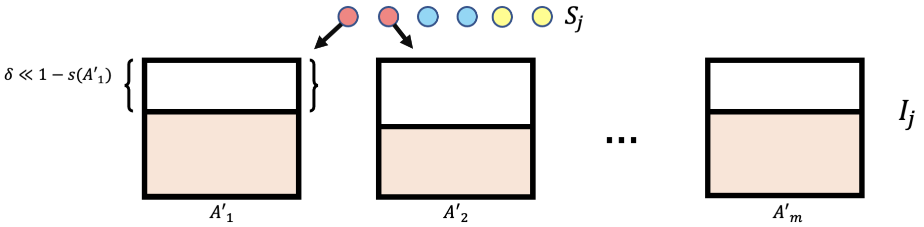

Figure 1 The set I_j in the partition $I_1, \dots, I_r$, along with a partial packing $A'_1, \dots, A'_m$ of the large items, L_j; the set S_j of remaining small items is represented by circles, whose colors indicate the groups. The items in S_j are added using a greedy algorithm.

A main building block in our scheme is an association of a polytope with each prototype. A non-empty polytope indicates the feasibility of a prototype. The partition of I into $I_1, \dots, I_r$ and S, and the generation of the partial packings $(A'_1, \dots, A'_m)$ relies on integrality properties of vertices in the polytope (associated with a prototype). However, for the integrality properties to be useful, we must obtain a *good prototype* $\bar{z}$, having a small number of configurations on the support (i.e, $\{C \in \mathcal{C} \mid \bar{z}_C > 0\}$), while the number of items in each configuration on the support must be small. We give below a high level description of how we construct a good prototype.

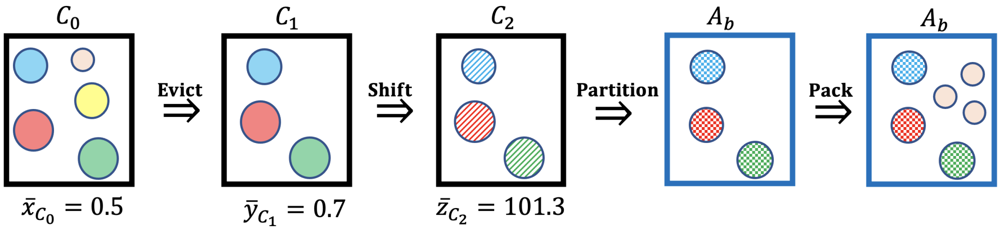

Figure 2 An illustration of the rounding process. Starting from a prototype $\bar{x}$, we follow a configuration C_0. The eviction process generates a prototype $\bar{y}$, where the value $\bar{x}_{C_0}$ is added to $\bar{y}_{C_1}$. In the shifting phase, $\bar{y}$ is transformed into a *good* prototype $\bar{z}$ in which items are replaced by a small number of representatives, and the entry $\bar{y}_{C_1}$ is added to $\bar{z}_{C_2}$. The partition phase uses the prototype $\bar{z}$ to define a partition $I_1, \dots, I_r$ of the items, and an initial packing $A_1, \dots, A_m$ for each I_j (containing the bin A_b in our example). Finally, in the packing phase, the remaining small items are added to the existing bins.

An initial prototype is obtained by solving a standard configuration-LP formulation of the problem. In this prototype, each item serves as a placeholder for itself. The algorithm modifies the prototype sequentially using two steps: *eviction* and *shifting*. The eviction step reduces the number of items per configuration on the support of the prototype. The shifting step reduces the overall number of distinct items used by configurations on the support. Thus, after the shifting, an item (or, a *slot*) may be used as a placeholder for many other items in the same group. Our construction in this step is non-trivial. Specifically, we use the *fractional grouping* technique introduced in [16] *constructively* (see the full version of the paper [9]). By the above, the number of configurations on the support of the constructed prototype is small, and our scheme can easily find a packing of the instance. We illustrate the main components of our multi-step rounding process in Figure 2.

Our technique may be useful in solving other packing problems, including, e.g., *bin packing with matching constraints* (see Section 4).

1.2 Prior Work

The special case of Group Bin Packing (GBP) (in which $k(G) = 1$ for all $G \in \mathcal{G}$) was first studied by Oh and Son [37]. This problem is a special case of *bin packing with conflicts (BPC)*, where the conflict graph is a *cluster graph* (see, e.g., [11] for a survey on recent results on BPC). An approximation ratio of 2.5 follows from the results of Jansen and Öhring [31] (for a generalization of GBP); this ratio was later improved by Epstein and Levin [14]. Better constants were given in several papers (e.g., [36, 1]). The best known asymptotic approximation for GBP prior to our work is an APTAS due to Doron-Arad et al. [8]. We summarize the known results for GBP in Table 1.

Table 1 Known Results for the special case of Group Bin Packing; $V(\mathcal{I}) = \max_{G \in \mathcal{G}} |G|$. The results of [31, 14, 1] for GBP follow as a special case from results for more general problems.

Authors	Year	Approximation
Oh and Son [37]	1995	$1.7 \cdot \text{OPT}(\mathcal{I}) + 2.19 \cdot V(\mathcal{I})$
Jansen and Öhring [31]	1997	$2.5 \cdot \text{OPT}(\mathcal{I})$
McCloskey and Shankar [36]	2005	$2 \cdot \text{OPT}(\mathcal{I}) + V(\mathcal{I})$
Epstein and Levin [14]	2008	$\frac{7}{3} \cdot \text{OPT}(\mathcal{I})$
Adany et al. [1]	2013	$2 \cdot \text{OPT}(\mathcal{I})$
Doron-Arad et al. [8]	2021	APTAS
This paper	2023	**AFPTAS**

The APTAS of [8] for GBP is based on extensive guessing of properties of an optimal solution which are then used as guidance for the assignment of items to bins; such enumeration is commonly used in studies of BP (e.g., [3]). We note that the algorithm of [8] does not round a solution for a configuration-LP, and cannot be viewed as a rounding algorithm in general. The extensive guessing leads to running time that is exponential in $\frac{1}{\varepsilon}$. For a special case of GBP, where the maximum cardinality of a group is some constant, an AFPTAS follows from a result of [27].

GBP was studied also in the context of scheduling on identical machines. Das and Wiese [6] introduced the problem of *makespan minimization with bag constraints*. In this generalization of the classic makespan minimization problem, each job belongs to a *bag*. The goal is to schedule the jobs on a set of m identical machines, for some $m \geq 1$, such that no two jobs in the same bag are assigned to the same machine, and the makespan is minimized. Das and Wiese [6] developed a PTAS for the problem with bag constraints. Later, Grage et al. [21] obtained an EPTAS.

Another special case of BPP is Bin Packing with Cardinality Constraints (BPCC), in which $|\mathcal{G}| = 1$, i.e., we have a single group G with $k(G) = k$, for some integer $k \geq 1$. BPCC has been studied since the 1970's [34, 35, 33, 4]. Epstein and Levin [15] presented an AFPTAS which relies on rounding a non-standard configuration-LP formulation of the problem. Later, Jansen et al. [30] gave an AFPTAS with improved additive term. The AFPTASs of [15, 30] rely on the property that if $k < \frac{1}{\varepsilon}$ then only $\frac{1}{\varepsilon}$ items fit into a bin; thus, linear shifting can be applied to the whole instance. We note that in a BPP instance (which consists of multiple groups) the cardinality bound for each group may be small (or even equal to 1), yet the number of items that can be packed in a single bin may be arbitrarily large. This is one of several hurdles encountered when attempting to adapt the techniques of [15, 30] to our setting of BP with a partition matroid constraint.

In the *matroid partitioning* problem, we are given a ground set U and a matroid $\mathcal{M} = (U, \mathcal{S})$, where $\mathcal{S}$ is a family of subsets of U, known as the *independent sets* of the matroid. We seek a partition of U into as few independent sets as possible. The problem is polynomially solvable for any matroid $\mathcal{M}$ over U using a combinatorial algorithm (see, e.g., [12, 19]). When $\mathcal{M}$ is a partition matroid, the matroid partitioning problem can be viewed as a variant of BPP with unbounded bin capacities.

The use of configuration-LP (c-LP) in approximation algorithms started in the seminal paper of Karmakar and Karp on BP [32]. Their approach is to round the item sizes prior to solving a c-LP. Similar approaches, in which item sizes are rounded or the instance is restructured prior to solving the c-LP, can be found also in later works (e.g., [15]). Other works obtain an integral solution by applying randomized rounding to the solution of a standard c-LP. This includes the *Round & Approx* technique of Bansal et al. [2] and the tight approximation for the *separable assignment problem (SAP)* due to Fleischer et al. [18]. In [28] and [29], Jansen combines techniques for *2D strip packing* to round the solution of c-LP for multiple knapsack. Our deterministic rounding technique deviates significantly from these known approaches.

To the best of our knowledge, Bin Packing with Partition Matroid is studied here for the first time.

1.3 Organization

In Section 2 we include some definitions and notation. Section 3 gives an overview of our scheme, that is applied to a *structured* instance. Due to space constraints, the technical sections along with most of the proofs are relegated to the full version of the paper [9]. In Section 4 we give a summary and directions for future work.

2 Preliminaries

Let $\mathcal{A}$ be an algorithm that accepts as input $\varepsilon > 0$. We say the running time of $\mathcal{A}$ is poly$(|\mathcal{I}|, \frac{1}{\varepsilon})$ if there is a two-variable polynomial $p(x, y)$ such that $p(|\mathcal{I}|, \frac{1}{\varepsilon})$ is an upper bound on the running time of $\mathcal{A}(\mathcal{I}, \varepsilon)$. To allow a simpler presentation of the results, we assume throughout the paper that the set of items I is $\{1, 2, \ldots, n\}$, and the items are sorted in non-increasing order by sizes, i.e., $s(1) \geq s(2) \geq \ldots s(n)$.

2.1 Tackling the Small Items

The classic asymptotic approximation schemes for Bin Packing (see, e.g., [17, 32]) rely on the key property that *small* items can be added to a partial packing of the instance with little overhead, using simple algorithms such as First-Fit (see, e.g., [40]). We note that packing small items in the presence of a partition matroid constraint is more involved. Even for the special case of BP with a cardinality constraint, the small items cannot be packed using simple classic BP heuristics (see, e.g., [15]).

We show below that an efficient packing of the small items of a BPP instance can still be found using a relatively simple algorithm; however, the setting in which the algorithm can be applied is more restrictive, and items cannot be easily added to a partial packing of the instance (i.e., a set of configurations). Furthermore, the quality of such a packing depends on the *cardinality bound* of the BPP instance $\mathcal{I} = (I, \mathcal{G}, s, k)$, defined by $V(\mathcal{I}) = \max_{G \in \mathcal{G}} \left\lceil \frac{|G|}{|k(G)|} \right\rceil$. Formally,

▶ **Lemma 2.** *Given a* BPP *instance $\mathcal{I} = (I, \mathcal{G}, s, k)$ and $\delta \in (0, 0.5)$, such that $s(\ell) \leq \delta$ for all $\ell \in I$, there is an algorithm* Greedy *that returns in polynomial time a packing of $\mathcal{I}$ in at most $(1 + 2\delta) \cdot \max\{s(I),\ V(\mathcal{I})\} + 2$ bins.*

The proof of Lemma 2 is given in [9].

2.2 Structuring the Instance

Our scheme initially transforms a given BPP instance into one having a structure which depends on the parameter $\varepsilon > 0$. In this new instance, only a small number of groups may contain relatively large items. Let $K : (0, 0.1) \to \mathbb{R}$, where $K(\varepsilon) = \varepsilon^{-\varepsilon^{-2}}$ for all $\varepsilon \in (0, 0.1)$. We use K for defining a structured instance.

▶ **Definition 3.** *Given a BPP instance $\mathcal{I} = (I, \mathcal{G}, s, k)$ and $\varepsilon \in (0, 0.1)$, we say that $\mathcal{I}$ is* ε-structured *if there is $\mathcal{B} \subseteq \mathcal{G}$ such that $|\mathcal{B}| \leq K(\varepsilon)$ and for all $G \in \mathcal{G} \setminus \mathcal{B}$ and $\ell \in G$ it holds that $s(\ell) < \varepsilon^2$.*

Following the structuring step, our scheme proceeds to solve BPP on the structured instance. As a final step, the packing found for the structured instance is transformed into a packing of the original instance. This is formalized in the next result.

▶ **Lemma 4.** *There is a pair of algorithms,* Reduce *and* Reconstruct, *which satisfy the following.*

1. *Given a* BPP *instance $\mathcal{J}$ and $\varepsilon > 0$ such that $\varepsilon^{-1} \in \mathbb{N}$, algorithm* Reduce *returns in time* $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$ *an ε-structured BPP instance $\mathcal{I}$, where* $\text{OPT}(\mathcal{I}) \leq \text{OPT}(\mathcal{J})$.
2. *Given a* BPP *instance $\mathcal{J}$, $\varepsilon > 0$ such that $\varepsilon^{-1} \in \mathbb{N}$, and a packing A' for $\mathcal{I} =$* Reduce$(\mathcal{J}, \varepsilon)$ *of size m', algorithm* Reconstruct *returns in time* $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$ *a packing A for the instance $\mathcal{J}$ of size m, where $m \leq m' + 13\varepsilon \cdot \text{OPT}(\mathcal{J}) + 1$.*

The structured instance $\mathcal{I}$ is obtained from $\mathcal{J}$ by reassigning items of size at least ε^2 from all but a few groups to a new group. The reconstruction algorithm modifies the packing of $\mathcal{I}$ such that each bin in the solution is a configuration of $\mathcal{J}$. The proof of Lemma 4 (given in [9]) is inspired by ideas of [6, 21, 8]. By Lemma 4, an AFTPAS for ε-structured BPP instances implies an AFTPAS for general BPP instances.

3 Approximation Algorithm for ε-Structured Instances

In this section we give an overview of our scheme. For $\varepsilon \in (0, 0.1)$ such that $\varepsilon^{-1} \in \mathbb{N}$, let $\mathcal{I} = (I, \mathcal{G}, s, k)$ be an ε-structured BPP instance. Recall that a *configuration* of $\mathcal{I}$ is a subset of items $C \subseteq I$ such that $\sum_{\ell \in C} s(\ell) \leq 1$, and $|C \cap G| \leq k(G)$ for all $G \in \mathcal{G}$. Let $\mathcal{C}(\mathcal{I})$ be the set of all configurations of $\mathcal{I}$; we use $\mathcal{C}$ when the instance $\mathcal{I}$ is clear from the context. Also, for every item $\ell \in I$ let $\mathcal{C}[\ell] = \{C \in \mathcal{C} \mid \ell \in C\}$ be the set of configurations of $\mathcal{I}$ that contain ℓ. A key component in our scheme is the construction of a *prototype* of a packing; a prototype gives a non-negative value to each configuration, which (informally) indicates the selection of the configuration. Specifically,

▶ **Definition 5.** *Given a* BPP *instance $\mathcal{I}$, a* prototype *is a vector $\bar{x} \in \mathbb{R}^{\mathcal{C}}_{\geq 0}$.*

In the context of prototypes, each configuration $C \in \mathcal{C}$ is interpreted as a set of placeholders called *types*. Each item $j \in C$ is a *slot-type*, which is a placeholder for a smaller or equally sized item of the same group. Also, the unused capacity of the configuration C (i.e., $1 - s(C)$) serves as a placeholder for additional items; we refer to this placeholder as the *configuration-type* C. Thus, C is interpreted as the set of slot-types of j for each $j \in C$ and the configuration-type of C itself.

Intuitively, a slot-type (configuration-type) can be replaced by an item (items) which *fit* into it. For any $j \in I$ define $\mathsf{group}(j) = G$, where $G \in \mathcal{G}$ is the unique group such that $j \in G$. The subset of items that fit in place of the slot-type $j \in I$ is

$$\mathsf{fit}(j) = \{\ell \in \mathsf{group}(j) \mid s(\ell) \leq s(j)\} \qquad \forall j \in I. \tag{1}$$

For our algorithm to work, the items which fit into the configuration-type $C \in \mathcal{C}$ must be *small* relative to the unused capacity of C. We define the subset of items that fit into the configuration-type $C \in \mathcal{C}$ by

$$\mathsf{fit}(C) = \{\ell \in I \mid s(\ell) \leq \min\{\varepsilon^2, \varepsilon \cdot (1 - s(C))\}\} \qquad \forall C \in \mathcal{C}. \tag{2}$$

In words, $\mathsf{fit}(C)$ contains items of sizes smaller than ε^2 and also at most ε-fraction of the unused capacity of C. Figure 3 illustrates the above definitions.

For any prototype $\bar{x}$ we define the *$\bar{x}$-polytope* as a set of fractional packings, in which items are fractionally assigned to slot-types and configuration-types. The set of *types* of the instance $\mathcal{I}$ is $I \cup \mathcal{C}$. That is, the slot-types I and configuration-types $\mathcal{C}$. A point in the $\bar{x}$-polytope has an entry for each pair of an item $\ell \in I$ and a type $t \in I \cup \mathcal{C}$ which represents the fractional *assignment* of the item to the type. Formally,

▶ **Definition 6.** *Given a* BPP *instance $\mathcal{I}$, the set $\mathcal{C}$ of configurations for $\mathcal{I}$, and a prototype $\bar{x}$ of $\mathcal{I}$, the $\bar{x}$-polytope is the set containing all points $\bar{\gamma} \in [0,1]^{I \times (I \cup \mathcal{C})}$ which satisfy the following constraints.*

$$\bar{\gamma}_{\ell,t} = 0 \qquad \forall \ell \in I, t \in I \cup \mathcal{C} \text{ s.t. } \ell \notin \mathsf{fit}\,(t) \tag{3}$$

$$\sum_{\ell \in I} \bar{\gamma}_{\ell,C} \cdot s(\ell) \leq (1 - s(C)) \cdot \bar{x}_C \qquad \forall C \in \mathcal{C} \tag{4}$$

$$\sum_{\ell \in G} \bar{\gamma}_{\ell,C} \leq \bar{x}_C \cdot (k(G) - |C \cap G|) \qquad \forall G \in \mathcal{G}, C \in \mathcal{C} \tag{5}$$

$$\sum_{\ell \in I} \bar{\gamma}_{\ell,j} \leq \sum_{C \in \mathcal{C}[j]} \bar{x}_C \qquad \forall j \in I \tag{6}$$

$$\sum_{t \in I \cup \mathcal{C}} \bar{\gamma}_{\ell,t} \geq 1 \qquad \forall \ell \in I \tag{7}$$

Constraints (3) indicate that an item $\ell \in I$ cannot be assigned to type t if ℓ does not fit in t. Constraints (4) set an upper bound on the total (fractional) size of items assigned to each configuration-type $C \in \mathcal{C}$. This bound is equal to the residual capacity of C times the fractional number of bins packed with C, given by $\bar{x}_C$. Constraints (5) bound the number of items in each group G assigned to configuration-type C; at most $k(G) - |C \cap G|$ items in G can be added to C without violating the cardinality constraint of G. Constraints (6) bound the number of items assigned to slot-type $j \in I$ by the total selection of configurations containing j in $\bar{x}$. Finally, constraints (7) guarantee that each item is fully assigned to the types.

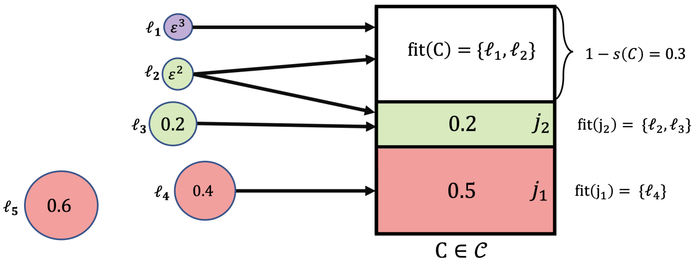

Figure 3 An example of items $\ell_1, \ldots, \ell_5$ of sizes $\varepsilon^3, \varepsilon^2, 0.2, 0.4, 0.6$, respectively, along with a configuration $C = \{j_1, j_2\} \in \mathcal{C}$ interpreted as the slot-types j_1, j_2 of sizes 0.5, 0.2 and the configuration-type C. The colors of the items and slot-types indicate their corresponding groups. An arrow indicates that the item on the left fits with a slot-type or with the configuration-type C.

Let $\mathsf{supp}(\bar{x}) = \{C \in \mathcal{C} \mid \bar{x}_C > 0\}$ be the *support* of $\bar{x}$. Throughout this paper, we use prototypes $\bar{x}$ for which $\mathsf{supp}(\bar{x})$ is polynomial in the input size; thus, these prototypes have sparse representations. Our scheme first converts an initial prototype $\bar{x}$ (defined by a solution for the configuration-LP) into a *good* prototype $\bar{z}$ as defined below, and then constructs a packing based on $\bar{z}$. Let $Q : (0, 0.1) \rightarrow \mathbb{R}$ where $Q(\varepsilon) = \exp(\varepsilon^{-17})$ for all $\varepsilon \in (0, 0.1)$. Then,

▶ **Definition 7.** *Given $\varepsilon \in (0, 0.1)$ and an ε-structured* BPP *instance $\mathcal{I}$, a prototype $\bar{z}$ of $\mathcal{I}$ is a* good prototype *if the $\bar{z}$-polytope is non-empty, $|\mathsf{supp}(\bar{z})| \leq Q(\varepsilon)$, and $|C| \leq \varepsilon^{-10}$ for all $C \in \mathsf{supp}(\bar{z})$.*

To construct a good prototype, our algorithm first finds an initial prototype $\bar{x}$ using a Configuration-LP of the problem.[5] However, $\bar{x}$ is not necessarily a good prototype, since it may have a support of large size. Therefore, we apply a non-trivial rounding process, starting from the initial prototype $\bar{x}$, and eventually generate a good prototype $\bar{z}$. We consider this rounding process, along with the notions of prototype and $\bar{x}$-polytope, the core technical contribution of this paper. The next result summarizes the main properties of our algorithm for finding a good prototype, presented in Section 3.1. We use $\|\bar{x}\| = \sum_{C \in \mathcal{C}} \bar{x}_C$ to denote the ℓ_1-norm of a prototype $\bar{x}$.

▶ **Lemma 8.** *There is an algorithm* Prototype *that given $\varepsilon \in (0, 0.1)$ and an ε-structured* BPP *instance $\mathcal{I}$, returns in time* $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$ *a good prototype $\bar{z}$ of $\mathcal{I}$ such that $\|\bar{z}\| \leq (1 + 19\varepsilon) \cdot \text{OPT}(\mathcal{I}) + Q(\varepsilon)$.*

Given a good prototype $\bar{z}$, our scheme finds an efficient packing of the instance. This phase relies on integrality properties of the $\bar{z}$-polytope, combined with a matching-based algorithm and a greedy assignment of relatively small items using Algorithm Greedy (Lemma 2).

▶ **Lemma 9.** *There is an algorithm* Solution *that given $\varepsilon \in (0, 0.1)$, an ε-structured* BPP *instance $\mathcal{I}$, and a good prototype $\bar{z}$ of $\mathcal{I}$, returns in time* $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$ *a packing of $\mathcal{I}$ in at most $(1 + 2\varepsilon) \cdot \|\bar{z}\| + 5\varepsilon^{-22} \cdot Q^2(\varepsilon)$ bins.*

The proof of Lemma 9 is given in Section 3.2. Using the above components, we obtain an AFPTAS for ε-structured instances. The pseudocode of the scheme is given in Algorithm 1.

▶ **Lemma 10.** *Given $\varepsilon \in (0, 0.1)$, $\varepsilon^{-1} \in \mathbb{N}$, and an ε-structured* BPP *instance $\mathcal{I}$, Algorithm 1 returns in time* $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$ *a packing of $\mathcal{I}$ of size at most $(1 + 60\varepsilon) \cdot \text{OPT}(\mathcal{I}) + (Q(\varepsilon))^3$.*

[5] See Section 3.1.

Algorithm 1 AFPTAS$(\mathcal{I}, \varepsilon)$.

```
Input   : An $\varepsilon$-structured instance $\mathcal{I}$ and $\varepsilon \in (0, 0.1)$ such that $\varepsilon^{-1} \in \mathbb{N}$
Output  : A packing of $\mathcal{I}$
1 Find a good prototype $\bar{z} = \mathsf{Prototype}(\mathcal{I}, \varepsilon)$.
2 Return a packing $\Phi = \mathsf{Solution}(\mathcal{I}, \varepsilon, \bar{z})$.
```

Lemma 10 follows from Lemmas 8 and 9. Theorem 1 can be easily derived using Lemmas 10 and 4. We give the full proofs in [9].

3.1 Algorithm Prototype

In this section we present Algorithm Prototype which finds a good prototype for a given ε-structured instance. The algorithm uses an LP relaxation of the given BPP instance. For $\varepsilon \in (0, 0.1)$ such that $\varepsilon^{-1} \in \mathbb{N}$, let $\mathcal{I} = (I, \mathcal{G}, s, k)$ be an ε-structured BPP instance. Define the *configuration-LP* of $\mathcal{I}$ as:

$$\begin{array}{lll} \min & \sum_{C \in \mathcal{C}} \bar{x}_C & \\ \text{s.t.} & \sum_{C \in \mathcal{C}[\ell]} \bar{x}_C = 1 & \forall \ell \in I \\ & \bar{x}_C \geq 0 & \forall C \in \mathcal{C} \end{array} \tag{8}$$

A solution for the LP (8) assigns to each configuration $C \in \mathcal{C}$ a real number $\bar{x}_C \in [0, 1]$ which indicates the fractional selection of C for the solution such that each item is fully *covered*. Observe that a solution for (8) is in particular a prototype of $\mathcal{I}$.

Note that the configuration-LP (8) has an exponential number of variables; thus, it cannot be solved in polynomial time by applying standard techniques. A common approach for solving such linear programs is to use a *separation oracle* for the dual program.

Consider the *configuration maximization problem (CMP)* in which we are given a BPP instance $\mathcal{I} = (I, \mathcal{G}, s, k)$ and a weight function $w : I \to \mathbb{R}_{\geq 0}$; the objective is to find a configuration $C \in \mathcal{C}$ such that $\sum_{\ell \in C} w(\ell)$ is maximized. By a well known connection between separation and optimization, an FPTAS for CMP implies an FPTAS for the configuration-LP of $\mathcal{I}$ [22, 18, 23, 38]. CMP can be solved via an easy reduction to *knapsack with partition matroid*, that is known to admit an FPTAS [10]. Thus, we have

▶ **Lemma 11.** *There is an algorithm* SolveLP *that given a* BPP *instance* $\mathcal{I}$ *and* $\varepsilon > 0$*, returns in time* poly$(|\mathcal{I}|, \frac{1}{\varepsilon})$ *a solution for the configuration*-LP *of* $\mathcal{I}$ *of value at most* $(1 + \varepsilon)\text{OPT}$*, where* OPT *is the value of an optimal solution for the configuration*-LP *of* $\mathcal{I}$*.*

We give the proof of Lemma 11 in [9]. A solution $\bar{x}$ for the Configuration-LP (8) is a prototype of the instance such that the $\bar{x}$-polytope is non-empty; in particular, it contains the point $\bar{\gamma}$ where $\bar{\gamma}_{\ell,j} = 1 \; \forall \ell, j \in I$ such that $\ell = j$, and $\bar{\gamma}_{\ell,t} = 0$ otherwise (note that this property does not hold for the good prototype $\bar{z}$ returned by Algorithm Prototype). Our intermediate goal is an *evicted prototype* $\bar{y}$, having configurations of bounded cardinality on its support, but with properties similar to those of solutions for (8). We say that an item $\ell \in I$ is ε-large if $s(\ell) \geq \varepsilon^2$. We use $L(\varepsilon, \mathcal{I})$ to denote the set of ε-large items of an instance $\mathcal{I}$. If $\mathcal{I}$ and ε are known by context we simply use L (instead of $L(\varepsilon, \mathcal{I})$). We now formalize the above.

▶ **Definition 12.** *Let $\varepsilon \in (0, 0.1)$ such that $\varepsilon^{-1} \in \mathbb{N}$ and $\mathcal{I}$ an ε-structured BPP instance. A prototype $\bar{y}$ of $\mathcal{I}$ is called an* evicted prototype *if the following holds.*

1. *For all $C \in \mathsf{supp}(\bar{y})$ it holds that $|C| \leq \varepsilon^{-10}$ and $s(C \setminus L) \leq \varepsilon$.*
2. *There exists $\bar{\gamma}$ in the $\bar{y}$-polytope such that $\bar{\gamma}_{\ell,j} = 0$ for all $\ell, j \in I$ where $\ell \neq j$.*
3. *$\sum_{C \in \mathcal{C}[\ell]} \bar{y}_C \leq 2$ for every $\ell \in I$.*

Given a solution $\bar{x}$ for the configuration-LP (8), we construct an evicted prototype $\bar{y}$ with $\|\bar{y}\| \approx \|\bar{x}\|$. Our technique fractionally maps each configuration $C \in \mathsf{supp}(\bar{x})$ to other configurations, where relatively small items are discarded in the mapping. To show that the $\bar{y}$-polytope is non-empty, we generate a point in the $\bar{y}$-polytope by assigning (fractionally) discarded items to configuration-types (see Definition 6). The result of this process is outlined in the next lemma.

▶ **Lemma 13.** *There is an algorithm* Evict *which given $\varepsilon \in (0, 0.1)$ such that $\varepsilon^{-1} \in \mathbb{N}$, an ε-structured* BPP *instance $\mathcal{I}$, and a solution $\bar{x}$ for the configuration-LP* (8)*, returns in time* $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$ *an evicted prototype $\bar{y}$ such that $\|\bar{y}\| \leq (1 + \varepsilon)\|\bar{x}\|$.*

A complete presentation of algorithm Evict and the proof of Lemma 13 are given in [9]. Observe that property 2 of Definition 12 allows $\bar{\gamma}_{\ell,C} > 0$ for item $\ell \in I$ and a configuration-type $C \in \mathcal{C}$; the property that $\bar{\gamma}_{\ell,j} > 0$ for $\ell \neq j$ is obtained only in the next step. Moreover, note that Evict does not return the vector $\bar{\gamma}$ but only guarantees its existence.

Given an evicted prototype $\bar{y}$, our scheme uses algorithm Shift to generate a good prototype $\bar{z}$ with $\|\bar{z}\| \approx \|\bar{y}\|$. As in algorithm Evict, we rely on a fractional mapping between configurations to construct $\bar{z}$; here, our goal is to significantly decrease $|\mathsf{supp}(\bar{z})|$ w.r.t. $|\mathsf{supp}(\bar{y})|$ while keeping the $\bar{z}$-polytope non-empty. One key observation utilizes combinatorial properties of the instance to show that items from most groups can be discarded in the mapping (the items may be assigned to configuration-types in the $\bar{z}$-polytope). Items of the remaining groups are mapped to a small number of *representatives*, using a non-trivial application of fractional grouping.

▶ **Lemma 14.** *There is an Algorithm* Shift *that given $\varepsilon \in (0, 0.1)$ such that $\varepsilon^{-1} \in \mathbb{N}$, an ε-structured* BPP *instance $\mathcal{I}$ and an evicted prototype $\bar{y}$, returns in time* $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$ *a good prototype $\bar{z}$ such that $\|\bar{z}\| \leq (1 + 5\varepsilon)\|\bar{y}\| + Q(\varepsilon)$.*

An elaborate presentation of Algorithm Shift and the proof of Lemma 14 are given in [9]. Finally, Algorithm Prototype finds a good prototype by computing Algorithms SolveLP, Evict, and Shift sequentially. We give the pseudocode in Algorithm 2. The proof of Lemma 8 easily follows from Lemmas 11, 13, and 14; we give the proof in [9].

Algorithm 2 Prototype$(\mathcal{I}, \varepsilon)$.

```
Input  : An $\varepsilon$-structured instance $\mathcal{I}$ and $\varepsilon \in (0, 0.1)$ such that $\varepsilon^{-1} \in \mathbb{N}$
Output : A good prototype
Find a solution for the configuration-LP of $\mathcal{I}$; that is, $\bar{x} = \mathsf{SolveLP}(\mathcal{I}, \varepsilon)$.
Find an evicted prototype $\bar{y} = \mathsf{Evict}(\mathcal{I}, \bar{x}, \varepsilon)$.
Return a good prototype $\bar{z} = \mathsf{Shift}(\mathcal{I}, \bar{y}, \varepsilon)$.
```

3.2 Algorithm Solution

In this section we show how integrality properties of a good prototype yield an efficient packing of the instance. For $\varepsilon \in (0, 0.1)$ such that $\varepsilon^{-1} \in \mathbb{N}$, let $\mathcal{I} = (I, \mathcal{G}, s, k)$ be an ε-structured BPP instance. The next lemma shows that if a prototype $\bar{x}$ has a small support, and each configuration in the support contains a few items (as for good prototypes), then the vertices of the $\bar{x}$-polytope are almost integral. Thus, given a vertex $\bar{\lambda}$ of such $\bar{x}$-polytope, the items assigned fractionally by $\bar{\lambda}$ can be packed using only a small number of extra bins.

▶ **Lemma 15.** *Let $\mathcal{I}$ be a* BPP *instance, $k \in \mathbb{N}_{\geq 1}$, and a prototype $\bar{x}$ of $\mathcal{I}$ such that for all $C \in \mathsf{supp}(\bar{x})$ it holds that $|C| \leq k$ and $\bar{x}_C \in \mathbb{N}$. Then, for any vertex $\bar{\lambda}$ in the $\bar{x}$-polytope for which constraints* (7) *hold with equality,*

$$\left|\left\{\ell \in I \mid \exists t \in I \cup \mathcal{C} \text{ s.t. } \bar{\lambda}_{\ell,t} \in (0,1)\right\}\right| \leq 8k^2 \cdot |\mathsf{supp}(\bar{x})|^2.$$

The proof of Lemma 15 bears some similarity to a proof of [7], which shows the integrality properties of a somewhat different polytope. We give the detailed proof in [9].

Given a good prototype $\bar{z}$, our scheme finds a packing of the instance using a partition of the items into slot-types and configuration-types; intuitively, items assigned to slot-types are already packed (using the integrality property of the $\bar{z}$-polytope) and items assigned to configuration-types will be added using Greedy. This relies on the following construction.

For configurations $S, C \in \mathcal{C}$, we say that S is *allowed* in C if each item $\ell \in S$ can be mapped to a distinct slot $j \in C$, such that $\ell \in \mathsf{fit}(j)$. We consider packings of a subset of items to which we call a *category.* Each category is associated with (i) a configuration $C \in \mathcal{C}$ such that all bins in the category are allowed in C, and (ii) a *completion*: a subset of (unpacked) items bounded by total size and number of items per group, where each item fits with C. This is formalized in the next definition.

▶ **Definition 16.** *Let $\varepsilon \in (0, 0.1)$, an ε-structured BPP instance $\mathcal{I} = (I, \mathcal{G}, s, k)$, a configuration $C \in \mathcal{C}$, a packing $B = (B_1, \ldots, B_m)$ of a subset of I (category), and $D \subseteq I$ (completion). We say that B is a category of C and D if the following holds.*

- *For any $i \in [m]$, B_i is allowed in C.*
- *$D \subseteq \mathsf{fit}(C)$.*
- *$s(D) \leq (1 - s(C)) \cdot m$.*
- *For any $G \in \mathcal{G}$ it holds that $|D \cap G| \leq m \cdot (k(G) - |C \cap G|)$.*

The motivation behind this construction, is that Algorithm Greedy (Lemma 2) can be used to assign the completion to the existing bins of the category using only a small number of extra bins. Thus, our end-goal from the good prototype $\bar{z}$ is to obtain an *ε-nice partition*: a packing of a subset of I such that the bins in the packing are partitioned into a bounded number of categories; also, we require that each item $\ell \in I$ is either in this packing or in a completion of a category. The above constraints are analogous to constraints (3)-(7) of the $\bar{z}$-polytope, that is used for finding an assignment of the items to slots and configurations. This is formalized in Definition 17. An example is given in Figure 4.

▶ **Definition 17.** *Given $\varepsilon \in (0, 0.1)$, an ε-structured BPP instance $\mathcal{I} = (I, \mathcal{G}, s, k)$, an ε-*nice partition *$\mathcal{B}$ of $\mathcal{I}$ is a packing $(A_1, ..., A_m)$ of a subset of I, configurations $\mathcal{H} \subseteq \mathcal{C}$, categories $(B_C)_{C \in \mathcal{H}}$, and completions $(D_C)_{C \in \mathcal{H}}$ such that the following holds.*

- *$|\mathcal{H}| \leq \varepsilon^{-22} Q^2(\varepsilon)$.*
- *$\{B_C\}_{C \in \mathcal{H}}$ is a partition of $\{A_i \mid i \in [m]\}$.*
- *$\{D_C\}_{C \in \mathcal{H}}$ is a partition of $I \setminus \bigcup_{i \in [m]} A_i$.*
- *For all $C \in \mathcal{H}$ it holds that B_C is a category of C and D_C.*

The size *of $\mathcal{B}$ is m.*

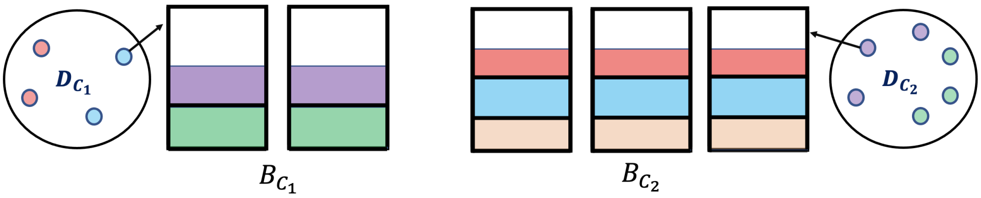

Figure 4 An example of an ε-nice partition, which consists of a packing in five bins partitioned into two categories $\mathcal{H} = \{B_{C_1}, B_{C_2}\}$. In addition, D_{C_1} and D_{C_2} are the completions of B_{C_1} and B_{C_2}, respectively. Colors indicate groups: if the cardinality bound of the blue group is 1, then D_{C_1} contains at most 2 blue items and D_{C_2} cannot contain blue items.

To obtain an ε-nice partition, Algorithm Partition initially rounds up the entries of $\bar{z}$ to obtain the prototype $\bar{z}^*$. It then finds a vertex $\bar{\lambda}$ of the $\bar{z}^*$-polytope, which is almost integral by Lemma 15. Thus, with the exception of a small number of items, each item is fully assigned either to a slot or to a configuration. Algorithm Partition uses $\bar{\lambda}$ to construct an ε-nice partition. We generate a category for each $C \in \mathsf{supp}(\bar{z}^*)$ and let $D_C = \{\ell \in I \mid \bar{\lambda}_{\ell,C} = 1\}$ be the set of all items assigned to C. We also generate $\bar{z}^*_C$ copies (bins) of each configuration and replace its slots by items via matching.

▶ **Lemma 18.** *There is an algorithm* Partition *that given $\varepsilon \in (0, 0.1)$ such that $\varepsilon^{-1} \in \mathbb{N}$, an ε-structured BPP instance $\mathcal{I}$, and a good prototype $\bar{z}$ of $\mathcal{I}$, returns in time* $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$ *an ε-nice partition of $\mathcal{I}$ of size at most $\|\bar{z}\| + \varepsilon^{-22}Q^2(\varepsilon)$.*

Algorithm Partition is presented in [9]. Given an ε-nice partition of size m, a packing of the instance in roughly m bins is obtained using the next lemma.

▶ **Lemma 19.** *There is a polynomial-time algorithm* Pack *which given $\varepsilon \in (0, 0.1)$ such that $\varepsilon^{-1} \in \mathbb{N}$, an ε-structured BPP instance $\mathcal{I}$, and ε-nice partition of $\mathcal{I}$ of size m, returns in time* $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$ *a packing of $\mathcal{I}$ in at most $(1 + 2\varepsilon)m + 2\varepsilon^{-22}Q^2(\varepsilon)$ bins.*

Algorithm Pack utilizes Algorithm Greedy to add the items in a completion of a category to the bins of this category, possibly using a few extra bins. Algorithm Pack and Algorithm Greedy are presented in [9]. Finally, we construct Algorithm Solution, which first finds an ε-nice partition and then use it to find a packing for the instance. We give the pseudocode in Algorithm 3.

Proof of Lemma 9. By Lemma 18, $\mathcal{B}$ is an ε-nice partition with size at most $\|\bar{z}\| + \varepsilon^{-22} \cdot Q^2(\varepsilon)$. Then, by Lemma 19, Φ is a full packing of $\mathcal{I}$ using at most $(1 + 2\varepsilon) \cdot \|\bar{z}\| + 5\varepsilon^{-22} \cdot Q^2(\varepsilon)$ bins. The running time is $\text{poly}(|\mathcal{I}|, \frac{1}{\varepsilon})$ by Lemmas 18, 19. ◀

Algorithm 3 Solution($\mathcal{I}, \bar{z}, \varepsilon$).

```
Input  : $\varepsilon \in (0, 0.1)$, $\varepsilon^{-1} \in \mathbb{N}$, an $\varepsilon$-structured instance $\mathcal{I}$, a good prototype $\bar{z}$ of $\mathcal{I}$
Output : A packing of $\mathcal{I}$
Find an $\varepsilon$-nice partition $\mathcal{B}$ of $\mathcal{I}$ by Partition($\mathcal{I}, \bar{z}, \varepsilon$).
Return a packing $\Phi$ = Pack($\mathcal{I}, \mathcal{B}, \varepsilon$).
```

4 Discussion

In this paper we present an AFPTAS for Bin Packing with Partition Matroid. While BPP is a natural generalization of Bin Packing variants that have been studied in the past, to the best of our knowledge it is studied here for the first time. Our result improves upon the APTAS of [8] for the well studied special case of Group Bin Packing, and generalizes the AFPTASs of [15, 30] for the special case of Bin Packing with Cardinality Constraints. Our scheme applies a novel rounding method to solutions of the configuration-LP formulation of the problem. The rounding process relies on the key notion of a *prototype*, in which items are placeholders for other items, and sophisticated use of fractional grouping [16]. Our scheme demonstrates the power of this fractional version of linear grouping in solving constrained packing problems; it also shows how fractional grouping can be used *constructively*.

The rounding method introduced in this paper seems useful also for other settings. A preliminary study shows we can apply our method to obtain a polynomial time approximation scheme for *Multiple Knapsack with Partition Matroid*, a generalization of the Multiple Knapsack problem (see, e.g., [5, 28]) in which the items assigned to each bin form an independent set of a partition matroid. Furthermore, we can derive approximation algorithms for Machine Scheduling with Partition Matroid, a generalization of the classic Machine Scheduling problem in which the jobs assigned to a machine must be an independent set of a partition matroid. We note that this problem is a generalization of Machine Scheduling with Bag Constraints studied in [6, 21].

Another intriguing direction for future work is to apply our framework to Bin Packing with other types of constraints. We give two potential examples. The problem of Bin Packing with Partition Matroid is a special case of Bin Packing with Matroid, for which the input is a set of items I, a size function $s : I \to [0, 1]$ and a matroid $\mathcal{M}$. The objective is to partition I into a minimal number of bins $A_1, \ldots, A_m$ such that A_b is an independent set of the matroid $\mathcal{M}$, and $s(A_b) \leq 1$ for all $b \in [m]$. While this problem is a natural generalization of both Bin Packing and Matroid Partitioning, we were unable to find any published results. It would be interesting to obtain an APTAS for Bin Packing with Matroid using our framework. To this end, the reduction of the instance to a structured instance and the fractional shifting (see the full version of the paper [9]) need to be modified to tackle general matroids.

Finally, consider the Bin Packing with Matching Constraints problem (or, equivalently: Bin Packing with Line Graph Conflicts). The input is a graph $G = (V, E)$ and a size function on the edges $s : E \to [0, 1]$. The objective is to partition E into a minimal number of bins $A_1, \ldots, A_m$ such that $A_b \subseteq E$ is a matching in G, and $s(A_b) \leq 1$ for all $b \in [m]$. Our preliminary results suggest it may be possible to adapt the main components of our scheme for solving this problem.

Abstract

Optimization problems often involve vector norms, which has led to extensive research on developing algorithms that can handle objectives beyond ℓ_p norms. Our work introduces the concept of *submodular norms*, which are a versatile type of norms that possess marginal properties similar to submodular set functions. We show that submodular norms can either accurately represent or approximate well-known classes of norms, such as ℓ_p norms, ordered norms, and symmetric norms. Furthermore, we establish that submodular norms can be applied to optimization problems such as online facility location and stochastic probing. This allows us to develop a logarithmic-competitive algorithm for online facility location with symmetric norms, and to prove logarithmic adaptivity gap for stochastic probing with symmetric norms.

1 Introduction

In the field of combinatorial optimization, norm objectives are frequently encountered. Canonical problems, such as the min-weight spanning tree and the k-median, involve searching for a feasible solution that minimizes the sum of costs, which is equivalent to the ℓ_1 norm of the edge cost vector. On the other hand, canonical problems like bottleneck spanning tree and k-center aim to minimize the maximum of costs, which is equivalent to the ℓ_∞ norm of the edge cost vector. However, because ℓ_1 and ℓ_∞ norms only capture the extreme Utilitarian and Egalitarian objectives respectively, significant research has been devoted to developing combinatorial optimization algorithms for more general norms (see references in Section 1.3). Among the commonly studied norms are ℓ_p norms, ordered norms, Orlicz norms, symmetric norms, and arbitrary monotone norms.

Over the past decade, there is also a lot of effort towards designing online and stochastic algorithms for more general norms. For instance, remarkable progress has been made in developing algorithms beyond ℓ_p norms for various problems, such as load balancing [16, 17, 29, 30, 31, 32], set cover [7, 36], spanning trees [28], and bandits with knapsacks [33, 32]. Notably, most of the recent progress is for the class of symmetric norms, i.e., monotone norms that remain unchanged upon permutation of coordinates. This progress is partly due to Ky Fan's Dominance Theorem (refer to [11]), which reduces the problem of designing algorithms for symmetric norms to ordered norms (see Section 1.1 for a formal definition). Ordered norms are comparatively more manageable due to their explicit form. Given this progress on some combinatorial problems for symmetric norms, a natural question arises:

> *What general norms and what combinatorial problems admit algorithms with good performance guarantees?*

A challenge in making progress beyond symmetric norms is that such norms are not explicit, e.g., they may not be well approximated by ordered norms. In this work we introduce the class of *submodular norms*, which is a broad class of norms with marginals properties mimicking submodular set functions. We show that submodular norms either capture or approximate popular classes of norms like ℓ_p norms, ordered norms, and symmetric norms. Moreover, submodular norms are amenable to some of the optimization problems that were previously intractable like online facility location and stochastic probing.

1.1 Norms and Submodularity

We start with the definitions of monotone, symmetric, and ordered norms. We will be only interested in norms defined in the positive orthant.

▶ **Definition 1** (Monotone Norm). *A* monotone norm *is a function* $\|\cdot\| : \mathbb{R}^n_+ \to \mathbb{R}_+$ *and is defined as*

$$\|x\| := \sup_{\boldsymbol{a} \in \mathcal{A}} \sum_i a_i x_i,$$

i.e, by a max of non-negative linear functions over set $\mathcal{A}$. This is equivalent to saying that $\|x\| \geq \|y\|$ whenever $x \geq y \geq 0$ coordinatewise (hence, the name monotone*).*

▶ **Definition 2** (Symmetric Norm). *A monotone norm $\|\cdot\|$ is a* symmetric norm *if, for any vector $x \in \mathbb{R}^n_+$ and for all of its coordinate permutations $\pi : [n] \to [n]$, $\|x\| = \|(x_{\pi(i)})_{i\in[n]}\|$.*

We remark that any symmetric norm can be written as $\sup_{\boldsymbol{a}\in\mathcal{A}}\langle \boldsymbol{a}, x^{\downarrow}\rangle$, where $x^{\downarrow}$ represents the sorted (in descending order) vector x, and $\mathcal{A}$ is a set on non-negative descending vectors. This follows from the fact that $\max_\pi \sum_i a_i x_{\pi(i)} = \langle \boldsymbol{a}^{\downarrow}, x^{\downarrow}\rangle$ for non-negative vectors a, x. In the special case where $\mathcal{A}$ is a singleton, we have ordered norms.

▶ **Definition 3** (Ordered Norm). *A monotone norm is an* ordered norm *if it can be written as $\|x\| = \sum_i a_i x_i^{\downarrow}$, where $a_1 \geq \ldots \geq a_n \geq 0$.*

Submodular Norms

Submodular set functions and their applications to optimization have been extensively studied; see books [38, 22]. Intuitively, they capture the notion of decreasing marginal gains. Although submodular functions were originally defined for discrete settings, the notion has been generalized to arbitrary lattices, in particular to real vectors [8]. This leads to the following notion of continuous submodularity, which has found several applications in machine learning [12, 10] and will be crucial in our definition of submodular norms. We discuss standard properties of continuous submodularity in Appendix A.1.

▶ **Definition 4** (Continuous Submodularity). *A real-valued function $f : \mathbb{R}_+^n \to \mathbb{R}_+$ is* continuously submodular *if for all $x, y \in \mathbb{R}_+^n$, we have $f(x \vee y) + f(x \wedge y) \le f(x) + f(y)$, where $x \vee y$ and $x \wedge y$ are the coordinate-wise max and min of x and y respectively.*

Our first contribution is to define the following natural class of submodular norms.

▶ **Definition 5** (Submodular Norm). *A monotone norm $\|\cdot\|$ is* submodular *if it is continuously submodular.*

Examples of submodular norms include all ℓ_p norms and Ordered norms (see Observation 12). Moreover, the following theorem proved in Section 2.2 shows that any symmetric norm can be approximated by a submodular norm.

▶ **Theorem 6.** *Any symmetric norm can be $O(\log \rho)$ approximated by a submodular norm, where $\rho := \frac{\|(1,1,\ldots,1)\|}{\|(1,0,0,\ldots,0)\|} \le n$. This approximation factor is tight up to $O(\operatorname{loglog} \rho)$ terms.*

There is an intimate connection between submodular norms and submodular set functions. Given a submodular norm $\|\cdot\|$, the set function $f : 2^{[n]} \to \mathbb{R}^+$ by $f(S) := \|\mathbf{1}_S\|$ is submodular, so every submodular norm is an extension of a submodular function. Moreover, if f is a monotone submodular function with $f(\emptyset) = 0$, then f can be extended to a submodular norm $\|\cdot\|$ by the *Lovász extension*:

$$\|x\| := \int_0^\infty f(\{j : t \le x_j\})dt.$$

This observation that every submodular set function induces a continuously submodular norm via its Lovász extension has appeared several times before [9, 8]. However, our definition of submodular norms can capture many more natural norms. E.g., all ℓ_p norms are submodular but for $1 < p < \infty$ they cannot be written as a Lovász extension of a submodular set function since the dual-norm unit ball has an infinite number of vertices.

▶ Remark 7. A commonly studied variant of continuous submodularity is DR-submodularity [13, 20, 37]: a function $f : \mathbb{R}_+^d \to \mathbb{R}_+$ is *DR-submodular* if it satisfies *diminishing returns* meaning $f(w + ae_i) - f(w) \le f(x + ae_i) - f(x)$ for all $x, w \in \mathbb{R}_+^d$ with $x \le w$, $i \in [d]$, and $a \ge 0$. It is known that continuous submodularity is equivalent to having this diminishing returns inequality only when $x_i = w_i$; hence continuous submodularity is a weaker property. The class of DR submodular functions turns out to be uninteresting when looking at norms since the only DR-submodular norm is the ℓ_1-norm (up to rescaling coordinate-wise). See Appendix A.1 for proofs.

1.2 Applications

In addition to being a natural class of norms, submodular norms find multiple applications. We will explore two specific applications-one in the domain of online algorithms and another in the field of stochastic optimization.

Online Facility Location

In this problem we are given a metric space $(\mathcal{M}, d)$ equipped with metric $d : \mathcal{M} \times \mathcal{M} \to \mathbb{R}_{\ge 0}$, along with a cost function $f : \mathcal{M} \to \mathbb{R}_+$ and a norm $\|\cdot\| : \mathbb{R}_+^n \to \mathbb{R}_+$. At each time step $i \in [n]$, an adversary produces a new request $x_i \in \mathcal{M}$ and the algorithm decides to either assign x_i to the closest already-open facility in the set F_{i-1}, thereby incurring a connection cost $d(x_i, F_{i-1})$, or to open a new facility q and assign request x_i to facility q, thereby incurring a connection cost $d(x_i, q)$ and an opening cost $f(q)$. Let F be the final set of opened facilities, let F_i be the set of facilities opened until (and including) the i-th request, and let $\boldsymbol{d} = (d_1, \ldots, d_n) \in \mathbb{R}_+^n$ be the vector of connection costs $d_i := d(x_i, F_i)$. Our goal is to minimize the total cost $\sum_{q \in F} f(q) + \|\boldsymbol{d}\|$.

Online facility location was introduced by Meyerson for ℓ_1 norm [35], where he showed an $O(\log n)$ competitive algorithm. A tight competitive ratio of $\Theta({}^{\log n}/_{\log\log n})$ was later obtained by Fotakis [21]. When all requests are given up front (offline setting), it is a classical NP-hard problem where we can design $O(1)$ approximation algorithm, even for general norms [27]. In the online setting, however, no non-trivial algorithm was previously known beyond ℓ_1 norms.

▶ **Theorem 8.** *For online facility location problem with a submodular norm $\|\cdot\|$, there exists a randomized online algorithm that obtains cost at most $O(\log \rho) \cdot \sum_{z \in F^*} f(z) + O(1) \cdot \|\boldsymbol{d}^*\|$, where F^* and $\boldsymbol{d}^*$ are the set of facilities and vector of assignment distances respectively given by the offline optimum algorithm and $\rho := \frac{\|(1,1,\ldots,1)\|}{\min_i \|e_i\|} \leq n \cdot \frac{\max_i \|e_i\|}{\min_i \|e_i\|}$.*

Since any symmetric norm can be $O(\log \rho)$ approximated by a submodular norm by Theorem 6, we get the following corollary.

▶ **Corollary 9.** *For online facility location problem with a symmetric norm, there exists an $O(\log \rho)$-competitive randomized algorithm.*

For concreteness, this corollary implies an $O(\log n)$-competitive algorithm for ℓ_1 norm, which matches Meyerson's bound [35], an $O(1)$-competitive algorithm for ℓ_∞ norm, and an $O(\log k)$-competitive algorithm for $\mathsf{Top}\text{-}k$ norm. This is tight up to an $O(\log \log \rho)$ factor for any symmetric norm by the lower bound construction given in Theorem 31.

The proof of Theorem 8 relies on generalizing Meyerson's algorithm beyond ℓ_1 norms. Meyerson's algorithm constructs a new facility at each demand point x_i with probability $d(x_i, F_{i-1})/f$, thereby balancing the cost of assigning the demand against the cost of constructing a new facility. A natural generalization of this algorithm to general norms is to construct a new facility with probability δ_i/f, where marginal cost $\delta_i = \|(d_1, \ldots, d_{i-1}, d(x_i, F_{i-1}), 0, \ldots, 0)\| - \|\boldsymbol{d}_{\leq i-1}\|$. Unfortunately, we will show that such an algorithm is $\Omega(n)$-competitive even for the ℓ_∞ norm. Our crucial change to Meyerson's algorithm is to carefully define *auxiliary assignment costs* $\hat{d}_i$ which upper bound the true costs d_i. Now we use $\hat{d}_i$ instead of d_i to calculate the marginal cost δ_i. Due to norm submodularity, this underestimates the marginal costs, making the algorithm more inclined to assign demand points instead of constructing new facilities.

Next, we discuss a stochastic optimization application of submodular norms.

Stochastic Probing

This problem is a natural stochastic generalization of constrained submodular maximization. Here, we are given probability distributions of n independent random variables $X = (X_1, \ldots, X_n) \in \mathbb{R}_+$, a downward-closed set family $\mathcal{F} \subseteq 2^{[n]}$, and a monotone objective $f : \mathbb{R}_+^n \to \mathbb{R}_+$. The goal is to select a feasible set $S \in \mathcal{F}$ of variables in order to maximize $f(X_S)$. The optimal strategy for this problem is generally *adaptive*, i.e., it selects elements of S one at a time and may change its decisions based on observations of the selected variables.

Since adaptive strategies are complicated (could be an exponential-sized decision tree) and hard to implement for many applications of stochastic probing, we are interested in finding non-adaptive algorithms that maximize $\max_{S \in \mathcal{F}} \mathbb{E}[f(X_S)]$. The main question, which has been studied in several papers [5, 24, 25, 26, 14, 19], is how much do we lose when we move from adaptive to non-adaptive algorithms, i.e., if $\mathsf{Adap}(X, \mathcal{F}, f)$ denotes the optimal adaptive strategy and $\mathsf{NA}(X, \mathcal{F}, f)$ denotes the optimal non-adaptive algorithm, then what is the maximum possible *adaptivity gap* $\frac{\mathsf{Adap}(X,\mathcal{F},f)}{\mathsf{NA}(X,\mathcal{F},f)}$.

For submodular set functions, the worst-case adaptivity gap is known to be 2 [26, 14]. An interesting conjecture posed in [26] is whether the adaptivity gap for *XOS* set functions is poly-logarithmic in n, where an XOS set function $f : 2^{[n]} \to \mathbb{R}_+$ is a max over linear set functions. Since a monotone norm is nothing but a max over linear functions (given by the dual-norm unit ball), they form an extension of XOS set functions from the hypercube to all non-negative real vectors. Thus, we can generalize the conjecture of [26] to the following:

▶ **Conjecture 10.** *The adaptivity gap for stochastic probing with monotone norms is poly-$\log(n)$.*

Although we are not able to resolve this general conjecture, we make progress by resolving it for all symmetric norms.

▶ **Theorem 11.** *The adaptivity gap for stochastic probing with symmetric norms is $O(\log n)$.*

The proof of this result relies on first approximating the symmetric norm by a submodular norm as given in Theorem 6. Next, we generalize the technique of bounding adaptivity gaps for submodular set functions in [14] to submodular norms.

1.3 Further Related Work

In recent years, there has been a surge of interest in the study of general norms. Some of the combinatorial problems that have been studied beyond ℓ_p norms are load balancing [16, 17, 29, 30], k-clustering [15, 16], vector scheduling [32, 18, 31], set cover [7, 36], spanning trees [28], and generalized assignment with convex costs [23, 32]. Beyond combinatorial optimization, general norms have been recently studied for problems such as mean estimation with statistical queries [34], nearest-neighbor search [4, 3], regression [2, 39], and communication complexity [1].

Continuous submodular functions have been extensively studied in the machine learning literature. We refer to the beautiful article of Bach [8] for their properties. Some of their applications to combinatorial optimization are discussed in [6, 37] and to learning are discussed in [40, 20]. The fact that submodular set function induces a norm via its Lovász extension has found several applications for regression since they induce sparsity [9, 10].

Paper Outline

Our work revolves around submodular norms and combinatorial optimization problems where the objective function is a submodular norm. In Section 2, we illustrate the key properties of submodular norms and the extent to which they serve as a good proxy for other classes of norms. In this respect, we identify a crucial parameter ρ that structurally characterizes a given submodular norm and may be of independent interest. In Section 3, we leverage these properties to derive a competitive algorithm for online facility location. Finally, in Section 4, we provide an application of submodular norms to adaptivity gaps for stochastic probing.

2 Submodular Norms

We study properties of submodular norms and how they relate to other commonly studied norms.

2.1 Properties and Important Special Cases

We first discuss some common examples of submodular norms.

▶ **Observation 12.** *The following norms are submodular:*

1. *All ℓ_p norms are submodular.*
2. *All* Top-k *and ordered norms are submodular.*
3. *For a matroid $\mathcal{M} = ([n], \mathcal{I})$, the* matroid rank norm $\|x\| := \max_{S\in\mathcal{I}}(\sum_{i\in S} x_i)$ *is submodular.*

Proof. To see that ℓ_p norms are submodular, it suffices to show that for any monotone concave $g : \mathbb{R}_+ \to \mathbb{R}_+$, and submodular $f : \mathbb{R}^n_+ \to \mathbb{R}_+$, the function $g \circ f$ is submodular. We can then apply this when $f = \|x\|_p^p$ and $g(y) = y^{1/p}$.

To prove the claim, notice that for $x, y \in \mathbb{R}^n_+$,

$$g(f(x \vee y)) - g(f(x)) \leq g(f(x \vee y) - f(x) + f(x \wedge y)) - g(f(x \wedge y)) \leq g(f(y)) - g(f(x \wedge y)).$$

On the other hand, Top-k norms and matroid rank norms are special cases of Lovász extensions. The matroid rank norm is the Lovász extension of the rank function, and a Top-k norm is a matroid rank norm for the k-uniform matroid. ◀

Submodular norms are also closed under several natural operations.

▶ **Lemma 13.** *The following operations return a submodular norm:*

1. *Any rescaling of the coordinates of a submodular norm.*
2. *Sums of partial*[1] *submodular norms.*
3. *Any conical combination of submodular norms is submodular.*[2]

Proof. The first property follows since coordinate-wise rescaling of vectors commutes with coordinate-wise max and min.

The second property follows from the fact that a partial submodular norm is a submodular semi-norm (i.e., a norm without the requirement to be positive definite). A sum of semi-norms remains a semi-norm, and from [8], a sum of continuously submodular functions is continuously submodular.

Finally, it is folklore that conical combinations of norms are norms, and it is also easy to show that such combinations also preserve continuous submodularity (see [8]). ◀

Besides their strict containment of many common norms, submodular norms are also powerful because they can be used to approximate other norms. In Section 2.2, we will discuss how symmetric norms can be approximated by submodular norms up to logarithmic factors. In addition, we note in Section 2.3 that submodular norms may approximate a much larger class of norms than just symmetric, although they are still far from the most general class of monotone norms. These approximation relations are summarized in Figure 1.

[1] Partial means norms defined on a subset of coordinates with every other coordinate treated as 0.

[2] Let $x_1, \ldots, x_m \in \mathbb{R}^n$ be real-valued vectors. We say that $y = \sum_{i\in[m]} \alpha_i x_i$ is a *conical* combination of the vectors if $\alpha_i \geq 0$ for all $i \in [m]$.

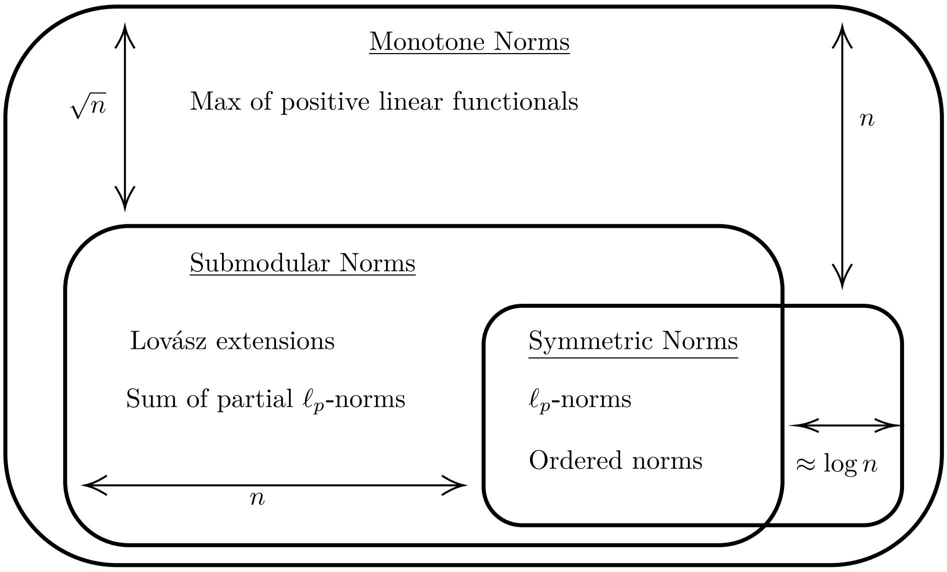

Figure 1 The containment relationships between monotone norms, submodular norms, and symmetric norms, along with some examples. The "distances" shown indicate the worst-case approximation factor (up to constants) for a norm in each outer class by a norm in the corresponding inner class.

2.2 Approximation of Symmetric Norms

A major benefit of studying submodular norms is that they can approximate any symmetric norm. Indeed, previous works have noted that symmetric norms can be approximated by an ordered norm up to a factor of $O(\log n)$ [16, 32]. For our purposes, it will be useful to make this approximation more precise by replacing $\log n$ with $\log \rho$, where parameter ρ is defined as follows:

▶ **Definition 14.** *If $e_1, \ldots, e_n$ denote the standard basis vector and let $\mathbf{1}_{\leq i} := \sum_{1\leq j\leq i} e_j$ denote the vector with 1s at the first i coordinates and 0 otherwise. Then for any monotone norm $\|\cdot\|$ we define the parameter*

$$\rho_{\|\cdot\|} := \frac{\|\mathbf{1}_{\leq n}\|}{\min_{i\in[n]} \|e_i\|}.$$

When the norm is clear from context, we simply write $\rho = \rho_{\|\cdot\|}$.

Notice that for symmetric norms, we have $\rho = \frac{\|\mathbf{1}_{\leq n}\|}{\|e_1\|} \leq n$. One can think of ρ for symmetric norms as a measure of how closely a norm behaves like $\|\cdot\|_1$ (large ρ) versus $\|\cdot\|_\infty$ (small ρ).

▶ **Observation 15.** *For ℓ_p norms, we have $\rho_{\|\cdot\|_p} = n^{1/p}$. For Top-$k$ norms, we have $\rho_{\|\cdot\|_{\text{Top-}k}} = k$.*

As we will see, the parameter ρ appears again in both the upper and lower bound analysis in Section 3 and Appendix B.3, making the improvement from $\log n$ to $\log \rho$ in Lemma 16 necessary for tight bounds in our applications.

▶ **Lemma 16.** *For any symmetric norm $\|\cdot\|$ with $\rho_{\|\cdot\|} = \rho$, there is an ordered norm $\|\cdot\|'$ such that $\|x\| \leq \|x\|' \leq 2(\log \rho + 1) \cdot \|x\|$.*

Proof. Let $\|x\| = \max_{a\in\mathcal{A}}\langle a, x^{\downarrow}\rangle$. Without loss of generality, assume $\|e_1\| = 1$, so $\|\mathbf{1}_{\le n}\| = \|(1,\dots,1)\| = \rho$.

Let $1 = m_0 \le m_1 \le \dots \le m_{\lfloor\log\rho\rfloor}$ be such that m_j is the least integer with $\|\mathbf{1}_{\le m_j}\| \ge 2^j$. Let $a_0,\dots,a_{\lfloor\log\rho\rfloor} \in \mathcal{A}$ be such that $\|\mathbf{1}_{\le m_j}\| = \langle a_j, \mathbf{1}_{\le m_j}\rangle$.

Now consider the ordered norm $\|x\|' := 2\langle a^*, x^{\downarrow}\rangle$, where $a^* = \sum_j a_j$. Clearly, we have

$$\frac{1}{2(\lfloor\log\rho\rfloor+1)}\|x\|' \le \max_j\langle a_j, x^{\downarrow}\rangle \le \max_{a\in\mathcal{A}}\langle a, x^{\downarrow}\rangle = \|x\|.$$

Additionally, notice that for any $x \in \mathbb{R}^n_+$, we can write $x^{\downarrow} = \sum_{k\in[n]}\lambda_k\mathbf{1}_{\le k}$ for some $\lambda_k \ge 0$. We have

$$\|x\|' = 2\sum_j\sum_k\lambda_k\langle a_j, \mathbf{1}_{\le k}\rangle \ge 2\sum_k\lambda_k\max_j\langle a_j, \mathbf{1}_{\le k}\rangle \ge^{\dagger} \sum_k\lambda_k\|\mathbf{1}_{\le k}\| \ge \|x\|.$$

Here, † follows from rounding each k down to the nearest m_j and using

$$\langle a_j, \mathbf{1}_{\le k}\rangle \ge \langle a_j, \mathbf{1}_{\le m_j}\rangle = \|\mathbf{1}_{\le m_j}\| \ge \frac{1}{2}\|\mathbf{1}_{\le k}\|. \qquad ◀$$

Tightness of approximation

In the worst case where $\rho = \Omega(n)$, the $\log n$ factor turns out to be nearly the best possible factor for approximation of a symmetric norm by a submodular norm. The following lemma shows that the construction in Lemma 16 is tight up to $O(\operatorname{loglog} n)$ factors.

▶ **Lemma 17.** *For any $\varepsilon \in (0, 1/2)$, define*

$$\|x\| := \max_{k\in[n]} k^{-\varepsilon}\cdot\langle\mathbf{1}_{\le k}, x^{\downarrow}\rangle.$$

For any submodular norm $\|\cdot\|'$ such that $\|x\|' \ge \|x\|$ for all $x \in \mathbb{R}^n_+$, there exists $y \in \mathbb{R}^n_+$ such that $\|y\|' \ge C\frac{\varepsilon}{1-\varepsilon}(\log n)^{1-\varepsilon}\|y\|$. Taking $\varepsilon = \frac{1}{\log\log n}$ gives $\|y\|' \ge \Omega(\frac{\log n}{\log\log n})\|y\|$.

Proof. Let y be defined by $y_k := \frac{k^{\varepsilon}-(k-1)^{\varepsilon}}{\varepsilon}$. A simple calculation yields that

$$k^{-(1-\varepsilon)} \le y_k \le (k-1)^{-(1-\varepsilon)}.$$

Additionally, we have

$$\|y\| = \max_{k\in[n]} k^{-\varepsilon}\cdot\sum_{i=1}^{k} y_i = \max_{k\in[n]} k^{-\varepsilon}\cdot\frac{k^{\varepsilon}}{\varepsilon} = \frac{1}{\varepsilon}.$$

Now to estimate $\|y\|'$, first note that we may assume $\|\cdot\|'$ to be symmetric, otherwise replace $\|\cdot\|'$ with its average over all permutations of inputs. We will inductively show that for $j \in [n/\log n]$, we have $\|y_{\le j}\|' \ge b_j := \frac{(\log(j+1))^{1-\varepsilon}}{4(1-\varepsilon)}$.

For $j = 1$, we check

$$b_1 \le \frac{1}{4(1-\varepsilon)} \le \frac{1}{2} \le 1 = \|y_{\le 1}\| \le \|y_{\le 1}\|'.$$

Now assume the claim holds for a given $j \ge 1$. Consider $z \in \mathbb{R}^d_+$ defined by

$$z_i = \begin{cases} y_i & 1 \le i \le j, \\ y_{j+1} & j < i \le j+\ell, \\ 0 & j+\ell < i, \end{cases}$$

where $\ell := \lceil (j+1)\log(j+1) \rceil$. Notice that by submodularity and symmetry, we have

$$\|y_{\leq j+1}\|' \geq \|y_{\leq j}\|' + \frac{\|z\|' - \|y_{\leq j}\|'}{\ell} \geq b_j + \frac{\|z\|' - b_j}{\ell}.$$

We see that

$$\|z\|' \geq \|z\| \geq (j+\ell)^{-\varepsilon} \cdot (j+\ell) y_{j+1} \geq \left(\frac{j+\ell}{j+1}\right)^{1-\varepsilon} \geq \log(j+1)^{1-\varepsilon}.$$

Thus, we have $\|z\|' - b_j \geq \frac{1}{2}\log(j+1)^{1-\varepsilon}$. Finally, we have

$$\|y_{\leq j+1}\|' \geq b_j + \frac{\log(j+1)^{1-\varepsilon}}{2\ell} \geq b_j + \frac{\log(j+1)^{-\varepsilon}}{4(j+1)} \geq b_j + \int_{j+1}^{j+2} \frac{(\log x)^{-\varepsilon}}{4x} dx = b_{j+1}. \blacktriangleleft$$

2.3 Beyond Symmetric Norms

Given that submodular norms allow us to approximate symmetric norms up to $\log n$ factors, we may ask if other classes of norms can be similarly approximated. We note that there exist submodular norms that are an $\Omega(n)$ factor away from any symmetric norm, which suggests that symmetric norms are not the largest class of norms which are approximated by submodular norms. Indeed, sums of partial ℓ_p or Top-k norms, such as those considered in [36], are submodular but can be highly asymmetric. Thus, although we focus on approximating symmetric norms by submodular norms, it is likely that many asymmetric norms admit submodular approximations. However, we leave the problem of characterizing these norms for future work.

