Let us now consider upper bounds for $\rho_{\mathrm{col}}(n)$. We first state the weaker constant bound holding for all n. The proof can be found in the full version of this paper. Note that the proof of Theorem 1.7 in [4], which came out independently and simultaneously, uses essentially the same techniques as the ones we employ in the proof of the lemma below, except that they optimize the calculations to get a bound of $\frac{1}{2} - \frac{1}{4n-6}$.

▶ **Lemma 20.** *For every n, we have $\rho_{col}(n) \leq \frac{1}{2}$.*

Next, we present the stronger upper bound holding for large enough n. This bound tends to $2 - \phi$ for $n \to \infty$ and thus matches the lower bound for large enough n, as conjectured in [4].

▶ **Theorem 21.** *For any $\varepsilon > 0$, there exists an $n_0(\varepsilon)$, such that for any coloring model distribution on graphs on $n \geq n_0(\varepsilon)$ vertices with minimum marginal edge probability at least $p' = 2 - \phi + \varepsilon$, the graph is connected with non-zero probability.*

To prove this theorem, we will need the following notation and setup. We write p for $2 - \phi$.

▶ **Observation 22.** *For $p = 2 - \phi$, we have the nice identities $\frac{1}{p} - 2 = 1 - p$ and $(1-p)^2 = p$.*

To begin, we color each vertex independently with a random color according to its own distribution.[6] For this fixed coloring, we write $N(v, c)$ for the set of neighbors of v, if v is recolored to the color c.

▶ **Lemma 23.** *In a random coloring, with high probability it holds that $\mathbb{E}_c[|N(v, c)|] > (p + \varepsilon/2)n$ for all v simultaneously.*

The proof of this lemma uses standard concentration bounds and can be found in the full version.

Thus, from now on, we condition on the high probability event of Lemma 23. This allows us to argue that we can recolor any vertex such that it has a large neighborhood. Furthermore, using Lemma 10, we can also argue that for every vertex, relatively large neighborhoods must exist with a somewhat large probability. This allows us to use union bounds to show that large neighborhoods must exist at the same time as some fixed edges.

Our general strategy for showing the graph is connected with positive probability will be to mostly rely on the random coloring of all vertices that we start with, but recolor some vertices as necessary, using some large neighborhoods to connect vertices to.

Since we will recolor some vertices, the true neighborhoods in the final graph may be different (possibly also smaller) than in the random coloring for which we get these bounds. We use the error term $C := C'(\varepsilon) \log_2 n$ for an upper bound on the number of vertices that we recolor and aim to connect to (we may recolor more vertices, but we do not argue that we connect to these vertices, thus recoloring them does not matter). If we can guarantee a desired intersection of neighborhoods (or of a neighborhood with a fixed set) to contain at least $C + 1$ vertices in the random coloring, we know that in the actual coloring at the end the intersection is non-empty.

Let (r, c_r) be a vertex-color pair which maximizes $|N(r, c_r)|$. We recolor r to c_r. If every vertex outside of $N(r, c_r)$ can be recolored to some color such that it has an edge to a vertex in $N(r, c_r)$, the graph can be connected. Otherwise, we pick a vertex-color pair (b, c_b) which maximizes $|N(b, c_b)|$ among all vertex-color pairs for which $b \notin N(r, c_r) \cup \{r\}$, and $|N(r, c_r) \cap N(b, c_b)| \leq C$. We recolor b to c_b.

In the following, we use the shorthands

$$R := N(r, c_r),\ B := N(b, c_b),\ \alpha := |R|/n,\ \text{and}\ \beta := |B|/n.$$

The vertices r and b, along with their respective neighborhoods R and B, will be central to our argument, and we will find various ways to connect all other vertices to those sets.

The next lemma is fairly straightforward and its proof can be found in the full version.

▶ **Lemma 24.** *$p < \alpha < 1 - p$, and $p < \beta \leq \alpha$.*

Note that if we have $R \cap B \neq \varnothing$, we can easily connect the graph: if we recolor each vertex $v \notin R \cup B \cup \{r, b\}$ to some color c such that $|N(v, c)| > pn$, $N(v, c)$ must intersect $R \cup B$. This follows from $|R \cup B| = |R| + |B| - |R \cap B| \geq \alpha n + \beta n - C \geq 2pn - C$, and $(2pn - C) + pn > n$. We thus assume in the following that $R \cap B = \varnothing$.

▶ **Lemma 25.** *$\beta \leq \min(1 - \alpha, 1/2)$.*

Proof. This follows directly from $R \cap B = \varnothing$ and thus $\alpha + \beta \leq 1$. ◀

[6] We assume that we have a finite number of colors, which we can do by Lemma 8.

To connect the graph in the remaining cases, we need to introduce some more definitions. Intuitively, we say that any vertex v is *obligate red*, if it cannot robustly be connected to the blue set B. More formally, we say that a vertex $v \notin B \cup \{b\}$ is obligate red, if there exists no color c, such that $|N(v,c) \cap B| > C$. Similarly, we say that a vertex $v \notin R \cup \{r\}$ is *obligate blue*, if there exists no color c such that $|N(v,c) \cap R| > C$. Let OR be the set of obligate red vertices, and OB the set of obligate blue vertices.

Note that no vertex can be both obligate blue and obligate red. When a vertex is neither obligate blue nor obligate red, we say it is *non-obligate*.

We start with giving some guarantees on the sizes of neighborhoods of obligate blue and obligate red vertices.

▶ **Lemma 26.** *Let $u \in OB, v \in OR$. Then, over the distribution of the color of u (v), the following hold for the neighborhood of u (v).*

1. $Pr[|N(u,c)| \geq \frac{p+p\beta-\beta}{p}n + \varepsilon n/2] \geq 1-p$.
2. $Pr[|N(v,c)| \geq \frac{p+p\alpha-\alpha}{p}n + \varepsilon n/2] \geq 1-p$.
3. $Pr[|N(u,c)| \geq (1-p)(1-\beta)n + \varepsilon n/2] \geq 1-\sqrt{p}$.
4. $Pr[|N(v,c)| \geq (1-p)(1-\alpha)n + \varepsilon n/2] \geq 1-\sqrt{p}$.

Proof (sketch). We can upper bound the size of a neighborhood of any vertex by αn. Furthermore, we can upper bound the size of a neighborhood of any obligate blue vertex u by βn. The lemma follows from applying Lemma 10 and simplifying. The full calculations are found in the full version. ◀

The next two corollaries follow from Lemma 26 and some calculations that can be found in the full version.

▶ **Corollary 27.** *Let S be a vertex set of size $|S| \leq C$. Let $u \in OB$. Then,*

$$Pr_c[N(u,c) \cap (B \setminus S) \neq \varnothing] \geq 1-p.$$

▶ **Corollary 28.** *Let S be a vertex set of size $|S| \leq C$. Let $v \in OR$. Then,*

$$Pr_c[N(v,c) \cap (R \setminus S) \neq \varnothing] \geq 1-p.$$

We will now prove Theorem 21 by case distinction on the number of obligate red and obligate blue vertices.

▶ **Lemma 29.** *If there are either no obligate red or no obligate blue vertices, the graph can be connected.*

Proof. If there are no obligate red vertices, we recolor every vertex $v \notin B \cup \{b\}$ to a color c such that $N(v,c)$ intersects B. Every vertex is thus connected to b either directly or through a vertex in B, proving that the graph is connected. Symmetrically, if there are no obligate blue vertices, all vertices can be connected to r or R. ◀

▶ **Lemma 30.** *If $|OR| > C$ or $|OB| > C$, the graph can be connected.*

The full proof of this lemma can be found in the full version.

Proof (sketch). Suppose without loss of generality that $|OB| > |OR|$ (the other case is symmetric). Let $OB' \subset OB \setminus \{b\}$ be a subset of C obligate blue vertices. We recolor all vertices in OB' as well as all non-obligate vertices such that they connect into $B \setminus OB'$. Crucially, each vertex in OB' has a color that allows it to connect to $B \setminus OB'$ as well as a

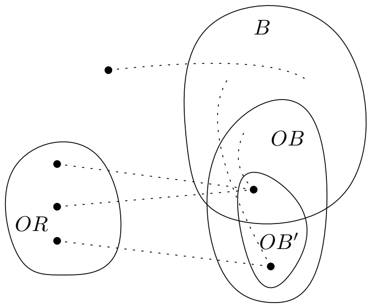

Figure 3 How to connect the graph when $|OB| > C$.

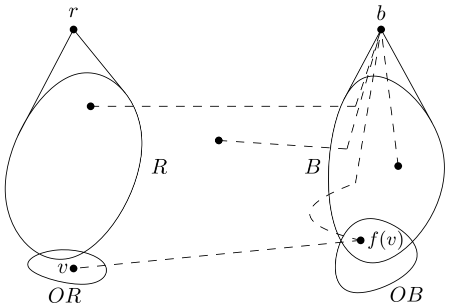

Figure 4 How to connect the graph given an injective mapping f from OR to $OB \setminus \{b\}$.

constant proportion of the remaining vertices in OR. Since C is logarithmic in n, we are able to cover all vertices in OR in this way, and thus connect the graph. An illustration of this can be seen in Figure 3. ◀

We thus assume in the following that the numbers of obligate red and obligate blue vertices are more than 0 and at most C.

▶ **Lemma 31.** *If there is an injective mapping from OR to $OB \setminus \{b\}$, or an injective mapping from OB to $OR \setminus \{r\}$, the graph can be connected.*

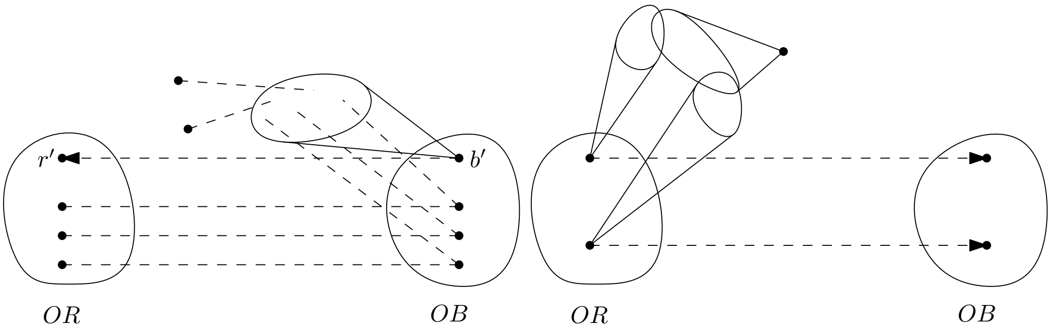
Proof. We first assume an injective mapping f from OR to $OB \setminus \{b\}$ exists. The opposite case works symmetrically. In this case we aim to connect every vertex to b, by connecting each obligate red vertex v to the vertex $f(v)$. These obligate blue vertices, as well as the non-obligate vertices outside $B \setminus \{b\}$ are then connected to some vertex in $B \setminus OB$. Since these vertices are connected to b, the whole graph is connected. This is shown in Figure 4. Note that we recolor the vertices in OB and outside B, but not those in $B \setminus OB$.

We let $v \in OR$ and $f(v) \in OB$ pick a color independently at random from their respective distributions. We have that $Pr[vf(v) \in E(G)] \geq p' = p + \varepsilon$. Furthermore, by Corollary 27, $Pr[N(f(v), c) \cap (B \setminus OB) \neq \varnothing] \geq (1 - p)$. Thus, letting $Y_{v,f(v)}$ be the indicator random variable that is 1 if and only if $vf(v) \in E(G)$ and $N(f(v), c) \cap (B \setminus OB) \neq \varnothing$, we have

$$Pr[Y_{v,f(v)} = 1] \geq p' + (1 - p) - 1 \geq \varepsilon.$$

Thus, we can pick colors for each pair of vertices $(v, f(v))$, for $v \in OR$, such that v connects to $f(v)$ and $f(v)$ connects to $B \setminus OB$. ◀

We can enhance the previous lemma by considering non-obligate vertices which also have a large probability (at least $1 - p$) to robustly connect to either of the two sets R and B (as obligate vertices are guaranteed to, by Corollary 27 and Corollary 28, respectively):



(a) Case 1: At least one edge is oriented towards OR. **(b)** Case 2: All edges are oriented towards OB.

Figure 5 Connecting the graph in Lemma 35.

▶ **Lemma 32.** *If there exists a non-obligate vertex $v \notin \{r, b\}$ such that for $S = R$ or $S = B$, it holds that $Pr_c[|N(v,c) \cap S| > C] \geq 1 - p$, then the graph can be connected.*

Proof. If the conditions of Lemma 30 or Lemma 31 are fulfilled, we can connect the graph. Otherwise, $|OR| = |OB| \leq C$ and $r \in OR$ and $b \in OB$. Assume there is a vertex v such that $Pr_c[|N(v,c) \cap B| > C] \geq 1 - p$ (the case $S = R$ works symmetrically). We can make a bijective mapping from OR to $(OB \cup \{v\}) \setminus \{b\}$. Since we have that $Pr_c[N(v,c) \cap (B \setminus (OB \cup \{v\} \setminus \{b\})) \neq \varnothing] \geq 1 - p$, the proof of Lemma 31 also works for this mapping. ◀

Furthermore, if there exists a vertex that can be used to join the red and blue sets, we can also connect the graph:

▶ **Lemma 33.** *If there exists a vertex $v \notin \{r, b\}$ and a color c, such that $N(v,c) \cap R \neq \varnothing$ and $N(v,c) \cap B \neq \varnothing$, we can connect the graph.*

Proof. We give the vertex v the color c. Every vertex $w \notin R \cup B \cup \{r, b, v\}$ is recolored to some color c_w such that $|N(w, c_w)| > pn$. Since $p > 1 - \alpha - \beta$, w is then connected to some vertex in R or B. After doing this for all w, the graph is connected. ◀

Finally, we will consider the cases which were not covered by the previous lemmas. For this, we need the following lower bounds regarding non-obligate vertices, the proofs of which can be found in the full version.

▶ **Lemma 34.** *For any non-obligate vertex $v \notin \{r, b\}$, we define*

$$p_v^r := \max_{c:|N(v,c)\cap B| \leq C} |N(v,c)|, \quad \textit{and} \quad p_v^b := \max_{c:|N(v,c)\cap R| \leq C} |N(v,c)|.$$

Assuming there exists no vertex fulfilling the conditions of either Lemma 32 or Lemma 33, we have $p_v^r > \frac{\beta p - \beta + p}{p} n$, and $p_v^b > \frac{\alpha p - \alpha + p}{p} n$.

Finally, we cover the only remaining case, whose proof can be found in Appendix B. The idea of the proof is sketched in Figure 5. We consider the potential edges $b'r'$ between $b' \in OB$ and $r' \in OR$. For each such edge we determine the vertex with a higher probability of picking a color such that the other vertex can be connected to it. We then orient the edge from this vertex to the other. If at least one edge is oriented from OB to OR, we can use this fact to connect every vertex to $B \cup OB$. Otherwise, we connect every vertex to $R \cup OR$.

▶ **Lemma 35.** *If $|OB| = |OR|$, and there exists no vertex as in Lemma 32 or Lemma 33, we can connect the graph.*

Proof of Theorem 21. Lemmas 29–33 and 35 cover all possible cases. Thus, we can always connect the graph, proving the theorem. ◀

A A Strict Hierarchy

This section is dedicated to proving Theorem 6:

▶ **Theorem 6.** $\mathcal{G}_{col} \subsetneq \mathcal{G}_{sub} \subsetneq \mathcal{G}_{esub} \subsetneq \mathcal{G}_{mat} \subsetneq \mathcal{G}_{pw}$.

We will prove each strict inclusion as its own lemma, from left to right. The first among these lemmas shows that each coloring model is subgraph independent but some subgraph independent distributions are not coloring models.

▶ **Lemma 36.** *$\mathcal{G}_{col} \subsetneq \mathcal{G}_{sub}$, i.e., every coloring model is subgraph independent, but there are some subgraph independent distributions that are not coloring models.*

Proof. We first prove $\mathcal{G}_{\text{col}} \subseteq \mathcal{G}_{\text{sub}}$. Consider some graph distribution $D \in \mathcal{G}_{\text{col}}$ and consider any two disjoint subsets of vertices V, W. The resulting graph within V depends only on elementary experiments on V, and the resulting graph within W depends only on elementary experiments on W. Since the elementary experiments are mutually independent, we have independence of the resulting graphs within V and W. Thus, $D \in \mathcal{G}_{\text{sub}}$.

The fact that $\mathcal{G}_{\text{col}} \neq \mathcal{G}_{\text{sub}}$ is well-known from prior work [1, 10, 14, 19]. ◀

▶ **Lemma 37.** *$\mathcal{G}_{sub} \subsetneq \mathcal{G}_{esub}$, i.e., every subgraph independent distribution is edge-subgraph independent, but there are some edge-subgraph independent distributions that are not subgraph independent.*

Proof. Clearly $\mathcal{G}_{\text{sub}} \subseteq \mathcal{G}_{\text{esub}}$ as subgraph independence implies edge-subgraph independence by definition, since a single edge is also a subgraph.

To prove $\mathcal{G}_{\text{sub}} \neq \mathcal{G}_{\text{esub}}$, we consider the following graph distribution $CC(n)$ on $n \geq 6$ vertices: with probability 1/2, the distribution returns a graph drawn from the Erdős-Rényi distribution $G_{n,1/2}$. Otherwise, the distribution picks a uniformly random decomposition of the vertex set $[n]$ into two sets A and B, and returns the graph consisting of the union of cliques on A and B. We first show that $CC(n)$ is edge-subgraph independent. In both the Erdős-Rényi regime as well as the two-cliques regime, for any edge e we have $Pr[X_e] = 1/2$. This holds even when we condition on the outcome within any subgraph disjoint from e, thus $CC(n)$ is edge-subgraph independent. On the other hand, we show that $CC(n)$ is not subgraph independent. To this end, we decompose the vertex set $[n]$ into the sets $P = \{u, v, w\}$ and $Q = [n] \setminus P$. We consider the two events $\mathcal{P}$:= "There are exactly two edges within P" and $\mathcal{Q}$:= "Q is a clique". Clearly, we have

$$Pr[\mathcal{Q}] = \frac{1}{2} \cdot 2^{-(n-4)} + \frac{1}{2} \cdot 2^{-\binom{n-3}{2}} > 2^{-\binom{n-3}{2}}.$$

On the other hand, $\mathcal{P}$ implies that we are in the Erdős-Rényi regime, and thus

$$Pr[\mathcal{Q}|\mathcal{P}] = 2^{-\binom{n-3}{2}}.$$

We conclude that $Pr[\mathcal{Q}] > Pr[\mathcal{Q}|\mathcal{P}]$ and thus $\mathcal{P}$ and $\mathcal{Q}$ are not independent, showing that $CC(n)$ is not subgraph independent. ◀

The graph distribution $CC(n)$ that we built in the proof above is a *convex combination* of its two regimes, as defined in the full version of this paper.

▶ **Lemma 38.** *$\mathcal{G}_{esub} \subsetneq \mathcal{G}_{mat}$, i.e., every edge-subgraph independent distribution is matching independent, but there are some matching independent distributions that are not edge-subgraph independent.*

Proof. To prove $\mathcal{G}_{\text{esub}} \subseteq \mathcal{G}_{\text{mat}}$, consider some edge-subgraph independent distribution. To prove that it is also matching independent, let $M = \{e_1, \ldots, e_k\}$ be some matching. We show for all $i \leq k$ that $Pr[X_{e_i}|X_{e_1}, \ldots, X_{e_{i-1}}] = Pr[X_{e_i}]$. This implies

$$Pr[X_{e_1} \text{ and } X_{e_2} \text{ and } \ldots \text{ and } X_{e_k}] = \prod_{i=1}^{k} Pr[X_{e_i}],$$

and thus implies matching independence. Let V' be the set of endpoints of the edges $e_1, \ldots, e_{i-1}$. Furthermore, let $\mathcal{G}(V')$ be the set of all possible graphs on V'. Then, by the law of total probability, we have

$$Pr[X_{e_i}|X_{e_1}, \ldots, X_{e_{i-1}}] = \sum_{G \in \mathcal{G}(V')} Pr[X_{e_i}|G] Pr[G|X_{e_1}, \ldots, X_{e_{i-1}}].$$

Due to edge-subgraph independence, $Pr[X_{e_i}|G] = Pr[X_{e_i}]$, and we thus have

$$Pr[X_{e_i}|X_{e_1}, \ldots, X_{e_{i-1}}] = Pr[X_{e_i}] \sum_{G \in \mathcal{G}(V')} Pr[G|X_{e_1}, \ldots, X_{e_{i-1}}] = Pr[X_{e_i}],$$

proving the desired claim.

For the second part of the statement, $\mathcal{G}_{\text{esub}} \neq \mathcal{G}_{\text{mat}}$, we consider the following graph distribution $SC(n)$ on n vertices for odd $n \geq 5$: every vertex independently and uniformly picks from the two colors red and blue. Since n is odd, one color was picked by an even number of vertices. The vertices with that color form a clique, and no other edges are present.

We first show that $SC(n)$ is matching independent: every edge individually occurs with probability $1/4$, since first both endpoints need to have the same color, and second this color must be the color picked by an even number of vertices. We prove that a matching of k edges occurs with probability $(1/4)^k$. For the matching to occur, all $2k$ vertices must pick the same color, which happens with probability $(1/2)^{2k-1}$. Second, that color must end up to be the color picked by an even number of vertices, which has probability $1/2$. Altogether, we have probability $(1/2)^{2k-1+1} = (1/4)^k$.

Finally, we show that $SC(n)$ is not edge-subgraph independent. Let W be a set of $n-2$ vertices, and e be the edge between the remaining 2 vertices. If W is a clique, e cannot be present. Since both W being a clique and e being present have non-zero marginal probabilities, edge-subgraph independence cannot hold. ◀

▶ **Lemma 39.** *$\mathcal{G}_{mat} \subsetneq \mathcal{G}_{pw}$, i.e., every matching independent distribution is pairwise independent, but there are some pairwise independent distributions that are not matching independent.*

To prove this final strict inclusion lemma, we define the following distribution. This distribution will also be useful later to prove a lower bound on ρ_{pw}.

▶ **Definition 40.** *$CM(n,q)$ for n even is the following distribution over the graphs on n vertices: to sample $G \sim CM(n,q)$, with probability q we sample from the* clique regime, *and otherwise from the* matching regime. *In the clique regime, we pick a vertex $x \in [n]$ uniformly at random and add all edges e with $x \notin e$ to G. In the matching regime, we pick a perfect matching on $[n]$ uniformly at random and add its edges to G.*

▷ Claim 41. There exists $0 \leq q(n) \leq 1$ with

$$q(n) = 1 - \Theta\Big(\frac{1}{n^2}\Big)$$

such that $CM(n, q(n))$ for n even is pairwise independent but not matching independent, and the probability of each edge is

$$p(n) = 1 - \frac{2}{n} - \Theta\Big(\frac{1}{n^2}\Big).$$

The proof of this claim is straightforward and just requires some calculations. It can be found in the full version.

Proof of Lemma 39. Clearly $\mathcal{G}_{\mathrm{mat}} \subseteq \mathcal{G}_{\mathrm{pw}}$ as matching independence implies pairwise independence by definition, since two vertex-disjoint edges e, f are a matching.

To see that $\mathcal{G}_{\mathrm{mat}} \neq \mathcal{G}_{\mathrm{pw}}$, recall that by Claim 41, there exists some $q(n)$ such that $CM(n,q)$ is pairwise independent but not matching independent. ◀

Proof of Theorem 6. Theorem 6 now follows directly from Lemmas 36–39. ◀

B Omitted Proofs from Section 3.5

Proof of Lemma 18. We first prove $\rho_{col,2}(n) \geq 1/4$ by defining the following coloring model which is always disconnected. Decompose the vertex set into three non-empty sets A, B, C. Every vertex chooses a color uniformly among the colors red and blue. Two vertices in the same set are connected if they are both red. A vertex $a \in A$ is connected to $b \in B$, if a is red and b is blue. The same goes for $b \in B$ and $c \in C$, as well as $c \in C$ and $a \in A$. Clearly, the marginal edge probability of every edge is 1/4. We now show that every connected component of a graph sampled from this distribution is a subset of the union of at most two of the sets A, B, C. To see this, we pick some edge $\{a, b\}$ for $a \in A$ and $b \in B$ to be present, and try to grow its connected component. Since the edge $\{a, b\}$ is present, a must be red and b blue. Now, a can only be connected to other red vertices in A, and to blue vertices in B. Similarly, b can only be connected to other red vertices in A. No red vertex in A or blue vertex in B can be connected to a vertex in C, thus the connected component containing the edge $\{a, b\}$ is contained in $A \cup B$. Symmetrically this holds for any pair of sets, and we conclude that the graph must be disconnected, proving the lower bound.

Next, we prove $\rho_{col,2}(n) \leq 1/4$ by showing that if every marginal edge probability is strictly larger than 1/4, we can always find a coloring that connects the graph. We say that a vertex v *covers* vertex w, if for both colors at vertex w, there exists a color at v, such that the edge $\{v, w\}$ is present under this coloring. We now remove vertices one by one, by repeatedly removing a vertex which covers some remaining vertex, until no more such vertices exist. If the graph on the remaining vertices V' can be connected using some coloring, we can add back the removed vertices in reverse order, and connect them to the vertex they cover, thus connecting the whole graph. We thus only have to show that the graph on V' can be connected. Since in this graph no vertex covers any other, each edge is only present under exactly one of the four possible color combinations of its endpoints.

We pick a vertex $v' \in V'$ which maximizes $\max(Pr[v \text{ is red}], Pr[v \text{ is blue}])$ among all $v \in V'$. We give this vertex v' the color which is more likely, let p be the probability of this color. One can see that for any other vertex $w \in V' \setminus \{v'\}$, there must be a color such that the edge $\{v', w\}$ is present. Otherwise, the color combination making $\{v', w\}$ present would have probability of at most $p \cdot (1 - p)$, which is at most 1/4. Thus, we can connect V' by simply coloring each vertex with the correct color to connect to v'. This concludes the proof of the upper bound, and thus the whole lemma. ◀

Proof of Lemma 35. We consider the potential edges between OR and OB. Each such edge $r'b'$ can be oriented in some direction, by considering the following two probabilities:

$$p_{r' \to b'} := Pr_{c_{r'}}[\exists c_{b'} \text{ such that } r'b' \in E(G) \text{ in coloring } c(r') = c_{r'}, c(b') = c_{b'}]$$
$$p_{b' \to r'} := Pr_{c_{b'}}[\exists c_{r'} \text{ such that } r'b' \in E(G) \text{ in coloring } c(r') = c_{r'}, c(b') = c_{b'}]$$

Note that $p_{r' \to b'} \cdot p_{b' \to r'} \geq Pr[r'b' \in E(G)] \geq p'$, and thus $\max(p_{r' \to b'}, p_{b' \to r'}) \geq \sqrt{p'}$. We now direct the potential edge $r'b'$ from r' to b' if $p_{r' \to b'} > p_{b' \to r'}$, and from b' to r' otherwise. We pick an arbitrary perfect matching M among the potential edges between OR and OB, using $|OR| = |OB|$.

Case 1: There exists an arc $(b', r') \in M$ directed towards $r' \in OR$. In this case we will connect the graph as shown in Figure 5a. Every obligate red vertex is connected to its matching obligate blue vertex. The vertex b' must have a large neighborhood size that can be guaranteed with probability $\geq 1 - \sqrt{p}$, so that it can simultaneously be connected to r'. Every obligate blue and every non-obligate vertex connects to this neighborhood.

By Lemma 26, part 3, we have

$$Pr[|N(b', c)| \geq (1 - p)(1 - \beta)n + \varepsilon n/2] \geq 1 - \sqrt{p}.$$

Thus, with positive probability over the choice of color for b', the size of the neighborhood of b' is at least $(1 - p)(1 - \beta)n + \varepsilon n/2$ and there is a choice of color for r' such that $r'b'$ is an edge, since $1 - \sqrt{p} + \sqrt{p'} > 0$.

Similarly, for all other obligate blue vertices u, by Lemma 26, part 1, we have

$$Pr[|N(u,c)| \geq \frac{p+p\beta-\beta}{p}n + \varepsilon n/2] \geq 1-p,$$

so with positive probability there is an edge between u and its matching vertex in OR and u's neighborhood has size at least $\frac{p+p\beta-\beta}{p}n + \varepsilon n/2$.

We need to prove that these guaranteed sizes of neighborhoods intersect outside of $OB \cup OR$. Let $S := (1-p)(1-\beta)n + \varepsilon n/2$ and $T := \frac{p+p\beta-\beta}{p}n+\varepsilon n/2$. Since both neighborhoods can intersect R in at most C vertices, we need to prove that $(S-3C)+(T-3C) > n-|R|$, i.e.,

$$S + T + \alpha n - n - 6C \overset{!}{>} 0. \tag{1}$$

Additionally, to guarantee that each non-obligate vertex u outside the neighborhood of b' can connect to that neighborhood, we need to guarantee that u has a neighborhood which intersects that of b' outside $OB \cup OR$. Thus, we check that $(S-3C)+(p_u^b-3C) > n-|R|$, i.e.,

$$S + p_u^b + \alpha n - n - 6C \overset{!}{>} 0. \tag{2}$$

Since our lower bound on p_u^b is smaller than T (as $\alpha \geq \beta$), (2) implies (1), so it suffices to show (2). The proof of (2) can be found in the full version.

Case 2: All edges in M are oriented towards OB. In this case we will connect the graph as shown in Figure 5b. We give each obligate red vertex a large neighborhood such that we can still guarantee to be able to connect the obligate blue vertices to their matching partner. Then, we give each non-obligate vertex which is not yet connected directly to any of the obligate vertices a large neighborhood not intersecting B (as guaranteed by Lemma 34). These neighborhoods must intersect all neighborhoods of the obligate red vertices due to their sizes, thus the graph is connected.

Let $Y := (1-p)(1-\alpha)n + \varepsilon n/2$. For any obligate red vertex v, by Lemma 26, part 4, we have $Pr[|N(v,c_v)| \geq Y] \geq 1-\sqrt{p}$, so with probability $1-\sqrt{p}+\sqrt{p'} > 0$ there is a color for v's obligate blue partner vertex so that they are connected by an edge and also $|N(v,c_v)| \geq Y$.

We now check that every non-obligate vertex u has a neighborhood which intersects with every neighborhood of size at least Y of the obligate red vertices. Recall that by Lemma 34, every u has a neighborhood not robustly intersecting B of size p_u^r. Note that we need to show that these neighborhoods intersect outside of $OR \cup OB$ since these vertices may change their colors. To this end, it suffices to show that $(p_u^r - 3C) + (Y - 3C) > n - |B|$, i.e.,

$$p_u^r + Y + \beta n - n - 6C \overset{!}{>} 0,$$

which is easy to verify as can be seen in the full version. ◀

C Finitely Many Colors Suffice for the Coloring Model

Proof of Lemma 8. Let $\mathcal{D}$ be a random graph distribution given as a coloring model. We will reduce the number of colors for each vertex one by one, preserving the probability distribution $\mathcal{D}$. By a slight abuse of notation, here we refer to any outcome of the experiment at some vertex as its *color*, even if there are infinitely many of them. Suppose we're considering vertex v and for each graph H on n vertices and color c of v, let $p_{H,c}$ be the probability that H is sampled from $\mathcal{D}$ conditioned on vertex v having color c, and let p_H be the unconditional probability of H being sampled from $\mathcal{D}$. Now for each color c of v, consider the vector $\vec{p}_{*,c}$ in $2^{\binom{n}{2}}$-dimensional space that consists of all the $p_{H,c}$ for all possible graphs H on n vertices in some canonical order. Consider also the vector $\vec{p}_*$ of the same dimension with the p_H for all possible graphs H on n vertices as entries in the same canonical order. By the law of total probability, $\vec{p}_*$ is contained in the convex hull of all the $\vec{p}_{*,c}$ vectors (of which there may be infinitely many). It follows by Carathéodory's theorem [11] that $\vec{p}_*$ is a convex combination of some $2^{\binom{n}{2}} + 1$ many vectors among $\{\vec{p}_{*,c} \mid c \text{ is a color of vertex } v\}$. Thus we can pick the corresponding $2^{\binom{n}{2}} + 1$ colors for v, use the coefficients given by that convex combination as probabilities for these colors in the experiment at vertex v, and we end up with the same distribution $\mathcal{D}$. We repeat this process for each vertex, completing the proof. ◀

Synergy Between Circuit Obfuscation and Circuit Minimization

Abstract

We study close connections between Indistinguishability Obfuscation (IO) and the Minimum Circuit Size Problem (MCSP), and argue that efficient algorithms/construction for MCSP and IO create a *synergy*[1]. Some of our main results are:

- If there exists a perfect (imperfect) IO that is computationally secure against nonuniform polynomial-size circuits, then for all $k \in \mathbb{N}$: $\mathsf{NP} \cap \mathsf{ZPP}^{\mathsf{MCSP}} \not\subseteq \mathsf{SIZE}[n^k]$ ($\mathsf{MA} \cap \mathsf{ZPP}^{\mathsf{MCSP}} \not\subseteq \mathsf{SIZE}[n^k]$).
- In addition, if there exists a perfect IO that is computationally secure against nonuniform polynomial-size circuits, then $\mathsf{NEXP} \cap \mathsf{ZPEXP}^{\mathsf{MCSP}} \not\subseteq \mathsf{P/poly}$.
- If $\mathsf{MCSP} \in \mathsf{BPP}$, then statistical security and computational security for IO are equivalent.
- If computationally-secure perfect IO exists, then $\mathsf{MCSP} \in \mathsf{BPP}$ iff $\mathsf{NP} = \mathsf{ZPP}$.
- If computationally-secure perfect IO exists, then $\mathsf{ZPEXP} \neq \mathsf{BPP}$.

To the best of our knowledge, this is the first consequence of strong circuit lower bounds from the existence of an IO. The results are obtained via a construction of an optimal *universal distinguisher*, computable in randomized polynomial time with access to the MCSP oracle, that will distinguish any two circuit-samplable distributions with the advantage that is the statistical distance between these two distributions minus some negligible error term. This is our main technical contribution. As another immediate application, we get a simple proof of the result by Allender and Das (*Inf. Comput.*, 2017) that $\mathsf{SZK} \subseteq \mathsf{BPP}^{\mathsf{MCSP}}$.

1 Introduction

Circuit Obfuscation

The main purpose of program obfuscation is to transform a given program into an "unintelligible" one, while preserving the program's original functionality. A natural way to represent a program is via a Boolean circuit. Given that, the most common notion of obfuscation is the notion of *indistinguishability obfuscation*, introduced in [8]. Roughly speaking, a (potentially) randomized procedure IO is an *indistinguishability obfuscator*, if the obfuscations of two circuits C_1 and C_2 of the same size and functionality are "indistiguishable". In other words, no algorithm can "distinguish" between the outputs of $\mathsf{IO}(C_1)$ and $\mathsf{IO}(C_2)$ with a "noticeable" advantage.

The kind of security provided by the IO is defined by the class of the allowed distinguishing algorithms. More formally, consider a particular class of algorithms $\mathcal{A}$ and ask whether IO is "secure against" $\mathcal{A}$. For example, if $\mathcal{A}$ is the class of *all* (possibly inefficient) algorithms, we say that IO is *statistically* secure. On the other hand, if $\mathcal{A}$ is the class of *efficient* (i.e. randomized polynomial-time) algorithms, we say that IO is *computationally* secure.

The correctness of an IO procedure is called *perfect* if the functionality of the input circuit is preserved with probability one (over the internal randomness of the IO), or *imperfect* if the functionality is preserved with high probability only.

Circuit obfuscation turned out to be a very useful tool in many cryptographic and complexity-theoretic applications, see, e.g., [19, 43, 20, 10, 35]. The past decade saw numerous candidate constructions, culminating with the work of [29]. Yet, identifying the exact necessary and sufficient conditions for the existence of indistinguishability obfuscators remains an important open question. One reason for that is that unlike the vast majority of cryptographic primitives, obfuscators could still exist even if $\mathsf{P} = \mathsf{NP}$! In fact, in this case we get an "ultimate" obfuscator: for each circuit C, the IO will output some canonical equivalent $\hat{C}$[2].

The place of IO within the Five Worlds

Thus, in the language of Impagliazzo's Five Worlds [26], an IO exists in Algorithmica. The work of [29], on the other hand, makes a good argument that an IO may exist in Cryptomania. What about the other three worlds: Heuristica, Pessiland, and Minicrypt? It turns out that none of these remaining three worlds can accommodate an IO. The results of [43] show that an IO plus a one-way function imply public key encryption (and more), and hence IO cannot exist in Minicrypt. The results of [34] essentially show that an (even imperfect) IO cannot exist in Pessiland: if there are no one-way functions but an (imperfect) IO exists, then $\mathsf{NP} \subseteq \mathsf{io\text{-}BPP}$. This result also rules out Heuristica as a possible home for an IO. We will prove a stronger connection: if an (imperfect) IO exists in Heuristica (where $\mathsf{DistNP} \subseteq \mathsf{AvgP}$), then $\mathsf{NP} = \mathsf{P}$ (see Theorem 31 below).

So IO can exist in either Algorithmica or Cryptomania. Many of the results that we shall present in this paper can be viewed as instantiations of this fact, for various settings of parameters of IO: *If you assume* IO *exists, and assume something that threatens the existence of cryptography, then you find yourself in* Algorithmica*.*

[2] For example, given a circuit C one can find the lexicographically-smallest, equivalent circuit $\hat{C}$ in PH.

Circuit Minimization

Minimum Circuit Size Problem (MCSP) [45, 31] asks for a given truth table of an n-variate Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ and a parameter $0 \leq s \leq 2^n$, if f is computable by a Boolean circuit of size at most s. It is easy to see that $\mathsf{MCSP} \in \mathsf{NP}$. Yet, it is unknown if MCSP is NP-hard, or if MCSP is easy, say in BPP. What is known is that MCSP is powerful enough to "kill" cryptography. That is, any one-way function candidate can be efficiently inverted on average by a randomized polynomial-time algorithm with access to the MCSP oracle [41, 3]. Hence, an efficient algorithm for MCSP cannot exist in Minicrypt or Cryptomania.[3]

Interplay between IO and MCSP

By the preceding discussion, if we assume that both an IO exists and that MCSP is "easy", then we should get that NP is also "easy" (as we must be in some version of Algorithmica; see Theorems 5 & 6 for more details)[4]. In fact, we shall argue that MCSP and IO act in a *synergy*. That is, the assumed existence of an appropriate version of IO makes MCSP more powerful that it is known to be. And, on the other hand, we show results where assumed "easiness" of MCSP makes an IO stronger (i.e., more secure). We state some of our main results next.

1.1 Our Main Results

We show that the existence of an (even imperfect) IO secure against P/poly implies new circuit lower bounds.

▶ **Theorem 1.** *Suppose there exists a perfect* IO *secure against* P/poly*. Then:*
1. $\mathsf{NEXP} \cap \mathsf{ZPEXP}^{\mathsf{MCSP}} \not\subseteq \mathsf{P/poly}$.
2. *For all* $k \in \mathbb{N}$*:* $\mathsf{NP} \cap \mathsf{ZPP}^{\mathsf{MCSP}} \not\subseteq \mathsf{SIZE}[n^k]$.

▶ **Theorem 2.** *Suppose there exists an imperfect* IO *secure against* P/poly*. Then for all* $k \in \mathbb{N}$*:*
$\mathsf{MA} \cap \mathsf{ZPP}^{\mathsf{MCSP}} \not\subseteq \mathsf{SIZE}[n^k]$.

The two preceding theorems should be contrasted with the unconditional circuit lower bounds proved in [44] and [27]. There it is shown that $\mathsf{ZPEXP}^{\mathsf{MCSP}} \not\subseteq \mathsf{P/poly}$ and that, for every $k > 0$, $\mathsf{ZPP}^{\mathsf{MCSP}}/1 \not\subseteq \mathsf{SIZE}[n^k]$ and $\mathsf{MA}/1 \not\subseteq \mathsf{SIZE}[n^k]$. Although removing the extra bit of advice from the lower bounds may seem incremental, it actually has been a long standing open problem that resisted many attempts! Indeed, the same issue arises in other instances involving lower bounds for randomized complexity classes; see, e.g., [7, 18, 46, 47]. Additionally, while widely *believed* to be true, showing that $\mathsf{NEXP} \not\subseteq \mathsf{P/poly}$ seems to require techniques beyond our current reach. For a further discussion, see the seminal paper of Williams [50] where it was shown that $\mathsf{NEXP} \not\subseteq \mathsf{ACC}$ and subsequent improvements (e.g. [38]). In conclusion, the two new theorems above prove stronger circuit lower bounds, but under an assumption that a certain IO exists. One interpretation of that is that a construction of these kinds of IO will require novel techniques.

Our next result is a uniform version of Theorem 1.

[3] In fact, even an efficient one-sided average-case algorithm for MCSP (i.e., an efficiently computable natural property in the sense of [41], which is useful against exponential-size circuits) would "kill" one-way functions.

[4] This observation was made in [27] and previously a similar observation was made in [34].

▶ **Theorem 3.** *Suppose there exists a computationally-secure perfect* IO*. Then* $\mathsf{ZPEXP} \neq \mathsf{BPP}$*.*

While we do not have hierarchy theorems for randomized complexity classes, one can show that $\mathsf{ZPEXP} \neq \mathsf{ZPP}$ (see Appendix C). Yet, separating ZPEXP (or even NEXP and $\mathsf{EXP}^{\mathsf{NP}}$) from BPP appears to be a longstanding open problem (see e.g. [15, 49]). In that sense our result resolves the problem under the assumption that a computationally-secure perfect IO exists.

The following theorems are examples of results where MCSP empowers IO, and where IO empowers MCSP.

▶ **Theorem 4.** *An* IO *(both imperfect and perfect) is statistically-secure if and only if it is secure against* $\mathsf{FBPP}^{\mathsf{MCSP}}$*. Hence, assuming* $\mathsf{MCSP} \in \mathsf{BPP}$*, statistically-secure* IO *exists if and only if computationally-secure* IO *exists.*

▶ **Theorem 5.** *Let* $\Gamma \in \{\mathsf{ZPP}, \mathsf{BPP}\}$*. Suppose there exists a computationally-secure imperfect* IO*. Then* $\mathsf{MCSP} \in \Gamma$ *iff* $\mathsf{NP} \subseteq \Gamma$*.*

Note that Theorem 5 strengthens a similar result of [27] to the imperfect setting.

▶ **Theorem 6.** *Suppose there exists a computationally-secure perfect* IO*. Then* $\mathsf{MCSP} \in \mathsf{BPP}$ *iff* $\mathsf{NP} = \mathsf{ZPP}$*.*

▶ Remark 1. Note that all the results still hold true if we only have an obfuscator IO for a class of circuits $\mathcal{C}$ for which the *equivalence* problem (i.e., testing if two given circuits $C_0, C_1 \in \mathcal{C}$ agree on all inputs) is coNP-hard such as: 3-CNFs (even read-thrice 3-CNFs), read-twice depth-3 formulas, monotone depth-3 formulas[5] and others. All these circuit classes are small subsets of NC^1, which is the starting points of most candidate IO constructions (see e.g. [40, 21, 36, 29] and references within).

▶ Remark 2. Recall that the results of [34] show that if there are no one-way functions yet an imperfect IO exists, then $\mathsf{NP} \subseteq \mathsf{io}\text{-}\mathsf{BPP}$. The authors subsequently pose an open problem to get a similar result only relying on an obfuscator for 3-CNFs. While we do not solve their open problem, we believe that Theorem 5, adjusted according to the previous remark, can be viewed as partial progress towards the resolution of the problem especially in light of the recent characterizations of one-way functions in terms of "MCSP"-like problems [37, 4, 25, 24].

1.2 Our Techniques

Our main technical tool is a *universal distinguisher* that, given any two circuits C_0 and C_1 that are samplers for some distributions D_0 and D_1, will distinguish between D_0 and D_1 essentially as well as is information-theoretically possible (with the distinguishing advantage equal to the statistical distance between D_0 and D_1 minus a negligible error term). We show (see Corollary 17) that such a universal distinguisher is computable in $\mathsf{FBPP}^{\mathsf{MCSP}}$[6]. The main idea is to use a distributional inverter and a connection between one-way functions and distributional one-way functions from [28]. In particular, we argue (see Lemma 32) that a distributional inverter suffices to get a distinguisher for **any** two circuit-samplable distributions D_0 and D_1. We then use the result of [3] that allows to invert any candidate

[5] Monotone depth-3 formulas are the only class on the list for which the equivalence problem is coNP-hard ,but the satisfiability problem is trivial. See [16] for more details.

[6] $\mathsf{FBPP}^{\mathsf{MCSP}}$ denotes the class of randomized polynomial-time algorithms with MCSP oracle.

one-way (and, in fact, any polynomial-time computable) function in randomized-polynomial time given an MCSP oracle (see Lemma 15 for more details). Indeed, we generalize the inverter of [3] to get a *distributional* inverter for any candidate distributional one-way function (see Lemma 16). We believe that this extension could be of independent interest.

We note, however, that it is fairly easy to construct a universal distinguisher in $\mathsf{FBPP}^{\mathsf{SAT}}$ by approximating the "maximum likelihood" distinguisher using the well-known fact that approximate counting can be done in $\mathsf{FBPP}^{\mathsf{NP}}$ [30]. For completeness, we provide the full proof in Theorem 40 of the appendix. From this perspective, our construction constitutes another example of a computational task that can still be performed with the MCSP oracle instead of the SAT oracle. See [27] for further discussion.

With this universal distinguisher in hand, we immediately get Theorem 4. We then obtain the circuit lower bounds in Theorems 1 and 2 by a "win-win" argument on the circuit complexity of MCSP. If $\mathsf{MCSP} \notin \mathsf{P/poly}$, we are done. Otherwise (i.e., if $\mathsf{MCSP} \in \mathsf{P/poly}$) security against $\mathsf{P/poly}$ implies security against $\mathsf{FBPP}^{\mathsf{MCSP}}$ and hence, by our universal distinguisher result above, is equivalent to statistical security for our IO. Then we leverage this very secure IO to get into $\mathsf{Algorithmica}$ where NP is "easy" by extending some ideas from [23, 48]. The latter leads to certain "collapses" of high complexity classes (such as $\mathsf{NEXP}^{\mathsf{NP}}$), which are known to contain languages outside $\mathsf{P/poly}$, to smaller complexity classes (such as NEXP). Hence we get circuit lower bounds for these smaller complexity classes, as required. Theorem 6 is proved using similar ideas.

1.3 Relation to Previous Work

The results in [22, 3] imply the following: For any two samplable distribution ensembles $\{A_n\}, \{B_n\}$, we have that $\{A_n\}, \{B_n\}$ are statistically indistinguishable if and only if they are indistinguishable by $\mathsf{FBPP}^{\mathsf{MCSP}}$ algorithms. While this result says that statistical indistinguishability and $\mathsf{FBPP}^{\mathsf{MCSP}}$-computable indistinguishability are the same for efficiently *uniformly* computable distribution ensembles, we need a stronger result applicable also to efficiently *nonuniformly* computable distributions. That is, we need a *universal* distinguisher that will distinguish any two distributions given by sampler circuits, with the distinguishing advantage close to the statistical distance between these distributions.

In [39], Naor and Rothblum used similar techniques to prove a similar result, yet with **different** quantifier order: for any *uniformly* computable distribution ensembles there exist a $\mathsf{FBPP}^{\mathsf{MCSP}}$-computable distinguisher with the distinguishing advantage close to the statistical distance between these distributions. Yet, by using the MCSP oracle as a *universal* inverter, one can "extract" a universal distinguisher from their proofs. For completeness we include a self-contained proof in the universal setting.

In [23], Goldwasser and Rothblum showed that the existence of statistically-secure obfuscators IO implies that $\mathsf{NP} \subseteq \mathsf{coAM}$, which in turn results in a collapse of the polynomial hierarchy by [11]. In particular, their idea was to solve SAT in SZK[7]. This is done by leveraging the IO to reduce SAT to *Statistical Difference* (SD) - the standard SZK-complete promise problem of [42]. The result then follows from [17, 2] where it was shown that $\mathsf{SZK} \subseteq \mathsf{AM} \cap \mathsf{coAM}$. In [48] a simplified and quantified proof of the result was presented. We use some of these ideas as a part our "win-win" argument (see Lemma 22 for more details).

[7] The class of decision problems for which a "yes" answer can be verified by a statistical zero-knowledge proof protocol.

Finally, it follows from the definition that the existence of non-uniform one-way functions (i.e. secure against P/poly) already implies very strong circuit lower bounds. Namely, NP $\not\subseteq$ P/poly. However, this approach cannot be used to derive lower bounds from the existence of an IO since the very same lower bound is already required in order to obtain a one-way function from an IO! In other words, given an IO, one-way functions exist iff NP $\not\subseteq$ P/poly. Our results allow us to obtain a weaker, but still strong circuit lower bound NEXP $\not\subseteq$ P/poly from the existence of an IO, thus avoiding this circular reference.

The rest of the paper

The necessary background is given in Section 2. Our main technical contribution (a universal distinguisher) is given in Section 3. In Section 4, we give a simple proof that SZK $\subseteq$ BPP$^{\mathsf{MCSP}}$ [5]. We give some consequences for MCSP from IO assumptions (including Theorems 5 and 6) in Section 5, and those for IO from MCSP assumptions (including Theorem 4) in Section 6. We prove Theorems 1 and 2 in Section 7. In Section 8, we prove that even an imperfect IO cannot exist in Heuristica. We conclude with some open questions in Section 9. Some auxiliary results are stated in the appendix.

2 Preliminaries

2.1 Definitions

A function negl(n) is *negligible* if for any $k \in \mathbb{N}$ there exists $n_k \in \mathbb{N}$ such that, for all $n > n_k$, negl$(n) < 1/n^k$.

▶ **Definition 3** (Statistical Distance). *Let X_0 and X_1 be two random variables taking values in some finite universe $\mathcal{U}$. The* Statistical Distance *between X_0 and X_1 is defined as*

$$\Delta(X_0, X_1) \triangleq \max_{A\colon \mathcal{U}\to\{0,1\}} \left\{\mathbf{Pr}_{u\sim X_0}[A(u)=1] - \mathbf{Pr}_{u\sim X_1}[A(u)=1]\right\},$$

where $A : \mathcal{U} \to \{0,1\}$ is an arbitrary statistical test (distinguisher).[8] *Another equivalent definition is that*

$$\Delta(X_0, X_1) = (1/2) \cdot \sum_{u\in\mathcal{U}} \left|\mathbf{Pr}_{X_0}[X_0 = u] - \mathbf{Pr}_{X_1}[X_1 = u]\right|.$$

We say that X_0 and X_1 are δ-close*, if $\Delta(X_0, X_1) \le \delta$.*

▶ **Definition 4** (Indistinguishability Obfuscator [8, 34, 12]). *We say that a randomized procedure* IO$(C; r)$ *(with randomness r) is an* Indistinguishability Obfuscator *for a circuit class $\mathcal{C}$ with the following:*

1. ***(Perfect/Imperfect) Correctness:*** IO *is* ε-imperfect *if for every circuit $C \in \mathcal{C}$:*

   $$\mathbf{Pr}_r[C \equiv \mathsf{IO}(C; r)] \ge 1 - \varepsilon(|C|).$$

   If $\varepsilon = 0$, then we say that IO *is* perfect.
2. ***Polynomial slowdown:*** *There are $a, k \in \mathbb{N}$ such that, for every circuit $C \in \mathcal{C}$ and every r,*

   $$|\mathsf{IO}(C; r)| \le a \cdot |C|^k.$$

[8] Note that the maximum is attained by the statistical test A such that $A(u) = 1 \iff \mathbf{Pr}[X_0 = u] \ge \mathbf{Pr}[X_1 = u]$.

3. ***Security:***
   a. ***Statistical:*** IO *is* statistically $(1-\delta)$-secure *if for all pairs of circuits $C_1, C_2 \in \mathcal{C}$ such that $C_1 \equiv C_2$ and $|C_1| = |C_2| = s$, we have*

   $$\Delta(\mathsf{IO}(C_1; r), \mathsf{IO}(C_2; r')) \leq \delta(s),$$

   where $\mathsf{IO}(C; r)$ is a distribution over the outputs of $\mathsf{IO}(C; r)$ for random r. We say that IO *is* statistically secure, *if $\delta(s)$ is a negligible function.*

   b. ***Computational:*** *Let $\mathcal{A}$ be a class of (randomized) algorithms. We say that IO is* $(1-\delta)$-secure against $\mathcal{A}$, *if for every algorithm $A \in \mathcal{A}$, for all pairs of sufficiently large circuits $C_1, C_2 \in \mathcal{C}$ such that $C_1 \equiv C_2$ and $|C_1| = |C_2| = s$, we have*

   $$|\mathbf{Pr}_{r,A}[A(\mathsf{IO}(C_1; r)) = 1] - \mathbf{Pr}_{r,A}[A(\mathsf{IO}(C_2; r)) = 1]| \leq \delta(s),$$

   where the probabilities are over the internal randomness r of IO as well as over possible internal randomness of A. If $\delta(s)$ is negligible, we say that IO is secure against $\mathcal{A}$. *We say that IO is* computationally secure *if it is secure against the class FBPP.*

▶ Remark 5 (Efficiency of IO). By default, we assume $\mathsf{IO}(C; r)$ is computable by a randomized polynomial-time algorithm with internal randomness r. We consider IO computable in other complexity classes, e.g., $\mathsf{FBPP}^{\mathsf{MCSP}}$. In such a case, we shall explicitly say that an IO is $\mathsf{FBPP}^{\mathsf{MCSP}}$-computable.

▶ Remark 6. Some definitions in the literature also contain a security parameter. In the above definition it is incorporated in the circuit size. Any reasonable encoding scheme for Boolean circuits allows one to represent a circuit of size s as a circuit of larger size.

We will need the following definition and result for our proofs.

▶ **Definition 7** (Statistical Difference [42]). *Let $\alpha(n) : \mathbb{N} \to \mathbb{N}$ and $\beta(n) : \mathbb{N} \to \mathbb{N}$ be computable functions, such that $\alpha(n) > \beta(n)$. Then $\mathsf{SD}^{(\alpha(n)\ ,\ \beta(n))}$ is promise problem defined as $\mathsf{SD}^{(\alpha(n)\ ,\ \beta(n))} \triangleq (\mathsf{SD}_{\text{YES}}^{(\alpha(n)\ ,\ \beta(n))}, \mathsf{SD}_{\text{NO}}^{(\alpha(n)\ ,\ \beta(n))})$, where*

$$\mathsf{SD}_{\text{YES}}^{(\alpha(n)\ ,\ \beta(n))} = \{(C_0, C_1) \mid \Delta(C_0, C_1) \geq \alpha(n)\},\quad \mathsf{SD}_{\text{NO}}^{(\alpha(n)\ ,\ \beta(n))} = \{(C_0, C_1) \mid \Delta(C_0, C_1) \leq \beta(n)\}.$$

Here, C_0 and C_1 are Boolean circuits $C_0, C_1 : \{0,1\}^n \to \{0,1\}^m$ of size $\mathsf{poly}(n)$ that are samplers for some distributions D_0 and D_1, respectively.
For the standard parameters, we define $\mathsf{SD} \triangleq \mathsf{SD}^{(2/3\ ,\ 1/3)}$.
For an oracle O, we define the relativized version of the problem $\mathsf{SD}^{O\ (\alpha(n)\ ,\ \beta(n))}$ as above, when C_0 and C_1 are O-oracle circuits.

▶ **Lemma 8** ([42]). *Suppose $\alpha(n)^2 - \beta(n) \geq 1/\mathsf{poly}(n)$. Then for any oracle O, the problem $\mathsf{SD}^{O\ (\alpha(n)\ ,\ \beta(n))}$ is SZK^O-complete. In particular, SD is SZK-complete.*

2.2 Useful Lemmas

Let $\mathsf{FBPP}^{\mathsf{MCSP}}$ denote the class of randomized polynomial-time algorithms with MCSP oracle.

▶ **Lemma 9** (implicit in [27]). *If there exists an IO $(1-\delta)$-secure against $\mathsf{FBPP}^{\mathsf{MCSP}}$, for some $\delta \leq 1 - 1/n^{\ell}$ for a constant $\ell > 0$, then $\mathsf{NP} \subseteq \mathsf{ZPP}^{\mathsf{MCSP}}$ and hence $\mathsf{ZPP}^{\mathsf{NP}} = \mathsf{ZPP}^{\mathsf{MCSP}}$.*

▶ **Lemma 10** ([48]). *If there exists an IO statistically $(1-\delta)$-secure, for some $\delta < 1$, then $\mathsf{NP} \subseteq \mathsf{coNP}$ and hence $\mathsf{PH} = \mathsf{NP} \cap \mathsf{coNP}$.*

▶ **Lemma 11** ([48]). *Let IO be an ε-imperfect obfuscator and let C_1, C_2 be such that $C_1 \not\equiv C_2$. Then $\Delta(\mathsf{IO}(C_1; r), \mathsf{IO}(C_2; r')) \geq 1 - 2\varepsilon$, over the internal randomness r, r' of the IO.*

▶ **Lemma 12** ([32]). *For any $k \in \mathbb{N}$: $\mathsf{NP}^{\mathsf{NP}} \not\subseteq \mathsf{SIZE}[n^k]$. In addition, $\mathsf{NEXP}^{\mathsf{NP}} \not\subseteq \mathsf{P/poly}$.*

▶ **Lemma 13** ([13, 33]). *If $\mathsf{SAT} \in \mathsf{P/poly}$, then $\mathsf{PH} = \mathsf{ZPP}^{\mathsf{SAT}}$, and polynomial-size circuits for SAT can be constructed in $\mathsf{ZPP}^{\mathsf{SAT}}$.*

▶ **Lemma 14** ([27]). *If $\mathsf{MCSP} \in \mathsf{P/poly}$, then $\mathsf{BPP}^{\mathsf{MCSP}} = \mathsf{ZPP}^{\mathsf{MCSP}}$.*

We require the following result of [3] that allows to find preimages of functions computable in polynomial time.

▶ **Lemma 15** ([3]). *Let $f_y(x) = f(y, x)$ be a function computable uniformly in time polynomial in $|x|$. There exists a polynomial-time probabilistic oracle Turing machine M such that for any $n, K \in \mathbb{N}$ and any y:*

$$\mathbf{Pr}_{|x|=n,r}\left[f_y\left(M^{\mathsf{MCSP}}(1^K, y, f_y(x), r)\right) = f_y(x)\right] \geq 1/K,$$

where $x \in \{0,1\}^n$ is chosen uniformly at random and r denotes the internal randomness of M.

We generalize this result to get a *distributional* inverter for any candidate distributional one-way function in the sense of [28]. Roughly speaking, such a distributional inverter finds uniformly random preimages of a given polynomial-time computable function. More precisely, we have the following.

▶ **Lemma 16.** *Let $f_y(x) = f(y, x)$ be a function computable uniformly in time polynomial in $|x|$. There exists a polynomial-time probabilistic oracle Turing machine M such that, for any $n, K \in \mathbb{N}$ and any y, the following two distributions*

$$(x,\, f_y(x)) \qquad \text{and} \qquad \left(M^{\mathsf{MCSP}}(1^K, y, f_y(x), r),\, f_y(x)\right),$$

for $x \in \{0,1\}^n$ chosen uniformly at random, and r the internal uniform randomness of M, are at most $(1/K)$-far in statistical distance.

Proof. We combine Lemma 15 with the reduction from [28] showing that an inverter for candidate one-way functions can be used to get a distributional inverter for every distributional one-way function candidate $f_y(x)$ computable in polynomial time. ◀

3 From Computational to Statistical Security

Below we will argue the existence of a universal distinguisher. We will describe an algorithm $\mathcal{D}(C_0, C_1; 1^{1/\gamma})$ in $\mathsf{FBPP}^{\mathsf{MCSP}}$ that, given any pair of circuits C_0 and C_1 that are samplers for some distributions D_0 and D_1, and a parameter $0 < \gamma < 1$, will distinguish D_0 and D_1 with advantage at least $\delta - \gamma$, where δ is the statistical distance between D_0 and D_1.

▶ **Corollary 17.** *There is an $\mathsf{FBPP}^{\mathsf{MCSP}}$ algorithm $\mathcal{D}$ satisfying the following. Given any pair of circuits C_0 and C_1 that are samplers for some distributions D_0 and D_1, and given a parameter K in unary, the algorithm $\mathcal{D}(C_0, C_1; 1^K)$ will distinguish D_0 and D_1 with advantage at least $\delta - 1/K$, where δ is the statistical distance between D_0 and D_1.*

As was mentioned, a similar proof was given in [39]. We defer the proof to Section A of the appendix.

▶ Remark 18. We note that a universal distinguisher as in Corollary 17 is fairly easy to construct in $\mathsf{FBPP}^{\mathsf{SAT}}$ (using the well-known fact that approximate counting can be done in $\mathsf{FBPP}^{\mathsf{NP}}$ [30]); see Theorem 40 in Section B of the appendix. Thus, Corollary 17 is another example of a computational task that can still be performed with the MCSP oracle instead of the SAT oracle.

4 Another Proof that $\mathsf{SZK} \subseteq \mathsf{BPP}^{\mathsf{MCSP}}$

Corollary 17 can be used to give another proof of the following result by Allender and Das [5].

▶ **Theorem 19** ([5]). $\mathsf{SZK} \subseteq \mathsf{BPP}^{\mathsf{MCSP}}$.

Proof. Recall the standard SZK-complete promise problem Statistical Difference (SD) (see Definition 7): Given a pair of circuits (C_0, C_1) that are samplers for the distributions D_0 and D_1 such that either D_0 and D_1 have the statistical distance less than $1/3$, or they have the statistical distance greater than $2/3$, decide which is the case.

By Corollary 17, we get an $\mathsf{FBPP}^{\mathsf{MCSP}}$ universal distinguisher $\mathcal{D}$. Consider the distinguisher $B = \mathcal{D}(C_0, C_1; 1^{10})$. Let δ be the statistical distance between D_0 and D_1. Note that in case $\delta < 1/3$, the algorithm B (and, in fact, any algorithm) has distinguishing advantage less than $1/3$, whereas for $\delta > 2/3$, B has advantage at least $(2/3) - (1/10) = 17/30 > 1/3$. Using random sampling and the Chernoff bounds, we can estimate in $\mathsf{FBPP}^{\mathsf{MCSP}}$ the advantage of our algorithm B at distinguishing between D_0 and D_1, with high probability and sufficient accuracy. The theorem follows. ◀

▶ Remark 20. Note that the $\mathsf{BPP}^{\mathsf{MCSP}}$ algorithm for SZK in the proof of Theorem 19 works for any version of the Statistical Difference problem with a non-negligible gap between the yes- and no-instances, not just for the $1/3$ vs. $2/3$ gap.

Next, we extend the result above to the relativized version of the problem SD^O (see Definition 7) for any $O \in \mathsf{BPP}^{\mathsf{MCSP}} \cap \mathsf{P/poly}$.

▶ **Theorem 21.** *Let $O \in \mathsf{BPP}^{\mathsf{MCSP}} \cap \mathsf{P/poly}$ be any language. Then for any $\alpha(n)$ and $\beta(n)$ such that $\alpha(n) \geq \beta(n) + n^{-\ell}$, for some $\ell > 0$, we have that:*

$$\mathsf{SD}^{O\ (\alpha(n)\ ,\ \beta(n))} \in \mathsf{BPP}^{\mathsf{MCSP}}. \tag{1}$$

In particular, if $\mathsf{MCSP} \in \mathsf{P/poly}$, then

$$\mathsf{SZK}^{\mathsf{MCSP}} \subseteq \mathsf{BPP}^{\mathsf{MCSP}}. \tag{2}$$

Proof. To prove (1), we proceed exactly as in the proof of Theorem 19 above, except using Corollary 38 instead of Corollary 17, and using the observation in Remark 20. To prove (2), we use (1) for $O = \mathsf{MCSP}$ and the fact that $\mathsf{SD}^{\mathsf{MCSP}\ (2/3\ ,\ 1/3)}$ is $\mathsf{SZK}^{\mathsf{MCSP}}$-complete (by Lemma 8). ◀

5 Implications for Circuit Minimization from Obfuscation

The following lemma provides some consequences of the existence of an imperfect, computationally-secure IO, with an appropriate range of parameters. Among other things, the proof uses some ideas from [23] and [27].

▶ **Lemma 22.** *Let $\Gamma \in \{\mathsf{FBPP}, \mathsf{P/poly}\}$. Suppose there exist an ε-imperfect $\mathsf{IO}(C; r)$ that is $(1-\delta)$-secure against Γ, where $(1-2\varepsilon)^2 - \delta \geq 2/n^\ell$ for some constant $\ell > 0$. If $\mathsf{MCSP} \in \Gamma$, then:*

1. $\mathsf{NP} \subseteq \mathsf{SZK}$,
2. $\mathsf{PH} = \mathsf{MA} = \mathsf{ZPP}^{\mathsf{MCSP}}$, *and*
3. *There is a $\mathsf{ZPP}^{\mathsf{MCSP}}$ algorithm A and a constant $k > 0$, such that $A(1^n)$ outputs an $O(n^k)$-size circuit for SAT (and for MCSP) on n-bit inputs.*

Proof.

1. First, observe that since $\mathsf{MCSP} \in \Gamma$, $\mathsf{FBPP}^{\mathsf{MCSP}} \subseteq \Gamma$. Consequently, an IO that is secure against Γ is also secure against $\mathsf{FBPP}^{\mathsf{MCSP}}$. It follows from Corollary 17 that this IO is statistically $(1-\delta')$-secure, for $\delta' = \delta + 1/n^{\ell}$ (since we can make the distributional inverter's error α to be smaller than any inverse polynomial of our choice). We now use this IO to reduce SAT to the Statistical Difference problem (see Definition 7): Given a SAT instance ϕ, construct some unsatisfiable instance $\perp$ of the same size as ϕ and on the same set of input variables. Consider the distributions

$$\mathsf{IO}(\phi; r) \text{ and } \mathsf{IO}(\perp; r') \tag{3}$$

over all random strings r, r'.
We have two cases:

- If ϕ is unsatisfiable, then $\phi \equiv \perp$, and by the statistical $(1-\delta')$-security property of our IO, we get that these two distributions in (3) have statistical distance at most δ'.
- If ϕ is satisfiable, then by Lemma 11, the statistical distance between the distributions in (3) is at least $1-2\varepsilon$.

Since $(1-2\varepsilon)^2 \geq \delta + 2n^{-\ell} = \delta' + n^{-\ell}$, by Lemma 8, the resulting instance of the SD problem is SZK-complete, and so $\mathsf{NP} \subseteq \mathsf{SZK}$.[9]

2. By [17, 2], we have $\mathsf{SZK} \subseteq \mathsf{AM} \cap \mathsf{coAM}$. By [11], since $\mathsf{NP} \subseteq \mathsf{SZK} \subseteq \mathsf{coAM}$, it follows that

$$\mathsf{PH} = \mathsf{AM}. \tag{4}$$

Next, by Theorem 19, $\mathsf{SZK} \subseteq \mathsf{BPP}^{\mathsf{MCSP}}$. By Lemma 14, $\mathsf{BPP}^{\mathsf{MCSP}} = \mathsf{ZPP}^{\mathsf{MCSP}}$. Hence, we get that

$$\mathsf{NP} \subseteq \mathsf{SZK} \subseteq \mathsf{ZPP}^{\mathsf{MCSP}}. \tag{5}$$

As $\mathsf{MCSP} \in \mathsf{P/poly}$, we also get from (5) that

$$\mathsf{NP} \subseteq \mathsf{P/poly}. \tag{6}$$

By [6], (6) implies that $\mathsf{AM} = \mathsf{MA}$. So by (4), we conclude that

$$\mathsf{PH} = \mathsf{MA}.$$

Finally, (6) also implies $\mathsf{PH} = \mathsf{ZPP}^{\mathsf{NP}}$ by Lemma 13. Hence, by (5), we get that

$$\mathsf{PH} = \mathsf{ZPP}^{\mathsf{NP}} \subseteq \mathsf{ZPP}^{\mathsf{ZPP}^{\mathsf{MCSP}}} = \mathsf{ZPP}^{\mathsf{MCSP}}.$$

3. By Lemma 13, if $\mathsf{SAT} \in \mathsf{P/poly}$, then polynomial-size circuits for SAT can be found by a $\mathsf{ZPP}^{\mathsf{NP}}$ algorithm. By (6), we get that polynomial-size circuits for SAT can be found by a $\mathsf{ZPP}^{\mathsf{ZPP}^{\mathsf{MCSP}}}$ algorithm, which can be simulated by a $\mathsf{ZPP}^{\mathsf{MCSP}}$ algorithm. As $\mathsf{MCSP} \in \mathsf{NP}$ and SAT is NP-complete, polynomial-size circuits for SAT can be used to construct polynomial-size circuits for MCSP as well. ◀

[9] Note that this reduction to SZK actually allows one to solve not just SAT but an *equivalence* problem for any class of circuits that an IO can obfuscate. Thus, to conclude that $\mathsf{NP} \subseteq \mathsf{SZK}$, it suffices to pick any coNP-hard circuit equivalence problem for the class of circuits where SAT may be easy. For example, one can take the problem of testing equivalence of depth-3 *monotone* formulas, known to be coNP-complete [16]

Items (2) and (3) in the lemma should be contrasted with the result of [13, 33] that $\mathsf{SAT} \in \mathsf{P/poly}$ implies both that polynomial-size circuits for SAT can be constructed by a $\mathsf{ZPP}^{\mathsf{SAT}}$ algorithm, and that $\mathsf{PH} = \mathsf{ZPP}^{\mathsf{SAT}}$. Under an additional assumption that a $\mathsf{P/poly}$-secure imperfect IO exists, we get similar implications for MCSP instead of SAT.
The following corollary strengthens a result of [27] to the imperfect setting.

▶ **Corollary 23** (Theorem 5 re-stated). *Let $\Gamma \in \{\mathsf{ZPP}, \mathsf{BPP}\}$. Suppose there is an ε-imperfect* IO *that is $(1-\delta)$-secure against* FBPP*, where $(1-2\varepsilon)^2 \geq \delta + 2/n^\ell$ for some constant $\ell > 0$. Then* $\mathsf{MCSP} \in \Gamma$ *iff* $\mathsf{NP} \subseteq \Gamma$.

Proof. The first direction is clear since $\mathsf{MCSP} \in \mathsf{NP}$. For the other direction, by Lemma 22, $\mathsf{NP} \subseteq \mathsf{ZPP}^{\mathsf{MCSP}}$ and hence $\mathsf{NP} \subseteq \mathsf{ZPP}^{\Gamma}$. ◀

For the case of a perfect IO, we get a somewhat stronger statement.

▶ **Theorem 24** (Theorem 6 re-stated). *Suppose there is a perfect* IO *that is $(1-\delta)$-secure against* FBPP*, where $\delta \leq 1 - 2/n^\ell$ for some constant $\ell > 0$. If* $\mathsf{MCSP} \in \mathsf{BPP}$*, then* $\mathsf{NP} = \mathsf{ZPP}$.

Proof. Since $\mathsf{MCSP} \in \mathsf{BPP}$, computational $(1-\delta)$-security implies $(1-\delta)$-security against $\mathsf{FBPP}^{\mathsf{MCSP}}$. It follows by Corollary 17 that this IO is statistically $(1-\delta')$-secure, for $\delta' = \delta + 1/n^\ell \leq 1 - 1/n^\ell$.

By Lemma 10, $\mathsf{PH} = \mathsf{NP} = \mathsf{coNP}$. By Lemma 9, $\mathsf{PH} = \mathsf{NP} = \mathsf{ZPP}^{\mathsf{MCSP}} \subseteq \mathsf{BPP}$. But $\mathsf{NP} \subseteq \mathsf{BPP}$ implies that $\mathsf{NP} = \mathsf{RP}$. Since $\mathsf{coNP} = \mathsf{NP}$, we get $\mathsf{NP} = \mathsf{ZPP}$. ◀

6 Implications for Obfuscation from Circuit Minimization

▶ **Theorem 25.** *Suppose* $\mathsf{MCSP} \in \mathsf{P/poly}$*. There is an* $\mathsf{FZPP}^{\mathsf{MCSP}}$*-computable perfect* IO *that is statistically secure if and only if there is an* $\mathsf{FBPP}^{\mathsf{MCSP}}$*-computable ε-imperfect* IO *that is $(1-\delta)$ secure against* $\mathsf{P/poly}$*, for any $0 \leq \varepsilon, \delta \leq 1$ such that $1 - 2\varepsilon \geq \delta + 2/n^\ell$, for some constant $\ell > 0$.*

Proof. The interesting direction is from the right to the left. Since $\mathsf{MCSP} \in \mathsf{P/poly}$, $(1-\delta)$-security against $\mathsf{P/poly}$ implies, by Corollary 17, statistical $(1-\delta')$-security, for $\delta' = \delta + n^{-\ell}$.

▷ Claim 26. If $\mathsf{MCSP} \in \mathsf{P/poly}$ and there is an $\mathsf{FBPP}^{\mathsf{MCSP}}$-computable ε-imperfect IO that is statistically $(1-\delta')$-secure for $1 - 2\varepsilon \geq \delta' + n^{-\ell}$, for some constant $\ell > 0$, then $\mathsf{SAT} \in \mathsf{ZPP}^{\mathsf{MCSP}}$.

Proof of Claim 26. Given an instance ϕ of SAT, let $\bot$ be an unsatisfiable formula of the same size as ϕ (over the same variables). Consider the two distributions $\mathsf{IO}(\phi; r)$ and $\mathsf{IO}(\bot; r')$ over random r, r'. If $\phi \equiv \bot$, the two distributions are at most statistical distance δ' apart; if ϕ is in SAT, then the two distributions have the statistical distance at least $1 - 2\varepsilon$.

Each distribution is samplable using a polynomial-size MCSP-oracle circuit, which we can obtain from our IO algorithm. Thus, we get an $\mathsf{FP}^{\mathsf{MCSP}}$-reduction from coSAT to $\mathsf{SD}^{\mathsf{MCSP}\ (1-2\varepsilon\ ,\ \delta')}$. Since $\delta' + n^{-\ell} \leq 1 - 2\varepsilon$, we conclude by Theorem 21 that $\mathsf{SAT} \in \mathsf{BPP}^{\mathsf{MCSP}}$. By Lemma 14, $\mathsf{BPP}^{\mathsf{MCSP}} = \mathsf{ZPP}^{\mathsf{MCSP}}$, concluding the proof. ◁

Since $\mathsf{SAT} \in \mathsf{ZPP}^{\mathsf{MCSP}} \subseteq \mathsf{P/poly}$, we get by Lemma 13 that $\mathsf{PH} = \mathsf{ZPP}^{\mathsf{MCSP}}$. Given a circuit C, we can find the lexicographically smallest equivalent circuit D (of size at most that of C) in $\mathsf{FP}^{\mathsf{PH}} \subseteq \mathsf{FZPP}^{\mathsf{MCSP}}$. This gives us a perfect $\mathsf{IO}(C; r)$ that is statistically secure.[10] ◀

[10] Technically, this $\mathsf{IO}(C; r)$ outputs either a smallest equivalent circuit D, or, with a tiny probability, the "don't know" answer. We can modify it to output the input circuit C in the latter case, getting perfect correctness, and only slightly decreasing statistical security.

Along the same lines:

▶ **Corollary 27.** *Suppose* $\mathsf{MCSP} \in \mathsf{BPP}$*. There is an* ε*-imperfect* IO *with statistical security if and only if there is an* ε*-imperfect* IO *with computational* $(1-\delta)$*-security where* $1-2\varepsilon \geq \delta+2/n^{\ell}$*. (Assuming* $\mathsf{MCSP} \in \mathsf{ZPP}$*, you get a similar equivalence but for a perfect* IO *with statistical security.)*

Proof sketch. The interesting direction is from the right to the left. We first argue as in the proof of Theorem 25 to conclude that $\mathsf{SAT} \in \mathsf{ZPP}^{\mathsf{MCSP}}$. Since $\mathsf{MCSP} \in \mathsf{BPP}$, we get that $\mathsf{NP} \subseteq \mathsf{BPP}$, and hence, $\mathsf{PH} = \mathsf{BPP}$. So, given an input circuit C, we can find the lexicographically smallest equivalent circuit D (of size at most that of C), using an $\mathsf{FP}^{\mathsf{PH}} = \mathsf{FBPP}$ algorithm. This algorithm is a (negligibly) imperfect IO with statistical security. (In case of $\mathsf{MCSP} \in \mathsf{ZPP}$, we argue in a similar way, getting that $\mathsf{PH} = \mathsf{ZPP}$, and so a canonical circuit D for a given input circuit C can be found in FZPP.) ◀

7 Circuit Lower Bounds from Obfuscation

Here we prove Theorems 1 and 2, re-stated below.

▶ **Theorem 28** (Theorem 1 re-stated)**.** *Suppose there exist a perfect* IO $(1-\delta)$*-secure against* P/poly*, where* $\delta \leq 1 - 2/n^{\ell}$ *for some* $\ell > 0$*. Then:*
1. $\mathsf{NEXP} \cap \mathsf{ZPEXP}^{\mathsf{MCSP}} \not\subseteq \mathsf{P/poly}$.
2. *For all* $k \in \mathbb{N}$*,* $\mathsf{NP} \cap \mathsf{ZPP}^{\mathsf{MCSP}} \not\subseteq \mathsf{SIZE}[n^k]$*.*

Proof. The proof of all items goes by a "win-win" argument. Suppose $\mathsf{MCSP} \notin \mathsf{P/poly}$. Then both claims follow immediately since $\mathsf{MCSP} \in \mathsf{NP}$.

Now suppose $\mathsf{MCSP} \in \mathsf{P/poly}$. Then randomized polynomial-time algorithms with MCSP oracle can be simulated by polynomial-size circuits. Consequently, IO is $(1-\delta)$-secure against these algorithms. By Corollary 17, this IO is statistically $(1-\delta')$-secure, for $\delta' = \delta + n^{-\ell} \leq 1 - n^{-\ell}$. By Lemmas 9 and 10, we get that

$$\mathsf{NP}^{\mathsf{NP}} \subseteq \mathsf{PH} = \mathsf{NP} \cap \mathsf{coNP} \subseteq \mathsf{ZPP}^{\mathsf{MCSP}} \subseteq \mathsf{NP}^{\mathsf{NP}}.$$

So, $\mathsf{NP}^{\mathsf{NP}} = \mathsf{NP} \cap \mathsf{coNP} = \mathsf{ZPP}^{\mathsf{MCSP}}$. By padding, $\mathsf{NEXP}^{\mathsf{NP}} = \mathsf{NEXP} \cap \mathsf{coNEXP} = \mathsf{ZPEXP}^{\mathsf{MCSP}}$, and so both claims follow from Lemma 12. ◀

▶ **Theorem 29** (Theorem 2 re-stated)**.** *Suppose there exist an* ε*-imperfect* IO $(1-\delta)$*-secure against* P/poly*, where* $(1-2\varepsilon)^2 \geq \delta + 2/n^{\ell}$ *for some* $\ell > 0$*. Then for all* $k \in \mathbb{N}$*,* $\mathsf{MA} \cap \mathsf{ZPP}^{\mathsf{MCSP}} \not\subseteq \mathsf{SIZE}[n^k]$*.*

Proof. Again we use a "win-win" argument. If $\mathsf{MCSP} \notin \mathsf{P/poly}$, then the theorem follows. Otherwise, we get by Lemma 22 (Item 2) that $\mathsf{PH} = \mathsf{MA} = \mathsf{ZPP}^{\mathsf{MCSP}}$, which is not in $\mathsf{SIZE}[n^k]$ for any fixed $k > 0$ by Lemma 12. ◀

▶ **Theorem 30** (Theorem 3 re-stated)**.** *Suppose there is a perfect* IO *that is* $(1-\delta)$*-secure against* FBPP*, where* $\delta \leq 1 - 2/n^{\ell}$ *for some constant* $\ell > 0$*. Then* $\mathsf{ZPEXP} \neq \mathsf{BPP}$*.*

Proof of Theorem 3. Suppose for a contradiction that $\mathsf{ZPEXP} = \mathsf{BPP}$. Then, in particular, $\mathsf{MCSP} \in \mathsf{BPP}$. By Theorem 6, $\mathsf{NP} = \mathsf{ZPP}$ and hence

$$\mathsf{ZPEXP} = \mathsf{BPP} \subseteq \mathsf{ZPP}^{\mathsf{NP}} = \mathsf{ZPP}^{\mathsf{ZPP}} = \mathsf{ZPP}$$

which leads to a contradiction (see Appendix C). ◀

8 Excluding an Imperfect IO from Heuristica

Below we assume that the reader is familiar with the basic definitions of average-case complexity (in particular, the definitions of DistNP and AvgP); see, e.g., [9].

▶ **Theorem 31.** *Suppose* $\mathsf{DistNP} \subseteq \mathsf{AvgP}$*. If an* ε*-imperfect computationally* $(1-\delta)$*-secure* IO *exists for* $1-2\varepsilon \geq \delta + 2n^{-\ell}$ *for some* $\ell > 0$*, then* $\mathsf{NP} = \mathsf{P}$.

Proof. Consider MCSP with $s = 2^{0.9n}$ under the uniform distribution over 2^n-bit inputs. This is a language in DistNP. If $\mathsf{DistNP} \subseteq \mathsf{AvgP}$, we get a language $L' \in \mathsf{P}$ that agrees with MCSP for $s = 2^{0.9n}$ on almost all instances, but may be incorrect on a tiny fraction of "no" instances of MCSP (here we use the zero-error property of problems in AvgP). Then the complement $L = \bar{L}'$ is a language in P of polynomial density (because almost all strings are very hard) such that for every $x \in L$, the circuit complexity of x (when viewed as a truth table of a boolean function) is at least $|x|^{0.9}$. All results in this paper that use MCSP as an oracle continue to hold with any such L as an oracle instead. In particular, as in the proof of Theorem 25 (see Claim 26), we conclude that $\mathsf{NP} \subseteq \mathsf{BPP}^L = \mathsf{BPP}$. Finally, by [14], if $\mathsf{DistNP} \subseteq \mathsf{AvgP}$ then $\mathsf{BPP} = \mathsf{P}$, and so $\mathsf{NP} = \mathsf{P}$. ◀

9 Open Questions

In this paper we showed that an (even imperfect) IO secure against non-uniform polynomial-size circuits implies non-trivial circuit lower bounds. Can one prove circuit lower bounds from the assumption that a (uniform) computationally-secure IO exists?

Can we leverage the connection between one-way functions and a close relative of MCSP (time-bounded Kolmogorov complexity) [37, 4, 25, 24] to get better understanding of IO?

A A Universal Distinguisher in $\mathsf{FBPP}^{\mathsf{MCSP}}$

We will first argue that such a distinguisher for a pair of distributions sampled by circuits C_0 and C_1 can be obtained given oracle access to a distributional inverter (in the sense of Impagliazzo and Luby [28]) for a function defined in terms of C_0 and C_1 (see Lemma 32 below). Then we appeal to Lemma 16 to get a universal distributional inverter.

▶ **Lemma 32.** *There is an oracle* FBPP *algorithm $\hat{\mathcal{D}}$ satisfying the following. Let C_0 and C_1 be two circuits that are samplers for distributions D_0 and D_1 over some finite universe $\mathcal{U}$, and let δ be the statistical distance between D_0 and D_1. Let $F(b,r)$ use r to sample from D_b. Let A be a distributional inverter for F so that the distributions*

$$((b,r),\ F(b,r)) \qquad \text{and} \qquad (A(F(b,r)),\ F(b,r))$$

are at most α^2-close in statistical distance, where $0 \leq \alpha \leq \delta/28$. Then $\hat{\mathcal{D}}^A(C_0, C_1; 1^{1/\alpha})$ is a distinguisher for D_0 and D_1 with advantage at least $\delta - 14\alpha \geq \delta/2$.

Proof. Let $B(x)$ be the first bit of $A(x)$, and let $Q(x)$ be the probability that $B(x)$ is 0, i.e.,

$$Q(x) = \mathbf{Pr}_A[B(x) = 0],$$

where the probability is over the internal randomness of A. Let K be such that an empirical estimate of K iid $\{0,1\}$-valued random variables is within α of its expectation with probability $1-(\alpha/2)$; by the Chernoff bounds, we have that $K = O((\log 1/\alpha)/\alpha^2)$. Let $\tilde{Q}(x;\rho)$ be the random variable where we use randomness ρ to sample from $A(x)$ independently K times and use these to create an empirical estimate of $Q(x)$; so ρ is K times the internal randomness of A. Let $C(x;\rho)$ be the probabilistic Boolean algorithm where we accept x if $\tilde{Q}(x;\rho) \geq 1/2$. We will show that

$$\mathbf{Pr}_{x\sim D_0,\rho}[C(x;\rho)=1] - \mathbf{Pr}_{x\sim D_1,\rho}[C(x;\rho)=1] \geq \delta - 14\alpha. \tag{7}$$

Let $p_0(x)$ be the probability of x for D_0, and $p_1(x)$ that for D_1. Note that

$$q(x) = p_0(x)/(p_0(x)+p_1(x))$$

is the conditional probability that $b=0$ given that $F(b,r)=x$. Then

$$\mathbf{Pr}_{x\sim D_0,\rho}[C(x;\rho)=1] - \mathbf{Pr}_{x\sim D_1,\rho}[C(x;\rho)=1] = \mathbf{Exp}_\rho\left[\sum_{x:\ \tilde{Q}(x;\rho)\geq 1/2}(p_0(x)-p_1(x))\right], \tag{8}$$

and

$$\delta = \sum_{x:\ q(x)\geq 1/2}(p_0(x)-p_1(x)). \tag{9}$$

Note that if, for "typical" randomness ρ used by $\tilde{Q}$, we had for all $x \in \mathcal{U}$ that $\tilde{Q}(x;\rho) \geq 1/2 \Leftrightarrow q(x) \geq 1/2$, then the right-hand sides of (8) and (9) would be identical (for that randomness ρ of $\tilde{Q}$), and we would get our goal of (7) minus the error term for "atypical" randomness of $\tilde{Q}$. We formalize this argument next.

For given internal randomness ρ of $\tilde{Q}$, let the error set $E = E(\rho)$ be the set of those $x \in \mathcal{U}$ so that exactly one of $\tilde{Q}(x;\rho)$ and $q(x)$ is at least $1/2$, i.e.,

$$E(\rho) = \{x \in \mathcal{U} \mid \tilde{Q}(x;\rho) \geq 1/2 \not\Leftrightarrow q(x) \geq 1/2\}.$$

Then

$$\begin{aligned}
&\mathbf{Pr}_{x\sim D_0,\rho}[C(x;\rho)=1] - \mathbf{Pr}_{x\sim D_1,\rho}[C(x;\rho)=1] \\
&= \mathbf{Exp}_\rho\left[\sum_{x:\ \tilde{Q}(x;\rho)\geq 1/2}(p_0(x)-p_1(x))\right] \\
&= \mathbf{Exp}_\rho\left[\sum_{x\notin E(\rho):\ \tilde{Q}(x;\rho)\geq 1/2}(p_0(x)-p_1(x)) + \sum_{x\in E(\rho):\ \tilde{Q}(x;\rho)\geq 1/2}(p_0(x)-p_1(x))\right] \\
&= \mathbf{Exp}_\rho\left[\sum_{x\notin E(\rho):\ q(x)\geq 1/2}(p_0(x)-p_1(x)) + \sum_{x\in E(\rho):\ q(x)<1/2}(p_0(x)-p_1(x))\right] \\
&= \mathbf{Exp}_\rho\left[\sum_{x:\ q(x)\geq 1/2}(p_0(x)-p_1(x)) + \sum_{x\in E(\rho):\ q(x)<1/2}(p_0(x)-p_1(x)) - \sum_{x\in E(\rho):\ q(x)\geq 1/2}(p_0(x)-p_1(x))\right] \\
&\geq \delta - \mathbf{Exp}_\rho\left[\sum_{x\in E(\rho)}|p_0(x)-p_1(x)|\right],
\end{aligned}$$

where we used (9) to get the last line.

We bound the sum under the expectation in the last line above by looking at three sets whose union contains $E = E(\rho)$:

$$\begin{aligned} E_1(\rho) &= \{x \mid |\tilde{Q}(x;\rho) - Q(x)| \geq \alpha\}, \\ E_2 &= \{x \mid |Q(x) - q(x)| \geq 2\alpha, \\ E_3 &= \{x \mid |q(x) - 1/2| \leq 3\alpha\}. \end{aligned}$$

▷ Claim 33. For every ρ, $E(\rho) \subseteq E_1(\rho) \cup E_2 \cup E_3$.

Proof of Claim 33. If $\tilde{Q}(x;\rho) \geq 1/2$, and $x \notin (E_1 \cup E_2)$, then $q(x) > 1/2 - 3\alpha$. So either $q(x) \geq 1/2$, or $x \in E_3$. Similar reasoning applies if $\tilde{Q}(x;\rho) < 1/2$. So these three sets cover E. ◁

We bound the sum for E_1 just by using Chernoff bounds, the sum for E_2 by the statistical distinguishability of our distributional inverter A, and the sum for E_3 using the fact that having q close to $1/2$ means $p_0(x)$ and $p_1(x)$ are relatively close. For $E_1(\rho)$ and E_2, we will actually upperbound the summation of $p_0(x) + p_1(x)$, over x from the respective set.

▷ Claim 34. $\mathbf{Exp}_\rho\left[\sum_{x\in E_1(\rho)}(p_0(x) + p_1(x))\right] \leq \alpha$.

Proof of Claim 34. By linearity of expectation, it suffices to upperbound

$$\mathbf{Exp}_\rho\left[\sum_{x\in E_1(\rho)} p_0(x)\right] + \mathbf{Exp}_\rho\left[\sum_{x\in E_1(\rho)} p_1(x)\right].$$

The first expectation can be thought of as the probability that, if we sample x from D_0, and then perform the empirical estimate (using randomness ρ), that we are off by at least α. The second expectation is the same but for D_1. By the Chernoff bounds (our choice of K), each probability is at most $\alpha/2$. ◁

▷ Claim 35. $\sum_{x\in E_2}(p_0(x) + p_1(x)) \leq \alpha$.

Proof of Claim 35. We use the accuracy of the inverter A. The distinguishing probability between $(A(F(b,r)),\ F(b,r))$ and $((b,r),\ F(b,r))$ is at least that between any distributions computable from these. So in particular, the statistical distance between $(B(x),\ x)$ and $(b,\ x)$, for $x = F(b,r)$, is at most α^2. Using the fact that the statistical distance is the half of the ℓ_1-norm of the difference between the distributions, we get

$$\begin{aligned} \alpha^2 &\geq (1/2)\cdot\sum_x (1/2)\cdot(p_0(x)+p_1(x))\cdot(|q(x)-Q(x)| + |1-Q(x)-(1-q(x))|) \\ &= (1/2)\cdot\sum_x (p_0(x)+p_1(x))\cdot|q(x)-Q(x)|, \end{aligned}$$

Since for all x in E_2, $|q(x) - Q(x)| \geq 2\alpha$, and restricting to $x \in E_2$ only reduces the sum in the last line, we have

$$\alpha^2 \geq (1/2)\cdot\sum_{x\in E_2}(p_0(x)+p_1(x))(2\alpha),$$

or $\sum_{x\in E_2}(p_0(x) + p_1(x)) \leq \alpha$, as required. ◁

▷ Claim 36. $\sum_{x\in E_3} |p_0(x) - p_1(x)| \leq 12\alpha$.

Proof of Claim 36. If $x \in E_3$ then

$$\left|\frac{p_0(x)}{p_0(x)+p_1(x)} - \frac{1}{2}\right| \leq 3\alpha.$$

Multiplying through by $2(p_0(x) + p_1(x))$,

$$|p_0(x) - p_1(x)| \leq 6\alpha(p_0(x) + p_1(x)).$$

Thus,

$$\begin{aligned}\sum_{x\in E_3} |p_0(x) - p_1(x)| &\leq \sum_{x\in E_3} 6\alpha(p_0(x) + p_1(x))\\ &\leq 12\alpha,\end{aligned}$$

as required. ◁

Combining Claims 34–36, we get that the advantage of our probabilistic circuit C at distinguishing D_0 and D_1 is at least $\delta - 14\alpha$, as required. Given oracle access to A, our algorithm $\hat{\mathcal{D}}^A(C_0, C_1; 1^{1/\alpha})$ will construct such a circuit C in time polynomial in $1/\alpha$. ◀

We now prove Corollary 17. We repeat it here for convenience.

▶ **Corollary 37.** *There is an $\mathsf{FBPP}^{\mathsf{MCSP}}$ algorithm $\mathcal{D}$ satisfying the following. Given any pair of circuits C_0 and C_1 that are samplers for some distributions D_0 and D_1, and given a parameter K in unary, the algorithm $\mathcal{D}(C_0, C_1; 1^K)$ will distinguish D_0 and D_1 with advantage at least $\delta - 1/K$, where δ is the statistical distance between D_0 and D_1.*

Proof. Use Lemma 16 to get an $\mathsf{FBPP}^{\mathsf{MCSP}}$-computable universal distributional inverter that achieves statistical distance α^2 for $\alpha = 1/(14K)$. Define the algorithm $\mathcal{D}$ as follows. For given input circuits C_0 and C_1, run the oracle algorithm $\hat{\mathcal{D}}^A(C_0, C_1; 1^{1/\alpha})$ from Lemma 32, invoking the universal distributional inverter from Lemma 16 on every oracle query to A made by $\hat{\mathcal{D}}$. ◀

Next, we show that we can extend our universal distinguisher for distributions samplable by O-oracle circuits for languages O satisfying certain technical conditions.

▶ **Corollary 38.** *Let $O \in \mathsf{BPP}^{\mathsf{MCSP}} \cap \mathsf{P/poly}$ be any language. Then there is an $\mathsf{FBPP}^{\mathsf{MCSP}}$ algorithm $\mathcal{D}$ that, given any pair of O-oracle circuits C_0 and C_1 that are samplers for some distributions D_0 and D_1, and given a parameter K in unary, the algorithm $\mathcal{D}(C_0, C_1; 1^K)$ will distinguish D_0 and D_1 with advantage at least $\delta - 1/K$, where δ is the statistical distance between D_0 and D_1.*

Proof. Use Lemma 16 to get an $\mathsf{FBPP}^{\mathsf{MCSP}}$-computable universal distributional inverter that achieves statistical distance α^2 for $\alpha = 1/(14K)$. As in the proof of Lemma 32, we use MCSP-oracle circuit samplers for distributions D_0 and D_1 to get a circuit for distributional one-way function candidate F. We then use our universal inverter to get a distributional inverter A needed in Lemma 32 for any given input circuits C_0 and C_1. Observe that we can invert F since F is computable by a small O-oracle circuit (given the O-oracle circuits for sampling D_0 and D_1), and hence F is also computable by a circuit of polynomial size with *no* oracle gates (since by assumption $O \in \mathsf{P/poly}$). The correctness proof of the inverting algorithm relies on the fact that a small circuit for F *exists*. Yet, the inverting algorithm for

F does not need to know a small circuit for F; it just must be able to evaluate F efficiently, given a small description of F. Using the encoding of an O-oracle circuit for F works since the inverting algorithm can evaluate the circuit with probability close to 1, given access to the MCSP oracle (since $O \in \mathsf{BPP}^{\mathsf{MCSP}}$). ◀

B A Universal Distinguisher in $\mathsf{FBPP}^{\mathsf{NP}}$

▶ **Lemma 39** ([30]). *There exists a randomized algorithm that given oracle access to* NP *can approximate any function $f(x)$ in* #P *to within the multiplicative factor $(1 \pm \varepsilon)$, with probability at least $1-\gamma$, in time polynomial in $|x|$, $1/\varepsilon$, and $\log(1/\gamma)$.*

▶ **Theorem 40.** *There is an $\mathsf{FBPP}^{\mathsf{NP}}$ algorithm $\mathcal{D}$, that given circuits C_0 and C_1 that are samplers for distributions D_0 and D_1, and $K \in \mathbb{N}$ in unary, will distinguish D_0 and D_1 with the distinguishing advantage at least $\delta - 1/K$, where δ is the statistical distance between D_0 and D_1.*

Proof. Given C_0 and C_1, let $p_0(x)$ be the probability of x according to D_0, and $p_1(x)$ that according to D_1. For $0 < \gamma = \varepsilon \leq 1/2$ to be determined, consider the following probabilistic circuit $A(x;r)$: Compute the estimates $\tilde{p}_0(x) = (1 \pm \varepsilon)p_0(x)$ and $\tilde{p}_1(x) = (1 \pm \varepsilon)p_1(x)$ with probability at least $1-\gamma$ (using the algorithm from Lemma 39), and accept iff $\tilde{p}_0(x) > \tilde{p}_1(x)$.

We say that randomness r is good for x if both estimates $\tilde{p}_0(x)$ and $\tilde{p}_1(x)$ are correct within the multiplicative factor $(1 \pm \varepsilon)$. Note that by Lemma 39, for every x, r is good for x with probability at least $1 - 2\gamma$. We have

$$\begin{aligned}
&\mathbf{Pr}_{x\sim D_0,r}[A(x;r)=1] - \mathbf{Pr}_{x\sim D_1,r}[A(x;r)=1] \\
&\geq \mathbf{Pr}_{x\sim D_0,r}[A(x;r)=1 \mid \ r \text{ is good for } x] - \mathbf{Pr}_{x\sim D_1,r}[A(x;r)=1 \mid \ r \text{ is good for } x] - 2\gamma \\
&= \sum_{x:\ p_0(x)>p_1(x)} (p_0(x)-p_1(x)) - 2\gamma \\
&\quad - \sum_{x:\ p_0(x)>p_1(x)\ \wedge\ \tilde{p}_0(x)<\tilde{p}_1(x)} (p_0(x)-p_1(x)) \\
&\quad + \sum_{x:\ p_0(x)\leq p_1(x)\ \wedge\ \tilde{p}_0(x)>\tilde{p}_1(x)} (p_0(x)-p_1(x)).
\end{aligned}$$

Note that

$$\begin{aligned}
&\sum_{x:\ p_0(x)>p_1(x)\ \wedge\ \tilde{p}_0(x)<\tilde{p}_1(x)} (p_0(x)-p_1(x)) \\
&\leq \sum_{x:\ (p_0(x)>p_1(x))\ \wedge\ ((1-\varepsilon)p_0(x)<(1+\varepsilon)p_1(x))} (p_0(x)-p_1(x)) \\
&\leq \sum_x ((1+\varepsilon)/(1-\varepsilon)-1)\cdot p_1(x) \\
&= (2\varepsilon)/(1-\varepsilon).
\end{aligned}$$

Similarly,

$$\sum_{x:\ p_0(x)\leq p_1(x)\ \wedge\ \tilde{p}_0(x)>\tilde{p}_1(x)} (p_1(x)-p_0(x)) \leq (2\varepsilon)/(1-\varepsilon).$$

Putting everything together, we get

$$\mathbf{Pr}_{x\sim D_0,r}[A(x;r)=1] - \mathbf{Pr}_{x\sim D_1,r}[A(x;r)=1] \geq \delta - (2\gamma + (4\varepsilon)/(1-\varepsilon)),$$

which is at least $\delta - 10\varepsilon$. Setting $\varepsilon = 1/(10K)$ concludes the proof. ◀

C Separating ZPEXP from ZPP

▷ Claim 41. $\mathsf{ZPEXP} \neq \mathsf{ZPP}$.

Proof. Suppose for a contradiction that $\mathsf{ZPEXP} = \mathsf{ZPP}$. Then

$$\mathsf{NP}^{\mathsf{NP}} \subseteq \mathsf{EXP} \subseteq \mathsf{ZPEXP} \subseteq \mathsf{ZPP}.$$

By translation, $\mathsf{NEXP}^{\mathsf{NP}} \subseteq \mathsf{ZPEXP}$ and hence by Lemma 12, $\mathsf{ZPEXP} \not\subseteq \mathsf{P/poly}$. Yet, by Adleman's Theorem ([1]) $\mathsf{ZPP} \subseteq \mathsf{BPP} \subseteq \mathsf{P/poly}$. ◁

▶ Remark 42. Similarly, one can show that $\mathsf{BPEXP} \neq \mathsf{BPP}$. However, separating ZPEXP or even NEXP or $\mathsf{EXP}^{\mathsf{NP}}$ from BPP remains a longstanding open question. See e.g. [15, 49].

Interactive Error Correcting Codes: New Constructions and Impossibility Bounds

Meghal Gupta
University of California Berkeley, CA, USA

Rachel Yun Zhang
Massachusetts Institute of Technology, Cambridge, MA, USA

Abstract

An *interactive error correcting code (*iECC*)* is an interactive protocol with the guarantee that the receiver can correctly determine the sender's message, even in the presence of noise. It was shown in works by Gupta, Kalai, and Zhang (STOC 2022) and by Efremenko, Kol, Saxena, and Zhang (FOCS 2022) that there exist iECC's that are resilient to a larger fraction of errors than is possible in standard error-correcting codes without interaction. In this work, we improve upon these existing works in two ways:

- First, we improve upon the erasure iECC of Kalai, Gupta, and Zhang, which has communication complexity quadratic in the message size. In our work, we construct the first iECC resilient to $> \frac{1}{2}$ adversarial erasures that is also positive rate. For any $\epsilon > 0$, our iECC is resilient to $\frac{6}{11} - \epsilon$ adversarial erasures and has size $O_\epsilon(k)$.
- Second, we prove a better upper bound on the maximal possible error resilience of any iECC in the case of bit flip errors. It is known that an iECC can achieve $\frac{1}{4} + 10^{-5}$ error resilience (Efremenko, Kol, Saxena, and Zhang), while the best known upper bound was $\frac{2}{7} \approx 0.2857$ (Gupta, Kalai, and Zhang). We improve upon the upper bound, showing that no iECC can be resilient to more than $\frac{13}{47} \approx 0.2766$ fraction of errors.

1 Introduction

Consider the following task: Alice wishes to communicate a message to Bob such that even if a constant fraction of the communicated bits are adversarially tampered with, Bob is still guaranteed to be able to determine her message. This task motivated the prolific study of *error correcting codes*, starting with the seminal works of [16, 15]. An error correcting code encodes a message x into a longer codeword $\mathsf{ECC}(x)$, such that the Hamming distance between any two distinct codewords is a constant fraction of the length of the codewords.

An important question in the study of error correcting codes is determining the maximal possible error resilience. It is known that in the adversarial bit-flip model, any ECC can be resilient to at most $\frac{1}{4}$ corruptions, and in the adversarial erasure error model any ECC can be resilient to at most $\frac{1}{2}$ corruptions.

This prompts the following natural question: *Can we achieve better error resilience if we use interaction?*

In [9], Gupta, Kalai and Zhang introduce the notion of an *interactive error correcting code (*iECC*)*, which is an interactive protocol with a fixed length and speaking order, such that Bob can correctly learn Alice's input x as long as not too large a fraction of the *total communication* is erased. They demonstrate that iECC's can in fact achieve a higher erasure resilience than standard error correcting codes. In particular, they design an iECC that is resilient to adversarial erasure of $\frac{3}{5} - \epsilon$ of the total communication.

Note that a classical error correcting code is an iECC in which Alice speaks in every round. Their result essentially shows that Bob talking occasionally *instead of Alice* actually improves the error resilience. It is not obvious that this should be the case – since Bob can only send feedback, while Alice can actually send new information, Bob's messages a priori seem a lot less valuable than Alice's. Nevertheless, they are able to leverage this to improve the erasure resilience past $\frac{1}{2}$. Later, [7] present an iECC that achieves an error (bit flip) resilience greater than $\frac{1}{4}$.

In this paper, we present two new results about iECC's. We mention that this conference version of the paper is a combination of two separate works on the arXiv: [10] and [11]. We also note the relevant context that the result of [7], which constructed a binary iECC with $> \frac{1}{4}$ error resilience, was published after the positive rate result in this paper, but before the impossbility bound in this paper.

1.1 Positive Rate iECC

One weakness of the erasure-resilient iECC presented by [9] is that the size of their protocol is quadratic in the length of Alice's original message x. This leaves open the question of whether there exists an iECC achieving $> \frac{1}{2}$ erasure resilience with size *linear* in the length of the original message. In this paper, we answer this question in the affirmative.

Specifically, we show a positive rate iECC that achieves an erasure resilience of $\frac{6}{11} - \epsilon$ over the binary erasure channel, which is larger than $\frac{1}{2}$.

▶ **Theorem 1.** *For any $\epsilon > 0$, there exists an* iECC *over the binary erasure channel resilient to $\frac{6}{11} - \epsilon$ erasures, such that the communication complexity for inputs of size n is $O_\epsilon(n)$ and the time complexity is $\text{poly}_\epsilon(n)$.*

We remark that our iECC achieves a lower erasure resilience than the quadratic sized iECC of [9], which is resilient to $\frac{3}{5} - \epsilon$ erasures. However, we believe that an iECC achieving both positive rate and $\frac{3}{5} - \epsilon$ erasure resilience can likely be constructed by combining ideas from this paper and [9]. Nevertheless, we leave open the existence of such an iECC.

▶ Remark 2. Since the original paper [10] was posted to arXiv, the work of [7] constructed a positive rate iECC resilient to $\frac{1}{4} + 10^{-5}$ bit flip errors, thereby resolving whether iECC's can achieve better error resilience in the case of bit flip errors as well! Since bit flip errors are stronger than erasures, their iECC is also a positive rate iECC resilient to $> \frac{1}{2}$ erasures. Comparing this work with theirs, theirs works in the case of bit flips errors while ours does not, but our work achieves the higher erasure resilience.

1.2 Upper Bound on Maximal Error Resilience of iECC

The current best known upper (impossibility) bound for the error resilience of an iECC (in the bit flip setting, rather than erasure setting) was given in [9], who showed that no iECC can be resilient to more than $\frac{2}{7}$ adversarial errors. This upper bound came from the combination of two natural attacks, one of which is guaranteed to work no matter how the rounds in which Alice and Bob speak are distributed.

1. Corrupt *none* of Bob's bits. Then, Bob's messages provide perfect reliable feedback, in which case works about *error-correcting codes with feedback* beginning with [2] tell us that it suffices to corrupt $\frac{1}{3}$ of Alice's bits.
2. Corrupt *half* of Bob's bits so that his messages appear random and thus essentially are useless: then Alice's communication essentially reduces to the case of a standard error-correcting code, in which case an adversary can corrupt $\frac{1}{4}$ of her bits to confuse Bob between two possible values of x.

The largest error resilience known so far is achieved by [7], who construct an iECC resilient to $\frac{1}{4} + 10^{-5}$ bit flip errors. This leaves a large gap between the best known achievable error resilience and the best known upper bound. *What is the largest possible error resilience of an iECC? Is it possible to achieve error resilience equal to this natural upper bound of $\frac{2}{7}$?*

In this work, we answer the latter question in the negative, providing a new upper bound of $\frac{13}{47} \approx 0.2766$, improving upon the previous best upper bound of $\frac{2}{7} \approx 0.2857$.

▶ **Theorem 3.** *For sufficiently small $\epsilon > 0$, there exists $k_0 = k_0(\epsilon) \in \mathbb{N}$ such that for any $k > k_0$, no iECC over the binary bit flip channel where Alice is trying to communicate $x \in \{0,1\}^k$ is resilient to $\frac{13}{47} + \epsilon$ fraction of adversarial bit flips.*

2 Related Works

In this section, we discuss previous work on interactive error-correcting codes, as well as prior work on error-correcting codes with feedback.

2.1 Interactive Error-Correcting Codes

The notion of an *interactive error-correcting code* (iECC) was first introduced in [9], who demonstrated an iECC resilient to $\frac{3}{5}$ fraction of adversarial erasures, surpassing the best possible erasure resilience of standard ECC's of $\frac{1}{2}$. They also gave an upper bound of $\frac{2}{3}$ on the erasure resilience of any iECC. In the case of bit flip errors, they proved an upper bound of $\frac{2}{7}$ on the error resilience achievable by any iECC, leaving open the problem of constructing an iECC resilient to greater than $\frac{1}{4}$ adversarial errors.

The followup work of [10] improved upon the erasure iECC of [9], giving a construction of an iECC with *positive rate* but resilient to only $\frac{6}{11}$ adversarial erasures.

In the bit flip error model, [7] answered [9]'s question in the affirmative, constructing an iECC with error resilience $\frac{1}{4} + 10^{-5}$. This narrowed the optimal error resilience of any iECC to the range $[\frac{1}{4} + 10^{-5}, \frac{2}{7}]$.

2.2 Error-Correcting Codes with Feedback

The use of interaction in the noise resilient communication of a message has been studied previously in the form of *error-correcting codes with feedback*. In an error-correcting code with feedback, Alice wishes to communicate a message to Bob in an error-resilient fashion, provided that after every message she sends she receives some feedback from Bob about what he has received. She can then use this noiseless feedback to choose the next bit that she sends. Error-correcting codes with feedback were first introduced in the Ph.D. thesis of Berlekamp [2] and have been studied in a number of followup works, including [3, 19, 17, 14, 8, 1]. Originally, this feedback was considered in the *noiseless* setting, meaning that none of Bob's messages are allowed to be corrupted, and error rate is calculated solely as a function of the number of messages Alice sends. That is, Bob's feedback is free and always correct, so that Alice can tailor her next message to specifically the bit of information Bob most needs to hear.

In the bit flip error model, [3, 19, 17, 14] showed that the maximal error resilience of an error-correcting code with noiseless feedback is $\frac{1}{3}$. [8] show this is achievable even by protocols that only send logarithmically many bits of feedback over a constant number of rounds. For explicit constant number of rounds of feedback, [4] initiated the study of the noise resilience vs. round complexity tradeoff for both erasures and errors. For larger alphabets, the maximal error resilience was studied in [1].

When the feedback is *noisy*, i.e. the feedback may be corrupted as well, much less is known. Several works such as [5, 6] considered ECC's with noisy feedback over the binary symmetric channel. [18] considers adversarial corruption, under a model which places separate corruption budgets on the forward and feedback rounds. They construct a scheme that is resilient to $\frac{1}{2}$ of the forward communication and 1 of the feedback being erased. We note that their scheme's forward erasure resilience is equal to that achievable by standard error-correcting codes.

3 Preliminaries and Definitions

Before we dive into the technical part of our paper, we present important preliminaries on classical error correcting codes, and define an iECC formally and what it means for one to be resilient to α-fraction of erasures.

Notation

In this work, we use the following notations.

- The function $\Delta(x, y)$ represents the Hamming distance between x and y.
- The interval $[a, b]$ for $a, b \in \mathbb{Z}_{\geq 0}$ denotes the integers from a to b inclusive. The interval $[n]$ denotes the integers $1, \ldots, n$.
- The symbol $\perp$ in a message represents the erasure symbol that a party might receive in the erasure model.
- When we say Bob k-decodes a message, we mean that he list decodes it to exactly k possible messages Alice could have sent in the valid message space.
- The output of an ECC is 0-indexed. All other strings are 1-indexed.

3.1 Interactive Error Correcting Codes

We formally define our notion of an *interactive error correcting code (*iECC*)*. The two types of corruptions we will be interested in are erasures and bit flips. We first start by defining a non-adaptive interactive protocol.

▶ **Definition 4** (Non-Adaptive Interactive Protocol). *A non-adaptive interactive protocol $\pi = \{\pi_n\}_{n\in\mathbb{N}}$ is an interactive protocol between Alice and Bob, where in each round a single party sends a single bit to the other party. The order of speaking, as well as the number of rounds in the protocol, is fixed beforehand. The number of rounds is denoted $|\pi|$.*

▶ **Definition 5** (Interactive Error Correcting Code). *An interactive error correcting code (*iECC*) is a non-adaptive interactive protocol $\pi = \{\pi_n\}_{n\in\mathbb{N}}$, with the following syntax:*

- *At the beginning of the protocol, Alice receives as private input some $x \in \{0, 1\}^n$.*
- *At the end of the protocol, Bob outputs some $\hat{x} \in \{0, 1\}^n$.*

We say that π is α-resilient to adversarial bit flips (resp. erasures) if there exists $n_0 \in \mathbb{N}$ such that for all $n > n_0$ and $x \in \{0, 1\}^n$, and for all online adversarial attacks consisting of flipping (resp. erasing) at most $\alpha \cdot |\pi|$ of the total communication, Bob outputs x at the end of the protocol with probability 1.

3.2 Classical Error Correcting Codes

▶ **Definition 6** (Error Correcting Code). *An error correcting code (*ECC*) is a family of maps* $\mathsf{ECC} = \{\mathsf{ECC}_n : \{0,1\}^n \to \{0,1\}^{m(n)}\}_{n\in\mathbb{N}}$. *An* ECC *has* relative distance $\alpha > 0$ *if for all* $n \in \mathbb{N}$ *and any* $x \neq y \in \{0,1\}^n$,

$$\Delta\left(\mathsf{ECC}_n(x), \mathsf{ECC}_n(y)\right) \geq \alpha m(n).$$

Binary error correcting codes with relative distance $\approx \frac{1}{2}$ are well known to exist with linear blowup in communication complexity.

▶ **Theorem 7** ([13]). *For all* $\epsilon > 0$*, there exists an explicit linear error correcting code* $\mathsf{ECC}_\epsilon = \{\mathsf{ECC}_{\epsilon,n} : \{0,1\}^n \to \{0,1\}^m\}_{n\in\mathbb{N}}$ *with relative distance* $\frac{1}{2} - \epsilon$ *and with* $m = m(n) = O_\epsilon(n)$*. Furthermore, all codewords other than* $\mathsf{ECC}_{\epsilon,n}(0^n)$ *are relative distance* $\frac{1}{2} - \epsilon$ *from* 0^m *and* 1^m *as well.*

A relative distance of $\frac{1}{2}$ is in fact optimal in the sense that as the number of codewords N approaches ∞, the maximal possible relative distance between N codewords approaches $\frac{1}{2}$. We remark, however, that for small values of N, the distance can be much larger: for $N = 2$, the relative distance between codewords can be as large as 1, e.g. the codewords 0^M and 1^M, and for $N = 4$, the relative distance can be as large as $\frac{2}{3}$, e.g. the codewords $(000)^M, (110)^M, (101)^M, (011)^M$. Our constructions leverage this fact that codes with higher relative distance exist for a small constant number of codewords.

We will also need the following important lemma about the number of shared bits between any three codewords in an error correcting code scheme that has distance $\frac{1}{2}$.

▶ **Lemma 8.** *For any error correcting code* $\mathsf{ECC}_\epsilon = \{\mathsf{ECC}_{\epsilon,n} : \{0,1\}^n \to \{0,1\}^m\}_{n\in\mathbb{N}}$ *with relative distance* $\frac{1}{2} - \epsilon$*, and any large enough* $n \in \mathbb{N}$*, any three codewords in* $\mathsf{ECC}_{\epsilon,n}$ *overlap on at most* $\left(\frac{1}{4} + \frac{3}{2}\epsilon\right) \cdot m$ *locations.*

Lemma 8 means that assuming that $< \frac{3}{4}$ of a codeword is erased, the resulting message is list-decodable to a set of size ≤ 2, at least in theory. The following theorem says such a code exists with list-decoding being polynomial time, while also satisfying a couple other properties necessary in the protocol construction in Section 4.2.

▶ **Theorem 9** ([12]). *For all* $\epsilon > 0$*, any explicit (given with its encoding matrix) linear code* $\mathsf{ECC}_\epsilon = \{\mathsf{ECC}_{\epsilon,n} : \{0,1\}^n \to \{0,1\}^m\}_{n\in\mathbb{N}}$ *with relative distance* $(\frac{1}{2} - \epsilon)$*, can be efficiently decoded and list-decoded. That is, there exists a* $\mathrm{poly}_\epsilon(n)$*-time decoding algorithm* $\mathsf{DEC}_\epsilon = \{\mathsf{DEC}_{\epsilon,n} : \{0,1\}^m \to \mathcal{P}(\{0,1\}^n)\}_{n\in\mathbb{N}}$*, such that for any* $n \in \mathbb{N}$*,* $x \in \{0,1\}^n$*, and corruption* σ *consisting of fewer than* $(\frac{1}{2} - \epsilon) \cdot m$ *erasures,*

$$x = \mathsf{DEC}_{\epsilon,n}(\sigma \circ \mathsf{ECC}_{\epsilon,n}(x)).$$

Moreover, for any corruption σ *consisting of fewer than* $(\frac{3}{4} - \frac{3}{2}\epsilon) \cdot m$ *erasures,*

$$|\mathsf{DEC}_{\epsilon,n}(\sigma \circ \mathsf{ECC}_{\epsilon,n}(x))| \leq 2, \qquad x \in \mathsf{DEC}_{\epsilon,n}(\sigma \circ \mathsf{ECC}_{\epsilon,n}(x)).$$

Our following theorem gives an ECC such that any two codewords differ on most segments of length α.

▶ **Theorem 10.** *For all $n \in \mathbb{N}, \epsilon > 0$, there exists $\alpha = \Theta_\epsilon(\log n)$ such that, there exists an explicit linear code $\mathsf{ECC}_\epsilon = \{\mathsf{ECC}_{\epsilon,n} : \{0,1\}^n \to \{0,1\}^m\}_{n\in\mathbb{N}}$ with $m = m(n) = O_\epsilon(n)$, satisfying the following property: For all $n \in \mathbb{N}, \epsilon > 0$, it holds that $\alpha | m$ and for any $x \neq x' \in \{0,1\}^n$ and $j \in \{0 \dots \frac{m}{\alpha} - 1\}$,*

$$\mathsf{ECC}_{\epsilon,n}(x)[j\alpha : (j+1)\alpha - 1] = \mathsf{ECC}_{\epsilon,n}(x')[j\alpha : (j+1)\alpha - 1]$$

for at most $\frac{\epsilon m}{\alpha}$ values of j.

▶ **Lemma 11.** *Let $\mathsf{ECC}'_\epsilon = \{\mathsf{ECC}'_{n,\epsilon} : \{0,1\}^n \to \{0,1\}^{m(n)}\}$ be a explicit linear code satisfying the properties of Theorem 10 with $\alpha = \alpha_n = \Theta_\epsilon(\log n)$. For all linear $\mathsf{ECC}_\epsilon = \{\mathsf{ECC}_{n,\epsilon} : \{0,1\}^\alpha \times \{0,1\}^\beta \to \{0,1\}^{p(n)}\}$ with relative distance $\frac{1}{2} - \epsilon$ and for all β, the code defined by*

$$C(x) = \mathsf{ECC}_\epsilon(\mathsf{ECC}'_\epsilon(x)[0, \alpha - 1], 0^\beta) || \dots || \mathsf{ECC}_\epsilon(\mathsf{ECC}'_\epsilon(x)[m - \alpha, m - 1], 0^\beta)$$

is a linear code with relative distance $\frac{1}{2} - \frac{3}{2}\epsilon$. In particular, assuming that less than $\frac{3}{4} - \frac{9}{4}\epsilon$ of $C(x)$ is erased, there is an efficient algorithm to obtain a set of size 2 containing x.

4 A New Positive Rate iECC Resilient to $6/11$ Erasures

In this section, we discuss our positive rate iECC that is resilient to $6/11$ adversarial erasures.

4.1 Overview of Ideas

We begin with an overview of the ideas that go into our positive rate iECC. We first briefly review the iECC of [9] then describe how to modify it to have a linear communication complexity.

The overarching goal of the original protocol, as well as ours, is to perform the following three steps.

1. Bob learns that Alice's value of x is one of two possible values. (This idea is known as list decoding, which achieves better noise resilience than unique decoding.)
2. Bob conveys to Alice an index i on which the two possible inputs differ.
3. Alice sends the value of her input at index i.

Summary of the Protocol of [9]

The original protocol consists of many (say $\approx \frac{n}{\epsilon}$) *chunks*, where in each chunk Alice sends a message followed by Bob's reply. The protocol is designed so that each such chunk will make *progress* towards Bob's unambiguously learning Alice's input, as long as the adversary did not invest more than $\frac{3}{5} - \epsilon$ erasures in that chunk. At a high level, in the first chunk with $< \frac{3}{5} - \epsilon$ erasures, Bob narrows down Alice's input to at most two options. In every future chunk with $< \frac{3}{5} - \epsilon$ erasures, either Alice gets closer to learning the index i on which the two options differ, or Bob fully determines x by ruling out one of the two values of x, e.g. by learning the value of $x[i]$ or by uniquely decoding Alice's message. Alice keeps track of a counter cnt initially set to 0 indicating her guess for i. The main purpose of Bob's messages is to increment Alice's counter to i.

At the beginning of the protocol, Alice sends $\mathsf{ECC}(x, \mathsf{cnt})$ to Bob in every chunk. At the first point, there are $< \frac{3}{5} - \epsilon$ erasures in a chunk, Bob will be able to list decode Alice's message to at most two options, say $(x_0, \mathsf{cnt}_0 = 0)$ and $(x_1, \mathsf{cnt}_1 = 0)$. This must happen because the relative message lengths of Alice and Bob will be such that the adversary cannot corrupt too much of Alice's message even if they corrupt none of Bob's message. Since we are in the setting of erasures, one of the two decodings must be Alice's true state, and in particular, must contain Alice's true input.

At this point, Bob begins signaling to Alice to increment cnt. His goal is to tell Alice to increment cnt until $\mathsf{cnt} = i$. He does this by only sending one of two codewords[1] every message that have relative distance 1 apart. This way, if Bob's message is not entirely erased, Alice learns what Bob tried to send. The key is that every time $< \frac{3}{5} - \epsilon$ of a chunk is corrupted, we can guarantee *both that Bob will decode Alice's message to two possible messages, and Alice uniquely decodes Bob's message*,[2] so that Alice and Bob make progress towards Alice learning i. Once Alice has discovered i, Bob signals for Alice to send the bit $x[i]$ for the rest of the protocol,[3] which allows him to distinguish whether Alice has x_0 or x_1.

Modifications to Achieve Positive Rate

The communication complexity of the above protocol is $O(n^2)$. This comes from two parts: (1) $O(n)$ chunks are necessary for Bob to communicate the index $i \in [n]$ to Alice via incrementation, and (2) Alice sends her length n input in every chunk. We show how to lessen both requirements, thus making the final protocol linear in length.

First, for Bob to communicate $i \in [n]$ to Alice, instead of incrementing cnt by 1 until it equals i. More specifically, we describe a process where Bob writes i out in binary, and then sends Alice each bit of this binary representation in sequence. This only requires $O(\log n)$ rounds of interaction, as opposed to the $O(n)$ rounds required by [9]. Designing a protocol to communicate a binary string rather than a unary string requires significant changes to the procedure used in [9].

Second, we show that instead of sending x every message, it suffices for Alice to encode a shorter string that is different than the corresponding short string for any other x' in *most* chunks. More precisely, consider an error correcting code ECC with the following property: set some α and for any $x \neq x'$,

$$\mathsf{ECC}(x)[j\alpha, (j+1)\alpha - 1] \neq \mathsf{ECC}(x')[j\alpha, (j+1)\alpha - 1]$$

for all but an ϵ fraction of values j. Then, Alice rotates through the sections, sending $\mathsf{ECC}(x)[j\alpha, (j+1)\alpha - 1]$ in the $\left(j \bmod \frac{|\mathsf{ECC}(x)|}{\alpha}\right)$'th chunk. Then, if Bob has narrowed down Alice's input to x_0 and x_1, he can simply ignore the ϵ fraction of chunks in which $\mathsf{ECC}(x_0)[j\alpha, (j+1)\alpha - 1] = \mathsf{ECC}(x_1)[j\alpha, (j+1)\alpha - 1]$. In the remainder of chunks, the segment $\mathsf{ECC}(x)[j\alpha, (j+1)\alpha - 1]$ is sufficient for Bob to distinguish between x_0 and x_1. If we were to let $\alpha \approx \log n$,[4] then our chunks are now only length $O(\log n)$.

Combining the two modifications, we see that $\Theta(n)$ communication from Alice is necessary for Bob to narrow down Alice's input to two options, and then after that, Bob can convey i to Alice in $O(\log n)$ chunks each of size $O(\log n)$. This results in an iECC with total communication $O(n + \log^2 n) = O(n)$.

[1] In our protocol, Bob will send one of four codewords each message. This contributes to the lower erasure resilience of $\frac{6}{11} - \epsilon$.

[2] It is also possible that instead Bob uniquely decodes Alice's message, but then he will have uniquely learned x.

[3] The reader familiar with the iECC of [9] may recall that in the case that the two Alices Bob sees have different values of cnt, Bob may instruct Alice to send a different bit for the rest of the protocol, but we do not address this for now.

[4] $\alpha = \Theta(\log n)$ is necessary since Alice also sends her current guess of i each message, which has length $\log n$.

We remark that our protocol has erasure resilience $\frac{6}{11} - \epsilon$. The limiting factor is in the construction of a protocol in which Bob builds i bit by bit: our protocol requires Bob sending 4 codewords with distance $\frac{2}{3}$, rather than 2 codewords with distance $\frac{1}{2}$ to achieve $\frac{3}{5} - \epsilon$ erasure resilience. However, combining our second observation with the protocol from [9] would be enough to give an iECC with $\frac{3}{5} - \epsilon$ erasure resilience with communication $O(n \log n)$.

4.2 Positive Rate iECC Protocol (Informal)

Let $\mathsf{ECC}' : \{0,1\}^n \to \{0,1\}^m$ be an error correcting code satisfying the statement of Theorem 10 with $\alpha = \Theta(\log n)$, and let $\mathsf{ECC} : \{0,1\}^\alpha \times \{0,1\}^{\le \log n} \to \{0,1\}^p$ be an error correcting code with distance $\frac{1}{2}$ that is also relative distance $\frac{1}{2}$ from $0^p, 1^p$.

Our iECC consists of $O_\epsilon\left(\frac{m}{\alpha}\right)$ chunks, each consisting of Alice sending a p-bit message followed by Bob sending a $\frac{3p}{8}$-bit message. Bob's messages are always one of four words $\bar{0}, \bar{1}, \bar{2}, \bar{3} \in \{0,1\}^{3p/8}$ with relative distance $\frac{2}{3}$. We outline our protocol below. In what follows, we assume that all messages Bob receives are consistent with the same two values of x, otherwise Bob can rule out one of the values of x and determine Alice's true input.

1. Alice initially holds a string $\mathsf{ind} \in \{0,1\}^{\le \log n}$ initially set to the empty string $\mathsf{ind} = \emptyset$. Alice begins the protocol by sending $\mathsf{ECC}(\mathsf{ECC}'(x)[j\alpha, (j+1)\alpha - 1], \mathsf{ind})$ to Bob in every chunk.
2. Bob begins the protocol sending $\bar{0}$ every message. Every $\frac{m}{\alpha}$ chunks, he attempts to list-decode Alice's previous $\frac{m}{\alpha}$ messages to find consistent values of x. Note that by Lemma 11, if there are at most $\frac{3}{4} - \frac{3}{2}\epsilon$ erasures in Alice's message in those $\frac{m}{\alpha}$ chunks, then Bob is guaranteed to find at most two possible values of x.
3. When Bob has found two consistent values of x, say $\hat{x}_0$ and $\hat{x}_1$, he determines an index $i \in [n] = \{0,1\}^{\log n}$ such that $\hat{x}_0[i] \ne \hat{x}_1[i]$. His goal is now to communicate i to Alice, bit by bit. He does this by sending either $\bar{0}$, $\bar{1}$, or $\bar{2}$ every chunk.
   To communicate the next'th bit of i, Bob adds $i[\mathsf{next}] + 1$ to mes modulo 3, where $\overline{\mathsf{mes}}$ was the last message he sent, to get his new message mes', and begins sending $\overline{\mathsf{mes}'}$ every chunk. (When Alice receives a message from Bob that is different from the last message she received, she can calculate the difference in the two messages to determine the bit.) He does this until he list-decodes Alice's message to two possibilities $\mathsf{ECC}(\mathsf{ECC}'(\hat{x}_0)[j\alpha, (j+1)\alpha - 1, \mathsf{ind}_0)$ and $\mathsf{ECC}(\mathsf{ECC}'(\hat{x}_1)[j\alpha, (j+1)\alpha - 1], \mathsf{ind}_1)$ such that $\mathsf{ECC}'(\hat{x}_0)[j\alpha, (j+1)\alpha - 1] \ne \mathsf{ECC}'(\hat{x}_1)[j\alpha, (j+1)\alpha - 1]$, where at least one of ind_0, ind_1 has length next. If both have length next, he proceeds to communicate the $(\mathsf{next} + 1)$'th bit of i in the same way. If only one of the two Alice's has $|\mathsf{ind}_b| = \mathsf{next}$, Bob switches to sending $\bar{3}$ for the rest of the protocol, signaling to Alice to send him the parity of $|\mathsf{ind}|$ so that he can distinguish between whether Alice has $(\hat{x}_0, \mathsf{ind}_0)$ or $(\hat{x}_1, \mathsf{ind}_1)$.
4. Whenever Alice unambiguously sees a *change* in Bob's message from a $\bar{0}$ to a $\bar{1}$ or $\bar{2}$ (or cyclic), she calculates $b = \mathsf{mes}' - \mathsf{mes} - 1 \mod 3$ and appends b to ind. If she ever receives a $\bar{3}$, she switches to sending $(|\mathsf{ind}| \mod 2)^p$ for the rest of the protocol. Otherwise, at some point she has $|\mathsf{ind}| = \log n$, so she can convert ind into an index $i \in [n]$ and send $(x[i])^p$ for the rest of the protocol. Note that Bob can distinguish between $\hat{x}_0$ and $\hat{x}_1$ using the value of x at the index i.

In the above outline, one has to be careful around $|\mathsf{ind}| = \log n - 1$. In particular, if one Alice has $|\mathsf{ind}| = \log n - 1$ and the other has $|\mathsf{ind}| = \log n$, the second will be sending $x[i]$ for the rest of the protocol and it is thus incorrect for Bob to send $\bar{3}$ to signal the first Alice to send the parity of the length of ind. Instead, once Bob has list-decoded Alice's message such that $|\mathsf{ind}_0| = |\mathsf{ind}_1| = \log n - 1$, Bob commits to sending the next message $\in \{\bar{0}, \bar{1}, \bar{2}\}$ that conveys to Alice the final bit of i for the rest of the protocol.

▶ **Theorem 12.** *The above* iECC *is resilient to a $\frac{6}{11} - O(\epsilon)$ fraction of erasures. For an input of size n, the total communication is $O_\epsilon(n)$. Alice and Bob run in $poly_\epsilon(n)$ time.*

The formal version of this protocol is excluded from this conference version of the paper. The full protocol can be found in [10].

5 Impossibility Bound on Maximal Noise Resilience of iECC

In this section, we present our main upper bound, that for any non-adaptive iECC, there is some attack consisting of at most $\frac{13}{47}$ corruptions such that Bob cannot guess Alice's input x correctly with probability better than $\frac{1}{2}$.

▶ **Theorem 13.** *main For sufficiently small $\epsilon > 0$, then for all $k > 100\epsilon^{-4}$, no* iECC *for $x \in \{0,1\}^k$ is resilient to more than $\frac{13}{47} + 2\epsilon$ fraction of errors with probability greater than $\frac{1}{2}$.*

The rest of this section will be devoted to the proof of this theorem. Throughout this section, Alice's input will always be denoted $x \in \{0,1\}^k$. The length of the iECC will be denoted by n.

At a high level, our proof will proceed as follows. We will split any candidate protocol into two sections, the first consisting of the first $\frac{21}{47}n$ rounds of the protocol, and the second consisting of the remaining $\frac{26}{47}n$ rounds of the protocol. In the first section, we denote the number of bits that Alice sends by A_1, and the number that Bob sends by B_1. Likewise, in the second section, we denote the number of bits that Alice and Bob send by A_2 and B_2 respectively. We will present three attacks in Sections 5.1, 5.2, and 5.3 such that depending on the values of A_1, B_1, A_2, B_2, at least one attack is guaranteed to succeed while using at most $\frac{13}{47}$ corruptions.

Throughout this section, a *transcript* is the sequence of bits that is received by either of the parties. Note that since the adversary may corrupt messages, the transcript may be different than what was sent by Alice and Bob. We say that an attack *succeeds* with α corruption if there exist two inputs $x_1, x_2 \in \{0,1\}^k$ along with respective strategies corrupting at most αn bits such that Bob's view of the transcript in both cases is identical. Then, Bob cannot guess Alice's true value of $x \in \{x_1, x_2\}$ with probability better than $\frac{1}{2}$.

5.1 Attack 1

In the first attack, the adversary behaves the same on both sections of the protocol. She corrupts Alice's bits while leaving Bob's untouched, such that there exist two inputs for which at most of $\frac{1}{3}$ of Alice's communication is corrupted. We remark that this attack has been known since [2].

▶ **Lemma 14.** *For any protocol consisting of A bits from Alice and B bits from Bob, and for any three possible inputs x_1, x_2, x_3, there exists two of the three inputs $y_1, y_2 \in \{x_1, x_2, x_3\}$ and a transcript $T \in \{0,1\}^{A+B}$ such that the adversary can corrupt at most $\frac{1}{3}A + 1$ bits so that the protocol transcript is T in both the case Alice has y_1 or y_2.*

The proof is omitted in this conference version.

The attack is stated below.

Attack 1

Let $x_1, x_2, x_3 \in \{0,1\}^k$ be three of Alice's possible inputs. By Lemma 14, there exist $y_1, y_2 \in \{x_1, x_2, x_3\}$ and transcript $T \in \{0,1\}^n$ such that the adversary can corrupt at most $\frac{1}{3}(A_1 + A_2) + 1$ bits to obtain transcript T in both the case Alice has y_1 and if she has y_2. The adversary simply corrupts the protocol so that the resulting transcript is T.

▶ **Lemma 15.** *Attack 1 succeeds with corrupting* $\frac{1}{3}A_1 + \frac{1}{3}A_2 + 1$ *bits.*

Proof. This follows immediately from Lemma 14: regardless of whether Alice has y_1 or y_2, the adversary is able to have Bob receive the same transcript, using $\frac{1}{3}(A_1 + A_2) + 1$ bits of corruption. ◀

5.2 Attack 2

In our second attack, the adversary behaves differently in the two sections of the protocol. In the first section, the adversary essentially causes Bob's feedback to look random, so that Alice can do no better than to send a distance $\frac{1}{2}$ error-correcting code. This allows the adversary to corrupt $\frac{1}{4}$ of Alice's bits during this first section so that Bob cannot distinguish between three inputs. Then, in the second section, we use Lemma 14 from the previous section to show that the adversary has a strategy corrupting only $\frac{1}{3}A_2$ bits to confuse Bob between two of the remaining three inputs.

To argue that the adversary can perform her attack in the first section, we need the following lemma.

▶ **Lemma 16.** *For any* $0 < \epsilon < 0.1$*, suppose Alice has* K *possible inputs where* $K > (4/\epsilon)^{1/3}$*. Then for any protocol consisting of* A *bits from Alice and* B *bits from Bob where* $A + B \geq \frac{3\log(1/\epsilon)}{\epsilon^3}$*, there exist three inputs* x_1, x_2, x_3 *and a transcript* T *such that regardless of which of* x_1, x_2, x_3 *Alice has as input, the adversary can corrupt at most* $\left(\frac{1}{4} + \frac{3\epsilon}{2}\right) \cdot A + \left(\frac{1}{2} + \epsilon\right) \cdot B + 1$ *bits so that the protocol transcript is* T*.*

The proof is omitted in this conference version.

We now state our second attack.

Attack 2

Let inputs $x_1, x_2, x_3 \in \{0,1\}^k$ and transcript $T_1 \in \{0,1\}^{21n/47}$ be such that they satisfy Lemma 16 for the first section of the protocol. Then, for the first section of the protocol, the adversary corrupts the transcript to look like T_1, using at most $\left(\frac{1}{4} + \frac{3\epsilon}{2}\right) A_1 + \left(\frac{1}{2} + \epsilon\right) B_1 + 1$ bits of corruption in the cases where Alice had x_1, x_2, x_3.

For the second section of the protocol, the adversary corrupts the communication to the transcript $T_2 \in \{0,1\}^{26n/47}$ as found in Lemma 14 such that there exist two of x_1, x_2, x_3, denoted y_1, y_2, for which the adversary can corrupt at most $\frac{1}{3}A_2 + 1$ of the communication so that the transcript of received bits is T_2 if Alice has y_1 or y_2.

▶ **Lemma 17.** *Suppose that* $k \geq \frac{141\log(1/\epsilon)}{21\epsilon^3}$*. Attack 2 succeeds with corrupting* $\left(\frac{1}{4} + \frac{3\epsilon}{2}\right) \cdot A_1 + \left(\frac{1}{2} + \epsilon\right) \cdot B_1 + \frac{1}{3}A_2 + 2$ *bits.*

Proof. Regardless of whether Alice has y_1 or y_2, the transcript from Bob's perspective when the adversary employs this attack looks like T_1 followed by T_2 (restricted to Bob's viewpoint). Since $A_1 + B_1 \geq \max\{\frac{21}{26}A_2, k - A_2\}$ (where $A_1 + A_2 \geq k$ holds since Alice needs to send k

bits to communicate x, even noiselessly), it follows that $A_1+B_1 \geq \frac{21}{47}k \geq 3\log(1/\epsilon)/\epsilon^3$, so the condition of Lemma 16 is satisfied. Then, by Lemma 16, the number of corruptions used in the first section of the protocol when Alice has y_1 or y_2 is at most $\left(\frac{1}{4}+\frac{3\epsilon}{2}\right)\cdot A_1+\left(\frac{1}{2}+\epsilon\right)\cdot B_1$, and by Lemma 14, the number of corrupted bits in the second section whether Alice has y_1 or y_2 is at most $\frac{1}{3}A_2+1$. ◀

5.3 Attack 3

In our third attack, we employ the following strategy. At a high level, we choose two inputs x_1 and x_2. In the first section of the protocol, Bob's view is as if Alice had x_1, while Bob's bits are corrupted so that Alice thinks that he has been receiving and responding correctly. In the second section of the protocol, Bob's bits are flipped randomly, and Alice's communication is corrupted to look like she has x_2.

The first lemma we will need is to show that for the first section of the protocol, there are many inputs for which the uncorrupted transcripts have pairwise small Hamming distance.

▶ **Lemma 18.** *Let $\epsilon > 0$ and suppose Alice has K possible inputs. Then for any protocol consisting of A bits from Alice and B bits from Bob, there exists a set Γ of size $K'_\epsilon(K) = K^\epsilon - \frac{1}{\epsilon}$ inputs such that for any two $x_1, x_2 \in \Gamma$, the relative distance of the (uncorrupted) transcripts in the case where Alice has x_1 or x_2 is $\leq \left(\frac{1}{2}+\epsilon\right)\cdot(A+B)$.*

The proof is omitted in this conference version.

▶ **Lemma 19.** *Let $\epsilon > 0$, and suppose Alice has $K' > \sqrt{2/\epsilon}$ possible inputs. For any protocol consisting of A bits from Alice and B bits from Bob such that $A+B > \frac{3\log(1/\epsilon)}{\epsilon^3}$, there exist two inputs x_1, x_2 such that for any advice α that Bob receives at the beginning of the protocol (after both Alice and Bob have fixed their strategies), there exist two transcripts T_1, T_2 such that the Bob's view of the two transcripts is the same, and that in the case of Alice having x_1, the adversary needs only corrupt $\left(\frac{1}{2}+2\epsilon\right)A+\left(\frac{1}{2}+\epsilon\right)B$ bits to get transcript T_1, and in the case of Alice having x_2, the adversary needs only corrupt $\left(\frac{1}{2}+\epsilon\right)B$ bits so that the transcript is T_2.*

The proof is omitted in this conference version.

Attack 3

Denote by $T_1(y)$ the uncorrupted transcript corresponding to Alice having input y in the first section of the protocol. By Lemma 18, there exists a set M of $2^{\epsilon k}-\frac{1}{\epsilon}$ inputs such that for every $y_1, y_2 \in M$, it holds that $\Delta(T_1(y_1), T_1(y_2)) \leq \left(\frac{1}{2}+\epsilon\right)\cdot n$. Next, consider the second section of the protocol, conditioned on Alice having seen $T_1(x)$ (restricted to her view) in the first section of the protocol. By Lemma 19 there exist $x_1, x_2 \in M$ such that no matter what advice α Bob receives at the beginning of this second section, there exist transcripts $T_{2,1}(\alpha)$ and $T_{2,2}(\alpha)$ such that Bob's view of the two transcripts are the same, and these $T_{2,1}(\alpha), T_{2,2}(\alpha)$ satisfy the properties listed in Lemma 19.

In the first section of the protocol, the adversary corrupts the communication so that Bob always receives $T_1(x_1)$ (restricted to the bits that Bob sees), and so that Alice receives $T(x)$ (restricted to the bits that she sees), where x denotes Alice's input.

In the second section of the protocol, the adversary corrupts the communication so that the transcript is $T_{2,1}(\alpha = T_1(x_1))$ in the case of Alice having x_1, and $T_{2,2}(\alpha = T_1(x_1))$ otherwise.

▶ **Lemma 20.** *Suppose that $k > \frac{141\log(1/\epsilon)}{26\epsilon^3}$. Attack 3 succeeds with corrupting*

$$\max\left\{\left(\frac{1}{2}+2\epsilon\right)\cdot A_2+\left(\frac{1}{2}+\epsilon\right)\cdot B_2\ ,\quad \left(\frac{1}{2}+\epsilon\right)\cdot A_1+\left(\frac{1}{2}+\epsilon\right)\cdot B_1+\left(\frac{1}{2}+\epsilon\right)\cdot B_2\right\}$$

bits.

Proof. Regardless of whether Alice has x_1 or x_2, Bob receives the same transcript (restricted to his view). Since $A_2 + B_2 \geq \max\{\frac{26}{21}A_1, k - A_1\}$ (where $A_1 + A_2 \geq k$ holds since Alice needs to send k bits to communicate x, even noiselessly), it follows that $A_2 + B_2 \geq \frac{26}{47}k > \frac{3\log(1/\epsilon)}{\epsilon^3}$, so the condition of Lemma 19 is satisfied. If Alice has x_1, the amount of corruption in the first section is 0, while in the second section the adversary corrupted at most $\left(\frac{1}{2}+2\epsilon\right)A_2 + \left(\frac{1}{2}+\epsilon\right)\cdot B_2$ bits. If Alice has x_2, the amount of corruption in the first section is $\Delta(T_1(x_1), T_1(x_2)) \leq \left(\frac{1}{2}+\epsilon\right)\cdot(A_1+B_1)$, and in the second section the adversary corrupts at most $\left(\frac{1}{2}+\epsilon\right)\cdot B_2$ bits. ◀

5.4 Proof of Theorem 13

In this section, we prove our main result, restated below.

▶ **Theorem 21.** *For sufficiently small $\epsilon > 0$, there exists $k_0 = k_0(\epsilon) \in \mathbb{N}$ such that for any $k > k_0$, no* iECC *over the binary bit flip channel where Alice is trying to communicate $x \in \{0,1\}^k$ is resilient to $\frac{13}{47}+\epsilon$ fraction of adversarial bit flips.*

We begin with the following lemma.

▶ **Lemma 22.** *For any nonnegative $a_1, b_1, a_2, b_2 \in \mathbb{R}$ where $a_1+b_1 = \frac{21}{47}$ and $a_1+b_1+a_2+b_2 = 1$, define*

$$\begin{aligned}\delta_1 &= \frac{1}{3}a_1+\frac{1}{3}a_2,\\ \delta_2 &= \frac{1}{4}a_1+\frac{1}{2}b_1+\frac{1}{3}a_2,\\ \delta_3 &= \max\left\{\frac{1}{2}a_2+\frac{1}{2}b_2, \frac{1}{2}a_1+\frac{1}{2}b_1+\frac{1}{2}b_2\right\}.\end{aligned}$$

It holds that

$$\min\{\delta_1,\delta_2,\delta_3\} \leq \frac{13}{47}.$$

Proof. Using that $b_1 = \frac{21}{47} - a_1$ and $b_2 = \frac{26}{47} - a_2$, we can substitute:

$$\begin{aligned}\delta_1 &= \frac{1}{3}a_1+\frac{1}{3}a_2,\\ \delta_2 &= \frac{21}{94}-\frac{1}{4}a_1+\frac{1}{3}a_2,\\ \delta_3 &= \max\left\{\frac{13}{37}, \frac{1}{2}-\frac{1}{2}a_2\right\}.\end{aligned}$$

Then,

$$\min\{\delta_1,\delta_2,\delta_3\} \leq \frac{13}{47} \iff \min\{\delta_1,\delta_2,\delta_3'\} \leq \frac{13}{47},$$

where $\delta_3' = \frac{1}{2} - \frac{1}{2}a_2$. But note that

$$\frac{9}{35}\delta_1+\frac{12}{35}\delta_2+\frac{2}{5}\delta_3' = \frac{13}{47}$$

where the weights $\frac{9}{35}, \frac{12}{35}, \frac{2}{5}$ sum to 1, so at least one of $\delta_1, \delta_2, \delta_3'$ must be at most $\frac{13}{47}$. ◀

Proof of Theorem 13. Recall that the length of the iECC is $n := A_1 + B_1 + A_2 + B_2 \geq A_1 + A_2 \geq k > \epsilon^{-3}$ (since Alice needs to send at least k bits to communicate x, even in the noiseless setting). Our goal is to show that regardless of the values of A_1, B_1, A_2, B_2, at least one of Attacks 1, 2, and 3 will require at most $\left(\frac{13}{47} + 2\epsilon\right) \cdot n$ corruptions.

By Lemma 15, Attack 1 succeeds using

$$\frac{1}{3}A_1 + \frac{1}{3}A_2 + 1 \leq (\delta_1 + 2\epsilon)\, n$$

bits of corruption, where $\delta_1 := (\frac{1}{3}A_1 + \frac{1}{3}A_2)/n$.

By Lemma 17, Attack 2 succeeds using

$$\left(\frac{1}{4} + \frac{3\epsilon}{2}\right) \cdot A_1 + \left(\frac{1}{2} + \epsilon\right) \cdot B_1 + \frac{1}{3}A_2 + 2 \leq \frac{1}{4}A_1 + \frac{1}{2}B_1 + \frac{1}{3}A_2 + 2\epsilon n = (\delta_2 + 2\epsilon)n$$

bits of corruption, where we define $\delta_2 = (\frac{1}{4}A_1 + \frac{1}{2}B_1 + \frac{1}{3}A_2)/n$.

By Lemma 20, Attack 3 succeeds using

$$\begin{aligned}
&\max\left\{\left(\frac{1}{2} + 2\epsilon\right) \cdot A_2 + \left(\frac{1}{2} + \epsilon\right) \cdot B_2\ ,\ \ \left(\frac{1}{2} + \epsilon\right) \cdot A_1 + \left(\frac{1}{2} + \epsilon\right) \cdot B_1 + \left(\frac{1}{2} + \epsilon\right) \cdot B_2\right\} \\
&\quad \leq \max\left\{\frac{1}{2}A_2 + \frac{1}{2}B_2 + 2\epsilon n, \frac{1}{2}A_1 + \frac{1}{2}B_1 + \frac{1}{2}B_2 + 2\epsilon n\right\} \\
&\quad = (\delta_3 + 2\epsilon)n
\end{aligned}$$

bits of corruption, where we define $\delta_3 = \max\left\{\frac{1}{2}A_2 + \frac{1}{2}B_2, \frac{1}{2}A_1 + \frac{1}{2}B_1 + \frac{1}{2}B_2\right\}/n$.

By Lemma 22, we have that $\min\{\delta_1, \delta_2, \delta_3\} \leq \frac{13}{47}$, so at least one of the three attacks succeeds with $\left(\frac{13}{47} + 2\epsilon\right) \cdot n$ corruption, regardless of the relative ratios of A_1, B_1, A_2, B_2. ◀

Abstract

We study the mixing time of the single-site update Markov chain, known as the Glauber dynamics, for generating a random independent set of a tree. Our focus is obtaining optimal convergence results for arbitrary trees. We consider the more general problem of sampling from the Gibbs distribution in the hard-core model where independent sets are weighted by a parameter $\lambda > 0$; the special case $\lambda = 1$ corresponds to the uniform distribution over all independent sets. Previous work of Martinelli, Sinclair and Weitz (2004) obtained optimal mixing time bounds for the complete Δ-regular tree for all λ. However, Restrepo et al. (2014) showed that for sufficiently large λ there are bounded-degree trees where optimal mixing does not hold. Recent work of Eppstein and Frishberg (2022) proved a polynomial mixing time bound for the Glauber dynamics for arbitrary trees, and more generally for graphs of bounded tree-width.

We establish an optimal bound on the relaxation time (i.e., inverse spectral gap) of $O(n)$ for the Glauber dynamics for unweighted independent sets on arbitrary trees. Moreover, for $\lambda \leq .44$ we prove an optimal mixing time bound of $O(n \log n)$. We stress that our results hold for arbitrary trees and there is no dependence on the maximum degree Δ. Interestingly, our results extend (far) beyond the uniqueness threshold which is on the order $\lambda = O(1/\Delta)$. Our proof approach is inspired by recent work on spectral independence. In fact, we prove that spectral independence holds with a constant independent of the maximum degree for any tree, but this does not imply mixing for general trees as the optimal mixing results of Chen, Liu, and Vigoda (2021) only apply for bounded degree graphs. We instead utilize the combinatorial nature of independent sets to directly prove approximate tensorization of variance/entropy via a non-trivial inductive proof.

1 Introduction

This paper studies the mixing time of the Glauber dynamics for the hard-core model assuming that the underlying graph is an *arbitrary* tree. In the hard-core model, we are given a graph $G = (V, E)$ and an activity $\lambda > 0$. The model is defined on the collection of all independent sets of G (regardless of size), which we denote as Ω.

Each independent set $\sigma \in \Omega$ is assigned a weight $w(\sigma) = \lambda^{|\sigma|}$ where $|\sigma|$ is the number of vertices contained in the independent set σ. The Gibbs distribution μ is defined on Ω: for $\sigma \in \Omega$, let $\mu(\sigma) = w(\sigma)/Z$ where $Z = \sum_{\tau\in\Omega} w(\tau)$ is known as the partition function. When $\lambda = 1$ then every independent set has weight one and hence the Gibbs distribution μ is the uniform distribution over (unweighted) independent sets.

Our goal is to sample from μ (or estimate Z) in time polynomial in $n = |V|$. Our focus is on trees. These sampling and counting problems are computationally easy on trees using dynamic programming algorithms. Nevertheless, our interest is to understand the convergence properties of a simple Markov Chain Monte Carlo (MCMC) algorithm known as the Glauber dynamics for sampling from the Gibbs distribution.

The Glauber dynamics (also known as the Gibbs sampler) is the simple single-site update Markov chain for sampling from the Gibbs distribution of a graphical model. For the hard-core model with activity λ, the transitions $X_t \to X_{t+1}$ of the Glauber dynamics are defined as follows: first, choose a random vertex v. Then, with probability $\frac{\lambda}{1+\lambda}$ set $X' = X_t \cup \{v\}$ and with the complementary probability set $X' = X_t \setminus \{v\}$. If X' is an independent set, then set $X_{t+1} = X'$ and otherwise set $X_{t+1} = X_t$.

We consider two standard notions of convergence to stationarity. The *relaxation time* is the inverse spectral gap, i.e., $(1 - \lambda^*)^{-1}$ where $\lambda^* = \max\{\lambda_2, |\lambda_N|\}$ and $1 = \lambda_1 > \lambda_2 \geq \cdots \geq \lambda_N > -1$ are the eigenvalues of the transition matrix P for the Glauber dynamics. The relaxation time is a key quantity in the running time for approximate counting algorithms (see, e.g., [29]). The *mixing time* is the number of steps, from the worst initial state, to reach within total variation distance $\leq 1/2e$ of the stationary distribution, which in our case is the Gibbs distribution μ.

We say that $O(n)$ is the optimal relaxation time and that $O(n \log n)$ is the optimal mixing time (see Hayes and Sinclair [18] for a matching lower bound for any constant degree graph). Here, n denotes the size of the underlying graph. More generally, we say the Glauber dynamics is rapidly mixing when the mixing time is poly(n).

We establish bounds on the mixing time of the Glauber dynamics by means of *approximate tensorization inequalities* for the variance and the entropy of the hard-core model. Interestingly, our analysis utilizes nothing further than the inductive nature of the tree, e.g., we do not make any assumptions about spatial mixing properties of the Gibbs distribution. As a consequence, the bounds we obtain have no dependence on the maximum degree of the graph.

To be more specific we derive the following two group of results: We establish approximate tensorization of variance of the hard-core model on the tree for all $\lambda < 1.1$. This implies *optimal* $O(n)$ relaxation time for the Glauber dynamics. Notably this also includes the uniform distribution over independent sets, i.e., $\lambda = 1$. Furthermore, we establish approximate tensorization of entropy for the hard-core model on any tree for all $\lambda < 0.44$. In turn, this implies *optimal* mixing time $O(n \log n)$ for the Glauber dynamics.

We can now state our main results.

▶ **Theorem 1.** *For any n-vertex tree, for any $\lambda < 1.1$ the Glauber dynamics for sampling λ-weighted independent sets in the hard-core model has an optimal relaxation time of $O(n)$.*

Moreover, when $\lambda \leq 0.44$ then we can prove an optimal bound on the mixing time. (This extends to $\lambda \leq 1.05$ under an intriguing conjecture that we can numerically verify.)

▶ **Theorem 2.** *For any n-vertex tree, for any $\lambda \leq 0.44$ the Glauber dynamics for sampling λ-weighted independent sets in the hard-core model has an optimal mixing time of $O(n \log n)$.*

We believe the optimal mixing results of Theorems 1 and 2 are related to the reconstruction threshold, which we describe now. Consider the complete Δ-regular tree of height h; this is the rooted tree where all nodes at distance $\ell < h$ from the root have $\Delta - 1$ children and all nodes at distance h from the root are leaves. We are interested in how the configuration at the leaves affects the configuration at the root.

Consider fixing an assignment/configuration σ to the leaves (i.e., specifying which leaves are fixed to occupied and which are unoccupied), we refer to this fixed assignment to the leaves as a boundary condition σ. Let μ_σ denote the Gibbs distribution conditional on this fixed boundary condition σ, and let p_σ denote the marginal probability that the root is occupied in μ_σ.

The uniqueness threshold $\lambda_c(\Delta)$ measures the affect of the *worst-case* boundary condition on the root. For all $\lambda < \lambda_c(\Delta)$, all $\sigma \neq \sigma'$, in the limit $h \to \infty$, we have $p_\sigma = p'_\sigma$; this is known as the (tree) uniqueness region. In contrast, for $\lambda > \lambda_c(\Delta)$ there are pairs $\sigma \neq \sigma'$ (namely, all even occupied vs. odd occupied) for which the limits are different; this is the non-uniqueness region. The uniqueness threshold is at $\lambda_c(\Delta) = (\Delta - 1)^{\Delta-1}/(\Delta - 2)^{\Delta} = O(1/\Delta)$.

In contrast, the reconstruction threshold $\lambda_r(\Delta)$ measures the affect on the root of a random/typical boundary condition. In particular, we fix an assignment c at the root and then generate the Gibbs distribution via an appropriately defined broadcasting process. Finally, we fix the boundary configuration σ and ask whether, in the conditional Gibbs distribution μ_σ, the root has a bias towards the initial assignment c. The non-reconstruction region $\lambda < \lambda_r(\Delta)$ corresponds to when we cannot infer the root's initial value, in expectation over the choice of the boundary configuration σ and in the limit $h \to \infty$, see Mossel [24] for a more complete introduction to reconstruction.

The reconstruction threshold is not known exactly but close bounds were established by Bhatnagar, Sly, and Tetali [3] and Brightwell and Winkler [5] who showed that: $C_1 \log^2 \Delta / \log\log \Delta \leq \lambda_r(\Delta) \leq C_2 \log^2 \Delta$ for sufficiently large Δ, and hence $\lambda_r(\Delta)$ is "increasing asymptotically" with Δ whereas the uniqueness threshold is a decreasing function of Δ. Martin [21] showed that $\lambda_r(\Delta) > e - 1$ for all Δ. As a consequence, we conjecture that Theorems 1 and 2 holds for all trees for all $\lambda < e - 1$, which is close to the bound we obtain. A slowdown in the reconstruction region is known: as described below, Restrepo et al. [26] showed that there are trees for which there is a polynomial slow down for $\lambda > C$ for a constant $C > 0$; an explicit constant C is not stated in [26] but using the Kesten-Stigum bound one can show $C \approx 28$.

For general graphs the appropriate threshold is the uniqueness threshold, which is $\lambda_c(\Delta) = O(1/\Delta)$. In particular, for bipartite random Δ-regular graphs the Glauber dynamics has optimal mixing in the uniqueness region [13], and is exponentially slow in the non-uniqueness region [25, 17]. Moreover, for general graphs there is a computational phase transition at the uniqueness threshold: optimal mixing on all graphs of maximum degree Δ in the uniqueness region [13, 9, 10], and NP-hardness to approximately count/sample in the non-uniqueness region [27, 17, 28].