In the following lemmas, we adopt the notation x_S for $x \in \mathbb{R}^n$ and $S \subseteq [n]$ to denote x after zeroing out all entries except those at indices in S, as well as $\mathbf{1}_S$ to denote the indicator vector of S.

▶ **Lemma 18.** *There exists a submodular norm $\|\cdot\|'$ for which any symmetric norm $\|\cdot\|$ satisfying $\|x\| \leq \|x\|'$ for all $x \in \mathbb{R}^n_+$, also has $\|y\|' \geq \Omega(n) \cdot \|y\|$ for some $y \in \mathbb{R}^n_+$.*

Proof. Let $A := \{1, \ldots, n/2\}$ and $B := \{n/2+1, \ldots, n\}$. Define the norm $\|x\|' := \|x_A\|_\infty + \|x_B\|_1$. Notice that $\|\cdot\|'$ is a sum of partial ℓ_p norms, so it is submodular by Lemma 13. Now suppose $\|\cdot\|$ is a symmetric norm with $\|x\| \leq \|x\|'$ for all $x \in \mathbb{R}^n_+$. Then $\|\mathbf{1}_A\| \leq \|\mathbf{1}_A\|' = 1$. However, we also have $\|\mathbf{1}_B\| = \|\mathbf{1}_A\|$ by symmetry, and $\|\mathbf{1}_B\|' = n/2$. Thus, taking $y = \mathbf{1}_B$, we have our lemma. ◀

In the most general setting of monotone norms, however, submodular norms cannot give better than an $\Omega(\sqrt{n})$ approximation. The proof of this fact is similar to the canonical proof of the $\Omega(\sqrt{n})$ factor gap between submodular set functions and XOS set functions.

▶ **Lemma 19.** *There exists a monotone norm $\|\cdot\|$ for which any submodular norm $\|\cdot\|'$ satisfying $\|x\| \leq \|x\|'$ for all $x \in \mathbb{R}^n_+$, also has $\|y\|' \geq \Omega(\sqrt{n}) \cdot \|y\|$ for some $y \in \mathbb{R}^n_+$.*

Proof. Partition $[n]$ into $\sqrt{n}$ blocks $B_1, \ldots, B_{\sqrt{n}}$, each of size $\sqrt{n}$. Define the norm $\|x\| := \max_{k \in [\sqrt{n}]} \left(\sum_{i \in B_k} x_i\right)$. Now suppose $\|\cdot\|'$ is a submodular norm satisfying $\|x\| \leq \|x\|'$ for all $x \in \mathbb{R}^n_+$. We will construct y by starting with the zero vector and iteratively choosing one element i_k of each B_k to activate (set $y_{i_k} = 1$). Clearly $\|y\| = 1$, so we just need to show $\|y\|' \geq \Omega(\sqrt{n})$.

Formally, let $y^{(0)} = 0$, and for each $k = 1, \dots, \frac{\sqrt{n}}{2}$, do the following. If $\|y^{(k-1)}\|' \geq \frac{\sqrt{n}}{2}$, we are done and simply choose $y = y^{(k-1)}$. Otherwise, notice that $\|y^{(k-1)} + \mathbf{1}_{B_k}\|' \geq \|y^{(k-1)} + \mathbf{1}_{B_k}\| = \sqrt{n}$, so $\|y^{(k-1)} + \mathbf{1}_{B_k}\|' - \|y^{(k-1)}\| \geq \frac{\sqrt{n}}{2}$. By submodularity, there exists some $i_k \in B_k$ such that $\|y^{(k-1)} + e_{i_k}\|' \geq \|y^{(k-1)}\|' + \frac{1}{2\sqrt{n}}$, for which we set $y^{(k)} := y^{(k-1)} + e_{i_k}$ By induction, if we do not terminate early, we have $\|y^{(\sqrt{n})}\|' \geq \frac{n}{2\sqrt{n}} = \frac{\sqrt{n}}{2}$. ◀

3 Online Facility Location with Submodular Norms

In this section, we illustrate how submodular norms can be applied to Online Facility Location. Recall from Section 1.2, in this problem we are given a metric space $(\mathcal{M}, d)$ along with a cost function $f : \mathcal{M} \to \mathbb{R}_+$. At each time step $i \in [n]$, an adversary produces a new request $x_i \in \mathcal{M}$, and the algorithm decides whether to assign x_i to the closest open facility F_{i-1} or to open a new facility q and assign request x_i to q. The goal is to minimize the total facility opening costs plus a given norm $\|\cdot\|$ of the connection costs, i.e., $\min \sum_{q \in F} f(q) + \|\boldsymbol{d}\|$, where $\boldsymbol{d} = (d_1, \dots, d_n) \in \mathbb{R}^n_+$ is the vector of connection costs $d_i := d(x_i, F_i)$.

In the case of uniform costs, $f(q) = f$ for all q, so the total facility opening cost becomes $f \cdot |F|$. We use $\boldsymbol{d}_{\leq i} = (d_1, \dots, d_i, 0, \dots, 0)$ to denote the first i coordinates of vector $\boldsymbol{d}$.

3.1 Uniform Costs

For now, we will focus on the case when facility costs are uniformly f.

▶ **Theorem 20.** *Let $\|\cdot\|$ be a submodular norm, and let $\rho := \rho_{\|\cdot\|}$. For the $\|\cdot\|$ norm online facility location problem with uniform facility costs f, there exists a randomized online algorithm that obtains cost at most $O(\log \rho) \cdot |F^*| f + O(1) \cdot \|\boldsymbol{d}^*\|$, where F^* and $\boldsymbol{d}^*$ are the set of facilities and vector of assignment distances, respectively, given by the optimal offline algorithm.*

Notice that because our algorithm obtains a constant factor approximation for the assignment costs, we have the following corollary.

▶ **Corollary 21.** *There is an $O(\log \rho)$-competitive algorithm for uniform costs online facility location with symmetric norms.*

Proof. Given the uniform cost facility location problem with a monotone symmetric norm $\|\cdot\|$, let F^* and $\boldsymbol{d}^*$ be the set of facilities and assignments distances given by the optimal offline algorithm. For our online algorithm, we will approximate $\|\cdot\|$ by a submodular norm $\|\cdot\|'$ using Lemma 16, and then run the algorithm in Theorem 20 on norm $\|\cdot\|'$. Since $\log \rho = \log \rho_{\|\cdot\|} = \Theta(\log \rho_{\|\cdot\|'})$, this algorithm will incur cost at most

$$|F|f + \|\boldsymbol{d}\| \;\leq\; |F|f + \|\boldsymbol{d}\|' \;\leq\; O(\log \rho)|F^*|f + O(1)\|\boldsymbol{d}^*\|' \;\leq\; O(\log \rho)|F^*|f + O(\log \rho)\|\boldsymbol{d}^*\|. \blacktriangleleft$$

Proof outline for Theorem 20

We want to generalize Meyerson's algorithm beyond ℓ_1 norms and use submodularity to complete the analysis. Meyerson's algorithm constructs a new facility at each demand point x_i with probability $d(x_i, F_{i-1})/f$, thereby balancing the cost of assigning the demand against the cost of constructing a new facility. To adapt this algorithm to more general norms, it is natural to construct a new facility at x_i with probability δ_i/f, where $\delta_i = \|(d_1, \dots, d_{i-1}, d(x_i, F_{i-1}), 0, \dots, 0)\| - \|\boldsymbol{d}_{\leq i-1}\|$ is the marginal cost of assigning x_i.

Unfortunately, the above natural generalization of Meyerson's algorithm can have an $\Omega(n)$ competitive ratio. For instance, consider the star graph $K_{1,n}$ equipped with the standard unweighted graph distance metric. Suppose that our construction costs are $f = 1$, our submodular norm is the ℓ_∞ norm, and the demand points are all the leaves of the star graph. The optimal solution constructs a single facility at the center, yielding a total cost of $1 + \|(1, \dots, 1)\|_\infty = 2$. On the other hand, the suggested algorithm constructs a facility for every demand point, as $\delta_i = 2$ for each $i \geq 2$, incurring a total cost of n.

To get around this issue, we will define *auxiliary assignment costs* $\hat{d}_i$ that upper bound the true costs d_i. The key modification to the algorithm is that we will use $\hat{d}_i$ instead of d_i for calculating the marginals δ_i. By overestimating the assignment costs that we have incurred, the algorithm underestimates potential marginal costs due to submodularity, making it more inclined to assign demand points instead of constructing new facilities. Moreover, the flexibility of the analysis allows us to show that the increased costs of $\hat{d}_i$ still obtain an $O(\log \rho)$ competitive ratio.

We now present the formal proof.

Proof of Theorem 20. To formalize the outline above, we will first inductively define our auxiliary cost vector $\hat{\boldsymbol{d}}$ and the marginals δ_i by

$$\hat{d}_i := \min\left\{d(x_i, F_{i-1}),\;\; \max\{z \geq 0 : f \geq \|(\hat{d}_1, \dots, \hat{d}_{i-1}, z, 0, \dots, 0)\| - \|\hat{\boldsymbol{d}}_{\leq i-1}\|\}\right\} \quad \text{and}$$
$$\delta_i := \|\hat{\boldsymbol{d}}_{\leq i}\| - \|\hat{\boldsymbol{d}}_{\leq i-1}\|.$$

Thus, $\hat{d}_i$ is the assignment distance $d(x_i, F_{i-1})$ capped such that $\delta_i \leq f$. For our algorithm, we construct a facility at x_i with probability δ_i/f, and assign x_i to the nearest facility otherwise. These are well-defined probabilities since $\delta_i \leq f$. To see the upper-bound $d_i \leq \hat{d}_i$, notice that if $\delta_i < f$, then $\hat{d}_i = d(x_i, F_{i-1}) \geq d(x_i, F_i) = d_i$. If $\delta_i = f$, then $d_i = 0$ since a facility is constructed at x_i with probability 1, so $d_i = 0 \leq \hat{d}_i$.

Let $\mathsf{cost}(i) := f \cdot \mathbb{1}_{|F_i| > |F_{i-1}|} + \delta_i$ be the marginal increase in auxiliary cost at step i, so $\sum_{i \in [n]} \mathsf{cost}(i) = f \cdot |F| + \|\hat{\boldsymbol{d}}\|$. We will bound separately the cost of demand points that arrive before and after the first nearby facility is constructed. Similar to Meyerson's proof, we have the following bound on costs incurred before a facility is constructed in a given set.

▷ Claim 22. Let $A \subseteq [n]$ be a fixed set of indices, and let $S \subseteq A$ be the subset of indices that arrive before the first facility is constructed at any step in A. Then $\mathbb{E}[\sum_{i \in S} \mathsf{cost}(i)] \leq 2f$.

The proof of this claim is essentially identical to Meyerson's, so we will defer it to Appendix B.1.

Now, let us enumerate our offline algorithm's facility set as $F^* = \{c_1^*, \dots, c_K^*\}$, where $K = |F^*|$. Let $C_1^*, \dots, C_K^*$ be the offline clusters, i.e., C_k^* is the set of $i \in [n]$ for which x_i is assigned to c_k^*.

Let $r := \frac{\|\boldsymbol{d}^*\|}{\|(1,\dots,1)\|}$. We partition each cluster into rings as $C_k^* = \bigcup_{\ell=0}^{L} C_k^\ell$, where $L = \lceil \log \rho \rceil$,

$$C_k^0 := \{i \in C_k^* : d(x_i, c_k^*) \leq r\}, \quad \text{and}$$
$$C_k^\ell := \{i \in C_k^* : 2^{\ell-1} r \leq d(x_i, c_k^*) \leq 2^\ell r\} \quad \text{for } \ell \in \{1, \dots, L\}.$$

Notice that this is a partition since

$$\max_{i \in C_k^*} d(x_i, C_k^*) \leq \|\boldsymbol{d}^*\|_\infty \leq \frac{\|\boldsymbol{d}^*\|}{\min_i \|e_i\|} = r\rho \leq 2^L r.$$

We will analyze the costs incurred by our algorithm on demand points in each ring. Within each ring, we will consider two types of demands separately: *long-distance* demands LD_k^ℓ and *short-distance* demands SD_k^ℓ, defined as

$$\mathsf{LD}_k^\ell := \{i \in C_k^\ell : d(c_k^*, F_{i-1}) > 2^\ell r\} \quad \text{and} \quad \mathsf{SD}_k^\ell := \{i \in C_k^\ell : d(c_k^*, F_{i-1}) \le 2^\ell r\}.$$

In other words, long (respectively, short) distance demands arrive before (respectively, after) a facility has been constructed within the outer perimeter of its corresponding ring. We now make the following claims.

▷ Claim 23. We have

$$\mathbb{E}\Big[\sum_{\ell=0}^{L}\sum_{k=1}^{K}\sum_{i\in\mathsf{LD}_k^\ell} \mathsf{cost}(i)\Big] \le 2(L+1)Kf.$$

▷ Claim 24. We have

$$\mathbb{E}\Big[\sum_{\ell=0}^{L}\sum_{k=1}^{K}\sum_{i\in\mathsf{SD}_k^\ell} \mathsf{cost}(i)\Big] \le 8\|\boldsymbol{d}^*\|.$$

These claims together give Theorem 20, since $L = O(\log \rho)$.

Notice that Claim 23 follows immediately from Claim 22 since long-distance demands must arrive before a facility is constructed in $C_\ell^{(j)}$. This implies $\mathbb{E}\left[\sum_{i\in\mathsf{LD}_k^\ell} \mathsf{cost}(i)\right] \le 2f$ for each ℓ and k.

To show Claim 24, let $\mathsf{SD} := \bigcup_{\ell=0}^{L}\bigcup_{k=1}^{K} \mathsf{SD}_k^\ell$. We seek to show that $\sum_{i\in\mathsf{SD}} \mathsf{cost}(i) \le 8\|\boldsymbol{d}^*\|$. Notice that if $i \in \mathsf{SD}_k^0$ for some k, then we have $\hat{d}_i \le d(x_i, F_{i-1}) \le d(x_i, c_k^*) + d(c_k^*, F_{i-1}) \le d_i^* + r$. Similarly, if $i \in \mathsf{SD}_k^\ell$ for some k and $\ell \ne 0$, we have $\hat{d}_i \le 3d_i^*$. Thus, we can say that $\hat{d}_i \le 3d_i^* + r$ for all $i \in \mathsf{SD}$. This gives

$$\mathbb{E}\Big[\sum_{i\in\mathsf{SD}} \mathsf{cost}(i)\Big] \;\le\; \mathbb{E}\Big[\sum_{i\in\mathsf{SD}} 2\delta_i\Big] \;\le\; 2\mathbb{E}\Big[\|\hat{\boldsymbol{d}}_{\mathsf{SD}}\|\Big] \;\le\; 2\|r\mathbf{1}_{\le n} + 3\boldsymbol{d}^*\| \;=\; 2r\|\mathbf{1}_{\le n}\| + 6\|\boldsymbol{d}^*\| \;\le\; 8\|\boldsymbol{d}^*\|,$$

where the second inequality comes from the submodular property, the third comes from norm monotonicity, and the last inequality is by choice of r. In particular, for the second inequality, we crucially use the submodularity of the norm to say

$$\sum_{i\in\mathsf{SD}} \delta_i \;=\; \sum_{i\in\mathsf{SD}} \Big(\|\hat{\boldsymbol{d}}_{\le i}\| - \|\hat{\boldsymbol{d}}_{\le i-1}\|\Big) \;\le\; \sum_{i\in\mathsf{SD}} \Big(\|\hat{\boldsymbol{d}}_{\mathsf{SD}\cap[i]}\| - \|\hat{\boldsymbol{d}}_{\mathsf{SD}\cap[i-1]}\|\Big) \;=\; \|\hat{\boldsymbol{d}}_{\mathsf{SD}}\|. \qquad ◀$$

3.2 Non-Uniform Costs

In this section, we argue how one could develop the ideas of the previous section further to extend the algorithm to Online Facility Location with different opening costs across facilities. We will show how to modify Meyerson's algorithm for non-uniform costs in a similar manner to the uniform cost setting, but in a way that also handles new challenges that arise. We motivate and describe the new algorithm, but to avoid clutter, we defer most of the proof details to Appendix B.2.

▶ **Theorem 8.** *For online facility location problem with a submodular norm $\|\cdot\|$, there exists a randomized online algorithm that obtains cost at most $O(\log\rho)\cdot\sum_{z\in F^*} f(z) + O(1)\cdot\|\boldsymbol{d}^*\|$, where F^* and $\boldsymbol{d}^*$ are the set of facilities and vector of assignment distances respectively given by the offline optimum algorithm and $\rho := \frac{\|(1,1,\ldots,1)\|}{\min_i \|e_i\|} \le n\cdot\frac{\max_i\|e_i\|}{\min_i\|e_i\|}$.*

Recall that previously, the algorithm's only choice at step i was whether to construct a facility at x_i or not. In the non-uniform setting, it might not be feasible to only ever construct at x_i, since the cost of opening there might be prohibitively high. Meanwhile a nearby location might have a much lower cost. Instead, the algorithm must consider all possible cost levels at which it could construct and how far facilities at different cost levels are from x_i.

First, let us recap how Meyerson's algorithm handles this in the ℓ_1 norm setting. By losing at most a factor of 2, we can assume that all opening costs are in some set $\{f_1, \dots, f_m\}$, where each f_j is a power of 2. For each $j \in [m]$, we define the $W_i^{(j)}$ to be the set of facilities which at step i are open or have opening cost at most f_j:

$$W_i^{(j)} := F_{i-1} \cup \{x \in \mathcal{M} : f(x) \leq f_j\}.$$

Additionally, $W_i^{(0)} := F_{i-1}$. Now Meyerson's algorithm [35] will, for each $j \in [m]$, open a facility at the nearest location in W_j with probability $\frac{d(x_i, W_i^{(j-1)}) - d(x_i, W_i^{(j)})}{f_j}$, capped at 1, then assign x_i to the nearest open facility. As in the uniform case, we can see that the expected facility opening cost incurred is $d(x_i, W_i^{(0)}) = d(x_i, F_{i-1})$. This allows us to again consider a "long-distance" and "short-distance" phase within each ring of each optimal cluster.

To adapt this algorithm to the submodular norm setting, the idea will again be to consider construction probabilities, not based on the distances $d(x_i, W_i^{(j)})$, but instead based on the marginal increase in an auxiliary assignment cost $\|\hat{\boldsymbol{d}}\|$. However, the definition of $\hat{\boldsymbol{d}}$ is not as straightforward as in the uniform cost setting. In particular, we need to satisfy $d_i \leq \hat{d}_i$ for each i deterministically. However, without carefully controlling dependencies between facility construction (for instance, by constructing independently for each j), it may be possible that $d_i = d(x_i, F_{i-1})$ if no facilities are constructed. This would force $\hat{d}_i$ to be too large to serve as a useful upper bound.

To avoid this, we instead construct facilities by sampling a single cost level f_j at which to build a facility. The probability of sampling f_j is given by a version of the probabilities used above. Suppose these probabilities sum to a value greater than 1. In that case, we crucially limit the probabilities for smaller f_j (corresponding to a facility at a greater distance) until the total probability is capped at 1: We name these probabilities $p_i^{(j)}$'s (Definition 30). This ensures that the true assignment distance d_i is never too large, which allows us to pick a conveniently small upper bound $\hat{d}_i$.

Algorithm 1 Non-Uniform Submodular Online Facility Location.

```
Data: Metric space $(\mathcal{M}, d)$ and online requests $x_1, \dots, x_n$
Result: Opened facilities set $F$ and assignment of requests to facilities (at the time
        of arrival)
for request $x_i$, $i = 1, \dots, n$ do
    Sample $j \in \{0, \dots, m\}$ according to the distribution given by $p_i^{(j)}$;
    Assign $x_i$ to the nearest location in $W_i^{(j)}$, constructing a facility there if necessary;
end
```

Our analysis proceeds by considering the partition of arrival indices into optimal clusters $[n] = \bigcup_{k \in [K]} C_k$, each with center c_k^*. Similarly to the uniform cost setting, we partition each cluster into rings as $C_k^* = \bigcup_{\ell=0}^{L} C_k^\ell$, where $L = \lceil \log \rho \rceil$ and

$$C_k^0 := \{i \in C_k^* : d(x_i, c_k^*) \leq r\},$$
$$C_k^\ell := \{i \in C_k^* : 2^{\ell-1} r \leq d(x_i, c_k^*) \leq 2^\ell r\}, \quad \text{for } \ell \in [L].$$

For each ring C_k^ℓ, we divide the analysis into two main stages: the *short-distance* and *long-distance* stages. We leave the formal definition of these stages for the proof details, but intuitively, each demand is considered a long-distance demand until a facility is constructed at a distance which is a constant multiple of the radius of C_k^ℓ. After this happens, subsequent demands in the ring are considered short-distance demands. In each of these stages, the algorithm obtains the following.

▶ **Lemma 25** (Short-Distance Stage). *The expected cost incurred by the algorithm in the short-distance stage is*

$$\mathbb{E}\left[\mathit{ALG}_{\mathit{SD}}\right] = \mathbb{E}\Big[\sum_{i \in \mathit{SD}} \mathit{cost}(i)\Big] \leq 36 \|\boldsymbol{d}^*\|.$$

▶ **Lemma 26** (Long-Distance Stage). *The expected cost incurred in the long-distance stage is*

$$\mathbb{E}\Big[\mathit{ALG}_{\mathit{LD}}\Big] \leq 48(\log \rho + 1) \cdot \sum_{k \in [K]} f(c_k^*).$$

It is now easy to see that Theorem 8 directly follows by combining Lemma 25 and Lemma 26. The proofs of these lemmas, along with a more formal definition of the probabilities $p_i^{(j)}$, are given in Appendix B.2.

4 Adaptivity Gaps for Stochastic Probing

In this section, we use submodular norms to prove small adaptivity gaps for the stochastic probing problem. Recall the stochastic probing problem from Section 1.2: Given n independent random variables $X = (X_1, \ldots, X_n) \in \mathbb{R}_+$, a downward closed set family $\mathcal{F} \subseteq 2^{[n]}$, and a monotone objective $f : \mathbb{R}_+^n \to \mathbb{R}_+$, the stochastic probing problem $(X, \mathcal{F}, f)$ is to open a feasible set $S \in \mathcal{F}$ of variables to maximize $f(X_S)$.

Denote by $\mathsf{Adap}(X, \mathcal{F}, f)$ the maximum expected objective achievable by an adaptive algorithm, i.e., one which selects elements of S one at a time, and may change its strategy based on its observations of the selected variables. We denote by $\mathsf{NA}(X, \mathcal{F}, f)$ the maximum expected objective by a non-adaptive algorithm, i.e., $\mathsf{NA}(X, \mathcal{F}, f) := \max_{S \in \mathcal{F}} \mathbb{E}[f(X_S)]$.

▶ **Theorem 27.** *If f is a submodular norm, then $\mathsf{Adap}(X, \mathcal{F}, f) \leq 2 \cdot \mathsf{NA}(X, \mathcal{F}, f)$.*

The following result for symmetric norms is an immediate corollary due to Theorem 6.

▶ **Theorem 11.** *The adaptivity gap for stochastic probing with symmetric norms is $O(\log n)$.*

Proof of Theorem 27. We follow the same proof approach as in [14]. Consider an adaptive algorithm Adap, and a non-adaptive algorithm Alg which selects each $S \in \mathcal{F}$ with the same probabilities as Adap, only non-adaptively. We will show by induction on n that Adap achieves an expected objective at most twice that of Alg. This is trivially true for $n = 1$, so we only need to show the inductive step.

We can compare the performance of these two algorithms by coupling their actions. Let's say Adap runs on random variables $X = (X_1, \ldots, X_n)$, and let $S \in \mathcal{F}$ be the (random) set of adaptively chosen variables. We can say Alg runs on variables $Y = (Y_1, \ldots, Y_n)$, i.i.d. copies of X, by choosing the same set S as Adap. Without loss of generality, say that Adap starts by selecting X_1. Since $1 \in S$ deterministically, we have that Adap achieves reward

$$\begin{aligned}
\mathbb{E}[f(X_S)] &= \mathbb{E}[f(X_1)] + \mathbb{E}\big[f_{X_1}(X_{S \setminus \{1\}}) \mid X_1\big] \\
&\leq \mathbb{E}[f(X_1 \vee Y_1)] + \mathbb{E}\big[f_{X_1 \vee Y_1}(X_{S \setminus \{1\}}) \mid X_1\big] \\
&\leq 2\mathbb{E}[f(Y_1)] + \mathbb{E}\big[f_{X_1 \vee Y_1}(X_{S \setminus \{1\}}) \mid X_1, Y_1\big],
\end{aligned}$$

where $f_x(Z) := f(x, Z) - f(x, 0)$ for $Z = (Z_2, \ldots, Z_n) \in \mathbb{R}_+^{n-1}$. Notice that, since f is submodular, we have f_x is submodular and decreasing in x for all $x \in \mathbb{R}_+$.

Now, notice that Alg achieves reward

$$\begin{aligned}\mathbb{E}[f(Y_S)] &= \mathbb{E}[f(Y_1)] + \mathbb{E}\big[f_{Y_1}(Y_{S\setminus\{1\}}) \mid X_1\big] \\ &\geq \mathbb{E}[f(Y_1)] + \mathbb{E}\big[f_{X_1 \vee Y_1}(Y_{S\setminus\{1\}}) \mid X_1, Y_1\big].\end{aligned}$$

Notice that given X_1, the set $S \setminus \{1\} \in \mathcal{F}|_{-1}$ is adaptively chosen among the variables $X_2, \ldots, X_n$ by Adap. Thus, by induction we can say $\mathbb{E}\big[f_{X_1 \vee Y_1}(X_{S\setminus\{1\}}) \mid X_1, Y_1\big] \leq 2 \cdot \mathbb{E}\big[f_{X_1 \vee Y_1}(Y_{S\setminus\{1\}}) \mid X_1, Y_1\big]$. Combining this with the above inequalities gives

$$\mathbb{E}[f(X_S)] \leq 2\mathbb{E}[f(Y_1)] + 2\mathbb{E}\big[f_{X_1 \vee Y_1}(Y_{S\setminus\{1\}}) \mid X_1, Y_1\big] \leq 2\mathbb{E}[f(Y_S)]. \qquad \blacktriangleleft$$

5 Conclusion

This paper introduces the concept of submodular norms and demonstrates their application in proving the efficiency of optimization problems beyond traditional ℓ_p objectives. We provide examples showcasing the utility of submodular norms in various scenarios. Specifically, we establish bounds on the competitive ratio of online facility location problems and the adaptivity gap of stochastic probing techniques when using symmetric norm objectives. These bounds crucially depend on the norm parameter ρ, and are approximately tight in the case of facility location. There are several natural directions for future work:

(i) *General Monotone Norms:* We have shown a logarithmic competitive ratio and adaptivity gap for online facility location and stochastic probing, respectively, when the objective is a symmetric norm or approximately a submodular norm. However, it remains open whether poly-logarithm bounds exist for either problem when the norm can be an arbitrary monotone norm.

(ii) *Symmetric Norm Stochastic Probing.* The logarithmic factor we get in our adaptivity gap bound for symmetric norm stochastic probing comes from the loss in approximating a symmetric norm by a submodular norm. However, it is not clear if such a loss is necessary. It would be interesting to determine if the true adaptivity gap is sub-logarithmic or even a constant.

(iii) *Parameter ρ.* Similar to online facility location, there are other optimization problems (e.g., online fractional set cover) which are known to have differing performance guarantees for ℓ_1 and ℓ_∞ objectives. We hypothesize that for such problems with symmetric norm objectives, the parameter ρ could provide a way of interpolating between ℓ_1 and ℓ_∞.

A Omitted Proofs from Section 2

A.1 Properties of Continuous Submodularity

As with submodular set functions, there are many equivalent definitions for continuous submodularity which may be helpful in different settings. These are folklore properties, but we prove them for completeness.

▶ **Lemma 28.** *Let $f : \mathbb{R}^d_+ \to \mathbb{R}_+$. The following are equivalent.*

1. *f is continuously submodular.*
2. *For all $x, y, z \in \mathbb{R}^d_+$ with $\mathsf{Supp}(y) \cap \mathsf{Supp}(z) = \emptyset$, we have*

$$f(x) + f(x + y + z) \leq f(x + y) + f(x + z).$$

3. *For all $x, y \in \mathbb{R}^d_+$ with $x \leq w$, and $i \in [d]$ such that $x_i = w_i$, and $a \geq 0$, we have*

$$f(w + ae_i) - f(w) \leq f(x + ae_i) - f(x).$$

4. *For all $x \in \mathbb{R}^d_+$ and $a, b \geq 0$ and distinct $i, j \in [d]$, we have*

$$f(x) + f(x + ae_i + be_j) \leq f(x + ae_i) + f(x + be_j).$$

Proof of Lemma 28. ($1 \iff 2$) Let $x, y, z \in \mathbb{R}^d_+$ with $y \perp z$. Notice that for non-negative vectors y, z, orthogonality implies that they have disjoint support. Hence, $(x+y) \vee (x+z) = x$ and $(x+y) \wedge (x+z) = x+y+z$. Then 2 follows from the definition of continuous submodularity. Likewise, if f satisfies condition 2, then applying condition 2 with $x' := x \wedge y$, $y' := y_{\{i : y_i > x_i\}}$, and $z' := x_{\{i : x_i > y_i\}}$ gives continuous submodularity.

($2 \implies 3$) Simply take $y = w - x$ and $z = ae_i$.

($3 \implies 4$) Simply take $w = a + be_j$.

($4 \implies 2$) Let $x^{(i,j)} := x + y_{<i} + z_{<j}$. Consider the sum

$$\begin{aligned} &f(x+y) + f(x+z) - f(x) - f(x+y+z) \\ &= \sum_{i,j \in [d]} \left[f(x^{(i,j)} + y_i e_i) + f(z_i^{(i,j)} + be_j) - f(x^{(i,j)}) - f(x^{(i,j)} + y_i e_i + z_j e_j) \right]. \end{aligned}$$

By condition 4, every term in the RHS sum is non-negative, so the LHS is non-negative as well. ◀

A commonly studied variant of continuous submodularity is DR-submodularity [13, 20, 37]: a function $f : \mathbb{R}^d_+ \to \mathbb{R}_+$ is *DR-submodular* if it satisfies the stronger condition that for all $x, w \in \mathbb{R}^d_+$ with $x \leq w$, $i \in [d]$, and $a \geq 0$, we have $f(w + ae_i) - f(w) \leq f(x + ae_i) - f(x)$. In other words, f satisfies condition 3 of Lemma 28 even where $w_i \neq x_i$. However, the only DR-submodular norm is the ℓ_1-norm.

▶ **Lemma 29.** *Any DR-submodular norm is equivalent to ℓ_1 up to rescaling the coordinates.*

Proof. Suppose $\|\cdot\| : \mathbb{R}^d_+ \to \mathbb{R}$ is a DR-submodular norm with $\|e_i\| = 1$ for each $i \in [d]$. Clearly, $\|x\| \leq \sum x_i = \|x\|_1$ by triangle inequality. Suppose that $\|x\| < \|x\|_1$ for some $x \in \mathbb{R}^d_+$. Then for some $i \in [d]$, we have $\|x_{\leq i}\| - \|x_{\leq i-1}\| \leq x_i - \varepsilon$, where $\varepsilon > 0$. By DR submodularity, this means $\|x_{\leq i-1} + kx_i e_i\| \leq k(x_i - \varepsilon)$ for all $k \in \mathbb{N}$. However, with the continuity of norms, this gives

$$x_i - \varepsilon \geq \lim_{k \to \infty} \frac{\|x_{\leq i-1} + kx_i e_i\|}{k} = \lim_{k \to \infty} \left\| \frac{1}{k} \cdot x_{\leq i-1} + x_i e_i \right\| = \|x_i e_i\| = x_i,$$

which is a contradiction, so we have $\|x\| = \|x\|_1$. ◀

B Omitted Proofs from Section 3

B.1 Uniform Costs

▷ Claim 22. Let $A \subseteq [n]$ be a fixed set of indices, and let $S \subseteq A$ be the subset of indices that arrive before the first facility is constructed at any step in A. Then $\mathbb{E}[\sum_{i \in S} \mathsf{cost}(i)] \leq 2f$.

Proof. Consider the following game: For $i \in A$, a player is shown δ_i, and has to option to pay a cost of δ_i to play a lottery, which has a $\frac{\delta_i}{f}$ chance of giving reward f. Since the expected reward of playing the lottery is exactly the cost, the player is indifferent to playing at each step. This means any strategy for the player has zero expected reward. In particular, the strategy of playing the lottery only until the first win has an expected reward of 0.

Let R be the total lottery winnings of this strategy and C be the total cost of playing. We have that $\mathbb{E}[R - C] = 0$, and since at most one lottery is won, $\mathbb{E}[R] \leq f$. Thus, $\mathbb{E}[R + C] = 2\mathbb{E}[R] \leq 2f$. But $R + C$ has exactly the distribution of $\sum_{i \in S} \mathsf{cost}(i)$, which gives the desired result. ◁

B.2 Non-uniform Costs

We now introduce the notation needed to prove that Algorithm 1 shows Theorem 8. Let us recall that $f : X \to \mathbb{R}_+$ is the cost function of opening a facility. First, we assume without loss of generality that $f(x)$ is a power of 2 for each $x \in X$.[3] Let $f^{(1)} \leq \cdots \leq f^{(m)}$ be the distinct cost levels, so $2f^{(i)} \leq f^{(i+1)}$. Additionally, let $f^{(0)} := 0$ for completeness. As before, let F_i denote the set of facilities that have been opened after the arrival of x_i, before the arrival of x_{i+1}.

▶ **Definition 30.** *For each step $i \in [n]$ and cost level $j \in \{0, \ldots, m\}$, let us define*

1. $W_i^{(j)} := F_{i-1} \cup \{x \in X : f(x) \leq f^{(j)}\}$ *to be the set of locations which are open or have an opening cost at most $f^{(j)}$;*
2. $\hat{d}_i^{(j)} := \min\{d(x_i, W_i^{(j)}), \tau_i\}$ *to be the capped value of $d_i^{(j)}$ (where cap τ_i is defined in Item 6);*
3. $\hat{d}_i := \hat{d}_i^{(0)} = \min\{d(x_i, F_{i-1}), \tau_i\}$ *for simplicity.*
4. $\delta_i^{(j)} := \frac{\hat{d}_i^{(j)}}{\hat{d}_i^{(0)}} \left(\|\hat{\boldsymbol{d}}_{\leq i}^{(0)}\| - \|\hat{\boldsymbol{d}}_{\leq i-1}^{(0)}\|\right)$ *to be the fraction of marginal increase in assignment cost we attribute to cost levels $\leq j$;*
5. $p_i^{(j)} := \frac{\delta_i^{(j-1)} - \delta_i^{(j)}}{f^{(j)}}$ *for $j \geq 1$ to be the assigned probability of opening a facility in $W_i^{(j)}$, and $p_i^{(0)} := 1 - \sum_{j=1}^m p_i^{(j)}$;*
6. $\tau_i := \arg\max\{\tau \in \mathbb{R}_{\geq 0} \cup \{+\infty\} \mid \sum_{j=1}^m p_i^{(j)} \leq 1\}$ *to be the cap value, i.e., the largest nonnegative cap such that $\sum_{j=1}^m p_i^{(j)} \leq 1$. This exists as each $p_i^{(j)}$ is monotone decreasing in τ_i.*

Given the above definitions, we notice that since $d_i^{(j)}$ is decreasing in j, this means for some j we have

$$0 = \hat{d}_i^{(m)} \leq \hat{d}_i^{(m-1)} \leq \cdots \leq \hat{d}_i^{(j+1)} \leq \tau_i = \hat{d}_i^{(j)} = \cdots = \hat{d}_i^{(0)}.$$

We shall prove the following theorem as discussed in Section 3.2.

▶ **Theorem 8.** *For online facility location problem with a submodular norm $\|\cdot\|$, there exists a randomized online algorithm that obtains cost at most $O(\log \rho) \cdot \sum_{z \in F^*} f(z) + O(1) \cdot \|\boldsymbol{d}^*\|$, where F^* and $\boldsymbol{d}^*$ are the set of facilities and vector of assignment distances respectively given by the offline optimum algorithm and $\rho := \frac{\|(1,1,\ldots,1)\|}{\min_i \|e_i\|} \leq n \cdot \frac{\max_i \|e_i\|}{\min_i \|e_i\|}$.*

To prove this theorem, we will separately the so-called short distance demands SD_k^ℓ and long distance demands LD_k^ℓ in each ring C_k^ℓ. Formally, we define

$$\mathsf{LD}_k^\ell := \{i \in C_k^\ell : \hat{d}_i^{(0)} > (\lambda+1)2^\ell r\}, \qquad \mathsf{LD} := \bigcup_{k=1}^{K} \bigcup_{\ell=0}^{L} \mathsf{LD}_k^\ell,$$

$$\mathsf{SD}_k^\ell := \{i \in C_k^\ell : \hat{d}_i^{(0)} \leq (\lambda+1)2^\ell r\}, \qquad \mathsf{SD} := \bigcup_{k=1}^{K} \bigcup_{\ell=0}^{L} \mathsf{SD}_k^\ell.$$

[3] That is, by rounding costs down to powers of 2, we lose only a factor of 2.

B.2.1 Short-distance stage

▶ **Lemma 25** (Short-Distance Stage). *The expected cost incurred by the algorithm in the short-distance stage is*

$$\mathbb{E}\left[ALG_{SD}\right] = \mathbb{E}\Big[\sum_{i \in SD} cost(i)\Big] \leq 36\|\boldsymbol{d}^*\|.$$

Proof. Let us fix a set C_k^ℓ. If $\ell = 0$, then for all $i \in \mathsf{SD}_k^\ell$, we have that $\hat{d}_i \leq (\lambda+1)r$. If $\ell > 0$, we still have that $\hat{d}_i \leq (\lambda+1)2^\ell r \leq 2(\lambda+1)d_i^*$. Summing up overall demands arriving in the short distance stage we have,

$$\begin{aligned}\mathbb{E}\left[\mathsf{ALG}_{\mathsf{SD}}\right] &\leq \sum_{i \in \mathsf{SD}} \mathbb{E}[\mathsf{cost}(i)] \leq \sum_{i \in \mathsf{SD}} 2\delta_i^{(0)} = \sum_{i \in \mathsf{SD}: d_i^* \leq r} 2\delta_i^{(0)} + \sum_{i \in \mathsf{SD}: d_i^* > r} 2\delta_i^{(0)} \\ &\leq 2 \cdot \|(\hat{d}_i)_{i \in \mathsf{SD}: d_i^* \leq r}\| + 2 \cdot \|(\hat{d}_i)_{i \in \mathsf{SD}: d_i^* > r}\| \\ &\leq 2(\lambda+1) \cdot r \cdot \|(1 \dots 1)\| + 4(\lambda+1) \cdot \|\boldsymbol{d}^*\| \\ &\leq 6(\lambda+1) \cdot \|\boldsymbol{d}^*\|.\end{aligned}$$

Here, the second inequality comes from the fact that we need to account for the facility opening cost as well as the connection cost. Moreover, the third inequality holds by norm submodularity, the fourth by what was argued earlier on distances, and the last by definition of r. The lemma then follows from choosing $\lambda = 5$, which is needed for the proof of Lemma 26. ◀

B.2.2 Long-distance stage

▶ **Lemma 26** (Long-Distance Stage). *The expected cost incurred in the long-distance stage is*

$$\mathbb{E}\Big[ALG_{LD}\Big] \leq 48(\log\rho + 1) \cdot \sum_{k \in [K]} f(c_k^*).$$

Proof. Let us fix a cluster ring C_k^ℓ, and let j_k^* be defined such that $f(c_k^*) = f^{(j_k^*)}$. Denote by $\gamma_i^{(j)} := d(c_k^*, W_i^{(j)})$, the distance at step i between the cluster center and a facility whose opening cost is at most $f^{(j)}$. We denote by $\mathcal{E}_\ell^{(j)}$ the event that a facility is opened within a $\gamma_0^{(j)} + 2^{\ell+1}r$ distance from optimal center c_k^*. It is easy to see that such an event occurs whenever the algorithm constructs a facility of cost $f^{(j)}$ or higher for a demand in C_k^ℓ. We now analyze the expected cost accumulated by the algorithm before, and after $\mathcal{E}_\ell^{(j)}$ has occurred. We denote by $t_\ell^{(j)}$ the time of event $\mathcal{E}_\ell^{(j)}$ occurrence.

Before $\mathcal{E}_\ell^{(j)}$ has occurred, we have $\sum_{i \leq t_\ell^{(j)}} \mathbb{E}[\mathsf{cost}^{(j)}(i)] \leq 2f^{(j)}$, by the same reasoning as Claim 22. Hence, we have that the total cost all levels $j \leq j_k^*$ before event $\mathcal{E}_\ell^{(j)}$ is

$$\sum_{j \leq j_k^*} \sum_{\substack{i \in \mathsf{LD}_k^\ell \\ i \leq t_\ell^{(j)}}} \mathbb{E}[\mathsf{cost}^{(j)}(i)] \leq 2 \sum_{j \leq j_k^*} f^{(j)} \leq 4 f^{(j_k^*)}.$$

We seek to demonstrate that these costs make up a constant fraction of all costs during the long-distance stage. Notice that by re-indexing, we can write

$$\sum_{j \leq j_k^*} \sum_{\substack{i \in \mathsf{LD}_k^\ell \\ i < t_\ell^{(j)}}} \mathbb{E}[\mathsf{cost}^{(j)}(i)] = \sum_{j=0}^{j_k^*-1} \sum_{\substack{i \in \mathsf{LD}_k^\ell \\ t_\ell^{(j)} < i \leq t_\ell^{(j+1)}}} \sum_{j'=j+1}^{j_k^*} \mathbb{E}[\mathsf{cost}^{(j')}(i)] = \mathbb{E} \sum_{j=0}^{j_k^*-1} \sum_{\substack{i \in \mathsf{LD}_k^\ell \\ t_\ell^{(j)} < i \leq t_\ell^{(j+1)}}} 2(\delta_i^{(j)} - \delta_i^{(j_k^*)}),$$

i.e., these are also the costs that occur in the range $\{j+1,\dots,j_k^*\}$, during each period between event $\mathcal{E}_\ell^{(j)}$ and $\mathcal{E}_\ell^{(j+1)}$. In particular, we will show for each term in the sum, ${(\delta_i^{(j)}-\delta_i^{(j_k^*)})}/{\delta_i^{(0)}} \geq {\lambda-4}/{\lambda+1}$, so these costs comprise a constant fraction of the total expected cost $2\delta_i^{(0)}$ at each step i.

We start with the simple observation that

$$\frac{\delta_i^{(j)}-\delta_i^{(j_k^*)}}{\delta_i^{(0)}} = \frac{\hat{d}_i^{(j)}-\hat{d}_i^{(j_k^*)}}{\hat{d}_i^{(0)}} \geq \frac{d(x_i, W_i^{(j)})}{d(x_i, F_{i-1})} - \frac{d(x_i, c_k^*)}{\hat{d}_i^{(0)}},$$

by definition and subadditivity. We now proceed with bounding each term. Since $\mathcal{E}_\ell^{(j)}$ has occurred, but we are still in the long distance stage, we have

$$(\lambda+1)2^\ell r < \hat{d}_i^{(0)} \leq d(x_i, F_{i-1}) \leq d(x_i, c_k^*) + d(c_k^*, F_{i-1}) \leq \gamma_i^{(j)} + 3\cdot 2^\ell r.$$

This implies both $d(x_i, F_{i-1}) \leq \gamma_i^{(j)} + 3\cdot 2^\ell r$ and $\gamma_i^{(j)} \geq (\lambda-2)2^\ell r$. Additionally, we have $d(x_i, c_k^*) \leq 2^\ell r$, and by triangle inequality, we have that $\gamma_i^{(j)} \leq d(x_i, W_i^{(j)}) + 2^\ell r$.

Altogether, we get

$$\frac{d(x_i, W_i^{(j)})}{d(x_i, F_{i-1})} - \frac{d(x_i, c_k^*)}{\hat{d}_i^{(0)}} \geq \frac{\gamma_i^{(j)} - 2^\ell r}{\gamma_i^{(j)} + 3\cdot 2^{\ell+1} r} - \frac{2^\ell r}{(\lambda+1)2^\ell r} \geq \frac{\lambda-4}{\lambda+1},$$

as desired. Thus, the total cost of points in LD_k^ℓ is bounded as follows:

$$\begin{aligned}\sum_{i\in\mathsf{LD}_k^\ell} \mathbb{E}[\mathsf{cost}(i)] &= \sum_{j=0}^{j_k^*-1} \sum_{\substack{i\in\mathsf{LD}_k^\ell \\ t_\ell^{(j)}<i\leq t_\ell^{(j+1)}}} \mathbb{E}[\mathsf{cost}(i)] = \mathbb{E}\sum_{j=0}^{j_k^*-1} \sum_{\substack{i\in\mathsf{LD}_k^\ell \\ t_\ell^{(j)}<i\leq t_\ell^{(j+1)}}} 2\delta_i^{(0)} \\ &\leq 2\frac{\lambda+1}{\lambda-4}\cdot\mathbb{E}\sum_{j=0}^{j_k^*-1} \sum_{\substack{i\in\mathsf{LD}_k^\ell \\ t_\ell^{(j)}<i\leq t_\ell^{(j+1)}}} (\delta_i^{(j)}-\delta_i^{(j_k^*)}) \\ &\leq 8\frac{\lambda+1}{\lambda-4} f^{(j_k^*)}.\end{aligned}$$

We now sum across all concentric rings across all K optimal clusters, to obtain that

$$\sum_{i\in\mathsf{LD}} \mathbb{E}[\mathsf{cost}(i)] = \sum_{k=1}^{K}\sum_{\ell=0}^{L}\sum_{i\in\mathsf{LD}_k^\ell} \mathbb{E}[\mathsf{cost}(i)] \leq 8L\left(\frac{\lambda+1}{\lambda-4}\right)\cdot\sum_{k\in[K]} f^{(j_k^*)},$$

and the claim follows from choosing $\lambda = 5$. ◀

B.3 Lower Bound

▶ **Theorem 31.** *For any monotone norm $\|\cdot\|$, there exists a uniform-cost OFL problem with norm $\|\cdot\|$ such that any online algorithm only achieves $\Omega\left(\frac{\log\sigma}{\log\log\sigma}\right)$ competitive ratio, where $\sigma = \frac{\|\mathbf{1}_{\leq n}\|}{\max_i \|e_i\|}$. Notice that for symmetric norms, $\sigma = \rho$.*

Proof. We may assume $\max_i \|e_i\| = 1$ (otherwise we rescale costs), so $\|\mathbf{1}_{\leq n}\| = \sigma$. Let k be the largest integer such that $k^k \leq \sigma$, so we have $k = \Theta\left(\frac{\log \sigma}{\log \log \sigma}\right)$. Assume $k \geq 2$.

Now, let $G = (V, E)$ be a complete N-ary tree with height k, where N is sufficiently large (intuitively, think of N as infinite). For $j = 0, \dots k-1$, each downwards edge from a node at depth level j will have length k^{-j}. We also define the facility opening cost to be k.

Let $0 \leq m_0 \leq m_1 \leq \cdots \leq m_k$ be defined such that m_j is the least positive integer with $\|\mathbf{1}_{\leq m_j}\| \geq k^j$. Notice that this implies $\|\mathbf{1}_{\leq m_j}\| \leq \|\mathbf{1}_{\leq m_j - 1}\| + \|e_{m_j}\| < k^j + 1$.

Our adversary will supply the demand locations as follows. First, they will choose a random path $v_0 v_1 \dots v_k$ from the root v_0 to a leaf v_k. Then, for $j = 0, \dots, k$, the adversary supply v_j as a demand repeated $m_j - m_{j-1}$ times (m_0 times for $j = 0$).

In the offline setting, one may simply place a single facility at v_k and assign all demands to it. This gives

$$\mathsf{OPT} = k + \|\boldsymbol{d}^*\| \leq k + \sum_{j=0}^{k-1} k^{-j} \|\mathbf{1}_{\leq m_j}\| \leq k + \sum_{j=0}^{k-1} k^{-j}(k^j + 1) = O(k).$$

In the online setting, we will show that no algorithm can achieve an expected cost of less than $\Omega(k^2)$.

Notice that any online algorithm, upon receiving a demand at v_j, should only consider the options of allocating the demand or constructing a facility at v_j. Constructing a facility anywhere else is strictly disadvantageous, as there is a negligible probability (by choice of N) that the chosen location is in the subtree rooted at v_{j+1}. Thus, after the algorithm is complete, it will have constructed a set of facilities $F \subseteq \{v_0, \dots, v_k\}$, and each demand will be allocated to the most recently constructed facility above it. Let $\boldsymbol{d}$ be the vector of allocation distances.

If there is some $j \geq 2$ such that $v_j, v_{j-1} \notin F$, then notice that every demand at v_j will have allocation distance at least k^{-j+2}. Thus, we have

$$\|\boldsymbol{d}\| \geq k^{-j+2} \|\mathbf{1}_{\leq m_j} - \mathbf{1}_{\leq m_{j-1}}\| \geq k^{-j+2}(\|\mathbf{1}_{\leq m_j}\| - \|\mathbf{1}_{\leq m_{j-1}}\|) \geq k^2 - k - k^{-j+2} = \Omega(k^2)$$

However, if no such j exists, then $|F| \geq k/2$, so construction costs are at least $k^2/2 = \Omega(k^2)$. ◀

▶ **Corollary 32.** *In the case of a symmetric norm $\|\cdot\|$, our lower bound becomes $\Omega\left(\frac{\log \rho}{\log \log \rho}\right)$ as $\rho = \sigma = \frac{\|\mathbf{1}_{\leq n}\|}{\|e_1\|}$.*

Independent Sets in Elimination Graphs with a Submodular Objective

Abstract

Maximum weight independent set (MWIS) admits a $\frac{1}{k}$-approximation in inductively k-independent graphs [2, 40] and a $\frac{1}{2k}$-approximation in k-perfectly orientable graphs [34]. These are a parameterized class of graphs that generalize k-degenerate graphs, chordal graphs, and intersection graphs of various geometric shapes such as intervals, pseudo-disks, and several others [40, 34]. We consider a generalization of MWIS to a submodular objective. Given a graph $G = (V, E)$ and a non-negative submodular function $f : 2^V \to \mathbb{R}_+$, the goal is to approximately solve $\max_{S \in \mathcal{I}_G} f(S)$ where $\mathcal{I}_G$ is the set of independent sets of G. We obtain an $\Omega(\frac{1}{k})$-approximation for this problem in the two mentioned graph classes. The first approach is via the multilinear relaxation framework and a simple contention resolution scheme, and this results in a randomized algorithm with approximation ratio at least $\frac{1}{e(k+1)}$. This approach also yields parallel (or low-adaptivity) approximations.

Motivated by the goal of designing efficient and deterministic algorithms, we describe two other algorithms for inductively k-independent graphs that are inspired by work on streaming algorithms: a preemptive greedy algorithm and a primal-dual algorithm. In addition to being simpler and faster, these algorithms, in the monotone submodular case, yield the first deterministic constant factor approximations for various special cases that have been previously considered such as intersection graphs of intervals, disks and pseudo-disks.

1 Introduction

Given a graph $G = (V, E)$ a set $S \subseteq V$ of vertices is an independent set (also referred to as a stable set) if there is no edge between any two vertices in S. Let $\alpha(G)$ denote the cardinality of a maximum independent set in G. Finding $\alpha(G)$ is a classical problem with many applications; we refer to the search problem of finding a maximum cardinality independent set as MIS. We also consider the weighted version where the input consists of G and a vertex weight function $w : V \to \mathbb{Z}_+$ and the goal is to find a maximum weight independent set; we refer to the weighted problem as MWIS. MIS is NP-Hard, and moreover it is also NP-Hard to approximate $\alpha(G)$ to within a $\frac{1}{n^{1-\epsilon}}$-factor for any fixed $\epsilon > 0$ [32, 41]. For this reason, MIS and MWIS are studied in various special classes of graphs that capture interesting problems while also being tractable. It is easy to see that graphs with maximum degree k admit a $\frac{1}{k}$-approximation. In fact, the same approximation ratio holds for k-degenerate graphs – a

graph $G = (V, E)$ is a k-degenerate if there is an ordering of the vertices $\mathcal{V} = \{v_1, \ldots, v_n\}$ such that for each v_i, $|N(v_i) \cap \{v_i, \ldots, v_n\}| \leq k$. A canonical example is the class of planar graphs which are 5-degenerate.

In this paper we are interested in two parameterized classes of graphs called inductively k-independent graphs [40] and k-perfectly orientable graphs [34]. These graphs are motivated by the well-known class of chordal graphs, and capture several other interesting classes such as intersection graphs of intervals, disks (and hence planar graphs), low-treewidth graphs, t-interval graphs, and many others. A more recent example is the intersection graph of a collection of pseudo-disks which were shown to be inductively 156-independent [38]. Graphs in these classes can be dense and have large cliques. We formally define the classes.

Given a graph $G = (V, E)$ and a vertex v we let $N(v)$ denote the set of neighbors of v (excluding v). A graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with n vertices has a *perfect elimination ordering* if there is an ordering of vertices $\mathcal{V} = \{v_1, \ldots, v_n\}$ such that for each v_i, $\alpha(G[N(v_i) \cap \{v_i, \ldots, v_n\}]) = 1$; in other words $N(v_i) \cap \{v_i, \ldots, v_n\}$ is a clique. It is well-known that these graphs are the same as chordal graphs.[1] For example, the intersection graph of a given set of intervals is chordal. One can generalize the perfect elimination property ordering of chordal graphs.

▶ **Definition 1** ([34]). *For a fixed integer $k \geq 1$, $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ is* k-simplicial *if there is an ordering of vertices $\mathcal{V} = \{v_1, \ldots, v_n\}$ such that for each v_i, $G[N(v_i) \cap \{v_i, \ldots, v_n\}]$ can be covered by k cliques.*

Note that if $G[N(v_i) \cap \{v_i, \ldots, v_n\}]$ is covered by k cliques then $\alpha(G[N(v_i) \cap \{v_i, \ldots, v_n\}]) \leq k$. Hence one can define a class based on this weaker property.

▶ **Definition 2** ([2, 40]). *For a fixed integer $k \geq 1$, $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ is* inductively k-independent *if there is an ordering of vertices $\mathcal{V} = \{v_1, \ldots, v_n\}$ such that for each v_i, $\alpha(G[N(v_i) \cap \{v_i, \ldots, v_n\}]) \leq k$. The* inductive independence number *of $\mathcal{G}$ is the minimum k for which $\mathcal{G}$ is inductively k-independent.*

Although inductively k-independent graphs generalize k-simplicial graphs there is no known natural class of graphs that differentiates the two; typically one establishes inductive k-independence via k-simpliciality. The ordering-based definition can be further relaxed based on orientations of G.

▶ **Definition 3** ([34]). *For a fixed integer $k \geq 1$, $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ is* k-perfectly orientable *if there is an orientation $H = (V, A)$ of $\mathcal{G}$ such that for each vertex $v \in \mathcal{V}$, $G[S_v]$ can be covered by k cliques, where $S_v = N_H^+(v)$ is the out-neighborhood of v in H.*

▶ Remark 4. In this paper we will use the term k-perfectly orientable for the following class of graphs: there is an orientation $H = (V, A)$ of $\mathcal{G}$ such that for each vertex $v \in \mathcal{V}$, $\alpha(G[S_v]) \leq k$ where $S_v = N_H^+(v)$ is the out-neighborhood of v in H. This is more general than the preceding definition. We observe that the algorithm in [34] for MWIS works also for this larger class, although there are no known natural examples that differentiate the two.

We observe that if G is inductively k-independent then it is also k-perfectly orientable according to our relaxed definition. Indeed, if $v_1, v_2, \ldots, v_n$ is an ordering that certifies inductive k-independence we simply orient the edges of G according to this ordering which yields a DAG. The advantage of the k-perfect orientability is that it allows arbitrary orientations. Note that a cycle is 1-perfectly orientable while it is 2-inductively independent. This factor

[1] A graph is chordal iff there is no induced cycle of length more than 3.

of 2 gap shows up in the known approximation bounds for MWIS in these two classes of graphs. It is known that for arbitrarily large n there are 2-perfectly orientable graphs on n vertices such that the graphs are not inductively $\sqrt{n}$-independent [5]. These come from the intersection graphs of so-called 2-interval graphs. Thus, k-perfect orientability can add substantial modeling power.

Akcoglu et al. [2] described a $\frac{1}{k}$-approximation for the MWIS problem in graphs that are inductively k-independent. They used the local-ratio technique, and subsequently [40] derived it using a stack-based algorithm. Both algorithms require as input an ordering of the vertices that certifies the inductive k-independent property. For k-perfectly orientable graphs [34] described a $\frac{1}{2k}$-approximation for the MWIS problem following the ideas in [5] for a special case. Given a graph $G = (V, E)$ and integer k there is an $n^{O(k)}$-time algorithm to check if G is inductively k-independent [40]. Typically, the proof that a specific class of graphs is inductively k-independent for some fixed value of k, yields an efficient algorithm that also computes a corresponding ordering. This is also true for k-perfect orientability. We refer the reader to [30] for additional discussion on computational aspects of computing orderings. In this paper we will assume that we are given both G and the ordering that certifies inductive k-independence, or an orientation that certifies k-perfect orientability.

1.1 Independent sets with a submodular objective

We consider an extension of MWIS to submodular objectives. A real-valued set function $f : 2^V \to \mathbb{R}$ is modular iff $f(A)+f(B) = f(A\cup B)+f(A\cap B)$ for all $A, B \subseteq V$. It is easy to show that f is modular iff there a weight function $w : V \to \mathbb{R}$ where $f(A) = w(A) = \sum_{v\in A} w(v)$. A real-valued set function $f : 2^V \to \mathbb{R}$ is *submodular* if $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$ for all $A, B \subseteq V$. An equivalent definition is via decreasing marginal value property: for any $A \subset B \subset V$ and $v \in V - B$, $f(A + v) - f(A) \geq f(B + v) - f(B)$. Here $A + v$ is a convenient notation for $A \cup \{v\}$. f is monotone if $f(A) \leq f(B)$ for all $A \subseteq B$. We will confine our attention in this paper to non-negative submodular functions and we will also assume that $f(\emptyset) = 0$. Given a graph $G = (V, E)$ and a non-negative submodular function $f : 2^V \to \mathbb{R}_+$, we consider the problem $\max_{S\subseteq \mathcal{I}_G} f(S)$ where $\mathcal{I}_G$ is the collection of independent sets in G. This problem generalizes MWIS since a modular function is also submodular. We assume throughout that f is available through a value oracle that returns $f(S)$ on query S. Our focus is on developing approximation algorithms for this problem in the preceding graph classes, since even very simple special cases are NP-Hard.

Motivation and related work. Submodular function maximization subject to various "independence" constraints has been a very active area of research in the last two decades. There have been several important theoretical developments, and a variety of applications ranging from algorithmic game theory, machine learning and artificial intelligence, data analysis, and network analysis; see [10, 6, 22] for some pointers. We are motivated to consider this objective in inductive k-independent graphs and k-perfectly orientable graphs for several reasons. First, it is a natural generalization of MWIS. Second, various special cases of this problem have been previously studied: Feldman [24] considered the case of interval graphs, and Chan and Har-Peled considered the case of intersection graphs of disks and pseudo-disks [16]. Third, previous algorithms have relied on the multilinear relaxation based approach combined with contention resolution schemes for rounding. This is a computationally expensive approach and also requires randomization. The known approximation algorithms for MWIS in inductive k-independent graphs are based on simple combinatorial methods such as local-ratio, and this raises the question of developing similar combinatorial algorithms for submodular objectives. In particular, we are inspired by the connection to *preemptive* greedy algorithms for submodular function maximization that have been developed in the context of streaming algorithms [15, 3, 17]. Although a natural greedy algorithm has been extensively studied for submodular function maximization [36, 28], the utility of the preemptive version for offline approximation has not been explored as far as we are aware of. This is partly due to the fact that the standard greedy algorithm works well for matroid like constraints. More recently [35] developed a primal-dual based algorithm for submodular streaming under b-matching constraints which is inspired by the stack based algorithm of [37] for the modular setting; the latter has close connections to stack based algorithms for inductive k-independent graphs [40]. The algorithm in [35] was generalized to matroid intersection in [29]. Finally, at a meta-level, we are also interested in understanding the relationship in approximability between optimizing with modular objectives and submodular objectives. For many "independence" constraints the approximability of the problem with a submodular objective is often within a constant factor of the approximability with a modular objective, but there are also settings in which the submodular objective is provably harder (see [7]). A substantial amount of research on submodular function optimization is for constraints defined by *exchange* systems such as (intersections of) matroids and their generalizations such as k-exchange systems [27] and k-systems [33, 14]. Independent sets in the graph classes we consider provide a different parameterized family of constraints.

1.2 Results

We obtain an $\Omega(\frac{1}{k})$-approximation for $\max_{S\subseteq\mathcal{I}} f(S)$ in inductively k-independent graphs and in k-perfectly orientable graphs. We explore different techniques to achieve these results since they have different algorithmic benefits.

First, we obtain a randomized algorithm via the multilinear relaxation framework [21] by considering a natural polyhedral relaxation and developing simple contention resolution schemes (CRS). The CRS schemes are useful since one can combine the rounding with other side constraints in various applications.

► **Theorem 5.** *There is a randomized algorithm that given a k-perfectly orientable graph G (along with its orientation) and a monotone submodular function f, outputs an independent set S' such that with high probability $f(S') \geq (\frac{1}{k+1} \cdot \frac{1}{(1+1/k)^k}) \max_{A\in\mathcal{I}_G} f(A)$. For non-negative functions there is an algorithm that outputs an independent set S' such that with high probability $f(S') \geq \frac{1}{e(k+1)} \max_{A\in\mathcal{I}_G} f(A)$.*

The multilinear relaxation based approach yields parallel (or low-adaptivity) algorithms with essentially similar approximation ratios, following ideas in [20, 23]. Although the multilinear approach is general and powerful, there are two drawbacks; algorithmic complexity and randomization which are inherent to the approach. An interesting question in the submodular maximization literature is whether one can obtain deterministic algorithms via alternate methods, or by derandomizing the multilinear relaxation approach. There have been several results along these lines [9, 11, 31], and several open problems.

Motivated by these considerations we develop simple and efficient approximation algorithms for inductively k-independent graphs. We show that a preemptive greedy algorithm, inspired by the streaming algorithm in [17], yields a deterministic $\Omega(\frac{1}{k})$-approximation when f is monotone. This can be combined with a simple randomized approach when f is non-monotone. Inspired by [35], we describe a primal-dual algorithm that also yields a $\Omega(\frac{1}{k})$-approximation; the primal-dual approach yields better constants and we state the result below.

▶ **Theorem 6.** *There is a deterministic combinatorial algorithm that given an inductively k-independent graph G (along with its orientation) and a monotone submodular function f, outputs an independent set S' such that $f(S') \geq \frac{1}{k+1+2\sqrt{k}} \max_{A \in \mathcal{I}_G} f(A)$. For non-negative functions there is a randomized algorithm that outputs an independent set S' such that $\mathbf{E}[f(S')] \geq \frac{1}{2k+1+\sqrt{8k}} \max_{A \in \mathcal{I}_G} f(A)$. Both algorithms use $O(|V(G)|)$ value oracle calls to f and in addition take linear time in the size of G.*

▶ Remark 7. We obtain deterministic $1/4$-approximation for monotone submodular function maximization for independent sets in chordal graphs, and hence also for interval graphs. This matches the best ratio known via the multilinear relaxation approach [24], and is the first deterministic algorithm as far as we know. Similarly, this is the first deterministic algorithm for disks and pseudo-disks that were previously handled via the multilinear relaxation approach [16]. Are there deterministic algorithms for k-perfectly orientable graphs? See Section 5.

▶ Remark 8. Matchings in a graph G, when viewed as independent sets in the line graph H of G, form an inductively 2-independent graph. In fact *any* ordering of the edges of G forms a valid 2-inductive ordering of H. Thus our algorithm is also a semi-streaming algorithm. Our approximation bound for monotone functions matches the approximation achieved in [35] for matchings although we use a different LP relaxation and view the problem from a more general viewpoint. However, for non-monotone functions, our ratio is slightly weaker, and highlights some differences.

The primal-dual algorithm is a two-phase algorithm. The preemptive greedy algorithm is a single phase algorithm. It gives slightly weaker approximation bounds when compared to the primal-dual algorithm, but has the advantage that it can be viewed as an *online preemptive* algorithm. Algorithms in such a model for submodular maximization were developed in [12, 25]. Streaming algorithms for submodular function maximization in [15, 17] can be viewed as online preemptive algorithms. Our work shows that there is an online preemptive algorithm for independent sets of inductive k-independent graphs if the vertices arrive in the proper order. There are interesting examples where any ordering of the vertices is a valid k-inductive ordering.

Our main contribution in this paper is conceptual. We study the problem to unify and generalize existing results, understand the limits of existing techniques, and raise some directions for future research (see Section 5). As we mentioned, our techniques are inspired by past and recent work on submodular function maximization [21, 24, 17, 35].

Organization

Section 2 sets up the relevant technical background on submodular functions. Section 3 describes the multilinear relaxation approach and proves Theorem 5. Section 4 describes the primal-dual approach and proves Theorem 6. Section 5 concludes with a discussion of some open problems. The description and analysis of the preemptive greedy algorithm can be found in Appendix A.

2 Preliminaries

Let $f : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ be a real-valued nonnegative set function defined over a finite ground set $\mathcal{N}$. The function f is *monotone* if $f(S) \leq f(T)$ for any nested sets $S \subseteq T \subseteq \mathcal{N}$, and *submodular* if it has decreasing marginal returns: if $S \subseteq T \subseteq \mathcal{N}$ are two nested sets and $e \in \mathcal{N} \setminus T$ is an element, then $f(S+e) - f(S) \geq f(T+e) - f(T)$. For two sets $A, B \subseteq \mathcal{N}$, we denote the marginal value of adding B to A by $f_A(B) \overset{\text{def}}{=} f(A \cup B) - f(A)$.

Incremental values

In this paper, there is always an implicit ordering $<$ over the ground set $\mathcal{N}$. For a set $S \subseteq \mathcal{N}$ and an element $e \in \mathcal{N}$, the *incremental value* of e in S, denoted $\nu(f, S, e)$, is defined as

$$\nu(f, S, e) = f_{S'}(e), \text{ where } S' = \{s \in S : s < e\}.$$

Incremental value has some simple but very useful properties, proved in [17, Lemmas 1–3] and summarized in the following.

▶ **Lemma 9.** *Let $\mathcal{N}$ be an ordered set and $f : 2^{\mathcal{N}} \to \mathbb{R}$ a set function.*

(a) *For any set $S \subseteq \mathcal{N}$, we have $f(S) = \sum\limits_{e \in S} \nu(f, S, e)$.*

(b) *Let $S \subseteq T \subseteq \mathcal{N}$ be two nested subsets of $\mathcal{N}$ and $e \in \mathcal{N}$ an element. If f is submodular, then $\nu(f, T, e) \leq \nu(f, S, e)$.*

(c) *Let $S, Z \subseteq \mathcal{N}$ be two sets, and $e \in S$. If f is submodular, then $\nu(f_Z, S, e) \leq \nu(f, Z \cup S, e)$.*

Multilinear Extension and Relaxation

▶ **Definition 10.** *Given a set function $f : 2^{\mathcal{N}} \to \mathbb{R}$, the* multilinear extension *of f, denoted F, extends f to the product space $[0,1]^{\mathcal{N}}$ by interpreting each point $x \in [0,1]^{\mathcal{N}}$ as an independent sample $S \subseteq \mathcal{N}$ with sampling probabilities given by x, and taking the expectation of $f(S)$. Equivalently,*

$$F(x) = \sum_{S \subseteq \mathcal{N}} \left(\prod_{i \in S} x_i \prod_{i \notin S} (1 - x_i) \right).$$

An *independence family* $\mathcal{I}$ over a ground set $\mathcal{N}$ is a subset of $2^{\mathcal{N}}$ that is downward closed, that is, if $A \in \mathcal{I}$ and $B \subset A$ then $B \in \mathcal{I}$. A polyhedral/convex relaxation P for a given independence family $\mathcal{I}$ over $\mathcal{N}$ is a polyhedra/convex subset of $[0,1]^{\mathcal{N}}$ such that for each $A \in \mathcal{I}$, $\chi_A \in P$ where χ_A is the characteristic vector of A (a vector in $\{0,1\}^{\mathcal{N}}$ with a 1 in coordinate i iff $i \in A$). We say that P is a *solvable* relaxation for $\mathcal{I}$ if there is a polynomial time algorithm to optimize a linear objective over P. Given a ground set $\mathcal{N}$, and a non-negative submodular function f over $\mathcal{N}$, and an independence family $\mathcal{I} \subseteq 2^{\mathcal{N}}$,[2] we are interested in the problem $\max_{S \in \mathcal{I}} f(S)$. For this general problem the multilinear relaxation approach is to approximately solve the multilinear relaxation $\max_{x \in P} F(x)$ followed by rounding – see [14, 21, 10]. For monotone f there is a randomized $(1 - 1/e)$-approximation to the multilinear relaxation when P is solvable [14]. For general non-negative functions there is a 0.385-approximation [11].

Concave closure and relaxation

▶ **Definition 11.** *Given a set function $f : 2^{\mathcal{N}} \to \mathbb{R}$, the* concave closure *of f, denoted f^+, extends f to the product space $[0,1]^{\mathcal{N}}$ as follows. For $x \in [0,1]^{\mathcal{N}}$ we let*

$$f^+(x) = \max \left\{ \sum_{S \subseteq \mathcal{N}} \alpha_S f(S) : \sum_{S \ni i} \alpha_S = x_i \textit{ for all } i \in \mathcal{N}, \sum_{S} \alpha_S = 1, \alpha_S \geq 0 \textit{ for all } S \subseteq N \right\}.$$

[2] We assume that an independence family is specified implicitly via an independence oracle that returns whether a given $A \subseteq \mathcal{N}$ belongs to $\mathcal{I}$.

As the name suggests, f^+ is a concave function over $[0,1]^{\mathcal{N}}$ for any set function f. The definition of $f^+(x)$ involves the solution of an exponential sized linear program. The concave closure of a submodular set function is in general NP-Hard to evaluate. Nevertheless, the concave closure is useful indirectly in several ways. One can relate the concave closure to the multilinear extension via the notion of correlation gap [1, 13, 39, 19]. We can consider a relaxation based on the concave closure for the problem of $\max_{S \in \mathcal{I}} f(S)$, namely, $\max_{x \in P} f^+(x)$ where P is a polyhedral or convex relaxation for the constraint set $\mathcal{I}$. Although we may not be able to solve this relaxation directly, it provides an upper bound on the optimum solution and moreover, unlike the multilinear relaxation, the relaxation can be rewritten as a large linear program when P is polyhedral.