There are a variety of mixing results for the special case on trees, which is the focus of this paper. In terms of establishing optimal mixing time bounds for the Glauber dynamics, previous results only applied to complete, Δ-regular trees. Seminal work of Martinelli, Sinclair, and Weitz [22, 23] proved optimal mixing on complete Δ-regular trees for all λ. The intuitive reason this holds for all λ is that the complete tree corresponds to one of the two extremal phases (all even boundary or all odd boundary) and hence it does not exhibit the phase co-existence which causes mixing. As mentioned earlier, Restrepo et al. [26] shows that there is a there is a fixed assignment τ for the leaves of the complete, Δ-regular tree so that the mixing time slows down in the reconstruction region; intuitively, this boundary condition τ corresponds to the assignment obtained by the broadcasting process.

For more general trees the following results were known. A classical result of Berger et al. [2] proves polynomial mixing time for trees with constant maximum degree [2]. A very recent result of Eppstein and Frishberg [16] proved polynomial mixing time $n^{C(\lambda)}$ of the Glauber dynamics for graphs with bounded tree-width which includes arbitrary trees, however the polynomial exponent is roughly $C(\lambda) = 11 + 6\log(\lambda)$ for trees. For other combinatorial models, rapid mixing for the Glauber dynamics on trees with bounded maximum degree was established for k-colorings in [20] and edge-colorings in [15].

Spectral independence is a powerful notion in the analysis of the convergence rate of Markov Chain Monte Carlo (MCMC) algorithms. For independent sets on an n-vertex graph $G = (V, E)$, spectral independence considers the $n \times n$ pairwise influence matrix I_G where $I_G(v, w) = \mathrm{Prob}_{\sigma\sim\mu}(v \in \sigma \mid w \in \sigma) - \mathrm{Prob}_{\sigma\sim\mu}(v \in \sigma \mid w \notin \sigma)$; this matrix is closely related to the vertex covariance matrix. We say that spectral independence holds if the maximum eigenvalue of $I_{G'}$ for all vertex-induced subgraphs G' of G are bounded by a constant. Spectral independence was introduced by Anari, Liu, and Oveis Gharan [1]. Chen, Liu, and Vigoda [13] proved that spectral independence, together with a simple condition known as marginal boundedness which is a lower bound on the marginal probability of a valid vertex-spin pair, implies optimal mixing time of the Glauber dynamics for *constant-degree graphs.* This has led to a flurry of optimal mixing results, e.g., [14, 4, 19, 12, 11].

The limitation of the above spectral independence results is that they only hold for graphs with constant maximum degree Δ. There are several noteworthy results that achieve a stronger form of spectral independence which establishes optimal mixing for unbounded degree graphs [9, 10]; however all of these results for general graphs only achieve rapid mixing in the tree uniqueness region which corresponds to $\lambda = O(1/\Delta)$ whereas we are aiming for $\lambda = \Theta(1)$.

The inductive approach we use to establish approximate tensorization inequalities can also be utilized to establish spectral independence. In fact, we show that spectral independence holds for any tree when $\lambda < 1.3$, including the case where $\lambda = 1$, see Appendix A of the full version of this paper. Applying the results of Anari, Liu, and Oveis Gharan [1] we obtain a poly(n) bound on the mixing time, but with a large constant in the exponent of n. For constant degree trees we obtain the following optimal mixing result by applying the results of Chen, Liu, and Vigoda [13] (see also [4, 9, 10]).

▶ **Theorem 3.** *For all constant Δ, all $\lambda \le 1.3$, for any tree T with maximum degree Δ, the Glauber dynamics for sampling λ-weighted independent sets has an optimal mixing time of $O(n \log n)$.*

In the next section we recall the key functional definitions and basic properties of variance/entropy that will be useful later in the proofs. In Section 3 we prove approximate tensorization of variance which establishes Theorem 1. Then in Section 4 we prove Theorem 2. We establish spectral independence and prove Theorem 3 in Appendix A of the full version of this paper.

2 Preliminaries

2.1 Standard Definitions

Let P be the transition matrix of a Markov chain $\{X_t\}$ with a finite state space Ω and equilibrium distribution μ. For $t \geq 0$ and $\sigma \in \Omega$, let $P^t(\sigma, \cdot)$ denote the distribution of X_t when the initial state of the chain satisfies $X_0 = \sigma$. The *mixing time* of the Markov chain $\{X_t\}_{t \geq 0}$ is defined by

$$T_{\mathrm{mix}} = \max_{\sigma \in \Omega} \min \left\{ t > 0 \mid \|P^t(\sigma, \cdot) - \mu\|_{\mathrm{TV}} \leq \frac{1}{2\mathrm{e}} \right\} \ . \tag{1}$$

The transition matrix P with stationary distribution μ is called *time reversible* if it satisfies the so-called *detailed balance relation*, i.e., for any $x, y \in \Omega$ we have $\mu(x)P(x,y) = P(y,x)\mu(y)$. For P that is time reversible the set of eigenvalues are real numbers and we denote them as $1 = \lambda_1 \geq \lambda_2 \geq \ldots \lambda_{|\Omega|} \geq -1$. Let $\lambda^* = \max\{|\lambda_2|, |\lambda_{|\Omega|}|\}$, then we define the *relaxation time* T_{relax} by

$$T_{\mathrm{relax}}(P) = \frac{1}{1 - \lambda^*} \ . \tag{2}$$

The quantity $1 - \lambda^*$ is also known as the *spectral gap* of P. We use T_{relax} to bound T_{mix} by using the following inequality

$$T_{\mathrm{mix}}(P) \leq T_{\mathrm{relax}}(P) \cdot \log \left(\frac{2e}{\min_{x \in \Omega} \mu(x)} \right) \ . \tag{3}$$

2.2 Gibbs Distributions and Functional Analytic Definitions

For a graph $G = (V, E)$ and $\lambda > 0$, let $\mu = \mu_{G,\lambda}$ be the hard-core model on this graph with activity λ, while let $\Omega \subseteq 2^V$ be the support of μ. For any $\Lambda \subseteq V$ and any $\tau \subseteq \Lambda$, we let $\mu^{\Lambda,\tau}$ be the distribution μ conditional on that from Λ we choose exactly the vertices in τ. When there is no danger of confusion, we omit Λ. We let $\Omega^\tau \subseteq \Omega$ be the support of $\mu^{\Lambda,\tau}$, while we call τ *feasible* if Ω^τ is nonempty.

For any subset $S \subseteq V$, let μ_S denote the marginal of μ at S, while let $\Omega_S \subseteq 2^S$ denote the support of μ_S. That is, for any $\sigma \subseteq S$, we have that

$$\mu_S(\sigma) = \sum_{\eta \in 2^V} \mathbf{1}\{\eta \cap S = \sigma\} \mu(\eta) \ . \tag{4}$$

In a natural way, we define the conditional marginal. That is, for $\Lambda \subseteq V \setminus S$ and $\tau \subseteq \Lambda$, we let $\mu_S^{\Lambda,\tau}$ denote the marginal at S conditional on the configuration at Λ being τ. Similarly to what we had before, when there is no danger of confusion, we omit Λ. We let Ω_S^τ denote the support of μ_S^τ.

For any function $f : \Omega \to \mathbb{R}_{\geq 0}$, we let $\mu(f)$ is the expected value of f with respect to μ, i.e.,

$$\mu(f) = \sum_{\sigma \in \Omega} \mu(\sigma) f(\sigma) \ .$$

Analogously, we define variance of f with respect to μ by

$$\mathrm{Var}(f) = \mu(f^2) - (\mu(f))^2 \ . \tag{5}$$

We are also using the following equation for $\mathrm{Var}(f)$,

$$\mathrm{Var}(f) = \tfrac{1}{2}\textstyle\sum_{\sigma,\tau\in\Omega}\mu(\sigma)\mu(\tau)\left(f(\sigma)-f(\tau)\right)^2 \quad . \tag{6}$$

For any $S \subseteq V$, for any $\tau \in \Omega_{V\setminus S}$, we define the function $f_\tau : \Omega_S^\tau \to \mathbb{R}_{\geq 0}$ such that $f_\tau(\sigma) = f(\tau \cup \sigma)$ for all $\sigma \in \Omega_S^\tau$. Let $\mathrm{Var}_S^\tau(f_\tau)$ denote the variance of f_τ with respect to the conditional distribution μ_S^τ:

$$\begin{aligned}\mathrm{Var}_S^\tau(f_\tau) &= \mu_S^\tau(f_\tau^2) - \left(\mu_S^\tau(f_\tau)\right)^2 &(7)\\ &= \frac{1}{2}\sum_{\sigma,\eta\in\Omega}\frac{\mathbf{1}\{\sigma\setminus S=\tau,\ \eta\setminus S=\tau\}\mu(\sigma)\mu(\eta)}{\left(\sum_{\hat\sigma\in\Omega}\mathbf{1}\{\hat\sigma\setminus S=\tau\}\mu(\hat\sigma)\right)^2}\left(f(\sigma)-f(\eta)\right)^2 \quad . &(8)\end{aligned}$$

Furthermore, we let

$$\mu(\mathrm{Var}_S(f)) = \sum_{\tau\in\Omega_{V\setminus S}}\mu_{V\setminus S}(\tau)\cdot\mathrm{Var}_S^\tau(f_\tau) \quad , \tag{9}$$

i.e., $\mu(\mathrm{Var}_S(f))$ is the average of $\mathrm{Var}_S^\tau(f_\tau)$ with respect to the τ being distributed as in $\mu_{V\setminus S}(\cdot)$. For the sake of brevity, when $S=\{v\}$, i.e., the set S is a singleton, we use $\mu(\mathrm{Var}_v(f))$.

Similarly to $\mu(f)$ and $\mathrm{Var}(f)$ we define the entropy with respect to μ by

$$\mathrm{Ent}(f) = \mu\left(f\log\tfrac{f}{\mu(f)}\right) \quad , \tag{10}$$

where we use the convention that $0\log 0 = 0$. Analogously to $\mu(\mathrm{Var}_S(f))$, we let

$$\mu(\mathrm{Ent}_S(f)) = \sum_{\tau\in\Omega_{V\setminus S}}\mu_{V\setminus S}(\tau)\mathrm{Ent}_S^\tau(f_\tau) \quad . \tag{11}$$

That is, $\mu(\mathrm{Ent}_S(f))$ is the average of the entropy $\mathrm{Ent}_S^\tau(f_\tau)$ with respect to the measure $\mu_{V\setminus S}(\cdot)$.

When X is a Bernoulli random variable, i.e.,

$$X = \begin{cases} A & \text{with probability } p \\ B & \text{with probability } 1-p, \end{cases}$$

one formulation for the variance that will be convenient for us is

$$\mathrm{Var}(X) = p(1-p)(A-B)^2. \tag{12}$$

2.3 Approximate Tensorization of Variance/Entropy

To bound the convergence rate of the Glauber dynamics we consider the approximate tensorization of variance/entropy as introduced in [7].

We begin with the definition of approximate tensorization of variance.

▶ **Definition 4** (Variance Tensorization). *A distribution μ with support $\Omega \subseteq \{\pm 1\}^V$ satisfies the approximate tensorisation of Variance with constant $C > 0$, denoted using the predicate $VT(C)$, if for all $f : \Omega \to \mathbb{R}_{\geq 0}$ we have that*

$$\mathrm{Var}(f) \leq C \cdot \sum_{v\in V}\mu\left(\mathrm{Var}_v(f)\right) \quad .$$

For a vertex x, recall that $\mathrm{Var}_x[f] = \sum_\sigma \mu_{V\setminus\{x\}}(\sigma)\mathrm{Var}_x^\sigma[f_\sigma]$. Variance tensorization $VT(C)$ yields the following bound on the relaxation time of the Glauber dynamics [7, 6]:

$$T_{\text{relax}} \leq Cn. \tag{13}$$

We continue with the analog for entropy, which is the key step in our proofs establishing optimal mixing bounds of the Glauber dynamics.

▶ **Definition 5** (Entropy Tensorization)**.** *A distribution μ with support $\Omega \subseteq \{\pm 1\}^V$ satisfies the approximate tensorisation of Entropy with constant $C > 0$, denoted using the predicate $ET(C)$, if for all $f : \Omega \to \mathbb{R}_{\geq 0}$ we have that*

$$\mathrm{Ent}(f) \leq C \cdot \sum_{v\in V} \mu\left(\mathrm{Ent}_v(f)\right) \quad .$$

For a vertex x, recall that $\mathrm{Ent}_x[f] = \sum_\sigma \mu_{V\setminus\{x\}}(\sigma)\mathrm{Ent}_x^\sigma[f_\sigma]$. Entropy tensorization $ET(C)$ immediately yields the following mixing time bound for the Glauber dynamics [7, 6]:

$$T_{\text{mix}} \leq Cn\left(\log(\log(1/\mu^*)) + \log 2 + 2\right) \quad . \tag{14}$$

2.4 Decomposition of Variance/Entropy

We use the following basic decomposition properties for entropy and variance. The following lemma follows from a decomposition of relative entropy, see [8, Lemma 3.1] (see also [4, Lemma 2.3]).

▶ **Lemma 6.** *For any $S \subset V$, for any $f \geq 0$:*

$$\mathrm{Var}(f) = \mu[\mathrm{Var}_S(f)] + \mathrm{Var}(\mu_S(f)) \ , \tag{15}$$
$$\mathrm{Ent}(f) = \mu[\mathrm{Ent}_S(f)] + \mathrm{Ent}(\mu_S(f)) \ . \tag{16}$$

We utilize the following decomposition of a product measure, see [6, Eqn (4.7)].

▶ **Lemma 7.** *Consider $U, W \subset V$ where $\mathrm{dist}(U, W) \geq 2$. Then for all $f \geq 0$ we have:*

$$\mu[\mathrm{Var}_U(\mu_W f)] \leq \mu[\mathrm{Var}_U(f)] \ , \tag{17}$$
$$\mu[\mathrm{Ent}_U(\mu_W f)] \leq \mu[\mathrm{Ent}_U(f)] \ . \tag{18}$$

Proof. We apply [6, Eqn (4.7)], which reaches the same conclusion under the assumptions that $U \cap W = \emptyset$ and $\mu_U\mu_W = \mu_W\mu_U$. In the current context, the reason these conditional expectation operators commute here is that, because $\mathrm{dist}(U, W) \geq 2$, if we let S be an independent set sampled according to distribution μ, then the random variables $S \cap U$ and $S \cap W$ are conditionally independent given $S \setminus (U \cup W)$. ◀

3 Variance Factorization

In this section we prove Theorem 1, establishing an optimal bound on the relaxation time for the Glauber dynamics on any tree for $\lambda < 1.1$. We will prove this by establishing variance tensorization, see Definition 4.

Let $T' = (V', E')$ be a tree, let $\{\lambda'_w\}_{w\in V'}$ be a collection of fugacities and let μ' be the corresponding hard-core measure. We will establish the following variance tensorization inequality: for all $f' : 2^{V'} \to \mathbb{R}$

$$\mathrm{Var}(f') \le \sum_{x\in V'} F(\lambda'_x)\mu'(\mathrm{Var}_x(f')), \tag{19}$$

where $F : \mathbb{R}_{\ge 0} \to \mathbb{R}_{\ge 0}$ is a function to be determined later (in Lemma 8). We refer to $\mathrm{Var}(f')$ as the "global" variance and we refer to $\mu'(\mathrm{Var}_x(f'))$ as the "local" variance (of f' at x).

We will establish (19) using induction. Let v be a vertex of degree 1 in T' and let u be the unique neighbor of v. Let $T = (V, E)$ be the tree which is the induced subgraph of G' on $V = V' \setminus \{v\}$. Let $\{\lambda_w\}_{w\in V}$ be a collection of fugacities where $\lambda_w = \lambda'_w$ for $w \ne u$ and $\lambda_u = \lambda'_u/(1 + \lambda'_v)$. Let μ be the hard-core measure on T with fugacities $\{\lambda_w\}_{w\in V}$.

Note that for $S \subseteq V$ we have

$$\mu(S) = \mu'(S) + \mu'(S \cup \{v\}) = \mu'_V(S). \tag{20}$$

Fix a function $f' : 2^{V'} \to \mathbb{R}$. Let $f : 2^V \to \mathbb{R}$ be defined by

$$f(S) = \frac{\mu'(S)f'(S) + \mu'(S \cup \{v\})f'(S \cup \{v\})}{\mu'(S) + \mu'(S \cup \{v\})} = \mathbb{E}_{Z\sim\mu'}[f'(Z) \mid Z\cap V = S] = \mu'_v(f')(S). \tag{21}$$

Note that f' is defined on independent sets of the tree T' and f is the natural projection of f' to the tree T. Since $f = \mu'_v(f')$, then by Lemma 6 we have that:

$$\mathrm{Var}(f') = \mu'(\mathrm{Var}_v(f')) + \mathrm{Var}(f). \tag{22}$$

When we condition on the configuration at u then μ' becomes a product measure on $V \setminus \{u\}$ and $\{v\}$. Hence, from Equation (17) then for any $x \notin \{u, v\}$ (by setting $U = \{x\}$ and $W = \{v\}$) we have:

$$\mu'(\mathrm{Var}_x(f)) \le \mu'(\mathrm{Var}_x(f')).$$

Since by (20) we have $\mu(\mathrm{Var}_x(f)) = \mu'(\mathrm{Var}_x(f))$, the above implies that

$$\mu(\mathrm{Var}_x(f)) \le \mu'(\mathrm{Var}_x(f')). \tag{23}$$

The following lemma is the main technical ingredient. It bounds the local variance at u for the smaller graph T in terms of the local variance at u and v in the original graph T'.

▶ **Lemma 8.** *For $F(x) = 1000(1 + x)^2 \exp(1.3x)$ and any $\lambda_v, \lambda_u \in (0, 1.1]$ we have:*

$$F(\lambda_u)\mu(\mathrm{Var}_u(f)) \le (F(\lambda'_v) - 1)\mu'(\mathrm{Var}_v(f')) + F(\lambda'_u)\mu'(\mathrm{Var}_u(f')). \tag{24}$$

We now utilize the above lemma to prove the main theorem for the relaxation time. We then go back to prove Lemma 8.

Proof of Theorem 1. Note Equation (24) is equivalent to:

$$\mu'(\mathrm{Var}_v(f')) + F(\lambda_u)\mu(\mathrm{Var}_u(f)) \le F(\lambda'_v)\mu'(\mathrm{Var}_v(f')) + F(\lambda'_u)\mu'(\mathrm{Var}_u(f')). \tag{25}$$

We can prove variance tensorization by induction as follows:

$$\begin{aligned}
\mathrm{Var}(f') &= \mu'(\mathrm{Var}_v(f')) + \mathrm{Var}(f) \\
&\le \mu'(\mathrm{Var}_v(f')) + \sum_{x\in V} F(\lambda_x)\mu(\mathrm{Var}_x(f)) \\
&\le \mu'(\mathrm{Var}_v(f')) + F(\lambda_u)\mu(\mathrm{Var}_u(f)) + \sum_{x\in V\setminus\{u\}} F(\lambda'_x)\mu'(\mathrm{Var}_x(f')) \\
&\le F(\lambda'_v)\mu'(\mathrm{Var}_v(f')) + F(\lambda'_u)\mu'(\mathrm{Var}_u(f')) + \sum_{x\in V\setminus\{u\}} F(\lambda'_x)\mu'(\mathrm{Var}_x(f')) \\
&= \sum_{x\in V'} F(\lambda'_x)\mu'(\mathrm{Var}_x(f')),
\end{aligned}$$

where the first line follows by by Equation (22), the second line by induction, the third line by Equation (23), and the fourth line by Equation (25). ◀

Our task now is to prove Lemma 8. The following technical inequality will be useful.

▶ **Lemma 9.** *Let $p \in [0,1]$. Suppose $s_1, s_2 > 0$ satisfy $s_1 s_2 \ge 1$. Then for all $A, B, C \in \mathbb{R}$ we have*

$$(C - pA - (1-p)B)^2 \le (1+s_1)(C-A)^2 + (1-p)^2(1+s_2)(B-A)^2. \tag{26}$$

The proof of Lemma 9 is in Appendix B of the full version of this paper. We can now prove the main lemma.

Proof of Lemma 8. Our goal is to prove Equation (24), let us recall its statement:

$$F(\lambda_u)\mu(\mathrm{Var}_u(f)) \le (F(\lambda'_v) - 1)\mu'(\mathrm{Var}_v(f')) + F(\lambda'_u)\mu'(\mathrm{Var}_u(f')). \tag{24}$$

We will consider each of these local variances $\mu(\mathrm{Var}_u(f))$, $\mu'(\mathrm{Var}_v(f'))$, and $\mu'(\mathrm{Var}_u(f'))$. We will express each of them as a sum over independent sets S of V'. We can then establish Equation (24) in a pointwise manner by considering the corresponding inequality for each independent set S.

Let us begin by looking at the general definition of the expected local variance $\mu'(\mathrm{Var}_x(f'))$ for any $x \in V'$. Applying the definition in Equation (9) and then simplifying we obtain the following (a reader familar with the notation can apply Equation (12) to skip directly to the last line):

$$\begin{aligned}
&\mu'(\mathrm{Var}_x(f')) \\
&= \sum_{S\subseteq V'\setminus\{x\}} \mu'_{V'\setminus\{x\}}(S)\cdot \mathrm{Var}_x^S(f_S) \\
&= \sum_{S\subseteq V'\setminus\{x\}} \left(\sum_{T\subseteq\{x\}} \mu'(S\cup T)\right)\left(\frac{1}{2}\sum_{T,U\subseteq\{x\},T\ne U} \mu_x'^S(T)\mu_x'^S(U)(f'(S\cup T) - f'(S\cup U))^2\right) \\
&= \sum_{S\subseteq V'\setminus\{x\}} \left(\sum_{T\subseteq\{x\}} \mu'(S\cup T)\right)\left(\mu_x'^S(x)\mu_x'^S(\emptyset)(f'(S) - f'(S\cup\{x\}))^2\right) \\
&= \sum_{S\subseteq V'\setminus\{x\}} \Big(\mu'(S) + \mu'(S\cup\{x\})\Big)\frac{\mu'(S)\mu'(S\cup\{x\})}{(\mu'(S)+\mu'(S\cup\{x\}))^2}\Big(f'(S) - f'(S\cup\{x\})\Big)^2.
\end{aligned} \tag{27}$$

Notice in Equation (27) that the only $S \subset V' \setminus \{x\}$ which contribute are those where x is unblocked (i.e., no neighbor of x is included in the independent set S) because we need that S and $S \cup \{x\}$ are both independent sets and hence have positive measure in μ'.

Let us now consider each of the local variances appearing in Equation (24) (expressed using carefully chosen summations that will allow us to prove (24) term-by-term in terms of S).

Let $Q_1 := \mu(\mathrm{Var}_u(f))$ denote the expected local variance of f at u. We will use (27); note that only S where u is unblocked (that is, when no neighbor of u is occupied) contribute to the local variance. Such an S where u is unblocked and $u \notin S$ has the same contribution as $S \cup \{u\}$ times $1/\lambda_u$ (since $\mu(S \cup \{u\}) = \lambda_u \mu(S)$). Hence the expected local variance of f at u is given by

$$Q_1 := \mu(\mathrm{Var}_u(f)) = \sum_{S \subseteq V; u \in S} \mu(S) \left(1 + \frac{1}{\lambda_u}\right) \frac{\lambda_u}{1+\lambda_u} \frac{1}{1+\lambda_u} \left(f(S \setminus \{u\}) - f(S)\right)^2 .$$

We have $f(S) = f'(S)$ (since $u \in S$) and $f(S \setminus \{u\}) = \frac{1}{1+\lambda'_v} f'(S \setminus \{u\}) - \frac{\lambda'_v}{1+\lambda'_v} f'(S \setminus \{u\} \cup \{v\})$. Plugging these in and simplifying we obtain the following:

$$Q_1 = \frac{1+\lambda'_v}{1+\lambda'_u+\lambda'_v} \sum_{S \subseteq V; u \in S} \mu(S) \left(f'(S) - \frac{1}{1+\lambda'_v} f'(S-u) - \frac{\lambda'_v}{1+\lambda'_v} f'(S-u+v)\right)^2 . \quad (28)$$

We now consider $Q_2 := \mu'(\mathrm{Var}_u(f'))$. To compute the expected local variance of f' at u we need to generate Z from μ' but only Z where u is unblocked contribute to the local variance. We can generate Z by first generating S from μ and if $u \notin S$ adding v with probability $\lambda'_v/(1+\lambda'_v)$. The S where $u \notin S$ contribute only if u is unblocked; contributing the same amount as $S \cup \{u\}$ multiplied by $1/\lambda'_u$ (since $\mu'(S \cup \{u\}) = \lambda'_u \mu'(S)$) and by $1/(1+\lambda'_v)$ (since they only contribute if we do not add v). Hence, we have the following:

$$\begin{aligned} Q_2 := \mu(\mathrm{Var}_u(f')) &= \sum_{S \subseteq V; u \in S} \mu(S) \left(1 + \frac{1}{\lambda'_u} \frac{1}{1+\lambda'_v}\right) \frac{\lambda'_u}{1+\lambda'_u} \frac{1}{1+\lambda'_u} \left(f'(S-u) - f'(S)\right)^2 \\ &= \left(\lambda'_u + \frac{1}{1+\lambda'_v}\right) \frac{1}{(1+\lambda'_u)^2} \sum_{S \subseteq V; u \in S} \mu(S) \left(f'(S) - f'(S-u)\right)^2 . \quad (29) \end{aligned}$$

Finally, we consider $\mu'(\mathrm{Var}_v(f'))$, the expected local variance of f' at v. We will establish a lower bound which we will denote by Q_3 (note, Q_1 and Q_2 were identities but here we will have an inequality).

To compute $\mu'(\mathrm{Var}_v(f'))$, the expected local variance of f' at v, we need to generate an independent set Z from μ'. Only those Z where v is unblocked (that is where u is missing) contribute to the local variance. We can generate Z by generating S from μ (whether we add or do not add v does not change the contribution to the local variance). As in Equation (27), we obtain the following:

$$\begin{aligned} \mu'(\mathrm{Var}_v(f')) &= \sum_{S \subseteq V; u \notin S} \mu(S) \frac{1}{1+\lambda'_v} \frac{\lambda'_v}{1+\lambda'_v} \left(f'(S \cup \{v\}) - f'(S)\right)^2 \\ &\geq \sum_{S \subseteq V; u \in S} \mu(S) \frac{1}{\lambda'_u} \frac{1}{1+\lambda'_v} \frac{\lambda'_v}{1+\lambda'_v} \left(f'(S \cup \{v\} \setminus \{u\}) - f'(S \setminus \{u\})\right)^2 , \end{aligned}$$

where in the summation in the second line we effectively sum over a subset of sets not containing u (the ones that can be obtained by removing u from a set containing u).

Let Q_3 denote the lower bound we obtained above:

$$Q_3 := \frac{1}{\lambda'_u}\frac{1}{1+\lambda'_v}\frac{\lambda'_v}{1+\lambda'_v}\sum_{S\subseteq V;u\in S}\mu(S)\left(f'(S\cup\{v\}\setminus\{u\})-f'(S\setminus\{u\})\right)^2 \geq \mu'(\mathrm{Var}_v(f')). \tag{30}$$

Plugging in (28), (29), (30) we obtain that Equation (24) follows from the following inequality:

$$F(\lambda_u)Q_1 \leq (F(\lambda'_v)-1)Q_3 + F(\lambda'_u)Q_2. \tag{31}$$

We will establish (31) term-by-term, that is, for each S in the sums of (28), (29), (30). Fix $S \subseteq V$ such that $u \in S$ and let $A = f'(S-u)$, $B = f'(S-u+v)$, and $C = f'(S)$. We need to show

$$\begin{aligned}&\frac{1+\lambda'_v}{1+\lambda'_u+\lambda'_v}\left(C-\frac{1}{1+\lambda'_v}A-\frac{\lambda'_v}{1+\lambda'_v}B\right)^2 F\left(\frac{\lambda'_u}{1+\lambda'_v}\right)\\ &\leq \frac{1+\lambda'_v+\lambda'_u}{1+\lambda'_v}\frac{1}{(1+\lambda'_u)^2}(C-A)^2F(\lambda'_u)+\frac{1}{\lambda'_u(1+\lambda'_v)^2}(B-A)^2(F(\lambda'_v)-1).\end{aligned} \tag{32}$$

Let $p = 1/(1+\lambda'_v)$. We will match (26) to (32), by first dividing both sides of (32) by $\frac{1+\lambda'_v}{1+\lambda'_u+\lambda'_v}F\left(\frac{\lambda'_u}{1+\lambda'_v}\right)$ and then choosing

$$1+s_1 = \left(\frac{1+\lambda'_u+\lambda'_v}{(1+\lambda'_v)(1+\lambda'_u)}\right)^2\cdot\frac{F(\lambda'_u)}{F\left(\frac{\lambda'_u}{1+\lambda'_v}\right)} \quad\text{and}\quad 1+s_2 = \frac{1+\lambda'_u+\lambda'_v}{\lambda'_u(1+\lambda'_v){\lambda'_v}^2}\cdot\frac{F(\lambda'_v)-1}{F\left(\frac{\lambda'_u}{1+\lambda'_v}\right)}.$$

Note that with this choice of s_1 and s_2 equations (26) and (32) are equivalent, and hence to prove (32) it is enough to show $s_1s_2 \geq 1$.

▷ Claim 10. $s_1s_2 \geq 1$.

We defer the proof of this technical inequality to Appendix B of the full version of this paper. This completes the proof of the lemma. ◀

4 Entropy Factorization

Here we will prove Theorem 2 establishing $O(n\log n)$ mixing time for $\lambda \leq .44$. We will accomplish this task by proving the following approximate tensorization inequality:

$$\mathrm{Ent}(f') \leq \sum_{x\in V'} F(\lambda'_x)\mu'(\mathrm{Ent}_x(f')), \tag{33}$$

where $F : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ is a function to be determined later. By Equation (14) this implies a mixing time bound of $O(n\log n)$ and hence Theorem 2 follows from Equation (33).

We use the same notation as Section 3. Let T' be a tree and μ' be the hard-core measure on T' with fugacities $\{\lambda'_w\}_{w\in V'}$. Let v be a vertex of degree 1 in T' and u is the unique neighbor of v. Let v be a vertex of degree 1 in T' and let u be the unique neighbor of v. Let $T = (V, E)$ be the tree which is the induced subgraph of G' on $V = V' \setminus \{v\}$. Let $\{\lambda_w\}_{w\in V}$ be a collection of fugacities where $\lambda_w = \lambda'_w$ for $w \neq u$ and $\lambda_u = \lambda'_u/(1+\lambda'_v)$. Let μ be the hard-core measure on T with fugacities $\{\lambda_w\}_{w\in V}$.

Fix a function $f' : 2^{V'} \to \mathbb{R}_{\geq 0}$. Let $f : 2^V \to \mathbb{R}_{\geq 0}$ be defined by $f(S) = \mathbb{E}_{Z\sim\mu'}[f'(Z) \mid Z \cap V = S] = \mu'_v(f')(S)$, which is the same definition as in Equation (21).

Our main technical lemma is the following.

▶ **Lemma 11.** *For $F(x) = 1000(1+x)\exp(x)$ and $\lambda_u, \lambda'_v, \lambda'_u \in [0, 0.44]$ we have the following.*

$$F(\lambda_u)\mu(\mathrm{Ent}_u(f)) \le (F(\lambda'_v) - 1)\mu'(\mathrm{Ent}_v(f')) + F(\lambda'_u)\mu'(\mathrm{Ent}_u(f')). \tag{34}$$

Using the above lemma we will establish (33) using induction as done in Section 3 for variance.

Proof of Theorem 2.

$$\begin{aligned}
\mathrm{Ent}(f') &= \mu'(\mathrm{Ent}_v(f')) + \mathrm{Ent}(f) && \text{by Equation (16)}\\
&\le \mu'(\mathrm{Ent}_v(f')) + \sum_{x\in V} F(\lambda_x)\mu(\mathrm{Ent}_x(f)) && \text{by induction}\\
&\le \mu'(\mathrm{Ent}_v(f')) + F(\lambda_u)\mu(\mathrm{Ent}_u(f)) + \sum_{x\in V\setminus\{u\}} F(\lambda'_x)\mu'(\mathrm{Ent}_x(f')) && \text{by Equation (18)}\\
&= \sum_{x\in V'} F(\lambda'_x)\mu'(\mathrm{Var}_x(f')) && \text{by Equation (34).}
\end{aligned}$$

Hence, Theorem 2 follows from Lemma 11. ◀

Let

$$G(p, A, B) = pA\ln A + (1-p)B\ln B - (pA + (1-p)B)\ln(pA + (1-p)B).$$

Let $Q_1 := \mu(\mathrm{Ent}_u(f))$. Then we have the following analog of Equation (28):

$$Q_1 = \left(1 + \frac{1+\lambda'_v}{\lambda'_u}\right) \sum_{S\subseteq V; u\in S} \mu(S) G\left(\frac{1+\lambda'_v}{1+\lambda'_v+\lambda'_u}, \frac{f'(S\setminus\{u\})}{1+\lambda'_v} + \frac{\lambda'_v f'(S\cup\{v\}\setminus\{u\})}{1+\lambda'_v}, f'(S)\right). \tag{35}$$

Let $Q_2 := \mu'(\mathrm{Ent}_u(f'))$ denote the expected local entropy of f' at u. Then we have the analog of Equation (29):

$$Q_2 = \left(1 + \frac{1}{\lambda'_u(1+\lambda'_v)}\right) \sum_{S\subseteq V; u\in S} \mu(S) G\left(\frac{1}{1+\lambda'_u}, f'(S-u), f(S)\right). \tag{36}$$

Finally, as in Equation (30), we use Q_3 for a lower bound on the expected local entropy of f' at v. We prove $\mu'(\mathrm{Ent}_v(f')) \ge Q_3$ where:

$$Q_3 = \frac{1}{\lambda'_u} \sum_{S\subseteq V; u\in S} \mu(S) G\left(\frac{1}{1+\lambda'_v}, f'(S-u), f(S-u+v)\right). \tag{37}$$

Plugging in (35), (36), (37) we obtain that Equation (34) follows from the following inequality

$$F(\lambda_u)Q_1 \le F(\lambda'_u)Q_2 + (F(\lambda'_v) - 1)Q_3. \tag{38}$$

We will establish (34) term-by-term, that is, for each S in the sums of (35), (36), (37). Fix $S \subseteq V$ such that $u \in S$ and let $A = f'(S-u)$, $B = f'(S-u+v)$, and $C = f'(S)$. We need to show

$$\begin{aligned}
&\left(1 + \frac{1+\lambda'_v}{\lambda'_u}\right) G\left(\frac{1+\lambda'_v}{1+\lambda'_v+\lambda'_u}, \frac{1}{1+\lambda'_v}A + \frac{\lambda'_v}{1+\lambda'_v}B, C\right) F\left(\frac{\lambda'_u}{1+\lambda'_v}\right) \le\\
&\quad \left(1 + \frac{1}{\lambda'_u(1+\lambda'_v)}\right) G\left(\frac{1}{1+\lambda'_u}, A, C\right) F(\lambda'_u) + \frac{1}{\lambda'_u} G\left(\frac{1}{1+\lambda'_v}, A, B\right)(F(\lambda'_v) - 1).
\end{aligned} \tag{39}$$

We will show that the following lemma implies an optimal mixing time bound of $O(n \log n)$ for all $\lambda \leq .44$.

▶ **Lemma 12.** *Let $b, p \in (0,1)$. For any $A, B, C \geq 0$ we have*

$$G(b, A, C) + (1-b)G(p, A, B) - (b+p-bp)G\left(\frac{b}{b+p-bp}, pA + (1-p)B, C\right) \geq 0. \tag{40}$$

The proof of Lemma 12 appears in Appendix D of the full version of this paper.

Before finishing the proof of Lemma 11 using Lemma 12, we have the following conjecture which is a generalization of Lemma 12. This conjecture implies (39) for all $\lambda \leq 1.05$ and hence an optimal mixing time bound of $O(n \log n)$ for all $\lambda \leq 1.05$. Lemma 12 corresponds to Conjecture 13 "around" $W = 1$ (note that for $W = 1$ both sides of the below inequality are zero). We can numerical verify the conjecture.

▶ **Conjecture 13.** *Let $b, p \in (0,1)$. For any $W \in (1-b, 1/(1-p))$ and any $A, B, C \geq 0$ we have*

$$\Big|\ln W\Big|(b+p-bp)G\left(\frac{b}{b+p-bp}, pA + (1-p)B, C\right) \leq$$
$$p\Big|\ln \frac{pW}{pW - W + 1}\Big|G(b, A, C) + b\Big|\ln \frac{W+b-1}{bW}\Big|G(p, A, B).$$

In Appendix C of the full version of this paper we prove that Conjecture 13 implies a strengthening of Lemma 11 with the interval $[0, 1.05]$ and hence $O(n \log n)$ mixing time.

4.1 Proof of Lemma 11

Here we prove that Lemma 12 implies Equation (39), and hence Lemma 11. Recall, $F(x) = 1000(1+x)\exp(x)$.

Let

$$p = \frac{1}{1+\lambda'_v} \quad \text{and} \quad b = \frac{1}{1+\lambda'_u} \quad \text{and} \quad \alpha = \frac{1}{p(1-b)} F\left(\frac{p(1-b)}{b}\right).$$

Note that

$$1 + \frac{1+\lambda'_v}{\lambda'_u} = \frac{b+p-bp}{p(1-b)}, \qquad \frac{1+\lambda'_v}{1+\lambda'_v+\lambda'_u} = \frac{b}{b+p-bp}, \qquad \frac{\lambda'_u}{1+\lambda'_v} = \frac{p(1-b)}{b}.$$

We aim to prove (39) using the following sequence of inequalities

$$\left(1 + \frac{1+\lambda'_v}{\lambda'_u}\right) G\left(\frac{1+\lambda'_v}{1+\lambda'_v+\lambda'_u}, \frac{1}{1+\lambda'_v}A + \frac{\lambda'_v}{1+\lambda'_v}B, C\right) F\left(\frac{\lambda'_u}{1+\lambda'_v}\right)$$

$$= \alpha(b+p-bp)G\left(\frac{b}{b+p-bp}, pA + (1-p)B, C\right) \tag{41}$$

$$\leq \alpha p\Big(\frac{1}{p}\Big)G(b, A, C) + \alpha b\Big(\frac{1-b}{b}\Big)G(p, A, B) \tag{42}$$

$$\leq \left(1 + \frac{1}{\lambda'_u(1+\lambda'_v)}\right) G\left(\frac{1}{1+\lambda'_u}, A, C\right) F(\lambda'_u) + \frac{1}{\lambda'_u} G\left(\frac{1}{1+\lambda'_v}, A, B\right)(F(\lambda'_v) - 1), \tag{43}$$

Here, Eq. (41) follows from the definitions.

Inequality (42) follows from Lemma 12 (we avoided simplifying (42) in order to make the match to Lemma 12 easier).

Inequality (43) follows from the following two inequalities:

$$\alpha p\Big(\frac{1}{p}\Big) \le \frac{b+p-bp}{p(1-b)} F\Big(\frac{1-b}{b}\Big), \text{ and} \tag{44}$$

$$\alpha b\Big(\frac{1-b}{b}\Big) \le \frac{b}{1-b}\Big(F\Big(\frac{1-p}{p}\Big)-1\Big). \tag{45}$$

Replacing α by its definition, equations (44) and (45) become

$$F\left(\frac{p(1-b)}{b}\right) \le (b+p-bp)F\Big(\frac{1-b}{b}\Big), \quad \text{and} \tag{46}$$

$$F\left(\frac{p(1-b)}{b}\right)(1-b) \le bp\left(F\Big(\frac{1-p}{p}\Big)-1\right). \tag{47}$$

Let x and y be such that $b = 1/(1+x)$ and $p = 1/(1+y)$. Equations (46) and (47) simplify to the following

$$F\left(\frac{x}{1+y}\right) \le \frac{1+x+y}{(1+x)(1+y)}F(x) \quad \text{and} \quad F\left(\frac{x}{1+y}\right)x \le \frac{F(y)-1}{1+y}.$$

Note that $F(y) \ge 1000$ and hence it is enough to satisfy the following inequalities.

$$F\left(\frac{x}{1+y}\right) \le \frac{1+x+y}{(1+x)(1+y)}F(x) \quad \text{and} \quad F\left(\frac{x}{1+y}\right)x \le \frac{999}{1000}\frac{F(y)}{1+y}.$$

Recalling the definition of F, the constraints further simplify to:

$$\exp\left(\frac{x}{1+y}\right) \le \exp(x) \quad \text{and} \quad \exp\left(\frac{x}{1+y}\right)\frac{(1+x+y)x}{1+y} \le \frac{999}{1000}\exp(y). \tag{48}$$

Note that the first constraint follows from the fact that exp() is increasing and $x, y > 0$. The second constraint is addressed in the following lemma.

▶ **Lemma 14.** *For $x, y \in [0, u]$, where $u = 0.44$, we have*

$$\exp\left(\frac{x}{1+y}\right)\frac{(1+x+y)x}{1+y} \le \frac{999}{1000}\exp(y). \tag{49}$$

Proof. Let

$$Q = \frac{999}{1000}\exp(y) - \exp\left(\frac{x}{1+y}\right)\frac{(1+x+y)x}{1+y}.$$

We have

$$\frac{\partial}{\partial y}Q = \frac{999}{1000}\exp(y) + \frac{x^2(x+2y+2)\exp\left(\frac{x}{1+y}\right)}{(1+y)^3} > 0,$$

that is, Q is increasing in y and hence we only need to prove (49) for $y = 0$. We need to show

$$\frac{999}{1000} \ge \exp(x)(1+x)x. \tag{50}$$

Note that RHS of (50) is increasing in x and hence we need to check (50) for $x = u$. For $x = u = 0.44$ we have that (50) is satisfied (checked using interval arithmetic). ◀

▶ Remark 15. In order for (48) to hold for $x, y \in [0, u]$ we need it to hold for $x = y(y+1) \leq u$. Equation (48) then simplifies to

$$(1+y)^2 y \leq 1.$$

For (48) to hold (for all $x, y \in [0, u]$) we need $y \leq 0.47$ which in turn implies $u \leq 0.7$. This means that if we want to prove rapid mixing for unweighted independent sets ($\lambda = 1$) we have to go beyond Lemma 12, see Conjecture 13.

Superpolynomial Lower Bounds for Learning Monotone Classes

Nader H. Bshouty
Department of Computer Science, Technion, Haifa, Israel

Abstract

Koch, Strassle, and Tan [SODA 2023], show that, under the randomized exponential time hypothesis, there is no distribution-free PAC-learning algorithm that runs in time $n^{\tilde{O}(\log\log s)}$ for the classes of n-variable size-s DNF, size-s Decision Tree, and $\log s$-Junta by DNF (that returns a DNF hypothesis). Assuming a natural conjecture on the hardness of set cover, they give the lower bound $n^{\Omega(\log s)}$. This matches the best known upper bound for n-variable size-s Decision Tree, and $\log s$-Junta.

In this paper, we give the same lower bounds for PAC-learning of n-variable size-s Monotone DNF, size-s Monotone Decision Tree, and Monotone $\log s$-Junta by DNF. This solves the open problem proposed by Koch, Strassle, and Tan and subsumes the above results.

The lower bound holds, even if the learner knows the distribution, can draw a sample according to the distribution in polynomial time, and can compute the target function on all the points of the support of the distribution in polynomial time.

1 Introduction

In the distribution-free PAC learning model [13], the learning algorithm of a class of functions C has access to an unknown target function $f \in C$ through labeled examples $(x, f(x))$ where x are drawn according to an unknown but fixed probability distribution $\mathcal{D}$. For a class of hypothesis $H \supseteq C$, we say that the learning algorithm $\mathcal{A}$ *PAC-learns* C *by* H in time T and error ϵ if for every target $f \in C$ and distribution $\mathcal{D}$, $\mathcal{A}$ runs in time T and outputs a hypothesis $h \in H$ which, with probability at least $2/3$, is ϵ-close to f with respect to $\mathcal{D}$. That is, satisfies $\Pr_{\boldsymbol{x}\sim\mathcal{D}}[f(\boldsymbol{x}) \neq h(\boldsymbol{x})] \leq \epsilon$.

Koch et al., [10], show that, under the randomized exponential time hypothesis (ETH), there is no PAC-learning algorithm that runs in time $n^{\tilde{O}(\log\log s)}$ for the classes of n-variable size-s DNF, size-s Decision Tree and $\log s$-Junta by DNF. Assuming a natural conjecture on the hardness of set cover, they give the lower bound $n^{\Omega(\log s)}$. Their lower bound holds, even if the learner knows the distribution, can draw a sample according to the distribution in polynomial time and can compute the target function on all the points of the support of the distribution in polynomial time.

In this paper, we give the same lower bounds for PAC-learning of the classes n-variable size-s Monotone DNF, size-s Monotone Decision Tree and Monotone $\log s$-Junta by DNF. This solves the open problem proposed by Koch, Strassle, and Tan [10].

In various learning models, it is widely recognized that the task of learning classes of monotone Boolean functions is significantly simpler compared to learning classes of non-monotone Boolean functions. An illustrative example is the distribution-free PAC learning of monotone DNF within a model that permits membership queries, which can be accomplished efficiently in polynomial time [2]. Conversely, the challenge of learning DNF in the same model remains an unsolved problem, emphasizing the inherent difficulty associated with non-monotone Boolean functions. In this paper, we demonstrate that for specific classes, the task of PAC-learning monotone Boolean functions under the uniform distribution is equally challenging as learning non-monotone Boolean functions.

1.1 Our Results

In this paper, we prove the following three Theorems.

▶ **Theorem 1.** *Assuming randomized ETH, there is a constant c such that any PAC learning algorithm for n-variable* MONOTONE $(\log s)$*-*JUNTA*, size-s* MONOTONE *DT and size-s* MONOTONE *DNF*[1] *by DNF with $\epsilon = 1/(16n)$ must take at least*

$$n^{c\frac{\log\log s}{\log\log\log s}}$$

time.

▶ **Theorem 2.** *Assuming a plausible conjecture on the hardness of* SET-COVER [2]*, there is a constant c such that any PAC learning algorithm for n-variable* MONOTONE $(\log s)$*-*JUNTA*, size-s* MONOTONE *DT and size-s* MONOTONE *DNF by DNF with $\epsilon = 1/(16n)$ must take at least*

$$n^{c\log s}$$

time.

▶ **Theorem 3.** *Assuming randomized ETH, there is a constant c such that any PAC learning algorithm for n-variable* MONOTONE $(\log s)$*-*JUNTA*, size-s* MONOTONE *DT and size-s* MONOTONE *DNF by size-s* DNF *with $\epsilon = 1/(16n)$ must take at least*

$$n^{c\log s}$$

time.

All the above lower bound holds, even if the learner knows the distribution, can draw a sample according to the distribution in polynomial time and can compute the target on all the points of the support of the distribution in polynomial time.

In the following two subsections, we give the technique used in [10] to prove Theorem 1 for $(\log s)$-JUNTA, and the technique we use here to extend the result to MONOTONE $(\log s)$-JUNTA.

[1] The results concerning *size-s* MONOTONE DT and *size-s* MONOTONE DNF stem from the result on MONOTONE $(\log s)$-JUNTA. This relationship also holds for the other theorems. Here, we present a comprehensive list of all these classes to highlight their significance.

[2] See Conjecture 1.

1.2 Previous Technique

In [10], Koch, Strassle, and Tan show that under the randomized exponential time hypothesis, there is no PAC-learning algorithm that runs in time $n^{\tilde{O}(\log\log n)}$ for the class of $\log n$-Junta[3] by DNF. The results for the other classes follow immediately from this result, since all other classes contain $\log n$-Junta. All prior works [1, 6] ruled out only $poly(n)$ time algorithms.

The result in [10] uses the hardness result of (k,k')-Set-Cover where one needs to distinguish between instances that have set cover of size at most k from instances that have minimum-size set cover greater than k':

1. For some parameters k and k' that depends on N, assuming randomized ETH, there is a constant $\lambda<1$ such that (k,k')-Set-Cover on N vertices cannot be solved in time $N^{\lambda k}$.

First, for each set cover instance $\mathcal{S}$, they identify each element in the universe with an assignment in $\{0,1\}^n$ and construct in polynomial time a target function $\Gamma^{\mathcal{S}}:\{0,1\}^n\to\{0,1\}$ and a distribution $\mathcal{D}^{\mathcal{S}}$ that satisfies:

2. The instance $\mathcal{S}$ has minimum-size set cover $\mathrm{opt}(\mathcal{S})$ if and only if the function $\Gamma^{\mathcal{S}}$ is a conjunction of $\mathrm{opt}(\mathcal{S})$ unnegated variables[4] over the distribution $\mathcal{D}^{\mathcal{S}}$.[5]

For a DNF F and $x\in\{0,1\}^n$, they define $\mathrm{width}_F(x)$ to be the size of the smallest term T in F that satisfies $T(x)=1$. They then show that

3. Any DNF F with expected width $\mathbf{E}_{\boldsymbol{x}\sim\mathcal{D}^{\mathcal{S}}}[\mathrm{width}_F(\boldsymbol{x})]\le \mathrm{opt}(\mathcal{S})/2$ is $(1/(2N))$-far from $\Gamma^{\mathcal{S}}$ with respect to $\mathcal{D}^{\mathcal{S}}$ where N is the size[6] of $\mathcal{S}$. That is, $\Pr_{\boldsymbol{x}\sim\mathcal{D}^{\mathcal{S}}}[F(\boldsymbol{x})\ne\Gamma^{\mathcal{S}}(\boldsymbol{x})]\ge 1/(2N)$.

They then use the following gap amplification technique. They define the function $\Gamma^{\mathcal{S}}_{\oplus\ell}:(\{0,1\}^\ell)^n\to\{0,1\}$ where for $y=(y_1,\ldots,y_n)$, $y_i=(y_{i,1},\ldots,y_{i,\ell})\in\{0,1\}^\ell$, $i\in[n]$, we have $\Gamma^{\mathcal{S}}_{\oplus\ell}(y)=\Gamma^{\mathcal{S}}(\oplus y_1,\ldots,\oplus y_n)$ and $\oplus y_i=y_{i,1}+\cdots+y_{i,\ell}$. They also extend the distribution $\mathcal{D}^{\mathcal{S}}$ to a distribution $\mathcal{D}^{\mathcal{S}}_{\oplus\ell}$ over domain $(\{0,1\}^\ell)^n$ and prove that

4. $\Gamma^{\mathcal{S}}_{\oplus\ell}(y)$ is a $(\mathrm{opt}(\mathcal{S})\ell)$-Junta over $\mathcal{D}^{\mathcal{S}}_{\oplus\ell}$.
5. Any DNF formula F with expected width $\mathbf{E}_{\boldsymbol{y}\sim\mathcal{D}^{\mathcal{S}}_{\oplus\ell}}[\mathrm{width}_F(\boldsymbol{y})]\le\mathrm{opt}(\mathcal{S})\ell/4$ is $(1/(4N))$-far from $\Gamma^{\mathcal{S}}_{\oplus\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\oplus\ell}$.

Item 4 follows from the definition of $\Gamma^{\mathcal{S}}_{\oplus\ell}$ and item 2. To prove Item 5, they show that if, to the contrary, there is a DNF F of expected width at most $\mathrm{opt}(\mathcal{S})\ell/4$ that is $1/(4N)$-close to $\Gamma^{\mathcal{S}}_{\oplus\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\oplus\ell}$, then there is $j\in[\ell]$ and a projection of all the variables that are not of the form $y_{i,j}$ that gives a DNF F^* of expected width at most $\mathrm{opt}(\mathcal{S})/2$ that is $1/(2N)$-close to $\Gamma^{\mathcal{S}}$ with respect to $\mathcal{D}^{\mathcal{S}}$. Then, by item 3, we get a contradiction.

They then show that

6. Any size-s DNF that is $(1/(4N))$-close to $\Gamma^{\mathcal{S}}_{\oplus\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\oplus\ell}$ has average width $\mathbf{E}_{\boldsymbol{y}\sim\mathcal{D}^{\mathcal{S}}_{\oplus\ell}}[\mathrm{width}_F(\boldsymbol{y})]\le 4\log s$.

If F is $(1/(4N))$-close to $\Gamma^{\mathcal{S}}_{\oplus\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\oplus\ell}$, then, by items 5 and 6, $4\log s\ge\mathbf{E}_{\boldsymbol{y}\sim\mathcal{D}^{\mathcal{S}}_{\oplus\ell}}[\mathrm{width}_F(\boldsymbol{y})]\ge\mathrm{opt}(\mathcal{S})\ell/4$ and then $s\ge 2^{\mathrm{opt}(\mathcal{S})\ell/16}$. Therefore,

7. Any DNF of size less than $2^{\mathrm{opt}(\mathcal{S})\ell/16}$ is $(1/(4N))$-far from $\Gamma^{\mathcal{S}}_{\oplus\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\oplus\ell}$.

Now, let $k=\tilde{O}(\log\log n)$. Suppose, to the contrary, that there is a PAC-learning algorithm for $\log n$-Junta by DNF with error $\epsilon=1/(8N)$ that runs in time $t=n^{\lambda k/2}=n^{\tilde{O}(\log\log n)}$, where λ is the constant in item 1. Given a (k,k')-Set-Cover instance, we run the learning

[3] k-Junta are Boolean functions that depend on at most k variables
[4] Their reduction gives a conjunction of negated variable. So here, we are referring to the dual function.
[5] That is, there is a term T with $\mathrm{opt}(\mathcal{S})$ variables such that for every x in the support of $\mathcal{D}^{\mathcal{S}}$, $\Gamma^{\mathcal{S}}(x)=T(x)$.
[6] N is the number of sets plus the size of the universe in $\mathcal{S}$.

algorithm for $\Gamma^{\mathcal{S}}_{\oplus\ell}$ for $\ell = \log n/k$. If the instance has set cover at most k, then by item 4, $\Gamma^{\mathcal{S}}_{\oplus\ell}$ is $\log n$-Junta. Then the algorithm learns the target and outputs a hypothesis that is $(1/(8N))$-close to $\Gamma^{\mathcal{S}}_{\oplus\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\oplus\ell}$.

On the other hand, if the instance has a minimum-size set cover of at least k', then any learning algorithm that runs in time $t = n^{\lambda k/2} = n^{\tilde{O}(\log\log n)}$ cannot output a DNF of size more than t terms. By item 7, any DNF of size less than $2^{k'\log n/(16k)} \le 2^{\mathrm{opt}(\mathcal{S})\ell/16}$ is $(1/(4N))$-far from $\Gamma^{\mathcal{S}}_{\oplus\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\oplus\ell}$. By choosing the right parameters k and k', we have $2^{k'\log n/(16k)} > t$, and therefore, any DNF that the algorithm outputs has error of at least $1/(4N)$.

Therefore, by estimating the distance of the output of the learning algorithm from $\Gamma^{\mathcal{S}}_{\oplus\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\oplus\ell}$, we can distinguish between instances that have set cover of size less than or equal to k from instances that have a minimum-size set cover greater than k' in time $t = n^{\lambda k/2}$. Thus, we got an algorithm for (k, k')-Set-Cover that runs in time $n^{\lambda k/2} < n^{\lambda k}$. This contradicts item 1 and finishes the proof of the first lower bound.

Assuming a natural conjecture on the hardness of set cover, they give the lower bound $n^{\Omega(\log s)}$. We will discuss this in Section 5.

1.3 Our Technique

In this paper, we also use the hardness result of (k, k')-Set-Cover . As in [10], we identify each element in the universe with an assignment in $\{0,1\}^n$ and use the function $\Gamma^{\mathcal{S}}$ and the distribution $\mathcal{D}^{\mathcal{S}}$ that satisfies:

1. The instance $\mathcal{S}$ has minimum-size set cover $\mathrm{opt}(\mathcal{S})$ if and only if the function $\Gamma^{\mathcal{S}}$ is a conjunction of $\mathrm{opt}(\mathcal{S})$ variables over the distribution $\mathcal{D}^{\mathcal{S}}$.

We then build a *monotone* target function $\Gamma^{\mathcal{S}}_{\ell}$ and a distribution $\mathcal{D}^{\mathcal{S}}_{\ell}$ and use a different approach to show that any DNF of size less than $2^{\mathrm{opt}(\mathcal{S})\ell/20}$ is $(1/(8N) - 2^{-\mathrm{opt}(\mathcal{S})\ell/20})$-far from $\Gamma^{\mathcal{S}}_{\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\ell}$.

We define, for any odd ℓ, the monotone function $\Gamma^{\mathcal{S}}_{\ell} : (\{0,1\}^{\ell})^n \to \{0,1\}$ where for $y = (y_1, \ldots, y_n)$, $y_i = (y_{i,1}, \ldots, y_{i,\ell})$, $i \in [n]$, we have $\Gamma^{\mathcal{S}}_{\ell}(y) = \Gamma^{\mathcal{S}}(\textsc{Majority}(y_1), \ldots, \textsc{Majority}(y_n))$ where Majority is the majority function. A distribution $\mathcal{D}^{\mathcal{S}}_{\ell}$ is also defined such that

2. $\Pr_{\boldsymbol{y}\sim\mathcal{D}^{\mathcal{S}}_{\ell}}[\Gamma^{\mathcal{S}}_{\ell}(\boldsymbol{y}) = 0] = \Pr_{\boldsymbol{y}\sim\mathcal{D}^{\mathcal{S}}_{\ell}}[\Gamma^{\mathcal{S}}_{\ell}(\boldsymbol{y}) = 1] = 1/2.$

In the paper, $\mathcal{D}^{\mathcal{S}}_{\ell}$ is denoted by $\mathcal{D}_{\ell}$. To see the definition, refer to Definitions 3 and 4. Roughly speaking, the distribution is defined in such a way that removing a few coordinates results in the distribution becoming almost uniform. It is clear from the definition of $\Gamma^{\mathcal{S}}_{\ell}$ and item 1 that

3. $\Gamma^{\mathcal{S}}_{\ell}(y)$ is a monotone $(\mathrm{opt}(\mathcal{S})\ell)$-Junta over $\mathcal{D}^{\mathcal{S}}_{\ell}$.

We then define the *monotone size* of a term T to be the number of unnegated variables that appear in T. The intuition for this definition is that negated variables do not contribute to reducing the size of the DNF of monotone functions, and therefore they may as well be ignored. We first show that

4. For every DNF $F : (\{0,1\}^{\ell})^n \to \{0,1\}$ of size $|F| \le 2^{\mathrm{opt}(\mathcal{S})\ell/5}$ that is ϵ-far from $\Gamma^{\mathcal{S}}_{\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\ell}$, there is another DNF F' of size $|F'| \le 2^{\mathrm{opt}(\mathcal{S})\ell/5}$ with terms of monotone size at most $\mathrm{opt}(\mathcal{S})\ell/5$ that is $(\epsilon - 2^{-\mathrm{opt}(\mathcal{S})\ell/20})$-far from $\Gamma^{\mathcal{S}}_{\ell}$ with respect to $\mathcal{D}^{\mathcal{S}}_{\ell}$.

This is done by simply showing that terms of large monotone size in the DNF F have a small weight according to the distribution $\mathcal{D}^{\mathcal{S}}_{\ell}$ and, therefore, can be removed from F with the cost of $-2^{-\mathrm{opt}(\mathcal{S})\ell/20}$ in the error.

We then, roughly speaking, show that

5. Let F' be a DNF of size $|F'| \le 2^{\mathrm{opt}(\mathcal{S})\ell/5}$ with terms of monotone size at most $\mathrm{opt}(\mathcal{S})\ell/5$. For every $y \in (\{0,1\}^\ell)^n$ in the support of $\mathcal{D}_\ell^{\mathcal{S}}$ that satisfies $\Gamma_\ell^{\mathcal{S}}(y) = 1$, either
   - $F'(y) = 0$ or
   - $F'(y) = 1$, and at least $1/(2N)$ fraction of the points z below y in the lattice $(\{0,1\}^\ell)^n$ that are in the support of $\mathcal{D}_\ell^{\mathcal{S}}$ satisfies $F'(z) = 1$ and $\Gamma_\ell^{\mathcal{S}}(z) = 0$.

Roughly speaking, the latter sub-item follows from the fact that when the monotone size of the terms of F is small and $F'(y) = 1$ then y satisfies a small term T in F'. Now, if z with $\Gamma_\ell^{\mathcal{S}}(z) = 0$ is a randomly chosen point that is almost uniformly distributed below y, but not significantly distant from y, then there exists a sufficiently large probability for $T(z) = 1$ and then $F'(z) = 1$.

By item 5, either $1/(4N)$ fraction of the vectors y that satisfy $\Gamma_\ell^{\mathcal{S}}(y) = 1$ satisfy $F'(y) = 0$ or $(1 - 1/(4N))/(2N) > 1/(4N)$ fraction of the points z that satisfy $\Gamma_\ell^{\mathcal{S}}(z) = 0$ satisfy $F'(z) = 1$. Therefore, with item 2, we get that F' is $1/(8N)$-far from $\Gamma_\ell^{\mathcal{S}}$ with respect to $\mathcal{D}_\ell^{\mathcal{S}}$. This, with item 4, implies that

6. If $F : (\{0,1\}^\ell)^n \to \{0,1\}$ is a DNF of size $|F| < 2^{\mathrm{opt}(\mathcal{S})\ell/20}$, then F is $(1/(8N) - 2^{-\mathrm{opt}(\mathcal{S})\ell/20})$-far from $\Gamma_\ell^{\mathcal{S}}$ with respect to $\mathcal{D}_\ell^{\mathcal{S}}$.

The rest of the proof is almost the same as in [10]. See the discussion in subsection 1.2 after item 7.

Assuming a natural conjecture on the hardness of set cover, we establish a lower bound of $n^{\Omega(\log s)}$. The details and proof of this result will be discussed in Section 5, where we utilize a stronger version of item 4.

1.4 Upper Bounds

The only known distribution-free algorithm for $\log s$-Junta is the trivial algorithm that, for every set of $m = \log s$ variables $S = \{x_{i_1}, \ldots, x_{i_m}\}$, checks if there is a function that depends on S and is consistent with the examples. This algorithm takes $n^{O(\log s)}$ time.

For size-s decision tree and monotone size-s decision tree, the classic result of Ehrenfeucht and Haussler [5] gives a distribution-free time algorithm that runs in time $n^{O(\log s)}$ and outputs a decision tree of size $n^{O(\log s)}$.

The learning algorithm is as follows: Let T be the target decision tree of size s. First, the algorithm guesses the variable at the root of the tree T and then guesses which subtree of the root has size at most $s/2$. Then, it recursively constructs the tree of size $s/2$. When it succeeds, it continues to construct the other subtree.

For size-s DNF and monotone size-s DNF, Hellerstein et al. [7] gave a distribution-free proper learning algorithm that runs in time $2^{\tilde{O}(\sqrt{n \log s})}$.

To the best of our knowledge, all the other results in the literature for learning the above classes are either restricted to the uniform distribution or, in addition, use black box queries or return hypotheses that are not DNF.

We recommend that readers who are not experts in the field refer to the first two sections in [10].

2 Definitions and Preliminaries

In this section, we give the definitions and preliminary results that are needed to prove our results.

2.1 Set Cover

Let $\mathcal{S} = (S, U, E)$ be a bipartite graph on $N = n + |U|$ vertices where $S = [n]$, and for every $u \in U$, $\deg(u) > 0$. We say that $C \subseteq S$ is a set cover of $\mathcal{S}$ if every vertex in U is adjacent to some vertex in C. The Set-Cover problem is to find a minimum-size set cover. We denote by $\mathrm{opt}(\mathcal{S})$ the size of a minimum-size set cover for $\mathcal{S}$.

We identify each element $u \in U$ with the vector $(u_1, \ldots, u_n) \in \{0,1\}^n$ where $u_i = 0$ if and only if $(i, u) \in E$. We will assume that those vectors are distinct. If there are two distinct elements $u, u' \in U$ that have the same vector, then you can remove one of them from the graph. This is because every set cover that covers one of them covers the other.

▶ **Definition 1.** *The (k, k')-Set-Cover problem is the following: Given as input a set cover instance $\mathcal{S} = (S, U, E)$, and parameters k and k'. Output Yes if* $\mathrm{opt}(\mathcal{S}) \le k$ *and No if* $\mathrm{opt}(\mathcal{S}) > k'$.

2.2 Hardness of Set-Cover

Our results are conditioned on the following randomized exponential time hypothesis (ETH) **Hypothesis:** [3, 4, 8, 9, 12]. There exists a constant $c \in (0, 1)$ such that 3-SAT on n variables cannot be solved by a randomized algorithm in $O(2^{cn})$ time with success probability at least 2/3.

The following is proved in [11]. See also Theorem 7 in [10]

▶ **Lemma 2** ([11]). *Let $k \le \frac{1}{2}\frac{\log\log N}{\log\log\log N}$ and $k' = \frac{1}{2}\left(\frac{\log N}{\log\log N}\right)^{1/k}$ be two integers. Assuming randomized ETH, there is a constant $\lambda \in (0, 1)$ such that there is no randomized $N^{\lambda k}$ time algorithm that can solve (k, k')-Set-Cover on N vertices with high probability.*

2.3 Concept Classes

In Appendix A we give the definition of *monotone* function, *literal*, *term*,*clause*, *monotone term*, *DNF*, *monotone DNF*. Then the classes, size-s Monotone DNF, size s-Monotone DT and Monotone k-Junta.

The *size* of a term T, $|T|$, is the number of literals in the term T. The *size* $|F|$ of a DNF (resp. CNF) F is the number of terms (resp. clauses) in F.

It is well known that

$$\text{Monotone } (\log s)\text{-Junta} \subset \text{size-}s \text{ Monotone DT} \subset \text{size-}s \text{ Monotone DNF} . \qquad (1)$$

2.4 Functions and Distributions

For any set R, we define $\mathcal{U}(R)$ to be the uniform distribution over R. For a distribution $\mathcal{D}$ over $\{0,1\}^n$ and two Boolean functions f and g, we define $\mathrm{dist}_{\mathcal{D}}(f, g) = \Pr_{\boldsymbol{x}\sim\mathcal{D}}[f(\boldsymbol{x}) \ne g(\boldsymbol{x})]$. Here, bold letters denote random variables. If $\mathrm{dist}_{\mathcal{D}}(f, g) = 0$, then we say that $f = g$ *over* $\mathcal{D}$. For a class of functions C, we say that f is in C over $\mathcal{D}$ (or just, is C over $\mathcal{D}$) if there is a function $g \in C$ such that $f = g$ over $\mathcal{D}$.

▶ **Definition 3** ($\Gamma^{\mathcal{S}}$ and $\mathcal{D}^{\mathcal{S}}$). *Let $\mathcal{S} = (S, U, E)$ be a set cover instance with $S = [n]$. Recall that we identify each element $u \in U$ with the vector $(u_1, \ldots, u_n) \in \{0,1\}^n$ where $u_i = 0$ if and only if $(i, u) \in E$. We define the partial function $\Gamma^{\mathcal{S}} : \{0,1\}^n \to \{0,1\}$ where $\Gamma^{\mathcal{S}}(x) = 0$ if $x \in U$ and $\Gamma^{\mathcal{S}}(1^n) = 1$. We define the distribution $\mathcal{D}^{\mathcal{S}}$ over $\{0,1\}^n$ where $\mathcal{D}^{\mathcal{S}}(x) = 1/2$ if $x = 1^n$, $\mathcal{D}^{\mathcal{S}}(x) = 1/(2|U|)$ if $x \in U$, and $\mathcal{D}^{\mathcal{S}}(x) = 0$ otherwise. We will remove the superscript $\mathcal{S}$ when it is clear from the context and write Γ and $\mathcal{D}$.*

▶ **Fact 1.** *We have*

1. *$C \subseteq S$ is a set cover of $\mathcal{S} = (S, U, E)$, if and only if $\Gamma(x) = \bigwedge_{i\in C} x_i$ over $\mathcal{D}$.*
2. *In particular, If T is a monotone term of size $|T| < \mathrm{opt}(\mathcal{S})$, then there is $u \in U$ such that $T(u) = 1$.*

Proof. Let C be a set cover of $\mathcal{S}$. First, we have $\Gamma(1^n) = 1$. Now, since C is a set cover, every vertex $u \in U$ is adjacent to some vertex in C. This is equivalent to: for every assignment $u \in U$, there is $i \in C$ such that $u_i = 0$. Therefore, $\wedge_{i\in C} u_i = 0$ for all $u \in U$. Thus, $\Gamma(x) = \bigwedge_{i\in C} x_i$ over $\mathcal{D}$.

The other direction can be easily seen by tracing backward in the above proof. ◀

For an odd ℓ, define $\Delta^0 = \{a \in \{0,1\}^\ell | \mathrm{wt}(a) = \lfloor \ell/2 \rfloor\}$ and $\Delta^1 = \{a \in \{0,1\}^\ell | \mathrm{wt}(a) = \lceil \ell/2 \rceil\}$, where $\mathrm{wt}(a)$ is the Hamming weight of a. Notice that $|\Delta^0| = |\Delta^1| = \binom{\ell}{\lfloor \ell/2 \rfloor}$.

▶ **Definition 4** **(Γ_ℓ, $\mathcal{D}_\ell$, Δ^0_n and Δ^1_n).** *For an odd ℓ, define $\Delta^1_n = (\Delta^1)^n$ and*[7] *$\Delta^0_n := \cup_{u\in U} \prod_{i=1}^n \Delta^{u_i} = \cup_{u\in U}(\Delta^{u_1} \times \Delta^{u_2} \times \cdots \times \Delta^{u_n})$. Define the distribution $\mathcal{D}_\ell : (\{0,1\}^\ell)^n \to [0,1]$ to be $\mathcal{D}_\ell(y) = 1/(2|\Delta^1_n|) = 1/(2|\Delta^1|^n)$ if $y \in \Delta^1_n$, $\mathcal{D}_\ell(y) = 1/(2|\Delta^0_n|) = 1/(2|U| \cdot |\Delta^0|^n)$ if $y \in \Delta^0_n$, and $\mathcal{D}_\ell(y) = 0$ otherwise. We define the partial function Γ_ℓ over the support $\Delta^0_n \cup \Delta^1_n$ of $\mathcal{D}_\ell$ to be 1 if $y \in \Delta^1_n$ and 0 if $y \in \Delta^0_n$.*

We note here that the distribution $\mathcal{D}_\ell$ is well-defined. This is because: First, the sum of the distribution of the points in Δ^1_n is $1/2$. Second, for two different $u, u' \in U$, we have that $\prod_{i=1}^n \Delta^{u_i}$ and $\prod_{i=1}^n \Delta^{u'_i}$ are disjoint sets. Therefore, $|\Delta^0_n| = |U| \cdot |\Delta^0|^n$, and therefore, the sum of the distribution of all the points in Δ^0_n is half. In particular,

▶ **Fact 2.** *We have* $\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[\Gamma_\ell(\boldsymbol{y}) = 1] = \Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[\Gamma_\ell(\boldsymbol{y}) = 0] = \Pr_{\mathcal{D}_\ell}[\Delta^1_n] = \Pr_{\mathcal{D}_\ell}[\Delta^0_n] = \frac{1}{2}$.

For $y \in (\{0,1\}^\ell)^n$, we write $y = (y_1, \ldots, y_n)$, where $y_j = (y_{j,1}, y_{j,2}, \ldots, y_{j,\ell}) \in \{0,1\}^\ell$. Let $(\textsc{Majority}(y_i))_{i\in[n]} = (\textsc{Majority}(y_1), \ldots, \textsc{Majority}(y_n))$ where $\textsc{Majority}$ is the majority function.

▶ **Fact 3.** *If $C \subseteq S$ is a set cover of $\mathcal{S}$, then $\Gamma_\ell(y) = \Gamma((\textsc{Majority}(y_i))_{i\in[n]}) = \bigwedge_{i\in C}$ $\textsc{Majority}(y_i)$ over $\mathcal{D}$. In particular, Γ_ℓ is $\textsc{Monotone}$ $\mathrm{opt}(\mathcal{S})\ell$-$\textsc{Junta}$ over $\mathcal{D}$.*

Proof. First notice that $\textsc{Majority}(x) = 1$ if $x \in \Delta^1$ and $\textsc{Majority}(x) = 0$ if $x \in \Delta^0$. Therefore, for $x \in \Delta^\xi$, $\xi \in \{0,1\}$ we have $\textsc{Majority}(x) = \xi$.

For $y \in \Delta^1_n = (\Delta^1)^n$, $(\textsc{Majority}(y_i))_{i\in[n]} = 1^n$ and $\Gamma_\ell(y) = 1 = \Gamma(1^n)$.

For $y \in \Delta^0_n = \cup_{u\in U}(\Delta^{u_1} \times \Delta^{u_2} \times \cdots \times \Delta^{u_n})$, there is u such that $y \in \Delta^{u_1} \times \Delta^{u_2} \times \cdots \times \Delta^{u_n}$. Then, $(\textsc{Majority}(y_i))_{i\in[n]} = u$ and $\Gamma_\ell(y) = \Gamma((\textsc{Majority}(y_i))_{i\in[n]}) = \Gamma(u) = 0$. ◀

For $t \in [\ell], \xi \in \{0,1\}$ and $u \in \{0,1\}^\ell$, we define $u^{t\leftarrow\xi} \in \{0,1\}^\ell$ the vector that satisfies

$$u_i^{t\leftarrow\xi} = \begin{cases} u_i & i \neq t \\ \xi & i = t \end{cases}.$$

Let $z \in (\{0,1\}^\ell)^n$. For $j \in [\ell]^n$ and $a \in \{0,1\}^n$, define $z^{j\leftarrow a} = (z_1^{j_1\leftarrow a_1}, \ldots, z_n^{j_n\leftarrow a_n})$. For a set $V \subseteq \{0,1\}^n$, we define $z^{j\leftarrow V} = \{z^{j\leftarrow v} | v \in V\}$.

We define $\mathrm{one}(z) = \prod_{i=1}^n \{m_i | z_{i,m_i} = 1\} = \{m_1 | z_{1,m_1} = 1\} \times \cdots \times \{m_n | z_{n,m_n} = 1\}$.

[7] Here $\Delta^\xi = \Delta^0$ if $\xi = 0$ and Δ^1 if $\xi = 1$.

▶ **Fact 4.** *Let $w \in \Delta_n^1$, $j \in \mathrm{one}(w)$, and T be a term that satisfies $T(w) = 1$. Then*

1. $w^{j\leftarrow U} \subseteq \Delta_n^0$.
2. $|w^{j\leftarrow U}| = |U|$.
3. *If $T^j(y_{1,j_1}, \dots, y_{n,j_n})$ is the conjunction of all the variables that appear in T of the form y_{i,j_i}, then $T(w^{j\leftarrow a}) = T^j(a)$.*

Proof. We first prove item 1. Let $u \in U$ and i be any integer in $[n]$. Since $w \in \Delta_n^1$, we have $w_i \in \Delta^1$. Since $j \in one(w)$, we have $w_{i,j_i} = 1$. Therefore, $w_i^{j_i \leftarrow u_i} \in \Delta^{u_i}$ for all $i \in [n]$ and $w^{j\leftarrow u} \in \prod_{i=1}^n \Delta^{u_i}$. Thus, $w^{j\leftarrow u} \in \Delta_n^0$ for all $u \in U$.

To prove item 2, let u, u' be two distinct elements of U. There is i such that $u_i \neq u'_i$. Therefore $w_i^{j_i\leftarrow u_i} \neq w_i^{j_i \leftarrow u'_i}$ and $w^{j\leftarrow u} \neq w^{j\leftarrow u'}$.

We now prove item 3. Let T' be the conjunction of all the variables that appear in T that are not of the form y_{i,j_i}. Then $T = T' \wedge T^j$. Since $T(w) = 1$, we have $T'(w) = 1$. Since the entries of $w^{j\leftarrow a}$ are equal to those in w on all the variables that are not of the form y_{i,j_i}, we have $T'(w^{j\leftarrow a}) = 1$. Therefore, $T(w^{j\leftarrow a}) = T'(w^{j\leftarrow a}) \wedge T^j(w_{1,j_1}^{j\leftarrow a}, \dots, w_{n,j_n}^{j\leftarrow a}) = T^j(a)$. ◀

We now give a different way of sampling according to the distribution $\mathcal{D}_\ell$. The proof is in Appendix B.

▶ **Fact 5.** *Let $\mathcal{S}$ be a SET-COVER instance. The following is an equivalent way of sampling from $\mathcal{D}_\ell$.*

1. *Draw $\xi \in \{0,1\}$ u.a.r.*[8]
2. *Draw $w \in \Delta_n^1$ u.a.r.*
3. *If $\xi = 1$ then output $y = w$.*
4. *If $\xi = 0$ then*
   a. *draw $j \in \mathrm{one}(w)$ u.a.r.*
   b. *draw $v \in w^{j\leftarrow U}$ u.a.r.*
   c. *output $y = v$.*

In particular, for any event X,

$$\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^0)}[X] = \Pr_{\boldsymbol{w}\sim\mathcal{U}(\Delta_n^1), \boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(\boldsymbol{w})), \boldsymbol{y}\sim\mathcal{U}(\boldsymbol{w}^{\boldsymbol{j}\leftarrow U})}[X].$$

3 Main Lemma

In this section, we prove

▶ **Lemma 5.** *Let $\mathcal{S} = (S, U, E)$ be a set cover instance. If $F : (\{0,1\}^\ell)^n \to \{0,1\}$ is a DNF of size $|F| < 2^{\mathrm{opt}(\mathcal{S})\ell/20}$, then $\mathrm{dist}_{\mathcal{D}_\ell}(F, \Gamma_\ell) \geq 1/(8|U|) - 2^{-\mathrm{opt}(\mathcal{S})\ell/20}$.*

Note that Lemma 5 is used to prove Theorem 1 and 2. To prove Theorem 3, we will need Lemma 11, a stronger version of Lemma 5.

To prove the lemma, we first establish some results.

For a term T, let $T_\mathcal{M}$ be the conjunction of all the unnegated variables in T. We define the *monotone size* of T to be $|T_\mathcal{M}|$. The proof of the following Claim is in Appendix B.

▷ Claim 6. Let $\mathcal{S} = (S, U, E)$ be a set cover instance and $\ell \geq 5$. If $F : (\{0,1\}^\ell)^n \to \{0,1\}$ is a DNF of size $|F| < 2^{\mathrm{opt}(\mathcal{S})\ell/20}$, then there is a DNF, F', of size $|F'| \leq 2^{\mathrm{opt}(\mathcal{S})\ell/20}$ with terms of monotone size at most $\mathrm{opt}(\mathcal{S})\ell/5$ such that $\mathrm{dist}_{\mathcal{D}_\ell}(\Gamma_\ell, F') \leq \mathrm{dist}_{\mathcal{D}_\ell}(\Gamma_\ell, F) + 2^{-\mathrm{opt}(\mathcal{S})\ell/20}$.

[8] Uniformly at random.

We now prove

▷ Claim 7. Let $z\in\Delta_n^1$. Let F be a DNF with terms of monotone size at most $\lceil\ell/2\rceil(\mathrm{opt}(\mathcal{S})-1)/2$ that satisfies $F(z)=1$. Then

$$\Pr_{\boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(z)),\boldsymbol{y}\sim\mathcal{U}(z^{\boldsymbol{j}\leftarrow U})}[F(\boldsymbol{y})=1]\ge\frac{1}{2|U|}.$$

Proof. Since $F(z)=1$, there is a term T in F that satisfies $T(z)=1$. Let $Y_0=\{y_{i,m}|z_{i,m}=0\}$ and $Y_1=\{y_{i,m}|z_{i,m}=1\}$. Since $T(z)=1$, every variable in Y_0 that appears in T must be negated, and every variable in Y_1 that appears in T must be unnegated. For $j\in\mathrm{one}(z)$, define $q(j)$ to be the number of variables in $\{y_{1,j_1},\ldots,y_{n,j_n}\}$ that appear in $T(y)$. All those variables appear unnegated in T because $j\in\mathrm{one}(z)$. Recall that $T_{\mathcal{M}}$ is the conjunction of all unnegated variables in T. Then $|T_{\mathcal{M}}|\le\lceil\ell/2\rceil(\mathrm{opt}(\mathcal{S})-1)/2$. Each variable in $T_{\mathcal{M}}$ contributes $\lceil\ell/2\rceil^{n-1}$ to the sum $\sum_{j\in one(z)}q(j)$ and $|\mathrm{one}(z)|=\lceil\ell/2\rceil^n$. Therefore,

$$\mathop{\mathbb{E}}_{\boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(z))}[q(\boldsymbol{j})]=\frac{|T_{\mathcal{M}}|}{\lceil\ell/2\rceil}\le\frac{\mathrm{opt}(\mathcal{S})-1}{2}.$$

By Markov's bound, at least half the elements $j\in\mathrm{one}(z)$ satisfies $q(j)\le\mathrm{opt}(\mathcal{S})-1$. Let $J=\{j\in\mathrm{one}(z)|q(j)<\mathrm{opt}(\mathcal{S})\}$. Then $\Pr_{\boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(z))}[\boldsymbol{j}\in J]\ge 1/2$. Consider $j\in J$ and let T^j be the conjunction of all the variables that appear in T of the form y_{i,j_i}. Then $|T^j|=q(j)\le\mathrm{opt}(\mathcal{S})-1$. By Fact 1, there is $u\in U$ such that $T^j(u)=1$. By Fact 4, we have $T(z^{j\leftarrow u})=T^j(u)=1$. Then $F(z^{j\leftarrow u})=1$. Since by item 1 in Fact 4, $|z^{j\leftarrow U}|=|U|$, we have

$$\Pr_{\boldsymbol{j}\sim\mathcal{U}(one(z)),\boldsymbol{y}\sim\mathcal{U}(z^{\boldsymbol{j}\leftarrow U})}[F(\boldsymbol{y})=1|\boldsymbol{j}\in J]\ge\frac{1}{|U|}.$$

Therefore,

$$\Pr_{\boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(z)),\boldsymbol{y}\sim\mathcal{U}(z^{\boldsymbol{j}\leftarrow U})}[F(\boldsymbol{y})=1]\ge\Pr_{\boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(z))}[\boldsymbol{j}\in J]\times$$
$$\Pr_{\boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(z)),\boldsymbol{y}\sim\mathcal{U}(z^{\boldsymbol{j}\leftarrow U})}[F(\boldsymbol{y})=1|\boldsymbol{j}\in J]\ge\frac{1}{2|U|}.$$ ◁

We are now ready to prove Lemma 5

Proof. By Claim 6, there is a DNF, F', of size $|F'|\le 2^{\mathrm{opt}(\mathcal{S})\ell/20}$ with terms of monotone size at most $\mathrm{opt}(\mathcal{S})\ell/5$ such that $\mathrm{dist}_{\mathcal{D}_\ell}(\Gamma_\ell,F')\le\mathrm{dist}_{\mathcal{D}_\ell}(\Gamma_\ell,F)+2^{-\mathrm{opt}(\mathcal{S})\ell/20}$. Therefore, it is enough to prove that $\mathrm{dist}_{\mathcal{D}_\ell}(\Gamma_\ell,F')\ge 1/(8|U|)$.

If $\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^1)}[F'(\boldsymbol{y})\ne 1]\ge 1/(4|U|)$, then by Fact 2, for the event $Y(\boldsymbol{y})=[\Gamma_\ell(\boldsymbol{y})=1]$, we have

$$\mathrm{dist}_{\mathcal{D}_\ell}(\Gamma_\ell,F')\ge\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[\Gamma_\ell(\boldsymbol{y})\ne F'(\boldsymbol{y})|Y(\boldsymbol{y})]\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[Y(\boldsymbol{y})]=\frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^1)}[F'(\boldsymbol{y})\ne 1]\ge\frac{1}{8|U|}.$$

If $\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^1)}[F'(\boldsymbol{y}) \neq 1] < 1/(4|U|)$, then by Fact 2 and 5, and Claim 7,

$$\begin{aligned}
\mathrm{dist}_{\mathcal{D}_\ell}(\Gamma_\ell, F') \geq & \Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[\Gamma_\ell(\boldsymbol{y}) \neq F'(\boldsymbol{y}) | \Gamma_\ell(\boldsymbol{y}) = 0] \cdot \Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[\Gamma_\ell(\boldsymbol{y}) = 0] \\
=& \frac{1}{2} \Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^0)}[F'(\boldsymbol{y}) = 1] \\
=& \frac{1}{2} \Pr_{\boldsymbol{z}\sim\mathcal{U}(\Delta_n^1), \boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(\boldsymbol{z})), \boldsymbol{y}\sim\mathcal{U}(\boldsymbol{z}^{\boldsymbol{j}\leftarrow U})}[F'(\boldsymbol{y}) = 1] \\
\geq & \frac{1}{2} \Pr_{\boldsymbol{z}\sim\mathcal{U}(\Delta_n^1), \boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(\boldsymbol{z})), \boldsymbol{y}\sim\mathcal{U}(\boldsymbol{z}^{\boldsymbol{j}\leftarrow U})}[F'(\boldsymbol{y}) = 1 | F'(\boldsymbol{z}) = 1] \times \\
& \Pr_{\boldsymbol{z}\sim\mathcal{U}(\Delta_n^1)}[F'(\boldsymbol{z}) = 1] \\
\geq & \frac{1}{2}\frac{1}{2|U|}\left(1 - \frac{1}{4|U|}\right) \geq \frac{1}{8|U|}.
\end{aligned}$$

◀

4 Superpolynomial Lower Bound

In this section, we prove the first results of the paper. First, we prove the following result for Monotone $(\log n)$-Junta.

▶ **Lemma 8.** *Assuming randomized ETH, there is a constant c such that any PAC learning algorithm for n-variable* Monotone $(\log n)$-Junta *by DNF with $\epsilon = 1/(16n)$ must take at least $n^{c\frac{\log\log n}{\log\log\log n}}$ time.*

The lower bound holds, even if the learner knows the distribution, can draw a sample according to the distribution in polynomial time and can compute the target on all the points of the support of the distribution in polynomial time.

Proof. Consider the constant λ in Lemma 2. Let $c = \min(1/40, \lambda/4)$. Suppose there is a PAC learning algorithm $\mathcal{A}$ for Monotone $(\log n)$-Junta by DNF with $\epsilon = 1/(16n)$ that runs in time $n^{c\frac{\log\log n}{\log\log\log n}}$. We show that there is k such that for

$$k' = \frac{1}{2}\left(\frac{\log N}{\log\log N}\right)^{1/k},$$

(k, k')-Set-Cover can be solved in time $N^{4ck} \leq N^{\lambda k}$. By Lemma 2, the result then follows.

Let $\mathcal{S} = (S, U, E)$ be an N-vertex (k, k')-Set-Cover instance where

$$k = \frac{1}{2}\frac{\log\log N}{\log\log\log N} \text{ and } k' = \frac{1}{2}\left(\frac{\log N}{\log\log N}\right)^{1/k}.$$

Let $\ell = \frac{\log N}{k}$ and consider Γ_ℓ and $\mathcal{D}_\ell$.

Consider the following algorithm $\mathcal{B}$

1. Input $\mathcal{S} = (S, U, E)$ an instance for (k, k')-Set-Cover .
2. Construct Γ_ℓ and $\mathcal{D}_\ell$.
3. Run $\mathcal{A}$ using Γ_ℓ and $\mathcal{D}_\ell$. If it runs more than N^{4ck} steps, then output No .
4. Let F be the output DNF.
5. Estimate $\eta = \mathrm{dist}_{\mathcal{D}_\ell}(F, \Gamma_\ell)$.
6. If $\eta \leq \frac{1}{16N}$, output Yes , otherwise output No .

The running time of this algorithm is $N^{4ck} \leq N^{\lambda k}$. Therefore, it is enough to prove the following

▷ Claim 9. Algorithm $\mathcal{B}$ solves (k,k')-SET-COVER .

Proof. YES case: Let $\mathcal{S}=(S,U,E)$ be a (k,k')-SET-COVER instance and $\mathrm{opt}(\mathcal{S})\le k$. Then, $\mathrm{opt}(\mathcal{S})\cdot\ell\le k\ell=\log N$, and by Fact 3, Γ_ℓ is MONOTONE $\log N$-JUNTA. Therefore, w.h.p., algorithm $\mathcal{A}$ learns Γ_ℓ and outputs a DNF that is $\eta=1/(16N)$ close to the target with respect to $\mathcal{D}_\ell$. Since $\mathcal{B}$ terminates $\mathcal{A}$ after N^{4ck} time, we only need to prove that $\mathcal{A}$ runs at most N^{4ck} time.

The running time of $\mathcal{A}$ is $N^{c\frac{\log\log N}{\log\log\log N}}<N^{4ck}$.

NO Case: Let $\mathcal{S}=(S,U,E)$ be a (k,k')-SET-COVER instance and $\mathrm{opt}(\mathcal{S})>k'$. By Lemma 5, any DNF, F, of size $|F|<2^{k'\ell/20}$ satisfies $\mathrm{dist}_{\mathcal{D}_\ell}(F,\Gamma_\ell)\ge 1/(8|U|)-2^{-k'\ell/20}$. First, we have

$$(2k)^{2k}=\left(\frac{\log\log N}{\log\log\log N}\right)^{\frac{\log\log N}{\log\log\log N}}<\frac{\log N}{\log\log N}.$$

Therefore, since $c\le 1/40$,

$$k'=\frac{1}{2}\left(\frac{\log N}{\log\log N}\right)^{1/k}>\frac{1}{2}(2k)^2>80ck^2.$$

So $k'\ell/20>(k\ell)(4ck)$ and $2^{k'\ell/20}>(2^{k\ell})^{4ck}=N^{4ck}$. Now since the algorithm runs in time N^{4ck}, it cannot output a DNF F of size more than $N^{4ck}<2^{k'\ell/20}$, and by Lemma 5,

$$\mathrm{dist}_{\mathcal{D}_\ell}(F,\Gamma_\ell)\ge\frac{1}{8|U|}-\frac{1}{N^{4ck}}\ge\frac{1}{9N}.$$

So it either runs more than N^{4ck} steps and then outputs NO in step 3 or outputs a DNF with an error greater than $1/(9N)>1/(16N)$ and outputs NO in step 6. ◁

Notice that the learning algorithm knows Γ_ℓ and $\mathcal{D}_\ell$. It is also clear from the definition of Γ_ℓ and $\mathcal{D}_\ell$ that the learning algorithm can draw a sample according to the distribution $\mathcal{D}_\ell$ in polynomial time and can compute the target Γ_ℓ on all the points of the support of the distribution in polynomial time. ◀

We now prove

▶ **Theorem 1.** *Assuming randomized ETH, there is a constant c such that any PAC learning algorithm for n-variable size-s MONOTONE DT and size-s MONOTONE DNF by DNF with $\epsilon=1/(16n)$ must take at least*

$$n^{c\frac{\log\log s}{\log\log\log s}}$$

time.

The lower bound holds, even if the learner knows the distribution, can draw a sample according to the distribution in polynomial time and can compute the target on all the points of the support of the distribution in polynomial time.

Proof. By Lemma 8, assuming randomized ETH, there is a constant c such that any PAC learning algorithm for n-variable MONOTONE $(\log n)$-JUNTA by DNF with $\epsilon=1/(16n)$ runs in time

$$n^{c\frac{\log\log n}{\log\log\log n}}.$$

Now by (1) and since $s=n$, the result follows. ◀

5 Tight Bound Assuming some Conjecture

A plausible conjecture on the hardness of SET-COVER is the following.

▶ **Conjecture 1** ([10]). *There are constants $\alpha, \beta, \lambda \in (0, 1)$ such that, for $k < N^\alpha$, there is no randomized $N^{\lambda k}$ time algorithm that can solve $(k, (1-\beta)\cdot k \ln N)$-SET-COVER on N vertices with high probability.*

We now prove

▶ **Theorem 2.** *Assuming Conjecture 1, there is a constant c such that any PAC learning algorithm for n-variable MONOTONE $(\log s)$-JUNTA, size-s MONOTONE DT and size-s MONOTONE DNF by DNF with $\epsilon = 1/(16n)$ must take at least*

$$n^{c \log s}$$

time.

The lower bound holds, even if the learner knows the distribution, can draw a sample according to the distribution in polynomial time and can compute the target on all the points of the support of the distribution in polynomial time.

Proof. We give the proof for MONOTONE $(\log s)$-JUNTA. As in the proof of Theorem 1, the result then follows for the other classes.

Consider the constants α, β and λ in Conjecture 1. Let $c = \min(\lambda/10, (1-\beta)/(20 \log e))$. Suppose there is a PAC learning algorithm $\mathcal{A}$ for MONOTONE $(\log s)$-JUNTA by DNF with $\epsilon = 1/(16n)$ that runs in time $n^{c \log s}$. We show that there is $k < N^\alpha$, $k = \omega(1)$, such that (k, k')-SET-COVER can be solved in time $N^{\lambda k}$ where $k' = (1-\beta)k \ln N$. By Conjecture 1, the result then follows.

Consider the following algorithm $\mathcal{B}$

1. Input $\mathcal{S} = (S, U, E)$ an instance for (k, k')-SET-COVER .
2. Construct Γ_5 and $\mathcal{D}_5$.
3. Run $\mathcal{A}$ using Γ_5 and $\mathcal{D}_5$ with $s = 2^{5k}$. If it runs more than N^{5ck} steps, then output NO .
4. Let F be the output DNF.
5. Estimate $\eta = \mathrm{dist}_{\mathcal{D}_5}(F, \Gamma_5)$.
6. If $\eta \le \frac{1}{16N}$, output YES , otherwise output NO .

Since $c < \lambda/10$, the running time of this algorithm is $N^{5ck} < N^{\lambda k}$. Therefore, it is enough to prove the following

▷ Claim 10. Algorithm $\mathcal{B}$ solves (k, k')-SET-COVER .

Proof. YES case: Let $\mathcal{S} = (S, U, E)$ be a (k, k')-SET-COVER instance and $\mathrm{opt}(\mathcal{S}) \le k$. Then, $5 \cdot \mathrm{opt}(\mathcal{S}) \le 5k = \log s$, and by Fact 3, Γ_5 is MONOTONE $\log s$-JUNTA. Therefore, w.h.p., algorithm $\mathcal{A}$ learns Γ_5 and outputs a DNF that is $\eta = 1/(16N)$ close to the target with respect to $\mathcal{D}_5$. Since $\mathcal{B}$ terminates $\mathcal{A}$ after N^{5ck} time, we only need to prove that $\mathcal{A}$ runs at most N^{5ck} time.

The running time of $\mathcal{A}$ is

$$n^{c \log s} \le N^{5ck}.$$

No Case: Let $\mathcal{S} = (S, U, E)$ be a (k, k')-SET-COVER instance and $\mathrm{opt}(\mathcal{S}) > k' = (1-\beta)k \ln N$. By Lemma 5, any DNF, F, of size $|F| < 2^{k'/4}$ satisfies $\mathrm{dist}_{\mathcal{D}_5}(F, \Gamma_5) \ge 1/(8|U|) - 2^{-k'/4}$. Since, $c < (1-\beta)/(20 \log e)$,

$$2^{k'/4} = 2^{\frac{(1-\beta)k \ln N}{4}} = N^{\frac{(1-\beta)k}{4 \log e}} > N^{5ck},$$

any DNF, F, that the learning outputs satisfies

$$\mathrm{dist}_{\mathcal{D}_5}(F,\Gamma_5) \geq \frac{1}{8|U|} - 2^{-k'/4} \geq \frac{1}{8N} - \frac{1}{N^{5ck}} \geq \frac{1}{9N}.$$

Therefore, with high probability the algorithm answer No . ◁

◀

6 Strictly Proper Learning

In this section, we prove

▶ **Theorem 3.** *Assuming randomized ETH, there is a constant c such that any PAC learning algorithm for n-variable* Monotone $(\log s)$-Junta*, size-s* Monotone *DT and size-s* Monotone *DNF by size-s DNF with $\epsilon = 1/(16n)$ must take at least*

$$n^{c\log s}$$

time.

The lower bound holds, even if the learner knows the distribution, can draw a sample according to the distribution in polynomial time and compute the target on all the points of the support of the distribution in polynomial time.

We first prove the following stronger version of Lemma 5

▶ **Lemma 11.** *Let $\mathcal{S} = (S, U, E)$ be a set cover instance, and let $\ell \geq 5$. If $F : (\{0,1\}^\ell)^n \to \{0,1\}$ is a DNF of size $|F| < 2^{\mathrm{opt}(\mathcal{S})\ell/16}$, then $\mathrm{dist}_{\mathcal{D}_\ell}(F,\Gamma_\ell) \geq 1/(8|U|)$.*

To prove this lemma, we will give some more results.

Recall that, for a term T, $T_{\mathcal{M}}$ is the conjunction of all the unnegated variables in T. We define the *monotone size* of T to be $|T_{\mathcal{M}}|$. For a DNF $F = T_1 \vee T_2 \vee \cdots \vee T_s$ and $z \in (\{0,1\}^\ell)^n$, we define the *monotone width* of z in F as

$$\mathrm{mwidth}_F(z) := \left\{ \begin{array}{ll} \min_{T_i(z)=1} |(T_i)_{\mathcal{M}}| & F(z)=1 \\ 0 & F(z)=0 \end{array} \right. .$$

We define $F^{-1}(1) = \{z | F(z) = 1\}$ and

$$\Omega = \Delta_n^1 \cap F^{-1}(1).$$

▷ Claim 12. Let F be a DNF with

$$\mathop{\mathbb{E}}_{\boldsymbol{z}\sim\mathcal{U}(\Omega)}[\mathrm{mwidth}_F(\boldsymbol{z})] \leq \mathrm{opt}(S)\cdot \ell/4.$$

Then

$$\Pr_{\boldsymbol{z}\sim\mathcal{U}(\Omega),\boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(\boldsymbol{z})),\boldsymbol{y}\sim\mathcal{U}(\boldsymbol{z}^{\boldsymbol{j}\leftarrow U})}[F(\boldsymbol{y})=1] \geq \frac{1}{2|U|}.$$

Proof. Let $z \in \Omega$. Then $F(z) = 1$ and $z \in \Delta_n^1$. Let T^z be the term in F with $|T^z_{\mathcal{M}}| = \mathrm{mwidth}_F(z)$ that satisfies $T^z(z) = 1$. Let $Y_0 = \{y_{i,m} | z_{i,m} = 0\}$ and $Y_1 = \{y_{i,m} | z_{i,m} = 1\}$. Since $T^z(z) = 1$, every variable in Y_0 that appears in T^z must be negated, and every variable in Y_1 that appears in T^z must be unnegated. For $j \in \text{one}(z)$, define $q_z(j)$ to be the number of variables in $\{y_{1,j_1}, \ldots, y_{n,j_n}\}$ that appear in $T^z(y)$. All those variables appear unnegated in T because $j \in \text{one}(z)$. Each variable in $T^z_{\mathcal{M}}$ contributes $\lceil \ell/2 \rceil^{n-1}$ to the sum $\sum_{j \in one(z)} q_z(j)$ and $|\text{one}(z)| = \lceil \ell/2 \rceil^n$. Therefore,

$$\mathop{\mathbb{E}}_{\boldsymbol{j} \sim \mathcal{U}(\text{one}(z))}[q_z(\boldsymbol{j})] = \frac{|T^z_{\mathcal{M}}|}{\lceil \ell/2 \rceil} = \frac{\text{mwidth}_F(z)}{\lceil \ell/2 \rceil}.$$

Now,

$$\begin{aligned} \mathop{\mathbb{E}}_{\boldsymbol{z} \sim \mathcal{U}(\Omega), \boldsymbol{j} \sim \mathcal{U}(\text{one}(\boldsymbol{z}))}[q_{\boldsymbol{z}}(\boldsymbol{j})] &= \frac{\mathop{\mathbb{E}}_{\boldsymbol{z} \sim \mathcal{U}(\Omega)}[\text{mwidth}_F(\boldsymbol{z})]}{\lceil \ell/2 \rceil} \\ &\le \frac{\text{opt}(\mathcal{S})}{2}. \end{aligned}$$

By Markov's bound,

$$\Pr_{\boldsymbol{z} \sim \mathcal{U}(\Omega), \boldsymbol{j} \sim \mathcal{U}(\text{one}(\boldsymbol{z}))}[q_{\boldsymbol{z}}(\boldsymbol{j}) < \text{opt}(\mathcal{S})] \ge \frac{1}{2}.$$

Suppose for some $z \in \Omega$ and $j \in \text{one}(z)$, we have $q_z(j) < \text{opt}(\mathcal{S})$. Let T^j be the conjunction of all the variables that appear in $T^z_{\mathcal{M}}$ of the form y_{i,j_i}. Then $|T^j| = q_z(j) < \text{opt}(\mathcal{S})$. By Fact 1, there is $u \in U$ such that $T^j(u) = 1$. By Fact 4, we have $T^z(z^{j \leftarrow u}) = T^j(u) = 1$. Then $F(z^{j \leftarrow u}) = 1$. Since by item 1 in Fact 4, $|z^{j \leftarrow U}| = |U|$, we have

$$\Pr_{\boldsymbol{z} \sim \mathcal{U}(\Omega), \boldsymbol{j} \sim \mathcal{U}(one(\boldsymbol{z})), \boldsymbol{y} \sim \mathcal{U}(\boldsymbol{z}^{\boldsymbol{j} \leftarrow U})}[F(\boldsymbol{y}) = 1 | q_{\boldsymbol{z}}(\boldsymbol{j}) < \text{opt}(\mathcal{S})] \ge \frac{1}{|U|}.$$

Therefore, for $\mathcal{D}'(\boldsymbol{y}) = [\boldsymbol{z} \sim \mathcal{U}(\Omega), \boldsymbol{j} \sim \mathcal{U}(\text{one}(\boldsymbol{z})), \boldsymbol{y} \sim \mathcal{U}(\boldsymbol{z}^{\boldsymbol{j} \leftarrow U})]$

$$\begin{aligned} \Pr_{\mathcal{D}'}[F(\boldsymbol{y}) = 1] \ge & \Pr_{\boldsymbol{z} \sim \mathcal{U}(\Omega), \boldsymbol{j} \sim \mathcal{U}(\text{one}(\boldsymbol{z}))}[q_{\boldsymbol{z}}(\boldsymbol{j}) < \text{opt}(\mathcal{S})] \cdot \\ & \Pr_{\boldsymbol{z} \sim \mathcal{U}(\Omega), \boldsymbol{j} \sim \mathcal{U}(one(\boldsymbol{z})), \boldsymbol{y} \sim \mathcal{U}(\boldsymbol{z}^{\boldsymbol{j} \leftarrow U})}[F(\boldsymbol{y}) = 1 | q_{\boldsymbol{z}}(\boldsymbol{j}) < \text{opt}(\mathcal{S})] \\ \ge & \frac{1}{2|U|}. \end{aligned}$$

◁

▷ Claim 13. Let $\mathcal{S} = (S, U, E)$ be a set cover instance, and let $\ell \ge 5$. If $F : (\{0,1\}^\ell)^n \to \{0,1\}$ is a DNF and $\mathop{\mathbb{E}}_{\boldsymbol{z} \sim \mathcal{U}(\Omega)}[\text{mwidth}_F(\boldsymbol{z})] \le \text{opt}(\mathcal{S})\ell/4$, then $\text{dist}_{\mathcal{D}_\ell}(F, \Gamma_\ell) \ge 1/(8|U|)$.

Proof. If $\Pr_{\boldsymbol{y} \sim \mathcal{U}(\Delta^1_n)}[F(\boldsymbol{y}) \ne 1] \ge 1/(4|U|)$, then by Fact 2, for the event $Y(\boldsymbol{y}) = [\Gamma_\ell(\boldsymbol{y}) = 1]$, we have

$$\text{dist}_{\mathcal{D}_\ell}(\Gamma_\ell, F) \ge \Pr_{\boldsymbol{y} \sim \mathcal{D}_\ell}[\Gamma_\ell(\boldsymbol{y}) \ne F(\boldsymbol{y}) | Y(\boldsymbol{y})] \Pr_{\boldsymbol{y} \sim \mathcal{D}_\ell}[Y(\boldsymbol{y})] = \frac{1}{2} \Pr_{\boldsymbol{y} \sim \mathcal{U}(\Delta^1_n)}[F(\boldsymbol{y}) \ne 1] \ge \frac{1}{8|U|}.$$

If $\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^1)}[F(\boldsymbol{y})\neq 1] < 1/(4|U|)$, then by Fact 2 and 5, and Claim 12,

$$\begin{aligned}
\mathrm{dist}_{\mathcal{D}_\ell}(\Gamma_\ell, F) &\geq \Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[\Gamma_\ell(\boldsymbol{y})\neq F(\boldsymbol{y})|\Gamma_\ell(\boldsymbol{y})=0] \Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[\Gamma_\ell(\boldsymbol{y})=0]\\
&= \frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^0)}[F(\boldsymbol{y})=1]\\
&= \frac{1}{2}\Pr_{\boldsymbol{z}\sim\mathcal{U}(\Delta_n^1),\boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(\boldsymbol{z})),\boldsymbol{y}\sim\mathcal{U}(\boldsymbol{z}^{\boldsymbol{j}\leftarrow U})}[F(\boldsymbol{y})=1]\\
&\geq \frac{1}{2}\Pr_{\boldsymbol{z}\sim\mathcal{U}(\Delta_n^1),\boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(\boldsymbol{z})),\boldsymbol{y}\sim\mathcal{U}(\boldsymbol{z}^{\boldsymbol{j}\leftarrow U})}[F(\boldsymbol{y})=1|F(\boldsymbol{z})=1]\cdot \Pr_{\boldsymbol{z}\sim\mathcal{U}(\Delta_n^1)}[F(\boldsymbol{z})=1]\\
&= \frac{1}{2}\Pr_{\boldsymbol{z}\sim\mathcal{U}(\Omega),\boldsymbol{j}\sim\mathcal{U}(\mathrm{one}(\boldsymbol{z})),\boldsymbol{y}\sim\mathcal{U}(\boldsymbol{z}^{\boldsymbol{j}\leftarrow U})}[F(\boldsymbol{y})=1]\cdot \Pr_{\boldsymbol{z}\sim\mathcal{U}(\Delta_n^1)}[F(\boldsymbol{z})=1]\\
&\geq \frac{1}{2}\frac{1}{2|U|}\left(1-\frac{1}{4|U|}\right)\geq\frac{1}{8|U|}.
\end{aligned}$$

◁

▷ Claim 14. Let F be a size-s DNF formula for $s\geq 2$ such that $\mathrm{dist}_{\mathcal{D}_\ell}(F,\Gamma_\ell)\leq 1/4$, then

$$\mathop{\mathbb{E}}_{\boldsymbol{y}\sim\mathcal{U}(\Omega)}[\mathrm{mwidth}_F(\boldsymbol{y})]\leq 4\log s.$$

Proof. First, we have

$$\begin{aligned}
\frac{3}{4} &\leq \Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F(\boldsymbol{y})=\Gamma_\ell(\boldsymbol{y})]\\
&= \frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F(\boldsymbol{y})=\Gamma_\ell(\boldsymbol{y})|\Gamma_\ell(\boldsymbol{y})=1]+\frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F(\boldsymbol{y})=\Gamma_\ell(\boldsymbol{y})|\Gamma_\ell(\boldsymbol{y})=0]\\
&\leq \frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^1)}[F(\boldsymbol{y})=1]+\frac{1}{2}.
\end{aligned}$$

Therefore, $\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^1)}[F(\boldsymbol{y})=1]\geq 1/2$.

Let $F=T_1\vee T_2\vee\cdots\vee T_s$. For $y\in\Omega$, let $\omega(y)\in[s]$ be the minimum integer such that $\mathrm{mwidth}_F(y)=|(T_{\omega(y)})_{\mathcal{M}}|$ and $T_{\omega(y)}(y)=1$.

Then, by (6),

$$\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Omega)}[T_i(\boldsymbol{y})=1]=\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^1)}[T_i(\boldsymbol{y})=1|F(\boldsymbol{y})=1]=\frac{\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^1)}[T_i(\boldsymbol{y})=1]}{\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^1)}[F(\boldsymbol{y})=1]}\leq 2^{-|(T_i)_{\mathcal{M}}|/2+1}.$$

Now, by the concavity of log,

$$\begin{aligned}
\frac{1}{2}\mathop{\mathbb{E}}_{\boldsymbol{y}\sim\mathcal{U}(\Omega)}[\mathrm{mwidth}_F(\boldsymbol{y})]-1 &= \mathop{\mathbb{E}}_{\boldsymbol{y}\sim\mathcal{U}(\Omega)}\left[\log\left(2^{\mathrm{mwidth}_F(\boldsymbol{y})/2-1}\right)\right]\\
&\leq \log\left(\mathop{\mathbb{E}}_{\boldsymbol{y}\sim\mathcal{U}(\Omega)}\left[2^{\mathrm{mwidth}_F(\boldsymbol{y})/2-1}\right]\right)\\
&= \log\left(\sum_{i\in[s]}2^{|(T_i)_{\mathcal{M}}|/2-1}\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Omega)}[\omega(\boldsymbol{y})=i]\right)\\
&\leq \log\left(\sum_{i\in[s]}2^{|(T_i)_{\mathcal{M}}|/2-1}\Pr_{\boldsymbol{y}\sim\mathcal{U}(\Omega)}[T_i(\boldsymbol{y})=1]\right)\\
&\leq \log\left(\sum_{i\in[s]}2^{|(T_i)_{\mathcal{M}}|/2-1}2^{-|(T_i)_{\mathcal{M}}|/2+1}\right)\\
&= \log s.
\end{aligned}$$

Therefore, $\mathop{\mathbb{E}}_{\boldsymbol{y}\sim\mathcal{U}(\Omega)}[\mathrm{mwidth}_F(\boldsymbol{y})]\leq 4\log s$. ◁

We are now ready to prove Lemma 11

Proof. If $\mathrm{dist}_{\mathcal{D}_\ell}(F,\Gamma_\ell) > 1/4$, then the result follows. Now suppose $\mathrm{dist}_{\mathcal{D}_\ell}(F,\Gamma_\ell) \le 1/4$. If $s = |F| < 2^{\mathrm{opt}(\mathcal{S})\ell/16}$, then by Claim 14, $\mathop{\mathbb{E}}_{\boldsymbol{y}\sim\mathcal{U}(\Omega)}[\mathrm{mwidth}_F(\boldsymbol{y})] \le 4\log s = \mathrm{opt}(\mathcal{S})\ell/4$. Then by Claim 13, $\mathrm{dist}_{\mathcal{D}_\ell}(F,\Gamma_\ell) \ge 1/(8|U|)$. ◀

The proof of Theorem 3 is the same as the proof of Theorem 14 in [10]. We give the proof in Appendix C for completeness.

A Definitions

A.1 Concept Classes

For the lattice $\{0,1\}^n$, and $x, y \in \{0,1\}^n$, we define the partial order $x \le y$ if $x_i \le y_i$ for every i. When $x \le y$ and $x \ne y$, we write $x < y$. If $x < y$, we say that x is *below* y, or y is *above* x. A Boolean function $f : \{0,1\}^n \to \{0,1\}$ is *monotone* if, for every $x \le y$, we have $f(x) \le f(y)$. A *literal* is a variable or negated variable. A *term* is a conjunction ($\wedge$) of literals. A *clause* is a disjunction ($\vee$) of literals. A *monotone term* (resp. clause) is a conjunction (resp. disjunction) of unnegated variables. The *size* of a term T, $|T|$, is the number of literals in the term T. A DNF (resp. CNF) is a disjunction (resp. conjunction) of terms (resp. clauses). The *size* $|F|$ of a DNF (resp. CNF) F is the number of terms (resp. clauses) in F. A *monotone DNF* (resp. monotone CNF) is a DNF (resp. CNF) with monotone terms (resp. clauses).

We define the following classes

1. size-s DNF and size-s Monotone DNF are the classes of DNF and monotone DNF, respectively, of size at most s.
2. size s-DT and size-s Monotone DT are the classes of decision trees and monotone decision trees, respectively, with at most s leaves.
3. k-Junta and Monotone k-Junta are the classes of Boolean functions and monotone Boolean functions that depend on at most k variables.

It is well known that

$$\textsc{Monotone } (\log s)\text{-}\textsc{Junta} \subset \text{ size-}s \textsc{ Monotone DT} \subset \text{ size-}s \textsc{ Monotone DNF} .$$

B Proofs

B.1 Proof of Fact 5

Proof. Denote the above distribution by $\mathcal{D}'$. By Item 1 in Fact 4, if $w \in \Delta_n^1$ and $j \in \text{one}(w)$, then $w^{j\leftarrow U} \subseteq \Delta_n^0$. Therefore, for $z \in \Delta_n^1$, $\Pr_{\boldsymbol{y}\sim\mathcal{D}'}[\boldsymbol{y} = z|\boldsymbol{\xi} = 0] = 0$ and then

$$\Pr_{\boldsymbol{y}\sim\mathcal{D}'}[\boldsymbol{y} = z] = \Pr_{\boldsymbol{\xi}\sim\mathcal{U}(\{0,1\})}[\boldsymbol{\xi} = 1] \cdot \Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta_n^1)}[\boldsymbol{y} = z] = \frac{1}{2|\Delta_n^1|} = \frac{1}{2|\Delta^1|^n}.$$

For $z \in \Delta_n^0$, suppose $z \in \Delta^{u_1} \times \cdots \times \Delta^{u_n}$ where $u \in U$. In the sampling according to $\mathcal{D}'$ and when $\xi = 0$, since for $j \in \text{one}(w)$, the elements of $w^{j\leftarrow U}$ are below w, we have $\Pr_{\boldsymbol{y}\sim\mathcal{D}'}[\boldsymbol{y} = z|\boldsymbol{w} \not> z] = 0$. Therefore,

$$\begin{aligned}\Pr_{\boldsymbol{y}\sim\mathcal{D}'}[\boldsymbol{y} = z] \quad &= \quad \Pr_{\boldsymbol{\xi}\sim\mathcal{U}(\{0,1\})}[\boldsymbol{\xi} = 0] \cdot \Pr_{\boldsymbol{w}\sim\mathcal{U}(\Delta_n^1)}[\boldsymbol{w} > z] \times \\ &\qquad \Pr_{\boldsymbol{j}\sim\mathcal{U}(one(\boldsymbol{w}))}[z \in \boldsymbol{w}^{\boldsymbol{j}\leftarrow U}|\boldsymbol{w} > z, \boldsymbol{w} \in \Delta_n^1] \times \\ &\qquad \Pr_{\boldsymbol{v}\sim\mathcal{U}(\boldsymbol{w}^{\boldsymbol{j}\leftarrow U})}[\boldsymbol{v} = z|z \in \boldsymbol{w}^{\boldsymbol{j}\leftarrow U}]. \end{aligned} \tag{2}$$

Now, since, for $x \in \Delta^0$, the number of elements in Δ^1 that are above x is $\lceil \ell/2 \rceil$, we have that the number of $w \in \Delta_n^1 = (\Delta^1)^n$ that are above $z \in \Delta^{u_1} \times \cdots \times \Delta^{u_n}$ is $\lceil \ell/2 \rceil^{n-\text{wt}(u)}$. Therefore,

$$\Pr_{\boldsymbol{w}\sim\mathcal{U}(\Delta_n^1)}[\boldsymbol{w} > z] = \frac{\lceil \ell/2 \rceil^{n-\text{wt}(u)}}{|\Delta_n^1|}. \tag{3}$$

Now let $w > z$ and $w \in \Delta_n^1$. Since for two different $u, u' \in U$, we have $\prod_{i=1}^n \Delta^{u_i}$ and $\prod_{i=1}^n \Delta^{u'_i}$ are disjoint sets, and since $z \in \Delta^{u_1} \times \cdots \times \Delta^{u_n}$, we have $z \in w^{j\leftarrow U}$ if and only if $z = w^{j\leftarrow u}$. Therefore, the number of elements $j \in \text{one}(w)$ that satisfy $z \in w^{j\leftarrow U}$ is the number of elements $j \in \text{one}(w)$ that satisfy $z = w^{j\leftarrow u}$. This is the number of elements $j \in \text{one}(w)$ that satisfies for every $u_i = 0$, $z_{i,j_i} = 0$. For a j u.a.r. and a fixed i where $u_i = 0$, the probability that z_i and w_i differ only in entry j_i is $1/\lceil \ell/2 \rceil$. Therefore,

$$\Pr_{\boldsymbol{j}\sim\mathcal{U}(one(\boldsymbol{w}))}[z \in \boldsymbol{w}^{\boldsymbol{j}\leftarrow U}|\boldsymbol{w} > z, \boldsymbol{w} \in \Delta_n^1] = \frac{1}{\lceil \ell/2 \rceil^{n-\text{wt}(u)}}. \tag{4}$$

Finally, by item 2 in Fact 4, since $|w^{j\leftarrow U}| = |U|$, we have

$$\Pr_{\boldsymbol{v}\sim\mathcal{U}(\boldsymbol{w}^{j\leftarrow U})}[\boldsymbol{v} = z | z \in \boldsymbol{w}^{j\leftarrow U}] = \frac{1}{|\boldsymbol{w}^{j\leftarrow U}|} = \frac{1}{|U|}. \tag{5}$$

By (2), (3), (4), and (5), we have

$$\Pr_{\boldsymbol{y}\sim\mathcal{D}'}[\boldsymbol{y} = z] = \frac{1}{2}\cdot\frac{\lceil \ell/2\rceil^{n-\mathrm{wt}(u)}}{|\Delta^1_n|}\cdot\frac{1}{\lceil \ell/2\rceil^{n-\mathrm{wt}(u)}}\cdot\frac{1}{|U|} = \frac{1}{2|U|\cdot|\Delta^1_n|} = \frac{1}{2|U|\cdot|\Delta^0|^n}. \quad ◀$$

B.2 Proof of Claim 6

Proof. Let T be a term of monotone size at least $\mathrm{opt}(\mathcal{S})\ell/5$. Let b_i denote the number of unnegated variables of T of the form $y_{i,j}$ and let T_i be their conjunction. Then $T_{\mathcal{M}} = \wedge_{i=1}^n T_i$ and $\sum_{i=1}^n b_i = |T_{\mathcal{M}}| \geq \mathrm{opt}(\mathcal{S})\ell/5$. If, for some i, $b_i > \lceil \ell/2\rceil$, then the term T_i is zero on all $\Delta^0 \cup \Delta^1$, and therefore, T is zero on all $\Delta^0_n \cup \Delta^1_n$. Thus, it can be just removed from F. So, we may assume that $b_i \leq \lceil \ell/2\rceil$ for all i. First,

$$\begin{aligned}
\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[T(\boldsymbol{y}) = 1 | \Gamma_\ell(\boldsymbol{y}) = 1] &= \Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta^1_n)}[T(\boldsymbol{y}) = 1] \leq \Pr_{\boldsymbol{y}\sim\mathcal{U}(\Delta^1_n)}[T_{\mathcal{M}}(\boldsymbol{y}) = 1] \\
&= \prod_{i=1}^n \Pr_{\boldsymbol{y}_i\sim\mathcal{U}(\Delta^1)}[T_i(\boldsymbol{y}_i) = 1] \\
&= \prod_{i=1}^n \frac{\binom{\ell-b_i}{\lceil \ell/2\rceil - b_i}}{\binom{\ell}{\lceil \ell/2\rceil}} \\
&= \prod_{i=1}^n \left(1 - \frac{b_i}{\ell}\right)\left(1 - \frac{b_i}{\ell-1}\right)\cdots\left(1 - \frac{b_i}{\lceil \ell/2\rceil + 1}\right) \\
&\leq \prod_{i=1}^n \prod_{j=\lceil \ell/2\rceil+1}^{\ell} \exp(-b_i/j) = \prod_{i=1}^n \exp\left(-b_i \sum_{j=\lceil \ell/2\rceil+1}^{\ell} 1/j\right) \\
&= \exp\left(-|T_{\mathcal{M}}| \sum_{j=\lceil \ell/2\rceil+1}^{\ell} 1/j\right) \\
&\leq 2^{-|T_{\mathcal{M}}|/2} \leq 2^{-\mathrm{opt}(\mathcal{S})\ell/10}.
\end{aligned} \tag{6}$$

Let F' be the disjunction of all the terms in F of monotone size at most $\mathrm{opt}(\mathcal{S})\ell/5$. Let $T^{(1)}, \ldots, T^{(m)}$ be all the terms of monotone size greater than $\mathrm{opt}(\mathcal{S})\ell/5$ in F. Then, by (6) and the union bound,

$$\begin{aligned}
\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F(\boldsymbol{y}) \neq F'(\boldsymbol{y}) | \Gamma_\ell(\boldsymbol{y}) = 1] &\leq \Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[\vee_{i=1}^m T^{(i)}(\boldsymbol{y}) = 1 | \Gamma_\ell(\boldsymbol{y}) = 1] \\
&\leq 2^{-\mathrm{opt}(\mathcal{S})\ell/10} m \leq 2^{-\mathrm{opt}(\mathcal{S})\ell/20}.
\end{aligned} \tag{7}$$

and (Here we abbreviate $F'(\boldsymbol{y}), F(\boldsymbol{y})$ and $\Gamma_\ell(\boldsymbol{y})$ by F', F and Γ_ℓ)

$$\begin{aligned}
\mathrm{dist}_{\mathcal{D}_\ell}(\Gamma_\ell, F') &= \Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F' \neq \Gamma_\ell] \\
&= \frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F' \neq \Gamma_\ell | \Gamma_\ell = 1] + \frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F' \neq \Gamma_\ell | \Gamma_\ell = 0] \qquad (8)\\
&= \frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F' \neq F | \Gamma_\ell = 1] + \\
&\quad \frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F \neq \Gamma_\ell | \Gamma_\ell = 1] + \frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F' \neq \Gamma_\ell | \Gamma_\ell = 0] \qquad (9)\\
&\leq 2^{-\mathrm{opt}(\mathcal{S})\ell/20} + \frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F \neq \Gamma_\ell | \Gamma_\ell = 1] + \frac{1}{2}\Pr_{\boldsymbol{y}\sim\mathcal{D}_\ell}[F \neq \Gamma_\ell | \Gamma_\ell = 0] \quad (10)\\
&= 2^{-\mathrm{opt}(\mathcal{S})\ell/20} + \mathrm{dist}_{\mathcal{D}_\ell}(\Gamma_\ell, F).
\end{aligned}$$

In (8), we used Fact 2. In (9), we used the probability triangle inequality. In (10), we used (7) and the fact that if $F'(\boldsymbol{y}) \neq 0$, then $F(\boldsymbol{y}) \neq 0$. ◀

C The proof of Theorem 3

Proof. Consider the constant λ in Lemma 2. Let $c = \lambda/6$. Suppose there is a PAC learning algorithm $\mathcal{A}$ for Monotone $(\log s)$-Junta by size-s DNF with $\epsilon = 1/(16n)$ that runs in time $n^{c \log s}$. We show that there is k such that for

$$k' = \frac{1}{2}\left(\frac{\log N}{\log\log N}\right)^{1/k},$$

(k,k')-Set-Cover can be solved in time $N^{5ck} \leq N^{\lambda k}$. By Lemma 2, the result then follows.

Let $\mathcal{S} = (S, U, E)$ be an N-vertex (k,k')-Set-Cover instance where

$$k = \frac{1}{2}\frac{\log\log N}{\log\log\log N} \text{ and } k' = \frac{1}{2}\left(\frac{\log N}{\log\log N}\right)^{1/k}.$$

Consider the following algorithm $\mathcal{B}$

1. Input $\mathcal{S} = (S, U, E)$ an instance for (k,k')-Set-Cover .
2. Construct Γ_5 and $\mathcal{D}_5$.
3. Run $\mathcal{A}$ using Γ_5 and $\mathcal{D}_5$ with $s = 2^{5k}$ and $n = N$. If it runs more than N^{5ck} steps, then output No .
4. Let F be the output DNF.
5. If $|F| > s$ then output No .
6. Estimate $\eta = \mathrm{dist}_{\mathcal{D}_5}(F, \Gamma_5)$.
7. If $\eta \leq \frac{1}{16N}$, output Yes , otherwise output No .

The running time of this algorithm is $N^{5ck} \leq N^{\lambda k}$. Therefore, it is enough to prove the following

▷ Claim 15. Algorithm $\mathcal{B}$ solves (k,k')-Set-Cover .

Proof. Yes case: Let $\mathcal{S} = (S, U, E)$ be a (k,k')-Set-Cover instance and $\mathrm{opt}(\mathcal{S}) \leq k$. Then, $size(\Gamma_5) \leq 2^{5\cdot\mathrm{opt}(\mathcal{S})} \leq 2^{5k} = s$, and by Fact 3, Γ_5 is Monotone $\log s$-Junta. Therefore, w.h.p., algorithm $\mathcal{A}$ learns Γ_5 and outputs a DNF that is $\eta = 1/(16N)$ close to the target with respect to $\mathcal{D}_5$. Since $\mathcal{B}$ terminates $\mathcal{A}$ after N^{5ck} time, we only need to prove that $\mathcal{A}$ runs at most N^{5ck} time.

The running time of $\mathcal{A}$ is

$$n^{c\log s} = N^{c\log s} \leq N^{5ck}.$$

No Case: Let $\mathcal{S} = (S, U, E)$ be a (k, k')-Set-Cover instance and $\text{opt}(\mathcal{S}) > k'$. By Lemma 11, any DNF, F, of size $|F| < 2^{5k'/16}$ satisfies $\text{dist}_{\mathcal{D}_5}(F, \Gamma_5) \geq 1/(8|U|)$. First, we have, for large N

$$k' = \frac{1}{2}\left(\frac{\log N}{\log\log N}\right)^{1/k} > 32k.$$

Therefore, any DNF, F, of size $|F| < 2^{10k}$ satisfies $\text{dist}_{\mathcal{D}_5}(F, \Gamma_5) \geq 1/(8|U|)$.

We have $2^{10k} > s$. So, $\mathcal{B}$ either runs more than N^{5ck} steps and then outputs No in step 3 or outputs a DNF of size more than s and then outputs No in step 4 or outputs a DNF of size at most s with $\text{dist}_{\mathcal{D}_5}(F, \Gamma_5) \geq 1/(8|U|) > 1/(8N) > 1/(16N)$ and outputs No in step 6. ◁

An Embarrassingly Parallel Optimal-Space Cardinality Estimation Algorithm

Emin Karayel
Department of Computer Science, Technische Universität München, Germany

Abstract

In 2020 Błasiok (ACM Trans. Algorithms 16(2) 3:1-3:28) constructed an optimal space streaming algorithm for the cardinality estimation problem with the space complexity of $\mathcal{O}(\varepsilon^{-2}\ln(\delta^{-1}) + \ln n)$ where ε, δ and n denote the relative accuracy, failure probability and universe size, respectively. However, his solution requires the stream to be processed sequentially. On the other hand, there are algorithms that admit a merge operation; they can be used in a distributed setting, allowing parallel processing of sections of the stream, and are highly relevant for large-scale distributed applications. The best-known such algorithm, unfortunately, has a space complexity exceeding $\Omega(\ln(\delta^{-1})(\varepsilon^{-2}\ln\ln n + \ln n))$. This work presents a new algorithm that improves on the solution by Błasiok, preserving its space complexity, but with the benefit that it admits such a merge operation, thus providing an optimal solution for the problem for both sequential and parallel applications. Orthogonally, the new algorithm also improves algorithmically on Błasiok's solution (even in the sequential setting) by reducing its implementation complexity and requiring fewer distinct pseudo-random objects.

1 Introduction

In 1985 Flajolet and Martin [14] introduced a space-efficient streaming algorithm for the estimation of the count of distinct elements in a stream $a_1, \ldots, a_m$ whose elements are from a finite universe U. Their algorithm does not modify the stream, observes each stream element exactly once and its internal state requires space logarithmic in $n = |U|$. However, their solution relies on the model assumption that a given hash function can be treated like a random function selected uniformly from the family of all functions with a fixed domain and range. Despite the ad-hoc assumption, their work spurred a large number of publications[1], improving the space efficiency and runtime of the algorithm. In 1999 Alon et al. [4] identified

[1] Pettie and Wang [33, Table 1] summarized a comprehensive list.

a solution that avoids the ad-hoc model assumption. They use 2-independent families of hash functions, which can be seeded by a logarithmic number of random bits in $|U|$ while retaining a restricted set of randomness properties. Their refined solution was the first rigorous Monte-Carlo algorithm for the problem. Building on their work, Bar-Yossef et al. in 2002 [6], then Kane et al. in 2010 [24] and lastly, Błasiok in 2020 [9][2] developed successively better algorithms achieving a space complexity of $\mathcal{O}(\varepsilon^{-2}\ln(\delta^{-1}) + \ln n)$, which is known to be optimal [23, Theorem 4.4].

Table 1 Important cardinality estimation algorithms.

Year, Author	Space Complexity	Merge
1981, Flajolet and Martin	$\mathcal{O}(\varepsilon^{-2}\ln n)$ for constant δ a)	Yes
1999, Alon et al.	$\mathcal{O}(\ln\ln n)$ for $\delta = 2(\varepsilon+1)^{-1}$	Yes
2002, Bar-Yossef et al.b)	$\mathcal{O}(\ln(\delta^{-1})(\varepsilon^{-2}\ln\ln n + \mathrm{poly}(\ln(\varepsilon^{-1}), \ln\ln n)\ln n))$ c)	Yes
2010, Kane et al.	$\mathcal{O}(\ln(\delta^{-1})(\varepsilon^{-2} + \ln n))$	No
2020, Błasiok	$\mathcal{O}(\ln(\delta^{-1})\varepsilon^{-2} + \ln n)$	No
This work	$\mathcal{O}(\ln(\delta^{-1})\varepsilon^{-2} + \ln n)$	Yes

a) Random oracle model.
b) Algorithm 2 from the publication.
c) The notation $\mathrm{poly}(a, b)$ stands for a term polynomial in a and b.

These algorithms return an approximation Y of the number of distinct elements $|A|$ (for $A := \{a_1, \ldots, a_m\}$) with relative error ε and success probability $1-\delta$, i.e.:

$$\mathcal{P}(|Y - |A|| \le \varepsilon\,|A|) \ge 1 - \delta$$

where the probability is only over the internal random coin flips of the algorithm but holds for all inputs.

Unmentioned in the source material is the fact that it is possible to run the older algorithms by Alon et al. and Bar-Yossef et al. in a parallel mode of operation. This is due to the fact that the algorithms make the random coin flips only in a first initialization step, proceeding deterministically afterwards and that the processing step for the stream elements is commutative. For example, if two runs for sequences a and b of the algorithm had been started with the same coin flips, then it is possible to introduce a new operation that merges the final states of the two runs and computes the state that the algorithm would have reached if it had processed the concatenation of the sequences a and b sequentially.

This enables processing a large stream using multiple processes in parallel. The processes have to communicate at the beginning and at the end to compute an estimate. The communication at the beginning is to share random bits, and the communication at the end is to merge the states. Because there is no need for communication in between, the speed-up is optimal with respect to the number of processes, such algorithms are also called embarrassingly parallel [15, Part 1]. This mode of operation has been called the distributed streams model by Gibbons and Tirthaputra [17]. Besides the distributed streams model, such a merge operation allows even more varied use cases, for example, during query processing in a Map-Reduce pipeline [11]. Figure 1 illustrates two possible modes of operation (among many) enabled by a merge function.

[2] An earlier version of Błasiok's work was presented in the ACM-SIAM Symposium on Discrete Algorithms in 2018. [8]

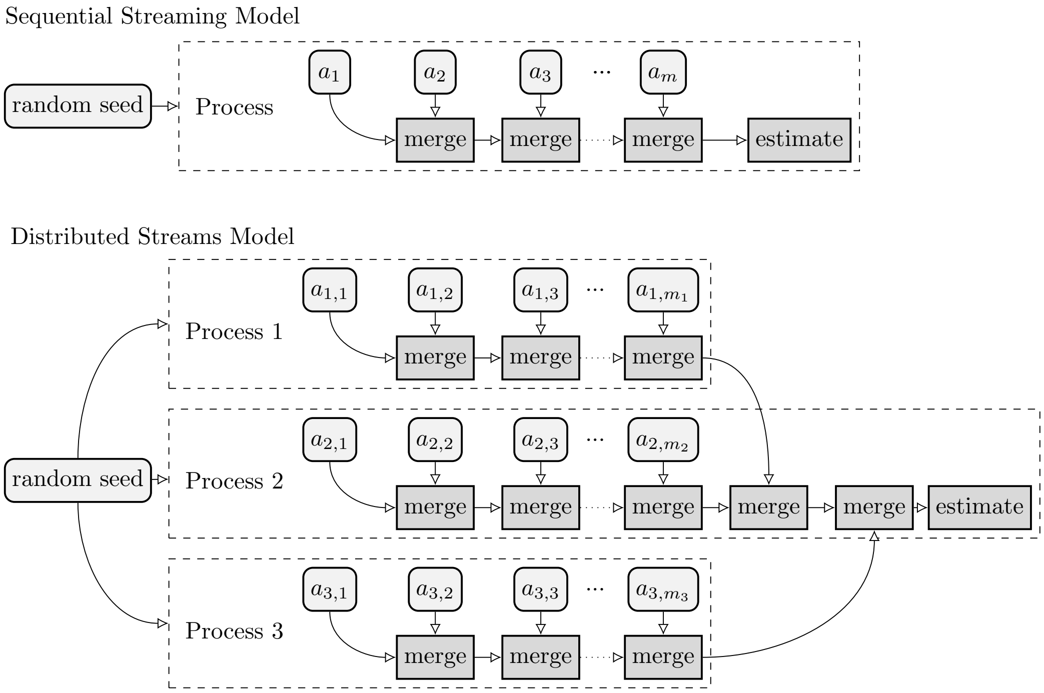

Figure 1 Example use cases for cardinality estimation algorithms that support merge.

However, an extension with such a merge operation is not possible for the improved algorithms by Kane et al. and Błasiok. This is because part of their correctness proof relies inherently on the assumption of sequential execution, in particular, that the sequence of states is monotonically increasing, which is only valid in the sequential case. This work introduces a new distributed cardinality estimation algorithm which supports a merge operation with the same per-process space usage as the optimal sequential algorithm by Błasiok: $\mathcal{O}(\varepsilon^{-2}\ln(\delta^{-1}) + \ln n)$. Thus the algorithm in this work has the best possible space complexity in *both* the sequential and distributed streaming model.[3] (Table 1 provides a summary of the algorithms mentioned here.)

The main idea was to modify the algorithm by Błasiok into a history-independent algorithm. This means that the algorithm will, given the same coin-flips, reach the same state independent of the order in which the stream elements arrive, or more precisely, independent of the execution tree as long as its nodes contain the same set of elements. This also means that the success event, i.e., whether an estimate computed from the state has the required accuracy, only depends on the set of distinct stream elements encountered (during the execution tree) and the initial random coin flips. As a consequence and in contrast to previous work, the correctness proof does not rely on bounds on the probability of certain events over the entire course of the algorithm, but can be established independent of past events.

Błasiok uses a pseudo-random construction based on hash families, expander walks, an extractor based on Parvaresh-Vardy codes [21] and a new sub-sampling strategy [9][Lem. 39]. I was able to build a simpler stack that only relies on hash families and a new two-stage expander graph construction, for which I believe there may be further applications. To summarize – the solution presented in this work has two key improvements:

[3] That the complexity is also optimal for the distributed setting is established in Section 7.

- Supports the sequential *and* distributed streaming model with optimal space.
- Requires fewer pseudo-random constructs, i.e., only hash families and expander walks.

The next section introduces notation. After that, I present new results on expander walks (Section 3) needed in the new pseudo-random construction and a self-contained presentation of the new algorithm and its correctness proof (Sections 5 and 6). Concluding with a discussion of its optimality in the distributed setting (Section 7) and a discussion of open research questions (Section 8). It is worthwhile noting that an extended version of this work [26] is available, which includes more background and more detailed proofs.

The results obtained in this work have also been formally verified [25] using the proof assistant Isabelle [31]. Isabelle has been used to verify many [1] advanced results from mathematics (e.g. the prime number theorem [12]) and computer science (e.g. the Cook-Levin theorem [5]). For readers mainly interested in the actual results, the formalization can be ignored as the theorems all contain traditional mathematical proofs. Nevertheless, Table 3 references the corresponding formalized fact for every theorem in this work.

2 Notation and Preliminaries

General constants are indicated as $C_1, C_2, \cdots$ etc. Their values are fixed throughout this work and are summarized in Table 2. For $n \in \mathbb{N}$, let us define $[n] := \{0, 1, \ldots, n-1\}$. The notation $[P]$ for a predicate P denotes the Iverson bracket, i.e., its value is 1 if the predicate is true and 0 otherwise. The notation $\operatorname{ld} x$ (resp. $\ln x$) stands for the logarithm to base 2 (resp. e) of $x \in \mathbb{R}_{>0}$. The notations $\lfloor x \rfloor$ and $\lceil x \rceil$ represent the floor and ceiling functions: $\mathbb{R} \to \mathbb{Z}$. For a probability space Ω, the notation $\mathcal{P}_{\omega\sim\Omega}(F(\omega))$ is the probability of the event: $\{\omega | F(\omega)\}$. And $\mathbb{E}_{\omega\sim\Omega}(f(\omega))$ is the expectation of f if ω is sampled from the distribution Ω, i.e., $\mathbb{E}_{\omega\sim\Omega}(f(\omega)) := \int_\Omega f(\omega)\, d\omega$. Similarly, $\mathbb{V} f = \mathbb{E}(f - \mathbb{E} f)^2$. For a finite non-empty set S, $U(S)$ is the uniform probability space over S, i.e., $\mathcal{P}(\{x\}) = |S|^{-1}$ for all $x \in S$. (Usually, we will abbreviate $U(S)$ with S when it is obvious from the context.) All probability spaces mentioned in this work will be discrete, i.e., measurability will be trivial.

All graphs in this work are finite and are allowed to contain parallel edges and self-loops. For an ordering of the vertices of such a graph, it is possible to associate an adjacency matrix $A = (a_{ij})$, where a_{ij} is the count of the edges between the i-th to the j-th vertex. We will say it is undirected d-regular if the adjacency matrix is symmetric and all its row (or equivalently) column sums are d. Such an undirected d-regular graph is called a λ-expander if the second largest absolute eigenvalue of its adjacency matrix is at most $d\lambda$.

Given an expander graph G, we denote by $\text{Walk}(G, l)$, the set of walks of length l. For a walk $w \in \text{Walk}(G, l)$ we write w_i for the i-th vertex and $w_{i,i+1}$ for the edge between the i-th and $(i+1)$-th vertex. Because of the presence of parallel edges, two distinct walks may have the same vertex sequence. As a probability space $U(\text{Walk(G,l)})$ corresponds to choosing a random starting vertex and performing an $(l-1)$-step random walk.

3 Chernoff-type estimates for Expander Walks

The following theorem has been shown implicitly by Impagliazzo and Kabanets [22, Th. 10]:

▶ **Theorem 1** (Impagliazzo and Kabanets). *Let $G = (V, E)$ be a λ-expander graph and f a boolean function on its vertices, i.e.: $f : V \to \{0, 1\}$ s.t. $\mu = \mathbb{E}_{v\sim U(V)} f(v)$, $6\lambda \leq \mu$ and $2\lambda < \varepsilon < 1$ then:*

$$\mathcal{P}_{w\sim\text{Walk}(G,l)}\left(\textstyle\sum_{i\in[l]} f(w_i) \geq (\mu + \varepsilon)l\right) \leq \exp(-lD(\mu + \varepsilon || \mu + 2\lambda))$$

Especially, the restriction $\mu \geq 6\lambda$ in the above result causes technical issues since usually one only has an upper bound for μ. The result follows in Impagliazzo and Kabanets work as a corollary from the application of their main theorem [22][Thm. 1] to the hitting property established by Alon et al. [3, Th. 4.2] in 1995. It is easy to improve Theorem 1 by using an improved hitting property:

▶ **Theorem 2** (Hitting Property for Expander Walks). *Let $G = (V, E)$ be a λ-expander graph and $W \subseteq V$, $I \subseteq [l]$ and let $\mu := \frac{|W|}{|V|}$ then:*

$$\mathcal{P}_{w \sim \text{Walk}(G,l)} \left(\bigwedge_{i \in I} w_i \in W \right) \leq (\mu(1-\lambda)+\lambda)^{|I|} \leq (\mu+\lambda)^{|I|}$$

The above theorem for the case where $I = [l]$ is shown by Vadhan [37, Theorem 4.17]. The extended, full version [26] of this manuscript describes how to extend Vadhan's proof to the case where $I \subset [l]$. With the previous result, it is possible to obtain a new, improved version of Theorem 1:

▶ **Theorem 3** (Improved version of Theorem 1). *Let $G = (V, E)$ be a λ-expander graph and f a boolean function on its vertices, i.e.: $f : V \to \{0, 1\}$ s.t. $\mu = \mathbb{E}_{v \sim U(V)} f(v)$ and $\mu + \lambda \leq \gamma \leq 1$ then:*

$$\mathcal{P}_{w \sim \text{Walk}(G,l)} \left(\sum_{i \in [l]} f(w_i) \geq \gamma l \right) \leq \exp\left(-lD\left(\gamma || \mu + \lambda\right)\right)$$

Proof. This follows from Theorem 2 and the generalized Chernoff bound [22][Thm. 1]. ◀

Impagliazzo and Kabanets approximate the divergence $D(\gamma||\mu + \lambda)$ by $2(\gamma - (\mu + \lambda))^2$. In this work, we are interested in the case where $\mu + \lambda \to 0$, where such an approximation is too weak, so we cannot follow that approach. (Note that $D(\gamma||\mu + \lambda)$ can be arbitrarily large, while $(\gamma - (\mu + \lambda))^2$ is at most 1.) Instead, we derive a bound of the following form:

▶ **Lemma 4.** *Let $G = (V, E)$ be a λ-expander graph and f a boolean function on its vertices, i.e.: $f : V \to \{0, 1\}$ s.t. $\mu = \mathbb{E}_{v \sim U(V)} f(v)$ and $\mu + \lambda \leq \gamma < 1$ then:*

$$\mathcal{P}_{w \sim \text{Walk}(G,l)} \left(\sum_{i \in [l]} f(w_i) \geq \gamma l \right) \leq \exp\left(-l(\gamma \ln((\mu+\lambda)^{-1}) - 2e^{-1})\right)$$

Proof. The result follows from Theorem 3 and the inequality: $D(\gamma||p) \geq \gamma \ln(p^{-1}) - 1$ for $0 < \gamma < 1$ and $0 < p < 1$. ◀

An application for the above inequality, where the classic Chernoff-bound by Gillman [18] would not be useful, is establishing a failure probability for the repetition of an algorithm that already has a small failure probability. For example, if an algorithm has a failure probability of δ^*, then it is possible to repeat it $\mathcal{O}\left(\frac{\ln(\delta^{-1})}{\ln((\delta^*)^{-1})}\right)$-times to achieve a failure probability of δ. (This is done in Section 6.) Another consequence of this is a deviation bound for unbounded functions with a sub-gaussian tail bound:

▶ **Lemma 5** (Deviation Bound). *Let $G = (V, E)$ be a λ-expander graph and $f : V \to \mathbb{R}_{\geq 0}$ s.t. $\mathcal{P}_{v \sim U(V)}(f(v) \geq x) \leq \exp(-x(\ln x)^3)$ for $x \geq 20$ and $\lambda \leq \exp(-l(\ln l)^3)$ then*

$$\mathcal{P}_{w \sim \text{Walk}(G,l)} \left(\sum_{i \in [l]} f(w_i) \geq C_1 l \right) \leq \exp(-l)$$

where $C_1 := e^2 + e^3 + (e - 1) \leq 30$.

Note that the class includes sub-gaussian random variables but is even larger. The complete proof is in Appendix A. The proof essentially works by approximating the function f using the Iverson bracket: $f(x) \leq \Sigma_k [e^k \leq f(x) \leq e^{k+1}] e^{k+1}$ and establishing bounds on the frequency of each bracket. For large k this is established using the Markov inequality, and for small k the previous lemma is used. The result is a stronger version of a lemma established by Błasiok [9][Lem. 36], and the proof in this work is heavily inspired by his.

4 Explicit Pseudo-random Constructions

4.1 Strongly explicit expander graphs

For the application in this work, it is necessary to use *strongly explicit expander graphs*. For such a graph, it is possible to sample a random walk without having to represent the graph in memory. Moreover, sampling a random walk from a d-regular graph G with n-vertices is possible using a random sample from $[nd^{l-1}]$, i.e., we can map such a number to a walk algorithmically, such that the resulting distribution corresponds to the distribution from $\text{Walk}(G, l)$ – this allows the previously mentioned two-stage construction.

A possible construction for strongly explicit expander graphs for every vertex count n and spectral bound λ is described by Murtagh et al. [29][Thm. 20, Apx. B]. Note that the degree d in their construction only grows polynomially with λ^{-1}, hence $\ln(d(\lambda)) \in \mathcal{O}(\ln(\lambda^{-1}))$. We will use the notation $\mathcal{E}([n], \lambda, l)$ for the sample space of random walks of length l in the described graph over the vertex set $[n]$. The same construction can also be used on arbitrary finite vertex sets S, if it is straightforward to map $[|S|]$ to S algorithmically. Thus we use the notation $\mathcal{E}(S, \lambda, l)$ for such S. Importantly $|\mathcal{E}(S, \lambda, l)| = |S|\, d(\lambda)^{l-1}$. Thus a walk in such a graph requires $\mathcal{O}(\text{ld}\, |S| + l\, \text{ld}(\lambda^{-1}))$ bits to represent.

4.2 Hash Families

Let us introduce the notation: $\mathcal{H}_k([n], [2^c])$ for the k-independent hash-family [39] from $[n]$ to $[2^c]$. Note that $\text{ld}\,(|\mathcal{H}_k([n], [2^c])|) \in \mathcal{O}(k(c + \ln n))$.

For our application, we will need a second family with a geometric distribution (as opposed to uniform) on the range, in particular such that $\mathcal{P}(f(a) \geq k) = 2^{-k}$. A straightforward method to achieve that is to compose the functions of the hash family $\mathcal{H}_k([2^d], [2^d])$ with the function that computes the number of trailing zeros of the binary representation of its input $[2^d] \to [d]$. We denote such a hash family with $\mathcal{G}_k([2^d])$ where the range is $[d+1]$. Such a hash family is also one for a domain $[n] \subseteq [2^d]$, and hence we can extend the notation: $\mathcal{G}_k([n])$. Note that: $\mathcal{P}_{f \sim G_k([n])}(f(a) \geq k) = 2^{-k}$ for all $k \leq \lceil \text{ld}\, n \rceil$ and also $\text{ld}\,(|\mathcal{G}_k([n])|) \in \mathcal{O}(k \ln n)$.

5 The Algorithm

Because of all the distinct possible execution models, it is best to present the algorithm as a purely functional data structure with four operations:

$$\begin{aligned} \text{init} &: () \to \text{seed} & \text{single} &: [n] \to \text{seed} \to \text{sketch} \\ \text{merge} &: \text{sketch} \to \text{sketch} \to \text{sketch} & \text{estimate} &: \text{sketch} \to \mathbb{R} \end{aligned}$$

The init step should be called only once globally – it is the only random operation – its result forms the seed and must be the same during the entire course of the algorithm. The operation single returns a sketch for a singleton set corresponding to its first argument. The operation merge computes a sketch representing the union of its input sketches and the operation estimate returns an estimate for the number of distinct elements for a given sketch.

The algorithm will be introduced in two successive steps. The first step is a solution that works for $(\ln n)^{-1} \leq \delta < 1$. The sketch requires only $\mathcal{O}(\ln(\delta^{-1})\varepsilon^{-2} + \ln\ln n)$, but the initial coin flips require $\mathcal{O}(\ln n + \ln(\varepsilon^{-1})^2 + \ln(\delta^{-1})^3)$ bits. For $\delta \geq (\ln n)^{-1}$ this is already optimal. In the second step (Section 6) a black-box vectorization of the previous algorithm will be needed to achieve the optimal $\mathcal{O}(\ln(\delta^{-1})\varepsilon^{-2} + \ln n)$ space usage for all $0 < \delta < 1$.

For this entire section let us fix a universe size $n > 0$, a relative accuracy $0 < \varepsilon < 1$, a failure probability $(\ln n)^{-1} \leq \delta < 1$ and define:

$$\begin{array}{ll}
l := \lceil C_6 \ln(2\delta^{-1}) \rceil & b := 2^{\lceil \operatorname{ld}(C_4 \varepsilon^{-2}) \rceil} \\
k := \lceil C_2 \ln b + C_3 \rceil & \lambda := \min\left(\dfrac{1}{16}, \exp(-l(\ln l)^3)\right) \\
\Psi := \mathcal{G}_2([n]) \times \mathcal{H}_2([n],[C_7 b^2]) \times \mathcal{H}_k([C_7 b^2],[b]) & \Omega := \mathcal{E}(\Psi, \lambda, l)
\end{array}$$

The implementation of the operations is presented in Algorithm 1. Note that these are functional programs and pass the state as arguments and results; there is no global (mutable) state. The sketch consists of two parts (B, q). The first part is a two-dimensional table of sizes b and l. The second part is a single natural number, the cut-off level. The function compress is an internal operation and is not part of the public API. It increases the cut-off level and decreases the table values if the space usage is too high.

Algorithm 1 Algorithm for $\delta > (\ln n)^{-1}$.

```
function init() : $\Omega$
    return random $U(\Omega)$

function compress($(B, q) : \mathcal{S}$) : $\mathcal{S}$
    while $\sum_{i \in [l], j \in [b]} \lfloor \operatorname{ld}(B[i,j] + 2) \rfloor > C_5 b l$
        $q \leftarrow q + 1$
        $B[i,j] \leftarrow \max(B[i,j] - 1, -1)$ for $i \in [l], j \in [b]$
    return $(B, q)$

function single($x : U, \omega : \Omega$) : $\mathcal{S}$
    $B[i,j] \leftarrow -1$
    for $i \in [l]$
        $B[i, h(g(x))] = f(x)$ where $(f, g, h) = \omega_i$
    return compress$(B, 0)$

    return median$(Y_0, \ldots, Y_{l-1})$
```

5.1 History-Independence

As mentioned in the introduction, this algorithm is history-independent, meaning that given the initial coin flips, it will reach the same state no matter in which permutation or frequency the stream elements are encountered. More precisely, the final state only depends on the set of encountered distinct elements over the execution tree and the initial coin flips, but not the shape of the tree. Informally, this is easy to see because the chosen cut-off level is the smallest possible with respect to the size of the values in the bins, and that property is maintained because the values in the bins are monotonically increasing with respect to the set of elements in the execution tree. Nevertheless, let us prove the property more rigorously. Let $\omega \in \Omega$ be the initial coin flips. Then there is a function $\tau(\omega, A)$ fulfilling the equations:

$$\begin{aligned} \mathrm{single}(\omega, x) &= \tau(\omega, \{x\}) && (1) \\ \mathrm{merge}(\tau(\omega, A), \tau(\omega, B)) &= \tau(\omega, A \cup B) && (2) \end{aligned}$$

The function τ is defined as follows:

$$\begin{aligned} \tau_0((f,g,h),A) &:= j \to \max\{f(a) \mid a \in A \wedge h(g(a)) = j\} \cup \{-1\} \\ \tau_1(\psi, A, q) &:= j \to \max\{\tau_0(\psi, A) - q, -1\} \\ \tau_2(\omega, A, q) &:= (i,j) \to \tau_1(\omega_i, A, q)[j] \\ q(\omega, A) &:= \min\left\{q \geq 0 \,\middle|\, \textstyle\sum_{i \in [l], j \in [b]} \lfloor \mathrm{ld}(\tau_2(\omega, A, q)[i,j] + 2) \rfloor \leq C_5 bl \right\} \\ \tau_3(\omega, A, q) &:= (\tau_2(\omega, A, q), q) \\ \tau(\omega, A) &:= \tau_3(\omega, A, q(\omega, A)) \end{aligned}$$

The function τ_0 describes the values in the bins if there were no compression, i.e., when $q = 0$. The function τ_1 describes the same for the given cut-off level q. Both are with respect to the selected hash functions $\psi = (f, g, h)$. The function τ_2 represents the state of all tables based on a seed for the expander. The next function τ_3 represents the entire state, which consists of the tables and the cut-off level. The function q represents the actual cut-off level that the algorithm would choose based on the values in the bins. Finally, the full state is described by the function τ for a given seed ω and set of elements A.

▶ **Lemma 6.** *Equations 1 and 2 hold for all $\omega \in \Omega$ and $\emptyset \neq A \subset [n]$.*

Proof. Let us also introduce the algorithms merge_1 and single_1. These are the algorithms merge and single but without the final compression step.

The following properties follow elementarily[4] from the definition of τ, s and the algorithms:

(i) $\tau(\omega, A) = \mathrm{compress}(\tau_3(\omega, A, q))$ for all $0 \leq q \leq q(\omega, A)$
(ii) $\tau_3(\omega, A_1 \cup A_2, \max(q(\omega, A_1), q(\omega, A_2))) = \mathrm{merge}_1(\tau(\omega, A_1), \tau(\omega, A_2))$
(iii) $\tau_3(\{x\}, 0) = \mathrm{single}_1(\omega, x)$
(iv) $q(\omega, A_1) \leq q(\omega, A_2)$ if $A_1 \subseteq A_2$
(v) $q(A) \geq 0$

To verify Eq. 1 we can use i, iii and v and to verify Eq. 2 we use i, ii taking into account that $\max(q(\omega, A_1), q(\omega, A_2)) \leq q(\omega, A_1 \cup A_2)$ because of iv. ◀

[4] The verification relies on the semi-lattice properties of the max operator, as well as its translation invariance (i.e. $\max(a + c, b + c) = \max(a, b) + c$).

5.2 Overall Proof

Because of the argument in the previous section, $\tau(\omega, A)$ will be the state reached after any execution tree over the set A and the initial coin flips, i.e., $\omega \in \Omega$. Hence for the correctness of the algorithm, we only need to show that:

▶ **Theorem 7.** *Let $\emptyset \neq A \subseteq [n]$ then $\mathcal{P}_{\omega \in U(\Omega)} (\text{estimate}(\tau(\omega, A)) - |A| > \varepsilon\, |A|) \leq \delta$.*

Proof: Postponed. This will be shown in two steps: First, we want to establish that the cut-off threshold q will be equal to or smaller than $q_{\max} := \max(0, \lceil \text{ld}\, |A| \rceil - \text{ld}\, b)$ with high probability. And if the latter is true, then the estimate will be within the desired accuracy with high probability. For the second part, we verify that the estimation step will succeed with high probability for all $0 \leq q \leq q_{\max}$. (This will be because the sub-sampling threshold s in the estimation step will be $\geq q_{\max}$ with high probability.)

For the remainder of this section, let $\emptyset \neq A \subset [n]$ be fixed and we will usually omit the dependency on A. For example, we will write $\tau(\omega)$ instead of $\tau(\omega, A)$. Then, we can express the decomposition discussed above using the following chain:

$$\begin{aligned}&\mathcal{P}_{\omega \in \Omega} (|\text{estimate}(\tau(\omega)) - |A|| > \varepsilon\, |A|) \leq \\ &\mathcal{P}_{\omega \in \Omega} (\exists q \leq q_{\max}.\, |\text{estimate}(\tau_2(\omega, q)) - |A|| > \varepsilon\, |A| \vee q(\omega) > q_{\max}) \leq \frac{\delta}{2} + \frac{\delta}{2}\end{aligned} \tag{3}$$

Thus we only have to show the following two inequalities:

- $\mathcal{P}_{\omega \in \Omega} (q(\omega) > q_{\max}) \leq \frac{\delta}{2}$
- $\mathcal{P}_{\omega \in \Omega} (\exists q \leq q_{\max}.\, |\text{estimate}(\tau_2(\omega, q)) - |A|| > \varepsilon\, |A|) \leq \frac{\delta}{2}$

The first will be shown in the following subsection, and the next in the subsequent one.

5.3 Cut-off Level

This subsection proves that the cut-off level will be smaller than or equal to $q_{\max}$. This is the part where the tail estimate for sub-gaussian random variables over expander walks (Lemma 5) is applied:

▶ **Lemma 8.** $\mathcal{P}_{\omega \in \Omega} (q(\omega) > q_{\max}) \leq \frac{\delta}{2}$

Proof. Let us make a few preliminary observations:

$$\lfloor \text{ld}(x+2) \rfloor \leq \text{ld}(x+2) \leq (c+2) + \max(x - 2^c, 0) \text{ for } (-1) \leq x \in \mathbb{R} \text{ and } c \in \mathbb{N}. \tag{4}$$

This can be verified using case distinction over $x \geq 2^c + 2$.

$$\mathbb{E}_{f \sim \mathcal{G}_2([n])} \max(f(a) - q_{\max} - 2^c, 0) \leq 2^{-q_{\max}} 2^{-2^c} \text{ for all } a \in [n] \text{ and } c \in \mathbb{N} \tag{5}$$

Note that this relies on the fact f is geometrically distributed.

$$|A|\, b^{-1} 2^{-q_{\max}} \leq 1 \tag{6}$$

This follows from the definition of $q_{\max}$ via case distinction.

To establish the result, we should take into account that $q(\omega)$ is the smallest cut-off level q fulfilling the inequality: $\sum_{i \in [l], j \in [b]} \lfloor \text{ld}(\tau_2(\omega, q)[i,j] + 2) \rfloor \leq C_5 bl$. In particular, if the inequality is true for $q_{\max}$, then we can conclude that $q(\omega)$ is at most $q_{\max}$, i.e.:

$$\mathcal{P}_{\omega \in \Omega} (q(\omega) > q_{\max}) = \mathcal{P}_{\omega \in \Omega} \left(\sum_{i \in [l], j \in [b]} \lfloor \text{ld}(\tau_2(\omega, q_{\max})[i,j] + 2) \rfloor > C_5 bl \right) \tag{7}$$

Let us introduce the random variable X over the seed space Ψ. It describes the space usage of a single column of the table B:

$$X(\psi) := \sum_{j\in[b]} \lfloor \mathrm{ld}(\tau_1(\psi, q_{\max})[j] + 2) \rfloor$$

Which can be approximated using Eq. 4 as follows:

$$X(\psi) \le \sum_{j\in[b]} c + 2 + \max(\tau_1(\psi, q_{\max})[j] - 2^c, 0) = \sum_{j\in[b]} c + 2 + \max(\tau_0(\psi)[j] - q_{\max} - 2^c, 0)$$

for all $0 \le c \in \mathbb{N}$. Hence:

$$\begin{aligned}
&\mathcal{P}_{\psi\sim\Psi}\left(X(\psi) \ge (c+3)b\right) \le \mathcal{P}_{\psi\sim\Psi}\left(\textstyle\sum_{j\in[b]} \max(\tau_0(\psi)[j] - q_{\max} - 2^c, 0) \ge b\right) \le \\
&\mathcal{P}_{(f,g,h)\sim\Psi}\left(\textstyle\sum_{j\in[b]} \max\{f(a) - q_{\max} - 2^c \mid a \in A \wedge h(g(a)) = j\} \cup \{0\} \ge b\right) \le \\
&\mathcal{P}_{(f,g,h)\sim\Psi}\left(\textstyle\sum_{a\in A} \max(f(a) - q_{\max} - 2^c, 0) \ge b\right) \le \\
&b^{-1} \sum_{a\in A} \mathbb{E}_{(f,g,h)\sim\Psi} \max(f(a) - q_{\max} - 2^c, 0) \le b^{-1}\, |A|\, 2^{-q_{\max}} 2^{-2^c} \le 2^{-2^c}
\end{aligned}$$

where the third and second-last inequality follow from Eq. 5 and 6. It is straightforward to conclude from the latter that for *all* $20 \le x \in \mathbb{R}$:

$$\mathcal{P}_{\psi\sim\Psi}\left(\frac{X(\psi)}{b} - 3 \ge x\right) \le \mathcal{P}_{\psi\sim\Psi}\left(X(\psi) \ge b(\lfloor x\rfloor + 3)\right) \le \exp(-2^{\lfloor x\rfloor} \ln 2) \le e^{-x(\ln x)^3}$$

Hence, it is possible to apply Lemma 5 on the random variables $b^{-1}X(\psi) - 3$ obtaining:

$$\mathcal{P}_{\omega\in\Omega}\left(\textstyle\sum_{i\in[l]} b^{-1}X(h(\omega, i)) - 3 \ge C_1 l\right) \le \exp(-l) \le \frac{\delta}{2}$$

This lemma now follows using $C_5 \ge C_1 + 3$ and that $\sum_{i\in[l]} X(h(\omega, i)) \le C_5 bl$ implies $q(\omega) \le q_{\max}$ as discussed at the beginning of the proof (Eq. 7). ◀

5.4 Accuracy

Let us introduce the random variables:

$$\begin{aligned}
t(f) &:= \max\{f(a) \mid a \in A\} - \mathrm{ld}\, b + 9 & s(f) &:= \max(0, t(f)) \\
p(f, g, h) &:= |\{j \in [b] \mid \tau_1((f, g, h), 0)[j] \ge s(f)\}| & Y(f, g, h) &:= 2^{s(f)} \rho^{-1}(p(f, g, h))
\end{aligned}$$

where $\rho(x) := b(1 - (1 - b^{-1})^x)$ – the expected number of hit bins when x balls are thrown into b bins. Note that the definitions t, p and Y correspond to the terms within the loop in the estimate function under the condition that the approximation threshold q is 0. In particular: $\mathrm{estimate}(\tau_3(\omega, 0)) = \mathrm{median}_{i\in[l]} Y(\omega_i)$ for $\omega \in \Omega$. Moreover, we denote by $R(f)$ the set of elements in A whose level is above the sub-sampling threshold, i.e.: $R(f) := \{a \in A \mid f(a) \ge s(f)\}$. The objective is to show that the individual estimates obtained in the loop in the estimate function (assuming $q = 0$) have the right accuracy and that the threshold $s \ge q_{\max}$ with high probability, i.e.:

$$\mathcal{P}_{\psi\sim\Psi}\left(|Y(\psi) - |A|| > \varepsilon\, |A| \vee s(f) < q_{\max}\right) \le \frac{1}{16} \tag{8}$$

In Lemma 14 this will be generalized to $0 \le q \le q_{\max}$. To be able to establish a bound on the above event, we need to check the likelihood of the following 4 events:

- The computed sub-sampling threshold $s(f)$ is approximately $\operatorname{ld}(|A|)$.
- The size of the sub-sampled elements $R(f)$ is a good approximation of $2^{-s(f)}|A|$.
- There is no collision during the application of g on the sub-sampled elements $R(f)$.
- The count of elements above the sub-sampling threshold in the table is close to the expected number $\rho(R(f))$ (taking collisions due to the application of h into account).

Then it will be possible to conclude that one of the above must fail if the approximation is incorrect. More formally:

$$E_1(\psi) :\leftrightarrow 2^{-16}b \le 2^{-t(f)}|A| \le 2^{-1}b \qquad E_2(\psi) :\leftrightarrow \left||R(f)| - 2^{-s(f)}|A|\right| \le \tfrac{\varepsilon}{3}2^{-s(f)}|A|$$
$$E_3(\psi) :\leftrightarrow \forall a \ne b \in R(f). g(a) \ne g(b) \qquad E_4(\psi) :\leftrightarrow |p(\psi) - \rho(|R(f)|)| \le \tfrac{\varepsilon}{12}|R(f)|$$

for $\psi = (f, g, h) \in \Psi$. The goal is to show all four events happen simultaneously w.h.p.:

$$\mathcal{P}_{\psi\sim\Psi}(\neg E_1(\psi) \vee \neg E_2(\psi) \vee \neg E_3(\psi) \vee \neg E_4(\psi)) \le \frac{1}{16} \tag{9}$$

which can be shown by verifying: $\mathcal{P}_{\psi\sim\Psi}\left(\bigwedge_{j<i} E_j(\psi) \wedge \neg E_i(\psi)\right) \le 2^{-6}$ for each $i \in \{1, \ldots, 4\}$. Let us start with the $i = 1$ case:

▶ **Lemma 9.** $\mathcal{P}_{\psi\in\Psi}(\neg E_1(\psi)) \le 2^{-6}$

Proof. For $X(f) = \max\{f(a) \mid a \in A\}$ it is possible to show:

$$\mathcal{P}_{(f,g,h)\sim\Psi}(X(f) < \operatorname{ld}(|A|) - k - 1) \le 2^{-k} \qquad \mathcal{P}_{(f,g,h)\sim\Psi}(X(f) > \operatorname{ld}(|A|) + k) \le 2^{-k}$$

using the proof for the F_0 algorithm by Alon et al. [4][Proposition 2.3]. The desired result follows taking $k = 7$ and that $t(f) = X(f) - \operatorname{ld} b + 9$. ◀

The following lemma is the interesting part of the proof in this subsection. In previous work, the sub-sampling threshold is obtained using a separate parallel algorithm, which has the benefit that it is straightforward to verify that $|R(f)|$ approximates $2^{-s}|A|$. The drawback is, of course, additional algorithmic complexity and an additional independent hash function. However, in the solution presented here, the threshold is determined from the data to be sub-sampled itself, which means it is not possible to assume independence. The solution to the problem is to show that $|R(f)|$ approximates $2^{-s}|A|$ with high probability for *all* possible values $s(f)$ assuming E_1.

▶ **Lemma 10.** $L := \mathcal{P}_{\psi\sim\Psi}(E_1(\psi) \wedge \neg E_2(\psi)) \le 2^{-6}$

Proof. Let $r(f, t) := |\{a \in A \mid f(a) \ge t\}|$ and $t_{\max}$ be maximal, s.t. $2^{-16}b \le 2^{-t_{\max}}|A|$. Then $2^7 \le \frac{\varepsilon^2}{9}2^{-16}b \le \frac{\varepsilon^2}{9}2^{-t_{\max}}|A|$. Hence: $2^{7+t_{\max}-t} \le \frac{\varepsilon^2}{9}2^{-t}|A| = \frac{\varepsilon^2}{9}\mathbb{E}\, r(f, t)$. Thus:

$$2^{7+t_{\max}-t}\,\mathbb{V}\, r(f, t) \le 2^{7+t_{\max}-t}\,\mathbb{E}\, r(f, t) \le \frac{\varepsilon^2}{9}(\mathbb{E}\, r(f, t))^2$$

for all $0 < t \le t_{\max}$. (This may be a void statement if $t_{\max} \le 0$.) Hence:

$$\mathcal{P}_{(f,g,h)\in\Psi}\left(\exists t. 0 < t \le t_{\max} \wedge |r(f, t) - \mathbb{E}\, r(\cdot, t)| > \frac{\varepsilon}{3}\mathbb{E}\, r(\cdot, t)\right) \le$$
$$\sum_{t=1}^{t_{\max}} \mathcal{P}_{(f,g,h)\in\Psi}\left(|r(f, t) - \mathbb{E}\, r(\cdot, t)| > \sqrt{2^{7+t_{\max}-t}\,\mathbb{V}\, r(f, t)}\right) \le \sum_{t=1}^{t_{\max}} 2^{-7-t_{\max}+t} \le 2^{-6}$$

Note that the predicate $E_2(\psi)$ is always true if $s(f) = 0$ because, in that case, there is no sub-sampling, i.e., $|R(f)| = |A|$. On the other hand if $s(f) > 0$, then $s(f) = t(f) \leq t_{\max}$ assuming $E_1(\psi)$. Hence:

$$\begin{aligned} L &\leq \mathcal{P}_{(f,g,h)} \left(s(f) > 0 \wedge E_1(f,g,h) \wedge \neg E_2(f,g,h) \right) \\ &\leq \mathcal{P}_{(f,g,h)} \left(0 < t(f) \leq t_{\max} \wedge \left| |R(f)| - 2^{-t(f)} |A| \right| > \tfrac{\varepsilon}{3} 2^{-t(f)} |A| \right) \\ &\leq \mathcal{P}_{(f,g,h)} \left(0 < t(f) \leq t_{\max} \wedge \left| r(f,t(f)) - 2^{-t(f)} |A| \right| > \tfrac{\varepsilon}{3} 2^{-t(f)} |A| \right) \leq 2^{-6} \end{aligned}$$

where the last step follows from the previous equation. ◀

$$\text{Note that: } E_1(f,g,h) \wedge E_2(f,g,h) \rightarrow |R(f)| \leq \frac{2}{3} b \text{ for } (f,g,h) \in \Psi \qquad (10)$$

▶ **Lemma 11.** $L := \mathcal{P}_{\psi \sim \Psi}(E_1(\psi) \wedge E_2(\psi) \wedge \neg E_3(\psi)) \leq 2^{-6}$

Proof. Using Eq. 10 we can conclude:

$$\begin{aligned} L &\leq \mathcal{P}_{(f,g,h) \sim \Psi} \left(|R(f)| \leq b \wedge (\exists a < b \in R(f). g(a) = g(b)) \right) \\ &\leq \int_{\mathcal{G}_2([n])} [|R(f)| \leq b] \, \mathcal{P}_{g \sim \mathcal{H}_2([n],[C_7 b^2])} (\exists a < b \in R(f). g(a) = g(b)) \, df \\ &\leq \int_{\mathcal{G}_2([n])} [|R(f)| \leq b] \sum_{a < b \in R(f)} \mathcal{P}_{g \sim \mathcal{H}_2([n],[C_7 b^2])} (g(a) = g(b)) \, df \\ &\leq \int_{\mathcal{G}_2([n])} \frac{b(b-1)}{2 C_7 b^2} \, df \leq \frac{1}{2 C_7} = 2^{-6}. \end{aligned}$$

◀

▶ **Lemma 12.** $L := \mathcal{P}_{\psi \sim \Psi}(E_1(\psi) \wedge E_2(\psi) \wedge E_3(\psi) \wedge \neg E_4(\psi)) \leq 2^{-6}$

Proof. Let $\tilde{R}(f,g,h) = \{ i \in [C_7 b^2] \mid f(a) \geq t(f) \wedge g(a) = i \wedge a \in A \}$ denote the indices hit in the domain $[C_7 b^2]$ by the application of g on the elements above the sub-sampling threshold. If $E_3(f,g,h)$, then $\left| \tilde{R}(f,g,h) \right| = |R(f)|$ and if $E_1(f,g,h) \wedge E_2(f,g,h)$,then $|R(f)| \leq b$ (see Eq. 10). Recalling that $p(\psi)$ is the number of bins hit by the application of k-independent family from $\tilde{R}(\psi) \subseteq [C_7 b^2]$ to $[b]$ we can apply Lemma 20. This implies:

$$\begin{aligned} &\mathcal{P}_{(f,g,h) \sim \Psi} \left(\textstyle\bigwedge_{i \in \{1,2,3\}} E_i(f,g,h) \wedge |p(f,g,h) - \rho(|R(f)|)| \geq \frac{\varepsilon}{12} |R(f)| \right) \leq \\ &\mathcal{P}_{\psi \sim \Psi} \left(\left| \tilde{R}(\psi) \right| \leq b \wedge \left| p(\psi) - \rho\left(\left| \tilde{R}(\psi) \right| \right) \right| \geq \frac{\varepsilon}{12} \left| \tilde{R}(\psi) \right| \right) \leq \\ &\mathcal{P}_{\psi \sim \Psi} \left(\left| \tilde{R}(\psi) \right| \leq b \wedge \left| p(\psi) - \rho\left(\left| \tilde{R}(\psi) \right| \right) \right| \geq 9 b^{-1/2} \left| \tilde{R}(\psi) \right| \right) \leq 2^{-6} \end{aligned}$$

where we used, that $b \geq 9^2 12^2 \varepsilon^{-2}$ (i.e. $C_4 >= 9^2 12^2$). ◀

▶ **Lemma 13.** *Equation 8 is true.*

Proof. Let us start by observing that $E_1(\psi) \wedge E_2(\psi) \wedge E_4(\psi) \rightarrow |A^*(\psi) - |A|| \leq \varepsilon |A|$. This is basically an error propagation argument. First note that by using Eq. 10: $p(f,g,h) \leq \rho(R(f)) + \frac{\varepsilon}{12} |R(f)| \leq \rho(\frac{2}{3} b) + \frac{1}{12} |R(f)| \leq \frac{41}{60} b$. Moreover, using the mean value theorem:

$$\left| \rho^{-1}(p(f,g,h)) - |R(f)| \right| = (\rho^{-1})'(\xi) \, |p(f,g,h) - \rho(|R(f)|)| \leq \tfrac{\varepsilon}{3} |R(f)|$$

for some ξ between $\rho(|B(f)|)$ and $p(f,g,h)$ where we can approximate $(\rho^{-1})'(\xi) < 4$. Hence:

$$\begin{aligned}\left|\rho^{-1}(p(f,g,h)) - 2^{-s(f)}\,|A|\right| &\leq \left|\rho^{-1}(p(f,g,h)) - |R(f)|\right| + \left||R(f)| - 2^{-s(f)}\,|A|\right| \\ &\leq \frac{\varepsilon}{3}\,|R(f)| + \left||R(f)| - 2^{-s(f)}\,|A|\right| \\ &\leq \left(\frac{2\varepsilon}{3} + \frac{\varepsilon^2}{9}\right) 2^{-s(f)}\,|A| \leq \varepsilon 2^{-s(f)}\,|A|\end{aligned}$$

It is also possible to deduce that $E_1(f,g,h) \to t(f) \geq \lceil \mathrm{ld}(|A|)\rceil - \mathrm{ld}\, b \to s(f) \geq q_{\max}$. Using Lemma 9 to 12 we can conclude that Equation 9 is true. And the implications derived here show that then Equation 8 must be true as well. ◀

To extend the previous result to the case: $q \leq q_{\max}$, let us introduce the random variables:

$$\begin{aligned} t_c(\psi,q) &:= \max\{\tau_1(\psi,q)[j] + q \mid j \in [b]\} - \mathrm{ld}\, b + 9 & s_c(\psi,q) &:= \max(0, t_c(\psi,q)) \\ p_c(\psi,q) &:= |\{j \in [b] \mid \tau_1(\psi,q)[j] + q \geq s_c(\psi,q)\}| & Y_c(\psi,q) &:= 2^{s_c(\psi,q)}\rho^{-1}(p_c(\psi,q))\end{aligned}$$

These definitions t_c, p_c and Y_c correspond to the terms within the loop in the estimate function for arbitrary q.

▶ **Lemma 14.** $\mathcal{P}_{\psi\sim\Psi}\left(\exists q \leq q_{\max}.\, |Y_c(\psi,q) - |A|| > \varepsilon\,|A|\right) \leq \frac{1}{16}$

Proof. It is possible to see that $t_c(\psi,q) = t(\psi)$ if $q \leq t(\psi)$. This is because $\tau_1(\psi,q) + q$ and $\tau_1(\psi,0)$ are equal except for values strictly smaller than q. With a case distinction on $t(\psi) \geq 0$ it is also possible to deduce that $s(\psi,q) = s(\psi)$ if $q \leq s(\psi)$. Hence: $p_c(\psi,q) = p(\psi)$ and $Y_c(\psi,q) = Y(\psi)$ (for $q \leq s(\psi)$). Thus this lemma is a consequence of Lemma 13. ◀

▶ **Lemma 15.** $L := \mathcal{P}_{\omega\in\Omega}\left(\exists q \leq q_{\max}.\, |\mathrm{estimate}(\tau_2(\omega,q)) - |A|| > \varepsilon\,|A|\right) \leq \frac{\delta}{2}$

Proof. Because the median of a sequence will certainly be in an interval, if more than half of the elements are in it, we can approximate the left-hand side as:

$$\begin{aligned} L &\leq \mathcal{P}_{\omega\in\Omega}\left(\exists q \leq q_{\max}.\, \sum_{i\in[l]} [|Y(\omega_i,q) - |A|| > \varepsilon\,|A|] \geq \frac{l}{2}\right) \\ &\leq \exp\left(-l\left(\frac{1}{2}\ln\left(\left(\frac{1}{16}+\frac{1}{16}\right)^{-1}\right) - 2e^{-1}\right)\right) \leq \exp\left(-\frac{l}{4}\right) \leq \frac{\delta}{2}\end{aligned}$$

The second inequality follows from Lemma 4 and 14 as well as $\lambda \leq \frac{1}{16}$. ◀

Proof of Theorem 7. Follows from Lemma 8 and the previous lemma, as well as the reasoning established in Equation 3. ◀

5.5 Space Usage

It should be noted that the data structure requires an efficient storage mechanism for the levels in the bins. We need to store the table values in a manner in which the number of bits required for a value x is proportional to $\ln x$. A simple strategy would be to store each value using a prefix-free universal code and concatenating the encoded variable-length bit strings.[5] A well-known universal code for positive integers is the Elias-gamma code, which

[5] Note that a vector of prefix-free values can be decoded even if they are just concatenated.

requires $2\lfloor \operatorname{ld} x \rfloor + 1$ bits for $x \geq 1$ [13]. Since, in our case, the values are integers larger or equal to (-1), they can be encoded using $2\lfloor \operatorname{ld}(x+2) \rfloor + 1$ bits.[6] In combination with the condition established in the compress function of Algorithm 1 the space usage for the table is thus $(2C_5 + 1)bl \in \mathcal{O}(bl) \subseteq \mathcal{O}(\ln(\delta^{-1})\varepsilon^2)$. Additionally, the approximation threshold needs to be stored. This threshold is a non-negative integer between 0 and $\operatorname{ld} n$ requiring $\mathcal{O}(\ln \ln n)$ bits to store. In summary, the space required for the sketch is $\mathcal{O}(\ln(\delta^{-1})\varepsilon^2 + \ln \ln n)$. For the coin flips, we need to store a random choice from Ω, i.e., we need to store $\ln(|\Omega|)$ bits. The latter is in $\mathcal{O}(\ln(|\Omega|)) \subseteq \mathcal{O}(\ln(|\Psi|) + l \ln(\lambda^{-1})) \subseteq \mathcal{O}(\ln n + \ln(\varepsilon^{-1})^2 + \ln(\delta^{-1})^3)$. Overall the total space for the coin flips and the sketch is $\mathcal{O}(\ln(\delta^{-1})\varepsilon^{-2} + \ln n + \ln(\delta^{-1})^3)$.

6 Extension to small failure probabilities

The data structure described in the previous section has a space complexity that is close but exceeds the optimal $\mathcal{O}(\ln(\delta^{-1})\varepsilon^{-2} + \ln n)$. The main reason this happens is that, with increasing length of the random walk, the spectral gap of the expander is increasing as well – motivated by the application of Lemma 5 in Subsection 5.3, with which we could establish that the cut-level could be shared between all tables. A natural idea is to restrict that.

If δ^{-1} is smaller than $\ln n$ the term $(\ln(\delta^{-1}))^3$ in the complexity of the algorithm is not a problem because it is dominated by the $\ln n$ term. If it is larger, we can split the table into sub-groups and introduce multiple cut-levels. Hence a single cut-level would be responsible for a smaller count of tables, and thus the spectral gap would be lower. (See also Figure 2).

A succinct way to precisely prove the correctness of the proposal is to repeat the previous algorithm, which has only a single shared cut-level, in a black-box manner for the same universe size and accuracy but for a higher failure probability. The seeds of each repetition are selected again using an expander walk. Here the advantage of Lemma 4 is welcome, as the inner algorithm needs to have a failure probability depending on n – the natural choice is $(\ln n)^{-1}$. The length of the walk of the inner algorithm matches the number of bits of the cut-level $\mathcal{O}(\ln \ln n)$. The repetition count of the outer algorithm is then $\mathcal{O}\left(\frac{\ln(\delta^{-1})}{\ln \ln n}\right)$.

▶ **Theorem 16.** *Let $n > 0$, $0 < \varepsilon < 1$ and $0 < \delta < 1$. Then there exists a cardinality estimation data structure for the universe $[n]$ with relative accuracy ε and failure probability δ with space usage $\mathcal{O}(\ln(\delta^{-1})\varepsilon^{-2} + \ln n)$.*

Proof. If $\delta^{-1} < \ln n$, then the result follows from Theorem 7 and the calculation in Subsection 5.5. Moreover, if $n < \exp(e^5)$, then the theorem is trivially true, because there is an exact algorithm with space usage $\exp(e^5) \in \mathcal{O}(1)$. Hence we can assume $e^5 \leq \ln n \leq \delta^{-1}$. Let Ω^*, single*, merge* and estimate* denote the seed space and the API of Algorithm 1 for the universe $[n]$, relative accuracy ε and failure probability $\delta^* := (\ln n)^{-1}$. Moreover, let $m := \left\lceil 4\frac{\ln(\delta^{-1})}{\ln \ln n} \right\rceil$ – the plan is to show that with these definitions Algorithm 2 fulfills the conditions of this theorem. Let $\nu(\theta, A)[i] := \tau^*(\theta_i, A)$ for $i \in [m]$ and $\theta \in \Theta := U(\mathcal{E}(\Omega^*, \delta^*, m))$. Then it is straightforward to check that:

$$\operatorname{single}(\theta, x) = \nu(\theta, \{x\}) \qquad \operatorname{merge}(\nu(\theta, A), \nu(\theta, B)) = \nu(\theta, A \cup B)$$

for $x \in [n]$ and $\emptyset \neq A, B \subseteq [n]$ taking into account Lemma 6. Hence the correctness follows if: $\mathcal{P}_{\theta \in \Theta}(|\operatorname{estimate}(\nu(\theta, A)) - |A|| > \varepsilon |A|) \leq \delta$. Because the estimate is the median of the individual estimates, this is true if at least half of the individual estimates are in the desired range. Similar to the proof of Lemma 15 we can apply Lemma 4. This works if

[6] There are more sophisticated strategies for representing a sequence of variable-length strings that allow random access. [7]

$$\exp\left(-m\left(\frac{1}{2}\ln\left((\delta^* + \delta^*)^{-1}\right) - 2e^{-1}\right)\right) \leq \delta$$

which follows from $m \geq 4\ln(\delta^{-1})(\ln\ln n)^{-1}$ and $\ln\ln n \geq 5$. The space usage for the seed is: $\ln|\Theta| \in \mathcal{O}(\ln n + \ln(\varepsilon^{-1})^2 + (\ln((\delta^*)^{-1}))^3 + m\ln((\delta^*)^{-1})) \subseteq \mathcal{O}(\ln n + \ln(\varepsilon^{-1})^2 + \ln(\delta^{-1}))$. The space usage for the sketch is: $\mathcal{O}(m\ln((\delta^*)^{-1})\varepsilon^{-2} + m\ln\ln n) \subseteq \mathcal{O}(\ln(\delta^{-1})\varepsilon^{-2} + \ln\ln n)$. ◀

Algorithm 2 Algorithm for $0 < \delta < (\ln n)^{-1}$.

```
function init() : $\Theta$
    return random $U(\Theta)$

function single($x : U, \theta : \Theta$) : $\mathcal{S}$
    $D[i] = \text{single}^*(x, \theta_i)$ for $i \in [m]$
    return $D$

function merge($D_a : \mathcal{S}, D_b : \mathcal{S}$) : $\mathcal{S}$
    $D[i] \leftarrow \text{merge}^*(D_a[i], D_b[i])$ for $i \in [m]$
    return $D$

function estimate($D : \mathcal{S}$) : $\mathbb{R}$
    $Y_i \leftarrow \text{estimate}^*(D[i])$ for $i \in [m]$
    return median($Y_0, \ldots, Y_{m-1}$)
```

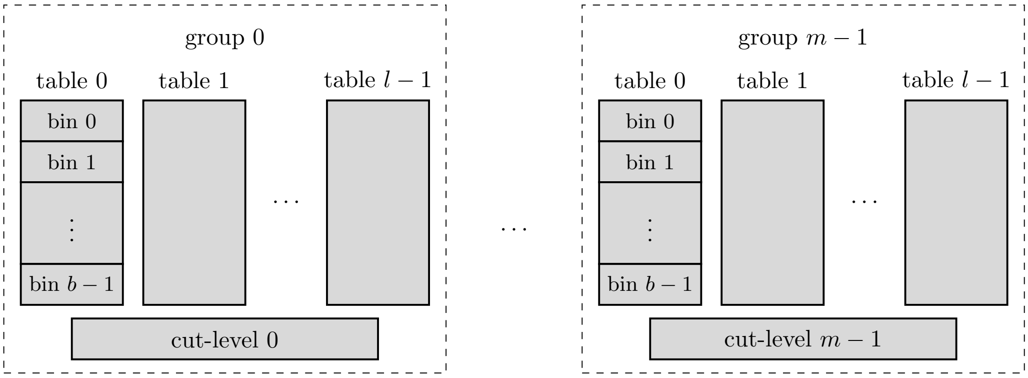

Figure 2 Schematic representation of the states of Algorithm 2 with $m \in \mathcal{O}\left(\frac{\ln(\delta^{-1})}{\ln\ln n}\right)$ repetitions of the inner algorithm. The inner algorithm uses $b \in \mathcal{O}(\varepsilon^{-2})$ bins and $l \in \mathcal{O}(\ln\ln n)$ tables.

7 Optimality

The optimality of the algorithm introduced by Błasiok [9] follows from the lower bound established by Jayram and Woodruff [23, Theorem 4.4]. The result (as well as its predecessors [4, 40]) follows from a reduction to a communication problem. This also means that their theorem is a lower bound on the information the algorithm needs to retain between processing successive stream elements.

An immediate follow-up question to Theorem 16 is whether the space usage is also optimal in the distributed setting. Let us assume there are p processes, each retaining m stream elements, and they are allowed to communicate at the beginning, before observing the stream elements, and after observing all stream elements. Even with these relaxed constraints, the number of bits that each process will need to maintain will be the same as the minimum number of bits of a sequential streaming solution. This follows by considering a specific subset of the input set where except for process 0, the stream elements on all the other processes are equal to the last stream element of process 0. In particular, the information the processes $1, 2, \ldots, p-1$ have is 0 bits from the perspective of process 0. If our distributed hypothetical algorithm is correct, it can only be so if the worst-case space usage per process is $\Omega(\ln(\delta^{-1})\varepsilon^{-2} + \ln n)$.

8 Conclusion

A summary of this work would be that for the space complexity of cardinality estimation algorithms, there is no gap between the distributed and sequential streaming models. Moreover, it is possible to solve the problem optimally (in either model) with expander graphs and hash families without using code-based extractors (as they were used in previous work). The main algorithmic idea is to avoid using a separate rough estimation data structure for quantization (cut-off); instead, the cut-off is guided by the space usage. During the estimation step at the end, an independent rough estimate is still derived, but it may be distinct from the cut-off reached at that point. This is the main difference between this solution and the approach by Kane et al. [24]. The main mathematical idea is to take the tail estimate based on the Kullback-Leibler divergence for random walks on expander graphs, first noted by Impagliazzo and Kabanets [22, Th. 10] seriously. With which, it is possible to achieve a failure probability of δ using $\mathcal{O}\left(\frac{\ln(\delta^{-1})}{\ln((\delta^*)^{-1})}\right)$ repetitions of an inner algorithm with a failure probability $\delta^* > \delta$. Note that the same cannot be done with the standard Gillman-type Chernoff [18] bounds. This allows the two-stage expander construction that we needed. As far as I can tell, this strategy is new and has not been used before.

An interesting question is whether the two-stage expander construction can somehow be collapsed into a single stage. For that, it is best to consider the following non-symmetric aggregate:

$$\mathcal{P}_{\omega \in \mathcal{E}(\mathcal{E}(S, \exp(-l(\ln l)^3), l), \exp(-l/m), m)} \left(\sum_{i \in [m]} \left[\sum_{j \in [l]} X(\omega_{ij}) \geq C_1 \right] \geq \frac{m}{2} \right) \leq \exp(-\mathcal{O}(lm))$$

where X may be an unbounded random variable with, e.g., sub-gaussian distribution. Indeed, the bound on the count of too-large cut-off values from Algorithm 2 turns out to be a tail estimate of the above form. I tried to obtain such a bound using only a single-stage expander walk but did not succeed without requiring too large spectral gaps, i.e., with $\lambda^{-1} \in \mathcal{O}(1)$ for $m \ll l$. There is a long list of results on more advanced Chernoff bounds for expander walks [2, 28, 30, 34, 35, 38] and investigations into more general aggregation (instead of summation) functions [10, 16, 19, 20, 32, 36], but I could not use any of these results/approaches to avoid the two-stage construction. This suggests that either there are more advanced results to be found or multi-stage expander walks are inherently more powerful than single-stage walks.

A Proof of Lemma 5

▶ **Lemma 5** (Deviation Bound). *Let* $G = (V, E)$ *be a* λ*-expander graph and* $f : V \to \mathbb{R}_{\geq 0}$ *s.t.* $\mathcal{P}_{v\sim U(V)}(f(v) \geq x) \leq \exp(-x(\ln x)^3)$ *for* $x \geq 20$ *and* $\lambda \leq \exp(-l(\ln l)^3)$ *then*

$$\mathcal{P}_{w\sim \mathrm{Walk}(G,l)}\left(\textstyle\sum_{i\in[l]} f(w_i) \geq C_1 l\right) \leq \exp(-l)$$

where $C_1 := e^2 + e^3 + (e-1) \leq 30$.

Proof. Let $\mu_k := \mathbb{E}_{v\sim V}[e^k \leq f(v)] \leq \exp(-e^k k^3)$ for $k \geq 3$. We will show

$$L_k := \mathcal{P}_{w\sim \mathrm{Walk}(G,l)}\left(\sum_{i\in[l]} [e^k \leq f(w_i)] \geq l e^{-k} k^{-2}\right) \leq \exp(-l-k+2) \text{ for all } k \geq 3 \quad (11)$$

by case distinction on the range of k:

Case $k \geq \max(\ln l, 3)$: In this case the result follows using Markov's inequality. Note that the random walk starts from and remains in the stationary distribution, and thus for any index $i \in [l]$ the distribution of the i-th walks step w_i will be uniformly distributed over V, hence:

$$\begin{aligned} L_k &\leq e^k k^2 l^{-1}\,\mathbb{E}_{w\sim \mathrm{Walk}(G,l)} \textstyle\sum_{i\in[l]}[e^k \leq f(w_i)] = e^k k^2\,\mathbb{E}_{v\sim V}[e^k \leq f(v)] \\ &\leq e^k k^2 \exp(-e^k k^3) = \exp(k + 2\ln k - e^k k^3) \leq \exp(2k - e^k(k^2+2)) \\ &\leq \exp(2k - e^k k^2 - e^k - e^k) \leq \exp(-l-k+2) \end{aligned}$$

Here we use that $k^3 \geq k^2 + 2$ and $e^k \geq k$ for $k \geq 3$ and $e^k \geq l$.

Case $3 \leq k < \ln l$: Then we have

$$\begin{aligned} L_k &\leq \exp\left(-l(e^{-k}k^{-2}\ln((\mu_k+\lambda)^{-1}) - 2e^{-1})\right) \text{ using Lemma 4} \\ &\leq \exp\left(-l(e^{-k}k^{-2}(e^k k^3 - \ln 2) - 2e^{-1})\right) \leq \exp\left(-l(k - e^{-k}k^{-2}\ln 2 - 2e^{-1})\right) \\ &\leq \exp\left(-l(k-1)\right) \leq \exp\left(-l-k+2\right) \end{aligned}$$

Concluding the proof of Eq. 11.

Note that:

$$\begin{aligned} \sum_{i\in[l]} f(w_i) &\leq e^2 l + \sum_{i\in[l]}\sum_{k\geq 2} e^{k+1}[e^k \leq f(w_i) < e^{k+1}] \\ &\leq e^2 l + \sum_{i\in[l]}\left(\sum_{k\geq 2} e^{k+1}[e^k \leq f(w_i)] - \sum_{k\geq 2} e^{k+1}[e^{k+1} \leq f(w_i)]\right) \\ &\leq (e^2+e^3)l + (e-1)\sum_{i\in[l]}\left(\sum_{k\geq 3} e^k [e^k \leq f(w_i)]\right) \end{aligned}$$

Hence:

$$\begin{aligned}\mathcal{P}_{w\sim\mathrm{Walk}(G,l)}\left(\sum_{i\in[l]} f(w_i)\geq C_1 l\right) &\leq \mathcal{P}_{w\sim\mathrm{Walk}(G,l)}\left(\sum_{k\geq 3, i\in[l]} e^k[e^k\leq f(w_i)]\geq l\right)\\ &\leq \mathcal{P}_{w\sim\mathrm{Walk}(G,l)}\left(\bigvee_{k\geq 3}\sum_{i\in[l]}[e^k\leq f(w_i)]\geq le^{-k}k^{-2}\right)\\ &\leq \sum_{k\geq 3} L_k \leq \sum_{k\geq 3}\exp\left(-l-k+2\right)\leq \exp(-l).\end{aligned}$$ ◀

B Balls and Bins

Let $\Omega = U([r]\to[b])$ be the uniform probability space over the functions from $[r]$ to $[b]$ for $b\geq 1$ and $0\leq r\leq b$ and let $X(\omega) = |\omega([r])|$ be the size of the image of such a function. This models throwing r balls into b bins independently, where X is the random variable counting the number of hit bins. Moreover, let $E_i(\omega) = \{\omega \mid i\in\omega([r])\}$ be the event that the bin i was hit. Note that $X(\omega) = \sum_{i\in[b]} E_i(\omega)$. And we want to show that

$$\mathbb{E}_{\omega\sim\Omega} X(\omega) = b\left(1-\left(1-\frac{1}{b}\right)^r\right) \qquad \mathbb{V}_{\omega\sim\Omega} X(\omega)\leq \frac{r(r-1)}{b}$$

▶ **Lemma 17.** $\mathbb{E}_{\omega\sim\Omega} X(\omega) = b\left(1-\left(1-\frac{1}{b}\right)^r\right)$

The proof is available in the full version [26].

▶ **Lemma 18.** $\mathbb{V}_{\omega\sim\Omega} X(\omega)\leq\frac{r(r-1)}{b}$

The proof is available in the full version [26]. The above is a stronger version of the result by Kane et al. [24][Lem. 1]. Their result has the restriction that $r\geq 100$ and a superfluous factor of 4.

Interestingly, it is possible to obtain a similar result for k-independent balls into bins. For that let Ω' be a probability space of functions from $[r]$ to $[b]$ where

$$\mathcal{P}_{\omega\sim\Omega'}\left(\bigwedge_{i\in I}\omega(i) = x(i)\right) = r^{-|I|}$$

for all $I\subset[r]$, $|I|\leq k$ and all $x: I\to[b]$. As before let us denote $X'(\omega) := |\omega([r])|$ the number of bins hit by the r balls. Then the expectation (resp. variance) of X' approximates that of X with increasing independence k, more precisely:

▶ **Lemma 19.** *If* $\varepsilon\leq e^{-2}$ *and* $k\geq 1+5\ln(b\varepsilon^{-1})(\ln(\ln(b\varepsilon^{-1})))^{-1}$ *then:*

$$|\mathbb{E}_{\omega'\in\Omega'} X'(\omega') - \mathbb{E}_{\omega\in\Omega} X(\omega)|\leq\varepsilon r \qquad |\mathbb{V}_{\omega'\in\Omega'} X'(\omega') - \mathbb{V}_{\omega\in\Omega} X(\omega)|\leq\varepsilon^2\,.$$

This has been shown[7] by Kane et al. [24][Lem. 2]. The proof relies on the fact that $X = \sum_{i\in[b]}\max(1, Y_i)$ where Y_i denotes the random variable that counts the number of balls in bin i. It is possible to show that $\mathbb{E}(Y_i)^j = \mathbb{E}(Y_i')^j$ for all $j\leq k$ (where Y_i' denotes the same notion over Ω'). Their approach is to approximate $\max(1,\cdot)$ with a polynomial g of

[7] Without the explicit constants mentioned in here.

degree k. Since $\mathbb{E}\, g(Y_i) = \mathbb{E}\, g(Y'_i)$ they can estimate the distance between $\mathbb{E}\, X$ and $\mathbb{E}\, X'$ by bounding the expectation of each approximation error: $g(Y_i) - \max(1, Y_i)$. Obviously, larger degree polynomials (and hence increased independence) allow better approximations. The reasoning for the variance is analogous.

▶ **Lemma 20.** *If $k \geq C_2 \ln b + C_3$ then:*

$$L := \mathcal{P}_{\omega' \in \Omega'} \left(|X'(\omega') - \rho(r)| > 9b^{-1/2} r \right) \leq 2^{-6}$$

Proof. This follows from Lemma 17, 18 and the previous lemma for $\varepsilon = \min(e^{-2}, b^{-1/2})$ in particular: $\mathbb{V}\, X' \leq \mathbb{V}\, X + \frac{1}{b} \leq \frac{r^2}{b}$ and hence:

$$\begin{aligned} L &\leq \mathcal{P}_{\omega' \in \Omega'} \left(|X'(\omega') - \mathbb{E}\, X'| + |\mathbb{E}\, X' - \rho(r)| \geq 9b^{-1/2} r \right) \\ &\leq \mathcal{P}_{\omega' \in \Omega'} \left(|X'(\omega') - \mathbb{E}\, X'| + b^{-1/2} r \geq 9b^{-1/2} r \right) \\ &\leq \mathcal{P}_{\omega' \in \Omega'} \left(|X'(\omega') - \mathbb{E}\, X'| \geq 8b^{-1/2} r \right) \\ &\leq \mathcal{P}_{\omega' \in \Omega'} \left(|X'(\omega') - \mathbb{E}\, X'| \geq 8\sqrt{\mathbb{V}\, X'} \right) \leq 2^{-6} \end{aligned}$$

where the last line follows from Chebychev's inequality. ◀

D Formalization

As mentioned in the introduction the proofs in this work have been machine-checked using Isabelle. They are available [25, 27] in the AFP (Archive of Formal Proofs) [1] – a site hosting formal proofs verified by Isabelle. Table 3 references the corresponding facts in the AFP entries. The first column refers to the lemma in this work. The second is the corresponding name of the fact in the formalization. The formalization can be accessed in two distinct forms: As a source repository with distinct theory files, as well as two "literate-programming-style" PDF documents with descriptive text alongside the Isabelle facts (optionally with the proofs). The latter is much more informative. The third column of the table refers to the file name [8] of the corresponding source file, while the last column contains the reference of the AFP entry, including the section in the PDF versions.

[8] `Distributed_Distinct_Elements` is abbreviated by `DDE` and `Without` with `WO`.

Abstract

A circuit $\mathcal{C}$ samples a distribution $\boldsymbol{X}$ with an error ε if the statistical distance between the output of $\mathcal{C}$ on the uniform input and $\boldsymbol{X}$ is ε. We study the hardness of sampling a uniform distribution over the set of n-bit strings of Hamming weight k denoted by $\boldsymbol{U}^n_k$ for *decision forests*, i.e. every output bit is computed as a decision tree of the inputs. For every k there is an $O(\log n)$-depth decision forest sampling $\boldsymbol{U}^n_k$ with an inverse-polynomial error [26, 11]. We show that for every $\varepsilon > 0$ there exists τ such that for decision depth $\tau \log(n/k)/\log\log(n/k)$, the error for sampling $\boldsymbol{U}^n_k$ is at least $1-\varepsilon$. Our result is based on the recent robust sunflower lemma [1, 23].

Our second result is about matching a set of n-bit strings with the image of a d-*local* circuit, i.e. such that each output bit depends on at most d input bits. We study the set of all n-bit strings whose Hamming weight is at least $n/2$. We improve the previously known locality lower bound from $\Omega(\log^* n)$ [5] to $\Omega(\sqrt{\log n})$, leaving only a quartic gap from the best upper bound of $O(\log^2 n)$.

1 Introduction

Studying the hardness of sampling has been proposed in the paper [26], which spurred an active line of research [27, 21, 3, 28, 29, 30, 14, 31, 6, 8]. The basic setting is the following: we are given an infinite supply of independent uniform random bits as input, and our goal is to design a circuit with multiple output bits whose output is close in statistical distance to a given target distribution. Sampling circuit constructions have been applied in

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

cryptography [18, 7] and algorithms [15]. Sampling hardness results[1] have been instrumental in inspiring and improving two-source extractor constructions [28, 9, 10] (see [30] for an extended discussion), and have yielded lower bounds on succinct data structures [26, 30, 31].

Sampling hardness results are more challenging than computational ones. For example, while it is known since Smolensky's classical work [25] that parity requires an exponential number of gates to compute by an $\mathbf{AC}^0[3]$ circuit, no hard distributions are known for the circuit class $\mathbf{AC}^0[p]$ for any p, and while $\mathbf{AC}^0$ requires exponentially many gates to compute parity [17], a random vector with parity 0 can be sampled by an $\mathbf{NC}^0$ circuit. Moreover, this distribution can be sampled by a 2-local circuit, in the sense that each output bit depends only on two input bits [2, 19]. A very simple mapping achieves this: $(x_1, \dots, x_n) \mapsto (x_1, x_1 \oplus x_2, x_2 \oplus x_3, \dots, x_{n-1} \oplus x_n, x_n)$. A more general and striking fact is that $\mathbf{AC}^0$ can sample random permutations and all distributions of form $(\boldsymbol{X}, f(\boldsymbol{X}))$ where $\boldsymbol{X}$ is uniform over $\{0,1\}^n$ and f is *symmetric* i.e. its value depends only on the Hamming weight of the input [26].

We conjecture that the power of $\mathbf{NC}^0$ in regard to sampling symmetric distributions is in essence limited to the parity example above. Observe that a function is computable by an $\mathbf{NC}^0$ circuit if and only if it is $O(1)$-*local* i.e. each of its output bits depends on at most a constant number of input bits. For simplicity, we focus only on uniform distributions with symmetric support: let $\boldsymbol{U}^n_S$ be the uniform distribution over strings in $\{0,1\}^n$ with Hamming weight in the set $S \subseteq \{0, \dots, n\}$.

▶ **Conjecture 1.** *For every $d \in \mathbb{N}, \varepsilon \in (0,1)$ for all large enough n, if $\boldsymbol{X}$ is samplable by a d-local function and is ε-close to $\boldsymbol{U}^n_S$ for some $S \subseteq \{0, \dots, n\}$, then $\boldsymbol{X}$ is $O(\varepsilon)$-close to $\boldsymbol{U}^n_T$, where T is one of the following: $\{0\}, \{n\}, \{0, n\}, \{0, 2, 4, \dots\}, \{1, 3, 5, \dots\}, [n]$.*

Our results on sampling slices (namely, Theorem 2) imply this conjecture for all sets S which only contain small values, in the sense that $\max_{x \in S} x = o(n)$.

Quantum separations

A stronger version of Conjecture 1 would identify the family of sets S such that every $\mathbf{NC}^0$-samplable distribution is $1 - o(1)$-far from $\boldsymbol{U}^n_S$. There exists a set S for which this implies a separation between $\mathbf{NC}^0$ and $\mathbf{QNC}^0$ for sampling. This is due to the recent partial separation in [32]: they show that there exists a symmetric function f such that $(\boldsymbol{X}, f(\boldsymbol{X}))$ for uniform $\boldsymbol{X} \sim \{0,1\}^n$ can be sampled by a $\mathbf{QNC}^0$ circuit. Observe, however, that if an $\mathbf{NC}^0$-samplable distribution $\boldsymbol{Y}$ is at distance η from $(\boldsymbol{X}, f(\boldsymbol{X}))$, then the first n bits of $\boldsymbol{Y}$ are $(1/2 + \eta + o(1))$-close to the uniform distribution over $f^{-1}(0)$, due to the fact that the function f used in [32] is almost balanced (in the sense that $|f^{-1}(0)| = (1 + o(1)) \cdot |f^{-1}(1)|$). Now, if the uniform distribution over $f^{-1}(0)$ is not $\mathbf{NC}^0$-samplable within the distance $1 - \Omega(1)$, we get the separation. Conjecture 1 implies a weaker lower bound for the distance: a constant instead of a function approaching 1, but most of the known lower bounds for distribution sampling have very strong distance guarantees.

Local certificates

One interesting class of sets which is also not covered by our and prior results is $M_a = \{x \in \{0, \dots, n\} \mid x \bmod a = 0\}$, where a is a constant. However, the simple construction for sampling parity-0 vectors can be adapted to *match the support* of any $\boldsymbol{U}^n_{M_a}$, i.e. generate

[1] That is, showing that any circuit from a certain class produces a distribution that is far from the target.

a (not necessarily uniform) distribution whose support is exactly the set of strings with Hamming weight in M_a. This construction was given in [5, Proposition 3.1], where it was presented as a *proof system*. The idea is to interpret the input bits as a *certificate* that the output is in the target language (in this case, all n-bits strings whose Hamming weight is divisible by a). This connection motivates our study of locality in the context of proof systems. We drastically simplify and improve the locality lower bound of [20] for the language of n-bit strings whose Hamming weight is at least $n/2$ (in other words, 1-inputs of the majority function).

1.1 Notation

We use boldface letters for random variables, e.g. $\boldsymbol{a}, \boldsymbol{A}, \boldsymbol{b}, \boldsymbol{B}$. We write $\boldsymbol{a} \sim A$ to say that $\boldsymbol{a}$ is distributed according to a distribution A, or if A is a set, according to the uniform distribution over it. For $x \in \{0,1\}^n$, we denote its Hamming weight by $w(x) = |x| \coloneqq \{i \in [n] \mid x_i = 1\}$. We denote $e_i = 0^{i-1}10^{n-i} \in \{0,1\}^n$. For a string $x \in \{0,1\}^n$ and a set $T \subseteq [n]$, we write $x_T \coloneqq (x_i)_{i \in T} \in \{0,1\}^T$. We write $\boldsymbol{U}_k^n$ for the uniform distribution of Hamming weight k vectors.

For two distributions S and T over the same domain $\mathcal{X}$, the *statistical distance* is defined as

$$\Delta(S,T) \coloneqq \max_{A \subseteq \mathcal{X}} \left| \Pr_{\boldsymbol{x} \sim S}[\boldsymbol{x} \in A] - \Pr_{\boldsymbol{x} \sim T}[\boldsymbol{x} \in A] \right| = \frac{1}{2} \sum_{a \in \mathcal{X}} \left| \Pr_{\boldsymbol{x} \sim S}[\boldsymbol{x} = a] - \Pr_{\boldsymbol{x} \sim T}[\boldsymbol{x} = a] \right|.$$

The statistical distance between two random variables is the statistical distance between their distributions. We say that the distribution S is *ε-close* from the distribution T if $\Delta(S,T) < \varepsilon$. Otherwise, the distributions are *ε-far.*

We say that an input bit $i \in [m]$ *affects* an output bit $j \in [n]$, or equivalently that the output bit j *depends* on the input bit i, if there exist inputs $x, x' \in \{0,1\}^m$, differing only in the ith bit, such that $f(x)_j \neq f(x')_j$. A function $f\colon \{0,1\}^m \to \{0,1\}^n$ is *d-local* if each of its output bits depends only on d input bits. A function $f\colon \{0,1\}^m \to \{0,1\}^n$ has *decision depth d* if each of its output bits can be computed as a depth-d decision tree, i.e. decided with at most d adaptive input bit queries. If a function is d-local, then it has decision depth at most d.

1.2 Sampling Slices

The *k-slice* is the set of all n-bit strings of Hamming weight k. We denote the uniform distribution over the k-slice by $\boldsymbol{U}_k^n$. A simple computation (see Section 3.5) shows that $\boldsymbol{U}_S^n$ and $\boldsymbol{U}_{\max S}^n$ are close in statistical distance whenever $\max S = o(n)$. This means that in order to show the hardness of sampling from symmetric distributions over sublinear-Hamming-weight strings it is sufficient to study $\boldsymbol{U}_k^n$ for $k = o(n)$.

Although in the context of Conjecture 1 it is sufficient to lower bound the locality of a sampler, in the context of slices the more natural complexity measure is *decision depth.* A function $f\colon \{0,1\}^m \to \{0,1\}^n$ is computable by a *decision forest* of depth d if every output bit of f can be computed by a decision tree of depth d, i.e. with at most d *adaptive* queries to the input (in contrast, a d-local function is computed by d *non-adaptive* queries). Viola [26, Lemma 6.4] shows that a decision depth d sampler for $\boldsymbol{U}_k^n$ can be obtained from a depth-d *switching network.* Czumaj [11, Theorem 3.7] proves the existence of such switching networks with $d = O(\log n)$. The following theorem shows that for $k = o(n)$, this construction is almost tight.

▶ **Theorem 2.** *Suppose that $\boldsymbol{U}_k^n$ can be sampled with decision depth d and error η in variation distance.*

1. *For every $\varepsilon > 0$ there exists a constant τ such that $d \leq \tau \log(n/k)/\log\log(n/k)$ implies $\eta \geq 1 - \varepsilon$.*
2. *There exists a constant τ for which the following holds. For every $\varepsilon \in (0, 1)$, if $k \in [\log_2 n, 2^{\log^{1-\varepsilon} n}]$ and $d \leq \tau \log^{\varepsilon} n$, then $\eta = 1 - n^{-\Omega(k)}$. The same bound holds for $k \in [1, \log_2 n)$ and $d \leq \tau \log^{\varepsilon} n/\log\log n$.*

Moreover, Item 1 holds for any $\boldsymbol{U}_S^n$ with $\max_{x \in S} x = k$ or $\min_{x \in S} x = n - k$.

The first key observation in our proof of Theorem 2 is that it is sufficient to prove it for $k = 1$, namely:

▶ **Theorem 3.** *There exists a constant $\tau > 0$ such that any distribution sampled with decision depth $\tau \log n/\log\log n$ is $(1 - n^{-\Omega(1)})$-far from $\boldsymbol{U}_1^n$.*

To see why this implies Item 1, observe that the marginal distribution of the first n/k bits of $\boldsymbol{U}_k^n$ is $(1 - 1/e + o(1))$-close to $\boldsymbol{U}_1^{n/k}$. Theorem 3 then implies the distance lower bound $1/e - o(1)$ for sampling $\boldsymbol{U}_k^n$ with depth $\tau \log(n/k)/\log\log(n/k)$. The $1 - \varepsilon$ distance lower bound for every ε is achieved by generalizing Theorem 3 so it applies to distributions of the form "first $\Theta(n/k)$ bits of $\boldsymbol{U}_k^n$" directly.

Item 2 is implied by another reduction from Theorem 3. Suppose we have a depth-d sampler for $\boldsymbol{U}_k^n$. Using this sampler, we can construct a depth-kd sampler for $\boldsymbol{U}_1^{\binom{n}{k}}$ as follows. Identify each output bit with a unique subset of $[n]$ of size k, and assign to it the conjunction of the corresponding k bits in the output of the sampler for $\boldsymbol{U}_k^n$. It is easy to see that the resulting distribution has the same distance to $\boldsymbol{U}_1^{\binom{n}{k}}$ as the initial sampler has to $\boldsymbol{U}_k^n$.

Technique for Proving Theorem 3

The locality of a sampler is the maximum number of input bits that an output bit depends on. The locality is always bounded from above by the decision depth. As a warm-up, let us discuss an $\Omega(\log\log n)$ locality lower bound for sampling $\boldsymbol{U}_1^n$ which is close in spirit to [30, Theorem 3].

The main idea in the locality lower bound is a *hitting set* versus *independent set* dichotomy: for a d-local source, it is easy to see that either there are $\tau 2^d$ independent output bits, or there is a hitting set of input bits of size $\tau d 2^d$ such that every output bit depends on one of the bits in this set. In the former case, we can show that it is very likely that at least two of the independent bits evaluate to 1, since for each output bit its probability to be 1 is at least 2^{-d}.[2] In the latter case, by fixing the hitting set bits in every possible way, we observe that our source is a mixture (convex combination) of $2^{\tau d 2^d}$ many $(d-1)$-local sources. If we show that $(d-1)$-local sources must be $(1-\varepsilon)$-far from the target distribution, then our source is $(1 - \varepsilon 2^{\tau d 2^d})$-far by [30, Corollary 18]. Picking $d = \delta \log\log n$ for small enough δ yields a $1 - o(1)$ lower bound on the distance to the target distribution.

In order to improve this lower bound from $\log\log n$ to $\log n/\log\log n$, we introduce several new ideas.

[2] There is a caveat that some bits might be identically zero, but it is not a real issue, since there cannot be too many of them.

Monotonization. We observe that it is in some sense sufficient to deal with sources where each bit is a *monotone term* in the input bits. The intuitive reason is that the expected number of output bits evaluating to 1 is $2^{-d} \cdot n$ (again, this is not always true, since there are identically zero outputs), so there exists an assignment where that many bits evaluate to 1. By focusing on those bits and replacing them with terms corresponding to the satisfying assignments, we show that it is likely that at least two of these terms evaluate to 1.

Sunflowers. Let us pretend that all of the output bits are monotone terms. For $i \in [n]$, let N_i be the set of inputs mentioned by the term of the ith output bit. We find a sunflower $\mathcal{S} \subseteq \{N_1, \dots, N_n\}$, i.e. there exists a kernel K such that the intersection of any pair of sets in $\mathcal{S}$ is K. If the kernel is fixed to 1, the output bits in the sunflower become independent, so if the sunflower is large enough, it is likely that at least two of them evaluate to 1. For some small enough $d = \Omega(\sqrt{\log n})$, a large sunflower always exists among any n sets. Moreover, we can cover all but $o(n)$ output bits with sunflowers. Then we have the following dichotomy: either all kernels evaluate to 0, so the source is likely to be identically zero, or at least one kernel evaluates to 1, which makes it very likely that at least two output bits from the corresponding sunflower evaluate to 1.

Using *robust sunflowers* instead of classical sunflowers, we obtain a lower bound of $\Omega(\log n/\log\log n)$ on the decision depth.

1.3 Local Proof Systems

Local proof systems, introduced in [5] and further studied in [20], are defined as follows: a local proof system for a language L is an $\mathbf{NC}^0$-circuit family C_n such that $L \cap \{0,1\}^n$ is exactly the set of all possible outputs of C_n. A language L has a *d-local* proof system if for each n there exists a d-local function whose image is $L \cap \{0,1\}^n$. In relation to the sampling, it can be viewed as follows: the "sampler" needs to match the support of the given distribution exactly, but we do not care about matching the actual probabilities.

The hardness landscape in this setting is different from the setting of sampling distributions. The most notable difference is that the language of strings with Hamming weight divisible by p always has an $O(1)$-local proof system, while we conjecture that sampling from the uniform distribution over this language requires a super-constant locality, unless $p = 1$ or $p = 2$.

Our main contribution is in improving the locality lower bound for another symmetric language: $\textsc{Maj}^{-1}(1) := \{x \in \{0,1\}^n \mid |x| \geq n/2\}$. The previous best locality lower bound for proof systems for this language was $\Omega(\log^* n)$ [20], with a very complex proof which we expose in Appendix B. We simplify this proof and improve the locality lower bound to $\Omega(\sqrt{\log n})$, which is only polynomially smaller than the current best upper bound of $O(\log^2 n)$. The key idea is to consider proof systems with bounded locality of both input and output bits. For such proof systems it is easy to derive very strong requirements on locality. These can then be used to count the number of input-output bit pairs where the input affects the output, which yields the output locality lower bounds.

1.4 Switching Networks

The technique behind Theorem 2 breaks down for linear slices $\boldsymbol{U}^n_{\alpha n}$. Does it mean there is a low-depth sampler for such distributions? The only construction of a sampler we have is based on switching networks [11, Theorem 3.7].

A switching network of depth d is a layered graph with d layers and n nodes in each layer. The edges of the switching network do not cross between layers, and in each layer, the edges form a partial matching. A switching network defines a process over permutations of $[n]$: we start with the identity permutation, and then, for each layer, we toss a coin for each edge in the matching of this layer, and if the coin comes up heads, we transpose the endpoints of the edge.

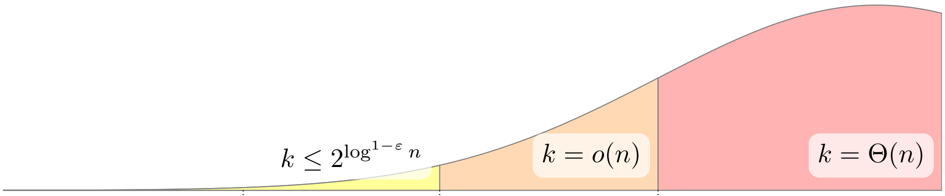
Currently, the best upper bound on the depth of a switching network which produces a distribution close to the uniform distribution over all permutations is $O(\log^2 n)$ [11]. The situation is better if the switching network only needs to shuffle sequences of zeroes and ones: the input is now $1^k 0^{n-k}$. [11, Theorem 3.7] gives a $O(\log n)$ depth upper bound for this case (the construction is randomized), [13] gives an *explicit* lower bound for generating $\boldsymbol{U}_k^n$ for $k \leq \sqrt{n}$.

It is almost immediate that a switching network that samples $\boldsymbol{U}_k^n$ within a non-trivial distance must have depth $\Omega(\log(n/k))$: each input bit of a network of depth d has at most 2^d potential positions that it can take in the output, so if $d = o(\log(n/k))$, the switching network produces a distribution where only $o(n)$ bits have a non-zero probability to have value 1, which is $(1 - o(1))$-far from $\boldsymbol{U}_k^n$.

In Appendix A we show that switching networks that produce a distribution close to $\boldsymbol{U}_{\alpha n}^n$ must have depth $\Omega(\log \log n)$. We use the following properties of samplers that are constructed from switching networks of depth d: the first is that each input bit of such a sampler affects at most 2^d output bits, the second is that the error is one-sided, i.e. such a sampler never outputs a string outside the domain of $\boldsymbol{U}_{\alpha n}^n$. The second property highlights the similarity with local certificates, and indeed our lower bound proof uses similar ideas.

1.5 Further Research

Our results on sampling slices with decision forests taken together with results of Viola [26] are summarized in Figure 1.



Theorem 2	$d = \tilde{\Omega}(\log^{\varepsilon} n)$ $\Delta = 1 - n^{-\Omega(k)}$	$d = \tilde{\Omega}(\log(n/k))$ $\Delta = 1 - \delta$	
[26, Thm 1.6]			$\Delta = 2^{-O(d)} - O(1/n)$

Figure 1 The table above depicts the implications of Theorem 2 and [26, Theorem 1.6] for sampling $\boldsymbol{U}_k^n$ for different k. The plot above it illustrates the size of the corresponding set of bitstrings in the boolean cube.

Here are some important challenges that are left open:

- Give any non-trivial decision depth (or even locality!) lower bound for linear Hamming weight in the constant-error regime. For a non-dyadic α[3] an $\omega(1)$ decision depth lower bound for sampling $\boldsymbol{U}_{\alpha n}^n$ follows (in a not completely straightforward way) from the new separator theorem in [31]: the key idea is to use the fact that biases of all bits of a distribution generated by a decision forest all have form $a/2^d$, so they are $\Theta(2^{-d})$-off from any non-dyadic number. The challenge is to show any non-trivial lower bound for, say $\boldsymbol{U}_{n/2}^n$ or $\boldsymbol{U}_{n/4}^n$, where the bit biases can be matched exactly by a decision forest.

[3] That is, not representable in the form $a/2^t$ for integers a and t, e.g. $1/3$.

- Tighten up the decision depth lower bound for $\boldsymbol{U}_1^n$ to $\Omega(\log n)$. This would immediately yield tight (up to a constant) decision depth lower bounds for all polynomial k.
- Give any locality lower bound for $(\boldsymbol{X}, f(\boldsymbol{X}))$, where $\boldsymbol{X} \sim \{0,1\}^n$ and $f = [(x_1 + \cdots + x_n) \bmod p \geq p/2] \oplus x_1 \oplus \cdots \oplus x_n$, as this would separate quantum and classical $\mathbf{NC}^0$ circuits for sampling, improving on the partial separation of [32].
- Find any non-trivial lower bounds for sampling a uniform vector with Hamming weight divisible by k, for any $k > 2$. This is likely to give insights on the $\mathbf{QNC}^0$ versus $\mathbf{NC}^0$ separation for sampling.
- Determine the optimal depth of a switching network that samples a uniform permutation or a uniform vector in a slice.

2 Tools

In this section, we describe two off-the-shelf tools we use in our proof.

2.1 FKG inequality

▶ **Theorem 4** ([16, 12]). *Suppose that X is a product distribution over $\{0,1\}^n$ (that is, $\Pr[X = x] = \prod_{i \in [n]} \Pr[X_i = x_i]$). Let $A, B \subseteq \{0,1\}^n$ be two monotone events (if $x \in A$ and $x_i \leq y_i$ for all $i \in [n]$ then $y \in A$, and similarly for B). Then*

$$\Pr_{\boldsymbol{x} \sim X}[\boldsymbol{x} \in A \cap B] \geq \Pr_{\boldsymbol{x} \sim X}[\boldsymbol{x} \in A] \cdot \Pr_{\boldsymbol{x} \sim X}[\boldsymbol{x} \in B].$$

2.2 Robust Sunflowers

In this section, we discuss robust sunflowers.

▶ **Definition 5** (Robust sunflower). *Let $0 < \alpha, \beta < 1$ be parameters, let $\mathcal{F}$ be a set system over a finite universe, and let $K := \bigcap_{S \in \mathcal{F}} S$ be the intersection of all sets in $\mathcal{F}$, which we refer to as the* kernel. *The family $\mathcal{F}$ is an (α, β)-*robust sunflower *if*

1. *$K \notin \mathcal{F}$;*
2. *$\Pr_{\boldsymbol{R}}[\exists S \in \mathcal{F} \colon S \subseteq \boldsymbol{R} \cup K] \geq 1 - \beta$, where each element of the universe appears in $\boldsymbol{R}$ with probability α independently.*

   We can write this condition in the equivalent form $\Pr_{\mathbf{R}}[\exists S \in \mathcal{F} \colon \mathbf{R} \supseteq S \mid \mathbf{R} \supseteq K] \geq 1 - \beta$.

*A set system is called (α, β)-*satisfying *if it is an (α, β)-robust sunflower with an empty kernel.*

Large enough set systems always contain a robust sunflower, as proved by Rossman [24] and improved by later authors.

▶ **Theorem 6** ([1, 4, 23]). *There exists a constant $B > 0$ such that the following holds for all $p, \varepsilon \in (0, 1/2]$. Let $\mathcal{F}$ be a family of sets of size exactly d such that $|\mathcal{F}| \geq (B \log(d/\varepsilon)/p)^d$. Then $\mathcal{F}$ contains a (p, ε)-robust sunflower.*

▶ **Corollary 7.** *There exists a constant $B > 0$ such that the following holds for all $p, \varepsilon \in (0, 1/2]$. Let $\mathcal{F}$ be a family of non-empty sets of size* at most *d such that $|\mathcal{F}| \geq d \cdot (B \log(d/\varepsilon)/p)^d$. Then $\mathcal{F}$ contains a (p, ε)-robust sunflower.*

Proof. Let $d_0 \in [d]$ be the most common size of sets in $\mathcal{F}$. Then the number of sets of size d_0 is at least $(B \log(d/\varepsilon)/p)^d$, which allows us to apply Theorem 6 to these sets. ◀

If we remove a single petal from a robust sunflower, then it remains a robust sunflower (with slightly worse parameters).

▶ **Lemma 8.** *Suppose that $N_1, \dots, N_k \subseteq X$ is a (p, ε)-robust sunflower with kernel K. Then for every i, the sets $N_1, \dots, N_{i-1}, N_{i+1}, \dots, N_k$ form a $(2p, 2\varepsilon)$-robust sunflower with kernel K.*

Proof. Let $\boldsymbol{\tau}$ be distributed over $[3]^{X \setminus K}$ such that $\Pr[\boldsymbol{\tau}_i = 1] = \Pr[\boldsymbol{\tau}_i = 2] = p$, $\Pr[\boldsymbol{\tau}_i = 3] = 1 - 2p$, and the coordinates of $\boldsymbol{\tau}$ are independent. For $\ell \in [3]$, let $\boldsymbol{\tau}^\ell = \{j \in X \mid \boldsymbol{\tau}_j = \ell\} \cup K$. The definition of (p, ε)-robust sunflower implies that for every $\ell \in [2]$ we have $\Pr[\exists j \in [k] \colon \boldsymbol{\tau}^\ell \supseteq N_j] \geq 1 - \varepsilon$. An application of the union bound implies that

$$\Pr\left[\exists j \in [k] \colon \boldsymbol{\tau}^1 \supseteq N_j \wedge \exists j' \in [k] \colon \boldsymbol{\tau}^2 \supseteq N_{j'}\right] \geq 1 - 2\varepsilon.$$

If $j = j'$, then since $\boldsymbol{\tau}^1 \cap \boldsymbol{\tau}^2 = K$, we have $N_j = K$, which is impossible by the definition of a sunflower. Thus $j \neq j'$ whenever the event happens. Let $\boldsymbol{R}$ be a distribution of subsets of X where each element appears in $\boldsymbol{R}$ independently with probability $2p$. Then since $(\boldsymbol{R} | \boldsymbol{R} \supseteq K)$ has the same distribution as $\boldsymbol{\tau}^1 \cup \boldsymbol{\tau}^2$, we have

$$\Pr_{\boldsymbol{R}}\left[\exists j \neq j' \in [k] \colon \boldsymbol{R} \supseteq N_j \wedge \boldsymbol{R} \supseteq N_{j'} \mid \boldsymbol{R} \supseteq K\right] \geq 1 - 2\varepsilon.$$

In particular, for every $i \in [k]$ we have

$$\Pr_{\boldsymbol{R}}\left[\exists j \neq i \in [k] \colon \boldsymbol{R} \supseteq N_j \mid \boldsymbol{R} \supseteq K\right] \geq 1 - 2\varepsilon,$$

and so the sets $N_1, \dots, N_{i-1}, N_{i+1}, N_k$ form a $(2p, 2\varepsilon)$-robust sunflower with kernel K. ◀

Another lemma we use is very similar to the standard connection between robust sunflowers and the classical ones (see e.g. Lemma 1.6 in [1]):

▶ **Lemma 9.** *Suppose that $N_1, \dots, N_m \subseteq X$ is a $(1/(2k), \varepsilon)$-robust sunflower with a kernel K. Then*

$$\Pr_{\boldsymbol{R} \sim 2^X}\left[\exists I \in \binom{[m]}{k} \forall i \in I \colon \boldsymbol{R} \supseteq N_i \middle| \boldsymbol{R} \supseteq K\right] \geq 1 - \varepsilon k.$$

Proof. Let $\tau \sim [2k]^{X \setminus K}$, and $\tau^i := \{j \in X \setminus K \mid \tau_j = i\} \cup K$ for $i \in [2k]$. Then $\boldsymbol{\tau}^1 \cup \dots \cup \boldsymbol{\tau}^k$ is distributed equivalently to $(\boldsymbol{R} \mid \boldsymbol{R} \supseteq K)$ where $\boldsymbol{R} \sim 2^X$. On the other hand, by the definition of the $(1/(2k), \varepsilon)$-robust sunflower, for each $i \in [2k]$ we get

$$\Pr[\exists j \in [m] \colon \boldsymbol{\tau}^i \supseteq N_j] \geq 1 - \varepsilon.$$

Since $\boldsymbol{\tau}^i \cap \boldsymbol{\tau}^{i'} = K$ for any $i \neq i' \in [2k]$, the lemma follows by the union bound over $i \in [k]$. ◀

3 Sampling Uniform Hamming Weight k Distributions

In this section we prove the following results mentioned in the introduction, which we restate here for convenience.

▶ **Theorem 2.** *Suppose that $\boldsymbol{U}_k^n$ can be sampled with decision depth d and error η in variation distance.*

1. *For every $\varepsilon > 0$ there exists a constant τ such that $d \leq \tau \log(n/k)/\log\log(n/k)$ implies $\eta \geq 1 - \varepsilon$.*

2. *There exists a constant τ for which the following holds. For every $\varepsilon \in (0,1)$, if $k \in [\log_2 n, 2^{\log^{1-\varepsilon} n}]$ and $d \leq \tau \log^{\varepsilon} n$, then $\eta = 1 - n^{-\Omega(k)}$. The same bound holds for $k \in [1, \log_2 n)$ and $d \leq \tau \log^{\varepsilon} n / \log\log n$.*

Moreover, Item 1 holds for any $\boldsymbol{U}_S^n$ with $\max_{x \in S} x = k$ or $\min_{x \in S} x = n - k$.

▶ **Theorem 3.** *There exists a constant $\tau > 0$ such that any distribution sampled with decision depth $\tau \log n / \log\log n$ is $(1 - n^{-\Omega(1)})$-far from $\boldsymbol{U}_1^n$.*

We first prove Theorem 3, in Section 3.1. We then prove Item 2 of Theorem 2 in Section 3.3, and Item 1 of the Theorem in Section 3.4. We prove the "moreover" part in Section 3.5.

3.1 Proof of Theorem 3

We prove a more general result which immediately yields Theorem 3.

First let us sketch a proof of Theorem 3 for d-local functions. Suppose that $\Delta(\boldsymbol{U}_1^n, \boldsymbol{X}) \leq 1 - \eta$. Call a coordinate i *good* if $\Pr[\boldsymbol{X} = e_i] \geq 1/n^2$. Since $\Pr[U_1 = e_i] = 1/n$, many coordinates are good: at least $\Omega(\eta n)$.

Let $\boldsymbol{Y} \sim \{0,1\}^m$ denote the random input bits. Each X_i depends on some subset $N_i \subseteq [m]$ of coordinates of size at most $d = \tau \log n / \log\log n$, say $\boldsymbol{X}_i = f_i(\boldsymbol{Y}_{N_i})$.

For each good coordinate i, we choose an assignment $\alpha_i \in f_i^{-1}(1)$ which maximizes the conditional probability $\Pr[\boldsymbol{X} = e_i \mid \boldsymbol{Y}_{N_i} = \alpha_i]$, that is, the probability that if $\boldsymbol{Y}_{N_i} = \alpha_i$ then all other output bits are 0. This probability is at least $1/(2^d n^2) = \Omega(1/n^3)$.

The assignments α_i do not necessarily agree with each other. However, a random assignment ρ to $\boldsymbol{Y}$ agrees with at least $\Omega(\eta n / 2^d) = \Omega(\eta n^{1-o(1)})$ of them. Let T consists of the domains of the assignments α_i which agree with ρ. These domains are distinct since $N_i = N_j$ implies $\alpha_i = \alpha_j$ and hence that $\Pr[\boldsymbol{X} = e_i \mid \boldsymbol{Y}_{N_i} = \alpha_i] = 0$. The choice of d guarantees that T supports a $(1/4, \varepsilon)$-robust sunflower $\mathcal{S}$, for any ε which is inverse-polynomial in n. Let K be the kernel of $\mathcal{S}$.

If we remove any single petal i from $\mathcal{S}$ then by Lemma 8 the result is a $(1/2, 2\varepsilon)$-robust sunflower, and so given that $\boldsymbol{Y}_K$ agrees with ρ, the probability that $\boldsymbol{X}_j = 1$ for some $j \neq i$ is at least $1 - 2\varepsilon$. If we replace the condition with "$\boldsymbol{Y}_{N_i}$ agrees with ρ" (and so with α_i), then intuitively, the probability can only increase, and this can be formalized using the FKG inequality (Theorem 4). By definition of α_i, this means that $\Pr[\boldsymbol{X} = e_i] \leq |f_i^{-1}(1)| 2\varepsilon \leq 2^{d+1}\varepsilon$. Choosing $\varepsilon = 1/2^{d+1} n^2$ shows that i is not good, and we reach a contradiction.

We move on to prove the generalization of Theorem 3.

▶ **Theorem 10.** *Let $\boldsymbol{Y} \sim \{0,1\}^m$ be the input bits of the n-bit source $\boldsymbol{X}$. Suppose that every bit of $\boldsymbol{X}$ is computed as a DNF of bits of $\boldsymbol{Y}$ of size at most s and width at most d. For every $\kappa \in \mathbb{R}$ there exists a constant τ such that for $d = \tau \log n / \log\log n$ and $s \leq \kappa n^{\kappa}$, we have $\Delta(\boldsymbol{X}, \boldsymbol{U}_1^n) = 1 - \eta = 1 - n^{-\Omega(1)}$.*

This implies Theorem 3 since the output of a decision tree of depth d can be represented as a DNF of size at most 2^d and width at most d. In our case $d = o(\log n)$ and so $2^d \leq n$ (for large enough n).

Proof. We say that an output bit $i \in [n]$ is *good* if $\Pr[\boldsymbol{X} = e_i] \geq 1/n^2$. Let $G \subseteq [n]$ be the set of all good bits, and let $\overline{G} = [n] \setminus G$. Let us estimate the size of G: $\Pr[\boldsymbol{X} \in \{e_i \mid i \notin G\}] \leq |\overline{G}|/n^2$, but $\Pr[\boldsymbol{U}_1^n \in \{e_i \mid i \notin G\}] = |\overline{G}|/n)$, so $|\overline{G}| \cdot (1/n - 1/n^2) \leq 1 - \eta$, which yields $|G| = \Omega(\eta n)$.

For each $i \in G$, since each bit of $\boldsymbol{X}$ is represented as a DNF we have $\boldsymbol{X}_i = \bigvee_{j\in[s_i]}[\boldsymbol{Y}_{N_i^j} = \alpha_i^j]$, where $N_i^1,\ldots,N_i^{s_i} \subseteq [m]$ are sets, $\alpha_i^j \in \{0,1\}^{N_i^j}$ are truth assignments, and $s_i \le s$. By the law of total probability we have

$$\Pr[\boldsymbol{X}=e_i] \le \sum_{j\in[s_i]} \Pr[\boldsymbol{X}=e_i \wedge \boldsymbol{Y}_{N_i^j}=\alpha_i^j] \le s\Pr[\boldsymbol{X}=e_i\wedge \boldsymbol{Y}_{N_i^{\max}}=\alpha_i^{\max}],$$

where $N_i^{\max}$ and $\alpha_i^{\max}$ correspond to the term in the DNF maximizing the probability $\Pr[\boldsymbol{X}=e_i\wedge\boldsymbol{Y}_{N_i^j}=\alpha_i^j]$.

Consider the expected number of good output bits such that $\boldsymbol{Y}_{N_i^{\max}}=\alpha_i^{\max}$:

$$\mathbb{E}\left[\sum_{i\in G}[\boldsymbol{Y}_{N_i^{\max}}=\alpha_i^{\max}]\right] \ge |G|2^{-d}.$$

Hence there exists an assignment ρ to the input bits such that for at least $|G|2^{-d}$ good output bits, we have $\rho_{N_i^{\max}}=\alpha_i^{\max}$. Let $T\subseteq G$ be the set of those output bits. If $i,j\in T$ then $N_i^{\max}\neq N_j^{\max}$, since otherwise $\boldsymbol{Y}_{N_i^{\max}}=\alpha_i^{\max}$ implies that also $\boldsymbol{Y}_{N_j^{\max}}=\alpha_j^{\max}$ and so $\boldsymbol{X}\neq e_i$, and so $\Pr[\boldsymbol{X}=e_i]=0$, contradicting $i\in G$. Observe moreover that none of the sets N_i for $i\in T$ is empty, since otherwise $|T|=1$ and we get an immediate contradiction with the size of G for any $d=o(\log n)$.

Case 1. $|T|<d(4B\log(d/\varepsilon))^d$. In this case, we immediately get the lower bound on δ. Indeed, the inequality $|G|2^{-d}\le|T|<d(4B\log(d/\varepsilon))^d$ implies $|G|\le d(8B\log(d/\varepsilon))^d$, which together with $|G|=\Omega(\eta n)$ yields $\eta\le d(8B\log(d/\varepsilon))^d/n$. If ε is inverse polynomial in n, then for small enough τ we get $\eta=n^{-\Omega(1)}$ with $d=\tau\log n/\log\log n$.

Case 2. $|T|\ge d(4B\log(d/\varepsilon))^d$. Then by Corollary 7 there exists a $(1/4,\varepsilon)$-robust sunflower formed by the sets $N_{t_1}^{\max},\ldots,N_{t_k}^{\max}$ for $\{t_1,\ldots,t_k\}\subseteq T$ (recall the sets $N_i^{\max}$ for $i\in T$ are all distinct, and none of them is empty). Let K denote the kernel of this sunflower. Consider an arbitrary petal t_i of this sunflower. By Lemma 8 we have that $\{N_i^{\max}\}_{i\in T\smallsetminus\{t_i\}}$ is a $(1/2,2\varepsilon)$-robust sunflower. Let $\boldsymbol{U}$ be the set of indices such that $\boldsymbol{Y}_k=\rho_k$. Then

$$\begin{aligned}
\Pr[\boldsymbol{X}_j=1\text{ for some }j\in T\smallsetminus\{t_i\}\mid \boldsymbol{Y}_{N_{t_i}^{\max}}=\rho_{N_{t_i}^{\max}}]\ge{}&\\
\Pr[\boldsymbol{U}\supseteq N_j^{\max}\text{ for some }j\in T\smallsetminus\{t_i\}\mid \boldsymbol{U}\supseteq N_{t_i}^{\max}]={}&\\
\frac{\Pr[\boldsymbol{U}\supseteq N_{t_i}^{\max}\text{ and }\boldsymbol{U}\supseteq N_j^{\max}\text{ for some }j\in T\smallsetminus\{t_i\}\mid \boldsymbol{U}\supseteq K]}{\Pr[\boldsymbol{U}\supseteq N_{t_i}^{\max}\mid\boldsymbol{U}\supseteq K]}\ge{}& \qquad\text{Theorem 4}\\
\Pr[\boldsymbol{U}\supseteq N_j^{\max}\text{ for some }j\in T\smallsetminus\{t_i\}\mid \boldsymbol{U}\supseteq K]\ge{}&\\
1-2\varepsilon,&
\end{aligned}$$

where the last inequality is due to the definition of a $(1/2,2\varepsilon)$-robust sunflower. Recall that by the choice of T, we have $\rho_{N_{t_i}^{\max}}=\alpha_{t_i}^{\max}$. Therefore

$$\Pr[\boldsymbol{X}\neq e_{t_i}\mid \boldsymbol{Y}_{N_{t_i}^{\max}}=\alpha_{t_i}^{\max}]=\Pr[\boldsymbol{X}_j=1\text{ for some }j\in T\smallsetminus\{t_i\}\mid \boldsymbol{Y}_{N_{t_i}^{\max}}=\rho_{N_{t_i}^{\max}}]\ge1-2\varepsilon.$$

Thus $\Pr[\boldsymbol{X}=e_{t_i}\wedge\boldsymbol{Y}^{N_{t_i}^{\max}}=\alpha_{t_i}^{\max}]\le2\varepsilon$. By the choice of $\alpha_{t_i}^{\max}$, $\Pr[\boldsymbol{X}=e_{t_i}]\le s\cdot2\varepsilon$. Picking $\varepsilon<1/(2sn^2)$, which is inverse polynomial in n as required in Case 1, we get that $\Pr[\boldsymbol{X}=e_{t_i}]<1/n^2$, so t_i is bad, which contradicts the choice of T. ◀

3.2 A Generalized Version of Theorem 10

In this section, we generalize Theorem 10 so it can be used to prove Item 1 of Theorem 2. The proof follows the same path as the proof of Theorem 10, we decided to include both proofs for simplicity.

▶ **Theorem 11.** *Let $\boldsymbol{Y} \sim \{0,1\}^m$ be the input bits of the n-bit source $\boldsymbol{X}$. Suppose that every bit of $\boldsymbol{X}$ is computed as a DNF of bits of $\boldsymbol{Y}$ of size at most s and width at most d. Let $t \in [n]$ be a parameter, $\alpha(n)$ be a function and let $\boldsymbol{F}$ be distributed over $\{0,1\}^n$ and have the following properties:*

- *For every set $T \subseteq [n]$ such that $T \geq n/2$ we have $\Pr[\boldsymbol{F}_T = 0^T] \leq \alpha(n)$;*
- $\Pr[|\boldsymbol{F}| > t] \leq \alpha(n)$.

If $2d \cdot t \cdot (40Bt \log n)^d \leq n$ then $\Delta(\boldsymbol{X}, \boldsymbol{F}) \geq 1 - 2\alpha(n) - 1/2n$. Here B is the constant from Corollary 7.

Proof. We say that an output bit $i \in [n]$ is *good* if $\Pr[\boldsymbol{X}_i = 1 \wedge |\boldsymbol{X}| \leq t] \geq 1/n^2$. Let G be the set of good bits and let $\overline{G} \coloneqq [n] \setminus G$. Suppose that $|G| \leq n/2$. Then by the conditions on $\boldsymbol{F}$ we have $\Pr[\boldsymbol{F}_{\overline{G}} = 0^{\overline{G}}] \leq \alpha(n)$. On the other hand $\Pr[\boldsymbol{X}_{\overline{G}} \neq 0^{\overline{G}} \wedge |\boldsymbol{X}| \leq t] < |\overline{G}|/n^2 < 1/2n$. Then $\Delta(\boldsymbol{X}, \boldsymbol{F}) \geq 1 - 2\alpha(n) - 1/2n$, as required. In the rest of the proof, we derive a contradiction with $|G| \geq n/2$.

As in the proof of Theorem 10, we pick the likeliest term in the DNF representation of each of the output bits. For each $i \in G$, since each bit of $\boldsymbol{X}$ is represented as a DNF, we have $\boldsymbol{X}_i = \bigvee_{j \in [s_i]} [\boldsymbol{Y}_{N_i^j} = \alpha_i^j]$, where $N_i^1, \dots, N_i^{s_i} \subseteq [m]$ are sets, $\alpha_i^j \in \{0,1\}^{N_i^j}$ are truth assignments, and $s_i \leq s$. By the law of total probability, we have

$$\Pr[\boldsymbol{X}_i = 1 \wedge |\boldsymbol{X}| \leq t] \leq \sum_{j \in [s_i]} \Pr[|\boldsymbol{X}| \leq t \wedge \boldsymbol{Y}_{N_i^j} = \alpha_i^j] \leq s \Pr[|\boldsymbol{X}| \leq t \wedge \boldsymbol{Y}_{N_i^{\max}} = \alpha_i^{\max}],$$

where $N_i^{\max}$ and $\alpha_i^{\max}$ correspond to the term in the DNF maximizing the probability $\Pr[|\boldsymbol{X}| \leq t \wedge \boldsymbol{Y}_{N_i^j} = \alpha_i^j]$. The expected number of good output bits with $\boldsymbol{Y}_{N_i^{\max}} = \alpha_i^{\max}$ is at least $2^{-d}|G|$, so there exists an assignment ρ to the input bits such that $\rho_{N_i^{\max}} = \alpha_i^{\max}$ for at least $|G|2^{-d}$ good output bits. Let $T \subseteq G$ be the set of these output bits.

Let us estimate how many distinct elements are in the set $\mathcal{N} \coloneqq \{N_i^{\max} \mid i \in T\}$. Suppose there exist $i_1, \dots, i_{t+1} \in T$ such that $N_{i_1}^{\max} = \cdots = N_{i_{t+1}}^{\max}$. Then, by the definition of ρ, we have $\alpha_{i_1}^{\max} = \cdots = \alpha_{i_{t+1}}^{\max}$ as well. Thus $\boldsymbol{Y}_{N_{i_1}^{\max}} = \alpha_{i_1}^{\max}$ implies that for every $j \in [t+1]$ we have $\boldsymbol{Y}_{N_{i_j}^{\max}} = \alpha_{i_j}^{\max}$, which in turn implies that $|\boldsymbol{X}| \geq t+1$, and so $\Pr[\boldsymbol{Y}_{N_{i_1}^{\max}} = \alpha_{i_1}^{\max} \wedge |\boldsymbol{X}| \leq t] = 0$, which contradicts that i_1 is good. Hence $|\mathcal{N}| \geq |T|/t \geq |G|2^{-d}/t \geq 2^{-d}n/2t$.

Let $\varepsilon > n^{-5}$ be a parameter to be chosen later. By the condition on n we have $|\mathcal{N}| \geq 2^{-d}n/2t \geq d \cdot (4Bt \log(d/\varepsilon))^d$, and so $\mathcal{N}$ contains a $(1/(4t), \varepsilon)$-robust sunflower $\mathcal{S}$. Let K denote the kernel of this sunflower.

Fix an arbitrary petal $p \in \mathcal{N}$. Then $\mathcal{N} \setminus \{p\}$ is a $(1/(2t), 2\varepsilon)$-robust sunflower by Lemma 8. Now by Lemma 9 we have

$$\Pr_{\boldsymbol{R} \sim 2^{[m]}}[\text{There are } t \text{ distinct petals of } \mathcal{N} \setminus \{p\} \text{ contained in } \boldsymbol{R} \mid \boldsymbol{R} \supseteq K] \geq 1 - 2t\varepsilon.$$

Let $P \subseteq T$ be the indices of the output bits corresponding to the elements of $\mathcal{N} \setminus \{p\}$, let i be the index of the output bit corresponding to the petal p, and let $\boldsymbol{U}$ be the set of indices of input bits such that $\boldsymbol{Y}_t = \rho_t$. Then

$$\begin{aligned}
&\Pr[|\boldsymbol{X}| > t \mid \boldsymbol{Y}_{N_i^{\max}} = \rho_{N_i^{\max}}] = \\
&\Pr[|\boldsymbol{X}_{[n]\smallsetminus\{i\}}| \geq t \mid \boldsymbol{Y}_{N_i^{\max}} = \rho_{N_i^{\max}}] \geq \\
&\Pr\left[\sum_{j\in P}[\boldsymbol{U} \supseteq N_j^{\max}] \geq t \,\middle|\, \boldsymbol{U} \supseteq N_i^{\max}\right] = \\
&\frac{\Pr[\sum_{j\in P\cup\{i\}}[\boldsymbol{U} \supseteq N_j^{\max}] \geq t \mid \boldsymbol{U} \supseteq K]}{\Pr[\boldsymbol{U} \supseteq N_i^{\max} \mid \boldsymbol{U} \supseteq K]} \geq \ \text{Theorem 4} \\
&\Pr\left[\sum_{j\in P}[\boldsymbol{U} \supseteq N_j^{\max}] \geq t \,\middle|\, \boldsymbol{U} \supseteq K\right] \geq \\
&1 - 2t\varepsilon.
\end{aligned}$$

Recall that by the choice of T we have $\rho_{N_i^{\max}} = \alpha_i^{\max}$, hence $\Pr[|\boldsymbol{X}| > t \mid \boldsymbol{Y}_{N_i^{\max}} = \alpha_i^{\max}] \geq 1 - 2t\varepsilon$. Thus

$$\Pr[|\boldsymbol{X}| \leq t \wedge \boldsymbol{X}_i = 1] \leq s \cdot \Pr[|\boldsymbol{X}| \leq t \wedge \boldsymbol{Y}_{N_i^{\max}} = \alpha_i^{\max}] \leq 2st \cdot \varepsilon.$$

Picking $\varepsilon = 1/(4stn^2) \geq n^{-5}$, we get a contradiction with i being good. ◀

3.3 Subpolynomial Weights

Although Theorem 11 implies Item 2 of Theorem 2, we give a simpler proof via a reduction from $\boldsymbol{U}_1^n$.

▶ **Lemma 12.** *Let $S \subseteq \{0,1\}^n$ and let $\boldsymbol{S} \sim S$. Suppose that $\boldsymbol{S}$ can be sampled with a depth-d decision forest with error η. Assume furthermore that for each $s \in S$ there exists a decision tree T_s of depth k that accepts s and does not accept any of $S \smallsetminus \{s\}$. Then there exists a decision depth-kd sampler for $\boldsymbol{U}_1^{|S|}$ with error η.*

Proof. Let $\boldsymbol{Y}$ be the distribution sampled by the sampler for $\boldsymbol{S}$. For each output bit of our sampler for $\boldsymbol{U}_1^{|S|}$ we take a unique element $s \in S$ and implement each of the queries of T_s via the query to the bits of $\boldsymbol{Y}$ (which makes at most d queries to the input bits). This results in a kd-deep decision tree T'_s. Let $\boldsymbol{X}$ be the sampled distribution. Then

$$\begin{aligned}
\Delta(\boldsymbol{X}, \boldsymbol{U}_1^{|S|}) &= \frac{1}{2}\left(\Pr[w(\boldsymbol{X}) \neq 1] + \sum_{s\in S}\bigl|\Pr[\boldsymbol{X} = e_s] - 1/|S|\bigr|\right) \\
&= \frac{1}{2}\left(\Pr[\boldsymbol{Y} \notin S] + \sum_{s\in S}\bigl|\Pr[\boldsymbol{Y} = s] - 1/|S|\bigr|\right) = \Delta(\boldsymbol{Y}, \boldsymbol{S}) = \eta.
\end{aligned}$$

◀

▶ **Corollary 13.** *For some constant $\tau' > 0$ and every $\varepsilon \in (0,1)$ every $(\tau' \log^{\varepsilon} n)$-decision depth sampler outputs a distribution $(1 - n^{-\Omega(k)})$-far from $\boldsymbol{U}_k^n$ for $k \in [\log n, 2^{\log^{1-\varepsilon} n}]$. If $k < \log_2 n$, this holds for every $(\tau' \log^{\varepsilon} n/\log\log n)$-local sampler.*

Proof. The decision tree that queries all the elements of a k-size set and accepts iff all of them are 1 satisfies the condition in Lemma 12. If we had a $(1-\delta)$-error sampler for $\boldsymbol{U}_k^n$, we would get a $(1-\delta)$-error sampler for $\boldsymbol{U}_1^{\binom{n}{k}}$ with decision depth kd, which by Theorem 3 yields that $\delta = \binom{n}{k}^{-\Omega(1)} = n^{-\Omega(k)}$ whenever $kd \leq \tau \log\binom{n}{k}/\log\log\binom{n}{k}$. Since $\log\binom{n}{k} = \Theta(k\log(n/k))$, we get $d = \Omega(\log(n/k)/(\log k + \log\log n))$. ◀

3.4 Sublinear Weights

In this section, we prove Item 1 of Theorem 2.

▶ **Lemma 14.** *Suppose $\boldsymbol{X}$ is sampled with decision depth d. Then for every small enough $\varepsilon > 0$ there exists a constant τ such that if $d \le \tau \log(n/k)/\log\log(n/k)$ then $\Delta(\boldsymbol{X}, \boldsymbol{U}^n_k) \ge 1 - 2\varepsilon - \frac{1}{2n}$.*

Proof. Consider the first $\ell := \varepsilon^{-1} \cdot n/k$ bits of the sampler: $\boldsymbol{X}_{\le \ell} := \boldsymbol{X}_1, \dots, \boldsymbol{X}_\ell$. Let $\boldsymbol{Y}$ be the first ℓ bits of the distribution $\boldsymbol{U}^n_k$. We show that $\boldsymbol{Y}$ satisfies the conditions of Theorem 11 for $t = \varepsilon^{-2}$ and $\alpha(n) = \varepsilon$. First, we have

$$\Pr[|\boldsymbol{Y}| > t] = \Pr\left[|\boldsymbol{Y}| > \varepsilon^{-1}\mathbf{E}[|\boldsymbol{Y}|]\right] < \varepsilon.$$

Now let T be any subset of $[\ell]$ of size at least $\ell/2$. Then

$$\Pr[\boldsymbol{Y}_T = 0^T] = \binom{n-\ell/2}{k}\binom{n}{k}^{-1} = \prod_{i=0}^{k-1} \frac{n-i-\ell/2}{n-i} \le \left(1 - \frac{\ell}{2n}\right)^k = \left(1 - \frac{1}{2\varepsilon k}\right)^k \le e^{-2\varepsilon^{-1}} < \varepsilon.$$

Here we assumed $k < n/2$, since otherwise the lemma is trivially true.

Applying Theorem 11, for small enough τ (which depends on ε) we have $\Delta(\boldsymbol{X}_{\le \ell}, \boldsymbol{Y}) = 1 - 2\varepsilon - 1/2n$. To finish the proof, observe that $\Delta(\boldsymbol{X}, \boldsymbol{U}^n_k) \ge \Delta(\boldsymbol{X}_{\le \ell}, \boldsymbol{Y})$, since the random variables on the RHS are the marginals of the variables on the LHS. ◀

3.5 Unions of Slices

In this section, we prove the "moreover" part of Theorem 2 by observing that the distribution $\boldsymbol{U}^n_S$ is close to $\boldsymbol{U}^n_{\max_{x \in S} x}$ as long as $\max_{x \in S} x = o(n)$.

▶ **Proposition 15.** *Let $k = o(n)$ and suppose that $S \subseteq \{0, 1, \dots, k\}$ with $k \in S$. Then we have $\Delta(\boldsymbol{U}^n_k, \boldsymbol{U}^n_S) = o(1)$.*

Proof. We use the notation $\binom{n}{S} := \sum_{i \in S} \binom{n}{i}$.

$$\begin{aligned}\Delta(\boldsymbol{U}^n_k, \boldsymbol{U}^n_S) &= \frac{1}{2}\binom{n}{S \setminus \{k\}}\binom{n}{S}^{-1} + \frac{1}{2}\left(1 - \binom{n}{k}\binom{n}{S}^{-1}\right) \\ &= \binom{n}{S \setminus \{k\}}\binom{n}{S}^{-1} \\ &\le \binom{n}{k}^{-1} \sum_{i \in S \setminus \{k\}} \binom{n}{i} \\ &\le \sum_{i=0}^{k-1} \left(\frac{k}{n-i}\right)^{i-k} = \Theta(k/n).\end{aligned}$$ ◀

The case of S with $n - \min_{x \in S} x = o(n)$ reduced to the case where $\max_{x \in S} x = o(n)$ by observing that flipping all output bits can be done with no increase in the decision depth of the sampler.

4 Local Certificates

In this section, we explore the power of local proof systems. Section 4.1 gives an example of a language that requires locality $\Omega(n)$, which is inspired by a similar lower bound in the context of sampling [22]. Section 4.2 then gives our main result, a lower bound on the locality of proof systems for $\textsc{Maj}^{-1}(1)$.

4.1 Error-correcting codes

In this section, we show that a good error-correcting code requires a proof system of a linear locality. This showcases the simple counting technique that we also use for our majority lower bound.

▶ **Proposition 16.** *Let $C \subseteq \{0,1\}^n$ be a good code, that is, $|C| \geq 2^{\alpha n}$ and for every $x \neq y \in C$, the Hamming distance between x and y is at least βn, where α and β are constants in $(0,1)$.*

If $f\colon \{0,1\}^m \to \{0,1\}^n$ is a d-local function and $f(\{0,1\}^m) = C$ then $d \geq \alpha\beta n$

Proof. We may assume w.l.o.g. that all input bits of f affect some output bits. Take an arbitrary input bit $i \in [m]$ and an output bit $j \in [n]$ that depends on i. Then take $x, x' \in \{0,1\}^m$ that differ only in the ith coordinate and such that $f(x)_j \neq f(x')_j$. Since $f(x)$ and $f(x')$ are two distinct codewords of C, they must be at Hamming distance at least βn, hence i must affect at least βn output bits, as x and x' only differ in i. Thus every bit affects at least βn output bits.

There are at least αn input bits since $|C| = 2^{\alpha n}$. Therefore there are $\alpha\beta n^2$ input-output pairs in which the input bit affects the output bit. On the other hand, there are at most dn such pairs, hence $d \geq \alpha\beta n$. ◀

4.2 Majority

Let $\textsc{Maj}_n$ be the the set $\{x \in \{0,1\}^n \mid |x| \geq n/2\}$. First, let us give a simple upper bound on locality which is implicit in [20].

▶ **Proposition 17** (essentially Theorem 3.9 and Corollary 3.10 in [20]). *There exists an $O(\log^2 n)$-local function $f\colon \{0,1\}^* \to \{0,1\}^n$ such that $f(\{0,1\}^*) = \textsc{Maj}_n^{-1}(1)$.*

Proof. For simplicity, suppose that n is odd. Construct a binary tree whose root is the interval $[1,n]$, whose leaves are the singletons $\{1\}, \dots, \{n\}$, and in which each internal node $[\ell, r]$ has two children $[\ell, c], [c+1, r]$, where $c = \lfloor (\ell + r)/2 \rfloor$. We can construct such a tree whose depth is $O(\log n)$. For each interval $[\ell, r]$ in the tree we will have a label $w(\ell, r)$ whose value ranges from 0 to $r - \ell + 1$, which is supposed to indicate $x_\ell + \cdots + x_r$ (where $x_1, \dots, x_n$ is the output). We implement the variables using $O(\log n)$ input bits.

An internal node $[\ell, r]$ with children $[\ell, c], [c+1, r]$ is *consistent* if $w(\ell, r) = w(\ell, c) + w(c+1, r)$. In addition, if the internal node is the root $[1,n]$, we require $w(1,n) \geq (n+1)/2$. Each position $i \in \{1, \dots, n\}$ corresponds to the leaf $w(i,i)$, which has $O(\log n)$ ancestors. We say that position i is *good* if all its non-leaf ancestors are consistent. The i'th output is $w(i,i)$ if i is good, and 1 otherwise. Since each $w(\ell, r)$ is encoded using $O(\log n)$ bits, this system has locality $O(\log^2 n)$.

Every vector $x_1, \dots, x_n$ of weight at least $(n+1)/2$ can be generated using this system by taking $w(\ell, r) = x_\ell + \cdots + x_r$. In the other direction, consider any assignment of weights to the tree. If the root is inconsistent, then the output is $1, \dots, 1$, so we can assume that the root is consistent. Prune the tree by removing all children of inconsistent nodes. If $[\ell, r]$ is any node in the pruned tree then either $\ell = r$ and $x_\ell = w(\ell, r)$, or $\ell < r$ and $x_\ell + \cdots + x_r = r - \ell + 1 \geq w(\ell, r)$. It follows that $x_1 + \cdots + x_n \geq w(1,n) \geq (n+1)/2$. ◀

The $\Omega(\log^* n)$ locality lower bound in [5] is inspired by the following observation:

▶ **Proposition 18.** *Let $f\colon \{0,1\}^m \to \{0,1\}^n$ be such that every output bit is a function of at most c input bits, and every input bit affects at most d output bits. Suppose that $cd \leq (n+1)/2$. Then $f(\{0,1\}^m) \neq \textsc{Maj}^{-1}(1)$.*

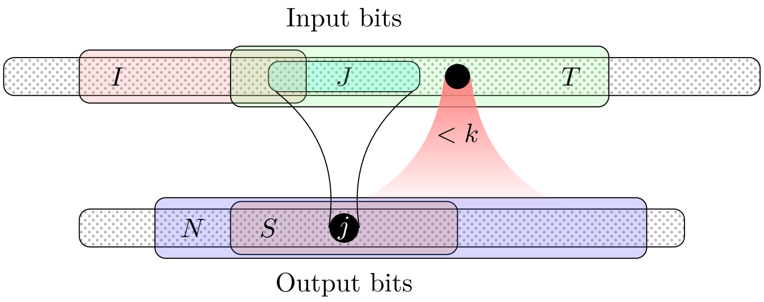


Figure 2 I is the set of k-influential inputs bits, and S is the given set. The set T consists of all inputs bits affecting S, and the set N consists of all bits influenced by $T \setminus I$.

Proof. Let $i \in [n]$ be an arbitrary output bit. There are at most cd many output bits in the "neighborhood" $N(i)$ of i, which is the set of outputs that share an input bit with i. If $|N(i)| \le (n+1)/2$ then we can find an output y of weight $(n+1)/2$ such that $y_{N(i)} = 1^{N(i)}$. Suppose that y is generated by the input x. There must be some setting to the inputs of i which sets it to zero (since there is a valid output z with $z_i = 0$). If we modify x using this setting then the new output z agrees with y outside of $N(i)$, and furthermore $z_i = 0$. Since $y_{N(i)} = 1^{N(i)}$, it follows that $|z| < |y|$, which is impossible, since y had the smallest possible weight. ◀

One of the steps in our proof (namely, Lemma 20) is essentially an adaptation of the proof of Proposition 18 for the sources with influential input bits.

We give a simplified exposition of their proof in Appendix B. Our own lower bound is contained in the following theorem.

▶ **Theorem 19.** *Let $f\colon \{0,1\}^m \to \{0,1\}^n$ be a d-local function such that $f(\{0,1\}^m) = \textsc{Maj}_n^{-1}(1)$, where n is odd. Then $d = \Omega(\sqrt{\log n})$.*

Proof. We say that an input bit $i \in [m]$ is *k-influential* if at least k output bits of f depend on it. We are going to show that there are $\Omega(n/(dk))$ many k-influential bits for every k. Then the number of input-output bit pairs where the output depends on the input is at least $\sum_{k\in[n]} cn/(dk) = \Omega(n \log n/d)$. On the other hand, there are at most nd such pairs since f is d-local. Therefore $d = \Omega(\sqrt{\log n})$.

It remains to show the lower bound on the number of k-influential bits. This is done by combining the following two lemmas.

▶ **Lemma 20.** *Let I be the set of all k-influential input bits. Then for every set of output bits S of size at most $n/(4kd)$ there exists an assignment ρ to I such that*

1. *All bits in S are fixed to 1 by ρ, i.e. for every total extension ρ' of ρ we have $f(\rho')_S = 1^S$.*
2. *ρ fixes to 1 at most $(n+1)/2$ output bits.*

Proof. Fix a set S of size at most $n/(4kd)$.

Let T be the set of input bits that affect S, so $|T| \le d|S|$. Let N be the set of all bits influenced by $T \setminus I$. See Figure 2 for a pictorial representation of these definitions.

Since I contains all k-influential input bits, $|N| \le kd|S|$. Let ρ' be a total assignment such that $f(\rho')_N = 1^N$ and $|f(\rho')| = (n+1)/2$. This is possible since $|N| \le n/4$ by the statement of the lemma. Let $\rho := \rho'_I$.

Since $|f(\rho')| = (n+1)/2$, in particular ρ fixes to 1 at most $(n+1)/2$ bits. We claim that ρ fixes all bits in S to 1. Suppose for the sake of contradiction that it doesn't fix to 1 the bit $j \in S$. Let J be the set of input bits affecting j. Let ρ'' be a total assignment consistent with ρ' everywhere except $J \setminus I$ such that $f(\rho'')_j = 0$. Observe that $f(\rho'')_{[n]\setminus N} = f(\rho')_{[n]\setminus N}$, hence $f(\rho'') \leq f(\rho')$ coordinate-wise. Since $f(\rho'')_j = 0$ and $f(\rho')_j = 1$, we have $|f(\rho'')| < n/2$, which contradicts the fact that the image of f is $\textsc{Maj}_n^{-1}(1)$. ◀

▶ **Lemma 21.** *Let I be an arbitrary set of input bits of size at most $n/20$. Then there exists a set S of output bits such that $|S| = O(|I|)$ and for every assignment ρ to I that fixes to 1 at most $(n+1)/2$ output bits, there exists a bit in S that is not fixed to 1 by ρ.*

Proof. Let $\rho_1, \dots, \rho_K$ be all assignments to I that fix at most $(n+1)/2$ output bits. Denote by $U_1, \dots, U_K \subseteq [n]$ the sets of bits that are not fixed by $\rho_1, \dots, \rho_K$, respectively, so that $|U_1|, \dots, |U_K| \geq (n-1)/2 \geq n/3$. Then

$$K\frac{n}{3} \leq \sum_{i=1}^{K} |U_i| = \sum_{j\in[n]} |\{i \in [K] \mid U_i \ni j\}|.$$

Hence there exists j such that $|\{i \in [K] \mid U_i \ni j\}| \geq K/3$. Let $S_1 \coloneqq \{j\}$, and continue this process for the set of bits $[n] \setminus \{j\}$ and the set of assignments $\{\rho_i \colon U_i \not\ni j\}$. Suppose the previous iteration yields a set $S_k \subseteq [n]$ of size k and a set of indices $T_k \subseteq [K]$. Then let $U'_i \coloneqq U_i \setminus S_k$ for $i \in T_k$. Then $|U'_1|, \dots, |U'_K| \geq (n-1)/2 - k \geq n/3$, where the last inequality is true if $k < n/6$. As before, there exists $j \notin S_k$ such that $|\{i \in T_k \mid U'_i \ni j\}| \geq |T_k|/3$. We then let $S_{k+1} \coloneqq S_k \cup \{j\}$ and $T_{k+1} \coloneqq \{i \in T_k \mid U'_i \not\ni j\}$.

Clearly $|T_k| \leq K \cdot (2/3)^{k-1}$, hence in $\tau = \lceil \log_{3/2} K \rceil \leq 2\log_2 K \leq 2|I| \leq n/10$ steps we eliminate all assignments from the set, i.e. S_τ satisfies that for every assignment ρ to I that fixes at most $(n+1)/2$ output bits, there exists $j \in S_\tau$ that is not fixed by ρ. (The bound $2|I| \leq n/10$ guarantees that the condition $k < n/6$ holds). ◀

Let I be the set of all k-influential bits. If $|I| \geq n/20$ we get the desired lower bound immediately, so assume otherwise. Then let S be the set given by Lemma 21, $|S| = O(|I|)$. By Lemma 20 we get that $|S| = \Omega(n/(dk))$, so $|I| = \Omega(n/(dk))$ as well. ◀

A Switching Networks for Sampling Linear Slices

In this section, we discuss the limitations of switching networks for constructing decision tree samplers.

▶ **Definition 22.** *A switching network of depth d is a sequence of d matchings $M_1, \dots, M_d$. Each M_i is a set of $n/2$ disjoint pairs of elements from $[n]$. The distribution generated by a switching network over a slice $\binom{[n]}{\ell}$ is defined as follows:*

- *Initialize the string as $1^\ell 0^{n-\ell}$;*
- *For each $i \in [d]$: for every pair in $(a, b) \in M_i$, we toss a fair coin, and if it comes up heads, we swap the ath and the bth bits of the current sequence.*

▶ **Lemma 23** (A variation of [26]). *Suppose there exists a switching network of depth d that generates the variable $\boldsymbol{X}$ over $\binom{[n]}{\ell}$. Then there exists a decision depth d sampler for $\boldsymbol{X}$ such that each input bit affects at most 2^d output bits. Moreover, the support of $\boldsymbol{X}$ is a subset of $\binom{[n]}{\ell}$.*

Proof. The input bits correspond to the coin tosses in the switching network. Each output bit is computed by tracing back its initial position: first, we query the coin corresponding to the pair in M_d containing the bit, then we query the coin corresponding to the pair in M_{d-1} and so on until we compute the location of the bit in the initial sequence. Then if the location is in $[\ell]$ we output 1 and otherwise output 0. It is easy to see that the described sampler has the required properties. ◀

▶ **Lemma 24.** *Let $\alpha \in (0, 1)$ be a constant. Suppose $\boldsymbol{X}$ is samplable with a d-local sampler such that each input bit affects at most c output bits, the support of $\boldsymbol{X}$ is within $\binom{[n]}{\alpha n}$, and $n/(cd)^2 = \omega(2^{cd})$. Then $\Delta(\boldsymbol{X}, \boldsymbol{U}^n_{\alpha n}) = 1 - o(1)$.*

Proof. For each output bit $i \in [n]$ of $\boldsymbol{X}$, let $N(i) \subseteq [n]$, the *neighborhood* of i, be the set of output bits that share an affecting input bit with i. By assumption, $|N(i)| \le cd$. Let us greedily choose a set of output bits with disjoint neighborhoods: $t_1 = 1$, and for $j > 1$,

$t_j \in [n]$ is a bit such that $N(t_j) \cap (N(t_1) \cup \cdots \cup N(t_{j-1})) = \emptyset$. For each output bit i there are at most $(cd)^2$ output bits j for which $N(i) \cap N(j) \neq \emptyset$, so the greedy process yields $\ell \geq n/(cd)^2$ bits.

Suppose that there is a bit $i \in \{t_1, \ldots, t_\ell\}$ such that $\Pr[\boldsymbol{X}_i = 0] > 0$ and $\Pr[\boldsymbol{X}_{N(i)} = 1^{N(i)}] > 0$. Then we use the approach from Proposition 18: let $x \in \binom{[n]}{\alpha n}$ be a string in the support of $\boldsymbol{X}$ such that $x_{N(i)} = 1^{N(i)}$, and let ρ be the input bits that yield x. Since $\Pr[\boldsymbol{X}_i = 0] > 0$, we can change the bits of ρ affecting the ith output bit such that its value switches to 0. Denote the resulting input by x'. Observe then that $x_{[n] \setminus N(i)} = x'_{[n] \setminus N(i)}$, since $N(i)$ is the set of output bits that are affected by the input bits affecting the ith bit. Then $|x'| < |x|$, hence $x' \notin \binom{[n]}{\alpha n}$, so it does not lie in the support of $\boldsymbol{X}$, which is a contradiction.

Now let us analyze the case when there are no bits satisfying the condition. Let $I \subseteq \{t_1, \ldots, t_\ell\}$ consist of those output bits for which $\Pr[\boldsymbol{X}_i = 0] = 0$. If $|I| \geq \ell/2$ then

$$\begin{aligned}\Delta(\boldsymbol{X}, \boldsymbol{U}^n_{\alpha n}) &\geq \left|\Pr[\boldsymbol{X}_I = 1^I] - \Pr[(\boldsymbol{U}^n_{\alpha n})_I = 1^I]\right| = 1 - \binom{n-|I|}{\alpha n}\binom{n}{\alpha n}^{-1} \\ &= 1 - \prod_{j=0}^{\alpha n - 1} \frac{n - |I| - j}{n - j} \geq 1 - \left(1 - \frac{|I|}{n - \alpha n + 1}\right)^{\alpha n} \geq 1 - 2^{-\Omega(\frac{\alpha}{1-\alpha}|I|)} = 1 - 2^{-\Omega(\ell)}.\end{aligned}$$

Since $\ell = \Omega(n/(cd)^2) = \omega(1)$, in this case $\Delta(\boldsymbol{X}, \boldsymbol{U}^n_{\alpha n}) = 1 - o(1)$.

Now suppose that $|I| \leq \ell/2$, and let $J = \{t_1, \ldots, t_\ell\} \setminus I$. Assume that all bits in J satisfy $\Pr[\boldsymbol{X}_{N(i)} \neq 1^{N(i)}] = 1$. Let us compute the probability of this event for $\boldsymbol{U}^n_{\alpha n}$:

$$\begin{aligned}\Pr[(\boldsymbol{U}^n_{\alpha n})_{N(i)} \neq 1^{N(i)}] &= 1 - \binom{n - |N(i)|}{\alpha n}\binom{n}{\alpha n}^{-1} = 1 - \prod_{j=0}^{\alpha n - 1} \frac{n - |N(i)| - j}{n - j} \\ &\leq 1 - \left(1 - \frac{|N(i)|}{n}\right)^{\alpha n} \leq 1 - 2^{-\Omega(\alpha |N(i)|)} = 1 - 2^{-\Omega(cd)}.\end{aligned}$$

Therefore

$$\Pr[(\boldsymbol{U}^n_{\alpha n})_{N(i)} \neq 1^{N(i)} \text{ for all } i \in J] = \prod_{i \in J}(1 - 2^{-\Omega(cd)}) \leq (1 - 2^{-\Omega(cd)})^{\ell/2}.$$

Since $\ell/2 = n/(2(cd)^2) = \omega(2^{cd})$, we get the desired lower bound on the statistical distance in this case as well. ◀

▶ **Corollary 25.** *Let $\alpha \in (0,1)$ be a constant. Any switching network that generates a distribution that is $1 - \Omega(1)$ close to $\boldsymbol{U}^n_{\alpha n}$ has depth $\Omega(\log \log n)$.*

Proof. Consider a switching network of depth d that generates a distribution that is $1 - \Omega(1)$ close to $\boldsymbol{U}^n_{\alpha n}$. Lemma 23 translates it to a decision depth d sampler for $\boldsymbol{U}^n_{\alpha n}$ such that each input bit affects at most $c = 2^d$ output bits. The sampler is $1 - \Omega(1)$ close to $\boldsymbol{U}^n_{\alpha n}$, and supported within $\binom{[n]}{\alpha n}$. The result now follows from Lemma 24. ◀

B Exposition of the $\Omega(\log^* n)$ lower bound for Majority

The following is an exposition of the proof of [5, Theorem 5.1].

Suppose that n is odd, and consider a locality c proof system for the vectors containing more 1s than 0s, that is, having Hamming weight at least $(n+1)/2$. We can assume that $c \geq 2$.[4]

The proof system has *inputs* and *outputs*. The number of outputs is n, and each one depends on at most c input bits. An input bit is *d-influential* if at least d output bits depend on it. There are at most cn/d many d-influential input bits.

Let $1 = B(0) < B(1) < \cdots < B(c+1)$ be a sequence of constants (depending on c but not on n), and let $d(\ell) = cn/B(\ell)$, so that $cn = d(0) > d(1) > \cdots > d(c+1) = \Omega(n)$. Thus there are at most $B(\ell)$ many input bits which are $d(\ell)$-influential.

We will construct a sequence of sets $\emptyset = R_0 \subseteq R_1 \subseteq \cdots \subseteq R_c \subseteq [n]$ with the following property: *If ρ is a truth assignment to the $d(\ell)$-influential variables which extends to a complete truth assignment setting all coordinates in R_ℓ to zero, then for each coordinate $i \notin R_\ell$, ρ also extends to a complete truth assignment setting coordinate i to zero.*[5]

Given $R_{\ell-1}$, here is how we construct R_ℓ. We start with $R \coloneqq R_{\ell-1}$, and will potentially add more output coordinates to R. At any point, suppose that there is a truth assignment ρ to the $d(\ell)$-influential variables which (i) extends to a complete truth assignment setting all coordinates in R to zero, and (ii) for some coordinate $i \notin R$, any complete truth assignment extending ρ sets coordinate i to one. If that happens, then we add i to R. Henceforth, ρ will not come up again, since no complete truth assignment extending ρ sets i to one, and i belongs to R. Eventually, there is no such "bad" truth assignment, and we set $R_\ell \coloneqq R$.

If $i \in R_\ell$ then there exists some $r \leq \ell$, some $R \subseteq R_r$, and some truth assignment ρ_i to the $d(r)$-influential variables, such that ρ_i extends to a complete truth assignment setting all coordinates in R to zero, and any complete truth assignment extending ρ_i sets i to one. If $j \in R_\ell$ was added after i then the truth assignment ρ_j extends to a complete truth assignment which sets all coordinates in $R \cup \{i\}$ to zero. In particular, ρ_j doesn't extend ρ_i (as a special case, $\rho_j \neq \rho_i$). It follows that if we extend each ρ_i arbitrarily to a truth assignment to the $d(\ell)$-influential variables, then the resulting assignments will all be different. Consequently,

$$|R_\ell| \leq 2^{B(\ell)}.$$

For large enough n, this will be at most $\frac{n-1}{2}$.

We show below that for a proper choice of parameters, there is an output coordinate i which satisfies the following, for all $\ell \in \{0, \ldots, c\}$: *$i \notin R_\ell$, and all inputs to i which are also inputs to R_ℓ are $d(\ell+1)$-influential.* We will show that for each $\ell \in \{0, \ldots, c\}$, i has an input which is $d(\ell+1)$-influential but not $d(\ell)$-influential. For different ℓ these inputs are different (since an input which is not $d(\ell)$-influential is also not $d(r)$-influential for all $r < \ell$), and so i depends on $c+1$ inputs, which is impossible.

Let $\ell \in \{0, \ldots, c\}$. Let us show that i has an input which is $d(\ell+1)$-influential but not $d(\ell)$-influential. We do this by contradiction: suppose that all $d(\ell+1)$-influential inputs of i are $d(\ell)$-influential. By assumption, $i \notin R_\ell$ and all inputs to i which are also inputs to R_ℓ are $d(\ell)$-influential. Let $N(i)$ consist of i together with all other output bits which share some non-$d(\ell)$-influential bit with i. All of these shared input bits are in fact non-$d(\ell+1)$-influential, and so

$$|N(i)| \leq 1 + cd(\ell+1) \leq 1 + cd(1) = 1 + \frac{c^2 n}{B(1)}.$$

[4] Alternatively, change $B(0)$ or redefine d-influential as having *more than* d output bits depending on it.
[5] In the paper, ρ extends to a complete truth assignment setting both R_ℓ and i to zero.

If $B(1) > 2c^2$ then $|N(i)| < 1 + \frac{n}{2}$ and so $|N(i)| \leq (n+1)/2$. Since $|R_c| \leq \frac{n-1}{2}$, the proof system generates some vector v of weight $(n+1)/2$ in which all coordinates of R_c are zero and all coordinates of $N(i)$ are one. Consider an arbitrary complete truth assignment α which generates v, and let ρ be its restriction to the $d(\ell)$-influential coordinates. Since $i \notin R_\ell$, by construction, we know that ρ extends to some complete truth assignment β which sets i to zero. Now consider the following complete truth assignment:

$$\gamma(j) = \begin{cases} \rho(j) & \text{if } j \text{ is } d(\ell)\text{-influential,} \\ \beta(j) & \text{if } j \text{ is not } d(\ell)\text{-influential and influences } N(i), \\ \alpha(j) & \text{if } j \text{ is not } d(\ell)\text{-influential and doesn't influence } N(i). \end{cases}$$

Since α, β both extend ρ, γ agrees with them on the $d(\ell)$-influential variables. Therefore the output generated by γ agrees with that generated by α except for the coordinates in $N(i)$, which could change from one to zero. Moreover, the i'th output of γ agrees with the i'th output of β, namely, it is zero. Therefore the output generated by γ has Hamming weight strictly less than $(n+1)/2$, which is impossible.

It remains to show that there exists an output bit i such that $i \notin R_c$, and for all $\ell \in \{0, \ldots, c\}$, all inputs to i which are also inputs to R_ℓ are $d(\ell+1)$-influential. We do this by giving an upper bound on the number of bad output bits. An output bit is bad if it either belongs to R_c, or for some $\ell \in \{0, \ldots, c\}$, there is a joint input of i and R_ℓ which is not $d(\ell+1)$-influential. If i is bad due to some ℓ, then there must be some non-$d(\ell+1)$-influential input of R_ℓ which is an input of i. Therefore the number of bad inputs is at most

$$|R_c| + \sum_{\ell=0}^{c} |R_\ell| \cdot c \cdot d(\ell+1) \leq 2^{B(c)} + n \cdot c^2 \sum_{\ell=0}^{c} \frac{2^{B(\ell)}}{B(\ell+1)}.$$

For a judicious choice of the sequence $B(\ell)$, the coefficient of n will be strictly less than 1, and so for large enough n, there are fewer than n bad inputs.

One choice for the sequence $B(\ell)$ is

$$B(\ell+1) = 2^{B(\ell)} \cdot 2c^2(c+1).$$

In particular, $B(1) = 4c^2(c+1) > 2c^2$, which was needed above. For this choice of $B(0), \ldots, B(c)$, the number of bad inputs is at most

$$2^{B(c)} + \frac{n}{2},$$

which less than n if $2^{B(c)} \leq \frac{n-1}{2}$, a condition which was required at a different step of this proof.

Roughly speaking, $B(\ell+1) \approx 2c^3 \cdot 2^{B(\ell)}$, and so $B(c) \approx 2 \uparrow\uparrow c$. Therefore $2^{B(c)} \leq \frac{n-1}{2}$, and so the argument works, for $c \leq \kappa \log^* n$, for an appropriate constant κ.

Hardness of the (Approximate) Shortest Vector Problem: A Simple Proof via Reed-Solomon Codes*

Abstract

We give a *simple* proof that the (approximate, decisional) Shortest Vector Problem is NP-hard under a randomized reduction. Specifically, we show that for any $p \geq 1$ and any constant $\gamma < 2^{1/p}$, the γ-approximate problem in the ℓ_p norm (γ-GapSVP$_p$) is not in RP unless NP $\subseteq$ RP. Our proof follows an approach pioneered by Ajtai (STOC 1998), and strengthened by Micciancio (FOCS 1998 and SICOMP 2000), for showing hardness of γ-GapSVP$_p$ using *locally dense lattices.* We construct such lattices simply by applying "Construction A" to Reed-Solomon codes with suitable parameters, and prove their local density via an elementary argument originally used in the context of Craig lattices.

As in all known NP-hardness results for GapSVP$_p$ with $p < \infty$, our reduction uses randomness. Indeed, it is a notorious open problem to prove NP-hardness via a deterministic reduction. To this end, we additionally discuss potential directions and associated challenges for derandomizing our reduction. In particular, we show that a close deterministic analogue of our local density construction would improve on the state-of-the-art explicit Reed-Solomon list-decoding lower bounds of Guruswami and Rudra (STOC 2005 and IEEE Transactions on Information Theory 2006).

As a related contribution of independent interest, we also give a polynomial-time algorithm for decoding n-dimensional "Construction A Reed-Solomon lattices" (with different parameters than those used in our hardness proof) to a distance within an $O(\sqrt{\log n})$ factor of Minkowski's bound. This asymptotically matches the best known distance for decoding near Minkowski's bound, due to Mook and Peikert (IEEE Transactions on Information Theory 2022), whose work we build on with a somewhat simpler construction and analysis.

1 Introduction

> [I]t may easily happen that other, perhaps in some sense simpler, lattices also have the properties that are required from L to complete the proof... There are different reasons which may motivate the search for such a lattice: to make the proof deterministic; to improve the factor in the approximation result; to make the proof simpler.
>
> Miklós Ajtai, [3, Remark 2]

A *lattice* $\mathcal{L}$ is the set of all integer linear combinations of some n linearly independent vectors $\boldsymbol{b}_1, \ldots, \boldsymbol{b}_n \in \mathbb{R}^m$. The matrix $B = (\boldsymbol{b}_1, \ldots, \boldsymbol{b}_n)$ whose columns are these vectors is called a *basis* of $\mathcal{L}$, and n is called its *rank*. Formally, the lattice $\mathcal{L}$ generated by B is defined as

$$\mathcal{L} = \mathcal{L}(B) := \left\{ \sum_{i=1}^{n} a_i \boldsymbol{b}_i : a_1, \ldots, a_n \in \mathbb{Z} \right\} .$$

Lattices are classically studied mathematical objects, and have proved invaluable in many computer science applications, especially the design and analysis of cryptosystems. Indeed, the area of lattice-based cryptography, which designs cryptosystems whose security is based on the apparent intractability of certain computational problems on lattices, has flourished over the past quarter century. (See [36] and its bibliography for a comprehensive summary and list of references.)

The central computational problem on lattices is the Shortest Vector Problem (SVP): given a lattice basis B as input, the goal is to find a shortest non-zero vector in $\mathcal{L}(B)$. This paper is concerned with its γ-approximate decision version in the ℓ_p norm (γ-GapSVP$_p$), where $p \geq 1$ is fixed and the approximation factor $\gamma = \gamma(n) \geq 1$ is some function of the lattice rank n (often a constant). Here the input additionally includes a distance threshold $s > 0$, and the goal is to determine whether the length (in the ℓ_p norm) $\lambda_1^{(p)}(\mathcal{L}) := \min_{\boldsymbol{v} \in \mathcal{L} \setminus \{\boldsymbol{0}\}} \|\boldsymbol{v}\|_p$ of the shortest non-zero vector in $\mathcal{L}$ is at most s, or is strictly greater than γs, when one of the two cases is promised to hold. For the exact problem, where $\gamma = 1$, we often simply write GapSVP$_p$.

Motivated especially by its central role in the security of lattice-based cryptography, understanding the complexity of γ-GapSVP has been the subject of a long line of work. In an early technical report, van Emde Boas [38] initiated the study of the hardness of lattice problems more generally, and in particular showed that GapSVP$_\infty$ is NP-hard. Seventeen years later, Ajtai [3] finally showed similar hardness for the important Euclidean case of $p = 2$, i.e., he showed that exact GapSVP$_2$ is NP-hard, though under a *randomized* reduction. Subsequent work [10, 31, 27, 26, 23, 32] improved this by showing that γ-GapSVP$_p$ in any ℓ_p norm is NP-hard to approximate for any constant $\gamma \geq 1$, and hard for nearly polynomial factors $\gamma = n^{\Omega(1/\log\log n)}$ assuming stronger complexity assumptions, also using randomized reductions. Recent work [1, 7] has also shown the *fine-grained* hardness of γ-GapSVP$_p$ for small constants γ (again under randomized reductions). On the other hand, γ-GapSVP$_p$ for finite $p \geq 2$ is unlikely to be NP-hard for approximation factors $\gamma \geq C_p\sqrt{n}$ (where C_p is a constant depending only on p) [18, 2, 35], and the security of lattice-based cryptography relies on the conjectured hardness of GapSVP or other problems for even larger (but typically polynomial) factors.

While this line of work has been very successful in showing progressively stronger hardness of approximation and fine-grained hardness for γ-GapSVP$_p$, it leaves some other important issues unresolved. First, for $p \neq \infty$ the hardness reductions and their analysis are rather complicated, and second, they are randomized. Indeed, it is a notorious, long-standing open problem to prove that GapSVP_p is NP-hard, even in its exact form, under a deterministic reduction for some finite p. While there have been some potential steps in this direction [31, 32], e.g., using plausible number-theoretic conjectures that appear very hard to prove, there has been no new progress on this front for a decade.

1.1 Our Contributions

The primary contribution of this work is to give a substantially simpler proof that γ-GapSVP_p is NP-hard under a randomized reduction, for any $p \geq 1$ and constant $\gamma < 2^{1/p}$. The heart of our reduction is a family of "gadget" lattices $\mathcal{L}$ derived from Reed-Solomon codes $\mathcal{C} \subseteq \mathbb{F}_q^n$ (for prime q) via the very natural "Construction A" [13], which simply sets $\mathcal{L} = \mathcal{C} + q\mathbb{Z}^n$. These lattices and their properties were previously studied in work of Karabed, Roth, and Siegel [25, 37]. Additionally, they are closely related to a family of algebraic lattices studied by Craig [14]. We take advantage of this prior work in our analysis (see Section 1.3 for details).

▶ **Theorem 1** (Hardness of γ-GapSVP_p)**.** *For any $p \geq 1$ and constant γ satisfying $1 \leq \gamma < 2^{1/p}$, γ-GapSVP_p is not in* RP *unless* NP $\subseteq$ RP*.*

We note that Theorem 1 is actually identical to the main result in [31]. As such, it matches the best known NP-hardness of approximation for γ-GapSVP_p (i.e., largest γ) achieved by a "one-shot" reduction for all sufficiently small p, including $p = 2$. By "one-shot," we mean that the reduction does not amplify the approximation factor from an initial fixed constant to an arbitrary constant (or more) via tensoring, as is done in [26, 23, 32]. (It is an interesting question whether our hard γ-GapSVP_p instances are amenable to tensoring; see Section 1.4.)

Although our reduction still uses randomness, we believe that it may be easier to derandomize than previous reductions, both due to its simplicity, and because of its close connection to prior work showing hardness of minimum distance problem on codes via a deterministic reduction [12]. To that end, in the full version of our paper [6] we also describe two approaches to potentially derandomizing our reduction, both of which aim to deterministically construct a particular lattice coset and lower bound the number of short vectors in it (see Section 1.2 for the motivation for this). The first approach is based on Fourier analysis, using similar techniques to those in [12], and the second is based on "smooth" proxies for point-counting functions.

In the full version of our paper [6] we also show that a close deterministic analog of our randomized local-density construction would imply improved explicit Reed-Solomon list-decoding lower bounds, going beyond the current state of the art from [20]. One may interpret this implication either pessimistically, as a barrier to a very strong derandomization of our reduction, or optimistically, as a potential route to improve Reed-Solomon list-decoding lower bounds. Here there is a further connection between the two problems, in that [20] obtains its list-decoding lower bounds by using the same Fourier-analytic tool underlying one of our derandomization attempts – specifically, the Weil bound for character sums . Unfortunately, the Weil bound falls just short of what we need in our context. (The Weil bound and related techniques were first used for counting Reed-Solomon code words in [11], and were also used in the deterministic hardness reduction for the minimum distance problem on codes in [12].)

Efficient decoding near Minkowski's bound. As a separate contribution of independent interest, in Appendix A we give a polynomial-time algorithm for decoding "Construction A Reed-Solomon lattices" of rank n – the same family of lattices as in our hardness reduction, but instantiated with different parameters – to a distance within a $O(\sqrt{\log n})$ factor of

Minkowski's bound.[1] The $O(\sqrt{\log n})$ factor in our result asymptotically matches the best factor known from prior work [34], which is for a different family of lattices. In fact, we rely on one of the main underlying theorems from that work, but give a simpler construction and analysis based on individual Reed-Solomon codes instead of towers of BCH codes.

Let $\mathrm{RS}_q[k, S]$ denote the dimension-k Reed-Solomon code over $\mathbb{F}_q$ with evaluation set S (defined below in Equation (3)). Note that $n = q$ is the rank of the lattice $\mathcal{L}$ in the following theorem.

▶ **Theorem 2** (Decoding near Minkowski's bound, informal). *Let q be prime and let $k := \lfloor q/(2\log_2 q)\rfloor \leq q/2$. Then for the "Construction A Reed-Solomon" lattice $\mathcal{L} := \mathrm{RS}_q[q-k, \mathbb{F}_q] + q\mathbb{Z}^q \subseteq \mathbb{Z}^q$:*

1. *We have $\Omega(\sqrt{q/\log q}) \leq \lambda_1(\mathcal{L}) \leq \sqrt{q} \cdot \det(\mathcal{L})^{1/q} \leq O(\sqrt{q})$, i.e., the minimum distance is within a $O(\sqrt{\log q})$ factor of Minkowski's bound.*
2. *There is an algorithm that, on input q and a vector $\boldsymbol{y} \in \mathbb{R}^q$, outputs all lattice vectors $\boldsymbol{v} \in \mathcal{L}$ satisfying $\|\boldsymbol{y} - \boldsymbol{v}\| \leq C\sqrt{k} \approx C\sqrt{q/(2\log_2 q)}$ in time polynomial in q, for some universal constant $C > 0$.*

This result adds to a separate line of work on efficient (list) decoding for various families of lattices [33, 19, 15, 34]. Recently, Ducas and van Woerden [16] further motivated this study by showing cryptographic applications of lattices that can be efficiently decoded near Minkowski's bound. (However, their application is most compelling when the minimum distances of both the lattice and its dual are close to Minkowski's bound, which is not the case in the present setting.)

1.2 Technical Overview

Here we give an overview of the key new elements in the proof of our main hardness theorem (Theorem 1), which are the focus of Section 3. For concision, we defer the technical aspects of our efficient decoding algorithm to Appendix A and of our derandomization attempts to the full version of our paper [6], respectively.

Besides using randomness, another common feature in nearly all prior hardness results for GapSVP_p is the use of *locally dense lattices* as advice (the only exception being [27]). Roughly speaking, a locally dense lattice for relative distance $\alpha \in (0, 1)$ in the ℓ_p norm is a lattice $\mathcal{L}$ and a coset $\boldsymbol{x} + \mathcal{L}$ (i.e., the lattice "shifted by" some vector $\boldsymbol{x}$) such that there are at least subexponentially many (in the lattice rank) vectors $\boldsymbol{v} \in \boldsymbol{x} + \mathcal{L}$ satisfying $\|\boldsymbol{v}\|_p \leq \alpha \cdot \lambda_1^{(p)}(\mathcal{L})$. One may view such a coset $\boldsymbol{x} + \mathcal{L}$ as a "bad" configuration for list-decoding $\mathcal{L}$ to within relative distance α in the ℓ_p norm, because there are many lattice vectors relatively close to $-\boldsymbol{x}$.[2]

Prior works have obtained locally density from a variety of lattice families: the Schnorr-Adelman prime number lattices [3, 10, 31]; a variant of Construction A [26] and Construction D [32] applied to (towers of) BCH codes; and random sublattices of $\mathbb{Z}^n$ and lattices with exponential kissing number [1, 7]. In this work, we give a simple construction of locally dense lattices from Reed-Solomon codes, as described below.

[1] Minkowski's bound gives an upper bound on the "normalized density" of a lattice $\mathcal{L}$. Specifically, it asserts that $\lambda_1^{(2)}(\mathcal{L}) \leq \sqrt{n} \cdot \det(\mathcal{L})^{1/n}$ for all rank-n lattices $\mathcal{L}$, where $\det(\mathcal{L}) = \sqrt{\det(B^T B)}$ for any basis B of $\mathcal{L}$.

[2] For technical reasons, the formal definition of local density, given in Definition 8, also requires a linear transform that maps the short vectors in $\boldsymbol{x} + \mathcal{L}$ onto the set of all binary vectors of a given dimension. Such a transform can be obtained by random sampling using a probabilistic version of Sauer's Lemma (see Theorem 9) that is now standard in this context [3, 31]. Therefore, we defer further discussion of this issue to the main body.

Our main reduction (Theorem 12) shows how to use a locally dense lattice for relative distance α in the ℓ_p norm to prove NP-hardness (via a randomized reduction) of γ-GapSVP$_p$ for any constant $\gamma > 1/\alpha$. This reduction is very similar to those from prior works, so for the remainder of this section we focus on summarizing our new construction of locally dense lattices.

Locally dense lattices from Reed-Solomon codes. We start with some basic definitions and facts used in our construction. Recall that the Construction A lattice obtained from a linear code $\mathcal{C} \subseteq \mathbb{F}_q^n$ for some prime q is defined as $\mathcal{L} := \mathcal{C} + q\mathbb{Z}^n$, i.e., an integer vector $\boldsymbol{z} \in \mathbb{Z}^n$ is in the lattice if and only if $\boldsymbol{z} \bmod q$ is a code word. In fact, it will often be convenient to work with an equivalent "dual view" of Construction A lattices. Namely, if $H \in \mathbb{F}_q^{k \times n}$ is a parity-check matrix of a linear code $\mathcal{C} := \ker(H) \subseteq \mathbb{F}_q^n$ for prime q, then the *parity-check lattice* $\mathcal{L}^\perp(H)$ obtained from H is defined as

$$\mathcal{L}^\perp(H) := \{\boldsymbol{z} \in \mathbb{Z}^n : H\boldsymbol{z} = \boldsymbol{0} \in \mathbb{F}_q^k\} = \ker(H) + q\mathbb{Z}^n = \mathcal{C} + q\mathbb{Z}^n \ . \tag{1}$$

Such lattices have determinant $\det(\mathcal{L}^\perp(H)) = |\mathbb{Z}^n/\mathcal{L}^\perp(H)| \leq q^k$, with equality exactly when H has full row rank (see Lemma 4).

We next define the family of parity-check matrices $H = H_q(k, S)$ that we use to construct our family of locally dense lattices. Such a matrix is parameterized by a prime q, a positive integer k, and a set $S \subseteq \mathbb{F}_q$. Letting $s_0, \ldots, s_{n-1}$ be the elements of S in some arbitrary order, we define

$$H = H_q(k, S) := \begin{pmatrix} 1 & 1 & 1 & \cdots & 1 \\ s_0 & s_1 & s_2 & \cdots & s_{n-1} \\ s_0^2 & s_1^2 & s_2^2 & \cdots & s_{n-1}^2 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ s_0^{k-1} & s_1^{k-1} & s_2^{k-1} & \cdots & s_{n-1}^{k-1} \end{pmatrix} \in \mathbb{F}_q^{k \times n} \ . \tag{2}$$

That is, $H_q(k, S)$ is the transposed Vandermonde matrix whose (i, s)th entry is s^i, where for convenience we index the rows and columns of $H_q(k, S)$ by $i \in \{0, \ldots, k-1\}$ and $s \in S$, respectively, and define $0^0 := 1$.

The matrix $H = H_q(k, S)$ defined in Equation (2) is a *generator matrix* of the dimension-k Reed-Solomon code

$$\mathrm{RS}_q[k, S] := \{(p(s))_{s \in S} : p \in \mathbb{F}_q[x], \deg(p) < k\} \tag{3}$$

over $\mathbb{F}_q$ with evaluation set S, and hence is a parity-check matrix of its dual code, which is a so-called *generalized* Reed-Solomon (GRS) code (see [22, Theorem 5.1.6]). Moreover, in the special case where $S = \mathbb{F}_q$, it turns out that $H_q(k, S)$ is a parity-check matrix for the (ordinary) Reed-Solomon code $\mathrm{RS}_q[q-k, \mathbb{F}_q]$ of dimension $q - k$ with evaluation set $S = \mathbb{F}_q$. So, $\mathcal{L}^\perp(H_q(k, \mathbb{F}_q)) = \mathrm{RS}_q[q-k, \mathbb{F}_q] + q\mathbb{Z}^q$ is the Construction A lattice corresponding to the Reed-Solomon code $\mathrm{RS}_q[q-k, \mathbb{F}_q]$. For simplicity, in this overview we restrict to these "Construction A Reed-Solomon" lattices by taking $S = \mathbb{F}_q$, but note that our results generalize to any sufficiently large $S \subseteq \mathbb{F}_q$.

It is easy to see that for $k < q$, the GRS code having parity-check matrix H has minimum distance (in the Hamming metric) $k + 1$: any k columns of H are linearly independent, because they form a transposed Vandermonde matrix, while any $k + 1$ obviously are not. Therefore, the corresponding Construction A lattice $\mathcal{L} := \ker(H) + q\mathbb{Z}^q$ has minimum distance $\lambda_1^{(1)}(\mathcal{L}) \geq k + 1$ in the ℓ_1 norm. The key to our local density construction and its $\alpha \approx 1/2^{1/p}$

relative distance is that the ℓ_1 minimum distance is in fact almost *twice* this large (at least): in Theorem 14 we show that $\lambda_1^{(1)}(\mathcal{L}) \geq 2k$ when $k \leq q/2$. The proof is short and elementary, proceeding via Newton's identities. Essentially the same result and proof originally appeared in work by Roth and Siegel [37], and closely related analysis also appeared in work on Craig lattices [14] (see Section 1.3).

Obtaining a dense coset. Because the determinant of $\mathcal{L}$ (i.e., the number of its integer cosets) is q^k, the pigeonhole principle immediately implies that there exists an integer coset of $\mathcal{L}$ containing at least $\binom{q}{h}/q^k$ *binary* vectors in $\{0,1\}^q$ with Hamming weight h, which have ℓ_1 norm h. By setting parameters appropriately, this yields a coset with subexponentially many vectors of ℓ_1 norm at most $\alpha \cdot \lambda_1^{(1)}(\mathcal{L})$, for any constant $\alpha > 1/2$.

More specifically, set $h := \alpha \cdot (2k) \leq \alpha \cdot \lambda_1^{(1)}(\mathcal{L})$ and $q \approx k^{1/\varepsilon}$ for some positive constant $\varepsilon < 1 - 1/(2\alpha)$. (For simplicity, assume that h is an integer.) Then there must exist an integer coset of $\mathcal{L}$ containing at least

$$\frac{\binom{q}{h}}{q^k} \geq \left(\frac{q}{h}\right)^h \cdot q^{-k} = \frac{q^{(2\alpha-1)k}}{(2\alpha k)^{2\alpha k}} \approx \frac{q^{(2\alpha-1)k}}{q^{2\varepsilon\alpha k}} = q^{(2(1-\varepsilon)\alpha-1)k} = q^{\Omega(k)} = q^{\Omega(q^{\varepsilon})} \tag{4}$$

weight-h binary vectors, which is subexponentially large in q.

The above shows the *existence* of a suitable coset, but following previous works, it is straightforward to show that a *randomly sampled* coset from a suitable distribution is likely to have enough short vectors (see Lemma 16). Indeed, the difference between showing that such a coset exists, versus sampling one efficiently, versus deterministically computing one efficiently, is the main technical difference between getting a non-uniform, versus randomized, versus deterministic hardness reduction (respectively) for GapSVP_p using these techniques.

The above argument generalizes to arbitrary ℓ_p norms for finite p, albeit for larger relative distances $\alpha > 1/2^{1/p}$. Because $\mathcal{L}$ is integral, $\lambda_1^{(1)}(\mathcal{L}) \geq 2k$ implies that $\lambda_1^{(p)}(\mathcal{L}) \geq (2k)^{1/p}$ for any finite $p \geq 1$. Moreover, reparameterizing the calculation in Equation (4) by choosing $\alpha > 1/2^{1/p}$ and setting $h := \alpha^p \cdot (2k)$ shows that some coset of $\mathcal{L}$ contains subexponentially many binary vectors of Hamming weight h, and hence of ℓ_p norm $h^{1/p} = \alpha \cdot (2k)^{1/p} \leq \alpha \cdot \lambda_1^{(p)}(\mathcal{L})$. Therefore, this construction yields locally dense lattices in the ℓ_p norm for any constant relative distance $\alpha > 1/2^{1/p}$, which by our main reduction implies Theorem 1, i.e., randomized NP-hardness of γ-GapSVP_p for any constant $\gamma < 2^{1/p}$.

1.3 Additional Related Work

First, we note that after this work was first published [5] used the properties of the gadget lattices $\mathcal{L} = \mathcal{L}^{\perp}(H_q(k, S))$ we construct to show improved results and answer an open question about the *parameterized* complexity of GapSVP. Somewhat more specifically, [5] gave a parameterized analog of Theorem 1 by showing $\mathsf{W}[1]$-hardness (under randomized reductions) of γ-GapSVP_p for any $p \geq 1$ and any γ satisfying $1 \leq \gamma < 2^{1/p}$. This in particular answered a question from [17, 9], which asked whether γ-GapSVP was $\mathsf{W}[1]$-hard in the ℓ_1 norm. Prior to [5] (which crucially relied on this work), such hardness was not known even in the exact case of $\gamma = 1$.

The key lower bound of $\lambda_1^{(1)}(\mathcal{L}) \geq 2k$ for $\mathcal{L} = \mathcal{L}^{\perp}(H_q(k, S))$ follows immediately from works by Karabed, Roth, and Siegel [25, 37], which adapted an argument by Immink and Beenker [24]. In fact, [25, 37] showed their lower bounds for the *Lee* minimum distance of a family of BCH codes, including ones that are Reed-Solomon codes with parity check matrices of the form $H_q(k, S)$. However, their results immediately apply to the ℓ_1 minimum distance of $\mathcal{L} = \mathcal{L}^{\perp}(H_q(k, S))$ as well, because Lee distance is essentially "ℓ_1 distance with wrap-around."[3] Even earlier, Berlekamp [8, Chapter 9] gave an argument using Newton's identities to prove a similar lower bound on the Lee minimum distance of negacyclic codes, which are codes whose parity check matrices are of the form in Equation (2) but with its even-power rows deleted (i.e., with only its odd-power rows). Additionally, our Construction A Reed-Solomon lattices $\mathcal{L}$ are closely related to a family of algebraic lattices studied by Craig [14]; see also [13, Chapter 8, Section 6].[4] Indeed, [13, Chapter 8, Section 6, Theorem 7] again gives a very similar argument for lower bounding the minimum distance of Craig lattices using Newton's identities.Our proof of Theorem 14 is inspired by and similar to all of these "minimum distance lower bounds via Newton's identities" arguments, and in particular is very similar to the ones in [37] and [13, Chapter 8, Section 6, Theorem 7].

We omit further discussion of related work due to space constraints and encourage the reader to view the full version of this work [6].

1.4 Open Questions

The obvious question left open by our work is whether our reduction can be derandomized, using the same family of lattices. Addressing this is the main focus of Section 5 in the full version of this paper [6]. The full version also discusses several other open questions. We omit this material due to space constraints, but strongly encourage the reader to view [6].

2 Preliminaries

Throughout this work we adopt the convention that $0^0 := 1$ in any ring. For a positive integer k, define $[k] := \{0, 1, \ldots, k-1\}$.

In general, every vector or matrix is indexed by some specified set S. For example, $\boldsymbol{x} \in \mathbb{Z}^S$ is an integer vector indexed by S, having an entry $x_s \in \mathbb{Z}$ for each $s \in S$ (and no other entries). When the index set is $[n]$ for some non-negative integer n, we usually omit the brackets in the exponent and just write, e.g., $\mathbb{Z}^n$. We emphasize that in this case the indices start from zero. An object indexed by a finite set S of size $n = |S|$ can be reindexed by $[n]$, simply by enumerating $S = \{s_0, \ldots, s_{n-1}\}$ under some arbitrary order, and identifying index s_i with index i.

For a finite set S and a positive integer $h \leq |S|$, let $B_{S,h} := \{\boldsymbol{v} \in \{0,1\}^S : \|\boldsymbol{v}\|_1 = h\}$ be the set of binary vectors indexed by S of Hamming weight h. As above, when $S = [n]$ we often write $B_{n,h}$. Finally, let $\mathcal{B}_p^n(r) := \{\boldsymbol{x} : \|\boldsymbol{x}\|_p \leq r\} \subset \mathbb{R}^n$ denote the real n-dimensional ℓ_p ball of radius r centered at the origin.

2.1 Basic Lattice Definitions

Given a lattice $\mathcal{L} = \mathcal{L}(B)$ with basis $B \in \mathbb{R}^{m \times n}$, we define the *rank* of $\mathcal{L}$ to be n and the (ambient) *dimension* of $\mathcal{L}$ to be m. We denote the *minimum distance* of $\mathcal{L}$ in the ℓ_p norm, which is the length of a shortest non-zero vector in $\mathcal{L}$, by

[3] More precisely, the Lee distance of $\boldsymbol{x} \in \mathbb{F}_q^n$ is $\sum_{i=1}^n \min\{x_i, q - x_i\}$, where elements of the prime-order field $\mathbb{F}_q$ are identified in the natural way with the integers $\{0, 1, \ldots, q-1\}$. This is the natural analog of ℓ_1 distance on $\mathbb{F}_q$ (or $\mathbb{Z}_q$). Moreover, the ℓ_1 minimum distance of the Construction A lattice $\mathcal{C} + q\mathbb{Z}^n$ is equal to the minimum of q and the Lee minimum distance of $\mathcal{C}$.

[4] Specifically, [13] considers Craig lattices obtained from the coefficient vectors of polynomials in principal ideals of the form $(x-1)^m R$ in rings of the form $R = \mathbb{Z}[x]/(x^p - 1)$, for some prime p and integer $m \geq 1$. The original definition of [14] is slightly different, and uses the "canonical" (Minkowski) embedding of such ideals in the ring of integers $R = \mathbb{Z}[x]/(\Phi_p(x))$ of the pth cyclotomic number field.

$$\lambda_1^{(p)}(\mathcal{L}) := \min_{\boldsymbol{x}\in\mathcal{L}\setminus\{0\}} \|\boldsymbol{x}\|_p \ .$$

The central problem that we study in this work asks about the value of $\lambda_1^{(p)}(\mathcal{L})$ for a given input lattice $\mathcal{L}$.

▶ **Definition 3.** *For $p \geq 1$ and $\gamma = \gamma(n) \geq 1$, the decisional, γ-approximate Shortest Vector Problem in the ℓ_p norm (γ-GapSVP_p) is the promise problem defined as follows. The input consists of a basis $B \in \mathbb{Z}^{m\times n}$ of an integer lattice $\mathcal{L}$ and a distance threshold $s > 0$, and the goal is to determine whether the input is a YES instance or a NO instance, where these are defined as follows:*

- *YES instance: $\lambda_1^{(p)}(\mathcal{L}) \leq s$.*
- *NO instance: $\lambda_1^{(p)} > \gamma s$.*

We define the *determinant* of $\mathcal{L}$ to be $\det(\mathcal{L}) := \sqrt{\det(B^T B)}$, which is equal to $|\det(B)|$ when $m = n$ (i.e., when $\mathcal{L}$ is full-rank). We note that determinant is well defined because, although lattice bases are not unique, they are equivalent up to multiplication on the right by unimodular matrices.

The density of a rank-n lattice $\mathcal{L}$ is captured by its so-called *root Hermite factor* $\lambda_1(\mathcal{L})/\det(\mathcal{L})^{1/n}$.[5] The density of a lattice corresponds to its quality in various applications, including as the set of centers of a sphere packing and as an error-correcting code. Minkowski's bound asserts that the root Hermite factor of such a rank-n lattice is at most $\sqrt{n}$, which is convenient to write in expanded form as

$$\lambda_1(\mathcal{L}) \leq \sqrt{n} \cdot \det(\mathcal{L})^{1/n} \ . \tag{5}$$

2.2 Parity-Check Matrices and Lattices

For a prime q and a matrix $H \in \mathbb{F}_q^{k\times n}$, we define the *parity-check lattice* $\mathcal{L}^\perp(H)$ obtained from H as

$$\mathcal{L}^\perp(H) := \{\boldsymbol{z} \in \mathbb{Z}^n : H\boldsymbol{z} = \boldsymbol{0}\} = \ker(H) + q\mathbb{Z}^n \ . \tag{6}$$

Note that $\mathcal{L}^\perp(H)$ is simply the "Construction A" lattice [13, Chapter 5, Section 2] of the linear error-correcting code $\mathcal{C}$ having H as a parity-check matrix, i.e., $\mathcal{C} = \{\boldsymbol{c} \in \mathbb{F}_q^n : H\boldsymbol{c} = \boldsymbol{0}\}$. More generally, for any "syndrome" $\boldsymbol{u} \in \mathbb{F}_q^k$ we define

$$\mathcal{L}_{\boldsymbol{u}}^\perp(H) := \{\boldsymbol{x} \in \mathbb{Z}^n : H\boldsymbol{x} = \boldsymbol{u}\} \ .$$

If there exists some $\boldsymbol{x} \in \mathbb{Z}^n$ such that $H\boldsymbol{x} = \boldsymbol{u}$, then it follows immediately that $\mathcal{L}_{\boldsymbol{u}}^\perp(H)$ is simply the lattice coset $\boldsymbol{x}+\mathcal{L}^\perp(H)$. So, we can identify cosets of $\mathcal{L}^\perp(H)$ by their corresponding syndromes. We recall some standard properties of parity-check lattices, and give a proof for self-containment.

▶ **Lemma 4.** *Let q be a prime, let k and n be positive integers, and let $H \in \mathbb{F}_q^{k\times n}$ be a parity-check matrix. Then the parity-check lattice $\mathcal{L} = \mathcal{L}^\perp(H)$ has rank n and determinant $\det(\mathcal{L}) \leq q^k$, with equality if and only if the rows of H are linearly independent.*

[5] This ratio is the square root of the Hermite factor $\gamma(\mathcal{L}) := (\lambda_1(\mathcal{L})/\det(\mathcal{L})^{1/n})^2$, which is defined in this way for historical reasons.

Proof. The first claim follows simply by noting that $q\mathbb{Z}^n \subseteq \mathcal{L}^\perp(H) \subseteq \mathbb{Z}^n$. For the determinant, observe that the map $\boldsymbol{x} \mapsto H\boldsymbol{x}$ is an additive-group homomorphism from $\mathbb{Z}^n$ to $\mathbb{F}_q^k$, and that $\mathcal{L}^\perp(H)$ is its kernel by definition. So, by the first isomorphism theorem, the map induces an isomorphism from the quotient group $\mathbb{Z}^n/\mathcal{L}^\perp(H)$ to the image $\mathrm{Im}(H) = \{H\boldsymbol{x} : \boldsymbol{x} \in \mathbb{Z}^n\} \subseteq \mathbb{F}_q^k$, where the subset relation is an equality if and only if the rows of H are linearly independent. The claim then follows from the fact that $\det(\mathcal{L}^\perp(H)) = \left|\mathbb{Z}^n/\mathcal{L}^\perp(H)\right| = |\mathrm{Im}(H)|$. ◀

We next formally define the family of parity-check lattices that are at the heart of our construction of locally dense lattices.

▶ **Definition 5.** *For a prime q, positive integer k, and set $S \subseteq \mathbb{F}_q$, define $H_q(k, S) \in \mathbb{F}_q^{k\times S}$ to be the matrix H whose rows and columns are respectively indexed by $[k] = \{0, 1, \dots, k-1\}$ and S, and whose (i, s)th entry is*

$$H_{i,s} := s^i \in \mathbb{F}_q \ .$$

(Recall that $0^0 := 1$.) Equivalently, if we enumerate $S = \{s_0, \dots, s_{n-1}\}$ in some arbitrary order, we have

$$H = H_q(k, S) := \begin{pmatrix} 1 & 1 & 1 & \cdots & 1 \\ s_0 & s_1 & s_2 & \cdots & s_{n-1} \\ s_0^2 & s_1^2 & s_2^2 & \cdots & s_{n-1}^2 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ s_0^{k-1} & s_1^{k-1} & s_2^{k-1} & \cdots & s_{n-1}^{k-1} \end{pmatrix} \in \mathbb{F}_q^{k\times n} \ . \tag{7}$$

Notice that H is a transposed Vandermonde matrix. In particular, if $k \le n$ then its rows are linearly independent, and so $\det(\mathcal{L}^\perp(H)) = q^k$ by Lemma 4.

We recall from the introduction that $H = H_q(k, S)$ is a generator matrix (of row vectors) of the dimension-k Reed-Solomon code over $\mathbb{F}_q$ with evaluation set S, and hence H is a parity-check matrix of its dimension-$(n-k)$ dual code. So, $\mathcal{L}^\perp(H)$ is the Construction A lattice of this dual code. These dual codes are in fact *generalized Reed-Solomon codes*, a family of codes that include Reed-Solomon codes as a special case and that are closed under taking duals (see [22, Theorem 5.1.6]). Moreover, in the special case where $S = \mathbb{F}_q$, the matrix $H = H_q(k, \mathbb{F}_q)$ is in fact a parity-check matrix of an (ordinary) Reed-Solomon code. For our hardness proof it suffices to use this special case; i.e., we show NP-hardness (under a randomized reduction) of GapSVP by using Construction A lattices of (ordinary) Reed-Solomon codes as gadgets. See Appendix A and the section on derandomization in the full version of this paper [6] for other connections between these lattices and Reed-Solomon codes.

2.3 Symmetric Polynomials

A *symmetric polynomial* $P(x_1, x_2, \dots, x_m)$ is a polynomial that is invariant under any permutation of its variables, i.e., $P(x_1, \dots, x_m) = P(x_{\pi(1)}, \dots, x_{\pi(m)})$ as formal polynomials for all permutations π of $\{1, 2, \dots, m\}$. Because the order of the variables is immaterial, we usually just write a symmetric polynomial as $P(X)$, where $X = \{x_1, \dots, x_m\}$ is the set of variables, and we write $P(T)$ for its evaluation on a multiset T of values.

We next recall two important symmetric polynomials and the relationship between them. For a non-negative integer i, the ith *power sum* of a set X of variables is defined as

$$p_i(X) := \sum_{x\in X} x^i \ . \tag{8}$$

(Recall that $0^0 := 1$.) For $1 \le i \le |X|$, the ith *elementary symmetric polynomial* of X is defined as

$$e_i(X) := \sum_{\substack{Z \subseteq X, \\ |Z|=i}} \prod_{z \in Z} z \ . \tag{9}$$

That is, $e_i(X)$ is the multilinear polynomial whose monomials consist of all products of i distinct variables from X. We extend this definition to $i = 0$ by setting $e_0(X) := 1$ and to integers $i > |X|$ by setting $e_i(X) := 0$.