Contention Resolution Schemes

Contention resolution schemes are a way to round fractional solutions for relaxations to packing problems and they are a powerful and useful tool in submodular function maximization [21]. For a polyhedral relaxation P for $\mathcal{I}$ and a real $b \in [0,1]$, bP refers to the polyhedron $\{bx \mid x \in P\}$.

▶ **Definition 12.** *Let $b, c \in [0,1]$. A (b,c)-balanced* CR *scheme π for a polyhedral relaxation P for $\mathcal{I}$ is a procedure that for every $bx \in bP$ and $A \subseteq N$, returns a* random *set $\pi_x(A) \subseteq A \cap \mathit{support}(x)$ and satisfies the following properties:*
(a) *$\pi_x(A) \in \mathcal{I}$ with probability 1 $\quad \forall A \subseteq N, x \in bP$, and*
(b) *for all $i \in \mathit{support}(x)$, $\mathbf{P}[i \in \pi_x(R(x)) \mid i \in R(x)] \geq c \quad \forall x \in bP$.*
The scheme is said to be monotone *if $\mathbf{P}[i \in \pi_x(A_1)] \geq \mathbf{P}[i \in \pi_x(A_2)]$ whenever $i \in A_1 \subseteq A_2$. A $(1,c)$-balanced* CR *scheme is also called a* c-balanced CR scheme. *The scheme is* deterministic *if π is a deterministic algorithm (hence $\pi_x(A)$ is a single set instead of a distribution). It is* oblivious *if π is deterministic and $\pi_x(A) = \pi_y(A)$ for all x, y and A, that is, the output is independent of x and only depends on A. The scheme is* efficiently implementable *if π is a polynomial-time algorithm that given x, A outputs $\pi_x(A)$.*

3 Approximating via Contention Resolution Schemes

Let $G = (V,E)$ be an inductively k-independent graph and let $\mathcal{V} = \{v_1, v_2, \ldots, v_n\}$ be the corresponding order. Let $\mathcal{I}$ denote the set of independent sets of G. We consider the following simple polyhedral relaxation for $\mathcal{I}$ where there is a variable x_i for each vertex v_i. For notational simplicity we let A_i denote the set $N(v_i) \cap \{v_{i+1}, \ldots, v_n\}$ which is the set of neighbors of v_i that come after v_i in the ordering.

$$x_i + \sum_{v_j \in A_i} x_j \leq k \quad \text{for all } i \in [n]$$

$$x_i \in [0,1] \quad \text{for all } i \in [n]$$

This is a valid polyhedral relaxation for $\mathcal{I}$. Indeed, consider an independent set $S \subseteq V$, and let x be the indicator vector of S. Fix a vertex v_i and consider the first inequality. If $v_i \in S$, then since $A_i \subseteq N(v_i)$, we have $A_i \cap S = \emptyset$, and the left hand side (LHS) is 1. Otherwise $\sum_{v_j \in A_i} x_j = |A_i \cap S| \leq \alpha(A_i) \leq k$, so the LHS is at most k.

In fact, the $\frac{1}{k}$-approximation for MWIS in [2, 40] are implicitly based on this relaxation. Moreover, the relaxation has a polynomial number of constraints and hence is solvable. We refer to this relaxation as Q_G and omit G when clear from the context. The multilinear relaxation is to solve $\max_{x \in Q_G} F(x)$.

Now we consider the case when $G = (V, E)$ is a k-perfectly orientable graph. Let $H = (V, A)$ be an orientation of G. For a given $v \in V$ we let $N^+_H(v) = \{u \in V \mid (v, u) \in A\}$ denote the out-neighbors of v in H. We can write a simple polyhedral relaxation for independent sets in G where we have a variable x_v for each $v \in V$ as follows:

$$x_v + \sum_{u \in N^+_H(v)} x_u \leq k \quad \text{for all } v \in V$$

$$x_v \in [0,1] \quad \text{for all } v \in V$$

To avoid notational overhead we will use Q_G to refer to the preceding relaxation for a k-perfectly orientable graph G. In [34] a stronger relaxation than the preceding relaxation is used to obtain a $\frac{1}{2k}$-approximation for MWIS. It is not hard to see, however, that the proof in [34] can be applied to the simpler relaxation above.

We will only consider k-perfectly orientable graphs in the rest of this section since the CR scheme applies for this more general class and we do not have a better scheme for inductively k-independent graphs. We consider two simple CR schemes for Q. The first is an oblivious deterministic one. Given a set R it outputs S where $S = \{v \in R \mid N^+_H(v) \cap R = \emptyset\}$. In other words it discards from R any vertex v which has an out-neighbor in R. We claim that S is an independent set. To see this suppose $uv \in E(G)$. In H, uv is oriented as (u, v) or (v, u). Thus, both u and v cannot be in S even if they are both are picked in R. It is also easy to see that the scheme is monotone.

We now describe a randomized non-oblivious scheme which yields slightly better constants and is essentially the same as the one from [24] where interval graphs were considered (a special case of $k = 1$). This scheme works as follows. Given R and x it creates a subsample $R' \subseteq R$ by sampling each $v \in R$ independently with probability $(1 - e^{-x_v})/x_v$ (Note that $1 - e^{-y} \leq y$ for all $y \in [0, 1]$.). Equivalently R' is obtained from x by sampling each v with probability $1 - e^{-x_v}$. It then applies the preceding deterministic scheme to R'. Note that this scheme is randomized and non-oblivious since it uses x in the sub-sampling step. It is also easy to see that it is monotone.

We analyze the two schemes.

▶ **Theorem 13.** *For each $b \in [0, 1]$ there is a deterministic, oblivious, monotone $(b/k, 1 - b)$ CR scheme for Q. There is a randomized monotone $(b/k, e^{-b})$ CR scheme for Q.*

Proof. Let $x \in \frac{b}{k} Q$ and Let R be a random set obtained by picking each $v \in V$ independently with probability x_v. We first analyze the deterministic CR scheme. Fix a vertex $v \in \text{support}(x)$ and condition on $v \in R$. The vertex v is included in the final output iff $N^+_H(v) \cap R = \emptyset$. Since $x \in \frac{b}{k} Q$ we have $\sum_{u \in N^+(v)} x_u \leq b - x_v \leq b$.

$$\mathbf{P}[v \in S \mid v \in R] = \mathbf{P}[N^+(v) \cap R = \emptyset] = \prod_{u \in N^+(v)} (1 - x_u) \geq 1 - \sum_{u \in N^+(v)} x_u \geq 1 - b.$$

This shows that the scheme is a $(b/k, 1 - b)$ CR scheme.

Now we analyze the randomized scheme which follows [24]. Consider $v \in R(x)$. We see that $v \in S$ conditioned on $v \in R$, if $v \in R'$ and $R' \cap N^+(v) = \emptyset$. Since the vertices are picked independently,

$$\mathbf{P}[v \in S \mid v \in R] = \mathbf{P}[v \in R' \mid v \in R] \cdot \mathbf{P}[N^+(v) \cap R' = \emptyset] = \frac{(1 - e^{-x_v})}{x_v} \prod_{u \in N^+(v)} e^{-x_u}$$

$$\geq \frac{(1 - e^{-x_v})}{x_v} e^{-(b - x_v)} \geq \frac{(e^{x_v} - 1)}{x_v} e^{-b} \geq e^{-b}.$$

This finishes the proof. ◀

One can apply the preceding CR schemes for Q_G along with the known framework via the multilinear relaxation to approximate $\max_{S\in\mathcal{I}} f(S)$. Let OPT be the value of an optimum solution. For monotone functions the Continuous Greedy algorithm [14] can be used to find a point $x \in \frac{b}{k}Q$ such that $F(x) \geq (1-e^{-b/k})\,\mathrm{OPT}$. When combined with the $(b/k, 1-b)$ CR scheme this yields a $(1-e^{-b/k})(1-b)$-approximation. The randomized CR scheme yields a $(1-e^{-b/k})e^{-b}$-approximation; this bound is maximized when $b = k\ln(1+1/k)$ and the ratio is $\frac{1}{k+1}\cdot\frac{1}{(1+1/k)^k} \geq \frac{1}{e(k+1)}$. For non-negative functions one can use Measured Continuous Greedy [26, 24] to obtain $x \in \frac{b}{k}Q$ such that $F(x) \geq \frac{b}{k}e^{-b/k}\,\mathrm{OPT}$. Combined with the CR scheme this yields a $(\frac{b}{k}e^{-b(1+/k)})$-approximation. Setting $b = k/(k+1)$ yields a $\frac{1}{e(k+1)}$-approximation.

▶ **Theorem 14.** *There is a randomized algorithm that given a k-perfectly orientable graph G (along with its orientation) and a monotone submodular function f, outputs an independent set S' such that with high probability $f(S') \geq (\frac{1}{k+1}\cdot\frac{1}{(1+1/k)^k})\max_{A\in\mathcal{I}} f(A)$. For non-negative functions there is an algorithm that outputs an independent set S' such that with high probability $f(S') \geq \frac{1}{e(k+1)}\max_{A\in\mathcal{I}} f(A)$.*

Efficiency and Parallelism

Approximately solving the multilinear relaxation is typically a bottleneck. [18] develops faster algorithms via the multiplicative-weight update (MWU) based method. We refer the reader to [18] for concrete running times that one can obtain in terms of the number of oracle calls to f or F. Once the relaxation is solved, rounding via the CR scheme above is simple and efficient. Another aspect is the design of parallel algorithms, or algorithms with low adaptivity – we refer the reader to [4] for the motivation and set up. Via results in [20, 23], and the CR scheme above, we can obtain algorithms with adaptivity $O(\frac{\log^2 n}{\epsilon^2})$ while only losing a $(1-\epsilon)$-factor in the approximation compared to the sequential approximation ratios. We defer details.

4 Primal-Dual Approach for Inductively k-Independent Graphs

We now consider a primal-dual algorithm. This is inspired by previous algorithms for MWIS in inductively k-independent graphs, and the work of Levin and Wajc [35] who considered a primal-dual based semi-streaming algorithm for submodular function maximization under matching constraints.

The stack based algorithm in [40] for MWIS is essentially a primal-dual algorithm. It is instructive to explicitly consider the LP relaxation and the analysis for MWIS before seeing the algorithm and analysis for the submodular setting. An interested reader can find this exposition in the full version.

Following [35] we consider an LP relaxation based on the concave closure of f. For independent sets in an inductively k-independent graph, we consider the relaxation $\max_{x\in Q_G} f^+(x)$. We write this as an explicit LP and describe its dual. See Fig 1. The primal has a variable x_i for each $v_i \in \mathcal{V}$ as we saw in the relaxation for MWIS. In addition to these variables, we have variables $\alpha_L, L \subseteq \mathcal{V}$ to model the objective $f^+(x)$. The dual has three types of variables. μ is for the equality constraint $\sum_L \alpha_L = 1$, y_i is corresponds to the primal packing constraint for x_i coming from the independence constraint, and z_i is for the equality constraint coming from modeling $f^+(x)$.

$$
\begin{array}{rcll}
\max \sum_{S\subseteq V} \alpha_L f(L) & & & \\
\sum_{L\subseteq V} \alpha_L & = & 1 & \\
\sum_{L\ni v_i} \alpha_L & = & x_i & i\in[n] \\
x_i + \sum_{v_j\in A_i} x_j & \leq & k & i\in[n] \\
x_i & \geq & 0 & i\in[n]
\end{array}
$$

$$
\begin{array}{rcll}
\min \mu + k\sum_{i=1}^{n} y_i & & & \\
\mu + \sum_{v_i\in L} z_i & \geq & f(L) & L\subseteq V \\
y_i + \sum_{v_j\in B_i} y_j & \geq & z_i & i\in[n] \\
y_i & \geq & 0 & i\in[n]
\end{array}
$$

Figure 1 Primal and Dual LPs via the concave closure relaxation for an inductively k-independent graph $\mathcal{G}=(\mathcal{V},\mathcal{E})$ with a given ordering $\{v_1,v_2,\ldots,v_n\}$.

4.1 Algorithm for monotone submodular functions

We describe a deterministic primal-dual algorithm for the monotone case. The algorithm and analysis are inspired by [35] and we note that the algorithm has some similarities to the preemptive greedy algorithm. The primal-dual algorithm takes a two phase approach similar to algorithm for the modular case. In the first phase it processes the vertices in the given order and creates a set $S\subseteq\mathcal{V}$. In the second phase it process the vertices in the reverse order of insertion and creates a maximal independent set. Unlike the modular case, the decision to add a vertex v_i to S in the first phase is based on an inflation factor $(1+\beta)$. The formal algorithm is described in Fig 2. The algorithm creates a feasible dual as it goes along – the variables y,z,μ are from the dual LP. It also maintains and uses auxiliary weight variables w_i, $1\leq i\leq n$ that will be useful in the analysis.

```
primal-dual-monotone-submod($f:2^{\mathcal{V}}\to\mathbb{R}_{\geq 0}$,$k\in\mathbb{N}$,$\beta\in\mathbb{R}_{>0}$).
1. Initialize an empty stack $S$. Let $\mathcal{V}=\{v_1,\ldots,v_n\}$ be a $k$-independence ordering of $\mathcal{V}$.
   Set $w,z,y\leftarrow\mathbb{0}_n$.
2. For $i=1,\ldots,n$:
   A. Let $C_i=N(v_i)\cap S=\{u\in S: uv_i\in\mathcal{E}\}$
   B. If $(f_S(v_i)>(1+\beta)\sum_{v_j\in C_i} w_j)$ then
      1. Call $S$.push($v_i$) and set $x_i\leftarrow 1$.
      2. Set $w_i\leftarrow f_S(v_i)-\sum_{v_j\in C_i} w_j$ and $y_i\leftarrow(1+\beta)w_i$.
   C. Otherwise set $z_i\leftarrow f_S(v_i)$
3. Let $\mu\leftarrow f(S)$ and $\hat{S}\leftarrow\emptyset$
4. While $S$ is not empty:
   A. $v\leftarrow S$.pop()
   B. If $\hat{S}+v_i$ is independent in $\mathcal{G}$ then set $\hat{S}\leftarrow\hat{S}+v_i$.
5. Return $\hat{S}$
```

Figure 2 Primal-dual algorithm for monotone submodular maximization. The algorithm creates a feasible dual solution in the first phase along with a set S_{end}. In the second phase it processes S_{end} in reverse order of insertion and creates a maximal independent set.

Let S_{end} be the set of vertices in the stack S at the end of the first phase. S is a monotonically increasing set during the algorithm. Note that $\mu = f(S_{\text{end}})$ at the end of the algorithm. We observe that for each i, the algorithm sets the variables w_i, y_i, z_i exactly once when v_i is processed, and does not alter the values after they are set.

▶ **Lemma 15.** *The algorithm* `primal-dual-monotone-submod` *creates a feasible dual solution* $\mu, \bar{y}, \bar{z}$ *when* f *is monotone.*

Proof. We observe that $z_i = 0$ if $v_i \in S_{\text{end}}$ and $z_i = \nu\big(f, S^-_{v_i}, v_i\big)$ otherwise. By submodularity it follows that if $v_i \notin S_{\text{end}}$, $z_i \geq f_{S_{\text{end}}}(v_i)$ since $S^-_{v_i} \subseteq S_{\text{end}}$.

Consider the first set of constraints in the dual of the form $\mu + \sum_{v_i \in L} z_i \geq f(L)$ for $L \subseteq V$. We have

$$\mu + \sum_{v_i \in L} z_i \geq f(S_{\text{end}}) + \sum_{v_i \in L \setminus S_{\text{end}}} f_{S_{\text{end}}}(v_i) \geq f(S_{\text{end}} \cup L) \geq f(L).$$

We used submodularity in the second inequality and monotonicity of f in the last inequality.

Now consider the second set of constraints in the dual of the form $y_i + \sum_{v_j \in B_i} y_j \geq z_i$ for each i. If $v_i \in S_{\text{end}}$ then $z_i = 0$ and the constraint is trivially satisfied since the y variables are non-negative. Assume $v_i \notin S_{\text{end}}$. The algorithm did not add v_i to S because

$$z_i = \nu\big(f, S^-_{v_i}, v_i\big) \leq (1+\beta) \sum_{v_j \in C_i} w_j = \sum_{v_j \in C_i} y_j$$

which implies that the constraint for v_i is satisfied. ◀

Feasibility of the dual solution implies an upper bound on the optimal value.

▶ **Corollary 16.** $\text{OPT} \leq f(S_{end}) + k(1+\beta) \sum_{i=1}^{n} w_i$.

We now lower bound the value of $f(\hat{S})$.

▶ **Lemma 17.** $f(\hat{S}) \geq \sum_{i=1}^{n} w_i$.

Proof. A vertex v_i is added to S_{end} since $\nu\big(f, S^-_{v_i}, v_i\big) > (1+\beta) \sum_{v_j \in C_i} w_j$. Moreover, we have $w_i + \sum_{v_j \in C_i} w_j = \nu\big(f, S^-_{v_i}, v_i\big)$ via the algorithm. Therefore,

$$f(\hat{S}) = \sum_{v_i \in \hat{S}} \nu\Big(f, \hat{S}, v_i\Big) \geq \sum_{v_i \in \hat{S}} \nu\big(f, S^-_{v_i}, v_i\big) = \sum_{v_i \in \hat{S}} (w_i + \sum_{j \in C_i} w_j).$$

We see that for every i' such that $v_{i'} \in S_{\text{end}}$ the term $w_{i'}$ appears at least once in $\sum_{v_i \in \hat{S}}(w_i + \sum_{j \in C_i} w_j)$; either $v_{i'} \in \hat{S}$ or if it is not then it was removed in the second phase since $v_{i'} \in C_i$ for some $v_i \in \hat{S}$. In the latter case $w_{i'}$ appears in the $\sum_{j \in C_i} w_j$. Thus $f(\hat{S}) \geq \sum_{i=1}^{n} w_i$ (recall that $w_i = 0$ if $v_i \notin S_{\text{end}}$). ◀

We now upper bound $f(S_{\text{end}})$ via the weights.

▶ **Lemma 18.** $f(S_{end}) \leq \frac{1+\beta}{\beta} \sum_{i=1}^{n} w_i$.

Proof. Let $v_i \in S_{\text{end}}$. Recall that $\nu\big(f, S^-_{v_i}, v_i\big) \geq (1+\beta) \sum_{j \in C_i} w_j$ and $w_i = \nu\big(f, S^-_{v_i}, v_i\big) - \sum_{j \in C_i} w_j$. This implies that $w_i \geq \frac{\beta}{1+\beta} \nu\big(f, S^-_{v_i}, v_i\big)$. Therefore

$$f(S_{\text{end}}) = \sum_{v_i \in S_{\text{end}}} \nu(f, S_{\text{end}}, v_i) = \sum_{v_i \in S_{\text{end}}} \nu\big(f, S^-_{v_i}, v_i\big) \leq \frac{1+\beta}{\beta} \sum_{v_i \in S_{\text{end}}} w_i,$$

as desired. ◀

▶ **Theorem 19.** $\mathrm{OPT} \leq (1+\beta)(1/\beta + k)f(\hat{S})$*. In particular, for* $\beta = \frac{1}{\sqrt{k}}$, $\mathrm{OPT} \leq (k+1+2\sqrt{k})f(\hat{S})$.

Proof. From Corollary 16 and Lemma 18 and Lemma 17,

$$\mathrm{OPT} \leq f(S_{\text{end}}) + k(1+\beta)\sum_{i=1}^{n} w_i \leq \frac{1+\beta}{\beta}\sum_{i=1}^{n} w_i + k(1+\beta)\sum_{i=1}^{n} w_i$$
$$\leq (1+\beta)(\frac{1}{\beta}+k)\sum_{i=1}^{n} w_i \leq (1+\beta)(\frac{1}{\beta}+k)f(\hat{S}),$$

as desired. ◀

▶ Remark 20. For $k = 1$ we obtain a 1/4-approximation which yields a deterministic 1/4-approximation for chordal graphs and interval graphs. For $k = 2$ we obtain a bound of $3 + 2\sqrt{2}$ which is the same as what [35] obtain for matchings. Note that matchings can be interpreted, via the line graph, as inductive 2-independent and in fact any ordering of the edges is an inductive 2-independent order. This explains why the ordering does not matter. [35] use a different LP relaxation for matchings, and hence it is a bit surprising that we obtain the same bound for all 2-independent graphs. For the non-monotone case we obtain a weaker bound for 2-independent graphs than what [35] obtain for matchings.

4.2 Non-monotone submodular maximization

We now consider the case of non-negative submodular function which may not be necessarily monotone. This class of functions requires some additional technical care and a key lemma that is useful in handling non-monotone function is the following.

▶ **Lemma 21** ([8]). *Let* $f : 2^V \to \mathbb{R}_+$ *be a non-negative submodular function. Fix a set* $T \subseteq V$*. Let* S *be a random subset of* V *such that for any* $v \in V$ *the probability of* $v \in S$ *is at most* p *for some* $p < 1$*. Then* $\mathbf{E}[f(S \cup T)] \geq (1-p)f(T)$*.*

We describe a randomized primal-dual algorithm which is adapted from the one form [35]. It differs from the monotone algorithm in one simple but crucial way; even when a vertex v has good value compared to its conflict set it adds it to the stack only with probability p which is a parameter that is chosen later.

As in the monotone case let S_{end} be the set of vertices in the stack at the end of the first phase (note that S_{end} is now a random set). The analysis of the randomized version of the algorithm is technically more involved. The sets $S_{\text{end}}, \hat{S}$ and the dual variables are now random variables. Since very high-value vertices can be discarded probabilistically, the dual values constructed by the algorithm may not satisfy the dual constraints for each run of the algorithm. Levin and Wajc [35] analyze their algorithm for matchings via an "expected" dual solution. We do a more direct analysis via weak duality.

The following two lemmas are essentially the same as in the monotone case and they relate the expected value of $\hat{S}$ and S_{end} to the dual weight values.

▶ **Lemma 22.** *For each run of the algorithm:* $f(\hat{S}) \geq \sum_{i=1}^{n} w_i$ *and hence* $\mathbf{E}\Big[f(\hat{S})\Big] \geq \sum_{i=1}^{n} \mathbf{E}[w_i]$.

▶ **Lemma 23.** *For each run of the algorithm,* $f(S_{end}) \leq \frac{1+\beta}{\beta}\sum_{i=1}^{n} w_i$ *and hence*

$$\mathbf{E}[f(S_{end})] \leq \frac{1+\beta}{\beta}\sum_{i=1}^{n} \mathbf{E}[w_i].$$

```
primal-dual-nonneg-submod($f : 2^{\mathcal{V}} \to \mathbb{R}_{\geq 0}$, $k \in \mathbb{N}$, $\beta \in \mathbb{R}_{>0}$).
1. Initialize an empty stack $S$. Let $\mathcal{V} = \{v_1, \dots, v_n\}$ be a $k$-independence ordering of $\mathcal{V}$.
   Let $w, y, z = \mathbb{0}_n$.
2. For $i = 1, \dots, n$:
   A. Let $C_i = N(v_i) \cap S = \{u \in S : uv_i \in \mathcal{E}\}$
   B. If $(f_S(v_i) > (1+\beta) \sum_{v_j \in C_i} w_j)$, then with probability $p$:
      1. Call $S$.push($v_i$) and $x_i \leftarrow 1$
      2. Set $w_i \leftarrow f_S(v_i) - \sum_{v_j \in C_i} w_j$ and $y_i \leftarrow (1+\beta) w_i$
   C. Otherwise set $z_i \leftarrow f_S(v_i)$.
3. Set $\mu \leftarrow f(S)$ and $\hat{S} \leftarrow \emptyset$
4. While $S$ is not empty:
   A. $v \leftarrow S$.pop().
   B. If $\hat{S} + v_i$ is independent in $\mathcal{G}$ then set $\hat{S} \leftarrow \hat{S} + v_i$
5. Return $\hat{S}$
```

Figure 3 Randomized primal-dual algorithm for non-negative submodular maximization.

The next two lemmas provide a way to upper bound the optimum value via the expected dual objective value.

▶ **Lemma 24.** *For each vertex v_i, let $1_{v_i \notin S_{end}}$ indicate if v_i is excluded from S_{end}. Let $B_i' = B_i + v_i$. Then*

$$\mathbf{E}[f(v_i \,|\, S_i) 1_{v_i \notin S_{end}}] \leq \max\left\{\frac{1-p}{p}, 1+\beta\right\} \mathbf{E}[w(B_i' \cap S_{end})].$$

Proof. Let E_i be the event that $f(v_i \,|\, S_i) > (1+\beta) w(B_i \cap S_i)$. Condition on $\bar{E}_i$, that is E_i *not* occurring, in which case v_i is not added to the stack. In this case we have

$$\begin{aligned}\mathbf{E}\big[w(B_i) \,\big|\, \bar{E}_i\big] &= \mathbf{E}\big[w(B_i' \cap S_{\text{end}}) \,\big|\, \bar{E}_i\big] \geq \frac{1}{1+\beta} \mathbf{E}\big[f(v_i \,|\, S_i) \,\big|\, \bar{E}_i\big] \\ &= \frac{1}{1+\beta} \mathbf{E}\big[f(v_i \,|\, S_i) 1_{v_i \notin S_{\text{end}}} \,\big|\, \bar{E}_i\big]\end{aligned}$$

On the other hand, condition on E_i, we have

$$\mathbf{E}[w(B_i' \cap S_{\text{end}}) \,|\, E_i] \overset{\text{(a)}}{\geq} p\, \mathbf{E}[f(v_i \,|\, S_i) \,|\, E_i] \overset{\text{(b)}}{=} \frac{p}{1-p} \mathbf{E}[f(v_i \,|\, S_i) 1_{v_i \notin S_{\text{end}}} \,|\, E_i].$$

(a) is because with probability p, we add v to the stack, in which case $w(B_i' \cap S_{\text{end}}) \geq f(v_i \,|\, S_i)$. (b) is because conditional on E_i and $f(v_i \,|\, S_i)$, $v_i \notin S_{\text{end}}$ with probability $1-p$. We combine the two bounds by taking conditional expectations, as follows:

$$\begin{aligned}\mathbf{E}\big[f(v_i \,|\, S_i) 1_{v_i \notin S_{\text{end}}}\big] &= \mathbf{E}\big[f(v_i \,|\, S_i) 1_{v_i \notin S_{\text{end}}} \,\big|\, E_i\big] \mathbf{P}[E_i] + \mathbf{E}\big[f(v_i \,|\, S_i) 1_{v_i \notin S_{\text{end}}} \,\big|\, \bar{E}_i\big] \mathbf{P}\big[\bar{E}_i\big] \\ &\leq \frac{1-p}{p} \mathbf{E}\big[w(B_i' \cap S_{\text{end}}) \,\big|\, E_i\big] \mathbf{P}[E_i] + (1+\beta) \mathbf{E}\big[w(B_i' \cap S_{\text{end}}) \,\big|\, \bar{E}_i\big] \mathbf{P}\big[\bar{E}_i\big] \\ &\leq \max\left\{\frac{1-p}{p}, 1+\beta\right\} \Big(\mathbf{E}\big[w(B_i' \cap S_{\text{end}})\big] \mathbf{P}[E_i] + \mathbf{E}\big[w(B_i' \cap S_{\text{end}})\big] \mathbf{P}\big[\bar{E}_i\big]\Big) \\ &= \max\left\{\frac{1-p}{p}, 1+\beta\right\} \mathbf{E}\big[w(B_i' \cap S_{\text{end}})\big],\end{aligned}$$

as desired. ◀

▶ **Lemma 25.** *For any set T, $\mathbf{E}[f(S_{end} \cup T)] \leq \mathbf{E}[f(S)] + k \max\left\{\frac{1-p}{p}, 1+\beta\right\} \mathbf{E}[w(S_{end})]$.*

Proof. We have

$$\begin{aligned}\mathbf{E}[f(T \cup S_{\text{end}}) - f(S_{\text{end}})] &\overset{\text{(c)}}{\leq} \mathbf{E}\left[\sum_{v_i \in T \setminus S_{\text{end}}} f(v_i \mid S_{\text{end}})\right] \overset{\text{(d)}}{\leq} \mathbf{E}\left[\sum_{v_i \in T \setminus S_{\text{end}}} f(v_i \mid S_i)\right] \\ &= \sum_{v_i \in T} \mathbf{E}[f(v_i \mid S_i) 1_{v_i \notin S_{\text{end}}}] \\ &\overset{\text{(e)}}{\leq} \max\left\{\frac{1-p}{p}, 1+\beta\right\} \sum_{v_i \in T} \mathbf{E}[w(B_i' \cap S_{\text{end}})] \\ &\overset{\text{(f)}}{\leq} \max\left\{\frac{1-p}{p}, 1+\beta\right\} k\, \mathbf{E}[w(S_{\text{end}})],\end{aligned}$$

as desired up to rearrangement of terms. Here (c,d) is by submodularity. (e) is by the Lemma 24. (f) is by k-inductive independence. ◀

We now put the lemmas together to relate $\mathbf{E}\left[f(\hat{S})\right]$ to the optimum.

▶ **Lemma 26.** *Let T^* be an optimum independent set with* OPT $= f(T^*)$. *Then*

$$\text{OPT} \leq \frac{k \max\left\{\frac{1-p}{p}, 1+\beta\right\} + \left(\frac{1+\beta}{\beta}\right)}{1-p} \mathbf{E}\left[f\left(\hat{S}\right)\right].$$

Proof. Let T be any independent set, in particular T^*. We observe that the algorithm ensures that for any vertex v, $\mathbf{P}[v \in S_{\text{end}}] \leq p$ and hence $\mathbf{P}\left[v \in \hat{S}\right] \leq p$.

$$\begin{aligned}(1-p) f(T) &\leq \mathbf{E}[f(T \cup S_{\text{end}})] \quad \text{(Lemma 21)} \\ &\leq \mathbf{E}[f(S)] + k \max\left\{\frac{1-p}{p}, 1+\beta\right\} \mathbf{E}[w(S_{\text{end}})] \quad \text{(Lemma 25)} \\ &\leq \left(k \max\left\{\frac{1-p}{p}, 1+\beta\right\} + \left(\frac{1+\beta}{\beta}\right)\right) \mathbf{E}[w(S_{\text{end}})] \quad \text{(Lemma 23)} \\ &\leq \left(k \max\left\{\frac{1-p}{p}, 1+\beta\right\} + \left(\frac{1+\beta}{\beta}\right)\right) \mathbf{E}\left[f\left(\hat{S}\right)\right] \quad \text{(Lemma 22)}.\end{aligned}$$ ◀

It remains to choose $p \in [0,1]$ and $\beta > 0$ to minimize the RHS. Consider the term $\max\{(1-p)/p, 1+\beta\}$. If $(1-p)/p \geq 1+\beta$, then $p \geq 1/2$ (to force $(1-p)/p \geq 1$), and the RHS is minimized by taking β as large as possible – that is, such that $1+\beta = (1-p)/p$. If $(1-p)/p \leq 1+\beta$, then the RHS is minimized by taking p as small as possible – that is, such that $(1-p)/p = 1/p - 1 = 1+\beta$. Thus $(1-p)/p = 1+\beta$ at the optimum. In terms of just p, then, we have

$$\text{OPT} \leq \left(\frac{1}{1-p}\right)\left(\frac{k(1-p)}{p} + \frac{1-p}{1-2p}\right) \mathbf{E}\left[f\left(\hat{S}\right)\right] = \left(\frac{k}{p} + \frac{1}{1-2p}\right) \mathbf{E}\left[f\left(\hat{S}\right)\right].$$

(Here we note that $\beta = (1-2p)/p$, hence $(1+\beta)/\beta = (1-p)/(1-2p)$.)

In the special case of $k = 2$, as in matching, the RHS is

$$\text{OPT} \leq \left(\frac{2}{p} + \frac{1}{1-2p}\right) \mathbf{E}\left[f\left(\hat{S}\right)\right]$$

The RHS is minimized by $p = 1/3$, giving an approximation factor of 9.

For general k, the minimum is $2k + \sqrt{8k} + 1$.

It is easy to see that the primal-dual algorithm makes $O(n)$ evaluation calls to f and the overall running time is linear in the size of the graph. The results for the monotone and non-negative functions, together yield Theorem 6.

5 Concluding Remarks and Open Problems

We described $\Omega(\frac{1}{k})$-approximation algorithms for independent sets in two parameterized families of graphs that capture several problems of interest. Although the multilinear relaxation based framework yields such algorithms, the resulting algorithms are computationally expensive and randomized. We utilized ideas from streaming and primal-dual based algorithms to give simple and fast algorithms for inductively k-independent graphs with the additional property that they are deterministic for monotone functions. Our work raises several interesting questions that we summarize below.

- The CR scheme that we described in Section 3 is unable to distinguish k-perfectly orientable graphs and inductive k-independent graphs. Is a better bound possible for inductively k-independent graphs?
- Our combinatorial algorithms only apply to inductively k-independent graphs. Can we obtain combinatorial algorithms for k-perfectly orientable graphs? Even for MIS the only approach appears to be via primal rounding of the LP solution [34].
- Can we obtain deterministic $\Omega(\frac{1}{k})$-approximation algorithms for these graph classes when f is non-negative? Interval graphs seem to be a natural first step to consider.
- Are better approximation ratios achievable? For instance, can we obtain better than 1/4-approximation for monotone submodular function maximization in interval graphs? Can we prove better lower bounds under complexity theory assumptions or in the oracle model for interval graphs or other concrete special cases of interest?
- For both classes of graphs our algorithms are based on having an ordering that certifies that they belong to the class. For MWIS in k-simplicial and k-perfectly orientable graphs, [30] describes algorithms based on the Lovász number of a graph and the Lovász θ-function of a graph, and these algorithms do not require an ordering. It may be feasible to extend their approach to the submodular setting via the multilinear relaxation. However, the resulting algorithms are computationally quite expensive. It would be interesting to obtain fast algorithms for these classes of graphs (or interesting special cases) when the ordering is not explicitly given.

A A Preemptive Greedy Algorithm

We now describe a preemptive greedy algorithm for maximizing a monotone submodular function $f : 2^V \to \mathbb{R}_+$ over independent sets of a inductively k-independent graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ assuming that we are also given the ordering. The algorithm is simple and intuitive, and is inspired by algorithms developed in the streaming model.

The pseudocode for the algorithm is given in Figure 4, and is designed as follows. Starting from an empty solution $S = \emptyset$, `preemptive-greedy` processes the vertices in the given ordering one by one. When considering v_i, the algorithm gathers the subset $C_i \subseteq S$ of all vertices in the current set S that are neighbors of v_i (those that conflict with v_i). The algorithm has to decide whether to reject v_i or to accept v_i in which case it has to remove C_i from S. It accepts v_i if the marginal gain $f_S(v_i) \overset{\text{def}}{=} f(S + v_i) - f(S)$ of adding v_i directly to S is at least $(1 + \beta)$ times the value $\sum_{u \in C_i} f_{S \setminus C_i}(u)$. Here $\beta > 0$ is a parameter that is fixed based on the analysis. After processing all vertices, we return the final set S.

```
preemptive-greedy($\mathcal{G} = (\mathcal{V}, \mathcal{E})$, $f : 2^{\mathcal{V}} \to \mathbb{R}_{\geq 0}$, $k \in \mathbb{N}$, $\beta \in \mathbb{R}_{>0}$).
1. Let $S = \emptyset$. Let $\mathcal{V} = \{v_1, \ldots, v_n\}$ by a $k$-independence ordering of $\mathcal{V}$
2. For $i = 1, \ldots, n$:
   A. Let $C_i = N(v_i) \cap S = \{u \in S : uv_i \in \mathcal{E}\}$
   B. If $f_S(v_i) \geq (1 + \beta) \sum_{u \in C_i} \nu(f, S, u)$
      1. Set $S \leftarrow (S \setminus C_i) + v_i$
3. Return $S$
```

Figure 4 The algorithm `preemptive-greedy` for finding an independent set in a inductively k-independent graph to maximize a monotone submodular objective function.

`preemptive-greedy` for inductively k-independent graphs has the following approximation bound. The proof is deferred to the subsection following the theorem statements.

▶ **Theorem 27.** *Given an inductively k-independent graph with a k-inductive ordering, the algorithm* `preemptive-greedy` *returns an independent set $\hat{S}$ such that for any independent set T, $f(T) \leq (k(1 + \beta) + 1)(1 + \beta^{-1}) f(\hat{S})$.*

`preemptive-greedy` can be extended to nonnegative (and non-monotone) submodular functions with a constant factor loss in approximation by random sampling. As a preprocessing step, we let $\mathcal{V}'$ randomly sample each vertex in $\mathcal{V}$ independently with probability $1/2$. We then apply `preemptive-greedy` to the subgraph $\mathcal{G}' = \mathcal{G}[\mathcal{V}']$ induced by $\mathcal{V}'$. It is easy to see that any subgraph of an inductively k-independent graph is also inductively k-independent. The net effect of the random sampling is an approximation factor for nonnegative submodular functions that is a factor 4 worse than for the monotone case. The modified algorithm, called `randomized-preemptive-greedy`, is given in Figure 5.

▶ **Theorem 28.** *Given an inductively k-independent graph with a k-inductive ordering, the algorithm* `randomized-preemptive-greedy` *returns an independent set $\hat{S}$ such that for any independent set T, $f(T) \leq 4(k(1 + \beta) + 1)(1 + \beta^{-1}) f(\hat{S})$.*

```
randomized-preemptive-greedy($\mathcal{G} = (\mathcal{V}, \mathcal{E})$, $f : 2^{\mathcal{V}} \to \mathbb{R}_{\geq 0}$, $k \in \mathbb{N}$, $\beta \in \mathbb{R}_{>0}$).
1. Let $\mathcal{V}' \subseteq \mathcal{V}$ sample each $v \in \mathcal{V}$ independently with probability $1/2$
2. Let $\mathcal{G}' = \mathcal{G}[\mathcal{V}']$ be the subgraph of $\mathcal{G}$ induced by $\mathcal{V}'$
3. Return preemptive-greedy($\mathcal{G}'$, $f : 2^{\mathcal{V}'} \to \mathbb{R}_{\geq 0}$, $k \in \mathbb{N}$, $\beta \in \mathbb{R}_{>0}$).
```

Figure 5 The algorithm `randomized-preemptive-greedy` for finding an independent set in an inductively k-independent graph to maximize a nonnegative submodular objective function.

▶ Remark 29. The randomized strategy we outline is simple and oblivious. It loses a factor of 4 over the monotone case. One could try to improve the approximation ratio by using randomization within the algorithm which would make the analysis more involved. However, we have not done this since the primal-dual algorithm yields better approximation bounds. This subsampling strategy is not new and has been used previously in [25], and is also implicit in [17].

The rest of the section is devoted to proving the claimed approximation guarantees.

A.1 Analysis of preemptive greedy

We follow the notation of [17]. Let $\hat{S}$ be the final set of vertices returned by `preemptive-greedy`. It is easy to see that the algorithm returns an independent set. For each $u \in \mathcal{V}$ let S_u^- denote the set of vertices in S just before u is processed, and let S_u^+ denote the set after u is processed. Thus a vertex u is added to S iff $S_u^+ \setminus S_u^- = \{u\}$. Let $U = \bigcup_{u \in \mathcal{V}} S_u^+$ be the set of all vertices that were ever (even momentarily) added to S. Alternatively, $\mathcal{V} \setminus U$ is the set of vertices that are discarded by the algorithm when it considers them. For each vertex u, let $\delta_u \overset{\text{def}}{=} f(S_u^+) - f(S_u^-)$ be the value added to S from processing u. We have $\delta_u = 0$ for all $u \notin U$, and $f(\hat{S}) = \sum_{u \in \mathcal{V}} \delta_u = \sum_{u \in U} \delta_u$.

Let $T \subseteq \mathcal{V}$ be an independent set in the given graph, in particular an optimum set. We would like to compare $f(\hat{S})$ with $f(T)$. Directly comparing T with $\hat{S}$ is difficult since $\hat{S}$ is obtained by deleting vertices in S along the way; thus a vertex $v \in T \setminus \hat{S}$ may have been discarded due to a vertex $u \in S$ when v was considered but u may not be in $\hat{S}$. Thus, the analysis is broken into two parts that detour through U. First, we relate the value of $f(\hat{S})$ to the value of $f(U)$. This part of the analysis bounds the amount of value lost by kicking out vertices from S during the exchanges. We then relate $f(U)$ and $f(T)$; this is easier because any vertex in T is always compared against *some* subset of vertices in U. Chaining the inequalities from $f(\hat{S})$ to $f(U)$ to $f(T)$ gives the final approximation ratio.

Relating $f(\hat{S})$ to $f(U)$

The analysis is similar to that in [17]. We provide proofs for the sake of completeness. The following claim is easy to see since elements before s can only be deleted from S as the algorithm proceeds.

▷ Claim 30. Over the course of the algorithm, the incremental value $\nu(f, S, s)$ of an element $s \in S$ is nondecreasing.

For a vertex $u \in U \setminus \hat{S}$ we let u' denote the vertex that caused u to be removed from S. And we let $\chi(u)$ denote its incremental value just before it is removed. Therefore, $\chi(u) = \nu\big(f, S_{u'}^-, u\big)$.

▶ **Lemma 31.** *Let $u \in U$ then $\delta_u \geq \beta \sum_{c \in C_u} \nu(f, S_u^-, c)$.*

Proof. Since the vertex u was added to S when it was considered, we have $\delta_u = f(S_u^+) - f(S_u^-)$ where $S_u^+ = S_u^- - C_u + u$. The vertex u was added by the algorithm since $f_S(u) \geq (1 + \beta) \sum_{c \in C_u} \nu(f, S, c)$ where $S = S_u^-$. Therefore $\beta \sum_{c \in C_u} \nu(f, S_u^-, c) \leq f_{S_u^-}(u) - \sum_{c \in C_u} \nu(f, S_u^-, c)$. It suffices to prove that $f(S_u^+) - f(S_u^-) \geq f_S(u) - \sum_{c \in C_u} \nu(f, S, c)$ which we do below. For notational convenience let $A = S_u^- - C_u$.

$$\begin{aligned} f(S_u^+) - f(S_u^-) &= f(A+u) - f(S_u^-) \\ &= f_A(u) + f(A) - f(S_u^-) \\ &\geq f_{S_u^-}(u) - (f(S_u^-) - f(A)) && \text{by submodularity since } A \subseteq S_u^- \\ &\geq f_{S_u^-}(u) - \sum_{c \in C_u} \nu\big(f, S_u^-, c\big) && \text{by submodularity and defn of } \nu. \end{aligned}$$ ◀

▶ **Lemma 32.** $\sum_{u \in U \setminus \hat{S}} \chi(u) \leq \beta^{-1} f(\hat{S})$.

Proof. Indeed,

$$\begin{aligned} \sum_{u \in U \setminus \hat{S}} \chi(u) &= \sum_{u \in U} \sum_{c \in C_u} \chi(c) && \text{since } \{C_u : u \in U\} \text{ partitions } U \setminus \hat{S} \\ &\leq \sum_{u \in U} \frac{1}{\beta} \sum_{u \in U} \delta_u && \text{from Lemma 31} \\ &= \frac{1}{\beta} f(\hat{S}). \end{aligned}$$ ◀

The next lemma shows that $f(U)$ is not much larger than $f(\hat{S})$.

▶ **Lemma 33.** $f(U) \leq \big(1 + \beta^{-1}\big) f(\hat{S})$.

Proof. Let $U' = U \setminus \hat{S}$ and let $U' = \{v_{i_1}, \ldots, v_{i_h}\}$ where $i_1 < i_2 \ldots < i_h$. We have $f(U) = f(\hat{S}) + f_{\hat{S}}(U')$. It suffices to upper bound $f_{\hat{S}}(U')$ by $f(\hat{S})/\beta$. For $1 \leq j \leq h$ let $U'_j = \{v_{i_1}, \ldots, v_{i_j}\}$. We have $f_{\hat{S}}(U') = \sum_{j=1}^{h} f_{\hat{S} \cup U'_{j-1}}(v_{i_j})$. We claim that $f_{\hat{S} \cup U'_{j-1}}(v_{i_j}) \leq \chi\big(v_{i_j}\big)$. This follows by submodularity and the fact that $\hat{S} \cup U'_{j-1}$ is a superset of the vertices that are in S when v_{i_j} is deleted. Putting things together,

$$f_{\hat{S}}(U') = \sum_{j=1}^{h} f_{\hat{S} \cup U'_{j-1}}(v_{i_j}) \leq \sum_{u \in U'} \chi(u) \leq \frac{1}{\beta} f(\hat{S})$$

where the last inequality follows from Lemma 32. ◀

Relating OPT to $f(U)$

It remains to bound $f(T)$ (for some competing set T) to $f(U)$ and hence to $f(\hat{S})$. The critical question, addressed in the following lemmas, is how to charge the value of elements in T off to elements in U.

▶ **Lemma 34.** *Let $T \subseteq \mathcal{V}$ be an independent set disjoint from U. Each element $u \in U$ appears in the conflict list C_t for at most k vertices $t \in T$.*

Proof. Fix $u \in U$. The set $T \cap N(u) \cap \{v : v > u\}$ consists of precisely the vertices $t \in T$ for which $u \in C_t$. As a subset of T, this set is certainly independent. By definition of k-inductive independence, the cardinality of this set is at most k. ◀

▶ **Lemma 35.** *Let $T \subseteq \mathcal{V}$ be an independent set. Then*

$$f_U(T) \leq k(1+\beta)(1+\beta^{-1}) f(\hat{S}).$$

Proof. Since $f_U(T) = f_U(T \setminus U)$, it suffices to assume that T is disjoint from U. For each vertex $t \in T$, since t is not in U, we have $f_{S_t^-}(t) \le (1+\beta)\sum_{c \in C_t} \nu\big(f, S_t^-, c\big)$. Fix a vertex $u \in C_t$. If $u \in \hat{S}$, then u is in the final output; then we have $\nu\big(f, S_t^-, u\big) \le \nu\Big(f, \hat{S}, u\Big)$ because the incremental value of an element in S is nondecreasing. If $u \notin \hat{S}$, and u was deleted to make room for some later element u', then we have $\nu\big(f, S_t^-, u\big) \le \chi(u)$ again because incremental values are nondecreasing.

By the preceding lemma, each element $u \in U$ appears in C_t for at most k choices of t. Therefore, in sum, we have

$$\begin{aligned} f_U(T) &\le \sum_{t \in T} f_{S_t^-}(t) && \text{by submodularity,} \\ &\le (1+\beta)\sum_{t \in T}\sum_{c \in C_t} \nu\big(f, S_t^-, c\big) && \text{since } t \notin U, \\ &\le k(1+\beta)\left(\sum_{u \in \hat{S}} \nu\Big(f, \hat{S}, u\Big) + \sum_{u \in U \setminus \hat{S}} \chi(u)\right) && \text{Lemma 34 and argument above,} \\ &\le k(1+\beta)\left(f(\hat{S}) + \sum_{u \in U \setminus \hat{S}} \chi(u)\right) \\ &\le k(1+\beta)(1+\beta^{-1})f(\hat{S}) && \text{by Lemma 32} \end{aligned}$$

as desired. ◀

From here, it is relatively straightforward to get a final approximation bound.

▶ **Theorem 36.** *Given an inductively k-independent graph with a k-inductive ordering, the algorithm* `preemptive-greedy` *returns an independent set $\hat{S}$ such that for any independent set T,*

$$f(T) \le (k(1+\beta)+1)(1+\beta^{-1})f(\hat{S}).$$

Proof. Let T be an optimal solution. We have

$$f(T) \le f_U(T) + f(U) \le (k(1+\beta)+1)(1+\beta^{-1})f(\hat{S}) \tag{1}$$

via Lemma 35 and Lemma 33. ◀

The bound is minimized by taking $\beta = \sqrt{1+k^{-1}}$, which at which point

$$f(T) \le (4k+2+o(1))f(\hat{S}),$$

where the $o(1)$ goes to 0 as k increases. For $k = 1$, the approximation ratio is $3 + 2\sqrt{2}$.

A.2 Randomized preemptive greedy for nonnegative functions

Here we analyze the `randomized-preemptive-greedy` for non-negative submodular functions that may not be monotone. A key observation is that the analysis of `preemptive-greedy` does not invoke the monotonicity of f until the very end, in equation (1). In particular, Lemma 35 and Lemma 33 hold for nonnegative submodular functions.

(1) invokes monotonicity when it takes the inequality $f(U \cup T) \geq f(T)$. Informally speaking, by injecting randomization, we will be able recover a similar inequality, except losing a factor of 4.

Fix a set T. Let $\mathcal{V}'$ sample each element in $\mathcal{V}$ with probability 1/2. Let $T' = T \cap \mathcal{V}'$. Conditional on $\mathcal{V}'$, we have

$$f(U) \leq \left(1 + \beta^{-1}\right) f\left(\hat{S}\right)$$

and

$$f_U(T') \leq k(1+\beta)(1+\beta)^{-1} f\left(\hat{S}\right)$$

via Lemma 33 and Lemma 35 respectively.

Now, conditional on T', $U \setminus T = U \setminus T'$ is a randomized set, where any vertex $v \in \mathcal{V}$ appears in $U \setminus T$ with probability at most 1/2. By Lemma 21,

$$\mathbf{E}[f(U \cup T') \mid T'] \geq \frac{1}{2} f(T').$$

We also have, via the concavity of F along any non-negative direction [39],

$$\mathbf{E}[f(T')] = F(\frac{1}{2}\mathbb{1}_T) \geq \frac{1}{2} F(\mathbb{1}_T) = \frac{1}{2} f(T)$$

where $\mathbb{1}_T$ is the indicator vector of T.

Altogether, we have

$$\begin{aligned} f(T) &\leq 2\,\mathbf{E}[f(T')] \leq 4\,\mathbf{E}[f(U \cup T')] \\ &= 4\,\mathbf{E}[f_U(T') + f(U)] \leq 4(k(1+\beta)+1)(1+\beta)^{-1}\,\mathbf{E}\left[f\left(\hat{S}\right)\right], \end{aligned}$$

as desired.

Improved Diversity Maximization Algorithms for Matching and Pseudoforest

Abstract

In this work we consider the diversity maximization problem, where given a data set X of n elements, and a parameter k, the goal is to pick a subset of X of size k maximizing a certain diversity measure. Chandra and Halldórsson [11] defined a variety of diversity measures based on pairwise distances between the points. A constant factor approximation algorithm was known for all those diversity measures except "remote-matching", where only an $O(\log k)$ approximation was known. In this work we present an $O(1)$ approximation for this remaining notion. Further, we consider these notions from the perpective of composable coresets. Indyk et al. [23] provided composable coresets with a constant factor approximation for all but "remote-pseudoforest" and "remote-matching", which again they only obtained a $O(\log k)$ approximation. Here we also close the gap up to constants and present a constant factor composable coreset algorithm for these two notions. For remote-matching, our coreset has size only $O(k)$, and for remote-pseudoforest, our coreset has size $O(k^{1+\varepsilon})$ for any $\varepsilon > 0$, for an $O(1/\varepsilon)$-approximate coreset.

1 Introduction

Diverse Subset Selection is the task of searching for a subset of the data that preserves its diversity as much as possible. This task has a large number of applications in particular while dealing with large amounts of data, including data summarization (e.g. [26, 18, 25]), search and information retrieval (e.g. [5, 2, 24, 13, 31]), and recommender systems (e.g. [33, 1, 34, 32]), among many others (e.g. [17, 29]). Here, given a ground set of n vectors X in a metric space $(\mathcal{X}, \rho)$, representing a data set of objects (e.g. using their feature vectors), and a parameter k, the goal is to choose a subset $S \subseteq X$ of this data set of size k, that maximizes a pre-specified optimization function measuring the diversity.

Many diversity measures have been introduced and used in the literature that fit different tasks. A large number of these measures are defined based on pairwise distances between the vectors in X. In particular the influential work of [11] introduced a taxonomy of pairwise-distance based diversity measures which is shown in Table 1. For example, remote-edge measures the distance of the closest points picked in the subset S, and remote-clique measures the sum of pairwise distances between the points in the subset S. Remote-pseudoforest falls between these two where it wants to ensure that the average distance of a point to its nearest

Table 1 This table includes the notions of diversity considered by [11] ($S = S_1|...|S_t$ is used to denote that $S_1 \dots S_t$ is a partition of S into t sets). We also include the best previously-known approximation factors, both in the standard (offline) and coreset setting. If not explicitly stated, the approximation factor holds for both the offline setting and the coreset setting. We note that the previously known $O(1)$-approximate remote-pseudoforest offline algorithm is randomized, whereas the rest of the previously known algorithms are deterministic.

Problem	Diversity of the point set S	Apx factor
Remote-edge	$\min_{x,y \in S} dist(x, y)$	$O(1)$
Remote-clique	$\sum_{x,y \in S} dist(x, y)$	$O(1)$
Remote-tree	$wt(MST(S))$, weight of the minimum spanning tree of S	$O(1)$
Remote-cycle	$\min_C wt(C)$ where C is a TSP tour on S	$O(1)$
Remote t-trees	$\min_{S=S_1\|...\|S_t} \sum_{i=1}^{t} wt(MST(S_i))$	$O(1)$
Remote t-cycles	$\min_{S=S_1\|...\|S_t} \sum_{i=1}^{t} wt(TSP(S_i))$	$O(1)$
Remote-star	$\min_{x \in S} \sum_{y \in S \setminus \{x\}} dist(x, y)$	$O(1)$
Remote-bipartition	$\min_B wt(B)$, where B is a bipartition (i.e., bisection) of S	$O(1)$
Remote-pseudoforest	$\sum_{x \in S} \min_{y \in S \setminus \{x\}} dist(x, y)$	$O(1)$ (Offline) $O(\log k)$ (Coreset)
Remote-matching	$\min_M wt(M)$, where M is a perfect matching of S	$O(\log k)$

neighbor is large. Remote-matching measures the diversity as the cost of minimum-weight-matching. Various other measures have also been considered: Table 1 includes each of their definitions along with the best known approximation factor for these measures known up to date. In particular, by [11] it was known that all these measures except remote-pseudoforest and remote-matching admit a constant factor approximation. More recently, [7] showed a constant factor randomized LP-based algorithm for remote-pseudoforest. They also showed the effectiveness of the remote-pseudoforest measure on real data over the other two common measures (remote-edge and remote-clique). On the lower bound side, it was known by [20] that for remote-matching, one cannot achieve an approximation factor better than 2. However, despite the fact that there has been a large body of work on diversity maximization problems [8, 3, 9, 10, 14], the following question had remained unresolved for over two decades.

▶ **Question 1.** *Is it possible to get an $O(1)$ approximation algorithm for the remaining notion of remote-matching?*

Later following a line of work on diversity maximization in big data models of computations, [23] presented algorithms producing a composable coreset for the diversity maximization problem under all the aforementioned diversity measures. An α-approximate composable coreset for a diversity objective is a mapping that given a data set X, outputs a small subset $C \subset X$ with the following composability property: given multiple data sets $X^{(1)}, \cdots, X^{(m)}$, the maximum achievable diversity over the union of the composable coresets $\bigcup_i C^{(i)}$ is within an α factor of the maximum diversity over the union of those data sets $\bigcup_i X^{(i)}$. It is shown that composable coresets naturally lead to solutions in several massive data processing models including distributed and streaming models of computations, and this has lead to recent interest in composable coresets since their introduction [28, 6, 27, 22, 4, 15]. [23] showed α-approximate compsable coresets again for all measures of diversity introduced by [11]. They presented constant factor α-approximate composable coresets for all diversity measures except remote-pseudoforest and remote-matching, where they provided only $O(\log k)$-approximations for these measures. Again the following question remained open.

▶ **Question 2.** *Is it possible to get a constant factor composable coreset for the remote-pseudoforest and remote-matching objective functions?*

In this work we answer above two questions positively and close the gap up to constants for these problems.

Our Results

In this work, we resolve a longstanding open question of [11] by providing polynomial-time $O(1)$-approximation algorithms for the remote-matching problem. We also resolve a main open question of [23] by providing polynomial-time algorithms that generate $O(1)$-approximate composable coresets for both the remote-pseudoforest and remote-matching problems. Hence, our paper establishes $O(1)$-approximate offline algorithms *and* $O(1)$-approximate composable coresets for *all* remaining diversity measures proposed in [11]. Specifically, we have the following theorems.

▶ **Theorem 3** (Remote-Matching, Offline Algorithm). *Given a dataset $X = \{x_1, \ldots, x_n\}$ and an integer $k \le \frac{n}{3}$, w.h.p. Algorithm 4 outputs an $O(1)$-approximate set for remote-matching.*

While we assume n is at least a constant factor bigger than k, this is usually a standard assumption (for instance both the remote-pseudoforest and remote-matching algorithms in [11] assume $n \ge 2k$, and the $O(1)$-approximate remote-pseudoforest algorithm in [7] assumes $n \ge 3k$). We now state our theorems regarding composable coresets.

▶ **Theorem 4** (Pseudoforest, Composable Coreset). *Given a dataset $X = \{x_1, \ldots, x_n\}$ and an integer $k \le n$, Algorithm 2 outputs an $O(1/\varepsilon)$-approximate composable coreset C for remote-pseudoforest, of size at most $O(k^{1+\varepsilon})$.*

By this, we mean that if we partitioned the dataset X into $X^{(1)}, \ldots, X^{(m)}$, and ran the algorithm separately on each piece to obtain $C^{(1)}, \ldots, C^{(m)}$, each $C^{(i)}$ will have size at most $O(k^{1+\varepsilon})$ and $\max_{Z \subset C : |Z| = k} \mathrm{PF}(Z) \ge \Omega(\varepsilon) \cdot \max_{Z \subset X : |Z| = k} \mathrm{PF}(Z)$, where $C = \bigcup_{i=1}^{m} C^{(i)}$.

▶ **Theorem 5** (Minimum-Weight Matching, Composable Coreset). *Given a dataset $X = \{x_1, \ldots, x_n\}$ and an integer $k \le n$, Algorithm 3 outputs an $O(1)$-approximate composable coreset C for remote-matching, of size at most $3k$.*

In all of our results, we obtain $O(1)$-approximation algorithms, whereas the previous best algorithms for all 3 problems was an $O(\log k)$-approximation algorithm, meaning the diversity was at most $\Omega(\frac{1}{\log k})$ times the optimum. We remark that our composable coreset in Theorem 4 has size $k^{1+\varepsilon}$, for some arbitrarily small constant ε (to obtain a constant approximation) which is possibly suboptimal. We hence ask an open question as to whether an $O(1)$-approximate composable coreset for remote-pseudoforest, of size $O(k)$, exists.

Finally, as an additional result we also prove an alternative method of obtaining an $O(1)$-approximate offline algorithm for remote-pseudoforest. Unlike [7], which uses primal-dual relaxation techniques, our techniques are much simpler and are based on ε-nets and dynamic programming. In addition, our result works for all $k \le n$, whereas the work of [7] assumes $k \le \frac{n}{3}$ and that k is at least a sufficiently large constant. Also, our algorithm is deterministic, unlike [7]. We defer the statement and proof to the full version of the paper on arXiv.

2 Preliminaries

2.1 Definitions and Notation

We use $\rho(x, y)$ to represent the metric distance between two points x and y. For a point x and a set S, we define $\rho(x, S) = \min_{s \in S} \rho(x, s)$. Likewise, for two sets S, T, we define $\rho(S, T) = \min_{s \in S, t \in T} \rho(S, T)$. We define the diameter of a dataset X as $\text{diam}(X) = \max_{x,y \in X} \rho(x, y)$.

Costs and diversity measures

For a set of points $Y = \{y_1, \ldots, y_k\}$, we use $\text{div}(Y)$, as a generic term to denote its diversity which we measure by the following cost functions.

If $k = |Y|$ is even, we define the minimum-weight matching cost $\text{MWM}(Y)$ as the minimum total weight over all perfect matchings of Y. Equivalently,

$$\text{MWM}(Y) := \min_{\text{permutation } \pi:[k]\to[k]} \sum_{i=1}^{k/2} \rho(y_{\pi(2i)}, y_{\pi(2i-1)}).$$

Likewise, we define the pseudoforest cost $\text{PF}(Y)$, also known as the sum-of-nearest-neighbor cost, of Y as

$$\text{PF}(Y) := \sum_{y \in Y} \rho(y, Y \backslash y).$$

Finally, we define the minimum spanning tree cost $\text{MST}(Y)$ of Y as the minimum total weight over all spanning trees of Y. Equivalently,

$$\text{MST}(Y) = \min_{G\text{: spanning tree of } [k]} \sum_{e=(i,j)\in G} \rho(y_i, y_j).$$

The pseudoforest cost and minimum spanning tree cost do not require Y to be even.

▶ **Definition 6** (Diversity maximization). *Given a dataset X, and a parameter k, the goal of the diversity maximization problem is to choose a subset $Y \subset X$ of size k with maximum diversity, where in this work we focus on $\text{div}(Y) = \text{MWM}(Y)$ and $\text{div}(Y) = \text{PF}(Y)$.*

We also define $\text{div}_k(X)$ to be this maximum achievable diversity, i.e., $\text{div}_k(X) = \max_{Y \subset X, |Y|=k} \text{div}(Y)$. In particular we use $\text{MWM}_k(X)$, or the remote-matching *cost of X, as $\max_{Y \subset X, |Y|=k} \text{MWM}(Y)$, and define $\text{PF}_k(X) = \max_{Y \subset X, |Y|=k} \text{PF}(Y)$. These objectives are also known as k-*matching *and k-*pseudoforest*.*

For a specific diversity maximization objective div_k (such as MWM_k), an *α-approximation algorithm* ($\alpha \ge 1$) for div is an algorithm that, given any dataset $X = \{x_1, \ldots, x_n\}$, outputs some dataset $Z \subset X$ of size k such that

$$\text{div}(Z) \ge \frac{1}{\alpha} \cdot \text{div}_k(X) = \frac{1}{\alpha} \cdot \max_{Y \subset X : |Y|=k} \text{div}(Y).$$

▶ **Definition 7** (Composable coresets). *We say that an algorithm $\mathcal{A}$ that acts on a dataset X and outputs a subset $\mathcal{A}(X) \subset X$ forms an α-*approximate composable coreset *($\alpha \ge 1$) for* div *if, for any collection of datasets $X^{(1)}, \ldots, X^{(m)}$, we have*

$$\text{div}_k\left(\bigcup_{i=1}^m \mathcal{A}(X^{(i)})\right) \ge \frac{1}{\alpha} \cdot \text{div}_k\left(\bigcup_{i=1}^m X^{(i)}\right).$$

Algorithm 1 The GMM Algorithm.

```
Input: data $X = \{x_1, \dots, x_n\}$, integer $k$.
$y_1$ is an arbitrary point in $X$.
Initialize $Y \leftarrow \{y_1\}$.
for $p = 2$ to $k$ do
    $y_p \leftarrow \arg\max_{y \in X} \rho(y, Y)$, i.e., $y_p$ is the furthest point in $X$ from the current $Y = \{y_1, \dots, y_{p-1}\}$.
    $Y \leftarrow Y \cup \{y_p\}$.
end for
Return $Y$.
```

Throughout the paper, for our coreset construction algorithms, we use $X^{(1)}, \cdots, X^{(m)}$ to denote the collection of the data sets. Note that since $\mathcal{A}(X^{(i)}) \subset X^{(i)}$, the diversity of the combined coresets is always at most the diversity of the combined original datasets. We also say that the coreset is of size k' if $|\mathcal{A}(X^{(i)})| \le k'$ for each $X^{(i)}$. We desire for the size k' to only depend (polynomially) on k, and not on n.

2.2 The GMM Algorithm

The GMM algorithm [19] is an algorithm that was first developed for the k-center clustering, but has since been of great use in various diversity maximization algorithms and dispersion problems, starting with [30]. The algorithm is a simple greedy procedure that finds k points Y in a dataset X that are well spread out. It starts by picking an arbitrary point $y_1 \in X$. Given $y_1, \dots, y_p$ for $p < k$, it chooses y_{p+1} as the point that maximizes the distance $\rho(y, \{y_1, \dots, y_p\})$ over all choices of $y \in X$. We provide pseudocode in Algorithm 1.

The GMM algorithm serves as an important starting point in many of our algorithms, as well as in many of the previous state-of-the-art algorithms for diversity maximization. The GMM algorithm has the following crucial property.

▶ **Proposition 8.** *Suppose we run GMM for k steps to produce $Y = \{y_1, \dots, y_k\}$. Let $r = \max_{x \in X} \rho(x, Y)$. Then, every pair of points y_i, y_j has $\rho(y_i, y_j) \ge r$.*

3 Composable Coreset Constructions

In this section, we design algorithms for constructing $O(1)$-approximate composable coresets for remote-pseudoforest and remote-matching. In this section, we provide a technical overview and pseudocode for the algorithms, but defer the proof (and algorithm descriptions in words) to Appendix A (for remote-pseudoforest) and Section 5 (for remote-matching).

3.1 Coreset Constructions: Technical Overview

For both remote-pseudoforest and remote-matching, we start by considering the heuristic of GMM, where in each group we greedily select k points. For simplicity, suppose we only have one group for now. After picking the set $Y = \{y_1, \dots, y_k\}$ from GMM, define r to be the maximum distance $\rho(x, Y)$ over all remaining points x. Then, Proposition 8 implies that all distances $\rho(y_j, y_{j'}) \ge r$ for $j, j' \le k$. Hence, running GMM will ensure we have a set of k points with minimum-weight-matching or pseudoforest cost at least $\Omega(k \cdot r)$. Hence, we only fail to get an $O(1)$-approximation if the optimum remote-matching (or remote-pseudoforest) cost is much larger than $k \cdot r$.

However, in this case, note that every point $x \in X$ satisfies $\rho(x, Y) \leq r$, meaning every point x is within r of some y_i. This suggests that if the optimum cost is $\omega(k \cdot r)$, achieved by some points $z_1, \dots, z_k$, we could just map each z_i to its closest y_i, and this would change each distance by no more than $O(k \cdot r)$. Hence, we can ostensibly use the GMM points to obtain a cost within $O(k \cdot r)$ of the right answer, which is within an $\Omega(1)$ (in fact a $1 - o(1)$) multiplicative factor! Additionally, this procedure will compose nicely, because if we split the data into m components $X^{(1)}, \dots, X^{(m)}$, each with corresponding radius $r^{(1)}, \dots, r^{(m)}$, then each individual coreset has cost at least $r^{(j)}$ (so the combination has cost at least $\max r^{(i)}$), whereas we never move a point more than $r^{(i)} \leq \max r^{(i)}$.

The problem with this, however, is that we may be using each y_j multiple times: for instance, if both z_1 and z_2 are closest to y_1, we would use y_1 twice. Our goal is to find a subset of k points, meaning we cannot duplicate any point.

Note that in this duplication, it is never necessary to duplicate a point more than k times. So, if we could somehow pick k copies of each y_i, we would have a coreset. However, note that it is not crucial for each z_i to be mapped to its closest GMM point y_j: any point within distance r of y_j is also acceptable. Using this observation, it suffices to pick k points among those closest to y_j if possible - if there are fewer than k points, picking all of the points is sufficient. It is also important to choose all of Y, in the case where the optimum cost is only $O(k \cdot r)$. Together, this generates a composable coreset for both remote-matching and remote-pseudoforest, of size only k^2.

3.1.1 Improving the coreset for remote-matching

In the case of remote-matching, we can actually improve this to $O(k)$. The main observation here is to show that if a set Z of size k had two identical points, getting rid of both of them does not affect the minimum-weight-matching cost. (This observation does *not* hold for pseudoforest). One can similarly show that if the two points were close in distance, removing both of the points does not affect the matching cost significantly. This also implies we can, rather than removing both points, move them both to a new location as long as they are close together. At a high level, this means that there must exist a near-optimal k-matching that only has $O(1)$ points closest to each y_j: as a result we do not have to store k points for each y_j: only $O(1)$ points suffice.

3.1.2 Improving the coreset for remote-pseudoforest

In the case of remote-pseudoforest, the improvement is more involved. Consider a single group, and suppose GMM gives us the set $Y = \{y_1, \dots, y_k\}$. Let X_i represent the set of points in X closest to Y_i. The first observation we make is that if the optimal solution had multiple points in a single X_i, each such point can only contribute $O(r)$ cost. Assuming that the optimum cost is $\omega(k \cdot r)$, it may seem sufficient to simply pick 1 point in each Y_i for the coreset, as we can modify the optimum solution by removing points in X_i if there are two or more of them. While this will allow us to obtain a set with nearly optimum cost, the problem is the set has size less than k. So, we need to add additional points while preventing the pseudoforest cost from decreasing by too much.

To develop intuition for how this can be accomplished, we first suppose that $|X_1|, |X_2| \geq k$. In this case, we could choose the coreset as $X_1 \cup X_2 \cup Y$. We know there is a subset $Z \subset Y$ with pseudoforest cost close to optimum, though $|Z|$ may be much smaller than k. However, since y_1, y_2 are far away from each other (they were chosen first in the greedy procedure of GMM), so all points in X_1 and all points in X_2 are far from each other. That means

Algorithm 2 PFCoreset: $O(1)$-approximate remote-pseudoforest composable coreset algorithm.

```
Input: data $X = \{x_1, \dots, x_n\}$, integer $k$, parameter $\varepsilon \in (0, 1]$.
if $n < 2k^{1+\varepsilon} + k$ then
    Return $X$.
end if
$Y = \{y_1, \dots, y_k\} \leftarrow \mathrm{GMM}(x_1, \dots, x_n, k)$.
for $i = 1$ to $n$ do
    $\tilde{r}_i \leftarrow (k+1)^{\text{th}}$ largest value of $\rho(x_i, x_j)$ across all $j \le n$.
end for
$\tilde{r} \leftarrow \min_i \tilde{r}_i$, $x \leftarrow \arg\min_i \tilde{r}_i$
$U \leftarrow k$ furthest points in $X$ from $x$.
$P \leftarrow k$ arbitrary points within distance $\tilde{r}$ of $x$.
$S, T \leftarrow \mathrm{FindST}(X, k, \varepsilon, \tilde{r})$. {See Algorithm 5}
Return $C \leftarrow P \cup S \cup T \cup U \cup Y$.
```

that if we randomly choose either X_1 or X_2, and add enough points from the chosen set so that we have k points, each point $y \in Y$, with 50% probability, is not close to the new points added (because every point y must either be far from X_1 or far from X_2). Thus, the expected distance from y to the closest new point is large.

In general, it is not actually important that the points come from X_1 and X_2: we just need two sets S, T of k points such that $\rho(S, T)$, the minimum distance between $s \in S$ and $t \in T$, is large. Then, any point y cannot be close to points in both S and T. This also composes nicely, because to find the final set of k points, we only need there to be two sets S, T throughout the union of the coresets with large $\rho(S, T)$.

To find large S, T with large $\rho(S, T)$, we will require $|X| \ge k^{1+\varepsilon}$ for some small constant ε. For simplicity, we focus on the case when $|X| \ge k^{1.5}$. Suppose all but k points are in some ball B of radius r. If there exists x that is within distance $r/10$ of k points (we can make S these k points), then all points in S must be far away from the furthest k points from x (which we can set as T), or else we could have found a smaller ball B'. Otherwise, there are two options.

1. The majority of points $x \in X$ are within $r/100$ of at least $\sqrt{k}$ other points, but no $x \in X$ is within $r/10$ of at least k other points. Intuitively (we will make this intuition formal in Appendix A), a random set S_0 of size $O(\sqrt{k})$ should be within $r/100$ of at least k other points in total (we can make S these k points), but there are at least $|X| - k \cdot |S_0| \ge k$ points (we can make T these points) that are not within $r/10$ of S_0.
2. The majority of points aren't within $r/100$ of even $O(\sqrt{k})$ points. In this case, we can pick k of these points to form S, and they will not be within $r/100$ of at least $|X| - O(\sqrt{k}) \cdot |S| \ge k$ points. We make this intuition formal and prove the result for the more general $k^{1+\varepsilon}$.