Power sums and elementary symmetric polynomials are related by *Newton's identities* (see, e.g., [30]), which assert that for $1 \le i \le |X|$,

$$i \cdot e_i(X) = \sum_{j=1}^{i} (-1)^{j-1} \cdot e_{i-j}(X) \cdot p_j(X) \ . \tag{10}$$

The following standard claim uses Newton's identities to show that if the first k power sums of two *multisets* of field elements coincide, then so do the first k elementary symmetric polynomials of those multisets.

► **Lemma 6.** *Let T, U be multisets over a prime field $\mathbb{F}_q$, let $k \le q$ be a positive integer, and suppose that $p_i(T) = p_i(U)$ for all $i \in [k]$. Then $e_i(T) = e_i(U)$ for all $i \in [k]$.*

Proof. The proof is by (strong) induction. For the base case where $i = 0$, we have by definition that $e_0(T) = e_0(U) = 1$. For the inductive case where $1 \le i < k$, because $i \ne 0 \in \mathbb{F}_q$ we have that

$$e_i(T) = i^{-1} \cdot \sum_{j=1}^{i} (-1)^{j-1} \cdot e_{i-j}(T) \cdot p_j(T) = i^{-1} \cdot \sum_{j=1}^{i} (-1)^{j-1} \cdot e_{i-j}(U) \cdot p_j(U) = e_i(U) \ ,$$

where the first and third equalities follow from Newton's identities (Equation (10)), and the second equality follows from the claim's hypothesis and the inductive hypothesis (note that the sums involve elementary symmetric polynomials e_{i-j} only for $i - j < i$). ◄

We define the *root polynomial* $f_T(x) \in \mathbb{F}[x]$ of a multiset T over a field $\mathbb{F}$ to be

$$f_T(x) := \prod_{t \in T} (x - t) = \sum_{i=0}^{|T|} (-1)^i \cdot e_i(T) \cdot x^{|T|-i} \ . \tag{11}$$

We then get the following result, which uses Lemma 6 to show that if sufficiently many of the initial power sums of two multisets are equal, then the multisets themselves are equal.

► **Proposition 7.** *Let q be a prime, let $k \le q/2$ be a positive integer, let T, U be multisets over $\mathbb{F} = \mathbb{F}_q$ of total cardinality $|T| + |U| < 2k$, and suppose that $p_i(T) = p_i(U)$ for all $i \in [k]$. Then $T = U$.*

Proof. Because

$$|T| \equiv p_0(T) = p_0(U) \equiv |U| \pmod q$$

and $0 \le |T| + |U| < 2k \le q$, it follows that $|T| = |U|$ and hence both $f_T(x), f_U(x)$ have degree $|T| < k$.

Next, by the hypotheses and Lemma 6, we have that $e_i(T) = e_i(U)$ for all $i \le |T|$. Therefore, by the equality in Equation (11), $f_T(x)$ and $f_U(x)$ are identical as formal polynomials in $\mathbb{F}[x]$. Finally, because the polynomial ring $\mathbb{F}[x]$ is a unique factorization domain, and because $f_T(x)$ and $f_U(x)$ split over $\mathbb{F}$ by construction, it follows that $T = U$. ◄

2.4 Locally Dense Lattices

Roughly speaking, *locally dense lattices* are lattices that have one or more cosets with many relatively short vectors. Somewhat more precisely, a locally dense lattice consists of an integer lattice $\mathcal{L} \subset \mathbb{Z}^n$ and a shift $\boldsymbol{x} \in \mathbb{Z}^n$ such that for some $\alpha \in (0, 1)$, the number of points in the coset $\boldsymbol{x} + \mathcal{L}$ of norm at most $\alpha \cdot \lambda_1(\mathcal{L})$ is large (for our purposes, greater than 2^{n^ε} for some constant $\varepsilon > 0$). Therefore, locally dense lattices are not efficiently list decodable, even combinatorially, to within distance $\alpha \cdot \lambda_1(\mathcal{L})$ in the worst case (in particular, around center $-\boldsymbol{x}$). For the purposes of proving hardness, we also require a linear map T that projects the short vectors in $\boldsymbol{x} + \mathcal{L}$ onto a lower-dimensional hypercube $\{0, 1\}^r$.

▶ **Definition 8.** *For $p \in [1, \infty)$, real $\alpha > 0$, and positive integers r and R, a (p, α, r, R)*-locally dense lattice *consists of an integer lattice of rank R (and some dimension n) represented by a basis matrix $A \in \mathbb{Z}^{n \times R}$, a positive integer ℓ, a shift $\boldsymbol{x} \in \mathbb{Z}^n$, and a matrix $T \in \mathbb{Z}^{r \times n}$, where*

1. $\lambda_1^{(p)}(\mathcal{L}(A)) \geq \ell^{1/p}$ *and*
2. $\{0, 1\}^r \subseteq T(V) := \{T\boldsymbol{v} : \boldsymbol{v} \in V\}$*, where* $V := (\boldsymbol{x} + \mathcal{L}(A)) \cap \mathcal{B}_p^n(\alpha \cdot \ell^{1/p})$ *is the set of all vectors of ℓ_p norm at most $\alpha \cdot \ell^{1/p}$ in the lattice coset $\boldsymbol{x} + \mathcal{L}(A)$.*

A useful tool for satisfying Item 2 in the above definition is the following probabilistic version of Sauer's Lemma due to Micciancio [31]. It roughly says that for $n \gg r$, for any large enough collection of vectors $W \subseteq B_{n,h}$ (the weight-h slice of $\{0, 1\}^n$), and for a random matrix $T \in \{0, 1\}^{r \times n}$ whose coordinates are sampled independently with a suitable bias, $\{0, 1\}^r \subseteq T(W)$ with good probability. We emphasize that all the arithmetic in this theorem is done over the integers (not over $\mathbb{F}_2$).

▶ **Theorem 9** ([31, Theorem 4]). *Let r, n, h be positive integers, let $W \subseteq B_{n,h}$, and let $\varepsilon > 0$. If $|W| \geq h! \cdot n^{24r\sqrt{h}/\varepsilon}$ and $T \in \{0, 1\}^{r \times n}$ is sampled by setting each entry to 1 independently with probability $1/(4hr)$, then $\{0, 1\}^r \subseteq T(W)$ with probability at least $1 - \varepsilon$.*

2.5 Hardness of GapSVP via Locally Dense Lattices

We next recall a variant of (the decision version of) the Closest Vector Problem (CVP), which will be the hard problem that we reduce to GapSVP_p. In this variant, called GapCVP'_p, the target vector is either within a specified distance of a lattice vector given by a *binary* combination of basis vectors, or *all non-zero integer multiples* of the target vector are more than a γ multiple of this distance from the lattice (where distance is measured in the ℓ_p norm).

▶ **Definition 10.** *For $p \in [1, \infty]$, an instance of the γ-GapCVP'_p problem consists of a rank-r lattice basis $B \in \mathbb{Z}^{d \times r}$, a target vector $\boldsymbol{t} \in \mathbb{Z}^d$, and a distance threshold $s > 0$. The goal is to determine whether an input is a YES instance or a NO instance, where these are defined as follows:*

- *YES instance: there exists a* binary $\boldsymbol{c} \in \{0, 1\}^r$ *such that* $\|B\boldsymbol{c} - \boldsymbol{t}\|_p \leq s$.
- *NO instance:* $\mathrm{dist}_p(w\boldsymbol{t}, \mathcal{L}(B)) > \gamma s$ *for all* $w \in \mathbb{Z} \setminus \{0\}$.

The following hardness theorem follows via a reduction from Exact Set Cover to GapCVP'_p.

▶ **Theorem 11** ([4]). *For every $p \in [1, \infty)$ and every constant $\gamma \geq 1$, γ-GapCVP'_p is* NP*-hard.*

The following theorem gives a polynomial-time reduction from γ-GapCVP'_p to γ'-GapSVP_p for some approximation factors $\gamma > \gamma' \geq 1$, which uses a locally dense lattice as advice. In general, this advice makes the reduction non-uniform, but when the advice is efficiently computable by a (randomized) algorithm, as it is in this and prior works, the procedure is an efficient (randomized) reduction. The reduction below is very similar to the one in [32, Theorem 5.1], but written so as to allow for using an arbitrary locally dense lattice as advice. Due to this similarity, and for concision we defer its proof to the full version of our paper [6].

▶ **Theorem 12.** *Let $p \geq 1$, r and n be positive integers, $\alpha > 0$ be a constant, and γ, γ' be constants satisfying*

$$1/\alpha > \gamma' \geq 1 \text{ and } \gamma \geq \gamma' \cdot \left(\frac{1}{1-(\alpha\gamma')^p}\right)^{1/p} .$$

There is a deterministic polynomial-time algorithm that, given a γ-GapCVP'_p instance $(B, \boldsymbol{t}, s)$ of rank r and a (p, α, r, R)-locally dense lattice $(A, \ell, \boldsymbol{x}, T)$ as input, outputs a γ'-GapSVP_p instance (B', s') of rank $R+1$ which is a YES (respectively, NO) instance if $(B, \boldsymbol{t}, s)$ is a YES (resp., NO) instance.

From these two theorems we get the following hardness results for GapSVP.

▶ **Corollary 13.** *Let $p \geq 1$, let r be a positive integer, let $\alpha > 0$ be a constant, and suppose that there is an algorithm A that computes a $(p, \alpha, r, \mathrm{poly}(r))$-locally dense lattice in $\mathrm{poly}(r)$ time. Let γ be a constant satisfying $1 \leq \gamma < 1/\alpha$. Then:*

1. *If A is deterministic, then γ-GapSVP_p is* NP*-hard (and exact GapSVP_p is* NP*-complete).*
2. *If A is randomized and its output satisfies Item 1 of Definition 8 with probability 1 and Item 2 of Definition 8 with probability at least 2/3, then γ-GapSVP_p is not in* RP *unless* NP ⊆ RP.[6]
3. *If A is randomized, and its output satisfies Items 1 and 2 of Definition 8 with probability at least 2/3, then there is no* randomized *polynomial-time algorithm for γ-GapSVP_p unless* NP ⊆ BPP.

Proof. Items 1 and 3 follow immediately by combining Theorems 11 and 12. Inspection of the proof of Theorem 12 shows that for NO instances to be mapped to NO instances, only Item 1 of Definition 8 is needed, from which Item 2 of the claim follows. ◀

3 Local Density from Reed-Solomon Codes

In this section we show how to obtain locally dense lattices from Reed-Solomon codes with appropriate parameters. More specifically, we show to satisfy Definition 8 using a lattice $\mathcal{L} := \mathcal{L}^{\perp}(H)$ corresponding to a parity-check matrix $H = H_q(k, S)$ from Definition 5. (Recall that H is the parity-check matrix of a Reed-Solomon code when $S = \mathbb{F}_q$, and of a generalized Reed-Solomon code for any $S \subseteq \mathbb{F}_q$.)

The overall structure of the argument is as follows. First, in Section 3.1 we give a lower bound of $\lambda_1^{(p)}(\mathcal{L}) \geq (2k)^{1/p}$, which corresponds to Item 1 of Definition 8, by using the connection between power sums and symmetric polynomials (see Section 2.3). Then, in Section 3.2 we use the upper bound $\det(\mathcal{L}) \leq q^k$ from Lemma 4 and the pigeonhole principle to show that there exists a lattice coset with many short (binary) vectors, and in fact a suitably sampled random coset has this property with good probability. Finally, in Section 3.3 we set parameters and use Theorem 9 to satisfy Item 2 of Definition 8 with good probability.

[6] The condition "γ-GapSVP_p is not in RP" is a slight abuse of notation, since γ-GapSVP_p for $\gamma > 1$ is a promise problem rather than a language. However, the definition of RP can naturally be extended to encompass promise problems, which is the intended meaning here.

3.1 Minimum Distance

The following theorem says that for any $k \le |S|/2$, the ℓ_1 minimum distance of $\mathcal{L} = \mathcal{L}^{\perp}(H)$ for $H = H_q(k, S)$ is at least $2k$. Essentially the same result and proof appeared in works of Karabed, Roth, and Siegel [25, 37], and a very similar theorem and proof for lower bounding the minimum distance of Craig lattices appears in [14] and [13, Chapter 8, Theorem 7]. We reprove the result here in a slightly different form for completeness.

Note that a weaker bound of $\lambda_1^{(1)}(\mathcal{L}) \ge k + 1$ (for any $k < q$) follows trivially from the minimum Hamming distance $k + 1$ of the (generalized Reed-Solomon) code having parity-check matrix H. However, this bound is not strong enough for the rest of the local-density argument below, which requires $\lambda_1^{(1)}(\mathcal{L}) \ge (1 + \Omega(1))k$.

▶ **Theorem 14.** *Let q be a prime, let $S \subseteq \mathbb{F}_q$, let $k \le |S|/2$ be a positive integer, and let $H := H_q(k, S) \in \mathbb{F}_q^{k \times S}$ be the matrix from Definition 5. Then $\mathcal{L} = \mathcal{L}^{\perp}(H)$ has ℓ_1 minimum distance $\lambda_1^{(1)}(\mathcal{L}) \ge 2k$.*
As a consequence, for any $p \in [1, \infty)$ the ℓ_p minimum distance satisfies $\lambda_1^{(p)}(\mathcal{L}) \ge (2k)^{1/p}$.

We point out that the $2^{1/p}$ factor in Theorem 14 propagates to the relative-distance bound for local density in Theorem 17 below, and then to the GapSVP approximation factor in our main hardness theorem, Theorem 1.

Proof. The consequence follows immediately from the fact that $\mathcal{L} \subseteq \mathbb{Z}^S$ and $\|\boldsymbol{v}\|_p \ge \|\boldsymbol{v}\|_1^{1/p}$ for all $\boldsymbol{v} \in \mathbb{Z}^S$.

Now consider some arbitrary $\boldsymbol{x} \in \mathcal{L} \subseteq \mathbb{Z}^S$ for which $\|\boldsymbol{x}\|_1 < 2k$; we will show that $\boldsymbol{x} = \boldsymbol{0}$. Let $\boldsymbol{x}^+, \boldsymbol{x}^- \in \mathbb{Z}^S$ be the unique non-negative integer vectors satisfying $\boldsymbol{x} = \boldsymbol{x}^+ - \boldsymbol{x}^-$. Define multisets T^+ and T^- over S that respectively depend on $\boldsymbol{x}^+$ and $\boldsymbol{x}^-$ as follows. For each $s \in S$ with $x_s^+ > 0$ (respectively, $x_s^- > 0$), let T^+ (respectively, T^-) contain s with multiplicity x_s^+ (respectively, x_s^-).[7]

Note that $|T^+| + |T^-| = \|\boldsymbol{x}\|_1 < 2k$. Because $H\boldsymbol{x} = H(\boldsymbol{x}^+ - \boldsymbol{x}^-) = \boldsymbol{0} \in \mathbb{F}_q^k$, by definition of H we have that $p_i(T^+) = p_i(T^-)$ for all $i \in [k]$ (where recall that p_i denotes the ith power sum). Because $k \le |S|/2 \le q/2$, by Proposition 7 it follows that $T^+ = T^-$. Since $T^+ \cap T^- = \emptyset$ by construction, we must have $T^+ = T^- = \emptyset$, and hence $\boldsymbol{x} = \boldsymbol{0}$, as desired. ◀

The following lemma (which is well known in other forms) shows that the lower bound $\lambda_1^{(p)}(\mathcal{L}^{\perp}(H)) \ge (2k)^{1/p}$ from Theorem 14 is in fact an equality under mild conditions on the parameters, by giving an explicit lattice coset that has multiple short vectors. However, because it proves only that the number of such vectors is polynomial in the dimension, it is insufficient to establish local density.

▶ **Lemma 15.** *Let q be a prime, let k be a positive integer that divides $q - 1$, and let $H := H_q(k, S) \in \mathbb{F}_q^{k \times S}$ where $\mathbb{F}_q^* \subseteq S \subseteq \mathbb{F}_q$. Then for $\boldsymbol{u} := (k, 0, \ldots, 0) \in \mathbb{F}_q^k$, the lattice coset $\mathcal{L}_{\boldsymbol{u}}^{\perp}(H) = \{\boldsymbol{x} \in \mathbb{Z}^S : H\boldsymbol{x} = \boldsymbol{u}\}$ contains $(q-1)/k$ binary vectors of Hamming weight k and pairwise disjoint support. As a consequence, when $k < q - 1$, we have $\lambda_1^{(p)}(\mathcal{L}^{\perp}(H)) = (2k)^{1/p}$ for any $p \in [1, \infty)$.*

Proof. Let G be the order-k subgroup of the (cyclic, multiplicative) group $\mathbb{F}_q^*$, i.e., the subgroup of the kth roots of unity. Then the binary indicator vectors $\boldsymbol{x}_C \in \{0, 1\}^S$ of each of the $(q-1)/k$ pairwise disjoint cosets $C = cG$ of G all belong to the coset $\mathcal{L}_{\boldsymbol{u}}^{\perp}(H)$. This

[7] For example, if $S = \{0, 1, 2, 3, 4\} = \mathbb{F}_q$ and $\boldsymbol{x} = (x_0, x_1, x_2, x_3, x_4)^t = (1, -2, 0, 1, 0)^t$, then $x^+ = (1, 0, 0, 1, 0)$, $x^- = (0, 2, 0, 0, 0)$, and accordingly $T^+ = \{0, 3\}$, $T^- = \{1, 1\}$.

is simply because for any such coset, the 0th power sum of its elements is k, and the ith power sum for $0 < i < k$ is zero; this can be seen by Newton's identities and the fact that the root polynomial of C is $f_C(x) = \prod_{c \in C}(x - c) = x^k - r_C$, where $r_C = c^k$ for every $c \in C$. Finally, when $k < q - 1$, there is more than one such vector $\boldsymbol{x}_C$, and the differences between distinct pairs of them are lattice vectors in $\{0, \pm 1\}^S$ of Hamming weight $2k$, and hence ℓ_p norm $(2k)^{1/p}$. ◀

3.2 Dense Cosets

Following an approach previously used in [31, 26, 32] (and implicitly in [3]), we first show via a pigeonhole argument that a dense lattice coset must exist, and then show how to sample such a coset efficiently (with good probability).

For a prime q, a positive integer k, and a set $S \subseteq \mathbb{F}_q$ of size n (with some arbitrary ordering of its elements), let $H = H_q(k, S) \in \mathbb{F}_q^{k \times n}$ be the parity-check matrix from Definition 5. By Lemma 4, the lattice $\mathcal{L} = \mathcal{L}^{\perp}(H) \subseteq \mathbb{Z}^n$ has $\det(\mathcal{L}) \leq q^k$ integer cosets. Recall that $B_{n,h}$ is the set of n-dimensional binary vectors of Hamming weight h, which has cardinality $|B_{n,h}| = \binom{n}{h}$. Therefore, by the pigeonhole principle, there must exist some integer coset $\boldsymbol{x} + \mathcal{L}$ with $|(\boldsymbol{x} + \mathcal{L}) \cap B_{n,h}| \geq \binom{n}{h}/q^k$ weight-h binary vectors. In particular, taking $n \approx q$, $h \approx \alpha^p \cdot (2k)$ for some constant $\alpha > 1/2^{1/p}$, and $k = q^{\varepsilon}$ for a suitable small constant $\varepsilon > 0$ implies the existence of a coset with roughly $q^{(2\alpha^p - 1)k} = q^{\Omega(q^{\varepsilon})}$ such vectors. These vectors have ℓ_p norm $h^{1/p} \approx \alpha \cdot (2k)^{1/p}$, whereas by Theorem 14 the lattice minimum distance is at least $(2k)^{1/p}$, yielding a local-density relative distance of roughly α.

The following lemma extends the above existential result by showing that something very similar holds for a *uniformly random* shift $\boldsymbol{x} \in B_{n,h}$: for any $\delta > 0$, the coset $\boldsymbol{x} + \mathcal{L}$ contains at least $\delta \cdot \binom{n}{h}/q^k$ weight-h binary vectors with probability greater than $1 - \delta$. The proof given below closely follows the structure of the very similar one of [26, Lemma 4.3].

▶ **Lemma 16.** *For a prime q, positive integer k, and set $S \subseteq \mathbb{F}_q$ of size n, let $H = H_q(k, S) \in \mathbb{F}_q^{k \times n}$ be the parity-check matrix from Definition 5. There is an efficient randomized algorithm that, for any $\delta \geq 0$, and on input H and any $h \in [n]$, outputs a shift $\boldsymbol{x} \in B_{n,h}$ such that*

$$\Pr_{\boldsymbol{x}}\left[|(\boldsymbol{x} + \mathcal{L}) \cap B_{n,h}| \geq \delta \cdot \binom{n}{h}/q^k\right] > 1 - \delta \ .$$

Proof. The algorithm simply samples and outputs a uniformly random binary vector $\boldsymbol{x} \in B_{n,h}$. This is clearly efficient. To show correctness, we will use the syndromes of H. For each $\boldsymbol{u} \in \mathbb{F}_q^k$, define $K_{\boldsymbol{u}} := |\{\boldsymbol{z} \in B_{n,h} : H\boldsymbol{z} = \boldsymbol{u}\}|$, and define $\boldsymbol{s} := H\boldsymbol{x} \in \mathbb{F}_q^k$ to be the syndrome corresponding to $\boldsymbol{x}$. So, we need to prove that $K_{\boldsymbol{s}} \geq \delta \cdot \binom{n}{h}/q^k$ with probability greater than $1 - \delta$. Indeed, we have:

$$\begin{aligned}
\Pr_{\boldsymbol{x}}\left[|(\boldsymbol{x} + \mathcal{L}) \cap B_{n,h}| < \delta \cdot \binom{n}{h}/q^k\right] &= \Pr_{\boldsymbol{x}}\left[K_{\boldsymbol{s}} < \delta \cdot \binom{n}{h}/q^k\right] \\
&= \sum_{\boldsymbol{u} \in \mathbb{F}_q^k : K_{\boldsymbol{u}} < \delta \cdot \binom{n}{h}/q^k} \Pr_{\boldsymbol{x}}[H\boldsymbol{x} = \boldsymbol{u}] \\
&= \sum_{\boldsymbol{u} \in \mathbb{F}_q^k : K_{\boldsymbol{u}} < \delta \cdot \binom{n}{h}/q^k} \frac{K_{\boldsymbol{u}}}{\binom{n}{h}} \\
&< \sum_{\boldsymbol{u} \in \mathbb{F}_q^k : K_{\boldsymbol{u}} < \delta \cdot \binom{n}{h}/q^k} \frac{\delta}{q^k} \\
&\leq \delta \ ,
\end{aligned}$$

where the first inequality uses the fact that the sum is over syndromes $\boldsymbol{u}$ with $K_{\boldsymbol{u}} < \delta \cdot \binom{n}{h}/q^k$, and the second inequality uses the fact that there are at most q^k terms in the sum. ◀

3.3 The Main Argument

▶ **Theorem 17** (Locally dense lattices from Reed-Solomon codes). *For any $p \in [1, \infty)$ and constant $\alpha > 1/2^{1/p}$, there exists a randomized polynomial-time algorithm that, given any sufficiently large positive integer r in unary as input, outputs a $(p, \alpha, r, R = \mathrm{poly}(r))$-locally dense lattice (Definition 8) with probability at least $2/3$. Moreover, the algorithm's output satisfies Item 1 of Definition 8 with probability 1.*

Proof. The algorithm starts by setting its parameters as follows. It sets $\varepsilon := 2\alpha^p - 1 > 0$, and chooses:

- a poly(r)-bounded integer $k \geq r^{1/(1/2-\delta)}$ for some arbitrary constant $\delta \in (0, 1/2)$, and
- a poly(r)-bounded prime $q \geq k^{3(1+\varepsilon)/\varepsilon}$. (Such a prime q always exists by Bertrand's Postulate.)

The algorithm then computes the components of a $(p, \alpha, r, R = q)$-locally dense lattice $(A, \ell, \boldsymbol{x}, T)$ as follows. It lets:

- $A \in \mathbb{Z}^{q \times q}$ be a basis of $\mathcal{L} := \mathcal{L}^\perp(H)$, where $H = H(k, S) \in \mathbb{F}_q^{k \times q}$ for $S = \mathbb{F}_q$;[8]
- $\ell := 2k$;
- $\boldsymbol{x} \in B_{q,h}$ be a uniformly random q-dimensional binary vector of Hamming weight $h := \lfloor (1+\varepsilon)k \rfloor$;
- $T \in \{0,1\}^{r \times q}$ be chosen by independently setting each of its entries to be 1 with probability $1/(4hr)$, and to be 0 otherwise.

It then outputs $(A, \boldsymbol{x}, \ell, T)$.

We first analyze the algorithm's running time. A suitable prime q can be found in poly(r) time using, e.g., trial division (recall that r is given in unary). The basis A can be computed in deterministic polynomial time from the generating set of column vectors $(B \mid qI_q)$, where B is a basis of $\ker(H) \subseteq \mathbb{F}_q^q$ (lifted to the integers). It is clear that ℓ can be computed in deterministic polynomial time, and that $\boldsymbol{x}$ and T can be computed in randomized polynomial time. So, the algorithm runs in randomized polynomial time.

It remains to show correctness, i.e., that $(A, \boldsymbol{x}, \ell, T)$ satisfies the two conditions in Definition 8 with suitable probability over the random choices of $\boldsymbol{x}$ and T. First, Item 1 is always satisfied, because by Theorem 14 we have

$$\lambda_1(\mathcal{L}) \geq (2k)^{1/p} = \ell^{1/p} \ .$$

In the rest of the proof we consider Item 2 of Definition 8. Let $W := (\boldsymbol{x} + \mathcal{L}) \cap B_{q,h}$. Because

$$\|\boldsymbol{w}\|_p^p = h \leq (1+\varepsilon)k = \alpha^p \cdot \ell$$

for each $\boldsymbol{w} \in W$, we have $W \subseteq V := (\boldsymbol{x} + \mathcal{L}) \cap \mathcal{B}_p^q(\alpha \cdot \ell^{1/p})$.

By Lemma 16, $\Pr_{\boldsymbol{x}}[|W| \geq \binom{q}{h}/(10q^k)] > 1 - 1/10 = 9/10$. If this event holds, and

$$\frac{\binom{q}{h}}{10q^k} \geq h! \cdot q^{240r\sqrt{h}} \ , \tag{12}$$

[8] For appropriate parameters, our argument works more generally for any sufficiently large subset $S \subseteq \mathbb{F}_q$, with $R = |S|$; we use $S = \mathbb{F}_q$ for simplicity.

then by Theorem 9 we have $\{0,1\}^r \subseteq T(W) \subseteq T(V)$ with probability at least $1-1/10 = 9/10$ (over the choice of T). So, it suffices to show that the condition in Equation (12) holds for all sufficiently large k, and hence for all sufficiently large r. By taking a union bound over the $1/10$ failure probabilities from Lemma 16 and Theorem 9, we get that the algorithm's overall success probability is at least $1 - 2/10 > 2/3$ for all sufficiently large r, as needed.

Using the standard bound $\binom{q}{h} \geq (q/h)^h$ for binomial coefficients and that $h \geq (1+\varepsilon)k - 1$, we have that

$$\frac{\binom{q}{h}}{10q^k} \geq \frac{q^{h-k}}{10h^h} = \Omega\Big(\frac{q^{\varepsilon k - 1}}{h^h}\Big) \ . \tag{13}$$

Furthermore, by the choice of k relative to r and $h \leq (1+\varepsilon)k$, we have that

$$h! \cdot q^{240r\sqrt{h}} \leq h^h \cdot q^{240k^{1/2-\delta}\sqrt{(1+\varepsilon)k}} \leq h^h \cdot q^{o(k)} \ . \tag{14}$$

So, by combining Equations (13) and (14), in order to establish Equation (12) it suffices to show that $q^{(1-o(1))\varepsilon k} \geq h^{2h}$. By taking logs, this is equivalent to

$$(1 - o(1)) \cdot \varepsilon k \log q \geq 2h \log h \ . \tag{15}$$

Finally, using that $k^{3(1+\varepsilon)/\varepsilon} \leq q \leq \mathrm{poly}(k)$ and $h \leq (1+\varepsilon)k$, in order for Equation (15) to hold it suffices to have

$$(1 - o(1)) \cdot \varepsilon k \cdot \frac{3(1+\varepsilon)}{\varepsilon} \cdot \log k = (3 - o(1)) \cdot (1+\varepsilon) \cdot k \log k \geq 2(1+\varepsilon) \cdot k \log k + O(k) \ ,$$

which indeed holds for all sufficiently large k, as needed. ◀

We emphasize that Theorem 17 uses randomness only to sample $\boldsymbol{x}$ and T. As an immediate corollary, we obtain our main hardness result, Theorem 1 – which, to recall, asserts that for all constants $p \in [1, \infty)$ and $\gamma < 2^{1/p}$, there is no polynomial-time algorithm for γ-GapSVP$_p$ unless $\mathsf{NP} \subseteq \mathsf{RP}$.

Proof of Theorem 1. Combine Item 2 of Corollary 13 with Theorem 17. ◀

A Efficient Decoding Near Minkowski's Bound

In this appendix, we show that a recent result of Mook and Peikert [34], which builds on work of Guruswami and Sudan [21] and Koetter and Vardy [28] on list-decoding Reed-Solomon codes, yields a polynomial-time algorithm for decoding lattices $\mathcal{L} = \mathcal{L}^{\perp}(H)$ with $H = H_q(k, \mathbb{F}_q)$ up to distance $\Theta(\sqrt{k})$. We additionally observe that by choosing $k = \Theta(q/\log q)$, such lattices are asymptotically nearly tight with Minkowski's bound (Equation (5)). Putting these observations together, we obtain an efficient algorithm for decoding to a distance within a $O(\sqrt{\log q})$ factor of Minkowski's bound (here $q = n$ is the lattice rank and dimension).

A.1 Construction and Algorithm

Define the additive quotient group $\mathbb{R}_q := \mathbb{R}/(q\mathbb{Z})$ and the Euclidean norm of any $\hat{\boldsymbol{y}} \in \mathbb{R}_q^n$ as

$$\|\hat{\boldsymbol{y}}\| := \min\{\|\boldsymbol{y}\| : \boldsymbol{y} \in \hat{\boldsymbol{y}} + q\mathbb{Z}^n\} \ . \tag{16}$$

Equivalently, $\|\hat{\boldsymbol{y}}\|$ is the standard $\mathbb{R}^n$ Euclidean norm of the unique real vector $\boldsymbol{y} \equiv \hat{\boldsymbol{y}} \pmod{q\mathbb{Z}^n}$ having coordinates in $[-q/2, q/2)$. In additive arithmetic that mixes elements of $\mathbb{F}_q$ and $\mathbb{R}_q$, we implicitly "lift" the former to the latter in the natural way.

We again use the fact that for evaluation set $S = \mathbb{F}_q$, the matrix $H = H_q(k, \mathbb{F}_q)$ defined in Equation (7) is a parity-check matrix of the Reed-Solomon code $\mathrm{RS}_q[q-k, \mathbb{F}_q]$, and therefore $\mathcal{L}^{\perp}(H_q(k, \mathbb{F}_q)) = \mathrm{RS}_q[q-k, \mathbb{F}_q] + q\mathbb{Z}^q$. This view lets us take advantage of the decoding algorithm from the following theorem of [34], which gives an efficient (list) decoder in the ℓ_2 norm for Reed-Solomon codes.[9]

[9] In fact, the cited result from [34] is more general, giving a decoder for $\mathbb{F}_p$-*subfield subcodes* of Reed-Solomon codes over finite fields of order $q = p^r$, for a prime p. Here we need only the special case where the Reed-Solomon code is over a prime field (i.e., where $r = 1$). On the other hand, we note that if Proposition 18 were extended to handle *generalized* Reed-Solomon codes, then we would get a corresponding strengthening of Corollary 19 for decoding lattices $\mathcal{L}^{\perp}(H_q(k, S))$ with general S, not just $S = \mathbb{F}_q$.

▶ **Proposition 18** ([34, Algorithm 1 and Theorem 3.4]). *Let q be a prime, $S \subseteq \mathbb{F}_q$ be an evaluation set of size $n := |S|$, $k \leq n$ be a nonnegative integer, and $\varepsilon > 0$. There is a deterministic algorithm that, on input q, S, k, ε, and a vector $\hat{\boldsymbol{y}} \in \mathbb{R}_q^n$, outputs all codewords $\boldsymbol{c} \in \mathrm{RS}_q[n-k, S]$ such that $\|\hat{\boldsymbol{y}} - \boldsymbol{c}\|^2 \leq (1-\varepsilon)(k+1)/2$, in time polynomial in n, $\log q$, and $1/\varepsilon$.*[10]

The following corollary, which is the main result of this section, says that by taking $S = \mathbb{F}_q$ and $k = \Theta(q/\log q)$, (1) the root Hermite factor of $\mathcal{L}^\perp(H)$ is within an $O(\sqrt{\log q})$ factor of Minkowski's bound (Equation (5)), and (2) it is possible to efficiently decode this lattice to a distance of $\Omega(\sqrt{k}) = \Omega(\sqrt{q/\log q})$, which is again within an $O(\sqrt{\log q})$ factor of Minkowski's bound.

We remark that by setting $\varepsilon \leq 1/(k+1)$ in Corollary 19, we get efficient decoding to a distance at least $\sqrt{k/2}$ but less than $\sqrt{(k+1)/2}$, which is slightly more than half the lower bound of $\sqrt{2k}$ on the minimum Euclidean distance of the lattice (Theorem 14). Recall that this lower bound is tight when k is a proper divisor of $q-1$ (see Lemma 15), so with this parameterization we get efficient *list* decoding (i.e., the algorithm may return more than one lattice vector) slightly beyond the unique-decoding bound of half the minimum distance.

▶ **Corollary 19** (Efficient decoding near Minkowski's bound). *Let $H = H_q(k, \mathbb{F}_q)$ for a prime q and $k := \lfloor q/(2\log q) \rfloor \leq q/2$, where all logarithms are base two. Then for $\mathcal{L} := \mathcal{L}^\perp(H) \subseteq \mathbb{Z}^q$:*

1. $\sqrt{q/\log q - 2} \leq \sqrt{2k} \leq \lambda_1(\mathcal{L}) \leq \sqrt{q} \cdot \det(\mathcal{L})^{1/q} \leq \sqrt{2q}$.
2. *For any $\varepsilon > 1/\mathrm{poly}(q)$, there is an algorithm that, on input q and a vector $\boldsymbol{y} \in \mathbb{R}^q$, outputs all lattice vectors $\boldsymbol{v} \in \mathcal{L}$ satisfying $\|\boldsymbol{y} - \boldsymbol{v}\| \leq \sqrt{(1-\varepsilon)(k+1)/2}$ in time polynomial in q.*

Proof. For Item 1, we have

$$\sqrt{q/\log q - 2} \leq \sqrt{2k} \leq \lambda_1(\mathcal{L}) \leq \sqrt{q} \cdot \det(\mathcal{L})^{1/q} = \sqrt{q} \cdot q^{k/q} \leq \sqrt{2q} \ .$$

The first inequality follows from the choice of k, the second inequality is by Theorem 14, the third inequality is Minkowski's bound (Equation (5)), the equality follows from Lemma 4 (recall that the rows of H are linearly independent), and the final inequality again follows from the choice of k.[11]

The algorithm claimed in Item 2 works as follows. First, it computes k and $\hat{\boldsymbol{y}} = \boldsymbol{y} \bmod q\mathbb{Z}^q \in \mathbb{R}_q^q$ from the input q and $\boldsymbol{y}$. It then calls the algorithm from Proposition 18 on q, $S = \mathbb{F}_q$, k, ε, and $\hat{\boldsymbol{y}}$, and receives as output zero or more codewords $\boldsymbol{c} \in \mathrm{RS}_q[q-k, \mathbb{F}_q]$. For each such $\boldsymbol{c}$, it outputs the unique vector $\boldsymbol{v} := \arg\min_{\boldsymbol{v}' \in \boldsymbol{c} + q\mathbb{Z}^q} \|\boldsymbol{y} - \boldsymbol{v}'\| \in \mathcal{L}$.

The value k and vectors $\hat{\boldsymbol{y}}, \boldsymbol{v}$ can be computed efficiently (assuming that $\boldsymbol{v}$ is well defined), so it is clear from Proposition 18 that this algorithm runs in time polynomial in q (recall that the dimension $n = q$). It remains to show correctness. First, it is immediate from the definitions that for any $r < q/2$, the function $f(\boldsymbol{v}) = \boldsymbol{v} \bmod q\mathbb{Z}^q$ is a bijection from the set of lattice vectors

$$\{\boldsymbol{v} \in \mathcal{L} : \|\boldsymbol{y} - \boldsymbol{v}\| \leq r\} \ ,$$

[10] Formally, the runtimes of the decoding algorithms in Proposition 18 and Corollary 19 additionally depend on the lengths of the respective "received words" $\hat{\boldsymbol{y}}$ and $\boldsymbol{y}$ that they take as input, which must be specified to finite precision. However, for simplicity we describe the algorithms in the "Real RAM model," while noting that their runtime dependence on the encoding lengths of $\hat{\boldsymbol{y}}, \boldsymbol{y}$ is polynomial.

[11] Analyzing the derivative of $\log(\sqrt{2k}/q^{k/q})$ with respect to k shows that our choice of k is asymptotically optimal for maximizing the root Hermite factor of $\mathcal{L}^\perp(H_q(k, \mathbb{F}_q))$.

to the set of codewords

$$\{\boldsymbol{c} \in \mathrm{RS}_q[q-k, \mathbb{F}_q] : \|\hat{\boldsymbol{y}} - \boldsymbol{c}\| \leq r\} ,$$

and that $g(\boldsymbol{c}) := \arg\min_{\boldsymbol{v}' \in \boldsymbol{c} + q\mathbb{Z}^q} \|\boldsymbol{y} - \boldsymbol{v}'\|$ is the inverse function of f, i.e., $g = f^{-1}$. Moreover, because $q \geq 2$, we have that the decoding distance r satisfies

$$r := \sqrt{(1-\varepsilon)(k+1)/2} \leq \sqrt{(1-\varepsilon)(q/(2\log q)+1)/2} \leq \sqrt{1-\varepsilon} \cdot q/2 < q/2 .$$

Because the algorithm from Proposition 18 outputs (exactly) $\{\boldsymbol{c} \in \mathrm{RS}_q[q-k, \mathbb{F}_q] : \|\hat{\boldsymbol{y}} - \boldsymbol{c}\| \leq r\}$, it follows that the algorithm described above outputs (exactly) $\{\boldsymbol{v} \in \mathcal{L} : \|\boldsymbol{y} - \boldsymbol{v}\| \leq r\}$, as needed. ◀

▶ Remark 20. We remark that the main consequence of Item 1 of Corollary 19 – namely, an explicit construction of a family of lattices having root Hermite factors within a $O(\sqrt{\log n})$ factor of Minkowski's bound, obtained via Construction A (where n is the lattice dimension) – only needs a family of codes satisfying milder conditions than what (generalized) Reed-Solomon codes satisfy. Namely, achieving this result only requires a family of linear q-ary codes $\mathcal{C}$ for prime q with block length n, codimension $k = \Theta(n/\log n)$, and minimum distance (in the Hamming metric) $d = \Omega(k)$. The latter is a weaker condition than *maximum distance separability* (MDS), which requires that $d = k + 1$. Indeed, $d = \Omega(k)$ implies that the corresponding Construction-A lattice $\mathcal{C} + q\mathbb{Z}^n$ has an ℓ_2 minimum distance of $\Omega(\min\{\sqrt{k}, q\})$, which is $\Omega(\sqrt{k})$ when $k = O(q^2)$. So, unlike our main hardness result, Corollary 19 does not use Theorem 14 in any essential way.

Finally, we also note that obtaining a direct analog of Item 2 of Corollary 19 – i.e., efficiently decoding to within an $O(\sqrt{\log n})$ factor of Minkowski's bound on $\mathcal{C} + q\mathbb{Z}^n$ – additionally requires an efficient algorithm for decoding $\mathcal{C}$ to an ℓ_2 distance of $\Omega(\sqrt{k})$, but that this is in turn a weaker requirement than what Proposition 18 fulfills.

Perfect Sampling for Hard Spheres from Strong Spatial Mixing

Abstract

We provide a perfect sampling algorithm for the hard-sphere model on subsets of $\mathbb{R}^d$ with expected running time linear in the volume under the assumption of strong spatial mixing. A large number of perfect and approximate sampling algorithms have been devised to sample from the hard-sphere model, and our perfect sampling algorithm is efficient for a range of parameters for which only efficient approximate samplers were previously known and is faster than these known approximate approaches. Our methods also extend to the more general setting of Gibbs point processes interacting via finite-range, repulsive potentials.

1 Introduction

Gibbs point processes, or classical gases, are mathematical models of interacting particles. In statistical physics they are used to model gases, fluids, and crystals, while in other fields they are used to model spatial phenomena such as the growth of trees in a forest, the distribution of stars in the universe, or the location of cities on a map (see e.g. [68, 59, 73, 12]).

Perhaps the longest and most intensively studied Gibbs point process is the hard-sphere model: a model of a gas in which the only interaction between particles is a hard-core exclusion in a given radius around each particle. That is, it is a model of a random packing of equal-sized spheres. Despite the simplicity of its definition, the hard-sphere model is expected to exhibit the qualitative behavior of a real gas [2], and in particular exhibits gas, liquid, and solid phases, thus giving evidence for the hypothesis, dating back to at

least Boltzmann, that the macroscopic properties of a gas or fluid are determined by its microscopic interactions. This rich behavior exhibited by the hard-sphere model is very difficult to analyze rigorously, and the most fundamental questions about phase transitions in this model are open mathematical problems [68, 50].

In studying the hard-sphere model (or Gibbs point processes more generally), a fundamental task is to sample from the model. Sampling is used to estimate statistics, observe evidence of phase transitions, and perform statistical tests on data. A wide variety of methods have been proposed to sample from these distributions; for instance, the Markov chain Monte Carlo (MCMC) method was first proposed by Metropolis, Rosenbluth, Rosenbluth, Teller, and Teller [53] to sample from the two-dimensional hard-sphere model. Understanding sampling methods for point processes in theory and in practice is a major area of study [58, 59, 16, 39, 47], and advances in sampling techniques have led to advances in the understanding of the physics of these models [53, 2, 50, 7, 6, 16].

In this paper we will be concerned with provably efficient sampling from the hard-sphere model. Rigorous guarantees for sampling algorithms come in several different varieties. One question is what notion of "efficient" to use; another is what guarantee we insist on for the output. In this paper we will provide an efficient sampling algorithm under the strictest possible terms with respect to both running time and accuracy of the output: a linear-time, *perfect* sampling algorithm.

For simplicity we focus on sampling from the hard-sphere model defined on finite boxes in $\mathbb{R}^d$. For fixed parameter values of the model, the typical number of points appearing in such a region is linear in the volume, and so any sampling algorithm will require at least this much time.

As for guarantees on the output, there are two main types of guarantees. The first type is an *approximate sampler*: the output of such an algorithm must be distributed within ε total variation distance of the desired target distribution. Perhaps the main approach to efficient sampling from distributions normalized by intractable normalizing constants is the MCMC method. In this approach, one devises a Markov chain with the target distribution as the stationary distribution and runs a given number steps of the chain from a chosen starting configuration; if the number of steps is at least the ε-mixing time, then the final state has distribution within ε total variation distance of the target [42, 65, 13]. In general, however, computing or bounding the mixing time can be a very challenging problem.

The second type of guarantee is that of a *perfect sampler* [63]. Such an algorithm has a running time that is random, but the distribution of the output is guaranteed to be *exactly* that of the target distribution. The main advantage of perfect sampling algorithms – and the primary reason they are studied and used in practice – is that one need not prove a theorem or understand the mixing time of a Markov chain to run the algorithm and get an accurate sample; one can simply run the algorithm and know that the output has the correct distribution. The drawback is that the running time may be very large, depending on the specific algorithm and on the parameter regime. Some naive sampling methods such as rejection sampling return perfect samples but are inefficient on large instances (exponential expected running time in the volume). The breakthrough of Propp and Wilson in introducing "coupling from the past" [63, 64] was to devise a procedure for using a Markov chain transition matrix to design perfect sampling algorithms which, under some conditions, could run in time polylogarithmic in the size of a discrete state space (polynomial-time in the size of the graph of a spin system), matching the efficiency of fast mixing Markov chains which only return approximate samples (see also [5, 49] for precedents in perfect sampling). The work of Propp and Wilson led to numerous constructions of perfect sampling algorithms for problems with both discrete and continuous state spaces including [17, 27, 45, 60, 28, 21, 46, 58, 23]. Notably, many of the first applications of Propp and Wilson's technique were in designing perfect sampling algorithms for Gibbs point processes (though often without rigorous guarantees on the efficiency of the algorithms).

Perfect sampling continues to be a very active area of research today, with a special focus on improving the range of parameters for which perfect sampling algorithms can (provably) run in expected linear or polynomial time [9, 40, 30]

In this paper we design a perfect sampling algorithm for the hard-sphere model (and Gibbs point processes interacting with a finite-range, repulsive pair potential more generally) that is guaranteed to run in linear expected time for activity parameters up to the best known bound for efficient approximate sampling via MCMC.

What is this bound and how do we design the algorithm? One central theme in the analysis of discrete spin systems is the relationship between spatial mixing (correlation decay properties) and temporal mixing (mixing times of Markov chains) [35, 1, 72, 52, 15]. At a high level, these works show that for discrete lattice systems a strong correlation decay property (*strong spatial mixing*) implies a near-optimal convergence rate for local-update Markov chains like the Glauber dynamics. Recently it has been showed that strong spatial mixing in a discrete lattice model also implies the existence of efficient *perfect* sampling algorithms [18, 4]. In parallel, there has been work establishing the connection between strong spatial mixing and optimal temporal mixing for Markov chains in the setting of the hard-sphere model and Gibbs point processes [33, 55, 56]. At a high level, our aim is to combine these threads to show that strong spatial mixing for Gibbs point processes implies the existence of an efficient perfect sampler. One challenge is that the approaches of [18, 4] are inherently discrete in that key steps of the algorithms involve enumerating over all possible configurations in a subregion, something that is not possible in the continuum. To overcome this we make essential use of Bernoulli factories – a method for perfect simulation of a coin flip with a bias $f(p)$ given access to coin flips of bias p. Bernoulli factories have recently been used in perfect sampling algorithms for solutions to constraint satisfaction problems in [31, 32].

1.1 The hard-sphere model, strong spatial mixing, and perfect sampling

The hard-sphere model is defined on a bounded, measurable subset Λ of $\mathbb{R}^d$ with an activity parameter $\lambda \geq 0$ that governs the density of the model and a parameter $r > 0$ that governs the range of interaction (though by re-scaling there is really only one meaningful parameter, and we could take $r = 1$ without loss of generality). In words, the hard-sphere model is the distribution of finite point sets in Λ obtained by taking a Poisson point process of activity λ on Λ and conditioning on the event that all pairs of points are at distance at least r from each other; in other words, on the event that spheres of radius $r/2$ centered at the given points form a sphere packing.

We can equivalently define the model more explicitly, and in doing so, introduce objects and notation we work with throughout the paper. To begin, let $\mathcal{N}_\Lambda$ be the set of all finite point sets in Λ. Each point set $\eta \in \mathcal{N}_\Lambda$ represents a particle configuration in Λ. Write $\mathfrak{R}_\Lambda \subseteq 2^{\mathcal{N}_\Lambda}$ for the σ-field generated by the maps $\left\{\mathcal{N}_\Lambda \to \mathbb{N}_0, \eta \mapsto |\eta \cap B| \;\middle|\; B \subseteq \Lambda \text{ Borel-measurable}\right\}$. The hard-sphere model (or in fact any Gibbs point process) is a probability measure μ_λ on the space $(\mathcal{N}_\Lambda, \mathfrak{R}_\Lambda)$.

Define for every $x_1, \ldots, x_k \in \mathbb{R}^d$ the indicator that the points are centers of non-overlapping spheres of radius $r/2$; that is,

$$D(x_1,\dots,x_k) = \prod_{\{i,j\}\in\binom{[k]}{2}} \mathbb{1}_{\mathrm{dist}(x_i,x_j)\geq r} \,.$$

Then define the partition function

$$Z_\Lambda(\lambda) = \sum_{k\geq 0} \frac{\lambda^k}{k!} \int_{\Lambda^k} D(x_1,\dots,x_k)\,\mathrm{d}x_1 \dots \mathrm{d}x_k \,.$$

For an event $A \in \mathfrak{R}_\Lambda$, the hard-sphere model assigns the probability

$$\mu_\lambda(A) = \frac{1}{Z_\Lambda(\lambda)} \sum_{k\geq 0} \frac{\lambda^k}{k!} \int_{\Lambda^k} \mathbb{1}_{\{x_1,\dots,x_k\}\in A} D(x_1,\dots,x_k)\,\mathrm{d}x_1 \dots \mathrm{d}x_k \,. \tag{1}$$

A very useful generalization of this model is to allow for a non-constant (but measurable) activity function $\boldsymbol{\lambda} : \Lambda \to [0,\infty)$. Here the model is a Poisson process with inhomogenous activity $\boldsymbol{\lambda}$ conditioned on the points forming the centers of a sphere packing; the partition function is now

$$Z_\Lambda(\boldsymbol{\lambda}) = \sum_{k\geq 0} \frac{1}{k!} \int_{\Lambda^k} \prod_{i=1}^{k} \boldsymbol{\lambda}(x_i) D(x_1,\dots,x_k)\,\mathrm{d}x_1 \dots \mathrm{d}x_k$$

and the measure $\mu_{\boldsymbol{\lambda}}$ is defined analogously to (1). This generalization allows modeling of non-homogenous spaces and generalizes the concept of imposing boundary conditions on the model. To see this, suppose we fix a particle configuration $\eta \in \mathcal{N}_\Lambda$ as boundary conditions. Additional points are forbidden within the balls of radius r around each point $x \in \eta$; we can implement the distribution of additional points by considering the measure $\mu_{\boldsymbol{\lambda}}$ with $\boldsymbol{\lambda}(y) = 0$ if $\mathrm{dist}(y, x) < r$ for some $x \in \eta$; and $\boldsymbol{\lambda}(y) = \lambda$ otherwise. We denote the resulting activity function by $\boldsymbol{\lambda}$ by λ_η. Further, we can use this generalization to restrict a point process to only place points in a subregion $\Lambda' \subseteq \Lambda$ by considering the measure $\mu_{\lambda \mathbb{1}_{\Lambda'}}$ with activity function $\lambda \mathbb{1}_{\Lambda'} : x \mapsto \lambda \mathbb{1}_{x\in\Lambda'}$. Of course the generalization to measurable activity functions is much more general than this, and activity functions $\boldsymbol{\lambda}$ need not be realizable by boundary conditions or restriction to a subregion, nor take only two values.

This generalization to activity functions is crucial for defining *strong spatial mixing*, the condition under which we can guarantee the efficiency of our perfect sampling algorithm.

To define the concept of strong spatial mixing we consider projections of the measure $\mu_{\boldsymbol{\lambda}}$ to subregions $\Lambda' \subseteq \Lambda$. We write $\mu_{\boldsymbol{\lambda}}[\Lambda']$ for the probability measure on $(\mathcal{N}_{\Lambda'}, \mathfrak{R}_{\Lambda'})$ induced by $\mu_{\boldsymbol{\lambda}}$ (we make this definition formal in Section 3). We can impose two distinct boundary conditions on Λ' by choosing two different activity functions $\boldsymbol{\lambda}, \boldsymbol{\lambda}'$. Strong spatial mixing asserts that the distributions $\mu_{\boldsymbol{\lambda}}[\Lambda']$, $\mu_{\boldsymbol{\lambda}'}[\Lambda']$ are close in total variation when $\boldsymbol{\lambda}, \boldsymbol{\lambda}'$ differ only on points far from Λ'; i.e., when $\mathrm{dist}(\Lambda', \mathrm{supp}(\boldsymbol{\lambda} - \boldsymbol{\lambda}'))$ is large (as $\mathrm{supp}(\boldsymbol{\lambda} - \boldsymbol{\lambda}')$ is the set of points at which the two activity functions disagree).

Writing $|\Lambda'|$ for the volume of Λ', strong spatial mixing with exponential decay is defined as follows.

▶ **Definition 1.1.** *Given $a, b \in \mathbb{R}_{>0}$, the hard-sphere model on $\mathbb{R}^d$ exhibits (a, b)-**strong spatial mixing** up to $\lambda \in \mathbb{R}_{>0}$ if for all bounded measurable $\Lambda \subset \mathbb{R}^d$ the following holds: For all measurable $\Lambda' \subseteq \Lambda$ and all activity functions $\boldsymbol{\lambda}, \boldsymbol{\lambda}' \leq \lambda$ it holds that*

$$d_{TV}(\mu_{\boldsymbol{\lambda}}[\Lambda'], \mu_{\boldsymbol{\lambda}'}[\Lambda']) \leq a|\Lambda'|\mathrm{e}^{-b\cdot\mathrm{dist}\left(\Lambda',\mathrm{supp}\left(\boldsymbol{\lambda}-\boldsymbol{\lambda}'\right)\right)},$$

where $d_{TV}(\cdot,\cdot)$ denotes total variation distance.

This definition of strong spatial mixing comes from [56], which in turn adapted similar notions from discrete spin systems [15, 74]. Strong spatial mixing has proved to be an essential definition in the analysis, both probabilistic and algorithmic, of spin systems on graphs, and many recent works are focused on either proving strong spatial mixing for a particular model, range of parameters, and class of graphs (e.g. [74, 22, 51, 69, 66, 10]) or deriving consequences of strong spatial mixing (e.g. [70, 19, 48, 18, 4]).

Our main result is a linear expected-time perfect sampling algorithm for the hard-sphere model under the assumption of strong spatial mixing.

▶ **Theorem 1.2.** *There is a perfect sampling algorithm for the hard-sphere model on finite boxes $\Lambda \subset \mathbb{R}^d$ with the property that if the hard-sphere model exhibits (a, b)-strong spatial mixing up to λ, then the expected running time of the algorithm at activity λ is $O(|\Lambda|)$, where the implied constant is a function of a, b, and λ.*

In particular, one can run the algorithm for any value of λ (without knowing whether or not strong spatial mixing holds) and the algorithm will terminate in finite time with an output distributed exactly as μ_λ; under the assumption of strong spatial mixing the expected running time is guaranteed to be linear in the volume.

Using bounds from [56] on strong spatial mixing in the hard-sphere model, we obtain the following explicit bounds on the activities for which the algorithm is efficient.

▶ **Corollary 1.3.** *The above perfect sampling algorithm runs in expected time $O(|\Lambda|)$ when $\lambda < \frac{\mathrm{e}}{v_d(r)}$, where $v_d(r)$ is the volume of the ball of radius r in $\mathbb{R}^d$.*

In comparison, near-linear time MCMC-based approximate samplers were given in [56] for the same range of parameters (following results for more restricted ranges in [43, 33]). For perfect sampling from the hard-sphere model, linear expected time algorithms were given in [36, 25] for more restrictive ranges of parameters.

1.2 Gibbs point processes with finite-range repulsive potentials

We now give a closely related result in the more general setting of Gibbs point processes interacting via finite-range, repulsive pair potentials.

Gibbs point processes are defined via a density against an underlying Poisson point process. In general, this density is the exponential of (the negative of) an energy function on point sets that captures the interactions between points. In many of the most studied cases, this energy function takes a special form: it is the sum of potentials over pairs of points in a configuration.

A *pair potential* is a measurable symmetric function $\phi : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R} \cup \{\infty\}$. For a bounded, measurable activity function $\boldsymbol{\lambda}$ on Λ the Gibbs point process with pair potential ϕ on Λ is defined via the partition function

$$Z_\Lambda(\boldsymbol{\lambda}) = \sum_{k \geq 0} \frac{1}{k!} \int_{\Lambda^k} \left(\prod_{i \in [k]} \boldsymbol{\lambda}(x_i) \right) \mathrm{e}^{-H(x_1, \ldots, x_k)} \, \mathrm{d}x_1 \ldots \mathrm{d}x_k$$

where

$$H(x_1, \ldots, x_k) = \sum_{\{i,j\} \in \binom{[k]}{2}} \phi(x_i, x_j) \, .$$

Again the corresponding probability measure $\mu_{\boldsymbol{\lambda}}$ is obtained as in (1). A pair potential ϕ is *repulsive* if $\phi(x, y) \geq 0$ for all x, y. It is of *finite-range* if there exists $r \geq 0$ so that $\phi(x, y) = 0$ whenever $\mathrm{dist}(x, y) > r$. As with the hard-sphere model, we can use the activity function to encode the influence of boundary conditions by defining the activity function $\lambda_\eta : y \mapsto \lambda \mathrm{e}^{-\sum_{x\in\eta}\phi(x,y)}$ for any activity $\lambda \in [0,\infty)$ and particle configuration $\eta \in \mathcal{N}_\Lambda$. Moreover, strong spatial mixing for a Gibbs point process is defined exactly as in Definition 1.1.

The hard-sphere model is one example of a model interacting via a finite-range, repulsive pair potential; it is obtained by letting $\phi(x,y)$ take the value $+\infty$ if $\mathrm{dist}(x,y) \le r$ and 0 otherwise. The Strauss process [71, 44] is another such example.

Our next result is a near-linear expected time perfect sampling algorithm for Gibbs point processes interacting via finite-range, repulsive potentials under the assumption of strong spatial mixing.

▶ **Theorem 1.4.** *Suppose ϕ is a finite-range, repulsive potential on $\mathbb{R}^d$ and suppose ϕ exhibits (a,b)-strong spatial mixing up to λ for some constants $a, b > 0$. Then there is a perfect sampling algorithm for the Gibbs point process defined by ϕ and activity functions bounded by λ on boxes Λ in $\mathbb{R}^d$ with expected running time $O\Big(|\Lambda| \log^{O(1)}|\Lambda|\Big)$.*

One difference between this algorithm and the hard-sphere algorithm of Theorem 1.2 is that this algorithm needs knowledge of the constants a, b in the assumption of strong spatial mixing, whereas the hard-sphere algorithm does not.

Using the results of [56], we can get explicit bounds for the existence of efficient perfect sampling algorithms in terms of the *temperedness constant* of the potential defined by

$$C_\phi := \sup_{x\in\mathbb{R}^d} \int_{\mathbb{R}^d} |1 - e^{-\phi(x,y)}| \, dy \,. \tag{2}$$

Under the assumption that ϕ is repulsive and of finite range r, we have $0 \le C_\phi \le v_d(r)$.

▶ **Corollary 1.5.** *The above perfect sampling algorithm runs in expected time $O\Big(|\Lambda| \log^{O(1)}|\Lambda|\Big)$ when $\lambda < \frac{\mathrm{e}}{C_\phi}$.*

▶ Remark 1.6. In fact, using the results of Michelen and Perkins [54], one can push the bound for strong spatial mixing up to e/Δ_ϕ, where $\Delta_\phi \le C_\phi$ is the *potential-weighted connective constant* defined therein; our perfect sampling algorithm is efficient up to that point.

1.3 Related work and future directions

Related work

In recent years there has been a moderate flurry of activity around proving rigorous results for Gibbs point processes in both the setting of statistical physics and probability theory and in the setting of provably efficient sampling algorithms.

Work on provably efficient approximate sampling methods for the hard-sphere model begins with the seminal paper of Kannan, Mahoney, and Montenegro [43], who used techniques from the analysis of discrete spin systems to prove mixing time bounds for Markov chains for the hard-sphere model. Improvements to the range of parameters for which fast mixing holds came in [29, 33], before Michelen and Perkins proved the bound $\mathrm{e}/v_d(r)$ in [56], which we match with a perfect sampling algorithm in Corollary 1.3.

Perfect sampling algorithms for the hard sphere model have been considered in [27, 46, 21, 25, 38]. In terms of rigorous guarantees of efficiency, Huber proved a bound of $2/v_d(r)$ for a near-linear expected time perfect sampler in [36]. The perfect sampling algorithm of Guo and Jerrum in [25] does not match this bound, but the algorithm, based on "partial rejection sampling" [26] is novel and particularly simple. Several of these approaches also apply for finite-range, repulsive potentials or can be extended to that setting (e.g. [57]).

In parallel, there has been much work on proving bounds on the range of activities for which no phase transition can occur in the hard-sphere model; and, in recent years in particular, the techniques used have close connections to algorithms and the study of Markov chains. The classic approach to proving absence of phase transition is by proving convergence of the cluster expansion; the original bound here is $1/(\mathrm{e}v_d(r))$ due to Groeneveld [24]. In small dimensions (most significantly in dimension 2) improvements to the radius of convergence can be obtained [20]. On the other hand, this approach is inherently limited by the presence of non-physical singularities on the negative real axis. Alternative approaches avoiding this obstruction include using the equivalence of spatial and temporal mixing [33, 56]; or disagreement percolation [11, 34, 8]. The best current bound for absence of phase transition for the hard-sphere model and for repulsive pair potentials is the bound of e/C_ϕ (and e/Δ_ϕ) obtained by Michelen and Perkins [55, 56, 54]. Theorem 1.4 brings the bound for efficient perfect sampling up to this bound.

On a technical level, the most relevant past work is [18], in which the authors prove that for discrete spin systems, strong spatial mixing and subexponential volume growth of a sequence of graphs imply the existence of an efficient perfect sampling algorithm. We take their approach as a starting point but need new ideas to replace their exhaustive enumeration of configurations.

A key step in our algorithm is the use of a Bernoulli factory to implement a Bayes filter. Bernoulli factories are algorithms by which a Bernoulli random variable with success probability $f(p)$ can be simulated (perfectly) by an algorithm with access to independent Bernoulli p random variables, where the algorithm does not know the value p. Whether a Bernoulli factory exists (and how efficient it can be) depends on the function $f(\cdot)$ and a priori bounds on the possible values p. Bernoulli factories have been studied in [61, 37, 14] and recently used in the design of perfect sampling algorithms for CSP solutions in [31, 32].

Future directions

There are a number of extensions and improvements to these results one could pursue. Perhaps most straightforward would be to relax the notion of strong spatial mixing from exponential decay to decay faster than the volume growth of $\mathbb{R}^d$ and to extend the results to repulsive potentials of unbounded range but finite temperedness constant C_ϕ. Moreover, it would be nice to upgrade the guarantees of the algorithm in Theorem 1.4 to that of Theorem 1.2: that the algorithm does not need prior knowledge of the strong spatial mixing constants a, b to run correctly.

An ambitious and exciting direction would be to remove the assumption of a repulsive potential and find efficient perfect sampling algorithms for the class of *stable* potentials (see e.g. [62, 67, 68] for a definition). A stable potential is repulsive at short ranges but can include a weak attractive part; such potentials include the physically realistic Lenard-Jones potential among others [75]. This would require some very new ideas, as much of the recent probabilistic and algorithmic work on Gibbs point processes (e.g. [55, 56, 8, 54]) has used repulsiveness as an essential ingredient (for one, repulsiveness of the potential implies stochastic domination by the underlying Poisson point process). As a notable exception, a deterministic approximation algorithm for partition functions of finite-range stable potentials based on cluster expansion was recently proposed in [41].

1.4 Outline of the paper

In Section 2, we describe the high-level idea and intuition behind the algorithm. In Section 3 we introduce some notation and present some preliminary results that we will use throughout the paper. In Section 4 we present the algorithm that we will apply to both hard spheres and more general processes, and we state the main theorems and lemmas that we use for proving Theorem 1.2. The more general setting of bounded-range repulsive potentials (i.e., Theorem 1.4) can be found in the full version of the paper [3]. Intermediate steps and proves are omitted and can be found in the full version as well.

2 Intuitive idea behind the algorithm

Our algorithm is an adaptation to continuum models of the work by Feng, Guo, and Yin [18] on perfect sampling from discrete spin systems. We mimic their setting of a spin system on a graph $G = (V, E)$ by putting a graphical structure on sub-regions of our continuous space.

Let $\Lambda = [0, L)^d \subset \mathbb{R}^d$ be the region considered, $\lambda > 0$ the activity, and let ϕ be a repulsive potential of range $r > 0$. We subdivide Λ into $(\Lambda_{\boldsymbol{v}})_{\boldsymbol{v}\in\mathcal{V}}$, a set of smaller boxes of side length r indexed by vertices of a graph: each box corresponds to a vertex and boxes are connected if they are within r of each other, i.e., particles in the boxes can interact directly through the potential ϕ. We fix the index set for the boxes to be $\mathcal{V} \subset \mathbb{N}_0^d$, where each $\boldsymbol{v} \in \mathcal{V}$ corresponds to the box $\Lambda_{\boldsymbol{v}} = [v_1 r, (v_1 + 1)r) \times \cdots \times [v_d r, (v_d + 1)r)$. We extend this notation to sets of indices $S \subseteq \mathcal{V}$ by setting $\Lambda_S = \bigcup_{\boldsymbol{v}\in S} \Lambda_{\boldsymbol{v}}$. Further, we denote by $\mathbb{B}_k(\boldsymbol{v})$ the set of indices $\boldsymbol{w} \in \mathcal{V}$ with $\|\boldsymbol{v} - \boldsymbol{w}\|_\infty \le k$. To shorten notation, we write $\partial S = \left(\bigcup_{\boldsymbol{v}\in S} \mathbb{B}_1(\boldsymbol{v})\right) \setminus S$ for the outer boundary of a set of boxes indexed by $S \subseteq \mathcal{V}$.

Our algorithm runs iteratively, keeping track of two random variables: a point configuration $X_t \in \mathcal{N}_\Lambda$ with $X_0 = \emptyset$, and a set of "incorrect" boxes $\mathcal{U}_t \subseteq \mathcal{V}$ with $\mathcal{U}_0 = \mathcal{V}$. With each iteration t we maintain the following *invariant*: the partial configuration $X_t \cap (\Lambda_{\mathcal{U}_t})^{\mathrm{c}}$ is distributed according to the projection of μ_λ to $(\Lambda_{\mathcal{U}_t})^{\mathrm{c}}$ under the boundary condition $X_t \cap \Lambda_{\mathcal{U}_t}$. It follows that X_t is distributed according to μ_λ once we reach the state $\mathcal{U}_t = \emptyset$.

We proceed by sketching an iteration of the algorithm. An example for the involved subregions is given in Figure 1. Each iteration runs as follows:

1. We choose $\boldsymbol{u}_t \in \mathcal{U}_t$ uniformly at random and attempt to "repair" it by updating X_t on a neighborhood of boxes $B = \{\boldsymbol{u}_t\} \cup (\mathbb{B}_\ell(\boldsymbol{u}_t) \setminus \mathcal{U}_t)$ for some *update radius* $\ell \in \mathbb{N}$.
2. We sample a Bayes filter F_t (i.e., a Bernoulli random variable) with probability depending on the potential ϕ, the activity λ, and the current point configuration X_t on $\Lambda_{\boldsymbol{u}_t}$ and $\Lambda_{\partial B}$.
3. a) If $F_t = 1$, we set $\mathcal{U}_{t+1} = \mathcal{U}_t \setminus \{\boldsymbol{u}_t\}$ and we get X_{t+1} by updating X_t on Λ_B according to a projection of μ_λ conditioned on the boundary configuration $X_t \cap (\Lambda_B)^{\mathrm{c}}$.
   b) If $F_t = 0$, the configuration is unchanged and we add the boundary boxes to our "incorrect" list, i.e., $X_{t+1} = X_t$ and $\mathcal{U}_{t+1} = \mathcal{U}_t \cup \partial B$.

We use the Bayes filter, as in [18], to remove bias from the resulting distribution. To give some intuition for its role, suppose we run a naive version of the algorithm where we always update X_t on Λ_B as in step 3.a) above. Assuming the desired invariant holds after t iterations, this naive algorithm gives a bias to the distribution of X_{t+1} proportional to $\frac{Z_{\Lambda_{B\setminus\{\boldsymbol{u}_t\}}}\left(\lambda_{X_t\cap\Lambda_{\partial B\cup\{\boldsymbol{u}_t\}}}\right)}{Z_{\Lambda_B}\left(\lambda_{X_t\cap\Lambda_{\partial B}}\right)}$. We choose the Bayes filter such that, conditioned on $F_t = 1$, the bias term gets canceled. This suggests the choice

$$\mathbb{P}[F_t = 1 \mid X_t, \mathcal{U}_t, \boldsymbol{u}_t] = C(\mathcal{U}_t, \boldsymbol{u}_t, X_t) \cdot \frac{Z_{\Lambda_B}\left(\lambda_{X_t\cap\Lambda_{\partial B}}\right)}{Z_{\Lambda_{B\setminus\{\boldsymbol{u}_t\}}}\left(\lambda_{X_t\cap\Lambda_{\partial B\cup\{\boldsymbol{u}_t\}}}\right)}, \tag{3}$$

where the choice $C(\mathcal{U}_t, \boldsymbol{u}_t, X_t)$ serves three main purposes.

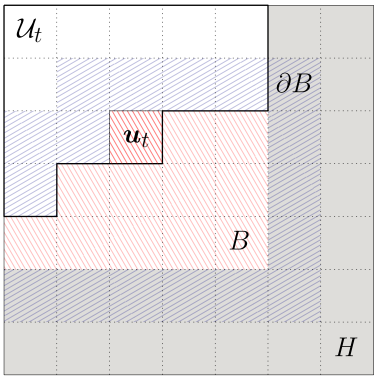

Figure 1 The box-shaped region $\Lambda \subset \mathbb{R}^2$ is divided into boxes of side length r (dotted lines). The boxes $\mathcal{U}_t$ are bordered by bold black lines. For $\boldsymbol{u}_t$ as given and update radius $\ell = 2$, the corresponding set B of boxes to be updated is indicated by the red hatched area (falling left to right). Its boundary boxes ∂B are shown as blue hatched area (rising left to right). The boxes in $H = (\mathcal{U}_t \cup B)^{\mathrm{c}}$ are shown with gray background.

First, it must guarantee that the right-hand side of (3) is a probability. To achieve this we need, for $H = (\mathcal{U}_t \cup B)^{\mathrm{c}}$ and almost all realizations of X_t, $\mathcal{U}_t$ and $\boldsymbol{u}_t$, that

$$C(\mathcal{U}_t, \boldsymbol{u}_t, X_t) \le \inf_{\xi \in \mathcal{N}_{\Lambda_H}} \frac{Z_{\Lambda_{B\setminus\{\boldsymbol{u}_t\}}}\left(\lambda_{\xi \cup (X_t \cap \Lambda_{\mathcal{U}_t})}\right)}{Z_{\Lambda_B}\left(\lambda_{\xi \cup (X_t \cap \Lambda_{\mathcal{U}_t \setminus \{\boldsymbol{u}_t\}})}\right)}. \tag{4}$$

Second, $C(\mathcal{U}_t, \boldsymbol{u}_t, X_t)$ must introduce no new bias. Carrying out the calculations, it can be seen that this is guaranteed if $C(\mathcal{U}_t, \boldsymbol{u}_t, X_t)$ only depends on $X_t \cap \Lambda_{\mathcal{U}_t}$. Finally, it must ensure that the algorithm terminates almost surely. It suffices to ensure $C(\mathcal{U}_t, \boldsymbol{u}_t, X_t)$ is uniformly bounded away from 0 for almost all realizations of X_t, implying that the same holds for the right-hand side of (3). We refer to a function $C(\cdot)$ satisfying these requirements as a *Bayes filter correction*.

If we use a Bayes filter as given in (3), keeping X_t and $\mathcal{U}_t$ unchanged whenever $F_t = 0$ introduces new bias. To prevent this, we set $\mathcal{U}_{t+1} = \mathcal{U}_t \cup \partial B$ in step 3.b), effectively deleting the part of the configuration that was revealed by the filter. Since the algorithm only terminates once $\mathcal{U}_t = \emptyset$, we further require the Bayes filter correction to ensure that the probability of $F_t = 0$ is small to guarantee efficiency.

Constructing a Bayes filter correction that satisfies the requirements above and allows for efficient sampling of F_t is a non-trivial task. In the next subsections, we present two approaches for this, the first specialized to the hard-sphere model without requirements, and the second one for more general potentials with strong spatial mixing of the point process. Crucially, assuming strong spatial mixing, both constructions allow us to control the success probability of the Bayes filter via the update radius ℓ in the construction of the updated set of boxes B (see step 1).

2.1 Bayes filter for the hard-sphere model

To construct a Bayes filter for the hard-sphere model, we efficiently approximate the right-hand side of (4). To approximate the infimum over the uncountable set of configurations $\xi \in \mathcal{N}_{\Lambda_H}$ we take the minimum over a finite, but sufficiently rich set of configurations, balancing the quality of approximation with the computation required. In fact the number of configurations needed will depend only on the volume of $\Lambda_{B \cup \partial B}$. We approximate the fraction of partition functions in (4) with running time only depending on the volume of $\Lambda_{B \cup \partial B}$. As a result, we efficiently compute a Bayes filter correction $C_\varepsilon(\cdot)$, with the parameter $\varepsilon > 0$ controlling how much $C_\varepsilon(\mathcal{U}_t, \boldsymbol{u}_t, X_t)$ deviates from the right-hand side of (4).

While our construction of $C_\varepsilon(\cdot)$ guarantees correctness of the sampling algorithm for any $\varepsilon > 0$, proving efficiency requires more. With strong spatial mixing, we choose ε so that the probability that $F_t = 0$ is uniformly bounded above, ensuring $\mathrm{O}(|\Lambda|)$ iterations in expectation.

It remains to argue that we can efficiently sample F_t, using the Bayes filter correction $C_\varepsilon(\cdot)$. Explicitly computing the success probability of F_t as in (3) would require computing the fraction of partition functions on the right-hand side exactly, while approximating these partition functions would require that the approximation error only depends on $X_t \cap \Lambda_{\mathcal{U}_t}$, to avoid new bias.

It is unclear how to implement these approaches, so instead we use Bernoulli factories to sample F_t without knowing the success probability. To do so, we observe that the fraction of partition functions can be written as a ratio of probabilities for drawing the empty set from a conditional hard-sphere model on Λ_B and $\Lambda_{B \setminus \{\boldsymbol{u}_t\}}$. Since both regions have constant volume, rejection sampling obtains Bernoulli random variables with these success probabilities in constant time. Hence, we obtain a Bernoulli factory for F_t with constant expected running time. Wald's identity yields a total expected running time $\mathrm{O}(|\Lambda|)$ for the algorithm.

2.2 Bayes filter for general potentials

We now consider the case of general bounded-range, repulsive potentials. Unlike the hard sphere model, it is not clear here how to approximate the infimum in (4) from a finite set of boundary configurations. However, given constants $a, b > 0$ such that ϕ satisfies (a, b)-strong spatial mixing, we can explicitly compute a function $\delta(a, b)$ so that

$$C_{a,b}(\mathcal{U}_t, \boldsymbol{u}_t, X_t) = \delta(a, b) \cdot \frac{Z_{\Lambda_{B \setminus \{\boldsymbol{u}_t\}}}\left(\lambda_{X_t \cap \Lambda_{\mathcal{U}_t}}\right)}{Z_{\Lambda_B}\left(\lambda_{X_t \cap \Lambda_{\mathcal{U}_t \setminus \{\boldsymbol{u}_t\}}}\right)}$$

is a Bayes filter correction. With strong spatial mixing, we use $C_{a,b}(\cdot)$ to construct a Bayes filter such that probability that $F_t = 0$ is bounded above, again implying a bound of $\mathrm{O}(|\Lambda|)$ on the expected number of iterations of the algorithm.

Note that in this setting, we require spatial mixing for both correctness and efficiency, while for the hard-sphere model we only need it for efficiency. Another crucial difference is that, while we can explicitly compute $\delta(a, b)$, the same does not hold for $C_{a,b}(\cdot)$ due to the fraction of partition functions involved. Again we circumvent this by rewriting the success probability of the Bayes filter in a suitable way and applying a Bernoulli factory for sampling F_t. Finally, we point out that we do not obtain a constant bound for the expected running time of each iteration, but instead the bound depends on the number of points in $X_t \cap \Lambda_{\partial B}$. Possible dependencies between the configuration X_t and the number of iterations prevent us from bounding the total expected running time using Wald's identity. Instead, we provide tail bounds on the number of iterations and the running time of each iteration, allowing us to derive an expected total running time that is linear in the volume of Λ up to polylogarithmic factors.

3 Preliminaries

Throughout the paper, we write $\mathbb{N}$ for the set of strictly positive integers, and we write $\mathbb{N}_0 = \mathbb{N} \cup \{0\}$. For any $k \in \mathbb{N}$, we denote by $[k]$ the set $[1, k] \cap \mathbb{N}$.

For a bounded measurable region $\Lambda \subset \mathbb{R}^d$ and any finite point configuration $\eta \in \mathcal{N}_\Lambda$, we write $|\eta|$ for the number of points in η. Note that this notation is the same that as the one we use for the volume of a region. The particular meaning will be clear from the context. Moreover, for $k \in \mathbb{N}$, we write $\binom{\eta}{k}$ for the set $\{\eta' \subseteq \eta \mid |\eta'| = k\}$.

3.1 Gibbs point processes

We introduce some additional notation for Gibbs point processes, used in the rest of the paper. Firstly, when dealing with a tuple $(x_1, \dots, x_k) \in (\mathbb{R}^d)^k$ we frequently denote it by the corresponding bold letter $\boldsymbol{x}$. Based on this, we write $\mathrm{d}\boldsymbol{x}$ for $\mathrm{d}x_1 \dots \mathrm{d}x_k$ and $H(\boldsymbol{x})$ for $H(x_1, \dots, x_k)$. Moreover, for any $k \in \mathbb{N}_0$ and $\boldsymbol{x} = (x_1, \dots, x_k) \in (\mathbb{R}^d)^k$ we write $\eta_{\boldsymbol{x}}$ for the set $\{x_1, \dots, x_k\}$, where the case $k = 0$ results in $\eta_{\boldsymbol{x}} = \emptyset$. Finally, for $\boldsymbol{x} \in \Lambda^k$ we write $\boldsymbol{\lambda}^{\boldsymbol{x}}$ for $\prod_{i\in[k]} \boldsymbol{\lambda}(x_i)$. This simplifies the definition of $\mu_{\boldsymbol{\lambda}}$ given in the introduction to

$$\mu_{\boldsymbol{\lambda}}(A) = \frac{1}{Z_\Lambda(\boldsymbol{\lambda})} \sum_{k\geq 0} \frac{1}{k!} \int_{\Lambda^k} \mathbb{1}_{\eta_{\boldsymbol{x}} \in A} \boldsymbol{\lambda}^{\boldsymbol{x}} \mathrm{e}^{-H(\boldsymbol{x})} \, \mathrm{d}\boldsymbol{x}.$$

Next, we formalize two different notions of restricting a Gibbs point process on Λ to a subregion $\Lambda' \subseteq \Lambda$ that are relevant throughout the paper.

The first is based on restricting the support of $\boldsymbol{\lambda}$ by defining a new activity function $\boldsymbol{\lambda}\mathbb{1}_{\Lambda'} : y \mapsto \boldsymbol{\lambda}(y) \cdot \mathbb{1}_{y\in\Lambda'}$ (for constant activity λ, we write $\lambda\mathbb{1}_{\Lambda'} : y \mapsto \lambda\mathbb{1}_{y\in\Lambda'}$). The resulting Gibbs point process is a probability measure on $(\mathcal{N}_\Lambda, \mathfrak{N}_\Lambda)$ with

$$\begin{aligned}\mu_{\boldsymbol{\lambda}\mathbb{1}_{\Lambda'}}(A) &= \frac{1}{Z_\Lambda(\boldsymbol{\lambda}\mathbb{1}_{\Lambda'})} \sum_{k\geq 0} \frac{1}{k!} \int_{\Lambda^k} \mathbb{1}_{\eta_{\boldsymbol{x}} \in A} (\boldsymbol{\lambda}\mathbb{1}_{\Lambda'})^{\boldsymbol{x}} \mathrm{e}^{-H(\boldsymbol{x})} \, \mathrm{d}\boldsymbol{x} \\ &= \frac{1}{Z_{\Lambda'}(\boldsymbol{\lambda})} \sum_{k\geq 0} \frac{1}{k!} \int_{\Lambda'^k} \mathbb{1}_{\eta_{\boldsymbol{x}} \in A} \boldsymbol{\lambda}^{\boldsymbol{x}} \mathrm{e}^{-H(\boldsymbol{x})} \, \mathrm{d}\boldsymbol{x}\end{aligned}$$

for all $A \in \mathfrak{N}_\Lambda$. In particular, for $A = \{\eta \in \mathcal{N}_\Lambda \mid \eta \cap (\Lambda')^{\mathrm{c}} > 0\}$, it holds that $\mu_{\boldsymbol{\lambda}\mathbb{1}_{\Lambda'}}(A) = 0$.

The second way of restricting a Gibbs point process $\mu_{\boldsymbol{\lambda}}$ is by projecting it to a measurable subregion $\Lambda' \subseteq \Lambda$. To this end, we write $\mu_{\boldsymbol{\lambda}}[\Lambda']$ for the image measure of $\mu_{\boldsymbol{\lambda}}$ under the map $\mathcal{N}_\Lambda \to \mathcal{N}_{\Lambda'}$, $\eta \mapsto \eta \cap \Lambda'$. By construction, $\mu_{\boldsymbol{\lambda}}[\Lambda']$ is a probability distribution on $(\mathcal{N}_{\Lambda'}, \mathfrak{N}_{\Lambda'})$ that, for every $A \in \mathfrak{N}_{\Lambda'}$, assigns a probability

$$\mu_{\boldsymbol{\lambda}}[\Lambda'](A) = \frac{1}{Z_\Lambda(\boldsymbol{\lambda})} \sum_{k\geq 0} \frac{1}{k!} \int_{\Lambda^k} \mathbb{1}_{\eta_{\boldsymbol{x}} \cap \Lambda' \in A} \boldsymbol{\lambda}^{\boldsymbol{x}} \mathrm{e}^{-H(\boldsymbol{x})} \, \mathrm{d}\boldsymbol{x}.$$

As discussed in Section 1, we frequently modify the activity function to encode the effect of fixing a certain point set (boundary condition). More precisely, for a fixed potential ϕ, an activity function $\boldsymbol{\lambda}$ and a point set $\eta \in \mathcal{N}_\Lambda$ we write $\boldsymbol{\lambda}_\eta$ for the function $y \mapsto \boldsymbol{\lambda}(y)\mathrm{e}^{-\sum_{x\in\eta} \phi(x,y)}$. Similarly, for $k \in \mathbb{N}$ and $\boldsymbol{x} \in \Lambda^k$ we write $\boldsymbol{\lambda}_{\boldsymbol{x}}$ for the activity function $y \mapsto \boldsymbol{\lambda}(y)\mathrm{e}^{-\sum_{i\in[k]} \phi(x_i,y)}$. We extend this notation to constant activity $\lambda \in \mathbb{R}_{\geq 0}$, writing $\lambda_\eta : y \mapsto \lambda\mathrm{e}^{-\sum_{x\in\eta} \phi(x,y)}$ and $\lambda_{\boldsymbol{x}} : y \mapsto \lambda\mathrm{e}^{-\sum_{i\in[k]} \phi(x_i,y)}$. Using this notation, a useful alternative definition of $\mu_{\boldsymbol{\lambda}}[\Lambda']$ is given by

$$\begin{aligned}\mu_{\boldsymbol{\lambda}}[\Lambda'](A) &= \frac{1}{Z_\Lambda(\boldsymbol{\lambda})} \sum_{k\geq 0} \frac{1}{k!} \int_{\Lambda'^k} \mathbb{1}_{\eta_{\boldsymbol{x}} \in A} \boldsymbol{\lambda}^{\boldsymbol{x}} \mathrm{e}^{-H(\boldsymbol{x})} Z_\Lambda\left(\boldsymbol{\lambda}_{\boldsymbol{x}}\mathbb{1}_{(\Lambda')^{\mathrm{c}}}\right) \mathrm{d}\boldsymbol{x} \\ &= \frac{1}{Z_\Lambda(\boldsymbol{\lambda})} \sum_{k\geq 0} \frac{1}{k!} \int_{\Lambda'^k} \mathbb{1}_{\eta_{\boldsymbol{x}} \in A} \boldsymbol{\lambda}^{\boldsymbol{x}} \mathrm{e}^{-H(\boldsymbol{x})} Z_{(\Lambda')^{\mathrm{c}}}(\boldsymbol{\lambda}_{\boldsymbol{x}}) \, \mathrm{d}\boldsymbol{x}\end{aligned}$$

for $A \in \mathfrak{N}_{\Lambda'}$. In particular, note that

$$\mu_{\boldsymbol{\lambda}\mathbb{1}_{\Lambda'}}[\Lambda'](A) = \frac{1}{Z_{\Lambda'}(\boldsymbol{\lambda})} \sum_{k \geq 0} \frac{1}{k!} \int_{\Lambda'^k} \mathbb{1}_{\eta_{\boldsymbol{x}} \in A} \boldsymbol{\lambda}^{\boldsymbol{x}} \mathrm{e}^{-H(\boldsymbol{x})} \, \mathrm{d}\boldsymbol{x}.$$

While $\mu_{\boldsymbol{\lambda}\mathbb{1}_{\Lambda'}}[\Lambda']$ and $\mu_{\boldsymbol{\lambda}\mathbb{1}_{\Lambda'}}$ seem similar, the former is a distribution on $(\mathcal{N}_{\Lambda'}, \mathfrak{N}_{\Lambda'})$ whereas the latter is defined on $(\mathcal{N}_{\Lambda}, \mathfrak{N}_{\Lambda})$.

3.2 Bernoulli factories

In designing our sampling algorithm, it will be useful to consider the following Bernoulli factory problem. We are given access to a sampler for $\mathrm{Ber}(p)$ and for $\mathrm{Ber}(q)$, that is samplers of Bernoulli random variables with parameters p and q respectively, where we further assume $p < q$. We want to sample a random variable $Z \sim \mathrm{Ber}\left(\frac{p}{q}\right)$.

Most work on Bernoulli factories studies their running time in terms of the number of coin flips required. In our setting, the time needed to generate each of these coin flips is random variable. Fortunately, suitable independence assumptions hold in our setting allowing us to prove the following lemma.

▶ **Lemma 3.1.** *Fix some $p, q \in [0, 1]$ such that $q - p \geq \epsilon$ for some $\epsilon > 0$. Further assume that we have oracle access to a sampler from $\mathrm{Ber}(p)$ and $\mathrm{Ber}(q)$ in the following sense:*

1. *every sample from $\mathrm{Ber}(p)$ (resp. $\mathrm{Ber}(q)$) is independent from all previous samples;*
2. *the expected running time for obtaining a sample from $\mathrm{Ber}(p)$ (resp. $\mathrm{Ber}(q)$), conditioned on previously obtained samples, is uniformly bounded by some $t \in \mathbb{R}_{\geq 0}$.*

Then we can sample from $\mathrm{Ber}\left(\frac{p}{q}\right)$ in $\mathrm{O}\left(t\epsilon^{-2}\right)$ expected time.

4 The algorithm

Let $\Lambda = [0, L)^d$ and consider a Gibbs point processes on Λ with uniform activity $\boldsymbol{\lambda}(x) \equiv \lambda$ for some $\lambda \in \mathbb{R}_{>0}$ and repulsive potential ϕ with finite range $r \in \mathbb{R}_{>0}$. Throughout the analysis of our algorithm, it will be useful to focus on configurations $\eta \in \mathcal{N}_{\Lambda}$ such that $\phi(x, y) < \infty$ for all $\{x, y\} \in \binom{\eta}{2}$, in which case we call η a *feasible configuration*.

Before stating our algorithm, we first formalize how we divide Λ into smaller boxes, following the description given in Section 2. For a r and L as above, let $N = \lceil L/r \rceil$. We set $\mathcal{V} = \{0, \dots, N-1\}^d$ to be the set of box indices and associate each box index $\boldsymbol{v} = (v_1, \dots, v_d) \in \mathcal{V}$ with the region $\Lambda_{\boldsymbol{v}} = \big([v_1 r, (v_1 + 1)r) \times \dots \times [v_d r, (v_d + 1)r)\big) \cap \Lambda$. As in Section 2, we extend this notation to sets of box indices $S \subseteq \mathcal{V}$ by setting $\Lambda_S = \bigcup_{\boldsymbol{v} \in S} \Lambda_{\boldsymbol{v}}$. Further, recall that, for $\boldsymbol{v} \in \mathcal{V}$, we write $\mathbb{B}_k(\boldsymbol{v})$ for the set of boxes $\boldsymbol{w} \in \mathcal{V}$ with $\|\boldsymbol{v} - \boldsymbol{w}\|_{\infty} < k$. As mentioned earlier, our algorithm tries to update in each step the point configuration on a subset of boxes $B \subseteq \mathcal{V}$. To this end, for $S \subseteq \mathcal{V}$, $\boldsymbol{v} \in S, r \in \mathbb{R}_{>0}$ and $\ell \in \mathbb{N}$, we define

$$B(S, \boldsymbol{v}, \ell) := \{\boldsymbol{v}\} \cup (\mathbb{B}_{\boldsymbol{v}}(\ell) \setminus S).$$

We refer to the parameter ℓ as the *update radius*. Finally, recall that we write $\partial S = \left(\bigcup_{\boldsymbol{v} \in S} \mathbb{B}_1(\boldsymbol{v})\right) \setminus S$ for the outer boundary of $S \subseteq \mathcal{V}$.

Whether the algorithm updates the point configuration in iteration t depends on the outcome of a Bernoulli random variable F_t, called the *Bayes filter*. We introduce the following definition.

▶ **Definition 4.1.** *Fix a repulsive potential ϕ of range $r \in \mathbb{R}_{>0}$, an activity $\lambda \in \mathbb{R}_{>0}$ and some $\ell \in \mathbb{N}$. We call a function $C : 2^{\mathcal{V}} \times \mathcal{V} \times \mathcal{N}_\Lambda \to [0,1]$ a* Bayes filter correction *if, for all non-empty $S \subseteq \mathcal{V}$ and $\boldsymbol{v} \in S$, it holds that*

1. *$C(S, \boldsymbol{v}, \cdot)$ is $\mathfrak{R}_{\Lambda_S}$-measurable (in particular $C(S, \boldsymbol{v}, \eta) = C(S, \boldsymbol{v}, \eta \cap \Lambda_S)$ for all $\eta \in \mathcal{N}_\Lambda$),*
2. *there is some $\varepsilon > 0$ such that for $B = B(S, \boldsymbol{v}, \ell)$, $H = (S \cup B)^{\mathrm{c}}$ and all feasible $\eta \in \mathcal{N}_\Lambda$ it holds that*

$$\varepsilon \le C(S, \boldsymbol{v}, \eta) \le \inf_{\substack{\xi \in \mathcal{N}_{\Lambda_H} \\ \xi \cup (\eta \cap \Lambda_S) \text{ is feasible}}} \left\{ \frac{Z_{\Lambda_{B \setminus \{\boldsymbol{v}\}}}\left(\lambda_{\xi \cup (\eta \cap \Lambda_S)}\right)}{Z_{\Lambda_B}\left(\lambda_{\xi \cup (\eta \cap \Lambda_{S \setminus \{\boldsymbol{v}\}})}\right)} \right\}.$$

Our perfect sampling procedure is stated in Algorithm 1.

Algorithm 1 Perfect sampling algorithm for repulsive Gibbs point processes.

```
   Data: region $\Lambda = [0, L)^d$, repulsive potential $\phi$ of range at most $r \in \mathbb{R}_{>0}$, activity
         $\lambda \in \mathbb{R}_{>0}$, update radius $\ell \in \mathbb{N}$
 1 set $t = 0$, $\mathcal{U}_t = \mathcal{V}$, $X_t = \emptyset$
 2 while $\mathcal{U}_t \neq \emptyset$ do
 3     draw $\boldsymbol{u}_t \in \mathcal{U}_t$ uniformly at random
 4     set $B = B(\mathcal{U}_t, \boldsymbol{u}_t, \ell)$
 5     draw $F_t$ from Ber$\left(C(\mathcal{U}_t, \boldsymbol{u}_t, X_t) \cdot \frac{Z_{\Lambda_B}(\lambda_{X_t \cap \Lambda_{\partial B}})}{Z_{\Lambda_{B \setminus \{\boldsymbol{u}_t\}}}(\lambda_{X_t \cap \Lambda_{\partial B \cup \{\boldsymbol{u}_t\}}})}\right)$ where $C$ is a Bayes
        filter correction as in Definition 4.1
 6     if $F_t$ = 1 then
 7         draw $Y$ from $\mu_{\lambda_{X_t \cap (\Lambda_B)^{\mathrm{c}}} \mathbb{1}_{\Lambda_B}}[\Lambda_B]$
 8         set $X_{t+1} = (X_t \setminus \Lambda_B) \cup Y$
 9         set $\mathcal{U}_{t+1} = \mathcal{U}_t \setminus \{\boldsymbol{u}_t\}$
10     else
11         set $\mathcal{U}_{t+1} = \mathcal{U}_t \cup \partial B$
12     increase $t$ by 1
13 return $X_t$
```

Before we get to the question of how to sample an appropriate Bayes filter in step 5, the following statement ensures that the algorithm produces the correct output distribution.

▶ **Theorem 4.2.** *Let $T = \inf_{t \in \mathbb{N}}\{\mathcal{U}_t = \emptyset\}$. Then T is almost surely finite and for all $t \in \mathbb{N}_0$ with $\mathbb{P}[t \ge T] > 0$ and all $A \in \mathfrak{R}_\Lambda$, it holds that $\mathbb{P}[X_t \in A \mid t \ge T] = \mu_\lambda(A)$.*

We proceed to exemplify how we use Bernoulli factories to sample the Bayes filter. For brevity, we focus on the hard-sphere model here. The more general case of bounded-range repulsive potential can be found in the full version of the paper [3].

Bayes filter for the hard-sphere model

Recall that for the hard-sphere model, we have $\phi(x, y) = \infty$ if $\mathrm{dist}(x, y) < r$ and 0 otherwise. Given a non-empty set of boxes $S \subseteq \mathcal{V}$, $\boldsymbol{v} \in S$ and a feasible configuration $\eta \in \mathcal{N}_\Lambda$, we want to construct a Bayes filter correction $C(S, \boldsymbol{v}, \eta)$ that allows us to efficiently sample the filter.

To this end, set $B = B(S, \boldsymbol{v}, \ell)$ and $H = (S \cup B)^{\mathrm{c}}$. Our construction makes use of two ingredients. Firstly, we argue that, instead of minimization over the uncountable set of boundary conditions $\mathcal{N}_{\Lambda_H}$, it suffices to minimize over subsets of the finite set $(\delta_1\mathbb{Z})^d \cap \Lambda_{H\cap\partial B}$ for a sufficiently small $\delta_1 > 0$. Secondly, choosing a sufficiently small $\delta_2 > 0$, we show that we can approximate the involved partition functions using the function

$$\hat{Z}(S, \eta, \delta_2) = \sum_{\gamma \subseteq (\delta_2\mathbb{Z})^d \cap \Lambda_S} \lambda^{|\gamma|} \delta_2^{|\gamma|} \cdot D(\gamma) \cdot D(\gamma \mid \eta \cap \Lambda_{\partial S}), \tag{5}$$

where $D(\gamma) = \prod_{\{x,y\} \in \binom{\gamma}{2}} \mathbb{1}_{\mathrm{dist}(x,y) \geq r}$ and $D(\gamma \mid \eta) = \prod_{x \in \gamma} \prod_{y \in \eta} \mathbb{1}_{\mathrm{dist}(x,y) \geq r}$.

The following lemma then gives a way to construct a Bayes filter correction for the hard-sphere model.

► **Lemma 4.3.** *For non-empty $S \subseteq \mathcal{V}$, $\boldsymbol{v} \in S$, feasible $\eta \in \mathcal{N}_\Lambda$ and $\varepsilon, \delta_1, \delta_2 > 0$ define*

$$C_\varepsilon(S, \boldsymbol{v}, \eta) := \mathrm{e}^{-\varepsilon} \cdot \min_{\gamma \subseteq (\delta_1\mathbb{Z})^d \cap \Lambda_{H\cap\partial B}} \frac{\hat{Z}(B \setminus \{\boldsymbol{v}\}, \gamma \cup (\eta \cap \Lambda_S), \delta_2)}{\hat{Z}\big(B, \gamma \cup (\eta \cap \Lambda_{S\setminus\boldsymbol{v}}), \delta_2\big)},$$

where $B = B(S, \boldsymbol{v}, \ell)$ and $H = (S \cup B)^{\mathrm{c}}$. For δ_1, δ_2 sufficiently small, depending only on d, r, ℓ and ε, it holds that $C_\varepsilon(S, \boldsymbol{v}, \eta)$ is a Bayes filter correction.

In fact, we will not use C_ε directly for our Bayes filter, but a slightly scaled version $0 < \mathrm{e}^{-\varepsilon} C_\varepsilon$, which is again a Bayes filter correction. The additional slack allows us to efficiently sample the Bayes filter by using a Bernoulli factory, as we argue in the next lemma.

► **Lemma 4.4.** *Let $S \subseteq \mathcal{V}$ be non-empty, $\boldsymbol{v} \in S$ and $\eta \in \mathcal{N}_\Lambda$ be feasible, and set $B = B(S, \boldsymbol{v}, \ell)$. For all $\varepsilon > 0$ we can sample a Bernoulli random variable with success probability*

$$\mathrm{e}^{-\varepsilon} C_\varepsilon(S, \boldsymbol{v}, \eta) \cdot \frac{Z_{\Lambda_B}(\lambda_{\eta\cap\Lambda_{\partial B}})}{Z_{\Lambda_{B\setminus\{\boldsymbol{v}\}}}\big(\lambda_{\eta\cap\Lambda_{\partial B\cup\{\boldsymbol{v}\}}}\big)}$$

with expected running time only depending on ε, ℓ, r, λ and d.

The core idea of the above lemma to express $\frac{Z_{\Lambda_B}(\lambda_{\eta\cap\Lambda_{\partial B}})}{Z_{\Lambda_{B\setminus\{\boldsymbol{v}\}}}\big(\lambda_{\eta\cap\Lambda_{\partial B\cup\{\boldsymbol{v}\}}}\big)}$ as a fraction of probabilities. Together with the fact that $\mathrm{e}^{-\varepsilon} C_\varepsilon(S, \boldsymbol{v}, \eta) < 1$, this allows us to write the success probability of the Bayes filter as a fraction of probabilities $\frac{p}{q}$. Arguing that $p < q$, and that we can sample $\mathrm{Ber}(p)$ and $\mathrm{Ber}(q)$ efficiently allows us to apply Lemma 3.1 to prove Lemma 4.4.

While the above suffices to perform each iteration of Algorithm 1 efficiently, we still need to bound the number of iterations. For this, we derive a lower bound on the success probability of the Bayes filter with correction $\mathrm{e}^{-\varepsilon} C_\varepsilon(\cdot)$ for a particular choice of ε, using the assumption of strong spatial mixing.

► **Lemma 4.5.** *Consider a hard-sphere model that exhibits (a, b)-strong spatial mixing up to λ. Then there are constants a', b', only depending on a, b, r, λ and d, such that for all non-empty $S \subseteq \mathcal{V}$, $\boldsymbol{v} \in S$ and feasible $\eta \in \mathcal{N}_\Lambda$ it holds that*

$$\mathrm{e}^{-\mathrm{e}^{-\ell}} C_{\mathrm{e}^{-\ell}}(S, \boldsymbol{v}, \eta) \cdot \frac{Z_{\Lambda_B}(\lambda_{\eta\cap\Lambda_{\partial B}})}{Z_{\Lambda_{B\setminus\{\boldsymbol{v}\}}}\big(\lambda_{\eta\cap\Lambda_{\partial B\cup\{\boldsymbol{v}\}}}\big)} \geq 1 - a'\mathrm{e}^{-b'\ell}.$$

Lemma 4.5 allows us to control the success probability of the Bayes filter in terms of ℓ. Combining the results above gives the following theorem.

▶ **Theorem 4.6.** *Consider Algorithm 1 on a hard-sphere model with* $C(\cdot) = \mathrm{e}^{-\mathrm{e}^{-\ell}} C_{\mathrm{e}^{-\ell}}(\cdot)$ *as Bayes filter correction in line 5. We can run the algorithm in almost-surely finite running time and, on termination, it outputs a sample from the hard-sphere Gibbs measure* μ_λ *on* Λ*. Moreover, if the hard-sphere model satisfies* (a, b)*-strong spatial mixing and if* ℓ *is chosen as a sufficiently large constant, depending on* a*,* b*,* r*,* λ *and* d*, then we can run the algorithm in expected time* $\mathrm{O}(|\Lambda|)$*.*

Abstract

A major goal in the area of exact exponential algorithms is to give an algorithm for the (worst-case) n-input Subset Sum problem that runs in time $2^{(1/2-c)n}$ for some constant $c > 0$. In this paper we give a Subset Sum algorithm with worst-case running time $O(2^{n/2} \cdot n^{-\gamma})$ for a constant $\gamma > 0.5023$ in standard word RAM or circuit RAM models. To the best of our knowledge, this is the first improvement on the classical "meet-in-the-middle" algorithm for worst-case Subset Sum, due to Horowitz and Sahni, which can be implemented in time $O(2^{n/2})$ in these memory models [16].

Our algorithm combines a number of different techniques, including the "representation method" introduced by Howgrave-Graham and Joux [17] and subsequent adaptations of the method in Austrin, Kaski, Koivisto, and Nederlof [4], and Nederlof and Węgrzycki [20], and "bit-packing" techniques used in the work of Baran, Demaine, and Pătraşcu [5] on subquadratic algorithms for 3SUM.

1 Introduction

One of the most well-known and simple-to-state NP-complete problems is the *Subset Sum* problem. An instance of Subset Sum consists of a list $X = (x_1, \dots, x_n)$ of n positive integer values and a positive integer target t, and the output is either a subset $S \subseteq X$ such that $\sum_{x_i \in S} x_i = t$ or a report that no such subset exists. Subset Sum was one of the original 21 problems proved NP-complete in Karp's seminal paper [18] and has been the subject of intensive study from many different perspectives for at least five decades.

This paper is motivated by the following open problem in the theory of exact exponential time algorithms: how quickly can we solve worst-case instances of Subset Sum? Exhaustive search over all possible solutions yields a trivial $2^n \cdot \mathrm{poly}(n)$-time algorithm. In 1974, Horowitz and Sahni introduced the "meet-in-the-middle" technique, which gives an algorithm that can be implemented in $O(2^{n/2})$ time in standard RAM models [16]. Since then, obtaining

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

a $2^{(1/2-c)n}$-time algorithm for some constant $c > 0$ has emerged as a major goal in the exact exponential time algorithms community (explicitly mentioned in [23, 11, 3, 4, 20] and numerous other works) which has attracted the attention of many researchers.

Intriguing progress has been made on a number of variants of the core worst-case Subset Sum problem. More than forty years ago Schroeppel and Shamir [22] improved the $2^{n/2} \cdot \mathrm{poly}(n)$ space complexity of the meet-in-the-middle algorithm by giving an algorithm that runs in $2^{n/2} \cdot \mathrm{poly}(n)$ time and $2^{n/4} \cdot \mathrm{poly}(n)$ space. An exciting recent breakthrough by Nederlof and Węgrzycki [20] further improved this space complexity to $2^{0.249999n}$. In [17] Howgrave-Graham and Joux gave an algorithm which can solve *average-case* Subset Sum instances in time $2^{0.337n}$,[1] and this was later improved to $2^{0.291n}$ in the work of Becker et al. [6]. The closely related *Equal Subset Sum* problem, which looks for two subsets with the same sum, can be solved exponentially faster than suggested by meet-in-the-middle [19] and also yields further improvements in the average case [10]. However, to the best of our knowledge, there have been no improvements on the worst-case $O(2^{n/2})$ runtime of the meet-in-the-middle algorithm for Subset Sum since it was first introduced almost fifty years ago.

Our contribution: Worst-case Subset Sum in $2^{n/2}/\mathrm{poly}(n)$ time. Given the longstanding difficulty of achieving a $2^{(1/2-c)n}$-time worst-case algorithm for Subset Sum, it is natural to consider the relaxed goal of achieving *some* nontrivial speedup of the meet-in-the-middle algorithm. In this paper we achieve this goal; more precisely, we give three different randomized algorithms for worst-case Subset Sum, each of which runs in time $O(2^{n/2} \cdot n^{-\gamma})$ for a specific constant $\gamma > 0$ in a standard word RAM or circuit RAM model (described in detail in Section 1.1 below). Our fastest algorithm, which combines techniques from our other two algorithms, runs in time $O(2^{n/2} \cdot n^{-0.5023})$.

The improvements we achieve over the $O(2^{n/2})$ runtime of the meet-in-the-middle algorithm for Subset Sum are analogous to "log-shaving" improvements on the runtimes of well-known and simple polynomial-time algorithms for various problems which have resisted attempts at polynomial-factor improvements. There is a substantial strand of research along these lines (see [9, 8] for a non-exhaustive overview); indeed, Abboud and Bringmann [1] have recently stated that: "A noticeable fraction of Algorithms papers in the last few decades improve the runtime of well-known algorithms for fundamental problems by logarithmic factors." In our setting, since the well-known and simple algorithm for Subset Sum (namely, meet-in-the-middle) runs in exponential time, saving a $\mathrm{poly}(n)$ factor, as we do, is analogous to "log-shaving". Indeed, as we discuss in Section 1.2 below, our first and most straightforward algorithm is based on "bit-packing" techniques that were used by Baran, Demaine, and Pătraşcu [5] to shave log factors from the standard $O(n^2)$-time algorithm for the 3SUM problem. We find it somewhat surprising that the "log-shaving" perspective has not previously appeared in the literature on Subset Sum, and we hope that our work will lead to further (and more substantial) runtime improvements for Subset Sum and other problems with well-known and simple exponential-time algorithms.

▶ Remark 1. We note that by a straightforward reduction, an algorithm for 4SUM running in time $O(n^2/\log(n)^\alpha)$ for any constant $\alpha > 0$ would immediately imply a Subset Sum algorithm running in time $O(2^{n/2}/n^\alpha)$, which would be a result comparable to ours. However, while log-shaving results for 3SUM are known [5, 14], giving an $o(n^2)$ algorithm for 4SUM is a well-known open problem.

[1] See the last paragraph of [6] for a discussion of the runtime of [17].

1.1 Our Computational Model

A Subset Sum instance is parameterized by the number of inputs n and the size of the target value t (without loss of generality, $x_1, x_2, \ldots, x_n \leq t$). Thus it is natural to adopt a memory model with word length $\ell = \Theta(\log t)$ such that each input integer can be stored in a single word. This is the framework used in the work of Pisinger [21], which studies dynamic programming approaches for Subset Sum in the word RAM model (see [21, Equation (1)]). We also note that this memory model is analogous to the standard RAM model that is commonly used for problems such as 3SUM (see e.g. [5]), where it is assumed that each input value is at most $\mathrm{poly}(n)$ and hence fits into a single $O(\log n)$-bit machine word.

This framework lets us consider arbitrary input instances of Subset Sum with no constraints on the size of the input integers. If $t = 2^{o(n)}$, standard dynamic programming algorithms [7] solve the problem in time $O(nt) = 2^{o(n)}$, which supersedes our $\mathrm{poly}(n)$-factor improvements over meet-in-the-middle; hence throughout the paper we assume $t = 2^{\Omega(n)}$. It is arguably most natural to think about instances in which $t = 2^{\Theta(n)}$, in which case $\ell = \Theta(n)$, and we encourage the first-time reader to imagine $\ell = \Theta(n)$ for easy digestion. More precisely, we make the assumption throughout the paper that the word size $\ell = \mathrm{poly}(n)$, although some of our results even hold for extremely large word sizes and are footnoted accordingly.

We consider runtime in two standard variants of the RAM model. The first is *circuit RAM*; in this model, any operation that maps a constant number of words to a single word and has a $\mathrm{poly}(\ell)$-size circuit with unbounded fan-in gates can be performed in time proportional to the depth of the circuit. Consequently, in the circuit RAM model, AC^0 operations on a *constant* number of words can be performed in *constant* time, and multiplying, performing modular division, etc., on two ℓ-bit words can be performed in time $O(\log \ell)$. The second is *word RAM*, in which the usual arithmetic operations, including multiplication, are assumed to take unit time, but arbitrary AC^0 operations are not atomic operations on words. We present each of our algorithms for the stronger circuit RAM model,[2] and explain adaptations that give corresponding word RAM algorithms.

1.2 Results, Techniques, and Organization

In Section 2 we establish our notation and review some background results and observations that will be used throughout the paper.

Sections 3–5 give our three new algorithms, which augment the standard meet-in-the-middle approach in different ways to achieve their respective runtime improvements. Each of our algorithms is a randomized decision algorithm that runs in the time bound claimed below and on every input instance outputs the correct answer with probability at least 3/4. Further, each of our algorithms has one-sided error, i.e., it never makes a mistake when it outputs "yes".

Our first and simplest algorithm, presented in Section 3, achieves a runtime of $\widetilde{O}(2^{n/2} \cdot \ell^{-1/2}) \leq \widetilde{O}(2^{n/2} \cdot n^{-1/2})$ in the circuit RAM model and $\widetilde{O}(2^{n/2} \cdot n^{-1/2})$ in the word RAM model, for all $\ell = \mathrm{poly}(n)$.[3] It works by adapting the *bit-packing* trick, a technique developed by Baran, Demaine, and Pătraşcu [5] for the 3SUM problem, for the `Meet-in-the-Middle` algorithm. The idea is to compress the two lists of partial subset sums used in `Meet-in-the-Middle` by packing hashes of multiple values into a machine

[2] Note that any algorithm in the word RAM model can be simulated in the circuit RAM model with no more than an $O(\log \ell)$-factor slowdown.

[3] The notation $\widetilde{O}(\cdot)$ suppresses $\mathrm{polylog}(\ell) = \mathrm{polylog}(n)$ factors.

word, while preserving enough information to make it possible to run (an adaptation of) `Meet-in-the-Middle` on the lists of hashed and packed values. This results in a runtime savings over performing `Meet-in-the-Middle` on the original lists (without hashing and packing), because processing a pair of words, each containing multiple hashed values, takes constant expected time in the circuit RAM model and can be memoized to take constant time in the word RAM model.

Our second algorithm, given in Section 4, achieves a runtime of $O(2^{n/2} \cdot \ell^{-\gamma}) \leq O(2^{n/2} \cdot n^{-\gamma})$ for some constant $\gamma > 0.01$ in the circuit RAM model and $O(2^{n/2} \cdot n^{-\gamma})$ in the word RAM model, for all $\ell = \text{poly}(n)$. Although the time savings is smaller than our first algorithm, we believe that this algorithm is conceptually interesting since it avoids bit-packing and instead combines `Meet-in-the-Middle` with two techniques devised in prior work on Subset Sum. The first of these is the "representation method" introduced by Howgrave-Graham and Joux [17]. Roughly speaking, the idea of this method is to (i) increase the size of the search space in such a way that a single solution has many "representations" in the space of enhanced solutions, and then (ii) search over only a fraction of the enhanced solution space. A consequence of expanding the solution space, though, is that a number of "pseudosolutions", solutions that contain certain input elements more than once, are introduced. This leads us to the second technique, i.e. the use of a fast subroutine for the Orthogonal Vectors (OV) problem (recall that OV is the problem of deciding whether two lists of $\{0, 1\}$-vectors contain a pair of vectors, one from each list, that are orthogonal). The fast OV subroutine lets us efficiently rule out pseudosolutions while running (an adaptation of) `Meet-in-the-Middle` on a fraction of the enhanced solution space.

In Section 5 we give our fastest algorithm, which uses a delicate combination of the techniques from Sections 3 and 4 to obtain a runtime of $O(2^{n/2} \cdot n^{-0.5023})$ for all $\ell = \text{poly}(n)$. While the runtime improvement over Section 3 is not large, this algorithm demonstrates that by leveraging insights specific to the Subset Sum problem, we can achieve time savings beyond what is possible with more "generic" log shaving techniques. Finally, in Section 6 we briefly discuss directions for future work.

Note that this version of the work is an extended abstract. Readers interested in a more complete presentation may wish to consult the full version.[4]

2 Preliminaries

To ease readability, we adopt the following notational conventions throughout the paper: lowercase Roman letters (ℓ, n, etc.) denote variables; lowercase Greek letters (ε, α, etc.) denote numerical constants; capital Roman letters (L, W, etc.) denote sets, multisets, or lists; and calligraphic capital letters ($\mathcal{W}$, $\mathcal{Q}$, etc.) denote collections of sets of numbers.

Logarithms. When written without a specified base, $\log(\cdot)$ denotes the base-2 logarithm.

Big-O Notation. We augment big-O notation with a tilde ($\widetilde{O}$, $\widetilde{\Omega}$, $\widetilde{\Theta}$ etc.) to suppress $\text{polylog}(\ell) = \text{polylog}(n)$ factors. For example, we have $\widetilde{O}(2^n) = O(2^n \cdot \text{polylog}(n))$ and $\widetilde{\Omega}(n) = \Omega(\frac{n}{\text{polylog}(n)})$.

Probability Notation. Random variables are written in boldface. In particular, we write "$\boldsymbol{x} \sim S$" to indicate that an element $\boldsymbol{x}$ is sampled uniformly at random from a finite multiset S.

[4] `https://arxiv.org/abs/2301.07134`

Set Notation. We write $[a : b]$ for the set of integers $\{a, a+1, \dots, b\}$ and $[a]$ for $\{1, 2, \dots, a\}$. We write $\mathbb{P}[a : b]$ for the set of all primes in the interval $[a : b]$.

Given a multiset or list Y of integers, we adopt several shorthands: $\Sigma(Y) := \sum_{y \in Y} y$ denotes the sum, $W(Y) := \{\Sigma(T) \mid T \subseteq Y\}$ denotes the set of *distinct* sub-multiset sums, and L_Y denotes the list containing the elements of $W(Y)$ sorted in increasing order.

Also, we often write $f(Y)$ for the multiset or list obtained by applying operation f element-wise, such as $Y + \alpha = \{y + \alpha \mid y \in Y\}$ and $\alpha Y = \{\alpha y \mid y \in Y\}$. The only exception is $(Y \bmod p)$, which denotes the set of *distinct* residues $\{(y \bmod p) \mid y \in Y\}$.

Stirling's Approximation for Binomial Coefficients. We use the following well-known consequence of Stirling's approximation (see e.g. [13, Lemma 16.19]): For each integer $j \in [0 : n/2]$,

$$\sum_{i \le j} \binom{n}{i} \;\le\; 2^{H(j/n) \cdot n}, \tag{1}$$

where $H(y) := -y \log(y) - (1 - y) \log(1 - y)$ is the binary entropy function.

Pseudolinear Hashing. Recall that $\ell = \mathrm{poly}(n)$ is the word length in our memory model. Given an integer $m \le \ell$, we write $\boldsymbol{h}_m$ to denote the random hash function defined as

$$\boldsymbol{h}_m(y) \;:=\; (\boldsymbol{u} \cdot y \pmod{2^\ell}) \gg \ell - m. \tag{2}$$

Here the input y is an ℓ-bit integer, $\boldsymbol{u}$ is selected uniformly at random from all odd ℓ-bit integers, and $\gg$ denotes a bit shift to the right, i.e., dividing $\boldsymbol{u} \cdot y \pmod{2^\ell}$ by $2^{\ell - m}$ and then truncating the result so that only the higher-order m bits remain.

This hash function $\boldsymbol{h}_m(y)$ can be evaluated in time $O(\log \ell) = O(\log n)$ for $\ell = \mathrm{poly}(n)$ in the circuit RAM model, i.e., essentially the time to multiply, or constant time $O_n(1)$ in the word RAM model. Further, $\boldsymbol{h}_m$ has the following useful properties [12, 5].

▶ **Lemma 2** (Pseudolinear Hashing [12, 5]). *The following hold for the hash function $\boldsymbol{h}_m$:*

1. ***Pseudolinearity.*** *For any two ℓ-bit integers y, z and any outcome of $\boldsymbol{h}_m$,*

$$\boldsymbol{h}_m(y) + \boldsymbol{h}_m(z) \;\in\; \boldsymbol{h}_m(y + z) - \{0, 1\} \pmod{2^m}.$$

2. ***Pseudouniversality.*** *For any two ℓ-bit integers y, z with $y \neq z$,*

$$\mathbf{Pr}\left[\boldsymbol{h}_m(y) = \boldsymbol{h}_m(z)\right] \;=\; O(2^{-m}).$$

2.1 Preliminary Results

For the purposes of this paper, we may assume that the input target t have size $2^{\Omega(n)}$:

▶ **Observation 3** (Assumptions about Input Instances). *Given a Subset Sum instance (X, t) with $t \le 2^{0.499n}$, the standard dynamic programming algorithm [7] takes time $O(nt) = 2^{0.499n + o(n)}$, much faster than the $\mathrm{poly}(n)$-factor speedups we are targeting, and cannot be improved to time $t^{1-\varepsilon} \cdot 2^{o(n)}$ unless SETH fails [2]. Hence without loss of generality, we assume $t = 2^{\Omega(n)}$ and $\ell = \Omega(\log t) = \Omega(n)$ throughout the paper.*

We further observe that the randomized *decision* algorithms that we give can be converted into randomized *search* algorithms with the same asymptotic runtimes using standard search-to-decision reductions.

Procedure `Sorted-Sum-Enumeration`(Y).

Input: An integer multiset $Y = \{y_1, \dots, y_k\}$.

Output: A sorted list $L_Y := L_k$ of $W(Y)$, all distinct subset sums for Y.

```
Initialize $L_0 := (0)$. Then for each $i \in [k]$:
    Create the sorted list $L'_{i-1} := L_{i-1} + y_i$.
    Create the sorted list $L_i$ obtained by merging $L_{i-1}$, $L'_{i-1}$ and removing duplicates.
```

Figure 1 Efficiently enumerating subset sums of $k \geq 1$ integers.

A basic primitive for our algorithms is the sorted list L_Y containing the elements of $W(Y)$, all *distinct* subset sums, for a given multiset Y of size $|Y| = k$. Figure 1 shows an $O(2^k)$-time folklore algorithm that enumerates L_Y:

▶ **Lemma 4** (Sorted Sum Enumeration; Folklore). `Sorted-Sum-Enumeration` *runs in time* $O(2^k)$.

Proof. We essentially adapt the classic *merge sort* algorithm. Since $|L_{i-1}| = |L'_{i-1}| \leq |L_i| \leq 2|L_{i-1}|$ for each $i \in [k]$, the runtime of `Sorted-Sum-Enumeration` is

$$\textstyle\sum_{i\in[k]} O(|L'_{i-1}| + |L_i|) \;=\; \sum_{i\in[k]} O(|L_i|) \;=\; \sum_{i\in[k]} O(2^i) \;=\; O(2^k). \qquad ◀$$

We can improve this runtime analysis if $|W(Y)|$ is smaller than 2^k by a $\mathrm{poly}(k)$ factor:

▶ **Lemma 5** (Sorted Sum Enumeration for Small $W(Y)$). *If Y is a multiset of $|Y| = k$ integers with $|W(Y)| \leq 2^k \cdot k^{-\varepsilon}$ for some constant $\varepsilon > 0$,* `Sorted-Sum-Enumeration` *runs in time $O(2^k \cdot k^{-\varepsilon} \cdot \log k)$.*

Proof. If $|W(Y)| \leq 2^k \cdot k^{-(1+\varepsilon)}$, then since $|L_i| \leq |L_k| = |W(Y)|$ for each $i \in [k]$, it is easy to check that the algorithm runs in time $O(k \cdot |W(Y)|) = O(2^k \cdot k^{-\varepsilon})$; so suppose that $|W(Y)| \geq 2^k \cdot k^{-(1+\varepsilon)}$. Using the bound $|L_i| \leq 2^i$ for $i \leq \log|W(Y)|$ and the bound $|L_i| \leq |W(Y)|$ for $\log|W(Y)| < i \leq k$, the runtime of `Sorted-Sum-Enumeration` is upper bounded by

$$\begin{aligned} \textstyle\sum_{i\in[k]} O(|L_i|) &= \textstyle\sum_{i\leq\log|W(Y)|} O(2^i) + \sum_{\log|W(Y)|<i\leq k} O(|W(Y)|) \\ &= O(|W(Y)|) + (1+\varepsilon)\cdot\log k \cdot O(|W(Y)|) \\ &= O(|W(Y)|\cdot\log k) \;=\; O(2^k\cdot k^{-\varepsilon}\cdot\log k). \qquad ◀ \end{aligned}$$

▶ Remark 6. Lemma 5 gives a tight analysis of the algorithm when $|W(Y)| = 2^k \cdot k^{-\varepsilon}$, as can be seen by considering the particular size-k multiset $Y = (2^0, 2^1, \dots, 2^{k-\varepsilon\log k-1}, 1, 1, \dots, 1)$.

Finally, Figure 2 shows the classic meet-in-the-middle algorithm for Subset Sum, by Horowitz and Sahni [16], which serves as our baseline for comparison.

▶ **Lemma 7.** *The worst-case runtime of* `Meet-in-the-Middle` *is $O(2^{n/2})$.*

Proof. This follows immediately from Lemma 4 as $|L_A|, |L_B| \leq 2^{n/2}$. ◀

```
Procedure Meet-in-the-Middle($X$, $t$).

Input: An integer multiset $X = \{x_1, x_2, \ldots, x_n\}$ and an integer target $t$.

Output: "yes" if $(X, t)$ is a Subset Sum instance that has a solution, "no" otherwise.

0. Fix any partition of $X = A \cup B$ such that $|A| = |B| = n/2$.
1. Enumerate the sorted lists $L_A$ and $L_B$ using Sorted-Sum-Enumeration.
2. Initialize two pointers at the smallest value in $L_A$ and the largest value in $L_B$.
   If these two values sum to the target $t$, then return "yes";
   if they sum to less than $t$, then increment the pointer into $L_A$ and repeat;
   and if they sum to more than $t$, then increment the pointer into $L_B$ and repeat.
   If either pointer goes past the end of its list, then return "no".
```

Figure 2 The classic `Meet-in-the-Middle` algorithm [16].

3 $\Omega(n^{0.5}/\log n)$-Factor Speedup via Bit Packing

In this section we analyze our first and simplest algorithm, `Bit-Packing` (see Figure 3).[5]

▶ **Theorem 8.** `Bit-Packing` *is a zero-error randomized algorithm for the Subset Sum problem with expected runtime* $O(2^{n/2} \cdot \ell^{-1/2} \cdot \log \ell) \le O(2^{n/2} \cdot n^{-1/2} \cdot \log n)$ *in the circuit RAM model.*[6]

`Bit-Packing` works by packing ℓ/m hashed values into a single word via our pseudolinear hash function $\boldsymbol{h}_m$, for $m = 3 \log \ell$, while preserving enough information to run `Meet-in-the-Middle` on the lists of hashed and packed values. This allows us to compare two length-(ℓ/m) sublists of L_A and L_B in constant expected time in the circuit RAM model, since each hashed and packed sublist fits into a constant number of words, instead of time $O(\ell/m)$ like the original `Meet-in-the-Middle` algorithm. So far, this is essentially the approach taken by [5] in their bit-packing algorithm for 3SUM. However, in our context the $O(\ell/m)$ speedup described above is offset by the following issue: if we follow the original `Meet-in-the-Middle` setup and take $|A| = |B| = \frac{n}{2}$, the lists L_A and L_B may have length $\Omega(2^{n/2})$, increasing the runtime.

To deal with this, we set aside a small set $D \subseteq X$ of $|D| = \log \ell$ many input elements and solve the remaining subinstance $X \setminus D$ for each shifted target $t' \in (t - W(D))$. Removing the elements in D shortens the lists L_A and L_B, which are now formed from the elements in $X \setminus D$, and allows us to enumerate and pack them quickly. Balancing the overhead of solving each of these subinstances against the savings described earlier, we get the claimed speedup $\Omega(\ell^{1/2}/\log \ell) \ge \Omega(n^{1/2}/\log n)$.

Proof of Correctness for `Bit-Packing`. The algorithm outputs "yes" only when a triple $(a, b, t') \in L_A \times L_B \times (t - W(D))$ with $a + b = t'$ is found, so it never returns a false positive.

[5] As explained in Section 1.1, we assume $\ell = \mathrm{poly}(n)$ throughout; however, our results for `Bit-Packing` apply for superpolynomial word length as long as $\ell = O(2^{n/3})$. We leave the extensional modifications to the proofs for this regime as an exercise for the interested reader.

[6] By halting `Bit-Packing` and returning "no" if its runtime exceeds $C \cdot 2^{n/2} \cdot \ell^{-1/2} \cdot \log \ell$ for a large enough constant $C > 0$, we get an one-sided error algorithm with success probability $\ge 3/4$, as claimed in Section 1.2.

```
Procedure Bit-Packing($X$, $t$).

Input: An integer multiset $X = \{x_1, x_2, \ldots, x_n\}$ and an integer target $t$.

Setup: Draw a random hash function $\boldsymbol{h}_m$ with $m = 3\log \ell$ (cf. Equation (2)).

0. Fix any partition of $X = A \cup B \cup D$ such that $|D| = \log \ell$ and $|A| = |B| = \frac{n-|D|}{2}$.
1. Create the set $W(D)$ and the sorted lists $L_A$, $L_B$ using Sorted-Sum-Enumeration.
2. Create lists $\boldsymbol{h}_m(L_A)$ and $\boldsymbol{h}_m(L_B)$ by applying $\boldsymbol{h}_m$ element-wise to $L_A$ and $L_B$.
   Let $\boldsymbol{H}_A$ be the list obtained from $\boldsymbol{h}_m(L_A)$ by packing $(\ell/m)$ elements of $\boldsymbol{h}_m(L_A)$
   into each $\ell$-bit word of $\boldsymbol{H}_A$ (preserving the sorted ordering) and likewise for $\boldsymbol{H}_B$.
3. For each $t' \in (t - W(D))$:
4.     Initialize indices $i := 0$ and $j := |\boldsymbol{H}_B| - 1$. While $i < |\boldsymbol{H}_A|$ and $j \geq 0$:
5.         If the indexed words $\boldsymbol{H}_A[i]$ and $\boldsymbol{H}_B[j]$ contain a pair of hashes
   $(\boldsymbol{h}_m(a'), \boldsymbol{h}_m(b'))$
           such that $\boldsymbol{h}_m(a') + \boldsymbol{h}_m(b') \in \boldsymbol{h}_m(t') - \{0, 1\} \pmod{2^m}$,
           use Meet-in-the-Middle to search for a solution
           $(a, b) \in L_A[i\ell/m : (i+1)\ell/m - 1] \times L_B[j\ell/m : (j+1)\ell/m - 1]$
           such that $a + b = t'$. Halt and return "yes" if a solution is found.
6.         If $L_A[(i+1)\ell/m - 1] + L_B[j\ell/m] < t'$, increment $i \leftarrow i + 1$.
           Otherwise, decrement $j \leftarrow j - 1$.
7. Return "no" (i.e., no solution was found for any $t' \in (t - W(D))$).
```

Figure 3 The Bit-Packing algorithm.

It remains to show that for any $t' \in (t - W(D))$, we are guaranteed to find a shifted solution $(a, b) \in L_A \times L_B$ such that $a + b = t'$, if one exists. Without loss of generality, we consider two sublists $L_A[i\ell/m : (i+1)\ell/m - 1]$ and $L_B[j\ell/m : (j+1)\ell/m - 1]$ that contain such a shifted solution (a, b) and correspond to two packed words $\boldsymbol{H}_A[i]$ and $\boldsymbol{H}_B[j]$ for some indices i and j. The existence of such a shifted solution $a+b = t'$ combined with the condition in Line 6 ensures that the algorithm will not step past either the packed word $\boldsymbol{H}_A[i]$ or $\boldsymbol{H}_B[j]$ before reaching the other one, so the algorithm will compare these two packed words at some point. Following Lemma 2, we have $\boldsymbol{h}_m(a) + \boldsymbol{h}_m(b) \in \boldsymbol{h}_m(t') - \{0, 1\} \pmod{2^m}$, satisfying the condition in Line 5. Thus we are guaranteed to find the shifted solution (a, b) by running Meet-in-the-Middle to check all pairs in $L_A[i\ell/m : (i+1)\ell/m - 1] \times L_B[j\ell/m : (j+1)\ell/m - 1]$. ◀

Proof of Runtime for Bit-Packing. Recalling the assumption $\ell = \mathrm{poly}(n)$:

- Line 1 takes time $O(2^{|A|} + 2^{|B|} + 2^{|D|}) = O(2^{n/2} \cdot \ell^{-1/2} + \ell) = O(2^{n/2} \cdot \ell^{-1/2})$ by Lemma 4, for the choices of $|A|$, $|B|$, and $|D|$.
- Line 2 takes time $(|L_A| + |L_B|) \cdot O(\log \ell) = O(2^{n/2} \cdot \ell^{-1/2} \cdot \log \ell)$, where $O(\log \ell)$ bounds the time for each evaluation of the hash function $\boldsymbol{h}_m$.
- Line 3 (the outer loop) is performed for at most $|W(D)| \leq 2^{|D|} = \ell$ iterations.
- Line 4 (the inner loop) is performed for at most $(|L_A| + |L_B|) \cdot \frac{1}{\ell/m} = O(2^{n/2} \cdot \ell^{-3/2} \cdot \log \ell)$ iterations, since each iteration either increments $i \leftarrow i + 1$ or decrements $j \leftarrow j - 1$.
- Line 5: (i) Checking whether the "If" condition holds for any two words $\boldsymbol{H}_A[i]$ and $\boldsymbol{H}_B[j]$ requires a single AC^0 operation on three words, taking constant time in the circuit RAM model. (ii) Finding a solution (a, b) using Meet-in-the-Middle on the two length-(ℓ/m) sublists takes time $O(\ell/m) = O(\ell/\log \ell)$.

The “If” test is passed (i) at most once for a correct solution and (ii) each time we encounter a hash collision. Note that the sequence of pairs of words $(\boldsymbol{H}_A[i], \boldsymbol{H}_B[j])$ we compare is completely determined by L_A and L_B and is unaffected by the outcome of the random hash function $\boldsymbol{h}_m$. Thus by Lemma 2, each of the $(\ell/m)^2$ hash pairs in $(\boldsymbol{H}_A[i], \boldsymbol{H}_B[j])$ incurs a collision with probability $O(2^{-m})$. By a union bound, the expected time taken for Line 5 because of hash collisions is at most $(\ell/m)^2 \cdot O(2^{-m}) \cdot O(\ell/m) = O(1/\log^3(\ell)) = o_n(1)$, since $m = 3\log \ell$ and $\ell = \Omega(n)$.

- Line 6 clearly takes time $O_n(1)$.

Consequently, Bit-Packing has expected runtime

$$\begin{aligned}
\mathrm{TIME}(n, \ell) &= O(2^{n/2} \cdot \ell^{-1/2} + \ell) + O(2^{n/2} \cdot \ell^{-1/2} \cdot \log \ell) && \text{Lines 1 and 2} \\
&\quad + 1 \cdot \big(O_n(1) + O(\ell/\log \ell) + O_n(1)\big) && \text{Lines 3 to 6} \\
&\quad + \ell \cdot O(2^{n/2} \cdot \ell^{-3/2} \cdot \log \ell) \cdot \big(O_n(1) + o_n(1) + O_n(1)\big) && \text{Lines 3 to 6} \\
&= O(2^{n/2} \cdot \ell^{-1/2} \cdot \log \ell).
\end{aligned}$$ ◀

▶ **Observation 9** (Adapting Bit-Packing to Word RAM). *In the word RAM model, multiplication and evaluation of our pseudolinear hash function $\boldsymbol{h}_m$ each take constant time. Hence, for any word length $\ell = \Omega(n)$ we can get a variant of* Bit-Packing *with expected runtime $O(2^{n/2} \cdot n^{-1/2} \cdot \log n)$, essentially by performing* Bit-Packing *as if the word length were $\ell' := 0.1n$. By a similar conversion from [5]:*

Run Bit-Packing *as if the word length were $\ell' = 0.1n$, which results in the modified parameters $m' = 3\log \ell'$, $|D'| = \log \ell'$, and $|A'| = |B'| = (n - |D'|)/2$ etc., except for two modifications:*

1. *Line 2 packs $q' := \min\{\ell', \ell\}/m' = \Theta(\frac{n}{\log n})$ many m'-bit hashes into each word of $\boldsymbol{H}_{A'}$, $\boldsymbol{H}_{B'}$, so every (ℓ'/m') hashes are stored in $\ell'/(m'q') = \Theta_n(1)$ words rather than a single word.*
2. *Before Line 5, create a table that memoizes the result of every comparison of two ℓ'-bit strings in time $(2^{\ell'})^2 \cdot \mathrm{poly}(\ell') = O(2^{0.21n})$. This table can then be accessed via a $2\ell'/(m'q') = \Theta_n(1)$-word index in constant time. Line 5 replaces the constant-time AC^0 circuit RAM operation on two ℓ'-bit strings with a constant-time lookup into this table.*

Compared with running Bit-Packing *itself for $\ell' = 0.1n$, the only difference of this variant is that $\boldsymbol{H}_{A'}$ and $\boldsymbol{H}_{B'}$ are stored in $\Theta_n(1)$ times as many words, so the correctness is easy to check. The expected time taken for the collisions in each execution of Line 5 is $(q')^2 \cdot O(2^{-m'}) \cdot O(q') = o_n(1)$. Thus, the overall runtime is as claimed:*

$$\underbrace{O(2^{|A'|} + 2^{|B'|} + 2^{|D'|} + 2^{0.21n})}_{\textit{Lines 1 and 2}} + \underbrace{O(q') + 2^{|D'|} \cdot O((2^{|A'|} + 2^{|B'|})/q')}_{\textit{Lines 3 to 6; solution versus collisions}}$$
$$= O(2^{n/2} \cdot n^{-1/2} \cdot \log n).$$

4 $\Omega(n^{0.01})$-Factor Speedup via Orthogonal Vectors and the Representation Method

Our second algorithm, Representation-OV (see Figure 4), achieves a speedup of $\Omega(\ell^\gamma) \geq \Omega(n^\gamma)$ over Meet-in-the-Middle for a constant $\gamma > 0.01$.[7] While this is a smaller speedup than that achieved by the Bit-Packing algorithm, the Representation-OV algorithm does

[7] Similar to Section 3, while we investigate Representation-OV in the regime $\ell = \mathrm{poly}(n)$, analogous results apply for word length ℓ as large as $O(2^{cn})$ for an absolute constant $c > 0$.

not use “bit tricks”. Instead, `Representation-OV` combines `Meet-in-the-Middle` with the *representation method* of Howgrave-Graham and Joux [17], so as to reduce the Subset Sum problem to many small instances of the Orthogonal Vectors (OV) problem: namely, instances with $O(\ell/\log\ell)$ many binary vectors of dimension $\Theta(\log\ell) = \Theta(\log n)$. Such instances of OV can be solved quickly through a single AC^0 word operation in the circuit RAM model (or through constantly many operations in the word RAM model after an initial memoization step), which leads to our speedup.

The high-level idea behind our algorithm is to partition the input $X = A \cup B \cup C$ into two large subsets[8] A and B and one small subset C of size $|C| = \Theta(\log\ell)$, and to run `Meet-in-the-Middle` on two lists formed from subsets of $(A \cup C)$ and $(B \cup C)$. We describe in more detail below just how these lists are formed, but roughly speaking they are created by modifying the representation method (in a way somewhat similar to the algorithm of Nederlof and Węgryzcki [20]) to ensure that the lists are not too long. Further, to eliminate the false positives due to overlapping subsets of C, we exploit a fast implementation of a function that computes a batch of small instances of Orthogonal Vectors. (To see the relevance of the Orthogonal Vectors problem in this context, note that a solution to an instance of OV on k-dimensional Boolean vectors corresponds to two disjoint subsets of the set $[k]$.) Before giving more details we provide some helpful notation:

Notation and setup. We write $\mathcal{Q}(C) := \{T \mid T \subseteq C \text{ and } |T| \leq \frac{|C|}{4}\}$ to denote the collection of all quartersets for C. While $\mathcal{Q}(C)$ is useful for intuition, in fact, as explained below, our algorithm will use a slight variant of it: we define $\mathcal{Q}^{+\varepsilon_2}(C)$ to be the collection of all subsets of size at most $(1+\varepsilon_2)\frac{|C|}{4}$, where $\varepsilon_2 > 0$ is a small constant that is fixed in the detailed description of the algorithm.

We denote by `OV` the Boolean function on $2\ell = \mathrm{poly}(n)$ many input bits that takes as input two lists $(x^1, \ldots, x^{\ell/|C|})$, $(y^1, \ldots, y^{\ell/|C|})$ of (at most) $\ell/|C|$ many binary vectors each, where each binary vector x^i, $y^j \in \{0,1\}^{|C|}$, and returns 1 if and only if the two lists contain an orthogonal pair, i.e., a pair (i, j) such that $x^i_k \cdot y^j_k = 0$ for every $1 \leq k \leq |C|$. It is easy to see that `OV` is an AC^0 operation on two ℓ-bit words, and thus it takes constant time in the circuit RAM model.

We return to the intuitive overview of our approach. At a high level, the representation method works by first expanding the search space of possible solutions; for our algorithm this is done by writing down the list $\mathcal{Q}^{+\varepsilon_2}(C)$ of all “near-quartersets”. If a certain Subset Sum solution $S \subseteq X$ satisfies $|S \cap C| \leq \frac{|C|}{2}$, the restricted solution $S \cap C = Q_1 \cup Q_2$ is the union of *many* different pairs of disjoint quartersets, namely $Q_1, Q_2 \in \mathcal{Q}(C)$ with $Q_1 \cap Q_2 = \emptyset$. In fact, we work on the list of near-quartersets, $\mathcal{Q}^{+\varepsilon_2}(C)$, rather than $\mathcal{Q}(C)$, so as to cover all disjoint pairs (Q_1, Q_2) with $|Q_1| + |Q_2| \approx |C|/2$.

We then *filter* the list $\mathcal{Q}^{+\varepsilon_2}(C)$: given a random prime modulus $\boldsymbol{p}$ we extract those near-quartersets that fall into two particular residue classes that sum to $\Sigma(S \cap C) \pmod{\boldsymbol{p}}$. With appropriate preprocessing checks and parameter settings, this significantly reduces the search space while ensuring that we retain some disjoint pair of near-quartersets Q_1, $Q_2 \in \mathcal{Q}^{+\varepsilon_2}(C)$ that recover the restricted solution, $Q_1 \cup Q_2 = S \cap C$ with $Q_1 \cap Q_2 = \emptyset$.

Finally, we use a modified `Meet-in-the-Middle` procedure to search for a solution, i.e., two sum-subset couples $(a, Q_1) \in (L_A \times \mathcal{Q}^{+\varepsilon_2}(C))$, $(b, Q_2) \times (L_B \times \mathcal{Q}^{+\varepsilon_2}(C))$ with $a + \Sigma(Q_1) + b + \Sigma(Q_2) = \Sigma(S \cap A) + \Sigma(S \cap B) + \Sigma(S \cap C) = \Sigma(S) = t$, verifying $Q_1 \cap Q_2 = \emptyset$ via the Boolean function `OV`.

[8] Technically, sub-multisets. We make the same simplification hereafter.

```
Procedure Representation-OV($X$, $t$).

Input: An integer multiset $X = \{x_1, x_2, \ldots, x_n\}$ and an integer target $t$.

Setup: Constants $\varepsilon_1 \approx 0.1579$ and $\varepsilon_2 \approx 0.2427$, the solutions to Equations (3) and (4).
       Parameters $\beta \approx 1.1186$, $\lambda \approx 0.0202$, $s(\ell)$, and $k(n, \ell)$, all to be specified in the proof.
       A uniform random prime modulus $\boldsymbol{p} \sim \mathbb{P}[\ell^{1+\beta/2} : 2\ell^{1+\beta/2}]$.
0. Fix any partition of $X = A \cup B \cup C$ such that $|C| = \beta \log(\frac{\ell}{\beta \log \ell})$ and
   $|A| = |B| = \frac{n-|C|}{2}$.
1. Use Lemma 13 to solve $(X, t)$ if there exists a solution $S \subseteq X$ with
   $|S \cap C| \notin (1 \pm \varepsilon_1)\frac{|C|}{2}$.
2. Use Lemma 12 to solve $(X, t)$ if $|W(C)| \leq 2^{|C|} \cdot \ell^{-\lambda}$.
3. Create the sorted lists $L_A$ and $L_B$ using Sorted-Sum-Enumeration. Let
   $\{\boldsymbol{L}_{A,\,i}\}_{i \in [\boldsymbol{p}]}$ be the sorted sublists given by $\boldsymbol{L}_{A,\,i} := \{a \in L_A \mid a \equiv_{\boldsymbol{p}} i\}$ and likewise
   for $\{\boldsymbol{L}_{B,\,i}\}_{i \in [\boldsymbol{p}]}$.
   Create the collection $\mathcal{Q}^{+\varepsilon_2}(C) = \{Q \mid Q \subseteq C \text{ and } |Q| \leq (1+\varepsilon_2)\frac{|C|}{4}\}$.
4. Repeat Lines 5 to 6 either $s(\ell)$ times or until a total of $k(n, \ell)$ many sum-subset
   couples have been created in Line 5 (whichever comes first):
5.     Sample a uniform random residue $\boldsymbol{r} \sim [\boldsymbol{p}]$. Then use Lemma 15 and the subroutine
       Residue-Couple-List to create the sorted lists $\boldsymbol{R}_{A,\,\boldsymbol{r}}$ and $\boldsymbol{R}_{B,\,\boldsymbol{r}}$:
       $\boldsymbol{R}_{A,\,\boldsymbol{r}} = \{(a' := a + \Sigma(Q_1),\, Q_1) \mid (a,\, Q_1) \in L_A \times \mathcal{Q}^{+\varepsilon_2}(C) \text{ with } a' \equiv_{\boldsymbol{p}} \boldsymbol{r}\}$ and
       $\boldsymbol{R}_{B,\,\boldsymbol{r}} = \{(b' := b + \Sigma(Q_2),\, Q_2) \mid (b,\, Q_2) \in L_B \times \mathcal{Q}^{+\varepsilon_2}(C) \text{ with } b' \equiv_{\boldsymbol{p}} (t - \boldsymbol{r})\}$.
   ▷ In fact, $\boldsymbol{R}_{A,\,\boldsymbol{r}}$ and $\boldsymbol{R}_{B,\,\boldsymbol{r}}$ are stored in a succinct format by Residue-Couple-List.
6.     Use Lemma 15 (based on Meet-in-the-Middle and the Boolean function OV)
       to search the sorted lists $\boldsymbol{R}_{A,\,\boldsymbol{r}}$ and $\boldsymbol{R}_{B,\,\boldsymbol{r}}$ for a solution $(a',\, Q_1)$, $(b',\, Q_2)$ such that
       $a' + b' = t$ and $Q_1 \cap Q_2 = \emptyset$. Halt and return "yes" if a solution is found.
7. Return "no" (i.e., no solution was found).          ▷ Possibly a false negative.
```

Figure 4 The Representation-OV algorithm.

▶ **Theorem 10.** Representation-OV *is a one-sided error randomized algorithm for the Subset Sum problem (with no false positives) with worst-case runtime* $O(2^{n/2} \cdot \ell^{-\gamma}) \leq O(2^{n/2} \cdot n^{-\gamma})$*, for some constant* $\gamma > 0.01$*, and a success probability of* $1/3$ *in the circuit RAM model.*

The proofs of correctness and runtime below rely on several auxiliary lemmas, namely Lemmas 12–15. These lemmas, along with an adaptation of the result to the Word RAM model, can be found in Appendix A.

Proof of Correctness for Representation-OV. The constants $\varepsilon_1 \approx 0.1579$ and $\varepsilon_2 \approx 0.2427$ given in the description of the algorithm are the solutions to the following equations:

$$\frac{1-H((1-\varepsilon_1)/2)}{(1-\varepsilon_1)/2} \;=\; 1 - H(\tfrac{1-\varepsilon_2}{2}), \tag{3}$$

$$1 + \varepsilon_1 - 3H(\tfrac{1-\varepsilon_1}{2}) \;=\; -2H(\tfrac{1+\varepsilon_2}{4}). \tag{4}$$

Also, we set $\beta := \frac{1}{H((1+\varepsilon_2)/4)} \approx 1.1186$ and $\lambda := (1 - 10^{-5}) \cdot \frac{1-\varepsilon_1}{2} \cdot \beta \cdot (1 - H(\frac{1-\varepsilon_2}{2})) \approx 0.0202$.

Lines 1 and 2 preprocess the instance $(X,\, t)$, solving it deterministically via Lemmas 12 and 13 unless both Conditions (1) and (2) hold:

Condition (1). $(X,\, t)$ is either a "yes" instance with $|S \cap C| \in [(1-\varepsilon_1)\frac{|C|}{2} : \frac{|C|}{2}]$ for each solution $S \subseteq X$,[9] or a "no" instance.

Condition (2). $|W(C)| > 2^{|C|} \cdot \ell^{-\lambda}$. Note that this implies $|W(T)| > 2^{|T|} \cdot \ell^{-\lambda}$ for each $T \subseteq C$.

Lines 3 to 7 accept only if a solution $t = a' + b' = (a + \Sigma(Q_1)) + (b + \Sigma(Q_2))$ is found in Line 6, for which $a \in L_A$, $b \in L_B$, and $Q_1,\, Q_2 \in \mathcal{Q}^{+\varepsilon_2}(C)$ are disjoint. As a consequence, the algorithm never reports false positives.

It remains to show that Lines 4 to 6 accept a "yes" instance $(X,\, t)$ with probability at least $1/3$ when $(X,\, t)$ satisfies Conditions (1) and (2). Consider a solution $S \subseteq X$ and the following set W' containing distinct sums of all "ε_2-balanced" subsets of $S \cap C$:

$$W' \;:=\; \{\, \Sigma(Q) \mid Q \subseteq (S \cap C) \text{ and } |Q| \in (1 \pm \varepsilon_2)\tfrac{|S \cap C|}{2} \,\}.$$

Line 3 creates the residue sublists $L_A = \{\boldsymbol{L}_{A,\,i}\}_{i \in [\boldsymbol{p}]}$ and $L_B = \{\boldsymbol{L}_{B,\,i}\}_{i \in [\boldsymbol{p}]}$. We say that a residue $i \in [\boldsymbol{p}]$ is *good* if it satisfies $i - \Sigma(S \cap A) \in (W' \bmod \boldsymbol{p})$, namely there exists a subset $Q_1 \subseteq (S \cap C)$ of size $|Q_1| \in (1 \pm \varepsilon_2)\frac{|S \cap C|}{2}$ such that $\Sigma(S \cap A) + \Sigma(Q_1) \equiv_{\boldsymbol{p}} i$. On sampling a good residue $\boldsymbol{r} = i$ in Line 5, both Q_1 and $Q_2 := (S \cap C) \setminus Q_1$ are of size at most $(1+\varepsilon_2)\frac{|S \cap C|}{2} \le (1+\varepsilon_2)\frac{|C|}{4}$, so they are included in the collection $\mathcal{Q}^{+\varepsilon_2}(C)$ and, respectively, in the lists $\boldsymbol{R}_{A,\,\boldsymbol{r}}$ and $\boldsymbol{R}_{B,\,\boldsymbol{r}}$ created in Line 5. Then using Lemma 15, we are ensured to find the solution $S = (S \cap A) \cup (S \cap B) \cup (Q_1 \cup Q_2)$.

Hence it suffices to **(i)** lower bound the probability that at least one of the $s(\ell)$ samples $\boldsymbol{r} \sim [\boldsymbol{p}]$ is good, and **(ii)** upper bound the probability that these samples generate a total of $k(n,\, \ell)$ or more sum-subset couples.

(i). We claim that the size of set W' is at least $\Omega(2^{|S \cap C|} \cdot \ell^{-\lambda}) \ge \widetilde{\Omega}(\ell^{(1-\varepsilon_1)\cdot\beta/2-\lambda})$ and is at most $2^{|S \cap C|} \le \ell^{\beta/2}$. The lower bound on the size comes from a combination of two observations. First, the set $(S \cap C)$ has at least $2^{|S \cap C|} \cdot \ell^{-\lambda}$ many distinct subset sums, by Condition (2). Second, the number of subsets $Q \subseteq (S \cap C)$ of size $|Q| \notin (1 \pm \varepsilon_2)\frac{|S \cap C|}{2}$ is at most $2 \cdot 2^{H(\frac{1-\varepsilon_2}{2})\cdot|S \cap C|} = o(2^{|S \cap C|} \cdot \ell^{-\lambda})$, given Stirling's approximation (Equation (1)) and the technical condition

$$\tfrac{|S \cap C|}{\log \ell} \cdot (1 - H(\tfrac{1-\varepsilon_2}{2})) \;\ge\; (1 - o_n(1)) \cdot \tfrac{1-\varepsilon_1}{2} \cdot \beta \cdot (1 - H(\tfrac{1-\varepsilon_2}{2})) \;>\; \lambda,$$

which is true for our choice of λ.

The upper and lower bounds on $|W'|$ allow us to apply Lemma 14: with probability at least $3/4$ over the modulus $\boldsymbol{p} \sim \mathbb{P}[\ell^{1+\beta/2} : 2\ell^{1+\beta/2}]$, there are $|W' \bmod \boldsymbol{p}| = \Omega(|W'|) = \widetilde{\Omega}(\ell^{(1-\varepsilon_1)\cdot\beta/2-\lambda})$ many good residues. Conditioned on this event, taking

$$s(\ell) \;:=\; \widetilde{\Theta}(\ell^{1+\lambda+\varepsilon_1\cdot\beta/2}) \;\ge\; \widetilde{\Omega}\left(\tfrac{\boldsymbol{p}}{|(W' \bmod \boldsymbol{p})|}\right)$$

many samples $\boldsymbol{r} \sim [\boldsymbol{p}]$ yields at least one good residue with probability $\ge 2/3$.

[9] Given Line 1, a solution $S \subseteq X$ or its complementary $(X \setminus S)$, as a solution to the complementary instance $(X,\, \Sigma(X) - t)$, must have this property.

(ii). All candidate lists $\{\boldsymbol{R}_{A,\,i}\}_{i\in[\boldsymbol{p}]}$, $\{\boldsymbol{R}_{B,\,i}\}_{i\in[\boldsymbol{p}]}$ together have a total of

$$(|L_A| + |L_B|)\cdot|\mathcal{Q}^{+\varepsilon_2}(C)| \le 2\cdot 2^{(n-|C|)/2}\cdot 2^{|C|/\beta} = O(2^{n/2}\cdot \ell^{1-\beta/2})$$

sum-subset couples, by construction (Line 3), the choices of $|A|$, $|B|$, $|C|$, and Stirling's approximation (Equation (1)). For any outcome of the random modulus $\boldsymbol{p} = p = \Theta(\ell^{1+\beta/2})$, a number of $s(\ell)$ samples $\boldsymbol{r}\sim[p]$ generate a total of $O(2^{n/2}\cdot\ell^{1-\beta/2})\cdot s(\ell)/p = \widetilde{O}(2^{n/2}\cdot \ell^{-((1-\varepsilon_1/2)\cdot\beta-(1+\lambda))})$ sum-subset couples in expectation. By setting a large enough cutoff

$$k(n,\,\ell) \;:=\; \widetilde{\Theta}(2^{n/2}\cdot\ell^{-((1-\varepsilon_1/2)\cdot\beta-(1+\lambda))}),$$

the probability that $k(n,\,\ell)$ or more sum-subset couples are generated is at most $1/6$.

Overall, our algorithm succeeds with probability $\ge (3/4)\cdot(2/3)-(1/6) = 1/3$. ◀

Proof of Runtime for `Representation-OV`. Recalling the assumption $\ell = \mathrm{poly}(n)$:

- Line 1 takes time $\widetilde{O}(2^{n/2}\cdot\ell^{-(1-H((1-\varepsilon_1)/2))\cdot\beta/2})$, by Lemma 13.
- Line 2 takes time $\widetilde{O}(2^{n/2}\cdot\ell^{-\lambda/2})$, by Lemma 12.
- Line 3 takes time $O(2^{|A|}+2^{|B|}+2^{|C|})\cdot O(\log\ell) = \widetilde{O}(2^{n/2}\cdot\ell^{-\beta/2})$, by Lemma 4, the choices of $|A|$, $|B|$, $|C|$, and that the modulo operation in the circuit RAM model takes time $O(\log\ell)$.
- Lines 4 to 6 take time $\widetilde{O}(k(n,\,\ell)) = \widetilde{O}(2^{n/2}\cdot\ell^{-((1-\varepsilon_1/2)\cdot\beta-(1+\lambda))})$, because a single iteration (Lemma 15) takes time $\widetilde{O}(|\boldsymbol{R}_{A,\,\boldsymbol{r}}|+|\boldsymbol{R}_{B,\,\boldsymbol{r}}|)$ and by construction we create a total of at most $\sum_{\boldsymbol{r}}(|\boldsymbol{R}_{A,\,\boldsymbol{r}}|+|\boldsymbol{R}_{B,\,\boldsymbol{r}}|)\le k(n,\,\ell)$ many sum-subset couples.

The runtime of Line 3 is dominated by that of Line 1, so the bottleneck occurs in Line 1, Line 2, or Lines 4 to 6. For the choices of constants given in the algorithm, we achieve a speedup of $\Omega(\ell^{\gamma})$ for any constant $\gamma\in(0,\,\gamma_*)$, where the

$$\gamma_* \;:=\; \min\Big\{\lambda/2,\quad (1-H(\tfrac{1-\varepsilon_1}{2}))\cdot\beta/2,\quad (1-\varepsilon_1/2)\cdot\beta-(1+\lambda)\Big\} \;=\; \lambda/2 \;\approx\; 0.0101. \blacktriangleleft$$

5 Subset Sum in Time $O(2^{n/2}\cdot n^{-0.5023})$

Our last algorithm is a delicate combination of `Bit-Packing` and `Representation-OV`. Our main result, Theorem 11, demonstrates that problem-specific features of Subset Sum can be exploited to obtain an additional nontrivial time savings beyond what can be achieved by augmenting `Meet-in-the-Middle` with generic bit-packing tricks. Although the bookkeeping to analyze the algorithm of this section is somewhat intricate, many of the ideas in this section are previewed in Section 4.

▶ **Theorem 11.** `Packed-Representation-OV`*is a one-sided error randomized algorithm for the Subset Sum problem (with no false positives) with worst-case runtime* $O(2^{n/2}\cdot n^{-(1/2+\gamma)})$*, for some constant* $\gamma > 0.0023$*, and success probability at least* $1/12$ *in the circuit RAM model.*

This extended abstract presentation omits the proof of Theorem 11 and the adaptation of Theorem 11 to the word RAM model. For the proof, the reader is referred to the full version of the paper.[10] Below, we describe a difficulty that arises in the attempt to directly combine the two building block algorithms, as well as the new AC^0 operation used in the approach.

First, we describe a difficulty that arises when attempting to combine our two previous algorithms. `Bit-Packing` saves time by removing a subset $D\subseteq X$ from the input, then running a `Meet-in-the-Middle` variant on the resulting subinstance multiple times, while

[10] `https://arxiv.org/abs/2301.07134`

`Representation-OV` runs a `Meet-in-the-Middle` variant on multiple subinstances indexed by residue classes modulo a random prime $\boldsymbol{p}$. This presents a problem: to get the time savings from bit packing, we would like to reuse subinstances multiple times, but to get the time savings from the representation method we need to build separate subinstances with respect to each residue class $\pmod{\boldsymbol{p}}$ that contains elements of $W(D)$. To solve this problem, we construct D in a way that ensures the elements of $W(D)$ fall into few residue classes $\pmod{\boldsymbol{p}}$. Specifically, we fix $\boldsymbol{p}$ and consider two cases. In one case , the elements of X fall into few residue classes $\pmod{\boldsymbol{p}}$ and it is possible to choose a small set D such that the elements of D (and $W(D)$) fall into very few residue classes $\pmod{\boldsymbol{p}}$. In this case we need to construct just $|W(D) \bmod \boldsymbol{p}| = \mathrm{polylog}(n)$ distinct subinstances. In the other case , the elements of X fall into many residue classes $\pmod{\boldsymbol{p}}$. Here a carefully selected D satisfies the weaker bound $|W(D) \bmod \boldsymbol{p}| = \widetilde{O}(n^{\delta})$ for a small constant $\delta > 0$, increasing the number of subinstances we need to construct. However, the fact that the elements of X fall into many residue classes $\pmod{\boldsymbol{p}}$ lets us select a larger set C such that the subset sums in $W(S \cap C)$ distribute well $\pmod{\boldsymbol{p}}$ for any solution S, offsetting the increase in runtime.

Like the AC^0 operation `OV` in the `Representation-OV` algorithm, the core of our new algorithm is another AC^0 operation, `Hash-OV`, that solves Orthogonal Vectors on small instances. Like `OV`, `Hash-OV` takes as input two ℓ-bit words containing multiple bit vectors of length $O(\log n)$, but now the bit vectors in either word may come from two or more lists, and each list is indexed by the m-bit hash $\boldsymbol{h}_m(s)$ of a corresponding subset sum s, for $m = 3\log \ell$. Thus `Hash-OV` may solve multiple small Orthogonal Vectors instances at once.

6 Extensions and Future Work

Our results open up several natural directions for future investigation:

- **Derandomization:** All of the $2^{n/2}/\mathrm{poly}(n)$-time algorithms we have given for Subset Sum use randomness. Can our results be extended to achieve deterministic algorithms with worst-case running time $2^{n/2}/\mathrm{poly}(n)$?
- **Counting:** It is straightforward to modify the `Meet-in-the-Middle` algorithm to output a count of the number of Subset Sum solutions in time $O(2^{n/2})$ (essentially, by keeping track of the multiplicity with which each value occurs in each list L_A, L_B). Can our techniques be extended to give counting algorithms for Subset Sum that run in time $2^{n/2}/\mathrm{poly}(n)$? In time $2^{n/2}/n^{0.501}$?
- **Faster runtimes:** Finally, an obvious goal is to quantitatively strengthen our results by developing faster algorithms for worst-case Subset Sum. It would be particularly interesting to achieve running times of the form $2^{n/2}/f(n)$ for some $f(n) = n^{\omega(1)}$.

A Auxiliary Lemmas for Representation-OV

A first “preprocessing lemma” stems from the observation that a not-too-large subset $Y \subseteq X$ with few distinct subset sums (i.e., $|W(Y)| \ll 2^{|Y|}$) can help speed up Meet-in-the-Middle. This idea goes back to [3, 4], although the condition of “few distinct subset sums” we use refers to sets with polynomially rather than exponentially fewer subset sums than the maximum possible number.

▶ **Lemma 12** (Speedup via Additive Structure). *Let $(X,\, t)$ be an n-integer Subset Sum instance. Given as input $(X,\, t)$ and a subset $Y \subseteq X$ of size $|Y| \le n/2$ such that $|W(Y)| \le 2^{|Y|}\cdot\ell^{-\varepsilon}$ for some constant $\varepsilon > 0$, the instance $(X,\, t)$ can be solved deterministically in time $\widetilde{O}(2^{n/2}\cdot\ell^{-\varepsilon/2})$.*

Proof. Fix any size-$(\frac{n+\varepsilon\log\ell}{2})$ subset A such that $Y \subseteq A \subseteq X$; we have $|W(A)| \le 2^{|A\setminus Y|}\cdot|W(Y)| \le 2^{n/2}\cdot\ell^{-\varepsilon/2}$. We also have $|W(X\setminus A)| \le 2^{|X\setminus A|} = 2^{n/2}\cdot\ell^{-\varepsilon/2}$. By Lemmas 4 and 5, it takes overall time $O(2^{n/2}\cdot\ell^{-\varepsilon/2}\cdot\log n)$ in the regime $\ell = \mathrm{poly}(n)$ to create the sorted lists L_A, $L_{X\setminus A}$ and to run Meet-in-the-Middle. ◀

Another useful preprocessing lemma shows that the existence of a solution that is “unbalanced” vis-a-vis a given small subset yields a speedup:

▶ **Lemma 13** (Speedup via Unbalanced Solutions). *Let $(X,\, t)$ be an n-integer Subset Sum instance that has a solution. Given as input $(X,\, t)$ and a subset $Y \subseteq X$ of size $|Y| = \beta\log(\ell/(\beta\log\ell))$ for β as specified in* Representation-OV *such that some solution $S \subseteq X$ satisfies $|S\cap Y| \notin (1\pm\varepsilon)\frac{|Y|}{2}$ for some constant $\varepsilon > 0$, the solution S can be found deterministically in time $\widetilde{O}(2^{n/2}\cdot\ell^{-\delta/2})$, where the constant $\delta := (1 - H(\frac{1-\varepsilon}{2}))\cdot\beta$.*

Proof. We can assume without loss of generality that the solution S satisfies $|S\cap Y| \le \frac{|Y|}{2}$ (since either the original instance $(X,\, t)$ or the complementary instance $(X,\, \Sigma(X) - t)$ must satisfy this property, and we can attempt both instances and only double the runtime). Hence we can suppose $|S\cap Y| \le (1-\varepsilon)\frac{|Y|}{2}$. Then the sorted list L'_Y of the set $\{\Sigma(T) \mid T \subseteq Y \text{ and } |T| \le (1-\varepsilon)\frac{|Y|}{2}\}$ can be created in time $O(2^{|Y|}) = O(\ell^{\beta}) = \mathrm{poly}(n)$ using Sorted-Sum-Enumeration (restricted to subsets of sizes $< (1-\varepsilon)\frac{|Y|}{2}$).

Fix any size-$(\frac{n+(\delta/\beta)|Y|}{2})$ subset A with $Y \subseteq A \subseteq X$. In the regime $\ell = \mathrm{poly}(n)$, we can use L'_Y and Lemma 5 to create the sorted list L'_A of $\{\Sigma(T) \mid T \subseteq A \text{ and } |T\cap Y| < (1-\varepsilon)\frac{|Y|}{2}\}$ in time

$$\widetilde{O}(|L'_A|) \le \widetilde{O}(2^{|A\setminus Y|}\cdot|L'_Y|) \le \widetilde{O}(2^{|A\setminus Y|}\cdot 2^{H(\frac{1-\varepsilon}{2})\cdot|Y|}) \le \widetilde{O}(2^{n/2}\cdot\ell^{-\delta/2}),$$

following Stirling’s approximation (Equation (1)) and the choices of $|Y|$ and $|A|$. Moreover, we can use Lemma 4 to create the sorted list $L_{X\setminus A}$ in time $O(2^{|X\setminus A|}) = \widetilde{O}(2^{n/2}\cdot\ell^{-\delta/2})$.

Provided $|S\cap Y| < (1-\varepsilon)\frac{|Y|}{2}$, running Meet-in-the-Middle on L'_A and $L_{X\setminus A}$ solves (X,t) and takes time $O(|L'_A| + |L_{X\setminus A}|) = \widetilde{O}(2^{n/2}\cdot\ell^{-\delta/2})$. The overall runtime is $\widetilde{O}(2^{n/2}\cdot\ell^{-\delta/2})$. ◀

The next lemma specifies a parameter space within which any set of distinct integers is likely to fall into many residue classes modulo a random prime. This allows us to reduce the search space by considering only solutions that fall into certain residue classes.

▶ **Lemma 14** (Distribution of Integer Sets modulo Random Primes). *Fix a set Y of at most $|Y| \le \ell^{\beta/2}$ distinct ℓ-bit integers for β as specified in* Representation-OV*. For a uniform random modulus $\boldsymbol{p} \sim \mathbb{P}[\ell^{1+\beta/2} : 2\ell^{1+\beta/2}]$, the residue set has size $|(Y \bmod \boldsymbol{p})| = \Theta(|Y|)$ with probability at least $3/4$.*

```
Subroutine Residue-Couple-List($\{L_{A,\,i}\}_{i \in [p]}$, $\mathcal{Q}^{+\varepsilon}(C)$, $r$).

Input: A collection of $p = \mathrm{poly}(\ell)$ sorted sublists $L_A = \bigcup_{i \in [p]} L_{A,\,i}$, for some subset
$A \subseteq X$, indexed by residue class modulo $p$.

Output: A sorted sum-subset list $R_{A,\,r}$ with elements in the sum-collection format
$(a',\, \mathcal{Q}_{a'})$.

1. For each $Q \in \mathcal{Q}^{+\varepsilon}(C)$, create the sum-subset sublist $R_Q := f_Q(L_{A,\,j(Q)})$ by applying
   $f_Q$, the element-to-couple operation $a \mapsto (a' := a + \Sigma(Q),\, Q)$, to the particular input
   sublist of index $j(Q) := ((r - \Sigma(Q)) \bmod p)$.   ▷ Each $R_Q$ is sorted by the sums $a'$.
2. Let $R_{A,\,r}$ be the list obtained by merging $\{R_Q\}_{Q \in \mathcal{Q}^{+\varepsilon}(C)}$, sorted by sums
   $a' = a + \Sigma(Q)$.
   For each distinct sum $a'$, compress all couples $(a',\, Q_1)$, $(a',\, Q_2)$, ... with the same
   first element $= a'$ into a single data object $(a',\, \mathcal{Q}_{a'} := \{Q_1, Q_2, \dots\})$.
           ▷ Note that for each sum $a'$ we have $a' \equiv_p r$ and $|\mathcal{Q}_{a'}| \le |\mathcal{Q}^{+\varepsilon}(C)|$.
```

Figure 5 The Residue-Couple-List subroutine.

Proof. By the prime number theorem [15, Equation (22.19.3)], there are at least $\frac{\ell^{1+\beta/2}}{(1+\beta/2)\cdot\log \ell}$ primes in $\mathbb{P}[\ell^{1+\beta/2} : 2\ell^{1+\beta/2}]$ (for any sufficiently large ℓ). Given any two distinct integers $y \neq z \in Y$, the difference $|y - z| \le 2^\ell$ has at most $\frac{\ell}{(1+\beta/2)\cdot\log \ell}$ distinct prime factors in $\mathbb{P}[\ell^{1+\beta/2} : 2\ell^{1+\beta/2}]$. Thus under a uniform random choice of modulus $\boldsymbol{p} \sim \mathbb{P}[\ell^{1+\beta/2} : 2\ell^{1+\beta/2}]$, the second frequency moment $\boldsymbol{f}_{(2)} := |\{(y,\, z) \mid y,\, z \in Y \text{ with } y \equiv_{\boldsymbol{p}} z\}|$ has the expectation

$$\mathbf{E}_{\boldsymbol{p}}[\boldsymbol{f}_{(2)}] = |\{y = z \in Y\}| + |\{y \neq z \in Y\}| \cdot \ell^{-\beta/2} \;=\; |Y| + (|Y|^2 - |Y|) \cdot \ell^{-\beta/2} \;\le\; 2|Y|.$$

Therefore, with an arbitrarily high constant probability, we have $\boldsymbol{f}_{(2)} = O(|Y|)$ and, by the Cauchy-Schwarz inequality $|Y \bmod \boldsymbol{p}| \cdot \boldsymbol{f}_{(2)} \ge |Y|^2$,

a residue set of size $|Y \bmod \boldsymbol{p}| = \Omega(|Y|)$. ◀

▶ **Lemma 15** (Sorted Lists $\boldsymbol{R}_{A,\,\boldsymbol{r}}$ and $\boldsymbol{R}_{B,\,\boldsymbol{r}}$; Lines 5 and 6). *In* Representation-OV*:*
(i) *Line 5 uses the subroutine* Residue-Couple-List *to create the sorted lists $\boldsymbol{R}_{A,\,\boldsymbol{r}}$, $\boldsymbol{R}_{B,\,\boldsymbol{r}}$ in time $\widetilde{O}(|\boldsymbol{R}_{A,\,\boldsymbol{r}}| + |\boldsymbol{R}_{B,\,\boldsymbol{r}}|)$. Moreover,* **(ii)** *Line 6 finds a solution pair $(a',\, Q_1) \in \boldsymbol{R}_{A,\,\boldsymbol{r}}$, $(b',\, Q_2) \in \boldsymbol{R}_{B,\,\boldsymbol{r}}$, if one exists, in time $O(|\boldsymbol{R}_{A,\,\boldsymbol{r}}| + |\boldsymbol{R}_{B,\,\boldsymbol{r}}|)$.*

Proof. Line 5 creates $\boldsymbol{R}_{A,\,\boldsymbol{r}}$ and $\boldsymbol{R}_{B,\,\boldsymbol{r}}$ using the subroutine Residue-Couple-List (see Figure 5). First, we claim that Residue-Couple-List takes time $\widetilde{O}(|\boldsymbol{R}_A|)$ in the regime $\ell = \mathrm{poly}(n)$:

- Line 1 takes time $\Sigma_{Q \in \mathcal{Q}^{+\varepsilon_2}(C)} O(|\boldsymbol{R}_Q|) = O(|\boldsymbol{R}_{A,\,\boldsymbol{r}}|)$, since all shifts $\Sigma(Q)$ for $Q \in \mathcal{Q}^{+\varepsilon_2}(C)$ can be precomputed and memoized when the collection $\mathcal{Q}^{+\varepsilon_2}(C)$ is created in Line 3.
- Line 2 builds one sorted list $\boldsymbol{R}_{A,\,\boldsymbol{r}}$ from $|\mathcal{Q}^{+\varepsilon_2}(C)| \le 2^{|C|/\beta} = \ell/(\beta \log \ell) = \mathrm{poly}(n)$ sorted sublists $\{\boldsymbol{R}_Q\}_{Q \in \mathcal{Q}^{+\varepsilon_2}(C)}$, taking time $O(|\boldsymbol{R}_{A,\,\boldsymbol{r}}| \cdot \log n)$ via the classic *merge sort* algorithm.

After Line 5 creates the sorted lists $\boldsymbol{R}_{A,\,\boldsymbol{r}} = \{(a',\, \boldsymbol{\mathcal{Q}}_{a'})\}$ and $\boldsymbol{R}_{B,\,\boldsymbol{r}} = \{(b',\, \boldsymbol{\mathcal{Q}}_{b'})\}$, Line 6 can run Meet-in-the-Middle based on the (ordered) indices a' and b' in time $O(|\boldsymbol{R}_{A,\,\boldsymbol{r}}| + |\boldsymbol{R}_{B,\,\boldsymbol{r}}|)$. This ensures that we discover every pair $(a',\, \boldsymbol{\mathcal{Q}}_{a'})$, $(b',\, \boldsymbol{\mathcal{Q}}_{b'})$ such that $a' + b' = t$.

Such a pair yields a solution if and only if it contains two disjoint near-quartersets $Q_1 \in \boldsymbol{\mathcal{Q}}_{a'}$, $Q_2 \in \boldsymbol{\mathcal{Q}}_{b'}$ with $Q_1 \cap Q_2 = \emptyset$, which we can check in constant time by one call of the Boolean function `OV`. Namely, each near-quarterset $Q \in \mathcal{Q}^{+\varepsilon_2}(C)$ is stored in $|C| < \beta \log \ell$ bits, so each collection $\boldsymbol{\mathcal{Q}}_{a'}$, $\boldsymbol{\mathcal{Q}}_{b'} \subseteq \mathcal{Q}^{+\varepsilon_2}(C)$ can be stored a single word $|C| \cdot |\mathcal{Q}^{+\varepsilon_2}(C)| \leq \ell$. Thus one call of `OV` suffices to check a given pair $(a', \boldsymbol{\mathcal{Q}}_{a'})$, $(b', \boldsymbol{\mathcal{Q}}_{b'})$. Overall, Line 6 takes time $O(|\boldsymbol{R}_{A,\boldsymbol{r}}| + |\boldsymbol{R}_{B,\boldsymbol{r}}|)$. ◀

▶ **Observation 16** (Adapting `Representation-OV` to Word RAM). *In the word RAM model, it may take superconstant time to evaluate the Boolean function* `OV`*. Similar to the strategy used in Section 3, our word RAM variant avoids this issue by performing* `Representation-OV` *as if the word length were $\ell' := 0.1n$ (using sets A', B', C', etc., with appropriate size modifications), except for three modifications:*

1. *In lines 3 and 2, on creating a (sub)collection $\mathcal{Q} \subseteq \mathcal{Q}^{+\varepsilon_2}(C')$ as a bit string, store it in at most $\leq \lceil |\mathcal{Q}^{+\varepsilon_2}(C')| \cdot |C'|/\ell \rceil \leq \lceil \ell'/\ell \rceil = \Theta(1)$ words (since a single word with ℓ bits may be insufficient).*
2. *In Line 3, after creating the collection $\mathcal{Q}^{+\varepsilon_2}(C')$, create a lookup table* `OV'` *that memoizes the input-output result of the Boolean function* `OV` *on each subcollection pair $\mathcal{Q}_{a'}$, $\mathcal{Q}_{b'} \subseteq \mathcal{Q}^{+\varepsilon_2}(C')$ in time $(2^{|\mathcal{Q}^{+\varepsilon_2}(C')|})^2 \cdot \mathrm{poly}(|\mathcal{Q}^{+\varepsilon_2}(C')|) \leq (2^{\ell'})^2 \cdot \mathrm{poly}(\ell') = O(2^{0.21n})$. This table can then be accessed using a $2\lceil \ell'/\ell \rceil = \Theta(1)$-word index in constant time.*
3. *Line 6 replaces the Boolean function* `OV` *(namely a constant-time AC^0 circuit RAM operation) with constant-time lookup into* `OV'`*.*

Compared with running `Representation-OV` *itself for $\ell' = 0.1n$, the only difference of this variant is that $\boldsymbol{R}_{A,\boldsymbol{r}}$ and $\boldsymbol{R}_{B,\boldsymbol{r}}$ are stored in $\lceil \ell'/\ell \rceil = \Theta(1)$ times as many words, given $\ell = \Omega(n)$. Hence, it is easy to check the correctness and the runtime $O(2^{n/2} \cdot \ell'^{-\gamma} \cdot \lceil \ell'/\ell \rceil) = O(2^{n/2} \cdot n^{-\gamma})$, for the same constant $\gamma > 0.01$.*

On Optimization and Counting of Non-Broken Bases of Matroids

Abstract

Given a matroid $M = (E, \mathcal{I})$, and a total ordering over the elements E, a broken circuit is a circuit where the smallest element is removed and an NBC independent set is an independent set in $\mathcal{I}$ with no broken circuit. The set of NBC independent sets of any matroid M define a simplicial complex called the broken circuit complex which has been the subject of intense study in combinatorics. Recently, Adiprasito, Huh and Katz showed that the face of numbers of any broken circuit complex form a log-concave sequence, proving a long-standing conjecture of Rota.

We study counting and optimization problems on NBC bases of a generic matroid. We find several fundamental differences with the independent set complex: for example, we show that it is NP-hard to find the max-weight NBC base of a matroid or that the convex hull of NBC bases of a matroid has edges of arbitrary large length. We also give evidence that the natural down-up walk on the space of NBC bases of a matroid may not mix rapidly by showing that for some family of matroids it is NP-hard to count the number of NBC bases after certain conditionings.

1 Introduction

A matroid $M = (E, \mathcal{I})$ is consists of a finite ground set E and a collection $\mathcal{I}$ of subsets of E, called independent sets, satisfying:

- **Downward closure:** If $S \subseteq T$ and $T \in \mathcal{I}$, then $S \in \mathcal{I}$.
- **Exchange axiom:** If $S, T \in \mathcal{I}$ and $|T| > |S|$, then there exists an element $i \in T \setminus S$ such that $S \cup \{i\} \in \mathcal{I}$.

The rank of a set $S \subseteq E$ is the size of the largest independent set contained in S. All maximal independent sets of M, called the bases of M, have the same size r, which is called the rank of M.

Sampling and counting problems on matroids have captured the interest of many researchers for several decades with applications to reliability [6], liquidity of markets [19], etc. A recent breakthrough in this field proved that the down-up walk on the bases of a matroid mixes rapidly to the (uniform) stationary distribution and can be used to count the number of bases of a matroid [3, 7], resolving the conjecture of Mihail and Vazirani from 1989 [18]. The down-up walk is easy to describe: Start with an arbitrary base B and repeatedly execute the following two steps:

1. Choose a uniformly random element $i \in B$ and delete it.
2. Among all bases (of M) that contain $B \smallsetminus \{i\}$, choose one uniformly at random.

A central question that has puzzled researchers since then is sampling a non-broken (circuit) basis (NBC basis) of a matroid [4].

A set $C \subseteq E$ is a *circuit* iff $C \setminus \{e\} \in \mathcal{I}$ for any $e \in C$. A *broken circuit* (with respect to a total ordering $\mathcal{O}$) is a set $C \setminus \{e\}$, where $C \subseteq E$ is a circuit and e is the **smallest** element of C with respect to $\mathcal{O}$. An independent set $S \subseteq E$ is a *non-broken* independent set (NBC independent set) if it contains no broken circuits. The NBC independent sets are closely related to several interesting combinatorial objects. The number of NBC independent sets of size k in a graphic matroid is equal to the absolute value of the $(n-1)-k$-th coefficient of the chromatic polynomial of the underlying graph where n is the number of vertices. As a corollary the following facts hold:

► **Fact 1.** *The following facts are well-known about the counts of NBC bases/independent sets of different family of matroids.*

- *The number of all NBC independent sets of a graphic matroid is equal to the the number of acyclic orientations of the graph [22].*
- *The number of all NBC independent sets of a co-graphic matroid is equal to the number of strongly connected orientations of the graph (see e.g., [13]).*
- *The number of non-broken spanning trees of a graph is equal to the number of parking functions with respect to a unique source vertex [4]*
- *The number of NBC independent of sets of linear matroid with vectors $v_1, \dots, v_n$ is equal to the number of regions defined by the intersection of the orthogonal hyperplanes (see e.g., [23]).*

We emphasize that although the set of NBC independent sets/bases of a matroid are functions of the underlying total order $\mathcal{O}$, the counts of the number NBC independent sets of rank k for any $0 \leq k \leq r$ are invariant under $\mathcal{O}$ [23]. We remark that, to the best of our knowledge as of this date, none of the above counting problems are known to be computationally tractable.

Given a matroid M with an arbitrary total ordering $\mathcal{O}$, one can analogously run the down-up walk only on the NBC bases of M. It is not hard to see that this chain is irreducible and converges to the uniform stationary distribution. Following the work of [3] it was conjectured that the down-up walk on the NBC bases of any matroid mixes rapidly [1].

► **Conjecture 2.** *For any matroid M, and any total ordering $\mathcal{O}$ of the elements of M, the down-up walk on the NBC bases of a matroid mixes in polynomial time.*

[1] In fact, this conjecture was raised an an open problem in several recent workshops UC Santa Barbara workshop on New tools for Optimal Mixing of Markov Chains: Spectral Independence and Entropy Decay, and Simon's workshop on Geometry of Polynomials

It turns out that the above conjecture, if true, would be give a generalization of the result of [3], because of the following fact.

▶ **Fact 3** ([5])**.** *For any matroid M one can construct another matroid M' with an ordering $\mathcal{O}$ with only one extra element such that there is a bijection between bases of M and non-broken bases of M'.*

Furthermore, if the above conjecture is true, then since matroids are closed under truncation, one can also count the number of all NBC independent sets of M, thus resolving all of the open problems in Fact 1.

A promising reason to expect these problems to be tractable in the first place is the remarkable work of Adiprasito, Huh and Katz [1] who proved the Rota's conjecture showing that the face numbers of a broken circuit complex (see below for definition) of any matroid forms a log-concave sequence. For comparison, it is well-known that the coefficients of the matching polynomial of any graph form a log-concave sequence and the classical algorithm of Jerrum-Sinclair [15] gives an efficient algorithm to count the number of matchings of any graph (although to this date we still don't know an efficient algorithm to count the number of **perfect** matchings of general graphs).

1.1 Background

The existing analyses of the mixing time of the down-up walk for bases of matroids, crucially rely on the theory of high dimensional simplicial complxes [3, 17], which has found many intriguing applications in several areas of computer science and math in the past few years [14].

Simplicial Complex. A *simplicial complex* X on a finite ground set U is a downwards closed set system, i.e. if $\tau \in X$ and $\sigma \subset \tau \subseteq U$, then $\sigma \in X$. The elements of X are called faces, and the maximal faces are called facets. We say X is a pure d-dimensional complex if all of its facets are of size d. We denote the set of facets by $X(d)$. A weighted simplicial complex (X, π) is a simplicial complex X paired with a probability distribution π on its facets. The global walk (down-up walk) $P^\vee$ on the facets of a d-dimensional complex (X, π) is defined as follows: starting at a facet τ, we transition to the next facet τ' by the following two steps:

1. Select a uniformly random element $x \in \tau$ and remove x from τ.
2. Select a random facet τ' containing $\tau \setminus \{x\}$ with probability proportional to $\pi(\tau')$.

Broken Circuit Complex. For a concrete example, it turns out that the set NBC independent sets of any matroid M (with respect to any ordering $\mathcal{O}$) form a **pure** simplicial complex that is known as the *broken circuit complex.* We denote this complex by $\mathrm{BC}(M, \mathcal{O})$. We state purity as the following fact.

▶ **Fact 4.** *For every NBC independent set I, there exists an NBC base B such that $I \subseteq B$.*

The face numbers of the complex $BC(M, \mathcal{O})$ is the sequence $n_0, n_1, \ldots, n_r$ where n_i is the number of NBC independent sets of rank i. As alluded to above this sequence is in variant over $\mathcal{O}$. The down-up walk over this complex equipped with a uniform distribution over its facets is the same as the down-up walk over NBC bases we explained before.

The link of a face $\tau \in X$ is the simplicial complex $X_\tau \coloneqq \{\sigma \setminus \tau : \sigma \in X, \sigma \supset \tau\}$. For each face τ, we define the induced distribution π_τ on the facets of X_τ as

$$\pi_\tau(\eta) = \Pr_{\sigma \sim \pi}[\sigma \supset \eta \mid \sigma \supset \tau]. \tag{1}$$

Local Walks. For any face τ of size $0 \le k \le d-2$, the local walk for τ is a Markov chain on the ground set of X_τ with transition probability matrix P_τ is defined as

$$P_\tau(x,y) = \frac{1}{d-k-1} \Pr_{\sigma \sim \pi_\tau}[y \in \sigma \mid \sigma \supset \tau \cup \{x\}]. \tag{2}$$

for distinct x, y in the ground set of X_τ.

The following theorem shows that the spectral expansion of the global walk $P^\vee$ on a simplicial complex can be bounded through bounding the local spectral expansion of the complex.

▶ **Theorem 5** (Local-to-Global Theorem [10, 17, 9, 2]). *Say a d-dimensional weighted simplicial complex (X, π) is a $(\gamma_0, \dots, \gamma_{d-2})$-local spectral expander if for every face τ of size $0 \le k \le d-2$, the second largest eigenvalue of P_τ is at most γ_k, i.e., $\lambda_2(P_\tau) \le \gamma_k$.*

Given a weighted simplical complex (X, π_d) that is a $(\gamma_0, \dots, \gamma_{d-2})$-local spectral expander, the down-up walk which samples from π has spectral gap lower bounded by

$$1 - \lambda_2(P^\vee) \ge \frac{1}{d} \prod_{j=0}^{d-2} (1 - \gamma_j)$$

To prove that the down-up walk mixes rapidly on the bases of any matroid, [3] proved that the independent set complex of any matroid M is a $(0, 0, \dots, 0)$-local spectral expander. Building on this, a natural method to prove Conjecture 2 is to show that the broken circuit complex of any matroid M of rank r and for any total ordering is a $(\gamma_0, \dots, \gamma_{r-2})$-local spectral expander for $\gamma_i \le \frac{O(1)}{r-i}$.

▶ **Conjecture 6.** *For any matroid M of rank r and any ordering $\mathcal{O}$ the broken circuit complex of M is a $(\gamma_0, \dots, \gamma_{r-2})$-local spectral expander for some $\gamma_i \le \frac{O(1)}{r-i}$*

1.2 Our results

Our main result is to disprove Conjecture 6 in a very strong form, namely for the class of (truncated) graphic matroids.

▶ **Theorem 7.** *There exists an infinite sequence of (truncated) graphic matroids $M_1, M_2, \dots$ with orderings $\mathcal{O}_1, \mathcal{O}_2, \dots$, such that for every $n \ge 1$, M_n has poly(n) elements, and there exists a face τ of the broken circuit complex of $X = \mathrm{BC}(M_n, \mathcal{O})$ for which the down-up walk on the facets of the link X_τ has a spectral gap of at most $n^{-\Omega(n)}$.*

In fact, we even prove a stronger statement

▶ **Theorem 8.** *Given a matroid $M = (E, \mathcal{I})$ and a total ordering $\mathcal{O}$ and a set $S \subseteq E$, unless RP=NP, there is no FPRAS for counting the number of NBC bases of M that contain S.*

Although this theorem does not refute Conjecture 2, it shows that one probably need different techniques (or probably a different chain) to sample/count NBC bases of a matroid. Indeed, one may even need a different proof for the performance of down-up walk to sample ordinary bases of matroids.

To complement our main results we also prove that, unlike optimization on bases of a matroid, optimization is NP-hard on the NBC bases of matroids. Moreover, unless NP= RP, there is no FPRAS for computing the sum of the weights of all NBC bases of a matroid subject to an external field, while the same computation over the bases of a matroid has a FPRAS.

▶ **Theorem 9.** *Given a matroid $M = (E, \mathcal{I})$ with $|E| = n$ elements, an arbitrary total ordering $\mathcal{O}$, and weights $w_1, \dots, w_n$, it is NP-hard to find the maximum weight NBC basis of M, where the weight of a NBC basis B is $\sum_{i \in B} w_i$.*

▶ **Theorem 10.** *Given a matroid $M = (E, \mathcal{I})$ with $|E| = n$ elements, a total ordering $\mathcal{O}$, and weights $\{1 \le \lambda_e \le O(n)\}_{e \in E}$, unless NP = RP, there is no FPRAS for computing the partition function of the λ-external field applied to uniform distribution of NBC independent sets, i.e., there is no FPRAS for computing :*

$$\sum_{B\ NBC\ Base} \prod_{e \in B} \lambda_e.$$

It is well known that a 0/1-polytope (i.e. the convex hull of a subset $S \subseteq \{0,1\}^n$) has all vertices of equal hamming weight r and edges of ℓ_2 length $\sqrt{2}$ iff the polytope is a matroid base polytope of rank r [12]. Moreover, assuming the Mihail-Vazirani conjecture, there is efficient algorithm to sample a uniformly random vertex of a 0/1-polytope with constant sized edge length [18].

We show that, unlike matroids, the NBC Base polytope, i.e. the convex hull of the indicator vectors of all NBC bases of a matroid M, has edges of arbitrarily long length.

▶ **Theorem 11.** *For any n, there exists a graphic matroid M with n elements and a total ordering $\mathcal{O}$ such that the convex hull of all NBC bases of M has edges of ℓ_2 length at least $\Omega(\sqrt{n})$.*

2 Preliminaries

Given a graph $G = (V, E)$, we denote the number of independent sets of size i of G by $i_k(G)$ For every set $S \subseteq V$, we define $N(S) := \{v \notin S : \exists u \in S, \{u, v\} \in E\}$ as the set of neighbors of S in G.

▶ **Definition 12** (Conductance)**.** *Given a weighted d-regular graph $G = (V, E, w)$, with weights $w : E \to \mathbb{R}_{\ge 0}$, for $S \subseteq V$, the conductance of S is defined as*

$$\phi(S) = \frac{w(S, \overline{S})}{d|S|},$$

where $w(S, \overline{S})$ is the sum of the weights of edges in the cut $(S, \overline{S})$. Note that since G is regular, the weighted degree of every vertex is d. The conductance of G is defined as

$$\phi(G) = \min_{S:|S| \le |V|/2} \phi(S).$$

Given a weighted graph $G = (V, E, w)$, the simple random walk is the following stochastic process: Given $X_0 = v \in V$, for every $u \sim v$, we have $X_1 = u$ with probability $\frac{w_{\{u,v\}}}{d_w(v)}$ and we let P be the transition probability matrix of the walk.

The following theorem is well-known and follows from the easy side of the Cheeger's inequality.

▶ **Theorem 13.** *For any regular graph $G = (V, E)$ and any set $S \subseteq V$ and $|S| \le |V|/2$*

$$\frac{1 - \lambda_2(P)}{2} \le \phi(G) \le \phi(S) \le \frac{|N(S)|}{|S|}$$

where $1 - \lambda_2(P)$ is the spectral gap of the simple random walk on G.

A graphic matroid $M = (E, \mathcal{I})$ is a matroid defined on the edges of a graph $G = (V, E)$ and its independent sets are all subsets of edges that do not contain any cycle. It is easy to verify that circuits of M correspond to cycles of G.

▶ **Definition 14** (Matroid Truncation). *Let $M = (E, \mathcal{I})$ be a matroid of rank r. The truncation of M to rank $r' \le r$ removes all independent sets of size strictly greater than r'. It is easy to see that the truncation of any matroid M to any $r' \le r$ is also a matroid.*

Let M' be the truncation to rank r' of a graphic matroid of rank r defined on the edges of a graph G. The bases of M' correspond to forests with r' edges and the circuits of M' are the circuits of G along with all spanning forests of size $r' + 1$.

The following fact about polytopes follows from convexity.

▶ **Fact 15.** *For any polytope $P \subseteq \mathbb{R}^d$ with vertices $v_1, \ldots, v_n \in \mathbb{R}^d$, $\{v_i, v_j\}$ is an edge of P iff there exists a weight function $w \in \mathbb{R}^d$ such that*

$$\langle w, v_i \rangle = \langle w, v_j \rangle > \langle w, v_k \rangle,$$

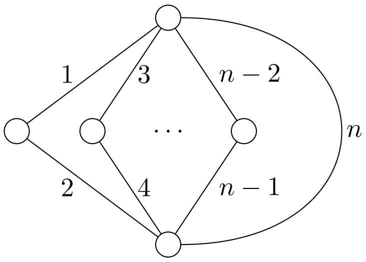
for any $k \ne i, j$.

3 Results

We start with proving Theorem 11.

▶ **Theorem 11.** *For any n, there exists a graphic matroid M with n elements and a total ordering $\mathcal{O}$ such that the convex hull of all NBC bases of M has edges of ℓ_2 length at least $\Omega(\sqrt{n})$.*

Proof. Let n be odd. Consider the following graphic matroid M (with n edges), with the ordering $\mathcal{O}$: $1 < 2 < \cdots < n$ defined by the edges of the following graph:



We show that for $B = \{n\} \cup \{2i - 1 : 1 \le i \le \frac{n-1}{2}\}$ and $B' = \{1\} \cup \{2i : 1 \le i \le \frac{n-1}{2}\}$, $\{B, B'\}$ forms an edge in the NBC matroid base polytope denoted as P_M. We define a $w \in \mathbb{R}^n$ and then use Fact 15 to prove the statement. Let $w_n = \frac{n+1}{2}$, and for any $1 \le i \le \frac{n-1}{2}$, let $w_{2i} = 1$ and $w_{2i-1} = 0$. It is easy to check that the function $\langle w, \mathbf{1}_B \rangle = \langle w, \mathbf{1}_{B'} \rangle = \frac{n+1}{2}$ and $\langle w, \mathbf{1}_{B''} \rangle < \frac{n+1}{2}$ for all NBC basis $B'' \ne B, B'$. Therefore $\{B, B'\}$ forms and edge in P_M. The statements follows from the fact that $\|\mathbf{1}_B - \mathbf{1}_{B'}\|_2 = \sqrt{n}$. ◀

Next, we prove Theorem 9 via a reduction from the MAX-INDEP-SET problem: Given a graph $G = (V, E)$, a weight function $w : V \to \mathbb{R}_{\ge 0}$, and an integer k, decide whether G has an independent set of weight at least k or not.

Note that independent sets of G and independents sets of a BC complex/matroid are two different notions. To complete the proof we use the following well-known hardness result.

▶ **Theorem 16** ([16]). *MAX-INDEP-SET is NP-complete.*

▶ **Theorem 9.** *Given a matroid $M = (E, \mathcal{I})$ with $|E| = n$ elements, an arbitrary total ordering $\mathcal{O}$, and weights $w_1, \ldots, w_n$, it is NP-hard to find the maximum weight NBC basis of M, where the weight of a NBC basis B is $\sum_{i \in B} w_i$.*

Proof. We prove this by a reduction from MAX-INDEP-SET. Let $G = (V, E)$ be a graph, a vertex weight function $w : V \to \mathbb{R}_{\geq 0}$ and k an integer. Construct a new graph $G' = (V', E')$ from G by first copying G and then adding a new vertex z and edges $e_v = \{z, v\}$ for all $v \in V$. We define $w' : E' \to \mathbb{R}_{\geq 0}$ as $w'(e_v) = w(v)$ for every $v \in V$, and $w'(e) = 0$ for every $e \in E$. Moreover, consider the following total ordering $\mathcal{O}$ on E':

$$E < \{e_v : v \in V\},$$

where the ordering within each set is arbitrary. Let M be the graphic matroid defined by the edges of G', we will be look at bases/independent sets of $\mathrm{BC}(M, \mathcal{O})$.

▷ Claim 17. There exists an independent set of G of weight at least k iff there exists an NBC basis of M with weight at least k.

We prove the claim in a straightforward manner. Suppose there is an independent set $I \subseteq V$ of G with $w(I) \geq k$ and consider the set $I' \subseteq E'$ defined by $I' = \{e_v : v \in I\}$. By definition, $w'(I') \geq k$. We argue that I' does not contain any broken circuit. Assume otherwise that there is a broken circuit $C \setminus \{e\} \subseteq I'$. Since C corresponds to a cycle in G' and $C \setminus \{e\}$ is contained in I', it is not hard to see that $C \setminus \{e\} = \{e_v, e_{v'}\}$ for some $v, v' \in I$ and $e = \{v, v'\}$ is an edge in G. But this is a contradiction with the fact that I is an independent set of G.

Hence I' is a NBC independent set. Since the broken circuit complex is pure (see Fact 4), there exists an NBC basis B containing I' which has weight $w'(B) \geq w'(I') \geq k$.

For the other direction, suppose we have a NBC basis $B' \subseteq E'$ of weight $w'(k) \geq k$, and define $I \subseteq V$ by $I = \{v : e_v \in B'\}$. Since all edges coming from E have zero weight, $w(I) = w'(B') \geq k$. To see that I is an independent set of G', note that if there is an edge $\{v, v'\}$ for some $v, v' \in I$, we have $e_v, e_{v'} \in B'$, then $\{e_v, e_{v'}\}$ forms a broken circuit according to the ordering $\mathcal{O}$. Therefore I is an independent set of G of weight at least k. ◀

It's important to note that the above proof works under the crucial assumption that the order $\mathcal{O}$ is chosen carefully based on the weights (and in some sense in the same order of the weights).

We can amplify the ideas in the previous construction to also argue Theorem 7. This is done by constructing a Broken Circuit complex for which the down-up walk of a carefully chosen link has inverse exponentially small spectral gap.

▶ **Theorem 7.** *There exists an infinite sequence of (truncated) graphic matroids $M_1, M_2, \ldots$ with orderings $\mathcal{O}_1, \mathcal{O}_2, \ldots$, such that for every $n \geq 1$, M_n has poly(n) elements, and there exists a face τ of the broken circuit complex of $X = \mathrm{BC}(M_n, \mathcal{O})$ for which the down-up walk on the facets of the link X_τ has a spectral gap of at most $n^{-\Omega(n)}$.*

Proof. Take the complete bipartite graph $G = K_{n,n} = (A, B, E = A \times B)$, with $|A| = |B| = n$. Also, let $V = A \cup B$. Let $\ell \geq 1$ be a parameter that we choose later, and construct a new graph

$$G' = (V' = V \cup \{y, z\} \cup \{z_{v,i} : v \in V, i \in [\ell]\}, E' = E \cup \{e_0\} \cup \{e_{v,i}, f_{v,i} : v \in V, i \in [\ell]\})$$

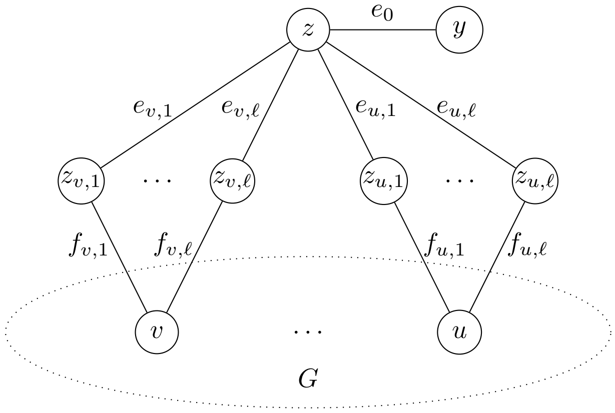


Figure 1 A schematic of the graph G' in the proofs of Theorem 7 and Theorem 8 where $G = K_{n,n}$ is the complete bipartite graph in the former and it is a hard instance of $\sharp$INDEP-SET-INC$(7, \frac{2}{19})$ in latter.

where $e_0 = \{y, z\}, e_{v,i} = \{z, z_{v,i}\}, f_{v,i} = \{z_{v,i}, v\}$ (see Figure 1). For a sanity check, note that $|V| = 2n$ and $|V'| = 2\ell n + 2n + 2$.

Let $M = (E', \mathcal{I})$ be the graphic matroid defined by G' truncated to rank $2\ell n + n + 1$, i.e., the bases of M are forests of G' with exactly $2\ell n + n + 1$ edges. Now, consider the following total ordering $\mathcal{O}$ on E':

$$e_0 < E < \{e_{v,i} : v \in V, i \in [\ell]\} < \{f_{v,i} : v \in V, i \in [\ell]\},$$

where the ordering within each set is arbitrary.

Moreover, let $X := \mathrm{BC}(M, \mathcal{O})$, and define

$$\tau = \{e_{v,i} : v \in V, i \in [\ell]\}.$$

For simplicity of notation, let $F_A := \{f_{v,i} : v \in A, i \in [\ell]\}$ and $F_B := \{f_{v,i} : v \in B, i \in [\ell]\}$.

▷ Claim 18. For any facet S of X_τ, either $S \cap F_A = \emptyset$, or $S \cap F_B = \emptyset$,

This follows from the fact that G is a complete bipartite graph and edges in E are smaller than $e_{v,i}$'s and $f_{u,j}$'s; so if $S \cap F_A, S \cap F_B \neq \emptyset$, then it has a broken circuit.

Therefore, the set of facets of X_τ can be partitioned into $2n + 1$ sets $(\cup_{i=1}^n \mathcal{S}_{A,i}) \cup (\cup_{i=1}^n \mathcal{S}_{B,i}) \cup \mathcal{S}_0$, where $\mathcal{S}_{A,i}$ is the set of all facets S with $|S \cap F_A| = i$, $\mathcal{S}_{B,i}$ is the set of all facets S with $|S \cap F_B| = i$, and $\mathcal{S}_0$ is the set of all facets with $|S \cap (F_A \cup F_B)| = 0$. Let $\mathcal{S}_A := \cup_{i=1}^n \mathcal{S}_{A,i}$ and similarly define $\mathcal{S}_B$. We show that $\frac{|N(\mathcal{S}_A)|}{|\mathcal{S}_A|} \leq n^{-\Omega(n)}$, where $N(\mathcal{S}_A)$ is the set of neighbors of $\mathcal{S}_A$ in the down-up walk $P_\tau^\vee$ on the facets of τ. WLOG we can assume that $|\mathcal{S}_A|$ is at most half of all facets. Applying Theorem 13, this would imply that $1 - \lambda_2(P_\tau^\vee) \leq n^{-\Omega(n)}$.

First, note that for every facet $S \in \mathcal{S}_A$ and $T \in \mathcal{S}_B \setminus \mathcal{S}_{B,1}$, we get $P^\vee(S, T) = 0$ since $|S \Delta T| > 2$. So, $N(\mathcal{S}_A) \subseteq \mathcal{S}_{B,1} \cup \mathcal{S}_0$. First, notice $|\mathcal{S}_0| \leq \binom{|E|}{n} \leq n^{2n}$. Furthermore, $|\mathcal{S}_{B,1}| \leq \binom{n}{1} \ell \binom{|E|}{n-1} \leq \ell n^{2n}$.

This follows from the fact that any facet in $\mathcal{S}_{B,1}$ can be written as $\{f_{v,i_v}\} \cup \{e_0\} \cup K$ for some $v \in A$, $i_v \in [\ell]$, and subset $K \subseteq E$ of size $n - 1$.

Lastly, $|\mathcal{S}_A| \geq |\mathcal{S}_{A,n}| = \ell^n$. This is because every choice of $\{i_v\}_{v \in A}$ corresponds to a set in $\mathcal{S}_{A,n}$ whose sets are of the form $\{f_{v,i_v} : v \in V\} \cup \{e_0\}$. These sets all don't contain a broken circuit because the circuits introduced through truncation are exactly the forests with

$2\ell n + n + 2$ edges. However, any proper superset of $\{f_{v,i_v} : v \in V\} \cup \{e_0\}$ must include e_0, so looking at the circuit introduced by the superset, the corresponding broken circuit will always remove e_0. Putting it all together,

$$1 - \lambda_2(P_\tau^\vee) \leq \frac{|N(\mathcal{S}_A)|}{|\mathcal{S}_A|} \leq \frac{n^{2n}(1+\ell)}{\ell^n} \underset{\text{assuming } \ell \geq n^3}{\leq} n^{-\Omega(n)}$$

as desired. ◀

We prove Theorem 10 and Theorem 8 by a reduction from ♯INDEP-SET-INC($7, \frac{2}{19}$), defined as the following.

▶ **Definition 19** (♯INDEP-SET-INC($7, \frac{2}{19}$)). *Given a 7-regular graph $G = (V, E)$ that satisfies $i_k(G) \leq i_{\lfloor \frac{2|V|}{19} \rfloor}(G)$ for any $k < \lfloor \frac{2|V|}{19} \rfloor$, where $i_k(G)$ are the independent sets of G of size k, count the number of independent sets of size $\lfloor \frac{2|V|}{19} \rfloor$.*

▶ **Theorem 20.** *Unless* NP = RP*, there is no randomized algorithm with constant approximation ratio for ♯INDEP-SET-INC*($7, \frac{2}{19}$)*.*

We leave the proof of this for the appendix.

Now, we are ready to prove Theorem 8. The high-level structure of the proof is similar to the proof of Theorem 7 where we apply a similar gadget to graphs on which it is hard to count independent sets (as opposed to the complete bipartite graph).

▶ **Theorem 8.** *Given a matroid $M = (E, \mathcal{I})$ and a total ordering $\mathcal{O}$ and a set $S \subseteq E$, unless RP=NP, there is no FPRAS for counting the number of NBC bases of M that contain S.*

Proof. For simplicity of notion, let $\alpha := \frac{2}{19}$. We prove by a reduction from ♯INDEP-SET-INC($7, \frac{2}{19}$). Take any arbitrary 7-regular graph $G = (V, E)$ whose number of independent sets of size $\lfloor \alpha |V| \rfloor$ is at least the number of its independent sets of size k for any $k < \lfloor \alpha |V| \rfloor$. Let $n := |V|$ and N be the number of independent sets of size $\lfloor \alpha n \rfloor$ of G. Also, define $\ell \geq 1$ to be a parameter that we choose later.

Now, construct a new graph

$$G' = (V' = V \cup \{y, z\} \cup \{z_{v,i} : v \in V, i \in [\ell]\}, E' = E \cup \{e_0\} \cup \{e_{v,i}, f_{v,i} : v \in V, i \in [\ell]\})$$

where $e_0 = \{y, z\}, e_{v,i} = \{z, z_{v,i}\}, f_{v,i} = \{z_{v,i}, v\}$ (see Figure 1). Let $M = (E', \mathcal{I})$ be the graphic matroid defined by G truncated at rank $\ell n + \lfloor \alpha n \rfloor + 1$, i.e., the bases of M are forests of G' with exactly $\ell n + \lfloor \alpha n \rfloor + 1$ edges. Now, consider the following ordering $\mathcal{O}$ on E':

$$e_0 < E < \{e_{v,i} : v \in V, i \in [\ell]\} < \{f_{v,i} : v \in V, i \in [\ell]\},$$

where the ordering within each set is arbitrary. Moreover, let $X := \mathrm{BC}(M, \mathcal{O})$, and define

$$\tau = \{e_{v,i} : v \in V, i \in [\ell]\}.$$

We claim that the number of facets of X_τ is at least $\ell^{\lfloor \alpha n \rfloor} N$ and at most $2\ell^{\lfloor \alpha n \rfloor} N$. So, a 1.5-approximation to the number facets of X_τ, i.e., the number NBC bases of M that contain τ, gives a 3-approximation to N, the number of independent sets of size $\lfloor \alpha n \rfloor$ of G.

We use the following crucial observation:

▷ Claim 21. For any facet S of X_τ, $\{v : \exists f_{v,i} \in S\}$ is an independent set of G and for any $f_{v,i}, f_{v,j} \in S$ we have $i = j$.

Conversely, for any $S \subseteq \{f_{v,i} : v \in V, i \in [\ell]\}$, such that the set $\{v : \exists f_{v,i} \in S\}$ is an independent set of size $\lfloor \alpha n \rfloor$ of G, and $f_{v,i}, f_{v,j} \in S \implies i = j$, we have $S \cup \{e_0\}$ is a facet of X_τ.

The proof simply follows from the fact that edges of E are smaller than $e_{v,i}$'s, and $f'_{u,j}s$ in $\mathcal{O}$. By the second part of the claim, we can write

$$|X_\tau(\lfloor \alpha n \rfloor + 1)| = \ell^{\lfloor \alpha n \rfloor} N + |\{S \in X_\tau(\lfloor \alpha n \rfloor + 1) : S \cap E \neq \emptyset\}| \geq \ell^{\lfloor \alpha n \rfloor} N. \tag{3}$$

Define $i_k := i_k(G)$ as the number of independent sets of size k of graph G. By the first part of the above claim we can write,

$$|\{S \in X_\tau(\lfloor \alpha n \rfloor + 1) : S \cap E \neq \emptyset\}| \leq \sum_{k=0}^{\lfloor \alpha n \rfloor - 1} \ell^k \cdot i_k \cdot \binom{|E|}{\lfloor \alpha n \rfloor - k} \tag{4}$$

$$\leq \sum_{k=0}^{\lfloor \alpha n \rfloor - 1} \ell^k \cdot i_k \cdot |E|^{\lfloor \alpha n \rfloor - k} \tag{5}$$

$$\underset{\text{using } i_k \leq N}{\leq} N|E|^{\lfloor \alpha n \rfloor} \sum_{k=0}^{\lfloor \alpha n \rfloor - 1} (\ell/|E|)^k \tag{6}$$

$$\underset{\text{assuming } \ell \geq 2|E|}{\leq} N|E|^{\lfloor \alpha n \rfloor} (\ell/|E|)^{\lfloor \alpha n \rfloor} \leq N\ell^{\lfloor \alpha n \rfloor} \tag{7}$$

Putting these together with (3) concludes the proof. ◀

▶ **Theorem 10.** *Given a matroid $M = (E, \mathcal{I})$ with $|E| = n$ elements, a total ordering $\mathcal{O}$, and weights $\{1 \leq \lambda_e \leq O(n)\}_{e \in E}$, unless NP = RP, there is no FPRAS for computing the partition function of the λ-external field applied to uniform distribution of NBC independent sets, i.e., there is no FPRAS for computing :*

$$\sum_{B \ NBC \ Base} \prod_{e \in B} \lambda_e.$$

Proof. For simplicity of notion, let $\alpha := \frac{2}{19}$. The proof is similar to the proof of Theorem 8 by a reduction from $\sharp$INDEP-SET-INC($7, \frac{2}{19}$). Take any arbitrary 7-regular graph $G = (V, E)$ with $n := |V|$ vertices whose number of independent sets of size $\lfloor \alpha |V| \rfloor$ is at least the number of its independent sets of size k for any $k < \lfloor \alpha |V| \rfloor$. Construct a new graph

$$G' = (V' = V \cup \{y, z\}, E' = E \cup \{e_0 = \{y, z\}\} \cup \{e_v = \{v, z\} : v \in V\})$$

Let $M = (E', \mathcal{I})$ be the graphic matroid given by G' truncated to rank $\lfloor \alpha n \rfloor + 1$ and consider the following ordering $\mathcal{O}$ on E'':

$$e_0 < E < \{e_v : v \in V\},$$

where as usual the ordering within each set is arbitrary. Define weights $\lambda : E' \to \mathbb{R}_{\geq 0}$ as follows:

$$\lambda_e = \begin{cases} \ell & \text{if } e = e_v \text{ for some } v \in V, \\ 1 & \text{o.w.} \end{cases},$$

for some ℓ that we choose later. We argue that

$$\lambda^{\lfloor \alpha n \rfloor} N \leq \sum_B \prod_{e \in B} \lambda_e \leq 2\lambda^{\lfloor \alpha n \rfloor} N.$$

where here (and henceforth) the sum is over B's that are NBC bases of M, and therefore a 1.5-approximation to the partition function, i.e., the quantity in the middle, is a 3-approximation to N. Similar to the previous theorem we have the following claim.

▷ Claim 22. For any NBC base B of M, we have $\{v : e_v \in B\}$ is an independent set of G. Conversely, for any independent set I of G of size $|I| = \lfloor \alpha n \rfloor$, $\{e_0\} \cup \{e_v : v \in I\}$ is a NBC base of M.

So,

$$\begin{aligned}\sum_{B}\prod_{e\in B}\lambda_e &= \sum_{B:B\cap E\neq\emptyset}\prod_{e\in B}\lambda_e + \sum_{B:B\cap E=\emptyset}\prod_{e\in B}\lambda_e \\ &= \sum_{B:B\cap E\neq\emptyset}\prod_{e\in B}\lambda_e + \ell^{\lfloor\alpha n\rfloor}|\{S\subseteq V : S \text{ independent set of } G, |S| = \lfloor\alpha n\rfloor\}|\end{aligned} \tag{8}$$

Define i_k as the number of independent sets of size k of graph G. We have

$$\sum_{B:B\cap E\neq\emptyset}\prod_{e\in B}\lambda_e \le \sum_{k=0}^{\lfloor\alpha n\rfloor-1}\ell^k i_k\binom{|E|}{\lfloor\alpha n\rfloor - k} \underset{\substack{\text{using } i_k\le N,\\ \text{assuming } \ell\ge 2|E|}}{\le} \ell^{\lfloor\alpha n\rfloor}N$$

where the last inequality follows from the same calculations as in Equation (4). ◀

A Proof of Theorem 20

In this section we prove Theorem 20. We use a reduction from the problem of computing the partition function of the Hardcore model when the fugacity is above the critical threshold. Define $\sharp$HC(Δ, λ) as follows: given a Δ-regular graph $G = (V, E)$, compute the partition function $Z_G(\lambda) = \sum_I \lambda^{|I|}$, where the sum is taken over the family of independent sets $I \subseteq V$ of G. The critical threshold is defined as $\lambda_c(\Delta) := \frac{(\Delta-1)^{\Delta-1}}{(\Delta-2)^{\Delta}}$.

▶ **Theorem 23** ([20, 21, 11]). *The following holds for any fixed $\epsilon > 0$, integer $\Delta \geq 3$ and $\lambda > \lambda_c(\Delta)$: unless NP=RP, for any $\lambda > \lambda_c(\Delta)$ there is no polynomial-time algorithm for for approximating $\sharp$HC(Δ, λ) up to a $1+\epsilon$ multiplicative factor.*

We give a polynomial-time algorithm that given a $e^{\pm\epsilon/2}$-approximation for $\sharp$INDEP-SET-INC$(7, \frac{2}{19})$ (see Definition 19), approximates $\sharp$HC$(7, \frac{2}{3})$ up to a $e^{\pm\epsilon}$-multiplicative error. Since $\frac{2}{3} > \lambda_c(7) = \frac{6^6}{5^7} \geq 0.6$, this finishes the proof of Theorem 20. Our reduction is a modification of Theorem 16 in [8].

▶ **Theorem 24.** *There exists a polynomial-time algorithm that for any given $\epsilon \leq 1$, satisfies the following properties:*

1. *Given an instance $G = (V, E)$ of $\sharp$HC$(7, \frac{2}{3})$, the algorithm constructs an instance $G' = (V', E')$ of the problem $\sharp$INDEP-SET-INC$(7, \frac{2}{19})$ with size polynomial in $|G|$.*
2. *Given a $e^{\pm\epsilon/2}$-multiplicative approximation to the number of independent sets of size $\lfloor \frac{2|V'|}{19} \rfloor$ of G', a $e^{\pm\epsilon}$-approximation of $Z_G(\frac{2}{3})$ can be computed in polynomial time.*

Proof. Given a 7-regular graph $G = (V, E)$, we define G' as the disjoint union of G with $r := \frac{c^2 n^2}{\epsilon}$ copies of the complete graph K_8, where $n = |V|$, for some $c > 1$ that we choose later. For simplicity of notation, let $N := |V'| = n + 8r$, $\alpha := \frac{2}{19}$, $\lambda := \frac{2}{3}$. It is enough to show that G' is an instance of $\sharp$INDEP-SET-INC$(7, \frac{2}{19})$ and

$$e^{-\epsilon/2} \frac{i_{\lfloor \alpha N \rfloor}(G')}{\binom{r}{\lfloor \alpha N \rfloor} 8^{\lfloor \alpha N \rfloor}} \leq Z_G(\lambda) \leq e^{\epsilon/2} \frac{i_{\lfloor \alpha N \rfloor}(G')}{\binom{r}{\lfloor \alpha N \rfloor} 8^{\lfloor \alpha N \rfloor}}, \tag{9}$$

where as usual $i_k(G)$ is the number of independent sets of size k in G, and

$$\binom{r}{\lfloor \alpha N \rfloor} 8^{\lfloor \alpha N \rfloor} = i_{\lfloor \alpha N \rfloor}(rK_8).$$

Here, rK_8 is a shorthand for the graph which is a disjoint union of r copies of K_8. We first show that Equation (9) holds. Note that

$$i_{\lfloor \alpha N \rfloor}(G') = \sum_{j=0}^{n} i_j(G) i_{\lfloor \alpha N \rfloor - j}(rK_8) = i_{\lfloor \alpha N \rfloor}(rK_8) \sum_{j=0}^{n} i_j(G) \frac{i_{\lfloor \alpha N \rfloor - j}(rK_8)}{i_{\lfloor \alpha N \rfloor}(rK_8)}.$$

Thus, to show Equation (9), it is enough to prove that for every $1 \le j \le n$,

$$e^{-\epsilon/2} \cdot \frac{i_{\lfloor \alpha N \rfloor - j}(rK_8)}{i_{\lfloor \alpha N \rfloor}(rK_8)} \le \lambda^j \le e^{\epsilon/2} \cdot \frac{i_{\lfloor \alpha N \rfloor - j}(rK_8)}{i_{\lfloor \alpha N \rfloor}(rK_8)}. \tag{10}$$

We can write

$$\frac{i_{\lfloor \alpha N \rfloor - j}(rK_8)}{i_{\lfloor \alpha N \rfloor}(rK_8)} = \frac{\binom{r}{\lfloor \alpha N \rfloor - j} 8^{\lfloor \alpha N \rfloor - j}}{\binom{r}{\lfloor \alpha N \rfloor} 8^{\lfloor \alpha N \rfloor}} = \frac{1}{8^j} \prod_{i=0}^{j-1} \frac{\lfloor \alpha N \rfloor - i}{r - \lfloor \alpha N \rfloor + j - i}. \tag{11}$$

To prove the upper bound, first note that

$$\frac{\alpha N}{r - \alpha N + j} \underset{\alpha N \ge 8\alpha r}{\ge} \frac{8\alpha r}{r(1 - 8\alpha) + n} \underset{\substack{n = \sqrt{\epsilon r}/c \\ \alpha = 2/19}}{=} \frac{16}{3} \left(\frac{1}{1 + \frac{19\sqrt{\epsilon}}{3c\sqrt{r}}} \right). \tag{12}$$

This implies that $\frac{\alpha N}{r - \alpha N + j} \ge 1$. So, $\frac{\alpha N}{r - \alpha N + j} \le \frac{\lfloor \alpha N \rfloor - i}{r - \lfloor \alpha N \rfloor + j - i}$ for every $i < r - \lfloor \alpha N \rfloor + j$. Thus,

$$\begin{aligned} \frac{1}{8^j} \cdot \prod_{i=0}^{j-1} \frac{\lfloor \alpha N \rfloor - i}{r - \lfloor \alpha N \rfloor + j - i} &\ge \frac{1}{8^j} \cdot \left(\frac{\alpha N}{r - \alpha N + j} \right)^j \\ &\underset{\substack{Equation\ (12) \\ j \le n = \sqrt{\epsilon r}/c}}{\ge} \frac{1}{8^j} \cdot (\tfrac{16}{3})^j \left(\frac{1}{1 + \frac{19\sqrt{\epsilon}}{3c\sqrt{r}}} \right)^{\sqrt{\epsilon r}/c} \ge (\tfrac{2}{3})^j e^{-\epsilon/2} = \lambda^j e^{-\epsilon/2}, \end{aligned}$$

for a large enough $c > 1$. Combining this with Equation (11), we get the upper bound in Equation (10).

To prove the lower bound, note that

$$\begin{aligned} \frac{1}{8^j} \cdot \prod_{i=0}^{j-1} \frac{\lfloor \alpha N \rfloor - i}{r - \lfloor \alpha N \rfloor + j - i} &\underset{j - i \ge 0}{\le} \frac{1}{8^j} \cdot \left(\frac{\lfloor \alpha N \rfloor}{r - \lfloor \alpha N \rfloor} \right)^j \\ &\underset{\lfloor \alpha N \rfloor = \lfloor \frac{16r}{19} + \frac{2\sqrt{\epsilon r}}{19c} \rfloor}{\le} \frac{1}{8^j} \cdot \left(\frac{\frac{16r}{19}(1 + \frac{\sqrt{\epsilon}}{8c\sqrt{r}})}{\frac{3r}{19}(1 - \frac{2\sqrt{\epsilon}}{3c\sqrt{r}})} \right)^j \\ &\le (\tfrac{2}{3})^j e^{\epsilon/2} = \lambda^j \cdot e^{\epsilon/2}, \end{aligned}$$

for a large enough $c > 1$. Combining this with Equation (11), the lower bound in Equation (10), thus (9) follows.

It remains to show that G' is an instance of ♯INDEP-SET-INC$(7, \frac{2}{19})$, i.e. $i_k(G') \le i_{\lfloor \alpha N \rfloor}(G')$ for any $k < \lfloor \alpha N \rfloor$.

For any $k < \lfloor \alpha N \rfloor$, and any independent set S in the original graph G, let $T_{S,k}$ be the set of all independent sets of size k of G' whose intersection with the vertices of G is S. It is enough to show that there exists a constant n_0 such that if $n \geq n_0$, then we have $|T_{S,k}| \leq |T'_{S,\lfloor \alpha N \rfloor}|$ for every independent set $S \subseteq V$ of G and $k < \lfloor \alpha N \rfloor$. We prove a stronger statement that there exists a constant n_0 such that if $n \geq n_0$, then for any fixed independent set $S \subseteq V$, $|T_{S,k}|$ is increasing as a function of k for all $k \leq \lfloor \alpha N \rfloor$. It is enough to show that $\frac{|T_{S,k}|}{|T_{S,k-1}|} \geq 1$ for any $|S| \leq k \leq \alpha N$. Note that $|T_{S,k}| = \binom{r}{k-|S|} 8^{k-|S|}$. So we have

$$\frac{|T_{S,k}|}{|T_{S,k-1}|} = \frac{\binom{r}{k-|S|} 8^{k-|S|}}{\binom{r}{k-1-|S|} 8^{k-1-|S|}} = 8 \cdot \frac{r-k+|S|+1}{k-|S|} \geq 8 \cdot \frac{r-k}{k} \geq 8 \frac{\frac{3r}{19} - n}{\frac{16r}{19} + n},$$

where the last inequality comes from the fact that $k \leq \frac{2N}{19} = \frac{2}{19}(8r+n) \leq \frac{16r}{19} + n$. But since $r = \frac{c^2 n^2}{\epsilon}$, there is a constant n_0 such that for $n \geq n_0$, we have $\frac{\frac{3r}{19} - n}{\frac{16r}{19} + n} \geq \frac{1}{8}$. This shows that $\frac{|T_{S,k}|}{|T_{S,k-1}|} \geq 1$, which finishes the proof. ◀

Low-Degree Testing over Grids

Abstract

We study the question of local testability of low (constant) degree functions from a product domain $\mathcal{S}_1 \times \cdots \times \mathcal{S}_n$ to a field $\mathbb{F}$, where $\mathcal{S}_i \subseteq \mathbb{F}$ can be arbitrary constant sized sets. We show that this family is locally testable when the grid is "symmetric". That is, if $\mathcal{S}_i = \mathcal{S}$ for all i, there is a probabilistic algorithm using constantly many queries that distinguishes whether f has a polynomial representation of degree at most d or is $\Omega(1)$-far from having this property. In contrast, we show that there exist asymmetric grids with $|\mathcal{S}_1| = \cdots = |\mathcal{S}_n| = 3$ for which testing requires $\omega_n(1)$ queries, thereby establishing that even in the context of polynomials, local testing depends on the structure of the domain and not just the distance of the underlying code.

The low-degree testing problem has been studied extensively over the years and a wide variety of tools have been applied to propose and analyze tests. Our work introduces yet another new connection in this rich field, by building low-degree tests out of tests for "junta-degrees". A function $f : \mathcal{S}_1 \times \cdots \times \mathcal{S}_n \to \mathcal{G}$, for an abelian group $\mathcal{G}$ is said to be a junta-degree-d function if it is a sum of d-juntas. We derive our low-degree test by giving a new local test for junta-degree-d functions. For the analysis of our tests, we deduce a small-set expansion theorem for spherical/hamming noise over large grids, which may be of independent interest.

1 Introduction

The main problem considered in this paper is "low-degree testing over grids". Specifically given a degree parameter $d \in \mathbb{Z}^{\geqslant 0}$ and proximity parameter $\delta > 0$ we would like to design a tester (a randomized oracle algorithm) that is given oracle access to a function $f : \mathcal{S}_1 \times \cdots \times \mathcal{S}_n \to \mathbb{F}$ where $\mathbb{F}$ is a field and $\mathcal{S}_1, \ldots, \mathcal{S}_n \subseteq \mathbb{F}$ are arbitrary finite sets, and accepts if f is a polynomial of degree at most d while rejecting with constant probability (say $1/2$) if f is δ-far (in relative Hamming distance) from every degree d polynomial. The main goal here is to identify settings where the test makes $O(1)$ queries when $d, 1/\delta$ and $\max_{i \in [n]}\{|\mathcal{S}_i|\}$ are all considered constants. (In particular the goal is to get a query complexity independent of n.)

Low-degree testing

The low-degree testing problem over grids is a generalization of the classical low-degree testing problem which corresponds to the special case where $\mathbb{F}$ is a finite field and $\mathcal{S}_1 = \cdots = \mathcal{S}_n = \mathbb{F}$. Versions of the classical problem were studied in the early 90s [5, 6, 11] in the context of program checking and (multi-prover) interactive proofs. The problem was formally defined and systematically studied by Rubinfeld and Sudan [24] and played a central role in the PCP theorem [2, 3] and subsequent improvements. While the initial exploration of low-degree testing focused on the case where $d \ll |\mathbb{F}|$ (and tried to get bounds that depended polynomially, or even linearly, on d), a later series of works starting with that of Alon, Kaufman, Krivelevich, Litsyn and Ron [1] initiated the study of low degree testing in the setting where $d > |\mathbb{F}|$. [1] studied the setting of $\mathbb{F} = \mathbb{F}_2$ and this was extended to the setting of other constant sized fields in [17, 19]. An even more recent sequence of works [10, 14, 15, 18] explores so-called "optimal tests" for this setting and these results have led to new applications to the study of the Gowers uniformity norm, proofs of XOR lemmas for polynomials [10], and novel constructions of small set expanders [8].

Part of the reason for the wide applicability of low-degree testing is the fact that evaluations of polynomials form error-correcting codes, a fact that dates back at least to the work of Ore [22]. Ore's theorem (a.k.a. the Schwartz-Zippel lemma) however applies widely to the evaluations of polynomial on entire "grids", i.e., sets of the form $\mathcal{S}_1 \times \cdots \times \mathcal{S}_n$ and bounds the distance between low-degree functions in terms of the degree d and minimum set size $\min_i\{|\mathcal{S}_i|\}$. This motivated Bafna, Srinivasan and Sudan [7] to introduce the low-degree testing problem over grids. They proposed and analyzed a low-degree test for the special case of the Boolean grid, i.e., where $|\mathcal{S}_1| = \cdots = |\mathcal{S}_n| = 2$. This setting already captures the setting considered in [1] while also including some novel settings such as testing the Fourier degree of Boolean functions (here the domain is $\{-1, +1\}^n$ while the range is $\mathbb{R}$). The main theorem in [7] shows that there is a tester with constant query complexity, thus qualitatively reproducing the theorem of [1] (though with a worse query complexity than [1] which was itself worse than the optimal result in [10]), while extending the result to many new settings.

In this work we attempt to go beyond the restriction of a Boolean grid. We discuss our results in more detail shortly, but the main outcome of our exploration is that the problem takes on very different flavors depending on whether the grid is symmetric ($\mathcal{S}_1 = \cdots = \mathcal{S}_n$) or not. In the former case, we get constant complexity testers for constant $|\mathcal{S}_i|$ whereas in the latter setting we show that even when $|\mathcal{S}_i| = 3$ low-degree (even $d = 1$) testing requires superconstant query complexity. (See Theorem 3 for details.) In contrast to previous testers, our tester goes via "junta-degree-tests", a concept that has been explored in the literature but not as extensively as low-degree tests, and not been connected to low-degree tests in the past. We describe this problem and our results for this problem next.

Junta-degree testing

A function $f : \mathcal{S}_1 \times \cdots \times \mathcal{S}_n \to \mathcal{G}$ for an arbitrary set $\mathcal{G}$ is said to be a d-junta if it depends only on d of the n variables. When $\mathcal{G}$ is an abelian group, a function $f : \mathcal{S}_1 \times \cdots \times \mathcal{S}_n \to \mathcal{G}$ is said to be of junta-degree d if it is the sum of d-juntas (where the sum is over $\mathcal{G}$).[1] In the special case where $|\mathcal{S}_i| = 2$ for all i and $\mathcal{G}$ is a field, junta degree coincides with the

[1] While in principle the problem could also be considered over non-abelian groups, in such a case it not clear if there is a fixed bound on the number of juntas that need to be summed to get to a function of bounded junta-degree.

usual notion of degree. More generally every degree d polynomial has junta degree d, while a function of junta-degree d is a polynomial of degree at most $d \cdot \max_i\{|\mathcal{S}_i|\}$. Thus junta-degree is softly related to algebraic degree and our work provides a step towards low-degree testing via the problem of junta-degree testing.

Junta-degree testing considers the task of testing if a given function has junta-degree at most d or if it is far from all functions of junta-degree at most d. While this problem has not been considered in full generality before, two works do consider this problem for the special case of $d = 1$. Dinur and Golubev [13] considered this problem in the setting where $\mathcal{G} = \mathbb{F}_2$, while Bogdanov and Prakriya [12] consider this for general abelian groups. This special case corresponds to the problem of testing if a function is a direct sum, thus relating to other interesting classes of properties studied in testing. Both works give $O(1)$ query testers in their settings, but even the case of $d = 2$ remained open.

In our work we give testers for this problem for general constant d in the general asymmetric domain setting with the range being an arbitrary finite group $\mathcal{G}$, though with the restriction that the maximum set size $|\mathcal{S}_i|$ is bounded. We then use this tester to design our low-degree test over symmetric grids. We turn to our results below. Even though our primary motivation in studying low-*junta*-degree testing is to ultimately use it for low-degree testing, we note that junta-degree testing even for the case of $\mathcal{G}$ being the additive group of $\mathbb{R}$ (or $\mathbb{C}$) and $\mathcal{S}_i = \Omega$ (which is some finite set) for all i, is by itself already interesting as in this case, junta-degree corresponds to the "degree" of the Fourier representation of the function (in any basis). Low-*Fourier*-degree functions and such approximations form a central object in complexity theory and computational learning theory, at least when the domain size is $|\Omega| = 2$. The problem of *learning* low-Fourier-degree functions in particular has received much attention over the years [20, 21], and hence *testing* the same family, over general domains Ω, is an interesting corollary of our results, especially since our techniques are more algebraic than analytic (modulo the usage of a hypercontractivity theorem).

1.1 Our results

We start by stating our theorem for junta-degree testing. (For a formal definition of a tester, see Definition 7).

▶ **Theorem 1.** *The family of junta-degree-d functions from $\mathcal{S}_1 \times \cdots \times \mathcal{S}_n$ to $\mathcal{G}$ is locally testable with a non-adaptive one-sided tester that makes $O_{s,d}(1)$ queries to the function being tested, where $s = \max_i |\mathcal{S}_i|$.*

In the special case where $|\mathcal{S}_i| = s$ for all i, the tester makes $s^{O(s^2 d)}$ queries.

In particular, if we treat all the parameters above except n as constant, this gives a test that succeeds with high probability by making only a constant number of queries. Taking $(\mathcal{G}, +) = (\mathbb{R}, +)$ or $(\mathbb{C}, +)$, the above theorem results in a local tester for Fourier-degree:

▶ **Corollary 2.** *The family of functions $f : \Omega^n \to \mathbb{R}$ of Fourier-degree at most d is locally testable in $s^{O(s^2 d)} = O_{s,d}(1)$ queries, where $s = |\Omega|$.*[2]

We now turn to the question of testing whether a given function $f : \mathcal{S}^n \to \mathbb{F}$ is *degree-d*, i.e., whether there is a polynomial of degree at most d agreeing with f, or δ-far from it. Here $\mathcal{S}$ can be any arbitrary finite subset of the field. Note that being junta-degree-d is a necessary condition for f being degree-d. Combining the above JUNTA-DEG with an additional test (called WEAK-DEG), we can test low-degree functions over a field, or rather over *any subset* of a field.

[2] The same result also holds if the co-domain is $\mathbb{C}$ instead of $\mathbb{R}$.

▶ **Theorem 3.** *For any subset $\mathcal{S} \subseteq \mathbb{F}$ of size s, the family of degree-d functions from $\mathcal{S}^n$ to $\mathbb{F}$ is locally testable with a non-adaptive, one-sided tester that makes $(sd)^{O(s^3 d)} = O_{s,d}(1)$ queries to the function being tested.*

The special case of $\mathcal{S} = \mathbb{F} = \mathbb{F}_q$ (finite field of size q) is especially interesting. Although this was already established for general finite fields first by Kaufman and Ron [19] and an optimal query complexity (in terms of d, for constant prime q) was achieved by Haramaty, Shpilka and Sudan [15], we nevertheless present it as a corollary of Theorem 3.

▶ **Corollary 4** (Kaufman and Ron [19]). *The family of degree-d functions $f : \mathbb{F}_q^n \to \mathbb{F}_q$ is locally testable in $(qd)^{O(q^3 d)} = O_{q,d}(1)$ queries.*

Turning our attention to more general product domains, we show that while junta-degree testing is still locally testable over there more general grids, testing degree in constantly many queries, even for $d = 1$, is intractable for all sufficiently large fields $\mathbb{F}$.

▶ **Theorem 5.** *For a growing parameter n, there exists a field $\mathbb{F}$ and its subsets $\mathcal{S}_1, \dots, \mathcal{S}_n$ of constant size (i.e., 3) such that testing the family of degree-1 functions $f : \mathcal{S}_1 \times \cdots \times \mathcal{S}_n \to \mathbb{F}$ requires $\Omega(\log n)$ queries.*

▶ Remark 6. A recent work of Arora, Bhattacharyya, Fleming, Kelman and Yoshida [4] considers low-degree testing over the reals and tests whether a given $f : \mathbb{R}^n \to \mathbb{R}$ is degree-d or ε-far with respect to a distribution $\mathcal{D}$. They give a test with query complexity independent of n for their problem ([4, Theorem 1.1]). This seems to contradict our result which seems to include the special case of their setting for $\mathcal{D} = \mathrm{Unif}(\mathcal{S}_1 \times \cdots \times \mathcal{S}_n)$ and $\mathbb{F} = \mathbb{R}$, where Theorem 5 shows that a dependence on n is necessary. The seeming contradiction is resolved by noting that the models in our paper and that of [4] are quite different. In particular, while in our setting the function f can only be queried on the support of the distribution $\mathcal{D}$ (namely $\mathcal{S}_1 \times \cdots \times \mathcal{S}_n$), in [4] the function can be queried at any point in $\mathbb{R}^n$ and the distribution $\mathcal{D}$ only shows up when defining the distance between two functions. (So in their model a function f that happens to agree with a degree d polynomial on the support of $\mathcal{D}$ but disagrees outside the support may be rejected with positive probability, while in our model such a function must be accepted with probability one.)

1.2 Technical contributions

All low-degree tests roughly follow the following pattern: Given a function f on n variables $x_1, \dots, x_n$ they select some $k = O_d(1)$ new variables $y = (y_1, \dots, y_k)$ and substitute $x_i = \sigma_i(y)$, where σ_i's are simple random functions, to get an $O(1)$-variate function $g(y) = f(\sigma(y))$; and then verify g is a low-degree polynomial in k variables by brute force. When the domain is $\mathbb{F}_q^n$ for some field $\mathbb{F}_q$, σ_i's can be chosen to be an affine form in y – this preserves the domain and ensures degree of g is at most the degree of f, thus at least ensuring completeness. While soundness of the test was complex to analyze, a key ingredient in the analysis is that for any pair of points $a \neq b \in \mathbb{F}_q^k$, $\sigma(a)$ and $\sigma(b)$ are uniform independent elements of $\mathbb{F}_q^n$ (over the randomness of σ). At least in the case where f is roughly $1/q^k$ distance from the degree d family, this ensures that with constant probability g will differ from a degree d polynomial in exactly one point making the test reject. Dealing with cases where f is much further away is the more complex part that we won't get into here.

When the domain is not $\mathbb{F}_q^n$ affine substitutions no longer preserve the domain and so we can't use them in our tests. In the cases of the domain being $\{-1, +1\}^n$, [7] used much simpler affine substitutions of the form $x_i = c_i y_{j(i)}$ where $c_i \in \{-1, +1\}$ uniformly and independently over i and $j(i) \in \{1, \dots, k\}$ uniformly though not independently over i. Then [7] iteratively reduce the number of variables as follows: When only r variables $x_1, \ldots, x_r$ remain, they pick two uniformly random indices $i \neq j \in \{1, \ldots, r-1\}$ and identify x_j with x_i, and then rename the $r-1$ remaining variables as $x_1, \ldots, x_{r-1}$. At the end when $r = k$, they pick a random bijection between $x_1, \ldots, x_k$ and $y_1, \ldots, y_k$. This iterative identification eventually maps every variable x_i to some variable $y_{j(i)}$. The nice feature of this identification scheme is it leads to a sequence of functions $f_n, f_{n-1}, ..., f_k$ with f_r being a function of r variables on the same domain, and of degree at most d if $f = f_n$ has degree at most d. If however we start with f_n being *very* far from degree d polynomials, there must exist r such that f_r is very far from high-degree functions while f_{r-1} is only *moderately* far. The probability of a bad event can be bounded (via some algebraic arguments) by $O(d^2/r^2)$. This step is the key to this argument and depends on the fact that f_{r-1} involves very small changes to f_r. Summing over r then gives the constant probability that the final function f_k (or equivalently g) is far from degree d polynomials. This still leaves [7] with the problem of dealing with functions f that are close to codewords: Here they use the fact that this substitution ensures that $\sigma(a)$ is distributed uniformly in $\{-1,+1\}^n$ for every $a \in \{-1,+1\}^k$. It is however no longer true that $\sigma(b)$ is uniform conditioned on $\sigma(a)$ for $b \neq a$, but it is still the case that if b is moderately far in Hamming distance from a then $\sigma(b)$ has sufficient entropy conditioned on $\sigma(a)$. (Specifically $\sigma(b)$ is distributed uniformly on a sphere of distance $\Omega(n)$ from $\sigma(a)$.) This entropy, combined with appropriate small-set expansion bounds on the Boolean hypercube, and in particular a spherical hypercontractivity result due to Polyanskiy [23]), ensures that if f is somewhat close to a low-degree polynomial then g is far from every degree d polynomial on an appropriately chosen subset of $\{-1,+1\}^k$ and so the test rejects.

To extend this algorithm and analysis to the setting on non-Boolean domains we are faced with two challenges: (1) We cannot afford to negate variables (using the random variables $c(i)$ above) when the domain is not $\{-1,+1\}$ – we can only work with identification of variables (or something similar). (2) The increase in the domain size forces us to seek a general spherical hypercontractivity result on non-Boolean alphabets and this is not readily available. Overcoming either one of the restrictions on its own seems plausible, but doing it together (while also ensuring that the sequence of restrictions/identifications do not make the distance to the family being tested to abruptly drop in distance as we go from $f_n, f_{n-1}, \ldots$ to f_k) turns out to be challenging and this is where we find it critical to go via junta-degree testing.

As a first step in our proof we extend the approach of [7] to junta-degree testing over the domain $\mathcal{S}^n$ for arbitrary finite $\mathcal{S}$. (It is relatively simple to extend this further to the case of $\mathcal{S}_1 \times \cdots \times \mathcal{S}_n$ – we don't discuss that here.) This is achieved by using substitutions of the form $x_i = \pi_i(y_{j(i)})$ where $\pi_i : \mathcal{S} \to \mathcal{S}$ is a random bijection. While this might increase the degree of the function, this preserves the junta-degree (or reduces it) and makes it suitable for analysis of the junta-degree test, which we now describe: Following the template of a low-degree test stated at the beginning of this subsection, the junta-tester would simply check whether $g(y) = f(\sigma(y))$ is of junta-degree at most d where σ is the random function induced by the identifications $j(.)$ and permutations π_i of variables. The permutations π_i here serve the same purpose as the coefficients c_i's do in the substitutions $x_i = c_i y_{j(i)}$ of [7] which is to ensure that for any $a \in \mathcal{S}^k$, $\sigma(a)$ is uniformly distributed in $\mathcal{S}^n$. With this idea in place extending the analysis of [7] to our setting ends up with a feasible path, except we had to address a few more differences; one such challenge is that in the analysis the rejection probability of junta-degree test on functions that are close to being junta-degree-d, we will need to analyze the effect of a spherical noise operator on grids (i.e., a subset of coordinates of fixed size is chosen uniformly at random and each coordinate in that subset is changed to a different value uniformly at random). While [23] shows that such a noise operator has the desired hypercontractivity behavior, and the corresponding small-set expansion theorem was used in the test of [7], this was only for a Boolean alphabet. In this paper, when the alphabet size $s = |\mathcal{S}|$ is more than 2, by doing Fourier analysis over $\mathbb{Z}_s^n$, we are able to relate it to the more standard Bernoulli i.i.d. noise operator for which we do have a small-set expansion theorem available – we believe this can be of independent interest.[3]

The other differences of our junta-degree test analysis compared to that of [7] are mainly to account for the fact that we are aiming for junta-degree testing over any (abelian) group whereas the low-degree testing ideas of [7] and other prior work utilize the properties of polynomials over fields. We also give a cleaner proof as compared to [7] for the fact that the sequence of functions of fewer and fewer variables obtained by the random identifications (along with permutations) does not abruptly decrease in distance to the junta-degree-d family like we pointed out earlier (see "large-distance lemma" Lemma 16).

We then return to the task of low-degree testing: For this we design a new test: We first test the given oracle for junta-degree d, then if it passes, we pick a fresh random identification scheme setting $x_i = y_{j(i)}$ for uniform independent $j(i) \in \{1, \ldots, k\}$ and verify (by brute-force) that the resulting k variate function has degree at most d. The advantage with this two stage tester is that in the second stage the given function is already known to be close to a polynomial of degree at most sd where $s = \max_i\{|\mathcal{S}_i|\}$. This makes the testing problem closer to a polynomial identity testing problem, though the problem takes some care to define, and many careful details to be worked out in the analysis. A particular challenge arises from the fact that the first phase only proves that our function is only *close* to a low-degree polynomial and may not be low-degree exactly – so in the second stage we have to be careful to sample the function on essentially uniform inputs. This prevents us from using all of $\mathcal{S}^k$ when looking at the restricted function $g(y)$, but only allows us to use balanced inputs in $\mathcal{S}^k$ (where a balanced input has an equal number of coordinates with each value $v \in \mathcal{S}$). In turn understanding what the lowest degree of function can be given its values on a balanced set leads to new algebraic questions. Section 4 gives a full proof of the low-degree test and analysis spelling out the many technical questions and our solutions to those.

The final testing-related result we prove is an impossibility result, showing that while low-degree functions are locally testable over $\mathcal{S}^n$, this cannot be extended to general grids $\mathcal{S}_1 \times \cdots \times \mathcal{S}_n$ for large enough fields (Theorem 5). From a coding theory perspective, this reveals that local testability of even polynomial evaluations codes requires more structure than simply having a large distance. To sketch the idea, let $d = 1$ and $\mathbb{F}$ be any field of size at least $n + 2$ with distinct elements $\{0, 1, a_1, \ldots, a_n\}$. For $i \in [n]$, let $\mathcal{S}_i = \{0, 1, a_i\}$. We will refer to $0, 1$ as Boolean elements and the remaining as non-Boolean ones. Let $\zeta(b) = b$ if b is Boolean and $\star$ otherwise. As degree-1 functions over $\mathcal{S}_1 \times \cdots \times \mathcal{S}_n$ form a linear subspace over $\mathbb{F}$, by a result due to Ben-Sasson, Harsha and Raskhodnikova [9] any test can be converted to a one-sided, non-adaptive one without changing the number of queries or the error by more than a factor of 2. Thus, we may assume that the test (call it TEST) is of the following form: TEST samples a matrix $M \in \mathbb{F}^{\ell \times n}$ according to a distribution $\mathcal{D}$ with rows $x^{(1)}, \ldots, x^{(\ell)} \in \mathcal{S}_1 \times \cdots \times \mathcal{S}_n$ and accepts f if and only if $P(f(x^{(1)}), \ldots, f(x^{(\ell)}))$ is true where P is some fixed predicate. We will show that if TEST accepts degree-1 functions with probability 1 and rejects $\Omega(1)$-far functions with probability $\Omega(1)$, then $\ell = \Omega(\log n)$. By the one-sidedness, we must have for all $M \in \sup(\mathcal{D})$ that if $f_M := (f(x^{(1)}), \ldots, f(x^{(\ell)})) \in \text{colspace}(M)$, then TEST accepts, where sup denotes the support and colspace denotes the column space. Picking $i \in [n]$ uniformly at random, note that the function $g(x) := x_i(x_i - 1)$ is $\Omega(1)$-far from degree-1.

[3] We note that the hypercontractivity setting we are considering and analyzing in this part is not sufficient to get a direct analysis of low-degree testing. Such an analysis would require hypercontractivity for more delicate noise models than the simpler "q-ary symmetric" models we analyze here.

Then we argue that the "evaluation vector" $g_M := (g(x^{(1)}), \ldots, g(x^{(\ell)}))$ lies in the column space of M with high probability (over i) if $\ell = o(\log n)$, so Test faultily accepts g. The idea is that if $\ell = o(\log n)$ then there are at least two columns (say $i \neq j \in [n]$) of M that are identical under the ζ mapping, so subtracting one from the other gives a vector in $\mathbb{F}^\ell$ that is (up to a constant factor) equal to g_M. This is because for $k \in [\ell]$, the k-th coordinate of the difference vector is $a_i - a_j$ (some constant) if $\zeta(x_i^{(k)}) = \star$ and 0 otherwise. Similarly the k-th coordinate of g_M is $a_i(a_i - 1)$ (some constant) if $\zeta(x_i^{(k)}) = \star$ and 0 otherwise.

2 Preliminaries

We denote $[n] = \{1, \ldots, n\} \subseteq \mathbb{Z}$, $[m..n] = [n] \setminus [m-1]$ and $\mathbb{Z}_s = \mathbb{Z}/s\mathbb{Z} = \{0, 1, \ldots, s-1\}$ for $s \geqslant 2$. Throughout the paper, let $(\mathcal{G}, +)$ be an arbitrary abelian group and $(\mathbb{F}, +, \cdot)$ an arbitrary field. $\mathbb{F}_q^n$ is a vector space over the finite field of q elements, to which we associate an inner product (bilinear form) as: $\langle x, y\rangle = \sum_{i=1}^n x_i \cdot y_i$.

For any finite set $\mathcal{S}$ and $a \in \mathcal{S}^n$ we denote the Hamming weight of a by $\#a = \{i \in [n] : a_i \neq 0\}$, assuming $\mathcal{S}$ contains an element called 0. If $I \subseteq [n]$, we use a^I to denote the tuple a restricted to the coordinates of I, i.e., $a^I = (a_i)_{i \in I}$. Similarly $\mathcal{S}^I = \{a^I : a \in \mathcal{S}^n\}$. For disjoint subsets $I, J \subseteq [n]$, and $a \in \mathcal{S}^I$ and $b \in \mathcal{S}^J$, we denote their concatenation by $a \circ b \in \mathcal{S}^{I \cup J}$. Denoting a product domain/grid by $\overline{\mathcal{S}} = \mathcal{S}_1 \times \cdots \times \mathcal{S}_n$, we let $\overline{\mathcal{S}}^I = \times_{i \in I} \mathcal{S}_i$ denote the Cartesian product of sets restricted to the coordinates of I.

We use $\binom{[n]}{\leqslant d}$ to denote the set of subsets of $[n]$ of size at most d. For m a multiple of s, let "balanced set" $\mathcal{B}(\mathcal{S}, m) \subseteq \mathcal{S}^m$ be the set of points that contain exactly m/s many repetitions of each element of $\mathcal{S}$. Abusing notation, sometimes we may think of $\mathcal{B}(\mathcal{S}, m)^{m'}$ as a subset of $\mathcal{S}^{mm'}$ by flattening the tuple of m-tuples. The *group-integer multiplication* operation $\cdot : \mathcal{G} \times \mathbb{Z} \to \mathcal{G}$ is defined by $g \cdot m = g + \cdots + g$ ($|m|$ times) if $m \geqslant 0$ and $-g - \cdots - g$ ($|m|$ times) otherwise.

2.1 Local testability

The *distance* between $f : \overline{\mathcal{S}} \to \mathcal{G}$ and a family of functions $\mathcal{F}$ with the same domain $\overline{\mathcal{S}}$ is $\delta_{\mathcal{F}}(f) = \min_{g \in \mathcal{F}} \delta(f, g)$, where $\delta(f, g) = \Pr_{x \sim \overline{\mathcal{S}}}[f(x) \neq g(x)]$. We say that f is δ-*far* from $\mathcal{F}$ if $\delta_{\mathcal{F}}(f) \geqslant \delta$. When $\mathcal{F}$ is the family of junta-degree-d functions, we denote $\delta_{\mathcal{F}}(.)$ by simply $\delta_d(.)$. Similarly f is δ-*close* to $\mathcal{F}$ if $\delta_{\mathcal{F}}(f) \leqslant \delta$.

▶ **Definition 7** (Local testability). *A randomized algorithm $\mathcal{A}$ with an oracle access to a function $f : \overline{\mathcal{S}} \to \mathcal{G}$ as its input, is said to be* q-local *if it performs at most q queries for any given f. For a family of functions $\mathcal{F}$ with domain $\overline{\mathcal{S}}$ and co-domain $\mathcal{G}$, we say that $\mathcal{F}$ is* q-locally testable *for $q = q(\mathcal{F})$ if there exists a q-local test $\mathcal{A}$ that accepts f with probability* 1 *if $f \in \mathcal{F}$, and rejects f with probability at least $\delta_{\mathcal{F}}(f)/2$ if $f \notin \mathcal{F}$. Further if $q(\mathcal{F}) = O(1)$ (i.e., independent of the number of variables n), we simply refer to $\mathcal{F}$ as being* locally testable.

One can define more general two-sided error and adaptive tests, but in the context of this paper, the above definition for local testability is without loss of generality as we know from the work of Ben-Sasson, Harsha and Raskhodnikova [9] that for *linear properties*[4], any "test" can be transformed to be one-sided and non-adaptive without altering the query complexity (locality) and success probability by more than constant factors.

[4] i.e., for families $\mathcal{F}$ for which $f \in \mathcal{F}$ and $g \in \mathcal{F}$ implies $c_1 f + c_2 g \in \mathcal{F}$ for all $c_1, c_2 \in \mathbb{F}$.

The family of functions $\mathcal{F}$ of our study (namely "junta-degree-d" and "degree-d" to be formally defined shortly) are parameterized by $s = \max_i |\mathcal{S}_i|$ and an integer d which we treat as constants. All tests we are going to present are $O_{s,d}(1)$-local, one-sided and non-adaptive. However, the probability of rejection in case of $f \notin \mathcal{F}$ is only $\Omega_{s,d}(\delta_{\mathcal{F}}(f))$; nevertheless by repeating the test an appropriate $O_{s,d}(1)$ number of times, we get a $O_{s,d}(1)$-local test for $\mathcal{F}$ that succeeds with probability $\delta_{\mathcal{F}}(f)/2$ when $f \notin \mathcal{F}$ and with probability 1 when $f \in \mathcal{F}$.

2.2 Junta-polynomials and polynomials

For this section, we let $\overline{\mathcal{S}} = \mathcal{S}_1 \times \cdots \times \mathcal{S}_n$ denote an arbitrary finite product domain (or grid) and $s = \max_i \{s_i\}$, where $s_i = |\mathcal{S}_i|$.

▶ **Definition 8** (Junta-degree). *A function $f : \overline{\mathcal{S}} \to \mathcal{G}$* [5] *is said to be* junta-degree-d *if*

$$f(x) = f_1(x^{D_1}) + \cdots + f_t(x^{D_t})$$

for some $t \in \mathbb{Z}, D_j \in \binom{[n]}{\leqslant d}$ and functions $f_j : \overline{\mathcal{S}}^{D_j} \to \mathcal{G}$ for $j \leqslant t$. If $t = 1$, we call f a d-junta.

The junta-degree *of f is the minimum $d \geqslant 0$ such that f is junta-degree-d.*

For junta-degree testing over arbitrary grids $\overline{\mathcal{S}} = \mathcal{S}_1 \times \cdots \times \mathcal{S}_n$, we may assume that $\mathcal{S}_i = \mathbb{Z}_{s_i}$ without loss of generality, where $s_i = |\mathcal{S}_i|$. The following claims about junta-polynomials are analogous to standard facts about multi-variate polynomials over a field.

▷ Claim 9. Any junta-degree-d function $f : \mathbb{Z}_s^n \to \mathcal{G}$ can be uniquely[6] expressed as

$$f(x_1, \ldots, x_n) = \sum_{\substack{a \in \mathbb{Z}_s{}^n \\ \#a \leqslant d}} g_a \cdot \prod_{i \in [n]:\ a_i \neq 0} \delta_{a_i}(x_i), \tag{1}$$

where $g_a \in \mathcal{G}$ and $\delta_b : \mathbb{Z}_s \to \mathbb{Z}$ is defined as $\delta_b(y) = 1$ if $b = y$ and 0 otherwise.

▶ **Definition 10** (Junta-polynomial). *We will call such a representation as a* junta-polynomial*, and the* degree *of a junta-polynomial is defined as $\max_{a \in \mathbb{Z}_s{}^n : g_a \neq 0} \#a$. It can be seen that the degree of a junta-polynomial is exactly equal to the junta-degree of the function it computes, assuming that the degree of the identically 0 junta-polynomial is 0.*

We will refer to the summands in (1) as terms*, the constants g_a as* coefficients*, the integer products $\prod_{i \in [n]:\ a_i \neq 0} \delta_{a_i}(x_i)$ as* monomials*. We say that a is a* root *of a junta-polynomial P if $P(a) = 0$ and a is a* non-root *otherwise.*

▷ Claim 11. Any non-zero junta-polynomial $P : \mathbb{Z}_s^n \to \mathcal{G}$ of degree at most d has at least s^{n-d} non-roots.

We will now discuss standard facts about formal polynomials. Let $\mathbb{F}$ be a field and $\mathcal{S} \subseteq \mathbb{F}$ be of size $s \geqslant 2$. For a polynomial $P(x_1, \ldots, x_n) \in \mathbb{F}[x_1, \ldots, x_n]$ the individual degree of x_i is the largest degree x_i takes in any (non-zero) monomial of P. The individual degree of P is the largest individual degree of any variable x_i. We say that P is *degree-d* if its degree is at most d. We say that $f : \mathcal{S}^n \to \mathbb{F}$ is degree-d iff there is a degree-d polynomial $P \in \mathbb{F}[x_1, \ldots, x_n]$ computing f. For the analysis of our degree-tester, we also need a notion of degree-d for non-product domains: for any $\mathcal{T} \subseteq \mathcal{S}^n$, we say that $f : \mathcal{T} \to \mathbb{F}$ is degree-d if there is a degree-d polynomial $P \in \mathbb{F}[x_1, \ldots, x_n]$ computing f.

[5] Here we treat a tuple of sets as the domain of the function

[6] up to the commutativity of the Σ (group addition) and Π (integer multiplication) operations

▷ Claim 12. Any degree-d function $f : \mathcal{S}^n \to \mathbb{F}$ has a unique polynomial representation with degree at most d and individual degree at most $s-1$.

By setting $d = n(s-1)$ (or ∞) in the above claim, we see that the set of all functions from $\mathcal{S}^n$ to $\mathbb{F}$ is a vector space over $\mathbb{F}$ of dimension s^n – the monomials with individual degree at most $s-1$ form a basis. More generally, for any $\mathcal{T} \subseteq \mathcal{S}^n$ the set of functions from $\mathcal{T}$ to $\mathbb{F}$ forms a vector space of dimension $|\mathcal{T}|$ with an inner product defined for $f, g : \mathcal{T} \to \mathbb{F}$ as $\langle f, g\rangle = \sum_{x\in\mathcal{T}} f(x)\cdot g(x)$. For any d, the set of degree-d functions is a subspace of this vector space.

It is easy to see that if $f : \mathcal{S}^n \to \mathbb{F}$ is degree-d, then it is also junta-degree-d (w.r.t. to the additive group of $\mathbb{F}$). Conversely, if $f : \mathcal{S}^n \to \mathbb{F}$ is junta-degree-d, then it is degree-$(s-1)d$: this follows by applying Claim 12 to the d-junta components of f. If $s = 2$, the degree is exactly equal to the junta-degree.

Let $\delta'_d(f)$ denote the distance of f to the degree-d family.

2.3 Fourier analysis

▶ **Definition 13** (Fourier representation). *Any function $f : \mathbb{Z}_s^n \to \mathbb{C}$ can be uniquely expressed as*

$$f(x) = \sum_{\alpha\in\mathbb{Z}_s^n} \widehat{f}(\alpha)\chi_\alpha(x) \tag{2}$$

where the characters *are defined as $\chi_\alpha(x) = \prod_{i\in[n]} \chi_{\alpha_i}(x_i)$ where $\chi_\beta(y) = \omega^{\beta y \mod s}$ for $\beta, y \in \mathbb{Z}_s$ and $\omega \in \mathbb{C}$ is a (fixed) primitive s-th root of unity.*

▶ **Definition 14** (Noise operators). *For $\nu \in [0,1]$ and $x \in \mathbb{Z}_s^n$, we define $N_\nu(x)$* [7] *to be the distribution over $\mathbb{Z}_s^n$ where each coordinate of x is unchanged with probability $1-\nu$, and changes to a* different *value uniformly at random with probability ν. Similarly, the* spherical noise *corresponds to $S_\nu(x)$ where a subset $J \subseteq [n]$ of fixed size νn is chosen uniformly at random and the coordinates outside J are unchanged and those within J are changed to a uniformly different value. Let $\mathcal{D}_\nu$ denote the probability distribution over $\mathbb{Z}_s$ with mass $1-\nu$ at 0 and $\nu/(s-1)$ at all the other points. Let $\mathcal{E}_\nu$ denote the uniform distribution over $\{y \in \mathbb{Z}_s^n : \#y = \nu n\}$. For $\mu_1 \sim \mathcal{D}_\nu^{\otimes n}$ and $\mu_2 \sim \mathcal{E}_\nu$, note that $N_\nu(x)$ and $x + \mu_1$ are identically distributed; so are $S_\nu(x)$ and $x + \mu_2$.*

3 Low-junta-degree testing

We note that junta-degree-d functions with domain $\mathcal{S}_1 \times \cdots \times \mathcal{S}_n$ such that $|\mathcal{S}_i| = s$ for all i are "equivalent" to those with domain $\mathbb{Z}_s^n$ as one can fix an arbitrary ordering of elements in each $\mathcal{S}_i$ and treat the function as being over $\mathbb{Z}_s^n$: this does not change the junta-degree. Hence, we will fix $\mathcal{S}_i = \mathbb{Z}_s$. The more general case of unequal domain sizes is handled in the full version of the paper.

We claim that the following test works to check if a given function $f : \mathbb{Z}_s^n \to \mathcal{G}$ is junta-degree-d.

[7] This is different from the standard usage N_ρ where ρ denotes the probability of "retention" and not of noise.

The junta-degree test (Junta-deg)

For a parameter $k = O_{s,d}(1)$ that is yet to be fixed, the junta-degree test (which we shall refer to as Junta-deg) for $f : \mathbb{Z}_s^n \to \mathcal{G}$ is the following algorithm with $I = [n]$, $r = n$ and $f_r = f$:

Test $\boldsymbol{T_{I,r}(f_r)}$: gets query access to $\boldsymbol{f_r : \mathbb{Z}_s^I \to \mathcal{G}}$ where $\boldsymbol{I \subseteq [n]}$ is of size $\boldsymbol{r}$.

1. If $r \leqslant k$, accept iff f_r is junta-degree-d (check this by querying f_r at all points in its domain). Otherwise,
2. Choose $i \neq j \in I$ and a permutation $\pi_j : \mathbb{Z}_s \to \mathbb{Z}_s$ independently and uniformly at random. Let $I' = I \setminus \{j\}$.
3. Apply the test $T_{I',r-1}(f_{r-1})$ where $f_{r-1} : \mathbb{Z}_s^{I'} \to \mathcal{G}$ is the function obtained by setting $x_j = \pi_j(x_i)$ in f_r: that is, $f_{r-1}(a^{I'}) := f_r(a^{I'} \circ (\pi_j(a_i))^{\{j\}})$ for $a \in \mathcal{S}^{I'}$.

The query complexity of the Junta-deg test is $s^k = O_{s,d}(1)$ regardless of the randomness within the test. Furthermore, if the function f happens to be a junta-degree-d function, then the test Junta-deg always accepts it, since permuting variables and substituting some variables with other variables does not change the junta-degree, so Step 1 succeeds. In this section, we will show that if $\delta := \delta_d(f) > 0$, then $\Pr[\text{Junta-deg rejects } f] \geqslant \varepsilon\delta$ for appropriate $\varepsilon = \Omega_{s,d}(1)$.

We follow the same approach as [7] (which itself follows [10]) and argue that if $\delta_d(f)$ is "small", then we will be able to prove $\Pr[\text{Junta-deg rejects } f] \geqslant \varepsilon{\cdot}\delta_d(f)$ and if not, at least we will be able to find some $r \in [k+1..n]$ such that $\delta_d(f_r)$ is small enough (but importantly, not too small). Then, we apply the small-distance analysis to that f_r.

We state here the two main lemmas to prove that the correctness of the junta-degree tester. Here, the parameters $\varepsilon_0 \leqslant \varepsilon_1$ and ε will be chosen to be at least $s^{-O(k)}$. In the context of the test $T_{I,r}(f_r)$ described above, we will set $k = \psi s^2 d$ for a sufficiently large but constant ψ to be fixed in the proofs of the below lemmas[8].

▶ **Lemma 15** (Small-distance lemma). *For any $I \subseteq [n]$ of size $r > k$, if $\delta = \delta_d(f_r) \leqslant \varepsilon_1$, then*

$$\Pr[T_{I,r} \textit{ rejects } f_r] \geqslant \varepsilon\delta.$$

▶ **Lemma 16** (Large-distance lemma). *For any $I \subseteq [n]$ of size $r > k$, if $\delta_d(f_r) > \varepsilon_1$, then*

$$\Pr_{i,j,\pi_j}[\delta_d(f_{r-1}) \leqslant \varepsilon_0] \leqslant k^2/2r(r-1).$$

Assuming the above two lemmas to be true, the proof of Theorem 1, at least for symmetric domains $\mathcal{S}_1 \times \cdots \times \mathcal{S}_n = \mathbb{Z}_s^n$, follows the same approach as in [7] and we omit it here. We also defer the proof of the large-distance lemma to the full version (and Appendix B). The case of junta-degree testing over *general* grids can be reduced to that of symmetric grids and we refer the reader to the full version for details.

3.1 Small-distance lemma

Proof of Lemma 15. We will "unroll" the recursion of the Junta-deg test and state it more directly as follows: Fix an arbitrary $r > k$. As r is fixed, we denote f_r by f (not to be confused with the initial function on n variables). For the proof, we will need the following alternate description of $T_{I,r}$ (subsequently, we shall drop the subscript I). Here, $\sigma : [r] \to [k]$ is a map chosen according to the following random process:

[8] For $d = 0$, we can take $k = \psi s^2$ so that it is non-zero.

- For $i = 1$ to k, set $\sigma(i) = i$.
- For $i = k+1$ to r, set $\sigma(i) = j$ with probability $|\{i' < i : \sigma(i') = j\}| / (i-1)$, for each $j \in [k]$.

The only property we need about the above distribution of σ is that it is "well-spread", which was already shown in [7] as the following lemma.

▶ **Lemma 17** (Corollary 6.9 in [7]). *With probability at least $1/2^{O(k)}$, we have $\left|\sigma^{-1}(j)\right| \geqslant r/4k$ for all $j \in [k]$ – we call such a σ* good.

Test $T_r(f)$: gets query access to $f : \mathcal{S}^{[r]} \to \mathcal{G}$ with variables $x_1, \ldots, x_r$.

1. Choose a tuple of permutations of $\mathbb{Z}_s$, $\pi = (\pi_1, \ldots, \pi_r)$ u.a.r.
2. Choose a bijection $\mu : [r] \to [r]$ u.a.r.
3. Choose a map $\sigma : [r] \to [k]$ according to the distribution described above Lemma 17.
4. For $y = (y_1, \ldots, y_k) \in \mathbb{Z}_s^k$, define $x_{\pi\sigma\mu}(y) = \left(\pi_1(y_{\sigma(\mu^{-1}(1))}), \ldots, \pi_r(y_{\sigma(\mu^{-1}(r))})\right)$.
5. Accept iff $f'(y) := f(x_{\pi\sigma\mu}(y))$ is junta-degree-d.

Let $\delta = \delta_d(f_r) = \delta(f, P) \leqslant \varepsilon_1$ where $P : \mathbb{Z}_s^{[r]} \to \mathcal{G}$ is junta-degree-d and $E \subseteq \mathcal{S}^r$ be the points where f and P differ. Our objective is to show that

$$\Pr_{\pi,\sigma,\mu}[T_r \text{ rejects } f] = \Pr_{\pi,\sigma,\mu}[f' \text{ is not junta-degree-}d] \geqslant \varepsilon\delta. \tag{3}$$

Let the functions $f' : \mathcal{S}^k \to \mathcal{G}$ and $P' : \mathcal{S}^k \to \mathcal{G}$ be defined by $f'(y) = f(x_{\pi\sigma\mu}(y))$ and $P'(y) = P(x_{\pi\sigma\mu}(y))$ respectively (these functions depend on π, σ, μ) and $E' \subseteq \mathcal{S}^k$ be the points where these two restricted functions differ.

To proceed further, we will need a subset U of $\mathbb{Z}_s^k$ with the following properties (we defer the proof to Appendix A and the full version):

▷ Claim 18. Let $w = \lceil \log(8\psi s^2)d \rceil < k$. There exists a set $U \subseteq \mathbb{Z}_s^k$ of size 2^w such that

1. (Code) For all $y \neq y' \in U$,

   $$k/4 \leqslant \Delta(y, y') \leqslant 3k/4$$

   where $\Delta(y, y')$ denotes the number of coordinates where y and y' differ.
2. (Hitting) No two junta-degree-d functions $P : \mathcal{S}^k \to \mathcal{G}$ and $Q : \mathcal{S}^k \to \mathcal{G}$ can differ at exactly one point in U.

Let $V = \{x_{\pi\sigma\mu}(y) : y \in U\} \subseteq \mathbb{Z}_s^r$. Because the mapping $y \mapsto x_{\pi\sigma\mu}(y)$ is one-one conditioned on σ being good, it holds that $|V \cap E| = |U \cap E'|$ under this conditioning. Now suppose the randomness is such that $|U \cap E'| = 1$. Then, since no two junta-degree-d functions can disagree at exactly one point in U (Property 2 of Claim 18), it must be the case that f' be of junta-degree greater than d (as P', being a restriction of a junta-degree-d function is already junta-degree-d). Therefore, for (3) we can set $\varepsilon := \Pr_\sigma[\sigma \text{ good}] \geqslant 1/2^{O(k)}$ and show

$$\Pr_{\pi,\sigma,\mu}[|U \cap E'| = 1 \mid \sigma \text{ good}] = \Pr_{\substack{\pi,\mu \\ \sigma \text{ good}}}[|U \cap E'| = 1] \geqslant \delta.$$

By a simple inclusion-exclusion, the above probability is

$$\Pr_{\substack{\pi,\mu \\ \sigma \text{ good}}}[|V \cap E| = 1] \geqslant \sum_{y \in U} \Pr_{\substack{\pi,\mu \\ \sigma \text{ good}}}[x_{\pi\sigma\mu}(y) \in E] - \sum_{y \neq y' \in U} \Pr_{\substack{\pi,\mu \\ \sigma \text{ good}}}[x_{\pi\sigma\mu}(y) \in E \text{ and } x_{\pi\sigma\mu}(y') \in E] \tag{4}$$

For any $y \in U$, $x_{\pi\sigma\mu}(y) = \big(\pi_1(y_{\sigma(\mu^{-1}(1))}), \ldots, \pi_r(y_{\sigma(\mu^{-1}(r))})\big)$ is uniformly distributed over $\mathbb{Z}_s^r$ since $\pi_1, \ldots, \pi_r$ are random permutations of $\mathbb{Z}_s$. Hence the first part of (4) is

$$\sum_{y \in U} \Pr[x_{\pi\sigma\mu}(y) \in E] = |U| \cdot \frac{|E|}{s^r} = |U| \cdot \delta. \tag{5}$$

For any fixed $y \neq y' \in U$ and good σ, using Property 1 of Claim 18 for points in U we claim that the random variables $x := x_{\pi\sigma\mu}(y)$ and $x' := x_{\pi\sigma\mu}(y')$ are related as follows:

▷ Claim 19. $x' \sim S_\nu(x)$, for some $\nu \in [1/32, 31/32]$.

For the second term of (4),

$$\Pr_{\substack{\pi,\mu \\ \sigma \text{ good}}}[x_{\pi\sigma\mu}(y) \in E \text{ and } x_{\pi\sigma\mu}(y') \in E] = \Pr_{\substack{x \sim \mathbb{Z}_s^r \\ x' \sim S_\nu(x)}}[x \in E \text{ and } x' \in E]$$

(for some $\nu \in [1/32, 31/32]$ depending on σ, using Claim 19)

$$\leqslant C \cdot \delta^{1+\lambda} \quad \text{for some constant } C \text{ and } \lambda = 1/2^{14} \log s. \tag{6}$$

(Using spherical noise small-set expansion (Theorem 23))

Plugging the bounds (5) and (6) back in (4), we get

$$\Pr_{\substack{\pi,\mu, \\ \sigma \text{ good}}}[|V \cap E| = 1] \geqslant |U|\,\delta - |U|^2\, C\delta^{1+\lambda} \geqslant |U|\,\delta/2 \geqslant \delta.$$

The above inequalities follow from $|U| = 2^w$ and $\delta \leqslant \varepsilon_1$; this is where we set $\varepsilon_1 := (1/2C\,|U|)^{1/\lambda} = (1/2C2^w)^{2^{14}\log s} \geqslant 1/s^{O(\log(8\psi s^2)d)} \geqslant 1/s^{O(k)}$. Hence we conclude that

$$\Pr_{\pi,\sigma,\mu}[T_r \text{ rejects } f] \geqslant \Pr_{\sigma}[\sigma \text{ good}] \cdot \Pr_{\substack{\pi,\mu \\ \sigma \text{ good}}}[|U \cap E'| = 1] \geqslant \varepsilon \Pr_{\substack{\pi,\mu \\ \sigma \text{ good}}}[|V \cap E| = 1] \geqslant \varepsilon\delta. \qquad ◀$$

4 Low-degree testing

We will describe our low-degree test now.

The degree test (Deg)

Given query access to $f : \mathcal{S}^n \to \mathbb{F}$, the following test (called Deg) works to test whether f is degree-d. We may assume that $s = |\mathcal{S}| \geqslant 2$ as f is a constant function otherwise.

Test Deg(f): gets query access to $f : \mathcal{S}^n \to \mathbb{F}$.
- Run Junta-deg(f) to check if f is junta-degree-d.
- Run Weak-deg(f).
- Accept iff both the above tests accept.

In the above description, the sub-routine Weak-deg corresponds to the following test.

Test Weak-deg(f)**: gets query access to** $f : \mathcal{S}^n \to \mathbb{F}$**.**

- Choose a map $\mu : [n] \to [K]$ u.a.r. where $K = t(d+1)$ and $t = s^3$.
- For $y = (y_1, \ldots, y_K) \in \mathcal{S}^K$, define $x_\mu(y) = (y_{\mu(1)}, \ldots, y_{\mu(n)})$.
- Define the function $f' : \mathcal{B}(\mathcal{S}, t)^{K/t} \to \mathbb{F}$ as $f'(y) = f(x_\mu(y))$, where $\mathcal{B}(\mathcal{S}, t)$, defined in Section 2, is the "balanced" subset of $\mathcal{S}^t$.
- Accept iff f' is degree-d.

We now move on to the analysis of this test, proving Theorem 3.

Proof of Theorem 3. Let $g : \mathcal{S}^n \to \mathbb{F}$ be a closest junta-degree-d function to f i.e., $\delta_d(f) = \delta(f, g)$. We shall assume that $\delta_d(f) \leqslant \varepsilon_2$ for a small enough $\varepsilon_2 = K^{-O(K)}$, and neither f nor g are degree-d. Otherwise, we will be able to appeal to the correctness of Junta-deg.

Let $E \subseteq \mathcal{S}^n$ be the points where f and g differ; thus $|E|/s^n = \delta_d(f) \leqslant \varepsilon_2$. Let

$$V_\mu = \left\{ x_\mu(y) : y \in \mathcal{B}(\mathcal{S}, t)^{K/t} \right\}.$$

Suppose $\mu : [n] \to [K]$ is such that $V_\mu \cap E = \emptyset$ and Weak-deg rejects g. Then Weak-deg does not distinguish between f and g and hence rejects f as well. We will show that both these events occur with good probability. For the first probability, we will upper bound

$$\begin{aligned}\Pr_\mu\left[V_\mu \cap E \neq \emptyset\right] &= \Pr_\mu\left[\exists y \in \mathcal{B}(\mathcal{S}, t)^{K/t} : x_\mu(y) \in E\right] \\ &\leqslant \left|\mathcal{B}(\mathcal{S}, t)^{K/t}\right| \cdot \Pr_\mu\left[\text{For fixed arbitrary } y \in \mathcal{B}(\mathcal{S}, t)^{K/t}, x_\mu(y) \in E\right].\end{aligned}$$

Note that since all points in $\mathcal{B}(\mathcal{S}, t)^{K/t}$ contain an equal number of occurrences of all the elements of $\mathcal{S}$, $x_\mu(y)$ is uniformly distributed in $\mathcal{S}^n$ for a uniformly random μ. Hence, the above probability is

$$\Pr_\mu\left[V_\mu \cap E \neq \emptyset\right] \leqslant |\mathcal{S}|^K \cdot \frac{|E|}{s^n} \leqslant s^K \varepsilon_2 < \frac{1}{2K^d}. \qquad (\text{by setting } \varepsilon_2 := 1/4s^K K^d \geqslant K^{-O(K)})$$

We show that Weak-deg indeed rejects g with good probability.

▷ Claim 20. $\Pr_\mu[\text{Weak-deg rejects } g] \geqslant 1/K^d$.

Assuming this claim,

$$\begin{aligned}&\Pr[\text{Deg rejects } f] \geqslant \Pr[\text{Weak-deg rejects } f] \\ &\qquad \geqslant \Pr[\text{Weak-deg rejects } g] - \Pr[V_\mu \cap E \neq \emptyset] \geqslant \frac{1}{2K^d} \geqslant \frac{\delta_d'(f)}{2K^d}.\end{aligned}$$

This finishes the analysis of the low-degree test assuming Claim 20. ◀

4.1 Soundness of Weak-deg

Proof of Claim 20. We will need the following lemma about the vector space formed by functions over $\mathcal{B}(\mathcal{S}, t)^{K/t} \subseteq \mathcal{S}^K$.

▶ **Lemma 21.** *For $\mathcal{T} \subseteq \mathcal{S}^K$, the vector space of functions from $\mathcal{T}$ to $\mathbb{F}$ has a basis $\{m_1, \ldots, m_\ell\}$ such that for any $f : \mathcal{T} \to \mathbb{F}$ of the form $f = c_1 m_1 + \ldots c_\ell m_\ell$ for some $c_i \in \mathbb{F}$, we have*

$$f \text{ is degree-}d \iff \forall i,\ c_i = 0 \text{ or } m_i \text{ is degree-}d. \qquad (7)$$

Let $g' : \mathcal{B}(\mathcal{S},t)^{K/t} \to \mathbb{F}$ be defined as $g'(y) = g(x_\mu(y))$ where $x_\mu(y) = (y_{\mu(1)}, \dots, y_{\mu(n)})$. Then, recall that WEAK-DEG rejects g iff g' is not degree-d. We use Lemma 21 above to fix a suitable basis $m_1, \dots, m_\ell$ for functions from $\mathcal{T} = \mathcal{B}(\mathcal{S},t)^{K/t}$ to $\mathbb{F}$. Then we can write each $g'(y)$ obtained above uniquely as

$$g'(y) = \sum_{i=1}^{\ell} c_i \cdot m_i$$

where the coefficients c_i are some functions of μ. We will treat $\mu : [n] \to [K]$ as a random element of $[K]^n$.

We argue that each c_i is junta-degree-d (as a function of μ). To see this, we recall that g is junta-degree-d. Consider the case when g is a function of only $x_{i_1}, \dots, x_{i_s}$ for some $s \leqslant d$. In this case, clearly the polynomial g' depends only on $\mu_{i_1}, \dots, \mu_{i_s}$. In particular, each c_i is just an s-junta. Extending the argument by linearity, we see that for any g that is junta-degree-d, the underlying coefficients c_i of $g'(y)$ are junta-degree-d polynomials in the co-ordinates of μ.

Now assume that there exists a $\mu^* : [n] \to [K]$ such that $g'(y)$ is not degree-d (we will show the existence of such a "good" μ in the next subsection). Thus, by Lemma 21 there exists $i^* \in [\ell]$ such that m_{i^*} is not degree-d and $c_{i^*}(\mu^*) \neq 0$. In particular, the function c_{i^*} is non-zero.

We have argued that there is an m_{i^*} in the basis such that the associated coefficient c_{i^*} is a non-zero junta-degree-d polynomial. In particular, Claim 11 implies that the probability that $c_i^*(\mu) \neq 0$ for a random μ is at least $1/K^d$. Therefore, using Lemma 21,

$$\Pr_\mu[\text{WEAK-DEG rejects } g] = \Pr_\mu[g' \text{ is not degree-}d] \geqslant \Pr_\mu[c_{i^*}(\mu) \neq 0] \geqslant 1/K^d. \quad ◀$$

4.2 Existence of a good map μ

We will show for any function $g : \mathcal{S}^n \to \mathbb{F}$ that is not degree-d, there exists a map $\mu : [n] \to [K]$ such that the function $g'(y) = g(x_\mu(y))$ defined for $y \in \mathcal{B}(\mathcal{S},t)^{K/t}$ is also not degree-d. This is easy to prove if the domain of g' were to be $\mathcal{S}^K$, but is particularly tricky in our setting.

Let $D = d + 1$. We will give a map $\mu : [n] \to [t] \times [D] \equiv [tD] = [K]$ instead. Let P be the polynomial with individual degree at most $s - 1$ representing g; suppose the degree of P is $d' > d$ and let $m(x) = c \cdot x_{i_1}^{a_1} \cdots x_{i_\ell}^{a_\ell}$ be a monomial of $P(x)$ of degree d' for some non-zero $c \in \mathbb{F}$, where $a_j \geqslant 1$ for all j and $i_1, \dots, i_\ell$ are some distinct elements of $[n]$ and $\ell \leqslant d$ as g is junta-degree-d. Then, we define μ as follows for $i \in [n]$:

$$\mu(i) = \begin{cases} (1,j), & \text{if } i = i_j \text{ for some } j \in [\ell] \\ (1,D), & \text{otherwise.} \end{cases}$$

It is easy to inspect that $P(x_\mu(y))$ (call it $Q(y)$) is a polynomial in variables $y_{(1,1)}, \dots, y_{(1,D)}$, and is of degree $d' > d$ – this is because the monomial $m(x)$, upon this substitution turns to

$$m(x_\mu(y)) = c \cdot y_{(1,1)}^{a_1} \cdots y_{(1,\ell)}^{a_\ell},$$

which cannot be cancelled by $m'(x_\mu(y))$ for any other monomial $m'(x)$ of $P(x)$, as if m' contains the variable x_i for some $i \notin \{i_1, \dots, i_\ell\}$ then $m'(x_\mu(y))$ contains the variable $y_{(1,D)}$ and on the other hand if m' only contains variables x_i for some $i \in \{i_1, \dots, i_\ell\}$, then the individual degree of $y_{(1,j)}$ in the two substitutions differs for some j. Hence, the degree of $Q(y)$ is $a_1 + \cdots + a_\ell = d'$. As we can express the function $y_{(1,D)}^a$ for $a > s - 1$ as a polynomial in $y_{1,D}$ of individual degree at most $s-1$, we can further transform $Q(y)$ so that it has individual degree at most $s-1$, while maintaining the properties that it still only contains the variables $y_{(1,1)}, \ldots, y_{(1,D)}$ (i.e., the first "row") and has degree d' and computes the function $g'(y)$. The following claim then completes the proof of the existence of a good μ by setting $w = D$ and $d' = d'$.

▷ Claim 22. For formal variables $y \equiv (y_1, \ldots, y_w) \equiv (y_{(i,j)})_{(i,j)\in[t]\times[w]}$, let $Q(y)$ be a polynomial of degree $d' \geqslant 0$ containing only the variables from the first row. Then the degree of $Q(y)$ as a function over $\mathcal{B}(\mathcal{S}, t)^w$ is exactly d'.

The proof of the above claim is deferred to Appendix C.

5 Small-set expansion for spherical noise

In this section, we will prove a small-set expansion theorem for spherical noise, which we have used for (6) in the proof of the small-distance lemma of junta-degree testing. Let $f : \mathbb{Z}_s^n \to \mathbb{C}$ be arbitrary. For $\nu \in [0,1]$ the Bernoulli noise operator is defined as $N_\nu f(x) = \mathbb{E}_{y\sim N_\nu(x)}[f(y)] = \mathbb{E}_{y\sim \mathcal{D}_\nu^{\otimes n}}[f(x+y)]$. Similarly, the spherical noise operator is defined for $\nu \in [0,1]$ such that $\nu n \in \mathbb{Z}$: $S_\nu f(x) = \mathbb{E}_{y\sim S_\nu(x)}[f(y)] = \mathbb{E}_{y\sim\mathcal{E}_\nu}[f(x+y)]$. For the rest of this section, let $\rho \in [0,1]$ and $\nu = (1-1/s)(1-\rho) \in [0,1]$; it is easy to check that if each coordinate of x is retained with probability ρ and randomized (uniformly over $\mathbb{Z}_s$) with probability $1-\rho$, the resulting string is distributed according to $N_\nu(x)$.

The goal of this section is to show for $s \geqslant 3$, that we can reduce the problem of small-set expansion for spherical noise to that of Bernoulli noise, for which such a theorem is already known.

▶ **Theorem 23** (Small-set expansion for spherical noise). *Let $s \geqslant 3$ and $A \subseteq \mathbb{Z}_s^n$ be such that $\Pr_{x\sim\mathbb{Z}_s^n}[x \in A] = \delta$. Then, for any $\nu \in [1/32, 1]$*

$$\Pr_{\substack{x\sim\mathbb{Z}_s^n\\ y\sim S_\nu(x)}}[x \in A \text{ and } y \in A] \leqslant 2 \cdot \delta^{1+\lambda}, \tag{8}$$

where $\lambda = \frac{1}{2^{14}\log s}$.

▶ Remark. When the size of the domain s is equal to 2 and $\nu \in [1/32, 31/32]$, the above statement still holds (with the factor 2 replaced with some other constant factor C) as proved by [23] (or Corollary 2.8 in [7]).

Proof of Theorem 23. Let $f : \mathbb{Z}_s^n \to \mathbb{C}$ be the indicator function of A and consider its Fourier representation as in Definition 13: $f(x) = \sum_{\alpha\in\mathbb{Z}_s^n} \widehat{f}(\alpha)\chi_\alpha(x)$. Then the probability in (8) is equal to

$$\Pr_{\substack{x\sim\mathbb{Z}_s^n\\ y\sim S_\nu(x)}}[x \in A \text{ and } y \in A] = \sum_{\alpha\in\mathbb{Z}_s^n} \left|\widehat{f}(\alpha)\right|^2 \mathop{\mathbb{E}}_{y\sim\mathcal{E}_\nu}[\chi_\alpha(y)]\,. \tag{9}$$

We will show that for any $\alpha \in \mathbb{Z}_s^n$, the quantity $\mathbb{E}_{y\sim\mathcal{E}_\nu}[\chi_\alpha(y)]$ above is upper bounded by $2 \cdot \widetilde{\rho}^{\#\alpha}$ for some constant $\widetilde{\rho}$. We have

$$\mathop{\mathbb{E}}_{y\sim\mathcal{E}_\nu}[\chi_\alpha(y)] = \mathop{\mathbb{E}}_{y\sim\mathcal{E}_\nu}[\chi_{\alpha_1}(y_1)\cdots\chi_{\alpha_n}(y_n)] = \mathop{\mathbb{E}}_{\substack{I\sim\binom{[n]}{\nu n}\\ \mu\sim\mathbb{Z}_s\setminus\{0\}\\ y\sim 0^{\overline{I}}\circ\mu^I}}\left[\prod_{i\in I}\chi_{\alpha_i}(y_i)\prod_{i\notin I}\chi_{\alpha_i}(y_i)\right]$$

(where I and μ are independent)

$$= \mathop{\mathbb{E}}_{I,\mu,y}\left[\prod_{i\in I}\chi_{\alpha_i}(\mu_i)\right] \qquad \text{(where } I \sim \tbinom{[n]}{\nu n}, \mu \sim \mathbb{Z}_s \setminus \{0\}, \text{ and } y \sim 0^{\overline{I}} \circ \mu^I\text{)}$$

$$= \mathop{\mathbb{E}}_{I}\left[\prod_{i\in I}\mathop{\mathbb{E}}_{\mu_i\sim\mathbb{Z}_s\setminus\{0\}}[\chi_{\alpha_i}(\mu_i)]\right]. \tag{10}$$

Now we note that the inner term

$$\mathop{\mathbb{E}}_{\mu_i\sim\mathbb{Z}_s\setminus\{0\}}[\chi_{\alpha_i}(\mu_i)] = \begin{cases} 1, \text{ if } \alpha_i = 0, \text{ and} \\ \frac{1}{s-1}\left(\sum_{\mu_i\in\mathbb{Z}_s\setminus\{0\}}\chi_{\alpha_i}(\mu_i)\right) = \frac{1}{s-1}\left(s\,\mathbb{E}_{\mu_i\sim\mathbb{Z}_s}[\chi_{\alpha_i}(\mu_i)] - 1\right) = \frac{-1}{s-1} \text{ otherwise.}\end{cases} \tag{11}$$

Therefore, denoting the coordinates of α with non-zero entries by $J \subseteq [n]$, plugging (11) into (10) gives

$$\mathop{\mathbb{E}}_{y\sim\mathcal{E}_\nu}[\chi_\alpha(y)] = \mathop{\mathbb{E}}_{I\sim\binom{[n]}{\nu n}}\left[\left(\frac{-1}{s-1}\right)^{|J\cap I|}\right] \leqslant \mathop{\mathbb{E}}_{I\sim\binom{[n]}{\nu n}}\left[\left(\frac{1}{2}\right)^{|J\cap I|}\right] \qquad \text{(as } s \geqslant 3\text{)}$$

$$\leqslant \mathop{\Pr}_{I\sim\binom{[n]}{\nu n}}[|J\cap I| < \nu k/2]\cdot 1 + \mathop{\mathbb{E}}_{I\sim\binom{[n]}{\nu n}}\left[\left(\frac{1}{2}\right)^{|J\cap I|} \middle| \, |J\cap I| \geqslant \nu k/2\right].$$

Denoting $|J| = \#\alpha$ by k, we observe that $|J\cap I|$ is distributed according to the hypergeometric distribution of k draws (without replacement) from a population of size n and νn many success states. Hence, by a tail bound [16] $\Pr[|J\cap I| < \nu k/2] \leqslant e^{-\nu^2 k/2}$ and using $\nu \geqslant 1/32$, we get that $\mathbb{E}_{y\sim\mathcal{E}_\nu}[\chi_\alpha(y)] \leqslant \Pr_{I\sim\binom{[n]}{\nu n}}[|J\cap I| < \nu k/2]\cdot 1 + \mathbb{E}_{I\sim\binom{[n]}{\nu n}}\left[\left(\frac{1}{2}\right)^{|J\cap I|} \middle| \, |J\cap I| \geqslant \nu k/2\right] \leqslant 2\cdot\widetilde{\rho}^k$ for $\widetilde{\rho} := 2^{-2^{-11}}$.

Plugging the above bound in (9), letting $\widetilde{\nu} = (1-1/s)(1-\widetilde{\rho})$ and $q = 2+\varepsilon = 2 + \frac{1}{2^{12}\log s}$, we get

$$\mathop{\Pr}_{\substack{x\sim\mathbb{Z}_s^n\\ y\sim S_\nu(x)}}[x \in A \text{ and } y \in A] \leqslant 2\sum_{\alpha\in\mathbb{Z}_s^n}\left|\widehat{f}(\alpha)\right|^2 \widetilde{\rho}^{\#\alpha} = 2\mathop{\Pr}_{\substack{x\sim\mathbb{Z}_s^n\\ y\sim N_{\widetilde{\nu}}(x)}}[x \in A \text{ and } y \in A] \leqslant 2\delta^{2-2/q},$$

where the last step uses the small-set expansion theorem corresponding to Bernoulli noise (e.g. Theorem 10.25 in [21]). ◀

A Existence of the code U

In order to prove Claim 18 we will need the following:

▷ Claim 24. There exists a matrix $M \in \mathbb{F}_2^{k\times w}$ such that $U := \{Mz : z \in \mathbb{F}_2^w\} \subseteq \mathbb{F}_2^k$ is if size 2^w and:

- For all $y \neq y' \in U$, we have $k/4 \leqslant \Delta(y, y') \leqslant 3k/4$.
- There exists a function $\chi : U \to \{\pm 1\}$ such that for all $I \in \binom{[k]}{\leqslant d}$, we have

$$\sum_{y\in U:\ y^I=1^I} \chi(y) = 0.$$

Proof. We will show that picking M uniformly at random satisfies both the items with positive probability. For Item 1, if suffices if for all $y \neq 0^k$ in U, $k/4 \leqslant \#y \leqslant 3k/4$; that is, for all $z \in \mathbb{F}_2^a \setminus \{0^{d+1}\}$, $k/4 \leqslant \#Mz \leqslant 3k/4$. For any fixed $z \neq 0^a$, we note that $y = Mz$ is uniformly distributed over $\mathbb{F}_2^k$ as $M \sim \mathbb{F}_2^{k\times w}$. Hence, by a Chernoff bound, we have $\Pr_M[\#Mz \notin [k/4, 3k/4]] \leqslant 2e^{-k/24}$. A union bound over all $z \in \mathbb{F}_2^w \setminus \{0^w\}$ gives

$$\Pr_M\left[\neg\left(\forall y \neq y' \in U,\ k/4 \leqslant \Delta(y, y') \leqslant 3k/4\right)\right] \leqslant 2^w \cdot 2e^{-k/24} < 1/2.$$

However, it is a known fact that a uniformly chosen rectangular matrix has full rank with probability at least 1/2. Therefore, with positive probability there must be a matrix M such that it is full rank and Item 1 holds. We fix such an M and prove Item 2.

For $y \in U$, as M is full rank there exists a unique $z \in \mathbb{F}_2^w$ such that $Mz = y$. Then we define

$$\chi(y) := (-1)^{\langle z,\eta\rangle} = (-1)^{z_1\eta_1+\cdots+z_w\eta_w},$$

where $\eta \in \mathbb{F}_2^w$ is an arbitrary vector such that it is not in the $\mathbb{F}_2^w$-span of any d rows of M. Such an η always exists as the number of vectors that *can* be expressed as a linear combination of d rows of M is at most

$$\binom{k}{d}2^d \leqslant \left(\frac{ek}{d}\right)^d 2^d = \left(2e\psi s^2\right)^d < 2^w,$$

the total number of vectors in $\mathbb{F}_2^w$.

Let $M_1, \ldots, M_k \in \mathbb{F}_2^w$ denote the rows of M. For any $I \in \binom{[k]}{\leqslant d}$ and $y = Mz$, the condition $y^I = 1^I$ is equivalent to: $\langle z, M_i\rangle = 1$ for all $i \in I$. Hence we have

$$\sum_{y\in U:\ y^I=1^I} \chi(y) = \sum_{z\in\mathbb{F}_2^a:\ \forall i\in I,\ \langle z,M_i\rangle=1} (-1)^{\langle z,\eta\rangle} \tag{12}$$

As η is linearly independent with $\{M_i\}_{i\in I}$, there exists $\eta' \neq 0^a$ such that $\langle \eta', M_i\rangle = 0$ for all $i \in I$ and $\langle \eta', \eta\rangle = 1$: this is because we can treat these conditions as a system of linear equations over $\mathbb{F}_2$.

Note that for any $z \in \mathbb{F}_2^w$, $\langle z, M_i\rangle = 1$ if and only if $\langle z + \eta', M_i\rangle = \langle z, M_i\rangle + \langle \eta', M_i\rangle = 1$. Since $z \neq z + \eta'$, we may partition the summation (12) into buckets of size 2, each bucket corresponding to z and $z + \eta'$ for some z. For each such bucket, the sum is

$$(-1)^{\langle z,\eta\rangle} + (-1)^{\left\langle z+\eta',\eta\right\rangle} = (-1)^{\langle z,\eta\rangle} + (-1)^{\langle z,\eta\rangle+\left\langle \eta',\eta\right\rangle} = (-1)^{\langle z,\eta\rangle}\left(1 + (-1)^{\left\langle \eta',\eta\right\rangle}\right) = 0,$$

so the overall sum is also 0. ◁

Using this result, we will prove Claim 18:

Proof of Claim 18. Identifying the 0's (resp. 1's) in $\mathbb{F}_2$ and $\mathbb{Z}_s$, we will rephrase the above claim as U being a subset of $\mathbb{Z}_s^k$ instead of $\mathbb{F}_2^k$: Then, this set $U \subseteq \{0,1\}^k \subseteq \mathbb{Z}_s^k$ immediately satisfies Item 1 of Claim 18. For Item 2, it suffices to show that for any non-zero junta-degree-d function $P : \mathbb{Z}_s^k \to \mathcal{G}$,

$$\sum_{y \in U} P(y) \cdot \chi(y) = 0 \tag{13}$$

where $\chi : \{0,1\}^k \to \mathbb{Z}$ is from Claim 24. Towards a contradiction, suppose that a junta-degree-d function P has exactly one point in $y^* \in U$ such that $P(y^*) \neq 0$. Then using (13), $0 + \cdots + 0 + P(y^*) \cdot \chi(y^*) + 0 + \cdots + 0 = 0$ and as $\chi(y^*) = \pm 1$, $P(y^*) = 0$, a contradiction.

To prove (13), we expand P into its junta-polynomial representation:

$$\begin{aligned}\sum_{y \in U} P(y) \cdot \chi(y) &= \sum_{y \in U} \sum_{\substack{a \in {\mathbb{Z}_s}^k \\ \#a \leqslant d}} g_a \cdot \left(\prod_{i \in [k]:\ a_i \neq 0} \delta_{a_i}(y_i) \right) \chi(y) \\ &= \sum_{\substack{a \in {\mathbb{Z}_s}^k \\ \#a \leqslant d}} g_a \cdot \left(\sum_{y \in U} \chi(y) \prod_{i \in [k]:\ a_i \neq 0} \delta_{a_i}(y_i) \right)\end{aligned}$$

For any $a \in \mathbb{Z}_s^k$, letting $I := \{i \in [k] : a_i \neq 0\}$, the inner factor is

$$\sum_{y \in U} \chi(y) \prod_{i \in [k]:\ a_i \neq 0} \delta_{a_i}(y_i) = \sum_{y \in U:\ y^I = a^I} \chi(y).$$

Now if a contains any coordinates taking values other than 0 and 1, the above sum is 0 since all the coordinates of $y \in U$ are either 0 or 1. On the other hand, if $a \in \{0,1\}^k$, then $a^I = 1^I$ and Claim 24 is applicable, again giving a sum of 0. Therefore,

$$\sum_{y \in U} P(y) \cdot \chi(y) = \sum_{\substack{a \in \mathcal{S}^k \\ \#a \leqslant d}} g_a \cdot \left(\sum_{y \in U} \chi(y) \prod_{i \in [k]:\ a_i \neq 0} \delta_{a_i}(y_i) \right) = \sum_{\substack{a \in \mathcal{S}^k \\ \#a \leqslant d}} g_a \cdot 0 = 0. \qquad \triangleleft$$

B Proof of the large-distance lemma

Proof of Lemma 16. For this proof, we may assume without loss of generality that $I = [r]$ as relabelling the variables does not affect the probability of a random restriction (i.e., $x_j = \pi_j(x_i)$) being ε_0-close to junta-degree-d. We will prove the contrapositive: assuming $\delta_d(f_{r-1}) \leqslant \varepsilon_0$ for more than $k^2/2r(r-1)$ fraction of choices of (i, j, π_j) (call these *bad* restrictions), we will construct a junta-degree-d function P such that $\delta(f_r, P) \leqslant \varepsilon_1$. Like in [7, 10], the high level idea is to "stitch" together low-junta-degree functions corresponding to the restrictions f_{r-1} (which we shall call $P^{(h)}$) into a low-junta-degree function that is close to f_r.

As there are more than $\frac{k^2}{2r(r-1)} r(r-1)s! = k^2 s!/2$ many bad tuples (i, j, π_j), by pigeonhole principle, there must be some permutation $\pi : \mathbb{Z}_s \to \mathbb{Z}_s$ such that the number of bad tuples of the form (i, j, π) is more than $k^2/2$. In fact, we can say something more: Consider the directed graph G_{bad} over vertices $[r]$ with a directed edge (i, j) for each bad tuple (i, j, π).

As the number of edges in G_{bad} is at least $k^2/2$, by the pigeon-hole principle, we can conclude that there is a *matching* or a *star*[9] in G_{bad} of size $L := k/4$. For the rest of the proof, we will handle both the cases in parallel as the differences are minor.

Suppose we are in the matching case and the corresponding bad tuples are

$$(i_1, j_1, \pi), \dots (i_L, j_L, \pi),$$

where $i_1, \dots, i_L, j_1, \dots, j_L$ are all distinct. Let id denote the identity permutation of $\mathbb{Z}_s$. Consider the function $\widetilde{f}_r(x_1, \dots, x_r)$ obtained by replacing the variables $x_{i_1}, \dots, x_{i_L}$ in f_r with $\pi(x_{i_1}), \dots, \pi(x_{i_L})$ respectively. Then, $\delta_d(\widetilde{f}_r) = \delta_d(f_r)$ and (i_h, j_h, π) is a bad restriction for f_r if and only if (i_h, j_h, id) is a bad restriction for $\widetilde{f}_r$, for all $h \in [L]$. Moreover, if $\widetilde{f}_r$ satisfies $\delta(\widetilde{P}, \widetilde{f}_r) \leqslant \varepsilon_1$, then there also exists a junta-degree-d P such that $\delta(P, f_r) \leqslant \varepsilon_1$ (obtained from $\widetilde{P}$ by applying the inverse permutation π^{-1} to $x_{i_1}, \dots, x_{i_L}$). Therefore, without loss of generality we may assume that $\pi = id$ to construct a junta-degree-d function P such that $\delta(P, f_r) \leqslant \varepsilon_1$. A similar reduction holds in the star case.

We may further assume w.l.o.g. that the matching case corresponds to the tuples

$$(L+1, 1, id), (L+2, 2, id), \dots (2L, L, id)$$

and the star case corresponds to

$$(r, 1, id), (r, 2, id), \dots, (r, L, id).$$

For $h \in [L]$, we define

$$R_h := \begin{cases} \{x \in \mathbb{Z}_s^r : x_{L+h} = x_h\} \text{ in the matching case,} \\ \{x \in \mathbb{Z}_s^r : x_h = x_r\} \text{ in the star case.} \end{cases}$$

as the points that agree with the h-th bad restriction (i, j, π) in the matching or star case correspondingly. Let R'_h denote the complement of R_h. Then for any function $P : \mathbb{Z}_s^r \to \mathcal{G}$,

$$\Pr_{x \sim \mathbb{Z}_s^r}[f_r(x) \neq P(x)] \leqslant \Pr_x\left[x \notin \bigcup_{h \leqslant L} R_h\right] + \sum_{h \leqslant L} \Pr_x\left[x \in R_h \setminus \bigcup_{h' < h} R'_h\right] \cdot \Pr_x\left[f_r(x) \neq P(x) \,\middle|\, x \in R_h \setminus \bigcup_{h'<h} R_{h'}\right] \tag{14}$$

To estimate the above probabilities, we note that in both the matching or the star case, $\Pr_{x \sim \mathbb{Z}_s^r}\left[x \notin \bigcup_{h \leqslant L} R_h\right] = \Pr_x\left[x \in \bigcap_{h \leqslant L} R'_h\right] = \left(1 - \frac{1}{s}\right)^L$, and $\Pr_{x \sim \mathbb{Z}_s^r}\left[x \in R_h \setminus \bigcup_{h'<h} R_{h'}\right] = \Pr_x\left[x \in R_h \cap \bigcap_{h'<h} R'_{h'}\right] = \frac{1}{s}\left(1 - \frac{1}{s}\right)^{h-1}$.

For $h \in [L]$, let $f_{r-1}^{(h)} : \mathbb{Z}_s^r \to \mathcal{G}$ be the restricted function corresponding to the h-th bad tuple, treated as a function of all the r many variables (rather than $r-1$). Let $P^{(h)}$ denote the junta-degree-d function that is of distance at most ε_0 from $f_{r-1}^{(h)}$. We will use the following claim that there is a junta-degree-d function P that agrees with $P^{(h)}$ over R_h, for all h.

▷ Claim 25. There exists a junta-degree-d function P such that $P(x) = P^{(h)}(x)$ for all $h \in [L]$ and $x \in R_h$.

[9] A matching is a set of disjoint edges and a star is a set of edges that share a common start vertex, or a common end vertex.

We defer its proof to the full version and only mention here that the idea is to first show for $h \neq h' \leqslant L$ that $P^{(h)}|_{h'} = P^{(h')}|_h$, since both these functions agree (with $f^{(h)}_{r-1}$ and $f^{(h')}_{r-1}$) over a "large" subset $R_h \cap R_{h'}$ of their domain. Then one can interpolate the restricted functions into a junta-degree-d function P. Then for such P and any $h \leqslant L$,

$$\begin{aligned}\Pr_x\left[f_r(x) \neq P(x) \middle| x \in R_h \setminus \bigcup_{h'<h} R_{h'}\right] &\leqslant \frac{\Pr_x\left[f_r(x) \neq P(x) \mid x \in R_h\right]}{\Pr\left[x \in R_h \setminus \bigcap_{h'<h} R_{h'} \mid x \in R_h\right]} \\ &= \frac{\Pr_x\left[f_r(x) \neq P(x) \mid x \in R_h\right]}{\left(1-\frac{1}{s}\right)^{h-1}} \\ &\leqslant \left(\frac{s}{s-1}\right)^{h-1} \varepsilon_0.\end{aligned}$$

Then we can bound (14) as $\Pr_{x\sim\mathbb{Z}_s^r}\left[f_r(x) \neq P(x)\right] \leqslant \left(1-\frac{1}{s}\right)^L + \frac{L\varepsilon_0}{s} \leqslant \varepsilon_1/2 + \varepsilon_1/2 = \varepsilon_1$ as we can set $\varepsilon_0 := 2s\varepsilon_1/k \geqslant 1/s^{O(k)}$ and

$$\left(1-\frac{1}{s}\right)^{k/4} \leqslant e^{-k/4s} = e^{-\psi sd/4} \leqslant \frac{1}{2}\left(\frac{1}{2C2^{\lceil \log(8\psi s^2)d\rceil}}\right)^{2^{14}\log s} = \frac{\varepsilon_1}{2}.$$

(for the last inequality, we can take ψ to be a sufficiently large constant)

◀

C Proof of Claim 22

Proof of Claim 22. The proof is by induction on w. The base case $w = 1$ is crucial and it is equivalent to the following claim:

▷ Claim 26. For $0 \leqslant d' \leqslant s-1$, the function $f_{d'} : \mathcal{B}(\mathcal{S}, t) \to \mathbb{F}$ defined as $f_{d'}(z) = z_1^{d'}$ for $z = (z_1, \ldots, z_t) \in \mathcal{B}(\mathcal{S}, t)$ has degree exactly d'.

Assuming the above claim to be true, let $w > 1$ be arbitrary. As $d' = 0$ is trivial to handle, we will assume that $d' \geqslant 1$. Hence, Q contains at least one monomial m of degree d' and containing some variable $y_{(1,j)}$ with individual degree $a \in [s-1]$. Without loss of generality, suppose $j = w$. Since Claim 26 states that the function $y^a_{(1,w)}$ is linearly independent of degree-$(a-1)$ functions over $\mathcal{B}(\mathcal{S}, t)$, there exists a function $C : \mathcal{B}(\mathcal{S}, t) \to \mathbb{F}$ such that for any $f : \mathcal{B}(\mathcal{S}, t) \to \mathbb{F}$

$$\langle C, f\rangle = \begin{cases} 1 \text{ if } f = y^a_{(1,w)} \text{ i.e., } a\text{-th power of the last coordinate} \\ 0 \text{ if } f \text{ is degree-}(a-1). \end{cases} \tag{15}$$

Now we decompose Q as a polynomial over variables in the first $w-1$ columns and coefficients being the monomials over variables in the last column: that is

$$Q(y) = \sum_{\alpha\in[0..a]} Q'_\alpha(y_1, \ldots, y_{w-1}) \cdot y^\alpha_{(1,w)}, \tag{16}$$

where y_j represents the variables in the j-th column $Q'_a \neq 0$ has degree $d' - a$. Here, we are using the fact that Q only contains variables from the first row.

Towards a contradiction, suppose there is some degree-$(d'-1)$ polynomial $R(y)$ such that $Q(y) = R(y)$ for all $y \in \mathcal{B}(\mathcal{S}, t)^w$. We may decompose R as follows:

$$R(y) = \sum_{\alpha \in [0..s-1]^t} R'_\alpha(y_1, \ldots, y_{w-1}) \cdot y_w^\alpha$$

where $y_w^\alpha = y_{(1,w)}^{\alpha_1} \cdots y_{(t,w)}^{\alpha_t}$ and for all α, either $R'_\alpha = 0$ or is of degree (as a formal polynomial) at most $d' - 1 - |\alpha|_1$, where $|\alpha|_1 = \alpha_1 + \cdots + \alpha_t$.

Fixing $y_1, \ldots, y_{w-1} \in \mathcal{B}(\mathcal{S}, t)$ to arbitrary values and treating $Q(y)$ and $R(y)$ as functions of y_w, we get

$$\begin{aligned}
\langle C, Q(y_1, \ldots, y_{w-1}, y_w) \rangle &= \left\langle C, \sum_{\alpha \in [0..a]} Q'_\alpha(y_1, \ldots, y_{w-1}) \cdot y_{(1,w)}^\alpha \right\rangle \\
&= \sum_{\alpha \in [0..a]} Q'_\alpha(y_1, \ldots, y_{w-1}) \cdot \left\langle C, y_{(1,w)}^\alpha \right\rangle \\
&= Q'_a(y_1, \ldots, y_{w-1}). && \text{(using (15))}
\end{aligned}$$

Similarly,

$$\begin{aligned}
\langle C, R(y_1, \ldots, y_{w-1}, y_w) \rangle &= \left\langle C, \sum_{\alpha \in [0..s-1]^t} R'_\alpha(y_1, \ldots, y_{w-1}) \cdot y_w^\alpha \right\rangle \\
&= \sum_{\alpha \in [0..s-1]^t :\ |\alpha|_1 \geqslant a} R'_\alpha(y_1, \ldots, y_{w-1}) \cdot \langle C, y_w^\alpha \rangle && \text{(using (15))}
\end{aligned}$$

As a polynomial in the variables of $y_1, \ldots, y_{w-1}$, the final expression above is of degree at most $d' - 1 - |\alpha|_1 \leqslant d' - 1 - a$. However, as a function it is equivalent to Q'_a, which has a strictly higher degree, $d' - a$. This contradicts the induction hypothesis. ◁

Improved Local Computation Algorithms for Constructing Spanners

Abstract

A spanner of a graph is a subgraph that preserves lengths of shortest paths up to a multiplicative distortion. For every k, a spanner with size $O(n^{1+1/k})$ and stretch $(2k+1)$ can be constructed by a simple centralized greedy algorithm, and this is tight assuming Erdős girth conjecture.

In this paper we study the problem of constructing spanners in a local manner, specifically in the Local Computation Model proposed by Rubinfeld et al. (ICS 2011).

We provide a randomized Local Computation Agorithm (LCA) for constructing $(2r-1)$-spanners with $\tilde{O}(n^{1+1/r})$ edges and probe complexity of $\tilde{O}(n^{1-1/r})$ for $r \in \{2,3\}$, where n denotes the number of vertices in the input graph. Up to polylogarithmic factors, in both cases, the stretch factor is optimal (for the respective number of edges). In addition, our probe complexity for $r = 2$, i.e., for constructing a 3-spanner, is optimal up to polylogarithmic factors. Our result improves over the probe complexity of Parter et al. (ITCS 2019) that is $\tilde{O}(n^{1-1/2r})$ for $r \in \{2,3\}$. Both our algorithms and the algorithms of Parter et al. use a combination of neighbor-probes and pair-probes in the above-mentioned LCAs.

For general $k \geq 1$, we provide an LCA for constructing $O(k^2)$-spanners with $\tilde{O}(n^{1+1/k})$ edges using $O(n^{2/3}\Delta^2)$ neighbor-probes, improving over the $\tilde{O}(n^{2/3}\Delta^4)$ algorithm of Parter et al.

By developing a new randomized LCA for graph decomposition, we further improve the probe complexity of the latter task to be $O(n^{2/3-(1.5-\alpha)/k}\Delta^2)$, for any constant $\alpha > 0$. This latter LCA may be of independent interest.

1 Introduction

A spanner is a sparse structure that is a subgraph of the input graph and preserves, up to a predetermined multiplicative factor, the pairwise distance of vertices. Formally, a k-spanner of a graph $G = (V, E)$ is a graph $G' = (V, E')$ such that $E' \subseteq E$, in which the distance between any pair of vertices in G' is at most k times longer than the corresponding distance in G. k is referred to as the *stretch* of the spanner.

Spanners have numerous applications in a wide variety of fields such as communication networks [4, 29, 30], biology [5] and robotics [11, 16]. Consequently, the problem of constructing spanners has been studied extensively in several models, such as the distributed model [6, 12, 13, 14, 15, 17, 31], streaming algorithms [1, 22] and dynamic algorithms [10, 9].

This problem was also considered in the realm of sublinear algorithms and in particular in the model of *Local computation algorithms* (LCAs) introduced by Rubinfeld et al. [32] (see also Alon et al. [2] and survey in [24]). In this model the goal is to avoid computing the entire output and instead to compute parts of the output on demand. This model is suitable for the case that not only the input is massive but also the output. Moreover, LCAs support queries from different users while preserving consistency with a single valid solution (although there might be several valid solutions) across different queries. The notion of computing the output locally goes back to local algorithms, locally decodable codes and local reconstruction algorithms. LCAs can be viewed as a generalization of these frameworks.

Recently, several works [26, 25, 23, 28] considered the problem of constructing spanners in the LCA model. The formulation of the problem in this model is as defined next.

▶ **Definition 1** ([2, 26]). *An* LCA $\mathcal{A}$ *for graph* spanners *is a (randomized) algorithm with the following properties.* $\mathcal{A}$ *has access to the adjacency list oracle* $\mathcal{O}^G$ *of the input graph* G*, a tape of random bits, and local read-write computation memory. When given an input (query) edge* $(u, v) \in E$*,* $\mathcal{A}$ *accesses* $\mathcal{O}^G$ *by making probes, then returns* YES *if* (u, v) *is in the spanner* H*, or returns* NO *otherwise. This answer must only depend on the query* (u, v)*, the graph* G*, and the random bits. For a fixed tape of random bits, the answers given by* $\mathcal{A}$ *to all possible edge queries, must be consistent with one particular sparse spanner.*

For specific details regarding the types of probes supported in the LCA model, we refer the reader to Section 2.

1.1 Our Results

We provide LCAs that with high probability construct the following spanners.

1. A 3-spanner with $\tilde{O}(n^{1+1/2})$ edges. The probe and time complexity of the algorithm is $\tilde{O}(n^{1/2})$ which is optimal up to polylogarithmic factors (and constitutes the first optimal algorithm for general graphs). The size-stretch trade-off is optimal as well (up to polylogarithmic factors). This improves over the algorithm of Parter et al. [28] whose probe and time complexity is $\tilde{O}(n^{3/4})$.
2. A 5-spanner with $\tilde{O}(n^{1+1/3})$ edges (the size-stretch trade-off is optimal up to polylogarithmic factors). The probe and time complexity of the algorithm is $\tilde{O}(n^{2/3})$. This improves over the algorithm of Parter et al. [28] whose probe and time complexity is $\tilde{O}(n^{5/6})$.
3. An $O(k^2)$-spanner with $\tilde{O}(n^{1+1/k})$ edges with high probability. The probe and time complexity of the algorithm is $O(n^{2/3}\Delta^2)$ where Δ denotes the maximum degree of the input graph. This improves over the algorithm of Parter et al. [28] whose probe and time complexity is $\tilde{O}(n^{2/3}\Delta^4)$. Our algorithm (and the algorithm of [28]) uses only neighbor probes for this task.
4. By additionally taking advantage of adjacency probes we further improve the probe and time complexity of the latter algorithm to be $O(n^{2/3-(1.5-\alpha)/k}\Delta^2)$, for any constant $\alpha > 0$. This result utilizes a new, efficient local computation algorithm for decomposing a graph into subgraphs with improved maximum degree that may be of independent interest.

1.2 Our algorithms and techniques

We next describe our algorithms in high-level. Our LCAs for constructing 3-spanners and 5-spanners share similarities with the LCAs in [28] (which are inspired by the algorithm of Baswana and Sen for constructing spanners [7]). The main novelty of our algorithms is in selecting several sets of centers, each designed to cluster different type of vertices. The basic idea is that for high-degree vertices we need to select less centers. Consequently, we can allow more edges per pair of vertex-cluster or cluster-cluster which decreases the probe complexity. To support this approach we also change the way each vertex finds its center. See more details in Subsections 1.3 and 1.4.

Our algorithm for constructing $O(k^2)$-spanners consists of two parts. The first, which is described in high-level is Subsection 1.5, closely follows the construction in [28]. The main novelty in this algorithm is in the way we partition the Voronoi cells, which are formed with respect to randomly selected centers, into clusters of smaller size. In addition, we make other adjustments in order to save an additional factor of Δ in the probe and time complexity. The second is a new LCA for decomposing a graph into subgraphs of smaller maximum degree. As the first algorithm depends quadratically on the degree, this allows for further savings. We elaborate on this algorithm, which may be of independent interest, in Subsection 1.6.

1.3 Algorithm for constructing 3-spanners

We begin with describing our algorithm for constructing 3-spanners from a global point of view. The local implementation of this global algorithm is relatively straight-forward.

The high level idea is as follows. We consider a partition of the vertices into *heavy* and *light* according to their degrees. All the edges incident to light vertices are added to the spanner. We now focus on the heavy vertices. As a first step, a random subset of vertices is selected. We refer to these vertices as *centers*. With high probability, every heavy vertex has a center in its neighborhood. Assuming this event occurs, each heavy vertex joins a *cluster* of at least one of the centers in its neighborhood. A cluster is composed from a center and a subset of its neighbors. On query $\{u, v\}$, where both u and v are heavy, we consider two cases.

1. u and v belong to the same cluster. In this case we add the edge $\{u, v\}$ to the spanner only in case u is the center of v or vice versa.
2. Otherwise, u and v belong to different clusters. Assume without loss of generality that the degree of v is not greater than the degree of u. We divide the edges incident to v into fixed size *buckets* and add the edge $\{u, v\}$ only if it has minimum rank amongst the edges that are incident to the cluster of u.

In order to make the above high-level description concrete we need to set up some parameters and describe how the centers are selected and how each vertex finds its center. We begin by defining vertices with degrees larger than $\sqrt{n}$ as heavy. Thus by adding all the edges incident to light vertices we add at most $O(n^{3/2})$ edges.