3.2 Algorithm Pseudocode

We provide pseudocode for the remote-pseudoforest coreset in Algorithm 2 and for the remote-matching coreset in Algorithm 3. The proofs, as well as algorithm descriptions in words, are deferred to Section 5 (for remote-matching) and Appendix A (for remote-pseudoforest).

Algorithm 3 MWMCoreset: $O(1)$-approximate remote-matching composable coreset algorithm.

```
**Input:** data $X = \{x_1, \dots, x_n\}$, integer $k$.
**if** $n \leq 3k$ **then**
    **Return** $X$
**else**
    $Y = \{y_1, \dots, y_k\} \leftarrow \mathrm{GMM}(x_1, \dots, x_n, k)$.
    **Initialize** $S_1, \dots, S_k \leftarrow \emptyset$.
    **for** $i = 1$ to $n$ **do**
        Add $i$ to $S_j$ for $j = \arg\min \rho(x_i, y_j)$.
    **end for**
    **Initialize** $C \leftarrow Y$.
    **for** $i = 1$ to $k/2$ **do**
        **Find** $x, x' \in X \backslash C$ such that $x, x'$ are in the same $S_j$.
        $C \leftarrow C \cup \{x, x'\}$.
    **end for**
    **Return** $C$.
**end if**
```

4 Offline Remote-Matching Algorithm

In this section, we design $O(1)$-approximate offline algorithms for remote-matching. In this section, we first provide a technical overview, then the algorithm description and pseudocode, and finally we provide the full analysis.

4.1 Technical Overview

The remote-matching offline algorithm first utilizes some simple observations that we made in Section 3.1. Namely, we may assume the largest minimum-weight matching cost of any subset of k points is $\omega(k \cdot r)$, or else GMM provides an $O(1)$-approximation. Next, if the optimum solution was some $Z = \{z_1, \dots, z_k\}$, we can again consider mapping each z_i to its closest y_j, at the cost of having duplicates. However, as noted in Section 3.1, we may delete a point twice without affecting the matching cost: this means we can keep deleting a point twice until each y_j is only there 0 times (if the total number of z_i's closest to y_j was even) or 1 time (if the total number of z_i's closest to y_j was odd).

However, we have no idea what Z actually is, so we have no idea whether each y_j should be included or not. However, this motivates the following simpler problem: among the k points Y, choose a (even-sized) subset of Y maximizing the matching cost.

One attempt at solving this problem is to choose $\{y_1, \dots, y_p\}$ for some $p \leq k$: this will resemble an argument in [11]. The idea is that if we define r_p to be the maximum value $\rho(x, \{y_1, \dots, y_p\})$ over all $x \in X$, the same argument as Proposition 8 implies that all points among $y_1, \dots, y_p$ are separated by at least r_p. Hence, for the best p we can obtain matching cost $\Omega(\max_{1 \leq p \leq k} p \cdot r_p)$. Conversely, it is known that the minimum-weight-matching cost of any set of points Z is upper-bounded by the cost of the minimum spanning tree of Z. But the minimum spanning tree has cost at most $\sum_{p=1}^{k} r_p$, since we can create a tree by adding an edge from each y_{p+1} to its closest center among $y_1, \dots, y_p$, which has distance r_p. Since $\max(p \cdot r_p) \geq \Omega\left(\frac{1}{\log k}\right) \cdot \sum_{p=1}^{k} r_p$ (with equality for instance if $r_p = \frac{1}{p}$), we can obtain an $O(\log k)$-approximation.

For simplicity, we focus on the case where $r_p = \Theta(1/p)$ for all $1 \le p \le k$. We would hope that either the minimum spanning tree cost of Y, which we call $\mathrm{MST}(Y)$, is actually much smaller than $\log k$, or there is some alternative selection to obtain matching cost $\Omega(\log k)$ rather than $O(1)$. Suppose that $\mathrm{MST}(Y) = \Omega(\log k)$: furthermore, for simplicity suppose the pth largest edge of the tree has weight $\frac{1}{p}$. If we considered the graph on Y connecting two points if their distance is less than $\frac{1}{p}$, it is well-known that the graph must therefore split into p disconnected components.

Now, for some fixed p suppose that we chose a subset Z of Y such that each connected component in the graph above has an odd number of points in Z. Then, any matching must send at least one point in each $Z \cap CC_j$ (where CC_j is the jth connected component) to a point in a different connected component, forcing an edge of weight at least $\frac{1}{p}$. Since each of p connected components has such a point, together we obtain weight at least 1. In addition, if we can ensure this property for $p = 2, 4, 8, 16 \dots, k$, we can in fact get there must be at least 2^i edges of weight $1/2^i$, making the total cost $\Omega(\log k)$, as desired.

While such a result may not be possible exactly, it turns out that even a *random* subset of Y satisfies this property asymptotically! Namely, if we choose each point $y \in Y$ to be in Z with 50% probability, each CC_j is odd with 50% probability. So in expectation, for all p, the number of connected components of odd size is $p/2$. Even if we make sure Z has even size, this will still be true, replacing $p/2$ with $\Omega(p)$. Since this is true for all p in expectation, by adding over powers of 2 for p, we will find k points with $\Omega(\log k)$ matching cost in expectation.

4.2 Algorithm Desciption and Pseudocode

Given a dataset $X = \{x_1, \dots, x_n\}$, we recall that the goal of the remote-matching problem is to find a subset $Z = \{z_1, \dots, z_k\} \subset X$ of k points, such that the minimum-weight matching cost of Z, $\mathrm{MWM}(Z)$, is approximately maximized. In this subsection, we describe our $O(1)$-approximate remote-matching algorithm. We also provide pseudocode in Algorithm 4.

Algorithm Description

The algorithm proceeds as follows. First, run the GMM algorithm for k steps, to obtain k points $Y = \{y_1, \dots, y_k\} \subset X$. Define the subsets $S_1, \dots, S_k$ as a partitioning of X, where $x \in X$ is in S_i if y_i is the closest point to x in Y. (We break ties arbitrarily.) We use the better of the following two options, with the larger minimum-weight matching cost.

1. Simply use $Y = \{y_1, \dots, y_k\}$.
2. Let $\hat{Z} \subset Y$ be a uniformly random subset of Y. Initialize W to $\hat{Z}$ if $|\hat{Z}|$ is even, and otherwise initialize W to $\hat{Z} \backslash \hat{z}$ for some arbitrary $\hat{z} \in \hat{Z}$. Now, if there exist two points not in $W \cup Y$ but in the same subset S_i, add both of them to W. Repeat this procedure until $|W| = k$.

We will use whichever of Y or W has the larger minimum-weight matching cost. Since minimum-weight matching can be computed in polynomial time, we can choose the better of these two in polynomial time.

In Theorem 3, we assume $n \ge 3k$. Because of this assumption, if $|W| < k$, then $|W \cup Y| \le 2k - 1$, which means $|X \backslash (W \cup Y)| \ge k + 1$. Hence, by Pigeonhole Principle, two of these points must be in the same set S_i, which means that the procedure described above is indeed doable.

Algorithm 4 MWMOffline: $O(1)$-approximate remote-matching algorithm.

```
 1: Input: data $X = \{x_1, \ldots, x_n\}$, even integer $k$.
 2: $Y = \{y_1, \ldots, y_k\} \leftarrow \mathrm{GMM}(x_1, \ldots, x_n, k)$.
 3: Initialize $S_1, \ldots, S_k \leftarrow \emptyset$.
 4: for $i = 1$ to $n$ do
 5:     Add $i$ to $S_j$ if $j = \arg\min \rho(x_i, y_j)$.
 6: end for
 7: $Z \leftarrow$ random subset of $Y$.
 8: if $|Z|$ is odd then
 9:     Remove an arbitrary element from $Z$
10: end if
11: Initialize $W \leftarrow Z$.
12: while $|W| < k$ do
13:     Find some $x, x' \in X \backslash (W \cup Y)$, such that $x, x'$ are in the same subset $S_j$.
14:     Add $x, x'$ to $W$.
15: end while
16: Return whichever of $Y, W$ has larger minimum-weight matching cost.
```

4.3 Analysis

The first ingredient in proving Theorem 3 is the following lemma, which shows that assuming the random subset Z we chose in Line 7 of Algorithm 4 is sufficiently good, the algorithm produces an $O(1)$-approximation.

▶ **Lemma 9.** *For some constant $\frac{1}{2} \geq \alpha > 0$, suppose that*

$$\mathrm{MWM}(Z) \geq \alpha \cdot \max_{Z' \subset Y : |Z'| \text{ is even}} \mathrm{MWM}(Z').$$

Then, Algorithm 4 provides a $\frac{4}{\alpha}$-approximation for the remote-matching problem.

Proof. Let M be the optimal remote-matching cost. Let r be the maximum distance from any point in $X \backslash Y$ to its closest point in Y. Note that $\rho(y_i, y_j) \geq r$ for all $i, j \leq k$, by Proposition 8.

First, suppose that $M \leq 2\alpha^{-1} \cdot r \cdot k$. In this case, because every pair in Y has pairwise distance at least r, we have $\mathrm{MWM}(Y) \geq r \cdot \frac{k}{2}$. Hence, $\mathrm{MWM}(Y) \geq \frac{\alpha}{4} \cdot M$, which means we have a $\frac{4}{\alpha}$-approximation.

Alternatively, suppose $M \geq 2\alpha^{-1} \cdot r \cdot k$. Let $W_0 \subset X$ be the set of p points that achieves this, i.e., $\mathrm{MWM}(W_0) = M$. Consider the following multiset $\tilde{W}_0$ of size p in Y, where each point in W_0 is mapped to its closest center in Y (breaking ties in the same way as in the algorithm). Then, every pair of distances between W_0 and $\tilde{W}_0$ changes by at most $2r$. This means *every* matching has its cost change by at most $\frac{k}{2} \cdot 2r = rk$, so $\mathrm{MWM}(\tilde{W}_0) \geq M - rk$.

Now, let $Z_0 \subset Y$ be the set of points where $y_i \in Z_0$ if and only if y_i is in $\tilde{W}_0$ an odd number of times. Then, $\mathrm{MWM}(\tilde{W}_0) = \mathrm{MWM}(Z_0)$. To see why, first note that $\mathrm{MWM}(\tilde{W}_0) \leq \mathrm{MWM}(Z_0)$ since we can convert any matching of Z_0 to a matching of $\tilde{W}_0$ by simply matching duplicate points in $\tilde{W}_0$ until only Z_0 is left. To see why $\mathrm{MWM}(\tilde{W}_0) \geq \mathrm{MWM}(Z_0)$, note that if an optimal matching of $\tilde{W}_0$ connected some copy of y to a point $y' \neq y$ and another copy of y to a point $y'' \neq y$, we can always replace the edges (y, y') and (y, y'') with (y, y) and (y', y''), which by Triangle inequality will never increase the cost. We may keep doing this until a maximal number of duplicate points are matched together, and only one copy of each element in Z_0 will be left. Hence, we have

$$\mathrm{MWM}(Z_0) = \mathrm{MWM}(\tilde{W}_0) \geq M - rk. \tag{1}$$

Similarly, let Z, W be the sets found in the algorithm described above, and let $\tilde{W}$ be the multiset formed by mapping each point in W to its nearest center in Y. As in the case with Z_0 and $\tilde{W}_0$, we have that for Z and $\tilde{W}$, a point z is in Z if and only if z is in $\tilde{W}$ an odd number of times. Hence, $\text{MWM}(\tilde{W}) = \text{MWM}(Z)$. Likewise, each point in $\tilde{W}$ has distance at most r from its corresponding point in W, which means $\text{MWM}(W) \ge \text{MWM}(\tilde{W}) - rk$. Hence, we have

$$\text{MWM}(Z) = \text{MWM}(\tilde{W}) \le \text{MWM}(W) + rk. \tag{2}$$

Overall, $\text{MWM}(Z) \ge \alpha \cdot \max_{Z \subset Y: |Z| \text{ is even}} \text{MWM}(Z) \ge \alpha \cdot \text{MWM}(Z_0)$, so

$$\begin{aligned} \text{MWM}(W) &\ge \text{MWM}(Z) - rk \ge \alpha \cdot \text{MWM}(Z_0) - rk \\ &\ge \alpha \cdot M - (1+\alpha) rk. \end{aligned}$$

But note that $M \ge 2\alpha^{-1} rk$, which means that $(1+\alpha)rk \le \frac{\alpha(1+\alpha)}{2} \cdot M \le \frac{3}{4} \cdot \alpha \cdot M$. Hence, $\text{MWM}(W) \ge \frac{\alpha}{4} \cdot M$, which again means we have a $\frac{4}{\alpha}$-approximation. ◀

The main technical lemma that we will combine with Lemma 9 shows that Z has the desired property. We now state the lemma, but we defer the proof slightly, to Section 4.5. We remark that the proof roughly follows the intuition described at the end of Section 4.1.

▶ **Lemma 10.** *Let $\hat{Z}$ be a random subset of Y where each element is independently selected with probability $1/2$. If $|\hat{Z}|$ is even, we set $Z = \hat{Z}$, and if $|\hat{Z}|$ is odd, we arbitrarily remove 1 element from $\hat{Z}$ to generate Z. Then,*

$$\mathbb{E}[\text{MWM}(Z)] \ge \frac{1}{16} \cdot \max_{Z' \subset Y: |Z'| \text{ is even}} \text{MWM}(Z').$$

Given Lemmas 9 and 10, we explain how combine them to prove Theorem 3.

Proof of Theorem 3. Suppose we generate a random subset Z of Y (possibly removing an element), and suppose that $\text{MWM}(Z) = \alpha \cdot \max_{Z \subset Y: |Z| \text{ is even}} \text{MWM}(Z)$. Then, the output of the algorithm has matching cost at least $\frac{\alpha}{4}$ times the optimum k-matching cost $\text{MWM}_k(X)$, by Lemma 9. However, by Lemma 10, $\mathbb{E}[\alpha] \ge \frac{1}{16}$, which means that the expected matching cost of the output is $\frac{\mathbb{E}[\alpha]}{4} \cdot \text{MWM}_k(X) \ge \frac{1}{64} \cdot \text{MWM}_k(X)$.

If we want this to occur with high probability, note that the matching cost of the output can never be more than $\text{MWM}_k(X)$. Hence, by Markov's inequality, with at least $\frac{1}{64^2} = \frac{1}{4096}$ probability, the output has matching cost at least $\frac{1}{65} \cdot \text{MWM}_k(X)$. If we repeat this $O(1)$ times and return the set with best matching cost, we can find a set of size k with matching cost at least $\frac{1}{65} \cdot \text{MWM}_k(X)$, with probability at least 0.99. ◀

Before proving Lemma 10, we will need some additional preliminaries.

4.4 Preliminaries for Lemma 10

To prove Lemma 10, we will need several preliminary facts relating to the cost of a minimum weight matching, as well as the cost of a minimum spanning tree of a set of points.

First, we have the following fact, bounding the minimum weight matching in terms of the MST.

▶ **Proposition 11** (Classical, see Proof of Lemma 5.2 in [11])**.** *For any (finite, even sized) set of data points Z in a metric space,* $\text{MWM}(Z) \le \text{MST}(Z)$.

Next, given a subset Z of Y in a metric space, we can bound the minimum spanning tree cost of Z in terms of the minimum spanning cost of Y.

▶ **Proposition 12** (Classical, see [16])**.** *Let $Z \subset Y$ be (finite) sets of data points in some metric space. Then,* $\mathrm{MST}(Z) \le 2 \cdot \mathrm{MST}(Y)$.

Next, we equate the minimum spanning tree of a dataset Y with the number of connected components in a family of graphs on Y. The following proposition essentially follows from the same argument as in [12, Lemma 2.1]. We prove it here for completeness since the statement we desire is not explicitly proven in [12].

▶ **Proposition 13.** *Given a dataset Y in a metric space and a radius $r > 0$, define $G_r(Y)$ to be the graph on Y that connects two data points if and only if their distance is at most r. Define $P_r(Y)$ to be the number of connected components in $G_r(Y)$. Then,*

$$\mathrm{MST}(Y) \in \left[\frac{1}{2}, 1\right] \cdot \left(\sum_{i \in \mathbb{Z}} 2^i \cdot (P_{2^i}(Y) - 1)\right).$$

Proof. Note that if 2^i is at least $\mathrm{diam}(Y)$, the diameter of Y, $P_{2^i}(Y) = 1$, which means we may ignore the summation for i with $2^i > \mathrm{diam}(Y)$. Hence, by scaling by some power of 2, we may assume WLOG that $\mathrm{diam}(Y) < 1$, and that the summation is only over $i < 0$.

Now, for any $t \ge 0$, let $Q_t(Y)$ be the number of edges in the MST of Y with weight at most 2^{-t} and strictly more than $2^{-(t+1)}$ (assuming we run Kruskal's algorithm for MST). Note that $R_t(Y) := \sum_{t' \ge t} Q_{t'}(Y)$ is the number of edges with weight at most 2^{-t}. Note that $R_t(Y)$ is precisely $n - P_{2^{-t}}(Y)$. To see why, note that the $R_t(Y)$ edges form a forest with $n - R_t(Y)$ connected components. In addition, in the graph $G_{2^{-t}}(Y)$, none of the $n - R_t(Y)$ components can be connected to each other, or else there would have been another edge of weight at most 2^{-t} that Kruskal's algorithm would have had to add. Therefore, $\sum_{t' \ge t} Q_{t'}(Y) = n - P_{2^{-t}}(Y)$. By subtracting this equation from the same equation replacing t with $t + 1$, we obtain

$$Q_t(Y) = P_{2^{-(t+1)}}(Y) - P_{2^{-t}}(Y). \tag{3}$$

Now, note that by definition of $Q_t(Y)$, the cost of $\mathrm{MST}(Y)$ is between $\sum_{t \ge 0} 2^{-(t+1)} \cdot Q_t(Y)$ and $\sum_{t \ge 0} 2^{-t} \cdot Q_t(Y)$. Equivalently, it equals $\alpha \cdot \left(\sum_{t \ge 0} 2^{-t} \cdot Q_t(Y)\right)$, for some $\alpha \in [1/2, 1]$. Therefore,

$$\begin{aligned}
\mathrm{MST}(Y) &= \alpha \cdot \left(\sum_{t \ge 0} 2^{-t} \cdot Q_t(Y)\right) \\
&= \alpha \cdot \left(\sum_{t \ge 0} 2^{-t} \cdot (P_{2^{-(t+1)}}(Y) - P_{2^{-t}}(Y))\right) \\
&= \alpha \cdot \left(\sum_{t \ge 0} (2^{-t} - 2^{-(t+1)}) P_{2^{-(t+1)}}(Y) - P_1(Y)\right) \\
&= \alpha \cdot \left(\sum_{t \ge 1} 2^{-t} P_{2^{-t}}(Y) - 1\right) \\
&= \alpha \cdot \left(\sum_{t \ge 1} 2^{-t} (P_{2^{-t}}(Y) - 1)\right).
\end{aligned}$$

The second-to-last line follows since the diameter is at most 1 so $G_1(Y)$ has one connected component, and the last line follows because $\sum_{t \ge 1} 2^{-t} = 1$. ◀

Finally, we need to consider the minimum weight matching cost in a *hierarchically well-separated tree* (HST).

▶ **Definition 14.** *A* hierarchically-well seprated tree (HST) *is a depth-d tree (for some integer $d \geq 1$) with the root as depth 0, and every leaf has depth d. For any node u in the tree of depth $1 \leq t \leq d$, each edge from u to its parent has weight 2^{-t}. For two nodes v, w in the HST, the distance $d_{\text{HST}}(v, w)$ is simply the sum of the edge weights along the shortest path from v to w in the tree.*

Note that for any two leaf nodes v, w in an HST, if their least common ancestor has depth t, the distance between v and w is $2 \cdot \left(2^{-(t+1)} + 2^{-(t+2)} + \cdots + 2^{-d}\right) = 2 \cdot (2^{-t} - 2^{-d})$.

We will make use of the following result about points in an HST metric.

▶ **Proposition 15** ([21], Claim 3)**.** *Let Z be a (finite, even sized) set of points that are leaves in a depth-d HST. Let m_i be the number of nodes at level i with an* odd *number of descendants in Z. Then, with respect to the HST metric, the minimum weight matching cost equals*

$$\text{MWM} = \sum_{i=0}^{d} 2^{-i} \cdot m_i.$$

We remark that the corresponding statement in [21] has an additional additive factor of $n = |Z|$ in the right-hand side. This is because we include the bottom level in our sum (which consists of n nodes each with exactly one descendant), whereas [21] does not.

4.5 Proof of Lemma 10

We are now ready to prove Lemma 10

Proof of Lemma 10. Assume WLOG (by scaling) that the diameter of Y is at most 1. Let Z be a subset of Y with even size. By Proposition 11, $\text{MWM}(Z) \leq \text{MST}(Z)$. By Proposition 12, $\text{MST}(Z) \leq 2 \cdot \text{MST}(Y)$. Combining these together, we have

$$\max_{Z \subset Y : |Z| \text{ even}} \text{MWM}(Z) \leq 2 \cdot \text{MST}(Y). \tag{4}$$

Now, for our dataset Y and any positive real $r > 0$, recall that $G_r(Y)$ is defined as the graph on Y that connects two data points if their distance is at most r. In addition, define $\mathcal{P}_r(Y)$ to be the partitioning of Y into connected components based on $G_r(Y)$, and recall that $P_r(Y) = |\mathcal{P}_r(Y)|$ equals the number of connected components in $G_r(Y)$. Then, Proposition 13 tells us that

$$\text{MST}(Y) \leq \sum_{i \in \mathbb{Z}} 2^i \cdot (P_{2^i}(Y) - 1). \tag{5}$$

Now, consider the following "embedding" of Y into a depth-d hierarchically well-separated tree (where we will choose d later) as follows. By scaling, assume WLOG that the diameter of Y is 1. For each integer $0 \leq t \leq d$, the nodes at level t will be the connected components in $G_{2^{-t}}(Y)$, where the children of any node at depth t, represented by a subset Z of Y, are simply the connected components in $\mathcal{P}_{2^{-(t+1)}}(Y)$ contained in Z.

The distance $d_{\text{HST}}(y_i, y_j)$ between any two vertices y_i, y_j in the HST is precisely $2(2^{-t} - 2^{-d})$ if y_i, y_j have common ancestor at level t of the HST. Note that if $d_{\text{HST}}(y_i, y_j) = 2(2^{-t} - 2^{-d})$, then y_i, y_j are not in the same connected component of $G_{2^{-(t+1)}}$, which means that $\rho(y_i, y_j) > 2^{-(t+1)}$. Importantly, this means that $d_{\text{HST}}(y_i, y_j) \leq 4\rho(y_i, y_j)$ for all pairs i, j. Hence, for any subset $Z \subset Y$ of even size, the minimum weight matching cost $\mathrm{MWM}_{\mathrm{HST}}(Z)$ with respect to the HST metric is at most 4 times the true minimum weight matching cost, i.e.,

$$\mathrm{MWM}_{\mathrm{HST}}(Z) \le 4 \cdot \mathrm{MWM}(Z). \tag{6}$$

Finally, we consider selecting a random subset $\hat{Z} \subset Y$, and provide a lower bound for $\mathrm{MWM}_{\mathrm{HST}}(Z)$, where $Z = \hat{Z}$ if $|\hat{Z}|$ is even and otherwise Z equals $\hat{Z}$ after removing a single (arbitrary) element. Note that for each node v of depth t, corresponding to a connected component in $\mathcal{P}_{2^{-t}}(Y)$, the probability that it has an odd number of descendants in $\hat{Z}$ if $\hat{Z}$ is picked at random is precisely $1/2$. This implies that the expectation of $\sum_{i=0}^d 2^{-i} \cdot m_i$, where m_i is the number of nodes at level i with an odd number of descendants in $\hat{Z}$, is $\frac{1}{2} \cdot \sum_{i=0}^d 2^{-i} \cdot P_{2^{-i}}(Y)$.

Note, however, that $\hat{Z}$ has odd size with $1/2$ probability. In this event, we remove an arbitrary element of $\hat{Z}$, which may reduce each m_i by 1. This only happens with 50% probability, so after this potential removal of a point, the expectation of $\sum_{i=0}^d 2^{-i} \cdot m_i(Z)$, where $m_i(Z)$ is the number of nodes at level i with an odd number of descendants in Z, is at least $\frac{1}{2} \cdot \sum_{i=0}^d 2^{-i} \cdot (P_{2^{-i}}(Y) - 1)$. Since $\mathrm{diam}(Y)$ is at most 1, this implies $P_{2^i}(Y) - 1 = 0$ for all $i \ge 1$. Also, for $i > d$, $2^{-i} \cdot (P_{2^{-i}}(Y) - 1) \le 2^{-i} \cdot n$. If we sum this up over all $i > d$, this is still at most $2^{-d} \cdot n$. Hence, we have that

$$\mathbb{E}_Z\left[\sum_{i=0}^{d} 2^{-i} \cdot m_i(Z)\right] \ge \frac{1}{2} \cdot \left(\sum_{i \in \mathbb{Z}} 2^i (P_{2^i}(Y) - 1)\right) - n \cdot 2^{-d}. \tag{7}$$

In summary, we have that

$$\begin{aligned}
\max_{Z' \subset Y : |Z'| \text{ even}} \mathrm{MWM}(Z') &\le 2 \cdot \mathrm{MST}(Y) && \text{By Equation (4)} \\
&\le 2 \cdot \sum_{i \in \mathbb{Z}} 2^i \cdot (P_{2^i}(Y) - 1) && \text{By Equation (5)} \\
&\le 4 \cdot \left(\mathbb{E}_Z\left[\sum_{i=0}^{d} 2^{-i} \cdot m_i(Z)\right] + n \cdot 2^{-d}\right) && \text{By Equation (7)} \\
&= 4 \cdot \left(\mathbb{E}_Z\left[\mathrm{MWM}_{\mathrm{HST}}(Z)\right] + n \cdot 2^{-d}\right) && \text{By Proposition 15} \\
&\le 16 \cdot \left(\mathbb{E}_Z\left[\mathrm{MWM}(Z)\right] + n \cdot 2^{-d}\right). && \text{By Equation (6)}
\end{aligned}$$

We can choose the depth of the HST to be arbitrarily large, which therefore implies that

$$\mathbb{E}_Z[\mathrm{MWM}(Z)] \ge \frac{1}{16} \cdot \max_{Z' \subset Y : |Z'| \text{ even}} \mathrm{MWM}(Z'). \qquad \blacktriangleleft$$

5 Coreset for Remote-Matching

In this section, we prove why the algorithm given in Algorithm 3 creates an $O(1)$-approximate composable coreset. First, we describe the algorithm in words.

5.1 Algorithm Description

We start by running GMM on the dataset X for k steps, to return k points $Y = \{y_1, \dots, y_k\}$. Again, let the subsets $S_1, \dots, S_k$ be a partitioning of X, where $x \in X$ is in S_i if y_i is the closest point in Y to x (breaking ties arbitrarily). Note that $y_i \in S_i$ for all i.

To create our coreset C for X, if $|X| \le 3k$ we simply define $C = X$. Otherwise, we start by initializing C to be Y, so C currently has size k. Next, for $k/2$ steps, we find any two points in $X \backslash C$ that are in the same partition piece S_i, and add both of them to C. Hence, at the end $|C| = 2k$. Note that this procedure is always doable, since we are assuming $|X| \ge 3k+1$, which means if we have picked at most $2k$ total elements, there are $k+1$ remaining elements in X, of which at least 2 must be in the same S_i by the pigeonhole principle.

5.2 Analysis

In this subsection, we prove that the algorithm generates an $O(1)$-approximate composable coreset, by proving Theorem 5.

Proof of Theorem 5. Suppose we run this algorithm for each of m datasets, $X^{(1)}, \dots, X^{(m)}$, to generate coresets $C^{(1)}, \dots, C^{(m)}$. We wish to show that the optimum k-matching cost of $C = \bigcup_{j=1}^m C^{(j)}$ is at least $\Omega(1)$ times the optimum k-matching cost of $X = \bigcup_{j=1}^m X^{(j)}$.

Let $Y^{(j)} = \{y_1^{(j)}, \dots, y_k^{(j)}\}$ represent the k points we obtained by running GMM on $X^{(j)}$, and let $r^{(j)}$ be the maximum distance from any point in $X^{(j)} \backslash Y^{(j)}$ to its closest point in $Y^{(j)}$. Then, note that all points in $Y^{(j)}$ are pairwise separated by at least $r^{(j)}$. Let $r = \max_{1 \le j \le m} r^{(j)}$.

First, suppose that the optimum k-matching cost of X is $M \le 5r \cdot k$. In this case, for the $r^{(j)}$ that equals r, the GMM algorithm finds k points that are pairwise separated by at least $r^{(j)} = r$. Since $C^{(j)} \supset Y^{(j)}$, this means that the full coreset C contains k points that are pairwise separated by r, which has k-matching cost at least $r \cdot \frac{k}{2}$. Hence, we have a 10-approximate coreset.

Alternatively, the optimum k-matching cost of X is $M \ge 5r \cdot k$. Let $S_i^{(j)}$ represent the set S_i for $X^{(j)}$, and suppose W is an optimal set of k points in X with $\text{MWM}(W) = M$. Let $W^{(j)} = W \cap X^{(j)}$. Also, let $W_i^{(j)} = W \cap S_i^{(j)}$ and $b_i^{(j)}$ be the *parity* of $|W_i^{(j)}|$, i.e., $b_i^{(j)} = 1$ if $|W_i^{(j)}|$ is odd and $b_i^{(j)} = 0$ if $|W_i^{(j)}|$ is even. In addition, let $\tilde{W}$ be the multiset of k points formed by mapping each point in $W_i^{(j)}$ to $y_i^{(j)}$. In other words, $\tilde{W}$ consists of each $y_i^{(j)}$ repeated $|W_i^{(j)}|$ times. Note that since each $W_i^{(j)}$ has distance at most $r^{(j)} \le r$ from $y_i^{(j)}$, all pairwise distances change by at most $2r$, which means the matching cost difference $|\text{MWM}(\tilde{W}) - \text{MWM}(W)| \le \frac{1}{2} \cdot 2r \cdot k = rk$. Also, note that $\tilde{W}$ only consists of points of the form $y_i^{(j)}$, with the parity of the number of times $y_i^{(j)}$ appears in $\tilde{W}$ equaling $b_i^{(j)}$.

Next, we create a similar set $W' \subset C$. For each $j \le m$, define $k^{(j)} = |W^{(j)}|$. We will find a set $(W')^{(j)} \subset C^{(j)}$ of size $k^{(j)}$, such that the parity of $|(W')^{(j)} \cap S_i^{(j)}|$ equals $b_i^{(j)}$ for all $i \le k$. To do so, first note that if $|X^{(j)}| \le 3k$, then $C^{(j)} = X^{(j)}$, so we can just choose $(W')^{(j)} = W^{(j)}$. Otherwise, $|X^{(j)}| \ge 3k+1$, and $C^{(j)}$ consists of $2k$ points. In addition, $C^{(j)} \supset Z^{(j)}$. Now, we start by including in $(W')^{(j)}$ each point $y_i^{(j)}$ such that $b_i^{(j)} = 1$. Since $b_i^{(j)} = 1$ means that $|W_i^{(j)}|$ is odd, for any fixed j the number of $b_i^{(j)} = 1$ is at most $k^{(j)}$ and has the same parity as $k^{(j)}$. Now, as long as $|(W')^{(j)}| < k^{(j)}$, this means $|C^{(j)} \backslash (W')^{(j)}| \ge k+1$, which means there are two points in $C^{(j)} \backslash (W')^{(j)}$ that are in the same $S_i^{(j)}$, by pigeonhole principle. We can add both of them to $(W')^{(j)}$. We can keep repeating this procedure until $|(W')^{(j)}| = k^{(j)}$, and note that this never changes the parity of each $|(W')^{(j)} \cap S_i^{(j)}|$.

Our set $W' \subset C$ will just be $\bigcup_{j=1}^m (W')^{(j)}$. Note that $|W'| = \sum_{j=1}^m k^{(j)} = k$, and $|W' \cap S_i^{(j)}|$ has parity $b_i^{(j)}$, just like W. Hence, we can create the multiset $\tilde{W}'$ by mapping each point $w' \in W' \cap S_i^{(j)}$ to $y_i^{(j)}$. Again, each point moves by at most r, so all pairwise distances change by at most $2r$, which means that $|\text{MWM}(\tilde{W}') - \text{MWM}(W')| \le rk$.

Finally, we will see that $\text{MWM}(\tilde{W}') = \text{MWM}(\tilde{W})$. Note that both $\tilde{W}$ and $\tilde{W}'$ are multisets of $y_i^{(j)}$ points, each repeated an odd number of times if and only if $b_i^{(j)} = 1$. However, we saw in the proof of Lemma 9 that $\text{MWM}(\tilde{W})$ equals the minimum-weight matching cost of simply including each point $y_i^{(j)}$ exactly $b_i^{(j)}$ times. This is because there exists an optimal matching that keeps matching duplicate points together as long as it is possible. The same holds for $\text{MWM}(\tilde{W}')$, which means $\text{MWM}(\tilde{W}) = \text{MWM}(\tilde{W}')$.

Overall, this means that $|\text{MWM}(W') - \text{MWM}(W)| \le |\text{MWM}(W') - \text{MWM}(\tilde{W}')| + |\text{MWM}(\tilde{W}') - \text{MWM}(\tilde{W})| + |\text{MWM}(\tilde{W}) - \text{MWM}(W)| \le rk + 0 + rk = 2rk$. But since we assumed that $\text{MWM}(W) = M \ge 5rk$, this means the k-matching for C is at least $M - 2rk \ge \frac{M}{2}$. Hence, we get a 2-approximate coreset.

In either case, we obtain an $O(1)$-approximate coreset, as desired. ◀

A Composable Coreset for Remote-Pseudoforest

In this section, we describe and analyze the composable coreset algorithm for remote-pseudoforest.

A.1 Algorithm

In this subsection, we prove why the algorithm given in Algorithm 2 creates an $O(1)$-approximate composable coreset. First, we describe the algorithm in words. We recall that we have m datasets $X^{(1)}, \dots, X^{(m)}$: we wish to create a coreset $C^{(j)}$ of each $X^{(j)}$ so that $\bigcup_{j=1}^m C^{(j)}$ contains a set Z of k points such that $\text{PF}(Z) \ge \Omega(1) \cdot \text{PF}_k\left(\bigcup_{j=1}^m X^{(j)}\right)$.

A.1.1 Coreset Construction

Suppose that $|X^{(j)}| \ge 2k^{1+\varepsilon} + k$. Let $\tilde{r}^{(j)}$ represent the smallest value such that there exists a ball $\tilde{B}^{(j)}$ of radius $\tilde{r}^{(j)}$ around some $x^{(j)} \in X^{(j)}$ that contains all but at most k of the points in $X^{(j)}$. The point $\tilde{r}^{(j)}$ and a corresponding $x^{(j)}, \tilde{B}^{(j)}$ can be found in $O(|X^{(j)}|^2)$ time.

Choose $U^{(j)}$ to be the set of k points furthest from $x^{(j)}$. These will either be precisely the k points outside $\tilde{B}^{(j)}$, or all of the points outside $\tilde{B}^{(j)}$ plus some points on the boundary of $\tilde{B}^{(j)}$, to make a total of k points. In addition, we choose some arbitrary set $P^{(j)} \subset X^{(j)}$ of any k points in the ball $B^{(j)}$.

Next, we will choose sets $S^{(j)}, T^{(j)} \subset X^{(j)}$ of size k, such that $\rho(S^{(j)}, T^{(j)}) \ge \frac{\varepsilon}{2} \cdot \tilde{r}^{(j)}$. It is not even clear that such sets exist, but we will show how to algorithmically find such sets in $O(|X^{(j)}|^2)$ time (assuming $|X^{(j)}| \ge 2k^{1+\varepsilon} + k$).

Finally, we run the GMM algorithm on $X^{(j)}$ to obtain $Y^{(j)} = \{y_1^{(j)}, y_2^{(j)}, \dots, y_k^{(j)}\}$. The final coreset will be $C^{(j)} := P^{(j)} \cup S^{(j)} \cup T^{(j)} \cup U^{(j)} \cup Y^{(j)}$. Note that each of $P^{(j)}, S^{(j)}, T^{(j)}, U^{(j)}, Y^{(j)}$ has size at most k, so $|C^{(j)}| \le 5k$.

Alternatively, if $|X^{(j)}| < 2k^{1+\varepsilon} + k$, we choose the coreset to simply be $X^{(j)}$. For convenience, in this setting, we define $U^{(j)} := X^{(j)}$ and $P^{(j)}, S^{(j)}, T^{(j)}, Y^{(j)}$ to all be empty.

We have not yet described how to find $S^{(j)}, T^{(j)}$, let alone prove they even exist. We now describe an $O(|X^{(j)}|^2)$ time algorithm that finds $S^{(j)}, T^{(j)} \subset X^{(j)}$ of size k, such that $\rho(S^{(j)}, T^{(j)}) \ge \frac{\varepsilon}{2} \cdot \tilde{r}^{(j)}$.

A.1.2 Efficiently finding $S^{(j)}, T^{(j)}$

Here, we show that we can efficiently find $S^{(j)}, T^{(j)}$ from the coreset construction, as long as $|X^{(j)}| \ge 2k^{1+\varepsilon} + k$. We formalize this with the following lemma.

▶ **Lemma 16.** *Let $\varepsilon > 0$ be a fixed constant, and consider a dataset X of size at least $2k^{1+\varepsilon} + k$, and suppose that no ball of radius smaller than $\tilde{r}$ around any $x \in X$ contains all but at most k points in X. (In other words, for every $x \in X$, there are at least k points in X of distance at least $\tilde{r}$ from x.) Then, we in $O(|X|^2)$ time, we can find two disjoint sets $S, T \subset X$, each of size k, such that $\rho(S, T) \ge \frac{\varepsilon \cdot \tilde{r}}{2}$.*

Proof. The algorithm works as follows. First, define $r' = \frac{\varepsilon \cdot \tilde{r}}{2}$. For each point $x \in X$, and for every nonnegative integer i, define $N_i(x)$ as the set of points in X of distance at most $i \cdot r'$ from x. We can compute the set $N_i(x)$ for all $x \in X$ and $0 \le i \le 2/\varepsilon$ in $O(|X|^2)$ time, as ε is a constant. Suppose there exists $x \in X$ such that $|N_{1/\varepsilon}(x)| \ge k$. By our assumption on $\tilde{r}$, there are at least k points of distance at least $\tilde{r} = \frac{2}{\varepsilon} \cdot r'$ from x (or else we could have chosen $\tilde{r}$ to be smaller). Therefore, we can let S be a subset of size k from $N_{1/\varepsilon}(x)$ and T be a subset of size k of points of distance at least $\frac{2}{\varepsilon} \cdot r'$ from x. The minimum distance between any $s \in S$ and $t \in T$ is at least $r' \cdot \left(\frac{2}{\varepsilon} - \frac{1}{\varepsilon}\right) = \frac{\tilde{r}}{2}$.

Alternatively, every $x \in X$ satisfies $|N_{1/\varepsilon}(x)| < k$. Now, consider the following peeling procedure. Let $X_0 := X$: for each $h \ge 1$, we will inductively create $X_h \subsetneq X_{h-1}$ from X_{h-1}, as follows. First, we pick an arbitrary point $x_h \in X_{h-1}$. For any point $x \in X_{h-1}$ and any integer $i \ge 0$, define $N_i(x_h; X_{h-1}) = N_i(x_h) \cap X_{h-1}$ to be the set of points of distance at most $i \cdot r'$ from x_h in X_{h-1}. By our assumption, we have that $|N_{1/\varepsilon}(x_h; X_{h-1})| \le |N_{1/\varepsilon}(x_h)| < k$, so there exists some $i(h)$ with $0 \le i(h) \le \frac{1}{\varepsilon}$, such that $\frac{|N_{i(h)+1}(x_h, X_{h-1})|}{|N_{i(h)}(x_h, X_{h-1})|} \le k^\varepsilon$ and $|N_{i(h)}(x_h, X_{h-1})| \le k$. Choose such an $i = i(h)$, and let $X_h := X_{h-1} \backslash N_{i(h)}(x_h, X_{h-1})$.

We repeat this process until we have found the first X_ℓ with $|X \backslash X_\ell| \ge k$. Note that each removal process removes at least 1 and at most k elements, so $|X \backslash X_\ell| \le 2k$. Let $S_h = N_{i(h)}(x_h, X_{h-1}) = X_{h-1} \backslash X_h$ for each $1 \le h \le \ell$, so $X \backslash X_\ell = S_1 \cup \cdots \cup S_\ell$. Note, however, that any point within distance r' of some $x \in S_h$ was either in $S_1 \cup \cdots \cup S_{h-1}$, or was in $N_{i(h)+1}(x_h, X_{h-1})$. In other words, every point of distance r' of $x \in S_1 \cup \cdots \cup S_\ell$ is in $\bigcup_{h=1}^{\ell} N_{i(h)+1}(x_h, X_{h-1})$. But this has size at most

$$\sum_{i=1}^{\ell} k^\varepsilon \cdot |N_{i(h)}(x_h, X_{h-1})| = k^\varepsilon \cdot \sum_{i=1}^{\ell} |S_i| \le k^\varepsilon \cdot 2k = 2k^{1+\varepsilon}.$$

So, assuming that $|X| \ge 2k^{1+\varepsilon} + k$, defining $S := S_1 \cup \cdots \cup S_\ell$, we have that $|S| \ge k$ and there are at least k points in X that are *not* within distance $r' = \frac{\varepsilon \cdot \tilde{r}}{2}$ of S. ◀

We include pseudocode for the algorithm described in the proof of Lemma 16, in Algorithm 5.

A.2 Analysis

In this section, we prove that the algorithm indeed generates an $O(1/\varepsilon)$-approximate composable coreset of size at most $O(k^{1+\varepsilon})$. By making ε an arbitrarily small constant, this implies we can find a constant-approximate composable coreset of size $O(k^{1+\varepsilon})$ for any arbitrarily small constant ε.

Let OPT represent the optimal set of k points in all of $X = \bigcup_{j=1}^{m} X^{(j)}$, that maximizes remote-pseudoforest cost. Our goal is to show that there exists a set of k points in $\bigcup_j (P^{(j)} \cup S^{(j)} \cup T^{(j)} \cup U^{(j)} \cup Y^{(j)})$ with pseudoforest cost at least $\Omega(\text{PF}(\text{OPT}))$.

Let $r^{(j)}$ represent the maximum distance from any point in $X^{(j)}$ to its closest point in $Y^{(j)}$. Note that by Proposition 8, $\text{PF}(Y^{(j)}) \ge k \cdot r^{(j)}$. Hence, if $\text{PF}(\text{OPT}) < 10 \cdot k \cdot \max_j r^{(j)}$, there exists some choice of j with $\text{PF}(Y^{(j)}) \ge 0.1 \cdot \text{OPT}$ and $|Y^{(j)}| = k$. Hence, we get a constant-factor approximation in this case. Otherwise, we may assume that $\text{PF}(\text{OPT}) \ge 10 \cdot k \cdot \max_j r^{(j)}$.

Next, for a fixed $X^{(j)}$, let $X_i^{(j)}$ represent the set of points in $X^{(j)}$ closest to $y_i^{(j)}$ among all points in $Y^{(j)}$. Given the optimal solution OPT of k points, let $\text{OPT}_i^{(j)} = \text{OPT} \cap X_i^{(j)}$.

Algorithm 5 FINDST: Find two sets S, T of size k with large $\rho(S, T)$.

```
Input: data $X = \{x_1, \dots, x_n\}$, integer $k$, parameter $\varepsilon \in (0, 1]$, radius $\tilde{r}$.
$r' \leftarrow \frac{\varepsilon \cdot \tilde{r}}{2}$.
for $x$ in $X$ do
    for $i = 0$ to $2/\varepsilon$ do
        $N_i(x) = \{z \in X : \rho(x, z) \leq i \cdot r'\}$.
    end for
    if $|N_{1/\varepsilon}(x)| \geq k$ then
        $S \leftarrow$ arbitrary subset of size $k$ in $N_{1/\varepsilon}(x)$.
        $T \leftarrow$ arbitrary $k$ points of distance at least $\tilde{r}$ from $x$.
        Return $S, T$.
    end if
end for
$S = \emptyset, X_0 \leftarrow X, h \leftarrow 0$
while $|S| < k$ do
    $h \leftarrow h + 1$
    $x_h \in X_{h-1}$ chosen arbitrarily.
    Find $0 \leq i \leq \frac{1}{\varepsilon}$ such that $\frac{|N_{i+1}(x_h) \cap X_{h-1}|}{|N_i(x_h) \cap X_{h-1}|} \leq k^{\varepsilon}$.
    $S_h \leftarrow N_i(x_h) \cap X_{h-1}$.
    $X_h \leftarrow X_{h-1} \backslash S_h$, $S \leftarrow S \cup S_h$
end while
$S \leftarrow$ arbitrary subset of size $k$ in $S$
$T \leftarrow$ arbitrary subset of $k$ points of distance at least $r'$ from all points in $S$.
Return $S, T$.
```

Now, we will define sets $G_i^{(j)}, G_i'^{(j)}$ based on the following cases.

1. If $|X^{(j)}| < 2k^{1+\varepsilon} + k$, define $G_i^{(j)} = G_i'^{(j)} = \mathrm{OPT}_i^{(j)}$ for all $i \leq k$.
2. Else, if $y_i^{(j)} \in \mathrm{OPT}_i^{(j)}$, define $G_i^{(j)}$ as $y_i^{(j)} \cup (U^{(j)} \cap \mathrm{OPT}_i^{(j)})$ and $G_i'^{(j)} = \mathrm{OPT}_i^{(j)}$.
3. Else, if $\mathrm{OPT}_i^{(j)} \backslash U^{(j)} = \emptyset$ (i.e., all points in $\mathrm{OPT}_i^{(j)}$ happen to be in $U^{(j)}$), define $G_i^{(j)} = G_i'^{(j)} = \mathrm{OPT}_i^{(j)}$.
4. Else, define $G_i^{(j)} = y_i^{(j)} \cup (U^{(j)} \cap \mathrm{OPT}_i^{(j)})$, and define $G_i'^{(j)}$ as $\mathrm{OPT}_i^{(j)}$ with the slight modification of moving a single (arbitrary) point in $\mathrm{OPT}_i^{(j)} \backslash U^{(j)}$ to $y_i^{(j)}$.

We will define the sets $G = \bigcup_{i,j} G_i^{(j)}$ and $G' = \bigcup_{i,j} G_i'^{(j)}$.

Importantly, the following five properties always hold for all $i \leq m, j \leq k$. (They even hold in the setting when $|X^{(j)}| < 2k^{1+\varepsilon} + k$, because we defined $U^{(j)} = X^{(j)}$ and $G_i^{(j)} = G_i'^{(j)} = \mathrm{OPT}_i^{(j)}$.)

1. $|G_i'^{(j)}| = |\,\mathrm{OPT}_i^{(j)}\,|$. This means that $|G'| = k$.
2. $G_i^{(j)} \subset G_i'^{(j)} \subset X_i^{(j)}$. This means that $G \subset G'$.
3. $G_i^{(j)} \subset U^{(j)} \cup Y^{(j)}$. This means that $G \subset \bigcup_j (U^{(j)} \cup Y^{(j)})$.
4. Every point in $G_i'^{(j)} \backslash G_i^{(j)}$ is not in $U^{(j)}$. This means that $\bigcup U^{(j)}$ and $G' \backslash G$ are disjoint.
5. If $G_i'^{(j)} \backslash G_i^{(j)}$ is nonempty, then $y_i^{(j)} \in G_i^{(j)}$, so $G_i^{(j)}$ is also nonempty.

Now, note that from changing OPT to G', we never move a point by more than $\max_j r^{(j)}$, which means that $|\,\mathrm{PF}(G') - \mathrm{PF}(\mathrm{OPT})| \leq 2k \cdot \max_j r^{(j)}$. As we are assuming that $\mathrm{PF}(\mathrm{OPT}) \geq 10k \cdot \max_j r^{(j)}$, we have $\mathrm{PF}(G') \geq 0.8 \cdot \mathrm{OPT}$. Next, if a point x is in $G_i'^{(j)}$ but not in $G_i^{(j)}$, then

$x \in X^{(j)} \backslash U^{(j)}$ and $y_i^{(j)} \in G_i^{(j)}$, which means that the cost of x with respect to G' is at most $\max_j r^{(j)}$. So for any set A, if we define $\text{cost}_A(x)$ for $x \in A$ to denote $\min_{y \in A: y \neq x} \rho(x, y)$, then

$$\sum_{x \in G} \text{cost}_{G'}(x) \geq \text{PF}(G') - \sum_{x \in G' \backslash G} \text{cost}_{G'}(x) \geq \text{PF}(G') - k \cdot \max_j r^{(j)} \geq 0.7 \cdot \text{OPT}\,. \tag{8}$$

We now try to find a set $G'' \supset G$ of size k with large pseudoforest cost, but this time we must ensure that $G'' \subset \bigcup_j (P^{(j)} \cup S^{(j)} \cup T^{(j)} \cup U^{(j)} \cup Y^{(j)})$. In other words, to finish the analysis, it suffices to prove the following lemma.

▶ **Lemma 17.** *There exists $G'' \subset \bigcup_j (P^{(j)} \cup S^{(j)} \cup T^{(j)} \cup U^{(j)} \cup Y^{(j)})$ of size at least k, such that $G'' \supset G$ and $\sum_{x \in G} \text{cost}_{G''}(x) \geq \Omega(\varepsilon) \cdot \text{PF}(\text{OPT})$.*

To see why Lemma 17 is sufficient to prove Theorem 4, since $|G| \leq k$ and $|G''| \geq k$ we can choose a set $\hat{G}$ of size k such that $G \subseteq \hat{G} \subseteq G''$. Then, $\hat{G} \subset \bigcup_j (P^{(j)} \cup S^{(j)} \cup T^{(j)} \cup U^{(j)} \cup Y^{(j)})$ and

$$\text{PF}(\hat{G}) = \sum_{x \in \hat{G}} \text{cost}_{\hat{G}}(x) \geq \sum_{x \in G} \text{cost}_{\hat{G}}(x) \geq \sum_{x \in G} \text{cost}_{G''}(x),$$

where the last inequality holds because the cost of x never increases from $\hat{G}$ to a larger set G''. Finally, by Lemma 17, this means $\text{PF}(\hat{G}) \geq \Omega(\varepsilon) \cdot \text{PF}(\text{OPT})$, as desired.

We now prove Lemma 17. First, we show how to construct G''. Let $g = |G|$: note that $g \leq k$. If $g = k$, then in fact $G = G'$ and we can set $G'' = G$, which completes the proof by (8) and Property 3.

Hence, from now on, we may assume that $g < k$. Recall that $X^{(j)} \backslash U^{(j)}$ is contained in a ball of radius $\tilde{r}^{(j)}$. Next, let $\tilde{r}$ be the radius of $\bigcup_j (X^{(j)} \backslash U^{(j)})$. (Note that for $|X^{(j)}| < 2k^{1+\varepsilon} + k$, $X^{(j)} \backslash U^{(j)}$ is empty.) We claim the following proposition.

▶ **Proposition 18.** *There exist $j, j' \leq m$, possibly equal, such that $\rho(S^{(j)}, T^{(j')}) \geq \frac{\varepsilon}{10} \cdot \tilde{r}$.*

Proof. Let $A \subset [m]$ be the subset of indices j such that $|X^{(j)}| \geq 2k^{1+\varepsilon} + k$. Suppose that $\tilde{r} \leq 5 \cdot \max_{j \in A} \tilde{r}^{(j)}$. Then, by setting $j = j'$ to be $\arg\max_{j \subset A} \tilde{r}^{(j)}$, we have that $\rho(S^{(j)}, T^{(j')}) \geq \frac{\varepsilon}{2} \cdot \max_{j \in A} \tilde{r}^{(j)} \geq \frac{\varepsilon}{10} \cdot \tilde{r}$.

Otherwise, $\tilde{r} > 5 \cdot \max_{j \in A} \tilde{r}^{(j)}$. So, if we pick j arbitrarily, the distance between the center of the ball $\tilde{B}^j$ and the furthest center $\tilde{B}^{j'}$ must be at least $0.8 \cdot \tilde{r}$, or else the ball of radius $0.8 \cdot \tilde{r} + \max_{j \in A} \tilde{r}^{(j)} < \tilde{r}$ around the center of $\tilde{B}^j$ contains all of $\bigcup_j (X^{(j)} \backslash U^{(j)})$. Then, $d(S^{(j)}, T^{(j')}) \geq 0.8 \cdot \tilde{r} - \tilde{r}^{(j)} - \tilde{r}^{(j')} \geq 0.4 \cdot \tilde{r}$, which is at least $\frac{\varepsilon}{10} \cdot \tilde{r}$. ◀

We now prove Lemma 17.

Proof. Recall that we already proved the lemma in the case that $G = G'$. So, we may assume $|G| < k$ and $G' \backslash G$ is nonempty. We claim that we can set G'' to be one of $G \cup P^{(j)}$, $G \cup S^{(j)}$, or $G \cup T^{(j')}$, for j, j' chosen in Proposition 18.

First, note that $P^{(j)}, S^{(j)}$, and $T^{(j')}$ have size k, so all three choices of G'' have size at least k.

First, note that $G' \backslash G$ is assumed to be nonempty, which means it is contained in $\bigcup_j (X^{(j)} \backslash U^{(j)})$ by Property 4, which is contained in the radius $\tilde{r}$ ball. Therefore, $G' \backslash G$ has nonempty intersection with $X \backslash (\bigcup_j U^{(j)})$. Now, fix any point $x \in G$. If $\text{cost}_{G'}(x) \geq 3 \cdot \tilde{r}$, then because $G' \backslash G$ has a point in the radius $\tilde{r}$ ball containing $X \backslash (\bigcup_j U^{(j)})$ (and this point is not x since $x \in G$), x has distance at least $\tilde{r}$ from the radius $\tilde{r}$ ball. So, $\text{cost}_{G \cup P^{(j)}}(x) \geq \text{cost}_{G'}(x) - 2\tilde{r} \geq \frac{1}{3} \cdot \text{cost}_{G'}(x)$. Alternatively, if $\text{cost}_{G'}(x) < 3 \cdot \tilde{r}$, then $\text{cost}_{G \cup S^{(j)}}(x) \geq \min(\text{cost}_{G'}(x), \rho(x, S^{(j)}))$ and likewise, $\text{cost}_{G \cup T^{(j')}}(x) \geq \min(\text{cost}_{G'}(x), \rho(x, T^{(j')}))$. So,

$$\begin{aligned}\text{cost}_{G \cup S^{(j)}}(x) + \text{cost}_{G \cup T^{(j')}}(x) &\geq \min(\text{cost}_{G'}(x), \rho(S^{(j)}, T^{(j')})) \\ &\geq \min\left(\text{cost}_{G'}(x), \frac{\varepsilon}{10} \cdot \tilde{r}\right) \geq \frac{\varepsilon}{30} \cdot \text{cost}_{G'}(x).\end{aligned}$$

In all cases, we have that

$$\text{cost}_{G \cup P^{(j)}}(x) + \text{cost}_{G \cup S^{(j)}}(x) + \text{cost}_{G \cup T^{(j')}}(x) \geq \frac{\varepsilon}{30} \cdot \text{cost}_{G'}(x),$$

so adding over all $x \in G$ and choosing among the three choices randomly, we have that the total cost in expectation is at least

$$\frac{1}{3} \cdot \left(\sum_{x \in G} \frac{\varepsilon}{30} \cdot \text{cost}_{G'}(x)\right) = \frac{\varepsilon}{90} \cdot \sum_{x \in G} \text{cost}_{G'}(x) \geq \frac{\varepsilon}{90} \cdot 0.7 \cdot \text{PF}(\text{OPT}) \geq \frac{\varepsilon}{150} \cdot \text{PF}(\text{OPT}).$$

Hence, for one of the three choices of G'', the pseudoforest cost is at least $\frac{\varepsilon}{150} \cdot \text{PF}(\text{OPT})$. ◀

Approximating Pandora's Box with Correlations

Abstract

We revisit the classic Pandora's Box (PB) problem under correlated distributions on the box values. Recent work of [13] obtained constant approximate algorithms for a restricted class of policies for the problem that visit boxes in a fixed order. In this work, we study the complexity of approximating the optimal policy which may adaptively choose which box to visit next based on the values seen so far.

Our main result establishes an approximation-preserving equivalence of PB to the well studied Uniform Decision Tree (UDT) problem from stochastic optimization and a variant of the Min-Sum Set Cover (MSSC_f) problem. For distributions of support m, UDT admits a $\log m$ approximation, and while a constant factor approximation in polynomial time is a long-standing open problem, constant factor approximations are achievable in subexponential time [43]. Our main result implies that the same properties hold for PB and MSSC_f.

We also study the case where the distribution over values is given more succinctly as a mixture of m product distributions. This problem is again related to a noisy variant of the Optimal Decision Tree which is significantly more challenging. We give a constant-factor approximation that runs in time $n^{\tilde{O}(m^2/\varepsilon^2)}$ when the mixture components on every box are either identical or separated in TV distance by ε.

1 Introduction

Many everyday tasks involve making decisions under uncertainty; for example driving to work using the fastest route or buying a house at the best price. Although we don't know how the future outcomes of our current decisions will turn out, we can often use some prior information to facilitate the decision making process. For example, having driven on the possible routes to work before, we know which is usually the busiest one. It is also common in such cases that we can remove part of the uncertainty by paying some additional cost. This type of online decision making in the presence of costly information can be modeled as the so-called Pandora's Box problem, first formalized by Weitzman in [52]. In this

problem, the algorithm is given n alternatives called *boxes*, each containing a value from a known distribution. The exact value is not known, but can be revealed at a known *opening* cost specific to the box. The goal of the algorithm is to decide which box to open next and whether to select a value and stop, such that the total *opening cost plus the minimum value revealed* is minimized. In the case of independent distributions on the boxes' values, this problem has a very elegant and simple optimal solution, as described by Weitzman [52]: calculate an index for each box[1], open the boxes in increasing order of index, and stop when the expected gain is worse than the value already obtained.

Weitzman's model makes the crucial assumption that the distributions on the values are independent across boxes. This, however, is not always the case in practice and as it turns out, the simple algorithm of the independent case fails to find the optimal solution under correlated distributions. Generally, the complexity of the Pandora's Box with correlations is not yet well understood. **In this work we develop the first approximately-optimal policies for the Pandora's Box problem with correlated values.**

We consider two standard models of correlation where the distribution over values can be specified explicitly in a succinct manner. In the first, the distribution over values has a small support of size m. In the second the distribution is a mixture of m product distributions, each of which can be specified succinctly. We present approximations for both settings.

A primary challenge in approximating Pandora's Box with correlations is that the optimal solution can be an adaptive policy that determines which box to open depending on the instantiations of values in all of the boxes opened previously. It is not clear that such a policy can even be described succinctly. Furthermore, the choice of which box to open is complicated by the need to balance two desiderata – finding a low value box quickly versus learning information about the values in unopened boxes (a.k.a. the state of the world or realized scenario) quickly. Indeed, the value contained in a box can provide the algorithm with crucial information about other boxes, and inform the choice of which box to open next; an aspect that is completely missing in the independent values setting studied by Weitzman.

Contribution 1: Connection to Decision Tree and a general purpose approximation

Some aspects of the Pandora's Box problem have been studied separately in other contexts. For example, in the Optimal Decision Tree problem (DT) [30, 43], the goal is to identify an unknown hypothesis, out of m possible ones, by performing a sequence of costly tests, whose outcomes depend on the realized hypothesis. This problem has an informational structure similar to that in Pandora's Box. In particular, we can think of every possible joint instantiation of values in boxes as a possible hypothesis, and every opening of a box as a test. The difference between the two problems is that while in Optimal Decision Tree we want to identify the realized hypothesis exactly, in Pandora's Box it suffices to terminate the process as soon as we have found a low value box.

Another closely related problem is the Min Sum Set Cover [21], where boxes only have two kinds of values – *acceptable* or *unacceptable* – and the goal is to find an *acceptable* value as quickly as possible. A primary difference relative to Pandora's Box is that unacceptable boxes provide no further information about the values in unopened boxes.

One of the main contributions of our work is to unearth connections between Pandora's Box and the two problems described above. We show that Pandora's Box is essentially equivalent to a special case of Optimal Decision Tree (called Uniform Decision Tree

[1] This is a special case of Gittins index [25].

or UDT) where the underlying distribution over hypotheses is uniform – the approximation ratios of these two problems are related within log-log factors. Surprisingly, in contrast, the non-uniform DT appears to be harder than non-uniform PANDORA'S BOX. We relate these two problems by showing that both are in turn related to a new version of MIN SUM SET COVER, that we call MIN SUM SET COVER WITH FEEDBACK (MSSC$_f$). These connections are summarized in Figure 1. We can thus build on the rich history and large collection of results on these problems to offer efficient algorithms for PANDORA'S BOX. We obtain a polynomial time $\tilde{O}(\log m)$ approximation for PANDORA'S BOX, where m is the number of distinct value vectors (a.k.a. scenarios) that may arise; as well as constant factor approximations in subexponential time.

$$\underbrace{\mathrm{PB} \xleftrightarrow{\text{Section 4}} \mathrm{UMSSC}_f}_{\text{Log-log factors}} \underbrace{\xleftrightarrow{\text{Section 5}} \mathrm{UDT}}_{\text{Constant factors}}$$

Figure 1 A summary of our approximation preserving reductions.

It is an important open question whether constant factor approximations exist for UNIFORM DECISION TREE: the best known lower-bound on the approximation ratio is 4 while it is known that it is not NP-hard to obtain super-constant approximations under the Exponential Time Hypothesis. The same properties transfer also to PANDORA'S BOX and MIN SUM SET COVER WITH FEEDBACK. Pinning down the tight approximation ratio for any of these problems will directly answer these questions for any other problem in the equivalence class we establish.

The key technical component in our reductions is to find an appropriate stopping rule for PANDORA'S BOX: after opening a few boxes, how should the algorithm determine whether a small enough value has been found or whether further exploration is necessary? We develop an iterative algorithm that in each phase finds an appropriate threshold, with the exploration terminating as soon as a value smaller than the threshold is found, such that there is a constant probability of stopping in each phase. Within each phase then the exploration problem can be solved via a reduction to UDT. The challenge is in defining the stopping thresholds in a manner that allows us to relate the algorithm's total cost to that of the optimal policy.

Contribution 2: Approximation for the mixture of distributions model

Having established the general purpose reductions between PANDORA'S BOX and DT, we turn to the mixture of product distributions model of correlation. This special case of PANDORA'S BOX interpolates between Weitzman's independent values setting and the fully general correlated values setting. In this setting, we use the term "scenario" to denote the different product distributions in the mixture. The information gathering component of the problem is now about determining which product distribution in the mixture the box values are realized from. Once the algorithm has determined the realized scenario (a.k.a. product distribution), the remaining problem amounts to implementing Weitzman's strategy for that scenario.

We observe that this model of correlation for PANDORA'S BOX is related to the noisy version of DT, where the results of some tests for a given realized hypothesis are not deterministic. One challenge for DT in this setting is that any individual test may give us very little information distinguishing different scenarios, and one needs to combine information across sequences of many tests in order to isolate scenarios. This challenge is inherited by Pandora's Box.

Previous work on noisy DT obtained algorithms whose approximations and runtimes depend on the amount of noise. In contrast, we consider settings where the level of noise is arbitrary, but where the mixtures satisfy a *separability assumption.* In particular, we assume that for any given box, if we consider the marginal distributions of the value in the box under different scenarios, these distributions are either identical or sufficiently different (e.g., at least ε in TV distance) across different scenarios. Under this assumption, we design a constant-factor approximation for Pandora's Box that runs in $n^{\tilde{O}(m^2/\varepsilon^2)}$ (Theorem 18), where n is the number of boxes. The formal result and the algorithm is presented in Section 6.

1.1 Related work

The Pandora's Box problem was first introduced by Weitzman in the Economics literature [52]. Since then, there has been a long line of research studying Pandora's Box and its many variants ; non-obligatory inspection [19, 8, 7, 22], with order constraints [37, 9], with correlation [13, 24], with combinatorial costs [6], competitive information design [18], delegated version [5], and finally in an online setting [20]. Multiple works also study the generalized setting where more information can be obtained for a price [12, 32, 15, 14] and in settings with more complex combinatorial constraints [50, 26, 33, 1, 35, 36, 31].

Chawla et al. [13] were the first to study Pandora's Box with correlated values, but they designed approximations relative to a simpler benchmark, namely the optimal performance achievable using a so-called *Partially Adaptive* strategy that cannot adapt the order in which it opens boxes to the values revealed. In general, optimal strategies can decide both the ordering of the boxes and the stopping time based on the values revealed. [13] designed an algorithm with performance no more than a constant factor worse than the optimal Partially Adaptive strategy.

In Min Sum Set Cover the line of work was initiated by [21], and continued with improvements and generalizations to more complex constraints by [3, 46, 4, 51].

Optimal decision tree is an old problem studied in a variety of settings ([49, 48, 30, 29]), while its most notable application is in active learning settings. It was proven to be NP-Hard by Hyafil and Rivest [38]. Since then the problem of finding the best approximation algorithm was an active one [23, 45, 42, 17, 10, 11, 30, 34, 16, 2], where finally a greedy $\log m$ for the general case was given by [30]. This approximation ratio is proven to be the best possible [10]. For the case of Uniform decision tree less is known, until recently the best algorithm was the same as the optimal decision tree, and the lower bound was 4 [10]. The recent work of Li et al. [43] showed that there is an algorithm strictly better than $\log m$ for the uniform decision tree.

The noisy version of optimal decision tree was first studied in [29][2], which gave an algorithm with runtime that depends exponentially on the number of noisy outcomes. Subsequently, Jia et al. in [40] gave an $(\min(r, h) + \log m)$-approximation algorithm, where r (resp. h) is the maximum number of different test results per test (resp. scenario) using a reduction to Adaptive Submodular Ranking problem [41]. In the case of large number of noisy outcome they obtain a $\log m$ approximation exploiting the connection to Stochastic Set Cover [44, 39].

[2] This result is based on a result from [27] which turned out to be wrong [47]. The correct results are presented in [28]

2 Preliminaries

In this paper we study the connections between three different sequential decision making problems – Optimal Decision Tree, Pandora's Box, and Min Sum Set Cover. We describe these problems formally below.

Optimal Decision Tree

In the Optimal Decision Tree problem (denoted DT) we are given a set $\mathcal{S}$ of m scenarios $s \in \mathcal{S}$, each occurring with (known) probability p_s; and n tests $\mathcal{T} = \{T_i\}_{i\in[n]}$, each with cost 1. Nature picks a scenario $s \in \mathcal{S}$ from the distribution p but this scenario is unknown to the algorithm. The goal of the algorithm is to determine which scenario is realized by running a subset of the tests $\mathcal{T}$. When test T_i is run and the realized scenario is s, the test returns a result $T_i(s) \in \mathbb{R}$.

Output. The output of the algorithm is a decision tree where at each node there is a test that is performed, and the branches are the outcomes of the test. In each of the leaves there is an individual scenario that is the only one consistent with the results of the test in the unique path from the root to this leaf. Observe that there is a single leaf corresponding to each scenario s. We can represent the tree as an *adaptive policy* defined as follows:

▶ **Definition 1** (Adaptive Policy π). *An adaptive policy $\pi : \cup_{X\subseteq\mathcal{T}}\mathbb{R}^X \to \mathcal{T}$ is a function that given a set of tests done so far and their results, returns the next test to be performed.*

Objective. For a given decision tree or policy π, let $\text{cost}_s(\pi)$ denote the total cost of all of the tests on the unique path in the tree from the root to the leaf labeled with scenario s. The objective of the algorithm is to find a policy π that minimizes the average cost $\sum_{s\in\mathcal{S}} p_s \text{cost}_s(\pi)$.
We use the term Uniform Decision Tree (UDT) to denote the special case of the problem where $p_s = 1/m$ for all scenarios s.

Pandora's Box

In the Pandora's Box problem we are given n boxes, each with cost $c_i \geq 0$ and value v_i. The values $\{v_i\}_{i\in[n]}$ are distributed according to known distribution $\mathcal{D}$. We assume that $\mathcal{D}$ is an arbitrary correlated distribution over vectors $\{v_i\}_{i\in[n]} \in \mathbb{R}^n$. We call vectors of values *scenarios* and use $s = \{v_i\}_{i\in[n]}$ to denote a possible realization of the scenario. As in DT, nature picks a scenario from the distribution D and this realization is a priori unknown to the algorithm. The goal of the algorithm is to pick a box of small value. The algorithm can observe the values realized in the boxes by opening any box i at its respective costs c_i.

Output. The output of the algorithm is an adaptive policy π for opening boxes and a stopping condition. The policy π takes as input a subset of the boxes and their associated values, and either returns the index of a box $i \in [n]$ to be opened next or stops and selects the minimum value seen so far. That is, $\pi : \cup_{X\subseteq[n]}\mathbb{R}^X \to [n] \cup \{\perp\}$ where $\perp$ denotes stopping.

Objective. For a given policy π, let $\pi(s)$ denote the set of boxes opened by the policy prior to stopping when the realized scenario is s. The objective of the algorithm is to minimize the expected cost of the boxes opened plus the minimum value discovered, where the expectation is taken over all possible realizations of the values in each box.[3] Formally the objective is given by

$$\mathbb{E}_{s\sim\mathcal{D}}\left[\min_{i\in\pi(s)} v_{is} + \sum_{i\in\pi(s)} c_i\right],$$

For simplicity of presentation, from now on we assume that $c_i = 1$ for all boxes, but we show in the Appendix of the full version how to adapt our results to handle non-unit costs, without any loss in the approximation factors.

We use UPB to denote the special case of the problem where the distribution $\mathcal{D}$ is uniform over m scenarios.

Min Sum Set Cover with Feedback

In Min Sum Set Cover, we are given n elements and a collection of m sets $\mathcal{S}$ over them, and a distribution $\mathcal{D}$ over the sets. The output of the algorithm is an ordering π over the elements. The cost of the ordering for a particular set $s \in \mathcal{S}$ is the index of the first element in the ordering that belongs to the set s, that is, $\text{cost}_s(\pi) = \min\{i : \pi(i) \in s\}$. The goal of the algorithm is to minimize the expected cost $\mathbb{E}_{s\sim\mathcal{D}}[\text{cost}_s(\pi)]$.

We define a variant of the Min Sum Set Cover problem, called Min Sum Set Cover with Feedback (MSSC$_f$). As in the original problem, we are given a set of n elements, a collection of m sets $\mathcal{S}$ and a distribution $\mathcal{D}$ over the sets. Nature instantiates a set $s \in \mathcal{S}$ from the distribution $\mathcal{D}$; the realization is unknown to the algorithm. Furthermore, in this variant, each element provides *feedback* to the algorithm when the algorithm "visits" this element; this feedback takes on the value $f_i(s) \in \mathbb{R}$ for element $i \in [n]$ if the realized set is $s \in \mathcal{S}$.

Output. The algorithm once again produces an ordering π over the elements. Observe that the feedback allows the algorithm to adapt its ordering to previously observed values. Accordingly, π is an adaptive policy that maps a subset of the elements and their associated feedback, to the index of another element $i \in [n]$. That is, $\pi : \cup_{X\subseteq[n]}\mathbb{R}^X \to [n]$.

Objective. As before, the cost of the ordering for a particular set $s \in \mathcal{S}$ is the index of the first element in the ordering that belongs to the set s, that is, $\text{cost}_s(\pi) = \min\{i : \pi(i) \in s\}$. The goal of the algorithm is to minimize the expected cost $\mathbb{E}_{s\sim\mathcal{D}}[\text{cost}_s(\pi)]$.