The selection of the centers proceeds as follows. We define $t = \Theta(\log \sqrt{n})$ sets of centers, which are picked uniformly at random, $S_1, \ldots, S_t$ such that the size of S_1 is $\Theta(\sqrt{n})$ and the size of S_{i+1} is roughly half of the size of S_i. Thus, overall, the number of centers is $\tilde{O}(\sqrt{n})$.

We next describe how each heavy vertex finds its center. We partition the heavy vertices into t sets, $V_1, \ldots, V_t$ according to their degrees. The set V_1 contains all the vertices with degree in $[\sqrt{n} + 1, 2\sqrt{n}]$ and in general for every $i \in [t]$, the set V_i contains all the vertices with degree in $[2^{i-1}\sqrt{n} + 1, 2^i\sqrt{n}]$. The centers for vertices in the set V_i are taken from the set S_i. With high probability, for every $i \in [t]$, each vertex $v \in V_i$ has at least one vertex from S_i in its neighborhood and at most $O(\log n)$. Thus, with high probability, each heavy vertex belongs to at least one cluster and at most $O(\log n)$ clusters.

Given a heavy vertex $v \in V_i$, the centers of v are found by going over all the vertices in S_i, u, and checking if $\{u, v\}$ is an edge in the graph. Since the total number of centers is $\tilde{O}(\sqrt{n})$, the probe and time complexity of finding the center of a given vertex is $\tilde{O}(\sqrt{n})$.

It remains to set the size of the buckets. Let $\{u, v\} \in E$ be such that $v \in V_i$ and $\deg(u) \leq \deg(v)$. Since $v \in V_i$, it follows that $\deg(v) \leq 2^i\sqrt{n}$. Since $|S_i| \leq c\sqrt{n}\log n/2^i$ for some constant c, by setting the size of the buckets to be $\sqrt{n}$ we obtain that the total number of edges between heavy vertices that belong to different clusters is $\tilde{O}(n^{3/2})$, as desired.

From the fact that the size of the buckets is $\sqrt{n}$ it follows that the total probe and time complexity of our algorithms is $\tilde{O}(\sqrt{n})$. From the fact that the diameter of every cluster is 2 we obtain that for every edge $\{u, v\}$ which we remove from the graph, there exists a path of length at most 3 between u and v. Hence, the stretch factor of our spanner is 3, as desired.

1.4 Algorithm for constructing 5-spanners

We extend the ideas from the previous section to obtain our algorithm for constructing 5-spanners as follows. We partition the vertices in the graph into three sets: *heavy*, *medium*, and *light*. The set of light vertices is defined to be the set of all vertices with a degree at most $n^{1/3}$ and the set of heavy vertices is defined to be the set of all vertices of degree at least $n^{2/3}$. The set of the medium vertices is defined to be all vertices that are not light nor heavy.

As before, we add to the spanner all the edges incident to light vertices and cluster all the heavy vertices into a cluster of diameter 2. The difference is that now when we partition the heavy vertices into sets according to their degrees the first set consists of all vertices with a degree in $[n^{2/3} + 1, 2n^{2/3}]$.

We partition the set of medium vertices into two sets according to the following random process. Each medium vertex v samples uniformly at random $\Theta(\log n)$ of its neighbors. If one of the vertices in the sample is heavy then v joins the cluster of the heavy vertex in the sample that has minimum rank. Otherwise we say that v is *bad*. This forms clusters of diameter 4.

In a similar manner to the process described above we define another a new collection of sets of centers for the bad vertices such that the total number of such centers is $\tilde{O}(n^{2/3})$ and each bad vertex belongs to at least one cluster and at most $O(\log n)$ clusters. The new centers are selected (randomly) only from the set of vertices which are not heavy. We call the corresponding clusters *light-clusters* since they contain at most $n^{2/3}$ vertices and have diameter 2. Since the total number of light-clusters is $\tilde{O}(n^{2/3})$ we can afford to take an edge between every pair of adjacent light-clusters. Moreover, we partition each light-cluster into buckets of size $n^{1/3}$ and take an edge between every pair of adjacent buckets. Since each bad vertex belongs to $O(\log n)$ light-clusters, the total number of pairs of buckets is $\tilde{O}(n^{4/3})$. The time and probe complexity of finding all the edges incident to two buckets is $\tilde{O}(n^{2/3})$, as desired.

To analyse the stretch factor we partition the edges we remove into three types. The first type of edges are edges between vertices in the same cluster. The second type of edges are edges between a vertex v and a cluster C which is not light, in which case there at least one edge in the spanner which is incident to both v and C. The third type of edges are edges which are incident to a pair of light-clusters, in which case there exists at least one edge in the spanner which is incident to each pair of such clusters. Thus, overall the stretch factor is 5, as claimed.

1.5 Algorithm for constructing $O(k^2)$-spanners

The high-level idea of the algorithm for constructing $O(k^2)$-spanners, which we describe from a global point of view, follows that of [28]. The vertices of the graph are first partitioned into $\tilde{O}(n^{2/3})$ Voronoi cells which are formed with respect to a randomly selected set of $\tilde{O}(n^{2/3})$ centers. We can assume that each Voronoi cell has diameter $O(k)$ by using a separate algorithm to handle *remote* vertices which may not be close to a center. Each Voronoi cell is then partitioned into clusters of size $L = \tilde{O}(n^{1/3})$. In addition each Voronoi cell is marked with probability $1/n^{1/3}$ which respectively also marks all the clusters of the cell. Each non-marked cluster connects to all the adjacent marked clusters using a single edge. This forms *clusters-of-clusters* around marked clusters. Instead of connecting every pair of adjacent clusters A and B, which we can not afford, our goal is to connect A with the cluster-of-clusters of some marked cluster C adjacent to B. Since we can not afford to reconstruct the cluster-of-clusters of C, we instead find the identity of all the Voronoi cells which are adjacent to C and try to connect A with at least one of these cells. We show that this is indeed the case although A may not be connected directly to any one of these cells. By applying an inductive argument we show that the number of hops between A and B is $O(k)$, where traversing from one Voronoi cell to another is considered one hop. Since the diameter of each Voronoi cell is $O(k)$ we obtain an overall stretch factor of $O(k^2)$.

We improve on the LCA of [28] in two main ways. The first main improvement is a new method for partitioning the Voronoi cells into clusters of size L, allowing the cluster containing a vertex to be reconstructed using $O(\Delta^2 L^2)$ probes instead of $O(\Delta^3 L^2)$. The second improvement relates to the problem of connecting a cluster A to the cluster-of-clusters of some marked cluster C adjacent to B. In particular there is an issue of which marked cluster C should be chosen, since it is too expensive to reconstruct every marked cluster adjacent to B. The LCA of [28] processes a single cluster of each adjacent marked Voronoi cell to B, of which there may be as many as $\tilde{O}(\Delta)$. We instead devise a rule by which B is *engaged* with a single marked cluster adjacent to it, and show that in fact it suffices to only consider this one cluster. Combining these improvements reduces the total number of probes from $\tilde{O}(n^{2/3}\Delta^4)$ to $O(n^{2/3}\Delta^2)$.

1.6 Algorithm for graph decomposition

To further reduce the runtime of Theorem 31, we develop a new local computation algorithm to decompose graphs into subgraphs with smaller degree. Observe that for a graph G, for subgraphs $G_1, \ldots, G_t$, if we have k-spanners $H_i \subset G_i$ for every i, the union $\bigcup_{i\in[t]} H_i$ is a k-spanner for G. As the runtime of Theorem 31 depends on the maximum degree Δ, we develop an efficient LCA to break G into t graphs, each with maximum degree $O(\max\{\Delta/t, \log n\})$, where t is a parameter to be chosen. Given v and an index $i \in [t]$, the LCA returns in time $O(\Delta/\sqrt{t})$ all neighbors of v in G_i (i.e. it supports `ALL_NBR` queries to each subgraph). We believe this algorithm may have other applications.

To apply this algorithm in the spanner framework, we compose the LCA for $O(k^2)$ spanners with the LCA for graph decomposition. This is more subtle than generic sequential composition of algorithms, as we must ensure the per-query overhead is mild. We do this by observing the $O(k^2)$-spanner algorithm only ever makes all neighbor queries, and so the decomposition LCA spends $O(\Delta/\sqrt{t})$ work per query the spanner LCA makes to the graph. In particular, as the spanner LCA makes $O(n^{2/3}\Delta)$ all neighbor queries, our new runtime is $O(n^{2/3}\Delta^2/t^{3/2})$ given our choice of t. As decomposing G into t subgraphs increases the size of the output spanner by a factor of t, we ultimately balance parameters and obtain a probe and time complexity of $O(n^{2/3-(1.5-\alpha)/k}\Delta^2)$ for any $\alpha > 0$.

1.6.1 Decomposing the Graph

To build this graph, consider assigning each edge of $G = (V, E)$ two colors $i, j \in [R]$, one from each endpoint. In particular, v assigns its first Δ/R edges to receive color 1, the next Δ/R to receive color 2, etc. Then if an edge (u, v) has received colors i, j from both endpoints, we can let the overall edge color be (i, j) where we assume w.l.o.g that $u < v$. Observe that if each color corresponds to a subgraph, then this decomposition breaks G into R^2 subgraphs. Moreover, given i, j and a vertex v, we can quickly enumerate blocks i and j from v and determine which edges lie in the specified subgraph. However, as these blocks may be poorly aligned, this as described results in a maximum subgraph degree of Δ/R rather than Δ/R^2. Instead, we have each vertex choose a random shift, and assign labels to its blocks according to this shift. Then via standard concentration bounds the maximum degree of every subgraph is as desired. We remark that as we must enumerate every element of bucket i and j from v to find edges with label (i, j), the worst-case time for an individual neighbor query can be up to $\Omega(\Delta/R)$. However, we only need to do this once to answer an all-neighbors query, so as long as all the neighbors are desired we can efficiently amortize this cost.

1.7 The number of random bits

All our algorithms are randomized and hence use random bits. For results 1-2 we use randomness in the selection of centers and representatives. In result 3 we use randomness in the selection of centers, marked clusters, and random ranking of edges.

When the centers and representatives are selected independently, the arguments for proving the guarantees on the sparsity of the spanner follow from standard concentration bounds. As shown by Parter at al. [28], by using a less standard analysis one is able to prove that the same guarantees on the sparsity hold even when the random bits are only $\Theta(\log n)$-wise independent (which requires only $O(\log^2 n)$ truly random bits). Furthermore, by using an intricate analysis, they showed that the guarantees on the stretch factor continue to hold as well. In this writing, we do not repeat the analysis in [28] since it lends itself quite easily to our setting.

For result 4, similar techniques to those of [28] allow the result to be implemented using polylog(n)-wise independence as well [1].

1.8 Related work

As mentioned above, the work which is the most closely related to our work is by Parter et el. [28]. In addition to the upper bounds mentioned in Section 1.1 they also observe that it is possible to obtain an LCA for constructing 5-spanners with $\tilde{O}(n^{1+1/k})$ edges and probe complexity $\tilde{O}(n^{1-1/(2k)})$ for the special case in which the minimum degree is known to be at least $n^{1/2-1/(2k)}$ (this builds on the fact that by picking $\tilde{O}(n^{(1+1/k)/2})$ centers, w.h.p. each vertex has a center in its neighborhood). In addition to upper bounds, they also provide a lower bound of $\Omega(\min\{\sqrt{n}, \frac{n^2}{m}\})$ probes for the simpler task of constructing a spanning graph with $o(m)$ edges, where m denotes the number of edges in the input graph.

Our work also builds on the upper bound in [23], designed originally for bounded degree graphs, which provide a spanner with $(1 + \epsilon)n$ edges on expectation, where ϵ is a parameter, stretch factor $O(\log^2 n \cdot \text{poly}(\Delta/\epsilon))$ and probe complexity of $O(\text{poly}(\Delta/\epsilon) \cdot n^{2/3})$. The work in [23] is a follow-up of [26, 25] which initiated the study of LCAs for constructing ultra-sparse (namely, with $(1 + \epsilon)n$ edges) spanning subgraphs.

[1] More specifically, by using the concentration bound from Fact 5.3 in [28] on the sum of d-wise independent random variables.

2 Preliminaries

The input graph $G = (V, E)$ is a simple undirected graph with $|V| = n$ vertices and a bound on the degree Δ. Both parameters n and Δ are known to the algorithm. Each vertex $v \in V$ is represented as a unique ID from $[n]$.

A local algorithm has access to the *adjacency list oracle* $\mathcal{O}^G$ which provides answers to the following probes (in a single step):

- **Degree probe:** Given $v \in V$, returns the degree of v, denoted by $\deg(v)$.
- **Neighbour probe:** Given $v \in V$ and an index i, returns the i^{th} neighbor of v if $i \leq \deg(v)$. Otherwise, $\perp$ is returned. Additionally, for $v \in V$, we define the all-neighbors query, denoted by $\texttt{ALL\_NBR}(v)$, which returns all the neighbors of v. Clearly, this query can be implemented by $\deg(v) + 1$ neighbor probes.
- **Adjacency probe:** Given an ordered pair $\langle u, v \rangle$ where $u \in V$ and $v \in V$, if v is a neighbor of u then i is returned where v is the i^{th} neighbor of u. Otherwise, $\perp$ is returned.

We denote the distance between two vertices u and v in G by $\mathrm{d}(u, v)$ and the set of neighbours of v in G by $N_G(v)$. We denote by $N_G(v)[i]$ the i-th neighbour of v in G. For vertex $v \in V$ and an integer k, let $\Gamma_k(v, G)$ denote the set of vertices at distance at most k from v. When the graph G is clear from the context, we shall use the shorthand $d(u, v)$, $N(v)$ and $\Gamma_k(v)$ for $d_G(u, v)$, $N_G(v)$ and $\Gamma_k(v, G)$, respectively. We define a ranking r of the edges as follows: $r(u, v) < r(u', v')$ if and only if $\min\{u, v\} < \min\{u', v'\}$ or $\min\{u, v\} = \min\{u', v'\}$ and $\max\{u, v\} < \max\{u', v'\}$.

We shall use the following definitions in our algorithms for constructing 3-spanners and 5-spanners.

▶ **Definition 2.** *We say that a vertex $v \in V$ is in* class $i \in \mathbb{N}$ w.r.t. Δ *if* $\deg(v) \in [2^{i-1}\Delta + 1, 2^i\Delta]$.

▶ **Definition 3.** *We say that an index $i \in \mathbb{N}$ is in* bucket $j \in \mathbb{N}$ w.r.t. Δ *if* $i \in [(j-1) \cdot \Delta + 1, j \cdot \Delta]$.

2.1 Probes in the LCA model

Since the introduction of the model in [32], there have been several formulations concerning, mainly, the measure of performance, the way the input is accessed, and whether preprocessing is allowed. In particular, when the input is a graph, there is the question of whether the LCA can probe the graph anywhere (i.e. ask for the neighbors of an arbitrary vertex). In contrast to message-passing models such as CONGEST and distributed LOCAL algorithms, in LCAs the standard assumption is that indeed the LCA can access the graph anywhere and more specifically that each vertex in the input graph is represented as a unique ID from $[n] = \{1, \ldots, n\}$. To support this claim, we refer the reader to the ultra-formal definition in [20] (Definition 12.11) as well as [3, 18].

We note that the utility of making far-probes [2] was studied in [21], in which the authors showed that for a large family of problems, this extra power is not so useful. Indeed, this extra power is not always used by LCAs. For example, in the recent result of Ghaffari [19], which provides an LCA for the problem of Maximal Independent Set, the assumption is that the IDs are taken from $[n^{10}]$. Nonetheless, we stress that this extra power is an important feature of

[2] Namely, probing vertices for which we do not yet know a path from the query vertex.

the LCA model, which, in particular, distinguishes it from message-passing models (see more on the difference between LCAs and distributed LOCAL algorithms in Section 4.1 in [24]) and comes into play in problems which have a more global nature. For example, this extra power is utilized in Prop. 12.13 in [20] for graph coloring and in [27] for approximate Maximum-Matching. The latter LCA is used in Behnezhad et al. [8] to obtain a state-of-the-art sublinear algorithm for the extensively studied problem of approximate Maximum-Matching.

3 LCA for constructing 3-spanners

In this section, we prove the following theorem. Due to space limitations, we defer the claims regarding probe and time complexities as well as the stretch factor to the appendix.

▶ **Theorem 4.** *There exists an LCA that given access to an n-vertex simple undirected graph G, constructs a 3-spanner of G with $\tilde{O}(n^{1+1/2})$ edges whose probe complexity and time complexity are $\tilde{O}(n^{1/2})$.*

Our algorithm is listed as Algorithm 1. As mentioned-above our algorithm proceeds by forming clusters around centers and connecting the different clusters. To make the description of our algorithm complete we begin with describing the selection of centers.

We define $t \stackrel{\text{def}}{=} \log\sqrt{n}$ sets of centers $S_1, \ldots, S_t$. For every $i \in [t]$, we pick u.a.r. x_i vertices to be in S_i where $x_1 = \sqrt{n}\log n$ and $x_{i+1} = x_i/2$ for every $i \in [t-1]$. The rest of the details of the algorithm appear in Algorithm 1. We next prove the correctness of the algorithm.

Recall that we refer to a vertex whose degree is greater than $\sqrt{n}$ as heavy. The next claim states that with high probability every heavy vertex has at least one center and $O(\log n)$ centers in its neighborhood.

▷ Claim 5. With high probability, for every $i \in [t]$ and every vertex $v \in V$ that is in class i w.r.t. $\sqrt{n}$ it holds that $N(v) \cap S_i \neq \emptyset$ and that $|N(v) \cap S_i| = O(\log n)$.

Algorithm 1 LCA for constructing 3-spanners.

```
Input: Access to an undirected graph $G = (V, E)$ and a query $\{u, v\} \in E$ where we assume w.l.o.g. that $\deg(u) \geq \deg(v)$.
Output: Returns whether $\{u, v\}$ belongs to the spanner or not.
1. If $\deg(v) \leq n^{1/2}$ then return YES (recall that $\deg(u) \geq \deg(v)$).
2. Otherwise, let $c$ denote the class of $u$ w.r.t. $\sqrt{n}$ (see Definition 2).
3. If $v \in S_c$ then return YES.
4. Otherwise, let $\mathcal{C} \stackrel{\text{def}}{=} S_c \cap N(u)$. If $\mathcal{C} = \emptyset$ then return YES.
5. Let $i$ denote the index of $u$ in $N(v)$ and let $b$ denote the bucket of $i$ w.r.t. $\sqrt{n}$ (see Definition 3).
6. For each $x \in \mathcal{C}$:
   a. Go over every $j < i$ such that $j$ is in bucket $b$ and return YES if for every such $j$, $N(v)[j]$ does not belong to the cluster of $x$.
7. Return NO.
```

▷ Claim 6. With high probability, the stretch factor of the spanner constructed by Algorithm 1 is 3.

Proof. Let $\{u, v\}$ be an edge in E such that $\deg(u) \geq \deg(v)$. We will show that there exists a path of length at most 3 between u and v in the the spanner constructed by Algorithm 1 denoted by $G' = (V, E')$. If $\deg(v) \leq \sqrt{n}$ then $\{u, v\} \in E'$ and we are done. Otherwise, if there exists a cluster C such that u and v are both belong to C then in G' they are both connected by an edge to the center of C. Thus there exists a path of length at most 2 between u and v in G'. Otherwise, let C' be a cluster for which u belongs to. We claim that v is adjacent to C' in G'. This follows by induction on the index of u in $N(v)$ and Sub-Step 6a. ◁

▷ Claim 7. The probe and time complexity of Algorithm 1 is $O(\sqrt{n} \log n)$.

Proof. Steps 1-2 can be implemented by making a single degree probe. Their time complexity is $O(1)$. Step 3 can be implemented by accessing the random coins. To implement Step 4 we need to go over all the vertices in S_c (we may assume w.l.o.g. that we generate all the centers in advance as there are only $O(\sqrt{n} \log n)$ centers) and check whether they are in $N(u)$ (by making a single adjacency probe). Thus the probe (and time) complexity of this step is $O(\sqrt{n} \log n)$. Step 5 can be implemented by a single adjacency probe. The total number of vertices we check in Sub-Step 6a is bounded by the size of $\mathcal{C}$ times the size of a bucket which is $\sqrt{n}$. For each vertex we check we make a single neighbor and then we check whether it belongs to the cluster of a specific center. The latter can be implemented by making a single degree probe and a single adjacency probe. By Claim 5, the size of $\mathcal{C}$ is bounded by $O(\log n)$, thus the probe (and time) complexity of Step 6 is $O(\sqrt{n} \log n)$. The claim follows. ◁

▷ Claim 8. With high probability, the number of edges of the spanner constructed by Algorithm 1 is $\tilde{O}(n^{1+1/2})$.

Proof. The number of edges added to E' due to Step 1 is at most $n^{3/2}$. By the bound on the number of centers, the number of edges added to E' due to Step 3 is $O(n^{3/2} \log n)$. To analyse the number of edges added to E' due to Step 6 consider an edge $\{u, v\}$ such that $\deg(u) \geq \deg(v)$, $\deg(v) > \sqrt{n}$ and $v \notin S_c$, where c denotes the class of u w.r.t. $\sqrt{n}$. Since u is in class c it follows that $\deg(u) \leq 2^c\sqrt{n}$. Since $\deg(v) \leq \deg(u)$ it follows that $N(v)$ has at most 2^c buckets. By Sub-Step 6a, for any cluster C, the number of edges in E' that are incident to v and a vertex from C is at most 2^c (since we add to E' at most a single edge for each bucket of $N(v)$). Since the number of clusters of class c is $O(\sqrt{n} \log n/2^c)$, the total number of clusters of class greater or equal to c is $O(\sqrt{n} \log n/2^c)$ as well. Therefore, the total number of edges that are incident to v and added to E' due to Step 6 is $O(\sqrt{n} \log n)$. By Claim 5, w.h.p., the number of edges that are added due to Step 4 is 0. We conclude that the $|E'| = O(n^{3/2} \log n)$, as desired. ◁

4 LCA for constructing 5-spanners

In this section, we prove the following theorem.

▶ **Theorem 9.** *There exists an LCA that given access to an n-vertex simple undirected graph G, constructs a 5-spanner of G with $\tilde{O}(n^{1+1/3})$ edges whose probe complexity and time complexity are $\tilde{O}(n^{2/3})$.*

Our algorithm for constructing 5-spanners also proceeds by forming clusters around centers and connecting the different clusters. For the sake of presentation, we first describe our local algorithm from a global point of view (see algorithm 2). In Section 4.1 we describe the local implementation of this algorithm.

As in the algorithm for constructing 3-spanners, the clusters are formed around randomly selected centers only that now we have two types of clusters (and centers), *heavy-clusters* and *light-clusters* that will be described in the sequel.

The selection of the first type of centers

The selection of the first type of centers proceeds as follows. We define $a \overset{\text{def}}{=} \log n^{1/3}$ sets of centers $S^1_1, \ldots, S^1_a$. For every $i \in [a]$, we pick u.a.r. y_i vertices to be in S^1_i where $y_1 = n^{1/3} \log n$ and $y_{i+1} = y_i/2$ for every $i \in [a-1]$. The clusters which are formed around the first type of centers are the *heavy-clusters*. The formation of the heavy-clusters is described in Step 2 of Algorithm 2.

The selection of the second type of centers

The selection of the second type of centers proceeds as follows. We define $b \overset{\text{def}}{=} \log n^{1/3}$ sets of centers $S^2_1, \ldots, S^2_b$. For every $i \in [b]$, we pick u.a.r. x_i vertices to be in S^2_i where $x_1 = n^{2/3} \log n$ and $x_{i+1} = x_i/2$ for every $i \in [b-1]$.

The clusters which are formed around the second type of centers are the *light-clusters*. The formation of the light-clusters is described in Step 3 of Algorithm 2.

The way we connect the different clusters is described in Steps 4 and 5.

In the next couple of claims we prove that with high probability every vertex v such that $\deg(v) > n^{1/3}$ joins at least one cluster and at most $O(\log n)$ clusters. To do so, we partition the vertices with degree greater than into $n^{1/3}$ into 3 sets. The first set, denoted by H, is the set of vertices, v, such that $\deg(v) \geq n^{2/3}$. The second set is the set of vertices, v, such that $n^{1/3} < \deg(v) < n^{2/3}$ for which at least half of the vertices in $N(v)$ have degree at least $n^{2/3}$. We denote this set by M_1. M_2 consists of the remaining vertices. Namely, M_2 is the set of vertices, v, such that $n^{1/3} < \deg(v) < n^{2/3}$ and for which less than half of the vertices in $N(v)$ have degree at least $n^{2/3}$.

The implication of the next claim is that w.h.p. every vertex in H joins at least one heavy-cluster and at most $O(\log n)$ heavy-clusters.

▷ Claim 10. With high probability, for every $v \in H$ it holds that $N(v) \cap S^1_c \neq \emptyset$ and that $|N(v) \cap S^1_c| = O(\log n)$ where $c \in [a]$ is the class of v w.r.t. $n^{2/3}$.

The implication of the next claim (when combined with Claim 10) is that w.h.p. every vertex in M_1 joins, via a representative, at least one heavy-cluster and at most $O(\log n)$ heavy-clusters.

▷ Claim 11. With high probability, for every $v \in M_1$ it holds that v has a representative.

Proof. Let $v \in M_1$. Consider Step 2b of Algorithm 2. Since at least half of the neighbors of v have degree at least $n^{2/3}$, it follows that w.h.p. $R_v \neq \emptyset$ and so v has a representative. ◁

The implication of the next claim is that w.h.p. every vertex in M_2 that does not have a representative joins at least one light-cluster and at most $O(\log n)$ light-clusters.

▷ Claim 12. With high probability, for every $v \in M_2$ it holds that $N(v) \cap S^2_c \neq \emptyset$ and that $|N(v) \cap S^2_c| = O(\log n)$ where $c \in [b]$ is the class of v w.r.t. $n^{1/3}$.

The following corollary follows directly from Claims 10–12.

Algorithm 2 Global algorithm for constructing 5-spanners.

```
Input: A graph $G = (V, E)$.
Output: Constructs a 5-spanner of $G$, $G' = (V, E')$.
1. For every $v$ such that $\deg(v) \leq n^{1/3}$ add to $E'$ all the edges that are incident to $v$.
2. Forming heavy-clusters:
   a. For each vertex $v$ such that $\deg(v) \geq n^{2/3}$ we define the centers of $v$ to be $N(v) \cap S_c^1$ where $c$ is the class of $v$ w.r.t. $n^{2/3}$ (see Definition 2). For every center $s$ of $v$, $v$ joins the cluster of $s$ by adding the edge $\{s, v\}$ to $E'$.
   b. Each vertex $v$ such that $n^{1/3} < \deg(v) < n^{2/3}$ sample u.a.r. $y \overset{\text{def}}{=} \Theta(\log n)$ of its neighbors. Let $R_v$ denote this set. The *representative* of $v$ is defined to be the vertex, $r$, of minimum id in $R_v$ such that $\deg(r) \geq n^{2/3}$ (if such vertex exists). If $v$ has a representative, $r$, then the edge $\{v, r\}$ is added to $E'$ (and hence $v$ joins all the clusters of $r$).
3. Forming light-clusters:
   a. For each vertex $v$ such that $n^{1/3} < \deg(v) < n^{2/3}$ for which $v$ does not have a representative we define the centers of $v$ to be $N(v) \cap S_c^2$ where $c$ is the class of $v$ w.r.t. $n^{1/3}$ (see Definition 2). For every center $s$ of $v$, $v$ joins the cluster of $s$ by adding the edge $\{s, v\}$ to $E'$.
4. Connecting vertices to adjacent heavy-clusters:
   a. Let $\{u, v\}$ be such that $\deg(u) \geq \deg(v)$ and $u$ belongs to a heavy-cluster. For each cluster $C$ that $u$ belongs to, do:
      i. Partition the interval $[\deg(v)]$ into sequential intervals, which we refer to as buckets, of size $n^{2/3}$: $b_1, \ldots, b_s$ (where only $b_s$ may have size which is smaller than $n^{2/3}$).
      ii. For each $i \in [s]$, go over every $j \in b_i$ in increasing order and check if $N(v)[j]$ belongs to $C$. If such $j$ is found, add $\{v, N(v)[j]\}$ to $E'$ and move to the next bucket.
5. Connecting adjacent light-clusters:
   a. Let $\{u, v\}$ be such that both $u$ and $v$ belong to different light-clusters. For each light clusters $C_u$ and $C_v$ that $u$ and $v$ belong to, respectively, do:
      i. Let $s_u$ and $s_v$ denote the centers of $C_u$ and $C_v$, respectively. Let $c_u$ and $c_v$ denote the classes of $u$ and $v$ w.r.t. $n^{1/3}$, respectively.
      ii. Partition the vertices in $N(s_u)$ that belong to the cluster $C_u$ (namely, the neighbors of $s_u$ that are in class $c_u$ w.r.t. $n^{1/3}$) into subsets of size $n^{1/3}$ greedily by their index in $N(s_u)$, $S_1^u, \ldots, S_t^u$ (all the subsets are of size $n^{1/3}$ except from perhaps $S_t^u$).
      iii. Repeat Step 5(a)ii for the vertices in $N(s_v)$ that belong to $C_v$ and let $S_1^v, \ldots, S_r^v$ denote the resulting subsets.
      iv. For each $i \in [t]$ and $j \in [r]$, add the edge of minimum rank in $E(S_i^u, S_j^v)$ to $E'$ (if such edge exists).
```

▶ **Corollary 13.** *With high probability every vertex v such that $\deg(v) > n^{1/3}$ joins at least one cluster and at most $O(\log n)$ clusters.*

▷ Claim 14. With high probability, $|E'| = \tilde{O}(n^{1+1/3})$.

Proof. The number of edges added to E' due to Step 1 is at most $n^{1+1/3}$. By Claims 10 and 12 the number of edges added to E' due to Steps 2a and 3a is $\tilde{O}(n)$. Since each vertex has at most one representative the number of edges added to E' due to Step 2b is at most n.

Consider $\{u, v\}$ such that $\deg(u) \geq \deg(v)$ and u belongs to a heavy-cluster C. According to Step 4(a)ii we connect v to C by adding to E' at most $\lceil \deg(v)/n^{2/3} \rceil$ edges (at most one edge for each bucket of $N(v)$).

If $\deg(u) \leq n^{2/3}$ then $\deg(v) \leq n^{2/3}$ as well and so $\lceil \deg(v)/n^{2/3} \rceil \leq 1$. Therefore the total number of edges that are incident to v and added to E' due to Step 4(a)ii is bounded by the total number of centers of the first type which is $\tilde{O}(n^{1/3})$.

Otherwise, let c denote the class of u w.r.t. $n^{2/3}$, then by definition $\deg(u) \leq 2^c \cdot n^{2/3}$. Therefore by our assumption $\deg(v) \leq 2^c \cdot n^{2/3}$ as well. The number of centers in S^1_c is $n^{1/3} \log n/2^c$ and so the total number of centers in $\bigcup_{c \leq i \leq a} S^1_i$ is $O(n^{1/3} \log n/2^c)$. Observe that the number of edges which are incident to v and added to E' due to Step 4(a)ii is at most $\lceil \deg(v)/n^{2/3} \rceil$ times the number of centers in $\bigcup_{c \leq i \leq a} S^1_i$. Thus the total number of edges that are incident to v and added to E' due to Step 4(a)ii is $\tilde{O}(n^{1/3})$ in this case as well. Therefore, the total number of edges which are added to E' in Step 4(a)ii is $\tilde{O}(n^{1+1/3})$.

By Claim 12 it follows that the total number of subsets partitioning the light clusters is $\tilde{O}(n^{2/3})$ as the size of each subset is $n^{1/3}$ except for at most $\tilde{O}(n^{2/3})$ subsets, and since each vertex may belong to $O(\log n)$ different clusters. Since in Step 5(a)iv we add at most a single edge between a pair of subsets the total number of edges added to E' due to this step is $\tilde{O}(n^{1+1/3})$. This concludes the proof of the claim. ◁

▷ Claim 15. With high probability, the stretch factor of the spanner constructed by Algorithm 2 is 5.

Proof. Let $\{u, v\}$ be an edge which is not included in E'. By Step 1 of the algorithm it follows that the degree of both u and v is greater than $n^{1/3}$. By Corollary 13 w.h.p. all vertices with degree greater than $n^{1/3}$ join at least one cluster. In the rest of the proof we condition on the event that both u and v join at least one cluster.

Assume w.l.o.g. that $\deg(u) \geq \deg(v)$. If both u and v belong to the same cluster (either heavy or light) then there exists a path of length at most 4 in G' between u and v as the diameter of each cluster is at most 4.

If u belongs to a heavy cluster, C, then by Step 4(a)ii of the algorithm it follows that there exists at least one edge in E' which is incident to v and a vertex in C. Since the diameter of C is at most 4 it follows that there exists a path in G' from v to u.

Otherwise, both u and v belong to different light clusters C_u and C_v. By Step 5(a)iv, there exists at least one edge in E' which is incident to a vertex in C_u and a vertex in C_v. Since the diameter of a light cluster is at most 2 we obtain that there exists a path in G' from u to v of length at most 5. This concludes the proof of the claim. ◁

4.1 The local implementation

In this section we prove the following claim. In the proof of the claim we also describe the local implementation of Algorithm 2.

▷ Claim 16. The probe and time complexity of the local implementation of Algorithm 2 is $\tilde{O}(n^{2/3} \log n)$.

Proof. On query $\{u, v\}$ we first probe the degree of u and v and return YES if either u or v have degree which is at most $n^{1/3}$. Otherwise, assume w.l.o.g. that $\deg(u) \geq \deg(v)$. we consider the following cases.

First case: $\deg(u) \geq n^{2/3}$. In this case we find the centers of u by going over all the centers, s, in S^1_c where c is the class of u w.r.t. $n^{2/3}$ and preforming the adjacency probe $\langle u, s\rangle$. If v belongs to the set of centers of u then we return YES. Overall, since the number of centers of the first type is $\tilde{O}(n^{1/3})$, finding the centers of u requires $\tilde{O}(n^{1/3})$ probes and time.

We then find the bucket b of u in $N(v)$ w.r.t. $n^{2/3}$ (see Definition 3) by preforming the adjacency probe $\langle v, u\rangle$. Let i denote the index of u in $N(v)$. For each center of u, s and for each $j \in b$ such that $j < i$, we check if $N(v)[j]$ belongs to the cluster of s. In order to do so we first probe the degree of $y = N(v)[j]$. If $\deg(y) \geq n^{2/3}$ then v is in the cluster of s if and only if it is a neighbour of s and is in class c w.r.t. $n^{2/3}$ where c is such that s belongs to S^1_c. If $\deg(y) < n^{2/3}$ then we first find the representative of y and if it has a representative we check if it belongs to the cluster of s. Since we have to check this for at most $n^{2/3}$ vertices and for $O(\log n)$ centers, overall the probe and time complexity of preforming this task is $\tilde{O}(n^{2/3})$.

Second case: $n^{1/3} < \deg(u) < n^{2/3}$ and either u or v have a representative. In this case we proceed as in the previous case only that we preform all the checks with respect to the centers of the representative of u (and/or the representative of v). Since finding the representative of a vertex requires $O(\log n)$ probes and time the probe and time complexity in this case is $\tilde{O}(n^{2/3})$ as well.

Third case: $n^{1/3} < \deg(u) < n^{2/3}$ and both u and v do not have representatives. This corresponds to the case in which both u and v belong to light clusters. In order to find the centers of u we simply go over all vertices, y, in $N(u)$ and check if y is in S^2_c where c denotes the class of u w.r.t. $n^{1/3}$. We repeat the same process for v. Since checking if a vertex belongs to S^2_c can be done in $O(\log n)$ time (we can generate all the centers in advance and store them in a binary search tree) this task requires $\tilde{O}(n^{2/3})$ probes and time.

Finally, for each pair of centers s_u and s_v of u and v, respectively, we go over all the neighbours of s_u and s_v and determine for each one, according to its degree, whether it belongs to the cluster of s_u and s_v, respectively. We then find the subsets that u and v belong to as defined in Steps 5(a)ii and 5(a)iii and return YES if and only of $\{u, v\}$ is the edge of minimum rank that connects these subsets.

The above three cases cover all possible scenarios which implies that the time (and probe) complexity of the local implementation of Algorithm 2 is $\tilde{O}(n^{2/3})$ as claimed. ◁

5 Graph Decomposition Via Ranking

We give the formal statement of the LCA of Item 4. We note that our decomposition gives a stronger promise than the maximum degree of each subgraph being bounded, in that we actually bound the degree vertex-wise. In particular, up to poly-logarithmic factors, the average degree of every subgraph is equal to the overall average degree divided by the number of subgraphs with high probability.

▶ **Theorem 17.** *There exists an LCA that, given a parameter $R \leq \sqrt{\Delta}$ and access to an n-vertex simple undirected graph $G = (V, E)$ with maximum degree Δ, decomposes G into edge-disjoint subgraphs $G_1, \ldots, G_{R^2}$ such that:*

1. *Given $(u, v) \in E$, the $i \in [R^2]$ such that $(u, v) \in G_i$ can be computed in time and space $O(1)$.*
2. *Given $v \in V$ and $i \in [R^2]$, $\texttt{ALL\_NBR}_i(v)$ can be computed in time and space $O(d_G(v)/R)$.*
3. *With high probability, the degree of v in G_i is $O(\max\{\log(n), d_G(v)/R^2\})$ for every $v \in V$ and $i \in [R^2]$. In particular, for every i the maximum degree of G_i is $O(\max\{\log(n), \Delta/R^2\})$ with high probability.*

We first describe the decomposition in a global manner. We refer to each subgraph as a color. We assign each edge in G one of R^2 colors, such that the degree and ALL_NBR query times are as claimed. We will identify the set of colors with $[R] \times [R]$, and assume $R^2 \leq \Delta$ since otherwise the statement is trivial. For convenience, let $d(v) := d_G(v)$ and $d_i(v) := d_{H_i}(v)$.

Each vertex v draws a random value $r_v \sim [R]$. Furthermore, for every vertex v, let the first $\lceil d(v)/R \rceil$ neighbors of v be $B_1(v)$, the second be $B_2(v)$, etc. Note that this divides the out-edges into R blocks. For an edge (u, v) with $u < v$ in blocks $B_i(u), B_j(v)$ respectively, the color of the edge is the pair $(i + r_u \mod R,\ j + r_v \mod R)$. Let $G_{a,b}$ for $a, b \in [R]$ be the subgraph consisting of all edges with color (a, b).

We can then combine Theorem 17 with Theorem 31 to give the final result.

▶ **Corollary 18.** *There exists an LCA that given access to an n-vertex simple undirected graph G with maximum degree Δ, constructs an $O(k^2)$-spanner with $\tilde{O}(n^{1+1/k})$ edges whose probe complexity and time complexity are $O(n^{2/3-(1.5-\alpha)/k}\Delta^2)$, for any constant $\alpha > 0$.*

5.1 Decomposition Implementation

▷ Claim 19. Given $(u, v) \in G$, we can determine the color (a, b) of the edge in time and space $O(1)$.

Proof. By making two adjacency probes, we can determine the indices of edge (u, v) in u and v. Then we can compute which blocks contain this edge using two degree queries and a constant number of arithmetic operations, and then compute the final color by looking up the random shifts of u and v. ◁

▷ Claim 20. With high probability, for every $v \in V$ and $(a, b) \in [R] \times [R]$ we have $d_{a,b}(v) = O(\max\{\log(n), d(v)/R^2\})$.

Proof. Fix an arbitrary vertex $v \in V$ and color $(a, b) \in [R] \times [R]$. Fix its shift of r_v of v arbitrarily. Let $S = B_{a-r_v}(v) \cup B_{b-r_v}(v)$ be the set of all edges incident to v (in G) in blocks $a - r_v$ and $b - r_v$. Then S is a superset of the set of edges incident to v with color (a, b), and $|S| = 2d(v)/R$.

For an arbitrary edge $e = (v, u)$ in S, let X_e be the indicator random variable which is 1 exactly when the color of e is (a, b). Let k be the block index of e in u so that $e \in B_k(u)$. There are four cases to consider regarding e:

- Case 1: $v < u$ and $e \in B_{a-r_v}(v)$. Then e has color (a, b) if and only if r_u is equal to $b - k$, which occurs with probability exactly $1/R$.
- Case 2: $v < u$ and $e \notin B_{a-r_v}(v)$. In this case e never has color (a, b).
- Case 3: $v > u$ and $e \in B_{b-r_v}(v)$. Similarly to case 1, e has color (a, b) if and only if r_u is equal to $a - k$, which occurs with probability $1/R$.
- Case 4: $v > u$ and $e \notin B_{b-r_v(v)}$. Similarly to case 2, e never has color (a, b).

In any case, we have $P[X_e = 1] \leq 1/R$ for all $e \in S$. Furthermore, the variables in $\{X_e\}_{e \in S}$ are independent random variables: for distinct edges $e, e' \in S$ where $e = (u, v)$ and $e = (u', v)$, X_e and $X_{e'}$ are independent since the random variables $r_u, r_{u'}$ are independent.

Letting $X = \sum_{e \in S} X_e$ and picking an arbitrary constant $c \geq 2$, we find

$$E[X] \leq 2d(v)/R^2 \leq c \max\{\log n, d(v)/R^2\} =: \mu.$$

By the multiplicative Chernoff's bound we have

$$\Pr[X > 3\mu] \leq \exp(-\mu) \leq \exp(-c \log n) = n^{-c},$$

and so the total number of neighbors of v with color (a, b) is $O(\max\{\log n, d(v)/R^2\})$ with high probability. Finally, a union bound over all n vertices and $R^2 \leq \Delta$ colors completes the proof. ◁

▷ Claim 21. $\texttt{ALL\_NBR}_i(v)$ can be computed in time and space $O(d(v)/R)$.

Proof. Given $v \in V$ and a color $i = (a, b)$, let $S = B_{a-r_v}(v) \cup B_{b-r_v}(v)$ as before. Note that these correspond to the blocks which have received labels a and b respectively, given the random shift of vertex v. We make $2d(v)/R$ neighbor probes to determine all elements of S, then $2d(v)/R$ adjacency probes to determine the indices of every edge in the other endpoint. Then for each edge, we can check in time $O(1)$ (by examining the random shift of the other endpoint) if the label is (a, b). ◁

Proof of Corollary 18. Let $\beta \in (0, 1]$ be such that $3/(2 + \beta) = 1.5 - \alpha$. Given a query if edge $(u, v) \in G$ is in the spanner, we apply the LCA of Theorem 17 with parameter[3] $R = \lceil n^{1/(k(2+\beta))} \rceil$ to determine the i such that $(u, v) \in G_i$. We then apply Theorem 31 with parameter $k' = \lceil k(1 + \frac{2}{\alpha}) \rceil$ to the graph G_i and query if (u, v) is contained in the spanner, and return the answer. Note that we ultimately obtain a $O(k'^2) = O(k^2)$-spanner for every subgraph (and thus for the overall graph), and the number of edges is bounded as $\tilde{O}(R^2 n^{1+1/k'}) \leq \tilde{O}\left(n^{1+\frac{2}{k(2+\alpha)}+\frac{1}{k(1+2/\alpha)}}\right) = \tilde{O}(n^{1+1/k})$. Furthermore, the time complexity is $O(n^{2/3}\Delta^2 R^{-3}) \leq O\left(n^{\frac{2}{3}-\frac{1.5-\alpha}{k}}\Delta^2\right)$. ◀

A LCA for constructing $O(k^2)$-spanners

In this section, we present our LCA for constructing $O(k^2)$-spanners.

A.1 The algorithm that works under a promise

We begin by describing a global algorithm for constructing an $O(k^2)$-spanner which works under the following promise on the input graph $G = (V, E)$. Let $L \stackrel{\text{def}}{=} cn^{1/3} \log n$, where c is a constant that will be determined later. For every $v \in V$, let $i_v \stackrel{\text{def}}{=} \min_r\{|\Gamma_r(v)| \geq L\}$. We are promised that $\max_{v \in V}\{i_v\} \leq k$. In words, we assume that the k-hop neighborhood of every vertex in G contains at least L vertices.

In addition, we assume without loss of generality that $k = O(\log n)$ as already for $k = \log n$ our construction yields a spanner with $\tilde{O}(n)$ edges on expectation.

Our algorithm builds on the partition of V which is described next.

Centers. Pick a set $S \subset V$ by independently including each vertex v in S with probability $n^{-1/3} \log n$, so that $|S| = \Theta(n^{2/3} \log n)$ w.h.p. We shall refer to the vertices in S as *centers*. For each vertex $v \in V$, its *center*, denoted by $c(v)$, is the center which is closest to v amongst all centers (break ties between centers according to the id of the center).

Voronoi cells. The *Voronoi cell* of a vertex v, denoted by $\mathrm{Vor}(v)$, is the set of all vertices u for which $c(u) = c(v)$. Additionally, we assign to each cell a random rank, so that there is a uniformly random total order on the cells; note carefully that the rank of a cell thus differs from the rank of its center (which is given by its identifier, which is not assigned randomly). We remark that we can determine the rank of the cell from the shared randomness and the cell's identifier, for which we simply use the identifier of its center.

The Voronoi cells are partitioned into clusters which are classified into a couple of categories as described next.

Singleton Clusters. For each Voronoi cell, consider the BFS tree spanning it, which is rooted at the respective center. For every $v \in V$, let $p(v)$ denote the *parent* of v in this BFS tree. If v is a center then $p(v) = v$. For every $v \in V \setminus S$, let $T(v)$ denote the subtree of v in the above-mentioned BFS tree when we remove the edge $\{v, p(v)\}$; for $v \in S$, $T(v)$ is simply the entire tree. Now consider a Voronoi cell. If the cell contains at most L vertices, then the *cluster* of all the vertices in the Voronoi cell is the cell itself. Otherwise, there are two cases. If $T(v)$ contains more than L vertices, then we say that v is *heavy* and define the cluster of v to be the singleton $\{v\}$. Otherwise, we say that v is *light* and its cluster is defined as follows.

Non-singleton clusters. Observe that if v is light then it has a unique ancestor u (including v) such that u is not heavy and $p(u)$ is heavy. We define the cluster of v to consist of $T(u)$ and possibly additional subtrees, $T(u')$, where u' is a also a child of $p(u)$ (in $T(p(u))$, as described next.

We begin with some definitions and notations. In order to determine the cluster of u (which is also the cluster of v) consider transforming the heavy vertex $r = p(u)$ into a binary tree which we call *the auxiliary tree of* r, B_r, as follows. B_r is rooted at r and has i complete layers where i is such that $2^i < \deg(r)$ and $2^{i+1} \geq \deg(r)$. These layers consist of *auxiliary vertices*, namely they do not correspond to vertices in G. We then add another layer to B_r consisting of the neighbors of r, sorted from left to right according to their index in $N(r)$. Note that except from the root and the vertices at the last layer of B_r, all vertices in B_r are auxiliary vertices. This completes the definition of B_r. For each vertex $x \in B_r$ we define $B_r(x)$ to be the subtree of B_r rooted at x. We define $S(x) \overset{\text{def}}{=} B_r(x) \cap N(r)$, namely $S(x)$ is the set of vertices of $N(r)$ which are in the subtree of B_r rooted at x. The descendants of x, denoted by the set $D(x)$, are defined to be the union of the vertices in $T(y)$ for every $y \in S(x)$, namely $D(x) \overset{\text{def}}{=} \bigcup_{y \in S(x)} T(y)$. The weight of x is defined to be the number of vertices in $D(x)$, namely, $w(x) \overset{\text{def}}{=} |D(x)|$.

We are now ready to define the cluster of u. Let $z(u)$ be the unique ancestor of u in B_r (including r), z, for which $w(z) \leq L$ and $w(p(z)) > L$ (where $p(z)$ denotes the parent of z in B_r). The cluster of u (and v) is defined to be the set $D(z)$. This completes the description of how the Voronoi cell is partitioned into clusters.

Special vertices. In order to bound the number of clusters (see Section A.3) we shall use the following definitions.

▶ **Definition 22** (Special vertex). *We say that a vertex u is* special *if $|T(u)| > L$ and for every child of u in $T(u)$, t, it holds that $|T(t)| \leq L$.*

Analogously we define special auxiliary vertex as follows.

▶ **Definition 23** (Special auxiliary vertex). *We say that an auxiliary vertex y is a* special auxiliary vertex *if either of the following conditions hold:*

1. *y is a parent of a (non auxiliary) vertex v which is heavy. In this case we say that y is a type (a) special vertex.*
2. *$w(y) > L$ and for every child of y, t, it holds that $w(t) \leq L$. In this case we say that y is a type (b) special vertex.*

For a cluster C, let $c(C)$ denote the center of the vertices in C (all the vertices in the cluster have the same center). Let $\text{Vor}(C)$ denote the Voronoi cell of the vertices in C.

A.2 The Edge Set

Our spanner, $G' = (V, E')$, initially contains, for each Voronoi cell, Vor, the edges of the BFS tree that spans Vor, i.e., the BFS tree rooted at the center of Vor spanning the subgraph induced by Vor. Clearly, the spanner spans the subgraph induced on every Voronoi cell. Next, we describe which edges we add to E' in order to connect adjacent clusters of different Voronoi cells.

Marked Clusters and Clusters-of-Clusters

Each center is *marked* independently with probability $p \overset{\text{def}}{=} 1/n^{1/3}$. If a center is marked, then we say that its Voronoi cell is marked and all the clusters in this cell are marked as well.

Cluster-of-clusters. For every marked cluster, C, define the *cluster-of-clusters* of C, denoted by $\mathcal{C}(C)$, to be the set of clusters which consists of C and all the clusters which are adjacent to C. Let B be a non-marked cluster which is adjacent to at least one marked cluster. Let Y denote the set of all edges such that one endpoint is in B and the other endpoint belongs to a marked cluster. The cluster B is *engaged* with the marked cluster C which is adjacent to B and for which the edge of minimum rank in Y has its other endpoint in C.

The Edges between Clusters

By saying that we *connect* two adjacent subsets of vertices A and B, we mean that we add the minimum ranked edge in $E(A, B)$ to E'. For a cluster A, define its *adjacent centers* $\text{Cen}(\partial A) \overset{\text{def}}{=} \{c(v) \,|\, u \in A \wedge \{u, v\} \in E\} \setminus \{c(A)\}$, i.e., the set of centers of Voronoi cells that are adjacent to A. This definition explicitly excludes $c(A)$, as there is no need to connect A to its own Voronoi cell.

We next describe how we connect the clusters. The high-level idea is to make sure that for every adjacent clusters A and B we connect A with the cluster engaging B (perhaps not directly) and vise versa. For clusters which are not adjacent to any marked cluster and hence not engaged with any cluster we make sure to keep them connected to all adjacent Voronoi cells. Formally:

1. We connect every cluster to every adjacent marked cluster.

2. Each cluster A that is not engaged with any marked cluster (i.e., no cell adjacent to A is marked) we connect to each adjacent cell.
3. Suppose cluster A is adjacent to cluster B, where B is adjacent to a marked cell. Denote by C the (unique) marked cluster that B is engaged with. We connect A with B if the following conditions hold:
   a. the minimum ranked edge in $E(A, \mathrm{Vor}(B))$ is also in $E(A, B)$
   b. $c(B)$ is amongst the $n^{1/k} \log n$ lowest ranked centers in $\mathrm{Cen}(\partial A) \cap \mathrm{Cen}(\partial C)$

A.3 Sparsity

▷ Claim 24. The number of clusters, denoted by s, is at most $|S| + O(nk \log \Delta)/L)$.

▷ Claim 25. The number of edges in E' is $O(n^{1+1/k} \cdot k^2 \log^3 n)$ with high probability.

Proof. Deferred to full version. ◁

A.4 Connectivity and Stretch

▷ Claim 26. G' is connected.

▷ Claim 27. Denote by G_{Vor} the graph obtained from G by contracting Voronoi cells and by G'_{Vor} its subgraph obtained when doing the same in G'. If the cells' ranks are uniformly random, w.h.p. G'_{Vor} is a spanner of G_{Vor} of stretch $O(k)$.

Proof. Deferred to the full version. ◁

▷ Claim 28. W.h.p., G' is a spanner of G of stretch $O(k^2)$.

Proof. Due to the promise on G, w.h.p. the spanning trees on Voronoi cells have depth $O(k)$. Hence, the claim holds for any edge within a Voronoi cell. Moreover, for an edge connecting different Voronoi cells, by Lemma 27, w.h.p. there is a path of length $O(k)$ in G'_{Vor} connecting the respective cells. Navigating with at most $O(k)$ hops in each traversed cell, we obtain a suitable path of length $O(k^2)$ in G'. ◁

A.5 The algorithm for general graphs

We use a combination of the algorithm in Section A with the algorithm by Baswana and Sen [7] which has the following guarantees.

▶ **Theorem 29** ([7]). *There exists a randomized k-round distributed algorithm for computing a $(2k-1)$-spanner $G' = (V, E')$ with $O(kn^{1+1/k})$ edges for an unweighted input graph $G = (V, E)$. More specifically, for every $\{u, v\} \in E'$, at the end of the k-round procedure, at least one of the endpoints u or v (but not necessarily both) has chosen to include $\{u, v\}$ in E'.*

We call a vertex v *remote* if the k-hop neighborhood of v contain less than L vertices. We denote by $\bar{R} \overset{\mathrm{def}}{=} V \setminus R$ the set of vertices which are not remote.

First Step. Run the algorithm from Section A on the subgraph induced by $\bar{R}$, i.e., $\{u, v\} \in E$ with $u, v \in \bar{R}$ is added to E' if and only if the algorithm outputs the edge.

Second Step. Run the algorithm of Baswana and Sen [7] on the subgraph $H = (V, \{\{u, v\} \in E \mid u \in R \text{ or } v \in R\})$, i.e., $\{u, v\} \in E$ with $u \in R$ or $v \in R$ is added to E' if and only if the algorithm outputs the edge.[4]

A.6 Stretch Factor

Consider any edge $e = \{u, v\} \in E \setminus E'$ we removed. If both u and v are in $\bar{R}$, then e was removed by the Algorithm from Section A, which was applied to the subgraph induced by $\bar{R}$. Applying Claim 27 to the connected component of e, we get that w.h.p. there is a path of length $O(k^2)$ from u to v in G'. If u or v are in R, by Theorem 29 there is a path of length $O(k)$ from u to v in G'.

▶ **Corollary 30.** *The above algorithm guarantees stretch $O(k^2)$ w.h.p. and satisfies that the expected number of edges in E' is $O(n^{1+1/k} \cdot k^2 \log^3 n)$*

A.7 The local implementation

In this section we prove the following theorem.

▶ **Theorem 31.** *There exists an LCA that given access to an n-vertex simple undirected graph G, with high probability constructs a $O(k^2)$-spanners with $\tilde{O}(n^{1+1/k})$ edges in expectation. The probe complexity and time complexity are $O(n^{2/3}\Delta^2)$. Moreover, the algorithm access the graph only by* `ALL_NBR` *queries (and performs $O(n^{2/3}\Delta)$ such queries).*

Proof. The local implementation of the algorithm which is described in the previous section is listed in Algorithm 3. The correctness of the algorithm follows from the previous sections. We shall prove that its complexity is as claimed.

The local implementation for remote vertices. For Step 1, we need to determine for both u and v if they are remote. Recall that a vertex u is remote if its k-hop neighborhood contains less than L vertices. Therefore, we can decide for any vertex u whether it is in R with at most L `ALL_NBR` probes. Thus the probe and time complexity is $O(L\Delta)$. If either u or v are remote then we need to determine for each vertex in their k-hop neighborhood whether it is remote or not. If either u or v are remote then the k-hop neighborhood of each of them contain at most $L\Delta$ vertices. This follows from the fact that the size of the k-hop neighborhood of v is at most Δ factor bigger from the k-hop neighborhood of u and vice versa. Thus, we need to call `ALL_NBR` at most $L^2\Delta$ times for this step. Hence, we obtain that the probe and time complexity of this step is $O(L^2\Delta^2)$, in total.

If $u, v \in \bar{R}$, namely, when both u and v are non-remote, the algorithm proceeds as in Section A.1. We next describe the local implementation of the algorithm for this case.

Finding the center and reconstructing the BFS tree. We first analyse the probe and time complexity of determining the center of a vertex. Given a vertex v we perform a BFS from v layer by layer and stop at the first layer in which we find a center or after exploring at least L vertices. Let i denote the layer in which the execution of the BFS stops. It follows that up to layer $i - 1$ we explored strictly less than L vertices. Thus this step can be implemented by $O(L)$ calls to `ALL_NBR`. In particular, the probe and time complexity of finding the center is $O(L\Delta)$.

[4] The algorithm is described for connected graphs; we simply apply it to each connected component of H.

Algorithm 3 LCA for constructing $O(k^2)$-spanners.

```
Input: $\{u, v\} \in E$
Output: whether $\{u, v\}$ is in $E'$ or not.
1. If $u$ or $v$ are in $R$, simulate the algorithm of Baswana and Sen at $u$ and $v$ when running it on the connected component of $u$ and $v$ in the subgraph $H$ (see Section A.5). Return YES if either $u$ or $v$ has chosen to include $\{u, v\}$ and NO otherwise.
2. Otherwise, $u, v \in \bar{R}$ and we proceed according to Section A.1, where all nodes in $R$ are ignored:
    a. If $\text{Vor}(u) = \text{Vor}(v)$, return YES if $\{u, v\}$ is in the BFS tree of $\text{Vor}(u)$ and NO otherwise.
    b. Otherwise, let $Q$ and $W$ denote the clusters of $u$ and $v$, respectively. Return YES if at least one of the following conditions hold for $A = Q$ and $B = W$, or symmetrically, for $A = W$ and $B = Q$, and NO otherwise.
        i. $A$ is a marked cluster and $\{u, v\}$ has minimum rank amongst the edges in $E(A, B)$.
        ii. $A$ is not engaged with any marked cluster. Namely, all the clusters which are adjacent to $A$ are not marked. In this case, we take $\{u, v\}$ if it has minimum rank amongst the edges in $E(A, \text{Vor}(B))$.
        iii. There exists a marked cluster $C$ such that $B$ is engaged with $C$, and the following holds:
            - $\{u, v\}$ has minimum rank amongst the edges in $E(A, \text{Vor}(B))$.
            - The cell $\text{Vor}(B)$ is amongst the $n^{1/k} \log n$ minimum ranked cells in $\text{Cen}(\partial A) \cap \text{Cen}(\partial C)$
```

We observe that at the same cost we also determine the path from $c(v)$ to v in the BFS tree rooted at $c(v)$ as follows. The parent of v in the tree is the neighbour of v that has minimum id amongst all neighbour of v that are closer than v to $c(v)$. Similarly, we can determine the parent of the parent of v and so on until we reach $c(v)$.

Determining if a vertex is heavy. In order to reconstruct the clusters we need to be able to determine if a vertex is heavy or not. Recall that a vertex v is heavy if $|T(v)| > L$. We explore $T(v)$ by performing a find center procedure on all the neighbours of v and then continuing recursively on all the neighbours of v that belong to $\text{Vor}(v)$. Since finding the center takes $O(L)$ calls to `ALL_NBR`, we conclude that we can determine whether v is heavy or light by using $O(L^2\Delta)$ calls to `ALL_NBR`. This follows from the fact that when we partially or completely reveal $T(v)$, we need to find the center of at most $L\Delta$ vertices. Thus, the overall probe and time complexity for this step is $O(L^2\Delta^2)$.

Reconstructing the clusters. Given a vertex v we reconstruct its cluster as follows. First, perform a find-center operation on v and let $v := u_0, u_1, \ldots, u_d$ be the path to the center. We then determine if v is heavy using the prior procedure (and if so we are done). Otherwise, iteratively find $T(u_i)$ for $i \in [d]$ (where we do not search down the path that we have already explored), terminating the search when $T(u_i) > L$. In this case, construct the tree of special vertices below u_i and again find the first ancestor of u_{i-1} in this tree that is heavy, and let the cluster be the children of the predecessor special vertex. As we ultimately explore only $O(L\Delta)$ vertices, this results in $O(L\Delta)$ calls to find-center, which results in at most $O(L^2\Delta)$ calls to `ALL_NBR`.

Determining the cells adjacent to clusters. For Step 2 we need to reconstruct the cluster of u, the cluster of v, and the clusters that u and v are engaged with; this takes $O(L^2\Delta)$ calls to `ALL_NBR`. In addition, for each of these clusters C, we need to determine the center of each vertex adjacent to C. Since the size of the clusters is bounded by L, the number of vertices adjacent to C is at most $L\Delta$. Therefore the number of calls to find-center is at most $L\Delta$. This likewise requires $O(L^2\Delta)$ calls to `ALL_NBR` and overall $O(L^2\Delta^2)$ probes and time.

We conclude that we can perform all necessary checks to decide whether $\{u,v\} \in E'$ or not using $O(L^2\Delta)$ calls to `ALL_NBR` which invokes $O(L^2\Delta^2)$ neighbour probes. By the analysis above, the time complexity is $O(L^2\Delta^2)$ as well. ◀

Classical Simulation of One-Query Quantum Distinguishers

Abstract

We study the relative advantage of classical and quantum distinguishers of bounded query complexity over n-bit strings, focusing on the case of a single quantum query. A construction of Aaronson and Ambainis (STOC 2015) yields a pair of distributions that is ε-distinguishable by a one-query quantum algorithm, but $O(\varepsilon k/\sqrt{n})$-indistinguishable by any non-adaptive k-query classical algorithm.

We show that every pair of distributions that is ε-distinguishable by a one-query quantum algorithm is distinguishable with k classical queries and (1) advantage $\min\{\Omega(\varepsilon\sqrt{k/n})), \Omega(\varepsilon^2 k^2/n)\}$ non-adaptively (i.e., in one round), and (2) advantage $\Omega(\varepsilon^2 k/\sqrt{n \log n})$ in two rounds.

As part of our analysis, we introduce a general method for converting unbiased estimators into distinguishers.

1 Introduction

A distinguisher is an algorithm for hypothesis testing. Its purpose is to tell whether its input was sampled from one distribution or from another. In algorithmic contexts including much of cryptography, pseudorandomness, and statistical inference, the computational complexity of distinguishers plays a crucial role.

In this work, we initiate the study of the classical simulation of quantum distinguishers. Quantum algorithms promise algorithmic speedups, but the realization of fully capable quantum computers is still a distant goal. It is thus important to investigate the capabilities of quantum devices of limited computational power. Our focus here is on devices of bounded *query complexity*, a fundamental efficiency measure in complexity theory and cryptographic analysis.

We are interested in the best possible advantage of simulating a quantum distinguisher of bounded query complexity by a classical distinguisher of bounded but possibly larger query complexity k. We focus on quantum distinguishers that make a single query to an n-bit Boolean-valued oracle. Although this model appears restrictive, we find it interesting for the following reasons.

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

First, Aaronson and Ambainis [1] showed that in the *constant* advantage regime, one-query quantum distinguishers already require $\Omega(\sqrt{n})$ non-adaptive classical queries to simulate with the same advantage. Subsequent works [4, 11] showed a rapid deterioration as more queries are added: In general, q classical queries to a Boolean oracle require $\Omega_q(n^{1-1/2q})$ classical queries to simulate. Beyond one or a handful of quantum queries, the improvement over brute-force classical simulation becomes marginal. Moreover, addressing the case of one quantum query already brings up interesting technical challenges and reveals connections to statistical estimation and random matrix theory.

Second, a one-query quantum algorithm can be viewed as a sensible model of a noise-prone quantum device. Motivated by the challenges quantum computers pose to cryptography, it is of interest to study the power of such devices as cryptographic adversaries. In this context, the best classical simulation of a quantum adversary tells us to what extent our confidence in cryptographic security of existing constructions carries over to the quantum setting. While quantum security analyses have been successfully carried out for specific constructions, e.g., [15, 14, 8], our work provides general black-box "transfer theorems" that yield quantum security directly from sufficiently strong classical security at a bounded cost in parameters.

Our results

Our starting point is the separation between quantum and classical query complexity of Aaronson and Ambainis [1]. In response to a question of Buhrman et al. [6], they constructed a random variable F (for "Forrelation") over $\{\pm1\}^{2n}$ (where n is a power of two) for which

- There exists a one query quantum algorithm that distinguishes F from a uniformly random input in $\{\pm1\}^{2n}$ with constant advantage.
- Every classical algorithm that makes $o(\sqrt{n})$ queries fails to distinguish F from random with constant advantage.

Moreover, their example is tight [5, 2]: Every one-query quantum distinguisher with constant advantage can be simulated by a $O(\sqrt{n})$-query non-adaptive classical distinguisher with constant advantage.

Here, as in the rest of the paper, a *distinguisher* is an algorithm that produces outputs in the range $[-1, 1]$. The output of a quantum algorithm is taken to be its probability that it collapses to an accepting state. The *advantage* of D on the pair of distributions $(\mathbf{A}, \mathbf{B})$ is $\frac{1}{2}|\mathsf{E}[D(\mathbf{A})] - \mathsf{E}[D(\mathbf{B})]|$.

We are interested in the best possible advantage that a classical distinguisher with $k \ll \sqrt{n}$ queries can attain for a pair of distributions that are ε-distinguishable by a one-query quantum algorithm. The example of Aaronson and Ambainis yields the following generalization:

▶ **Proposition 1.** *For every $\varepsilon \in (0, 1)$, $k \in \mathbb{N}$, and $n = 2^m$ for some $m \in \mathbb{N}$, there exists a $\{\pm1\}^{2n}$-valued random variable F_ε that is ε-distinguishable from a uniform random $2n$-bit string by 1 quantum query, but $O(\varepsilon k/\sqrt{n})$-indistinguishable by any non-adaptive $2k$-query classical algorithm.*

The random variable F_ε is a mixture of Forrelation F and a uniform random variable U. We believe that the bound $O(\varepsilon k/\sqrt{n})$ is the best possible gap in the advantage of k-query non-adaptive classical versus one-query quantum distinguisher. Our first result is the following lower bound on the classical advantage:

▶ **Theorem 2.** *Let $\varepsilon \in (0,1)$, $k, n \in \mathbb{N}$. Suppose $(\mathbf{A}, \mathbf{B})$ is a pair of random variables over $\{\pm 1\}^n$ that is ε-distinguishable by a one-query quantum algorithm. There exist $2k$-query non-adaptive classical algorithms P_{2a} and P_{2b}, such that*

a. *P_{2a} distinguishes $(\mathbf{A}, \mathbf{B})$ with advantage $\Omega(\varepsilon\sqrt{k/n})$,*

b. *P_{2b} distinguishes $(\mathbf{A}, \mathbf{B})$ with advantage $\Omega(\varepsilon^2 k^2/n)$, assuming $k = O(\sqrt{n})$.*

Assuming ε is constant, distinguisher P_{2a} works better when k is small but does not reach constant advantage as k approaches $\sqrt{n}$. In contrast, distinguisher P_{2b} has a constant advantage when $k = \Theta(\sqrt{n})$; but for the case of $k = 1$, the advantage is worse than the upper bound $O(\varepsilon/\sqrt{n})$ as given in Proposition 1 by a factor of $1/\sqrt{n}$.

We also show that for constant ε, an advantage of $\Omega(k/\sqrt{n \log n})$ can be achieved with two rounds of queries.

▶ **Theorem 3.** *For every $\varepsilon \in (0,1), n \in \mathbb{N}$, and $k \leq \sqrt{n \log n}/\varepsilon$, every pair of random variables over $\{\pm 1\}^n$ that is ε-distinguishable by a one-query quantum algorithm is also $\Omega(\varepsilon^2 k/\sqrt{n \log n})$-distinguishable by a $2k$-query two-round adaptive classical algorithm.*

Bansal and Sinha [4] showed that no k-query adaptive classical algorithm can distinguish F from random with advantage better than $O(\varepsilon k^{1/2}(\log n)^{1/4}/n^{1/4})$. Sherstov, Storozhenko, and Wu [11] proved the same bound with different distributions.

We prove that their bound can be improved to $\tilde{O}(\varepsilon k/\sqrt{n})$ for two-round algorithms, thereby showing that the simulation in Theorem 3 is optimal in k and n up to log factors.

▶ **Theorem 4.** *For every $\varepsilon > 0$, $k \in \mathbb{N}$, and $n = 2^m$ for some $m \in \mathbb{N}$, there exists a random variable F_ε on $\{\pm 1\}^n$, such that it is $O(\varepsilon k\sqrt{\log n}/\sqrt{n})$-indistinguishable from random by any two-round classical algorithm that makes k queries per round.*

Up to the factor of $\sqrt{\log n}$, Theorem 4 generalizes Proposition 1 to adaptive two-round algorithms. The results are summarized in Table 1.

Table 1 Bounds on the best possible advantage of a k-query classical simulation of a one-query quantum distinguisher with advantage ε for distributions over the n-dimensional Boolean cube.

Type	Upper bound	Ref.	Lower bound	Ref.
Non-adaptive	$O(\varepsilon k/\sqrt{n})$	Proposition 1	$\Omega(\varepsilon\sqrt{k/n})$	Theorem 2a
			$\Omega(\varepsilon^2 k^2/n)$	Theorem 2b
Two-round	$O(\varepsilon k\sqrt{\log n}/\sqrt{n})$	Theorem 4	$\Omega(\varepsilon^2 k/\sqrt{n \log n})$	Theorem 3
Adaptive	$O(\varepsilon k^{1/2}(\log n)^{1/4}/n^{1/4})$	[4, 11]		

While it is worth mentioning that the lower bound on advantage in Theorem 3 never exceeds the upper bound from Proposition 1, it remains open whether adaptivity helps in classical simulations of one-query quantum distinguishers.

Our techniques

The acceptance probability of a quantum algorithm that makes one query to an n-bit oracle can be represented by a *bounded* $(n+1) \times (n+1)$ *bilinear form*, that is a function of the form $p(x,y) = \sum A_{ij} x_i y_j$ for some matrix $A \in \mathbb{R}^{(n+1)\times(n+1)}$ with bounded ∞-to-1 norm (see Proposition 6). It suffices to prove our results under the assumption that the two distributions are distinguishable by such bilinear forms. Aaronson et al. [3] showed that this representation fully characterizes one-query quantum algorithms: every bilinear form of bounded ∞-to-1 norm represents the acceptance probability of some one-query quantum algorithm up to constant scaling.

The general problem of identifying the optimal distinguisher in a class of algorithm $\mathcal{A}$ against a class of distribution pairs $\mathcal{B}$ can be modeled as a zero-sum game between distinguishers in $\mathcal{A}$ and distribution pairs in $\mathcal{B}$ whose payoff is the advantage. In this setting, we take $\mathcal{A}$ to be the classical algorithms that make k queries to x and k queries to y, and $\mathcal{B}$ to be the distribution pairs ε-distinguishable by some one-query quantum algorithm.

By Yao's minimax theorem, a given distinguishing advantage is achievable against any given pair in $\mathcal{B}$ if and only if there exists a mixture of distinguishers that has the same expected advantage against all pairs in $\mathcal{B}$. Hence it is sufficient (and necessary) to construct a probabilistic distinguisher that is oblivious to the actual distributions. Such a distinguisher can be obtained from an unbiased estimator for some multiple of p: if $\mathsf{E}[D(x,y)] = \frac{1}{Z}p(x,y)$ for all inputs x, y then the distinguishing advantage of D is at most Z times smaller than that of p.

In the proof of Theorem 2a, we construct an unbiased estimator P_{2a} for p/Z with $Z = O(\sqrt{n/k})$ that is a mixture of $2k$-juntas. Each junta is a homogeneous quadratic function on k bits of x-input and k bits of y-input.

The approximation factor Z is derived based on an additional assumption of boundedness of the juntas, which we explain in detail in Proposition 6. The proposition states that a one-query quantum algorithm is fully characterized by a bilinear form with *∞-to-1 norm* bounded by 1 (we say this bilinear form is 1-bounded). It can be shown that Z is the best possible within this class of unbiased estimators:

▶ **Proposition 5.** *There exists a 1-bounded $n \times n$ bilinear form p such that if p/Z is represented as a mixture of 1-bounded $k \times k$ bilinear forms, then $Z = \Omega(\sqrt{n/k})$.*

In Theorem 2b, we bypass the limitation by truncating a different *unbounded* unbiased estimator P_{2b}. Corollary 13 lower bounds the advantage of the distinguisher obtained by truncating a scaled unbiased estimator in terms of its variance. The relevant estimator is obtained from independently sampled indices $i_1, \dots, i_k, j_1, \dots, j_k$ of x and y input coordinates, respectively, where each coordinate is chosen with probability weighted by Grothendieck's factorization (see Section 2 for the definition). Proposition 16, which is also implicit in the more general analysis of [5], shows that this estimator has variance $O(n/k^2)$.

One weakness of estimator P_{2b} is that it samples the bits of the inputs x and y independently and fails to detect relevant correlations between them. In contrast, the estimator P_3 in Theorem 3 computes the distribution on y-queries adaptively depending on the answers to the x-queries. Viewing the bilinear form $p(x,y)$ as a linear function of the y-inputs, the sample of x-inputs is used to estimate the coefficient $\sum_i A_{ij}x_i$ of y_j for every j. In the second round, the y-inputs are sampled with probabilities proportional to these estimates. Using Grothendieck's factorization and exponential tail bounds, in Proposition 17 we show that this improves the effective variance of P_{2b} by a factor of $\tilde{O}(\sqrt{k})$.

2 Quantum algorithms, bilinear forms, and norms

Notations

We write $[n]$ for the set $\{1, \dots, n\}$. We use the standard computer science asymptotic notations, and the tilde notations hide logarithmic factors. We write $\mathcal{N}(\mu, \Sigma)$ for a multivariate Gaussian with mean μ and covariance matrix Σ, sd for statistical distance, and kl for KL-divergence.

For $A \in \mathbb{R}^{m\times n}$, we use $A^{i,:}$ to denote the i-th row of A and $A^{:,j}$ for the j-th column of A. We write e_i the i-th standard basis vector, and Id_k the $k \times k$ identity matrix. For a symmetric matrix A, we denote the minimum and maximum eigenvalues (which are guaranteed to be real) by $\lambda_{\min}(A)$ and $\lambda_{\max}(A)$ respectively.

Norms

For a vector, we denote $\|v\|_p$ the p-norm of v. The 1-norm, 2-norm and ∞-norm will be relevant in this work. We drop the subscript for Euclidean norm (2-norm) of a vector. The Cauchy-Schwarz inequality says that $\sum_i u_i v_i \leq \|u\|\|v\|$ and in particular $\|v\|_1 \leq \sqrt{n}\|v\|$ for $v \in \mathbb{R}^n$.

For $A \in \mathbb{R}^{m\times n}$, the *spectral norm* $\|A\|$, *Frobenius norm* $\|A\|_F$, and ∞*-to-*1*-norm* $\|A\|_{\infty\to 1}$ are defined to be

$$\|A\| := \max_{u\in\mathbb{R}^n:\|u\|=1} \|Au\| = \max_{\substack{u\in\mathbb{R}^m, v\in\mathbb{R}^n\\ \|u\|=\|v\|=1}} u^\top Av$$

$$\|A\|_F := \sqrt{\sum_{i=1}^{m}\sum_{j=1}^{n} A_{ij}^2}$$

$$\|A\|_{\infty\to 1} := \max_{\substack{x\in\{\pm 1\}^m\\ y\in\{\pm 1\}^n}} x^\top Ay = \max_{\substack{x\in[-1,1]^m\\ y\in[-1,1]^n}} x^\top Ay = \max_{x\in\mathbb{R}^n:\|x\|_\infty=1} \|Ax\|_1$$

The relevance of the ∞-to-1 norm stems from the following connection to one-query quantum algorithms:

▶ **Proposition 6** ([3]). *For every quantum algorithm Q making one query to some oracle in $\{\pm 1\}^n$, there exists a bilinear form $p(x,y) = \sum_{i,j=1}^{n+1} A_{ij}x_iy_j$, $A_{ij} \in \mathbb{R}$, such that for every $x \in \{\pm 1\}^n$, the probability that Q accepts x equals $p((x_1,\ldots,x_n,1),(x_1,\ldots,x_n,1))$.*

We refer to p as the *advantage polynomial*, and by abuse of notation, we refer $\|p\|_\#$ to be $\|A\|_\#$ for any norm $\|\cdot\|_\#$. Clearly, the matrix defining any advantage polynomial must have ∞-to-1 norm at most 1 (hence every advantage polynomial is *1-bounded*). In general, this does not imply a constant upper bound on the spectral norm. However, the dual form of Grothendieck's inequality, also known as the *factorization Grothendieck's inequality* [9, P.239], shows that such a bound holds up to factorization.

Grothendieck's factorization

▶ **Proposition 7** ([9]). *There is a universal constant K_G such that if $A \in \mathbb{R}^{n\times n}$ satisfies that $\|A\|_{\infty\to 1} \leq 1$, then there exists $\alpha, \beta \in \mathbb{R}^n_{\geq 0}$ with $\|\alpha\| = \|\beta\| = 1$, such that A can be factored as $A_{ij} = \alpha_i \tilde{A}_{ij} \beta_j$ with $\|\tilde{A}\| \leq K_G$.*

If the matrix A has no all-zero row or all-zero column, then we can further assume that α and β are strictly positive, which is an assumption we can make for advantage polynomials.

If p is the advantage polynomial of a one-query quantum algorithm, the stronger conclusion $\|\tilde{A}\| \leq 1$ can be obtained in Proposition 6 without using Grothendieck's inequality but we will not rely on this fact (at the expense of constant factors in some proofs). We also remark that this factorization can be efficiently found by a semidefinite program.

3 Non-adaptive estimators: Proof of Theorem 2

3.1 Proof of Theorem 2a

Suppose $p(x,y) = \sum_{i,j=1}^{n} A_{ij}x_iy_j$ is the advantage polynomial of a quantum algorithm, so in particular $\|A\|_{\infty\to1} \le 1$. For $I, J \subseteq [n]$, we write A_{IJ} the submatrix of A restricted to rows indexed in I and columns indexed in J, and

$$p_{IJ}(x,y) = \sum_{i\in I, j\in J} A_{ij}x_iy_j.$$

We analyze the following $2k$-query classical distinguisher $P_{2a}(x,y)$:

1. Pick a pair of index sets $I, J \subseteq [n]$, $|I| = |J| = k$, with probability proportional to $\|p_{IJ}\|_{\infty\to1}$.
2. Query all x_i with $i \in I$ and all y_j with $j \in J$.
3. Output $p_{IJ}(x,y)/\|p_{IJ}\|_{\infty\to1}$.

As x and y take ±1 values, the step 3 above, always outputs a value $D(x,y) \in [-1,1]$ as required for a distinguisher. We first show that $D(x,y)$ is an unbiased estimator of $p(x,y)$ up to a scalar.

▷ Claim 8. $Z \cdot D(x,y)$ is an unbiased estimator of $p(x,y)$, where

$$Z = \sum_{I,J:|I|=|J|=k} \|p_{IJ}\|_{\infty\to1} \Big/ \binom{n-1}{k-1}^2.$$

Proof. The probability for choosing the index pair (I,J) in step 1 is given by

$$\frac{\|p_{IJ}\|_{\infty\to1}}{\sum_{I',J':|I'|=|J'|=k} \|p_{I'J'}\|_{\infty\to1}} = \frac{\|p_{IJ}\|_{\infty\to1}}{Z\binom{n-1}{k-1}^2}.$$

Therefore

$$\begin{aligned}
\mathsf{E}[Z \cdot D(x,y)] &= Z \sum_{|I|=|J|=k} \frac{\|p_{IJ}\|_{\infty\to1}}{Z\binom{n-1}{k-1}^2} \cdot \frac{p_{IJ}(x,y)}{\|p_{IJ}\|_{\infty\to1}} \\
&= \frac{1}{\binom{n-1}{k-1}^2} \sum_{|I|=|J|=k} \sum_{i\in I, j\in J} A_{ij}x_iy_j \\
&= \sum_{i=1}^{n}\sum_{j=1}^{n} A_{ij}x_iy_j \\
&= p(x,y).
\end{aligned}$$

The second-to-last line uses the fact that each index i appears in exactly $\binom{n-1}{k-1}$ sets I and likewise for j and J. ◁

To complete the analysis we use the following inequality.

▶ **Proposition 9.** *There is a constant C so that for any $n \times n$ matrix A,*

$$\frac{1}{\binom{n}{k}^2} \sum_{|I|=|J|=k} \|A_{IJ}\|_{\infty\to1} \le C\left(\frac{k}{n}\right)^{3/2} \|A\|_{\infty\to1}. \qquad (1)$$

Proof of Theorem 2a. Let p be the advantage polynomial of the one-query quantum algorithm with advantage ε on $(\mathbf{A}, \mathbf{B})$, and A be the matrix defining p. Without loss of generality, we assume

$$\mathsf{E}[p(\mathbf{A})] - \mathsf{E}[p(\mathbf{B})] \geq \varepsilon.$$

From Claim 8, we obtain

$$\mathsf{E}[D(\mathbf{A})] - \mathsf{E}[D(\mathbf{B})] = \frac{1}{Z}(\mathsf{E}[p(\mathbf{A})] - \mathsf{E}[p(\mathbf{B})]) \geq \frac{\varepsilon}{Z}.$$

It remains to upper bound the value of Z. Using Proposition 9 we get

$$Z = \frac{\binom{n}{k}^2}{\binom{n-1}{k-1}^2} \cdot \frac{1}{\binom{n}{k}^2} \sum_{|I|=|J|=k} \|A_{IJ}\|_{\infty\to 1} \leq \frac{n^2}{k^2} \cdot C\left(\frac{k}{n}\right)^{3/2} \|A\|_{\infty\to 1} \leq C\sqrt{\frac{n}{k}}.$$

This concludes the desired advantage bound of $\Omega(\varepsilon\sqrt{k/n})$. ◀

It follows from Proposition 5 that our analysis of D is tight up to constant factor.

Proposition 9 is similar to the following inequality proved by Rudelson and Vershynin [10, Equation (4.1)] who showed that for subsets I_ρ and J_ρ sampled by including each index independently with probability $\rho = k/n$,

$$\mathsf{E}[\|A_{I_\rho J_\rho}\|_{\infty\to 1}] \leq C'\rho^{3/2}\big(\|A\|_{\text{row}} + \|A\|_{\text{col}}\big) + C'\rho^2\|A\|_{\infty\to 1}, \tag{2}$$

for some constant C'. Here, $\|A\|_{\text{row}} = \sum_i \|A^{i,:}\|$ and $\|A\|_{\text{col}} = \sum_j \|A^{:,j}\|$ denote the sum of the 2-norms of its rows and columns, respectively. For completeness, we present the derivation Proposition 9 from (2) using Poissonization [13] (see also [12]).

Proof of Proposition 9. Tropp [13] showed that

$$\frac{1}{\binom{n}{k}^2} \sum_{|I|=|J|=k} \|A_{IJ}\|_{\#} \leq 4\mathsf{E}[\|A_{I_\rho J_\rho}\|_{\#}],$$

for every matrix norm $\|\cdot\|_{\#}$ that satisfies $\|A'\|_{\#} \leq \|A\|_{\#}$ for every submatrix A' of A. This is in particular true for the ∞-to-1 norm: if $\|A'\|_{\infty\to 1} = x'^{\top} A' y'$ for $x', y' \in [-1,1]^m$, then $\|A\|_{\infty\to 1} \geq x^{\top} A y = x'^{\top} A' y'$ where x and y are extended from x' and y' with zeros padded in the remaining entries. It remains to prove that $\|A\|_{\text{row}}, \|A\|_{\text{col}} \leq K_G \|A\|_{\infty\to 1}$. ◀

▷ Claim 10. For any $M \in \mathbb{R}^{m\times n}$, $\|M^{i,:}\| \leq \|M\|$ and $\|M^{:,j}\| \leq \|M\|$ for any $i \in [m]$, $j \in [n]$.

Proof. We prove the case of $\|M^{i,:}\|$ and the other case follows the same proof:

$$\|M^{i,:}\|^2 = e_i^{\top} M (M^{i,:}) \leq \|M\| \cdot \|M^{i,:}\| \implies \|M^{i,:}\| \leq \|M\|.$$ ◁

▷ Claim 11. $\|A\|_{\text{row}} \leq K_G \|A\|_{\infty\to 1}$.

Proof. By re-scaling, we assume $\|A\|_{\infty\to 1} = 1$ without loss of generality. Let $A_{ij} = \alpha_i \tilde{A}_{ij} \beta_j$be the Grothendieck's factorization of A (Proposition 7), by Cauchy-Schwarz inequality,

$$\|A\|_{\text{row}} = \sum_i \sqrt{\sum_j A_{ij}^2} = \sum_i \alpha_i \cdot \sqrt{\sum_j \beta_j^2 \tilde{A}_{ij}^2} \leq \sqrt{\sum_i \alpha_i^2}\sqrt{\sum_{ij} \beta_j^2 \tilde{A}_{ij}^2} = \sqrt{\sum_j \beta_j^2 \|\tilde{A}^{:,j}\|^2}.$$

By Claim 10 and the bound $\|\tilde{A}\| \leq K_G$, we conclude that $\|A\|_{\text{row}} \leq \sqrt{\sum_j \beta_j^2 \cdot K_G^2} = K_G$. ◁

3.2 The bias of truncated unbiased estimators

In preparation for the proof of Theorem 2b, we prove a general bound of the bias arising from truncating an unbiased estimator of low variance. Denote trunc: $\mathbb{R} \to [-1, 1]$ the truncation function

$$\mathrm{trunc}(t) = \begin{cases} t, & \text{if } |t| \leq 1, \\ \mathrm{sign}(t), & \text{if } |t| > 1. \end{cases}$$

▶ **Proposition 12.** *Assume $\|f\|_\infty = 1$, $Z \geq 1$, and $F_\mathbf{r}$ is a random function such that $\mathsf{E}[F_\mathbf{r}(x)] = f(x)$ for all x (here r denotes the randomness). The distinguisher $D_\mathbf{r}(x) = \mathrm{trunc}(F_\mathbf{r}(x)/Z)$ has advantage at least*

$$\frac{\varepsilon}{Z} - 2\max_x \int_{1-1/Z}^{\infty} \mathsf{Pr}_r\big(|F_\mathbf{r}(x) - f(x)| \geq Zt\big)dt.$$

for any pair of random variables that are ε-distinguishable by f.

▶ **Corollary 13.** *Under the assumptions of Proposition 12, D has advantage at least*

$$\frac{\varepsilon}{Z} - \frac{2}{Z(Z-1)} \cdot \max_x \mathsf{Var}\, F_\mathbf{r}(x).$$

Proof. Using Chebyshev's inequality, the integrand appearing in Proposition 12 is at most $(\mathsf{Var}\, F_\mathbf{r}(x))/Z^2t^2$ and so the integral is at most $(\mathsf{Var}\, F_\mathbf{r}(x))/Z(Z-1)$. ◀

The proposition is derived from the following claim:

▷ Claim 14. Let Y be a random variable with $|\mathsf{E}[Y]| \leq 1$, then

$$\big|\mathsf{E}[\mathrm{trunc}(Y)] - \mathsf{E}[Y]\big| \leq \int_{1-|\mathsf{E}[Y]|}^{\infty} \mathsf{Pr}(|Y - \mu| \geq t)dt.$$

Proof of Proposition 12. We apply Claim 14 to the random variable $F_\mathbf{r}(x)/Z$ to obtain

$$\begin{aligned} |\mathsf{E}[D_\mathbf{r}(x)] - f(x)/Z| &\leq \int_{1-|f(x)/Z|}^{\infty} \mathsf{Pr}_r\big(|F_\mathbf{r}(x)/Z - f(x)/Z| \geq t\big)dt \\ &\leq \int_{1-1/Z}^{\infty} \mathsf{Pr}_r\big(|F_\mathbf{r}(x) - f(x)| \geq Zt\big)dt. \end{aligned}$$

Suppose $(\mathbf{A}, \mathbf{B})$ is ε-distinguishable by f. By the triangle inequality, $|\mathsf{E}[D_\mathbf{r}(\mathbf{A})] - \mathsf{E}[f(\mathbf{A})]/Z|$ is at most the maximum of the integral over x, and the same bound holds for replacing $\mathbf{A}$ by $\mathbf{B}$. Now the bound on advantage follows from triangle inequality. ◀

In the proof of Claim 14 we use the following fact:

▶ **Fact 15.** $|\mathrm{trunc}(t) - t| = \max\{0, |t| - 1\}$.

Proof of Claim 14. Let $\mu = \mathsf{E}[Y]$.

$$\begin{aligned}
|\mathsf{E}[\mathrm{trunc}(Y)] - \mathsf{E}[Y]| &\le \mathsf{E}[|\mathrm{trunc}(Y) - Y|] \\
&= \int_0^\infty \Pr(|\mathrm{trunc}(Y) - Y| \ge t)dt \\
&= \int_0^\infty \Pr(|Y| - 1 \ge t)dt && \text{(Fact 15)} \\
&= \int_0^\infty \Pr(|Y| \ge t + 1)dt \\
&\le \int_0^\infty \Pr(|Y - \mu| \ge t + 1 - |\mu|)dt && \text{(triangle inequality)} \\
&= \int_{1-|\mu|}^\infty \Pr(|Y - \mu| \ge t)dt && \text{(change of variables)} \qquad \triangleleft
\end{aligned}$$

3.3 Proof of Theorem 2b

Let $p(x,y) = \sum_{ij} A_{ij}x_iy_j$ be the advantage polynomial so that $\|A\|_{\infty\to 1} = 1$. We let $A_{ij} = \alpha_i\tilde{A}_{ij}\beta_j$ to be the Grothendieck's factorization of A. We analyze the following $2k$-query estimator:

1. Sample a sequence $I = (I(1), \dots, I(k))$ of k i.i.d indices by picking each $i \in [n]$ with probability $p_i := \alpha_i/\|\alpha\|_1$. Query the inputs $x_{I(u)}$ for $u \in [k]$.
2. Sample a sequence $J = (J(1), \dots, J(k))$ of k i.i.d indices by picking each $j \in [n]$ with probability $q_j := \beta_j/\|\beta\|_1$. Query the inputs $y_{J(v)}$ for $v \in [k]$.
3. Output the empirical average

$$P(x,y) = \mathsf{E}_{i\sim I, j\sim J}\left[A_{ij}\frac{x_iy_j}{p_iq_j}\right].$$

Clearly this estimator makes at most $2k$ queries. Now we show that this is an unbiased estimator of bounded variance.

▶ **Proposition 16.** *$P(x,y)$ is an unbiased estimator of $p(x,y)$ of variance at most $O(n/k^2)$.*

Proof. Unbiasedness follows from linearity of expectation:

$$\mathsf{E}[P(x,y)] = \mathsf{E}\Big[\mathsf{E}\Big[A_{ij}\frac{x_iy_j}{p_iq_j} \Bigm| I, J\Big]\Big] = \mathsf{E}\Big[A_{ij}\frac{x_iy_j}{p_iq_j}\Big] = \sum_{i,j} A_{ij}\frac{x_iy_j}{p_iq_j}\cdot p_iq_j = p(x,y).$$

In preparation for calculating the variance, let $B_{uv} = A_{I(u)J(v)}/p_{I(u)}q_{J(v)}$. By independence and the fact that $x_i^2 = y_j^2 = 1$,

$$\mathsf{Cov}(B_{uv}, B_{u'v'}) = \begin{cases} \mathsf{E}\left[\frac{A_{ij}^2}{p_i^2q_j^2}\right] - p(x,y)^2, & \text{if } u = u' \text{ and } v = v' \\ \mathsf{E}\left[\frac{A_{ij}A_{ij'}y_jy_{j'}}{p_i^2q_jq_{j'}}\right] - p(x,y)^2, & \text{if } u = u' \text{ and } v \ne v' \\ \mathsf{E}\left[\frac{A_{ij}A_{i'j}x_ix_{i'}}{p_ip_{i'}q_j^2}\right] - p(x,y)^2, & \text{if } u \ne u' \text{ and } v = v' \\ 0, & \text{otherwise.} \end{cases}$$

Here i, i' and j, j' denote random indices chosen independently. Decomposing $\mathsf{Var}[P(x,y)]$ as an average of covariances, we obtain

$$\begin{aligned}\mathsf{Var}[P(x,y)] &= \frac{1}{k^4}\sum_{u,v,u',v'}\mathsf{Cov}\big(B_{uv},B_{u'v'}\big)\\ &\le \frac{1}{k^2}\mathsf{E}\left[\frac{A_{ij}^2}{p_i^2q_j^2}\right]+\frac{k-1}{k^2}\left(\mathsf{E}\left[\frac{A_{ij}A_{ij'}y_jy_{j'}}{p_i^2q_jq_{j'}}\right]+\mathsf{E}\left[\frac{A_{ij}A_{i'j}x_ix_{i'}}{p_ip_{i'}q_j^2}\right]\right).\end{aligned}\tag{3}$$

We bound the three types of terms using Grothendieck's factorization of A.

$$\begin{aligned}\mathsf{E}\left[\frac{A_{ij}^2}{p_i^2q_j^2}\right] &= \sum_{i,j}\frac{A_{ij}^2}{p_iq_j}\\ &= \|\alpha\|_1\cdot\|\beta\|_1\cdot\sum_{i,j}\alpha_i\beta_j\tilde{A}_{ij}^2 && \text{(Grothendieck's factorization)}\\ &\le \|\alpha\|_1\cdot\|\beta\|_1\cdot\sqrt{\sum_{i,j}\alpha_i^2\tilde{A}_{ij}^2}\cdot\sqrt{\sum_{i,j}\beta_j^2\tilde{A}_{ij}^2} && \text{(Cauchy-Schwarz inequality)}\\ &= \|\alpha\|_1\cdot\|\beta\|_1\cdot\sqrt{\sum_i\alpha_i^2\|\tilde{A}^{i,:}\|^2}\cdot\sqrt{\sum_j\beta_j^2\|\tilde{A}^{:,j}\|^2}\\ &\le \|\alpha\|_1\cdot\|\beta\|_1\cdot\|\tilde{A}\|\cdot\|\tilde{A}\| && \text{(Claim 10)}\\ &\le n\cdot K_G^2. && \text{(Cauchy-Schwarz inequality)}\end{aligned}$$

$$\begin{aligned}\mathsf{E}\left[\frac{A_{ij}A_{ij'}y_jy_{j'}}{p_i^2q_jq_{j'}}\right] &= \sum_{i,j,j'}\frac{A_{ij}A_{ij'}y_jy_{j'}}{p_i}\\ &= \sum_i\frac{1}{p_i}\left(\sum_j A_{ij}y_j\right)^2\\ &\le \|\alpha\|_1\sum_i\alpha_i\left(\sum_j\tilde{A}_{ij}y_j\beta_j\right)^2 && \text{(Grothendieck's factorization)}\\ &\le \|\alpha\|_1\sum_i(\tilde{A}\beta^y)_i^2 && \text{(Define } (\beta^y)_j:=y_j\beta_j\text{; and } \alpha_i\in[0,1])\\ &= \|\alpha\|_1\|\tilde{A}\beta^y\|^2\\ &\le \|\alpha\|_1\|\tilde{A}\|^2 && (\|\beta^y\|=\|\beta\|=1)\\ &\le \sqrt{n}\cdot K_G^2. && \text{(Cauchy-Schwarz inequality)}\end{aligned}$$

By symmetry the third term is also at most $\sqrt{n}K_G^2$. Plugging into (3), we obtain

$$\mathsf{Var}[P(x,y)] = O(n/k^2+\sqrt{n}/k) = O(n/k^2).$$ ◀

Proof of Theorem 2b. Unbiasedness follows from linearity of expectation. Let V be the variance bound from Proposition 16. We instantiate Corollary 13 with this P and $Z = 1+4V/\varepsilon$. This is at most 1 provided $k^2 = o(n)$. The resulting distinguishing advantage is $\Omega(\varepsilon^2/V)$. ◀

The advantage of any distinguisher with the same distribution over samples cannot be better than $\varepsilon k^2/n$. Therefore our analysis is optimal in terms of k and n. To see this, consider the distribution in which the bit-pairs (x_i,y_i) are unbiased, ε-correlated, and mutually independent. The resultant bilinear form $(\sum x_iy_i)/n$ is 1-bounded, which corresponds to a one-query quantum distinguisher; and it distinguishes this distribution from random with advantage ε. In contrast, the advantage of a classical distinguisher is at most ε times the expected number of collisions $i=j$ with $i\in I$ and $j\in J$, which is at most $\varepsilon k^2/n$.

4 An adaptive estimator: Proof of Theorem 3

We modify the estimator of Section 3.3 so that the values $\{x_i : i \in I\}$ adaptively affect the probabilities for index sampling of J. Again we assume $\|A\|_{\infty\to 1} = 1$ and let $A_{ij} = \alpha_i \tilde{A}_{ij}\beta_j$ to be the Grothendieck's factorization of A.

1. Choose a sample I of k i.i.d indices by picking each $i \in [n]$ with probability $p_i = \alpha_i/\|\alpha\|_1$. Query the inputs x_i for $i \in I$. Let $a_I^x \in \mathbb{R}^n$ be defined by $[a_I^x]_j := \mathsf{E}_{i\sim I}[A_{ij}x_i/p_i]$.
2. Choose a sample J of k i.i.d indices by picking each $j \in [n]$ with probability $q_j = |[a_I^x]_j|/\|a_I^x\|_1$. Query the inputs y_j for $j \in J$.
3. Output the empirical average $P(x,y) = \mathsf{E}_{j\sim J}[[a_I^x]_j y_j/q_j]$.

This estimator is unbiased by linearity of expectation. The main technical result of this section is the following deviation bound:

▶ **Proposition 17.** *There is a constant C such that for all x, y, $\varepsilon > 0$, and $t > 0$,*

$$\mathsf{Pr}\left(|P(x,y) - p(x,y)| \geq \frac{C\sqrt{n\log n}}{k}\frac{t}{\varepsilon}\right) \leq \frac{k}{\sqrt{n}\log n}\left(\frac{\varepsilon}{t}\right)^2 + 2n^{-(t/\varepsilon)^2}.$$

Proof of Theorem 3. With a (possible) change in the constant factor in the lower bound, we may assume that $\varepsilon \leq \varepsilon_0$ for a sufficiently small constant ε_0 and $Z := C\sqrt{n\log n}/k\varepsilon \geq 2$. We apply Proposition 17 to bound the integral in Proposition 12 by

$$\begin{aligned}
&\int_{1-1/Z}^{\infty} \mathsf{Pr}\big(|P(x,y) - p(x,y)| \geq Zt\big) \\
&\quad\leq \frac{C}{\sqrt{\log n}} \cdot \frac{\varepsilon}{Z} \int_{1-1/Z}^{\infty} \frac{dt}{t^2} + 2\int_{1-1/Z}^{\infty} n^{-(t/\varepsilon)^2} dt \\
&\quad= \frac{C}{\sqrt{\log n}} \cdot \frac{\varepsilon}{Z} \cdot \frac{1}{1-1/Z} + \sqrt{\frac{4\pi\varepsilon^2}{\log n}} \cdot \mathsf{Pr}\big(\mathcal{N}(0, \varepsilon^2/2\log n) \geq 1 - 1/Z\big) \\
&\quad\leq \frac{2C}{\sqrt{\log n}} \cdot \frac{\varepsilon}{Z} + \sqrt{\frac{4\pi\varepsilon^2}{\log n}} \cdot \mathsf{Pr}\big(\mathcal{N}(0,1) \geq \sqrt{\log n/2\varepsilon^2}\big) \\
&\quad\leq \frac{2C}{\sqrt{\log n}} \cdot \frac{\varepsilon}{Z} + \sqrt{\frac{4\pi\varepsilon^2}{\log n}} \cdot n^{-1/\varepsilon^2} \\
&\quad\leq \frac{\varepsilon}{6Z} + \frac{\varepsilon}{6Z}.
\end{aligned}$$

The second to last inequality is the Gaussian tail bound. The last inequality holds for sufficiently large n using the assumption that $\varepsilon \leq \varepsilon_0$. By Proposition 12, D has advantage at least $\varepsilon/3Z$. ◀

To prove Proposition 17, we split the difference between P and p via the "hybrid" $P'(x,y) = (a_I^x)^\top y = \sum_j [a_I^x]_j y_j$. Claims 18 show that P' has small variance and is therefore close to P. Claim 19 shows that P' is typically close to P.

▷ Claim 18. $\mathsf{Var}[P'(x,y)] \leq K_G^2\sqrt{n}/k$.

▷ Claim 19. $\mathsf{Pr}[|P(x,y) - P'(x,y)| \geq t \cdot K_G\sqrt{n}/k \mid I] \leq 2\exp(-t^2/2)$ for every $t > 0$.

Proof of Proposition 17. By Claim 18 and Chebyshev's inequality, for every $t_1 > 0$,

$$\mathsf{Pr}\big[|P'(x,y) - p(x,y)| \geq t_1 \cdot K_G(\sqrt{n}/k)^{1/2}\big] \leq \frac{1}{t_1^2}.$$

Using Claim 19 together with a union bound and the triangle inequality, it follows that

$$\mathsf{Pr}\big[|P(x,y)-p(x,y)| \geq t_1 \cdot K_G(\sqrt{n}/k)^{1/2} + t_2 \cdot K_G\sqrt{n}/k\big] \leq \frac{1}{t_1^2} + 2\exp(-t_2^2/2)$$

for every $t_1 > 0$ and $t_2 > 0$. Plugging in $t_1 = (t/\varepsilon)\cdot(\sqrt{n}\log n/k)^{1/2}$ and $t_2 = (t/\varepsilon)\cdot(2\log n)^{1/2}$ gives the desired inequality. ◀

Proof of Claim 18. As the samples in I are independent,

$$\mathsf{Var}[P'(x,y)] = \frac{1}{k}\mathsf{Var}_i\left[\sum_j \frac{A_{ij}x_iy_j}{p_i}\right] = \frac{1}{k}\mathsf{Var}_i\left[\sum_j \frac{A_{ij}y_j}{p_i}\right]$$

because $x_i^2 = 1$. As i is sampled with probability $p_i = \alpha_i/\|\alpha\|_1$, we get

$$\begin{aligned}
\mathsf{Var}\left[\sum_j \frac{A_{ij}y_j}{p_i}\right] &\leq \sum_i p_i\Big(\sum_j \frac{A_{ij}y_j}{p_i}\Big)^2 \\
&\leq \|\alpha\|_1 \sum_i \alpha_i\Big(\sum_j \tilde{A}_{ij}y_j\beta_j\Big)^2 && \text{(Grothendieck's factorization)} \\
&\leq \|\alpha\|_1 \sum_i (\tilde{A}\beta^y)_i^2 && \text{(Define } (\beta^y)_j := y_j\beta_j\text{; and } \alpha_i \in [0,1]) \\
&\leq \|\alpha\|_1 \cdot \|\tilde{A}\|^2 && (\|\beta^y\| = \|\beta\| = 1) \\
&\leq \sqrt{n}\cdot K_G^2. && \text{(Cauchy-Schwarz inequality)}
\end{aligned}$$

◀

Proof of Claim 19. Since $[a_I^x]_j y_j/q_j = \|a_I^x\|_1 y_j$, conditioned on I, $P(x,y)$ is an average of k independent random variables taking values either $-\|a_I^x\|_1$ or $\|a_I^x\|_1$ with mean $P'(x,y)$. Applying the Chernoff-Hoeffding bound to $kP/\|a_I^x\|_1$, we obtain

$$\mathsf{Pr}\big[|P(x,y)-P'(x,y)| \geq t\|a_I^x\|_1/\sqrt{k} \;\big|\; I\big] \leq 2\exp(-t^2/2).$$

It remains to show that $\|a_I^x\|_1 \leq K_G\sqrt{n/k}$ for every choice of I:

$$\begin{aligned}
\|a_I^x\|_1 &= \sum_j \left|\frac{1}{k}\sum_{i\in I}\frac{x_iA_{ij}}{p_i}\right| \\
&= \frac{\|\alpha\|_1}{k}\sum_j \beta_j\left|\sum_{i\in I} x_i\tilde{A}_{ij}\right| && \text{(Grothendieck's factorization)} \\
&\leq \frac{\|\alpha\|_1}{k}\sqrt{\sum_j\Big(\sum_{i\in I}x_i\tilde{A}_{ij}\Big)^2} && \text{(Cauchy-Schwarz inequality)} \\
&= \frac{\|\alpha\|_1}{k}\sqrt{\sum_j (x_I^\top\tilde{A})_j^2} && \text{(Define } (x_I)_i := x_i\cdot\mathbf{1}(i\in I)) \\
&= \frac{\|\alpha\|_1}{k}\|x_I^\top\tilde{A}\| \\
&\leq \frac{\|\alpha\|_1\cdot\|x_I\|\cdot\|\tilde{A}\|}{k} \\
&\leq \frac{\sqrt{n}\cdot\sqrt{k}\cdot K_G}{k}. && \text{(Cauchy-Schwarz inequality)}
\end{aligned}$$

◀

As mentioned, Theorem 4 shows that the distinguisher in Theorem 3 is best possible up to a factor of $\log n$.

5 Classical advantage upper bounds: Proofs of Proposition 1 and Theorem 4

To start this section, we first present the proof for the classical advantage upper bound of non-adaptive algorithms.

Proof of Proposition 1. Aaronson and Ambainis [1] show that F is $\Omega(1)$-distinguishable from the uniform random U by one quantum query. The random variable F is obtained by rounding a pair of n-dimensional Gaussians (X, Y) where X is standard Gaussian and Y is obtained by applying the Hadamard matrix to X. So the non-adaptive classical $2k$-query advantage is upper bounded by the maximum statistical distance between the projections (X_I, Y_J) over all sets I, J with $|I| + |J| = 2k$ and a standard $2k$-dimensional Gaussian.

In general, the statistical distance between centered multivariate Gaussians with covariance matrices Σ_1 and Σ_2 is $\Theta(1)\min\{1, \|\Sigma_2^{-1}\Sigma_1 - I\|_F\}$ [7]. As Σ_2 is the identity and all non-diagonal entries of Σ_1 are $\pm 1/\sqrt{n}$, it follows that $\|\Sigma_2^{-1}\Sigma_1 - Id\|_F = O(k/\sqrt{n})$.

Setting F_ε as $\varepsilon F + (1-\varepsilon)U$, the advantage of any distinguisher, classical or quantum, scales precisely by ε. ◀

As for the classical advantage upper bound of two-round algorithms, the proof of Theorem 4 bounds the statistical distance between the distinguisher's views on the two distributions via their KL-divergence. We need the following explicit formula for KL-divergence of multivariate Gaussians:

▶ **Fact 20.** $\mathsf{kl}(\mathcal{N}(\mu, \Sigma), \mathcal{N}(0, Id_k)) = \frac{1}{2}(\|\mu\|^2 + \mathsf{tr}(\Sigma - Id_k) - \log \mathsf{det}\Sigma)$.

The following consequence of this formula is implicit in [7]:

▷ Claim 21. Assuming $\lambda_{\min}(\Sigma) \geq 1/3$, $\mathsf{kl}((\mathcal{N}(\mu, \Sigma), \mathcal{N}(0, Id_k)) \leq \frac{1}{2}(\|\mu\|^2 + \|\Sigma - Id_k\|_F^2)$.

Proof. Let $\eta_1, \ldots, \eta_k$ be the eigenvalues of $\Sigma - Id_k$. By assumption $\eta_1, \ldots, \eta_k \geq -2/3$. Then

$$\mathsf{tr}(\Sigma - Id_k) - \log \mathsf{det}\Sigma = \sum_{i=1}^{k}(\eta_i - \log(1+\eta_i)) \leq \sum_{i=1}^{k}\eta_i^2 = \|\Sigma - Id_k\|_F^2,$$

where the inequality uses the fact that $\eta - \log(1+\eta) \leq \eta^2$ for all $\eta \geq -2/3$. ◁

The requirement $\lambda_{\min}(\Sigma) \geq 1/3$ is satisfied by matrices that are close to the identity in the following sense:

▶ **Fact 22.** *If $A \in \mathbb{R}^{k\times k}$ is a symmetric matrix with $|A_{ij}| \leq \varepsilon$ for all $i, j \in [k]$, then $\lambda_{\min}(Id_k + A) \geq 1 - k\varepsilon$ and $\lambda_{\max}(Id_k + A) \leq 1 + k\varepsilon$.*

In particular, as long as Σ is $2/3k$-close to the identity in (entrywise) infinity-norm, the bound in Claim 21 applies.

Another tool we need is the chain rule for KL-divergence:

▶ **Fact 23** (Chain rule for KL-divergence)**.** $\mathsf{kl}((U, V), (U', V')) = \mathsf{kl}(U, U') + \mathsf{kl}(V|U, V'|U')$, *where* $\mathsf{kl}(V|U, V'|U') = \mathsf{E}_{u\sim U}\mathsf{kl}(V|U = u, V'|U' = u)$.

In our application of Fact 23, $(U, V) = (U_1, \ldots, U_k, V_1, \ldots, V_k)$ is a multivariate Gaussian. This class of distributions is closed under conditioning. To calculate the effect of conditioning on the parameters, we identify the zero-mean (assumed without loss of generality) random variables $U_1, \ldots, U_k, V_1, \ldots, V_k$ with vectors in Hilbert space endowed with the inner product $\mathsf{E}[A \cdot B]$. The conditional means and conditional covariances of $V|U$ are given by

$$\mathsf{E}[V_j|U] = V_j^{\|} \tag{4}$$

$$\mathsf{Cov}[V_j, V_{j'}|U] = \mathsf{E}[V_j^{\perp} \cdot V_{j'}^{\perp}], \tag{5}$$

where $V_j = V_j^{\|} + V_j^{\perp}$ is the orthogonal decomposition of V_j into a parallel component $V_j^{\|} \in \mathrm{Span}(U)$ and a perpendicular component $V_j^{\perp} \in \mathrm{Span}(U)^{\perp}$. As $V_j^{\|}$ is in $\mathrm{Span}(U)$, its value is determined by $U_1, \ldots, U_k$. And as $V_j^{\perp}$ and $V_{j'}^{\perp}$ are in $\mathrm{Span}(U)^{\perp}$, their values are independent of $U_1, \ldots, U_k$.

Lastly we will use the following fact:

▶ **Fact 24.** *If M is the maximum of n standard Gaussian random variables, then $\mathsf{E}\big[M^2\big] \leq 4\log(\sqrt{2}n)$.*

Proof of Fact 24. By Jensen's inequality, for every $t \in (0, 1/2)$,

$$\exp(t\mathsf{E}[M^2]) \leq \mathsf{E}[\exp(tM^2)] \leq \mathsf{E}[n\exp(t\mathcal{N}(0,1)^2)] = \frac{n}{\sqrt{1-2t}}.$$

Here, the last equality follows from the formula of the moment-generating function of a squared Gaussian. We obtain the desired formula by setting $t = 1/4$ and taking logarithms. ◀

Proof of Theorem 4. The random variable $F = (\operatorname{sign} X, \operatorname{sign} Y)$ is the same as in Proposition 1. As in the previous proof, we first reduce to the case when ε is constant and use the same notations in that proof.

Aaronson and Ambainis showed that $\mathsf{E}[\mathrm{sign}(X)(H/n)\,\mathrm{sign}(Y)] = \Omega(1)$, where H is the $n \times n$ Hadamard matrix. As $\|H/n\|_{\infty\to 1} \leq \|H\| \leq 1$, this justifies the quantum advantage.

For the classical case, as taking signs can only decrease advantage, we upper bound the advantage of distinguishing $Z = (X, Y)$ from $\mathcal{N}(0, Id_{2n})$. The only relevant property of Z is that $\mathsf{E}[Z_i] = 1$ and $|\mathsf{E}[Z_i Z_j]| \leq 1/\sqrt{n}$ for all pairs $i \neq j$. Without loss of generality, we assume that $k \leq \sqrt{n}/4$.

The distinguisher's strategy is specified by the query sets I and J with $|I| = |J| = k$, issued in the first and second round, respectively. For the sake of upper bound, we can assume without loss of generality that J is a deterministic function of the coordinates $Z_I = (Z_i)_{i\in I}$ observed in the first round. The distinguisher's advantage is at most

$$\begin{aligned}
\varepsilon_C &= \max_{I,J} \mathsf{sd}((Z_I, Z_J), \mathcal{N}(0, Id_{2k})) \\
&\leq \sqrt{\frac{1}{2}\max_{I,J} \mathsf{kl}((Z_I, Z_J), \mathcal{N}(0, Id_{2k}))} && \text{(Pinsker's inequality)} \\
&= \sqrt{\frac{1}{2}\Big(\max_{I} \mathsf{kl}(Z_I, \mathcal{N}(0, Id_k)) + \max_{I}\max_{J} \mathsf{E}_{Z_I}\mathsf{kl}(Z_J|Z_I, \mathcal{N}(0, Id_k))\Big)} && \text{(Fact 23)} \\
&\leq \sqrt{\frac{1}{2}\Big(\max_{I} \mathsf{kl}(Z_I, \mathcal{N}(0, Id_k)) + \max_{I} \mathsf{E}_{Z_I}\max_{J} \mathsf{kl}(Z_J|Z_I, \mathcal{N}(0, Id_k))\Big)} && \text{(convexity of max)}
\end{aligned}$$

As $k \leq \frac{2}{3}\sqrt{n}$, the covariance matrix Σ_I of Z_I is $2/3k$-close to the identity in infinity norm, so using Claim 21, for every I one has

$$\mathsf{kl}(Z_I, \mathcal{N}(0, Id_k)) \leq \frac{1}{2}\|\Sigma_I - Id_k\|_F \leq \frac{k^2}{2n}. \tag{6}$$

For the second KL-divergence, let $\mu_{J|I}$ and $\Sigma_{J|I}$ denote the vector of conditional means $(\mathsf{E}[Z_j|Z_I])_{j\in J}$ and covariances $\mathsf{Cov}[Z_j, Z_{j'}|Z_I]$ for $j, j' \in J$, respectively. We will prove that for all choices of I and J, $\Sigma_{J|I}$ is $2/3k$-close to Id_k and apply Claim 21 to bound it by

$$\mathsf{E}_{Z_I} \max_J \mathsf{kl}(Z_J|Z_I, \mathcal{N}(0, Id_k)) \le \frac{1}{2} \max_J \mathsf{E}\big[\|\mu_{J|I}\|^2\big] + \frac{1}{2} \max_J \mathsf{E}\big[\|\Sigma_{J|I}\|_F^2\big]. \tag{7}$$

To bound the first term in (7), we analyze the projections $Z_j^{\|}$ of Z_j onto $\mathrm{Span}\{Z_i \colon i \in I\}$ for every $j \notin I$. Fix a basis for the vector space spanned by $Z_1, \dots, Z_{2n}$ and let z_i be the representation of Z_i under this basis. Let B be the $k \times n$ matrix whose rows are z_i for $i \in I$. The projection $z_j^{\|}$ of z_j onto the row-span of B is given by the formula

$$z_j^{\|} = B^\top (BB^\top)^{-1} B z_j.$$

The norm of this projection is at most

$$\|z_j^{\|}\| \le \lambda_{\max}(BB^\top)^{1/2} \cdot \lambda_{\min}(BB^\top)^{-1} \cdot \|Bz_j\| \le \left(1 + \frac{k}{\sqrt{n}}\right)^{1/2} \left(1 - \frac{k}{\sqrt{n}}\right)^{-1} \cdot \sqrt{\frac{k}{n}} \le 2\sqrt{\frac{k}{n}}.$$

The second inequality follows from Fact 22 as $BB^\top$ is $1/\sqrt{n}$-close to the identity and the entries of Bz_j are all bounded by $1/\sqrt{n}$. The third inequality follows from the assumption $k \le \sqrt{n}/3$.

By (4), for every j, $\mathsf{E}[Z_j|Z_I]$ is a Gaussian random variable of mean zero and standard deviation at most $2\sqrt{k/n}$. Letting $\mu_{J|I}$ denote the vector of conditional means $(\mathsf{E}[Z_j|Z_I])_{j \in J}$, by Fact 24, for any fixed I,

$$\max_J \mathsf{E}\big[\|\mu_{J|I}\|^2\big] \le k\mathsf{E} \max_{j \in [n] \setminus I} \mathsf{E}[Z_j|Z_I]^2 \le k \left(2\sqrt{\frac{k}{n}}\right)^2 \cdot 4 \log(\sqrt{2}n) = \frac{16k^2 \log(\sqrt{2}n)}{n}. \tag{8}$$

For the second term in (7), we apply (5) to obtain

$$\mathsf{Cov}[Z_j, Z_{j'}|Z_I] = \mathsf{E}[Z_j^\perp \cdot Z_{j'}^\perp] = \mathsf{E}[Z_j \cdot Z_{j'}] - \mathsf{E}[Z_j^{\|} \cdot Z_{j'}^{\|}]$$

by orthogonality, from which we have

$$\big|\mathsf{Cov}[Z_j, Z_{j'}|Z_I] - \mathsf{E}[Z_j \cdot Z_{j'}]\big| \le \|z_j^{\|}\| \cdot \|z_{j'}^{\|}\| \le \frac{4k}{n} \le \frac{1}{\sqrt{n}}. \tag{9}$$

As $\mathsf{E}[Z_j \cdot Z_{j'}]$ is $1/\sqrt{n}$ close to the identity, we conclude that $\Sigma_{J|I}$ is $2/\sqrt{n} \le 2/3k$-close to the identity. Therefore Claim 21 applies. Plugging (8) and (9) into (7) we obtain

$$\mathsf{E}_{Z_I} \max_J \mathsf{kl}(Z_J|Z_I, \mathcal{N}(0, Id_k)) \le \frac{1}{2} \cdot \frac{16k^2 \log(\sqrt{2}n)}{n} + \frac{1}{2} \cdot k^2 \cdot \frac{4}{n} = O\Big(\frac{k^2 \log n}{n}\Big).$$

Together with (6), this gives $\varepsilon_C = O(k\sqrt{\log n}/\sqrt{n})$ as desired. ◀

6 Optimality of local unbiased estimators: Proof of Proposition 5

Proof of Proposition 5. With a (possible) change in the constant factor in the lower bound, we may assume each form in the mixture depends on k bits of x and k bits of y. Let $p(x, y) = \sum A_{ij} x_i y_j$, and let B_{IJ} be a matrix supported on $I, J \subseteq [n]$ with $|I| = |J| = k$:

$$[B_{IJ}]_{ij} = \begin{cases} b_{ij} & \text{if } i \in I, j \in J \\ 0 & \text{otherwise} \end{cases}.$$

Suppose $\|A\|_{\infty\to 1} = 1$ and $A = \mathsf{E}_{I,J}[B_{IJ}]$, where the expectation is over an arbitrary distribution over pairs I, J. It is sufficient to show that $\|B_{IJ}\|_{\infty\to 1} = \Omega(\sqrt{n/k})$ for at least one choice of the index sets (I, J).

We prove the contrapositive. Suppose $\|B_{IJ}\|_{\infty\to 1} \le \varepsilon$ for all B_{IJ}. By Claim 11, $\|B_{IJ}\|_{\text{row}} \le K_G \cdot \varepsilon$, so $\sum_{i\in I, j\in J} |[B_{IJ}]_{ij}| \le K_G \cdot \varepsilon\sqrt{k}$. Therefore

$$\sum_{i,j} |A_{ij}| = \sum_{i,j} |\mathsf{E}_{I,J}\left[[B_{IJ}]_{ij}\right]| \le \mathsf{E} \sum_{i\in I, j\in J} |[B_{IJ}]_{ij}| \le K_G \cdot \varepsilon\sqrt{k}.$$

For n being a power of two, let A be the $n \times n$ Hadamard matrix scaled by $1/n$, such that $\|A\|_{\infty\to 1} = n$. Then $|A_{ij}| = n^{-3/2}$ for all i and j, thus $K_G \cdot \varepsilon\sqrt{k} \ge \sqrt{n}$ and hence $\varepsilon = \Omega(\sqrt{n/k})$ as desired. If n is not a power of two, we plant the largest possible Hadamard matrix and zero out the remaining entries, the same argument still applies. ◀

Abstract

We give new upper and lower bounds on the power of several restricted classes of arbitrary-order read-once branching programs (ROBPs) and standard-order ROBPs (SOBPs) that have received significant attention in the literature on pseudorandomness for space-bounded computation.

- Regular SOBPs of length n and width $\lfloor w(n+1)/2 \rfloor$ can *exactly* simulate general SOBPs of length n and width w, and moreover an $n/2 - o(n)$ blow-up in width is necessary for such a simulation. Our result extends and simplifies prior average-case simulations (Reingold, Trevisan, and Vadhan (STOC 2006), Bogdanov, Hoza, Prakriya, and Pyne (CCC 2022)), in particular implying that *weighted* pseudorandom generators (Braverman, Cohen, and Garg (SICOMP 2020)) for regular SOBPs of width poly(n) or larger automatically extend to general SOBPs. Furthermore, our simulation also extends to general (even read-many) oblivious branching programs.
- There exist natural functions computable by regular SOBPs of constant width that are average-case hard for permutation SOBPs of exponential width. Indeed, we show that Inner-Product mod 2 is average-case hard for arbitrary-order permutation ROBPs of exponential width.
- There exist functions computable by constant-width arbitrary-order permutation ROBPs that are worst-case hard for exponential-width SOBPs.
- Read-twice permutation branching programs of subexponential width can simulate polynomial-width arbitrary-order ROBPs.

1 Introduction

Read-once branching programs (ROBPs) have been extensively studied over the past four decades, motivated by the fact that these programs capture how small-space machines use random coins, and hence optimal and explicit pseudorandom generators for them would imply $\mathbf{BPL} = \mathbf{L}$, showing that every randomized logspace algorithm can be simulated deterministically with only a constant factor blow-up in space. Thus, there has been several decades of research on constructing pseudorandom generators for different variants of ROBPs.

In this paper, we study how those variants compare to each other in computational power, through new simulations and separations. To describe our results, we first define the models we are studying, starting from the most general model of read-many branching programs.

▶ **Definition 1.** *An **(oblivious) branching program (BP)** B of **length** m and **width** w computes a function $B\colon \{0,1\}^n \to \{0,1\}$. On an input $x \in \{0,1\}^n$, the branching program computes as follows. It has $m+1$ layers $V_0, \dots, V_m$, each with vertices labeled $\{1, \dots, w\}$. It starts at a fixed start state $v_{st} \in V_0$. Then for each step $t = 1, \dots, m$, it reads the next symbol $x_{i(t)}$ for some $i(t) \in [n]$, and updates its state according to a transition function $B_t\colon V_{t-1} \times \{0,1\} \to V_t$ by taking $v_t = B_t[v_{t-1}, x_{i(t)}]$. For $v \in V_s$ and $u \in V_t$ for $t > s$, we write $B[v, y] = u$ if the program transitions to state u starting from state v upon reading $y = (x_{i(s+1)}, \dots, x_{i(t)})$. Moreover, there is a set of accept states $V_{acc} \subseteq V_m$. For $x \in \{0,1\}^n$, we define $B(x) = 1$ if and only if $B[v_{st}, x] \in V_{acc}$. That is, B accepts the inputs x that lead it from the start state $v_{st} \in V_0$ in the first layer to an accept state in the last layer $v_{acc} \in V_{acc} \subseteq V_m$. We write $B(v, x) = 1$ if the program transitions to an accept state from a state v on input x. We call the function $i : [m] \to [n]$ the* read order *of B.*

▶ **Definition 2.** *A **read-k branching program** is a BP where the read order i satisfies $|i^{-1}(j)| \leq k$ for every $j \in [n]$. For $k = 1$ we denote this a **read-once branching program (ROBP)**.*

▶ **Definition 3.** *A **standard-order ROBP (SOBP)** is an ROBP whose read order is the identity function (i.e. $i(t) = t$ for every $t \in [n]$).*

Note that we have the inclusions

SOBPs ⊆ ROBPs ⊆ BPs.

To emphasize the distinction between the standard-order model and general ROBPs (which have $i(t) = \pi(t)$ for some permutation π), we denote the latter as **arbitrary-order ROBPs.**

▶ Remark 4. Our choice of notation follows the recent surveys of Hatami and Hoza [26] and Hoza [28]. There have been several (inconsistent) choices of notation in prior papers. In particular, prior works have referred to standard order ROBPs as simply ROBPs, or "ordered BPs". Other works have referred to ROBPs as "unordered ROBPs".

In 1990, Nisan [38] constructed an explicit pseudorandom generator (PRG) for SOBPs with seed length $O(\log n \cdot \log(nw/\varepsilon))$ (c.f. the optimal $O(\log(nw/\varepsilon))$ achieved by the probabilistic method). Despite extensive effort, this result has not been improved when the width of the programs w is at least 4 and at most $2^{n^{o(1)}}$. Motivated by this longstanding challenge, researchers have extensively studied restricted cases of the model, known as *regular* and *permutation* SOBPs:

▶ **Definition 5.** *A **regular BP** is a branching program where for all $t \in [m]$ and $i \in [w]$, there are exactly two distinct pairs $(j_1, b_1), (j_2, b_2)$ such that $B_t[j_1, b_1] = B_t[j_2, b_2] = i$. Equivalently, the graph of transitions from V_{t-1} to V_t is 2-in-regular.*

▶ **Definition 6.** *A **permutation BP** is an branching program where for all $t \in [m]$ and $\sigma \in \{0,1\}$, $B_t[\cdot, \sigma]$ is a permutation on $[w]$.*

Note that we have the inclusions

permutation BPs ⊆ regular BPs ⊆ BPs

and the same inclusions hold when restricting BPs to ROBPs or SOBPs.

There has been extensive prior work studying pseudorandomness for regular [31, 8, 16, 5, 34, 12] and permutation [32, 44, 41, 10, 29, 39, 22] SOBPs and ROBPs over roughly the last decade.

For regular SOBPs, the PRG of Braverman, Rao, Raz, and Yehudayoff [8] improves on Nisan's (which has seed length $O(\log^2 n)$ even for $w = 4$ and $\varepsilon = 1/3$) in the regime where *both* w and $1/\varepsilon$ are subpolynomial, i.e. $n^{o(1)}$. The later work [5] obtained better seed length than $O(\log^2 n)$ when *either* w or $1/\varepsilon$ was $n^{o(1)}$ (whereas Braverman et al. required both parameters to be small relative to n), at the cost of obtaining only a hitting set generator (HSG), a weaker object than pseudorandom generators that is sufficient for most derandomization tasks. For permutation SOBPs, Pyne and Vadhan [39] achieved seed length $\tilde{O}(\log^{3/2} n)$ for an object known as a *weighted PRG*,[1] in the $w = n$ regime motivated by derandomizing logspace.

Despite this extensive prior work, and the status quo where the known pseudorandom objects for regular and permutation SOBPs are better than those known for generic SOBPs in many regimes, there was relatively little work investigating the relative power of these models. As an example, it is well known that SOBPs can be simulated by a one-way two-party communication protocol, and therefore any program of width less than $2^{\Omega(n)}$ cannot compute the Inner-Product function $\mathsf{IP}_{2n}(x) := \sum_{i=1}^{n} x_i x_{n+i} \pmod 2$ on average. However, this result does not say anything about the relative power of general SOBPs versus regular and permutation SOBPs.

1.1 Our Results

We begin a systematic study of the relative power of SOBPs, regular SOBPs, and permutation SOBPs. We first survey the landscape of known results before stating our results.

1.1.1 General vs. Regular Programs

Perhaps the best known upper bound in this regard is the work of Reingold, Trevisan, and Vadhan [42] and its recent extension of Bogdanov, Hoza, Pyne, and Prakriya [5]. They showed that regular SOBPs of width poly(nw) and length $\tilde{O}(n)$ can *approximately* simulate general SOBPs of width w and length n. This implies a "transfer result": in the width-poly(n) regime, optimal PRGs or HSGs for regular ROBPs imply the equivalent objects for general ROBPs, and hence for logspace computation. However, these results have a few limitations. First, the simulation was average-case, and due to this did not imply a transfer result for weighted PRGs, a pseudorandom object that has seen extensive recent interest [7, 11, 14, 39, 27]. Moreover, both proofs are relatively involved.

We show that this upper bound can be improved and substantially simplified, and in fact, general and regular programs of the same length m, regardless of being read-once or not, are equivalent up to a factor of m in the width.

▶ **Theorem 7** (Informal statement of Theorem 18). *Let B be an oblivious branching program of length m and width $w \geq 4$. There exists a regular oblivious branching program R of length m and width $mw/2$ such that $R(x) = B(x)$ for all x. Moreover, R has the same read order as B.*

[1] A weighted PRG is a tuple of functions $(G, \rho)\colon \{0,1\}^s \to \{0,1\}^n \times \mathbb{R}$, where the weighted expectation $\mathbb{E}_x[\rho(x) \cdot B(G(x))]$ is within ε of $\mathbb{E}[B(U_n)]$ for all B in the class.

As a consequence, weighted PRGs for regular SOBPs with seed length matching those known for permutation SOBPs [39] would imply an improved derandomization of logspace:[2]

▶ **Corollary 8.** *Suppose there is an explicit weighted PRG for regular SOBPs of length n and width w with seed length $\tilde{O}(\log n \cdot (\log n + \sqrt{\log(w/\varepsilon)}) + \log(w/\varepsilon))$. Then $\mathbf{BPL} \subset \mathbf{L}^{4/3+o(1)}$.*

This follows as a corollary of Theorem 7 and the argument of Chattopadhyay and Liao [11] that the Saks–Zhou algorithm [43] can be instantiated with a weighted PRG.

As mentioned above, Theorem 7 holds even for *non-read-once* branching programs (as defined in Definition 1), in contrast to the prior results of [42, 5]. As a corollary, we derive that $\mathbf{L}$ can be computed by polynomial width regular branching programs:

▶ **Corollary 9.** *Every language in $\mathbf{L}$ can be decided by a (read-many) regular branching program of length and width* $\mathrm{poly}(n)$*, on inputs of size n.*

In terms of separation results, some simple observations were known. The AND function, which can be shown to require width n for permutation (in fact, regular) BPs, has a trivial general BP of width 2. (See Observation 19 for a proof.) We extend this separation to larger widths. This complements our simulation result (Theorem 7) by showing that in the case of ROBPs, the loss of a factor of $n/2$ is tight up to an *additive* term of $(w \log w)/2$.

▶ **Proposition 10.** *For every $w = 2^t, n \in \mathbb{N}$, there is a function $f : \{0,1\}^n \to \{0,1\}$ computable by an general SOBP of width w such that every regular SOBP computing f has width at least $\frac{nw}{2} - w \log w$.*

It is known that general SOBPs of constant width cannot be approximated by regular SOBPs of some $\mathrm{poly}(n)$ width in the “sandwiching notion” [3]. This can be derived by combining the results of [9, 8]. Brody and Verbin [9] showed that there is an instantiation of the Impagliazzo–Nisan–Wigderson PRG [31] that does *not* fool general SOBPs of width 3, and yet Braverman et al. [8] shows that this same PRG fools regular SOBPs of width n^c for some $c > 0$.

1.1.2 Regular vs. Permutation Programs

For the relationship between permutation and regular SOBPs, the situation was even less clear. As discussed in the previous section, despite extensive work on pseudorandomness for permutation and regular SOBPs, prior work has not proven separations between the two models. In fact, as far as we know, prior work did not exhibit *any* function computable by a regular program that was not computable by a permutation program of equal width.

We develop new lower bounds that separate these models to a near-maximal extent.

▶ **Theorem 11.** *There is $c > 0$ and $w_0 \in \mathbb{N}$ such that for every $\varepsilon > 0$ and n the following holds. There exists a function $f\colon \{0,1\}^n \to \{0,1\}$ computable by a regular SOBP of width w_0 such that no permutation SOBP of width $2^{cn/\log(1/\varepsilon)}$ agrees with f on a $1/2 + \varepsilon$ fraction of the inputs. In particular, no permutation SOBP of width $2^{c\sqrt{n}}$ agrees with f on a $1/2 + 2^{-\sqrt{n}}$ fraction of inputs.*

[2] A preprint circulated by the second author claimed this as a consequence of [5]. However, it does not follow from the argument in that work.

The hard function in Theorem 11 is the Inner-Product function with a specific variable-ordering. Our techniques for proving Theorem 11 are information-theoretic, and rely on showing that the entropy of the state over the $n+1$ layers of a permutation ROBP must be non-decreasing.

Our next result shows that the Inner-Product function is in fact average-case hard for *arbitrary-order* permutation ROBPs of exponential width.

▶ **Theorem 12.** *Every arbitrary-order permutation ROBP B that computes $\mathsf{IP}^{\oplus n}(x) := \sum_{i=1}^{n} x_{2i-1}x_{2i} \pmod 2$ on more than a $3/4+\varepsilon$ fraction of inputs has width at least $2^{4\varepsilon^2 n}$. Moreover, $\mathsf{IP}^{\oplus n}$ can be computed by a regular SOBP of width 4.*

We conjecture that Theorems 11 and 12 can be strengthened to give optimal average-case hardness, namely $1/2+2^{-n}$, but we have not been able to prove such a result.

▶ **Conjecture 13.** *There exists a constant $c > 0$ such that the following holds. Every arbitrary-order permutation ROBP B that computes $\mathsf{IP}^{\oplus n}(x) := \sum_{i=1}^{n} x_{2i-1}x_{2i} \pmod 2$ on more than a $1/2+2^{-cn}$ fraction of inputs has width at least 2^{cn}.*

1.1.3 Standard-Order vs. Arbitrary-Order Programs

In the past decade, researchers have turned their attention of constructing PRGs from SOBPs to the more general model of arbitrary-order ROBPs, as a way to generate new ideas to improve the state-of-the-art PRGs for SOBPs, and to develop PRGs for several natural subclasses of circuits that are not captured by SOBPs, as circuit classes are closed under permutation of the input coordinates. This line of research has received extensive interests [30, 41, 45, 25, 36, 21, 19], and in particular has resulted near-optimal PRGs for several well-studied models of computation, including read-once formulas [6, 23, 13, 17, 19], constant-width arbitrary-order permutation ROBPs [41, 10, 34], and read-once $\mathbb{F}_2$-polynomials [35, 36, 33, 18].

While Theorem 12 shows that there are regular SOBPs which cannot be approximated by arbitrary-order permutation ROBPs of exponential width, we show that the opposite direction is also true, by giving a function that is computable by an arbitrary-order permutation ROBP of constant width that requires exponential width for (even general) SOBPs.

▶ **Proposition 14** (Informal statement of Proposition 35)**.** *For every n, there exists a function $f\colon \{0,1\}^n \to \{0,1\}$ such that f is computable by an arbitrary-order permutation ROBP of width 6, and every SOBP computing f has width at least $2^{n/2}$.*

This result uses a non-Abelian group product and an adversarial argument.

1.1.4 Read Once vs. Read Many

Given our exponential lower bounds (Theorems 11 and 12) for permutation ROBPs, it is natural to ask whether any of them extends to read-k programs.

We show that even in the read-2 setting, permutation branching programs already become substantially more powerful. Specifically, read-twice permutation branching programs of subexponential width can simulate arbitrary-order ROBPs of polynomial width:

▶ **Proposition 15.** *Let $f\colon \{0,1\}^n \to [w]$ be computable by an arbitrary-order ROBP B of width w. Then for every $k \in \mathbb{N}$, f is computable by a read-(2^k) permutation branching program B' of width $w^{(k+1)n^{1/k}}$.*

Our simulation in Proposition 15 follows directly from Bennett's work on reversible computation [4]. We complement Proposition 15 by showing that a subexponential blow-up in the width is necessary for read-twice programs: there is no *fixed* read order such that read-twice permutation BPs reading bits in that order can simulate even regular SOBPs of constant width.

▶ **Theorem 16.** *For every read-twice ordering $i : [2n] \to [n]$, there exists a function $g\colon \{0,1\}^n \to \{0,1\}$ computable by a regular ROBP of width $O(1)$, such that every read-twice permutation branching program P of width $2^{n^{1/8}}$ with read order i computes g correctly on at most $1/2 + 2^{-\Omega(n^{1/8})}$ fraction of inputs.*

1.1.5 Permutation vs. Monotone Programs

Several works [37, 19] have studied the model of monotone branching programs, which correspond to branching programs where the edges labeled 1 do not cross, and likewise for the edges labeled 0. They are considered to be the "extreme opposite" of permutation programs [19]. We provide evidence for this belief by showing that read-once DNFs, which are computable by constant-width monotone programs, are worst-case hard for permutation SOBPs of exponential width:

▶ **Proposition 17.** *Let $f(x_1, y_1, \ldots, x_n, y_n) = \bigvee_i (x_i \wedge y_i)$. Then every permutation SOBP computing f has width at least 2^n.*

2 Regular Branching Programs

We show that regular programs can exactly simulate general programs with a moderate blow-up in width. We emphasize that our simulation is not restricted to the read-once setting.

▶ **Theorem 18.** *Let $B\colon \{0,1\}^n \to \{0,1\}$ be a branching program of length m and width w. There is a regular branching program $R\colon \{0,1\}^n \to \{0,1\}$ of length m and width $w' := \max\{w, \frac{wm}{2} + w(1 - \frac{\log w}{2})\}$ such that $R(x) = B(x)$ for all $x \in \{0,1\}^n$. Moreover, R has the same variable read order as B. In particular, for $w \geq 4$, we have $w' \leq wm/2$.*

Proof. We prove by induction on length m. We show the stronger claim that R exactly computes the states of B, i.e. that there are maps $\phi_t\colon [w'] \to [w]$ such that $\phi_i(R[v_{st}, (x_{i(1)}, \ldots, x_{i(t)})]) = B[v_{st}, (x_{i(1)}, \ldots, x_{i(t)})]$ for every $x \in \{0,1\}^n$ and $t \in [m]$.

When $m \leq \log w$, we can simulate B trivially by storing the bits read in at most $2^m \leq w$ states. Now, suppose $m \geq \log w + 1$. For each state v in the $(m-1)$-th layer B_{m-1} of B, let $C_{m-1}(v) := \phi_{m-1}^{-1}(v)$. By the inductive assumption, we have $\sum_{v \in B_{m-1}} |C_{m-1}(v)| \leq w(m-1)/2 + w(1 - \log(w)/2)$.

Now, for each state u in the m-th layer B_m of B, create

$$\left\lceil \frac{1}{2} \sum_{(v,b): B[v,b]=u} |C_{m-1}(v)| \right\rceil$$

states, denoted $C_m(u)$, and define ϕ_m such that $\phi_m(C_m(u)) := u$.

Finally, for each $b \in \{0,1\}$ and $v \in B_{m-1}$ such that $B[v,b] = u$, we add a b-edge from every state in $C_{m-1}(v)$ to some state in $C_m(u)$. There are $s_u := \sum_{(v,b): B[v,b]=u} |C_{m-1}(v)|$ many such edges, and hence there are enough states in $C_m(u)$ to accommodate this (with each state having at most 2 edges). Now, summing over all $u \in B_m$, we have

$$\begin{aligned}|R_m| &= \sum_{u \in B_m} |C_m(u)| \\ &= \sum_{u \in B_m} \left[\frac{1}{2} \sum_{(v,b):B[v,b]=u} |C_{m-1}(v)| \right] \\ &\leq \sum_{u \in B_m} \left(\frac{1}{2} + \frac{1}{2} \cdot \sum_{(v,b):B[v,b]=u} |C_{m-1}(v)| \right) \\ &= \frac{|B_m|}{2} + \sum_{v \in V_{m-1}} |C_{m-1}(v)| \\ &\leq \frac{w(m-1)}{2} + w\Big(1 - \frac{\log w}{2}\Big) + \frac{w}{2} \\ &= \frac{wm}{2} + w\Big(1 - \frac{\log w}{2}\Big).\end{aligned}$$

Let $k \leq w$ be the number of u such that s_u is odd. Note that k must be even. For each such u there is a state in $C_m(u)$ such that it has in-degree one. To preserve regularity, we add $k/2 \leq w/2$ of dummy states in R_{m-1} that are not reachable from the start state and connect the k outgoing edges of these states to these u's. ◀

We now show that for general SOBPs, this loss of a factor of m is tight, and in fact the loss is even tight in the leading constant.

▶ **Proposition 10.** *For every $w = 2^t, n \in \mathbb{N}$, there is a function $f : \{0,1\}^n \to \{0,1\}$ computable by an general SOBP of width w such that every regular SOBP computing f has width at least $\frac{nw}{2} - w \log w$.*

We recall the well-known fact that AND_n can be computed by a constant-width SOBP, but requires width n for regular ROBPs. We provide a proof for completeness.

▶ **Observation 19.** *Given $n \in \mathbb{N}$, $\mathsf{AND} := \mathsf{AND}_n$ can be computed by a general SOBP of width 2. However, every regular SOBP R computing AND must have $i+1$ distinct states reachable from v_{st} in layer i.*

Proof. The fact that AND can be computed by a general SOBP of width 2 is direct. We show the lower bound by induction. It is clearly true for layer 0 as v_{st} can reach itself. Assuming it holds for layer i, we note that from correctness, $u := R[v_{st}, 1^{i+1}] \neq R[v_{st}, 1^i||0]$ and hence there are two distinct states reachable in layer $i+1$ from $R[v_{st}, 1^i]$. Let R_i be the reachable states in layer i that are not $R[v_{st}, 1^i]$. We have that there are at least $2|R_i|$ edges from R_i (and every endpoint of such an edge is reachable). Moreover, we claim that these edges cannot reach u. Otherwise there would be $\tau \neq 1^{i+1}$ such that $B[v_{st}, \tau||1^{n-i-1}] = B[v_{st}, 1^n]$ which contradicts R computing AND. Thus there are at least $|R_i| + 1$ vertices reachable in layer $i+1$ that are not u, so we conclude. ◀

We can then bootstrap this separation to work for larger widths. Essentially, we use a multiplexer to force the program to remember a large amount of information before computing AND.

▶ **Definition 20.** *Given $n, w = 2^t$, let $m = n - 2(t-1)$. Define $f \colon \{0,1\}^{t-1} \times \{0,1\}^m \times \{0,1\}^{t-1} \to \{0,1\}$ as $f(x,y,z) = \langle x, z \rangle \oplus \mathsf{AND}(y) = \sum_{i=1}^{t-1} x_i z_i + \mathsf{AND}(y) \pmod 2$.*

We first argue that f can be computed by a SOBP of width w.

▷ Claim 21. f can be computed by an SOBP of width w.

Proof. We define a program $B(x, y, z)$. In the first t layers, B stores the entire input. For each state in layer t, B uses 2 states to compute $\mathsf{AND}(y)$, and hence at layer $m+t-1$ the states are labeled $(x, \mathsf{AND}(y))$. Then the program reads in z and computes $\langle x, z\rangle$, such that the states in the final layer are labeled $(\langle x, z\rangle, \mathsf{AND}(y))$ and hence B can return the value of f. It is clear from this description that B has width $2 \cdot 2^{t-1} = w$. ◁

We then argue that no regular SOBP can do better than remembering the first $t-1$ bits, and moreover must compute AND using essentially disjoint states.

▷ Claim 22. For every regular SOBP B computing f, for every $x \neq x' \in \{0,1\}^{t-1}$ we have $B[v_{st}, x] \neq B[v_{st}, x']$. Furthermore, for every $k < m$ the states reachable in layer $t-1+k$ from $B[v_{st}, x]$ must be disjoint from those reachable from $B[v_{st}, x']$.

Proof. First assume for contradiction there are $x, x' \in \{0,1\}^{t-1}$ with $x' \neq x$ where $B[v_{st}, x] = B[v_{st}, x']$. Let i be some index where $x'_i \neq x_i$ and hence $\langle x, e_i\rangle \neq \langle x', e_i\rangle$. Thus, $f(x, 0^m, e_i) \neq f(x', 0^m, e_i)$, but

$$B\big[v_{st}, x||0^m||e_i\big] = B\big[v_{st}, x'||0^m||e_i\big]$$

which is a contradiction. For the second claim, assume for contradiction there are $\tau, \tau' \in \{0,1\}^k$ (where we do not require $\tau \neq \tau'$) such that $B[v_{st}, x||\tau] = B[v_{\mathrm{acc}}, x'||\tau']$. But then $f(x, \tau||0^{m-k}, e_i) \neq f(x', \tau'||0^{m-k}, e_i)$ from before, but

$$B\big[v_{st}, x||\tau||0^{m-k}||e_i\big] = B\big[v_{st}, x'||\tau'||0^{m-k}||e_i\big]$$

which is a contradiction. ◁

We can then prove the result.

Proof of Proposition 10. Let f be the function in Definition 20 with $n, w = 2^t$. By Claim 21, f can be computed by a general SOBP of width w.

Now let R be an arbitrary regular SOBP computing f. By Claim 22, we must have $R[v_{st}, x] \neq R[v_{st}, x']$ for every $x \neq x' \in \{0,1\}^{t-1}$. Since R must correctly compute $\mathsf{AND}(y)$ (which can be shown by a similar extension argument), we obtain that for every x, there are at least m states reachable from $R[v_{st}, x]$ in layer $t+m-1$ for every x, and all of these states are disjoint by Claim 22. Thus, it follows from $m = n - 2(t-1)$ that R has width at least

$$2^{t-1} \cdot m = \frac{w}{2} \cdot m = \frac{nw}{2} + w(1 - \log w). \qquad ◀$$

3 Permutation Read-Once Branching Programs

In this section, we give explicit functions computable by small width regular SOBPs that are average-case hard against permutation SOBPs and ROBPs of large widths. We will be working with the Inner-Product functions with their input bits ordered in a certain manner.

▶ **Definition 23.** *For integers ℓ, m, define $\mathsf{IP}_{2\ell}^{\oplus m} \colon (\{0,1\}^{2\ell})^m \to \{0,1\}$ to be*

$$\mathsf{IP}_{2\ell}^{\oplus m}(x^1, y^1, \ldots, x^m, y^m) := \bigoplus_{i=1}^{m} \langle x^i, y^i\rangle,$$

where $\langle x_1, \ldots, x_\ell, y_1, \ldots, y_\ell\rangle := \bigoplus_{j=1}^{\ell} x_j y_j$. We omit the subscript 2ℓ when $\ell = 1$.

We first show that $\mathsf{IP}_{2\ell}^{\oplus m}$ can be computed by a regular SOBP of width $2^{2\ell+1}$ via a simple argument. This follows from the fact that regular SOBPs can compute the XOR of an arbitrary function on 2ℓ bits using $2\ell+1$ bits, because we can store all the 2ℓ bits and maintaining the prefix-XOR with 1 extra bit using a regular program. The program we construct is essentially the one used in simulating high-degree regular programs by binary regular programs in [5]:

▶ **Lemma 24.** *Let $f\colon \{0,1\}^k \to \{0,1\}$ be an arbitrary function. Then $g\colon (\{0,1\}^k)^n \to \{0,1\}$ defined as*

$$g(x^1,\dots,x^n) := \bigoplus_{i\in[n]} f(x^i),$$

where $x^i \in \{0,1\}^k$ for each $i \in [n]$, can be computed by a regular SOBP of width 2^{k+1}.

Proof. Let B be a program where each state has label $(s,b) \in \{0,1\}^k \times \{0,1\}$. On reading x^i_j where $j \in [k]$, the program updates as

$$(s,b) \to \begin{cases} (s',b) & \text{if } 1 \le j \le k-1 \\ (s', b \oplus f(s)) & \text{if } j = k. \end{cases}$$

where s' is s with the j-th coordinate replaced with the bit x^i_j. The width of this program is $2^k \cdot 2$, and the fact that it computes f is direct. Finally, the program is regular as every s' has a single $b \in \{0,1\}$ and two strings $s \in \{0,1\}^k$ for which the replacement of the j-th coordinate of s with b produces s'. ◀

We recall our average-case lower bound against permutation ROBPs computing inner product.

▶ **Theorem 12.** *Every arbitrary-order permutation ROBP B that computes $\mathsf{IP}^{\oplus n}(x) := \sum_{i=1}^n x_{2i-1}x_{2i} \pmod 2$ on more than a $3/4+\varepsilon$ fraction of inputs has width at least $2^{4\varepsilon^2 n}$. Moreover, $\mathsf{IP}^{\oplus n}$ can be computed by a regular SOBP of width 4.*

For permutation SOBPs, we can strengthen this to a strong average case lower bound:

▶ **Theorem 11.** *There is $c > 0$ and $w_0 \in \mathbb{N}$ such that for every $\varepsilon > 0$ and n the following holds. There exists a function $f\colon \{0,1\}^n \to \{0,1\}$ computable by a regular SOBP of width w_0 such that no permutation SOBP of width $2^{cn/\log(1/\varepsilon)}$ agrees with f on a $1/2+\varepsilon$ fraction of the inputs. In particular, no permutation SOBP of width $2^{c\sqrt{n}}$ agrees with f on a $1/2+2^{-\sqrt{n}}$ fraction of inputs.*

Our argument relies on the fact that the entropy of the states in each layer of a permutation ROBP is non-decreasing. Before stating this property formally, we first recall some basic facts in information theory. We use capital letters to denote random variables, and lower case to denote specific assignments.

▶ **Definition 25.** *Given a joint random variable (X,Y), let*

- *$H(X) := \sum_{x\in Supp(X)} p(x)\log_2(1/p(x))$ be the* (binary) entropy *of X;*
- *$H(X \mid Y) := H(X,Y) - H(Y)$ be the* conditional entropy *of X given Y, and*
- *$I(X;Y) := H(X) - H(X \mid Y)$ be the* mutual information *of X and Y.*

Moreover, given $p \in [0,1]$, let $H(p) := p\log_2(1/p) + (1-p)\log_2(1/(1-p))$ be the entropy of a p-biased Bernoulli random variable.

We define the distributions over states of a program.

▶ **Definition 26.** *Given a ROBP B of length n, for $i \in \{0, \dots, n\}$, let S_i be the distribution over the reachable states after reading X_i of a uniformly random $X \sim \{0,1\}^n$.*

We then note the most important property of permutation SOBPs from this perspective: given the state reached after reading x_i and the value of x_i, one can exactly recover the state after reading x_{i-1}. More generally, we have the following proposition.

▶ **Proposition 27.** *Let $(X_1, \dots, X_n) \leftarrow U_n$. For every SOBP B and $i < j$, we have $H(S_j \mid S_i, X_{i+1}, \dots, X_j) = 0$. Moreover, if B is a permutation SOBP then $H(S_i \mid S_j, X_{i+1}, \dots, X_j) = 0$.*

Proof. The first claim is immediate from the fact that knowing the current state S_i and next $j - i$ bits $X_{i+1}, \dots, X_j$ to be read determines the state S_j. The second claim is likewise immediate, as for a permutation SOBP there is exactly one state S_i in layer i that reaches the state S_j in layer j after reading $X_{i+1}, \dots, X_j$. ◀

We use this property to show that for permutation SOBPs, the entropy of the state at layer i must increase by at least the mutual information between the state and the i-th input bit, and use this to conclude a lower bound on the width.

▶ **Lemma 28.** *Let $(X_1, \dots, X_n) \sim \{0,1\}^n$ be a uniform n-bit input. For a permutation SOBP B of length n and width w, let $i_1 < \dots < i_m$ be some m layers in B, and $X^{i_j} := (X_{i_{j-1}+1}, \dots, X_{i_j})$, where $i_0 := 0$. Then*

$$\log w \geq \sum_{j=1}^{m} I(X^{i_j}; S_{i_j}).$$

Proof. We first prove that for every $j \in [m]$,

$$H(S_{i_j}) = I(X^{i_j}; S_{i_j}) + H(S_{i_j - 1}). \tag{1}$$

Given this, the lemma follows from $H(S_0) = 0$ and

$$\log w = \log \operatorname{supp}(S_{i_m}) \geq H(S_{i_m}) = \sum_{j=1}^{m} H(S_{i_j}) - H(S_{i_{j-1}}) = \sum_{j=1}^{m} I(X^{i_j}; S_{i_j}).$$

We now prove Equation (1). By Proposition 27 we have

$$H(S_{i_j} \mid S_{i_{j-1}}, X^{i_j}) = 0 = H(S_{i_{j-1}} \mid S_{i_{j-1}}, X^{i_j}).$$

Applying the chain rule to both sides we obtain

$$\begin{aligned} H(S_{i_{j-1}}, X^{i_j}) &= H(S_{i_j}, S_{i_{j-1}}, X^{i_j}) - H(S_{i_j} \mid S_{i_{j-1}}, X^{i_j}) \\ &= H(S_{i_{j-1}}, S_{i_j}, X^{i_j}) - H(S_{i_{j-1}} \mid S_{i_j}, X^{i_j}) \\ &= H(S_{i_j}, X^{i_j}). \end{aligned}$$

Another chain rule to both sides gives

$$H(X^{i_j} \mid S_{i_j}) + H(S_{i_j}) = H(X^{i_j} \mid S_{i_{j-1}}) + H(S_{i_{j-1}}).$$

Thus,

$$\begin{aligned}H(S_{i_j}) &= H(X^{i_j} \mid S_{i_{j-1}}) + H(S_{i_{j-1}}) - H(X^{j_i} \mid S_{j_i})\\ &= H(S_{i_{j-1}}) + \big(H(X_{i_j}) - H(X^{i_j} \mid S_{i_j})\big) - \big(H(X^{i_j}) - H(X^{i_j} \mid S_{i_{j-1}})\big)\\ &= H(S_{i_{j-1}}) + I(S_{i_j}; X^{i_j}) - I(S_{i_{j-1}}; X^{i_j})\\ &= H(S_{i_{j-1}}) + I(S_{i_j}; X^{i_j}),\end{aligned}$$

where the final step follows from the fact that X_{i_j} is independent of all prior bits, and thus the state at layer i_j. ◀

We are now prepared to prove the lower bounds. In both cases, we require Fano's inequality. For the inner product bound, we use a simple formulation due to Regev [40]:

▶ **Lemma 29** (Claim 2.1 [40]). *Let X be uniformly distributed over $\{0,1\}$. Let S be a random variable such that there exists f such that $\Pr_{X,S}[f(S) \neq X] =: p \leq 1/2$. Then $I(X;S) \geq 1 - H(p)$.*

3.1 Mild Average-Case Lower Bounds for Arbitrary-Order Programs

We now prove the lower bound in Theorem 12: To illustrate the idea, consider a permutation SOBP B that reads its input x in the order of $x_1, \ldots, x_{2n}$. We will show that when X is uniform over $\{0,1\}^{2n}$, for every $i \in [n]$, given the state S_{2i-1} reached by B after reading $X_1, \ldots, X_{2i-1}$, we can use B to predict the value of X_{2i-1} better than random guessing, showing that there is non-trivial amount of mutual information between S_{2i-1} and X_{2i-1}. To see this, note that for every $x \in \{0,1\}^n$,

$$x_{2i-1} = \mathsf{IP}^{\oplus 2n}(x_1, \ldots, x_{2i-1}, 0, x_{2i+1}, \ldots, x_{2n}) \oplus \mathsf{IP}^{\oplus 2n}(x_1, \ldots, x_{2i-1}, 1, x_{2i+1}, \ldots, x_{2n}).$$

Moreover, given a state S_{i+1}, we can simulate the remaining program on the two inputs $(x_{2i} = 0, X_{2i+1}, \ldots, X_{2n})$ and $(x_{2i} = 1, X_{2i+1}, \ldots, X_{2n})$, for a uniform $X_{2i+1}, \ldots, X_{2n}$, to compute the right hand side, which by a union bound, is correct and thus equals X_{2i-1} with probability at least $1/2 + 2\varepsilon$.

Proof of Theorem 12. Let $X = (X_1, \ldots, X_{2n}) := (X_1, Y_1, \ldots, X_n, Y_n)$ be a uniform random input. Fix an arbitrary-order permutation ROBP B that reads x in the order of $x_{\sigma(1)}, \ldots, x_{\sigma(2n)}$ for some permutation σ. By assumption we have $\Pr[B(X) \neq f(X)] \leq 1/4 - \varepsilon$.

For every $i \in [n]$, let $r_i := \min\{\sigma^{-1}(2i-1), \sigma^{-1}(2i)\}$ be the layer reached by B after reading the first bit of x_{2i-1} and x_{2i}. Let $L \subset [2n]$ be the indices of the variables of X read up to this point (i.e., $L = \{\sigma(1), \ldots, \sigma(r_i)\}$ and let $R := [2n] \setminus L = \{\sigma(r_i + 1), \ldots, \sigma(2n)\}$.

We now show that $I(X_{r_i}; S_{r_i}) \geq 1 - H(1/2 - 2\varepsilon)$, which suffices to prove the result by Lemma 28. To do so, given the state s_{r_i} in layer r_i, we let our guess of x_{r_i} be

$$g(s_{r_i}) = B\big[v, y^0\big] \oplus B\big[v, y^1\big],$$

where $y \leftarrow U_R$ is a random suffix and y^b is y with its $(t_i := \max\{\sigma^{-1}(2i-1), \sigma^{-1}(2i)\})$-th bit replaced with $b \in \{0,1\}$. Observe that $B[S_{r_i}, Y^{b*}]$ is identical to $f(X)$ conditioned on $X_{t_i} = b$. We have

$$\begin{aligned}\Pr_X\big[g(S_{r_i}) \neq X_{r_i}\big] &= \Pr_X\Big[B\big[S_{r_i}, Y^{0*}\big] \oplus B\big[S_{r_i}, Y^{1*}\big] \neq X_{r_i}\Big] \\ &\leq \Pr_X\Big[B\big[S_{r_i}, Y^{0*}\big] \neq f(X)\Big] + \Pr_X\Big[B\big[S_{r_i}, Y^{1*}\big] \neq f(X)\Big] \\ &\leq \Pr_X\big[B(X) \neq f(X) \mid X_{t_i} = 0\big] + \Pr\big[B(X) \neq f(X) \mid X_{t_i} = 1\big] \\ &= 2\Pr\big[B(X) \neq f(X)\big] \\ &\leq 1/2 - 2\varepsilon.\end{aligned}$$

By Lemma 29 we have $I(X_{r_i}; S_{r_i}) \geq 1 - H(1/2 - 2\varepsilon) \geq 4\varepsilon^2$. Therefore by Lemma 28 we have

$$\log w \geq \sum_{i=1}^{n} I(X_{r_i}; S_{r_i}) \geq 4\varepsilon^2 n,$$

and hence $w \geq 2^{4\varepsilon^2 n}$. The "moreover" claim follows from Lemma 24. ◀

3.2 Moderate Average-Case Lower Bounds

Before proving our strong average-case lower bound (Theorem 11), we have to extend Theorem 12 to improve the correlation bound from $3/4 + \varepsilon$ to $1/2 + \varepsilon_0$ for an arbitrary constant ε_0.

▶ **Theorem 30.** *Let $\ell \geq 8\log(1/\varepsilon)$. If B is a permutation SOBP of width w and length $2\ell m$ that agrees with $\mathsf{IP}_{2\ell}^{\oplus m}$ on a $1/2 + \varepsilon$ fraction of inputs, then $w \geq 2^{\varepsilon m \ell/4}$.*

The high-level idea is to combine the idea in the previous subsection with Goldreich–Levin list-decoding. Instead of predicting 1 bit, we will divide the input into blocks and show that we can predict the whole block of X^i given the state S_i reached by B upon reading X^i. To do so, we first show that with probability at least $\varepsilon/2$ over all-but-the-Y^i-part of the input, we have the following property: Given the state S_i, we can predict $\langle X^i, Y^i\rangle$ for a random sample $Y^i \sim \{0,1\}^\ell$ correctly with probability $1/2+\varepsilon$. Then by the Goldreich–Levin theorem, we can use this predictor to narrow X^i down to a list of size $1/\varepsilon^2$, showing that there is a non-trivial amount of mutual information between X^i and S_i.

Our argument only requires the following bound on the "list size," which follows from Parseval's identity.

▷ Claim 31. For every Boolean function $f\colon \{0,1\}^\ell \to \{0,1\}$, there are at most $1/\varepsilon^2$ many $a \in \{0,1\}^\ell$ such that $\Pr[f(U) = \langle a, x\rangle] \geq 1/2 + \varepsilon/2$.

Proof. This is equivalent to $\widehat{f}(a) \geq \varepsilon$, where $\widehat{f}(a) := \mathbb{E}_x[f(x)(-1)^{\langle a,x\rangle}]$. Let L be the number of such a's. Then by Parseval's identity, we have $L\varepsilon^2 \leq \sum_{a\in\{0,1\}^\ell} \widehat{f}(a)^2 = \mathbb{E}[f(x)^2] \leq 1$. Rearranging gives $L \leq 1/\varepsilon^2$. ◁

3.2.1 Proof of Theorem 30

Proof. Let $(X^1, \ldots, Y^m)$ be a uniformly random input of $\mathsf{IP}_{2\ell}^{\oplus m}$. Let B be a width-w permutation SOBP that agrees with $\mathsf{IP}_{2\ell}^{\oplus m}$ with probability $1/2 + \varepsilon$. Our goal is to show that $w \geq 2^{\varepsilon \ell m/4}$. For $i \in [m]$, let S_i denote the state B reaches after reading X^i. We will show that $I(S_i; X^i) \geq \varepsilon\ell/4$, from which the theorem follows from Lemma 28.

To proceed, fix an $i \in [m]$. Given an input $(x^1, y^1, \dots, x^m, y^m)$ of B, let $z \in (\{0,1\}^\ell)^{2m-1}$ denote all but the y^i-th block of y, that is, $z = (x^1, \dots, y^{i-1}, x^i, x^{i+1}, \dots, y^m)$. We will use the shorthand $B(z, y^i)$ to denote $B(x^1, y^1, \dots, x^m, y^m)$. Given $z \in (\{0,1\}^\ell)^{2m-1}$ and an auxiliary bit $a \in \{0,1\}$, consider the function $B_{z,a} \colon \{0,1\}^\ell \to \{0,1\}$ defined by

$$B_{z,a}(y^i) := B(z, y^i) \oplus \bigoplus_{j>i} \langle x^i, y^i \rangle \oplus a. \tag{2}$$

(One should think of a as a guess of the bit $\bigoplus_{j<i} \langle x^j, y^j \rangle$.) Let s_i be the state reached by B upon reading the prefix $(x^1, y^1 \dots, x^i) \in (\{0,1\}^\ell)^{2i-1}$. Observe that we can compute $B_{z,a}(y^i)$ by simulating B starting from state s_i on the remaining inputs $(y^i, x^{i+1}, \dots, y^m)$ and then XORing its output with a.

We claim that with probability at least $\varepsilon/2$ over $(Z, A) \sim (\{0,1\}^\ell)^{2m-1} \times \{0,1\}$, we have

$$\Pr_{Y^i \sim \{0,1\}^n} \Big[B_{Z,A}(Y^i) = \langle X^i, Y^i \rangle \Big] \geq 1/2 + \varepsilon/2. \tag{3}$$

To see this, note that A is a correct guess of the bit $\bigoplus_{j<i} \langle x^j, y^j \rangle$ with probability $1/2$, i.e. $\Pr_{A \sim \{0,1\}}[\bigoplus_{j<i} \langle x^j, y^j \rangle = A] = 1/2$. Conditioned on A being the correct guess, it follows by an averaging argument that with probability at least $\varepsilon/2$ over $Z \sim (\{0,1\}^\ell)^{2m-1}$ we have

$$\begin{aligned} \Pr_{Y^i \sim \{0,1\}^\ell} \Big[B_{Z,A}(Y^i) = \langle X^i, Y^i \rangle \Big] &= \Pr_{Y^i \sim \{0,1\}^\ell} \Big[B(Z, Y^i) = \langle X^i, Y^i \rangle + \bigoplus_{j>i} \langle X^j, Y^j \rangle + \bigoplus_{j<i} \langle X^j, Y^j \rangle \Big] \\ &= \Pr_{Y^i \sim \{0,1\}^\ell} \Big[B(Z, Y^i) = \mathsf{IP}^{\oplus k}(Z, Y^i) \Big] \geq 1/2 + \varepsilon/2. \end{aligned}$$

Let us call the pair (z, a) *good* if it satisfies Equation (3). Note that for a good (z, a), by Claim 31, there are at most $1/\varepsilon^2$ many choices of $r \in \{0,1\}^\ell$ such that

$$\Pr_{Y^i \sim \{0,1\}^\ell} \Big[B_{z,b}(Y^i) = \langle r, Y^i \rangle \Big] \geq 1/2 + \varepsilon/2,$$

and x^i is one of them, and thus we have the following claim.

▷ Claim 32. $H(X^i \mid S_i, (Z, A) \text{ is good}) \leq \log(1/\varepsilon^2)$.

We will use the following fact behind the proof of Fano's inequality.

▷ Claim 33 (Fano's inequality). Let X, Y, G be three random variables such that $H(G \mid X, Y) = 0$. Then

$$H(X \mid Y) = H(G \mid Y) + H(X \mid G, Y).$$

For a uniform $(X^1, \dots, Y^m) \sim (\{0,1\}^\ell)^{2m}$, let $G := G(Z, A)$ be the indicator random variable of whether (Z, A) is good. Let $Z_{>i}$ denote $(X^{i+1}, \dots, Y^m)$. Since X^i is independent of $Z_{>i}$ and A,

$$H(X^i \mid S_i) = H(X^i \mid S_i, Z_{>i}, A).$$

Now, given $S_i, Z_{>i}, A$, and X^i, we can compute $B_{Z,A}$ and determine if (Z, A) is good, and thus we have $H(G \mid S_i, X^i, Z_{>i}, A) = 0$. So by Claim 33,

$$H(X^i \mid S_i, Z_{>i}, A) = H(G \mid S_i, Z_{>i}, A) + H(X^i \mid G, S_i, Z_{>i}, A). \tag{4}$$

We can bound the first term $H(G \mid S_i, Z_{>i}, A)$ by $H(G)$. For the second term, we apply Claim 32 as follows:

$$\begin{aligned} H(X^i \mid S_i, Z_{>i}, A, G) &= \Pr[G] \cdot H(X^i \mid S_i, Z_{>i}, A, G = 1) + (1 - \Pr[G]) \cdot H(X^i \mid S_i, Z_{>i}, A, G = 0) \\ &\leq \Pr[G] \cdot \log(1/\varepsilon^2) + (1 - \Pr[G]) \cdot H(X^i). \end{aligned}$$

Applying both bounds to the right hand side of Equation (4) gives

$$H(X^i \mid S_i, Z_{>i}, A) \leq H(G) + \Pr[G] \cdot \log(1/\varepsilon^2) + (1 - \Pr[G]) \cdot H(X^i).$$

As $\Pr[G] \geq \varepsilon/2$, we have $H(G) \leq 2\Pr[G] \log(1/\Pr[G]) \leq 2\Pr[G] \log(2/\varepsilon)$. Therefore,

$$\begin{aligned} I(X^i; S_i) &= H(X^i) - H(X^i \mid S_i) \\ &= H(X^i) - H(X^i \mid S_i, Z_{>i}, A) \\ &\geq \Pr[G] \cdot \big(H(X^i) - \log(1/\varepsilon^2)\big) - H(G) \\ &\geq \Pr[G] \cdot \big(H(X^i) - 4\log(1/\varepsilon)\big) \\ &\geq (\varepsilon/2) \cdot \big(\ell - 4\log(1/\varepsilon)\big), \end{aligned}$$

which is at least $\varepsilon \cdot \ell/4$ for $\ell \geq 8\log(1/\varepsilon)$. It follows from Lemma 28 that

$$\log w \geq \sum_{i=1}^{m} I(S_i; X^i) \geq \varepsilon m \ell/4. \qquad \blacktriangleleft$$

3.3 Strong Average-Case Lower Bounds

We now prove Theorem 11. Assadi and N. [1] proved the following XOR Lemma for multi-pass streaming algorithms.[3] In the case of one pass this is essentially the same as SOBPs. Moreover, we observe that their argument also applies to permutation SOBPs.

▶ **Lemma 34** ([1]). *There exists an absolute constant $\varepsilon_0 > 0$ such that the following holds. Let $f\colon \{0,1\}^m \to \{0,1\}$ be any function and let $f^{\oplus \ell}$ be the XOR of ℓ copies of f on disjoint (sequential) blocks. Suppose $\Pr[P(U) = f(U)] \leq 1/2 + \varepsilon$ for some $\varepsilon \leq \varepsilon_0$ for every permutation SOBP P of width w. Then $\Pr[P(U) = f^{\oplus \ell}(U)] \leq 1/2 + \varepsilon^{\ell/7}$ for every permutation SOBP P of width w.*

Proof of Theorem 11. By Theorem 30, for every constant $\varepsilon_0 > 0$, there exists a constant ℓ such that the function $\mathsf{IP}_{2\ell}^{\oplus m}$ on $2\ell m$ bits is $(1/2 + \varepsilon_0)$-hard for permutation SOBPs of width $2^{\varepsilon_0 m \ell/8}$. By Lemma 34, the function $\mathsf{IP}_{2\ell}^{\oplus mk}$ on $2\ell mk$ bits is $(1/2 + \varepsilon_0^{k/7})$-hard for permutation SOBPs of width $2^{\varepsilon_0 m \ell/8}$. Choosing ε_0 to be a sufficiently small constant, $k = 7\log_{\varepsilon_0}(1/\varepsilon)$, and letting $n := 2\ell mk$ gives us a hard function on n bits that is $(1/2+\varepsilon)$-hard for permutation SOBPs of width $2^{cn/\log(1/\varepsilon)}$ for a universal constant c. ◀

3.4 Worst Case Lower Bounds Against Monotone Functions

Next, we show there are monotone functions (in fact, read-once DNFs) that are worst-case hard for permutation SOBPs of exponential width.

▶ **Proposition 17.** *Let $f(x_1, y_1, \ldots, x_n, y_n) = \bigvee_i (x_i \wedge y_i)$. Then every permutation SOBP computing f has width at least 2^n.*

[3] There is a mistake in the publicly available versions which has been corrected by the authors [2].

Proof. Let B be a permutation SOBP computing f. We will show that in layer $2i$ (the state after reading both variables in the ith term), there are 2^i states reachable by strings that have not yet satisfied a term. This holds vacuously for $i = 0$. Now suppose this holds for term i and let T_i be the set of such states, and for $b \in \{0, 1\}$ define

$$T_i[b] := \{v \in V_{2i+1} : \exists u \in T_i \text{ s.t. } B[u, b] = v\}.$$

We first observe that $|T_i[1]| = |T_i[0]| = |T_i| \geq 2^i$ and $T_i[1] \cap T_i[0] = \emptyset$. The first follows since B is a permutation SOBP (and hence all states in $T_i[1]$ can have a single in-1-edge and likewise for $T_i[0]$) and the second follows via an extension argument, since otherwise B fails to compute f. This implies $|T_i[10] \cup T_i[00]| \geq 2|T_i|$ again using that B is a permutation SOBP. Finally, we observe that $T_{i+1} \supseteq T_i[10] \cup T_i[00]$ and hence $|T_{i+1}| \geq 2^{i+1}$ as claimed, which completes the induction.

The "moreover" claim follows from inspection. ◀

3.5 Separating General SOBPs From Permutation ROBPs

We now give a function f that is computable by an arbitrary-order permutation ROBP of constant width but is hard for any SOBP of exponential width.

▶ **Proposition 35.** *Let D_3 be the Dihedral group of order 6 with identity element e and fix two reflections r, s such that $r^2 = s^2 = e$ and $rs \neq sr$. Let $S = \{r, s, sr\}$. Consider $f \colon \{0, 1\}^{2n} \to \{0, 1\}$ defined by*

$$f(x, y) := \mathbb{1}(r^{x_1} s^{y_1} \cdots r^{x_n} s^{y_n} \in S).$$

Then every general SOBP computing f has width at least 2^n. Moreover, f can be computed by a arbitrary-order permutation ROBP of width 6.

Proof. The "moreover" claim follows from the fact that any group product can be simulated by a permutation ROBP of width equal to the group's order. We now claim that for every $x \neq x' \in \{0, 1\}^n$, there is a $y \in \{0, 1\}^n$ such that $f(x, y) \neq f(x', y)$, and therefore any SOBP must use 2^n states to remember x after reading it.

First, consider the case where the Hamming weights of x and x' have different parities. Then by taking y to be the all-zero string 0^n and using $r^2 = e$, we have $f(x, y) = r^b$ and $f(x', y) = r^{1-b}$ for some $b \in \{0, 1\}$.

Now, suppose their parities are the same. Let $i \in [n]$ be the first position where x and x' differ, and without loss of generality assume $x_i = 1$ (and so $x'_i = 0$). Let $y = e_i$. Then $f(x, y) = rsr^b$ and $f(x', y) = sr^{1-b}$ for some $b \in \{0, 1\}$, but $s, sr \in S$ and $rsr, rs \notin S$. So in either case we have $f(x, y) \neq f(x', y)$. ◀

A Read-Twice Permutation Branching Programs

We first show that read-*twice* permutation branching programs can compute polynomial width arbitrary-order ROBPs in subexponential width. This follows from Bennett's simulation in reversible computation [4], but here we have to take into account the number of reads of the program. We remark that the proof of this result implicitly uses permutation branching programs where the bound on the number of accept states is much smaller than the width bound [29].

▶ **Proposition 15.** *Let $f\colon \{0,1\}^n \to [w]$ be computable by an arbitrary-order ROBP B of width w. Then for every $k \in \mathbb{N}$, f is computable by a read-(2^k) permutation branching program B' of width $w^{(k+1)n^{1/k}}$.*

Proof. As both programs can read inputs in arbitrary order, by permuting the indices of x we can without loss of generality assume B is a SOBP. Given a SOBP O of width w, we first how to simulate it using a permutation read-2 BP P of width w^m for some $m \leq \sqrt{2n}$, in which every state is represented by an m-tuple in $[w]^m$. We will show that every step in P is *reversible*, that is, for every state $s^p_{t-1} \in [w]^m$ in P, not only can we compute $s^p_t := B_t(s^p_{t-1}, x_{i(t)})$ given s^p_{t-1}, but we can also compute s^p_{t-1} given s^p_t and $x_{i(t)}$, where $i(t) \in [n]$ is the coordinate of x read by P at the t-th step. One can verify that this is equivalent to the condition that P is a permutation program.

We construct P as follows. At each step, P remembers the at most m out of the n states reached by O. Let $s_i \in [w]$ be the state reached by O after reading $x_1, \ldots, x_i$. The program P first reads $x_1, \ldots, x_m$ to compute and store the m states $(s_1, \ldots, s_m) \in [w]^m$ reached by O in the first m steps. Knowing s_{m-2}, we can read x_{m-1} again to erase s_{m-1} from the memory, reaching the state $(s_1, \ldots, s_{m-2}, 0, s_m)$. Knowing s_{m-3}, we can read x_{m-2} again to erase s_{m-2}, reaching $(s_1, \ldots, s_{m-3}, 0, 0, s_m)$. More generally, after reading $x_{m-2}, \ldots, x_1$ the second time [4], we can erase $s_{m-1}, \ldots, s_1$ from memory and we are left with

$$(0, \ldots, 0, s_m).$$

Now, given s_m, we read the next $m-1$ bits $x_{m+1}, \ldots, x_{2m-1}$ to compute and store $(s_{m+1}, \ldots, s_{2m-1}, s_m)$. Using a similar strategy, we can read $x_{2m-2}, \ldots, x_{m+1}$ again to erase $s_{2m-2}, \ldots, s_{m+1}$ from memory, giving us

$$(0, \ldots, 0, s_{2m-1}, s_m).$$

Continuing, we can compute $(s_{\sum_{i=1}^m i}, s_{\sum_{i=2}^m i}, \ldots, s_{2m-1}, s_m)$ reversibly with w^m states. Thus we can compute s_n as long as

$$\sum_{i=1}^{m} i = \frac{m(m+1)}{2} \ge n.$$

which holds when $m = \sqrt{2n}$.

We just showed how to compute the m-tuple of states $(s_{\sum_{i=1}^m i}, s_{\sum_{i=2}^m i}, \ldots, s_{2m-1}, s_m)$ reversibly by reading the input twice. By reading the input another two times, from $(s_{\sum_{i=1}^m i}, s_{\sum_{i=2}^m i}, \ldots, s_{2m-1}, s_m)$ we can erase everything but $s_{\sum_{i=1}^m i} =: s_{f(m)}$ to compute $(s_{f(m)}, 0, \ldots, 0)$ reversibly. We now repeat the above strategy recursively to compute $(s_{\sum_{i=1}^m f(i)}, s_{\sum_{i=2}^m f(i)}, \ldots, s_{2f(m)-1}, s_{f(m)})$ with a read-4 permutation program of width $\sum_{i=1}^m f(i)$.

By an inductive argument, we can compute the state s_n of the read-once branching program reversibly with a read-(2^k) permutation program of width w^m, whenever

$$n \le \sum_{i_k=1}^{m} \sum_{i_{k-1}=1}^{i_k} \cdots \sum_{i_1=1}^{i_2} i_1 = \binom{m+k}{k+1}.$$

Choosing $m \ge (k+1)n^{1/(k+1)}$ completes the proof. ◀

A.1 Hardness for Read-Twice Permutation Programs

We now show that an exponential blow-up in the width in Proposition 15 is necessary. We first restate the theorem.

▶ **Theorem 16.** *For every read-twice ordering $i : [2n] \to [n]$, there exists a function $g\colon \{0,1\}^n \to \{0,1\}$ computable by a regular ROBP of width $O(1)$, such that every read-twice permutation branching program P of width $2^{n^{1/8}}$ with read order i computes g correctly on at most $1/2 + 2^{-\Omega(n^{1/8})}$ fraction of inputs.*

[4] Note that the order of how the bits are read matters. For example, without knowing s_{m-2} we cannot compute s_{m-1} using x_{m-1}.

A 2-pass BP is a read-2 BP where the first read of all its n-bit input come before the second read of any bit. We first prove an average-case lower bound against 2-pass permutation programs of width $2^{\sqrt{n}}$, where the second pass of the n-bit input is read in the same or the reverse order as the first pass. We show that given any read-twice ordering of the input bits, either $\sqrt{n}$ of the bits can be read in a read-once manner, or $n^{1/4}$ of the bits can be read in the 2-pass manner described above. In either case, we can define our hard function on at least $n^{1/4}$ bits and apply our average-case lower bounds. As both programs in the theorem can read input bits in arbitrary order, by permuting the indices of the input we can assume the indices in the first pass of the read are in increasing order.

A.1.1 From 2-pass lower bound to read-once lower bound

We obtain our 2-pass lower bound by a reduction to our read-once lower bound (Theorem 11) based on an idea by David, Papakonstantinou, and Sidiropoulos [15].

▶ **Proposition 36.** *Let P be a 2-pass permutation BP of width w that reads its first pass of the input in the standard order, and its second pass in the same or reverse order as the first pass. If $\Pr[P(U) = f(U)] \geq 1/2 + \varepsilon$ for some $f\colon \{0,1\}^n \to \{0,1\}$, then there exists a permutation SOBP permutation program P' of width w^2 such that $\Pr[P'(U) = f(U)] \geq 1/2 + \varepsilon/w$.*

▶ **Corollary 37.** *There exists a function $f\colon \{0,1\}^n \to \{0,1\}$ computable by a regular SOBP of constant width that is $(1/2 + 2^{-\sqrt{n}})$-hard against 2-pass permutation BPs of width $2^{c\sqrt{n}}$ that reads its second pass of the input in the same or reverse order as the first pass for a universal constant c.*

Proof. Let f be the function in Theorem 11 with $\varepsilon = 2^{-(1+c)\sqrt{n}}$, which is hard against permutation SOBPs of width $2^{(c'/(1+c))\sqrt{n}}$ for some universal constant c. Suppose f is not $(1/2 + 2^{-\sqrt{n}})$-hard against a 2-pass permutation SOBP of width $w = 2^{c\sqrt{n}}$. Then by Proposition 36, f is not $(1/2 + 2^{-(1+c)\sqrt{n}})$-hard against a permutation SOBP of width $2^{2c\sqrt{n}}$. Choosing c such that $2c < c'/(1 + c)$, we get a contradiction. ◀

Proof of Proposition 36. We first handle the case where the second pass is in the same order as the first pass. Suppose

$$\Pr[P(U) = f(U)] - \Pr[P(U) \neq f(U)] > \varepsilon.$$

Let V_n be the layer P reaches after making its first pass on x. By an averaging argument, there must be a state $v^* \in V_n$ such that

$$\begin{aligned}
&\Pr\big[\big(P(U) = f(U)\big) \wedge P_{\to v^*}(U)\big] - \Pr\big[\big(P(U) \neq f(U)\big) \wedge P_{\to v^*}(U)\big] \\
&\quad \geq \frac{1}{|V_n|} \sum_{v \in V_n} \Big(\Pr\big[\big(P(U) = f(U)\big) \wedge P_{\to v}(U)\big] - \Pr\big[\big(P(U) \neq f(U)\big) \wedge P_{\to v}(U)\big]\Big) \\
&\quad \geq \frac{1}{|V_n|} \Big(\Pr\big[P(U) = f(U)\big] - \Pr\big[P(U) \neq f(U)\big]\Big) \\
&\quad \geq \frac{\varepsilon}{|V_n|}.
\end{aligned}$$

For $b \in \{0,1\}$, consider the new function P'_b that outputs $P(x)$ if $P_{v^*}(x) = 1$ and outputs b otherwise. Note that $\mathsf{adv}(P'_b, f) \geq \varepsilon/|V_n|$ for one of the $b \in \{0,1\}$. Assume $b = 0$ without loss of generality.

We now show that the function P'_0 can be computed by a permutation SOBP of width w^2 as follows. Its i-th layer V'_i is $V_i \times V_{n+i}$. Its start state is (v_0, v^*). Its accept states are $V'_{acc} := \{(v_1, v_2) : (v_1 = v^* \wedge v_2 \in V_{acc})\}$.

To handle the case where the second pass is in the reverse order, we use a similar idea. Suppose

$$\Pr[P(U) = f(U)] - \Pr[P(U) \neq f(U)] > \varepsilon.$$

Let $V_{acc} \subseteq V_{2n}$ be the set of accept states in the final layer. By an averaging argument, there must be a state $v^* \in V_{acc}$ such that

$$\Pr\big[P_{\to v^*}(U) = f(U)\big] - \Pr\big[P_{\to v^*}(U) \neq f(U)\big] \geq \frac{\varepsilon}{|V_{acc}|}.$$

We now show that the function $P_{\to v^*}$ can be computed by a permutation SOBP program of width w^2. Here we use the fact that P is a permutation BP, where we can reverse the transitions in the program as follows. Define the reversed transition $P_r^{-1}\colon V_r \times \{0,1\} \to V_{r-1}$ to be $P_r^{-1}[v_r, x_r] := v_{r-1}$, where v_{r-1} is the unique state $v \in V_{r-1}$ such that $P_r[v_{r-1}, x_r] = v_r$.

To implement $P_{\to v^*}$, its i-th layer V'_i is $V_i \times V_{2n-i}$. Its start state is $(v_0, v^*) \in V_0 \times V_{2n}$. Its transition $P'_i\colon V'_{i-1} \to V'_i$ is $P'_i((v_1, v_2), x_i) = (P_i(v_1, x_i), P^{-1}_{n-i+1}(v_2, x_i))$. Its accept states are $V'_{acc} := \{(v_1, v_2) : v_1, v_2 \in V_n : v_1 = v_2)\}$. ◀

A.1.2 From 2-pass lower bound to read-2 lower bound

We follow a similar idea that is used in [24]. Given a read-2 sequence, by permuting the indices of the input bits, we may assume the first pass is in increasing order. We will show that it contains a subsequence of the form $i_1 i_1 i_2 i_2 \cdots i_{\sqrt{n}} i_{\sqrt{n}}$, in which case we can define the hard function on $x_{i_1}, \ldots, x_{i_{\sqrt{n}}}$ and applying our read-once lower bound on $\sqrt{n}$ bits, or it contains a 2-pass subsequence of the form $i_1 \cdots i_{\sqrt{n}} i_{\sigma(1)} \cdots i_{\sigma(\sqrt{n})}$ for some permutation $\sigma\colon [\sqrt{n}] \to [\sqrt{n}]$, in which case by the Erdős–Szekeres theorem (Theorem 38 below), the sequence $i_{\sigma(1)} \cdots i_{\sigma(\sqrt{n})}$ must contain a monotone subsequence $i_{j_1} \cdots i_{j_{n^{1/4}-1}}$ of length $n^{1/4} - 1$, and so the read-2 sequence contains a 2-pass sequence on $n^{1/4} - 1$ bits where the second pass is in the same or reverse order as the first pass. So we can apply our 2-pass lower bound.

Before proving Theorem 16, we first state the Erdős–Szekeres theorem, which will be used in our proof.

▶ **Theorem 38** (Erdős–Szekeres [20]). *For any integers s and r, any sequence of distinct real numbers of length $sr + 1$ contains a monotonically increasing subsequence of length $s + 1$ or a monotonically decreasing subsequence of length $r + 1$.*

Proof of Theorem 16. Let $s \in [n]^{2n}$ be a read-2 sequence. For $i \in [n]$, let $\mathsf{pos}^1(i)$ and $\mathsf{pos}^2(i)$ be the locations of the first and second occurrence of i, respectively. Partition the $2n$ indices of the sequence into $\sqrt{n}$ blocks $B_k : k \in [\sqrt{n}]$, where $B_k := [\mathsf{pos}^1((k-1)\sqrt{n}+1) : \mathsf{pos}^1(k\sqrt{n})-1]$. We consider two cases.

Suppose each block contains both occurrences of some element. That is, for each block $B_k : k \in [\sqrt{n}]$, we have $\mathsf{pos}^1(i_k), \mathsf{pos}^2(i_k) \in B_k$ for some $i_k \in [n]$. Then s contains the subsequence

$$i_1 i_1 \cdots i_{\sqrt{n}} i_{\sqrt{n}}.$$

We define $g(x) := f(x_{i_1}, \ldots, x_{i_{\sqrt{n}}})$, where f is the hard function defined in Theorem 11 (but on $\sqrt{n}$ bits). Let P be a read-2 permutation BP of width $2n^{1/8} \leq 2^{n^{1/4}}$ which reads its input in the order given by s. By Theorem 11, we have that $\Pr[P(U) = g(U)] \leq 1/2 + 2^{-\Omega(n^{1/4})}$ and g is computable by a regular ROBP of constant width.

Otherwise, some block does not contain both occurrences of any element. In other words, there exists a block B_k such that none of $\mathsf{pos}^2((k-1)\sqrt{n}+1), \ldots, \mathsf{pos}^2(k\sqrt{n})$ lies in B_k. In this case, s contains the 2-pass subsequence

$$\big((k-1)\sqrt{n}+1\big) \cdots \big(k\sqrt{n}\big) \cdot \sigma\big((k-1)\sqrt{n}+1\big) \cdots \sigma\big(k\sqrt{n}\big)$$

for some permutation σ on the $\sqrt{n}$ elements in the subsequence. Applying the Erdős–Szekeres theorem to the second half of the subsequence, we obtain a 2-pass subsequence on $n^{1/4} - 1$ elements from s where the second pass in the same or reverse order as the first pass. As in the previous case, by defining g to be the hard function f in Theorem 11 on these $n^{1/4} - 1$ bits, we conclude that $\Pr[P(U) = g(U)] \leq 1/2 + 2^{-\Omega(n^{1/8})}$ for any read-twice permutation program reading its input in the order given by s, and g is computable by a regular ROBP of constant width. ◀

Private Data Stream Analysis for Universal Symmetric Norm Estimation

Abstract

We study how to release summary statistics on a data stream subject to the constraint of differential privacy. In particular, we focus on releasing the family of *symmetric norms*, which are invariant under sign-flips and coordinate-wise permutations on an input data stream and include L_p norms, k-support norms, top-k norms, and the box norm as special cases. Although it may be possible to design and analyze a separate mechanism for each symmetric norm, we propose a general parametrizable framework that differentially privately releases a number of sufficient statistics from which the approximation of all symmetric norms can be simultaneously computed. Our framework partitions the coordinates of the underlying frequency vector into different levels based on their magnitude and releases approximate frequencies for the "heavy" coordinates in important levels and releases approximate level sizes for the "light" coordinates in important levels. Surprisingly, our mechanism allows for the release of an *arbitrary* number of symmetric norm approximations without any overhead or additional loss in privacy. Moreover, our mechanism permits $(1+\alpha)$-approximation to each of the symmetric norms and can be implemented using sublinear space in the streaming model for many regimes of the accuracy and privacy parameters.

1 Introduction

The family of L_p norms represent important statistics on an underlying dataset, where the L_p norm[1] of an n-dimensional frequency vector x is defined as the number of nonzero coordinates of x for $p=0$ and $L_p(x)=(x_1^p+\ldots+x_n^p)^{1/p}$ for $p>0$. Thus, the L_0 norm counts the number of distinct elements in the dataset and, e.g., is used to detect denial of service or port scan attacks in network monitoring [3, 32], to understand the magnitude of quantities such as search engine queries or internet graph connectivity in data mining [55], to manage workload in database design [33], and to select a minimum-cost query plan in

[1] L_p for $p\in(0,1)$ does not satisfy the triangle inequality and therefore is not a norm, but is still well-defined/well-motivated and can be computed

query optimization [57]. The L_1 norm computes the total number of elements in the dataset and, e.g., is used for data mining [26] and hypothesis testing [39], while the L_2 norm, e.g., is used for training random forests in machine learning [20], computing the Gini index in statistics [50, 36], and network anomaly detection in traffic monitoring [44, 62], in particular in the context of heavy-hitters, e.g., [24, 16, 15, 17, 49, 14]. More generally, L_p norms for $p \in (0,2)$ have been used for entropy estimation [37]. Consequently, L_p estimation has been extensively studied in the data stream model [4, 40, 38, 45, 41, 5, 18, 35, 65, 66]. The simplest streaming model is perhaps the insertion-only model, in which a sequence of m updates increments coordinates of an n-dimensional frequency vector x and the goal is to compute or approximate some statistic of x in space that is sublinear in both m and n. For a more formal introduction to the streaming model, see Section 2.1.

In many cases, the underlying dataset contains sensitive information that should not be leaked. Hence, an active line of work has focused on estimating L_p norms for various values of p, while preserving differential privacy [53, 12, 59, 21, 63].

▶ **Definition 1** (Differential privacy, [29]). *Given $\varepsilon > 0$ and $\delta \in (0,1)$, a randomized algorithm $\mathcal{A} : \mathfrak{U}^* \to \mathcal{Y}$ is (ε, δ)-differentially private if, for every neighboring streams $\mathfrak{S}$ and $\mathfrak{S}'$ and for all $E \subseteq \mathcal{Y}$,*

$$\mathbf{Pr}\left[\mathcal{A}(\mathfrak{S}) \in E\right] \le e^{\varepsilon} \cdot \mathbf{Pr}\left[\mathcal{A}(\mathfrak{S}') \in E\right] + \delta.$$

For example, [12] showed that the Johnson-Lindenstrauss transformation preserves differential privacy (DP), thereby showing one of the main techniques in the streaming model for L_2 estimation already guarantees DP. Similarly, [59] showed that the Flajolet-Martin sketch, which is one of the main approaches for L_0 estimation in the streaming model, also preserves DP. However, algorithmic designs for L_p estimation in the streaming model differ greatly and require individual analysis to ensure DP, especially because it is known that for some problems, guaranteeing DP provably requires more space [28]. Unfortunately, the privacy and utility analysis can be quite difficult due to the complexity of the various techniques. This is especially pronounced in the work of [63], who studied the p-stable sketch [38], which estimates the L_p norm for $p \in (0,2]$. [63] showed that for $p \in (0,1]$, the p-stable sketch preserves DP, but was unable to show DP for $p \in (1,2]$, even though the general algorithmic approach remains the same. Thus the natural question is whether differential privacy can be guaranteed for an approach that simultaneously estimates the L_p norm in the streaming model, for all p. More generally, the family of L_p norms are all symmetric norms, which are invariant under sign-flips and coordinate-wise permutations on an input data stream. Symmetric norms thus also include other important families of norms such as the k-support norms and the top-k norms.

1.1 Our Contributions

In this paper, we show that not only does there exist a differentially private algorithm for the estimation of symmetric norms in the streaming model, but also that there exists an algorithm that privately releases a set of statistics, from which estimates of all (properly parametrized) symmetric norms can be simultaneously computed. To illustrate the difference, suppose we wanted to release approximations of the L_p norm of the stream for k different values of p. To guarantee (ε, δ)-DP for the set of k statistics, we would need, by advanced composition, to demand $\left(\mathcal{O}\left(\frac{\varepsilon}{\sqrt{k}}\right), \mathcal{O}\left(\frac{\delta}{k}\right)\right)$-DP from k instances of a single differentially private L_p-estimation algorithm, corresponding to the k different values of p. Due to accuracy-privacy tradeoffs, the quality of the estimation will degrade severely as k increases. For an extreme example, consider when k is some large polynomial of n and m so that the added noise will also be polynomial in n and m, and then there is no utility at all – the private algorithm might as well just release 0 for all queries!

In contrast, our algorithm releases a single set C of private statistics. By post-processing, we can then estimate the L_p norms for k different values of p while only requiring (ε, δ)-DP from C. Hence, our algorithm can simultaneously handle any large number of estimations of symmetric norms without compromising the quality of approximation.

We first informally introduce the definition of the maximum modulus of concentration of a norm, which measures the worst-case ratio of the maximum value of a norm on the L_2-unit sphere to the median value of a norm on the L_2-unit sphere, where the median can be taken over any restriction of the coordinates. Intuitively, maximum modulus of concentration of a norm quantifies the complexity of computing a norm. For example, the L_1 norm is generally "easy" to compute and has maximum modulus of concentration $\mathcal{O}(\log n)$. See Definition 18 for a more formal definition. Then our main result can informally be stated as follows:

▶ **Theorem 2** (Informal). *There exists a (ε, δ)-differentially private algorithm that outputs a set C, from which the $(1+\alpha)$-approximation to any norm, with* maximum modulus of concentration *at most M of a vector $x \in \mathbb{R}^n$ induced by a stream of length* $\text{poly}(n)$ *can be computed, with probability at least $1-\delta$. The algorithm uses $M^2 \cdot \text{poly}\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log n, \log \frac{1}{\delta}\right)$ bits of space.*

We remark that as is standard in differential privacy on data streams, both the privacy parameter ε and the accuracy parameter α cannot be too small or the additive noise will be too large and cannot be absorbed into the $(1+\alpha)$-multiplicative bounds. See Theorem 33 for the formal statement of Theorem 2 describing these bounds.

We also remark that in the statement of Theorem 2, the δ failure parameter of approximate DP is equal to the failure parameter δ of the utility guarantees of the algorithm. More generally, if the desired failure probability δ' of the utility guarantee is not equal to the privacy parameter δ, then the dependencies will change from $\log \frac{1}{\delta}$ to $\log \frac{1}{\delta\delta'}$.

We emphasize that prior to our work, there is no algorithm that can handle private symmetric norm estimation for arbitrary symmetric norms, much less simultaneously for all parametrized symmetric norms. Although there is specific analysis for various norm estimation algorithms, e.g., see the discussion on related work in Section 1.3, these algorithms require a specific predetermined norm for their input. Thus a separate private algorithm must be run for each estimation, which increases the overall space. Moreover, for a large number of queries, the privacy parameter will need to be much smaller due to the composition of privacy, and thus to ensure privacy, the utility of each algorithm is provably poor. Our algorithm sidesteps both the space and accuracy problems and is the first and only work to do so, as of yet.

Applications. We briefly describe a number of specific symmetric norms that are handled by Theorem 2 and commonly used across various applications in machine learning. We first note the following parameterization of the previously discussed L_p norms.

▶ **Lemma 3** ([52, 43]). *For L_p norms, we have that* $\text{mmc}(L) = \mathcal{O}(\log n)$ *for $p \in [1, 2]$ and* $\text{mmc}(L) = \mathcal{O}\left(n^{1/2-1/p}\right)$ *for $p > 2$.*

Thus our algorithm immediately introduces a differentially private mechanism for the approximation of L_p norms that unlike previous work, e.g., [12, 58, 25, 59, 21, 63], does not need to provide separate analysis for specific values of p. Moreover for constant-factor approximation, the space complexity is tight with the *optimal* L_p-approximation algorithms that do not consider privacy, up to polylogarithmic factors [42, 46, 34, 65] in the universe size n.

▶ **Definition 4** (Q-norm and Q'-norm). *We call a norm L a Q-norm if there exists a symmetric norm L' such that $L(x) = L'(x^2)^{1/2}$ for all $x \in \mathbb{R}^n$. Here, we use x^2 to denote the coordinate-wise square power of x. We also call a norm L' a Q'-norm if its dual norm is a Q-norm.*

The family of Q'-norms includes the L_p norms for $1 \le p \le 2$, the k-support norm, and the box norm [10] and thus Q'-norms have been proposed to regularize sparse recovery problems in machine learning. For instance, [7] showed that Q' norms have tighter relaxations than elastic nets and can thus be more effective for sparse prediction. Similarly, [51] used Q' norms to optimize sparse prediction algorithms for multitask clustering.

▶ **Lemma 5** ([11]). $\text{mmc}(L) = \mathcal{O}(\log n)$ *for every Q'-norm L.*

Theorem 2 and Lemma 5 thus present a differentially private algorithm for Q'-norm approximation that uses polylogarithmic space.

▶ **Definition 6** (Top-k norm). *The top-k norm for a vector $x \in \mathbb{R}^n$ is the sum of the largest k coordinates of $|x|$, where we use $|x|$ to denote the vector whose entries are the coordinate-wise absolute value of x.*

The top-k norm is frequently used to understand the more general Ky Fan k-norm [67], which is used to regularize optimization problems in numerical linear algebra. Whereas the Ky Fan k norm is defined as the sum of the k largest singular values of a matrix, the top-k norm is equivalent to the Ky Fan k norm when the input vector x represents the vector of the singular values of the matrix.

▶ **Lemma 7** ([11]). $\text{mmc}(L) = \tilde{\mathcal{O}}\left(\sqrt{\frac{n}{k}}\right)$ *for the top-k norm L.*

In particular, the top-k norm for a vector of singular values when $k = n$ is equivalent to the Schatten-1 norm of a matrix, which is a common metric for matrix fitting problems such as low-rank approximation [47].

▶ **Definition 8** (Shannon entropy). *For a frequency vector $v \in \mathbb{R}^n$, we define the Shannon entropy by $H(v) = -\sum_{i=1}^n v_i \log v_i$.*

To achieve an additive approximation to the Shannon entropy, we instead compute a multiplicative approximation to the exponential form, as follows:

▶ **Observation 9.** *A $(1+\alpha)$-multiplicative approximation of the function $h(v) := 2^{H(v)}$ corresponds to an α-additive approximation of the Shannon Entropy $H(v)$ (and vice versa).*

Moreover, computing a $(1+\alpha)$-approximation to $2^{H(v)}$ can be achieved through computing a $(1+\alpha)$-approximation to various L_p norms for $p \in (0, 2)$.

▶ **Lemma 10** (Section 3.3 in [37]). *Let $k = \log\frac{1}{\alpha} + \log\log m$ and $\alpha' = \frac{\alpha}{12(k+1)^3 \log m}$. There exists an explicit set $\{y_0, \ldots, y_k\}$ with $y_i \in (0, 2)$ for all i and a post-processing function that takes $(1+\alpha')$-approximations to $F_{y_i}(x)$, i.e., the (y_i)-th frequency moment of x, and outputs a $(1+\alpha)$-approximation to $h(v) = 2^{H(x)}$. Furthermore, the set $\{y_0, \ldots, y_k\}$ and post-processing function are both efficiently computable, i.e., polynomial runtime.*

Since our mechanism releases a private set of statistics from which $(1+\alpha)$-approximations to L_p norms can be computed for any $p \in (0, 2)$, then our mechanism also privately achieves an additive α-approximation to Shannon entropy.

1.2 Algorithmic Intuition and Overview

Our starting point is the L_p estimation algorithm of [40], which was parametrized by [11] to handle symmetric norms. For a $(1+\alpha)$-approximation, the algorithm partitions the n coordinates of the frequency vector x into powers of ξ-based on their magnitudes, where $\xi > 1$ is a fixed function of α. Each partition forms a level set, so that the i-th level set consists of the coordinates of x with frequency $[\xi^i, \xi^{i+1})$, but [40, 11] showed that it suffices to accurately count the size of each *important* level set and zero out to the other level sets, where a level set is considered important if its size is large enough to contribute an $\frac{\alpha^2}{\log m}$ fraction of the symmetric norm. In other words, if $\tilde{x}$ is a vector whose coordinates match those of x in important levels sets and are 0 elsewhere, then $(1-\alpha)L(x) \le L(\tilde{x}) \le (1+\alpha)L(x)$. We formalize the definition of importance in Section 2.2.

Private symmetric norm estimation in the centralized setting. To preserve (ε, δ)-differential privacy, one initial approach would be to view the frequency vector as a histogram and add Laplacian noise with scale $\mathcal{O}\left(\frac{1}{\varepsilon}\right)$ to the frequency of each element. However, the level sets consisting of elements with frequencies between $[\xi^i, \xi^{i+1})$ for small i, say $i = 0$, could be largely perturbed by such Laplacian noise. For example, it is possible that for some coordinate j in an important level set, we have $x_j = 1$, in which case adding Laplacian noise with scale $\mathcal{O}\left(\frac{1}{\varepsilon}\right)$ to x_j will heavily distort the coordinate. This can happen to all coordinates in the important level set, which results in an inaccurate estimation of the norm.

Fortunately, if i is small, the corresponding level set must contain a large number of elements if it is important, so it seems possible to privately release the size Γ_i of the level set. Indeed, we can show that the L_1 sensitivity of the vector corresponding to level set sizes is small and so we can add Laplacian noise with scale $\mathcal{O}\left(\frac{1}{\varepsilon}\right)$ to each level set size. Hence if the level set has size Γ_i roughly $\Omega\left(\frac{1}{\alpha\varepsilon}\right)$, then the Laplacian noise will affect Γ_i by a $(1+\alpha)$-factor.

Unfortunately, there can be level sets that are both important and small in size. For example, if there is a single element with frequency m, then the size of the corresponding level set is just one. Then adding Laplacian noise with scale $\mathcal{O}\left(\frac{1}{\varepsilon}\right)$ will severely affect the size of the level set and thus the estimation of the symmetric norm. On the other hand, for $m > \frac{1}{\alpha\varepsilon}$, the frequency of the coordinate is quite large so again it seems like we can just add Laplacian noise with scale $\mathcal{O}\left(\frac{1}{\varepsilon}\right)$ and output the noisy frequency of the coordinate.

New approach: classifying and separately handling high, medium, and low frequency levels. The main takeaway from these challenges is that we should handle different level sets separately. For the level sets of small coordinates, the important level sets must have large size and thus we would like to release noisy sizes. For the important level sets of large coordinates, we would like to release noisy frequencies of the coordinates.

In that vein, we partition the levels into three groups after defining thresholds T_1 and T_2, with $T_1 > T_2$. We define the “high frequency levels” as the levels whose coordinates exceed T_1 in frequency. The intuition is that because the high frequency levels have such large magnitude, their frequencies can be well-approximated by running an L_2-heavy hitters algorithm on the stream S.

We define the “medium frequency levels” as the levels whose coordinates are between T_1 and T_2 in frequency. These coordinates are not large enough to be detected by running an L_2-heavy hitters algorithm on the stream S. However, the sizes of these level sets must be large if the level set is important. Thus there exists a substream S_j for which a large number of these coordinates are subsampled and their frequencies can be well-approximated by running an L_2-heavy hitters algorithm on the substream S_j.

Finally, we define the "low frequency levels" as the levels whose coordinates are less than T_2 in frequency. These coordinates are small enough that we cannot add Laplacian noise to their frequencies without affecting the level sets they are mapped to. Instead, we show that the L_1 sensitivity for the level set estimations is particularly small for the low frequency levels. Thus, for these frequency levels, we report the size of the frequency levels rather than the approximate frequencies of the heavy-hitters. We remark that if our goal was to just approximate the symmetric norms without preserving differential privacy, then it would suffice to just consider the high and medium frequency levels, since the low frequency levels are particularly problematic when Laplacian noise is added to the frequency vector. We also remark that we only use the thresholds T_1 and T_2 for the purposes of describing our algorithm – in the actual implementation of the algorithm, the thresholds T_1 and T_2 will be implicitly defined by each of the substreams.

Private symmetric norm estimation in the streaming model. Although the previously discussed intuition builds towards a working algorithm, the main caveat is that so far, we have mainly discussed the centralized model, where space is not restricted and so each coordinate and thus each level set size can be counted exactly. In the streaming model, we cannot explicitly track the frequency vector, or even the frequencies of a constant fraction of coordinates. Instead, to estimate the sizes of each level set, [40, 11] take the stream S and form $s = \mathcal{O}(\log n)$ substreams $S_1, \ldots, S_s$, where the j-th substream is created by sampling the universe of size n at a rate of $\frac{1}{2^{j-1}}$. Then S_j will only consist of the stream updates to the particular coordinates of x that are sampled. Thus in expectation, the frequency vector induced by S_j will have sparsity $\frac{\|x\|_0}{2^{j-1}}$. Similarly, if a level set i has size Γ_i, then $\frac{\Gamma_i}{2^{j-1}}$ of its members will be sampled in S_j in expectation. It can then be shown through a variance argument that if level set i is important, then there exists an explicit substream j from which Γ_i can be well-approximated using the L_2-heavy hitter algorithm CountSketch and as a result, the symmetric norm of x can be well-approximated. The main point of the subsampling approach is that if there exists a level set with large size consisting of small coordinates, then the coordinates will not be detected by the CountSketch on S, but because S_j has significantly smaller L_2 norm, then the coordinates will be detected by CountSketch on S_j.

However, adapting the subsampling and heavy-hitter approach introduces additional challenges for privacy. For instance, we can analyze the L_2-heavy hitter algorithm CountSketch and show that although the L_1 sensitivity of the estimated frequency for a single coordinate is small, the L_1 sensitivity of the estimated frequency vector for all the coordinates may be large. Instead, we use the view that CountSketch is a composition function that first only estimates frequencies for the top poly $\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log n\right)$ and then outputs only those estimates that are above a certain threshold. Similarly, the Laplacian noise added to privately use CountSketch can alter the sizes of a significant number of level sets for small coordinates. Thus for the small coordinates (corresponding to the substreams S_j with large j), we invoke CountSketch with much higher accuracy, so that with high probability, it will return *exactly* the frequencies for the small coordinates. For example, note that if the frequency x_k of a coordinate $k \in [n]$ is at most $\frac{1}{2\alpha^2\varepsilon}$, then any $(1 + \alpha^2\varepsilon)$-approximation to x_k can be rounded to exactly recover x_k. This decreases the L_1 sensitivity of the vector of estimated level set sizes, therefore allowing us to add Laplacian noise without greatly affecting the quality of approximation.

1.3 Related Work

Non-private L_p norm estimation is one of the fundamental problems in the streaming model, beginning with [4]'s seminal work that tracks the inner product of the frequency vector with a random sign vector for L_2 estimation (as well as a telescoping argument for integer $p > 0$). [38, 45] later showed that this approach could be generalized for $p \in (0, 2]$ by tracking the inner product of the frequency vector with a vector with randomly generated p-stable variables, which only exist for $p \in (0, 2]$. For $p > 2$, [5] gave an L_p estimation algorithm using the max-stability property of exponential random variables. More generally, [40] introduced the framework of subsampling and using heavy-hitters for L_p estimation, which [11] parametrized to all symmetric norms. It should be emphasized that these techniques all handle the more general turnstile model, in which ± 1 updates are allowed to each coordinate, rather than single positive increments. Hence our techniques also extend to the turnstile model with a minor change on the conditions.

More recently, [13, 61] given a general framework for converting non-private approximation algorithms into private approximation algorithms, provided that the accuracy of these algorithms could be tuned with an input parameter $\varepsilon > 0$, i.e., the algorithms can achieve $(1 + \varepsilon)$-approximation for a wide range of $\varepsilon > 0$. Their results presented a solution that addresses the difficulty of adapting privacy specifically to each non-private algorithm separately. However, their framework only applies to problems with scalar outputs and thus do not handle synthetic data release. Therefore, privately answering multiple norm queries while circumventing composition bounds is still a challenge that their results cannot handle.

Symmetric norms have also recently received attention in other big data models as well. [6] studied approximate near neighbors for general symmetric norms while [48] studied symmetric norm estimation for network monitoring. [60] considered Orlicz norm regression and other loss functions where the penalty is a symmetric norm. [19] gave an algorithm to approximate the symmetric norm in the sliding window model, where updates in the data stream implicitly expire after a fixed amount of time.

Specific cases of private L_p estimation in the streaming model have also been previously well-studied. [25, 59] studied private L_0 estimation using the Flajolet-Martin sketch, while [63] studied private L_p estimation for $p \in (0, 1]$ using the p-stable sketch and [12, 58, 25, 21] studied private L_2 estimation using the Johnson-Lindenstrauss projection. Specifically, [12] gave an (ε, δ)-DP algorithm for L_2 estimation that achieves a $(1 + \varepsilon)$-approximation while using $\mathcal{O}\left(\frac{1}{\varepsilon^2} \log n \log \frac{1}{\delta}\right)$ bits of space and [63] gave an (ε, δ)-DP algorithm for L_p estimation that achieves a $(1 + \alpha)$-approximation while using $\mathcal{O}\left(\frac{1}{\alpha^2} \log n \log \frac{1}{\delta}\right)$ bits of space for constant ε and $p \in (0, 1)$. For fractional $p > 1$, private distribution estimation algorithms [2, 68, 9, 64] can be used to approximate the L_p norm, but since the algorithms provide information over a much larger distribution, e.g., much larger histograms of frequencies, the privacy-accuracy trade-off is sub-optimal and the space complexity is exponentially worse.

The related problem of privately releasing heavy-hitters in big data models has also been well-studied. [23] studied the problem of continually releasing L_1-heavy hitters in a stream, while [30] studied L_1-heavy hitters and other problems in the pan-private streaming model. The heavy-hitter problem has also received significant attention in the local model, e.g., [9, 27, 1, 22, 8], where individual users should locally randomize their data before sending differentially private information to an untrusted server that aggregates the statistics across all users.

2 Preliminaries

In this section, we introduce definitions and simple or well-known results from differential privacy, sketching algorithms, and symmetric norms. For notation, we use $[n]$ for an integer $n > 0$ to denote the set $\{1, \ldots, n\}$. We also use the notation $\text{poly}(n)$ to represent a constant degree polynomial in n and we say an event occurs *with high probability* if the event holds with probability $1 - \frac{1}{\text{poly}(n)}$. Similarly, we use $\text{polylog}(n)$ to denote $\text{poly}(\log n)$. Given a vector $x \in \mathbb{R}^n$, we define its second frequency moment $F_2(x) = x_1^2 + \ldots + x_n^2$. Finally, for a parameter $c \geq 1$, we say that X provides a C-approximation to a quantity Y if $\frac{X}{C} \leq Y \leq C \cdot X$.

Privately releasing multiple statistics that are individually differentially private can also be done, but comes at a slight cost.

▶ **Theorem 11** (Composition and post-processing of differential privacy, [31]). *Let $\mathcal{A}_i : \mathfrak{U}_i \to X_i$ be an $(\varepsilon_i, \delta_i)$-differential private algorithm for $i \in [k]$. Then $\mathcal{A}_{[k]}(x) = (\mathcal{A}_1(x), \ldots, \mathcal{A}_k(x))$ is $\left(\sum_{i=1}^k \varepsilon_i, \sum_{i=1}^k \delta_i\right)$-differentially private. Furthermore, if $g_i : X_i \to X_i'$ is an arbitrary random mapping, then $g_i(\mathcal{M}_i(x))$ is $(\varepsilon_i, \delta_i)$-differentially private.*

Although there exists more sophisticated approaches for composition, such as advanced composition, we do not need them for our purposes.

2.1 Streaming and Sketching Algorithms

In the streaming model, a frequency vector $x \in \mathbb{R}^n$ is induced by a sequence of updates. In the insertion-only streaming model, x is defined through a stream of m updates $u_1, \ldots, u_m$, where $u_t \in [n]$ for each $t \in [m]$ so that $x_i = |\{t \in [m] \,|\, u_t = i\}|$ for all $i \in [n]$. In other words, x_i is the number of times that $i \in [n]$ appears in the stream. We remark that our techniques generalize to some degree to turnstile streams, where each update is an ordered pair $u_t = (\Delta_t, c_t)$, so that the t-th update changes the c_t-th coordinate by Δ_t, i.e., $c_t \in [n]$ is a coordinate and $\Delta_t \in [-M, M]$ for some parameter $M > 0$. In this turnstile model, the vector x is defined so that $x_i = \sum_{t:c_t=i} \Delta_t$ for all $i \in [n]$. Although our techniques can apply to the general turnstile model with a minor change on the conditions and assumptions, we shall work with the insertion-only streaming model throughout the remainder of the paper.

Given a frequency vector $x \in \mathbb{R}^n$ on a data stream, the AMS algorithm for L_2-estimation first generates a sign vector $\sigma \in \{-1, +1\}^n$ and sets $S_1 = (\langle \sigma, x \rangle)^2$. We remark that to maintain σ in small space, it suffices for the coordinates of the sign vector σ to be 4-wise independent and therefore it suffices to randomly generate and store a 4-wise independent hash function. The AMS algorithm then repeats this process $b = \frac{6}{\alpha^2}$ independent times to obtain dot products $S_1, \ldots, S_b$, sets Z^2 to be the arithmetic mean of $S_1, \ldots, S_b$, and reports Z. We define the L_2 norm of a vector $x \in \mathbb{R}^n$ by $L_2(x) = \sqrt{x_1^2 + \ldots + x_n^2}$.

▶ **Definition 12** (ν-approximate η L_2-heavy hitters problem). *Given an accuracy parameter $\nu \in (0, 1)$, a threshold parameter η, and a frequency vector $x \in \mathbb{R}^n$, compute a set $H \subseteq [n]$ and a set of approximations $\widehat{x_k}$ for all $k \in H$ such that:*

(1) *If $x_k \geq \eta L_2(x)$ for any $k \in [n]$, then $k \in H$, so that H contains all η L_2-heavy hitters of x.*

(2) *There exists a universal constant $C \in (0, 1)$ so that if $x_k \leq \frac{C\eta}{2} L_2(x)$ for any $k \in [n]$, then $k \notin H$, so that H does not contain any index that is not an $\frac{C\eta}{2}$ L_2-heavy hitter of x.*

(3) *If $k \in H$ for any $k \in [n]$, then compute $(1 \pm \nu)$-approximation to the frequency x_k, i.e., a value $\widehat{x_k}$ such that $(1 - \nu)x_k \leq \widehat{x_k} \leq (1 + \nu)x_k$.*

The well-known CountSketch algorithm can be parametrized to provide an estimated frequency to each item and then releases the approximate frequencies of each item that surpasses a threshold proportional to the output of AMS:

▶ **Theorem 13** (CountSketch for ν-approximate η L_2-heavy hitters, [24]). *There exists a one-pass streaming algorithm* CountSketch *that takes an accuracy parameter $\nu \in (0,1)$ and a threshold parameter η^2 and outputs a list H that contains all indices $k \in [n]$ of an underlying frequency vector x with $x_k \ge \eta\, L_2(x)$ and no index $k \in [n]$ with $x_k \le \eta(1-\nu)\, L_2(x)$. For each $k \in H$,* CountSketch *also reports a estimated frequency $\widehat{x_k}$ such that $(1-\nu)x_k \le \widehat{x_k} \le (1+\nu)x_k$. The algorithm uses $\mathcal{O}\left(\frac{1}{\eta^2\nu^2}\log^2 n\right)$ bits of space and succeeds with probability $1-\frac{1}{\mathrm{poly}(m)}$.*

Algorithm 1 Heavy-hitter algorithm CountSketch.

```
Input: Stream $\mathfrak{S}$ inducing frequency vector $x \in \mathbb{R}^n$, accuracy parameter $\nu \in (0,1)$, and
    threshold parameter $\eta \in (0,1)$
Output: $L_2$ Heavy-hitter algorithm
$r \leftarrow \mathcal{O}(\log n)$, $b \leftarrow \mathcal{O}\left(\frac{1}{\eta^2\nu^2}\right)$
Pick hash functions $h^{(1)}, \ldots, h^{(r)} : [n] \to [b]$ and $s^{(1)}, \ldots, s^{(r)} : [n] \to \{-1,+1\}$
$S_{i,j} \leftarrow 0$ for $(i,j) \in [r] \times [b]$
for each update $u_i \in [n]$, $i \in [m]$ do
    for each $j \in [r]$ do
        $b_{i,j} \leftarrow h^{(j)}(u_i)$ and $s_{i,j} \leftarrow s^{(j)}(u_i)$
        $S_{j,b_{i,j}} \leftarrow S_{j,b_{i,j}} + s_{i,j}$
for each $i \in [n]$ do
    $b_{i,j} \leftarrow h^{(j)}(u_i)$ for each $j \in [r]$
    return $\mathrm{median}_{j\in[r]} |S_{j,b_{i,j}}|$ as the estimated frequency for $x_i$
```

We recall the following sensitivity analysis of CountSketch.

▶ **Lemma 14** (Sensitivity of CountSketch). *Let $x, x' \in \mathbb{R}^n$ with* $\max(\|x-x'\|_0, \|x-x'\|_1) \le 2$.

There exists a private variant PrivCountSketch of CountSketch that adds noise to each coordinate and then uses a standard private threshold routine to ensure differential privacy, giving the following guarantees:

▶ **Lemma 15.** *There exists a one-pass streaming algorithm* PrivCountSketch *that takes an accuracy parameter $\nu \in (0,1)$ and a threshold parameter η^2 and outputs a list H that contains all indices $k \in [n]$ of an underlying frequency vector x with $x_k \ge \eta\, L_2(x)$ and no index $k \in [n]$ with $x_k \le \eta(1-\nu)\, L_2(x)$. For each $k \in H$,* PrivCountSketch *also reports a estimated frequency $\widehat{x_k}$ such that $(1-\nu)x_k - \mathcal{O}\left(\frac{\log m}{\eta\nu}\right) \le \widehat{x_k} \le (1+\nu)x_k + \mathcal{O}\left(\frac{\log m}{\eta\nu}\right)$. The algorithm uses $\mathcal{O}\left(\frac{1}{\eta^2\nu^2}\log^2 n\right)$ bits of space and succeeds with probability $1-\frac{1}{\mathrm{poly}(m)}$.*

2.2 Symmetric Norms

In this section, we provide necessary preliminaries for symmetric norm estimation.

▶ **Definition 16** (Symmetric norm). *A function $L : \mathbb{R}^n \to \mathbb{R}$ is a* symmetric norm *if L is a norm and for all $x \in \mathbb{R}^n$ and any vector $y \in \mathbb{R}^n$ that is a permutation of the coordinates of x, we have $L(x) = L(y)$. Moreover, we have $L(x) = L(|x|)$, where $|x|$ is the coordinate-wise absolute value of x.*

▶ **Definition 17** (Modulus of concentration). *Let $x \in \mathbb{R}^n$ be a random variable drawn from the uniform distribution on the L_2-unit sphere S^{n-1} and let b_L denote the maximum value of $L(x)$ over S^{n-1}. The median of a symmetric norm L is the unique value M_L such that $\mathbf{Pr}\left[L(x) \geq M_L\right] \geq \frac{1}{2}$ and $\mathbf{Pr}\left[L(x) \leq M_L\right] \geq \frac{1}{2}$. Then the ratio $\mathrm{mc}(L) := \frac{b_L}{M_L}$ is the* modulus of concentration *of the norm L.*

Although the modulus of concentration quantifies the "average" behavior of the norm L on $\mathbb{R}^n$, norms with challenging behavior can still be embedded in lower-dimensional subspaces. For instance, the L_1 norm satisfies $\mathrm{mc}(L) = \mathcal{O}(1)$, but when $x \in \mathbb{R}^n$ has fewer than $\sqrt{n}$ nonzero coordinates, the norm $\max(L_\infty(x), L_1(x)/\sqrt{n})$ on the unit ball becomes identically $L_\infty(x)$ [11], which requires $\Omega(\sqrt{n})$ space [4] to estimate. Hence, we further quantify the behavior of a norm L by examining its behavior on all lower dimensions.

▶ **Definition 18** (Maximum modulus of concentration). *For a norm $L : \mathbb{R}^n \to \mathbb{R}$ and every $k \leq n$, define the norm $L^{(k)} : \mathbb{R}^k \to \mathbb{R}$ by $L^{(k)}((x_1, \ldots, x_k)) := L((x_1, \ldots, x_k, 0, \ldots, 0))$. Then the* maximum modulus of concentration *of the norm L is $\mathrm{mmc}(L) := \max_{k \leq n} \mathrm{mc}(L^{(k)}) = \max_{k \leq n} \frac{b_{L^{(k)}}}{M_{L^{(k)}}}$.*

▶ **Definition 19** (Important Levels). *For $x \in \mathbb{R}^n$ and $\xi > 1$, we define the level i as the set $B_i = \{k \in [n] \,:\, \xi^{i-1} \leq |x_k| \leq \xi^i\}$. We define $b_i := |B_i|$ as the size of level i. For $\beta \in (0, 1]$, we say level i is β-*important *if*

$$b_i > \beta \sum_{j > i} b_j, \qquad b_i \xi^{2i} \geq \beta \sum_{j \leq i} b_j \xi^{2j}.$$

Informally, level i is β-important if (1) its size is at least a β-fraction of the total sizes of the higher levels and (2) its contribution is roughly a β-fraction of the total contribution of all the lower levels. We would like to show that to approximate a symmetric norm $L(x)$, it suffices to identify the β-important levels and their sizes for a fixed base $\xi > 1$.

▶ **Definition 20** (Level Vectors and Buckets). *For $x \in \mathbb{R}^n$ and $\xi > 1$, the* level vector *for x is*

$$V(x) := (\underbrace{\xi^1, \ldots, \xi^1}_{b_1 \text{ times}}, \underbrace{\xi^2, \ldots, \xi^2}_{b_2 \text{ times}}, \ldots, \underbrace{\xi^k, \ldots, \xi^k}_{b_k \text{ times}}, 0, \ldots, 0) \in \mathbb{R}^n,$$

where each b_i is the size of level i. The i-th bucket of $V(x)$ is

$$V_i(x) := (\underbrace{0, \ldots, 0,}_{b_1 + \ldots + b_{i-1} \text{ times}} \underbrace{\xi^i, \ldots, \xi^i}_{b_i \text{ times}}, \ldots, \underbrace{0, \ldots, 0}_{b_{i+1} + \ldots + b_k \text{ times}}, 0, \ldots, 0) \in \mathbb{R}^n.$$

We similarly define the approximate level vectors $\widehat{V(x)}$ and $\widehat{V_i(x)}$ using approximations $\widehat{b_1}, \ldots, \widehat{b_k}$ for $b_1, \ldots, b_k$. We write $V(x) \setminus V_i(x)$ to denote the vector that replaces the i-th bucket in $V(x)$ with all zeros and we write $V(x) \setminus V_i(x) \cup \widehat{V_i(x)}$ to denote the vector that replaces the i-th bucket in $V(x)$ with $\widehat{b_i}$ instances of ξ^i.

Rather than directly handle the important levels, we define the β-contributing levels and instead work toward estimating the contribution of the β-contributing levels.

▶ **Definition 21** (Contributing Levels). *Given $x \in \mathbb{R}^n$, a level i defined by base $\xi > 1$ is β-*contributing *if $L(V_i(x)) \geq \beta L(V(x))$.*

[11] showed that even if all levels that are not β-contributing are removed, the contribution of the remaining levels forms a good approximation to $L(x)$.

▶ **Lemma 22** ([11]). *Given $x \in \mathbb{R}^n$ and levels defined by a base $\xi > 1$, let $V'(x)$ be the vector obtained by removing all levels that are not β-contributing from $V(x)$. Then $(1 - \mathcal{O}\left(\log_\xi n\right) \cdot \beta) L(V(x)) \le L(V'(x)) \le L(V(x))$.*

Hence for appropriate $\xi > 1$ and $\beta \in (0, 1]$, it suffices to identify the β-contributing levels, zero out the remaining levels, and determine the contribution of the resulting vector to approximate the symmetric norm $L(x)$.

▶ **Lemma 23** ([11]). *Given an accuracy parameter $\alpha \in (0, 1]$, let base $\xi = (1 + \mathcal{O}(\alpha))$, importance parameter $\beta = \mathcal{O}\left(\frac{\alpha^5}{\mathrm{mmc}(\ell)^2 \cdot \log^5 m}\right)$, and $\alpha' = \mathcal{O}\left(\frac{\alpha^2}{\log n}\right)$. Let $\widehat{b_i} \le b_i$ for all i and $\widehat{b_i} \ge (1 - \alpha') b_i$ for all β-important levels. Let $\widehat{V}$ be the level vector constructed using the estimates $\widehat{b_1}, \widehat{b_2}, \ldots$ and let V' be the level vector constructed by removing all the buckets that are not β-contributing in $\widehat{V}$. Then $(1 - \alpha) L(V(x)) \le L(V'(x)) \le L(V(x))$.*

To identify the β-contributing levels, [11] first notes that the size of the level must be at least a significant fraction of the total size of the higher levels.

▶ **Lemma 24** ([11]). *Given $x \in \mathbb{R}^n$, let the level sets be defined by a base $\xi > 1$. If level i is β-contributing, then there exists some fixed constant $\lambda > 0$ such that $b_i \ge \frac{\lambda \beta^2}{\mathrm{mmc}(\ell)^2 \log^2 n} \cdot \sum_{j > i} b_j$.*

Moreover, [11] observes that the squared mass of a β-contributing level must be at least a significant fraction of the total squared mass of the lower levels.

▶ **Lemma 25** ([11]). *Given $x \in \mathbb{R}^n$, let the level sets be defined by a base $\xi > 1$. If level i is β-contributing, then there exists some fixed constant $\lambda > 0$ such that $b_i \xi^{2i} \ge \frac{\lambda \beta^2}{\mathrm{mmc}(\ell)^2 (\log_\xi n) \log^2 n} \cdot \sum_{j \le i} b_j \xi^{2j}$.*

Observe that together, Lemma 24 and Lemma 25 imply that a β-contributing level i must also be an important level as defined in Definition 19. Crucially, since Lemma 25 states that the squared mass (or the F_2 frequency moment) of the β-contributing levels must be a significant fraction of the total squared mass of the lower levels, then it suggests we might be able to identify the β-contributing levels through an L_2-heavy hitters algorithm after removing the higher levels. Indeed, [11] show that the problem of identifying the size (and thus the contribution) of the β-contributing levels can be reduced to the task of finding ν-approximate η-heavy hitters for specific parameters of ν and η.

▶ **Lemma 26** ([11]). *Let $s = \mathcal{O}(\log n)$. If a level i is β-important, then either $\xi^{2i} \ge \frac{\alpha^2 \beta \varepsilon^2}{\log^2 m} F_2(x)$ or there exists $j \in [s]$ such that $b_i \ge \frac{2^j \log^2 m}{\alpha^2 \varepsilon^2}$ and $\xi^{2i} \in \left[\frac{\alpha^2 \beta \varepsilon^2}{\log^2 m} \cdot \frac{F_2(x)}{2^j}, \frac{\alpha^2 \beta \varepsilon^2}{\log^2 m} \cdot \frac{F_2(x)}{2^{j-1}}\right]$.*

Lemma 26 implies that if level i is β-important, then either (1) it will be identified by using PrivCountSketch, i.e., Lemma 15, with threshold $\frac{\alpha^2 \beta}{\log^2 m}$ on the stream or (2) its contribution can be well-approximated by using PrivCountSketch with threshold $\frac{\alpha^2 \beta \varepsilon^2}{\log^2 m}$ on a substream formed by sampling coordinates of the universe with probability $\frac{1}{2^j}$. We thus split our algorithm and analysis to handle these cases. In particular, we call a frequency level i "high" if $\xi^{2i} \ge \frac{\alpha^2 \beta \varepsilon^2}{\log^2 m} F_2(x)$. We call a frequency level i "medium" if $\xi^{2i} \ge \frac{\alpha^2 \beta' \varepsilon^2}{2^j} F_2(x) > T$ and $b_i \ge \mathcal{O}\left(\frac{2^j \log^2 m}{\alpha^2 \varepsilon^2}\right)$ for a certain $\beta' > 0$ and a threshold T. We call a frequency level i "low" if $\xi^{2i} \ge \frac{\alpha^2 \beta' \varepsilon^2}{2^j} F_2(x)$ and $b_i \ge \mathcal{O}\left(\frac{2^j \log^2 m}{\alpha^2 \varepsilon^2}\right)$, but $T \ge \frac{\alpha^2 \beta' \varepsilon^2}{2^j} F_2(x)$.

3 Private Symmetric Norm Estimation Algorithm

In this section, we give our algorithm that releases a set of private statistics from which an arbitrary number of symmetric norms can be well-approximated. In particular, recall that Lemma 23 suggests that it suffices to approximate the sizes of the important levels and identity the non-important levels, so that the contributions of the non-important levels can be set to zero. We partition the levels into three groups after defining explicit thresholds T_1 and T_2, with $T_1 > T_2$. Recall that we define the "high frequency levels" as the levels whose coordinates exceed T_1 in frequency, the "medium frequency levels" as the levels whose coordinates are between T_1 and T_2 in frequency, and the "low frequency levels" as the levels whose coordinates are less than T_2 in frequency.

The intuition is that because the high frequency levels have such large magnitude, their frequencies can be well-approximated by running an L_2-heavy hitters algorithm on the stream S. On the other hand, the medium frequency level coordinates are not large enough to be detected by running an L_2-heavy hitters algorithm on the stream S, but the sizes of these level sets must be large if the level set is important and therefore, there exists a substream S_j for which a large number of these coordinates are subsampled and their frequencies can be well-approximated by running an L_2-heavy hitters algorithm on the substream S_j. Here we form substreams $S_0, S_1, \ldots$ so that S_j first samples elements of the universe $[n]$ at a rate $\frac{1}{2^j}$ and then only contains the stream updates that are relevant to the sampled elements. Finally, the low frequency level coordinates are small enough that we cannot add Laplacian noise to their frequencies without affecting the level sets they are mapped to. We instead show that L_1 sensitivity for the level set estimations is particularly small for the low frequency levels and thus, we report the size of the level sets of the low frequency levels rather than the approximate frequencies of the heavy-hitters.

We emphasize that we only use the thresholds T_1 and T_2 for the purposes of describing our algorithm – in the actual implementation of the algorithm, the thresholds T_1 and T_2 will be implicitly defined by each of the substreams. For example, the items with threshold larger than T_1 will automatically be revealed through the stream S, while the items with thresholds between T_1 and T_2 will be revealed through the substreams S_j with $2^j > \frac{\log n}{\beta' \alpha \varepsilon}$ for explicit parameters α, β', and ε. More specifically, note that Algorithm 2 sets $\beta' = \mathcal{O}\left(\frac{\alpha^2 \beta \varepsilon^2}{\log^2 m}\right)$ or more specifically $\beta' = \frac{\alpha^2 \beta \varepsilon^2}{2 \log^2 m}$. Then $\beta' \cdot F_2(x)$ corresponds to the threshold T_1, which is utilized in the proofs of Section 3.1. Similarly, Algorithm 3 leverages the quantity $\frac{\log n}{\beta' \alpha \varepsilon}$ to define the threshold T_2, which is then utilized in the proofs of Section 3.2.

3.1 Recovery of High Frequency Levels

In this section, we describe our algorithm for recovering the high frequency levels, whose coordinates have sufficiently large magnitude and thus their frequencies can be well-approximated by running an L_2-heavy hitters algorithm on the stream S. Moreover, with high probability, adding Laplacian noise will not affect the level sets because the frequencies are so large. Thus it simply suffices to return the noisy estimated frequencies of each of the elements in the high frequency levels. This algorithm is the simplest of our cases and we give the algorithm in full in Algorithm 2.

We first show that coordinates in high frequency levels are identified and their frequencies are accurately estimated. Similarly, we show that if a coordinate does not have high frequency, it will not be output by Algorithm 2.

Algorithm 2 Algorithm to privately estimate the high levels.

```
Input: Privacy parameter $\varepsilon > 0$, accuracy parameter $\alpha \in (0,1)$
Output: Private estimation of the frequencies of the coordinates of the high frequency levels
$\beta \leftarrow \mathcal{O}\left(\frac{\alpha^5}{\mathrm{mmc}(L)^2 \log^5 m}\right)$, $\beta' \leftarrow \mathcal{O}\left(\frac{\alpha^2\beta\varepsilon^2}{\log^2 m}\right)$
Run PrivCountSketch on the stream $S$ with threshold $\alpha^2\beta'$ and failure probability $\frac{1}{\mathrm{poly}(m)}$
for each heavy-hitter $k \in [n]$ reported by PrivCountSketch do
    Let $\widetilde{x_k}$ be the frequency estimated by PrivCountSketch
    $\widehat{x_k} \leftarrow \widetilde{x_k} + \mathsf{Lap}\left(\frac{8}{\beta'\varepsilon}\right)$
    return $\widehat{x_k}$
```

▶ **Lemma 27.** *Suppose $m = \frac{\Omega(\log^5 m)}{\alpha^5\beta^2\varepsilon^5}$. Then with high probability Algorithm 2 outputs $\widehat{x_k}$ such that if $x_k^2 \geq \frac{\alpha^2\beta\varepsilon^2}{\log^2 m} F_2(x)$, then $(1-\alpha^2)x_k \leq \widehat{x_k} \leq x_k$ and if $x_k^2 < \frac{\alpha^2\beta\varepsilon^2}{2\log^2 m} F_2(x)$, then $\widehat{x_k} < \frac{3\alpha^2\beta\varepsilon^2}{4\log^2 m} F_2(x)$.*

We then show that Algorithm 2 preserves differential privacy and analyze its space complexity.

▶ **Lemma 28.** *Algorithm 2 is $\left(\frac{\varepsilon}{4}, \frac{\delta}{4}\right)$-differentially private for $\delta = \frac{1}{\mathrm{poly}(m)}$ and uses space* $\mathrm{mmc}(L)^2 \cdot \mathrm{poly}\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log m\right)$.

3.2 Recovery of Medium Frequency Levels

In this section, we describe our algorithm for recovering the medium frequency levels, whose coordinates do not have sufficiently large magnitude to be detected by running an L_2-heavy hitters algorithm on the stream S, but have sufficiently large size, so that there exists some $j \in [s]$ across the s subsampling levels such that the coordinates can be detected by running an L_2-heavy hitters algorithm on the stream S_j. On the other hand, their magnitudes are sufficiently large so that with high probability, adding Laplacian noise will not affect the level sets. We give the algorithm in full in Algorithm 3.

We first upper bound the second frequency moment (and hence the L_2 norm) of each substream. This is necessary because we want to detect the coordinates of the medium frequency levels as L_2-heavy hitters for each substream, but if the substream has overwhelmingly large L_2 norm, then we will not be able to find coordinates of the medium frequency levels. However, it may not be true that $F_2(S_j)$ is significantly smaller than $F_2(S)$ with high probability. For example, if there were a single large element, then the probability it is sampled at level s is $\frac{1}{2^s}$, which is roughly $\frac{1}{n} > \frac{1}{\mathrm{poly}(m)}$. Instead, we note that PrivCountSketch benefits from the stronger *tail guarantee*, which states that not only does PrivCountSketch with threshold $\eta < 1$ detect the elements k such that $(x_k)^2 \geq \eta F_2(S)$, but it also detects the elements k such that $(x_k)^2 \geq \eta F_2(S_{\mathrm{tail}(1/\eta)})$, where $S_{\mathrm{tail}(1/\eta)}$ is the frequency vector x induced by S, with the largest $\frac{1}{\eta}$ entries instead set to zero [15, 17].

▶ **Lemma 29.** *Consider a β-important level i with $\xi^{2i} \in \left[\frac{\beta\alpha^2\varepsilon^2}{\log^2 m} \cdot \frac{F_2(x)}{2^j}, \frac{\beta\alpha^2\varepsilon^2}{\log^2 m} \cdot \frac{F_2(x)}{2^{j-1}}\right]$ for some integer $j > 0$ and $\xi^i > \frac{\log n}{\beta'\alpha\varepsilon}$. If $F_2((S_j)_{1/(\alpha^2\beta'\varepsilon^2)}) \leq \frac{200\log m}{2^j} F_2(x)$ for all $j \in [s]$, then with high probability, Algorithm 3 outputs $\widehat{b_i}$ such that $(1-\mathcal{O}(\alpha))b_i \leq \widehat{b_i} \leq b_i$, where b_i is the size of level i.*

Algorithm 3 Algorithm to privately estimate the medium levels.

```
Input: Privacy parameter $\varepsilon > 0$, accuracy parameter $\alpha \in (0,1)$
Output: Private estimations of the sizes of the medium frequency levels
$\beta \leftarrow \mathcal{O}\left(\frac{\alpha^5}{\mathrm{mmc}(L)^2 \log^5 m}\right)$, $\beta' \leftarrow \mathcal{O}\left(\frac{\alpha^3 \beta \varepsilon^2}{\log^2 m}\right)$, $\xi \leftarrow (1 + \mathcal{O}(\varepsilon))$
$\gamma \leftarrow (1/2, 1)$ uniformly at random, $\ell \leftarrow \lceil \log_{\xi}(2m) \rceil$, $s \leftarrow \mathcal{O}(\log n)$
for $j \in [s]$ with $2^j > \frac{\log n}{\beta' \alpha \varepsilon}$ do
    Form stream $S_j$ by sampling elements of $[n]$ with probability $\frac{1}{2^j}$
    Run PrivCountSketch$_j$ on stream $S_j$ with threshold $\alpha^2 \beta' \varepsilon^2$ and failure probability $\frac{1}{\mathrm{poly}(m)}$
    for each heavy-hitter $k \in [n]$ reported by PrivCountSketch$_j$ do
        Let $\widehat{x_k}$ be the frequency estimated by PrivCountSketch$_j$
        if $\widehat{x_k} > \frac{\log n}{\beta' \alpha \varepsilon}$ then
            $\widetilde{x_k} \leftarrow \widehat{x_k} + \mathsf{Lap}\left(\frac{8}{\beta' \varepsilon}\right)$
    for $i \in [\ell]$ with $\frac{m^2}{2^{j+1}} > \gamma \xi^{2i} \geq 2^j > \mathcal{O}\left(\frac{\log n}{\beta' \alpha^2 \varepsilon}\right)$ do
        Let $\widetilde{b_i}$ be the number of indices $k \in [n]$ such that $\gamma \xi^{2i} \leq \widetilde{x_k} < \gamma \xi^{2i+2}$
        $\widehat{b_i} \leftarrow \frac{2^j}{(1+\mathcal{O}(\alpha))} \widetilde{b_i}$
        return $\widehat{b_i}$
```

We now show that Algorithm 3 preserves differential privacy and analyze its space complexity.

▶ **Lemma 30.** *Algorithm 3 is $\left(\frac{\varepsilon}{4}, \frac{\delta}{4}\right)$-differentially private for $\delta = \frac{1}{\mathrm{poly}(m)}$ and uses space* $\mathrm{mmc}(L)^2 \cdot \mathrm{poly}\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log m\right)$.

3.3 Recovery of Low Frequency Levels

In this section, we describe our algorithm for recovering the low frequency levels, whose coordinates have magnitude small enough that we cannot add Laplacian noise to their frequencies without affecting the corresponding level set sizes. We instead report the sizes of the level sets for the low frequency levels rather than the approximate frequencies of the heavy-hitters. Thus we must add Laplacian noise to the sizes of the level sets; we show that the L_1 sensitivity for the level set estimations is particularly small for the low frequency levels and thus the Laplacian noise does not greatly affect the estimates of the level set sizes. We note that this approach does not work for the high frequency levels because the high frequency levels may have small level set sizes, so that adding Laplacian noise to the sizes can significantly affect the resulting estimates of the level set sizes. Similarly, it is more challenging to argue the low L_1 sensitivity for the level set estimations for the medium frequency levels. Hence, both the algorithm and analysis are especially well-catered to the low frequency levels. We give the algorithm in full in Algorithm 4.

We first show that the estimates of the level set sizes for the low frequency levels are accurate.

▶ **Lemma 31.** *Consider a β-important level i with $\xi^{2i} \in \left[\frac{\beta\alpha^2\varepsilon^2}{\log^2 m} \cdot \frac{F_2(x)}{2^j}, \frac{\beta\alpha^2\varepsilon^2}{\log^2 m} \cdot \frac{F_2(x)}{2^{j-1}}\right]$ for some integer $j > 0$ and $\xi^i \leq \frac{\log n}{\beta' \alpha \varepsilon}$. If $F_2((S_j)_{1/(\alpha^2\beta'\varepsilon^2)}) \leq \frac{200 \log m}{2^j} F_2(x)$ for all $j \in [s]$, then with high probability, Algorithm 4 outputs $\widehat{b_i}$ such that*

$$(1 - \mathcal{O}(\alpha)) b_i \leq \widehat{b_i} \leq b_i,$$

where b_i is the size of level set i.

Algorithm 4 Algorithm to privately estimate the low levels.

```
Input: Privacy parameter $\varepsilon > 0$, accuracy parameter $\alpha \in (0,1)$
Output: Private estimations of the sizes of the low frequency levels
$\beta \leftarrow \mathcal{O}\left(\frac{\alpha^5}{\mathrm{mmc}(L)^2 \log^5 m}\right)$, $\beta' \leftarrow \mathcal{O}\left(\frac{\alpha^2\beta\varepsilon}{\log n}\right)$, $\xi \leftarrow (1+\mathcal{O}(\varepsilon))$
$\gamma \leftarrow (1/2,1)$ uniformly at random, $\ell \leftarrow \lceil \log_\xi(2m) \rceil$, $s \leftarrow \mathcal{O}(\log n)$
for $j \in [s]$ with $2^j \le \frac{\log n}{\beta'\alpha\varepsilon}$ do
    Form stream $S_j$ by sampling elements of $[n]$ with probability $\frac{1}{2^j}$
    Run PrivCountSketch$_j$ on stream $S_j$ with threshold $\beta'' := \mathcal{O}\left(\frac{\beta'\alpha^2\varepsilon^3}{\log^2 n}\right)$
    for each heavy-hitter $k \in [n]$ reported by PrivCountSketch$_j$ do
        Let $\widehat{x_k}$ be the frequency estimated by PrivCountSketch$_j$
    for $i \in [\ell]$ with $\mathcal{O}\left(\frac{\log n}{\beta'\alpha^2\varepsilon}\right) \ge 2^{j+1} > \gamma\xi^{2i} \ge 2^j$ do
        Let $\widetilde{b_i}$ be the number of indices $k \in [n]$ such that $\gamma\xi^{2i} \le \widehat{x_k} < \gamma\xi^{2i+2}$
        $\widehat{b_i} \leftarrow \frac{2^j}{(1+\mathcal{O}(\alpha))}\left(\widetilde{b_i} + \mathsf{Lap}\left(\frac{8}{\varepsilon}\right)\right)$
        return $\widehat{b_i}$
```

We then show that Algorithm 4 is differentially private and analyze its space complexity.

▶ **Lemma 32.** *Algorithm 4 is $\left(\frac{\varepsilon}{4}, \frac{\delta}{4}\right)$-differentially private for $\delta = \frac{1}{\mathrm{poly}(m)}$ and uses space* $\mathrm{mmc}(L)^2 \cdot \mathrm{poly}\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log m\right)$.

3.4 Putting Things Together

We would like to combine the subroutines from the previous sections to output a private dataset for symmetric norm estimation. Thus it remains to describe how to privately partition the coordinates into the high, medium, and low frequency levels. To that end, we remark that by Lemma 14, the sensitivity of PrivCountSketch in Algorithm 1 is at most 2. Moreover, although PrivCountSketch actually provides an estimated frequency for each coordinate, for our purposes, we only need estimated frequencies for the L_2-heavy hitters and there are at most $K := \mathcal{O}\left(\frac{1}{\eta^2}\right)$ possible L_2-heavy hitters with whichever threshold η that we choose, e.g., $\eta = \alpha^2\beta'$ in Algorithm 2. Thus it suffices to observe that we can privately partition the coordinates into the high, medium, and low frequency levels by first privately outputting the top K estimated frequencies and then partitioning the coordinates according to their noisy estimated frequencies, which can be viewed as post-processing. In particular, [56] observes that it suffices to add Laplacian noise with scale $\frac{8}{\eta\varepsilon}$ to each of the frequencies and then outputting the top K noisy estimated frequencies to achieve $\frac{\varepsilon}{4}$-differential privacy.

We now finally put together the results from the previous sections to show the following result. We remark that we set $\varepsilon, \alpha = \tilde{\Omega}\left(\left(\frac{M^2}{m}\right)^{\frac{1}{30}}\right)$ so that along with the assumption that $m \ge n$, the conditions of the previous statements are satisfied, e.g., Lemma 34, we obtain the following formalization of Theorem 2.

▶ **Theorem 33.** *Given a parameter $M > 1$, let $\varepsilon, \alpha = \tilde{\Omega}\left(\left(\frac{M^2}{m}\right)^{\frac{1}{30}}\right)$. There exists a (ε, δ)-differentially private algorithm that outputs a set C, from which the $(1+\alpha)$-approximation to any norm , with* maximum modulus of concentration *at most M of a vector $x \in \mathbb{R}^n$ induced by a stream of length* $\mathrm{poly}(n)$ *can be computed, with probability at least $1-\delta$. The algorithm uses* $M^2 \cdot \mathrm{poly}\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log n, \log \frac{1}{\delta}\right)$ *bits of space.*

A Missing Proofs

We first show that coordinates in high frequency levels are identified and their frequencies are accurately estimated.

▶ **Lemma 34.** *Suppose* $x_k^2 \geq \frac{\alpha^2\beta\varepsilon^2}{\log^2 m} F_2(x)$ *and* $m = \frac{\Omega\left(\log^5 m\right)}{\alpha^5\beta^2\varepsilon^5}$. *Then with high probability, Algorithm 2 outputs* $\widehat{x_k}$ *such that*

$$(1-\alpha^2)x_k \leq \widehat{x_k} \leq x_k.$$

Proof. Consider Algorithm 2. Since $x_k^2 \geq \frac{\alpha^2\beta\varepsilon^2}{2\log^2 m} F_2(x)$ and we call PrivCountSketch with threshold $\alpha^2\beta'$ with $\beta' := \mathcal{O}\left(\frac{\alpha^2\beta\varepsilon^2}{\log^2 m}\right)$, then with high probability, the output $\widetilde{x_k}$ satisfies

$$(1-\mathcal{O}\left(\alpha^2\right))x_k \leq \widetilde{x_k} \leq x_k.$$

We then add Laplacian noise $\mathsf{Lap}\left(\frac{8}{\beta'\varepsilon}\right)$ to $\widetilde{x_k}$ to form $\widehat{x_k}$. Since $x_k^2 \geq \frac{\alpha^2\beta\varepsilon^2}{2\log^2 m}\, F_2(x) = \beta'\, F_2(x)$ and $F_2(x) \geq m$, then with high probability, the Laplacian noise is at most an α^2 fraction of $\widehat{x_k}$ for $\frac{\mathcal{O}(\log m)}{\beta'\varepsilon} \leq \alpha^2 m$ or equivalently, $m \geq \frac{\Omega(\log m)}{\alpha(\beta')^2\varepsilon} \geq \frac{\Omega\left(\log^5 m\right)}{\alpha^5\beta^2\varepsilon^5}$. Hence with high probability,

$$(1-\alpha^2)x_k \leq \widehat{x_k} \leq x_k. \qquad ◀$$

Similarly, we show that if a coordinate does not have high frequency, it will not be output by Algorithm 2.

► **Lemma 35.** *Suppose $x_k^2 < \frac{\alpha^2\beta\varepsilon^2}{2\log^2 m}\, F_2(x)$ and $m = \frac{\Omega\left(\log^5 m\right)}{\alpha^5\beta^2\varepsilon^5}$. Then with high probability, Algorithm 2 outputs $\widehat{x_k}$ such that*

$$\widehat{x_k} < \frac{3\alpha^2\beta\varepsilon^2}{4\log^2 m}\, F_2(x).$$

Proof. Since $x_k^2 < \frac{\alpha^2\beta\varepsilon^2}{2\log^2 m}\, F_2(x)$ and we call PrivCountSketch with threshold $\alpha^2\beta'$ with $\beta' := \mathcal{O}\left(\frac{\alpha^2\beta\varepsilon^2}{\log^2 m}\right)$, then the output $\widetilde{x_k}$ satisfies

$$|(\widetilde{x_k})^2 - (x_k)^2| \leq 2\alpha^2\beta'\, F_2(x).$$

We then add Laplacian noise $\mathsf{Lap}\left(\frac{8}{\beta'\varepsilon}\right)$ to $\widetilde{x_k}$ to form $\widehat{x_k}$. Since $F_2(x) \geq m$, then with high probability, the Laplacian noise is at most an $\alpha^2\beta'$ fraction of $F_2(x)$ for $\frac{\mathcal{O}(\log m)}{\beta'\varepsilon} \leq \alpha^2 m$ or equivalently, $m \geq \frac{\Omega(\log m)}{\alpha(\beta')^2\varepsilon} \geq \frac{\Omega\left(\log^5 m\right)}{\alpha^5\beta^2\varepsilon^5}$. Hence with high probability,

$$|(\widetilde{x_k})^2 - (x_k)^2| \leq \frac{\alpha^2\beta\varepsilon^2}{4\log^2 m}\, F_2(x).$$

Since $x_k^2 < \frac{\alpha^2\beta\varepsilon^2}{2\log^2 m}\, F_2(x)$, then it follows that

$$\widehat{x_k} < \frac{3\alpha^2\beta\varepsilon^2}{4\log^2 m}\, F_2(x). \qquad ◀$$

We now show that Algorithm 2 preserves differential privacy.

► **Lemma 36.** *Algorithm 2 is $\left(\frac{\varepsilon}{4}, \frac{\delta}{4}\right)$-differentially private for $\delta = \frac{1}{\mathrm{poly}(m)}$. Algorithm 2 uses space $\mathrm{mmc}(L)^2 \cdot \mathrm{poly}\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log m\right)$.*

Proof. By Lemma 14, the sensitivity of PrivCountSketch is at most 2 and the failure probability is $\frac{1}{\mathrm{poly}(m)}$. Thus by adding Laplacian noise $\mathsf{Lap}\left(\frac{8}{\beta'\varepsilon}\right)$ to $\widetilde{x_k}$, each estimated frequency is $\left(\frac{\beta'\varepsilon}{4}, \frac{\delta}{4\beta}\right)$-differentially private for $\delta = \frac{1}{\mathrm{poly}(m)}$. Since PrivCountSketch with threshold β' can release at most $\frac{1}{\beta}$ estimated frequencies and post-processing does not cause loss in privacy, then by Theorem 11, Algorithm 2 is $\left(\frac{\varepsilon}{4}, \frac{\delta}{4}\right)$. ◀

Finally, we analyze the space complexity of Algorithm 2.

► **Lemma 37.** *Algorithm 2 uses space $\mathrm{mmc}(L)^2 \cdot \mathrm{poly}\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log m\right)$.*

Proof. The space complexity follows from running a single instance of PrivCountSketch with threshold $\alpha^2\beta'$ and failure probability $\frac{1}{\mathrm{poly}(m)}$, where $\beta' = \mathcal{O}\left(\frac{\alpha^2\beta\varepsilon^2}{\log^2 m}\right)$ and $\beta = \mathcal{O}\left(\frac{\alpha^5}{\mathrm{mmc}(L)^2\log^5 m}\right)$. ◀

▶ **Lemma 38.** *With high probability, we have that* $F_2((S_j)_{1/(\alpha^2\beta'\varepsilon^2)}) \le \frac{200\log m}{2^j}\,F_2(x)$ *for all* $j \in [s]$.

Proof. For each $j \in [s]$, we have that $\mathbb{E}\left[F_2(S_j)\right] = \frac{F_2(x)}{2^j}$. By Chernoff bounds with $\mathcal{O}\left(\log n\right)$-wise limited independence, we have that

$$\mathbf{Pr}\left[F_2((S_j)_{1/(\alpha^2\beta'\varepsilon^2)}) > \frac{200\log m}{2^j}\,F_2(x)\right] \le \frac{1}{\mathrm{poly}(m)}.$$

Since $s \le 2\log m$, then by a union bound over all $j \in [s]$, we have that $F_2(S_j) \le (200\log m)F_2(x)$ for all $j \in [s]$. ◀

We now show that conditioned on the event that the L_2 norm of the subsampled streams are not too large, then we can well-approximate the frequency of any coordinate of the medium frequency levels, provided that they are sampled in the substream.

▶ **Lemma 39.** *Suppose* i *is a* β*-important level and* $k \in [n]$ *is in level* i*, so that* $x_k \in [\xi^i, \xi^{i+1})$. *If* $F_2((S_j)_{1/(\alpha^2\beta'\varepsilon^2)}) \le \frac{200\log m}{2^j}\,F_2(x)$ *for all* $j \in [s]$ *and* k *is sampled in stream* S_j *with* $2^j > \frac{\log n}{\beta'\alpha\varepsilon}$*, then with high probability, Algorithm 3 outputs* $\widehat{x_k}$ *such that*

$$(1-\alpha^2)x_k \le \widehat{x_k} \le x_k.$$

Proof. Consider Algorithm 3. By Lemma 26, $x_2^2 \in \left[\frac{\alpha^2\beta\varepsilon^2}{\log^2 m}\cdot\frac{F_2(x)}{2^j}, \frac{\alpha^2\beta\varepsilon^2}{\log^2 m}\cdot\frac{F_2(x)}{2^{j-1}}\right]$. Conditioned on the event that $F_2((S_j)_{1/(\alpha^2\beta'\varepsilon^2)}) \le \frac{200\log m}{2^j}\,F_2(x)$ for all $j \in [s]$, then $x_k^2 \ge \frac{\alpha^2\beta\varepsilon^2}{200\log m}\,F_2(S_j)$. We call PrivCountSketch with threshold $\alpha^2\beta'\varepsilon^2 = \mathcal{O}\left(\frac{\alpha^4\beta\varepsilon^3}{\log^2 m}\right)$. Thus with high probability, the output $\widetilde{x_k}$ satisfies

$$(1-\mathcal{O}\left(\alpha^2\right))x_k \le \widetilde{x_k} \le x_k.$$

We then add Laplacian noise $\mathsf{Lap}\left(\frac{8}{\beta'\varepsilon}\right)$ to $\widetilde{x_k}$ to form $\widehat{x_k}$. Since $x_k^2 \ge \mathcal{O}\left(\frac{\log n}{\beta'\alpha^2\varepsilon}\right)$, then with high probability, the Laplacian noise is at most an α^2 fraction of $\widehat{x_k}$. Hence with high probability,

$$(1-\alpha^2)x_k \le \widehat{x_k} \le x_k.$$ ◀

Unfortunately, Lemma 39 only provides guarantees for the coordinates of the medium frequency levels that are sampled. Thus, we still need to use Lemma 39 to show that a good estimator to the sizes of the medium frequency levels can be obtained from the estimates of the coordinates of the medium frequency levels that are sampled. In particular, we show that rescaling the empirical sizes of the medium frequency levels forms a good estimator to the actual sizes of the medium frequency levels.

Proof of Lemma 29. Suppose i is a β-important level. Then by Lemma 26 and a shifting of the index j, $b_i \ge \mathcal{O}\left(\frac{2^j\log^2 m}{\alpha^2\varepsilon^2}\right)$. Thus in S_j, the expected number of items E_j from level i is at least $\frac{\log^2 m}{\alpha^2\varepsilon^2}$ and the variance V_j is at most E_j. Hence by Chernoff bounds with $\mathcal{O}\left(\log n\right)$-wise limited independence, we have that the number of items N_j from level i satisfies

$$(1-\mathcal{O}\left(\alpha\right))b_i \le 2^j\cdot N_j \le (1+\mathcal{O}\left(\alpha\right))b_i,$$

with high probability. [11] show that due to the uniformly random chosen $\gamma \in (1/2, 1)$, we further have

$$(1-\mathcal{O}\left(\alpha\right))N_j \le (1+\mathcal{O}\left(\alpha\right))\widehat{b_i} \le (1+\mathcal{O}\left(\alpha\right))N_j,$$

with high probability. Since $s \le 2\log m$, then by a union bound over all $j \in [s]$, we have that with high probability, Algorithm 3 outputs $\widehat{b_i}$ such that

$$(1 - \mathcal{O}(\alpha))b_i \le \widehat{b_i} \le b_i. \qquad ◀$$

We now show that Algorithm 3 preserves differential privacy.

▶ **Lemma 40.** *Algorithm 3 is $\left(\frac{\varepsilon}{4}, \frac{\delta}{4}\right)$-differentially private for $\delta = \frac{1}{\text{poly}(m)}$.*

Proof. By Lemma 14, the sensitivity of PrivCountSketch is at most 2 and the failure probability is $\frac{1}{\text{poly}(m)}$. Thus by adding Laplacian noise $\mathsf{Lap}\left(\frac{8}{\beta'\varepsilon}\right)$ to $\widetilde{x_k}$, each estimated frequency is $\left(\frac{\beta'\varepsilon}{4}, \frac{\delta}{4\beta}\right)$-differentially private for $\delta = \frac{1}{\text{poly}(m)}$. Since PrivCountSketch with threshold β' can release at most $\frac{1}{\beta}$ estimated frequencies, then by Theorem 11, Algorithm 3 is $\left(\frac{\varepsilon}{4}, \frac{\delta}{4}\right)$. ◀

It remains to analyze the space complexity of Algorithm 3.

▶ **Lemma 41.** *Algorithm 3 uses space* $\text{mmc}(L)^2 \cdot \text{poly}\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log m\right)$.

Proof. The space complexity follows from running s instances of PrivCountSketch with threshold $\alpha^2\beta'$ and failure probability $\frac{1}{\text{poly}(m)}$, where $\beta' = \mathcal{O}\left(\frac{\alpha^2\beta\varepsilon^2}{\log^2 m}\right)$ and $\beta = \mathcal{O}\left(\frac{\alpha^5}{\text{mmc}(L)^2\log^5 m}\right)$. Since $s = \mathcal{O}(\log n)$ and we assume $n \le m$ so that $\mathcal{O}(\log n) = \mathcal{O}(\log m)$, then the space complexity follows. ◀

Proof of Lemma 31. Suppose i is a β-important level. Hence by a shifting of the index j in Lemma 26, we have that $b_i \ge \mathcal{O}\left(\frac{2^j\log^2 m}{\alpha^2\varepsilon^2}\right)$. Therefore, the expected number of items E_j from level i sampled in the substream S_j is at least $\frac{\log^2 m}{\alpha^2\varepsilon^2}$ and the variance V_j is at most E_j. Thus by Chernoff bounds with $\mathcal{O}(\log n)$-wise limited independence, the number of items N_j from level i satisfies

$$(1 - \mathcal{O}(\alpha))b_i \le 2^j \cdot N_j \le (1 + \mathcal{O}(\alpha))b_i,$$

with high probability. [11] show that due to the uniformly random chosen $\gamma \in (1/2, 1)$, we further have

$$(1 - \mathcal{O}(\alpha))N_j \le (1 + \mathcal{O}(\alpha))\widehat{b_i} \le (1 + \mathcal{O}(\alpha))N_j,$$

with high probability. Since $s \le 2\log m$ and $\mathsf{Lap}\left(\frac{8}{\varepsilon}\right)$ is at most an ε-fraction of $b_i \ge \mathcal{O}\left(\frac{2^j\log^2 m}{\alpha^2\varepsilon^2}\right)$ with high probability, then by a union bound over all $j \in [s]$, we have that with high probability, Algorithm 3 outputs $\widehat{b_i}$ such that

$$(1 - \mathcal{O}(\alpha))b_i \le \widehat{b_i} \le b_i. \qquad ◀$$

We then show that Algorithm 4 is differentially private.

▶ **Lemma 42.** *Algorithm 4 is $\left(\frac{\varepsilon}{4}, \frac{\delta}{4}\right)$-differentially private for $\delta = \frac{1}{\text{poly}(m)}$.*

Proof. Note that since each instance of PrivCountSketch$_j$ uses threshold $\beta'' := \mathcal{O}\left(\frac{\beta'\alpha^2\varepsilon^3}{\log^2 n}\right)$ on a stream S_j with $F_2(S_j) \le \frac{200\log m}{2^j}F_2(x)$, then for any $k \in [n]$ with $x_k \le \mathcal{O}\left(\frac{\log n}{\beta'\alpha^2\varepsilon}\right)$, we have that PrivCountSketch$_j$ outputs x_k exactly. Hence, at most two estimates of the sizes of the level sets $\widehat{b_i}$ can change, and then can change by at most one. Thus the sensitivity is at most 2, so it suffices to add Laplcian noise $\mathsf{Lap}\left(\frac{8}{\varepsilon}\right)$ to each estimate $\widehat{b_i}$ to obtain $\left(\frac{\varepsilon}{4}, \frac{\delta}{4}\right)$-differentially private for $\delta = \frac{1}{\text{poly}(m)}$. ◀

Finally, we argue the space complexity of Algorithm 4.

▶ **Lemma 43.** *Algorithm 4 uses space* $\mathrm{mmc}(L)^2 \cdot \mathrm{poly}\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log m\right)$.

Proof. Similar to Algorithm 3, the space complexity follows as a result of running s instances of PrivCountSketch with threshold $\alpha^2\beta'$ and failure probability $\frac{1}{\mathrm{poly}(m)}$, where $\beta' = \mathcal{O}\left(\frac{\alpha^2\beta\varepsilon^2}{\log^2 m}\right)$ and $\beta = \mathcal{O}\left(\frac{\alpha^5}{\mathrm{mmc}(L)^2 \log^5 m}\right)$. Since $s = \mathcal{O}(\log n)$ and we assume $n \le m$ so that $\mathcal{O}(\log n) = \mathcal{O}(\log m)$, then the space complexity follows. ◀

▶ **Theorem 44.** *Given a parameter* $M > 1$*, let* $\varepsilon, \alpha = \tilde{\Omega}\left(\left(\frac{M^2}{m}\right)^{\frac{1}{30}}\right)$. *There exists a* (ε, δ)*-differentially private algorithm that outputs a set* C*, for* $\delta = \frac{1}{\mathrm{poly}(m)}$. *From* C*, the* $(1+\alpha)$*-approximation to any norm with* maximum modulus of concentration *at most* M *can be computed, with probability at least* $1-\delta$. *The algorithm uses* $M^2 \cdot \mathrm{poly}\left(\frac{1}{\alpha}, \frac{1}{\varepsilon}, \log m\right)$ *bits of space.*

Proof. Note that from Lemma 34 and Lemma 35, the frequencies of the coordinates in the high frequency levels are well-approximated with high probability. Similarly, from Lemma 29 and Lemma 31, the sizes of the level sets of the medium and low frequency levels are well-approximated with high probability. Moreover, all the level sets are partitioned into the high, medium, or low frequency levels. We would like to say that by Lemma 23, these statistics are sufficient to recover a $(1+\alpha)$-approximation to any norm with *maximum modulus of concentration* at most M and so we achieve a $(1+\alpha)$-approximation to any norm with maximum modulus of concentration at most M that with high probability. Indeed, in an idealized process where $\xi^i \le \widehat{x_k} \le \xi^{i+1}$ if and only if k is sampled by the substream j assigned to level i and $\xi^i \le x_k < \xi^{i+1}$, Lemma 23 would show that we achieve a $(1+\alpha)$-approximation to any norm with maximum modulus of concentration at most M that with high probability. However, this may not always be the case because the frequency x_k may lie near the boundary of the interval $[\xi^i, \xi^{i+1})$ and the estimate $\widehat{x_k}$ may lie outside of the interval, in which case $\widehat{x_k}$ is used toward the estimation of some other level set. Thus, our algorithm randomizes the boundaries of the level sets by instead defining the level sets as $[\gamma\xi^i, \gamma\xi^{i+1})$ for some $\gamma \in (1/2, 1)$ chosen uniformly at random. Since we call PrivCountSketch with threshold at most $\alpha^2\beta'$, then the probability that item $k \in [n]$ is misclassified over the choice of γ is at most $\mathcal{O}\left(\alpha^2\beta'\right)$. Furthermore, if k in level set i is misclassified, it can only be classified into level set $i-1$ or $i+1$, causing at most an incorrect multiplicative factor of two. Then in expectation across all $k \in [n]$, the error due to the misclassification is at most an $\mathcal{O}\left(\alpha^2\beta'\right)$ fraction of the symmetric norm. Hence by Markov's inequality, the error due to the misclassification is at most an additive $\frac{\alpha}{2}$ fraction of the symmetric norm with probability at least 0.99. To obtain high probability of success, it then suffices to take the median across $\mathcal{O}(\log m)$ independent instances, finally showing correctness of our algorithm.

The private partitioning of the coordinates into the high, medium, and low frequency levels is $\frac{\varepsilon}{4}$-differentially private. Each of the three sets of statistics released by the high, medium, and low frequency levels are $\left(\frac{\varepsilon}{4}, \frac{\delta}{4}\right)$-differentially private, by Lemma 36, Lemma 40, and Lemma 42. Then (ε, δ)-differential privacy follows from the composition of differential privacy, i.e., Theorem 11.

Finally, the space complexity follows from Lemma 37, Lemma 41, and Lemma 43. ◀

We remark that our algorithm is presented as having unlimited access to random bits but is analyzed using $\mathcal{O}\left(\log m\right)$-wise independence, so it can be properly derandomized to provide the space guarantees without needing to store a large number of random bits. Alternatively, our algorithm can also be derandomized using Nisan's pseudorandom generator, which induces an extra multiplicative factor of $\mathcal{O}\left(\log m\right)$ in the space overhead [54].

Finally, we remark that the failure probability can be raised from $\delta=\frac{1}{\mathrm{poly}(m)}$ to arbitrarily $\delta>0$ using additional space overhead $\mathrm{polylog}\,\frac{1}{\delta}$, since the space dependency in each subroutine on the failure probability δ is $\mathrm{polylog}\,\frac{1}{\delta}$.

Testing Versus Estimation of Graph Properties, Revisited

Abstract

A graph G on n vertices is ε-far from property $\mathcal{P}$ if one should add/delete at least εn^2 edges to turn G into a graph satisfying $\mathcal{P}$. A *distance estimator* for $\mathcal{P}$ is an algorithm that given G and $\alpha, \varepsilon > 0$ distinguishes between the case that G is $(\alpha - \varepsilon)$-close to $\mathcal{P}$ and the case that G is α-far from $\mathcal{P}$. If $\mathcal{P}$ has a distance estimator whose query complexity depends only on ε, then $\mathcal{P}$ is said to be *estimable*.

Every estimable property is clearly also testable, since testing corresponds to estimating with $\alpha = \varepsilon$. A central result in the area of property testing is the Fischer–Newman theorem, stating that an inverse statement also holds, that is, that every testable property is in fact estimable. The proof of Fischer and Newmann was highly ineffective, since it incurred a tower-type loss when transforming a testing algorithm for $\mathcal{P}$ into a distance estimator. This raised the natural problem, studied recently by Fiat–Ron and by Hoppen–Kohayakawa–Lang–Lefmann–Stagni, whether one can find a transformation with a polynomial loss. We obtain the following results.

- We show that if $\mathcal{P}$ is hereditary, then one can turn a tester for $\mathcal{P}$ into a distance estimator with an exponential loss. This is an exponential improvement over the result of Hoppen et. al., who obtained a transformation with a double exponential loss.
- We show that for every $\mathcal{P}$, one can turn a testing algorithm for $\mathcal{P}$ into a distance estimator with a double exponential loss. This improves over the transformation of Fischer–Newman that incurred a tower-type loss.

Our main conceptual contribution in this work is that we manage to turn the approach of Fischer–Newman, which was inherently ineffective, into an efficient one. On the technical level, our main contribution is in establishing certain properties of Frieze–Kannan Weak Regular partitions that are of independent interest.

1 Introduction

1.1 Background on graph property testing

Property testers are fast randomized algorithms that can distinguish between objects satisfying some predetermined property $\mathcal{P}$ and those that are ε-far from satisfying $\mathcal{P}$. In most cases, ε-far means that an ε-proportion of the object's representation needs to be changed in order

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

to obtain a new object satisfying $\mathcal{P}$. Hence, testing for $\mathcal{P}$ is a relaxed version of the classical decision problem which asks to decide whether an object satisfies $\mathcal{P}$. In this paper we study properties of graphs in the so called *adjacency matrix model* (which is also sometimes referred to as the *dense graph model*). This is arguably one of the most well studied models in the area of property testing. The reader is referred to [20] for more background and references on property testing.

We now introduce the model of testing graph properties in the adjacency matrix model. A graph property $\mathcal{P}$ is a family of graphs closed under isomorphism. A graph G on n vertices is ε-far from $\mathcal{P}$ if one should add/delete at least εn^2 edges to turn G into a graph satisfying $\mathcal{P}$. If G is not ε-far from $\mathcal{P}$ then it is ε-close to $\mathcal{P}$. A *tester* for $\mathcal{P}$ is a randomized algorithm that given $\varepsilon > 0$ distinguishes with high probability (say, $2/3$) between graphs satisfying $\mathcal{P}$ and those that are ε-far from $\mathcal{P}$. We assume the algorithm can query for each $1 \leq i, j \leq n$ whether the input G contains the edge (i, j). The *edge query complexity*, denoted $Q(\varepsilon)$, of a tester is the number of edge queries it performs. If $\mathcal{P}$ has a tester whose edge query complexity depends only on ε (and is independent of n) then $\mathcal{P}$ is called *testable*. In what follows we will mainly work with *vertex query complexity* which is the smallest $q = q(\varepsilon)$ so that we can ε-test $\mathcal{P}$ by inspecting a subgraph of the input graph G, induced by a set of q randomly selected vertices. By a theorem of Goldreich and Trevisan [22] we know that $q(\varepsilon) \leq 2Q(\varepsilon) \leq q^2(\varepsilon)$. In most (but not all) discussions below we will not care much about these quadratic factors. In such cases we might use the term *query complexity* without mentioning if this is vertex or edge query complexity.

Property testing in the adjacency matrix model was first introduced by Goldreich, Goldwasser and Ron [21], who proved that every *partition property* (e.g. k-colorability and MAX-CUT) is testable. There are several general results guaranteeing that a graph property is testable [3, 10]. A result of this nature was obtained by Alon and Shapira [5] who proved that every hereditary[1] graph property is testable. Their proof applied Szemerédi's regularity lemma [35] (see also [33]), which is one of the most useful tools when studying properties of dense graphs. Using this tool comes with a hefty price, since the bounds one obtains when using the regularity lemma are of tower-type[2].

One of the central open (meta) problems related to testing graph properties is when can one turn an ineffective (e.g. one with tower-type bounds) result into an efficient one, preferably with polynomial bounds. While this is a quantitative question, what lies beneath it is in fact the following qualitative problem; when can we prove a testability result while avoiding Szemerédi's regularity lemma, either by giving a direct combinatorial argument or by using a weaker variant of the regularity lemma (e.g. the Frieze–Kannan regularity lemma [18] which we discuss below). For example, Rödl and Duke [31] used the regularity lemma in order to (implicitly) prove that k-colorability is testable. The tower-type bounds obtained in [31] were improved to polynomial in [21] using a direct argument which avoided the use of the regularity lemma. A specific central open problem, due to Alon and Fox [4], concerns hereditary properties, and asks which hereditary properties are testable with query complexity $\text{poly}(1/\varepsilon)$. A systematic investigation of this problem was carried out in [19].

1.2 Distance estimation

In the dense graph model we say that a graph's distance from $\mathcal{P}$ is α, if α is the smallest real so that G is α-close to $\mathcal{P}$. In other words, this is the minimum number of edges one should add/delete in order to obtain a graph satisfying $\mathcal{P}$, normalised by n^2. We denote

[1] A graph property is hereditary if it is closed under vertex removal. Some examples are being 3-colorable, being triangle-free and being induced H-free, for some fixed H.

[2] The tower function $\text{tower}(x)$ is a tower of exponents of height x.

this quantity by $\mathrm{dist}_{\mathcal{P}}(G)$. A *distance estimator* for $\mathcal{P}$ is a randomized algorithm that given $\alpha, \varepsilon > 0$ distinguishes with high probability (say, 2/3) between graphs that are $(\alpha - \varepsilon)$-close to $\mathcal{P}$ and those that are α-far from $\mathcal{P}$. If for every α, ε there is a distance estimator for $\mathcal{P}$ whose query complexity depends only on ε, then $\mathcal{P}$ is said to be *estimable*. Note that testing $\mathcal{P}$ is equivalent to distance estimation with $\alpha = \varepsilon$, hence this notion is at least as strong as testability.

Distance estimation was first studied in [30] and has since been studied in various other settings such as distributions [7], strings [6], sparse graphs [11, 13, 28], boolean functions [1, 9], error correcting codes [23, 26] and image processing [8]. It is known that in certain settings, there are testable properties which are not estimable [15]. One of the central and most unexpected results in the area of graph property testing is the Fischer–Newman theorem [16], which states that in the setting of graphs, every testable property is also estimable. As with several of the main results in this area, the proof in [16] relied on Szemerédi's regularity lemma [35] and thus resulted in a tower-type loss when transforming a tester for $\mathcal{P}$ into a distance estimator for $\mathcal{P}$. Returning to the discussion in the last paragraph of the previous subsection, it is natural to ask if one can improve the transformation of [16] and turn a tester for $\mathcal{P}$ into a distance estimator with a polynomial loss.

1.3 New results concerning hereditary graph properties

As we mentioned in the previous subsection, the family of hereditary graph properties has been extensively studied within the setting of graph property testing. The fact that every hereditary property is testable follows from the following statement, where we use $ind(F, G)$ to denote the probability that a random mapping $\varphi : V(F) \to V(G)$ is an injective induced homomorphism. [3]

▶ **Lemma 1** (Induced Removal Lemma, [5]). *For every $\varepsilon > 0$ and every hereditary $\mathcal{P}$, there exists $M = M_1(\varepsilon, \mathcal{P})$, $\delta = \delta_1(\varepsilon, \mathcal{P}) > 0$ and $n_0 = n_1(\varepsilon, \mathcal{P})$ such that if a graph G on $n \geq n_0$ vertices is ε-far from $\mathcal{P}$ then there is a graph $F \notin \mathcal{P}$ with $|V(F)| \leq M$ such that $ind(F, G) \geq \delta$.*

The first version of the above lemma was obtained by Alon, Fischer, Krivelevich and Szegedy [2] who proved it when $\mathcal{P}$ can be characterized using a finite number of forbidden induced subgraphs. The lemma was proved in full generality by Alon and Shapira [5]. Alternative proofs were later obtained by Lovász and Szegedy [27], Conlon and Fox [12] and Borgs et al. [10]. It was also extended to the setting of hypergraphs by Rödl and Schacht [32].

Note that it follows immediately from Lemma 1 that every hereditary property is testable with vertex query complexity

$$q(\varepsilon) = \max\{n_0, M/\delta\} \ . \tag{1}$$

Indeed, the algorithm samples a set X of q vertices, queries about all pairs within X, and then accepts if and only if the graph on X satisfies $\mathcal{P}$. If G satisfies $\mathcal{P}$ then the algorithm clearly answers correctly (with probability 1). If G is ε-far from $\mathcal{P}$, then by Lemma 1 a random M-tuple of vertices spans an induced copy of a graph $F \notin \mathcal{P}$ with probability at least δ. Hence, a sample of size M/δ contains an induced copy of F with probability at least 2/3, thus guaranteeing that the sample of vertices does not satisfy $\mathcal{P}$ (since $\mathcal{P}$ is hereditary). Recall that [22] proved that if $\mathcal{P}$ is testable, then it is testable using an algorithm as above. Hence, the bounds in Lemma 1 more or less determine the query complexity of testing a

[3] A mapping $\varphi : V(F) \to V(G)$ is an induced homomorphism if $uv \in E(F)$ if and only if $\varphi(u)\varphi(v) \in E(G)$.

hereditary $\mathcal{P}$. This raises the following natural problem, introduced by Hoppen et al. [25, 24] and by Fiat and Ron [14], asking if it is possible to estimate every hereditary $\mathcal{P}$ with (roughly) the same query complexity with which it can be tested as in (1).

▶ **Problem 2.** *Determine if every hereditary graph property $\mathcal{P}$ is estimable with query complexity*

$$n_0 \cdot M/\delta \ ,$$

where $M = M_1(\varepsilon', \mathcal{P})$, $\delta = \delta_1(\varepsilon', \mathcal{P})$, $n_0 = n_1(\varepsilon', \mathcal{P})$ are given by Lemma 1 with $\varepsilon' = \mathrm{poly}(\varepsilon)$.

▶ Remark 3. There are hereditary graph properties (e.g. triangle-freeness) for which the best known bounds for M and δ in Lemma 1 are of tower-type. One can argue that in such cases there is little difference between the tower(M/δ) bounds given by [16] and those suggested by Problem 2. However, we should emphasize that for many of these properties (e.g. triangle-freeness) the tower-type bounds are not known to be tight (indeed, the best known lower bounds are just slightly super polynomial). Perhaps more importantly, there are numerous hereditary graph properties for which it is known that both M and δ in Lemma 1 are polynomial in ε (e.g. k-colorability, being an interval graph or being a line graph; see the detailed discussion in [19]). For all these properties, Problem 2 suggests a poly$(1/\varepsilon)$ bound, versus the tower$(1/\varepsilon)$ bound given by [16].

Problem 2 was studied by Hoppen et al. [25, 24]. Their main result was that every hereditary $\mathcal{P}$ is estimable with query complexity $2^{\mathrm{poly}((1/\delta)^{M^2}, \log n_0)}$. Our first main result is the following exponential improvement of this result, making a significant step towards resolving Problem 2.

▶ **Theorem 4.** *Every hereditary $\mathcal{P}$ is estimable with query complexity*

$$2^{\mathrm{poly}(M/\delta, \log n_0)} \ ,$$

where $M = M_1(\varepsilon/2, \mathcal{P})$, $\delta = \delta_1(\varepsilon/2, \mathcal{P})$ and $n_0 = n_1(\varepsilon/2, \mathcal{P})$ are the parameters of Lemma 1.

▶ Remark 5. In all known cases, the best bounds in Lemma 1 are such that $\log n_0 \ll 1/\delta$, hence the upper bound of [25] is $2^{(1/\delta)^{O(M^2)}}$ while the one in Theorem 4 is $2^{\mathrm{poly}(M/\delta)}$.

In almost all cases, results concerning testing of dense graphs rely on combinatorial statements which imply trivial algorithms. For example, the algorithm for testing a hereditary property $\mathcal{P}$ is trivial once we have Lemma 1 at our disposal. In sharp contrast, many estimation results involve sampling a set of vertices and then carrying out a highly non-trivial computation over this sample. This is certainly the case in the present paper, see the proofs of Lemmas 14 and 15. However, thanks to a well known sampling trick [21], one can transfer any estimation result into a combinatorial statement. For example, this trick gives the following corollary of Theorem 4.

▶ **Corollary 6.** *Set $q = 2^{\mathrm{poly}(M/\delta, \log n_0)}$ as in Theorem 4. Then*

$$\Pr_X \left[|\mathrm{dist}_{\mathcal{P}}(G[X]) - \mathrm{dist}_{\mathcal{P}}(G)| \le \varepsilon \right] \ge 2/3 \ ,$$

where the probability is over randomly selected subsets X of q vertices from G, and $G[X]$ is the graph induced by G on X.

It is interesting to note that with Corollary 6 at hand, we can now go back and reprove Theorem 4 using the "trivial/natural" algorithm which samples a set of q vertices X, computes $\text{dist}_{\mathcal{P}}(G[X])$, and then states that G is $(\alpha - \varepsilon)$-close to $\mathcal{P}$ if $\text{dist}_{\mathcal{P}}(G[X]) \leq \alpha - \varepsilon/2$ and is otherwise α-far from $\mathcal{P}$.

Our proof of Theorem 4 actually gives the bound $2^{\text{poly}(M/\varepsilon\delta, \log n_0)}$. One can speculate that $\text{poly}(M/\varepsilon\delta) = \text{poly}(M/\delta)$ since in all known cases δ is at best polynomial in ε, and in many cases much smaller. In order to formally be able to remove the dependence on ε from our bound, we prove the following proposition, where $\mathcal{P}$ is *trivial* if either $\mathcal{P}$ contains all graphs or if it contains finitely many graphs. The proof of this proposition relies on a subtle application of Ramsey's theorem.

▶ **Proposition 7.** *The following holds for every non-trivial hereditary property $\mathcal{P}$. If $q(\varepsilon)$ denotes the vertex query complexity of $\mathcal{P}$ then for every small enough ε, we have*

$$M/\delta \geq q(\varepsilon) \geq \Omega(1/\varepsilon) , \tag{2}$$

where $M = M_1(\varepsilon, \mathcal{P})$ and $\delta = \delta_1(\varepsilon, \mathcal{P})$ are the constants of Lemma 1.

The left inequality above follows from (1). Observe that the lower bound on $q(\varepsilon)$ is best possible since it is tight when $\mathcal{P}$ is the property of having no edges (in which case $q(\varepsilon) = O(1/\varepsilon)$). The proof of the proposition will appear in the journal version of the paper.

It is of course natural to study Problem 2 also for specific hereditary properties. A natural problem of this type is whether every hereditary $\mathcal{P}$ that is testable with query complexity $\text{poly}(1/\varepsilon)$ is also estimable with query complexity $\text{poly}(1/\varepsilon)$. Such an investigation was initiated recently by Fiat and Ron [14] who proved such a statement for many natural hereditary properties such as Chordality and not containing an induced path on 4 vertices.

1.4 New results concerning general graph properties

Given the discussion above, the following problem seems natural.

▶ **Problem 8.** *Determine if every property $\mathcal{P}$ that is testable with vertex query complexity $q(\varepsilon)$, is estimable with query complexity $q(\varepsilon')$ for some $\varepsilon' = \text{poly}(\varepsilon)$.*

Prior to this work, the only result concerning general graph properties $\mathcal{P}$ was the transformation of Fischer and Newman [16] which turns a testing algorithm for a graph property $\mathcal{P}$ with query complexity $q(\varepsilon)$ into a distance estimator with query complexity $\text{tower}(q(\varepsilon/2))$. Using the tools we develop in order to obtain Theorem 4, we also obtain the following improved bound.

▶ **Theorem 9.** *If $\mathcal{P}$ is testable with query complexity $q(\varepsilon)$ then it is estimable with query complexity $2^{\text{poly}(1/\varepsilon)\cdot 2^{q(\varepsilon/2)}}$.*

We would like to argue at this point that since any "natural" property satisfies $q(\varepsilon) \geq \log(1/\varepsilon)$ the above bound can be written as $\exp(\exp(\text{poly}(q(\varepsilon/2))))$. In order to formally make such a claim, we prove the following variant of Proposition 7, in which $\mathcal{P}$ is *unnatural* if there is ε_0 so that the following holds for every $0 < \varepsilon < \varepsilon_0$ and $n \geq n_0(\varepsilon)$: either every n-vertex graphs is ε-close to $\mathcal{P}$, or every n-vertex graph does not belong to $\mathcal{P}$. If $\mathcal{P}$ is not unnatural then it is (naturally) *natural.*

▶ **Proposition 10.** *Let $\mathcal{P}$ be a natural property and let $q(\varepsilon)$ be its vertex query complexity, and $Q(\varepsilon)$ be its edge query complexity. Then*

$$Q(\varepsilon) = \Omega(1/\varepsilon) . \tag{3}$$

In particular, $q(\varepsilon) = \Omega(\sqrt{1/\varepsilon})$.

The "in particular" part above follows directly from the Goldreich–Trevisan [22] theorem mentioned earlier. Observe that the general lower bound given in (3) is best possible since it is tight when $\mathcal{P}$ is the property of having no edges, where $Q(\varepsilon) = O(1/\varepsilon)$. The proof of the proposition will appear in the journal version of the paper.

1.5 Main technical contributions and comparison to previous approaches

Summary of previous approaches

The main reason why Szemerédi's regularity lemma is so useful when studying testing/estimation problems is that an ε-regular partition of a graph G determines (approximately) the values of $ind(F, G)$ for all small F. Hence, on a very high level, the way one can estimate a graph's distance to a hereditary property $\mathcal{P}$ is to take a *single* ε-regular partition of G (one such exists by the regularity lemma) and then try to modify this partition using the smallest possible number of edge modifications, so that the new partition "predicts" that there are no induced copies of graphs $F \notin \mathcal{P}$ in the new graph G'. A key "continuity" feature one has to use at this stage is that if G has a regular partition with certain edge densities between the clusters of the partition, and one would like to modify G so that in the new graph G' one has a regular partition where the edge densities between the clusters will change on average by γ, then one can achieve this by modifying $(\gamma + o(1))n^2$ edges of G. Fischer and Newman [16] critically relied on the fact that regular partitions in the sense of Szemerédi have this continuity property. The approach of [16] was ineffective since although a regular partition has constant size (i.e., depending only on ε), this constant has tower-type dependence on ε. We should point that one of the key novel ideas of [16] was a method for obtaining the densities of a single Szemerédi partition of the input G.

The way Hoppen et al. [25, 24] managed to improve upon [16] (for hereditary $\mathcal{P}$) was by first observing that in order to estimate $ind(F, G)$ for all small F, one does not need the full power of Szemerédi's regularity lemma. Instead, one can use the weak regularity lemma of Frieze and Kannan [17] which involves constants that are only exponential in ε. The main reason why their proof gave a doubly exponential bound is that Frieze–Kannan regular partitions do not (seem to) have the same continuity feature we mentioned in the previous paragraph with respect to Szemerédi partitions. To overcome this, Hoppen et al. [25, 24] introduced a sophisticated method that somehow combines working with Frieze–Kannan regular partitions in some parts of the proof, together with vertex partitions that have no regularity[4] features at all (these are sometimes called GGR partitions, after [21]) in other parts of the proof.

Our main technical contribution

Our main technical contribution in this paper establishes that Frieze-Kannan weak regular partitions "almost" satisfy the same continuity feature we mentioned above with respect to Szemerédi partitions. What we show is that one can indeed efficiently modify a Frieze–Kannan partition if one starts with a partition with guarantees slightly stronger than those of Frieze–Kannan, and one is content with ending with a usual Frieze–Kannan partition.

[4] Working with partitions that have no regularity requirements has the advantage that they trivially have the continuity property. Indeed, if we want to change the edge density between two sets A, B by γ we just add/remove $\gamma|A||B|$ edges. Needless to say that working with such partitions has various disadvantages resulting from their lack of regularity features.

See Lemma 28 for the precise statement, whose proof relies on a randomized-rounding-type argument. With the above continuity feature at hand, we can now go back to the Fischer–Newman approach and turn it into an effective one, by taking full advantage of the Frieze–Kannan lemma. One additional hurdle we need to overcome in order to make sure we only incur an exponential loss in our proof, is a method for finding a Frieze–Kannan partition of a graph using a constant number of queries. Here we introduce a variant of the method of Fischer–Newman tailored for Frieze–Kannan partitions, see Lemma 14. The main tools we develop for proving Theorem 4 turn out to be also applicable for proving Theorem 9. The reason why in Theorem 9 we have a double exponential loss is that it is not enough to estimate $ind(F, G)$ for a single F (as in Theorem 4 thanks to Lemma 1) but we instead need to control $ind(F, G)$ for all graphs F of order $q(\varepsilon)$. We expect Lemmas 14 and 28 to be applicable in future studies related to efficient testing and estimation of graph properties.

Paper overview

In Section 2 we introduce the two main lemmas in the paper, and show how they imply Theorem 4. These lemmas are proved in Sections 3 and 4. In Section 5 we prove Theorem 9. We prove Proposition 7 at the end of Section 2 and Proposition 10 at the end of Section 5. We use $a = \text{poly}(x)$ to denote the fact that a is bounded from above (or below, when $0 < x < 1$) by x^d for some fixed d, which is independent of n or ε. Also, when we say that "for every $a = \text{poly}(x)$ there is $b = \text{poly}(x)$" we mean that for every d there is d' so that if $a \le x^d$ then there is a $b \le x^{d'}$.

2 The Key Lemmas and Proof of Theorem 4

Our goal in this section is to state Lemmas 14 and 15 and then use them to derive Theorem 4. We prove these lemmas in Sections 3 and 4. At the end of this section we also prove Proposition 7.

To state Lemmas 14 and 15 we need some definitions. We first recall that given a graph $G = (V, E)$, an equipartition $A = \{V_1, \dots, V_k\}$ of $V(G)$ is a partition satisfying $||V_i| - |V_j|| \le 1$. Given a graph G and subsets $X, Y \subseteq V(G)$, we use $e(X, Y)$ to denote the number of edges between X and Y, and $d(X, Y) = e(X, Y)/|X||Y|$ to denote the *density* between them.

▶ **Definition 11** (Signature). *For an equipartition $A = \{V_1, \dots, V_t\}$ of $V(G)$, a (γ, ε)-signature of A is a sequence of reals $S = (\eta_{i,j})_{1 \le i < j \le t}$, such that $|d(V_i, V_j) - \eta_{i,j}| \le \gamma$ for all but at most $\varepsilon\binom{t}{2}$ of the pairs $i < j$. A (γ, γ)-signature is referred to as γ-signature.*

▶ **Definition 12** (Index of a partition). *For an equipartition A of a graph $V(G)$ into t sets, we define the* index *of A to be*

$$ind(A) = \frac{1}{t^2} \sum_{1 \le i < j \le t} d^2(V_i, V_j) .$$

▶ **Definition 13** (Final partition). *For a function $f : \mathbb{N} \to \mathbb{N}$ and $\gamma > 0$, we say that an equipartition A of G consisting of t sets is (f, γ)-final if there exists no equipartition B of $V(G)$ with at least t and up to $f(t)$ sets for which $ind(B) \ge ind(A) + \gamma$.*

The above notion of a final partition is useful since (as we show later) every graph has such a partition and furthermore, we can design an algorithm for finding a signature of one such partition of an input G. The first key lemma leading to the proof of Theorem 4 does exactly that.

▶ **Lemma 14.** *For every $k, \zeta > 0$, and every $\gamma = \mathrm{poly}(\zeta)$ and $f_\zeta(x) = x \cdot 2^{\mathrm{poly}(1/\zeta)}$, there are $q = q_{14}(\zeta, k)$, $N = N_{14}(\zeta, k)$ and $T = T_{14}(\zeta, k)$ so that*

$$q, N, T \leq \mathrm{poly}(k) \cdot 2^{\mathrm{poly}(1/\zeta)}$$

and such that the following holds. If G is a graph on at least N vertices then there is an algorithm making at most q queries to G, computing with probability at least $\frac{2}{3}$ a γ-signature of an (f_ζ, γ)-final partition of G into at least k and at most T sets.

We prove the above lemma is Section 3. The following is the second key lemma, which we prove in Section 4. In its statement we use the notion *ind*(F, G) which we defined before the statement of Lemma 1. What it roughly states, is that having a signature of G (with good parameters) is enough for estimating G's distance to satisfying $\mathcal{P}$.

▶ **Lemma 15.** *For every $h, \varepsilon, \delta > 0$, there are $\gamma = \gamma_{15}(h, \varepsilon, \delta)$, $s = s_{15}(h, \varepsilon, \delta)$ and $f_{15}^{(h,\varepsilon,\delta)} : \mathbb{N} \to \mathbb{N}$ so that*

$$\gamma = \mathrm{poly}(\varepsilon\delta/h), \quad s = \mathrm{poly}(h/\varepsilon\delta), \quad f_{15}(x) = x \cdot 2^{\mathrm{poly}(h/\varepsilon\delta)}$$

and the following holds. For every family $\mathcal{H}$ of graphs, each on at most h vertices, there exists a deterministic algorithm, that receives as an input a γ-signature S of an (f_{15}, γ)-final partition A into $t \geq s$ sets of a graph G with $n \geq N_{15}(h, \varepsilon, \delta, t) = \mathrm{poly}(t) \cdot 2^{\mathrm{poly}(h/\varepsilon\delta)}$ vertices, and distinguishes given any α between the following two cases:

(i) G is $(\alpha - \varepsilon)$ close to some graph G' for which $ind(H, G') = 0$ for every $H \in \mathcal{H}$.

(ii) G is α-far from every G' for which $ind(H, G') < \delta$ for every $H \in \mathcal{H}$.

Proof (of Theorem 4). Suppose $\mathcal{P}$ is a hereditary graph property, and let $\alpha, \varepsilon > 0$. Lemma 1 with inputs $\varepsilon/2$ and $\mathcal{P}$ asserts that there are

$$h = M_1(\varepsilon/2), \quad \delta = \delta_1(\varepsilon/2), \quad n_0 = n_1(\varepsilon/2)\ ,$$

so that if a graph G on at least n_0 vertices is $\varepsilon/2$-far from $\mathcal{P}$, then $ind(H, G) \geq \delta$ for some $H \notin \mathcal{P}$ with $|V(H)| \leq h$. We need to describe an algorithm making $2^{\mathrm{poly}(h/\delta, \log n_0)}$ queries to G and distinguishes with probability at least $2/3$ between the case that G is $(\alpha - \varepsilon)$-close to $\mathcal{P}$ and the case that G is α-far from $\mathcal{P}$. Set

$$\gamma = \gamma_{15}(h, \varepsilon/2, \delta), \quad s = s_{15}(h, \varepsilon/2, \delta), \quad f = f_{15}^{(h,\varepsilon/2,\delta)}\ .$$

Finally, set $\zeta = \delta\varepsilon/h$ and observe that

$$\gamma = \gamma_{15}(h, \varepsilon/2, \delta) = \mathrm{poly}(\varepsilon\delta/2h) = \mathrm{poly}(\zeta)\ ,$$

that

$$f(x) = f_{15}^{(h,\varepsilon/2,\delta)}(x) = x \cdot 2^{\mathrm{poly}(2h/\varepsilon\delta)} = x \cdot 2^{\mathrm{poly}(1/\zeta)}\ ,$$

that

$$s = s_{15}(h, \varepsilon/2, \delta) = \mathrm{poly}(2h/\varepsilon\delta) = \mathrm{poly}(1/\zeta)\ .$$

Also, note that by Proposition 7 we have $\mathrm{poly}(1/\zeta) = \mathrm{poly}(h/\delta)$. Let q, N, T be the parameters given by Lemma 14 when applied with $k = s$, and ζ, γ, f defined above. (note that γ and f satisfy the assumptions of the lemma). Lemma 14 then guarantees that $q, N, T \leq 2^{\mathrm{poly}(1/\zeta)} \leq 2^{\mathrm{poly}(h/\delta)}$.

If G has less than N vertices then we can just ask about all the edges of G and answer correctly with probability 1. The number of queries is then at most $N^2 \leq 2^{\mathrm{poly}(h/\delta)}$ as needed. If G has more than N vertices then we can use the algorithm of Lemma 14 with the parameters k, ζ, γ, f defined above. The algorithm makes at most $q \leq 2^{\mathrm{poly}(h/\delta)}$ queries and with probability at least $2/3$ returns a γ-signature S of an equipartition of G into $s \leq t \leq T$ sets that is (f, γ)-final. Let

$$N' = N_{15}(h, \varepsilon/2, \delta, T) = \mathrm{poly}(T) \cdot 2^{\mathrm{poly}(h/\varepsilon\delta)} = 2^{\mathrm{poly}(h/\delta)} .$$

Again, if G has less than $N_1 = \max\{N', n_0\}$ vertices then we can just ask about all the edges of G and answer correctly with probability 1. The number of queries is then at most $(N_1)^2 \leq 2^{\mathrm{poly}(h/\delta, \log n_0)}$ as needed.

Suppose then that G has at least $\max\{N, N_1\}$ vertices. Let $\mathcal{H}$ be the family of graph on at most h vertices which do not satisfy $\mathcal{P}$. Then we can now run the algorithm of Lemma 15 on the signature S, with respect to $\mathcal{H}$, with $\alpha' = \alpha - \varepsilon/2$ and with $\varepsilon/2$ instead of ε (note that we chose the parameters with $\varepsilon/2$). If the algorithm says that case (i) holds (namely that G is $(\alpha' - \varepsilon/2)$-close to some G' with $ind(H, G') = 0$ for every $H \in \mathcal{H}$) then we declare that G is $(\alpha - \varepsilon)$-close to $\mathcal{P}$, and if the algorithm says that case (ii) holds (namely that G is α'-far from every G' with $ind(H, G') < \delta$ for every $H \in \mathcal{H}$) then we declare that G is α-far from $\mathcal{P}$.

Let us prove the correctness of the above algorithm. If G is $(\alpha - \varepsilon)$-close to $\mathcal{P}$ then it is $(\alpha - \varepsilon)$-close to a graph G' satisfying $ind(H, G') = 0$ for every $H \in \mathcal{H}$. Since $\alpha - \varepsilon = \alpha' - \varepsilon/2$ the algorithm will say that case (i) holds, hence the algorithm answers correctly in this case. Suppose now that G is α-far from $\mathcal{P}$. Then any G' that is α'-close to G must be $\varepsilon/2$-far from $\mathcal{P}$. Hence, by Lemma 1 in any such G' we have $ind(H, G') \geq \delta$ for at least one $H \in \mathcal{H}$. We conclude that G is α'-far from every G' satisfying $ind(H, G') < \delta$ for every $H \in \mathcal{H}$. Hence, the algorithm of Lemma 15 will say that case (ii) holds , so our algorithm will answer correctly in this case as well. ◀

3 Proof of Lemma 14

The proof is similar to one in [16]. What they have shown is that for every f, γ, one can find an (f, γ)-final partition with a constant, albeit huge tower-type, query complexity. What we do here is show that for restricted types of f, one can get a much better bound. To do this we also need to rely on a recent result of [34].

3.1 Preliminary lemmas

In this subsection we describe some preliminary lemmas that will be used in the next subsection in which we prove Lemma 14. We will need the following Chernoff-type large deviation inequality.

▶ **Lemma 16.** *Suppose $X_1, \ldots, X_m$ are m independent Boolean random variables, so that for every $1 \leq i \leq m$ we have $\Pr[X_i = 1] = p_i$. Let $E = \sum_{i=1}^m p_i$. Then, $\Pr[|\sum_{i=1}^m X_i - E| \geq \theta m] \leq 2e^{-2\theta^2 m}$.*

▶ **Definition 17** (Partition Properties). *A partition property is a triple $\pi = (s, \ell, u)$ where s is an integer (the size of the partition property), ℓ is a vector of $\binom{s}{2}$ reals $0 \leq \alpha_{i,j} \leq 1$ for each $1 \leq i < j \leq s$, and u is a vector of $\binom{s}{2}$ reals $0 \leq \beta_{i,j} \leq 1$ for each $1 \leq i < j \leq s$. We say that a graph G satisfies π if there is an equipartition $\{V_1, \ldots, V_s\}$ of $V(G)$, such that $\alpha_{ij} \leq d(V_i, V_j) \leq \beta_{ij}$ for every $1 \leq i < j \leq s$.*

Given s and μ we use $\pi(s,\mu)$ to denote the family of partition properties π of size s in which every $\alpha_{i,j}$ and $\beta_{i,j}$ is an integer multiple of μ (so $\pi(s,\mu)$ contains $\{0,\mu,2\mu,\dots,1\}^{2\binom{s}{2}}$ partition properties). Finally, define $\Pi(t,\mu)=\bigcup_{s\le t}\pi(s,\mu)$.

Note that each π as above is one of the partition properties studied in [21], where it was shown that they are μ-testable with query complexity $(1/\mu)^{\mathrm{poly}(s)}$. This was improved recently to $\mathrm{poly}(s/\mu)$ in [34]. The next lemma states that with (roughly) the same query complexity we can in fact *simultaneously* test all properties in $\Pi(t,\mu)$.

The proof of the next lemma will appear in the journal version of the paper.

▶ **Lemma 18.** *For every t and $\mu>0$ there is $q=q_{18}(t,\mu)=\mathrm{poly}(t/\mu)$ satisfying the following. There is a randomized algorithm, that given a graph G, makes q queries to G and with probability at least $2/3$, for every $\pi\in\Pi(t,\mu)$, distinguishes between the case that G satisfies π and the case that G is μ-far from π.*

Proof (of Lemma 14): Given k,ζ,γ and f_ζ as in the statement of the lemma, we define $T_0=k$ and for $i\ge 1$ define $T_i=f_\zeta(T_{i-1})$. Now set the following parameters.

$$N=N_{14}(k,\zeta)=T_{2/\gamma}=k\cdot 2^{\mathrm{poly}(1/\zeta)},\quad T=T_{14}(k,\zeta)=T_{2/\gamma}=k\cdot 2^{\mathrm{poly}(1/\zeta)}\ ,$$

and

$$t=f_\zeta(T)=k\cdot 2^{\mathrm{poly}(1/\zeta)},\quad \mu=\frac{\gamma}{48(f_\zeta(T))^2}=\frac{1}{\mathrm{poly}(k)\cdot 2^{\mathrm{poly}(1/\zeta)}}\ .$$

We now describe the algorithm for finding a signature S satisfying the requirement of the lemma. For what follows let $\pi'(s,\mu)$ be the partition properties in which $\beta_{i,j}=\alpha_{i,j}+\mu$ for every $1\le i<j\le s$. Also for each $\pi\in\pi'(s,\mu)$ define the index of π to be $ind(\pi)=\frac{1}{t^2}\sum_{1\le i<j\le t}\alpha_{ij}^2$. In the Step-1 we run the algorithm of Lemma 18 with the parameters t,μ defined above. This is the only randomized part of the algorithm. In the Step-2 of the algorithm we do the following.

(i) For each $k\le s\le t$ set $M(s)=\max_\pi ind(\pi)$ where the maximum is taken over all $\pi\in\pi'(s,\mu)$ which the algorithm of Step-1 accepted.

(ii) Let $s^\star$ be the smallest number in $\{k,\dots,T\}$ such that $M(s')\le M(s^\star)+\frac{3}{4}\gamma$ for every $s'\in\{s^\star+1,\dots,f_\zeta(s^\star)\}$. If there exists such an $s^\star$, output the signature $S^\star$ that achieves the maximum over $s^\star$. Otherwise, the algorithm fails.

Note that the query complexity of the algorithm is $q=q_{18}(t,\mu)=\mathrm{poly}(t/\mu)=\mathrm{poly}(k)\cdot 2^{\mathrm{poly}(1/\zeta)}$, as needed. Also, Lemma 18 guarantees that Step-1 of the above described algorithm succeeds with probability at least $2/3$. It thus remains to show that assuming this event holds, Step-2 of the algorithm will return an (f_ζ,γ)-final partition. First of all note that if it succeeds then it returns a partition of size at least k and at most T, as required.

The proof that if Step-1 succeeded, then Step-2 returns an (f_ζ,γ)-final partition is identical to the proof of Claim 5.5 in [16], so we give a sketch of the proof. First, the reader might be wondering why every graph necessarily has an (f_ζ,γ)-final partition as in the statement of the lemma. Let us actually explain why every G has an $(f_\zeta,\gamma/2)$-final partition, while using the definitions we introduced above. Start from an arbitrary equipartition A_0 of G into $T_0=k$ sets, and let $ind_0=ind(A_0)$ denote the index of A_0 as in Definition 12. If A_0 is $(f_\zeta,\gamma/2)$-final then we are done. If not, then there must be another partition A_1 of G with at least T_0 and at most $f(T_0)=T_1$ parts, with index $ind(A_1)\ge ind(A_0)+\gamma/2$. Since $0\le ind(A)\le 1$ for every equipartition, we see that this process will eventually end up with a partition A of size $k \leq s \leq T$ so that all partitions of G into at least s and at most $f(s)$ parts have index less than $ind(A) + \gamma/2$. But this means that A is $(f_\zeta, \gamma/2)$-final. Note that we thus get that G has a $(f_\zeta, \gamma/2)$-final partition A of size $s \leq T$.

Let us now explain how to turn the above existential proof into a proof of correctness of the algorithm describe earlier. Let $M_G(s)$ denote the largest index of an equipartition of G of size s. First we claim that for every $k \leq s \leq t$,

$$M(s) - \gamma/8 \leq M_G(s) \leq M(s) + \gamma/8. \tag{4}$$

For the second inequality in (4), let A be an equipartition with s parts such that $M_G(s) = ind(A)$. Let $\pi \in \pi'(s, \mu)$ be the partition property obtained from A by rounding down the densities to the closest integer multiple of μ. Then we have $|ind(A) - ind(\pi)| \leq 3\mu \leq \gamma/8$. Hence, $M(s) \geq ind(\pi) \geq ind(A) - \gamma/8 = M_G(s) - \gamma/8$.

For the first inequality in (4), let $\pi \in \pi'(s, \mu)$ be a partition property which the algorithm accepted and such that $M(s) = ind(\pi)$. Then G must be μ-close to π (as otherwise π should have been rejected). Let G' be a graph μ-close to G that satisfies π, and let A be the vertex partition of G' witnessing that G' satisfies π. Note that when turning G into G', for each pair of parts of A, we change the density between this pair by at most μs^2. Hence, in G, the partition property π is a $2\mu s^2$-signature of A (here and in what follows, we view π as a signature). So $|ind(A) - ind(\pi)| \leq 6\mu s^2 \leq \gamma/8$, using our choice of μ. Now, $M_G(s) \geq ind(A) \geq ind(\pi) - \gamma/8 = M(s) - \gamma/8$. This proves (4).

It follows from the existential proof above that there is $k \leq s^\star \leq T$ and an equipartition A of G into $s^\star$ parts which is $(f_\zeta, \gamma/2)$-final. We can assume that $M_G(s^\star) = ind(A)$, because the equipartition satisfying this must also be final. We have $M_G(s') \leq M_G(s^\star) + \gamma/2$ for every $s^\star \leq s' \leq f_\zeta(s^\star)$. By (4), this implies that $M(s') \leq M(s^\star) + 3\gamma/4$ for every $s^\star \leq s' \leq f_\zeta(s^\star)$. So the algorithm will return a partition.

Note that the algorithm does not necessarily return the same signature/partition-property as above π that is μ-close to the above partition A. The reason for the algorithm to choose a different partition is that there might be another partition of size s with a larger index (which is of course also (f_ζ, γ)-final) or there might be an $s^* < s$ with the same properties, or there might be other partitions with the same index. However, one can invert the reasoning in the previous paragraph and show that if a π is returned then it must be the γ-signature of an (f_ζ, γ)-final partition. ◀

4 Proof of Lemma 15

4.1 Preliminary lemmas

In this subsection we describe some preliminary lemmas that will be used in the next subsection in which we prove Lemma 15. We start with introducing the Frieze–Kannan regularity lemma [17, 18]. We first state their notion of γ-regularity.

▶ **Definition 19** (Frieze–Kannan Regularity [18]). *Let $G = (V, E)$ be a graph and $A = \{V_1 \ldots, V_k\}$ be an equipartition of $V(G)$. For a subset $X \subseteq V$ and $1 \leq i \leq k$ denote $X_i = X \cap V_i$. We say that A is γ-Frieze–Kannan-regular if:*

$$d^A_\square(G) := \max_{S,T \subseteq V} \frac{1}{n^2} \left| \sum_{i,j \in [k]^2} \Big(d(S_i, T_j) - d_{ij} \Big) |S_i||T_j| \right| < \gamma \tag{5}$$

Roughly speaking, a partition A is γ-Frieze–Kannan-regular, or γ-FK-regular for short, if we can estimate the number of edges between large sets S, T from the intersection sizes $S \cap V_i$ and $T \cap V_i$. We will also need the following slightly stronger notion of weak regularity that was introduced in [29].

▶ **Definition 20** (Frieze–Kannan Regularity* [29]). *In the setting of Definition 19, we say that A is γ-Frieze–Kannan Regular* if:*

$$d_\square^{\star A}(G) := \max_{S,T\subseteq V} \frac{1}{n^2} \sum_{i,j\in[k]^2} \left| d(S_i, T_j) - d_{ij} \right| |S_i||T_j| < \gamma \tag{6}$$

The translation between these two notions will be crucial in Lemma 28 below. Suppose $A = \{V_1, \dots, V_k\}$ is an equipartition of $V(G)$. Then an equipartition $B = \{W_1, ..., W_\ell\}$ of $V(G)$ is said to *refine* A if each $W_i \in B$ is contained in some $V_j \in A$. The following lemma is proved in [29] using a simple variant of the original proof of Frieze and Kannan [18].

▶ **Lemma 21** (Frieze–Kannan Weak Regularity Lemma [18, 29]). *For every k_0 and $\gamma > 0$ there is $T = T_{21}(k_0, \gamma) = k_0 \cdot 2^{\mathrm{poly}(1/\gamma)}$ so that the following holds for every graph G on at least T vertices. If A is an equipartition of $V(G)$ into at most k_0 sets, then there is a refinement B of A into at most T sets such that $d_\square^{\star B}(G) < \gamma$.*

Let us now extend the definition of $d_\square$ to distance between pairs of weighted graph, where a weighted graph R is a complete graph, so that every edge (i, j) is assigned a weight $0 \le R(i, j) \le 1$.

If R, R' are two weighted graphs on n vertices then we define

$$d_1(R, R') = \frac{1}{n^2} \sum_{i<j} |R(i, j) - R'(i, j)| \,, \tag{7}$$

and

$$d_\square(R, R') = \max_{\alpha,\beta} \frac{1}{n^2} \left| \sum_{i<j} \alpha(i)\beta(j)(R(i, j) - R'(i, j)) \right| \,, \tag{8}$$

where the maximum is taken over all functions $\alpha, \beta : [n] \to [0, 1]$.

▶ **Definition 22** ($ind(F, R)$). *Let R be a weighted graph on $[k]$ and let φ be an injective function $\varphi : V(F) \to [k]$. We set*

$$ind_\varphi(F, R) = \prod_{i<j\in E(F)} R(\varphi(i), \varphi(j)) \prod_{i<j\notin E(F)} (1 - R(\varphi(i), \varphi(j)))$$

In the case of φ not being injective, we define

$$ind_\varphi(F, R) = 0$$

Denoting by Φ the set of functions from $V(F)$ to $[k]$, we define

$$ind(F, R) = \frac{1}{|\Phi|} \sum_{\varphi\in\Phi} ind_\varphi(F, R) \,. \tag{9}$$

Note that we can think of a signature $S = (\eta_{i,j})_{1\le i<j\le t}$ as a weighted graph on t vertices. This means that for a pair of signatures S, S' we can define $d_1(S, S')$ and $d_\square(S, S')$ as in (7) and (8) respectively, and we can also define $ind(F, S)$ as in (9). We will need the following lemmas from [25]. The proof of the next two lemmas will appear in the journal version of the paper.

▶ **Lemma 23.** *Suppose R, R' are two weighted graphs on n vertices, and H is a graph on h vertices. Then for any $\gamma \geq d_{\square}(R, R')$ and $n \geq \frac{2}{\gamma}$, we have $|ind(H, R) - ind(H, R')| \leq 2h^2 \cdot \gamma$*

Given a graph G on n vertices, and an equipartition $A = \{V_1, \dots, V_k\}$, we define the graph G_A on $V(G)$ to be the weighted graph with weights $G_A(u, v) = d(V_i, V_j)$ for every $u \in V_i$ and $v \in V_j$. Let S_A be the 0-signature of A, that is, the weighted graph on k vertices with $S(i, j) = d(V_i, V_j)$. Observe that if k divides n (so all sets of A are of equal size) then $ind(H, G_A)$ is almost the same as $ind(H, S_A)$. It is not hard to see that for general equipartitions these quantities do not differ my much.

▶ **Lemma 24.** *Given a graph G on n vertices, and an equipartition $A = \{V_1, \dots, V_k\}$, let G_A and S_A be defined as above. Then $|ind(H, G_A) - ind(H, S_A)| \leq \frac{2h^2}{k} + \frac{2kh}{n}$ for every graph H on h vertices.*

We now combine the above facts to conclude that a signature of a γ-FK-partition of a graph gives a good approximation of $ind(H, G)$. The proof of the next lemma will appear in the journal version of the paper.

▶ **Lemma 25.** *For every h, k and $\delta > 0$ there are*

$$\gamma = \gamma_{25}(h, \delta) = \text{poly}(\delta/h), \quad r = r_{25}(h, \delta) = \text{poly}(h/\delta), \quad N = N_{25}(h, k, \delta) = \text{poly}(hk/\delta) ,$$

so that if G is a graph on at least N vertices, and A is a γ-FK-regular partition of G with at least r and up to k parts, then for every γ-signature S of A, we have $|ind(H, G) - ind(H, S)| \leq \delta$ for every H on h vertices.

▶ **Definition 26** (Extension)**.** *Given a signature $S = (\eta_{ij})_{1 \leq i < j \leq t}$ of an equipartition A, and a refinement $B = \{W_1, \dots, W_s\}$ of A, the extension of S to B is the sequence $S' = (\eta'_{ij})_{1 \leq i < j \leq s}$ defined as $\eta'_{i,j} = \eta_{k,l}$ if there exist $k \neq l$ such that $W_i \subseteq V_k$ and $W_j \subseteq V_l$, and setting $\eta'_{i,j} = 0$ if W_i and W_j are both subsets of the same V_k.*

The proof of the next claim will appear in the journal version of the paper.

▷ Claim 27. For every ε and s there exists $r = r_{27}(\varepsilon) = \text{poly}(1/\varepsilon)$ and $N = N_{27}(\varepsilon, s) = \text{poly}(s/\varepsilon)$ so that the following holds for every pair of graphs G, G' on the same set of $n \geq N$ vertices. If G, G' are α-close and S, S' are γ, γ'-signatures of G, G' respectively, of the same equipartition A of the vertex set of G, G' into $s \geq r$ sets, then $d_1(S, S') \leq \alpha + \varepsilon + 2(\gamma + \gamma')$.

The proof of the next lemma will appear in the journal version of the paper.

▶ **Lemma 28.** *For every ε and t there exists $\gamma = \gamma_{28}(\varepsilon) = \text{poly}(\varepsilon)$ and $N = N_{28}(t, \varepsilon) = \text{poly}(t/\varepsilon)$, so that for every graph G on $n \geq N$ vertices, if S is a γ-signature of a γ-FK-regular* partition A of G with t sets, then for every signature S' satisfying $d_1(S, S') \leq \delta$ for some δ, there is a graph G' that is $(\delta + \varepsilon)$-close to G, so that A is an ε-FK-regular partition of G', and S' is an ε-signature of A.*

We will also need the following lemmas.