Commonalities and notation

As the reader has observed, we capture the commonalities between the different problems through the use of similar notation. Scenarios in DT correspond to value vectors in PB and to sets in MSSC$_f$; all are denoted by s, lie in the set $\mathcal{S}$, and are drawn by nature from a known joint distribution $\mathcal{D}$. Tests in DT correspond to boxes in PB and elements in MSSC$_f$;

[3] In the original version of the problem studied by Weitzman [52] the values are independent across boxes, and the goal is to maximize the value collected minus the costs paid, in contrast to the minimization version we study here.

we index each by $i \in [n]$. The algorithm for each problem produces an adaptive ordering π over these tests/boxes/elements. Test outcomes $T_i(s)$ in DT correspond to box values $v_i(s)$ in PB and feedback $f_i(s)$ in MSSC_f. We will use the terminology and notation across different problems interchangeably in the rest of the paper.

2.1 Modeling Correlation

In this work we study two general ways of modeling the correlation between the values in the boxes. **Explicit Distributions.** In this case, $\mathcal{D}$ is a distribution over m *scenarios* where the j'th scenario is realized with probability p_j, for $j \in [m]$. Every scenario corresponds to a fixed and known vector of values contained in each box. Specifically, box i has value $v_{ij} \in \mathbb{R}^+ \cup \{\infty\}$ for scenario j.

Mixture of Distributions. We also consider a more general setting, where $\mathcal{D}$ is a mixture of m product distributions. Specifically, each scenario j is a product distribution; instead of giving a deterministic value for every box i, the result is drawn from distribution $\mathcal{D}_{ij}$. This setting is a generalization of the explicit distributions setting described before.

3 Roadmap of the Reductions and Implications

In Figure 2, we give an overview of all the main technical reductions shown in Sections 4 and 5. An arrow $A \to B$ means that we gave an approximation preserving reduction from problem A to problem B. Therefore an algorithm for B that achieves approximation ratio α gives also an algorithm for A with approximation ratio $O(\alpha)$ (or $O(\alpha \log \alpha)$ in the case of black dashed lines). For the exact guarantees we refer to the formal statement of the respective theorem. The gray lines denote less important claims or trivial reductions (e.g. in the case of A being a subproblem of B).

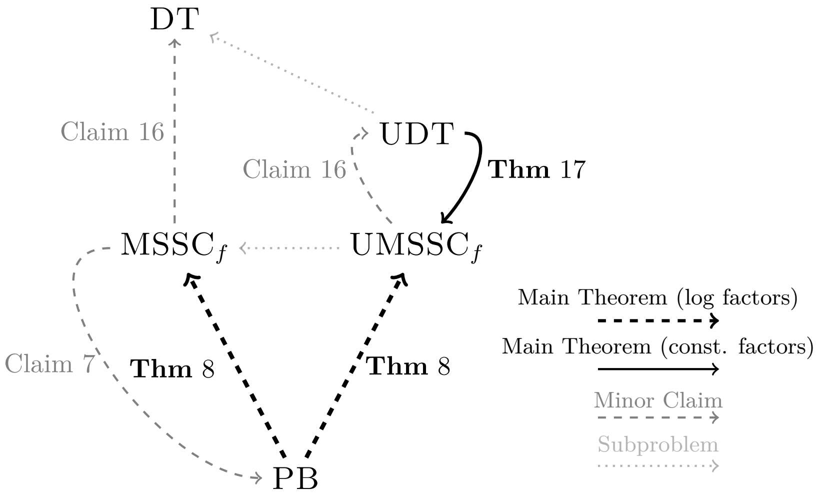

Figure 2 Summary of all our reductions. Bold black lines denote our main theorems, gray dashed are minor claims, and dotted lines are trivial reductions.

3.1 Approximating Pandora's Box

Given our reductions and using the best known results for Uniform Decision Tree from [43] we immediately obtain efficient approximation algorithms for Pandora's Box. We repeat the results of [43] below.

▶ **Theorem 2** (Theorems 3.1 and 3.2 from [43]).

- *There is a $O(\log m/\log \mathrm{OPT})$-approximation algorithm for UDT that runs in polynomial time, where OPT is the cost of the optimal solution of the UDT instance.*
- *There is a $\frac{9+\varepsilon}{\alpha}$-approximation algorithm for UDT that runs in time $n^{\tilde{O}(m^\alpha)}$ for any $\alpha \in (0,1)$.*

Using the results of Theorem 2 combined with Theorem 8 and Claim 16 we get the following corollary.

▶ **Corollary 3.** *From the best-known results for UDT, we have that*

- *There is a $\tilde{O}(\log m)$-approximation algorithm for PB that runs in polynomial time*[4].
- *There is a $\tilde{O}(1/\alpha)$-approximation algorithm for PB that runs in time $n^{\tilde{O}(m^\alpha)}$ for any $\alpha \in (0,1)$.*

An immediate implication of the above corollary is that it is not NP-hard to obtain a superconstant approximation for PB, formally stated below.

▶ **Corollary 4.** *It is not NP-hard to achieve any superconstant approximation for PB assuming the Exponential Time Hypothesis.*

Observe that the logarithmic approximation achieved in Corollary 3 loses a $\log\log m$ factor (hence the $\tilde{O}$) as it relies on the more complex reduction of Theorem 8. If we choose to use the more direct naive reduction (given in the full version of our paper) to the Optimal Decision Tree where the tests have non-unit costs (which also admits a $O(\log m)$-approximation [34, 41]), we get the following corollary.

▶ **Corollary 5.** *There exists an efficient algorithm that is $O(\log m)$-approximate for Pandora's Box and with or without unit-cost boxes.*

3.2 Constant approximation for Partially Adaptive PB

Moving on, we show how our reduction can be used to obtain and improve the results of [13]. Recall that in [13] the authors presented a constant factor approximation algorithm against a Partially Adaptive benchmark where the order of opening boxes must be fixed up front.

In such a case, the reduction of Section 4 can be used to reduce PB to the standard Min Sum Set Cover (i.e. without feedback), which admits a 4-approximation [21].

▶ **Corollary 6.** *There exists a polynomial time algorithm for PB that is $O(1)$-competitive against the partially adaptive benchmark.*

The same result applies even in the case of non-uniform opening costs. This is because a 4-approximate algorithm for Min Sum Set Cover is known even when elements have arbitrary costs [46]. The case of non-uniform opening costs has also been considered for Pandora's Box by [13] but only provide an algorithm to handle polynomially bounded opening costs.

[4] If additionally the possible number of outcomes is a constant K, this gives a $O(\log m)$ approximation without losing an extra logarithmic factor, since $\mathrm{OPT} \geq \log_K m$, as observed by [43].

4 Connecting Pandora's Box and MSSC$_f$

In this section we establish the connection between Pandora's Box and Min Sum Set Cover with Feedback. We show that the two problems are equivalent up to logarithmic factors in approximation ratio.

One direction of this equivalence is easy to see in fact: Min Sum Set Cover with Feedback is a special case of Pandora's Box. Note that in both problems we examine boxes/elements in an adaptive order. In PB we stop when we find a sufficiently small value; in MSSC$_f$ we stop when we find an element that belongs to the instantiated scenario. To establish a formal connection, given an instance of MSSC$_f$, we can define the "value" of each element i in scenario s as being 0 if the element belongs to the set s and as being $L + f_i(s)$ for some sufficiently large value L where $f_i(s)$ is the feedback of element i for set s. This places the instance within the framework of PB and a PB algorithm can be used to solve it. We formally describe this reduction in Section A of the Appendix.

▷ Claim 7. If there exists an $\alpha(n, m)$-approximation algorithm for PB then there exists a $\alpha(n, m)$-approximation for MSSC$_f$.

The more interesting direction is a reduction from PB to MSSC$_f$. In fact we show that a general instance of PB can be reduced to the simpler *uniform* version of Min Sum Set Cover with Feedback. We devote the rest of this section to proving the following theorem.

▶ **Theorem 8** (Pandora's Box to MSSC$_f$). *If there exists an $a(n, m)$ approximation algorithm for UMSSC$_f$ then there exists a $O(\alpha(n + m, m^2) \log \alpha(n + m, m^2))$-approximation for PB.*

Guessing a stopping rule and an intermediate problem

The feedback structure in PB and MSSC$_f$ is quite similar, and the main component in which the two problems differ is the stopping condition. In MSSC$_f$, an algorithm can stop examining elements as soon as it finds one that "covers" the realized set. In PB, when the algorithm observes a value in a box, it is not immediately apparent whether the value is small enough to stop or whether the algorithm should probe further, especially if the scenario is not fully identified. The key to relating the two problems is to "guess" an appropriate stopping condition for PB, namely an appropriate threshold T such that as soon as the algorithm observes a value smaller than this threshold, it stops. We say that the realized scenario is "covered".

To formalize this approach, we introduce an intermediate problem called *Pandora's Box with costly outside option T* (also called *threshold*), denoted by PB$_{\leq T}$. In this version the objective is to minimize the cost of finding a value $\leq T$, while we have the extra option to quit searching by opening an *outside option* box of cost T. We say that a scenario is *covered* in a given run of the algorithm if it does not choose the outside option box T.

We show that Pandora's Box can be reduced to PB$_{\leq T}$ with a logarithmic loss in approximation factor, and then PB$_{\leq T}$ can be reduced to Min Sum Set Cover with Feedback with a constant factor loss. The following two results capture the details of these reductions.

▷ Claim 9. If there exists an $\alpha(n, m)$ approximation algorithm for UMSSC$_f$ then there exists an $3\alpha(n + m, m^2)$-approximation for UPB$_{\leq T}$.

▶ **Main Lemma 10.** *Given a polynomial-time $\alpha(n,m)$-approximation algorithm for UPB$_{\leq T}$, there exists a polynomial-time $O(\alpha(n,m)\log\alpha(n,m))$-approximation for PB.*

The relationship between PB$_{\leq T}$ and Min Sum Set Cover with Feedback is relatively straightforward and requires explicitly relating the structure of feedback in the two problems. We describe the details in Section A of the Appendix.

Putting it all together. The proof of Theorem 8 follows by combining Claim 9 with Lemmas 11 and 10 presented in the following sections. Proofs of Claims 7, 9 deferred to Section A of the Appendix. The rest of this section is devoted to proving Lemmas 11 and 10.

4.1 Reducing Pandora's Box to PB$_{\leq T}$

Recall that a solution to Pandora's Box involves two components ; (1) the order in which to open boxes and (2) a stopping rule. The goal of the reduction to PB$_{\leq T}$ is to simplify the stopping rule of the problem, by making values either 0 or ∞, therefore allowing us to focus on the order in which boxes are opened, rather than which value to stop at. We start by presenting our main tool, a reduction to Min Sum Set Cover with Feedback in Section 4.1.1 and then improve upon that to reduce from the **uniform** version of MSSC$_f$ (Section 4.1.2).

4.1.1 Main Tool

The high level idea in this reduction is that we repeatedly run the algorithm for PB$_{\leq T}$ with increasingly larger value of T with the goal of covering some mass of scenarios at every step. The thresholds for every run have to be cleverly chosen to guarantee that enough mass is covered at every run. The distributions on the boxes remain the same, and this reduction does not increase the number of boxes, therefore avoiding the issues faced by the naive reduction given in the full version of the paper. Formally, we show the following lemma.

▶ **Main Lemma 11.** *Given a polynomial-time $\alpha(n,m)$-approximation algorithm for PB$_{\leq T}$, there exists a polynomial-time $O(\alpha(n,m)\log\alpha(n,m))$-approximation for PB.*

Algorithm 1 Reduction from PB to PB$_{\leq T}$.

```
Input: Oracle $\mathcal{A}(T)$ for PB$_{\leq T}$, set of all scenarios $\mathcal{S}$.
$i \leftarrow 0$ // Number of current Phase
while $\mathcal{S} \neq \emptyset$ do
    Use $\mathcal{A}$ to find smallest $T_i$ via Binary Search s.t.
      $\mathbf{Pr}$ [accepting the outside option $T_i$] $\leq 0.2$
    Call the oracle $\mathcal{A}(T_i)$ on set $\mathcal{S}$ to obtain policy $\pi_i$
    $\mathcal{S} \leftarrow \mathcal{S} \setminus$ {scenarios with total cost $\leq T_i$}
end
for $i \leftarrow 0$ to $\infty$ do
    Run policy $\pi_i$ until it terminates and selects a box, or accumulates probing cost
      $T_i$.
end
```

We will now analyze the policy produced by this algorithm.

Proof of Main Lemma 11. We start with some notation. Given an instance $\mathcal{I}$ of PB, we repeatedly run $\text{PB}_{\le T}$ in *phases*. Phase i consists of running $\text{PB}_{\le T}$ with threshold T_i on a sub instance of the original problem where we are left with a smaller set of scenarios, with their probabilities reweighted to sum to 1. Call this set of scenarios $\mathcal{S}_i$ for phase i and the corresponding instance $\mathcal{I}_i$. After every phase i, we remove the probability mass that was covered[5], and run $\text{PB}_{\le T}$ on this new instance with a new threshold T_{i+1}. In each phase, the boxes, costs and values remain the same, but the stopping condition changes: thresholds T_i increase in every subsequent phase. The thresholds are chosen such that at the end of each phase, 0.8 of the remaining probability mass is covered. The reduction process is formally shown in Algorithm 1.

Accounting for the cost of the policy. We first note that the total cost of the policy in phase i conditioned on reaching that phase is at most $2T_i$: if the policy terminates in that phase, it selects a box with value at most T_i. Furthermore, the policy incurs probing cost at most T_i in the phase. We can therefore bound the total cost of the policy as $\le 2\sum_{i=0}^{\infty}(0.2)^i T_i$. We will now relate the thresholds T_i to the cost of the optimal PB policy for $\mathcal{I}$. To this end, we define corresponding thresholds for the optimal policy that we call *p-thresholds*. Let $\pi^*_{\mathcal{I}}$ denote the optimal PB policy for $\mathcal{I}$ and let c_s denote the cost incurred by $\pi^*_{\mathcal{I}}$ when scenario i is realized. A p-threshold is the minimum possible threshold T such that at most p mass of the scenarios has cost more than T in PB, formally defined below.

▶ **Definition 12** (p-Threshold). *Let $\mathcal{I}$ be an instance of PB and c_s be the cost of scenario $s \in \mathcal{S}$ in $\pi^*_{\mathcal{I}}$, we define the p-threshold as*

$$t_p = \min\{T : \boldsymbol{Pr}\left[c_s > T\right] \le p\}.$$

The following two lemmas relate the cost of the optimal policy to the p-thresholds, and the p-thresholds to the thresholds T_i our algorithm finds. The proofs of both lemmas are deferred to Section A.1 of the Appendix. We first formally define a *sub-instance* of the given Pandora's Box instance.

▶ **Definition 13** (Sub-instance). *Let $\mathcal{I}$ be an instance of $\{PB_{\le T}, PB\}$ with set of scenarios $\mathcal{S}_{\mathcal{I}}$ each with probability $p^{\mathcal{I}}_s$. For any $q \in [0,1]$ we call $\mathcal{I}'$ a q-sub instance of $\mathcal{I}$ if $\mathcal{S}_{\mathcal{I}'} \subseteq \mathcal{S}_{\mathcal{I}}$ and $\sum_{s\in\mathcal{S}_{\mathcal{I}'}} p^{\mathcal{I}}_s = q$.*

▶ **Lemma 14** (Optimal Lower Bound). *Let $\mathcal{I}$ be the instance of PB. For any $q < 1$, any $\alpha > 1$, and $\beta \ge 2$, for the optimal policy $\pi^*_{\mathcal{I}}$ for PB it that*

$$\text{cost}(\pi^*_{\mathcal{I}}) \ge \sum_{i=0}^{\infty} \frac{1}{\beta\alpha} \cdot (q)^i\, t_{q^i/\beta\alpha}.$$

▶ **Lemma 15.** *Given an instance $\mathcal{I}$ of PB; an α-approximation algorithm $\mathcal{A}_T$ to $PB_{\le T}$; and any $q < 1$ and $\beta \ge 2$, suppose that the threshold T satisfies*

$$T \ge t_{q/(\beta\alpha)} + \beta\alpha \sum_{\substack{c_s\in[t_q, t_{q/(\beta\alpha)}]\\ s\in\mathcal{S}}} c_s \frac{p_s}{q}.$$

Then if $\mathcal{A}_T$ is run on a q-sub instance of $\mathcal{I}$ with threshold T, at most a total mass of $(2/\beta)q$ of the scenarios pick the outside option box T.

[5] Recall, a scenario is *covered* if it does not choose the outside option box.

Calculating the thresholds. For every phase i we choose a threshold T_i such that $T_i = \min\{T : \mathbf{Pr}\left[c_s > T\right] \leq 0.2\}$ i.e. at most 0.2 of the probability mass of the scenarios are not covered. In order to select this threshold, we do binary search starting from $T = 1$, running every time the α-approximation algorithm for $\mathrm{PB}_{\leq T}$ with outside option box T and checking how many scenarios select it. We denote by $\mathrm{Int}_i = [t_{(0.2)^i}, t_{(0.2)^i/(10\alpha)}]$ the relevant interval of costs at every run of the algorithm, then by Lemma 15 for $\beta = 10$, we know that for remaining total probability mass $(0.2)^i$, any threshold which satisfies

$$T_i \geq t_{(0.2)^{i-1}/10a} + 10\alpha \sum_{\substack{s\in\mathcal{S}\\ c_s\in\mathrm{Int}_i}} c_s \frac{p_s}{(0.2)^i}$$

also satisfies the desired covering property, i.e. at least 0.8 mass of the current scenarios is covered. Therefore the threshold T_i found by our binary search satisfies the following

$$T_i = t_{(0.2)^{i-1}/10a} + 10\alpha \sum_{\substack{s\in\mathcal{S}\\ c_s\in\mathrm{Int}_i}} c_s \frac{p_s}{(0.2)^i}. \tag{1}$$

Bounding the final cost. To bound the final cost, we recall that at the end of every phase we cover 0.8 of the remaining scenarios. Furthermore, we observe that each threshold T_i is charged in the above Equation (1) to optimal costs of scenarios corresponding to intervals of the form $\mathrm{Int}_i = [t_{(0.2)^i}, t_{(0.2)^i/(10\alpha)}]$. Note that these intervals are overlapping. We therefore get

$$\begin{aligned}
\mathrm{cost}(\pi_{\mathcal{I}}) &\leq 2\sum_{i=0}^{\infty}(0.2)^i T_i \\
&= 2\sum_{i=0}^{\infty}\left((0.2)^i t_{(0.2)^{i-1}/10a} + 10\alpha \sum_{\substack{s\in\mathcal{S}\\ c_s\in\mathrm{Int}_i}} c_s p_s\right) && \text{From equation (1)} \\
&\leq 4\cdot 10\alpha\pi^*_{\mathcal{I}} + 20\alpha\sum_{i=0}^{\infty}\sum_{\substack{s\in\mathcal{S}\\ c_s\in\mathrm{Int}_i}} c_s p_s && \text{Using Lemma 14 for } \beta = 10, q = 0.2 \\
&\leq 40\alpha\log\alpha\cdot\pi^*_{\mathcal{I}}.
\end{aligned}$$

Where the last inequality follows since each scenario with cost c_s can belong to at most $\log\alpha$ intervals, therefore we get the theorem. ◀

Notice the generality of this reduction; the distributions on the values are preserved, and we did not make any more assumptions on the scenarios or values throughout the proof. Therefore we can apply this tool regardless of the type of correlation or the way it is given to us, e.g. we could be given a parametric distribution, or an explicitly given distribution, as we see in the next section.

4.1.2 An Even Stronger Tool

Moving one step further, we show that if we instead of $\mathrm{PB}_{\leq T}$ we had an α-approximation algorithm for $\mathrm{UPB}_{\leq T}$ we can obtain the same guarantees as the ones described in Lemma 11. Observe that we cannot directly use Algorithm 1 since the oracle now requires that all scenarios have the same probability, while this might not be the case in the initial PB instance. The theorem stated formally follows.

▶ **Main Lemma 10.** *Given a polynomial-time $\alpha(n,m)$-approximation algorithm for $UPB_{\leq T}$, there exists a polynomial-time $O(\alpha(n,m)\log\alpha(n,m))$-approximation for PB.*

We are going to highlight the differences with the proof of Main Lemma 11, and show how to change Algorithm 1 to work with the new oracle, that requires the scenarios to have uniform probability. The function **Expand** shown in Algorithm 2 is used to transform the instance of scenarios to a uniform one where every scenario has the same probability by creating multiple copies of the more likely scenarios. The function is formally described in Algorithm 3 in Section A.2 of the Appendix, alongside the proof of Main Lemma 10.

Algorithm 2 Reduction from PB to $\text{UPB}_{\leq T}$.

```
Input: Oracle $\mathcal{A}(T)$ for $\text{UPB}_{\leq T}$, set of all scenarios $\mathcal{S}$, $c = 1/10, \delta = 0.1$.
$i \leftarrow 0$ // Number of current Phase
while $\mathcal{S} \neq \emptyset$ do
    Let $\mathcal{L} = \left\{ s \in \mathcal{S} : p_s \leq c \cdot \frac{1}{|\mathcal{S}|} \right\}$ // Remove low probability scenarios
    $\mathcal{S}' = \mathcal{S} \setminus \mathcal{L}$
    $\mathcal{UI} = \text{Expand}(\mathcal{S}')$
    In instance $\mathcal{UI}$ use $\mathcal{A}$ to find smallest $T_i$ via Binary Search s.t.
      $\mathbf{Pr}[\text{accepting } T_i] \leq \delta$
    Call the oracle $\mathcal{A}(T_i)$
    $\mathcal{S} \leftarrow \left( \mathcal{S}' \setminus \{ s \in \mathcal{S}' : c_s \leq T_i \} \right) \cup \mathcal{L}$
end
```

5 Connecting MSSC_f and Optimal Decision Tree

In this section we establish the connection between Min Sum Set Cover with Feedback and Optimal Decision Tree. We show that the uniform versions of these problems are equivalent up to constant factors in approximation ratio. The proofs of this section are deferred to the full version of the paper in ArXiv.

▷ Claim 16. If there exists an $\alpha(n,m)$-approximation algorithm for DT (UDT) then there exists a $(1+\alpha(n,m))$-approximation algorithm for MSSC_f (resp. UMSSC_f).

▶ **Theorem 17** (Uniform Decision Tree to UMSSC_f)**.** *Given an $\alpha(m,n)$-approximation algorithm for $UMSSC_f$ then there exists an $O(\alpha(n+m,m))$-approximation algorithm for UDT.*

The formal proofs of these statements can be found in the full version, here we sketch the main ideas.

One direction of this equivalence is again easy to see. The main difference between Optimal Decision Tree and MSSC_f is that the former requires scenarios to be exactly identified whereas in the latter it suffices to simply find an element that covers the scenario. In particular, in MSSC_f an algorithm could cover a scenario without identifying it by, for example, covering it with an element that covers multiple scenarios. To reduce MSSC_f to DT we simply introduce extra feedback into all of the elements of the MSSC_f instance such that the elements isolate any scenarios they cover. (That is, if the algorithm picks an element that covers some subset of scenarios, this element provides feedback about which of the covered scenarios materialized.) This allows us to relate the cost of isolation and the cost of covering to within the cost of a single additional test, implying Claim 16.

Proof Sketch of Theorem 17. The other direction is more complicated, as we want to ensure that covering implies isolation. Given an instance of UDT, we create a special element for each scenario which is the unique element covering the scenario and also isolates the scenario from all other scenarios. The intention is that an algorithm for MSSC_f on this new instance only chooses the special isolating element in a scenario after it has identified the scenario. If that happens, then the algorithm's policy is a feasible solution to the UDT instance and incurs no extra cost. The problem is that an algorithm for MSSC_f over the modified instance may use the special covering element before isolating a scenario. We argue that this choice can be "postponed" in the policy to a point at which isolation is nearly achieved without incurring too much extra cost. This involves careful analysis of the policy's decision tree and we present details in the appendix.

Why our reduction does not work for DT. Our analysis above heavily uses the fact that the probabilities of all scenarios in the UDT instance are equal. This is because the "postponement" of elements charges increased costs of some scenarios to costs of other scenarios. In fact, our reduction above fails in the case of non-uniform distributions over scenarios – it can generate an MSSC_f instance with optimal cost much smaller than that of the original DT instance.

To see this, consider an example with m scenarios where scenarios 1 through $m-1$ happen with probability $\varepsilon/(m-1)$ and scenario m happens with probability $1-\varepsilon$. There are $m-1$ tests of cost 1 each. Test i for $i \in [m-1]$ isolates scenario i from all others. Observe that the optimal cost of this DT instance is at least $(1-\varepsilon)(m-1)$ as all $m-1$ tests need to be run to isolate scenario m. Our construction of the MSSC_f instance adds another isolating test for scenario m. A solution to this instance can use this new test at the beginning to identify scenario m and then run other tests with the remaining ε probability. As a result, it incurs cost at most $(1-\varepsilon)+\varepsilon(m-1)$, which is a factor of $1/\varepsilon$ cheaper than that of the original DT instance.

6 Mixture of Product Distributions

In this section we switch gears and consider the case where we are given a mixture of m product distributions. Observe that using the tool described in Section 4.1.1, we can reduce this problem to $\mathrm{PB}_{\leq T}$. This now is equivalent to the noisy version of DT [28, 40] where for a specific scenario, the result of each test is not deterministic and can get different values with different probabilities.

Comparison with previous work. previous work on noisy decision tree, considers limited noise models or the runtime and approximation ratio depends on the type of noise. For example in the main result of [40], the noise outcomes are binary with equal probability. The authors mention that it is possible to extend the following ways:

- to probabilities within $[\delta, 1-\delta]$, incurring an extra $1/\delta$ factor in the approximation
- to non-binary noise outcomes, incurring an extra at most m factor in the approximation

Additionally, their algorithm works by expanding the scenarios for every possible noise outcome (e.g. to 2^m for binary noise). In our work the number of noisy outcomes does not affect the number of scenarios whatsoever.

In our work, we obtain a **constant approximation** factor, that does not depend in any way on the type of the noise. Additionally, the outcomes of the noisy tests can be arbitrary, and do not affect either the approximation factor or the runtime. We only require a *separability* condition to hold ; the distributions either differ *enough* or are exactly the same. Formally, we require that for any two scenarios $s_1, s_2 \in \mathcal{S}$ and for every box i, the distributions $\mathcal{D}_{is_1}$ and $\mathcal{D}_{is_2}$ satisfy $|\mathcal{D}_{is_1} - \mathcal{D}_{is_2}| \in \mathbb{R}_{\geq \varepsilon} \cup \{0\}$, where $|\mathcal{A} - \mathcal{B}|$ is the total variation distance of distributions $\mathcal{A}$ and $\mathcal{B}$.

6.1 A DP Algorithm for noisy PB$_{\leq T}$

We move on to designing a dynamic programming algorithm to solve the PB$_{\leq T}$ problem, in the case of a mixtures of product distributions. The guarantees of our dynamic programming algorithm are given in the following theorem.

▶ **Theorem 18.** *For any $\beta > 0$, let π_{DP} and π^* be the policies produced by Algorithm* DP(β) *described by Equation* (2) *and the optimal policy respectively and* $\text{UB} = \frac{m^2}{\varepsilon^2} \log \frac{m^2 T}{c_{\min} \beta}$. *Then it holds that*

$$c(\pi_{\text{DP}}) \leq (1 + \beta) c(\pi^*).$$

and the DP *runs in time n^{UB}, where n is the number of boxes and $c_{\min}$ is the minimum cost box.*

Using the reduction described in Section 4.1.1 and the previous theorem we can get a constant-approximation algorithm for the initial PB problem given a mixture of product distributions. Observe that in the reduction, for every instance of PB$_{\leq T}$ it runs, the chosen threshold T satisfies that $T \leq (\beta + 1)c(\pi^*_T)/0.2$ where π^*_T is the optimal policy for the threshold T. The inequality holds since the algorithm for the threshold T is a $(\beta + 1)$ approximation and it covers 80% of the scenarios left (i.e. pays $0.2T$ for the rest). This is formalized in the following corollary.

▶ **Corollary 19.** *Given an instance of PB on m scenarios, and the DP algorithm described in Equation* (2)*, then using Algorithm 1 we obtain an $O(1)$-approximation algorithm for PB that runs in $n^{\tilde{O}(m^2/\varepsilon^2)}$.*

Observe that the naive DP, that keeps track of all the boxes and possible outcomes, has space exponential in the number of boxes, which can be very large. In our DP, we exploit the separability property of the distributions by distinguishing the boxes in two different types based on a given set of scenarios. Informally, the *informative* boxes help us distinguish between two scenarios, by giving us enough TV distance, while the *non-informative* always have zero TV distance. The formal definition follows.

▶ **Definition 20** (Informative and non-informative boxes)**.** *Let $S \subseteq \mathcal{S}$ be a set of scenarios. Then we call a box k* informative *if there exist $s_i, s_j \in \mathcal{S}$ such that*

$$|\mathcal{D}_{ks_i} - \mathcal{D}_{ks_j}| \geq \varepsilon.$$

We denote the set of all informative *boxes by* IB(S)*. Similarly, the boxes for which the above does not hold are called* non-informative *and the set of these boxes is denoted by* NIB(S)*.*

Recursive calls of the DP. Our dynamic program chooses at every step one of the following options:

1. open an **informative** box: this step contributes towards *eliminating* improbable scenarios. From the definition of informative boxes, every time such a box is opened, it gives TV distance at least ε between at least two scenarios, making one of them more probable

than the other. We show (Lemma 21) that it takes a finite amount of these boxes to decide, with high probability, which scenario is the one realized (i.e. eliminating all but one scenarios).

2. open a **non-informative** box: this is a greedy step; the best non-informative box to open next is the one that maximizes the probability of finding a value smaller than T. Given a set S of scenarios that are not yet eliminated, there is a unique next non-informative box which is best. We denote by $\text{NIB}^*(S)$ the function that returns this next best non-informative box. Observe that the non-informative boxes do not affect the greedy ordering of which is the next best, since they do not affect which scenarios are eliminated.

State space of the DP. the DP keeps track of the following three quantities:

1. **a list $\boldsymbol{M}$** which consists of sets of informative boxes opened and numbers of non-informative ones opened in between the sets of informative ones. Specifically, M has the following form: $M = S_1|x_1|S_2|x_2|\dots|S_L|x_L$[6] where S_i is a set of informative boxes, and $x_i \in \mathbb{N}$ is the number of non-informative boxes opened exactly after the boxes in set S_i. We also denote by $\text{IB}(M)$ the informative boxes in the list M.
   In order to update M at every recursive call, we either append a new informative box b_i opened (denoted by $M|b_i$) or, when a non-informative box is opened, we add 1 at the end, denoted by $M + 1$.
2. **a list $\boldsymbol{E}$** of m^2 tuples of integers (z_{ij}, t_{ij}), one for each pair of distinct scenarios (s_i, s_j) with $i, j \in [m]$. The number z_{ij} keeps track of the number of informative boxes between s_i and s_j that the value discovered had higher probability for scenario s_i, and the number t_{ij} is the total number of informative for scenarios s_i and s_j opened. Every time an informative box is opened, we increase the t_{ij} variables for the scenarios the box was informative and add 1 to the z_{ij} if the value discovered had higher probability in s_i. When a non-informative box is opened, the list remains the same.We denote this update by E^{++}.
3. **a list $\boldsymbol{S}$** of the scenarios not yet eliminated. Every time an informative test is performed, and the list E updated, if for some scenario s_i there exists another scenario s_j such that $t_{ij} > 1/\varepsilon^2 \log(1/\delta)$ and $|z_{ij} - \mathbb{E}[z_{ij}|s_i]| \leq \varepsilon/2$ then s_j is removed from S, otherwise s_i is removed[7]. This update is denoted by S^{++}.

Base cases. if a value below T is found, the algorithm stops. The other base case is when $|S| = 1$, which means that the scenario realized is identified, we either take the outside option T or search the boxes for a value below T, whichever is cheapest. If the scenario is identified correctly, the DP finds the expected optimal for this scenario. We later show that we make a mistake only with low probability, thus increasing the cost only by a constant factor. We denote by $\text{Nat}(\cdot,\cdot,\cdot)$ the "nature's" move, where the value in the box we chose is realized, and $\text{Sol}(\cdot,\cdot,\cdot)$ is the minimum value obtained by opening boxes. The recursive formula is shown below.

$$\text{Sol}(M,E,S) = \begin{cases} \min(T, c_{\text{NIB}^*(S)} + \text{Nat}(M{+}1, E, S)) & \text{if } |S| = 1 \\ \min\Big(T, \min\limits_{i\in \text{IB}(M)} (c_i{+}\,\text{Nat}(M|i, E, S)) & \\ \qquad\qquad , c_{\text{NIB}^*(S)} + \text{Nat}(M{+}1, E, S)\Big) & \text{else} \end{cases}$$

[6] If b_i for $i \in [n]$ are boxes, the list M looks like this: $b_3b_6b_{13}|5|b_{42}b_1|6|b_2$

[7] This is the process of elimination in the proof of Lemma 21

$$\text{Nat}(M, E, S) = \begin{cases} 0 & \text{if } v_{\text{last box opened}} \leq T \\ \text{Sol}(M, E^{++}, S^{++}) & \text{else} \end{cases} \tag{2}$$

The final solution is $\text{DP}(\beta) = \text{Sol}(\emptyset, E^0, \mathcal{S})$, where E^0 is a list of tuples of the form $(0, 0)$, and in order to update S we set $\delta = \beta c_{\min}/(m^2 T)$.

▶ **Lemma 21.** *Let $s_1, s_2 \in \mathcal{S}$ be any two scenarios. Then after opening $\frac{\log(1/\delta)}{\varepsilon^2}$ informative boxes, we can eliminate one scenario with probability at least $1 - \delta$.*

A Proofs from Section 4

▷ Claim 7. If there exists an $\alpha(n,m)$-approximation algorithm for PB then there exists a $\alpha(n,m)$-approximation for MSSC$_f$.

Proof of Claim 7. Let $\mathcal{I}$ be an instance of MSSC$_f$. We create an instance $\mathcal{I}'$ of PB the following way: for every set s_j of $\mathcal{I}$ that gives feedback f_{ij} when element e_i is selected, we create a scenario s_j with the same probability and whose value for box i, is either 0 if $e_i \in s_j$ or $\infty_{f_{ij}}$ otherwise, where $\infty_{f_{ij}}$ denotes an extremely large value which is different for different values of the feedback f_{ij}. Observe that any solution to the PB instance gives a solution to the MSSC$_f$ at the same cost and vice versa. ◁

▷ Claim 9. If there exists an $\alpha(n, m)$ approximation algorithm for UMSSC_f then there exists an $3\alpha(n + m, m^2)$-approximation for $\text{UPB}_{\leq T}$.

Before formally proving this claim, recall the correspondence of scenarios and boxes of PB-type problems, to elements and sets of MSSC-type problems. The idea for the reduction is to create T copies of sets for each scenario in the initial $\text{PB}_{\leq T}$ instance and one element per box, where if the price a box gives for a scenario i is $< T$ then the corresponding element belongs to all T copies of the set i. The final step is to "simulate" the outside option T, for which we we create T elements where the k'th one belongs only to the k'th copy of each set.

Proof of Claim 9. Given an instance $\mathcal{I}$ of $\text{UPB}_{\leq T}$ with outside cost box b_T, we construct the instance $\mathcal{I}'$ of UMSSC_f as follows.

Construction of the instance. For every scenario s_i in the initial instance, we create T sets denoted by s_{ik} where $k \in [T]$. Each of these sets has equal probability $p_{ik} = 1/(mT)$. We additionally create one element e^B per box B, which belongs to every set s_{ik} for all k iff $v_{Bi} < T$ in the initial instance, otherwise gives feedback v_{Bi}. In order to simulate box b_T without introducing an element with non-unit cost, we use a sequence of T *outside option* elements e^T_k where $e^T_k \in s_{ik}$ for all $i \in [m]$ i.e. element e^T_{ik} belongs to "copy k" of every set [8].

Construction of the policy. We construct policy $\pi_{\mathcal{I}}$ by ignoring any outside option elements that $\pi_{\mathcal{I}'}$ selects until $\pi_{\mathcal{I}'}$ has chosen at least $T/2$ such elements, at which point $\pi_{\mathcal{I}}$ takes the outside option box b_T. To show feasibility we need that for every scenario either b_T is chosen or some box with $v_{ij} \leq T$. If b_T is not chosen, then less than $T/2$ isolating elements were chosen, therefore in instance of UMSSC_f some sub-sets will have to be covered by another element e^B, corresponding to a box. This corresponding box however gives a value $\leq T$ in the initial $\text{UPB}_{\leq T}$ instance.

Approximation ratio. Let s_i be any scenario in $\mathcal{I}$. We distinguish between the following cases, depending on whether there are outside option tests on s_i's branch.

1. **No outside option tests** on s_i's branch: scenario s_i contributes equally in both policies, since absence of *isolating elements* implies that all copies of scenario s_i will be on the same branch (paying the same cost) in both $\pi_{\mathcal{I}'}$ and $\pi_{\mathcal{I}}$
2. **Some outside option tests** on i's branch: for this case, from Lemma 22 we have that $c(\pi_{\mathcal{I}}(s_i)) \leq 3c(\pi_{\mathcal{I}'}(s_i))$.

   Putting it all together we get

   $$c(\pi_{\mathcal{I}}) \leq 3c(\pi_{\mathcal{I}'}) \leq 2\alpha(n + m, m^2)c(\pi^*_{\mathcal{I}'}) \leq 3\alpha(n + m, m^2)c(\pi^*_{\mathcal{I}}),$$

where the second inequality follows since we are given an α approximation and the last inequality since if we are given an optimal policy for $\text{UPB}_{\leq T}$, the exact same policy is also feasible for any $\mathcal{I}'$ instance of UDT, which has cost at least $c(\pi^*_{\mathcal{I}'})$. We also used that $T \leq m$, since otherwise the initial policy would never take the outside option. ◁

▶ **Lemma 22.** *Let $\mathcal{I}$ be an instance of $\text{UPB}_{\leq T}$, and $\mathcal{I}'$ the instance of UMSSC_f constructed by the reduction of Claim 9. For a scenario s_i, if there is at least one outside option test run in $\pi_{\mathcal{I}}$, then $c(\pi_{\mathcal{I}}(s_i)) \leq 3c(\pi_{\mathcal{I}'}(s_i))$.*

[8] Observe that there are exactly T possible options for k for any set. Choosing all these elements costs T and covers all sets thus simulating b_T.

Proof. For the branch of scenario s_i, denote by M the box elements chosen before there were $T/2$ *outside option* elements, and by N the number of *outside option* elements in $\pi_{\mathcal{I}'}$. Note that the smallest cost is achieved if all the outside option elements are chosen first[9]. The copies of scenario s_i can be split into two groups; those that were isolated **before** $T/2$ *outside option* elements were chosen, and those that were isolated **after**. We distinguish between the following cases, based on the value of N.

1. $N \geq T/2$: in this case each of the copies of s_i that are isolated after pays at least $M + T/2$ for the initial box elements and the initial sequence of *outside option* elements. For the copies isolated before, we lower bound the cost by choosing all *outside option* elements first.
   The cost of all the copies in $\pi_{\mathcal{I}'}$ then is at least
   $$\begin{aligned}\sum_{j=1}^{K_i}\sum_{k=1}^{T/2}\frac{cp_\ell}{T}k + \sum_{j=1}^{K_i}\sum_{k=T/2+1}^{T}\frac{cp_\ell}{T}(T/2+M) &= cp_i\frac{\frac{T}{2}(\frac{T}{2}+1)}{2T} + cp_i\frac{\frac{T}{2}(T/2+M)}{T}\\ &\geq cp_i(3T/8 + M/2)\\ &\geq \frac{3}{8}p_i(T+M)\end{aligned}$$
   Since $N \geq T/2$, policy $\pi_{\mathcal{I}}$ will take the outside option box for s_i, immediately after choosing the M initial boxes corresponding to the box elements. So, the total contribution s_i has on the expected cost of $\pi_{\mathcal{I}}$ is at most $p_i(M+T)$ in this case. Hence, we have that s_i's contribution in $\pi_{\mathcal{I}}$ is at most $\frac{8}{3} \leq 3$ times s_i's contribution in $\pi_{\mathcal{I}'}$.
2. $N < T/2$: policy $\pi_{\mathcal{I}}$ will only select the M boxes (corresponding to *box* elements) and this was sufficient for finding a value less than T. The total contribution of s_i on $c(\pi_{\mathcal{I}})$ is exactly $p_i M$. On the other hand, since $N < T/2$ we know that at least half of the copies will pay M for all of the box elements. The cost of all the copies is at least
   $$\sum_{j=1}^{K_i}\sum_{k=N}^{T}\frac{cp_\ell}{T}M = cp_i\frac{T-N}{T}M \geq cp_i M/2,$$
   therefore, the contribution s_i has on $c(\pi_{\mathcal{I}'})$ is at least $cp_i M/2$. Hence, we have $c(\pi_{\mathcal{I}}) \leq 3c(\pi_{\mathcal{I}'})$. ◀

A.1 Proofs from subsection 4.1.1

▶ **Lemma 15.** *Given an instance $\mathcal{I}$ of PB; an α-approximation algorithm $\mathcal{A}_T$ to PB$_{\leq T}$; and any $q < 1$ and $\beta \geq 2$, suppose that the threshold T satisfies*

$$T \geq t_{q/(\beta\alpha)} + \beta\alpha \sum_{\substack{c_s \in [t_q, t_{q/(\beta\alpha)}]\\ s \in \mathcal{S}}} c_s \frac{p_s}{q}.$$

Then if $\mathcal{A}_T$ is run on a q-sub instance of $\mathcal{I}$ with threshold T, at most a total mass of $(2/\beta)q$ of the scenarios pick the outside option box T.

[9] Since the outside option tests cause some copies to be isolated and so can reduce their cost.

Proof. Consider a policy $\pi_{\mathcal{I}_q}$ which runs $\pi^*_{\mathcal{I}}$ on the instance $\mathcal{I}_q$; and for scenarios with cost $c_s \geq t_{q/(\beta\alpha)}$ aborts after spending this cost and chooses the outside option T. The cost of this policy is:

$$c(\pi^*_{\mathcal{I}_q}) \leq c(\pi_{\mathcal{I}_q}) = \frac{T + t_{q/(\beta\alpha)}}{\beta\alpha} + \sum_{\substack{c_s \in [t_q, t_{q/(10\alpha)}] \\ s \in \mathcal{S}}} c_s \frac{p_s}{q}, \tag{3}$$

By our assumption on T, this cost is at most $2T/\beta\alpha$. On the other hand since $\mathcal{A}_T$ is an α-approximation to the optimal we have that the cost of the algorithm's solution is at most

$$\alpha c(\pi^*_{\mathcal{I}_q}) \leq \frac{2T}{\beta}$$

Since the expected cost of $\mathcal{A}_T$ is at most $2T/\beta$, then using Markov's inequality, we get that $\mathbf{Pr}\left[c_s \geq T\right] \leq (2T/\beta)/T = 2/\beta$. Therefore, $\mathcal{A}_T$ covers at least $1 - 2/\beta$ mass every time. ◀

▶ **Lemma 14** (Optimal Lower Bound). *Let $\mathcal{I}$ be the instance of PB. For any $q < 1$, any $\alpha > 1$, and $\beta \geq 2$, for the optimal policy $\pi^*_{\mathcal{I}}$ for PB it that*

$$\mathrm{cost}(\pi^*_{\mathcal{I}}) \geq \sum_{i=0}^{\infty} \frac{1}{\beta\alpha} \cdot (q)^i \, t_{q^i/\beta\alpha}.$$

Proof. In every interval of the form $\mathcal{I}_i = [t_{q^i}, t_{q^i/(\beta\alpha)}]$ the optimal policy for PB covers at least $1/(\beta\alpha)$ of the probability mass that remains. Since the values belong in the interval $\mathcal{I}_i$ in phase i, it follows that the minimum possible value that the optimal policy might pay is t_{q^i}, i.e. the lower end of the interval. Summing up for all intervals, we get the lemma. ◀

A.2 Proofs from subsection 4.1.2

Algorithm 3 **Expand**: rescales and returns an instance of UPB.

```
Input: Set of scenarios $\mathcal{S}$
Scale all probabilities by $c$ such that $c\sum_{s\in\mathcal{S}} p_s = 1$
Let $p_{\min} = \min_{s\in\mathcal{S}} p_s$
$\mathcal{S}' =$ for each $s \in \mathcal{S}$ create $p_s/p_{\min}$ copies
Each copy has probability $1/|\mathcal{S}'|$
return $\mathcal{S}'$
```

▶ **Main Lemma 10.** *Given a polynomial-time $\alpha(n,m)$-approximation algorithm for UPB$_{\leq T}$, there exists a polynomial-time $O(\alpha(n,m)\log\alpha(n,m))$-approximation for PB.*

Proof. The proof in this case follows the steps of the proof of Theorem 11, and we are only highlighting the changes. The process of the reduction is the same as Algorithm 1 with the only difference that we add two extra steps; (1) we initially remove all low probability scenarios (line 3 - remove at most c fraction) and (2) we add them back after running UPB$_{\leq T}$ (line 8). The reduction process is formally shown in Algorithm 2.

Calculating the thresholds. For every phase i we choose a threshold T_i such that $T_i = \min\{T : \mathbf{Pr}\left[c_s > T\right] \leq \delta\}$ i.e. at most δ of the probability mass of the scenarios are not covered, again using binary search as in Algorithm 1. We denote by

$\text{Int}_i = [t_{(1-c)(\delta+c)^i}, t_{(1-c)(\delta+c)^i/(\beta\alpha)}]$ the relevant interval of costs at every run of the algorithm, then by Lemma 15, we know that for remaining total probability mass $(1-c)(\delta+c)^i$, any threshold which satisfies

$$T_i \geq t_{(1-c)(\delta+c)^{i-1}/\beta\alpha} + \beta\alpha \sum_{\substack{s\in\mathcal{S}\\ c_s\in\text{Int}_i}} c_s \frac{p_s}{(1-c)(\delta+c)^i}$$

also satisfies the desired covering property, i.e. at least $(1-2/\beta)(1-c)(\delta+c)$ mass of the current scenarios is covered. Therefore the threshold T_i found by our binary search satisfies

$$T_i = t_{(1-c)(\delta+c)^{i-1}/\beta\alpha} + \beta\alpha \sum_{\substack{s\in\mathcal{S}\\ c_s\in\text{Int}_i}} c_s \frac{p_s}{(1-c)(\delta+c)^i}. \tag{4}$$

Following the proof of Theorem 11, **Constructing the final policy** and **Accounting for the values** remain exactly the same as neither of them uses the fact that the scenarios are uniform.

Bounding the final cost. Using the guarantee that at the end of every phase we cover $(\delta + c)$ of the scenarios, observe that the algorithm for $\text{PB}_{\leq T}$ is run in an interval of the form $\text{Int}_i = [t_{(1-c)(\delta+c)^i}, t_{(1-c)(\delta+c)^i/(\beta\alpha)}]$. Note also that these intervals are overlapping. Bounding the cost of the final policy $\pi_\mathcal{I}$ for all intervals we get

$$\begin{aligned}
\pi_\mathcal{I} &\leq \sum_{i=0}^{\infty}(1-c)(\delta+c)^i T_i \\
&= \sum_{i=0}^{\infty}\left((1-c)(\delta+c)^i t_{(1-c)(\delta+c)^{i-1}/\beta\alpha} + \beta\alpha \sum_{\substack{s\in\mathcal{S}\\ c_s\in\text{Int}_i}} c_s p_s\right) && \text{From equation (4)} \\
&\leq 2\cdot\beta\alpha\pi^*_\mathcal{I} + \beta\alpha\sum_{i=0}^{\infty}\sum_{\substack{s\in\mathcal{S}\\ c_s\in\text{Int}_i}} c_s p_s && \text{Using Lemma 14} \\
&\leq 2\beta\alpha\log\alpha\cdot\pi^*_\mathcal{I},
\end{aligned}$$

where the inequalities follow similarly to the proof of Theorem 11. Choosing $c = \delta = 0.1$ and $\beta = 20$ we get the theorem. ◀

Stable Approximation Algorithms for Dominating Set and Independent Set

Abstract

We study Dominating Set and Independent Set for dynamic graphs in the vertex-arrival model. We say that a dynamic algorithm for one of these problems is *k-stable* when it makes at most k changes to its output independent set or dominating set upon the arrival of each vertex. We study trade-offs between the stability parameter k of the algorithm and the approximation ratio it achieves. We obtain the following results.

- We show that there is a constant $\varepsilon^* > 0$ such that any dynamic $(1+\varepsilon^*)$-approximation algorithm for Dominating Set has stability parameter $\Omega(n)$, even for bipartite graphs of maximum degree 4.
- We present algorithms with very small stability parameters for Dominating Set in the setting where the arrival degree of each vertex is upper bounded by d. In particular, we give a 1-stable $(d+1)^2$-approximation, and a 3-stable $(9d/2)$-approximation algorithm.
- We show that there is a constant $\varepsilon^* > 0$ such that any dynamic $(1+\varepsilon^*)$-approximation algorithm for Independent Set has stability parameter $\Omega(n)$, even for bipartite graphs of maximum degree 3.
- Finally, we present a 2-stable $O(d)$-approximation algorithm for Independent Set, in the setting where the average degree of the graph is upper bounded by some constant d at all times.

1 Introduction

Given a simple, undirected graph $G = (V, E)$, a *dominating set* is a subset $D \subset V$ such that each vertex in V is either a neighbor of a vertex in D, or it is in D itself. An *independent set* is a set of vertices $I \subset V$ such that no two vertices in I are neighbors. Dominating Set (the problem of finding a minimum-size dominating set) and Independent Set (the problem of finding a maximum-size independent set) are fundamental problems in algorithmic graph theory. They have numerous applications and served as prototypical problems for many algorithmic paradigms.

We are interested in Dominating Set and Independent Set in a dynamic setting, where the graph G changes over time. In particular, we consider the well-known *vertex-arrival model.* Here one starts with an empty graph $G(0)$, and new vertices arrive one by one,

along with their edges to previously arrived vertices. In this way, we obtain a sequence of graphs $G(t)$, for $t = 0, 1, 2, \ldots$. Our algorithm is then required to maintain a valid solution – a dominating set, or an independent set – at all times. In the setting we have in mind, computing a new solution is not the bottleneck, but each change to the solution (adding or deleting a vertex from the solution) is expensive. Of course we also want that the maintained solution has a good approximation ratio. To formalize this, and following De Berg et al. [12], we say that a dynamic algorithm is a *k-stable ρ-approximation algorithm* if, upon the arrival upon each vertex, the number of changes (vertex additions or removals) to the solution is at most k and the solution is a ρ-approximation at all times. In this framework, we study trade-offs between the stability parameter k and the approximation ratio that can be achieved. Ideally, we would like to have a so-called *stable approximation scheme (SAS)*: an algorithm that, for any given yet fixed parameter $\varepsilon > 0$ is k_ε-stable and gives a $(1+\varepsilon)$ approximation algorithm, where k_ε only depends on ε and not on the size of the current instance. (There is an intimate relation between local-search PTASs and SASs; we come back to this issue in Section 2.)

The vertex-arrival model is a standard model for online graph algorithms, and our stability framework is closely related to online algorithms with bounded recourse. However, there are two important differences. First, computation time is free in our framework – for instance, the algorithm may decide to compute an optimal solution in exponential time upon each insertion – while in online algorithms with bounded recourse the update time is typically taken into account. Thus we can fully focus on the the trade-off between stability and approximation ratio. Secondly, we consider the approximation ratio of the solution, while in online algorithm one typically considers the competitive ratio. Thus we compare the quality of our solution at time t to the *static optimum*, which is simply the optimum for the graph $G(t)$. A competitive analysis, one the other hand, compares the quality of the solution at time t to the *offline optimum*: the best solution for $G(t)$ that can be computed by a dynamic algorithm that knows the sequence $G(0), \ldots, G(t)$ in advance but must still process the sequence with bounded recourse. See also the discussion in the paper by Boyar et al. [6]. Thus approximation ratio is a much stronger notion that competitive ratio. As a case in point, consider Dominating Set, and suppose that n singleton vertices arrive, followed by a single vertex with edges to all previous ones. Then the static optimum for the final graph is 1, while the offline optimum with bounded recourse is $\Omega(n)$.

Related work. We now review some of the most relevant existing literature on the online version of our problems. (Borodin and El-Yaniv [5] give a general introduction to online computation.) The classical online model, where a vertex that has been added to the dominating set or to the independent set, can never be removed from it – that is, the no-recourse setting – is e.g. considered by King and Tzeng [18] and Lipton and Tomkins [20]. They show that already for the special case of interval graphs no online algorithm has constant competitive ratio; see also De et al. [9], who study these two problems for geometric intersection graphs. For Dominating Set in the vertex-arrival model, Boyar et al. [6] give online algorithms with bounded competitive ratio for trees, bipartite graphs, bounded degree graphs, and planar graphs. They actually analyze both the competitive ratio and the approximation ratio (which, as discussed earlier, can be quite different). A crucial difference between the work of Boyar et al. [6] and ours is that they do not allow recourse: in their setting, once a vertex is added to the dominating set, it cannot be removed.

To better understand online algorithmic behavior, various ways to relax classical online models have been studied. In particular, for Independent Set, among others, Halldórsson et al. [16] consider the option for the online algorithm to maintain multiple solutions. Göbel et al. [13] analyze a stochastic setting where, among other variants, a randomly generated graph is presented in adversarial order (the prophet inequality model), and one where an adversarial graph is presented in random order. In these settings they find constant competitive algorithms for Independent Set on interval graphs, and more generally for graphs with bounded so-called inductive independence number.

One other key relaxation of the online model is to allow recourse. Having recourse can be seen as relaxing the irrevocability assumption in classical online problems, and allows to assess the impact of this assumption on the competitive ratio, see Boyar et al. [7]. The notion of (bounded) recourse has been investigated for a large set of problems. Without aiming for completeness, we mention Angelopoulos et al. [1] and Gupta et al. [15] who deal with online matching and matching assignments, Gupta et al. [14] who investigate the set cover problem, and Berndt et al. [4] who deal with online bin covering with bounded migration, and Berndt et al. [3] who propose a general framework for dynamic packing problems. For these problems, it is shown what competitive or approximation ratios can be achieved when allowing a certain amount of recourse (or migration). Notice that, in many cases, an amortized interpretation of recourse is used; then the average number of changes to a solution is bounded (instead of the maximum, as for k-stable algorithms defined above). For instance, Lsiu and Charington-Toole [21] show that, for independent set, there is an interesting trade-off between the competitive ratio and the amortized recourse cost: for any $t > 1$, they provide a t-competitive algorithm for independent set using $t - 1$ recourse cost. Their results however do not apply to our notion of stability.

Our contribution. We obtain the following results.

- In Section 2, we show that the existence of a local-search PTAS for the static version of a graph problem, implies, under certain conditions, the existence of a SAS for the problem in the vertex-arrival model (whereas the converse need not be true). This implies that for graphs with strongly sublinear separators, a SAS exists for Independent Set and for Dominating Set when the arrival degrees – that is, the degrees of the vertices upon arrival – are bounded by a constant.
- In Section 3, we consider Dominating Set in the vertex-arrival model. Let d denote the maximum arrival degree. We show (i) there does not exist a SAS even for bipartite graphs of maximum degree 4, (ii) there is a 1-stable $(d+1)^2$-approximation algorithm, and (iii) there is a 3-stable $\frac{9d}{2}$-approximation algorithm.
- In Section 4, we consider Independent Set in the vertex-arrival model. We show that there does not exist a SAS even for bipartite graphs of maximum degree 3. Further, we give a 2-stable $O(d)$-approximation algorithm for the case where the average degree of $G(t)$ is bounded by d at all times.

2 Stable Approximation Schemes versus PTAS by local search

In this section we discuss the relation between Stable Approximation Schemes (SASs) and Polynomial-Time Approximation Schemes (PTASs). Using known results on local-search PTASs, we then obtain SASs for Independent Set for Dominating Set on certain graph classes. While the results in this section are simple, they set the stage for our main results in the next sections.

The goals of a SAS and a PTAS are the same: both aim to achieve an approximation ratio $(1+\varepsilon)$, for any given $\varepsilon > 0$. A SAS, however, works in a dynamic setting with the requirement that k_ε, the number of changes per update, is a constant for fixed ε, while a

PTAS works in a static setting with the condition that the running time is polynomial for fixed ε. Hence, there are problems that admit a PTAS (or are even polynomial-time solvable) but no SAS [12].

One may think that the converse should be true: if a dynamic problem admits a SAS, then its static version admits a PTAS. Indeed, we can insert the input elements one by one and let the SAS maintain a $(1+\varepsilon)$-approximation, by performing at most k_ε changes per update. For a SAS, there is no restriction on the time needed to update the solution, but it seems we can simply try all possible combinations of at most k_ε changes in, say, $n^{O(k_\varepsilon)}$ time. This need not work, however, since there could be many ways to update the solution using at most k_ε changes. Even though we can find all possible combinations in polynomial time, we may not be able to decide which combination is the right one: the update giving the best solution at this moment may get us stuck in the long run. The SAS can avoid this by spending exponential time to decide what the right update is. Thus the fact that a problem admits a SAS does not imply that it admits a PTAS.

Notwithstanding the above, there is a close connection between SASs and PTASs and, in particular between SASs and so-called local-search PTASs: under certain conditions, the existence of a local-search PTAS implies the existence of a SAS. For simplicity we will describe this for graph problems, but the technique may be applied to other problems.

Let $G=(V,E)$ be a graph and suppose we wish to select a minimum-size (or maximum-size) subset $S \subset V$ satisfying a certain property. Problems of this type include Dominating Set, Independent Set, Vertex Cover, Feedback Vertex Set, and more. A local-search PTAS for such a graph minimization problem starts with an arbitrary feasible solution S – the whole vertex set V, say – and then it tries to repeatedly decrease the size of S by replacing a subset $S_{\text{old}} \subset S$ by a subset $S_{\text{new}} \subset V \setminus S$ such that $|S_{\text{new}}| = |S_{\text{old}}|-1$ and $(S \setminus S_{\text{old}}) \cup S_{\text{new}}$ is still feasible. (For a maximization problem we require $|S_{\text{new}}| = |S_{\text{old}}|+1$.) This continues until no such replacement can be found.[1] A key step in the analysis of a local-search PTAS is to show the following, where n is the number of vertices.

- **Local-Search Property.** If S is a feasible solution that is not a $(1+\varepsilon)$-approximation then there are subsets $S_{\text{old}}, S_{\text{new}}$ as above with $|S_{\text{old}}| \leqslant f_\varepsilon$, for some f_ε depending only on ε and not on n.

This condition indeed gives a PTAS, because we can simply try all possible pairs $S_{\text{old}}, S_{\text{new}}$, of which there are $O(n^{2f_\varepsilon})$.

Now consider a problem that has the Local-Search Property in the vertex-arrival model, possibly with some extra constraint (for example, on the arrival degrees of the vertices). Let $G(t)$ denote the graph after the arrival of the t-th vertex, and let $\textsc{opt}(t)$ denote the size of an optimal solution for for $G(t)$. We can obtain a SAS if the problem under consideration has the following properties.

- **Continuity Property.** We say that the dynamic problem (in the vertex-arrival model, possibly with extra constraints) is *d-continuous* if $|\textsc{opt}(t+1) - \textsc{opt}(t)| \leqslant d$. In other words, the size of an optimal solution should not change by more than d when a new vertex arrives. Note that the solution itself may change completely; we only require its size not to change by more than d.
- **Feasibility Property.** For maximization problems we require that any feasible solution for $G(t-1)$ is also a feasible solution for $G(t)$, and for minimization problems we require that any feasible solution for $G(t-1)$ can be turned into a feasible solution for $G(t)$ by

[1] See the paper by Antunes etal [2] for a nice exposition on problems solved using local-search PTAS.

adding the arriving vertex to the solution. (This condition can be relaxed to saying that we can repair feasibility by $O(1)$ modifications to the current solution, but for concreteness we stick to the simpler formulation above.)

Note that Independent Set, Vertex Cover, and Feedback Vertex Set are 1-continuous, and that Dominating Set is $(d-1)$-continuous when the arrival degree of the vertices is bounded by $d \geqslant 2$. Moreover, these problems all have the Feasibility Property.

For problems that have the Local-Search Property as well as the Continuity and Feasibility Properties, it is easy to give a SAS. Hence, non-existence of SAS for a problem with Continuity and Feasibility directly implies non-existence of local-search PTAS.[2] We give the pseudocode for minimization problems, but for maximization problems a similar approach works.

Algorithm 1 SAS-for-Continuous-Problems(v).

```
▷ $v$ is the vertex arriving at time $t$
$S_{\text{alg}} \leftarrow S_{\text{alg}}(t-1) \cup \{v\}$        ▷ $S_{\text{alg}}$ is feasible for $G(t)$ by the feasibility condition
while $S_{\text{alg}}$ is not a $(1+\varepsilon)$-approximation do
    Find sets $S_{\text{old}} \subset S_{\text{alg}}$ and $S_{\text{new}} \subset V(t) \setminus S_{\text{alg}}$ with $|S_{\text{old}}| \leqslant f_\varepsilon$ and $|S_{\text{new}}| = |S_{\text{old}}| - 1$
    such that $(S_{\text{alg}} \setminus S_{\text{old}}) \cup S_{\text{new}}$ is a valid solution, and set $S_{\text{alg}} \leftarrow (S_{\text{alg}} \setminus S_{\text{old}}) \cup S_{\text{new}}$.
$S_{\text{alg}}(t) \leftarrow S_{\text{alg}}$
```

▶ **Theorem 1.** *Any graph problem that has the Continuity Property, the Feasibility Property and the Local-Search Property admits a SAS in the vertex arrival model, with stability parameter $(d+1)\cdot(2f_\varepsilon - 1)+1$ for minimization problems and $d \cdot (2f_\varepsilon + 1)$ for maximization problems.*

Proof. First consider a minimization problem. By the Feasibility Property and the working of the algorithm, the solution that SAS-for-Continuous-Problems computes upon the arrival of a new vertex is feasible. Moreover, it must end with a $(1+\varepsilon)$-approximation because of the Local-Search Property. Before the while-loop we add v to S_{alg}, and in each iteration of the while-loop, at most f_ε vertices are deleted from S_{alg} and at most $f_\varepsilon - 1$ vertices are added. We claim that the number of iterations is at most $\lceil(1+\varepsilon)d\rceil + 1$. Indeed, before the arrival of v we have $|S_{\text{alg}}(t-1)| \leqslant (1+\varepsilon)\cdot|\text{OPT}(t-1)|$, and we have $|\text{OPT}(t-1) - \text{OPT}(t)| \leqslant d$ by the Local-Search Property. Hence, after $\lceil(1+\varepsilon)d\rceil + 1$ iterations we have

$$\begin{aligned} |S_{\text{alg}}| &= |S_{\text{alg}}(t-1)| + 1 - (\lceil(1+\varepsilon)d\rceil + 1) \\ &\leqslant (1+\varepsilon)\cdot|\text{OPT}(t-1)| - (1+\varepsilon)d \\ &\leqslant (1+\varepsilon)\cdot(\text{OPT}(t) + d) - (1+\varepsilon)d \\ &\leqslant (1+\varepsilon)\cdot\text{OPT}(t). \end{aligned}$$

For a maximization problem the proof is similar. The differences are that we do not add an extra vertex to S_{alg} in step 2, that the number of changes per iteration is at most $2f_\varepsilon + 1$, and that the number of iterations is at most d. (We do not get the factor $(1+\varepsilon)$ because if OPT increases, then the error that we can make, which is $\varepsilon \cdot \text{OPT}$, also increases.) ◀

This general result allows us to obtain a SAS for a variety of problems, for graph classes for which a local-search PTAS is known.

[2] Dominating Set and Independent Set, even with maximum degree bounded by 3, do not admit a PTAS assuming P ≠ NP [8, 22]. In sections 3.1 and 4.1, by proving the non-existence of a SAS for Dominating Set with maximum degree bounded by 4 and Independent Set with maximum degree bounded by 3, we thus show non-existence of local-search PTAS, independent of the assumption of P ≠ NP.

Recall that a balanced *separator* of a graph $G = (V, E)$ with n vertices is a subset $S \subset V$ such that $V \setminus S$ can be partitioned into subsets A and B with $|A| \leqslant 2n/3$ and $|B| \leqslant 2n/3$ and no edges between A and B. We say that a graph class[3] $\mathcal{G}$ has *strongly sublinear separators*, if any graph $G \in \mathcal{G}$ has a balanced separator of size $O(n^\delta)$, for some fixed constant $\delta < 1$. Planar graphs, for instance, have separators of size $O(\sqrt{n})$ [19]. A recent generalization of separators are so-called *clique-based separators*, which are separators that consist of cliques and whose size is measured in terms of the number of cliques [10]. (Actually, the cost of a separator S that is the union of cliques $C_1, \ldots, C_k$ is defined as $\sum_{i=1}^{k} \log(|C_i| + 1)$, but this refined measure is not needed here.) Disk graphs (which do not have normal separators of sublinear size) have a clique-based separator of size $O(\sqrt{n})$, for instance, and pseudo-disk graphs have a clique-based separator of size $O(n^{2/3})$ [11]. For graph classes with strongly sublinear separators there are local-search PTASs for several problems. Combining that with the technique above gives the following result.

▶ **Corollary 2.** *The following problems admit a SAS in the vertex-arrival model.*

(i) Independent Set *on graph classes with sublinear clique-based separators.*

(ii) Dominating Set *on graph class with sublinear separators, when the arrival degree of each vertex bounded by some fixed constant d.*

Proof. As noted earlier, Independent Set is 1-continuous and Dominating Set is $(d-1)$-continuous. Moreover, these problems have the Feasibility Property. It remains to check the Local-Search Property.

(i) Any graph class with a separator of size $O(n^\delta)$ has the Local-Search Property for Independent Set; see the paper by Her-Peled and Quanrud [17]. (In that paper they show the Local-Search Property for graphs of polynomial expansion – see Corollary 26 and Theorem 3.4 – and graphs of polynomial expansion have sublinear separators.) Theorem 1 thus implies the result for such graph classes. To extend this to clique-based separators, we note that (for Independent Set) we only need the Local-Search Property for graphs that are the union of two independent sets, namely the independent set S and an optimal independent set S_{opt}. Such graphs are bipartite, so the largest clique has size two. Hence, the existence of a clique-based separator of size $O(n^\delta)$ immediately implies the existence of a normal separator of size $O(n^\delta)$.

(ii) For Dominating Set on graphs with polynomial expansion (hence, on graphs with sublinear separators) the Local-Search Property holds [17, Theorem 3.15]. Theorem 1 thus implies an $O(d \cdot f_\varepsilon)$-stable $(1+\varepsilon)$-approximation algorithm, for some constant f_ε depending only on ε. Hence, if d is a fixed constant , we obtain a SAS. ◀

3 Dominating Set

In this section we study stable approximation algorithms for Dominating Set in the vertex arrival model. We first show that the problem does not admit a SAS, even when the maximum degree of the graph is bounded by 4. After that we will describe two algorithms that achieve constant approximation ratio with constant stability, in the setting where each vertex arrives with constant degree.

Let $G = (V, E)$ be a graph. For a subset $S \subset V$, we denote the open neighborhood of a subset $W \subset V$ in G by $N_G(W)$, so $N_G(W) := \{v \in V \setminus W : \text{there is a } w \in W \text{ with } (v, w) \in E\}$. The closed neighborhood $N_G[W]$ is defined as $N_G(W) \cup W$. When the graph G is clear from the context, we may omit the subscript G and simply write $N(W)$ and $N[W]$.

[3] We only consider hereditary graph classes, that is, graph classes $\mathcal{G}$ such that any induced subgraph of a graph in $\mathcal{G}$ is also in $\mathcal{G}$.

3.1 No SAS for graphs of maximum degree 4

Our lower-bound construction showing that Dominating Set does not admit a SAS – in fact, our construction will show a much stronger result, namely that there is a fixed constant $\varepsilon^* > 0$ such that any stable $(1+\varepsilon^*)$-approximation algorithm must have stability $\Omega(n)$ – is based on a certain type of expander graphs, as given by the following proposition. Note that L (the left part of the bipartition of the vertex set) is larger by a constant fraction than R (the right part of the bipartition), while the expansion property goes from L to R. The proof of the following proposition was communicated to us by Noga Alon.

▶ **Proposition 3.** *For any $\mu > 0$ and any n that is sufficiently large, there are constants $0 < \varepsilon, \delta < 1$ such that there is a bipartite graph $G_{\text{exp}}(L \cup R, E)$ with the following properties:*

- *$|L| = (1+\varepsilon)n$ and $|R| = n$.*
- *The degree of every vertex in G is at most 3.*
- *For any $S \subset L$ with $|S| \leqslant \delta n$ we have $|N(S)| \geqslant (2-2\mu)|S|$*

Proof. Let $\mu > 0$ and let t be an integer so that $t > 1/\mu$. Let $\varepsilon \leqslant 1/3^{2t+1}$ be a fixed positive number. Let $H = (A \cup B, E_H)$ be a 3-regular bipartite graph with vertex classes A and B, each of size $(1+\varepsilon)n$, in which for every subset $S \subset B$ of size at most δn we have $|N(S)| \geqslant (2-\mu)|S|$, for some fixed real number $\delta = \delta(\mu) > 0$. (It is known that random cubic bipartite graphs have this property with high probability.) Now pick a set $T \subset A$ of εn vertices so that the distance between any pair of them is larger that $2t$. Such a set exists, as one can choose its members one by one, making sure to avoid the balls of radius $2t$ around the already chosen vertices. This gives a set T of the desired size since $\varepsilon 3^{2t+1} < 1$. We define G_{exp} to be the induced subgraph of H on the classes of vertices $R = A \setminus T$ and $L = B$. It remains to show that G_{exp} has the desired properties.

We have $|L| = (1+\varepsilon)n$ and $|R| = n$ by construction, and the maximum degree of G_{exp} is clearly at most 3. Now let S be a set of at most δn vertices in L. We have to show that $N_{G_{\text{exp}}}(S)$, its neighbor set in G_{exp}, has size at least $(2-2\mu)|S|$. We can assume without loss of generality that $S \cup N_{G_{\text{exp}}}(S)$ is connected in G_{exp}, since we can apply the bound to each connected component separately and just add the inequalities. Note that this assumption implies that $S \cup N_H(S)$ is also connected in H. Observe that the neighborhood $N_H(S)$ of S in the original graph H, which is contained in B, is of size at least $(2-\mu)|S|$, by the property of H. If the set T of deleted vertices has at most $\mu|S|$ members in $N_H(S)$ then the desired inequality holds and we are done. Otherwise T has more than $\mu|S|$ vertices that belong to $N_H(S)$. But the distance between any two such vertices in H is larger than $2t$ (and so the balls of radius t around them are disjoint), and since $S \cup N_H(S)$ is connected this would imply $|S| > t|T \cap N_H(S)| > t\mu|S| > |S|$, which is a contradiction. ◀

Now consider Dominating Set for a dynamic graph in the vertex-arrival model. Let $G(t)$ denote the graph at time t, that is, after the first t insertions. Let $\varepsilon^* > 0$ be such that $\varepsilon^* < \min\left(\frac{\varepsilon}{2+\varepsilon}, \frac{0.49\delta}{2(1+\varepsilon)}\right)$, where ε and δ are the constants in the expander construction of Proposition 3. Consider a dynamic algorithm ALG for Dominating Set such that $|D_{\text{alg}}(t)| \leqslant (1+\varepsilon^*) \cdot \text{OPT}(t)$ at any time t, where $D_{\text{alg}}(t)$ is the output dominating set of ALG at time t and $\text{OPT}(t)$ is the minimum size of a dominating set for $G(t)$. Let $f_{\varepsilon^*}(n)$ denote the stability of ALG, that is, the maximum number of changes it performs on D_{alg} when a new vertex arrives, where n is the number of vertices before the arrival.

We now give a construction showing that, for arbitrarily large n, there is a sequence of n arrivals that requires $f_{\varepsilon^*}(n) \geqslant \frac{1}{6(7+6\varepsilon)}\lfloor \delta n \rfloor$. To this end, choose N large enough such that the bipartite expander graph $G_{\text{exp}} = (L \cup R, E)$ from Proposition 3 exists for $\mu = 0.005$ and

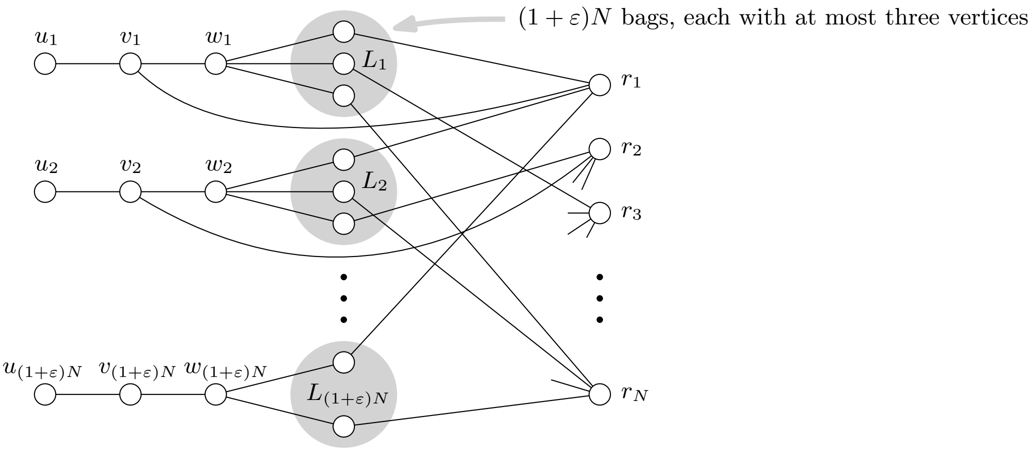

Figure 1 The lower-bound construction for Dominating Set.

$|R| = N$. Label the vertices in L as $\ell_1, \ldots, \ell_{|L|}$ and the vertices in R as $r_1, \ldots, r_{|R|}$. Our construction uses five layers of vertices, arriving one by one, as described next and illustrated in Fig. 1.

- *Layer 1:* The first layer consists of vertices $u_1, \ldots, u_{(1+\varepsilon)N}$, each arriving as a singleton.
- *Layer 2:* The second layer consists of vertices $v_1, \ldots, v_{(1+\varepsilon)N}$, where each v_i has an edge to vertex u_i from the first layer.
- *Layer 2:* The third layer consists of vertices $w_1, \ldots, w_{(1+\varepsilon)N}$, where each w_i has an edge to v_i from the second layer.
- *Layer 4:* Let $G_{\text{exp}} = (L \cup R, E)$ be the expander from Proposition 3. The fourth layer consists of $|L| = (1+\varepsilon)N$ bags, each with at most three vertices. More precisely, if $\deg(\ell_i)$ is the degree of vertex $\ell_i \in L$ in the expander G_{exp}, then bag L_i has $\deg(\ell_i)$ vertices. Each vertex in L_i has an edge to vertex w_i from the third layer.
- *Layer 5:* Finally, the fifth layer arrives. Each vertex in this layer corresponds to a vertex r_i from the bipartite expander G_{exp} and, with a slight abuse of notation, we will also denote it by r_i. If, in $G\exp$, r_i has an edge to some vertex ℓ_j in G_{exp}, then the corresponding vertex r_i in our construction will have an edge to some vertex in the bag L_j. Clearly, we can do this in such a way that each vertex in any of the bags L_i has an edge to exactly one vertex r_i. In addition to the edges to (vertices in) the bags, each vertex r_i also has an edge to the vertex v_i from the second layer.

Let t_1 be the time at which the last vertex of $L_{(1+\varepsilon)N}$ was inserted, and let t_2 be the time at which r_N was inserted. Let $G(t)$ denote the graph induced by all vertices inserted up to time t. Thus $G(t_1)$ consists of the layers 1–4, and $G(t_2)$ consists of layers 1–5.

▶ **Observation 4.** *For any t with $t_1 \leqslant t \leqslant t_2$ we have* $\text{OPT}(t) \leqslant (2+2\varepsilon)N$. *Moreover,* $\text{OPT}(t_2) \leqslant (2+\varepsilon)N$.

Proof. For any $t_1 \leqslant t \leqslant t_2$, the set $D_1 := \{v_1, \ldots, v_{(1+\varepsilon)N}\} \cup \{w_1, \ldots, w_{(1+\varepsilon)N}\}$ forms a dominating set for $G(t)$. Moreover, $D_1 := \{v_1, \ldots, v_{(1+\varepsilon)N}\} \cup \{r_1, \ldots, r_N\}$ forms a dominating set for $G(t_2)$. ◀

We call a bag L_i *fully dominated* by a set D of vertices if each vertex in L_i is dominated by some vertex in D. Observation 4 states that $\text{OPT}(t_2)$ is significantly smaller than $\text{OPT}(t_1)$, which is because the vertices in R can fully dominate all bags. This means that $D_{\text{alg}}(t_2)$ must contain most vertices of R, in order to achieve the desired approximation. Adding only a few vertices from R will be too expensive, however, since fully dominating a small number of bags will be expensive, because of the expander property of G_{exp}. Hence, if the stability parameter $f_{\varepsilon^*}(n)$ is small, then ALG cannot maintain the desired approximation ratio. Next we make this proof idea precise.

▶ **Lemma 5.** *Let $D_{\text{alg}}(t_2)$ denote the output dominating set for $G(t_2)$. Suppose $D_{\text{alg}}(t_2) \cap R$ fully dominates at most δN bags L_i. Then $|D_{\text{alg}}(t_2)| > (1+\varepsilon^*) \cdot \text{OPT}(t_2)$.*

Proof. Let $m < \delta N$ denote the number of bags fully dominated by $D_{\text{alg}}(t_2) \cap R$. Consider a bag L_i that is not fully dominated by $D_{\text{alg}}(t_2) \cap R$. Then $D_{\text{alg}}(t_2)$ must contain the vertex w_i or at least one vertex from the bag L_i. Hence, the number of vertices in $D_{\text{alg}}(t_2)$ from the third and fourth layer is at least $(1+\varepsilon)N - m$. Moreover, $D_{\text{alg}}(t_2)$ must have at least $(1+\varepsilon)N$ vertices from the first and second layer, to dominate all vertices from the first layer. Observe that in order to fully dominate a bag L_i by vertices in R, we need all vertices in R with an edge to some vertex of L_i. So if $D_{\text{alg}}(t_2) \cap R$ fully dominates $m \leqslant \delta N$ bags, then $|D_{\text{alg}}(t_2) \cap R| \geqslant 1.99m$ by the properties of the expander graph G_{exp} in Proposition 3. Hence,

$$|D_{\text{alg}}(t_2)| > (1+\varepsilon)N - m + (1+\varepsilon)N + 1.99m \geqslant (2+2\varepsilon)N.$$

Observation 4 thus implies that $\frac{|D_{\text{alg}}(t_2)|}{\text{OPT}(t_2)} \geqslant \frac{2+2\varepsilon}{2+\varepsilon} > 1+\varepsilon^*$. ◀

Lemma 5 means that, in order to achieve approximation ratio $1+\varepsilon^*$, the set $D_{\text{alg}}(t_2) \cap R$ must fully dominate more than δN bags. Next we show that this cannot be done when the stability parameter $f_{\varepsilon^*}(n)$ is $o(n)$.

▶ **Lemma 6.** *Let t^* be the first time when $D_{\text{alg}}(t^*) \cap R$ fully dominates at least δN bags. If $f_{\varepsilon^*}(n) < \frac{1}{6(7+6\varepsilon)}\lfloor \delta n \rfloor$ then $|D_{\text{alg}}(t^*)| > (1+\varepsilon^*) \cdot \text{OPT}(t^*)$.*

Proof. Let n_t denote the number of vertices of the graph $G(t)$, and observe that $n_{t^*} \leqslant (7+6\varepsilon)N$. Hence, $f_{\varepsilon^*}(n_{t^*}) \leqslant \frac{1}{6}\delta N$. By definition of t^*, we know that just before time t^* the set $D_{\text{alg}} \cap R$ fully dominates less than δN bags. Because ALG is $f_{\varepsilon^*}(n)$-stable, the number of vertices from R added to D_{alg} at time t^* is at most $f_{\varepsilon^*}(n_{t^*})$. Since these new vertices have degree at most three, they can complete the full domination of at most $3f_{\varepsilon^*}(n_{t^*})$ bags. Thus,

$$\big(\text{ number of bags fully dominated by } D_{\text{alg}}(t^*) \cap R\ \big) \quad < \quad \delta N + 3f_{\varepsilon^*}(n_{t^*}) \quad \leqslant \quad \frac{3}{2}\delta N.$$

Let L_i be a bag that is not fully dominated by $D_{\text{alg}}(t^*) \cap R$. Since $D_{\text{alg}}(t^*)$ is a dominating set, it must then contain the vertex w_i or at least one vertex from L_i. Hence, the number of vertices in $D_{\text{alg}}(t^*)$ from layers 3 and 4 is more than $(1+\varepsilon)N - \frac{3}{2}\delta N$. In addition, $D_{\text{alg}}(t^*)$ must have at least $(1+\varepsilon)N$ vertices from layers 1 and 2. Finally, in order to fully dominate a bag L_i by vertices in R, we need all the vertices in R that have an edge to some vertex of L_i. In other words, $D_{\text{alg}}(t^*) \cap R$ must contain all neighbors of the fully dominated bags. Since $D_{\text{alg}}(t^*) \cap R$ dominates at least δN bags, we know that $|D_{\text{alg}}(t^*) \cap R| \geqslant 1.99 \cdot \delta N$, by the properties of the expander graph in Proposition 3. Hence,

$$\begin{aligned} |D_{\text{alg}}(t^*)| &> (1+\varepsilon)N - \frac{3}{2}\delta N + (1+\varepsilon)N + 1.99 \cdot \delta N \\ &\geqslant \left(1 + \frac{0.49\delta}{2+2\varepsilon}\right)(2+2\varepsilon)N \\ &\geqslant (1+\varepsilon^*) \cdot \text{OPT}(t^*). \end{aligned}$$ ◀

By Lemmas 5 and 6 we obtain the following result.

▶ **Theorem 7.** *There is a constant $\varepsilon^* > 0$ such that any dynamic $(1+\varepsilon^*)$-approximation algorithm for* Dominating Set *in the vertex arrival model, must have stability parameter $\Omega(n)$, even when the maximum degree of any of the graphs $G(t)$ is bounded by 4.*

3.2 Constant-stability algorithms when the arrival degrees are bounded

In the previous section we saw that there is no SAS for Dominating Set, even when the maximum degree is bounded by 4. In this section we present stable algorithms whose approximation ratio depends on the arrival degree of the vertices. More precisely, we give a simple 1-stable algorithm with approximation ratio $(d+1)^2$ and a more complicated 3-stable algorithm with approximation ratio $9d/2$, where d is the maximum degree of any vertex upon arrival. Note we only restrict the degree upon arrival: the degree of a vertex may further increase due to the arrival of new vertices. This implies that deletions cannot be handled by a stable algorithm with bounded approximation ratio: even with arrival degree 1 we may create a star graph of arbitrarily large size, and deleting the center of the star cannot be handled in a stable manner without compromising the approximation ratio.

A 1-stable $(d+1)^2$-approximation algorithm. Recall that $G(t)$ denotes the graph after the arrival of the t-th vertex. We can turn $G(t)$ into a directed graph $\vec{G}(t)$, by directing each edge towards the older of its two incident vertices. In other words, when a new vertex arrives then its incident edges are directed away from it.

Let $N^+[v] := \{v\} \cup \{\text{out-neighbors of } v \text{ in } \vec{G}(t)\}$, where t is such that v is inserted at time t. In other words, $N^+[v]$ contains v itself plus the neighbors of v immediately after its arrival. Let $\text{OPT}_{\text{out}}(t)$ denote the minimum size of a dominating set in $\vec{G}(t)$ under the condition that every vertex v should be dominated by a vertex in $N^+[v]$. We call such a dominating set a *directed dominating set*. Note that a directed dominating set for $\vec{G}(t)$ is a dominating set in $G(t)$ as well. The following lemma states that $\text{OPT}_{\text{out}}(t)$ is not much larger than $\text{OPT}(t)$.

▶ **Lemma 8.** *At any time t we have $\text{OPT}_{\text{out}}(t) \leqslant (d+1) \cdot \text{OPT}(t)$.*

Proof. Let $D_{\text{opt}}(t)$ be a minimum dominating set for $G(t)$. Let $D := \bigcup_{v \in D_{\text{opt}}(t)} N^+[v]$. Observe that D is a directed dominating set for $\vec{G}(t)$. Since every vertex arrives with degree at most d, we have $|N^+[v]| = d+1$. The result follows. ◀

We call two vertices u, v *unrelated* if $N^+[u] \cap N^+[v] = \emptyset$, otherwise u, v are *related*. The following lemma follows immediately from the definition of $\text{OPT}_{\text{out}}(t)$.

▶ **Lemma 9.** *Let $U(t)$ be a set of pairwise unrelated vertices in $\vec{G}(t)$. Then $\text{OPT}_{\text{out}}(t) \geqslant |U(t)|$.*

Our algorithm will maintain a directed dominating set $D_{\text{alg}}(t)$ for $\vec{G}(t)$ and a set $U(t)$ of pairwise unrelated vert. Since the initial graph is empty, we initialize $D_{\text{alg}}(0) := \emptyset$ and $U(0) := \emptyset$. When a new vertex v arrives at time t, we proceed as follows.

Algorithm 2 Directed-DomSet(v).

```
▷ $v$ is the vertex arriving at time $t$
if $N^+[v] \cap D_{\text{alg}}(t-1) \neq \emptyset$ then                ▷ $v$ is already dominated
    Set $D_{\text{alg}}(t) \leftarrow D_{\text{alg}}(t-1)$ and $U(t) \leftarrow U(t-1)$
else
    if $v$ is unrelated to all vertices $u \in U(t-1)$ then
        Set $U(t) \leftarrow U(t-1) \cup \{v\}$ and $D_{\text{alg}}(t) \leftarrow D_{\text{alg}}(t-1) \cup \{v\}$
    else
        Let $u$ be a vertex related to $v$, that is, with $N^+[u] \cap N^+[v] \neq \emptyset$.
        Pick an arbitrary vertex $w \in N^+[u] \cap N^+[v]$.
        Set $D_{\text{alg}}(t) \leftarrow D_{\text{alg}}(t-1) \cup \{w\}$ and $U(t) \leftarrow U(t-1)$.
```

This leads to the following theorem.

▶ **Theorem 10.** *There is a* 1*-stable* $(d+1)^2$*-approximation algorithm for* Dominating Set *in the vertex-arrival model, where* d *is the maximum arrival degree of any vertex.*

Proof. Clearly the set D_{alg} maintained by Directed-DomSet is a directed dominating set. Moreover the algorithm is 1-stable as after each arrival, it either adds a single vertex to D_{alg} or does nothing. It is easily checked that the set U maintained by the algorithm is always a set of pairwise unrelated vertices, and that all vertices in D_{alg} are an out-neighbor of a vertex in U or are in U themselves. Hence, by Lemmas 8 and 9, at any time t we have

$$|D_{\text{alg}}(t)| \leqslant (d+1) \cdot |U(t)| \leqslant (d+1) \cdot \text{OPT}_{\text{out}}(t) \leqslant (d+1)^2 \cdot \text{OPT}(t),$$

which finishes the proof. ◀

In Appendix A we show that the approximation ratio $\Theta(d^2)$ is tight for this algorithm.

A 3-stable $(9d/2)$-approximation algorithm. The algorithm presented above has optimal stability, but its approximation ratio is $\Omega(d^2)$. We now present an algorithm whose stability is still very small, namely 3, but whose approximation ratio is only $O(d)$. This is asymptotically optimal, since, as is easy to see, any algorithm with constant stability must have approximation ratio $\Omega(d)$. Our approach is somewhat similar to that of Liu and Toole-Charignon [21], but a key difference is that we obtain a worst-case bound on the stability and they obtain an amortized bound. Our algorithm works in *phases*, as explained next. Suppose we start a new phase at time t and let $D_{\text{alg}}(t-1)$ be the output dominating set at time $t-1$. The algorithm then computes a minimum dominating set $D_{\text{opt}}(t)$ for the graph $G(t)$, which we call the *target dominating set*. The algorithm will then slowly migrate from $D_{\text{alg}}(t-1)$ to $D_{\text{opt}}(t)$, by first adding the vertices in $D^+ := D_{\text{opt}}(t) \setminus D_{\text{alg}}(t-1)$ and then removing the vertices in $D^- := D_{\text{alg}}(t-1) \setminus D_{\text{opt}}(t)$. This is done in $\lceil |D^+ \cup D^-|/2 \rceil$ steps. Vertices that arrive in the meantime are also added to the dominating set, to ensure that the output remains a dominating set at all time. After all vertices in D^+ and D^- have been added and deleted, respectively, the next phase starts. Next we describe and analyze the algorithm in detail.

At the start of the whole algorithm, at time $t = 0$, we initialize $D_{\text{alg}}(0) := \emptyset$, and $D(0)^+ = \emptyset$ and $D(0)^- = \emptyset$.

🟨 **Algorithm 3** Set-and-Achieve-Target(v).

```
▷ $v$ is the vertex arriving at time $t$ and $G(t)$ is the graph after arrival of $v$
$D_{\text{alg}} \leftarrow D_{\text{alg}}(t-1) \cup \{v\}$
if $D^+(t-1) = \emptyset$ and $D^-(t-1) = \emptyset$ then        ▷ start a new phase
    Let $D_{\text{opt}}(t)$ be a minimum dominating set for $G(t)$.
    Set $D^+(t) \leftarrow D_{\text{opt}}(t) \setminus D_{\text{alg}}(t-1)$ and $D^-(t) \leftarrow D_{\text{alg}}(t-1) \setminus D_{\text{opt}}(t)$.
else
    Set $D^+(t) \leftarrow D^+(t-1)$ and $D^-(t) \leftarrow D^-(t-1)$
Set $m^+ \leftarrow \min(2, |D^+(t)|)$. Delete $m^+$ vertices from $D^+(t)$ and add them to $D_{\text{alg}}$.
Set $m^- \leftarrow \min(2 - m^+, |D^-(t)|)$. Delete $m^-$ vertices from $D^-(t)$ and delete the same
    vertices from $D_{\text{alg}}$.
$D_{\text{alg}}(t) \leftarrow D_{\text{alg}}$
```

The algorithm defined above is 3-stable, as it adds one vertex to D_{alg} in step 2 and then makes two more changes to D_{alg} in steps 8 and 9. Next we prove that its approximation ratio is bounded by $9d/2$. Note that the size of a minimum dominating set can reduce over time, due to the arrival of new vertices. The next lemma shows that this reduction is bounded. Let $\textsc{max-opt}(t) := \max(\textsc{opt}(1), \textsc{opt}(2), \ldots, \textsc{opt}(t))$ denote the maximum size of any of the optimal solutions until (and including) time t.

▶ **Lemma 11.** *For any time t we have $\textsc{max-opt}(t) \leqslant d \cdot \textsc{opt}(t)$, where d is the maximum arrival degree of any vertex.*

Proof. Let $t^* \leqslant t$ be such that $\textsc{max-opt}(t) = \textsc{opt}(t^*)$. Let $D_{\text{opt}}(t)$ be an optimal dominating set for $G(t)$ and define $V(t^*)$ to be the set of vertices of $G(t^*)$. Let D be the set of vertices in $D_{\text{opt}}(t)$ that were not yet present at time t^*, and define $D^* := (D_{\text{opt}}(t) \setminus D) \cup N_{t^*}(D)$, where $N_{t^*}(D)$ contains the neighbors of D in $V(t^*)$. Then D^* is a dominating set for $G(t^*)$ since any vertex in $V(t^*)$ that is not dominated by a vertex in $D_{\text{opt}}(t^*) \setminus D$ is in D^* itself. Moreover, $|D^*| \leqslant d \cdot \textsc{opt}(t)$, since each vertex in D has at most d neighbors in $V(t^*)$. ◀

We first bound the size of D_{alg} at the start of each phase. Note that in the proofs below, $D^+(t)$ and $D^-(t)$ refer to the situation before the execution of line 8 and 9 in the algorithm SET-AND-ACHIEVE-TARGET.

▶ **Lemma 12.** *If a new phase starts at time t, then $D_{\text{alg}}(t-1) \leqslant 3 \cdot \textsc{max-opt}(t-1)$.*

Proof. We proceed by induction on t. The lemma trivially holds at the start of the first phase, when $t = 1$. Now consider the start of some later phase, at time t, and let t_{prev} be the previous time at which a new phase started. Recall that $D_{\text{alg}}(t) = D_{\text{opt}}(t_{\text{prev}}) \cup \{\text{vertices arriving at times } t_{\text{prev}}, t_{\text{prev}}+1, \ldots, t-1\}$.

Moreover,

$$|D^+(t_{\text{prev}}) \cup D^-(t_{\text{prev}})| \leqslant |D_{\text{alg}}(t_{\text{prev}}-1)| + |D_{\text{opt}}(t_{\text{prev}})| \leqslant 3 \cdot \textsc{max-opt}(t_{\text{prev}}-1) + \textsc{opt}(t_{\text{prev}}),$$

where the last inequality uses the induction hypothesis. From time t_{prev} up to time $t-1$, the vertices from $D^+(t_{\text{prev}}) \cup D^-(t_{\text{prev}})$ are added/deleted in pairs, so

$$t - t_{\text{prev}} = \left\lceil \frac{3 \cdot \textsc{max-opt}(t_{\text{prev}}-1) + \textsc{opt}(t_{\text{prev}})}{2} \right\rceil \leqslant \left\lceil \frac{4 \cdot \textsc{max-opt}(t_{\text{prev}})}{2} \right\rceil = 2 \cdot \textsc{max-opt}(t_{\text{prev}}).$$

Hence,

$$\begin{aligned} D_{\text{alg}}(t-1) &\leqslant \textsc{opt}(t_{\text{prev}}) + (t - t_{\text{prev}}) \\ &\leqslant \textsc{max-opt}(t_{\text{prev}}) + 2 \cdot \textsc{max-opt}(t_{\text{prev}}) \\ &\leqslant 3 \cdot \textsc{max-opt}(t-1) \end{aligned}$$ ◀

The previous lemma bounds $|D_{\text{alg}}|$ just before the start of each phase. Next we use this to bound $|D_{\text{alg}}|$ during each phase.

▶ **Lemma 13.** *For any time t we have $|D_{\text{alg}}(t)| \leqslant (9/2) \cdot \textsc{max-opt}(t)$.*

Proof. Consider a time t. If a new phase starts at time $t+1$ then the lemma follows directly from Lemma 12. Otherwise, let $t_{\text{prev}} \leqslant t$ be the last time at which a new phase started, and let t_{next} be the next time at which a new phase starts. Furthermore, let $t^* := \max\{t' : t_{\text{prev}} \leqslant t' < t_{\text{next}} \text{ and } D^+(t') \neq \emptyset\}$. In other words, t^* is the last time step in the interval $[t_{\text{prev}}, t_{\text{next}})$ at which we still add vertices from D^+ to D_{alg}. If $D^+(t_{\text{prev}})$ is empty then let $t^* = t_{\text{prev}}$. It is easy to see from the algorithm that $|D_{\text{alg}}(t)| \leqslant |D_{\text{alg}}(t^*)|$. Note that $D_{\text{alg}}(t^*)$ contains the vertices from $D_{\text{alg}}(t_{\text{prev}} - 1)$, plus the vertices from $D_{\text{opt}}(t_{\text{prev}})$, plus the vertices that arrived from time t_{prev} to time t^*. Hence,

$$\begin{aligned} |D_{\text{alg}}(t^*)| &\leqslant |D_{\text{alg}}(t_{\text{prev}} - 1)| + \text{OPT}(t_{\text{prev}}) + (t^* - t_{\text{prev}} + 1) \\ &\leqslant |D_{\text{alg}}(t_{\text{prev}} - 1)| + \text{OPT}(t_{\text{prev}}) + \tfrac{\text{OPT}(t_{\text{prev}})}{2} \\ &\leqslant 3 \cdot \text{MAX-OPT}(t_{\text{prev}} - 1) + \text{MAX-OPT}(t_{\text{prev}}) + \tfrac{\text{OPT}(t_{\text{prev}})}{2} \\ &\leqslant (9/2) \cdot \text{MAX-OPT}(t). \end{aligned}$$

Note that from the first to the second line we replaced $(t^* - t_{\text{prev}} + 1)$ by $\text{OPT}(t_{\text{prev}})/2$, which we can do because we add vertices from $D_{\text{opt}}(t_{\text{prev}})$ in pairs. It may seem that we should actually write $\left\lceil \frac{\text{OPT}(t_{\text{prev}})}{2} \right\rceil$ here. When $\text{OPT}(t_{\text{prev}})$ is odd, however, then the algorithm can already remove a vertex in D^- from D_{alg} when the last vertex from D^+ is added to D_{alg}. (This is not true in the special case when $D^-(t_{\text{prev}}) = \emptyset$, but in that case the second term is an over-estimation. Indeed, when $D^-(t_{\text{prev}}) = \emptyset$ then $D_{\text{alg}}(t_{\text{prev}} - 1) \subseteq D_{\text{opt}}(t_{\text{prev}})$ and so $|D^+(t_{\text{prev}})| = |D_{\text{opt}}(t_{\text{prev}}) \setminus D_{\text{alg}}(t_{\text{prev}} - 1)| < |\text{OPT}(t_{\text{prev}} - 1)|$.) This finishes the proof. ◀

Putting Lemmas 11 and 13 together, we obtain the following theorem.

▶ **Theorem 14.** *There is a 3-stable $(9d/2)$-approximation algorithm for* DOMINATING SET *in the vertex-arrival model, where d is the maximum arrival degree of any vertex.*

4 Stable Approximation Algorithms for INDEPENDENT SET

In this section we first show that INDEPENDENT SET does not admit a SAS, even when restricted to graphs of maximum degree 3. Then we give an 2-stable $O(d)$-approximation algorithm for graphs whose average degree is bounded by d.

4.1 No SAS for graphs of maximum degree 3

We prove our no-SAS result for INDEPENDENT SET in a similar (but simpler) way as for DOMINATING SET. Thus we actually prove the stronger result that there is a constant $\varepsilon^* > 0$ such that any dynamic $(1+\varepsilon^*)$-approximation algorithm for INDEPENDENT SET in the vertex arrival model, must have stability parameter $\Omega(n)$, in this case even when the maximum degree of any of the graphs $G(t)$ is bounded by 3.

Let $\varepsilon^* > 0$ be a real number less than $\min\left(\frac{0.82\delta}{1-0.82\delta}, \varepsilon\right)$. Let ALG be an algorithm that maintains an independent set I_{alg} such that $\text{OPT}(t) \leqslant (1+\varepsilon^*) \cdot |I_{\text{alg}}(t)|$ at all times. Let $f_{\varepsilon^*}(n)$ denote the stability of ALG, that is, the maximum number of changes it performs on I_{alg} when a new vertex arrives, where n is the number of vertices before the arrival. We will show that, for arbitrarily large n, there is a sequence of n arrivals that requires $f_{\varepsilon^*}(n) \geqslant \frac{1}{6(2+\varepsilon)} \lfloor \delta n \rfloor$. As before, choose N large enough such that the bipartite expander graph $G_{\text{exp}} = (L \cup R, E)$ from Proposition 3 exists for $\mu = 0.005$ and $|R| = N$. In our no-SAS construction for INDEPENDENT SET, we only need G_{exp}, not additional layers are needed. Thus the construction is simply as follows.

- First the vertices $r_1, \ldots, r_N$ from the set R arrive one by one, as singletons.
- Next the vertices $\ell_1, \ldots, \ell_{(1+\varepsilon)N}$ from L arrive one by one (in any order), along with their incident edges in G_{exp}.

▶ **Lemma 15.** *Let t^* be the first time when $|I_{\text{alg}}(t) \cap L| \geqslant \delta N$. If $f_{\varepsilon^*}(n) < \frac{1}{6(2+\varepsilon)} \lfloor \delta n \rfloor$ then* $\text{OPT}(t^*) > (1+\varepsilon^*) \cdot |I_{\text{alg}}(t^*)|$.

Proof. Let n_t denote the number of vertices of the graph $G(t)$, and observe that $n_{t^*} \leqslant (2+\varepsilon)N$. Hence, $f_{\varepsilon^*}(n_{t^*}) \leqslant \frac{1}{6}\delta N$. By definition of t^*, we know that just before time t^* we have $|I_{\text{alg}} \cap L| < \delta N$. Because ALG is $f_{\varepsilon^*}(n)$-stable, we have

$$|I_{\text{alg}}(t^*) \cap L| \leqslant \delta N + f(n_{t_f}) \leqslant \frac{7}{6}\delta N.$$

Since $\mu = 0.005$, from Proposition 3 we have $|N(I_{\text{alg}}(t^*) \cap L| \geqslant 1.99 \cdot \delta N$. Hence $|I_{\text{alg}}(t^*) \cap R| \leqslant N - 1.99 \cdot \delta N$, and so

$$|I_{\text{alg}}(t^*)| = |I_{\text{alg}}(t^*) \cap R| + |I_{\text{alg}}(t^*) \cap L| \leqslant \frac{7}{6}\delta N + N - 1.99 \cdot \delta N < N - 0.82\,\delta N$$

. We also have $|\text{OPT}(t^*)| \geqslant N$. Hence, $\text{OPT}(t^*) > \frac{N}{N-0.82\delta N}|I_{\text{alg}}(t^*)| > (1+\varepsilon^*) \cdot |I_{\text{alg}}(t^*)|$. ◀

▶ **Theorem 16.** *There is a constant $\varepsilon^* > 0$ such that any dynamic $(1+\varepsilon^*)$-approximation algorithm for* INDEPENDENT SET *in the vertex arrival model, must have stability parameter $\Omega(n)$, even when the maximum degree of any of the graphs $G(t)$ is bounded by 3.*

Proof. By Proposition 3 the maximum degree of the graph is always bounded by 3. Let $t = 2N + \varepsilon N$ and let $|I_{\text{alg}}(t) \cap L| = M$. We know by Lemma 15 that if ALG is a $(1+\varepsilon^*)$-approximation and if $f_{\varepsilon^*}(n) < \frac{1}{6(2+\varepsilon)}\lfloor \delta n \rfloor$ then $M \leqslant \delta n$. Hence $|I_{\text{alg}}(t) \cap R| \leqslant N - 1.99M$. So we have

$$|I_{\text{alg}}(t)| = |I_{\text{alg}}(t) \cap R| + |I_{\text{alg}}(t) \cap L| \leqslant N - 1.99M + M \leqslant N.$$

But we have $\text{OPT}(t) = (1+\varepsilon)N$. Hence the approximation ratio at time $t = 2N + \varepsilon N$ is greater than or equal to $\frac{(1+\varepsilon)N}{N} = 1 + \varepsilon > 1 + \varepsilon^*$ which is a contradiction. This finishes the proof. ◀

4.2 Constant-stability algorithms when the average degree is bounded

A 2-stable $O(d)$-approximation algorithm. In this section we consider the setting where the average degree of $G(t)$ is upper bounded by some constant d at all times. It is easy to observe that in this setting, if we allow just one change after each vertex arrival, then it's not possible to get a bounded approximation ratio. However, we are able to get a bounded approximation ratio with only two changes per arrival.

It is not hard to see that if the maximum degree is bounded by some constant d^*, then a simple greedy 1-stable algorithm maintains a $O(d^*)$ approximation. Our idea is to maintain an induced subgraph with a number of vertices that is linear in the number of vertices of $G(t)$, and whose maximum degree (rather than average degree) is bounded. We then use the induced subgraph to generate an independent set. Below we make the idea precise.

First we define a (trivial) subroutine algorithm below which takes in an independent set I^* and a subset W^* of vertices as an input, and tries to add a vertex v from $W^* \setminus I^*$ to I^* such that $I^* \cup \{v\}$ is still an independent set.

Algorithm 4 GREEDY-ADDITION(I^*, W^*).

```
if there exist a vertex $v \in W^* \setminus I^*$ such that $I^* \cup \{v\}$ is an independent set then
    Set $I^* = I^* \cup \{v\}$
```

Next we move on to describe our main algorithm, which uses GREEDY-ADDITION as a subroutine. Let $\Delta(G)$ denote the maximum degree of a graph $G = (V, E)$. For a subset $W \subset V$, define $G[W]$ to be the subgraph of G induced by W. Let $V(t)$ denote the set of vertices of $G(t)$.

Observe that by ordering the vertices of $G(t)$ in increasing order of their degree and by taking the first $\lceil \frac{99}{100}|V(t)| \rceil$ vertices, we can construct a set $V^*(t) \subseteq V$ such that $|V^*(t)| \geqslant \frac{99}{100}|V(t)|$ and $\Delta(G[V^*(t)]) \leqslant 100d$. (The number 100 has no special significance – it can be chosen much smaller – but we use it for convenience.) The idea of our algorithm is to maintain a vertex set $W(t) \subseteq V(t)$ such that $\Delta(G[W(t)]) \leqslant 100d$ and the size of $W(t)$ is linear in $|V(t)|$. In order to maintain such a subset, we work in phase, as before: at the start of each phase, the algorithm sets itself a target vertex set $V^*(t)$ of large size and with $\Delta(G[V^*(t)]) \leqslant 100d$. At time t, $W^+(t)$ and $W^-(t)$ denote the vertices that need to be added and removed respectively from $W(t)$ in order to achieve the target. This is done by the algorithm presented next, where we initialize $W^+(t), W^-(t), W(t) = \emptyset$.

Algorithm 5 SET-ACHIEVE-AND-USE-TARGET(v).

```
▷ $v$ is the vertex arriving at time $t$ and $G(t)$ is the graph after arrival of $v$
if $W^+(t-1) = \emptyset$ and $W^-(t-1) = \emptyset$ then                ▷ start a new phase
    Choose $V^*(t) \subseteq V$ such that $|V^*(t)| \geqslant \frac{99}{100}|V(t)|$ and $\Delta(G[V^*(t)]) \leqslant 100d$.
    Set $W^+(t) \leftarrow V^*(t) \setminus W(t-1)$ and $W^-(t) \leftarrow W(t-1) \setminus V^*(t)$.
else
    Set $W^+(t) \leftarrow W^+(t-1)$ and $W^-(t) \leftarrow W^-(t-1)$
Set $m^- \leftarrow \min(1, |W^-(t)|)$. Delete $m^-$ vertices from $W^-(t)$ and delete the same vertices from $W(t)$. Call the vertex deleted(if any) as $v^*$.
Set $I_{\text{alg}}(t) \leftarrow I_{\text{alg}}(t-1) \setminus \{v^*\}$
Set $m^+ \leftarrow \min(1 - m^-, |W^+(t)|)$. Delete $m^+$ vertices from $W^+(t)$ and add them to $W(t)$.
GREEDY-ADDITION($I_{\text{alg}}(t), W(t)$)
```

▶ **Lemma 17.** *At the start of each phase – that is, at a time t such that $W^+(t-1) = \emptyset$ and $W^-(t-1) = \emptyset$ – we have $|W(t-1)| \geqslant \frac{495}{1000} \cdot |V(t)|$.*

Proof. We proceed by induction on t. The lemma trivially holds at the start of the first phase, when $t = 1$. Now consider the start of some later phase, at time t, and let t_{prev} be the previous time at which a new phase started. Since the start of a phase is just after the end of the previous phase we have $|W(t-1)| \geqslant \frac{99}{100}|V(t_{\text{prev}})|$.

Observe that $W^+(t_{\text{prev}})$ and $W^-(t_{\text{prev}})$ are disjoint subsets of the vertices of $V(t_{\text{prev}})$. Hence $|W^+(t_{\text{prev}}) \cup W^-(t_{\text{prev}})| \leqslant |V(t_{\text{prev}})|$. So $(t - t_{\text{prev}}) \leqslant |V(t_{\text{prev}})|$, since we make one change at a time. So $|V(t)| \leqslant 2|V(t_{\text{prev}})|$ and we have

$$|W(t-1)| \geqslant \frac{99}{100} \cdot |V(t_{\text{prev}})| \geqslant \frac{495}{1000} \cdot 2 \cdot |V(t_{\text{prev}})| \geqslant \frac{495}{1000} \cdot |V(t)|$$

This finishes the proof of the lemma. ◀

The previous lemma gives lower bound of $|W(t)|$ at the start of each phase. Next we use this to give a lower bound of $|W(t)|$ at any time point t.

▶ **Lemma 18.** *For any time t, we have $|W(t)| \geqslant \frac{485}{1010} \cdot |V(t)|$.*

Proof. Consider a time t. If a new phase starts at time t then the lemma follows directly from Lemma 17. Otherwise, let t_{prev} be the previous time at which a new phase started, and let t_{next} be the next time at which a new phase starts.

Let $t^* := \max\{t' : t_{\text{prev}} \leqslant t' < t_{\text{next}}$ and $W^-(t') \neq \emptyset\}$. In other words, t^* is the last time step in the interval $[t_{\text{prev}}, t_{\text{next}})$ at which we still delete vertices from $W(t)$. It is easy to see from the algorithm that in the interval $[t_{\text{prev}}, t_{\text{next}})$, the value $\frac{|W(t)|}{|V(t)|}$ is minimum at $t = t^*$. Observe that $|W^-(t_{\text{prev}})| \leqslant \frac{1}{100} \cdot |V(t_{\text{prev}})|$, which implies $(t^* - t_{\text{prev}}) \leqslant \frac{1}{100} \cdot |V(t_{\text{prev}})|$. Hence, $|V(t^*)| \leqslant \frac{101}{100}|V(t_{\text{prev}})|$ and so by Lemma 17 we have

$$|W(t^*)| \geqslant \frac{495}{1000} \cdot |V(t_{\text{prev}})| - \frac{1}{100} \cdot |V(t_{\text{prev}})| = \frac{485}{1010} \cdot \frac{101}{100} \cdot |V(t_{\text{prev}})| \geqslant \frac{485}{1010} \cdot |V(t^*)|$$

This finishes the proof of the lemma. ◀

▶ **Lemma 19.** *For any time t we have $\frac{|W(t)|}{|I_{\text{alg}}(t)|} \leqslant c \cdot d$ for some constant c.*

Proof. Observe that at any time point t the maximum degree of $G[W(t)]$ is bounded by $100d$. Choose a constant c such that $c \cdot d > 100d + 1$. Hence if $I \subseteq W(t)$ is an independent set with $|I| < \frac{|W(t)|}{c \cdot d}$, then there always exist a vertex $v \in W(t) \setminus I$ such that $\{v\} \cup I$ is a independent set. If not then all vertices in $W(t) \setminus I$ have an edge to I. Now $|W(t) \setminus I| \geqslant \frac{(c \cdot d - 1)}{c \cdot d}|W(t)|$, so the average degree of I in $G[W(t)]$ is greater than $c \cdot d - 1 > 100d$, which is a contradiction.

Also observe that $I_{\text{alg}}(t) \subset W(t)$. Now we proceed by induction on t. The lemma holds trivially for $t = 0$. Now suppose the lemma holds for $t = k$. There are two cases.

Case 1: At t=k+1, a vertex v^* is deleted from $W(t)$

In this case initially $I_{\text{alg}}(t) = I_{\text{alg}}(t-1) \setminus \{v^*\}$. Then the subroutine Greedy-Addition tries to add a new vertex to $I_{\text{alg}}(t)$. If $\frac{|W(t)|}{|I_{\text{alg}}(t)|} \leqslant c \cdot d$ before Greedy-Addition is initiated then we are done. Else by the arguments above, we know that if $|I_{\text{alg}}| < \frac{|W(t)|}{c \cdot d}$ then the subroutine Greedy-Addition can always add a vertex. In that case $|I_{\text{alg}}(t)| \geqslant |I_{\text{alg}}(t-1)|$ and $|W(t)| = |W(t-1)| - 1$, so $\frac{|W(t)|}{|I_{\text{alg}}(t)|} \leqslant \frac{|W(t-1)|}{|I_{\text{alg}}(t-1)|} \leqslant c \cdot d$ by induction.

Case 2: At t=k+1, a vertex v^* is added to $W(t)$

If $\frac{|W(t)|}{|I_{\text{alg}}(t)|} \leqslant c \cdot d$ before Greedy-Addition is initiated then we are done. Else we know that if $|I_{\text{alg}}| < \frac{|W(t)|}{c \cdot d}$ then the subroutine Greedy-Addition can always add a vertex. In that case $|I_{\text{alg}}(t)| = |I_{\text{alg}}(t-1)| + 1$ and $|W(t)| = |W(t-1)| + 1$, so $\frac{|W(t)|}{|I_{\text{alg}}(t)|} \leqslant \frac{|W(t-1)|}{|I_{\text{alg}}(t-1)|} \leqslant c \cdot d$ by induction. ◀

▶ **Theorem 20.** *There is a 2-stable $O(d)$-approximation algorithm for* Independent Set *in the vertex-arrival model where the average degree of $G(t)$ is bounded by d at all times.*

Proof. We know that the size of the maximum independent set at time t is trivially bounded by $|V(t)|$. Now by Lemmas 18 and 19, we have,

$$\frac{|V(t)|}{|I_{\text{alg}}(t)|} \leqslant \frac{1010}{485} \frac{|W(t)|}{|I_{\text{alg}}(t)|} \leqslant \frac{1010}{485} \cdot c \cdot d$$

Hence the algorithm set-achieve-and-use-target is an $O(d)$ approximation. Also observe that the maximum number of changes to $I_{\text{alg}}(t)$ occurs when there is a induced deletion of a single vertex due to the deletion of a vertex from $W(t)$ and then adding a vertex during the execution of the subroutine algorithm Greedy-Addition. So clearly the stabilty of the algorithm set-achieve-and-use-target is bounded by 2. ◀

5 Concluding remarks

We studied the stability of dynamic algorithms for DOMINATING SET and INDEPENDENT SET in the vertex-arrival model. For both problems we showed that a SAS does not exist. For INDEPENDENT SET this even holds when the degrees of all vertices are bounded by 3 at all times. This is clearly tight, since a SAS is easily obtained on graphs of maximum degree 2. For DOMINATING SET the no-SAS result holds for degree-4 graphs. A challenging open problem is whether a SAS exists for DOMINATING SET for degree-3 graphs. We also gave algorithms whose approximation ratio and/or stability depends on the (arrival or average) degree. An interesting open problem here is: Is there a 1-stable $O(d)$-approximation algorithm for DOMINATING SET, when the arrival degree is at most d? Finally, we believe the concept of stability for dynamic algorithms, which purely focuses on the change in the solution (rather than computation time) is interesting to explore for other problems as well.

A Lower-bound example for Directed-DomSet

Fig. 2 shows that the Directed-DomSet has approximation ratio $\Omega(d^2)$. First, vertex a_1 arrives, which will be put into U and D_{alg}. Then a_2 and $v_1, \dots, v_{d^2}$ arrive, with an outgoing edge to a_1. These vertices are dominated by a_1, so U and D_{alg} are not modified. Next, $w_1, \dots, w_d$ arrive. Vertex w_1 arrives with neighbors $v_1, \dots, v_d$. We have $U = D_{\text{alg}} = \{a_1\}$, so w_1 is not dominated by any node in D_{alg} and it is not related to any node in D_{alg}. Hence, w_1 will be put into U and D_{alg}. Then vertex w_2 arrives with neighbors $v_{d+1}, \dots, v_{2d}$. We have $U = D_{\text{alg}} = \{a_1, w_1\}$, so w_1 is not dominated by any node in D_{alg} and it is not related to any node in D_{alg}. Hence, w_2 will be put into U and D_{alg}. Similarly, $w_3, \dots, w_d$ will all be put into U and D_{alg}. Then $x_1, \dots, x_{d(d-1}$ arrive, each with one outgoing edge, to a unique node among $v_1, \dots, v_{d^2}$, as shown in the figure. They are all related to a node in U, namely one of the w_i's, so their out-neighbors will be out into D_{alg}. Finally, z arrives, which is also put into D_{alg}. Hence, at the end of the algorithm $|D_{\text{alg}}| = d^2 + 2$, but $\text{OPT} = 3$ since $\{a_1, a_2, z\}$ is a dominating set.

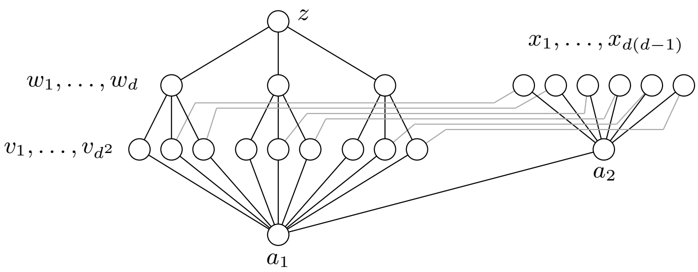

Figure 2 Example showing that DIRECTED-DOMSET has approximation ratio $\Omega(d^2)$.

Scalable Auction Algorithms for Bipartite Maximum Matching Problems

Quanquan C. Liu

Samir Khuller
Northwestern University, Evanston, IL, USA

Abstract

Bipartite maximum matching and its variants are well-studied problems under various models of computation with the vast majority of approaches centering around various methods to find and eliminate augmenting paths. Beginning with the seminal papers of Demange, Gale and Sotomayor [DGS86] and Bertsekas [Ber81], bipartite maximum matching problems have also been studied in the context of *auction algorithms*. These algorithms model the maximum matching problem as an auction where one side of the bipartite graph consists of bidders and the other side consists of items; as such, these algorithms offer a very different approach to solving this problem that do not use classical methods. Dobzinski, Nisan and Oren [DNO14] demonstrated the utility of such algorithms in distributed, interactive settings by providing a simple and elegant $O(\log n/\varepsilon^2)$ round *maximum cardinality bipartite matching (MCM)* algorithm that has small round and communication complexity and gives a $(1-\varepsilon)$-approximation for any (not necessarily constant) $\varepsilon > 0$. They leave as an open problem whether an auction algorithm, with similar guarantees, can be found for the *maximum weighted bipartite matching (MWM)* problem. Very recently, Assadi, Liu, and Tarjan [ALT21] extended the utility of auction algorithms for MCM into the semi-streaming and massively parallel computation (MPC) models, by cleverly using maximal matching as a subroutine, to give a new auction algorithm that uses $O(1/\varepsilon^2)$ rounds and achieves the state-of-the-art bipartite MCM results in the streaming and MPC settings.

In this paper, we give new auction algorithms for maximum weighted bipartite matching (MWM) and maximum cardinality bipartite b-matching (MCbM). Our algorithms run in $O\left(\log n/\varepsilon^8\right)$ and $O\left(\log n/\varepsilon^2\right)$ rounds, respectively, in the distributed setting. We show that our MWM algorithm can be implemented in the distributed, interactive setting using $O(\log^2 n)$ and $O(\log n)$ bit messages, respectively, directly answering the open question posed by Demange, Gale and Sotomayor [DNO14]. Furthermore, we implement our algorithms in a variety of other models including the the semi-streaming model, the shared-memory work-depth model, and the massively parallel computation model. Our semi-streaming MWM algorithm uses $O(1/\varepsilon^8)$ passes in $O(n \log n \cdot \log(1/\varepsilon))$ space and our MCbM algorithm runs in $O(1/\varepsilon^2)$ passes using $O\left(\left(\sum_{i\in L} b_i + |R|\right)\log(1/\varepsilon)\right)$ space (where parameters b_i represent the degree constraints on the b-matching and L and R represent the left and right side of the bipartite graph, respectively). Both of these algorithms improves *exponentially* the dependence on ε in the space complexity in the semi-streaming model against the best-known algorithms for these problems, in addition to improvements in round complexity for MCbM. Finally, our algorithms eliminate the large polylogarithmic dependence on n in depth and number of rounds in the work-depth and massively parallel computation models, respectively, improving on previous results which have large polylogarithmic dependence on n (and exponential dependence on ε in the MPC model).

1 Introduction

One of the most basic problems in combinatorial optimization is that of bipartite matching. This central problem has been studied extensively in many fields including operations research, economics, and computer science and is the cornerstone of many algorithm design courses and books. There is an abundance of existing classical and recent theoretical work on this topic [25, 12, 13, 19, 20, 27, 29, 30, 6, 11, 31]. Bipartite maximum matching and its variants are commonly taught in undergraduate algorithms courses and are so prominent to be featured regularly in competitive programming contests. In both of these settings, the main algorithmic solutions for maximum cardinality matching (MCM) and its closely related problems of maximum weight matching (MWM) are the Hungarian method using augmenting paths and reductions to maximum flow. Although foundational, such approaches are sometimes difficult to generalize to obtain efficient solutions in other *scalable models of computation*, e.g. distributed, streaming, and parallel models.

Although somewhat less popularly known, the elegant and extremely simple *auction-based maximum cardinality and maximum weighted matching algorithms* of Demange, Gale, and Sotomayor [10] and Bertsekas [8] solve the maximum cardinality/weighted matching problems in bipartite graphs. Their MCM auction algorithms denote vertices on one side of the bipartite input as *bidders* and the other side as *items*. Bidders are maintained in a queue and while the queue is not empty, the first bidder from the queue *bids* on an item with minimum price (breaking ties arbitrarily) from its neighbors. This bidder becomes the new owner of the item. Each time an item is reassigned to a new bidder, its price increases by some (not necessarily constant) $\varepsilon > 0$. If the assigned item still has price less than 1, the bidder is added again to the end of the queue. Setting $\varepsilon = \frac{1}{n+1}$ results in an algorithm that gives an exact maximum cardinality matching in $O(mn)$ time, where m and n refer to the number of edges and vertices respectively. Such an algorithm intuitively takes advantage of the fact that bidders prefer items in low demand (smaller price); naturally, such items should also be matched in a maximum cardinality matching.

One of the bottlenecks in the original auction algorithm is the need to maintain bidders in a queue from which they are selected, one at a time, to bid on items. Such a bottleneck is a key roadblock to the scalability of such algorithms. More recently, Dobzinski, Nisan, and Oren [11] extended this algorithm to the approximation setting for any (not necessarily constant) $\varepsilon > 0$. They give a simple and elegant randomized $(1 - \varepsilon)$-approximation algorithm for bipartite MCM in $O\left(\frac{\log n}{\varepsilon^2}\right)$ rounds of communication for any $\varepsilon > 0$. Furthermore, they illustrate an additional advantage for this algorithm beyond its simplicity. They show that in a distributed, interactive, blackboard setting, their auction MCM multi-round interactive algorithm uses less communication bits than traditional algorithms for this problem. This interactive setting is modeled via simultaneous communication protocols where agents simultaneously send a single message in each round to a central coordinator and some state is computed by the central coordinator after each round of communication. The goal in this model is to limit the total number of bits sent in all of the agents' messages throughout the duration of the algorithm. They leave as an open question whether an interactive, approximation auction algorithm that uses approximately the same number of rounds and bits of communication can be found for the maximum *weighted* bipartite matching problem.

Such an approach led to the recent simple and elegant paper of Assadi, Liu, and Tarjan [6] that adapted their algorithm to the semi-streaming setting and removed the $\log n$ factor in the semi-streaming setting from the number of passes to give an algorithm that finds an $(1-\varepsilon)$-approximate maximum cardinality matching in $O\left(1/\varepsilon^2\right)$ passes, where in each pass a maximal matching is found. Furthermore, they showed implementations of their algorithm in the massively parallel computation (MPC) model, achieving the best-known bounds in both of these settings. In this paper, we extend their algorithm to other variants of the problem on bipartite graphs, including maximum weight matching and maximum cardinality b-matching and achieve novel improvements in a variety of *scalable models*. The maximum cardinality b-matching problem (MCbM) is a well-studied generalization of MCM. In MCbM, each vertex is given an integer budget b_v where each vertex can be matched to at most b_v of their neighbors; a matching of maximum cardinality contains the maximum possible number of edges in the matching. The b-matching problem generalizes a number of real-life allocation problems such as server to client request serving, medical school residency matching, ad allocation, and many others. Although the problem is similar to MCM, often obtaining efficient algorithms for this problem requires non-trivial additional insights. As indicated in Ghaffari et al [16] b-matching problems can be considerably harder than matching.

Summary of Results. In this paper, we specifically give the following results. Our auction algorithms and their analyses are described in detail in Section 3 and Section 4.

▶ **Theorem 1** (Maximum Weight Bipartite Matching). *There exists an auction algorithm for maximum weight bipartite matching (MWM) that gives a $(1-\varepsilon)$-approximation for any $\varepsilon > 0$ and runs in $O\left(\frac{\log n \cdot \log(1/\varepsilon)}{\varepsilon^8}\right)$ rounds of communication (with high probability) and with $O\left(\log^2 n\right)$ bits per message. This algorithm can be implemented in the multi-round, semi-streaming model using $O\left(n \cdot \log n \cdot \log(1/\varepsilon)\right)$ space and $O\left(\frac{\log(1/\varepsilon)}{\varepsilon^7}\right)$ passes. This algorithm can be implemented in the work-depth model in $O\left(\frac{m \cdot \log(1/\varepsilon)}{\varepsilon^6}\right)$ work and $O\left(\frac{\log n \cdot \log(1/\varepsilon)}{\varepsilon^8}\right)$ depth. Finally, our algorithm can be implemented in the MPC model using $O(\log(1/\varepsilon)/\varepsilon^7)$ rounds, $O(n)$ space per machine, and $O\left(\frac{m \log(1/\varepsilon) \log n}{\varepsilon}\right)$ total space.*

The best-known algorithms in the semi-streaming model for the maximum weight bipartite matching problem are the $(1/\varepsilon)^{O(1/\varepsilon^2)}$ pass, $O\left(n \operatorname{poly}(\log(n)) \operatorname{poly}(1/\varepsilon)\right)$ space algorithm of Gamlath et al. [15] and the $O\left(\frac{\log(1/\varepsilon)}{\varepsilon^2}\right)$ pass, $O\left(\frac{n \log n}{\varepsilon^2}\right)$ space algorithm of Ahn and Guha [1]. To the best of our knowledge, our result is the first to achieve sub-polynomial dependence on $1/\varepsilon$ in the space for the MWM problem in the semi-streaming model. Thus, we improve the space bound exponentially compared to the previously best-known algorithms in the streaming model. The best-known algorithms in the distributed and work-depth models required $\operatorname{poly}(\log n)$ in the number of rounds and depth, respectively [21]; in the MPC setting, the best previously known algorithms have exponential dependence on ε [15]. We eliminate such dependencies in our paper and our algorithm is also simpler. A summary of previous results and our results can be found in Table 1.

▶ **Theorem 2** (Maximum Cardinality Bipartite b-Matching). *There exists an auction algorithm for maximum cardinality bipartite b-matching (MCbM) that gives a $(1-\varepsilon)$-approximation for any $\varepsilon > 0$ and runs in $O\left(\frac{\log n}{\varepsilon^2}\right)$ rounds of communication. This algorithm can be implemented in the multi-round, semi-streaming model using $O\left(\left(\sum_{i\in L} b_i + |R|\right)\log(1/\varepsilon)\right)$ space and $O\left(\frac{1}{\varepsilon^2}\right)$ passes. Our algorithm can be implemented in the shared-memory work-depth model in $O\left(\frac{\log^3 n}{\varepsilon^2}\right)$ depth and $O\left(\frac{m \log n}{\varepsilon^2}\right)$ total work.*

The best-known algorithms for maximum cardinality bipartite b-matching in the semi-streaming model is the $O\left(\frac{\log n}{\varepsilon^3}\right)$ pass, $\widetilde{O}\left(\frac{\sum_{i \in L \cup R} b_i}{\varepsilon^3}\right)$ space algorithm of Ahn and Guha [1]. In the general, non-bipartite setting (a harder setting than what we consider), a very recent $(1-\varepsilon)$-approximation algorithm of Ghaffari, Grunau, and Mitrović [16] runs in $\exp\left(2^{O(1/\varepsilon)}\right)$ passes and $\widetilde{O}\left(\sum_{i \in L \cup R} b_i + \text{poly}(1/\varepsilon)\right)$ space. Here, we also improve the space exponentially in $1/\varepsilon$ and, in addition, improve the number of passes by an $O(\log n)$ factor. More details comparing our results to other related works are given in Section 1.1. Due to the space constraints, most proofs in the following sections are deferred to the full version of our paper. Our results as well as comparisons with previous work are given in Table 1.

Table 1 We assume the ratio between the largest weight edge and smallest weight edge in the graph is $\text{poly}(n)$. Results for general graphs are labeled with (general); results that are specifically for bipartite graphs do not have a label. Upper bounds are given in terms of $O(\cdot)$ and lower bounds are given in terms of $\Omega(\cdot)$. "Space p.m." stands for space per machine. The complexity measures for the "blackboard distributed" setting is the total communication (over all rounds and players) in bits.

Concurrent, Independent Work. In concurrent, independent work, Zheng and Henzinger [34] study the maximum weighted matching problem in the sequential and dynamic settings using auction-based algorithms. Their simple and elegant algorithm makes use of a sorted list of items (by utility) for each bidder and then matches the bidders one by one individually (in round-robin order) to their highest utility item. They also extend their algorithm to give dynamic results. Due to the sequential nature of their matching procedure, they do not provide any results in scalable models such as the streaming, MPC, parallel, or distributed models.

1.1 Other Related Works

There has been no shortage of work done on bipartite matching. In addition to the works we discussed in the introduction, there has been a number of other relevant works in this general area of research. Here we discuss the additional works not discussed in Section 1. These include a plethora of results for $(1-\varepsilon)$-approximate maximum cardinality matching as well as some additional results for MWM and b-matching. Most of these works use various methods to find augmenting paths with only a few works focusing on auction-based techniques. We hope that our paper further demonstrates the utility of auction-based approaches in this setting and will lead to additional works in this area in the future. Although our work focuses on the bipartite matching problem, we also provide the best-known bounds for the matching problem on general graphs here, although this is a harder problem than our setting. We separate these results into the bipartite matching results, the general matching results, and lower bounds.

General Matching. A number of works have considered MCM in the streaming setting, providing state-of-the-art bounds in this setting. Fischer et al. [14] gave a deterministic $(1-\varepsilon)$-approximate MWM algorithm in general graphs in the semi-streaming model that uses $\text{poly}(1/\varepsilon)$ passes, improving exponentially on the number of passes of Lotker et al. [28]. Very recently, Assadi et al. [4] provided a semi-streaming algorithm in optimal $O(n)$ space and $O(\log n \log(1/\varepsilon)/\varepsilon)$ passes. They also provide a MWM algorithm that also runs in $O(n)$ space but requires $\widetilde{\Omega}(n/\varepsilon)$ passes. Please refer to these papers and references therein for older results in this area. Ahn and Guha [2] also considered the general weighted non-bipartite maximum matching problem in the semi-streaming model and utilize linear programming approaches for computing a $(2/3-\varepsilon)$-approximation and $(1-\varepsilon)$-approximation that uses $O(\log(1/\varepsilon)/\varepsilon^2)$ passes, $O\left(n \cdot \left(\frac{\log(1/\varepsilon)}{\varepsilon^2} + \frac{\log n/\varepsilon}{\varepsilon}\right)\right)$ space, and $O\left(\frac{\log n}{\varepsilon^4}\right)$ passes, $O\left(\frac{n\log n}{\varepsilon^4}\right)$ space, respectively.

Bipartite Matching. Ahn and Guha [2] also extended their results to the bipartite MWM and b-Matching settings with small changes. Specifically, in the MWM setting, they give a $O(\log(1/\varepsilon)/\varepsilon^2)$ pass, $O(n\cdot((\log(1/\varepsilon))/\varepsilon^2 + (\log n/\varepsilon)/\varepsilon))$ space algorithm. For maximum cardinality b-matching, they give a $O(\log n/\varepsilon^3)$ pass and $\widetilde{O}\left(\frac{\sum_{i\in L\cup R} b_i}{\varepsilon^3}\right)$ space algorithm. For exact bipartite MWM in the semi-streaming model, Liu et al. [26] gave the first streaming algorithm to break the n-pass barrier in the exact setting; it uses $\tilde{O}(n)$ space and $\tilde{O}(\sqrt{m})$ passes using interior point methods, SDD system solvers, and various other techniques to output the optimal matching with high probability. Work on bipartite MWM prior to [26] either required $\Omega(n\log n)$ passes[22] or only found approximate solutions [1, 2, 23].

Lower Bounds. Several papers have looked at matching problems from the lower bound side. Konrad et al. [24] considered the communication complexity of graph problems in a blackboard model of computation (for which the simultaneous message passing model of Dobzinski et al. [11] is a special variant). Specifically, they show that any non-trivial graph problem on n vertices require $\Omega(n)$ bits [24] in communication complexity. In a similar model called the *demand query model*, Nisan [32] showed that any *deterministic* algorithm that runs in $n^{o(1)}$ rounds where in each round at most $n^{1.99}$ demand queries are made, cannot find a MCM within a $n^{o(1)}$ factor of the optimum. This is in contrast to *randomized* algorithms which can make such an approximation using only $O(\log n)$ rounds. For streaming matching algorithms, Assadi [3] provided a conditional lower bound ruling out the possibilities of small constant factor approximations for two-pass streaming algorithms that solve the MCM problem. Such a lower bound also necessarily extends to MWM and MCbM. Goel et al. [17] provided a $n^{1+\Omega(1/\log\log n)}$ lower bound for the one-round message complexity of bipartite $(2/3+\varepsilon)$-approximate MCM (this also naturally extends to a space lower bound). For older papers on these lower bounds, please refer to references cited within each of the aforementioned cited papers. Finally, Assadi et al. [5] showed that any streaming algorithm that approximates MCM requires either $n^{\Omega(1)}$ space or $\Omega(\log(1/\varepsilon))$ passes.

Unweighted to Weighted Matching Transformations. Current transformations for transforming unweighted to weighted matchings all either:

- lose a factor of 2 in the approximation factor [18, 33], or
- increase the running time of the algorithm by an exponential factor in terms of $1/\varepsilon$, specifically, a factor of $\varepsilon^{-O(1/\varepsilon)}$ [7].

Thus, we cannot use such default transformations from unweighted matchings to weighted matchings in our setting since all of the complexity measures in this paper have only *polynomial* dependence on ε and all guarantee $(1-\varepsilon)$-approximate matchings. However, we do make use of *weighted to weighted matching transformations* provided our original weighted matching algorithms have only *polylogarithmic* dependence on the maximum ratio between edge weights in the graph. Such transformations from weighted to weighted matchings do not increase the approximation factor and also allows us to *eliminate the polylogarithmic dependence on the maximum ratio of edge weights.*

2 Preliminaries

This paper presents algorithms for bipartite matching under various settings. The input consists of a bipartite graph $G = (L \cup R, E)$. We denote the set of neighbors of any $i \in L, j \in R$ by $N(i), N(j)$, respectively. We present $(1-\varepsilon)$-approximation algorithms where $\varepsilon \in (0, 1)$ is our approximation parameter. All notations used in all of our algorithms in this paper are given in Table 2. The specified weight of an edge (i, j) will become the valuation of the bidder i for item j. Due to space constraints, we defer most of our proofs to the full version of our paper.

2.1 Scalable Model Definitions

In addition, we consider a number of scalable models in our paper including the ***blackboard distributed*** model, the ***semi-streaming*** model, the ***massively parallel computation (MPC)*** model, and the ***parallel shared-memory work-depth*** model.

Blackboard distributed model. We use the blackboard distributed model as defined in [11]. There are n *players*, one for each vertex of the left side of our bipartite graph (we assume wlog that the left side of the graph contains more vertices). The players engage in a fixed communication protocol using messages sent to a central coordinator. In other words, players write on a common "blackboard." Each players can receive a (not necessarily identical) message in each round from the coordinator. Players communicate using *rounds* of communication where in each round the player sends a message (of some number of bits) to the central coordinator. In every round, players choose to send messages depending solely on the contents of the blackboard and their private information. Termination of the algorithm and the final matching are determined by the central coordinator and the contents of the blackboard. The measure of complexity is the number of rounds of the algorithm and the message size sent by each player in each round. One can also measure the total number of bits send by all messages by multiplying the two.

Table 2 Table of Notations.

Symbol	Meaning
ε	approximation parameter
L, R	bidders, items, resp. WLOG $\lvert L\rvert \leq \lvert R\rvert$
i, j, i', j'	$i \in L, j \in R, i' \in L', j' \in R'$, i' (resp. j') indicates copy of i (resp. j)
p_j	current price of item j
D_i	demand set of bidder i
(i, a_i)	bidder $i \in L$ and currently matched item a_i
o_i	the item matched to bidder i in OPT
u_i	the utility of bidder i which is calculated by $1 - p_{a_i}$
$v_i(j)$	the valuation of bidder i for item j, i.e. the weight of edge (i, j)
C_i, C_j	copies of bidder $i \in L$, copies of item $j \in R$, resp.
L', R'	$L' = \bigcup_{i \in L} C_i$, $R' = \bigcup_{j \in R} C_j$
E', G'	$E' = \{(i^{(k)}, j^{(l)}) \mid (i, j) \in E, k \in [b_i], l \in [b_j]\}$, $G' = (L' \cup R', E')$
$c_{i'}$	price cutoff for bidder i'
N	ratio of the maximum weighted edge over the minimum weighted edge
v_i	the valuation function for bidder i
G_d	induced subgraph consisting of $(\cup_{i \in L} D_i) \cup L$
$\widehat{M}_d$	a non-duplicate maximal matching in G'_d
M'_d, M_d	produced matching in G', corresponding matching in G, resp.
$M_{\max}$	matching with largest cardinality produced

Semi-streaming model. In this paper, we use the semi-streaming model with arbitrary ordered edge insertions. Edges are arbitrarily (potentially adversarially) ordered in the stream. For this paper, we only consider insertion-only streams. The space usage for semi-streaming algorithms is bounded by $\widetilde{O}(n)$. The relevant complexity measures in this model are the number of passes of the algorithm and the space used.

Massively parallel computation (MPC) model. The massively parallel computation (MPC) model is a distributed model where different machines communicate with each other via a communication network. There are M machines, each with S space, and these machines communicate with each using Q rounds of communication. The initial graph is given in terms of edges and edges are partitioned arbitrarily across the machines. The relevant complexity measures are the total space usage $(M \cdot S)$, space per machine S, and number of rounds of communication Q.

Parallel shared-memory work-depth model. The parallal shared-memory work-depth model is a parallel model where different processors can process instructures in parallel and read and write from the same shared-memory. The relevant complexity measures for an algorithm in this model are the *work* which is the total amount of computation performed by the algorithm and the *depth* which is the longest chain of sequential dependencies in the algorithm.

3 An Auction Algorithm for $(1 - \varepsilon)$-Approximate Maximum Weighted Bipartite Matching

We present the following auction algorithm for maximum (weighted) bipartite matching (MWM) that is a generalization of the simple and elegant algorithm of Assadi et al. [6] to the weighted setting. Our generalization requires several novel proof techniques and recovers the round guarantee of Assadi et al. [6] in the maximum cardinality matching setting when the weights of all edges are 1. Furthermore, we answer an open question posed by Dobzinski et al. [11] for developing a $(1-\varepsilon)$-approximation auction algorithm for maximum *weighted* bipartite matching for which no prior algorithms are known. Throughout this section, we denote the maximum ratio between two edge weights in the graph by R. Our algorithm can also be easily extended into algorithms in various scalable models:

- a semi-streaming algorithm which uses $O\left(n \cdot \log n \cdot \log(1/\varepsilon)\right)$ space (the number of vertices in the bipartite graph) and which requires $O(\log(1/\varepsilon)/\varepsilon^7)$ rounds,
- a shared-memory parallel algorithm using $O\left(\frac{n \log n}{\varepsilon^9}\right)$ work and $O\left(\frac{1}{\varepsilon^8}\right)$ depth, and
- an MPC algorithm using $O(\log(1/\varepsilon)/\varepsilon^7)$ rounds, $O(n)$ space per machine, and $O\left(\frac{n \log n}{\varepsilon}\right)$ total space.

In contrast, the best-known semi-streaming MWM algorithm of Ahn and Guha [1] requires $\widetilde{O}(\log(1/\varepsilon)/\varepsilon^2)$ passes and $\widetilde{O}\left(\frac{n \log n}{\varepsilon^2}\right)$ space. Our paper shows a $\widetilde{O}(1/\varepsilon^5)$ round algorithm that instead uses $O(n \log(1/\varepsilon))$ space. Since $\varepsilon = \Omega(1/n)$ (or otherwise we obtain an exact maximum weight matching), our algorithm works in the semi-streaming model for all possible values of ε whereas Ahn and Guha [1] no longer works in semi-streaming when ε is small enough.

Our algorithm follows the general framework given in [6]. However, both our algorithm and our analysis require additional techniques. The main hurdle we must overcome is the fact that the weights may be much *larger* than the number of bidders and items. In that case, if we use the MCM algorithm trivially in this setting, the number of rounds can be very large, proportional to $\frac{w_{\max}}{\varepsilon^2}$ where $w_{\max}$ is the maximum weight of the edge. We avoid this problem in our algorithm, instead obtaining only poly $\log n$ and ε dependence in the number of rounds. Our main result in this section is the following (recall from Section 1).

▶ **Theorem 1** (Maximum Weight Bipartite Matching). *There exists an auction algorithm for maximum weight bipartite matching (MWM) that gives a $(1-\varepsilon)$-approximation for any $\varepsilon > 0$ and runs in $O\left(\frac{\log n \cdot \log(1/\varepsilon)}{\varepsilon^8}\right)$ rounds of communication (with high probability) and with $O\left(\log^2 n\right)$ bits per message. This algorithm can be implemented in the multi-round, semi-streaming model using $O\left(n \cdot \log n \cdot \log(1/\varepsilon)\right)$ space and $O\left(\frac{\log(1/\varepsilon)}{\varepsilon^7}\right)$ passes. This algorithm can be implemented in the work-depth model in $O\left(\frac{m \cdot \log(1/\varepsilon)}{\varepsilon^6}\right)$ work and $O\left(\frac{\log n \cdot \log(1/\varepsilon)}{\varepsilon^8}\right)$ depth. Finally, our algorithm can be implemented in the MPC model using $O(\log(1/\varepsilon)/\varepsilon^7)$ rounds, $O(n)$ space per machine, and $O\left(\frac{m \log(1/\varepsilon) \log n}{\varepsilon}\right)$ total space.*

Before we give our algorithm, we give some notation used in this section.

Notation. The input bipartite graphs is represented by $G = (L \cup R, E)$ where L is the set of bidders and R is the set of items. Let $N(v)$ denote the neighbors of node $v \in L \cup R$. We use the notation $i \in L$ to denote bidders and $j \in R$ to denote items. For a bidder $i \in L$, the *valuation* of i for items in R is defined as the function $v_i : R \to \mathbb{Z}_{\geq 0}$ where the function outputs a non-negative integer. If $v_i(j) > 0$, for any $j \in R$, then $j \in N(i)$. Each bidder can match to at most one item. We denote the bidder item pair by (i, a_i) where a_i is the matched item and $a_i = \perp$ if i is not matched to any item. For any agent i where $a_i \neq \perp$, the *utility* of a bidder i given its matched item a_i is $u_i \triangleq v_i(a_i) - p_{a_i}$ where p_{a_i} is the current price of item a_i. For an agent i where $a_i = \perp$, the utility of agent i is 0. We denote an optimum matching by OPT. We use the notation $i \in \text{OPT}$ to denote a bidder who is matched in OPT and o_i to denote the item matched to bidder i in OPT.

Input Specifications. In this section, we assume all weights are poly(n) where $n = |L| + |R|$. We additionally assume the following characteristics about our inputs because we can perform a simple pre-processing of our graph to satisfy these specifications. Provided an input graph $G = (L \cup R, E)$ with weights $v_i(j)$ for every edge $(i, j) \in E$, we find the maximum weight among all the weights of the edges, $w_{\max} = \max_{(i,j)\in E} (v_i(j))$. We rescale the weights of all the edges by $\frac{1}{w_{\max}}$ and remove all edges with rescaled weight $< \varepsilon^{\lceil \log_\varepsilon m \rceil + 1}$. This upper bound of $\varepsilon^{\lceil \log_\varepsilon m \rceil + 1}$ is crucial in our analysis.

In other words, we create a new graph $G' = (L \cup R, E')$ with the same set of bidders L and items R. We associate the new weight functions v'_i with each bidder $i \in L$ where $(i, j) \in E'$ if $v_i(j) \geq w_{\max} \cdot \varepsilon^{\lceil \log_\varepsilon m \rceil + 1}$ and $v'_i(j) = v_i(j)/w_{\max}$ for each $(i, j) \in E'$. Provided that finding the maximum weight edge can be done in $O(1)$ rounds in the blackboard distributed and MPC models, $O(1)$ passes in the streaming model, and $O(n + m)$ work and $O(1)$ depth in the parallel model, we assume the input to our algorithms is G' (instead of the original graph G). In other words, we assume all inputs $G = (V, E)$ to our algorithm have scaled edge weights and $v_i(j)$ for $i \in L, j \in R$ are functions that return the scaled edge weights in the rest of this section.

3.1 Detailed Algorithm

We now present our auction algorithm for maximum weighted bipartite matching in Algorithm 1. The algorithm works as follows. Recall that we also assume the input to our algorithm is the scaled graph. This means that the maximum weight of the scaled edges is 1 and there exists at least one edge with weight 1; hence, the maximum weight matching will have value at least 1. We also initialize the tuples that keep track of matched items. Initially, no items are assigned to bidders (Algorithm 1) and the prices of all items are set to 0 (Algorithm 1).

We perform $\lceil \frac{\log^2(N)}{\varepsilon^4} \rceil$ phases of bidding (Algorithm 1). In each phase, we form the *demand set* D_i of each unmatched bidder i. The demand set is defined to be the set of items with non-zero utility which have *approximately* the maximum utility value for bidder i (Algorithm 1). This procedure is different from both MCM and MCbM (where no slack is needed in creating the demand set) but we see in the analysis that we require this slack in the maximum utility value to ensure that enough progress is made in each round. Then, we create the induced subgraph consisting of all unmatched bidders and their demand sets (Algorithm 1). We find an arbitrary maximal matching in this created subgraph (Algorithm 1) by first finding the maximal matching in order of decreasing buckets (from highest – bucket with the largest weights – to lowest). This means that we call our maximal matching algorithm $O(\log(N))$ times first on the induced subgraph consisting of the highest bucket, removing the matches, and then on the induced subgraph of the remaining edges plus the next highest bucket, and so on. We use the folklore distributed maximal matching algorithm where in each round, a bidder uniformly-at-random picks a neighbor to match; this algorithm is also used in [11] for the maximal matching step. This simple algorithm terminates in $O(\log n)$ rounds with high probability using $O(\log n)$ communication complexity. Such randomization is necessary to obtain $O(\log n)$ rounds using $O(\log n)$ communication complexity.

We rematch items according to the new matching (Algorithm 1). We then increase the price of each rematched item. The price increase depends on the weight of the matched edge to the item; higher weight matched edges have larger increases in price than smaller weight edges. Specifically, the price is increased by $\varepsilon \cdot v_i(a_i)$ where $v_i(a_i)$ is the weight of the newly matched edge between i and a_i (Algorithm 1). The intuition behind this price increase is that we want to increase the price proportional to the weight gained from the matching since

Algorithm 1 Auction Algorithm for Maximum Weighted Bipartite Matching.

```
Input: A scaled graph $G = (L \cup R, E)$, parameter $0 < \varepsilon < 1$, and the scaling factor $w_{\max}$.
Output: An $(1-6\varepsilon)$-approximate maximum weight bipartite matching.
For each bidder $i \in L$, set $(i, a_i)$ to $a_i = \perp$.
For each item $j \in R$, set $p_j = 0$.
for $d = 1, \dots, \lceil \frac{\log^2(N)}{\varepsilon^4} \rceil$ do
    for each unmatched bidder $i \in L$ do
        Let $U_i \triangleq \max_{j \in N(i), v_i(j) - p_j > 0} (v_i(j) - p_j)$.
        Let $D_i \triangleq \{j \in R \mid p_j < v_i(j), v_i(j) - p_j \geq U_i - \varepsilon \cdot v_i(j)\}$.
    Create the subgraph $G_d$ as the subgraph consisting of $\left(\bigcup_{i \in L} D_i\right) \cup L$ and all edges.
    Find any arbitrary maximal matching $M_d$ of $G_d$ in order of highest bucket to lowest.
    for $(i, j) \in M_d$ do
        match $j$ to $i$ by setting $a_i = j$ and $a_{i'} = \perp$ for the previous owner $i'$ of $j$.
        Increase the price of $j$ to $p_j \leftarrow p_j + \varepsilon \cdot v_i(j)$.
    Let $M'$ be the matched edges in this current iteration.
Return the matching $M = \arg\max_{M'} \left(w_{\max} \cdot \sum_{i \in L} v_i(a_i)\right)$ as the approximate maximum
weight matching and $(i, a_i) \in M$ as the matched edges.
```

the price increase takes away from the overall utility of our matching. If not much weight is gained from the matching, then the price should not increase by much; otherwise, if a large amount of weight is gained from the matching, then we can afford to increase the price by a larger amount. We see later on in our analysis that this allows us to bucket the items according to their matched edge weight into $\lceil \log_{(1/\varepsilon)} m \rceil$ buckets. Such bucketing is useful in ensuring that we have sufficiently many happy bidders with a sufficiently large total matched weight. Finally, we return all matched items and bidders as our approximate matching and the sum of the weights of the matched items as the approximate weight. Obtaining the maximum weight of the matching in the original, unscaled graph is easy. We multiply the edge weights by $w_{\max}$ and the sum of these weights is the total weight of our approximate matching (Algorithm 1).

3.2 Analysis

In this section, we prove the approximation factor and round complexity of our algorithm. We use the same definition of happy that is defined in [6].

▶ **Definition 3** (ε-Happy [6]). *A bidder i is ε-happy if $u_i \geq v_i(j) - p_j - \varepsilon$ for every $j \in R$.*

▶ **Definition 4** (Unhappy). *A bidder i is **unhappy** at the end of round d if they are unmatched and their demand set is non-empty.*

Note that a happy bidder may never be unhappy and vice versa. For this definition, we assume that the demand set of a bidder can be computed at any point in time (not only when the Algorithm computers it).

Approach. The main challenge we face in our MWM analysis is that it is no longer sufficient to just show at least $(1-\varepsilon)$-fraction of bidders in OPT are happy in order to obtain the desired approximation. Consider this simple example. Suppose a given instance has an optimum solution OPT with six matched bidders where one bidder is matched to an item via a weight-1 edge. It also has five additional bidders matched to items via weight-$\frac{1}{\sqrt{n}}$ edges. Suppose we set $\varepsilon = 1/6$ to be a constant. Then, requiring 5/6-fraction of the bidders in OPT to be happy is not sufficient to get a 5/6-factor approximation. Suppose the five bidders matched with edges of weight $\frac{1}{\sqrt{n}}$ are the happy bidders. This is sufficient to satisfy the condition that 5/6-fraction of the bidders in OPT are happy. However, the total combined weight of the matching in this case is $\frac{5}{\sqrt{n}}$ while the weight of the optimum matching is $\left(1 + \frac{5}{\sqrt{n}}\right)$. The returned matching is then a $\frac{5}{\sqrt{n}}$-approximate MWM and for large n, this is much less than the desired 5/6-factor approximation.

Instead, we require a specific fraction of the total *weight* of the optimum solution, W_{OPT}, to be matched in our returned matching. We ensure this new requirement by considering two types of unhappy bidders. Type 1 unhappy bidders are bidders who are unhappy in round $k-1$ and remain unmatched in round k. Type 2 unhappy bidders are bidders who are unhappy in round $k-1$ and become matched in round k. We show that there exists a round where the following two conditions are satisfied:

1. We bucket the bidders in OPT according to the weight of their matched edge in OPT such that bidders matched with similar weight edges are in the same bucket; there exists a round where at most (ε^2)-fraction of the bidders in each bucket are Type 1 unhappy.
2. We charge the weight a Type 2 unhappy bidder obtains in round k to the bidder in round $k-1$; there exists a round $k-1$ where a total of at most $\varepsilon \cdot W_{\text{OPT}}$ weight is charged to Type 2 unhappy bidders.

Simultaneously satisfying both of the above conditions is enough to obtain our desired approximation. The rest of this section is devoted to showing our precise analysis using the above approach.

Detailed Analysis. Recall that we defined the utility of agent i to be the value of the item matched to her minus its price $u_i = v_i(a_i) - p_{a_i}$. In this section, we use the definition of ε-happy from Definition 3.

A similar observation to the observation made in [6] about the happiness of matched bidders can also be made in our case; however, since we are dealing with edge weights, we need to be careful to increment our prices in terms of the newly matched edge weight. In other words, two different bidders could be ε_1-happy and ε_2-happy after incrementing the price of their respective items by ε_1 and ε_2 where $\varepsilon_1 \neq \varepsilon_2$; the incremented prices ε_1 and ε_2 depend on the matched edge weights of the items assigned to the bidders. We prove the correct happiness guarantees given by our algorithm below.

▶ **Observation 5.** *At the end of every round, matched bidder i with matched edge (i, a_i) where a_i is priced at p_{a_i} are $(2\varepsilon \cdot v_i(a_i))$-happy. At the end of every round, unmatched bidders with empty demand sets D_i are ε-happy.*

For the weighted case, we need to consider what we call *weight buckets*. We define these weight buckets with respect to the optimum matching OPT. Recall our notation where $i \in \text{OPT}$ is a bidder who is matched in OPT and o_i is the matched item of the bidder in OPT. Bidder i is in the b-th weight bucket if $\varepsilon^{b-1} \leq v_i(o_i) < \varepsilon^{b-2}$.

▶ **Observation 6.** *All bidders $i \in OPT$ in bucket b satisfy $\varepsilon^{b-1} \leq v_i(o_i) < \varepsilon^{b-2}$.*

We now show that if a certain number of bidders in OPT are happy in our matching, then we obtain a matching with sufficiently large enough weight. However, our guarantee is somewhat more intricate than the guarantee provided in [6]. We show that in $\lceil \frac{\log^2(N)}{\varepsilon^4} \rceil$

rounds, there exists one round d where a set of sufficient conditions are satisfied to obtain our approximation guarantee. To do this, we introduce two types of unhappy bidders. Specifically, Type 1 and Type 2 unhappy bidders.

Each *unhappy* bidder results in some loss of total matched weight. However, at the end of round $k-1$ it is difficult to determine the exact amount of weight lost to unhappy bidders. Thus, in our analysis, we determine the amount of weight lost to unhappy bidders at the end of round $k-1$ in round k. The way that we determine the weight lost in round $k-1$ is by *retroactively* categorizing an unhappy bidder in round $k-1$ as a Type 1 or Type 2 unhappy bidder *depending on what happens in round* k. Thus, for our analysis, we categorize the bidders into categories of unhappy bidders for the *previous* round.

A ***Type* 1** unhappy bidder in round $k-1$ is a bidder i that remains unmatched at the end of round k. In other words, a Type 1 unhappy bidder was unhappy in round $k-1$ and either remains unhappy in round k or becomes happy because it does not have any demand items anymore (and remains unmatched). A ***Type* 2** unhappy bidder i in round $k-1$ is a bidder who was unhappy in round $k-1$ but is matched to an item in round k. Thus, a Type 2 unhappy bidder i in round $k-1$ becomes happy in round k because a new item is matched to i. Both types of bidders are crucial to our analysis given in the proof of Lemma 7 since they contribute differently to the potential amount of value that could be matched by our algorithm.

In the following lemma, let OPT be the optimum matching in graph G and $W_{\text{OPT}} = \sum_{i\in\text{OPT}} v_i(o_i)$. Let B_b be the set of bidders $i \in \text{OPT}$ in weight bucket b. If a Type 2 unhappy bidder i gets matched to a_i in round k, we say the weight $v_i(a_i)$ is ***charged*** to bidder i in round $k-1$. We denote this charged weight as $c_i(a_i)$ when performing calculations for round $k-1$.

▶ **Lemma 7.** *Provided $G = (L \cup R, E)$ and an optimum weighted matching OPT with weight $W_{OPT} = \sum_{i\in OPT} v_i(o_i)$, if in some round d of Algorithm 1 of Algorithm 1 both of the following are satisfied,*

1. *at most $\varepsilon^2 \cdot |B_b|$ of the bidders in each bucket b are Type 1 unhappy and*
2. *at most $\varepsilon \cdot W_{OPT}$ weight is charged to Type 2 unhappy bidders,*

then the matching in G has weight at least $(1-6\varepsilon)\cdot W_{OPT}$.

Proof. In such an iteration r, let Happy denote the set of all happy bidders. For any bidder $i \in \text{Happy} \cap \text{OPT}$, by Definition 3 and Observation 5, $u_i \geq v_i(o_i) - p_{o_i} - 2\varepsilon \cdot v_i(a_i)$ where o_i is the item matched to i in OPT and a_i is the item matched to i from our matching.

Before we go to the core of our analysis, we first make the observation that we can, in general, disregard prices of the items in our analysis. Let M be our matching. The sum of the utility of every matched bidder in our matching can be upper and lower bounded by the following expression:

$$\sum_{i\in M} (v_i(a_i) - p_{a_i}) \geq \sum_{i\in\text{OPT}\cap\text{Happy}} u_i \geq \sum_{i\in\text{OPT}\cap\text{Happy}} (v_i(o_i) - p_{o_i} - 2\varepsilon \cdot v_i(a_i)).$$

As in the maximum cardinality matching case, all items with non-zero price are matched to a bidder. We can then simplify the above expression to give

$$\sum_{i\in M} v_i(a_i) - \sum_{j\in R} p_j \geq \sum_{i\in \mathrm{OPT}\cap\textsc{Happy}} v_i(o_i) - \sum_{i\in \mathrm{OPT}\cap\textsc{Happy}} p_{o_i} - \sum_{i\in \mathrm{OPT}\cap\textsc{Happy}} 2\varepsilon\cdot v_i(a_i) \tag{1}$$

$$\sum_{i\in M\setminus(\mathrm{OPT}\cap\textsc{Happy})} v_i(a_i) + \sum_{i\in \mathrm{OPT}\cap\textsc{Happy}} (1+2\varepsilon)v_i(a_i) - \sum_{j\notin\{o_i \mid i\in \mathrm{OPT}\cap\textsc{Happy}\}} p_j \geq \sum_{i\in \mathrm{OPT}\cap\textsc{Happy}} v_i(o_i) \tag{2}$$

$$\sum_{i\in M}(1+2\varepsilon)v_i(a_i) - \sum_{j\notin\{o_i \mid i\in \mathrm{OPT}\cap\textsc{Happy}\}} p_j \geq \sum_{i\in \mathrm{OPT}\cap\textsc{Happy}} v_i(o_i). \tag{3}$$

Equation (1) follows from the fact that all non-zero priced items are matched. Equation (2) follows from separating $\mathrm{OPT}\cap\textsc{Happy}$ from the left hand side and moving the summation of the $2\varepsilon\cdot v_i(a_i)$ values over $\mathrm{OPT}\cap\textsc{Happy}$ from the right hand side to the left hand side. Finally, Equation (3) follows because $\sum_{i\in M}(1+2\varepsilon)v_i(a_i)$ upper bounds the left hand side expression for $\sum_{i\in M\setminus(\mathrm{OPT}\cap\textsc{Happy})} v_i(a_i) + \sum_{i\in\mathrm{OPT}\cap\textsc{Happy}}(1+2\varepsilon)v_i(a_i)$.

Let $\textsc{Unhappy}_1$ denote the set of Type 1 unhappy bidders and $\textsc{Unhappy}_2$ denote the set of Type 2 unhappy bidders. We let $c_i(a_i)$ be the weight charged to bidder i in $\textsc{Unhappy}_2$ in the next round. Recall that each bidder in $\textsc{Unhappy}_2$ is matched in the next round.

For each bucket, b, we can show the following using our assumption that at most $\varepsilon^2\cdot|B_b|$ of the bidders in bucket b are Type 1 unhappy,

$$\sum_{i\in B_b\cap\textsc{Happy}} v_i(o_i) \geq \sum_{i\in B_b\setminus\textsc{Unhappy}_2} v_i(o_i) - \varepsilon^2\cdot\varepsilon^{b-2}\cdot|B_b| \tag{4}$$

$$\geq \sum_{i\in B_b\setminus\textsc{Unhappy}_2} v_i(o_i) - \varepsilon\cdot\varepsilon^{b-1}\cdot|B_b| \tag{5}$$

$$\geq \sum_{i\in B_b\setminus\textsc{Unhappy}_2} v_i(o_i) - \sum_{i\in B_b}\varepsilon\cdot v_i(o_i). \tag{6}$$

Equation (4) shows that one can lower bound the sum of the optimum values of all happy bidders in bucket b by the sum of the optimum values of all bidders who are not Type-2 unhappy minus some factor. First, $\sum_{i\in B_b\setminus UNHAPPY_2} v_i(o_i)$ is the sum of the optimum values of all bidders in bucket b *except* for the Type-2 unhappy bidders. Now, we need to subtract the maximum sum of values given to the Type-1 unhappy bidders. We know that bucket b has at most $\varepsilon^2\cdot|B_b|$ Type-1 unhappy bidders. Each of these bidders could be assigned an optimum item with value at most ε^{b-2} (by Observation 6). Thus, the maximum value lost to Type-1 unhappy bidders is $\varepsilon^2\cdot\varepsilon^{b-2}\cdot|B_b|$, leading to Equation (4). Thus, the maximum value of weight lost to all Type 1 unhappy bidders in bucket b is $\varepsilon^2\cdot\varepsilon^{b-2}\cdot|B_b|$. Then, Equation (6) follows because $v_i(o_i)\geq\varepsilon^{b-1}$ for all $i\in B_b$. This means that $\sum_{i\in B_b} v_i(o_i)\geq\varepsilon^{b-1}\cdot|B_b|$.

Summing Equation (6) over all buckets b we obtain

$$\sum_{i\in \mathrm{OPT}\cap\textsc{Happy}} v_i(o_i) \geq \sum_{i\in \mathrm{OPT}\setminus\textsc{Unhappy}_2} v_i(o_i) - \sum_{i\in\mathrm{OPT}}\varepsilon\cdot v_i(o_i). \tag{7}$$

We now substitute our expression obtained in Equation (7) into Equation (3),

$$\sum_{i\in M}(1+2\varepsilon)v_i(a_i) - \sum_{j\notin\{o_i \mid i\in \mathrm{OPT}\cap\textsc{Happy}\}} p_j \geq \sum_{i\in \mathrm{OPT}\setminus\textsc{Unhappy}_2} v_i(o_i) - \sum_{i\in\mathrm{OPT}}\varepsilon\cdot v_i(o_i). \tag{8}$$

The last thing that we need to show is a bound on the weight lost due to bidders in $\text{OPT} \cap \textsc{Unhappy}_2$. We now consider our second assumption which states that at most $\varepsilon \cdot W_{\text{OPT}}$ weight is charged to Type 2 unhappy bidders. Since all bidders $i \in \textsc{Unhappy}_2$ become happy in the next round, we can bound the weights charged to the Type 2 unhappy bidders using Observation 5 by

$$\sum_{i \in \text{OPT} \cap \textsc{Unhappy}_2} c_i(a_i) \geq \sum_{i \in \text{OPT} \cap \textsc{Unhappy}_2} \left(v_i(o_i) - p_{o_i} - 2\varepsilon \cdot c_i(a_i)\right). \tag{9}$$

Note first that $\sum_{j \notin \{o_i \mid i \in \text{OPT} \cap \textsc{Happy}\}} p_j \geq \sum_{i \in \text{OPT} \cap \textsc{Unhappy}_2} p_{o_i}$ since $\text{OPT} \setminus (\text{OPT} \cap \textsc{Happy})$ includes $\text{OPT} \cap \textsc{Unhappy}_2$ so we can remove the prices from these bounds in Equation (10). We add Equation (9) to Equation (8) and use our assumptions to obtain

$$\sum_{i \in M} (1+2\varepsilon) v_i(a_i) + \sum_{i \in \text{OPT} \cap \textsc{Unhappy}_2} c_i(a_i) \geq \sum_{i \in \text{OPT}} (1-\varepsilon) \cdot v_i(o_i) - \sum_{i \in \text{OPT} \cap \textsc{Unhappy}_2} 2\varepsilon \cdot c_i(a_i) \tag{10}$$

$$\sum_{i \in M} (1+2\varepsilon) v_i(a_i) \geq \sum_{i \in \text{OPT}} (1-\varepsilon) \cdot v_i(o_i) - \sum_{i \in \text{OPT} \cap \textsc{Unhappy}_2} (1+2\varepsilon) \cdot c_i(a_i) \tag{11}$$

$$\geq \left(\sum_{i \in \text{OPT}} (1-\varepsilon) \cdot v_i(o_i) \right) - (1+2\varepsilon) \cdot \varepsilon \cdot W_{\text{OPT}} \tag{12}$$

$$\sum_{i \in M} v_i(a_i) \geq \frac{(1-4\varepsilon)}{(1+2\varepsilon)} \cdot \sum_{i \in \text{OPT}} v_i(o_i) \tag{13}$$

$$\sum_{i \in M} v_i(a_i) \geq (1-6\varepsilon) W_{\text{OPT}}. \tag{14}$$

Equation (10) follows from summing $\sum_{i \in \text{OPT}} (1-\varepsilon) \cdot v_i(o_i) = \sum_{i \in \text{OPT} \setminus \textsc{Unhappy}_2} v_i(o_i) + \sum_{i \in \text{OPT} \cap \textsc{Unhappy}_2} v_i(o_i) - \sum_{i \in \text{OPT}} \varepsilon \cdot v_i(o_i) = \sum_{i \in \text{OPT}} (1-\varepsilon) \cdot v_i(o_i)$. Equation (11) follows from moving $\sum_{i \in \text{OPT} \cap \textsc{Unhappy}_2} c_i(a_i)$ to the right hand side. Equation (12) follows from substituting our assumption that $\sum_{i \in \text{OPT} \cap \textsc{Unhappy}_2} c_i(a_i) \leq \varepsilon \cdot W_{\text{OPT}}$. Equation (13) follows from simple manipulations and since $W_{\text{OPT}} = \sum_{i \in \text{OPT}} v_i(o_i)$. Finally, Equation (14) follows because $\frac{(1-4\varepsilon)}{(1+2\varepsilon)} \geq (1-6\varepsilon)$ for all $\varepsilon > 0$ and gives the desired approximation given in the lemma statement. ◀

We show that the conditions of Lemma 7 are satisfied for at least one round if the algorithm is run for at least $\lceil \frac{\log^2(N)}{\varepsilon^4} \rceil$ rounds. We prove this using potential functions similar to the potential functions used for MCM. We first bound the maximum value of these potential functions.

▶ **Lemma 8.** *Define the potential function $\Phi_{items} \triangleq \sum_{j \in R} p_j$. Then the upper bound for this potential is $\Phi_{items} \leq W_{OPT}$.*

Proof. We show that the potential function Φ_{items} is always upper bounded by W_{OPT} via a simple proof by contradiction. Suppose that $\Phi_{items} > W_{\text{OPT}}$, then, we show that the matching obtained by our algorithm has weight greater than W_{OPT}, a contradiction. For a bidder/item pair, (i, a_i), the weight of edge (i, a_i) is at least $p_{a_i} - 2\varepsilon \cdot v_i(a_i)$. Let p'_{a_i} be the price of a_i before the last reassignment of a_i to i. Furthermore, since i picked a_i, it must mean that $v_i(a_i) > p'_{a_i}$ since a_i would not be included in D_i otherwise. This means that the sum of the weights of all the matched edges is at least $\sum_{(i,a_i)} v_i(a_i) > \sum_{(i,a_i)} p'_{a_i} \geq \Phi_{items} > W_{\text{OPT}}$ by our assumption that $\Phi_{items} > W_{\text{OPT}}$. Thus, we obtain that we get a matching with greater weight than the optimum weight matching, a contradiction. ◀

▶ **Lemma 9.** *There exists a phase $d \leq \frac{\log^2(N)}{\varepsilon^4}$ wherein* both *of the following statements are satisfied:*

1. *At most $\varepsilon^2 \cdot |B_b|$ bidders in bucket b are Type 1 unhappy for all buckets b;*
2. *The set of all Type 2 unhappy bidders results in a loss of less than $\varepsilon \cdot W_{OPT}$ weight (in charged weight) where W_{OPT} is the optimum weight attainable by the matching.*

Recall that we assign each bidder to a weight bucket using the weight assigned to the bidder in OPT.

Using the above lemmas, we can prove our main theorem that our algorithm gives a $(1-7\varepsilon)$-approximate maximum weight bipartite matching in $O\left(\frac{\log^3(N)\cdot\log(n)}{\varepsilon^4}\right)$ distributed rounds using $O(\log n)$ communication complexity.

▶ **Theorem 10.** *Algorithm 1 returns a $(1-7\varepsilon)$-approximate maximum weight bipartite matching M in $O\left(\frac{\log^3(N)\cdot\log n}{\varepsilon^4}\right)$ rounds whp using $O(\log n)$ bits of communication per message in the broadcast model.*

Reducing the Round Complexity. We can use the following transformation from Gupta-Peng [18] to reduce the round complexity at an increase in the communication complexity. For completeness, we give the theorem for the transformation the full version of our paper.

▶ **Theorem 11.** *There exists a $(1-\varepsilon)$-approximate distributed algorithm for maximum weight bipartite matching that runs in either:*

- *$O\left(\log n \cdot \frac{\log(1/\varepsilon)}{\varepsilon^7}\right)$ rounds of communication using $O\left(\frac{\log^2 n}{\varepsilon}\right)$ bits of communication, or*
- *$O\left(\log n \cdot \frac{\log(1/\varepsilon)}{\varepsilon^8}\right)$ rounds of communication using $O\left(\log^2 n\right)$ bits of communication*

where we assume the maximum ratio between weights of edges in the input graph is $\text{poly}(n)$. In the blackboard model, this requires a total of $O\left(\frac{n\log^3 n\log(1/\varepsilon)}{\varepsilon^8}\right)$ bits of communication.

3.3 Semi-Streaming Implementation

The implementation of this algorithm in the semi-streaming model is very similar to the implementation of the MCM algorithm of Assadi et al. [6].

▶ **Lemma 12.** *Given a weighted graph $G = (V, E)$ as input in an arbitrary edge-insertion stream where all weights are at most $\text{poly}(n)$, there exists a semi-streaming algorithm which uses $O\left(\frac{\log^2(N)}{\varepsilon^4}\right)$ passes and $O\left(n \cdot \log n \cdot \log(1/\varepsilon)\right)$ space that computes a $(1-\varepsilon)$-approximate maximum weight bipartite matching for any $\varepsilon > 0$.*

Reducing the Number of Passes. We use the transformation of [18] as stated the full version of our paper to eliminate our dependence on n within our number of rounds. The transformation is as follows. For each instance of $(1+\varepsilon)$-MWM, we maintain the prices in our algorithm for each of the nodes involved in each of the copies of our algorithm. When an edge arrives in the stream, we first partition it into the relevant level of the appropriate copy of the structure.

▶ **Theorem 13.** *There exists a $(1-\varepsilon)$-approximate streaming algorithm for maximum weight bipartite matching that uses $O\left(\frac{\log(1/\varepsilon)}{\varepsilon^7}\right)$ passes in $O\left(n \cdot \log n \cdot \log(1/\varepsilon)\right)$ space.*

3.4 Shared-Memory Parallel Implementation

The implementation of this algorithm in the shared-memory work-depth model follows almost directly from our auction algorithm. We show the following lemma when directly implementing our auction algorithm.

▶ **Lemma 14.** *Given a weighted graph $G = (V, E)$ as input where all weights are at most* $\mathrm{poly}(n)$*, there exists a shared-memory parallel algorithm which uses* $O\left(\frac{m\log^2 n}{\varepsilon^4}\right)$ *work and* $O\left(\frac{\log^4 n}{\varepsilon^4}\right)$ *depth that computes a* $(1-\varepsilon)$*-approximate maximum weight bipartite matching for any* $\varepsilon > 0$*.*

Using the transformations, we can reduce the number of rounds for our shared-memory parallel algorithms.

▶ **Theorem 15.** *Given a weighted graph $G = (V, E)$ as input where all weights are at most* $\mathrm{poly}(n)$*, there exists a shared-memory parallel algorithm which uses* $O\left(\frac{m\log(1/\varepsilon)}{\varepsilon^6}\right)$ *work and* $O\left(\frac{\log(n)\cdot\log(1/\varepsilon)}{\varepsilon^8}\right)$ *depth that computes a* $(1-\varepsilon)$*-approximate maximum weight bipartite matching for any* $\varepsilon > 0$*.*

3.5 MPC Implementation

We implement our auction algorithm in the MPC model below.

▶ **Lemma 16.** *Given a weighted graph $G = (V, E)$ as input where all weights are at most* $\mathrm{poly}(n)$*, there exists a MPC algorithm using* $O\left(\frac{\log^2(N)\cdot\log\log n}{\varepsilon^4}\right)$ *rounds,* $O(n)$ *space per machine, and* $O\left(n\log(1/\varepsilon)+m\right)$ *total space that computes a* $(1-\varepsilon)$*-approximate maximum weight bipartite matching for any* $\varepsilon > 0$*.*

As before, we can improve the complexity of our MPC algorithm using the transformations the full version of our paper.

▶ **Theorem 17.** *Given a weighted graph $G = (V, E)$ as input where all weights are at most* $\mathrm{poly}(n)$*, there exists a MPC algorithm using* $O\left(\frac{\log(1/\varepsilon)\cdot\log\log n}{\varepsilon^7}\right)$ *rounds,* $O(n)$ *space per machine, and* $O\left(\frac{m\log(1/\varepsilon)\log n}{\varepsilon}\right)$ *total space that computes a* $(1-\varepsilon)$*-approximate maximum weight bipartite matching for any* $\varepsilon > 0$*.*

4 A $(1-\varepsilon)$-approximation Auction Algorithm for b-Matching

We show in this section that we also obtain an auction-based algorithm for MCBM by extending the auction-based algorithm of [6]. This algorithm also leads to better streaming algorithms for this problem. We use the techniques introduced in the auction-based MCM algorithm of Assadi, Liu, and Tarjan [6] as well as new techniques developed in this section to obtain a $(1-\varepsilon)$-approximation algorithm for bipartite maximum cardinality b-matching. The maximum cardinality b-matching problem is defined in Definition 18.

▶ **Definition 18** (Maximum Cardinality Bipartite b-Matching (MCBM))**.** *Given an undirected, unweighted, bipartite graph $G = (L \cup R, E)$ and a set of values $\{b_v \leq |R| \mid v \in L \cup R\}$, a* ***maximum cardinality*** b***-matching*** *(MCBM) finds a matching of maximum cardinality between vertices in L and R where each vertex $v \in L \cup R$ is matched to at most b_v other vertices.*

The key difference between our algorithm for b-matching and the MCM algorithm of [6] is that we have to account for when more than one item is assigned to each bidder in L; in fact, up to b_i items in R can be assigned to any bidder $i \in L$. This one to many relationship calls for a different algorithm and analysis. The crux of our algorithm in this section is to create b_i copies of each bidder i and b_j copies of each item j. Then, copies of items maintain their own prices and copies of bidders can each choose at most one item. We define some notation to describe these copies. Let C_i be the set of copies of bidder i and C_j be the set of copies of item j. Then, we denote each copy of i by $i^{(k)} \in C_i$ for $k \in [b_i]$ and each copy of j by $j^{(k)} \in C_j$ for $k \in [b_j]$. As before, we denote a bidder and their currently matched item by $\left(i^{(k)}, a_{i^{(k)}}\right)$.

In MCbM, we require that the set of all items chosen by different copies of the same bidder to include at most one copy of each item. In other words, we require if $j^{(k)} \in \bigcup_{i' \in C_i} a_{i'}$, then no other $j^{(l)} \in \bigcup_{i' \in C_i} a_{i'}$ for any $j^{(k)}, j^{(l)} \in C_j$ and $k \neq l$. This *almost* reduces to the problem of finding a maximum cardinality matching in a $\sum_{i \in L} b_i + \sum_{j \in R} b_j$ sized bipartite graph but *not quite*. Specifically, the main challenge we must handle is when multiple copies of the same bidder want to be matched to copies of the *same* item. In this case, we cannot match any of these bidder copies to copies of the same item and thus must somehow handle the case when there exist items of lower price but we cannot match them.

In addition to handling the above hard case, as before, the crux of our proof relies on a variant of the ε-happy definition and the definitions of appropriate potential functions.

Recall from the MCM algorithm of [6] that an ε-happy bidder has utility that is at least the utility gained from matching to any other item (up to an additive ε). Such a definition is insufficient in our setting since it may be the case that matching to a copy of an item that is already matched to a different copy of the same bidder results in lower cost. However, such a match is not helpful since any number of matches between copies of the same bidder and copies of the same item contributes a value of one to the cardinality of the eventual matching.

Our algorithm solves all of the above challenges and provides a $(1-\varepsilon)$-approximate MCbM in asymptotically the same number of rounds as the MCM algorithm of [6]. We describe our auction based algorithm for MCbM next and the precise pseudocode is given in Algorithm 2. Our algorithm uses the parameters defined in Table 2. We show the following results using our algorithm. We discuss semi-streaming implementations of our algorithm in Section 4.3. Let L be the half with fewer numbers of nodes.

▶ **Theorem 2** (Maximum Cardinality Bipartite b-Matching). *There exists an auction algorithm for maximum cardinality bipartite b-matching (MCbM) that gives a $(1-\varepsilon)$-approximation for any $\varepsilon > 0$ and runs in $O\left(\frac{\log n}{\varepsilon^2}\right)$ rounds of communication. This algorithm can be implemented in the multi-round, semi-streaming model using $O\left(\left(\sum_{i \in L} b_i + |R|\right)\log(1/\varepsilon)\right)$ space and $O\left(\frac{1}{\varepsilon^2}\right)$ passes. Our algorithm can be implemented in the shared-memory work-depth model in $O\left(\frac{\log^3 n}{\varepsilon^2}\right)$ depth and $O\left(\frac{m \log n}{\varepsilon^2}\right)$ total work.*

4.1 Algorithm Description

The algorithm works as follows. We assign to each bidder, i, b_i unmatched slots and the goal is to fill all slots (or as many as possible). For each bidder $i \in L$ and each item $j \in R$, we create b_i and b_j copies, respectively, and assign these copies to new sets L' and R', respectively (Algorithm 2). This step of the algorithm changes slightly in our streaming implementation. For each bidder and item with an edge between them $(i, j) \in E$, we create

Algorithm 2 Auction Algorithm for Bipartite b-Matching.

```
Input: Graph $G = (L \cup R, E)$ and parameter $0 < \varepsilon < 1$.
Output: An $(1 - \varepsilon)$-approximate maximum cardinality bipartite $b$-matching.
Create $L', R', E'$ and graph $G'$. (Defined in Table 2.)
For each $i' \in L'$, set $(i', \perp)$ where $a_{i'} = \perp$, $c_{i'} \leftarrow 0$.
For each $j' \in R'$, set $p_{j'} = 0$.
Set $M_{\max} \leftarrow \emptyset$.
for $d = 1, \dots, \lceil \frac{2}{\varepsilon^2} \rceil$ do
    For each unmatched bidder $i' \in L'$, find $D_{i'} \leftarrow \text{FindDemandSet}(G', i', c_{i'})$ [Algorithm 3].
    Create $G'_d$.
    Find any arbitrary non-duplicate maximal matching $\widehat{M_d}$ of $G_d$.
    for $(i', j') \in \widehat{M_d}$ do
        Set $a_{i'} = j'$ and $a_{i_{prev}} = \perp$ for the previous owner $i_{prev}$ of $j'$.
        Increase $p_{j'} \leftarrow p_{j'} + \varepsilon$.
    For each $i' \in L'$ with $D_{i'} \neq \emptyset$ and $a_{i'} = \perp$, increase $c_{i'} \leftarrow c_{i'} + \varepsilon$.
    Using $M'_d$ compute $M_d$ where for each $(i', j') \in M'_d$, add $(i, j)$ to $M_d$ if $(i, j) \notin M_d$.
    If $|M_d| > |M_{\max}|$, $M_{\max} \leftarrow M_d$.
Return $M_{\max}$.
```

Algorithm 3 $\text{FindDemandSet}(G' = (L' \cup R', E'), i', c_{i'})$.

```
Let $N'(i') = \{j' \in R' \mid j^{(l)} \neq a_{i^{(k)}} \forall i^{(k)} \in C_i, \forall j^{(l)} \in C_j \wedge p_{j'} \geq c_{i'} \forall j' \in C_j\}$.
$D_{i'} \leftarrow \arg\min_{j' \in N'(i'), p_{j'} < 1} (p_{j'})$.
Return $D_{i'}$.
```

a biclique between C_i and C_j; the edges of all created bicliques is the set of edges E'. The graph $G' = (L' \cup R', E')$ is created as the graph consisting of nodes in $L' \cup R'$ and edges in E'. As before, we initialize each bidder's assigned item to $\perp$ (Algorithm 2). Then, we set the price for each copy in R' to 0 (Algorithm 2).

In our MCBM algorithm, we additionally set a price cutoff for each bidder $c_{i'}$ initialized to 0 (Algorithm 2). Such a cutoff helps us to prevent bidding on lower price items previously not bid on because they were matched to another copy of the same bidder. More details on how the cutoff prevents bidders from bidding against themselves can be found in the proof of Lemma 25. We maintain the maximum cardinality matching we have seen in $M_{\max}$ (Algorithm 2). We perform $\lceil \frac{2}{\varepsilon^2} \rceil$ rounds of assigning items to bidders (Algorithm 2). For each round, we first find the demand set for each unmatched bidder $i' \in L'$ using Algorithm 3 (Algorithm 2). The demand set is defined with respect to the cutoff price $c_{i'}$ and the set of items assigned to other copies of bidder i. The demand set considers all items $j' \in R'$ that are neighbors of i' where no copy of j, $j^{(k)} \in C_j$, is assigned to any copies of i and $p_{j'} \geq c_{i'}$ (Algorithm 3, Algorithm 3). From this set of neighbors, the returned demand set is the set of item copies with the minimum price in $N'(i')$ (Algorithm 3).

Using the induced subgraph of $\left(\bigcup_{i' \in L'} D_{i'}\right) \cup L'$ (Algorithm 2), we greedily find a maximal matching while avoiding assigning copies of the same item to copies of the same bidder (Algorithm 2). We call such a maximal matching that does not assign more than one copy of the same item to copies of the same bidder to be a ***non-duplicate*** maximal matching. This greedy matching prioritizes the unmatched items by first matching the unmatched items and then matching the matched items. We can perform a greedy matching by matching an edge if the item is unmatched and no copies of the bidder it will match to is matched to another copy of the item. For each newly matched item (Algorithm 2), we rematch the item to the newly matched bidder (Algorithm 2). We increase the price of the newly matched item (Algorithm 2). For each remaining unmatched bidder, we increase the cutoff price by ε (Algorithm 2).

We compute the corresponding matching in the original graph using M'_d (Algorithm 2) by including one edge (i, j) in the matching if and only if there exists at least one bidder copy $i' \in C_i$ matched to at least one copy of the item $j' \in C_j$. Finally, we return the maximum cardinality $M_{\max}$ matching from all iterations as our $(1-\varepsilon)$-approximate maximum cardinality b-matching (Algorithm 2).

4.2 Analysis

In this section, we analyze the approximation error of our algorithm and prove that it provides a $(1 - \varepsilon)$-approximate maximum cardinality b-matching.

Approach. We first provide an intuitive explanation of the approach we take to perform our analysis and then we give our precise analysis. Here, we describe both the challenges in performing the analysis and explain our choice of certain methods in the algorithm to facilitate our analysis. We especially highlight the parts of our algorithm and analysis that differ from the original MCM algorithm of [6]. First, in order to show the approximation factor of our algorithm, we require that the utility obtained by a large number of matched bidders from our algorithm is greater than the corresponding utility from switching to the optimum items in the optimum matching. For b-matching, any combination of matched items and bidder copies satisfy this criteria. Furthermore, matching multiple item copies of the same item to bidder copies of the same bidder does not increase the utility of the bidder. Thus, we look at matchings where at most one copy of each bidder is matched to at most one copy of each item. Recall our definition of ε-happy given in Definition 3 and we let Happy be the set of bidders satisfying that definition.

For b-matching, each bidder i is matched to a set of at most b_i items. Let $(i, O_i) \in \text{OPT}$ denote the set of items $O_i \subseteq R$ matched to bidder i in OPT. Recall [6] that the proof requires $u_i \geq 1 - p_{o_i} - \varepsilon$ for every bidder $i \in \textsc{Happy} \cap \text{OPT}$ to show that $\sum_{i \in L} u_i \geq \sum_{i \in \textsc{Happy} \cap \text{OPT}} 1 - p_{o_i} - \varepsilon$. Using our bidder copies, C_i, the crux of our analysis proof is to show that for every $(i, O_i) \in \text{OPT}$, we can *assign* the items in O_i to the set of happy bidder copies in C_i such that each happy bidder copy receives a unique item, denoted by $r_{i'}$, and $c_{i'} \leq p_{\min, r_{i'}}$ where $p_{\min, r_{i'}}$ is the price of the minimum priced copy of $r_{i'}$. Using this assignment, we are able to show once again that $\sum_{i' \in L'} u_{i'} \geq \sum_{i' \in \textsc{Happy} \cap \text{OPT}} 1 - p_{\min, r_{i'}} - \varepsilon$. This requires a precise definition of $\textsc{Happy} \cap \text{OPT}$. Let $S_i \subseteq C_i$ be the set of all happy bidders in C_i. Recall that the optimum solution gives a matching between a bidder $i \in L$ and potentially multiple items in R; we turn this matching into an optimum matching in G'. If $|S_i| \leq |O_i|$, then all happy copies in S_i are in OPT; otherwise, we pick an arbitrary set of $|O_i|$ happy bidder copies in S_i to be in OPT. Then, the summation is determined based on this set of happy bidder copies in $\textsc{Happy} \cap \text{OPT}$.

Once we have shown this, the only other remaining part of the proof is to show that in the $\lceil \frac{2}{\varepsilon^2} \rceil$ rounds that we run the algorithm the potential increases by ε for every unhappy bidder in OPT for each round that the bidder is unhappy. As in the case for MCM, the price of an item increases whenever it becomes re-matched. Hence, Π_{items} increases by ε each time a bidder who was happy becomes unhappy. To ensure that $\Pi_{bidders}$ increases by ε

for each bidder who was unhappy and remains unhappy, we set a ***cutoff*** price that increases by ε for each round where a bidder remains unhappy. Thus, this cutoff guarantees that $\Pi_{bidders}$ increases by ε each time.

Detailed Analysis. Now we show our detailed analysis that formalizes our approach described above. We first show that our algorithm maintains both Invariant 20 and Invariant 21. We also show our algorithm obeys the following invariant.

▶ **Invariant 19.** *The set of matched items of all copies of any bidder $i \in L$ contains at most one copy of each item. In other words, $\left|\bigcup_{i' \in C_i} a_{i'} \cap C_j\right| \leq 1$ for all $j \in R$.*

We restate two invariants used in [6] below. We prove that our Algorithm 2 also maintains these two invariants.

▶ **Invariant 20** (Non-Zero Price Matched [6]). *Any item j with positive price $p_j > 0$ is matched.*

▶ **Invariant 21** (Maximum Utility [6]). *The total utility of all bidders is at most the cardinality of the matching minus the total price of the items.*

▶ **Lemma 22.** *Algorithm 2 maintains Invariant 19, Invariant 20, and Invariant 21.*

We follow the style of analysis outlined in [6] by defining appropriate definitions of ε-happy and appropriate potential functions Π_{items} and $\Pi_{bidders}$. In the case of b-matching, we modify the definition of ε-happy in this setting to be the following.

▶ **Definition 23** ((ε, c)-Happy)**.** *A bidder $i' \in L'$ is (ε, c)-happy (at the end of a round) if $u_{i'} \geq 1 - p_{j'} - \varepsilon$ for all neighbors in the set $N'(i')$ where $N'(i')$ is as defined in Algorithm 3 of Algorithm 3 (i.e. contains all neighboring items j' where $p_{j'} \geq c_{i'}$ and no copy of the neighbor is matched to another copy of i').*

At the end of each round, it is easy to show that all matched i' and i' whose demand sets $D_{i'}$ are empty are $(\varepsilon, c_{i'})$-happy.

▶ **Lemma 24.** *At the end of any round, if bidder i' is matched or if their demand set is empty, $D_{i'} = \emptyset$, then i' is $(\varepsilon, c_{i'})$-happy.*

In addition to the new definition of happy, we require another crucial observation before we prove our approximation guarantee. Specifically, we show that for any set of bidder copies C_i and any set of $|C_i|$ items $I \subseteq R$, Lemma 24 is sufficient to imply there exists at least one assignment of items in I to happy bidders in S_i such that each item is assigned to at most one bidder and each happy bidder is assigned at least one item where the minimum price of the item is at least the cutoff price of the bidder.

▶ **Lemma 25.** *For a set of bidder copies C_i and any set $I \subseteq R$ of $|C_i|$ items where $(i, j) \in E$ for all items $j \in I$, there exists at least one assignment of items in I to bidders in C_i, where we denote the item assigned to copy i' by $r_{i'}$, that satisfy the following conditions:*

1. *The assignment is a one-to-one mapping between bidders in C_i and items in I.*
2. *Any item j matched to i' is assigned to i'.*
3. *Let $r^*_{i'}$ be the lowest cost copy of item $r_{i'}$, $r^*_{i'} = \arg\min_{j' \in C_{r_{i'}}} (p_{j'})$; then $p_{r^*_{i'}} \geq c_{i'}$ for all $i' \in C_i$.*

We now perform the approximation analysis. Suppose as in the case of MCM, we have at least $(1-\varepsilon)|\mathrm{OPT}|$ happy bidders in OPT (i.e. $|\textsc{Happy} \cap \mathrm{OPT}| \geq (1-\varepsilon)|\mathrm{OPT}|$), then we show that we can obtain a $(1-\varepsilon)$-approximate MCbM. Let OPT be an optimum MCbM matching and $|\mathrm{OPT}|$ be the cardinality of this matching.

▶ **Lemma 26.** *Assuming $|\textsc{Happy} \cap OPT| \geq (1-\varepsilon)|OPT|$, then we obtain a $(1-2\varepsilon)$-approximate MCbM.*

The potential argument proof is almost identical to that for MCM provided our use of $c_{i'}$. Specifically, as in the case for MCM, we use the same potential functions and using these potential functions, we show that our algorithm terminates in $O\left(\frac{1}{\varepsilon^2}\right)$ rounds. The key difference between our proof and the proof of MCM explained in [6] is our definition of $\Pi_{bidders}$ which is precisely defined in the proof of Lemma 27 below.

▶ **Lemma 27.** *In $\lceil \frac{2}{\varepsilon^2} \rceil$ rounds, there exists at least one round where $|OPT \cap \textsc{Happy}| \geq (1-\varepsilon)|OPT|$.*

Using the above lemmas, we can prove the round complexity of Theorem 2 to be $O\left(\frac{1}{\varepsilon^2}\right)$ by Lemma 26 and Lemma 27.

▶ **Theorem 28.** *There exists an auction algorithm for maximum cardinality bipartite b-matching (MCbM) that gives a $(1-\varepsilon)$-approximation for any $\varepsilon > 0$ and runs in $O\left(\frac{\log n}{\varepsilon^2}\right)$ rounds of communication using $O(b \log n)$ bits per message in the blackboard distributed model. In total, the number of bits used by the algorithm is $O\left(\frac{nb\log^2 n}{\varepsilon^2}\right)$.*

4.3 Semi-Streaming Implementation

We now show an implementation of our algorithm to the semi-streaming setting and show the following lemma which proves the semi-streaming portion of our result in Theorem 2. We are guaranteed $\varepsilon \geq \frac{1}{2n^2}$; otherwise, an exact matching is found. In order to show the space bounds, we use an additional lemma below that upper and lower bounds the prices of any copies of the same item in R'.

▶ **Lemma 29.** *For any $j \in R$, let $j_{\min}$ be the minimum priced copy in C_j and $j_{\max}$ be the maximum priced copy in C_j. Then, $p_{j_{\max}} - p_{j_{\min}} \leq \varepsilon$.*

Using the above, we prove our desired bounds on the number of passes and the space used.

▶ **Theorem 30.** *There exists a semi-streaming algorithm for maximum cardinality bipartite b-matching that uses $O\left(\frac{1}{\varepsilon^2}\right)$ rounds and $\widetilde{O}\left(\left(\sum_{i \in L} b_i + |R|\right)\log(1/\varepsilon)\right)$ space where L is the side with the smaller number of nodes in the input graph.*

We note that the space bound is necessary in order to report the solution. (There exists a given input where reporting the solution requires $\widetilde{O}\left(\left(\sum_{i \in L} b_i + |R|\right)\log(1/\varepsilon)\right)$ space.) Thus, our algorithm is tight with respect to this notion.

4.4 Shared-Memory Parallel Implementation

We now show an implementation of our algorithm to the shared-memory parallel setting. The main challenge for this setting is obtaining an algorithm for obtaining non-duplicate maximal matchings. To obtain non-duplicate maximal matchings, we just need to modify the maximal matching algorithm of [9] to obtain a maximal matching with the non-duplicate characteristic. Namely, the modification we make is to consider all copies of a node to be neighbors of each other. Since there can be at most n copies of a node, this increases the degree of each node by at most n. Hence, the same analysis as the original algorithm still holds in this new setting.

▶ **Theorem 31.** *There exists a shared-memory parallel algorithm for maximum cardinality bipartite b-matching that uses $O\left(\frac{\log^3 n}{\varepsilon^2}\right)$ depth and $O\left(\frac{m \log n}{\varepsilon^2}\right)$ total work where L is the side with the smaller number of nodes in the input graph.*

Abstract

A temporal graph is a graph whose edges appear only at certain points in time. In these graphs, reachability among nodes relies on paths that traverse edges in chronological order (*temporal paths*). Unlike standard paths, temporal paths may not be composable, thus the reachability relation is *not transitive* and connected components (i.e., sets of pairwise temporally connected nodes) do not form equivalence classes, a fact with far-reaching consequences.

Recently, Casteigts et al. [FOCS 2021] proposed a natural temporal analog of the seminal Erdős-Rényi random graph model, based on the same parameters n and p. The proposed model is obtained by randomly permuting the edges of an Erdős-Rényi random graph and interpreting this permutation as an ordering of presence times. Casteigts et al. showed that the well-known single threshold for connectivity in the Erdős-Rényi model fans out into multiple phase transitions for several distinct notions of reachability in the temporal setting.

The second most basic phenomenon studied by Erdős and Rényi in static (i.e., non-temporal) random graphs is the emergence of a *giant connected component*. However, the existence of a similar phase transition in the temporal model was left open until now. In this paper, we settle this question. We identify a sharp threshold at $p = \log n/n$, where the size of the largest temporally connected component increases from $o(n)$ to $n - o(n)$ nodes. This transition occurs significantly later than in the static setting, where a giant component of size $n - o(n)$ already exists for any $p \in \omega(1/n)$ (i.e., as soon as p is larger than a constant fraction of n). Interestingly, the threshold that we obtain holds for both *open* and *closed* connected components, i.e., components that allow, respectively forbid, their connecting paths to use external nodes – a distinction arising from the absence of transitivity.

We achieve these results by strengthening the tools from Casteigts et al. and developing new techniques that provide means to decouple dependencies between past and future events in temporal Erdős-Rényi graphs, which could be of general interest in future investigations of these objects.

1 Introduction

Many real-world networks vary with time, as exemplified by the dynamic nature of today's social media, telecommunication, transportation, and interaction in general in a complex network. Indeed, the examination of specific applications illustrates how networks endowed with temporal information enable more accurate and effective analysis of real-world systems compared to static networks [33].

This insight has motivated plethora of studies focusing on network modeling approaches that incorporate the time dimension [24, 25, 27]. A widely used model for these networks is given by *temporal graphs* (sometimes also called *time-varying graphs*, *evolving graphs*, or other names). A temporal graph is a pair $\mathcal{G} = (G, \lambda)$, where $G = (V, E)$ is an *underlying* (static) graph, and λ is an *edge labeling function* that assigns to every edge $e \in E$ a set of time labels $\lambda(e) \subseteq \mathbb{N}$ indicating when this edge is present. This definition, although simple, already captures two important aspects that determine temporal networks. Namely, (a) the topology of the network defined by the underlying graph G; and (b) the schedule of edge availabilities represented by the labeling function λ.

Even though this model has gained much traction recently, the available tools for analyzing temporal graphs are still nowhere near the level of tools that have been developed for understanding static networks. One of the main challenges is the fundamentally changed notion of *reachability*. In temporal graphs, reachability is naturally based on paths that traverse edges in ascending time, a.k.a. *temporal paths*. A first difference with standard paths is that temporal paths are inherently directed, regardless of whether the graph itself is directed, due to the arrow of time. Even more significantly, temporal reachability is *not transitive*, i.e., the fact that node u can reach node v and node v can reach node w does not imply that u can reach w. The resulting non-composability is a source of complication for structural studies, as well as a frequent source of computational hardness. In fact, many problems related to reachability are hard in temporal graphs, even when their classical analogs are polynomial time solvable – see, for instance, the seminal paper by Kempe, Kleinberg, and Kumar [27] on k-disjoint temporal paths (and many further examples appearing in more recent works [1, 8, 13–15, 20, 22]). As observed by Bhadra and Ferreira [6], the fact that *(temporally) connected components* do not form equivalence classes and intersect in non trivial ways implies, among other consequences, that finding one of maximum size is NP-hard.

Random Models of Temporal Graphs

One of the most important tools in (static) network theory are random network models [30]. They allow reproducing characteristics of real networks and studying their statistical properties. The random perspective enables prediction of properties, anomaly detection, identification of phase transitions, and other conclusions about the nature of typical networks.

The cornerstone of random network theory is the Erdős-Rényi random graph model [3]. It has proven tremendously useful as a source of insight into the structure of networks [32]. An Erdős-Rényi random graph $G_{n,p}$ is obtained by placing an edge between each distinct pair of n vertices[1] independently with probability p. The study of this model was sparked by a series of seminal papers published by Erdős and Rényi starting in 1959 [16–19]. Since then, an important number of articles and books have been devoted to this model. These

[1] We use the terms *vertex* and *node* interchangeably.

results laid a solid foundation for the development of other models of more practical interest, including the configuration model [28,29,31], the small-world model [34], and the preferential attachment model [4].

The number of models of random *temporal* networks proposed in the literature is still limited and no systematic foundations are available [24]. In establishing such foundations, a natural question is: *What is the temporal analog of the Erdős-Rényi random graph model?* The answer to this question is not unique, as the time dimension can be incorporated in different ways [32]. Some candidates considered in the literature consider a sequence of independent Erdős-Rényi graphs, some others incorporate some dependencies in such a sequence (see for example [2,5,10–12,23,35]).

Temporal Erdős-Rényi Random Graphs

Recently, another natural and more direct temporal analog of the Erdős-Rényi random graphs was proposed by Casteigts et al. [9], based on the same parameters n and p. In this model, which we refer to as the *temporal Erdős-Rényi random graph model*, a random temporal graph is obtained from an Erdős-Rényi random graph $G_{n,p}$ by assigning to each edge a unique label (presence time) according to a uniformly random permutation of its edges. The main motivation is to obtain a temporal graph model whose properties (such as threshold values) can be directly compared to the classical Erdős-Rényi model, thereby highlighting the qualitative impact of the time dimension. A systematic study of this model may also set a benchmark for practical models.

As already remarked, the time dimension leads to a number of distinctions between static and temporal graphs. Many of them come from the conceptual difference between the notions of path and temporal paths. The reachability of a temporal graph is not symmetric (even in the undirected case) and not transitive, which is in stark contrast with static graphs. Indeed, the results of [9] revealed that even the notion of connectivity translates to a rich spectrum of phase transitions in the temporal setting. Namely, at $p = \log n/n$, any *fixed* pair of vertices can asymptotically almost surely (a.a.s.) reach each other; at $2\log n/n$, at least one vertex (and in fact, any fixed vertex) can a.a.s. reach all the others; and at $3\log n/n$, all the vertices can a.a.s. reach all others, i.e., the graph is temporally connected.

Connected Components in Temporal Erdős-Rényi Random Graphs

Perhaps the most investigated aspects of Erdős-Rényi random graphs is the emergence of a “giant” connected component [7,21], which culminates in connectivity itself. The analogous question in a temporal setting is therefore natural. Interestingly, the lack of transitivity makes the very definition of temporal components ambiguous. If the vertices of the component need temporal paths traveling *outside* the component in order to reach each other, then the component is *open*; otherwise, it is *closed* [6].

Analyzing the emergence of (both types of) *temporally* connected components in the above model presents technical challenges that cannot be overcome by the only tools developed in [9]. These technical challenges and the importance of understanding connected components in temporal Erdős-Rényi random graphs motivated the present work.

1.1 Contributions

In this paper, we analyze the evolution of the largest connected component in a temporal Erdős-Rényi random graph with parameters n and p, as p increases (with $n \to \infty$). Our main result is that, in contrast to static graphs, the phase transition occurs at $p = \log n/n$. At this point, the size of the largest component jumps from $o(n)$ to $n - o(n)$.

▶ **Main Theorem** (informal). *There exists a function $\varepsilon(n) \in o(\log n/n)$ such that the size of a largest temporally connected component in a temporal Erdős-Rényi random graph is*

(i) *$o(n)$ a.a.s., if $p < \frac{\log n}{n} - \varepsilon(n)$; and*

(ii) *$n - o(n)$ a.a.s., if $p > \frac{\log n}{n} + \varepsilon(n)$.*

Notably, the same threshold holds for both open and closed connected components, although showing the latter requires more effort. We achieve these results by developing new techniques and combining them with strengthened versions of the tools from [9]. Informally, the new tools enable us to effectively contain the dependencies that exist between different time slices. Thus they facilitate building graph structures witnessing a desired property in *multiple independent phases.*

1.2 Significance of the Results & Techniques

Results. Our main result reveals a qualitative difference between the evolution of connected components in static random graphs and temporal random graphs. The emergence of a giant component in (static) Erdős–Rényi graphs follows a well-known pattern of events [19]. Below a critical probability $p_0 = 1/n$, almost all the components are trees, and no component is larger than $O(\log n)$. Then, at p_0, a single "giant" component of size $\Theta(n^{2/3})$ arises. Then, at $p = c/n > 1/n$, this component contains a constant fraction $1 - x/c$ of all vertices (with $0 < x < 1$ being defined through $xe^{-x} = ce^{-c}$). As soon as $p \in \omega(1/n)$, the component contains all but $o(n)$ vertices. The case of directed static graphs is similar. Namely, for $p = c/n < 1/n$, a.a.s. all strongly connected components have size less than $3c^{-2}\log n$, and when $p = c/n > 1/n$, the graph contains a strongly connected component of size approximately $(1 - x/c)^2\, n$ (with x as above) [21, 26], which implies that this component contains all but $o(n)$ vertices when $p \in \omega(1/n)$.

In the temporal setting, we show that the phase transition occurs at $p = \log n/n$. Namely, all components are of size $o(n)$ before that threshold and there is one component of size $n - o(n)$ afterwards. The fact that this transition occurs later in the temporal setting is not surprising, as the thresholds for *connectivity* is already known to be significantly smaller in the static setting than in the temporal setting; namely, connectivity occurs at $p = \log n/n$ in the static case (for both directed and undirected graphs) versus $p = 3\log n/n$ for temporal connectivity [9]. However, while these thresholds for connectivity are within a multiplicative constant of each other, our results show that in the case of connected components the static and the temporal threshold are of distinct asymptotic orders.

Techniques. In the temporal Erdős-Rényi model, the unicity of presence times for the edges causes delicate dependencies between past and future events. To contain these dependencies, we introduce a multiphase analysis that consists of splitting the time interval into several phases where these dependencies are decoupled. We believe that many further temporal graph properties will require such a multiphase analysis and could benefit from the tools developed here. In constrast, the techniques from [9] are well suited for analyzing single-phase processes, where temporal paths do not interact across different time intervals (e.g. through composition).

In particular, our switch from a fixed base graph $G = K_n$ to an arbitrary graph of high minimum degree provides the possibility to "encapsulate" all dependencies on events occurring in some fixed "short" phase into the choice of base graph, effectively eliminating the need to deal with these dependencies individually. As an unsurprising but quite useful technical extension, we study also the behaviour of sets of journeys starting from any of a set of source vertices. Furthermore, Lemma 5.2 is of independent interest for "bootstrapping" various such multiphase analysis attempts; it essentially proves that in the very early regime, there is only a small number of poorly connected vertices, and that these can be removed without compromising the connectivity of the remaining temporal graph.

Although our techniques handle specific dependencies of temporal Erdős-Rényi graphs, they remain general enough to be adaptable to models with less dependencies, such as models where several appearances of an edge is possible and these appearances follow an exponential distribution (Poisson process). The reasons for this are exactly the same as in [9]. Note, however, that weaker tools could suffice for such models, as past and future appearances of an edge are independent.

1.3 Organization

In Section 2, we provide all necessary definitions, and introduce the random temporal graph models used in the paper. In Section 3, we present the algorithm for constructing a foremost forest. We also state a core technical theorem (Theorem 3.3) concerned with reachability between two sets of nodes in a temporal graphs. The full proof of that theorem is deferred to the full version due to space restrictions, as are several other proofs and intermediate results. Using this theorem, we then prove in Section 4 that at $p = \log n/n$ the size of the largest *open* connected component jumps from $o(n)$ to $n - o(n)$. This also serves as a stepping stone towards Section 5, where we extend our technique to also apply to *closed* connected components. The proof is slightly more involved than for open components, as it requires further subdivisions of the phases. However, we show that both variants undergo essentially the same phase transition.

2 Preliminaries

In this paper, $[k]$ denotes the set of integers $\{1, \dots, k\}$, and $[a, b]$ denotes either the discrete interval from a to b, or the continuous interval from a to b, the distinction being clear from the context. All graphs are simple, i.e., without loops or multiple edges. For a graph G, we denote by $V(G)$ and $E(G)$ its vertex set and edge set respectively. We denote by $\delta(G)$ and $\Delta(G)$ the minimum and the maximum vertex degree of G respectively. As usual, K_n denotes the complete n-vertex graph.

2.1 Temporal Graphs

A *temporal graph* is a pair (G, λ), where $G = (V, E)$ is a *static* graph and λ is a function that assigns to every edge $e \in E$ a finite set of numbers, interpreted as presence times. The graph G is called the *underlying graph* of the temporal graph and the elements of $\lambda(e)$ are called the *time labels* of e. We will denote temporal graphs by calligraphic letters, e.g., by $\mathcal{G}$. Instead of (G, λ) we will sometimes use the notation (V, E, λ) to denote the same temporal graph. In most cases, time labels will be elements of the real unit interval $[0, 1]$. Furthermore, in this paper, we restrict our consideration only to *simple* temporal graphs[2], i.e., temporal graphs in which every edge $e \in E$ is only present at a single point in time, i.e., $|\lambda(e)| = 1$. We sometimes write $V(\mathcal{G})$ and $E(\mathcal{G})$ for the node and edge set of a temporal graph $\mathcal{G}$ respectively.

[2] We remark that all our results can be directly transferred to another, closely related model of non-simple temporal graphs; see Section 6.1.2 in [9].

A temporal graph $\mathcal{H} = (V_{\mathcal{H}}, E_{\mathcal{H}}, \lambda_{\mathcal{H}})$ is a *temporal subgraph* of a temporal graph $\mathcal{G} = (V_{\mathcal{G}}, E_{\mathcal{G}}, \lambda_{\mathcal{G}})$, if $V_{\mathcal{H}} \subseteq V_{\mathcal{G}}$, $E_{\mathcal{H}} \subseteq E_{\mathcal{G}}$ and $\lambda_{\mathcal{H}}(e) = \lambda_{\mathcal{G}}(e)$ for all $e \in E_{\mathcal{H}}$. For a vertex set $S \subseteq V(\mathcal{G})$, we denote by $\mathcal{G}[S]$ a temporal subgraph of $\mathcal{G}$ induced by S. We use $\mathcal{G}_{[a,b]}$ to denote the temporal subgraph of $\mathcal{G}$ with the same node set $V_{\mathcal{G}}$, the edge set $E' := \{e \in E_{\mathcal{G}} : \lambda_{\mathcal{G}}(e) \in [a, b]\}$, and the time labeling function $\lambda_{\mathcal{G}}|_{E'}$ which is the restriction of $\lambda_{\mathcal{G}}$ to E'.

A *temporal* (u, v)*-path* in $\mathcal{G} = (V, E, \lambda)$ between two nodes $u, v \in V$ is a sequence $u = u_0, u_1, \ldots, u_\ell = v$ such that $e_i = \{u_{i-1}, u_i\} \in E$ for each $i \in [\ell]$, and time labels are increasing, i.e., $\lambda(e_1) < \ldots < \lambda(e_\ell)$. We call $\lambda(e_\ell)$ the *arrival time* of the path. A temporal (u, v)-path is called *foremost* (u, v)*-path* if it has the earliest arrival time among all temporal (u, v)-paths. If there exists a temporal (u, v)-path, we say that u can reach v (every vertex reaches itself). A set $S \subseteq V$ is said to *reach* v if at least one of its elements reaches v. In that case, a *foremost* (S, v)*-path* in $\mathcal{G}$ is a temporal (u, v)-path with earliest arrival time among all $u \in S$.

A vertex $u \in V$ is called *temporal source* in $\mathcal{G} = (V, E, \lambda)$ if there exists a temporal (u, v)-path for each $v \in V$. Similarly, a vertex $v \in V$ is called *temporal sink* in $\mathcal{G}$ if there exists a temporal (u, v)-path for each $u \in V$.

A temporal graph $\mathcal{G} = (V, E, \lambda)$ is *temporally connected* if all nodes are temporal sources. We note that this also implies that all nodes are temporal sinks. An *open temporally connected component* or simply *connected component* in $\mathcal{G}$ is an inclusion-wise maximal set $Z \subseteq V$ of nodes such that for every ordered pair of vertices $u, v \in Z$, there exists a temporal (u, v)-path in $\mathcal{G}$. We stress that such a temporal (u, v)-path can contain nodes from $V \setminus Z$. If for every ordered pair $u, v \in Z$, there exists a temporal (u, v)-path in $\mathcal{G}[Z]$, then Z is called *closed connected component*.

2.2 Random Temporal Graph Models

The model of *temporal Erdős-Rényi random graphs* was introduced in [9][3] as a natural temporal generalization of the classical Erdős–Rényi model $G_{n,p}$ of random graphs. An n-vertex temporal Erdős-Rényi random graph with the parameter $p \in [0, 1]$ is obtained by first drawing a *static* random Erdős–Rényi $G_{n,p}$ and then defining a temporal order on its edges by ordering them according to a uniformly random permutation. An equivalent and technically more convenient way of defining the temporal order on the edges is to draw, for every edge e, independently and uniformly at random a time label $\lambda(e)$ from the unit interval $[0, 1]$. Since the event that two edges get the same time label happens with probability 0, all edge orderings induced by such random time labels are equiprobable. Therefore, as long as the absolute values of time labels are irrelevant (which is the case for the questions studied in [9] and in the present paper), the two models are indeed equivalent. This latter model is denoted as $\mathcal{F}_{n,p}$. A possible way of generating objects from $\mathcal{F}_{n,p}$ is to first draw a temporal graph $\mathcal{G} = (G, \lambda)$ from $\mathcal{F}_{n,1}$ (thus the underlying graph G is complete), and to then consider $\mathcal{G}' = (G', \lambda') = (G, \lambda)|_{[0,p]}$, i.e., the temporal graph obtained from $\mathcal{G}$ by removing edges with time labels greater than p. Observe that $G' \sim G_{n,p}$ and each time label $\lambda(e)$ is uniformly distributed on $[0, p]$. Hence, $\mathcal{G}'$ is distributed according to $\mathcal{F}_{n,p}$ up to multiplying all labels by a factor of $\frac{1}{p}$, which we can ignore as it neither changes the relative order of time labels nor the absolute values of time labels are of any importance to us. For similar reasons, for any $0 \leq a \leq b \leq 1$, up to rescaling time labels, the temporal subgraph $\mathcal{G}|_{[a,b]}$ is distributed according to $\mathcal{F}_{n,q}$, where $q = b - a$.

[3] In [9], this model was called Random Simple Temporal Graphs (RSTGs)

In order to overcome some technical challenges caused by interdependence of different temporal subgraphs, we define and study a natural generalization of $\mathcal{F}_{n,p}$ that we describe next. For an n-vertex graph G and a real value $p \in [0,1]$, we denote by $\mathcal{F}_p(G)$ the following random temporal graph model. A random temporal graph $\mathcal{G} = (V, E, \lambda) \sim \mathcal{F}_p(G)$ is obtained by (1) independently and uniformly sampling a time label $\lambda'(e) \in [0,1]$ for every $e \in E(G)$, and (2) setting $V = V(G)$, $E := \{e \in E(G) : \lambda(e) \leq p\}$ and $\lambda(e) = \lambda'(e)$ for every $e \in E$. We call G the *base graph* of $\mathcal{F}_p(G)$. We observe that the $\mathcal{F}_{n,p}$ model is obtained when choosing the base graph to be the complete n-vertex graph K_n.

In what follows we sometimes implicitly assume that $n = |V|$ is sufficiently large without restating this assumption. We note that some of our estimates hold only for rather large values of n. We did not attempt to reduce these bounds, but instead focused on achieving best possible readability.

At this point we refer the interested reader to Appendix A of the full version, where, as a warm-up, we give a simple upper bound on p which guarantees that $\mathcal{G} \sim \mathcal{F}_p(G)$ is temporally connected a.a.s.

3 The Foremost Forest Algorithm

The main aim of this section is to present an algorithm for constructing a foremost forest and to prove a property of this algorithm.

Foremost forests play a crucial role in the development of our main technical tool: for a fixed set of vertices S and a given number k, the estimation of the minimum value of p such that the vertices in S can reach k vertices in $\mathcal{G} = (V, E, \lambda) \sim \mathcal{F}_p(G)$ a.a.s.

We obtain such an estimation by examining the evolution of a foremost forest for S in $\mathcal{G}$ via analysis of the execution of the formost forest algorithm on random temporal graphs. To elaborate on this approach, let us consider $v \in V \setminus S$. We would like to estimate the probability that S reaches v in $\mathcal{G}$. For this, we follow an approach similar to the one used in [9]. Let $\mathcal{G}' \sim \mathcal{F}_1(G)$ and observe that the probability that S can reach v in $\mathcal{G}$ is equal to the probability that the temporal subgraph $\mathcal{G}'_{[0,p]}$ contains a temporal (u, v)-path P for some node $u \in S$. This again is equivalent to the arrival time of P in $\mathcal{G}'$ being at most p. Therefore, the estimation of the parameter p for which some node from S can reach v can be reduced to the estimation of the minimum arrival time of a foremost temporal path from S to v in $\mathcal{G}' \sim \mathcal{F}_1(G)$. A *foremost forest for S in $\mathcal{G}$* is a minimal temporal subgraph that preserves foremost reachabilities from S to all other vertices reachable from S in $\mathcal{G}$. We proceed with the necessary formal definitions.

▶ **Definition 3.1.** *Let $\mathcal{G} = (V, E, \lambda)$ be a temporal graph and let $S \subseteq V$ be a set of vertices. The graph $\mathcal{G}_F = (V_F, E_F, \lambda_F)$ is an* increasing temporal forest for S, *if*

(a) *$\mathcal{G}_F$ is a temporal subgraph of $\mathcal{G}$,*

(b) *the graph $F = (V_F, E_F)$ is a forest (i.e. acyclic graph) with $|S|$ components,*

(c) *for each $s \in S$ there is a connected component T_s of F such that s reaches all vertices of T_s in $\mathcal{G}_F$.*

We are now ready to define (partial) foremost forests.

▶ **Definition 3.2.** *Let $\mathcal{G} = (V, E, \lambda)$ be a temporal graph, let $S \subseteq V$ be a set of vertices and let $\mathcal{G}_F = (V_F, E_F, \lambda_F)$ be an increasing temporal forest for S.*

1. *Then $\mathcal{G}_F$ is a* partial foremost forest for S, *if, for all $v \in V_F \setminus S$, the unique temporal (S, v)-path in $\mathcal{G}_F$ is a foremost (S, v)-path in $\mathcal{G}$.*
2. *A partial foremost forest for S is a* foremost forest for S *if V_F contains all vertices reachable from S in $\mathcal{G}$, i.e., $V_F = \{v \in V : \exists (u, v)\text{-temporal path in } \mathcal{G} \text{ for some } u \in S\}$.*
3. *A (partial) foremost forest for $\{v\}$ is a* (partial) foremost tree for v.

The Algorithm

Next, we present an algorithm that, given a temporal graph $\mathcal{G} = (V, E, \lambda)$ and a set of nodes $S \subseteq V$ constructs a foremost forest $\mathcal{G}_F$ for S. This algorithm is a straightforward generalization of the foremost tree algorithm from [9], where the input set S is assumed to be singleton.

The idea of the algorithm similar to Prim's algorithm for minimum spanning trees in static graphs: Starting from $\mathcal{G}_F = (V_F, E_F, \lambda_F) = (S, \emptyset, \emptyset)$, which is trivially a partial foremost forest for S, the algorithm iteratively adds one node and one edge to V_F and E_F, λ_F, respectively, until $\mathcal{G}_F$ becomes a foremost forest for S. The main difference to Prim's algorithm is that, in every iteration, the next edge to be added is chosen as the edge of minimum time label among all edges that extend the current increasing temporal forest. For brevity, we introduce the following notation. We write $\mathcal{G}_F \cup e$ for adding the edge $e = \{u, v\}$ to $\mathcal{G}_F$, i.e., the result is the temporal graph $(V_F \cup \{u, v\}, E_F \cup \{e\}, \lambda_F \cup \{(e, \lambda(e))\})$. The set of edges that extend the current partial forest can then be defined as

$$\operatorname{ext}(\mathcal{G}_F) := \{e = \{u, v\} \in E : u \in V_F, v \in V \setminus V_F, \text{ and } \mathcal{G}_F \cup e \text{ is an increasing temporal forest for } S\}.$$

We now are ready to state the algorithm.

Algorithm 1 Foremost Forest.

```
Input   : Simple temporal graph $\mathcal{G} = (V, E, \lambda)$; set of nodes $S \subseteq V$.
Output : Foremost forest for $S$.
$k = |S| - 1$, $\mathcal{G}_F^k = (S, \emptyset, \emptyset)$
while $\operatorname{ext}(\mathcal{G}_F^k) \neq \emptyset$ do
    $k := k + 1$
    $e_k := \arg\min\{\lambda(e) \mid e \in \operatorname{ext}(\mathcal{G}_F^{k-1})\}$
    $\mathcal{G}_F^k := \mathcal{G}_F^{k-1} \cup e_k$
return $\mathcal{G}_F^k$
```

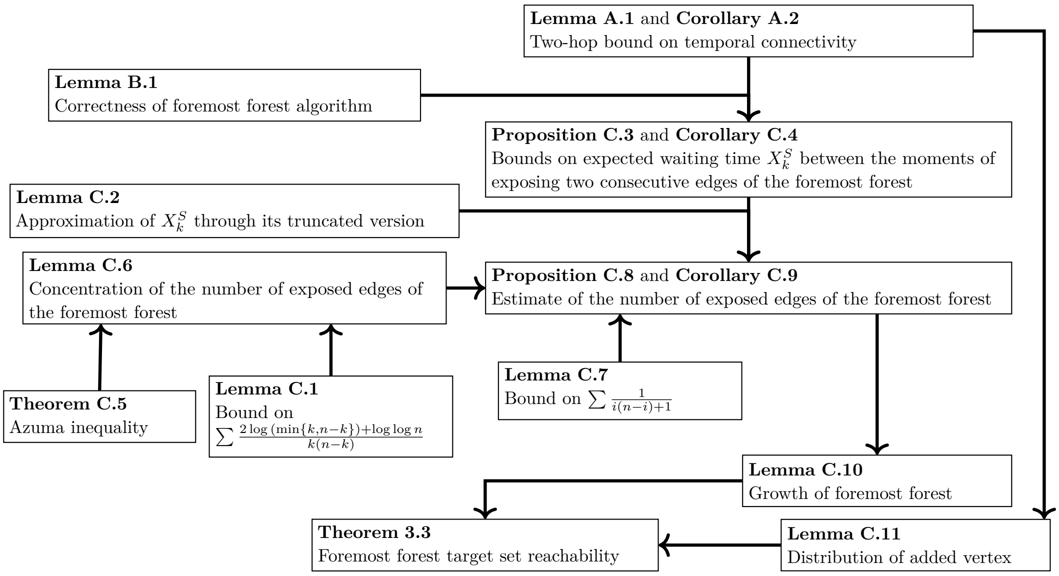
In Appendix B of the full version we prove that Algorithm 1 in fact builds a foremost forest.Furthermore, one of our main technical results is the following theorem which, for two given sets of nodes S and T, quantifies the probability that a foremost forest grown from set S reaches T.

▶ **Theorem 3.3** (Foremost Forest Target Set Reachability). *Let*

- *G be a graph of minimum degree $\delta(G) \geq n - (\log n)^a$ for some $a \in \mathbb{N}$,*
- *let S and T be two sets of nodes in G of cardinalities $s \in [(\log n)^{13}, n/2]$ and t, respectively,*
- *let $z = z(n)$ be a function with $\varepsilon \leq z(n) \leq 1 - \varepsilon$ for some constant $\varepsilon \in (0, 1)$, and*
- *let $\mathcal{G} \sim \mathcal{F}_p(G)$ with $p \geq \frac{z \log n - \log s}{n} + \frac{3 \log \log n}{n}$.*

Then the foremost forest algorithm from S on $\mathcal{G}$ reaches T with probability at least $1 - \frac{5}{2} n^{-\log \log n} - e^{-\frac{t}{2n}(n^z - s)}$.

The formal proof of Theorem 3.3 is one of the technically more involved portions of this work. It is divided into a number of lemmas and has to be deferred to Appendix C of the full version due to lack of space; for improved accessibility, a high level overview of the proof structure is depicted in Figure 1. We proceed with a short proof sketch.



Lemma A.1 and Corollary A.2
Two-hop bound on temporal connectivity
Lemma B.1
Correctness of foremost forest algorithm
Proposition C.3 and Corollary C.4
Bounds on expected waiting time X_k^S between the moments of exposing two consecutive edges of the foremost forest
Lemma C.2
Approximation of X_k^S through its truncated version
Lemma C.6
Concentration of the number of exposed edges of the foremost forest
Proposition C.8 and Corollary C.9
Estimate of the number of exposed edges of the foremost forest
Lemma C.7
Bound on $\sum \frac{1}{i(n-i)+1}$
Theorem C.5
Azuma inequality
Lemma C.1
Bound on $\sum \frac{2\log(\min\{k,n-k\})+\log\log n}{k(n-k)}$
Lemma C.10
Growth of foremost forest
Theorem 3.3
Foremost forest target set reachability
Lemma C.11
Distribution of added vertex

Figure 1 Overview of the proof of Theorem 3.3.

Proof Sketch. The theorem is deduced from Lemma C.10 and Lemma C.11 that can be found in Appendix C of the full version. Lemma C.10 essentially constitutes a generalization of the foremost tree growth analysis from [9], which estimates the number of vertices that a given vertex (referred to as a *source*) reaches by specific time in $\mathcal{F}_{n,p}$. Besides the difference that in Lemma C.10 we need to consider a fixed *set of source* vertices, the main technical challenge here is that we have to consider the $\mathcal{F}_p(G)$ model rather than the basic $\mathcal{F}_{n,p}$ model, resulting in fewer edges per node. While Lemma C.10 merely gives a statement over the number of nodes that are reached from a given source set, Lemma C.11 gives the second crucial ingredient for proving Theorem 3.3. It states that every new vertex reached by the foremost forest grown from S (i.e., every new vertex added to the foremost forest) is distributed almost uniformly on the vertices that are not reached yet and this allows us to estimate the probability that the forest reaches the target set T. ◀

4 Sharp Threshold for Giant Open Connected Component

In this section, we report on our first main result.

▶ **Theorem 4.1** (Main Result for Open Components)**.** *The function $\frac{\log n}{n}$ is a sharp threshold for Giant Open Connected Component. More specifically, there exists a function $\varepsilon(n) \in o\Big(\frac{\log n}{n}\Big)$, such that the size of a largest open temporally connected component in $\mathcal{G} \in \mathcal{F}_{n,p}$ is*

(i) *$o(n)$ a.a.s., if $p < \frac{\log n}{n} - \varepsilon(n)$; and*
(ii) *$n - o(n)$ a.a.s., if $p > \frac{\log n}{n} + \varepsilon(n)$.*

We prove the lower bound on the threshold (i.e. Theorem 4.1 (i)) in Section 4.1. The proof of this bound is a straightforward consequence of a result on foremost *tree* growth in $\mathcal{F}_p(K_n)$ from [9]. The upper bound (i.e. Theorem 4.1 (ii)) on the threshold is proved in Section 4.2 and is significantly more involved. In particular, it relies on Theorem 3.3 to measure foremost *forest* growth in $\mathcal{F}_p(G)$, where G is chosen to contain all edges that did *not* occur within some particular time window.

4.1 Lower Bound on the Threshold

We state the lower bound in form of the following theorem which says that a.a.s. there is no linear size component before time $\log n/n$. This theorem can be derived rather easily from results of Casteigts et al. [9]; we refer to Appendix D of the full version for the details.

▶ **Theorem 4.2** (Lower Bound in Theorem 4.1). *Let $\mathcal{G} \sim \mathcal{F}_p(K_n)$ with $p < \frac{\log n}{n} - \frac{3(\log n)^{0.8}}{n}$. Then, for any constant $c \in (0,1)$, the graph $\mathcal{G}$ does not contain a temporally connected component of size at least $c \cdot n$ with probability at least $1 - 2n^{-\sqrt{\log n}}$.*

4.2 Upper Bound on Threshold

Next, we present the first, weaker version of our main result, stating that an open temporally connected components containing almost all vertices appears already around time $\log n/n$.

▶ **Theorem 4.3** (Upper Bound in Theorem 4.1). *Let $\mathcal{G} \sim \mathcal{F}_p(K_n)$ with $p \geq (1 + \varepsilon(n)) \cdot \frac{\log n}{n}$. Then, the graph $\mathcal{G}$ contains a temporally connected component of size $n - o(n)$ a.a.s.*

We begin by giving a sketch of the proof idea.

Proof Sketch. The strategy is as follows, see also Figure 2. We split the time interval $[0, p]$ into three intervals I_1, I_2, and I_3 of equal duration $p/3$, and reveal the edges of the graph in two phases.

In Phase 1, we reveal the edges whose time labels are in one of the intervals I_1 and I_3. Using a result from [9] (Lemma D.2), we can conclude that there are $n - o(n)$ nodes (call them X), each of which a.a.s. reaches at least $\sqrt[3]{n} \log n$ vertices during I_1, and there are at least $n - o(n)$ nodes (call them Y) that a.a.s. is reached by at least $\sqrt[3]{n} \log n$ vertices during I_3.

In Phase 2, we reveal the edges appearing during the middle interval I_2. We show that for every ordered pair of nodes x, y in the set $Z := X \cap Y$ (which is our intended connected component), the set of vertices that x can reach during I_1, can reach during I_2 at least one vertex in the set of vertices that reach y during I_3; thus implying that x can reach y during $[0, p]$. For this purpose we can employ Theorem 3.3 with S being the set that x can reach during I_1 and T being the set of vertices that can reach y during I_3. Note that the analysis of this phase is what requires us to develop the generalization $\mathcal{F}_p(G)$ of the model $\mathcal{F}_{n,p}$. In fact, the static base graph G used in the application of Theorem 3.3 is the graph obtained from K_n by removing the edges that appeared during either I_1 or I_3. Finally a union bound over all pairs of nodes x and y yields the result. ◀

The remainder of this section is dedicated to proving Theorem 4.3. Throughout, we denote $\varepsilon(n) := \frac{1}{\log \log n}$.

Let $p = (1 + \varepsilon(n)) \cdot \frac{\log n}{n}$ and $\mathcal{G} \sim \mathcal{F}_p(K_n)$. We will prove Theorem 4.3 only for this value of p as it will then clearly follow for any larger value. Our strategy is to split the interval $[0, p]$ into three sub-intervals $[p_0, p_1]$, $[p_1, p_2]$, $[p_2, p_3]$, where $p_i := \frac{i}{3}(1 + \varepsilon(n))\frac{\log n}{n}$ for $i \in [0, 3]$. We now first deduce the following corollary about the connectivity of the subgraphs $\mathcal{G}_{[p_i, p_{i+1}]}$ for $i \in [0, 2]$ of $\mathcal{G}$ from Lemma D.2.

▶ **Corollary 4.4.** *For $i \in [0, 2]$, the number of vertices* reached by *(resp.* reaching*) a fixed vertex in $\mathcal{G}_{[p_i, p_{i+1}]}$ lies within $[n^{1/3} \log n, n^{1/3 + \varepsilon(n)}]$ with probability at least $1 - \frac{10}{\log n}$.*

For space reasons, the proof of Corollary 4.4 is found in Appendix E of the full version.

Using Markov's inequality we can obtain that, a.a.s., almost all nodes can reach (resp. be reached by) the above number of nodes.

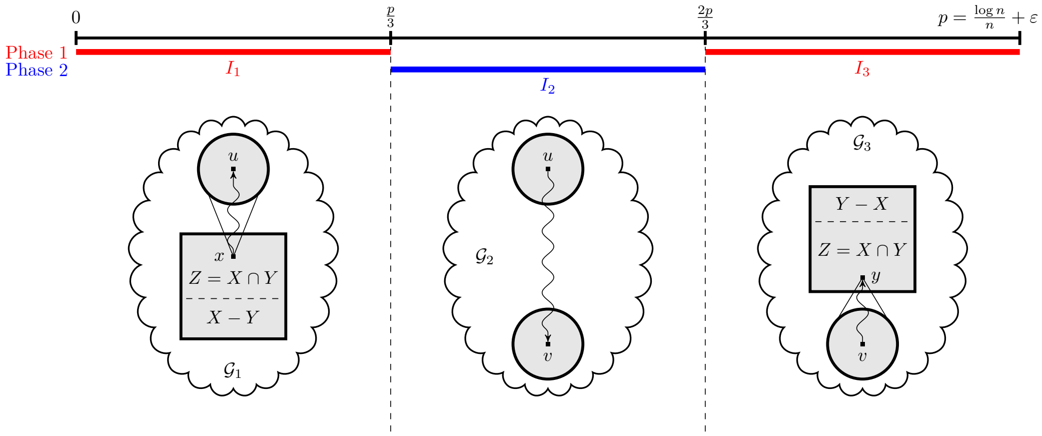


Figure 2 General strategy for upper bounding the value of p in the case of open components. Here, $\mathcal{G}_i$ denotes the restriction of the temporal graph to subinterval I_i. Wavy lines denote temporal paths. We show that any node $x \in Z$ can reach any other node $y \in Z$ by reaching a node u in $\mathcal{G}_1$, then a node v in $\mathcal{G}_2$, and finally y in $\mathcal{G}_3$.

▶ **Lemma 4.5.** *Let $i \in \{0, 1, 2\}$. The number of vertices that can reach (resp. be reached by) at least $n^{1/3} \log n$ and at most $n^{1/3+\varepsilon(n)}$ vertices in $\mathcal{G}_{[p_i,p_{i+1}]}$ is at least $n - \frac{n}{\log \log n}$ with probability at least $1 - \frac{10 \log \log n}{\log n}$.*

Proof. Let $\bar{X}$ denote the number of nodes in $\mathcal{G}_{[p_i,p_{i+1}]}$ that can reach (resp. be reached by) less than $n^{1/3} \log n$ or more than $n^{1/3+\varepsilon(n)}$ vertices in $\mathcal{G}_{[p_i,p_{i+1}]}$. Then $\mathbb{E}[\bar{X}] \leq 10n/\log n$ by Corollary 4.4. Using Markov's inequality $\mathbb{P}\left[\bar{X} \geq \frac{n}{\log \log n}\right] \leq \frac{10 \log \log n}{\log n}$. ◀

We now denote by X the set of nodes that can reach at least $n^{1/3} \log n$ and at most $n^{1/3+\varepsilon(n)}$ vertices in $\mathcal{G}_{[0,p_1]}$ and by Y the set of nodes that are reached by at least $n^{1/3} \log n$ and at most $n^{1/3+\varepsilon(n)}$ vertices in $\mathcal{G}_{[p_2,p_3]}$. Furthermore, we denote by $Z = X \cap Y$ their intersection. According to Lemma 4.5, it holds that $|Z| \geq n - \frac{2n}{\log \log n}$ with probability at least $1 - \frac{20 \log \log n}{\log n}$. The hardest part of our proof is to now show that, for a fixed ordered pair $x, y \in Z$, the probability that there is a temporal path from x to y is so large that we can take a union bound over all ordered pairs. To this end, let $A(x)$ be the set of nodes that x can reach in $\mathcal{G}_{[0,p_1]}$ and let $B(y)$ be the set of nodes that can reach y in $\mathcal{G}_{[p_2,p_3]}$. Furthermore, for $x \in X$, let

$$A'(x) := \{v \in V : \exists a \in A(x) \text{ s.t. } a \text{ reaches } v \text{ in } \mathcal{G}_{[p_1,p_2]}\}$$

be the set of nodes that x can reach in $\mathcal{G}_{[0,p_2]}$. Notice that x reaches y if and only if $A'(x)$ intersects $B(y)$.

Let $G'' = (V, E'')$ with $E'' = \{e \in \binom{V}{2} \mid \lambda(e) \in [0, p_1] \cup [p_2, p_3]\}$ be the graph containing all edges appearing in $\mathcal{G}_{[0,p_1]}$ or $\mathcal{G}_{[p_2,p_3]}$, and let $G' = (V, E')$ with $E' = \binom{V}{2} \setminus E''$ contain all other edges. Then we observe that the distribution of the set $A'(x)$ conditioned on the information about the edges appearing in $\mathcal{G}_{[0,p_1]}$ and $\mathcal{G}_{[p_2,p_3]}$ is identical to the node set of a foremost forest grown from $S := A(x)$ in $\mathcal{H} \sim \mathcal{F}_{p'}(G')$, where $p' = \frac{1}{3}(1 + \varepsilon(n))\frac{\log n}{n}$. Furthermore, G'' is distributed as an Erdős-Rényi graph $G'' \sim G_{n,p}$ with $p := \frac{2}{3}(1+\varepsilon(n))\frac{\log n}{n}$. From a standard result regarding the maximum degree in $G_{n,p}$ we can thus conclude the following fact.

▶ **Observation 4.6.** *It holds that $\Delta(G'') \leq 4\log n$ a.a.s. and, thus, $\delta(G') \geq n - (\log n)^2$ a.a.s.*

Proof. Recall that G'' is distributed according to $G_{n,p}$ with $p := \frac{2}{3}(1+\varepsilon(n))\frac{\log n}{n}$. Following [7, Corollary 3.13], with $m = 1$ and $\omega(n) = \log n$, we have that a.a.s.

$$\Delta(G'') \leq pn + \sqrt{2pn\log n} + \log n\sqrt{\frac{pn}{\log n}} \leq \log n + \sqrt{2(\log n)^2} + \log n \leq 4\log n.$$

The observation about the minimum degree now follows immediately for sufficiently large n. ◀

Thus, in order to lower bound the probability that $A'(x)$ intersects $B(y)$, we can use the following corollary of Theorem 3.3.

▶ **Corollary 4.7.** *Let*

- *G be a graph of minimum degree $\delta(G) \geq n - (\log n)^a$ for some $a \in \mathbb{N}$,*
- *let S and T be two sets of nodes in G, each of cardinality at least $n^{1/3}\log n$, and*
- *let $\mathcal{G} \sim \mathcal{F}_p(G)$ with $p \geq \frac{1}{3}(1+\varepsilon(n))\frac{\log n}{n}$.*

Then, the foremost forest algorithm from S on $\mathcal{G}$ reaches T with probability at least $1 - 3n^{-\log\log n}$.

Proof. Set $s := |S|$, $t := |T|$. Without loss of generality, we may assume $s \leq n^{1/3+\varepsilon(n)}$. Note that for large enough n it holds that

$$\begin{aligned}
p &\geq \frac{1}{3}\Big(1 + \frac{1}{\log\log n}\Big)\frac{\log n}{n} \\
&\geq \frac{\frac{1}{3}\log n + 4\log\log n}{n} \\
&= \frac{\frac{2}{3}\log n + 2\log\log n - \frac{1}{3}\log n - \log\log n}{n} + \frac{3\log\log n}{n} \\
&\geq \frac{z\log n - \log s}{n} + \frac{3\log\log n}{n},
\end{aligned}$$

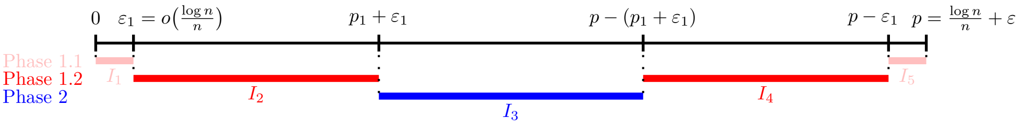
for $z = \frac{2}{3} + \frac{2\log\log n}{\log n}$. From Theorem 3.3 it then follows that the foremost forest algorithm from S reaches T with probability at least

$$\begin{aligned}
1 - \frac{5}{2}n^{-\log\log n} - e^{-\frac{t}{2n}(n^z - s)} &\geq 1 - \frac{5}{2}n^{-\log\log n} - e^{-\frac{n^{1/3}\log n}{2n}(n^{2/3}(\log n)^2 - n^{1/3+\varepsilon(n)})} \\
&\geq 1 - \frac{5}{2}n^{-\log\log n} - e^{-\frac{(\log n)^3}{4}} \geq 1 - 3n^{-\log\log n},
\end{aligned}$$

completing the proof. ◀

Using the above stated corollary, we can finally prove our first main result.

Proof of Theorem 4.3. Let $p = (1+\varepsilon(n)) \cdot \frac{\log n}{n}$ and $\mathcal{G} \sim \mathcal{F}_p(K_n)$. As above, let X be the nodes that can reach between $n^{1/3}\log n$ and $n^{1/3+\varepsilon(n)}$ vertices in $\mathcal{G}_{[0,p_1]}$ and let Y be the nodes that are reached by between $n^{1/3}\log n$ and $n^{1/3+\varepsilon(n)}$ vertices in $\mathcal{G}_{[p_2,p_3]}$. Furthermore, let $Z = X \cap Y$ be their intersection and recall that $|Z| \geq n - \frac{2n}{\log\log n}$ with probability at least $1 - \frac{20\log\log n}{\log n}$ according to Lemma 4.5. Now, conditioned on the information about the edges appearing in $\mathcal{G}_{[0,p_1]}$ and $\mathcal{G}_{[p_2,p_3]}$, let $G' = (V, E')$ be the static graph with the same node set as $\mathcal{G}$ and the edge set $E' = \{e \in \binom{V}{2} : \lambda(e) \notin [p_0,p_1] \cup [p_2,p_3]\}$, where λ is the time label function of $\mathcal{G}$. Note that according to Observation 4.6 the minimum degree in G' a.a.s. is at



0
$\varepsilon_1 = o(\frac{\log n}{n})$
$p_1 + \varepsilon_1$
$p - (p_1 + \varepsilon_1)$
$p - \varepsilon_1$
$p = \frac{\log n}{n} + \varepsilon$
Phase 1.1
Phase 1.2
Phase 2
I_1
I_2
I_3
I_4
I_5

Figure 3 Illustration of the three different phases in our proof for the case of closed components. Here, the length p_1 of I_2 and I_4 and the length p_2 of I_3 are each roughly $\frac{1}{3}\frac{\log n}{n}$. In Phase 1.1, we reveal edges in I_1 and I_5 and identify our target closed connected component, a set of n' nodes V' each of which can reach (be reached by) poly-logarithmically many vertices within V' during I_1 (I_5) via temporal paths in V'. For Phase 1.2 (consisting of intervals I_2 and I_4) we show that every vertex in $v \in V'$ reaches (is reached by) polynomially many vertices in V' during $I_1 \cup I_2$ ($I_4 \cup I_5$). We then show that during Phase 2 (consisting of I_3), for each ordered pair of vertices $u, w \in V'$, the set of vertices reached by u during $I_1 \cup I_2$ can reach the set of vertices that reach w during $I_4 \cup I_5$, implying that u can reach w during $[0, p]$.

least $n - (\log n)^2$. Now, let $x, y \in Z$ be a fixed ordered pair of vertices. Applying Corollary 4.7 to $\mathcal{H} \sim \mathcal{F}_{\frac{p}{3}}(G')$ with $S = A(x)$, $a = 2$, and $T = B(y)$, we can conclude that $A'(x) \cap B(y) \neq \emptyset$ with probability at least $1 - 3n^{-\log\log n}$, and, thus, x reaches y with at least that probability. Hence, after a union bound over all ordered pairs, we get that all nodes in Z reach each other with probability at least $1 - 3n^{-\log\log n + 2}$. Therefore, $\mathcal{G}$ has a temporally connected component of size at least $n - \frac{2n}{\log\log n} = n - o(n)$ a.a.s. ◀

5 Sharp Threshold for Giant Closed Connected Component

In this section we report on the result that $\frac{\log n}{n}$ is also a sharp threshold for the existence of a giant *closed* connected component. We first sketch the general proof idea; the formal proof given subsequently is based upon a lemma proven in Appendix F of the full version.

▶ **Theorem 5.1** (Main Result for Closed Components). *The function $\frac{\log n}{n}$ is a sharp threshold for Giant Closed Connected Component. More precisely, there exists a function $\varepsilon(n) \in o\left(\frac{\log n}{n}\right)$, such that the size of a largest closed temporally connected component in $\mathcal{G} \sim \mathcal{F}_{n,p}$ is*

(i) *$o(n)$ a.a.s., if $p < \frac{\log n}{n} - \varepsilon(n)$; and*
(ii) *$n - o(n)$ a.a.s., if $p > \frac{\log n}{n} + \varepsilon(n)$.*

Proof Sketch. The lower bound of Theorem 5.1 is obviously a trivial consequence of the lower bound in Theorem 4.1. Thus, it remains to prove the upper bound. We start from our strategy of splitting the time into three intervals. We do not need to make any changes to our approach in the middle one (Phase 2), which previously required the most effort. However, we now need to do additional work in the first and last interval (Phase 1), which is the main technical contribution of this part. Recall that in the proof of Theorem 4.3, we only required that $n - o(n)$ vertices can all reach (resp. be reached by) at least $n^{1/3} \log n$ vertices within each of the three intervals from Figure 2. Now, we will need to prove that there exists a set V' of $n - o(n)$ vertices, such that every vertex in this set can reach (resp. be reached by) at least $n^{1/3} \log n$ vertices *via temporal paths that use only vertices in V'*. Once this is achieved, we can use the same approach as in the case of open components for Phase 2.

In order to obtain the set of vertices V' mentioned above, we have to insert an additional Phase 1.1, which looks only at a short time interval I_1 at the very beginning (and symmetrically I_5 at the very end). The purpose of this new phase is to "bootstrap" the closed component by identifying a set V' of $n' = n - o(n)$ vertices, which each reach at least *poly-logarithmically* many vertices by paths that are contained in V'. Lemma 5.2 formalizes this result.

A technical difficulty in Phase 1.1 is the need to control possible cascading effects, where removing low-degree vertices from the graph can cause further vertices to become low-degree vertices, etc. We overcome this difficulty by partitioning the vertices into sectors $V_1, \dots, V_C$ and removing vertices from each sector V_i solely on the base of whether they have too few neighbors in the *next sector* V_{i+1}. This ensures that the sets of vertices removed from each sector are determined independently of each other. On this base, we are then able to prove that no cascading effects occur a.a.s. Subsequently, we show that after these removals, every remaining vertex can reach a poly-logarithmic number of others by considering *clocked* paths, which essentially march in lockstep, traversing the sectors in circular order (see Figure 4).

Subsequently, in Phase 1.2, we reveal edges that appear during I_2 or I_4. We use the foremost forest technique developed earlier to show that, conditioned on the edges revealed in Phase 1.1, for every vertex v in V' the poly-logarithmic set of vertices reached by v during I_1 reaches *polynomially many* (by which we mean n^p for some fixed $p < 1$) vertices during I_2. (Similarly, the set of vertices that reach v during I_5 is reached by polynomially many vertices during I_4.) ◀

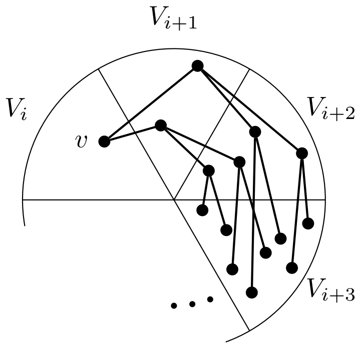


Figure 4 Example of a temporal tree formed by clocked paths starting at a vertex $v \in V_i$. By restricting the edges used between sectors V_{i+j} and V_{i+j+1} to an appropriate time interval I_{j-i}, we ensure that the time labels of all these paths are monotonically clockwise increasing.

▶ **Lemma 5.2.** *Let $C \geq 3$, $\frac{1}{2} < \gamma < \alpha < 1$, and let $\mathcal{G} \sim \mathcal{F}_{n,p}$, where $p = 2C^2 \frac{(\log n)^\alpha}{n}$. Then a.a.s. $\mathcal{G}$ contains a set V' of $n - o(n)$ vertices, such that, denoting $\mathcal{G}' := \mathcal{G}[V']$, every vertex in V' reaches at least $(\log n)^{(C-3)\gamma}$ vertices in $\mathcal{G}'_{[0,p/2]}$ and is reached by at least the same number of vertices in $\mathcal{G}'_{[p/2,p]}$.*

In the rest of this section we prove Theorem 5.1 using the above lemma, whose proof is found in Appendix F of the full version.

Proof of Theorem 5.1. Let $\gamma = 0.7$, $\alpha = 0.9$, $C = 30$, and let $n'(n) \in n - o(n)$ be the size of the vertex set guaranteed by Lemma 5.2. Set $\varepsilon_1 := C^2 \frac{(\log n)^\alpha}{n} \in o\Big(\frac{\log n}{n}\Big)$, $\varepsilon_2 := 4\frac{\log\log n'}{\log n'} \in o(1)$, and $\varepsilon_3 := \frac{1}{3\log\log n} \in o(1)$. Set also $p_1 := \left(\frac{1}{3} + \varepsilon_2\right) \frac{\log n'}{n'}$ and $p_2 := \left(\frac{1}{3} + \varepsilon_3\right) \frac{\log n'}{n'}$. Finally, define $p := 2\varepsilon_1 + 2p_1 + p_2$, which is equal to $\frac{\log n}{n} + \varepsilon$ for some $\varepsilon \in o\Big(\frac{\log n}{n}\Big)$.

Let $\mathcal{G} \sim \mathcal{F}_{n,p}$. We split $[0,p]$ into a total of five intervals I_i, $i \in [5]$. The first and the last interval are short and each has length ε_1, i.e., $I_1 = [0, \varepsilon_1]$ and $I_5 = [p - \varepsilon_1, p]$. The three middle intervals are long and have lengths p_1, p_2, and p_1, respectively, i.e., $I_2 = [\varepsilon_1, \varepsilon_1 + p_1]$, $I_3 = [\varepsilon_1 + p_1, \varepsilon_1 + p_1 + p_2]$, $I_4 = [p - (\varepsilon_1 + p_1), p - \varepsilon_1]$. We will reveal the edges of the graph in three phases (Phase 1.1, Phase, 1.2, and Phase 2), as was graphically summarized in Figure 3 in the introduction, and in each phase we condition on the edges revealed in the previous phases. In Phase 1.1 we reveal edges in the intervals I_1 and I_5 and apply Lemma 5.2 to identify a large set of nodes V', each of which can reach poly-logarithmically many vertices in V' during the first interval and can be reached by poly-logarithmically many vertices in V' during the last interval via temporal paths that use only nodes from V'. In the subsequent phases we restrict our attention to the subgraph induced by V', which is the target giant closed connected component. In Phase 1.2, we reveal edges appearing in the intervals I_2 and I_4. Because in Phase 1.1 a.a.s. we revealed poly-logarithmic number of edges for every vertex, we can use Lemma C.10 to argue that for every vertex $v \in V'$ the poly-logarithmic set of vertices reached by v during I_1 can reach polynomially many vertices during I_2. Similarly, during I_4 polynomially many vertices can reach the poly-logarithmic set of vertices that reach v during I_5. The main outcome of this phase is that every vertex in $v \in V'$ reaches polynomially many vertices in V' during $I_1 \cup I_2$ and is reached by at least as many vertices in $I_4 \cup I_5$. Finally, in Phase 2, because in the previous phases a.a.s. at most poly-logarithmically many edges were revealed for every vertex, we can apply Corollary 4.7 to prove that for each ordered pair of vertices $u, w \in V'$ the set of vertices reached by u during $I_1 \cup I_2$ can reach during I_3 the set of vertices that reach w during $I_4 \cup I_5$, implying that u can reach w during $[0, p]$. We now proceed with the formal details.

Phase 1.1. Let $\mathcal{G}_1$ be the temporal subgraph of $\mathcal{G}$ formed by the edges with time labels in the intervals $I_1 \cup I_5$. Note that, up to shifting the time labels in the interval I_5 by $p - 2\varepsilon_1$, $\mathcal{G}_1$ is distributed according to $\mathcal{F}_{n,2\varepsilon_1}$. Thus, by Lemma 5.2, a.a.s. there is a set $V' \subseteq V(\mathcal{G})$ containing n' vertices such that, denoting $\mathcal{G}' := \mathcal{G}[V']$, every vertex $v \in V'$ reaches a set $R_1(v)$ of at least $(\log n)^{(C-3)\gamma}$ vertices in $\mathcal{G}'_{I_1}$ and is reached by a set $R'_1(v)$ of at least $(\log n)^{(C-3)\gamma}$ vertices in $\mathcal{G}'_{I_5}$.

Phase 1.2. Let G_1 be the underlying graph of $\mathcal{G}_1$. Since G_1 is distributed as an Erdős-Rényi graph $G_{n,\,2\varepsilon_1}$, similarly to Observation 4.6, we have that $\Delta(G_1) < 4\log n$ a.a.s. Hence, in the graph $G'_2 = \left(V', \binom{V'}{2} \setminus E(G_1)\right)$ the minimum degree is at least $n' - 4\log n \geq n' - (\log n')^2$. Observe that, up to shifting time labels, $\mathcal{G}'_{I_2} \sim \mathcal{F}_{p_1}(G'_2)$ when conditioning on the knowledge about all edges seen in $I_1 \cup I_5$. Therefore, since $|R_1(v)| \geq (\log n')^{13}$ for every vertex $v \in V'$, by applying Lemma C.10 to $\mathcal{G}'_{I_2}$ and $R_1(v)$ (with parameter $z = 1/3 + \frac{\log\log n'}{\log n'}$), we conclude that the vertices in $R_1(v)$ reach in $\mathcal{G}'_{I_2}$ at least $r := (n')^{\frac{1}{3}+\frac{\log\log n'}{\log n'}} = (n')^{1/3}\log n'$ vertices with probability at least $1 - 2(n')^{-\log\log n'}$. By the union bound, we have that with probability at least $1 - 2(n')^{1-\log\log n'} \in 1 - o(1)$, every vertex $v \in V'$ can reach in $\mathcal{G}'_{I_1 \cup I_2}$ a set $R_2(v)$ of at least r vertices. Symmetrically, with probability at least $1 - 2(n')^{1-\log\log n'} \in 1 - o(1)$, every vertex $v \in V'$ is reached in $\mathcal{G}'_{I_4 \cup I_5}$ by a set $R'_2(v)$ of at least r vertices.

Phase 2. Let G'_3 be the static graph defined by the vertex set V' and all edges appearing in $\mathcal{G}'_{I_1 \cup I_2}$ and $\mathcal{G}'_{I_4 \cup I_5}$. As in Phase 1.2, we can argue that the maximum degree of G'_3 is at most $4\log n'$ a.a.s., and therefore the minimum degree of the graph $G'_4 = \left(V', \binom{V'}{2} \setminus E(G'_3)\right)$ is at least $n' - (\log n')^2$. Hence, up to shifting time labels, $\mathcal{G}'_{I_3}$ is distributed according to $\mathcal{F}_{p_2}(G'_4)$ when conditioned on the knowledge of all edges revealed in $I_1 \cup I_2 \cup I_4 \cup I_5$. Thus, by Corollary 4.7, a given set of at least $(n')^{1/3}\log n'$ vertices in $\mathcal{G}'_{I_3}$ can reach another given set of at least as many vertices with probability at least $1 - 3(n')^{-\log\log n'}$. Applying this to all ordered pairs of sets $(R_2(v), R'_2(w))$, $v, w \in V'$ and using the union bound, we conclude that the probability that all these pairs of sets reach each other in $\mathcal{G}'_{I_3}$ is at least $1 - 3(n')^{2-\log\log n'} \in 1 - o(1)$.

Putting all together, we conclude that a.a.s. in $\mathcal{G}' = \mathcal{G}[V']$ any vertex reaches every other vertex. Thus, V' is, as desired, a giant closed connected component. ◀

Abstract

For any positive edge density p, a random graph in the Erdős-Rényi $G_{n,p}$ model is connected with non-zero probability, since all edges are mutually independent. We consider random graph models in which edges that do not share endpoints are independent while incident edges may be dependent and ask: what is the minimum probability $\rho(n)$, such that for any distribution $\mathcal{G}$ (in this model) on graphs with n vertices in which each potential edge has a marginal probability of being present at least $\rho(n)$, a graph drawn from $\mathcal{G}$ is connected with non-zero probability?

As it turns out, the condition "edges that do not share endpoints are independent" needs to be clarified and the answer to the question above is sensitive to the specification. In fact, we formalize this intuitive description into a strict hierarchy of five independence conditions, which we show to have at least three different behaviors for the threshold $\rho(n)$. For each condition, we provide upper and lower bounds for $\rho(n)$. In the strongest condition, the *coloring model* (which includes, e.g., random geometric graphs), we show that $\rho(n) \to 2 - \phi \approx 0.38$ for $n \to \infty$, proving a conjecture by Badakhshian, Falgas-Ravry, and Sharifzadeh. This separates the coloring models from the weaker independence conditions we consider, as there we prove that $\rho(n) > 0.5 - o(n)$. In stark contrast to the coloring model, for our weakest independence condition – pairwise independence of non-adjacent edges – we show that $\rho(n)$ lies within $O(1/n^2)$ of the threshold $1 - 2/n$ for completely arbitrary distributions.

1 Introduction

The probabilistic method is an important tool in theoretical computer science, graph theory and combinatorics [3]. With this method, one proves that a random construction has some desirable property with positive probability, and concludes that some objects with this property must exist. Early examples of the probabilistic method include simple constructions of expander graphs [7], or graphs with high girth and large chromatic number [16]. Often, it is possible to express the property as the intersection of very simple events $A_1, \dots, A_k$. For example, we can express the property that a set S is a clique as the intersection of the events "u is adjacent to v" for all pairs $u, v \in S$. In many cases it is clear that each of the A_i has a large probability to occur, but this is generally not enough to conclude that the intersection of all A_i has positive probability to occur. Of course, if the probability space were a *product space* in which all components are *independent* of each other, then this would be trivial.

However, for many applications it is too limiting to restrict oneself to product spaces. The probabilistic method was significantly extended by the realization that it could still be applied to settings without perfect independence, provided there is some bound on the amount of dependence in the system. The seminal result was the Lovász Local Lemma (LLL), which we give here in the slightly stronger version due to Shearer [28]: for events $A_1, \dots, A_k$ that all occur with probability at least p, if each of the A_i depends on at most d other A_j, where $p \geq 1 - 1/(ed)$, then there is a positive probability that all of the A_i occur simultaneously.[1] In this context, the dependencies are captured by a *dependency graph*, a graph with vertex set $\{A_1, \dots, A_k\}$ such that each vertex is independent from all but its neighbors. There are many situations in which the dependency graph can be restricted, and we give some examples in Section 1.1 below.

The LLL allows to re-introduce a product space through the backdoor, because the LLL condition $p \geq 1 - 1/(ed)$ allows to couple the process to a product space. This was already implicit in the inductive proof of the LLL [29], and was made explicit by Liggett, Schonmann and Spacey [23]. They also generalized this coupling to a countably infinite number of variables and showed tightness of Shearer's condition (of the precise version in footnote 1). For a finite number of variables, coupling the probability space to a product space implies trivially that the all-one event has positive probability.

Unfortunately, the LLL scales badly in d, i.e., p needs to be very close to one if d is large. However, in some cases the degree d may grow. In particular, in this paper we will study the situation that the variables are associated with the edges of a complete graph on n vertices, and dependencies only run between adjacent edges (edges which share a common endpoint). This is a common situation, and examples are given in Section 1.1. In this case, the number of dependencies per edge is $2(n-2)$, and thus grows with n. Thus, if every edge is present with constant probability $p < 1$, then it is not possible to couple the probability space with a product space for large n, and it is not true that the complete graph appears with positive probability [23]. However, in this paper we will show that some weaker global properties *can* be guaranteed. Specifically, we will focus on connectivity because this is arguably the most fundamental global graph property. We will study the question:

> Consider a random graph in which every potential edge is inserted with probability at least p. Assume that non-adjacent edges are independent. For which values of p can we guarantee that the graph is connected with positive probability?

[1] The precise condition is $p > 1 - \frac{(d-1)^{(d-1)}}{d^d}$ for $d > 1$ and $p > 1/2$ for $d = 1$. The first expression can be simplified by the estimate $\frac{(d-1)^{(d-1)}}{d^{d-1}} \geq e^{-1}$, which becomes tight in the limit $d \to \infty$.

It turns out that the answer depends heavily on what exactly we mean by independence. Surprisingly, there are at least five different ways to interpret the innocent-looking condition that non-adjacent edges are independent, which we define next in order of increasing strength. For an edge $e = \{u, v\}$, let X_e be the event that e is present in the random graph.

▶ **Definition 1** (Pairwise independence). *For every pair of non-adjacent edges e, f, the random variables X_e and X_f are independent.*

▶ **Definition 2** (Matching independence). *For any set M of pairwise non-adjacent edges (also called a* matching*), $\{X_e \mid e \in M\}$ are mutually independent.*

▶ **Definition 3** (Edge-subgraph independence). *For any edge $e = \{u, v\}$, any vertex set W with $u, v \notin W$, and any choice of graph H_W on W, we have for the random graph G sampled from the distribution that*

$$Pr[G[W] = H_W \text{ and } X_e] = Pr[G[W] = H_W] \cdot Pr[X_e].$$

▶ **Definition 4** (Subgraph independence). *For any two disjoint subsets V, W of vertices, and any choice of graphs H_V and H_W on V and W, respectively, we have for the random graph G sampled from the dsitribution that*

$$Pr[G[V] = H_V \text{ and } G[W] = H_W] = Pr[G[V] = H_V] \cdot Pr[G[W] = H_W].$$

▶ **Definition 5** (Coloring model). *The graph distribution is given by a set of probability spaces (Ω_v, Pr_v), one for each vertex $v \in V$, and a set of deterministic functions $f_{u,v} : \Omega_u \times \Omega_v \to \{0, 1\}$ computing $X_{\{u,v\}}$, one for each edge $\{u, v\} \in \binom{V}{2}$. If every probability space (Ω_v, Pr_v) is finite, we call $\max_v |\Omega_v|$ the* number of colors *of the coloring model.*

We remark that the standard proof of LLL requires edge-subgraph independence. In the paper [23] that makes the coupling to product spaces explicit, the authors describe subgraph independence as the required property, but inspecting the proof shows that they only use the weaker condition of edge-subgraph independence.

Note that some of our models have been previously studied under different names. We summarize the bounds on the connectivity thresholds obtained before or simultaneously to this paper in Figure 1, and discuss this related work in more detail in Section 1.1. Our main results for large n are summarized in Table 1 and Figure 2. We give a refined exposition of our results for *all* n in Theorem 7. We do not have matching upper and lower bounds in all cases, but as can be seen in Figure 2, our bounds imply that there are at least three different thresholds among the five independence conditions discussed above, and four

Table 1 Lower and upper bounds for the threshold ρ s.t. every constant edge probability $> \rho$ guarantees connectivity with positive probability for all sufficiently large n, while a constant edge probability $< \rho$ does not guarantee connectivity with positive probability for infinitely many n.

Independence condition	Lower bound	Upper bound
Coloring model (2 colors)	1/4	1/4
Coloring model (general)	0.381966 . . .	0.381966 . . .
Subgraph independence	1/2 [14, Thm. 16]	1/2 [14, Thm. 16]
Edge-subgraph independence	1/2	3/4
Matching independence	1/2	1
Pairwise independence	1	1

different thresholds if we also include the coloring models with only 2 colors. Notably, our proofs give different intervals for the thresholds of all six independence conditions, although this does not imply that the thresholds are all different.

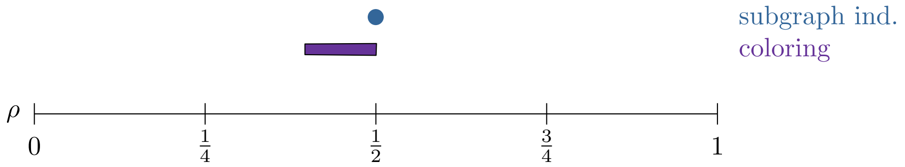

Figure 1 An illustration of the upper and lower bounds on the thresholds known from related work. The bounds for subgraph independence can be found in [14, Thm. 16]. The bounds on the coloring model have been obtained simultaneously and independently to ours [4, Thm. 1.7].

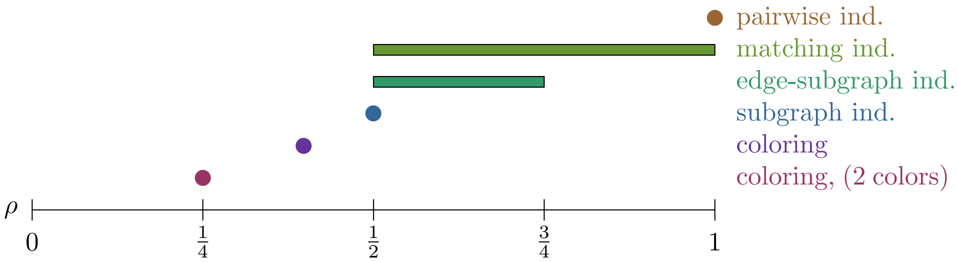

Figure 2 An illustration of the upper and lower bounds mentioned in Table 1 and Theorem 7. As can be seen, there must be at least four thresholds ρ among the six independence conditions.

Moreover, let us write $\mathcal{G}_{\text{pw}}(n,p)$ for the class of all random graph distributions on n vertices, with marginal edge probabilities at least p and with the property "pairwise independence". We write $\mathcal{G}_{\text{pw}} := \bigcup_{n\in\mathbb{N}} \mathcal{G}_{\text{pw}}(n,0)$ for the same class without restrictions on the number of vertices and the marginal probabilities. Likewise, we write $\mathcal{G}_{\text{mat}}$, $\mathcal{G}_{\text{esub}}$, $\mathcal{G}_{\text{sub}}$ and $\mathcal{G}_{\text{col}}$ for the random graph distributions satisfying matching independence, edge-subgraph independence, subgraph independence and the coloring models respectively. We show that those five models form a strict hierarchy in Appendix A.

▶ **Theorem 6.** $\mathcal{G}_{col} \subsetneq \mathcal{G}_{sub} \subsetneq \mathcal{G}_{esub} \subsetneq \mathcal{G}_{mat} \subsetneq \mathcal{G}_{pw}$.

1.1 Related Work and Examples

There are numerous applications in graph theory, theoretical computer science, and combinatorics in which dependency graphs are bounded or otherwise restricted. For example, if we want to find a vertex coloring in a hypergraph without monochromatic hyperedges, and we color the vertices independently, then any two disjoint hyperedges are independent. Therefore, often times LLL type arguments apply to coloring (hyper)graphs of bounded maximum degree. For instance, the seminal results by Johansson [20] and Molloy [24] stating that every graph of maxmimum degree Δ has (list) chromatic number $O(\frac{\Delta}{\log \Delta})$ were proved using this method. Similarly, if we want to find a satisfying assignment to a SAT-formula in conjunctive normal form, and assign the variables independently, then any two clauses are independently satisfied if they do not share a common literal, see for instance [18] for more detail and background. These are classical applications of LLL and fall into the class of coloring models.

Another important source of applications comes from percolation theory, which was also the main motivation for [23]. There, an important technique to study locally generated geometric graphs is *rescaling*: the geometric space is covered by boxes that may partially overlap, and boxes are called *good* under some conditions that depend only on the subgraph induced by the box. It is shown recursively that the probability for a box to be good increases with the box size. The goodness of two boxes is independent if they don't overlap, and typically every box only overlaps with constantly many other boxes.

So far, we gave general examples of bounded dependence. We now turn to examples where the random variables are naturally tied to the edge set of a complete graph. An important class of examples come from random graph models that are more complex than Erdős-Rényi graphs, in particular models that capture graph properties of real-world networks like clustering, communities, or heavy-tailed degree distributions. Many such models are generated by drawing some information for each vertex, and connecting two vertices based on this information. There is a large number of such random graph models: in Chung-Lu or Norros-Reittu random graphs, the vertices draw weights which determine their expected degrees [12, 27]; in Random Geometric Graphs (RGG) or Hyperbolic Random Graphs (HRG) the vertices draw some location in a geometric space [22, 26]; in scale-free percolation (SFP) the vertices lie on a grid and also draw random weights [15]; in Geometric Inhomogeneous Random Graphs (GIRG), they draw both a position and a weight [9]. In the Stochastic Block Model (SBM) they draw the community to which they should belong [21]. Many more applications of similar flavour that cannot all be listed here can be found in the literature. All these models fall in the class of coloring models.[2]

The class of coloring models is the most important one.[3] Models that do not fall into this class can arise when the graphs drawn from the distribution must fulfill some global property. For example, consider the following distribution for an *odd* number of vertices $n \geq 5$. Every vertex chooses a color from red and blue independently and uniformly at random. The resulting graph consists only of a clique on the color chosen an even number of times. We show later (in the proof of Lemma 38) that this distribution is matching independent, but not edge-subgraph independent (and thus also not a coloring model). As a second example, consider the Erdős-Rényi model $G_{n,1/2}$ with the additional side constraint that the total number of edges $|E|$ is divisible by three.[4] One can show quite easily that this distribution is not even pairwise independent. On the other hand, if we instead use the side constraint that $|E|$ is divisible by *two*, the distribution is actually a coloring model, indicating that independence conditions are surprisingly fickle. A proof of both of these facts can be found in the full version of this paper.

Two of our independence conditions have been previously considered under different names. Firstly, subgraph independent distributions have been studied under the name of 1-*independent* random graphs. More generally, a k-independent graph distribution is a distribution where any two sets of edges E, F are independent if the minimum distance

[2] The formulation of many models involves a coin flip for each edge, where the probability of inclusion is a function of the information of the two endpoints. In this formulation, the event X_e is not a *deterministic* function of the information. But one can simply define the coin flip as part of the random experiments of one of the endpoints.

[3] But note that it is not the model that arises naturally for the LLL. This raises the question whether stronger LLL-type results can be obtained for the coloring model.

[4] More formally, we consider the conditional probability distribution obtained by conditioning the $G_{n,1/2}$ distribution on the event that $|E| \equiv_3 0$.

between any vertex incident to an edge in E and any vertex incident to an edge in F is at least k. These k-independent graph distributions have been studied extensively in the context of percolation theory, for example on the infinite integer grid [5]. In [14], Day, Falgas-Ravry, and Hancock consider 1-independent random *finite* graphs. Among other results, they pin down the precise value of the connectivity threshold for 1-independent (i.e., subgraph independent) random graphs, as mentioned above in Table 1 and Figure 1.

Coloring models have been studied under two different names. First off, they have been studied as *vertex-based measures* in the context of percolation in [14]. Second off, a deterministic perspective on coloring models lies at the core of the well-studied *density Turán problem for multipartite graphs* [6, 8, 13, 17, 25]: instead of a random graph distribution, the density Turán problem for multipartite graphs considers $|V(G)|$-partite blow-ups G^* of a graph G, and the minimum density needed between parts of G^* to guarantee the existence of a graph H as a *transversal*, i.e., as a subgraph of G^* that picks precisely one vertex per part of G^*. This problem has also been considered for the more general case where we are not considering the occurrence of a single graph H as a transversal, but of any graph from some collection $\mathcal{H}$. Furthermore, one can consider the *weighted* case, where the vertices in each part of G^* each get a positive weight such that all the weights per part add up to 1. The density between two parts is then also computed in a weighted fashion. Now, considering G as the complete graph K_n, and $\mathcal{H}$ as the family of spanning trees on n vertices, one can see that the weighted density Turán problem for multipartite graphs is equivalent to the problem of determining the minimum edge probability needed to guarantee connectivity with non-zero probability in coloring models (except that the weighted density Turán setting only allows for modeling finitely many colors, which turns out to be without loss of generality, as we discuss in the following subsection). In [4], which appeared simultaneously and independently from this paper, Badakhshian, Falgas-Ravry, and Sharifzadeh consider exactly this question; they prove the same lower bound as us [4, Thm. 1.7], and propose our upper bound as a conjecture [4, Conj. 1.9].

Last but not least, let us mention that in a conceptually similar (but concretely rather different) direction, Alon and Nussboim [2] studied thresholds for the connectivity of random graph models in which only edge-sets of size at most k for a fixed parameter k are required to be independent, but dependencies between edge-sets may occur from size $k+1$ and up.

1.2 Detailed Results

In this section we give the main theorem with more detailed results. We denote by

$$\rho_{\mathrm{pw}}(n) := \inf\{p \in [0,1] \mid \forall \mathcal{D} \in \mathcal{G}_{\mathrm{pw}}(n,p), \Pr[G_n \sim \mathcal{D} \text{ is connected}] > 0\}$$

the smallest (infimum) marginal edge probability that guarantees a positive probability for G_n being connected. The quantities $\rho_{\mathrm{mat}}(n)$, $\rho_{\mathrm{esub}}(n)$, $\rho_{\mathrm{sub}}(n)$, and $\rho_{\mathrm{col}}(n)$ are defined similarly. Furthermore, let $\mathcal{G}_{\mathrm{col},k}$ denote the coloring models with at most k colors, and let $\rho_{\mathrm{col},k}(n)$ be the corresponding threshold.

▶ **Theorem 7.** *We have the following bounds on ρ:*

Pairwise independence: *For all $n \in \mathbb{N}$,*

$$1 - 2/n - \Theta(1/n^2) \leq \rho_{pw}(n) \leq 1 - 2/n.$$

Matching independence: *For all $n \in \mathbb{N}$,*

$$\frac{1}{2}(1 - \tan^2 \frac{\pi}{2n}) \leq \rho_{mat}(n) \leq 1 - 2/n.$$

Moreover, for any $k \in \mathbb{N}$,

$$\frac{1}{2} \leq \rho_{mat}(8k).$$

Edge-subgraph independence: *For all $n \in \mathbb{N}$,*

$$\frac{1}{2}(1 - \tan^2 \frac{\pi}{2n}) \leq \rho_{esub}(n) \leq 3/4.$$

Subgraph independence: *[14, Thm 16] For all $n \geq 2$,*

$$\rho_{sub}(n) = \frac{1}{2}(1 - \tan^2 \frac{\pi}{2n}).$$

Coloring model: *For all $n \geq 3$, we have $1/4 \leq \rho_{col}(n) \leq 1/2$. Moreover, let $\phi = \frac{1}{2}(1 + \sqrt{5})$ be the golden ratio. Then*

$$\lim_{n \to \infty} \rho_{col}(n) = 2 - \phi \approx 0.381966.$$

Coloring model, two colors: *For all $n \geq 3$, $\rho_{col,2}(n) = 1/4$.*

To the best of our knowledge, this question had not been considered so far for the pairwise independence, matching independence, or edge-subgraph independence models. For the subgraph independence model, the threshold was known precisely [14], but we include it in our theorem for completeness of the hierarchy of our models. Our results for the coloring model confirm a conjecture of Badakhshian, Falgas-Ravry, and Sharifzadeh [4].

We remark that, while $\mathcal{G}_{\text{col}}(n, p)$ includes models with infinitely many outcomes of the random experiment at each vertex, it has been shown[5] (in [8] for $n = 3$ and in [25, Lemma 2.1] for all n) that $\rho_{\text{col},k}(n) \geq \rho_{\text{col}}(n)$ for $k = n - 1$, which combined with the trivial $\rho_{\text{col},k}(n) \leq \rho_{\text{col}}(n)$ for any k gives $\rho_{\text{col},n-1}(n) = \rho_{\text{col}}(n)$. The proofs of $\rho_{\text{col},n-1}(n) \geq \rho_{\text{col}}(n)$ take a model which has probability 0 of being connected and modify it to use at most $n - 1$ many colors while preserving the fact that it is never connected and increasing or keeping the same its marginal edge probabilities. However, the probability distribution over all graphs on n vertices that the modified model gives is usually different from the original one. Here, we prove the even stronger statement that $\mathcal{G}_{\text{col}}(n, p) = \mathcal{G}_{\text{col},k}(n, p)$ for some $k = k(n)$, showing that finitely many colors suffice to model any probability distribution over all graphs that can be represented as a coloring model. The proof of Lemma 8 can be found in Appendix C.

▶ **Lemma 8.** *Consider a coloring model on n vertices along with its corresponding probability distribution $\mathcal{D}$ over the graphs on n vertices. Then there is a coloring model on n vertices with at most $2^{\binom{n}{2}} + 1$ colors per vertex which results in the same distribution $\mathcal{D}$.*

1.3 Open Questions

There are many interesting questions that remain open. Most obviously, for large n there are gaps between the upper and lower bounds for matching independence and edge-subgraph independence. For the coloring model we do have matching upper and lower bounds for

[5] In fact, these results are stated only for finitely many colors as they are in the density Turán setting, but the proofs go through in our more general set-up as well.

an unbounded number of colors and for $k = 2$, but not for other constant values of k. Moreover, for fixed n it is unclear how much richer the coloring model gets by adding more colors. As mentioned above, we know that $\mathcal{G}_{\text{col}}(n,p) = \mathcal{G}_{\text{col},k}(n,p)$ with $k = 2^{\binom{n}{2}} + 1$ and $\rho_{\text{col}}(n) = \rho_{\text{col},n-1}(n)$. But what is still an open question is the behavior of the functions $k^{\mathcal{G}}_{min}(n) = \min\{k \mid \mathcal{G}_{\text{col}}(n,p) = \mathcal{G}_{\text{col},k}(n,p)\}$ and $k^{\rho}_{min}(n) = \min\{k \mid \rho_{\text{col}}(n,p) = \rho_{\text{col},k}(n,p)\}$, that is, how many colors are enough to be able to express all coloring models on n vertices, respectively to capture the behaviour of the connectivity threshold of the coloring models on n vertices?

Finally, in this paper we focus on connectivity because that is arguably the most fundamental global property of a graph. We only see this as a starting point and we would find it interesting to explore analogous questions for other global properties. A natural extension might be to study the size of the largest connected component that can be achieved with non-zero probability, but the same questions arise for any other global graph properties such as Hamiltonicity, the chromatic number, and many more.

1.4 Proof Techniques

We prove the strict hierarchical structure of our considered independence conditions (Theorem 6) by giving concrete examples of distributions that fulfill the weaker independence condition, but not the stronger one. All of these examples are simple to describe and quite illustrative.

The lower bounds on the thresholds ρ are shown by concrete series of graph distributions on disconnected graphs. Here, the lower bound on ρ_{pw} (pairwise ind.) uses the same distribution as the distribution used to show $\mathcal{G}_{\text{pw}} \neq \mathcal{G}_{\text{mat}}$. The lower bounds on $\rho_{\text{mat}}, \rho_{\text{esub}}$, and ρ_{sub} all use the same construction, since we were not able to make use of the additional freedom available in the edge-subgraph or even the matching independence condition (except for the case when n is divisible by 8 in the matching independence model). This lower bound on ρ_{sub} has been previously proven in [14, Thm. 16]. While we do not restate the proof here, note that this bound uses a distribution that can be seen conceptually as a version of a coloring model with *complex probabilities*. The proof that the distribution fulfills subgraph independence follows from the fact that the coloring models are subgraph independent, and from the fundamental theorem of algebra. The lower bounds on ρ_{col} and $\rho_{\text{col},2}$ once again are simple constructions.

For the upper bounds on the thresholds ρ we use very different proof techniques depending on the independence condition. The upper bound for pairwise and matching independence does not make use of these independence conditions, and just combines a linearity of expectation argument with the maximum number of edges in a disconnected graph. As mentioned above, edge-subgraph independence is the first independence condition which allows us to apply Lovász Local Lemma to achieve a constant bound on ρ. For the coloring models, we give concrete strategies on how to pick a color for each vertex such that the graph is connected. For the two color case, this strategy is rather simple, while the strategy for the general case is based on adjusting a random coloring, which fulfills useful properties with high probability for large n. The proof of this bound (Theorem 21) is by far the most technically involved proof in this paper.

2 Preliminaries

We make use of the following version of the Lovász Local Lemma.

▶ **Lemma 9** ([28]). *Let $A_1, \dots A_k$ be a sequence of events, such that each event occurs with probability at least p and is independent of all the other events, except at most d of them. Then, if*

$$p > \begin{cases} 1 - \frac{(d-1)^{d-1}}{d^d} & \text{for } d \geq 2, \\ 1/2 & \text{for } d = 1, \end{cases}$$

there is a non-zero probability that all of the events occur.

The following lemma is a direct consequence of Markov's inequality.

▶ **Lemma 10.** *Let X be a random variable such that $Pr[X \leq u] = 1$. Then for $\ell < u$,*

$$Pr[X \geq \ell] \geq \frac{\mathbb{E}[X] - \ell}{u - \ell}.$$

Proof. Note that the random variable $u - X$ is non-negative and has expectation $u - \mathbb{E}[X]$. We can thus apply Markov's inequality.

$$Pr[X \geq \ell] = Pr[u - X \leq u - \ell] = 1 - Pr[u - X > u - \ell] \geq 1 - \frac{u - \mathbb{E}[X]}{u - \ell} = \frac{\mathbb{E}[X] - \ell}{u - \ell}. \blacktriangleleft$$

3 Bounds on ρ

In this section we prove Theorem 7, showing lower and upper bounds on ρ for our various models of independence. By the definition of ρ as in Section 1.2, any lower bound on ρ_X for some independence condition X also holds for ρ_Y for some weaker independence condition Y, i.e., one such that $\mathcal{G}_\mathrm{X} \subseteq \mathcal{G}_\mathrm{Y}$. Conversely, any upper bound on ρ_Y also holds for ρ_X.

3.1 Pairwise Independence

▶ **Lemma 11.** *For even $n \geq 4$, we have $\rho_{pw}(n) \geq 1 - \frac{2}{n} - \Theta(\frac{1}{n^2})$.*

Proof. Consider the distribution $CM(n, q)$ as defined in Definition 40 with $q = 1 - \Theta\left(\frac{1}{n^2}\right)$ chosen such that $CM(n, q)$ is pairwise independent, which can be done by Claim 41. The marginal edge probability p in $CM(n, q)$ is then $p = 1 - \frac{2}{n} - \Theta\left(\frac{1}{n^2}\right)$. Note that the probability of $G \sim CM(n, q)$ being connected is 0, since in the clique regime there is always an isolated vertex, and in the matching regime G only consists of a perfect matching. Thus, the threshold ρ_{pw} for non-zero probability of connectivity in the pairwise independence model is at least $p = 1 - \frac{2}{n} - \Theta\left(\frac{1}{n^2}\right)$. ◀

▶ **Lemma 12.** *For any n, we have $\rho_{pw}(n) \leq 1 - \frac{2}{n}$.*

Proof. If the minimum marginal edge probability p in any graph distribution (not even necessarily pairwise independent) is larger than $1 - \frac{2}{n}$, the expected number of edges $\mathbb{E}[\sum_e X_e]$ is larger than $(1 - \frac{2}{n})\binom{n}{2} = \binom{n-1}{2}$. Since any disconnected graph contains at most $\binom{n-1}{2}$ edges, the graph must be connected with non-zero probability. ◀

3.2 Matching Independence

We have no general bounds specifically holding for matching independence. Matching independence is a condition that is surprisingly difficult to exploit. We thus state the following corollary, following directly from Lemma 12 and Lemma 17.

▶ **Corollary 13.** *For any $n \geq 2$, we have $\frac{1}{2}(1 - \tan^2 \frac{\pi}{2n}) \leq \rho_{mat}(n) \leq 1 - \frac{2}{n}$.*

The lower bound in Corollary 13 can be improved slightly when n is divisible by 8, which in particular shows that $\rho_{mat}(n) \neq \rho_{sub}(n)$ for infinitely many n, illustrating again the different behavior of the connectivity thresholds for different independence conditions. The proof of this statement can be found in the full version.

▶ **Lemma 14.** *For any $n \in \mathbb{N}$ that is divisible by 8, we have $\rho_{mat}(n) \geq \frac{1}{2}$.*

3.3 Edge-Subgraph Independence

We have no lower bound specifically for edge-subgraph independence. We inherit this bound from the stricter subgraph independence, i.e., Lemma 17.

▶ **Corollary 15.** *For any $n \geq 2$, we have $\rho_{esub}(n) \geq \frac{1}{2}(1 - \tan^2 \frac{\pi}{2n})$.*

▶ **Lemma 16.** *For any n, we have $\rho_{esub}(n) \leq \frac{3}{4}$.*

Proof. We show that any edge-subgraph independent distribution with minimum marginal edge probability $p > \frac{3}{4}$ is connected with non-zero probability. To achieve this, we use the Lovász Local Lemma, as stated in Lemma 9.

We pick the edges of any Hamiltonian path $e_1, \ldots, e_{n-1}$ of K_n and consider their corresponding events $X_{e_1}, \ldots, X_{e_{n-1}}$. Since we have edge-subgraph independence, each of these events depends on only at most $d = 2$ of the other events (the ones corresponding to the neighboring edges). Furthermore, the probability of each of these events is at least $p > \frac{3}{4}$. By Lemma 9, since $p > \frac{3}{4} = 1 - \frac{1^1}{2^2}$, with non-zero probability all of the events $X_{e_1}, \ldots, X_{e_{n-1}}$ happen, all edges of the Hamiltonian path are present, and thus the graph is connected. ◀

3.4 Subgraph Independence

The exact behavior of ρ_{sub} has been determined in [14, Thm. 16]. For a proof, we point the reader to [14]. We also include a proof of the lower bound part of this statement in the full version of this paper.

▶ **Lemma 17** ([14, Thm. 16])**.** *For any $n \geq 2$, we have $\rho_{sub}(n) = \frac{1}{2}(1 - \tan^2 \frac{\pi}{2n})$.*

3.5 Coloring Models

We first consider coloring models with only 2 colors, since we can find matching lower and upper bounds for that case. Other restrictions of the coloring model could also be interesting to investigate, such as other bounded numbers of colors, or the case where every vertex must pick *uniformly* among its colors. We show that the threshold probability is exactly 1/4 in this case. The proof can be found in Appendix B.

▶ **Lemma 18.** *For all $n \geq 3$, we have $\rho_{col,2}(n) = 1/4$.*

We now consider the full generality of coloring models, with an unbounded or even infinite (although by Lemma 8 this can w.l.o.g. be excluded) number of outcomes of the local experiment at each vertex.

▶ **Lemma 19.** *For all $n \geq 3$, we have $\rho_{col}(n) \geq (n-2)\frac{3n-4-\sqrt{5n^2-16n+12}}{2(n-1)^2}$.*

Note that for $n = 3$, this bound is equal to $1/4$ (which matches the previous subsection, since our construction only uses 2 colors in this case), and for $n \to \infty$, it tends to $2 - \phi \approx 0.381966$. We remark that Lemma 19 was obtained simultaneously and independently in [4, Thm 1.7] with the exact same construction.

Proof. We show that for each number of vertices $n \geq 3$, there exists a coloring model with marginal edge probability $p(n) = (n-2)\frac{3n-4-\sqrt{5n^2-16n+12}}{2(n-1)^2}$ which is connected with probability 0.

We define the distribution $CS(n)$ for any $n \geq 3$. A fixed vertex v picks as its local experiment one other vertex $v' \in [n] \setminus \{v\}$ uniformly at random. All other vertices pick the color red with probability q (to be determined later), and blue with probability $1 - q$. Then, v connects to all vertices in $V \setminus \{v, v'\}$ that are colored blue. Between the vertices in $V \setminus \{v\}$, an edge is present if both endpoints are colored red. The resulting graph is clearly not connected: every red vertex is only connected to other red vertices, and in the case that all vertices in $V \setminus \{v\}$ are blue, only $n - 2$ edges exist.

For every edge e not incident to v we have $Pr[X_e] = q^2$, and for every edge e' incident to v we have $Pr[X_{e'}] = (1-q)\frac{n-2}{n-1}$. We pick q maximizing the minimum of these probabilities. Since q^2 is increasing in q for $q \geq 0$, and $(1-q)\frac{n-2}{n-1}$ is decreasing in q, the minimum is maximized when $q^2 = (1-q)\frac{n-2}{n-1}$. We can thus solve

$$q^2 + \frac{n-2}{n-1}q - \frac{n-2}{n-1} = 0$$

to get

$$q = \frac{2 - n \pm \sqrt{5n^2 - 16n + 12}}{2(n-1)}.$$

Only one of these solutions fulfills $q > 0$, namely the one with "+". Since the marginal edge probability $p(n)$ is equal to $(1-q)\frac{n-2}{n-1}$, we get the claimed bound. ◀