▶ **Lemma 29** ([2] Lemma 3.7)**.** *For every ε, t there exists $\gamma = \gamma_{29}(\varepsilon) = \text{poly}(\varepsilon)$ and $N = N_{29}(t, \varepsilon) = \text{poly}(t/\varepsilon)$ satisfying the following. Assume A is an equipartition into s sets of a graph G with $n \geq N$ vertices, and that B is a refinement of A into at most t sets. Assume further that S is any γ-signature of A, and that T is its extension to B. If B satisfies $ind(B) \leq ind(A) + \gamma$, then T is an ε-signature for B.*

▶ **Lemma 30** ([16] Lemma 6.6). *For every ε, t there exists $N = N_{30}(t, \varepsilon) = \mathrm{poly}(t/\varepsilon)$ so that for every equipartition A of G with $n \geq N$ vertices into s sets, and every refinement B of A into at most t sets, $ind(B) \geq ind(A) - \varepsilon$.*

The next observation is implicit in the proof of the Frieze–Kannan Regularity Lemma (i.e. Lemma 21). The main step of the proof involves showing that if A is an equipartition of G into t parts and A is not ε-FK-regular*, then A has a refinement B into $k \leq 16t/\varepsilon^4$ sets so that $ind(B) \geq ind(A) + \frac{\varepsilon^4}{2}$ (see, e.g., the proof of Theorem 1.1 in [33] and the proof of Theorem 6 in [29]).

▶ **Lemma 31.** *For every $\varepsilon > 0$ there exists $\gamma = \gamma_{31}(\varepsilon) = \mathrm{poly}(\varepsilon)$ and $f = f_{31}^{(\varepsilon)} : \mathbb{N} \to \mathbb{N}$ satisfying $f(x) = \mathrm{poly}(1/\varepsilon) \cdot x$ and such that every (f, γ)-final partition of a graph is also ε-FK-regular*.*

The proof of the next lemma will appear in the journal version of the paper.

▶ **Lemma 32.** *For every s and $\varepsilon > 0$ there are $\gamma = \gamma_{32}(\varepsilon)$, $T = T_{32}(s, \varepsilon)$, $f = f_{32}^{(\varepsilon)}$ and $N = N_{32}(\varepsilon, s)$ so that*

$$\gamma = \mathrm{poly}(\varepsilon), \quad T = s \cdot 2^{\mathrm{poly}(1/\varepsilon)}, \quad f(x) = x \cdot 2^{\mathrm{poly}(1/\varepsilon)}, \quad N = \mathrm{poly}(s) \cdot 2^{\mathrm{poly}(1/\varepsilon)}$$

and the following holds. Suppose G has at least N vertices and A is an (f, γ)-final partition of G into at most s sets and that S is a γ-signature of A. Then for every G' on the same vertex set of G, there exists a refinement A' of A into $t \leq T$ sets so that

(i) *A' is an ε-FK-regular* partition of G'.*

(ii) *Every refinement A'' of A with $t \leq T$ sets (and in particular A'), is an ε-FK-regular* partition of G.*

(iii) *For every refinement A'' of A with $t \leq T$ sets, the extension S'' of S (in the sense of Definition 26) with respect to A'' is an ε-signature of A'' with respect to G (note that A' is such an A'').*

4.2 Proof of Lemma 15

Given h, ε and δ we first choose

$$\gamma_0 = \min\{\varepsilon/10, \gamma_{25}(h, \delta/6), \gamma_{28}(\min\{\varepsilon/2, \gamma_{25}(h, \delta/6)\})\} = \mathrm{poly}(\varepsilon\delta/h) ,$$

and then define

$$\gamma = \gamma_{32}(\gamma_0) = \mathrm{poly}(\varepsilon\delta/h), \quad s = \max\{r_{25}(h, \delta/6), r_{27}(\varepsilon/10), 20h^2/\delta\} = \mathrm{poly}(h/\varepsilon\delta) ,$$

$$f(x) = f_{32}^{(\gamma_0)}(x) = x \cdot 2^{\mathrm{poly}(1/\gamma_0)} = x \cdot 2^{\mathrm{poly}(h/\varepsilon\delta)} ,$$

to be the constants and function in the statement of Lemma 15, noting that they satisfy the guarantees of that lemma. Given t as in the statement of Lemma 15, we set

$$T = T_{32}(t, \gamma_0)$$

and define

$$N = \max\{N_{25}(h, T, \delta/6), N_{27}(\varepsilon/10, T), N_{32}(\gamma_0, s), N_{28}(t, \gamma_0)\} = \mathrm{poly}(t) \cdot 2^{\mathrm{poly}(h/\varepsilon\delta)} ,$$

to be the constant in Lemma 15.

Given a family of graphs $\mathcal{H}$ on at most h vertices, we define a family of signatures as follows

$$\mathcal{C}_{\delta,\mathcal{H},T} = \{C : |C| \leq T \text{ and } ind(H,C) \leq \delta/2 \text{ for every } H \in \mathcal{H}\}\ .$$

In order for $\mathcal{C}_{\delta,\mathcal{H},T}$ to be finite, we only put in it signatures C with edge weights $\eta_{i,j}$ that are integer multiples of $\beta = \min\{\varepsilon/10, \delta/10h^2\}$. Intuitively, this is the set of signatures "certifying" (hence C) that a graph with that signature is close to being induced $\mathcal{H}$-free. We also define $\mathcal{S}_T$ to be the set of all signatures on up to T parts, that are extensions[5] of S. Intuitively, these are the signatures one can obtain by refining A into at most T sets (recall that the crucial point is that the algorithm only has access to S and not to G).

Suppose now that we are given a γ-signature S of some (f,γ)-final (with the above defined f,γ) partition A of a graph G, so that S has $t \geq s$ parts and G has at least N vertices. The algorithm checks if there are $S' \in \mathcal{S}_T$ and $C \in \mathcal{C}_{\delta,\mathcal{H},T}$ satisfying $d_1(S',C) \leq \alpha - \frac{\varepsilon}{2}$. If there is such a pair, the algorithm says that case (i) holds, otherwise it says that case (ii) holds. We now prove the correctness of the algorithm.

Proof of first direction

Suppose there is a graph G' which is $(\alpha - \varepsilon)$-close to G, and satisfies $ind(H,G') = 0$ for every $H \in \mathcal{H}$. We will show that the algorithm will declare that case (i) holds.

Recall that A is an (f,γ)-final partition of G into $t \geq s$ sets and that S is a γ-signature of A. By Lemma 32, there exists a refinement A' of A into at most T sets so that A' is γ_0-FK-regular* for both G **and** G'. Moreover, denoting by S' the corresponding extension of S to A', we have that S' is a γ_0-signature of A' with respect to G. Note that $S' \in \mathcal{S}_T$. By the choice of γ_0, this implies that A' is $\gamma_{25}(h,\delta/6)$-FK-regular* for both G and G', and that S' is a $\frac{1}{10}\varepsilon$-signature of A' with respect to G. Let C' be the 0-signature of A' over G'. Lemma 25 (using A' and G') implies that $|ind(H,G') - ind(H,C')| \leq \delta/6$ for all $H \in \mathcal{H}$. Thus $ind(H,C') \leq \delta/6$ for all $H \in \mathcal{H}$. Clearly there is a signature C of size C' so that all of C's weights are constant multiples of β and $d_1(C',C) \leq \beta$. Since $d_\square(C',C) \leq d_1(C',C) \leq \delta/10h^2$ we infer from Lemma 23 (applied on $\frac{\delta}{10h^2}$, as $s \geq \frac{20h^2}{\delta}$) that $ind(H,C) \leq \delta/6 + \delta/5 < \delta/2$ for all $H \in \mathcal{H}$, so $C \in \mathcal{C}_{\delta,\mathcal{H},T}$. In addition, by Claim 27 (since A' has at least $r_{27}(\varepsilon/10)$ parts and assuming that n is large enough), we infer that $d_1(S',C) \leq \alpha - \frac{\varepsilon}{2}$ (since G and G' are $(\alpha - \varepsilon)$-close and $d_1(C,C') \leq \varepsilon/10$). Thus, S' and C provide a witness that the algorithm will indeed declare that case (i) holds.

Proof of second direction

Suppose the algorithm declares that case (i) holds. We show that in this case there is a graph G', which is α-close to G, and satisfies $ind(H,G') < \delta$ for all $H \in \mathcal{H}$.

Indeed, if the algorithm declared that case (i) holds then there are signatures $S' \in \mathcal{S}_T$ and $C \in \mathcal{C}_{\delta,\mathcal{H},T}$ satisfying $d_1(S',C) \leq \alpha - \frac{\varepsilon}{2}$. As $S' \in \mathcal{S}_T$, there is a refinement A' of A, so that S' is the extension of S according to A'. Lemma 32 (regarding A' as a possible

[5] Note that strictly speaking, an extension per Definition 26 must be relative to a partition A and its refinement B, while here we only have the signature S. So what we mean here is that if one takes some graph that has a partition A whose 0-signature is S, then $\mathcal{S}_T$ is the family of all signatures that one obtains by taking all refinements of A into at most T sets, and then taking the extension of S to these refinements. Of course we do not need any graph in order to produce $\mathcal{S}_T$; we just break the "parts" of S into a total of at most T new "parts", and then define the densities $\eta'_{i,j}$ between the new vertices as in Definition 26.

refinement of A with respect to G) asserts that S' is a γ_0-signature of A' (with respect to G), which by the choice of γ_0 means that it is a $\gamma_{28}(\min\{\frac{\varepsilon}{2}, \gamma_{25}(h, \delta/6)\})$-signature for A' with respect to G. Now, Lemma 28 (applied with A' as the γ_0-FK-regular* partition of G, and with S' as S and C as S') implies that there is a graph G' that is $(\alpha - \frac{\varepsilon}{2} + \frac{\varepsilon}{2})$-close to G, namely α-close to G, and for which C is a $\gamma_{25}(h, \delta/6)$-signature of A', which in turn is $\gamma_{25}(h, \delta/6)$-FK-regular over G' . Lemma 25 implies that $|ind(H, G') - ind(H, C)| \le \delta/6$ for all $H \in \mathcal{H}$. Thus, $ind(H, G') < \delta/2 + \delta/6 < \delta$ for all $H \in \mathcal{H}$ as required. Hence we have found the required G'.

5 Proof of Theorem 9

The proof of Theorem 9 is very similar to that of Theorem 4. In order to assist the reader who is already familiar with the proof of Theorem 4, we mention in several places where certain lemmas are analogous to lemmas we introduced in one of the previous sections. The idea is the following: by a theorem of Goldreich and Trevisan [22], every testable property is testable by a canonical tester, which samples a set of vertices of size $q = q_{\mathcal{P}}(\varepsilon)$ and accepts/rejects based on the graph induced by these q vertices. Hence the acceptance/rejection of the algorithm only depends on the number of induced copies in G of graphs on q vertices. Hence, turning a graph into a graph satisfying $\mathcal{P}$ is equivalent to turning it into a graph with a certain number of copies of certain graphs on q vertices. As evident, this is very similar to the case of Theorem 4 where we wanted to have a very small number of copies of graphs not in $\mathcal{P}$. The reason why there is an additional exponential factor is that we need to control the number of induced copies of *all* graphs on q vertices.

We now state the key lemmas, which are variants of lemmas we used in the proof of Theorem 4.

▶ **Definition 33.** *Given two distributions μ and ν over a finite family $\mathcal{H}$ of combinatorial structures, their variation distance is defined as:* $|\mu - \nu| = \frac{1}{2}\sum_{H\in\mathcal{H}} |\Pr_\mu(H) - \Pr_\nu(H)|$

▶ **Lemma 34.** *If two distributions μ and ν over a finite family $\mathcal{H}$ of combinatorial structures satisfy $|\mu - \nu| \le \delta$, then for any set $A \subset \mathcal{H}$ we have* $|\Pr_\mu(A) - \Pr_\nu(A)| \le \delta$

▶ **Lemma 35.** *Suppose that μ and ν are two probability distributions over graphs with set of vertices $\{v_1, \dots, v_q\}$, where each edge v_iv_j is independently chosen to be an edge with probability $\mu_{i,j}$ and $\nu_{i,j}$ respectively. If $|\mu_{i,j} - \nu_{i,j}| \le \varepsilon/\binom{q}{2}$ for every $1 \le i < j \le q$, then the variation distance between μ and ν is bounded by ε.*

▶ **Definition 36** (q-statistic)**.** *The q-statistic of a graph G is the probability distribution over all (labeled) graphs with q vertices that result from picking at random q distinct vertices of G and considering the induced subgraph. For a given graph H we denote the probability for obtaining H when drawing a graph according to the q-statistic by* $\Pr_G(H)$*.*

▶ **Definition 37.** *For an equipartition $A = \{V_1, \dots, V_t\}$ of G, and a signature $S = (\eta_{i,j})_{1\le i<j\le t}$ of A, the perceived q-statistic according to S is the following distribution* $\Pr_S$ *over labeled graphs with q vertices $v_1, \dots, v_q$. Start by choosing a uniformly random sequence without repetitions of indices $i_1, \dots, i_q$ from $1, \dots, t$. Then, independently, take every v_kv_l for $k < l$ to be an edge with probability η_{i_k,i_l}if $i_k < i_l$ and with probability η_{i_l,i_k}if $i_l < i_k$. Then* $\Pr_S(H)$ *is defined as the probability that the resulting labeled graph equals H.*

The following lemma will replace Lemma 1 in the proof of Theorem 9.

▶ **Lemma 38** (see [22])**.** *If there is an ε-test for a graph property $\mathcal{P}$ that makes $Q = Q(\varepsilon)$ edge queries, then there exists an appropriate family $\mathcal{H}$ of labeled graphs on $q = 2Q$ vertices such that any graph G which satisfies $\mathcal{P}$, satisfies also $\Pr_G(\mathcal{H}) \geq \frac{2}{3}$, and any graph G that is ε-far from satisfying $\mathcal{P}$, satisfies also $\Pr_G(\mathcal{H}) < \frac{1}{3}$.*

We now introduce a variant of Lemma 25 that is suited for the proof of Theorem 9. The proof of the lemma will appear in the journal version of the paper.

▶ **Lemma 39.** *For every q, ε there are $\gamma = \gamma_{39}(q,\varepsilon)$, $r = r_{39}(q,\varepsilon)$ so that*

$$\gamma = \operatorname{poly}(\varepsilon \cdot 2^{-q^2}), \quad r = \operatorname{poly}(1/\varepsilon \cdot 2^{q^2})$$

and for every γ-signature S of a γ-FK-regular equipartition A into $t \geq r$ sets, of a graph G on $n \geq N_{39}(q,\varepsilon,t) = \operatorname{poly}(t/\varepsilon)2^{\operatorname{poly}(q)}$ vertices, we have $|\Pr_S - \Pr_G| \leq \varepsilon$, where $\Pr_G$ is the q-statistic and $\Pr_S$ is the perceived q-statistic according to S.

We now introduce a variant of Lemma 15 that is suited for the proof of Theorem 9. The proof of the lemma will appear in the journal version of the paper.

▶ **Lemma 40.** *For every q and ε there exist $\gamma = \gamma_{40}(q,\varepsilon)$, $s = s_{40}(q,\varepsilon)$ and $f_{40}^{(q,\varepsilon)} : \mathbb{N} \to \mathbb{N}$, such that*

$$\gamma = \operatorname{poly}(\varepsilon \cdot 2^{-q^2}), \quad s = \operatorname{poly}\left(\frac{2^{q^2}}{\varepsilon}\right), \quad f_{40}^{(q,\varepsilon)}(x) = x \cdot 2^{\operatorname{poly}\left(\frac{2^{q^2}}{\varepsilon}\right)}$$

with the following property. For every family $\mathcal{H}$ of graphs with q vertices, there exists a deterministic algorithm, that receives as an input a γ-signature S of an (f,γ)-final partition A into $t \geq s$ sets of a graph G with $n \geq N_{40}(q,\varepsilon,t) = t \cdot 2^{\operatorname{poly}(1/\varepsilon)\cdot 2^{\operatorname{poly}(q)}}$ vertices and distinguishes given any α between the following two cases:

(i) *G is $(\alpha - \varepsilon)$-close to some graph G' for which $\Pr_{G'}(\mathcal{H}) \geq \frac{2}{3}$.*
(ii) *G is α-far from every G' for which $\Pr_{G'}(\mathcal{H}) \geq \frac{1}{3}$.*

Theorem 9 is derived from Lemmas 14 and 40, similarly to how Theorem 4 is derived from Lemmas 14 and 15. This will appear in the journal version of the paper.

Efficient Interactive Proofs for Non-Deterministic Bounded Space

Joshua Cook
Department of Computer Science, University of Texas Austin, TX, USA

Ron D. Rothblum
Faculty of Computer Science, Technion, Haifa, Israel

Abstract

The celebrated **IP** = **PSPACE** Theorem gives an efficient interactive proof for any bounded-space algorithm. In this work we study interactive proofs for *non-deterministic* bounded space computations. While Savitch's Theorem shows that nondeterministic bounded-space algorithms can be simulated by deterministic bounded-space algorithms, this simulation has a quadratic overhead. We give interactive protocols for nondeterministic algorithms directly to get faster verifiers.

More specifically, for any non-deterministic space S algorithm, we construct an interactive proof in which the verifier runs in time $\tilde{O}(n+S^2)$. This improves on the best previous bound of $\tilde{O}(n+S^3)$ and matches the result for *deterministic* space bounded algorithms, up to polylog(S) factors.

We further generalize to *alternating* bounded space algorithms. For any language L decided by a time T, space S algorithm that uses d alternations, we construct an interactive proof in which the verifier runs in time $\tilde{O}(n+S\log(T)+Sd)$ and the prover runs in time $2^{O(S)}$. For $d=O(\log(T))$, this matches the best known interactive proofs for deterministic algorithms, up to polylog(S) factors, and improves on the previous best verifier time for nondeterministic algorithms by a factor of $\log(T)$. We also improve the best prior verifier time for *unbounded* alternations by a factor of S.

Using known connections of bounded alternation algorithms to bounded depth circuits, we also obtain faster verifiers for bounded depth circuits with *unbounded* fan-in.

1 Introduction

Interactive proofs, introduced by Goldwasser Micali and Rackoff [22], are proof systems that enable a prover to convince a verifier of the truth of a given statement. The interaction proceeds in rounds where in each round the prover sends a message and the verifier responds. Crucially, in every round the verifier uses randomness that the prover cannot predict. At the end of the interaction the verifier either accepts or rejects the statement. We require that the honest prover convinces the verifier to accept true statements with high probability (and

in fact, in most[1] protocols with probability 1) and that no prover, even a computationally unbounded one, can convince the verifier to accept a false statement other than with some small probability.

One of the most celebrated results in complexity theory is that **IP** = **PSPACE** [26, 34]. That is, the set of languages with polynomial space algorithms is exactly the set of languages with interactive protocols whose verifiers run in polynomial time. Interactive proofs have been prolific throughout other areas of complexity theory, including circuit lower bounds [33, 28], pseudorandomness from uniform assumptions [42], and has also been very influential in other proof systems, such as MIPs [5], PCPs [6, 14, 4, 3], and IOPs [7, 32].

The **IP** = **PSPACE** result can be generalized to any deterministic bounded space computation. For a space S deterministic algorithm, the interactive protocols with the fastest verifiers [9, 40] have a time $\tilde{O}(n + S^2)$ verifier and time $2^{O(S)}$ prover, where $\tilde{O}$ hides polylog(S) factors.[2]

In this work we study interactive proofs for more general forms of bounded space computations: *non-deterministic bounded space* and *alternating bounded space*. Recall that a non-deterministic space S algorithm is a space S Turing machine that gets in addition *read-once* access to a witness (which can be as long as 2^S). For example, the complexity class **NL** refers to non-deterministic logarithmic-space algorithms. Alternating algorithms are a generalization of nondeterministic algorithms that can "alternate" quantifiers. The prior best protocols [9] for space S nondeterministic algorithms have verifier time $\Omega(n + S^3)$, which is an S factor slower than the best verifiers for deterministic algorithms. See Table 1 for a more complete comparison with prior works.

1.1 Our Results

Our main result is an improved interactive proof for alternating algorithms. We start by highlighting a special-case of this result for nondeterministic bounded-space algorithms. We construct interactive proofs for space S nondeterministic algorithms whose verifier runs in time $\tilde{O}(n + S^2)$, matching the time bound for deterministic verifiers (up to polylog(S) factors). Broadly, our techniques combine the recent verifier efficient interactive proofs for bounded space by Cook [9], with an efficient interactive proof for $\mathbf{AC}^0_{\oplus}$ circuits of Goldreich and Rothblum [20], and an improved derandomization through random walks on expander graphs.

The new interactive proof for non-deterministic bounded space is a special case of a more general result that we show for alternating bounded space algorithms. To state the result precisely, we first set up the notation. Let $\mathbf{ATISP}_d[T, S]$ be the set of languages decided by a simultaneous time T, space S and d alternation algorithm. Alternating algorithms have 3 tapes, a read only input tape containing the input, a read once input containing a witness, and a work tape. Only the work tape is limited to have space S. The input tape is read only, but can be read many times. The witness tape can have T symbols on it, but must be read sequentially and each symbol can only be read once. The witness can be thought of as being separated into d segments, each with a different quantifier. The change of quantifier is called an alternation. For example, nondeterministic algorithms have $d = 1$ since they only use existential quantifiers.

[1] By [17], probability 1 can always be achieved, but that reduction has a significant cost to the prover's runtime.

[2] Throughout this work we mostly optimize for verification time and leave the proving time as a secondary consideration. This is in contrast to *doubly efficient interactive proofs* (see [19]) in which we insist on a polynomial-time prover. In this "doubly-efficient" regime, interactive proofs with a polynomial-time prover and almost linear time verifier are known for linear depth, poly-size, uniform circuits [21] and poly-time and bounded-poly space computation [32].

Let $\mathbf{ITIME}[T_V, T_P]$ be the set of languages with an interactive proof whose verifier runs in time T_V and whose prover runs in time T_P. If T_P is omitted, we assume it is the trivial bound of $T_P = O(2^{T_V})$. In this paper, all our protocols are public-coin and have perfect completeness.

Our most general result is an interactive protocol for alternating bounded-space algorithms.

▶ **Theorem 1** (Interactive Proof For Alternating Space). *For any T, S, and d constructible in time $O(S\log(T))$ and space $O(S)$:*

$$\mathbf{ATISP}_d[T,S] \subseteq \mathbf{ITIME}\left[\tilde{O}\left(n + S\log(T) + Sd\right), 2^{O(S)}\right].$$

Further, the verifier runs in space $O(S\log(d+S))$, the protocol is public coin, has $O(S\log(S)(\log(T)+d))$ rounds, $O(S\log(S)(\log(T)+d)\log(d+S))$ bits of communication, and perfect completeness.

For $d = O(\log(T))$, up to small polylog(S) factors, our protocol has the same verifier time and prover time as the best known protocol for deterministic bounded space algorithms [9]: verifier time $\tilde{O}(n + S\log(T))$ and prover time $2^{O(S)}$. As a special case for nondeterministic algorithms, this gives an interactive protocol with verifier time $\tilde{O}(n + S\log(T))$, improving upon the nondeterministic algorithms in [9], whose verifiers required time $\tilde{O}(n + S\log(T)^2)$, by a factor of $\log(T)$. We note $\log(T)$ may be as large as S.

In a limited sense, these results could be seen as tight, as they match, up to polylog(S) factors, the best known results for simulating deterministic algorithms by alternating ones. Chandra, Kozen, and Stockmeyer [8] show that any deterministic algorithm running in time T and space S has an alternating algorithm running in time $S\log(T)$. Specifically, $\mathbf{TISP}[T,S] \subseteq \mathbf{ATISP}_{\log(T)}[O(S\log(T)), O(S)]$. If we improved our verifier time dependence on $S\log(T)$ or Sd, this would improve the time of alternating algorithms simulating deterministic ones.

For $d = T$, Theorem 1 improves over the best known interactive proofs for alternating algorithms, with unbounded alternations, by Fortnow and Lund [16], which have verifier time $\tilde{O}(n + S^2T)$ and verifier space $O(S\log(T))$. Our protocol's verifier is at least a factor S faster (when $ST = \Omega(n)$).

See Table 1 for a comparison of how our protocol compares to prior protocols for nondeterministic algorithms, and Table 2 for a comparison of how our protocol compares to prior protocols for alternating algorithms.

The best verifiers [9, 40] for deterministic algorithms have verifier time $\tilde{O}(S\log(T) + n)$, verifier space $O(S\log(S))$, and provers with time $2^{O(S)}$. The best provers [32] for deterministic algorithms have prover time $T^{1+o(1)}\mathrm{poly}(S)$, but require verifier time $T^{o(1)}\mathrm{poly}(S) + n\mathrm{polylog}(T)$. These protocols are incomparable for T much larger than S, but much smaller than 2^S. For a more comprehensive summary, see the full version [11].

Table 1 Comparison of different protocols for $\mathbf{NTISP}[T,S]$ with polylog(S) factors omitted.

$\mathbf{NTISP}[T,S]$	Verifier Time	Verifier Space	Prover Time
[34]	$(n+S)\log(T)^2$	$(n+S)\log(n+T)$	$2^{\mathrm{poly}(S,n)}$
[16]	$n + S^3\log(T)$	$S\log(S)$	$2^{\mathrm{poly}(S,n)}$
[21]	$n + S^2\log(T)$	$S\log(S)$	$2^{O(S)}$
[9]	$n + S\log(T)^2$	$S\log(T)$	$2^{O(S)}$
This Work	$n + S\log(T)$	$S\log(S)$	$2^{O(S)}$

Table 2 Comparison of different protocols for $\mathbf{ATISP}_d[T, S]$ with polylog(S) factors omitted.

$\mathbf{ATISP}_d[T, S]$	Verifier Time	Verifier Space	Prover Time
[34]	$(n + S(\log(T) + d))S(\log(T) + d)$	$n + S\log(T) + Sd$	$2^{\text{poly}(S,n)}$
[16]	$n + S^2T$	$S\log(T)$	$2^{\text{poly}(S,n)}$
[21]	$n + S^2\log(T) + S^2d$	$S\log(S + d)$	$2^{O(S)}$
[9]	$n + (S\log(T) + Sd)^2$	$S\log(T) + Sd$	$2^{O(S\log(T)+Sd)}$
This Work	$n + S\log(T) + Sd$	$S\log(S + d)$	$2^{O(S)}$

When $S = O(\log(n))$, our prover runs in polynomial-time. This gives us doubly efficient proofs for alternating algorithms with few alternations and logarithmic space. As a special case, we give doubly efficient interactive proofs for **NL** where the number of bits communicated is $\tilde{O}(\log(n)^2)$. This improves on the amount of communication achieved by GKR (specialized for **NL**), which uses $\tilde{\Omega}(\log(n)^3)$ bits of communication.

▶ **Corollary 2** (Doubly Efficient Interactive Proofs for **NL**). **NL** *has interactive protocols whose provers run in polynomial time, verifiers run in quasilinear time, verifiers use* $\tilde{O}(\log(n))$ *space, the protocol uses* $\tilde{O}(\log(n)^2)$ *rounds,* $\tilde{O}(\log(n)^2)$ *bits of communication, is public coin and has perfect completeness.*

More generally, our protocols for nondeterministic algorithms use a factor $\log(T)$ less communication then the previous best protocols by Cook, and match the best prior protocols for deterministic algorithms, up to polylogarithmic factors.

1.1.1 Unbounded Fan in Circuit Results

Let $\mathbf{SIZE}-\mathbf{DEPTH}[2^S, d]$ be the set of space $O(S)$ uniform circuits of size 2^S and depth d with *unbounded* fan in AND and OR gates. Let T-uniform $\mathbf{SIZE}-\mathbf{DEPTH}[2^S, d]$ be the set of time T uniform, space S circuits of size 2^S and depth d with *unbounded* fan in AND and OR gates. Then due to a close relationship between alternating circuits and low depth circuits by Ruzzo and Tompa [37] (see the full version [11]), we have

▶ **Theorem 3** (Uniform Shallow Circuits Have Fast Interactive Proofs). *For any d, T, S constructible in time $O(S\log(T))$ and space $O(S)$, we have*

$$T\text{-uniform } \mathbf{SIZE}-\mathbf{DEPTH}\left[2^S, d\right] \subseteq \mathbf{ITIME}\left[\tilde{O}(n + S\log(T) + Sd), 2^{O(S)}\right]$$
$$\mathbf{SIZE}-\mathbf{DEPTH}\left[2^S, d\right] \subseteq \mathbf{ITIME}\left[\tilde{O}(n + S^2 + Sd), 2^{O(S)}\right].$$

Further, the verifier runs in space $O(S\log(d + S))$ and the protocol is public coin and has perfect completeness.

For fan in 2 circuits, this matches the verifier time of GKR [21], while the prover time remains polynomial in the circuit size[3]. For unbounded fan in circuits, or for alternating algorithms, our verifier is a factor of S faster than GKR.

[3] Note however that recent improvements [12, 39, 44, 45] of GKR have a (close to) linear prover, whereas our prover is only polynomial in the circuit size.

1.2 Proof Overview

We start by reviewing our efficient interactive proofs for deterministic algorithms. Then we explain the difficulty of extending this to nondeterministic algorithms, and how to overcome these problems. Finally we show how to extend this technique to alternating algorithms. We assume familiarity with the sumcheck protocol [26]. For a more detailed explanation of our interactive proofs for deterministic algorithms, see [9] or the nearly identical protocol by Thaler [41, Section 4.5.5] (see also [23, 40]).

1.2.1 Deterministic Algorithms

For a deterministic algorithm A, we first reduce the problem to repeated matrix squaring, then give an interactive protocol for that. Suppose A runs in time T on some input x and has unique start state a and accept state b. Let M be the adjacency matrix of A's computation graph on input x. Then A accepts x if and only if $(M^T)_{a,b} = 1$ (where M^T is M raised to the Tth power, *not* M transposed). For notation, we write $M_{a,b}$ as $M(a,b)$. At a high level, the idea is that if we have an interactive protocol that can reduce a claim that $M^{2i}(u,v) = \alpha$ to the claim that $M^i(u',v') = \alpha'$, then by applying this protocol $\log(T)$ times, we can verify the value of $M^T(a,b)$. We give such a reduction, but on the multilinear extensions of M^{2i} and M^i.

Like [9, 40], we reduce to matrix exponentiation and give an interactive protocol for that, instead of reducing to a quantified Boolean formula [34], or to a uniform circuit [21]. This both simplifies the protocol somewhat and makes it more efficient to compute the prover. The idea is to arithmetize these adjacency matrices, and then use a sum check [26] to reduce the statement about M^{2i} to the statement about M^i. In particular, we use the sum check for matrix exponentiation given by Thaler [39], details follow.

For a finite field $\mathbb{F}$, for any i define $\widehat{M^i} : \mathbb{F}^S \times \mathbb{F}^S \to \mathbb{F}$ as the multilinear extension of M^i. That is, $\widehat{M^i}$ is multilinear and for each $u, v \in \{0,1\}^S$ we have $\widehat{M^i}(u,v) = M^i(u,v)$. Then observe that for any i, and $u, v \in \mathbb{F}^S$ we have

$$\widehat{M^{2i}}(u,v) = \sum_{w \in \{0,1\}^S} \widehat{M^i}(u,w)\widehat{M^i}(w,v).$$

To see that this formula is correct, first observe that it is correct for *Boolean* values as it precisely corresponds to the definition of matrix multiplication. So the formula is correct on Boolean values. Since both sides of the equation are multi-linear[4], it follows that the formula holds for all values.

Then, we can use the sum check of [26] to reduce this to a claim that for some $w' \in \mathbb{F}^S$ and some $\beta \in \mathbb{F}$ we have $\beta = \widehat{M^i}(u,w')\widehat{M^i}(w',v)$. Then using a multi-point reduction, as was done in GKR [21], we reduce this to a claim that for some $u', v' \in \mathbb{F}^S$ and $\alpha' \in \mathbb{F}$ we have that $\alpha' = \widehat{M^i}(u',v')$.

Finally running this $\log(T)$ times gives the interactive protocol for deterministic algorithms, since the verifier can efficiently calculate $\widehat{M}$ itself.

[4] To show it is multilinear, we take any variable, say u_i, and show the formula is linear in u_i. For any w see that $\widehat{M^i}(u,w)$ is linear in u_i since $\widehat{M^i}$ is multilinear, and $\widehat{M^i}(w,v)$ is constant in u_i. Thus $\sum_{w \in \{0,1\}^S} \widehat{M^i}(u,w)\widehat{M^i}(w,v)$ is linear in u_i.

We remark that, using linearization type ideas (as in [35]), the above can be extended from the task of deciding whether a deterministic algorithm accepts, to verifying the multilinear extension of a function that the algorithm computes. This will be important for us later on when we use the above interactive proof as a subroutine in the protocol for nondeterministic algorithms.

1.2.2 Nondeterministic Algorithms and Changing Arithmetization

To try to apply this technique to a nondeterministic algorithm, A, we immediately encounter an issue with how to formulate the problem. Namely, if we are doing arithmetic over $\mathbb{Z}$, if the underlying matrix M corresponds to a non-deterministic computation, then the matrix $M^T_{a,b}$ is no longer 1 if and only if A accepts x. Rather, $M^T_{a,b}$ specifies the number of length T paths from a to b. This might be as large as $2^{\Omega(T)}$. If we do arithmetic over a field of characteristic q, then $M^T_{a,b}$ is the number of paths mod q. If the number of paths is some adversarial product of many small primes, we may need $q = \Omega(T)$ for the number of accepting paths to be non zero, mod q. This gave the less efficient verifier time for nondeterministic algorithms in [9].

We will still solve this problem by arithmetization, but we need to change our matrix multiplication from a field matrix multiplication to a binary multiplication, then arithmetize that. We define the matrix multiplication with binary operations where multiplication is AND and addition is OR. So let $M^{(2)} : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ denote this binary matrix multiplication, squaring, so that for any $u, v \in \{0,1\}^S$ we have

$$M^{(2i)}(u,v) = \bigvee_{w\in\{0,1\}^S} M^{(i)}(u,w)M^{(i)}(w,v).$$

With this form of matrix exponentiation, it suffices to check if $M^{(T)}_{a,b} = 1$. To do so, we convert binary matrix multiplication into an algebraic circuit. The obvious approach is to use a formula like

$$\tilde{M^{(2i)}}(u,v) = 1 - \prod_{w\in\{0,1\}^S} \left(1 - \widehat{M^{(i)}}(u,w)\cdot\widehat{M^{(i)}}(w,v)\right).$$

Unfortunately, this has too high of individual degree: 2^S. One can insert some linearization operations between the multiplications to reduce the degree, like those used by Shen [35]. But then for each of the S variables in w, one would need to add $O(S)$ linearization operations, giving a size $O(S^2)$ algebraic circuit, which we cannot afford.

Instead, we use an idea of Goldreich and Rothblum [20] to probabilistically reduce the degree of these large conjunctions by leveraging the Razborov-Smolensky [31, 36] approximation of large disjunctions as low degree polynomials. Razborov-Smolensky give a reduction from a large disjunction to a random parity check that succeeds with high probability:

$$\forall g \in \{0,1\}^n : \Pr_{r\in\{0,1\}^n}\left[\bigvee_{i\in[n]} g_i = \sum_{i\in[n]} g_i r_i \pmod 2\right] \geq \frac{1}{2}.$$

We note that if $g = 0^n$, then for any r, we have $\sum_{i\in[n]} g_i r_i \pmod 2 = 0$. That is, the error is one sided. The formula $\sum_{i\in[n]} g_i r_i \pmod 2$ is a linear polynomial in a field of characteristic 2. As this is useful for us, we shall only work with fields of characteristic 2 in this paper.

Then, taking an OR of k independent choices of randomness, we get an individual degree k polynomial that succeeds with probability $1 - \frac{1}{2^k}$. If $n = 2^S$ and $k = S$, this gives us a degree $\log(n)$ polynomial for the disjunction that is only wrong with probability $\frac{1}{n}$.

The idea is to replace our boolean formula with a low degree polynomial through Razborov-Smolensky. So let $D_r : \{0,1\}^\ell \times \{0,1\}^S \to \{0,1\}$ be a function outputting our random bits. Here $2^\ell = k = O(S)$ is the number of choices of random bits. Then our new approximation for $M^{(2i)}$ is

$$\widetilde{M^{(2i)}}(u,v) = 1 - \prod_{j\in\{0,1\}^\ell} \left(1 - \sum_{w\in\{0,1\}^S} D_r(j,w)\widehat{M^{(i)}}(u,w)\widehat{M^{(i)}}(w,v) \right). \tag{1}$$

Now we only need to insert $\ell = \log(S)$ levels of linearizations. In the technical details of the paper, we will not actually use algebraic circuits with linearization operations, but will work with these polynomials directly with an "unlinearization" procedure, to avoid discussing circuit uniformity.

1.2.3 Efficient Randomness

At this point we encounter a problem - Equation (1) calls for sampling $2^{\ell+S}$ random bits for D_r, which we cannot afford (since we want our verifier to run in time $\tilde{O}(S)$). So as in GR, we need to sample these using an ϵ biased set. For our ϵ biased set, we use the same one as GR, described in [1] (which is based on a Reed-Solomon code concatenated with a Hadamard code).

Thus, for every value of $j \in \{0,1\}^\ell$, we would like to set $D_r(j,\cdot)$ to be an ϵ-biased set. As $\ell = \log(S)$, if we were to sample these independently, as in GR (i.e., the protocol given in [20]), our verifier would require $O(S^2)$ bits of randomness. Instead, we sample these small bias sets in a correlated manner - via a random walk on an expander (each node in the expander specifies a seed for a small bias set). We use the Margulis [27] expander since it is a constant degree, constant spectral expander with extremely simple edge descriptions: simple additions and subtractions. This makes it very easy to take a start vertex and a (specification of a) random walk and compute any given step on that walk in both small space and small time.

Thus, we only require $R = O(S)$ truly random bits to describe a length $O(S)$ random walk on the ϵ biased sets described by a Reed-Solomon code concatenated with a Hadamard code. So let $D : \{0,1\}^R \times \{0,1\}^\ell \times \{0,1\}^S \to \{0,1\}$ be a function that generates our pseudorandomness, given R bits of true randomness. The verifier first chooses that randomness r, and then $D_r(j,w) = D(r,j,w)$.

Since D is both space and time efficient, we can have the prover compute its value for the verifier, and then have the verifier run the *deterministic* interactive protocol to confirm its value. In contrast, the GR verifier must calculate some low degree extension of D_r directly to use a constant number of rounds. This saves us time over GR.

Finally, as in GR, there is a chance that our pseudorandom bits give a polynomial that fails to compute the disjunctions correctly. In this case, to get perfect completeness we need to prove that the pseudorandom bits are incorrect. To do this, the prover just finds a disjunction closest to the input where the low degree approximation fails and tells the verifier where it fails. This would be a gate where its value in the low degree polynomial is one thing, but one of its input gates should force it to be something else. For instance, an OR gate with a value of 0, and an input to it with a value of 1. Then the verifier can run the interactive protocol to confirm that the low degree polynomial indeed says the gate's value conflicts with its input gate value, showing the pseudorandom bits were bad.

1.2.4 Alternating Algorithms In Terms Of Nondeterministic Algorithms

To use our protocol with alternating algorithms, we want to reduce the alternating algorithm to one with a few large disjunctions or conjunctions over a nondeterministic algorithm. This is similar to what is done when converting alternating algorithms to alternating circuits. Once we have few conjunctions and disjunctions over a nondeterministic algorithm, we can do the same low degree approximations again.

The idea is to, instead of quantifying over the symbols in the read once proof, quantify over the potential states the algorithm could be in when the quantifier changes. Then a nondeterministic algorithm describes if a proof could cause the state to change from one intermediate state to the next when the quantifier changes.

For example, suppose A is an algorithm with $d = 2$ alternations and running in space S recognizing language L. Think of A as a deterministic algorithm taking a proof and outputting true or false. Then since A is an alternating algorithm, $x \in L$ if and only if

$$\forall \text{BigProof1} : \exists \text{BigProof2} : A(x, (\text{BigProof1}, \text{BigProof2})).$$

We can instead be more fine grain with A and talk about its states. Let a be the start state of A and b be its unique accept state. Let B be the algorithm which takes an initial state u a final state v and a proof p, then checks if A starting at u is at state v when given the proof p after time $|p|$. Then our algorithm accepts x if and only if

$$\forall w \in \{0,1\}^S : ((\exists \text{Proof1} : B(x, a, w, \text{Proof1})) \implies (\exists \text{Proof2} : B(x, w, b, \text{Proof2}))) .$$

If we know how long Proof1 is supposed to be, we can replace

$$\exists \text{Proof1} : B(x, a, w, \text{Proof1})$$

with a nondeterministic algorithm C. Then our alternating algorithm becomes

$$\forall w \in \{0,1\}^S : C(x, a, w) \implies C(x, w, b).$$

Now, beside our nondeterministic algorithm, we are only quantifying over a variable of size $O(S)$, whereas Proof1 has size $O(T)$.

For a more general example, we can replace

$$\forall \pi_1 : \exists \pi_2 : \forall \pi_3 : \exists \pi_4 : A(x, (\pi_1, \pi_2, \pi_3, \pi_4))$$

with

$$\forall w_1 : C(x, a, w_1) \implies (\exists w_2 : C(x, w_1, w_2) \wedge (\forall w_3 : C(x, w_2, w_3) \implies C(x, w_3, b))).$$

1.2.5 Protocols for Alternating Algorithms

At this point, each quantification is now only over S variables, so we can use the same trick as before to replace these quantifications with low degree polynomials. Each of the universal quantifiers gets replaced with a large conjunction, and each of the existential quantifiers gets replaced with a large disjunction. Then we use Razborov-Smolensky to replace these conjunctions and disjunctions with low degree polynomials and use an interactive proof to remove the quantifiers one by one.

A few subtleties show up when doing this. One subtlety of this process is that in a straightforward reduction, a d alternation algorithm would give our verifier a claim about C at d different places. Running an interactive protocol d times to confirm each of these d

claims independently would require time $dS\log(T)$, which is too much for us. Instead, we need to use a multi point reduction again to reduce this to a claim about C at one location before running an interactive protocol to confirm that value.

Another subtlety is that it is not convenient to represent C as a nondeterministic algorithm taking two states as an input and checking if there is a computation path from one to the other. It is more convenient to describe C directly with the computation graph of A (now viewing A as a nondeterministic algorithm). For this to work, we need to make sure each alternation takes the same amount of time, say T. Then we write $C(x, u, v) = \widehat{M_x^{(T)}}(u, v)$.

So for example, consider the simple case of a 2 alternation algorithm. That is, suppose we want to verify that

$$\forall w \in \{0,1\}^S : C(x, a, w) \implies C(x, w, b).$$

As described before, we replace C with $\widehat{M^{(T)}}$. So we want to verify

$$\forall w \in \{0,1\}^S : \widehat{M_x^{(T)}}(a, w) \implies \widehat{M_x^{(T)}}(w, b).$$

Now we need to arithmetize the formula being quantified. So let

$$\widetilde{E}(w) = 1 - \widehat{M_x^{(T)}}(a, w)(1 - \widehat{M_x^{(T)}}(w, b)).$$

See that E is low degree and agrees with the predicate $\widehat{M_x^{(T)}}(a, w) \implies \widehat{M_x^{(T)}}(w, b)$ on binary inputs. Of course, $\tilde{E}$ is not multilinear, it has individual degree 2. Luckily, if we let $\widehat{E}$ be the multilinear function consistent with D on binary inputs, then one can use an unlinearization operation (similar to those used by Shen [35]) to reduce from a statement about $\widehat{E}$ to a statement about $\widetilde{E}$. So we need to verify that

$$\forall w \in \{0,1\}^S : \widehat{E}(w).$$

Using our low degree approximation, our verifier first chooses D_r, then wants to check if

$$1 = \prod_{j \in \{0,1\}^\ell} \left(1 - \sum_{w \in \{0,1\}^S} D_r(j, w)(1 - \widehat{E}(w)) \right). \tag{2}$$

Then we can reduce this to a statement about $\widehat{D_r}$ at a random location, and $\widehat{E}$ at a random location by using $\ell = O(\log(S))$ product reductions. We can unlinearize the statement about $\widehat{E}$ to get a claim about $\widetilde{E}$, or equivalently, about $\widehat{M_x^{(T)}}$ at two locations. Now we can verify the value of $\widehat{M_x^{(T)}}$ by using our protocol for nondeterministic algorithms. But to avoid doing this twice, we first run a multi-point reduction to reduce this to a statement about $\widehat{M_x^{(T)}}$ at one location first.

We can do a similar thing d times for an alternating algorithm. One more subtlety is that for $d > 2$, we need to make $\widehat{E}$ a function of a and b. This is so that we can view the formula in Equation (2) as a function of a and b so we can properly linearize and unlinearize it with respect to a and b. See the full proof for details.

▶ Remark 4 (Proof For Unbounded Fan in Depth Circuits Directly). We could have made an interactive protocol for unbounded fan-in circuits directly. After all, we start with a formula that is essentially the low depth, unbounded fan in circuit for an alternating algorithm, if we view C as a low depth circuit. We can think of our alternating algorithms as a particular kind of very uniform circuit. We don't give an interactive proof for circuits directly to avoid handling uniformity.

One reason we chose not to just provide an interactive protocol for circuits directly is that we need a faster interactive protocol for deterministic algorithms as a subroutine to verify our pseudorandom bits. Since we view this interactive protocol as a problem for bounded space, we find it natural to present the rest of the results in this framework.

An overview of the protocol for alternating algorithms are in Appendix A, but a full proof is given in the full version [11].

1.2.6 Extensions

We note that our paper focuses on verifier time, so we have not optimized other parameters, like verifier space. There are also some other straightforward extensions to further generalizations of alternations we don't prove here.

▶ Remark 5 (Parity Gates and Parity Quantifiers). Like GR, our techniques can also be used on alternating circuits with parity gates, or bounded space algorithms with parity quantifiers. This is clear since a parity gate is an addition gate over fields of characteristic 2, so is of low degree already.

We emphasize that our protocol is different from GR since we need more randomness efficient pseudorandom bits, efficient computation of those pseudorandom bits, more rounds of interaction to keep our degree (and thus verifier time) lower, use of an interactive protocol for deterministic algorithms as a subroutine, and by using connections between low space algorithms, low alternation algorithms, and uniform, low depth circuits.

▶ Remark 6 (Space Efficiency of Our Verifier). While we only achieve a verifier running in space $O(S\log(S))$, for any $\epsilon > 0$ we should be able to get verifier space $O(S/\epsilon)$ using standard techniques, at the cost of increasing verifier time by a factor of S^{ϵ}. Specifically, instead of using multilinear polynomials, we would use individual degree S^{ϵ} polynomials. Since we are focused on improving verifier time, we do not prove this result.

This technique was used by Shamir, Fortnow and Lund, and GKR [34, 16, 21] to give the space efficiency claimed in those papers. We state the special case where $\epsilon = \frac{1}{\log(S)}$ in our results since we want to compare verifier time.

2 Preliminaries

We assume the reader is familiar with basic complexity concepts like circuits, Turing machines, and big O notation. See [2] for a reference. For notation, we define $\tilde{O}$ to hide polylogarithmic factors in whatever is inside it in general, not specifically polylog(T) or polylog(n). That is:

▶ **Definition 7** (Big Tilde O). *For functions $f, g : \mathbb{N} \to \mathbb{N}$, we define $f(n) = \tilde{O}(g(n))$ if and only if there exists some constant c such that $f(n) = O(g(n)\log(g(n))^c)$.*

2.1 Bounded Space and Alternating Algorithms

We denote by $\mathbf{TISP}[T, S]$ languages that are computable by a Turing Machine running in time T and space S.

▶ **Definition 8** (TISP). *For functions $T, S : \mathbb{N} \to \mathbb{N}$, we say language L is in $\mathbf{TISP}[T, S]$ if there is an Turing Machine, A, running in time T and space S that decides L.*

We want interactive proofs for a generalization of nondeterministic algorithms called alternating algorithms, as was formally defined in [8]. Like how a nondeterministic algorithms have existential states where the algorithm accepts if any transition from that state accepts, alternating algorithms get both existential and accept states.

We further parameterize our alternating algorithms by the number of alternations. The number of alternations is the number of times it switches between existential and universal states, plus one. For instance, nondeterministic algorithms can be viewed as having one alternation, the second level of the polynomial hierarchy has two, and so on.

▶ **Definition 9** (**ATISP**). *For functions $T, S, d : \mathbb{N} \to \mathbb{N}$, we say a language L is in $\mathbf{ATISP}_d[T, S]$ if there is an alternating Turing Machine, A, running in time T and space S that recognizes L such that on any input x, our algorithm A only changes from no quantification to one, from existential to universal quantifiers, or from universal to existential quantifiers d times.*

So for instance, nondeterministic time T and space S algorithms would be contained in $\mathbf{ATISP}_1[T, S]$.

2.2 Interactive Proofs

An interactive proof informally is a proof system where a verifier with access to unpredictable randomness can verify a result such that if the statement is true, an honest prover can convince the verifier with high probability. And if the statement is false, no prover, no matter how powerful, can convince the verifier the statement is true above some constant probability.

For our definition of interactive time, let $\mathrm{Int}(V, P', x)$ denote the random variable that V outputs on input x when interacting with prover P'. See the full version for a more detailed definition [11]. Now we define interactive time. We note that in all our protocols, we achieve perfect completeness. That is, $c = 1$.

▶ **Definition 10** (Interactive Time ($\mathbf{ITIME}$)). *If for any language L, soundness $s \in [0, 1]$, completeness $c \in [0, 1]$, verifier V and prover P we have*
Completeness: *If $x \in L$, then $\Pr[\mathrm{Int}(V, P, x) = 1] \geq c$, and*
Soundness: *if $x \notin L$, then for any function P' we have $\Pr[\mathrm{Int}(V, P', x) = 1] \leq s$,*
then we say V and P are an interactive protocol for L with soundness s and completeness c.

If in addition verifier V runs in time T_V, soundness $s < \frac{1}{3}$, and completeness $c > \frac{2}{3}$, then

$$L \in \mathbf{ITIME}[T_V].$$

If P is also computable by an algorithm running in time T_P, we say

$$L \in \mathbf{ITIME}[T_V, T_P].$$

2.3 Expander Graphs

We will use expander graphs to create hitting samplers through the hitting properties of expanders [24]. See [43] for a more detailed review of expander graphs. We will assume some basic familiarity with graphs here.

We use an expander graph given by Margulis [27] proven by Gabber and Galil [18]. We use this expander because it's simple structure makes it very clear that we can compute random walks on it in very little time and linear space.

▶ **Lemma 11** (Efficient Expander Graphs). *For any square $n = m^2$, there exists an expander graph G with constant degree d and constant spectral expansion $\lambda < 1$.*

Let V be the vertex set of G, and $E : V \times [d] \to V$ be the edge function taking in a vertex, v, and the index of an edge, e, out of v, and outputting the other vertex incident to e. Then E can be computed in space $O(\log(n))$ and time $O(\log(n))$.

2.4 Arithmetization

A core technique of standard interactive proofs is called "arithmetization". Arithmetization is the process of converting some Boolean function, f, to a low degree formula over a larger field, $\mathbb{F}$, which agrees with f on Boolean inputs. The main function we will be arithmetizing is the state transition of Turing Machines. So for a given algorithm, on a length n input x and two states s_0 and s_1, let the state transition function $M_n(x, s_0, s_1)$ be one if and only if the algorithm on input x starting in state s_0 can transition to state s_1 in one step. See the full version for a more detailed definition [11].

We use [10, Lemma 36] for our arithmetization of the Turing Machine State transition.

▶ **Theorem 12** (Arithmetization of State Transition). *Suppose A is a space S nondeterministic algorithm with transition matrix $M_n : \{0,1\}^n \times \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ as above.*

Then we can compute the multilinear extension of M_n, denoted $\widehat{M_n} : \mathbb{F}^n \times \mathbb{F}^S \times \mathbb{F}^S \to \mathbb{F}$, in time $(n+S)\tilde{O}(\log(|\mathbb{F}|))$ and space $O((\log(S) + \log(n))\log(|\mathbb{F}|))$.

2.5 Standard Algebraic, Interactive Proof Tools

We use a few standard tools in interactive proofs. Like [21, 9, 40, 26, 34, 35], perhaps the most important tool is the original sum check from [26]. We also use an unlinearization protocol, like the one used by Shen [35]. And a multi-point reduction, like those used in [21, 9]. Similar query reductions have a long history in PCP literature [3, 15, 13, 30, 25]. To see statements of these lemmas, see the full version [11].

3 Interactive Proof For Deterministic Algorithms

Internally, our proof will need interactive proofs for deterministic algorithms. We use a variation of the deterministic protocols from [9, 40]. A full proof can be found in our full version [11], here is just an overview.

The idea of the algorithm is that for a time T algorithm A, if on an input x algorithm A has computation graph G with adjacency matrix M, then for unique start state a and end state b, algorithm A accepts A if and only if $M^T_{a,b} = 1$. Then by using a matrix square reduction repeatedly, this can be reduced to a statement about the value of $\widehat{M}$, the multilinear extension of M, at a random point. And $\widehat{M}$ can be calculated quickly using Theorem 12.

Our matrix square reduction is very similar to the matrix reduction by Thaler [39], except generalized to the case where the matrix is also a multilinear extension of a third input. The main difference with Thaler's is that we need to perform a few unlinearizations, similar to Shen's [35].

▶ **Lemma 13** (Matrix Square To Matrix Reduction). *Given a function $M : \{0,1\}^n \times \{0,1\}^S \times \{0,1\}^S \to \mathbb{F}$, denote for any $x \in \{0,1\}^n$ the matrix M_x such that $(M_x)_{u,v} = M(x, u, v)$. Then M_x^2 is defined in the usual way: $(M_x^2)_{u,v} = \sum_{w \in \{0,1\}^S} M_x(u,w)M_x(w,v)$. Now define $M^2 : \{0,1\}^n \times \{0,1\}^S \times \{0,1\}^S \to \mathbb{F}$ by $M_x^2(u,v) = (M_x^2)_{u,v}$. Let $\widehat{M}$ be the multilinear extension of M and $\widehat{M^2}$ be the multilinear extension of M^2.*

Then there is an $S+n+2$ round interactive protocol with $O((S+n)\log(|\mathbb{F}|))$ bits of communication, a verifier V that runs in time $(S+n)\tilde{O}(\log(|\mathbb{F}|))$ and space $O((S+n)\log(|\mathbb{F}|))$, and a prover P that runs in time $2^{S+n}\tilde{O}(\log(|\mathbb{F}|))$ with $O(2^{S+n})$ oracle queries to $\widehat{M}$. The protocol takes as input $\alpha \in \mathbb{F}$, $u, v \in \mathbb{F}^S$, and $x \in \mathbb{F}^n$ and acts such that

Completeness: *If $\alpha = \widehat{M^2}(x,u,v)$, then when V interacts with P, V outputs a $u',v' \in \mathbb{F}^S$, $x' \in \mathbb{F}^n$, and $\alpha' \in \mathbb{F}$ such that $\alpha' = \widehat{M}(x',u',v')$.*

Soundness: *If $\alpha \neq \widehat{M^2}(x,u,v)$, then for any prover P' with probability at most $\frac{4S+3n}{|\mathbb{F}|}$ will V output a $u',v' \in \mathbb{F}^S$, $x' \in \mathbb{F}^n$, and $\alpha' \in \mathbb{F}$ such that $\alpha' = \widehat{M}(x',u',v')$.*

Now applying this square reduction $\log(T)$ times gives our interactive proof for the multilinear extension of a space efficient function. The proof is essentially many calls to Lemma 13, along with a final check by computing $\hat{M}_n$ directly at the final point using Theorem 12.

▶ **Theorem 14** (Interactive Proof For Multilinear Extension of Bounded Space)**.** *For any function $D : \{0,1\}^n \times \{0,1\}^m \to \{0,1\}$, for any $x \in \{0,1\}^n$, denote $D_x : \{0,1\}^m \to \{0,1\}$ by $D_x(y) = D(x,y)$. Let $\widehat{D_x}$ be the multilinear extension of D_x. If D is computed by a space S time T deterministic algorithm, then there is a $(m+S+2)\log(T)$ round interactive protocol with $O((m+S)\log(T)\log(|\mathbb{F}|))$ bits of communication, a verifier V that runs in time $(n+(m+S)\log(T))\tilde{O}(\log(|\mathbb{F}|))$ and space $O((\log(n)+m+S)\log(|\mathbb{F}|))$, and a prover P that runs in time $2^{2m+2S}\log(T)\tilde{O}(\log(|\mathbb{F}|))$ which takes as input an $x \in \{0,1\}^n$, $w \in \mathbb{F}^S$ and $\alpha \in \mathbb{F}$ such that*

Completeness: *If $\widehat{D_x}(w) = \alpha$, then when V interacts with P, V accepts.*

Soundness: *If $\widehat{D_x}(w) \neq \alpha$, then for any prover P' with probability at most $\frac{(4S+3m)\log(T)}{|\mathbb{F}|}$ will V accept.*

4 Interactive Proofs For Nondeterministic Algorithms

Now we describe an interactive proof for nondeterministic algorithms because it is an interesting special case in its own right, it develops the tools needed for the more general alternating algorithm, and gives a good warm up for the general case. Here we give an outline of the proof, a full proof is in the full version [11].

But before we start, we quickly make a detour to explain that the matrix “multiplication” used here for nondeterministic algorithms is different than the one used for deterministic algorithms. For deterministic algorithms, we used standard multiplication and addition in some field. But for nondeterministic algorithms, we do binary matrix multiplication, with multiplication replaced with AND, and addition replaced with OR. To emphasize the difference, we use parentheses around the exponent to indicate we are performing binary matrix multiplication.

▶ **Definition 15** (Binary Matrix Multiplication)**.** *Let $M : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ be any function. Then by induction, define $M^{(1)} = M$ and for any i, define*

$$M^{(i+1)}(u,v) = \bigvee_w M^{(i)}(u,w)M(w,v).$$

See that if M is an adjacency matrix of a graph, then $M^{(i)}(s,t) = 1$ if and only if there is a path from s to t of length i.

▶ Remark 16. M^i is different from $M^{(i)}$ in that $M^{(i+1)}$ uses an OR function, whereas M^{i+1} uses a plus function. These are equivalent for the adjacency matrix of a deterministic algorithm, but crucially differ for a nondeterministic algorithm.

We emphasize that these binary matrix multiplications algebraically act very similarly to integer matrix multiplication. Specifically, $M^{(T)}$ can still be calculated with $\log(T)$ repeated binary squaring.

Now our goal is to replace the matrix sum check used for deterministic algorithms, with a new efficient reduction for nondeterministic algorithms. It is not clear how to do this directly, so we use a Razborov-Smolensky style low degree approximation, and give a reduction for that instead.

4.1 Extended Product Reduction

The main tool for this new reduction is this extended product reduction. This reduces a statement about the *multilinear extension* of a large product of terms to a statement about the *multilinear extension* of one term. This product reduction could be used to give a square reduction for nondeterministic algorithms directly, but is much more efficient if the number of multiplications is smaller. This is why we use Razborov-Smolensky.

The idea is to just apply many unlinearizations and product reductions, to one variable the product ranges over at a time. See the full version for a proof [11].

▶ **Lemma 17** (Extended Product Reduction). *Suppose $\widehat{f} : \mathbb{F}^\ell \times \mathbb{F}^S \to \mathbb{F}$ is multilinear. Let $g : \{0,1\}^S \to \mathbb{F}$ be defined by $g(v) = \prod_{u \in \{0,1\}^\ell} \widehat{f}(u,v)$ and let $\widehat{g}$ be the multilinear extension of g.*

Then there is an $\ell(S+1)$ round interactive protocol with $O(\ell S \log(|\mathbb{F}|))$ bits of communication, a verifier V that runs in time $\ell S \tilde{O}(\log(|\mathbb{F}|))$ and space $O((\ell + S)\log(|\mathbb{F}|))$, and a prover P that runs in time $2^{\ell+S}\tilde{O}(\log(|\mathbb{F}|))$ which takes as input $w \in \mathbb{F}^S$, and $\alpha \in \mathbb{F}$ such that

Completeness: *If $\widehat{g}(w) = \alpha$, then when V interacts with P, V outputs a $u' \in \mathbb{F}^\ell$, $v' \in \mathbb{F}^S$, and $\alpha' \in \mathbb{F}$ such that $\widehat{f}(u',v') = \alpha'$.*

Soundness: *If $\widehat{g}(w) \neq \alpha$, then for any prover P' with probability at most $\frac{l(3S+1)}{|\mathbb{F}|}$ will V output a $u' \in \mathbb{F}^\ell$, $v' \in \mathbb{F}^S$, and $\alpha' \in \mathbb{F}$ such that $\widehat{f}(u',v') = \alpha'$.*

4.2 Low degree Approximations

To use Razborov-Smolenski efficiently, we need to be able to sample and calculate our ϵ biased sets, D_r, so they work with high probability and can be calculated efficiently.

Construction of efficient ϵ-biased sets is well researched and very efficient constructions are known [29, 38] and is equivalent to constructing good, linear codes. We use the third construction in [1] as our ϵ biased sets. This is the same ϵ biased set used in [20], except that we need to sample them more efficiently.

▶ **Lemma 18** (ϵ-Biased Set). *For any S, there is an $m = O(S)$ and a function $D' : \{0,1\}^m \times \{0,1\}^S \to \{0,1\}$ such that for any $X \subseteq \{0,1\}^S \setminus \emptyset$*

$$\Pr_{r \in \{0,1\}^m}\left[\sum_{x \in X} D'(r,x) = 1 \pmod 2\right] \geq \frac{1}{4}$$

such that D' runs in $\mathrm{poly}(S)$ time and $O(S)$ space.

Now we have a D' which with constant probability correctly converts an OR to a parity. Now we need to sample enough of these so that with constant probability, we convert 2^S ORs into parities. If we take $O(S)$ independent samples of D', then with probability less than 2^{-2S} will any of these ORs fail to be converted into a parity, so by a union bound with probability at most 2^{-S} will any of them fail to be converted into parity. Of course, we can not afford to take $O(S)$ samples of a string of length $O(S)$. So we take correlated samples using random walks on an expander graph.

Then by using a random walk on the Margulis expander, Lemma 11, with our ϵ biased sets as vertices, we can sample a good choice of ϵ biased sets with high probability.

▶ **Lemma 19** (Sampling a Good D for Many ORs). *Suppose for $n = 2^S$ and $m = 2^{S'}$, for each $i \in [m]$ there is an $f_i \in \{0,1\}$ and $u^i \in \{0,1\}^i$ such that $f_i = \bigvee_{j\in[n]} u^i_j$.*

Then for any ϵ, for $R = O(S + S' + \log(1/\epsilon))$, $L = 2^\ell = O(S' + \log(1/\epsilon))$, there is a space $O(S + \log(1/\epsilon))$, time $\mathrm{poly}(S + \log(1/\epsilon))$ algorithm D such that for each $i \in [m]$ define

$$F_i^r = 1 + \prod_{k\in\{0,1\}^\ell} (1 + \sum_{j\in[n]} D_r(k,j)u^i_j) \mod 2.$$

If $\forall i \in [m] : F_i^r = f_i$, then we say D_r is good for each f. Then $\Pr_r[D_r$ is not good for $f] < \epsilon$.

4.3 Interactive Proofs For Nondeterministic Algorithms

Now we give a summary of our proof, full version available at [11]. We start by defining our interactive proof we wish to run, assuming we got a good D_r. This is a square reduction, assuming we can use the Razborov-Smolensky formula to describe $M^{(2)}$. We call the Razborov-Smolensky style polynomial given by our pseudorandomness D as "M relative to D". We say that our D_r is good if $M^{(T)}$ relative to D is $M^{(T)}$. If D_r is good, we are done. Otherwise, D_r is bad, and makes some mistake first. Then we give an interactive proof to show where it is bad.

First, we formally define M relative to D.

▶ **Definition 20** (M Relative to D). *For any $M : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$, and $D : \{0,1\}^\ell \times \{0,1\}^S \to \mathbb{F}$, we define M relative to D as the functions, for $k = 1$, $M_D^{(1)} = M_D = M$, and for any $k > 1$ the function $M_D^{(2^k)} : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ is*

$$M_D^{(2^k)}(u,v) = 1 + \prod_{j\in\{0,1\}^\ell} (1 + \sum_{w\in\{0,1\}^S} D(j,w)M_D^{(2^{k-1})}(u,w)M_D^{(2^{k-1})}(w,v)).$$

Similar to the deterministic case Lemma 13, we have a repeated square reduction for M relative to D. This is based on an extended product reduction, Lemma 17, and a sum check.

▶ **Lemma 21** (Repeated Square Reduction For M relative to D). *For some $M : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$, let $\widehat{M}$ be the multilinear extension of M and $\widehat{M^{(2)}}$ be the multilinear extension of $M^{(2)}$. For some $D : \{0,1\}^\ell \times \{0,1\}^S \to \mathbb{F}$ and $T = 2^t$ let $\widehat{M_D^{(T)}}$ be the multilinear extension of M relative to D given by Definition 20.*

Then there is an $O(\ell S \log(T))$ round interactive protocol with $O(\ell S \log(T) \log(|\mathbb{F}|))$ bits of communication, a verifier V that runs in time $\ell S \log(T)\tilde{O}(\log(|\mathbb{F}|))$ and space $O((S + \ell)\log(|\mathbb{F}|))$, and a prover P (with access to the truth table of M and D) that runs in time $2^{O(\ell+S)}\tilde{O}(\log(|\mathbb{F}|))$ which takes as input $u, v \in \mathbb{F}^S$, and $\alpha \in \mathbb{F}$ such that

Completeness: *If $\widehat{M_D^{(T)}}(u,v) = \alpha$, then when V interacts with P, V outputs a $u', v', w' \in \mathbb{F}^S$, $j' \in \mathbb{F}^\ell$, and $\alpha', \beta' \in \mathbb{F}$ such that $\widehat{M}(u', v') = \alpha'$ and $D(j', w') = \beta'$.*

Soundness: *If $\widehat{M_D^{(T)}}(u,v) \neq \alpha$, then for any prover P' with at most $\frac{\log(T)(\ell+2)(6S+2)}{|\mathbb{F}|}$ probability will V output a $u', v', w' \in \mathbb{F}^S$, $j' \in \mathbb{F}^\ell$, and $\alpha', \beta' \in \mathbb{F}$ such that $\widehat{M}(u', v') = \alpha'$ and $D(j', w') = \beta'$.*

If D is good, this gives our interactive protocol for nondeterministic algorithms. Unfortunately, D is not always good. But if it is not good, then a prover can show the verifier where it is bad, giving us perfect completeness. See [11] for full details.

We note here that the field size in our final protocol is $|\mathbb{F}| = \text{poly}(S)$ and $l = O(\log(S))$. So the specific polylog(S) hidden by $\tilde{O}$ in our main result is $O(\log(S)^2 \text{polylog}(\log(S)))$. This is worse than the polylog(S) overhead for deterministic algorithms given in [9], which was $O(\log(S)\text{polylog}(\log(S)))$. This is because our extended product reduction is slower than a sum check, but only a $\log(S)$ factor slower.

An overview of the protocol for alternating algorithms are in Appendix A, but a full proof is given in the full version [11].

5 Open Problems

While this mostly closes the gap between the best verifier for deterministic and nondeterministic algorithms, many interesting open problems remain, including:

1. Finding a stronger relationship between verifier time (or even alternating time) and bounded space. We know, for $S \geq n$, that

   $$\mathbf{TISP}[T, S] \subseteq \mathbf{ITIME}[\tilde{O}(S \log(T))].$$

   But it is unknown whether, even with the stronger class of alternating algorithms, if

   $$\mathbf{TISP}[T, S] \subseteq \mathbf{ATIME}[o(S \log(T))].$$

2. Finding a stronger relationship between verifier time and alternating time. We know, for $T \geq n$, that

   $$\mathbf{ATISP}[T, S] \subseteq \mathbf{ITIME}[\tilde{O}(ST)].$$

   Can this factor of S in verifier time be removed?
3. Find interactive protocols for $\mathbf{BPTISP}[T, S]$ with simultaneous verifier time $\tilde{O}(n + S\log(T))$, prover time $2^{O(S)}$ *and* perfect completeness.
   Cook [9] gave a protocol with that verifier and prover time, but with imperfect completeness. Perfect completeness can be achieved in a black box way [17], but these black box reductions do not preserve the prover time.
4. Better doubly efficient proofs. In our special case of alternating algorithms, we can not get provers who run in less than exponential time, without giving sub-exponential time deterministic algorithms for nondeterministic problems.
   But even in the deterministic time and space bounded setting, for $S \geq n$, a major open problem is whether

   $$\mathbf{TISP}[T, S] \subseteq \mathbf{ITIME}[\text{poly}(S), \text{poly}(T)].$$

   We do know from [21] that

   $$\mathbf{TISP}[T, S] \subseteq \mathbf{ITIME}[\text{poly}(S), 2^{O(S)}],$$

   and from [32] that

   $$\mathbf{TISP}[T, S] \subseteq \mathbf{ITIME}[T^{o(1)}, \text{poly}(T)],$$

   but it is unknown if both the fast verifier time and prover time can be achieved simultaneously.

5. Similar verifier time for algorithms with more general kinds of quantifiers. For instance, threshold quantifiers.
Currently the most verifier efficient known interactive protocol for threshold circuits is to use shallow circuits to compute threshold and run GKR. In this paper, we showed one can do better for unbounded fan-in AND and OR gates. Can this also be done for unbounded fan-in threshold gates? This would be interesting because threshold gates seem much more powerful than AND, OR, or parity gates.

A Interactive Proofs For Alternating Algorithms

Now we a sketch of our interactive protocols for alternating algorithms. This still uses the same Razborov-Smolensky degree reduction technique used for nondeterministic algorithms to reduce the degree of large fan in AND and ORs. The main conceptual challenge is rewriting the alternating algorithm in the correct format. So we do this first. For full proofs, see the full paper [11].

A.1 Alternation Reductions For Bounded Space

To prove our interactive protocol with alternating algorithms, we first must convert our algorithm into a simpler, layered algorithm. This is closely related to the reduction from an alternating algorithm to a low depth circuit by Ruzzo and Tompa [37], and a similar reduction was used by Fortnow and Lund [16] in their interactive proof for alternating algorithms.

▶ **Definition 22** (M with d Alternations). *For any $M : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ and integer d, define M with time T and d alternations inductively on d as a function $B^d : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ by*

$d = 1$: $B^1(u,v) = M(u,v)$.

d is even

$$\begin{aligned} B^d(u,v) =& \forall w \in \{0,1\}^S : M(u,w) \implies B^{d-1}(w,v) \\ =& \neg \bigvee_{w\in\{0,1\}^S} (M(u,w) \wedge \neg B^{d-1}(w,v)) \end{aligned}$$

d is odd

$$\begin{aligned} B^d(u,v) =& \exists w \in \{0,1\}^S : M(u,w) \wedge B^{d-1}(w,v) \\ =& \bigvee_{w\in\{0,1\}^S} M(u,w) \wedge B^{d-1}(w,v). \end{aligned}$$

Our interactive proof will focus on this intermediate representation of an alternating circuit as a matrix M with d quantifiers of S variables between them. Any alternating algorithm can be converted to a problem of a matrix M (which is the computation graph of a nondeterministic algorithm) with alternations. The idea is that the quantifiers guess the states at which the alternating algorithm switches quantifiers. A more detailed relationship is shown in the full version [11].

▶ **Lemma 23** (Layered Alternating Programs). *For any $L \in \mathbf{ATISP}_d[T,S]$, there is a nondeterministic algorithm A running in time $T' = O(T)$ and space $S' = O(S)$ such that on any input x, if M is the adjacency matrix of the computation graph of A on input x, then $x \in L$ if and only if the $M^{(T')}$ with d alternations, B^d as defined in Definition 22, has $B^d(a,b) = 1$ for some unique starting state a and unique accepting state b.*

A.2 Interactive Proof For Layered Alternations

Now the rest of the proof closely follows the proof for nondeterministic algorithms, defining M with alternations relative to D, showing how an alternation reduction for M with alternations relative to D, and a protocol to show that D is bad.

A subtle difference is that our interactive protocols actually reduce a statement about our alternating algorithm, to a statement about $M^{(T)}$, where M is the adjacency matrix of a nondeterministic algorithm. So we then have to apply our interactive proofs for nondeterministic algorithms. That is, we reduce our statement about alternating algorithms to one about nondeterministic ones, which we already developed the tools for.

▶ **Definition 24** (M with d Alternations, Relative to D). *For any $M : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$, and $D : \{0,1\}^\ell \times \{0,1\}^S \to \{0,1\}$, we define M with d alternations, relative to D, inductively on d as a function $B_D^d : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ by*

$d = 1$: $B_D^1(u,v) = M(u,v)$.

d is even $B_D^d(u,v) = \prod_{k\in\{0,1\}^\ell}(1 + \sum_{w\in\{0,1\}^S} D_r(k,w)(M(u,w) + M(u,w)B_D^{d-1}(w,v))) \mod 2$.

d is odd $B_D^d(u,v) = 1 + \prod_{k\in\{0,1\}^\ell}(1 + \sum_{w\in\{0,1\}^S} D_r(k,w)(M(u,w)B_D^{d-1}(w,v))) \mod 2$.

Now there is an interactive protocol for reducing the number of alternations by 1. Similar to our product reduction for nondeterministic algorithms, it uses our extended product reduction, Lemma 17, and a sum check.

▶ **Lemma 25** (IP for M with d Alternations, Relative To D, Single Step)**.** *For any $M : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ and integer $d > 1$, $D : \{0,1\}^\ell \times \{0,1\}^S \to \{0,1\}$ let $B^d_D : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ be M with d layered alternations relative to D, as defined in Definition 24. Let $\widehat{B^d_D}$ be the multilinear extension of B^d_D.*

Then there is an $O(\ell S)$ round interactive protocol with $O(\ell S \log(|\mathbb{F}|))$ bits of communication, a verifier V that runs in time $\ell S \tilde{O}(\log(|\mathbb{F}|))$, space $O((\ell + S)\log(|\mathbb{F}|))$, and a prover P (given the truth table of M, B^d_D and D) that runs in time $2^{O(\ell+S)}\tilde{O}(\log(|\mathbb{F}|))$ which takes as input $u, v \in \mathbb{F}^S$, and $\alpha \in \mathbb{F}$ such that

Completeness: *If $\widehat{B^d_D}(u,v) = \alpha$, then when V interacts with P, V outputs a $u', v', w' \in \mathbb{F}^S$, $j' \in \mathbb{F}^\ell$, and $\alpha', \beta', \gamma' \in \mathbb{F}$ such that $\widehat{B^{d-1}_D}(w',v') = \alpha'$, $\widehat{D}(j',w') = \beta'$, and $\widehat{M}(u',w') = \gamma'$.*

Soundness: *If $\widehat{B^d_D}(u,v) \neq \alpha$, then for any prover P' with probability at most $\frac{(\ell+1)(6S+1)}{|\mathbb{F}|}$ will V output a $u', v', w' \in \mathbb{F}^S$, $j' \in \mathbb{F}^\ell$, and $\alpha', \beta', \gamma' \in \mathbb{F}$ such that $\widehat{B^{d-1}_D}(w',v') = \alpha'$, $\widehat{D}(j',w') = \beta'$, and $\widehat{M}(u',w') = \gamma'$.*

Applying this many times gives an interactive protocol reducing a statement about our alternating algorithm to one about a nondeterministic one, which we can solve using the ideas in Lemma 21.

▶ **Lemma 26** (IP for M with d Alternations, Relative To D)**.** *For any $M : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ and integer d, $D : \{0,1\}^\ell \times \{0,1\}^S \to \{0,1\}$ let $B^d_D : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$ be M with d layered alternations relative to D, as defined in Definition 24. Let $\widehat{B^d_D}$ be the multilinear extension of B^d_D.*

Then there is an $O(\ell S d)$ round interactive protocol with $O(\ell S d \log(|\mathbb{F}|))$ bits of communication, a verifier V that runs in time $\ell S d \tilde{O}(\log(|\mathbb{F}|))$, space $O((\ell + S)\log(|\mathbb{F}|))$, and a prover P (given the truth table of M, B^d_D and D) that runs in time $d2^{O(\ell+S)}\tilde{O}(\log(|\mathbb{F}|))$ which takes as input $u, v \in \mathbb{F}^S$, and $\alpha \in \mathbb{F}$ such that

Completeness: *If $\widehat{B^d_D}(u,v) = \alpha$, then when V interacts with P, V outputs a $u', v', w' \in \mathbb{F}^S$, $j' \in \mathbb{F}^\ell$, and $\alpha', \beta' \in \mathbb{F}$ such that $\widehat{M}(u',v') = \alpha'$ and $\widehat{D}(j',w') = \beta'$.*

Soundness: *If $\widehat{B^d_D}(u,v) \neq \alpha$, then for any prover P' with probability at most $\frac{d(\ell+2)(6S+2)}{|\mathbb{F}|}$ will V output a $u', v', w' \in \mathbb{F}^S$, $j' \in \mathbb{F}^\ell$, and $\alpha', \beta' \in \mathbb{F}$ such that $\widehat{M}(u',v') = \alpha'$ and $\widehat{D}(j',w') = \beta'$.*

This would be enough if D was always good, but D may be bad, which must be handled to get perfect completeness. First, let us define what it means for D to be good.

▶ **Definition 27** (D is good for M up to d Alternations)**.** *For any $M : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$, d and $D : \{0,1\}^\ell \times \{0,1\}^S \to \{0,1\}$, we say that D is good for M with up to d alternations if for all $k \in [d]$ with $k > 1$ we have $B^k_D = B^k$.*

But when D is bad, we give a protocol showing where it is bad. A similar protocol exists for non deterministic algorithms. The idea is to find the first quantifier that D is not good for, and tell them both which clause it has the wrong value on, and which input should have given it a different value.

For instance, if D would claim $(\forall y : \phi(x, y)) = 1$, but it isn't, the prover says which y gives this wrong claim, and which x would have $\phi(x, y) = 0$. Our protocol can then show the verifier that indeed D claims that $\phi(x, y) = 1$, but $\phi(x, y) = 0$ since D is correct all the way up to the quantification on y.

More detailed proofs can be found in the full version [11].

▶ **Lemma 28** (Proving D is Bad for M with Alternations). *For some $M : \{0,1\}^S \times \{0,1\}^S \to \{0,1\}$, and integer d, let $\widehat{M}$ be the multilinear extension of M. Let ℓ be an integer and $D : \mathbb{F}^\ell \times \mathbb{F}^S \to \mathbb{F}$ a multilinear function.*

Then there is a round $O(\ell S d)$ interactive protocol with $O(\ell S d \log(|\mathbb{F}|))$ bits of communication, a verifier V that runs in time $\ell S d \tilde{O}(\log(|\mathbb{F}|))$ and space $O((\ell + S)\log(|\mathbb{F}|))$, and a prover P (with access tot he truth table of M) that runs in time $d2^{O(\ell+S)}\tilde{O}(\log(|\mathbb{F}|))$ such that

Completeness: *If D is not good for M up to d alternations, then when V interacts with P, V outputs $u', v', w' \in \mathbb{F}^S$, $j' \in \mathbb{F}^\ell$, and $\alpha', \beta' \in \mathbb{F}$ such that $\widehat{M}(u', v') = \alpha'$ and $\widehat{D}(j', w') = \beta'$.*

Soundness: *If D is good for M up to d alternations, then when V interacts with P, with probability at most $\frac{d(\ell+2)(6S+2)}{|\mathbb{F}|}$ will V output $u', v', w' \in \mathbb{F}^S$, $j' \in \mathbb{F}^\ell$, and $\alpha', \beta' \in \mathbb{F}$ such that $\widehat{M}(u', v') = \alpha'$ and $\widehat{D}(j', w') = \beta'$.*

Combining all of these gives our main theorem. Again, we see that the polylogarithmic factor overhead is $O(\log(S)^2 \text{polylog}(\log(S)))$. As noted in the nondeterministic section, this is worse than the $O(\log(S)\text{polylog}(\log(S)))$ factor overhead for deterministic algorithms in [9].

For a full proof, see [11].

On the Complexity of Triangle Counting Using Emptiness Queries

Abstract

Beame et al. [ITCS'18 & TALG'20] introduced and used the Bipartite Independent Set (BIS) and Independent Set (IS) oracle access to an unknown, simple, unweighted and undirected graph and solved the edge estimation problem. The introduction of this oracle set forth a series of works in a short time that either solved open questions mentioned by Beame et al. or were generalizations of their work as in Dell and Lapinskas [STOC'18 and TOCT'21], Dell, Lapinskas, and Meeks [SODA'20 and SICOMP'22], Bhattacharya et al. [ISAAC'19 & TOCS'21], and Chen et al. [SODA'20]. Edge estimation using BIS can be done using polylogarithmic queries, while IS queries need sub-linear but more than polylogarithmic queries. Chen et al. improved Beame et al.'s upper bound result for edge estimation using IS and also showed an almost matching lower bound. Beame et al. in their introductory work asked a few open questions out of which one was on estimating structures of higher order than edges, like triangles and cliques, using BIS queries.

In this work, we almost resolve the query complexity of estimating triangles using BIS oracle. While doing so, we prove a lower bound for an even stronger query oracle called Edge Emptiness (EE) oracle, recently introduced by Assadi, Chakrabarty, and Khanna [ESA'21] to test graph connectivity.

1 Introduction

Motivated by connections to group testing, to emptiness versus counting questions in computational geometry, and to the complexity of decision versus counting problems, Beame et al. introduced the Bipartite Independent Set (shortened as BIS) and Independent Set (shortened as IS) oracles as a counterpoint to the local queries [18, 16, 19]. The BIS query oracle can be seen in the lineage of the query oracles [24, 25, 23] that go beyond the local queries. The local queries for a graph $G = (V(G), E(G))$ are: (i) degree query: given $u \in V(G)$, the oracle reports the degree of u in $V(G)$; (ii) neighbour query: given $(u \in V(G))$, the oracle reports the i-th neighbor of u, if it exists; otherwise, the oracle reports

NULL; (iii) ADJACENCY query: given u, $v \in V(G)$, the oracle reports whether $\{u, v\} \in E(G)$. There is another related query oracle RANDOMEDGE query: the oracle reports an edge uniformly at random when we query.[1]

Let us start by looking into the formal definitions of BIS and IS.

▶ **Definition 1.1** (BIPARTITE INDEPENDENT SET). Given disjoint subsets $U, U' \subseteq V(G)$, a BIS query answers whether there exists an edge between U and U' in G.

▶ **Definition 1.2** (INDEPENDENT SET). Given a subset $U \subseteq V(G)$, a IS query answers whether there exists an edge between vertices of U in G.

The introduction of this new type of oracle access to a graph spawned a series of works that either solved open questions [12, 13] mentioned in Beame et al. or were generalizations [13, 8, 6]. Beame et al. used BIS and IS queries to estimate the number of edges in a graph [4, 5]. One of their striking observations was that BIS queries were more effective than IS queries for estimating edges. This observation also fits in with the fact that IS queries can be simulated in a randomized fashion using polylogarithmic BIS queries.[2] Edge estimation using BIS was also solved in [12] albeit in a higher query complexity than [4]. There were later generalizations of the BIS oracle to estimate higher order structures like triangles and hyperedges [13, 7, 6]. On the IS front, Beame et al.'s result for edge estimation using IS oracle was improved in [11] with an almost matching lower bound and thereby resolving the query complexity of estimating edges using IS oracle. One can observe the interest generated in these (bipartite) independent set based oracles in a short span of time. The results are summarized in Table 1: a cursory glance would tell us that commensurate higher order queries were needed for estimating higher order structures (TRIPARTITE INDEPENDENT SET (shortened as TIS) for counting triangles, COLORFUL INDEPENDENCE ORACLE (shortened as CID) for counting hyperedges) if polylogarithmic number of queries is the benchmark. We provide the definitions of TIS and CID below.

▶ **Definition 1.3** (TRIPARTITE INDEPENDENT SET (TIS) [7]). Given three disjoint subsets A, B, C of the vertex set V of a graph $G(V, E)$, the TIS oracle reports whether there exists a triangle having endpoints in A, B and C.

▶ **Definition 1.4** (COLORFUL INDEPENDENCE ORACLE (CID) [9, 13]). Given d pairwise disjoint subsets of vertices $A_1, \ldots, A_d \subseteq U(\mathcal{H})$ of a hypergraph $\mathcal{H}$ ($U(\mathcal{H})$ is the vertex set of the hypergraph $\mathcal{H}$) as input, CID query oracle answers whether $m(A_1, \ldots, A_d) \neq 0$, where $m(A_1, \ldots, A_d)$ denotes the number of hyperedges in $\mathcal{H}$ having exactly one vertex in each A_i, $\forall i \in \{1, 2, \ldots, d\}$.

Notice the use of number of disjoint subsets in the definition of TIS and CID. That is why, we call TIS and CID as higher order query oracles than BIS and IS.

1.1 The open questions suggested by Beame et al. [4, 5]

For a work that has spawned many interesting results in such a short span of time, let us focus on the open problems and future research directions mentioned in [4, 5].

[1] Note that that, in RANDOMEDGE query, the probability space is the set of all edges. So, it is not actually a local query.

[2] Let us consider an IS query with input U. Let us partition U into two parts X and Y by putting each vertex in U to X or Y independently and uniformly at random. Then we make a BIS query with inputs X and Y, and report U is an independent set if and only if BIS reports that there is no edge with one endpoint in each of X and Y. Observe that we will be correct with at least probability $1/2$. We can boost up the probability by repeating the above procedure suitable number of times.

Table 1 The whole gamut of results involving Local queries [17], BIS, IS and its generalizations. † Δ is the maximum number of triangles on an edge. ‡ Both these results estimate the number of hyperedges in a d-uniform hypergraph, where d is treated as a constant. Here n, m and T denote the number of vertices, edges and triangles in a graph G, respectively. $\widetilde{\mathcal{O}}(\cdot)$ and $\widetilde{\Omega}(\cdot)$ hide a multiplicative factor of *poly*$(\log n, 1/\varepsilon)$ and $1/$*poly*$(\log n, 1/\varepsilon)$, respectively.

Q1 Can we estimate the number of cliques using polylogarithmic number of BIS queries?

Q2 Can polylogarithmic number of BIS queries sample an edge uniformly at random?

Q3 Can BIS or IS queries possibly be used in combination with local queries for graph parameter estimation problems?

Q4 What other oracles, besides subset queries, allow estimating graph parameters with a polylogarithmic number of queries?

Answers to the above questions and a discussion

Only Q2 has been resolved till now in the positive [13] as can be observed from Table 1. At its core, Q1 asks if a query oracle can step up, that is, if it can estimate a structure that is of a higher order than what the oracle was designed for. The framing of Q1 seems that Beame et al. expected a polylogarithmic query complexity for estimation of the number of cliques using BIS. Pertinent to these questions, we also want to bring to focus a work [22] where the authors mention that it seems to them that estimation of higher order structures will require higher order queries (see the discussion after Proposition 23 of [22]). They showed that $\Omega(n^2/\log n)$ BIS queries are required to separate *triangle free* graph instances from graph instances having at least one triangle. This lower bound follows directly from the communication complexity of triangle freeness testing [3]. However, the full complexity of triangle estimation using emptiness queries like BIS remains elusive. It seems to us that the observations in [4, 5] and [22] about the power of BIS in estimating higher order structures stand in contrast. In this backdrop, we have almost resolved the lower bound for estimating triangles using BIS queries, and our upper bound result show that even if BIS can not estimate triangles using polylogarithmic queries but it is still more powerful than LOCAL + RANDOM EDGE queries on graph for estimating triangles (see Table 1). BIS has an inherent asymmetry in its structure in the following sense – when BIS says that there exists no edge between two disjoint sets, then BIS stands as a witness to the existence of two sets of vertices having no interdependence, while a yes answer implies that there can be any number of edges, varying from one to the product of the cardinality of the two sets, going across the two sets. We feel that this property of BIS gives it its power, but on the other hand, also makes it difficult to prove lower bounds. That is probably the reason why works related to upper bound for BIS and its generalizations exist, whereas works on lower bound were not forthcoming. Though not on BIS, the work of Chen et al. using IS queries gave an interesting lower bound construction for IS oracle. Our work goes one step further in being able to prove a lower bound for the BIS oracle which is much stronger than IS oracle. We have almost resolved the open question Q1 by proving almost matching lower and upper bounds involving BIS for estimating triangles.

1.2 A stronger oracle than BIS, our main result and its consequences

Now we define EDGE EMPTINESS (shortened as EE) query oracle which is stronger than both BIS and IS. The EDGE EMPTINESS query is a form of a *subset query* [24, 25, 23] where a subset query with a subset $P \subseteq U$ asks whether $P \cap T$ is empty or not, where T is also a subset of the universe U. The EDGE EMPTINESS query operates with U being the set of all vertex pairs in G, T being the set of edges E in G, and P being a subset of pairs of vertices of V.

▶ **Definition 1.5** (EDGE EMPTINESS). Given a subset $P \subseteq \binom{V(G)}{2}$, a EE query answers whether there exists an $\{u, v\} \in P$ such that $\{u, v\}$ is an edge in G.

EE query is recently introduce by Assadi et al. [1].[3] Note that BIS and IS queries can be simulated by an EE query. [4] We prove our lower bound in terms of the *stronger*[5] EE queries that will directly imply the lower bound in terms of BIS. But we prove matching upper bound in terms of BIS. Our main results are stated below in an informal setting. The formal statements are given in Theorems 3.1 and A.1.

▶ **Theorem 1.6** (Main lower bound (informal statement)). *Let m, n, $t \in \mathbb{N}$. Any (randomized) algorithm that has* EE *query access to a graph $G(V, E)$ with n vertices and $\Theta(m)$ edges, requires $\widetilde{\Omega}\left(\min\left\{\sqrt{t}, \frac{m^{3/2}}{t}\right\}\right)$* EE *queries to decide whether the number of triangles in G is at most t or at least $2t$.*

▶ **Theorem 1.7** (An upper bound (informal statement)). *There exists an algorithm, that has* BIS *query access to a graph $G(V, E)$, finds a $(1 \pm \varepsilon)$-approximation to the number of triangles in G with high probabilility, and makes $\widetilde{\mathcal{O}}\left(\min\left\{\frac{m}{\sqrt{T}}, \frac{m^{3/2}}{T}\right\}\right)$* BIS *queries in expectaton. Here m, n, T denote the number of vertices, edges and triangles in G.*

[3] Assadi et al. [1] named EE query as OR query in their paper.

[4] Let us consider a BIS query with inpus A and B. Let P be the set of vertex pairs with one vertex from each of A and B. We call EE oracle with input P, and report there is an edge having one vertex in each of A and B if and only if the EE oracle reports that there exists an $\{u, v\} \in P$ that forms an edge in G. Similarly, we can simulate an IS query with input U by using an EE query with input $P = \binom{U}{2}$.

[5] For an example to show how EE query can be powerful than that of BIS or IS, $\mathcal{O}(\log \log n)$ EE queries [24] are enough to estimate the number of edges in a graph, as opposed to high query complexity (compared to $\mathcal{O}(\log \log n)$) when we have BIS or IS queries (See Table 1).

Note that Edge Emptiness query is the *strongest* subset query on edges of the graph. Informally speaking, our lower bound states that no subset query on edges can estimate the number of triangles in a graph by using polylogarithmic queries. However, the results of Bhattacharya et al. [6] and Dell et al. [13] imply that polylogarithmic TIS queries are enough to estimate the number of triangles in the graph. Note that TIS query is also a subset query on triangles in the graph. To complement our lower bound result, we also give an algorithm (see Theorem 1.7) for estimating the number of triangles in a graph with BIS queries that matches our lower bound. Here we would also like to mention that the number of BIS queries our algorithm uses is less than that of the number of local queries [17] needed to estimate the number of triangles in a graph. This implies that we are resolving Q3 in positive in the sense that BIS queries are efficient queries for triangle estimation vis-a-vis local queries [14] coupled with even random edge queries [2] (see Table 1).

1.3 Notations

Throughout the paper, the graphs are undirected and simple. For a graph $G(V,E)$, $V(G)$ and $E(G)$ denote the set of vertices and edges, respectively; $|V(G)| = n$, $|E(G)| = m$ and the number of triangles is T, unless otherwise specified. We use $\binom{V(G)}{2}$ to denote the set of vertex pairs in G. Note that $E(G) \subseteq \binom{V(G)}{2}$. For $P \subseteq \binom{V(G)}{2}$, $V(P)$ represents the set of vertices that belong to at least one pair in P. The neighborhood of a vertex $v \in V(G)$ is denoted by $N_G(v)$, and $|N_G(v)|$ is called the degree of vertex v in G. $\Gamma(\{x,y\})$ denotes the set $N_G(x) \cap N_G(y)$, that is, the set of common neighbors of x and y in G. If $e = \{x,y\} \in E(G)$, $\Gamma(e)$ denotes the set of vertices that forms triangles with e as one of their edges. The induced degree of a vertex v in $Z \subseteq V(G) \setminus \{v\}$ is the cardinality of $N_G(v) \cap Z$. For $X \subseteq V(G)$, the subgraph of G induced by X is denoted by $G[X]$. Note that $E(G[X]) = \{\{x,y\} : x,y \in X\}$. For two disjoint sets A, $B \subset V(G)$, the bipartite subgraph of G induced by A and B is denoted by $G[A,B]$. Note that $E(G[A,B])$ is the set of edges having one vertex in A and the other vertex in B.

Throughout the paper, $\varepsilon \in (0,1)$ is the approximation parameter. When we say a is a $(1\pm\varepsilon)$-approximation of b, then $(1-\varepsilon)b \leq a \leq (1+\varepsilon)b$. Polylogarithmic means *poly* $(\log n, 1/\varepsilon)$. $\widetilde{\mathcal{O}}(\cdot)$ and $\widetilde{\Omega}(\cdot)$ hide a multiplicative factor of *poly*$(\log n, 1/\varepsilon)$ and $1/$*poly*$(\log n, 1/\varepsilon)$, respectively. We have avoided floor and ceiling for simplicity of presentation. The constants in this paper are not taken optimally. We have taken them to let the calculation work with clarity. However, those can be changed to other suitable and appropriate constants.

1.4 Paper organization

We start with the technical overview of our lower and upper bounds in Section 2.1 and Section 2.2, respectively. The detailed lower and upper bound proofs are in Section 3 and Appendix A, respectively. The missing proofs of Section 3 are presented in the full version of the paper [10].

2 Technical overview

In this section, we discuss about the techniques and proof overview, The overview of the lower bound is discussed in Section 2.1 and that of the upper bound is discussed in Section 2.2.

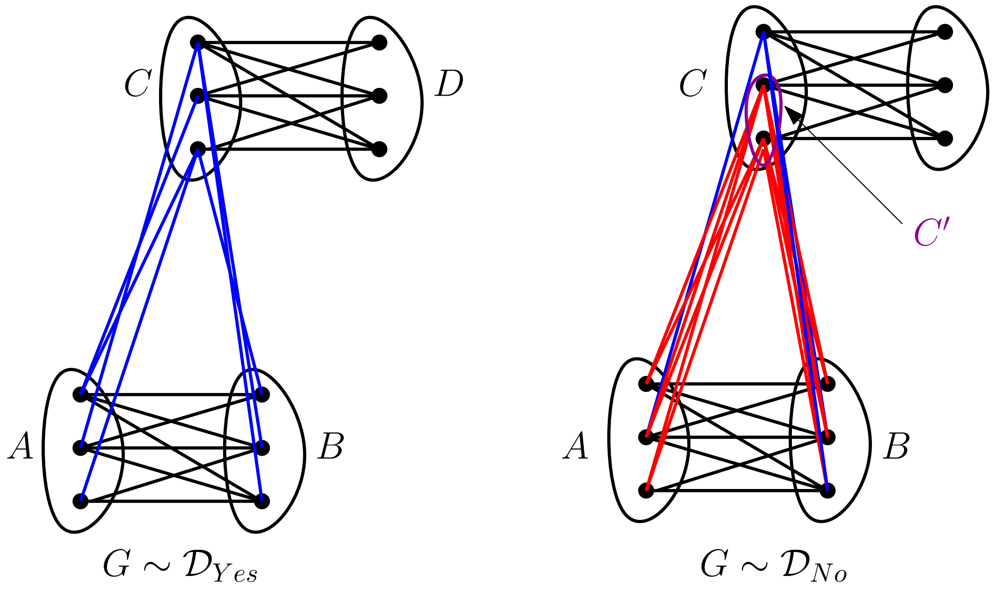

Figure 1 Illustration of $G \sim \mathcal{D}_{\mathbf{Yes}}$ and $G \sim \mathcal{D}_{\mathbf{No}}$ when $t = \Omega(m \log n)$.

2.1 Overview for the proof of our lower bound (Theorem 1.6)

Let us consider m, n, t as in Theorem 1.6. We prove the desired bound for BIS (stated in Theorem 1.6) by proving the lower bound is $\widetilde{\Omega}\left(\frac{m^{3/2}}{t}\right)$ when $t \geq km \log n$ and $\widetilde{\Omega}\left(\sqrt{t}\right)$ when $t < km \log n$ for EE query access, where k is a suitably chosen constant. In this Section, we discuss the overview of the proof when $t \geq km \log n$. The desired lower bound when $t < km \log n$ can be proved by using a reduction from the case when $t \geq km \log n$. The main intuition behind the lower bound is to "hide" a suitably generated vertex set such that a large number of queries is necessary to detect such a vertex.

The idea for the lower bound of $\widetilde{\Omega}\left(\frac{m^{3/2}}{t}\right)$ when $t \geq km \log n$

We prove by using Yao's method [21]. There are two distributions $\mathcal{D}_{\mathbf{Yes}}$ and $\mathcal{D}_{\mathbf{No}}$ (as described below) from which G is sampled satisfying $\mathbb{P}\left(G \sim \mathcal{D}_{\mathbf{Yes}}\right) = \mathbb{P}\left(G \sim \mathcal{D}_{\mathbf{No}}\right) = 1/2$. Note that, for each $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$, $|V(G)| = n = \Theta(\sqrt{m})$,[6] and $|E(G)| = \Theta(m)$ with a probability of at least $1 - o(1)$. But the number of triangles in each $G \sim \mathcal{D}_{\mathbf{No}}$ is at least two factor more than that of the number of triangles in any $G \sim \mathcal{D}_{\mathbf{Yes}}$, with a probability of at least $1 - o(1)$.

$\mathcal{D}_{\mathbf{Yes}}$: The vertex set $V(G)$ (with $|V(G)| = \Theta(\sqrt{m})$) is partitioned into four parts A, B, C, D uniformly at random. Vertex set A forms a biclique with vertex set B and vertex set C forms a biclique with vertex set D. Then every vertex pair $\{x, y\}$, with $x \in A \cup B$ and $y \in C$, is added as an edge to graph G with probability $\Theta\left(\sqrt{\frac{t}{m^{3/2}}}\right)$;

$\mathcal{D}_{\mathbf{No}}$: The vertex set $V(G)$ (with $|V(G)| = \Theta(\sqrt{m})$) is partitioned into four parts A, B, C, D uniformly at random. Vertex set A forms a biclique with vertex set B and vertex set C forms a biclique with vertex set D. Then every vertex pair $\{x, y\}$, with $x \in A \cup B$ and

[6] Without loss of generality, we assume that $\sqrt{m}$ is an integer. The proof can be extended to any graph having $n \geq \sqrt{m}$ vertices and m edges by adding $n - \sqrt{m}$ isolated vertices.

$y \in C$, is added as an edge to graph G with probability $\Theta\left(\sqrt{\frac{t}{m^{3/2}}}\right)$. Then each vertex of C is sampled with probability $\Theta\left(\frac{t}{m^{3/2}}\right)$. Let C' be the sampled set. Each vertex of C' is connected to every vertex of $A \cup B$ with an edge;

See Figure 1 for an illustration of the above construction. The constants, including k, in the order notations above are suitably set to have the following:

When $G \sim \mathcal{D}_{\text{Yes}}$: The number of triangles in each graph is at most t, with a probability of at least $1 - o(1)$;

When $G \sim \mathcal{D}_{\text{No}}$: $|C'| = \Theta\left(\frac{t}{m}\right)$ with a probability of at least $1 - o(1)$. Hence, the number of triangles in each $G \sim \mathcal{D}_{\mathbf{No}}$ is at least $2t$, with a probability of at least $1 - o(1)$.

Now, consider a particular EE query with input $P \subseteq \binom{V(G)}{2}$. Here, we divide the discussion into two parts, based on $|P| \leq \tau$ and $|P| > \tau$, where $\tau = \Theta(\log^2 n)$ is a threshold. If we query with the number of vertex pairs more than the threshold, chances are more we will not be able to distinguish between $G \sim \mathcal{D}_{\mathbf{Yes}}$ and $G \sim \mathcal{D}_{\mathbf{No}}$. When $|P| > \tau$, we can show that there exists a vertex pair $\{x, y\} \in P$ such that $\{x, y\}$ is an edge in G, with a probability of at least $1 - o(1)$, irrespective of whether $G \sim \mathcal{D}_{\mathbf{Yes}}$ or $G \sim \mathcal{D}_{\mathbf{No}}$. Intuitively, this is because the number of vertices and edges in G are $\Theta(\sqrt{m})$ and $\Theta(m)$, respectively. So, EE queries with input $P \subseteq \binom{V(G)}{2}$ such that $|P| > \tau$ will not be useful to distinguish whether $G \sim \mathcal{D}_{\mathbf{Yes}}$ or $G \sim \mathcal{D}_{\mathbf{No}}$.

We prove the desired lower bound by proving $\widetilde{\Omega}\left(\frac{m^{3/2}}{t}\right)$ EE queries are necessary to decide whether $G \sim \mathcal{D}_{\mathbf{Yes}}$ or $G \sim \mathcal{D}_{\mathbf{No}}$ with a probability of at least $2/3$. Note that $C' = \emptyset$ when $G \sim \mathcal{D}_{\mathbf{Yes}}$. So, the number of EE queries needed to decide whether $G \sim \mathcal{D}_{\mathbf{Yes}}$ or $G \sim \mathcal{D}_{\mathbf{No}}$, is at least the number of EE queries needed to *touch* at least one vertex of C' when $G \sim \mathcal{D}_{\mathbf{No}}$. Here, by touching at least a vertex of C', we mean $V(P) \cap C' \neq \emptyset$. As we have argued that only EE query with input $P \subseteq \binom{V(G)}{2}$ with $|P| \leq \tau$ can be useful, the probability that we touch a vertex in C' with such a query is at most $p = \mathcal{O}\left(\frac{C'}{\sqrt{m}} \cdot \tau\right) = \mathcal{O}\left(\frac{t \log^2 n}{m^{3/2}}\right)$. Hence the number of EE queries to touch at least a vertex of C', is at least $1/p$, that is, $\widetilde{\Omega}\left(\frac{m^{3/2}}{t}\right)$.

To let the the above discussion work, when $G \sim \mathcal{D}_{\mathbf{No}}$, $|C'| = \Theta\left(\frac{t}{m}\right)$ must be at least $\Omega(\log n)$. But $|C'| = \Theta\left(\frac{t}{m}\right)$ with a probability of at least $1 - o(1)$. Because of this, we take $t \geq km \log n$ in the above discussion. The formal statement of the lower bound, when $t \geq km \log n$, is given in Lemma 3.2 in Section 3. What we have discussed here is just an overview, the formal proof of Lemma 3.2 is much more invloved and delicate, which is presented in Section 3.1.

As we have already mentioned, the desired lower bound of $\widetilde{\Omega}\left(\sqrt{t}\right)$ when $t < km \log n$ can be proved by a reduction from the case when $t \geq km \log n$. The formal statement of the lower bound, when $t < km \log n$, is given in Lemma 3.3 in Section 3, and the proof is presented in Section 3.2.

2.2 Overview for our upper bound (Theorem 1.7)

We establish the upper bound claimed in Theorem 1.7 by giving two algorithms that report a $(1 \pm \varepsilon)$-approximation to the number of triangles in the graph:

(i) Triangle-Est-High(G, ε) that makes $\widetilde{\mathcal{O}}\left(\frac{m^{3/2}}{T}\right)$ BIS queries;

(ii) Triangle-Est-Low(G, ε) that makes $\widetilde{\mathcal{O}}\left(\frac{m+T}{\sqrt{T}}\right)$ BIS queries.

Informally speaking, our final algorithm Triangle-Est calls Triangle-Est-High(G, ε) and Triangle-Est-Low(G, ε) when $T = \Omega(m)$ and $T = \mathcal{O}(m)$, respectively. Observe that, if Triangle-Est knows T within a constant factor, then it can decide which one to use among Triangle-Est-High(G,ε) and Triangle-Est-Low(G,ε). If Triangle-Est does not know T within a constant factor, then it starts from a guess $L = \binom{n}{3}/2$ and makes a geometric search on L until the output of Triangle-Est is consistent with L. Depending on whether $L = \Omega(m)$ or $L = \mathcal{O}(m)$, Triangle-Est decides which one among Triangle-Est-High(G,ε) and Triangle-Est-Low(G,ε) to call. This guessing technique is very standard by now in property testing literature [19, 14, 15, 2]. Another point to note is that we do not know m. However, we can estimate m by using $poly(\log n)$ BIS queries (see Table 1). An estimate of m will perfectly work for us in this case.

Algorithm Triangle-Est-High(G,ε)

Algorithm Triangle-Est-High is inspired by the triangle estimation algorithm of Assadi et al. [2], where we have Adjacency, Degree, Random neighbor and Random Edge queries. Please see Appendix A.2 for formal definitions of these queries. Note that the algorithm by Assadi et al. can be *suitably* modified even if we have approximate versions of Degree, Random neighbor and Random Edge queries. Also refer Appendix A.2 for formal definitions of approximate version of the above queries. By Corollary A.8, $\widetilde{\mathcal{O}}(1)$ BIS queries are enough to simulate the approximate versions of Degree and Random neighbor, with a probability of at least $1 - o(1)$. By Proposition A.7, approximate version of Random Edge queries can also be simulated by $\widetilde{\mathcal{O}}(1)$ BIS queries, with a probability of at least $1 - o(1)$. Putting everything together, we get Triangle-Est-High(G,ε) for triangle estimation that makes $\widetilde{\mathcal{O}}(1)$ BIS queries. The formal statement of the corresponding triangle estimation result is given in Lemma A.2, and algorithm Triangle-Est-High(G,ε) is described in Appendix A.2.

Algorithm Triangle-Est-Low(G,ε)

This algorithm is inspired by the two pass streaming algorithm for triangle estimation by McGregor et al. [20]. Basically, we show that the steps of McGregor et al.'s algorithm can be executed by using $\widetilde{\mathcal{O}}\left(\frac{m+T}{\sqrt{T}}\right)$ BIS queries. To do so, we have used the fact that, given any $X \subseteq V(G)$, all the edges of the subgraph induced by X can be enumerated by using $\widetilde{\mathcal{O}}\left(|E(G[X])|\right)$ BIS queries (see Proposition A.4 for the formal statement). The formal statement of the corresponding triangle estimation result is given in Lemma A.3, and algorithm Triangle-Est-Low(G,ε) is described in Appendix A.3 along with its correctness proof and query complexity analysis.

3 Lower bound for estimating triangles using Edge Emptiness queries

In this Section, we prove the main lower bound result as sketched in Theorem 1.6; the formal theorem statement is stated below. As mentioned earlier, the lower bound proofs will be for the stronger query oracle EE. This will imply the lower bound for BIS.

▶ **Theorem 3.1** (Main lower bound result). *Let $m, n, t \in \mathbb{N}$ be such that $1 \leq t \leq \frac{m^{3/2}}{2}$. Any (randomized) algorithm that has* EE *oracle access to a graph $G(V,E)$ must make $\widetilde{\Omega}\left(\min\left\{\sqrt{t}, \frac{m^{3/2}}{t}\right\}\right)$* EE *queries to decide whether the number of triangles in G is at most t or at least $2t$ with a probability of at least $2/3$, where G has $n \geq 4\sqrt{m}$ vertices and $\Theta\left(m\right)$ edges.*

We prove the above theorem by proving Lemmas 3.2 and 3.3, as stated below. Note that Lemmas 3.2 and 3.3 talk about the desired lower bound when the number of triangles in the graph is *large* ($\Omega(m \log n)$) and *small* ($\mathcal{O}(m \log n)$), respectively.

▶ **Lemma 3.2** (Lower bound when there are *large* number of triangles)**.** *Let m, n, $t \in \mathbb{N}$ be such that $t \geq \frac{m \log n}{8}$. Any (randomized) algorithm that has* EE *oracle access to a graph $G(V, E)$ must make $\widetilde{\Omega}\left(\frac{m^{3/2}}{t}\right)$* EE *queries to decide whether the number of triangles in G is at most t or at least $2t$ with a probability of at least $2/3$, where G has $n \geq 4\sqrt{m}$ vertices, $\Theta(m)$ edges.*

▶ **Lemma 3.3** (Lower bound when there are *small* number of triangles)**.** *Let m, n, $t \in \mathbb{N}$ be such that $t < \frac{m \log n}{8}$. Any (randomized) algorithm that has* EE *oracle access to a graph $G(V, E)$ must make $\widetilde{\Omega}\left(\sqrt{t}\right)$* EE *queries to decide whether the number of triangles in G is at most t or at least $2t$ with a probability of at least $2/3$, where G has $n \geq 4\sqrt{m}$ vertices and $\Theta(m)$ edges.*

We first show Lemma 3.2 in Section 3.1, and then Lemma 3.3 in Section 3.2. Note that the proof of Lemma 3.3 will use Lemma 3.2.

3.1 Proof of Lemma 3.2

Without loss of generality, assume that $\sqrt{m}$ is an integer. We prove for the case when $n = 4\sqrt{m}$. But, we can make the proof work for any $n \geq 4\sqrt{m}$ by adding $n - 4\sqrt{m}$ isolated vertices. Note that $t \geq \frac{m \log n}{8}$ here. We further assume that $t \leq \frac{m^{3/2}}{128}$, and $m = \Omega(\log^2 n)$. Otherwise, the stated lower bound of $\widetilde{\Omega}\left(\frac{m^{3/2}}{t}\right)$ trivially follows as $\widetilde{\Omega}(\cdot)$ hides a multiplicative factor of $\frac{1}{poly(\log n)}$.

We use Yao's min-max principle to prove the lower bound. To do so, we consider two distributions $\mathcal{D}_{\mathbf{Yes}}$ and $\mathcal{D}_{\mathbf{No}}$ on graphs where

- Any graph $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$ has $4\sqrt{m}$ vertices;
- Any graph $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$ has $\Theta(m)$ edges with a probability of at least $1 - o(1)$;
- The number of triangles in any graph $G \sim \mathcal{D}_{\mathbf{Yes}}$ is at most t with a probability of at least $1 - o(1)$, and any graph $G \sim \mathcal{D}_{\mathbf{No}}$ has at least $2t$ triangles with a probability of at least $1 - o(1)$.

Note that, if we can show that any deterministic algorithm that distinguishes graphs from $\mathcal{D}_{\mathbf{Yes}}$ and $\mathcal{D}_{\mathbf{No}}$, with a probability of at least $2/3$, must make $\widetilde{\Omega}\left(\frac{m^{3/2}}{t}\right)$ EE queries, then we are done with the proof of Lemma 3.2.

3.1.1 The (hard) distribution for the input, its properties, and the proof set up

$\mathcal{D}_{\text{Yes}}$: A graph $G \sim \mathcal{D}_{\mathbf{Yes}}$ is sampled as follows:

- Partition the vertex set $V(G)$ into 4 parts A, B, C, D, by initializing A, B, C, D as empty sets, and then putting each vertex in $V(G)$ into one of the parts uniformly at random and independent of other vertices;
- Connect each vertex of A with every vertex of B with an edge to form a biclique. Also, connect each vertex of C with every vertex of D with an edge to form another biclique;
- For every $\{x, y\}$ where $x \in A \cup B$ and $y \in C$, add edge $\{x, y\}$ to G with probability $\sqrt{\frac{t}{16m^{3/2}}}$.

$\mathcal{D}_{\text{No}}$: A graph $G \sim \mathcal{D}_{\mathbf{No}}$ is sampled as follows:

- Partition the vertex set $V(G)$ into 4 parts A, B, C, D, by initializing A, B, C, D as empty sets, and then putting each vertex in $V(G)$ into one of the partitions uniformly at random and independent of other vertices;
- Connect each vertex of A with every vertex of B with an edge to form a biclique. Also, connect each vertex of C with every vertex of D with an edge to form another biclique;

- For every $\{x, y\}$ where $x \in A \cup B$ and $y \in C$, add edge $\{x, y\}$ to G with probability $\sqrt{\frac{t}{16m^{3/2}}}$.
- Select $C' \subseteq C$ by putting each $x \in C$ into C' with a probability of at least $\frac{32t}{m^{3/2}}$, independently, and then, add each edge in $\{x, y : x \in A \cup B, y \in C'\}$ to G.

The following observation establishes the number of vertices, edges, and the number of triangles in the graphs that can be sampled from $\mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$. The proof uses *large deviation inequalities* and is presented in the full version of the paper.

▶ **Observation 3.4** (Properties of the graph $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$).

(i) For $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$, the number of vertices in G is $4\sqrt{m}$. Also, $\frac{\sqrt{m}}{2} \le |A|, |B|, |C|, |D| \le 2\sqrt{m}$ holds with a probability of at least $1 - o(1)$, and the number of edges in G is $\Theta(m)$ with a probability of at least $1 - o(1)$;

(ii) If $G \sim \mathcal{D}_{\mathbf{Yes}}$, then there are at most t triangles in G with a probability of at least $1 - o(1)$,

(iii) If $G \sim \mathcal{D}_{\mathbf{No}}$, $\frac{8t}{m} \le |C'| \le \frac{64t}{m}$ with a probability of at least $1 - o(1)$, and there are at least $2t$ triangles in G with a probability of at least $1 - o(1)$.

The following remark is regarding the connection between graphs in $\mathcal{D}_{\mathbf{Yes}}$ and that in $\mathcal{D}_{\mathbf{No}}$. This will be used later in our proof, particularly in the proof of Claim 3.12.

▶ **Remark 1** (A graph $G' \sim \mathcal{D}_{\mathbf{No}}$ can be generated from a graph $G \sim \mathcal{D}_{\mathbf{Yes}}$). Let us first generate a graph $G \sim \mathcal{D}_{\mathbf{Yes}}$. Select $C' \subseteq C$ by putting each $x \in C$ into C' with a probability of at least $\frac{32t}{m^{3/2}}$, and then, add each edge in $\{x, y : x \in A \cup B, y \in C'\}$ to G to generate G', then (the resulting graph) $G' \sim \mathcal{D}_{\mathbf{No}}$.

The following observation says that a $\{x, y\} \in \binom{V(G)}{2}$ (with some condition) forms an edge with a probability of at least a constant. It will be used while we prove Claim 3.11.

▶ **Observation 3.5** (Any vertex pair $\{x, y\}$ is an edge in G with constant probability). Let $\{x, y\} \in \binom{V(G)}{2}$, and we are in the process of generating $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$. Let at most one of x and y has been put into one of the parts out of A, B, C and D. Then $\{x, y\}$ is an edge in G with probability at least $\frac{1}{4}$.

The above observation follows from the description of $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$ – each vertex in $V(G)$ is put into one of the parts out of A, B, C, D uniformly at random, each vertex of A is connected with every vertex in B, and each vertex of C is connected with every vertex in D.

In order to prove Lemma 3.2, by contradiction, assume that there is a randomized algorithm that makes $q = o\left(\frac{m^{3/2}}{t}\frac{1}{\log^2 n}\right)$ EE queries and decides whether the number of triangles in the input graph is at most t or at least $2t$, with a probability of at least 2/3. Then there exists a deterministic algorithm ALG that makes q EE queries and decides the following (when the input graph $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$ be such that both $G \sim \mathcal{D}_{\mathbf{Yes}}$ and $G \sim \mathcal{D}_{\mathbf{No}}$ holds with probability 1/2) –

$$\mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\text{ALG(G) reports NO}) - \mathbb{P}_{G \sim \mathcal{D}_{\mathbf{Yes}}}(\text{ALG(G) reports NO}) \ge \frac{1}{3} - o(1).$$

(Here $\mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\mathcal{E})$ and $\mathbb{P}_{G \sim \mathcal{D}_{\mathbf{Yes}}}(\mathcal{E})$ denote the probability of the event $\mathcal{E}$ under the conditional space $G \sim \mathcal{D}_{\mathbf{No}}$ and $G \sim \mathcal{D}_{\mathbf{Yes}}$, respectively.) Hence, we will be done with the proof of Lemma 3.2 by showing the following lemma.

▶ **Lemma 3.6** (Lower bound on the number of EE queries when $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$)**.** *Let the unknown graph G be such that $G \sim \mathcal{D}_{\mathbf{Yes}}$ and $G \sim \mathcal{D}_{\mathbf{No}}$ hold with equal probabilities. Consider any deterministic algorithm* ALG *that has* EE *access to G, and makes $q = o\left(\frac{m^{3/2}}{t}\frac{1}{\log^2 n}\right)$* EE *queries to G. Then*

$$\mathbb{P}_{G\sim\mathcal{D}_{\mathbf{No}}}(\text{ALG}(G) \textit{ reports } \text{NO}) - \mathbb{P}_{G\sim\mathcal{D}_{\mathbf{Yes}}}(\text{ALG}(G) \textit{ reports } \text{NO}) \le o(1).$$

Next, we define an augmented EE oracle (EE* oracle). EE* is tailor-made for the graphs coming from $\mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$. Moreover, it is *stronger* than EE, that is, any EE query can be simulated by a EE* query. We will prove the claimed lower bound in Lemma 3.6 when we have access to EE* oracle. Note that this will imply Lemma 3.6.

Before getting into the formal description of EE* oracle, note that the algorithm (with EE* access) maintains a four tuple data structure initialized with $\emptyset$. With each query to EE* oracle, the oracle updates the data structure and returns the updated data structure to the algorithm. Note that the updated data structure is a function of all previously made EE* queries, and it is enough to answer corresponding EE queries.

3.1.2 Augmented Edge Emptiness oracle (EE*)

Before describing the EE* query oracle and its interplay with the algorithm, first we present the data structure $(E_Q, V(E_Q), e, \ell_v)$ that the algorithm maintains with the help of EE* oracle. The data structure keeps track of the following information.

Information maintained by $(E_Q, V(E_Q), e, \ell_v)$

- E_Q is a subset of $\binom{V(G)}{2}$ that have been seen by the algorithm till now, $V(E_Q)$ is the set of vertices present in any vertex pair in E_Q.
- $e : \binom{V(E_Q)}{2} \to \{0,1\}$ such that $e(\{x,y\}) = 1$ means the algorithm knows that $\{x,y\}$ is an edge in G, $e(x,y) = 0$ means that $\{x,y\}$ is not an edge in G.
- $\ell_v : V(E_Q) \to \{A, B, C, C', D\}$, where

$$\ell_v(x) = \begin{cases} A, & x \in A \\ B, & x \in B \\ C, & x \in C \setminus C' \\ C', & x \in C' \\ D, & x \in D \end{cases}$$

Intuitively speaking, unless the algorithm knows about the presence of some vertex in C', it cannot distinguish whether the unknown graph $G \sim \mathcal{D}_{\mathbf{Yes}}$ or $G \sim \mathcal{D}_{\mathbf{No}}$. So, we define the notion of good and bad vertices, along with good and bad data structures. This notion will be used later in our proof.

▶ **Definition 3.7** (Bad vertex)**.** A vertex $x \in V(E_Q)$ is said to be a *bad* vertex if $\ell_v(x) = C'$. $(E_Q, V(E_Q), e, \ell_v)$ is said to be *good* if there does not exist any bad vertex in $V(E_Q)$.

EE* oracle and its interplay with the algorithm

The algorithm initializes the data structure $(E_Q, V(E_Q), e, \ell_v)$ with $E_Q = \emptyset$, $V(E_Q) = \emptyset$. So, e and ℓ_v are initialized with trivial functions with domain $\emptyset$. At the beginning of each round, the algorithm queries the EE* oracle with a subset $P \subseteq \binom{V(G)}{2}$ deterministically. Note that the choice of P depends on the current status of the data structure. Now, we explain how EE* oracle responds to the query and how the data structure is updated.

(1) If $|P| \leq \tau = 25\log^2 n$, the oracle sets $E_Q \leftarrow E_Q \cup P$, and changes $V(E_Q)$ accordingly. The oracle also sets the function e and ℓ_v as per their definitions, and then it sends the updated data structure to the algorithm.

(2) Otherwise (if $|P| > \tau$), the oracle finds a random subset $P' \subseteq P$ such that $|P'| = \tau$. The oracle checks if there is a pair $\{u, v\} \in P'$ such that $\{u, v\}$ is an edge. If yes, then the oracle responds as in (1) with P being replaced by P'. If no, the oracle sends the data structure corresponding to the entire graph along with a FAILURE signal.[7]

Owing to the way EE* oracle updates the data structure after each EE* query, we can make some assumptions on the inputs to the EE* oracle, as described in Remark 2. It will actually be useful when we prove Claim 3.11.

▶ **Remark 2** (Some assumptions on the EE* query). Let $(E_Q, V(E_Q), e, \ell_v)$ be the data structure just before the algorithm makes EE query with input P, and let $\left(E'_Q, V\left(E'_Q\right), e', \ell'_v\right)$ be the data structure updated by EE* oracle after the algorithm makes EE* query with input P. Without loss of generality, we assume that

(i) P is disjoint from $\binom{V(E_Q)}{2}$. It is because EE* maintains whether $\{x, y\}$ is an edge or not for each $\{x, y\} \in \binom{V(E_Q)}{2}$;

(ii) When $x, z \in V(E_Q)$, there does not exist $\{x, y\}$ and $\{y, z\}$ in P. It is because the oracle updates the data structure in the same way in each of the following three cases when $x, z \in V(E_Q)$ – (i) $\{x, y\}$ and $\{y, z\}$ are in P, (ii) $\{x, y\} \in P$ and $\{y, z\} \notin P$, and (iii) $\{x, y\} \notin P$ and $\{y, z\} \in P$. By the description of EE* oracle and its interplay with the algorithm, in all the three cases, the updated data structure $\left(E'_Q, V\left(E'_Q\right), e', \ell'_v\right)$ contains labels of all the three vertices x, y, z along with the information whether $\{x, y\}$ and $\{y, z\}$ form edges in G or not. So, instead of having both $\{x, y\}$ and $\{y, z\}$ in P with $x, z \in V(E_Q)$, it is *equivalent* to have exactly one among $\{x, y\}$ and $\{y, z\}$ in P.

In the following observation, we formally show that EE* oracle is stronger than that of EE. Then we prove Lemma 3.9 that says that $\Omega\left(\frac{m^{3/2}}{t}\frac{1}{\log^2 n}\right)$ EE* queries are necessary to distinguish between $G \sim \mathcal{D}_{\mathbf{Yes}}$ and $G \sim \mathcal{D}_{\mathbf{No}}$. Note that Lemma 3.9 will imply Lemma 3.6.

▶ **Observation 3.8** (EE* is stronger than EE). Let $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$. Each EE query to G can be simulated by using an EE* query to G.

Proof. Let us consider an EE query with input $P \subseteq \binom{V(G)}{2}$. We make a EE* query with the same input P, and answer the EE query as follows depending on whether $|P| \leq \tau$ or $|P| > \tau$.

$|P| \leq \tau$: The EE* oracle updates the data structure and let $\left(E'_Q, V\left(E'_Q\right), e', \ell'_v\right)$ be the updated data structure. It contains the the information about each $\{x, y\} \in P$ whether it forms an edge in G or not. So, from $\left(E'_Q, V\left(E'_Q\right), e', \ell'_v\right)$, the EE query with input P can be answered as follows: there exists an edge $\{x, y\} \in P$ with $\{x, y\} \in E(G)$ if and only if $e'(\{x, y\}) = 1$.

$|P| > \tau$: In this case, the EE* oracle finds a random subset $P' \subseteq P$ such that $|P'| = \tau$. It checks if there is an $\{x, y\} \in P'$ such that $\{x, y\}$ is an edge. If yes, the updated data structure contains the the information about each $\{x, y\} \in P'$ whether it forms an edge. In this case, we can report that there exists an $\{x, y\} \in P$ such that $\{x, y\}$ is an edge in G. If there is no $\{x, y\} \in P'$ such that $\{x, y\}$ is an edge, then (by the description of

[7] We later argue that FAILURE signal is sent with a very low probability.

EE oracle and its interplay with the algorithm) the EE* oracle sends the data structure corresponding to the entire graph. Obviously, we can report whether there exists an $\{x, y\} \in P$ such that $\{x, y\} \in E(G)$ or not.

Hence, in any case, we can report the answer to EE query with input P. ◀

We are left with proving the following technical lemma. As noted earlier, this will imply Lemma 3.6.

▶ **Lemma 3.9** (Lower bound on the number of EE* queries when $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$)**.** *Let the unknown graph G be such that $G \sim \mathcal{D}_{\mathbf{Yes}}$ and $G \sim \mathcal{D}_{\mathbf{No}}$ hold with equal probabilities. Consider any deterministic algorithm* ALG* *that has* EE* *access to G, and makes $q = o\left(\frac{m^{3/2}}{t}\frac{1}{\log^2 n}\right)$* EE* *queries to G. Then*

$$\mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\text{ALG}^* \textit{ (G) reports } \text{NO}) - \mathbb{P}_{G \sim \mathcal{D}_{\mathbf{Yes}}}(\text{ALG}^* \textit{ (G) reports } \text{NO}) \leq o(1).$$

3.1.3 Proof of Lemma 3.9

For clarity of explanation, we first describe ALG* as a decision tree. Then we will prove Lemma 3.9.

Decision tree view of ALG*

- Each internal node of $\mathcal{T}$ is labeled with a nonempty subset $\binom{V(G)}{2}$ and each leaf node is labeled with YES or NO;
- Each edge in the tree is labeled with a data structure $(E_Q, V(E_Q), e, \ell_v)$;
- The algorithm starts the execution from the root node r by setting r as the current node. Note that for the root node r, $E_Q = V(E_Q) = \emptyset$ and e and ℓ_v are the trivial functions. As the algorithm ALG* is deterministic, the first EE* query is same irrespective of the graph $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$ that we are querying. By making that query, we get an updated data structure from the oracle and let $\{r, u\}$ be the edge that is labeled with the updated data structure. Then ALG* sets u as the current node.
- If the current node u is not a leaf node in $\mathcal{T}$, ALG* makes a EE* query with a subset $P \subseteq \binom{V(G)}{2}$, where P is determined by the label of the node u. Note that P satisfies the condition described in Remark 2. The oracle updates the knowledge structure and ALG* moves to a child of u depending on the updated data structure;
- If the current node u is a leaf node in $\mathcal{T}$, report YES or NO according to the label of u.

Now, we define the notion of *good* and *bad* nodes in $\mathcal{T}$. The following definition is inspired from Definition 3.7.

▶ **Definition 3.10** (Bad node in the decision tree)**.** Let u be a node of $\mathcal{T}$ and $(E_Q, V(E_Q), e, \ell_v)$ be the current data structure. u is said to be *good* if there does not exist x in $V(E_Q)$ such that $\ell_v(x) = C'$. Otherwise, u is a *bad* node.

If $G \sim \mathcal{D}_{\mathbf{Yes}}$, then ALG* will never encounter a bad node. In other words, when ALG* reaches a bad node of the tree $\mathcal{T}$, then it can (easily) decide $G \sim \mathcal{D}_{\mathbf{No}}$. However, the inverse in not true. From this fact, consider two claims (Claims 3.11 and 3.12) about the traversal of the decision tree $\mathcal{T}$ when the graph $G \sim \mathcal{D}_{\mathbf{Yes}} \cup \mathcal{D}_{\mathbf{No}}$. These claims will be useful to show Lemma 3.9. Intuitively, Claim 3.11 says that the probability of reaching a bad node is very low when $G \sim \mathcal{D}_{\mathbf{No}}$. Claim 3.12 says that the probability to reach any particular good node is more when $G \sim \mathcal{D}_{\mathbf{Yes}}$ as compared to that of when $G \sim \mathcal{D}_{\mathbf{No}}$.

▶ **Claim 3.11** (Probability of reaching a bad node is very low when $G \sim \mathcal{D}_{\mathbf{No}}$). *Let $G \sim \mathcal{D}_{\mathbf{No}}$. Then the probability that* ALG* *reaches a bad node of the decision tree is $o(1)$. That is,*

$$\mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\text{ALG}^* \textit{ reaches a bad node}) = o(1).$$

▶ **Claim 3.12** (A technical claim to prove Lemma 3.9). *For any good node in the decision tree $\mathcal{T}$, the following holds:*

$$\mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\text{ALG}^* \textit{ reaches } v) \le \mathbb{P}_{G \sim \mathcal{D}_{\mathbf{Yes}}}(\text{ALG}^* \textit{ reaches } v).$$

The proofs of Claims 3.11 and 3.12 are non trivial and are in the full version due to paucity of space.

Now, we will prove Lemma 3.9.

Proof of Lemma 3.9. Let $\mathcal{L}_{\mathbf{No}}$ denote the set of leaf nodes of the decision tree $\mathcal{T}$ that are labeled NO. Also, let $\mathcal{L}_g \subseteq \mathcal{L}_{\mathbf{No}}$ be the set of leaf nodes that are good and labeled as NO.

$$\begin{aligned}
&\mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\text{ALG}^* \text{ (G) reports NO})\\
&\le \sum_{v \in \mathcal{L}_{\mathbf{No}}} \mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\text{ALG}^* \ (G) \text{ reaches } u)\\
&= \sum_{u \in \mathcal{L}_g} \mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\text{ALG}^* \ (G) \text{ reaches } u) + \sum_{u \in \mathcal{L}_{\mathbf{No}} \setminus \mathcal{L}_g} \mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\text{ALG}^* \ (G) \text{ reaches } u)\\
&\le \sum_{u \in \mathcal{L}_g} \mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\text{ALG}^* \ (G) \text{ reaches } u) + \mathbb{P}_{G \sim \mathcal{D}_{\mathbf{No}}}(\text{ALG}^* \ (G) \text{ reaches a bad node})\\
&\le \sum_{u \in \mathcal{L}_g} \mathbb{P}_{G \sim \mathcal{D}_{\mathbf{Yes}}}(\text{ALG}^* \ (G) \text{ reaches } u) + o(1) \qquad \text{(By Claims 3.11 and Claims 3.12)}\\
&\le \mathbb{P}_{G \sim \mathcal{D}_{\mathbf{Yes}}}(\text{ALG}^* \ (G) \text{ reports NO}) + o(1)
\end{aligned}$$

◀

3.2 Proof of Lemma 3.3

We assume that $t = \omega(\log^7 n)$. Otherwise, as $\widetilde{\Omega}(\cdot)$ hides a multiplicative term of $\frac{1}{poly(\log n)}$, the stated lower bound is trivial. Assume, for a contradiction, that there is an algorithm $\mathcal{A}$ for $t < \frac{m \log n}{8}$ such that

- it has EE oracle access to a graph $G_1(V_1, E_1)$ with $\Theta(\sqrt{m})$ vertices and $\Theta(m)$ edges;
- makes $o\left(\sqrt{t}\frac{1}{\log^{3.5} n}\right)$ EE queries;
- decides whether the number of triangles in G_1 is at most t or at least $2t$ with a probability of at least $2/3$.

Now we give an algorithm $\mathcal{A}'$ for

- it has EE oracle access to a graph $G_2(V_2, E_2)$ with $4\sqrt{t/\log n}$ vertices and $8t/\log n$ edges, that is, $t = \frac{|E_2| \log n}{8}$;
- makes $o\left(\frac{\sqrt{t}}{\log^{3.5} n}\right) = o\left(\frac{|E_2|^{3/2}}{t}\frac{1}{\log^2 n}\right)$ EE queries;
- decides whether the number of triangles in G_2 is at most t or at least $2t$ with a probability of at least $2/3$.

Description of $\mathcal{A}'$ using $\mathcal{A}$

- Let the unknown graph be $G_1 = G_2 \cup G'$ such that $V(G_1) = V(G_2) \sqcup V(G')$ and $E(G_1) = E(G_2) \sqcup E(G')$, where G' is a graph having $\Theta(\sqrt{m - t/\log n})$ vertices (disjoint from $V(G_2)$), $\Theta\left(\sqrt{(m - 8t/\log n)}\right)$ edges, and no triangles.[8] The number of vertices and edges in G_1 are $\Theta(\sqrt{m})$ and $\Theta(m)$, respectively. Also, the number of triangles in G_1 is same as in G_2;
- As an EE query to G_1 can be answered using one EE query to G_2, we can consider having EE query access to graph G_1;
- We run algorithm $\mathcal{A}$ assuming G_1 as the unknown graph;
- We report the output of $\mathcal{A}$ as the output of $\mathcal{A}$.

The correctness of $\mathcal{A}'$ follows from the correctness of $\mathcal{A}$. The number of queries made by the algorithm $\mathcal{A}'$ is $o\left(\sqrt{t}\frac{1}{\log^{3.5} n}\right)$. Recalling that $\mathcal{A}$ works on graph $G_2(V_2, E_2)$ satisfying $t = \frac{|E_2| \log n}{8}$ and by Lemma 3.2, algorithm $\mathcal{A}'$ does not exist as such an algorithm requires at least $\Omega\left(\frac{|E_2|^{3/2}}{t}\frac{1}{\log^2 n}\right)$ EE queries, which is $\Omega\left(\frac{\sqrt{t}}{\log^{3.5} n}\right)$.

Hence, we are done with the proof of Lemma 3.3.

4 Conclusion

We touched upon two open questions of Beame et al. [5] in this paper. We resolved the query complexity of triangle estimation when we have a Bipartite Independent Set oracle access to the unknown graph when $T = \Omega(m)$. But the query complexity of triangle counting remain illusive when $T = o(m)$ though we believe that our upper bound of $\widetilde{\mathcal{O}}(m/\sqrt{T})$ BIS queries is tight in this regard. It is also interesting if our upper bound can be improved when $T = o(m)$.

A Upper bound for estimating triangles using BIS

In this Section, we prove Theorem 1.7, which is formally stated as follows:

▶ **Theorem A.1** (Upper bound matching the lower bound in Theorem 3.1). *There exists an algorithm* Triangle-Est(G, ε) *that has* BIS *query access to a graph* $G(V, E)$ *having* n *vertices, takes a parameter* $\varepsilon \in (0, 1)$ *as input, and reports a* $(1 \pm \varepsilon)$*-approximation to the number of triangles in* G *with a probability of at least* $1 - o(1)$*. Moreover, the expected number of* BIS *queries made by the algorithm is* $\widetilde{\mathcal{O}}\left(\min\{\frac{m}{\sqrt{T}}, \frac{m^{3/2}}{T}\}\right)$*, where* m *and* T *denote the number of edges and triangles in* G*, respectively.*

In order to prove the above theorem, we first prove Lemmas A.2 and A.3.

▶ **Lemma A.2** (Upper bound when the number of triangles is *large*). *There exists an algorithm* Triangle-Est-High(G, ε) *that has* BIS *query access to a graph* $G(V, E)$ *having* n *vertices,* $\varepsilon \in (0, 1)$ *as input, and reports a* $(1 \pm \varepsilon)$*-approximation to the number of triangles in* G *with a probability of at least* $1 - o(1)$*. Moreover, the expected number of* BIS *queries made by the algorithm is* $\widetilde{\mathcal{O}}\left(\frac{m^{3/2}}{T}\right)$*, where* m *and* T *denote the number of edges and triangles in* G*, respectively.*

▶ **Lemma A.3** (Upper bound when the number of triangles is *small*). *There exists an algorithm* Triangle-Est-Low(G, ε) *that has* BIS *query access to a graph* $G(V, E)$ *having* n *vertices,* $\varepsilon \in (0, 1)$ *as input, and reports a* $(1 \pm \varepsilon)$*-approximation to the number of triangles in* G *with a probability of at least* $1 - o(1)$*. Moreover, the expected number of* BIS *queries made by the algorithm is* $\widetilde{\mathcal{O}}\left(\frac{m+T}{\sqrt{T}}\right)$*, where* m *and* T *denote the number of edges and triangles in* G*, respectively.*

Our final algorithm Triangle-Est(G, ε) (as stated in Theorem A.1) is a combination of Triangle-Est-High(G, ε) and Triangle-Est-Low(G, ε). Informally, Triangle-Est (G, ε) calls Triangle-Est-High(G, ε) and Triangle-Est-Low (G, ε) when $T = \Omega(m)$ and $T = \mathcal{O}(m)$, respectively. Observe that, if Triangle-Est knows T within a constant factor, then it can decide which one to use among Triangle-Est-High(G, ε) and Triangle-Est-Low(G, ε). If Triangle-Est does not know T within a constant factor, then it starts from a guess $L = \binom{n}{3}/2$ and updates L by making a *geometric* search until the output of Triangle-Est is consistent with L. Depending on whether $L = \Omega(m)$ or $L = \mathcal{O}(m)$, Triangle-Est decides which one among Triangle-Est-High(G, ε) and Triangle-Est-Low(G, ε) to call. This guessing technique is standard in the property testing literature. It has been used several times in the literature (for example in [19, 14], generalized in [15], and used directly in [2]). So, we explain Triangle-Est-High(G, ε) and Triangle-Est-Low(G, ε) assuming a promised lower bound on L, and the respective query complexities will be in terms of L instead of T.

Another important thing to observe is that to execute the above discussed steps of algorithm Triangle-Est(G, ε) must know m. But we note that an estimate of m will be good enough for our purpose, and that can be estimated by using $\widetilde{\mathcal{O}}(1)$ BIS queries (see Table 1).

In Appendix A.1, we discuss some properties of BIS and some tasks it can perform. These properties will be useful while describing our Triangle-Est-High(G, ε) and Triangle-Est-Low(G, ε), and proving Lemma A.2 and Lemma A.3, in Section A.2 and Section A.3, respectively.

A.1 Some preliminaries about BIS

Let $G(V, E)$ be the unknown graph to which we have BIS query access. One can compute the exact number of edges using $\widetilde{\mathcal{O}}(|E(G)|)$ queries [5] deterministically. Also, we can estimate the number of edges in graph G [5, 6, 13] and sample an edge from G *almost uniformly* [13], with a probability of at least $1 - o(1)$, and making $\widetilde{\mathcal{O}}(1)$ BIS queries. Here, we would like to note that, all three results we mentioned above hold for induced subgraphs as well as induced bipartite subgraph, as formally described below. Those will be used when we design our upper bounds in Appendix A.2 and A.3.

▶ **Proposition A.4** (Exact edge estimation using BIS [5]). *There exists a deterministic algorithm that has* BIS *query access to an unknown graph $G(V, E)$ with n vertices, takes $X \subseteq V(G)$ (alternatively, two disjoint subsets A, B) as input, makes $\widetilde{\mathcal{O}}(|E(G[X])|)$ (alternatively, $\widetilde{\mathcal{O}}(|E(G[A, B])|)$)* BIS *queries, and reports all the edges in $E(G)$ (alternatively, $E(G[A, B])$).*

▶ **Proposition A.5** (Approximate edge estimation using BIS [6, 13]). *There exists an algorithm that has* BIS *query access to an unknown graph $G(V, E)$ with n vertices, takes $X \subseteq V(G)$ (alternatively, two disjoint subsets A, B) and a parameter $\varepsilon \in (0, 1)$ as inputs, makes $\widetilde{\mathcal{O}}(1)$* BIS *queries, and reports a $(1 \pm \varepsilon)$-approximation to $|E(G[X])|$ (alternatively, $|E(G[A, B])|$), with a probability of at least $1 - o(1)$.*

To state the next proposition, we need the following definition.

▶ **Definition A.6** (Approximate uniform sample from a set). For a nonempty set X and $\varepsilon \in (0, 1)$, getting a $(1 \pm \varepsilon)$-approximate uniform sample from X means getting a sample from a distribution on X such that the probability of getting $x \in X$ lies in $[(1-\varepsilon)/|X|, (1+\varepsilon)/|X|]$.

▶ **Proposition A.7** (Approximate edge sampling using BIS [13]). *There exists an algorithm that has* BIS *query access to an unknown graph $G(V, E)$ with n vertices, takes $X \subseteq V(G)$ (alternatively, two disjoint subsets A, B) and a parameter $\varepsilon \in (0, 1)$ as inputs, makes $\widetilde{\mathcal{O}}(1)$* BIS *queries, and reports a $(1 \pm \varepsilon)$-approximate uniform sample from $E(G[X])$ (alternatively, $E(G[A, B]$), with a probability of at least $1 - o(1)$.*

Observe that the following corollary follows from Propositions A.4, A.5 and A.7, by taking $A = \{v\}$ and $B = Z$, where $v \in V(G)$ and $Z \subseteq V(G) \setminus \{v\}$.

▶ **Corollary A.8** (BIS query can extract useful information about the neighborhood of a given vertex).

(i) Entire neighbourhood of a vertex using BIS: *There exists a deterministic algorithm that has* BIS *query access to an unknown graph $G(V, E)$ with n vertices, takes $v \in V(G)$ and $Z \subseteq V(G) \setminus \{v\}$ as input, makes $\widetilde{\mathcal{O}}(|N_G(v) \cap Z|)$* BIS *queries, and reports all the neighbors of v in Z.*

(ii) Approximate degree using BIS: *There exists an algorithm that has* BIS *query access to an unknown graph $G(V, E)$ with n vertices, takes $v \in V(G)$, $Z \subseteq V(G) \setminus \{v\}$ and $\varepsilon \in (0, 1)$ as inputs, makes $\widetilde{\mathcal{O}}(1)$* BIS *queries, and reports a $(1 \pm \varepsilon)$-approximation to $|N_G(v) \cap Z|$, with a probability of at least $1 - o(1)$.*

(iii) Finding an approximate random neighbor of a vertex using BIS: *There exists an algorithm that has* BIS *query access to an unknown graph $G(V, E)$ with n vertices, takes $v \in V(G)$, $Z \subseteq V(G) \setminus \{v\}$ and $\varepsilon \in (0, 1)$ as inputs, makes $\widetilde{\mathcal{O}}(1)$* BIS *queries, and reports a $(1 \pm \varepsilon)$-approximate uniform sample from the set $N_G(v) \cap Z$, with a probability of at least $1 - o(1)$.*

A.2 Algorithm Triangle-Est-High and proof of Lemma A.2

Algorithm Triangle-Est-High is inspired by the triangle estimation algorithm of Assadi et al. [2] [9] when we have the following query access to the unknown graph.

Adjacency Query: Given vertices $u, v \in V(G)$ as input, the oracle reports whether (u, v) is an edge or not;

Degree Query: Given a vertex $u \in V(G)$ as input, the oracle reports the degree of vertex u in G;

Random Neighbor Query: Given a vertex $u \in V(G)$, the oracle reports a neighbor of u uniformly at random if the degree of u is nonzero. Otherwise, the oracle reports a special symbol $\perp$;

Random Edge Query: With this query, the oracle reports an edge from the graph G uniformly at random.

The number of queries to the oracle made by Assadi et al.'s algorithm [2] is $\widetilde{\mathcal{O}}\left(\frac{m^{3/2}}{L}\right)$, where m denotes the number of edges and L is a promised lower bound on the number of triangles in G. Also, note that, the triangle estimation algorithm by Assadi et al. [2] can be *suitably* modified even if we have approximate versions of Degree, Random Neighbor and Random Edge queries, as described below.

Apx Degree Query: Given a vertex $u \in V(G)$ and $\varepsilon \in (0, 1)$ as input, the oracle reports a $(1 \pm \varepsilon)$-approximation to the degree of vertex u in G;

Apx Random Neighbor Query: Given a vertex $u \in V(G)$ and $\varepsilon \in (0, 1)$ as input, the oracle reports a $(1 \pm \varepsilon)$-approximate uniform sample from $N_G(u)$ if the degree of u is nonzero. Otherwise, the oracle reports a special symbol $\perp$;

Apx Random Edge Query: Given $\varepsilon \in (0, 1)$, the oracle reports a $(1 \pm \varepsilon)$-approximate uniform sample from $E(G)$.

From Corollary A.8, $\widetilde{\mathcal{O}}(1)$ BIS queries are enough to simulate Apx Degree Query and Apx Random Neighbor Query, with a probability of at least $1 - o(1)$. Also, by Proposition A.7, Apx Random Edge Query can be simulated by $\widetilde{\mathcal{O}}(1)$ BIS queries, with a probability of at least $1 - o(1)$. Moreover, a BIS query can trivially simulate an Adjacency Query. Combining these facts with the fact that the triangle estimation algorithm by Assadi et al. [2] can be suitably modified even if we have approximate versions of Degree, Random Neighbor and Random Edge queries, we are done with the proof of Lemma A.2.

A.3 Algorithm Triangle-Est-Low and the proof of Lemma A.3

Algorithm Triangle-Est-Low is inspired by the streaming algorithm for triangle counting by McGregor et al. [20]. Algorithm Triangle-Est-Low extracts a subset of edges by making BIS queries in a specific way as explained below. Later, we discuss that those sets of edges will be enough to estimate the number of triangles in G.

[9] Actually, they have given an algorithm for estimating the number of copies of any given subgraph of fixed size.

Generating a random sample $S \subseteq V(G)$ and exploring its neighborhood

Algorithm Triangle-Est-Low adds each vertex in $V(G)$ to S with probability $\widetilde{\mathcal{O}}\left(\frac{1}{\sqrt{L}}\right)$. Recall Corollary A.8 (i). For each $v \in S$, we find all the neighbors of v (the set $N_G(v)$) by making $\widetilde{\mathcal{O}}(|N_G(v)|)$ BIS queries. Let E_S be the set of all the edges having at least one end point in S, that is, $E_S = \{(v,w) : v \in S \text{ and } w \in N_G(v)\}$. After finding E_S, we do the following. For each $v \in S$, we find all the edges in the subgraph induced by $N_G(v)$ by using $\widetilde{\mathcal{O}}\left(|E(G[N_G(v)])|\right)$ BIS queries. This is again possible by Corollary A.8 (i). Note that $|E(G[N_G(v)])|$ is the number of edges in the subgraph of G induced by $N_G(v)$. Let E'_S be the set of all edges present in the subgraph induced by $N_G(v)$ for some $v \in S$, that is, $E'_S = \bigcup\limits_{v \in S} E(G[N_G(v)])$. Later, we argue that the number of BIS queries that we make to generate E_S and E'_S is bounded in expectation.

Apart from S, E_S and E'_S, Triangle-Est-Low extracts some more required edges by making BIS queries, as explained below.

Generating F, a set of $(1 \pm \mathcal{O}(\varepsilon))$-approximate uniform sample from $E(G)$, and exploring the subgraphs induced by sets $N_G(v) \cap V(F)$ for each $v \in V(F)$

Algorithm Triangle-Est-Low calls the algorithm corresponding to Proposition A.7, for $\widetilde{\mathcal{O}}\left(\frac{m}{\sqrt{L}}\right)$ times. By this process, we get a set F of $(1 \pm \mathcal{O}(\varepsilon))$-approximate uniform sample from $E(G)$, with a probability of at least $1 - o(1)$. Note that $|F| = \widetilde{\mathcal{O}}\left(\frac{m}{\sqrt{L}}\right)$, and the number of BIS queries we make to generate F is $\widetilde{\mathcal{O}}\left(\frac{m}{\sqrt{L}}\right)$. Let $V(F)$ be the set of vertices present in at least one edge in F. For each vertex $v \in V(F)$, we find all the edges in the subgraph of G induced by $N_G(v) \cap V(F)$, by using $\widetilde{\mathcal{O}}\left(|E(G[N_G(v) \cap V(F)])|\right)$ BIS queries (see Corollary A.8 (i)). Note that $|E\left(G[N_G(v) \cap V(F)]\right)|$ is the number of edges in the subgraph of G induced by $N_G(v) \cap F$. Let E_F be the set of all the edges that are present in subgraphs induced by $N_G(v) \cap V(F)$ for some $v \in V(F)$, that is, $E_F = \bigcup\limits_{v \in V(F)} E(G[N_G(v) \cap V(F)])$. Later we show that the expected number of BIS queries needed to find F and E_F is bounded.

In algorithm Triangle-Est-Low, BIS queries are made only to generate S, E_S, E'_S, F and E_F. After these sets are generated, no more BIS queries are made by the algorithm. We formally prove the query complexity of Triangle-Est-Low. But, first, we show that S, E_S, E'_S, F and E_F can be carefully used to estimate T, the number of triangles in G.

Connection with streaming algorithm for triangle counting by McGregor et al. [20]

(Estimating the number of triangles from S, E_S, E'_S, F and E_F)

McGregor et al. [20] gave a two-pass algorithm that estimates the number of triangles in a graph G when the edges of G arrive in an arbitrary order. Moreover, the space complexity of their algorithm is $\widetilde{\mathcal{O}}\left(\frac{m}{\sqrt{L}}\right)$. Note that their algorithm assumes a lower bound L on the number of triangles in the graph. The high level sketch of their algorithm is as follows:

- Generate a subset X of $V(G)$ by sampling each vertex in $V(G)$ with probability $\widetilde{\mathcal{O}}\left(\frac{1}{\sqrt{L}}\right)$;
- In the first pass, the edges having at least one vertex in X is found, and let it be E_X. Also, in the first pass, a subset of edges Y is generated by sampling each edge with probability $\widetilde{\mathcal{O}}\left(\frac{1}{\sqrt{L}}\right)$;
- In the second pass, for each edge $e = \{x, y\}$ in the stream, their algorithm finds the vertices in X with which e forms a triangle. Also, for each edge, $e = \{x, y\}$ in the stream, their algorithm finds the pairs of edges in Y that forms a triangle with e. Let Z be the set of *useful* edges in the second pass, that is, the set of edges that either forms a triangle with a vertex in X or forms a triangle with two edges in Y.

Note that their algorithm does not talk about the set Z. We are introducing it for our analysis. Executing the two passes described above is straightforward. They have proved that performing two passes as described is good enough to estimate the number of triangles in the graph.

Now, we compare the information maintained by our algorithm with the information maintained by McGregor et al.'s algorithm. S and E_S in our algorithm Triangle-Est-Low follows the same probability distribution as that of X and E_X, respectively, in McGregor et al.'s algorithm. Recall that F is a set of $\widetilde{\mathcal{O}}\left(\frac{m}{\sqrt{L}}\right)$ $(1 \pm \varepsilon)$-approximate sample from $E(G)$ with a probability $1 - o(1)$. But Y in McGregor et al.'s algorithm is generated by sampling each edge with probability $\widetilde{\mathcal{O}}\left(\frac{1}{\sqrt{L}}\right)$. But observe that the *total variation* distance between the probability distributions of F and Y is $o(1)$.

Before discussing about E'_S and E_F in our algorithm Triangle-Est-Low, consider the following observation about the set Z. Note that we have defined Z while describing the second pass of McGregor et al.'s algorithm.

▶ **Observation A.9.** Consider X, E_X, and Y generated by the first pass of McGregor et al.'s algorithm. Let E'_X be the edges in the subgraph induced by $N_G(v)$ for some $v \in X$, and let E_Y be the set of edges in the subgraph induced by $N_G(v) \cap V(Y)$. Here $V(Y)$ denotes the set of vertices present in at least one vertex of Y. Then for each edge $e \notin E'_X \cup E_Y$, there is neither a vertex in X with which e forms a triangle in G nor there are two edges in Y with which e forms a triangle in G. Then the set of useful edges Z is $E'_X \cup E_Y$.

By the above observation, E'_S and E_F in our algorithm Triangle-Est-Low are essentially enough for maintaining the information and executing the same steps as that of the second pass of McGregor et al.'s algorithm.

Putting everything together, algorithm Triangle-Est-Low outputs a $(1 \pm \varepsilon)$-approximation to the number of triangles in the graph.

Query complexity analysis

The set S can be generated without making any BIS queries. The number of BIS queries we make to find the set E_S is at most $\sum\limits_{v \in S} \widetilde{\mathcal{O}}(|N_G(v)|)$, which in expectation is

$$\mathbb{E}\left[\sum_{v \in S} \widetilde{\mathcal{O}}(|N_G(v)|)\right] = \sum_{v \in V(G)} \Pr(v \in S) \cdot \widetilde{\mathcal{O}}(|N_G(v)|) = \widetilde{\mathcal{O}}\left(\frac{m}{\sqrt{L}}\right).$$

The number of BIS queries we make to find the set E'_S is at most $\sum\limits_{v \in S} \widetilde{\mathcal{O}}\left(|E(G[N_G(v)])|\right)$. Note that $|E(G[N_G(v)]|$ is T_v, that is, the number of triangles having v as one of the vertex. So, the expected number of BIS queries we make to find E'_S is at most

$$\mathbb{E}\left[\sum_{v \in S} \widetilde{\mathcal{O}}(T_v)\right] = \sum_{v \in V(G)} \Pr(v \in S) \cdot \widetilde{\mathcal{O}}(T_v) = \widetilde{\mathcal{O}}\left(\frac{T}{\sqrt{L}}\right).$$

The number of BIS queries we make to find the set F is $\widetilde{\mathcal{O}}(|F|) = \widetilde{\mathcal{O}}\left(\frac{m}{\sqrt{L}}\right)$

The number of BIS queries to generate E_F is at most $\sum\limits_{v \in V(F)} \widetilde{\mathcal{O}}\left(|E(G[N_G(v) \cap V(F)])|\right)$. Observe that an edge $\{x, y\}$ is present in E_F if there exists a $z \in V(G)$ such that $\{x, y, z\}$

forms a triangle in G and $\{x, z\}$ and $\{y, z\}$ are in F. So, the probability that an edge $\{x, y\}$ is in $E(G[N_G(v) \cap V(F)]$ is at most $|\Gamma(\{x, y\})| \cdot \widetilde{\mathcal{O}}\left(\frac{1}{L}\right)$, where $\Gamma(\{x, y\})$ denotes the set of common neighbors of x and y in G. So, the expected number of BIS queries to enumerate all the edges in E_F is at most

$$\sum_{\{x,y\} \in E(G)} \widetilde{\mathcal{O}}\left(\frac{|\Gamma(\{x, y\}|)}{\sqrt{L}}\right) = \widetilde{\mathcal{O}}\left(\frac{T}{\sqrt{L}}\right).$$

Hence, the expected number of BIS queries made by the algorithm is $\widetilde{\mathcal{O}}\left(\frac{m+T}{\sqrt{L}}\right)$.

Fine Grained Analysis of High Dimensional Random Walks

Roy Gotlib

Abstract

One of the most important properties of high dimensional expanders is that high dimensional random walks converge rapidly. This property has proven to be extremely useful in a variety of fields in the theory of computer science from agreement testing to sampling, coding theory and more. In this paper we present a state of the art result in a line of works analyzing the convergence of high dimensional random walks [13, 10, 15, 1], by presenting a *structured* version of the result of [1]. While previous works examined the expansion in the viewpoint of the worst possible eigenvalue, in this work we relate the expansion of a function to the entire spectrum of the random walk operator using the structure of the function; We call such a theorem a Fine Grained High Order Random Walk Theorem. In sufficiently structured cases the fine grained result that we present here can be much better than the worst case while in the worst case our result is equivalent to [1].

In order to prove the Fine Grained High Order Random Walk Theorem we introduce a way to bootstrap the expansion of random walks on the vertices of a complex into a fine grained understanding of higher order random walks, provided that the expansion is good enough.

In addition, our *single* bootstrapping theorem can simultaneously yield our Fine Grained High Order Random Walk Theorem as well as the well known Trickling down Theorem. Prior to this work, High order Random walks theorems and Tricking down Theorem have been obtained from different proof methods.

1 Introduction

In recent years much attention has been given to the field of high dimensional expanders which are high dimensioanl analogues of expander graphs. One extremely useful property of high dimensional expanders is that higher dimensional random walks (which are higher dimensional analogues of random walks on graphs) converge rapidly to their stationary distribution (For example, this property was used in [10, 14, 4, 9] and more). Consequently there has been some work studying the convergence of higher dimensional random walks [10, 13, 15, 1]. In this paper we improve upon these convergence results by relating the structure of the function to its expansion. Specifically we present the following improvements:

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

Fine grained analysis of random walk

Prior to this paper, the state of the art analysis of high dimensional random walks was done by Alev and Lau in [1] following [10, 13, 15]. Their work analyzed the eigenvalues of an important random walk called the *down-up random walk*. Their result, however, was only useful for the worst case analysis as it did not relate the structure of the function to its expansion and thus was forced to consider the worst possible function. In this paper we present an improvement upon Alev and Lau's result by finding a connection between the structure of a function and how well it expands and can therefore yield better results on cochains that posses a "nice" structure.

In two-sided spectral expanders a fine grained analysis of high dimensional random walks was already proven, based on Fourier analysis in high dimensional expanders [8, 15]. In the two sided case even stronger results following from hypercontractivity are known [5, 6, 12] and more. Our result is, importantly, about *one-sided* spectral expanders as there are cases when the use of one-sided high dimensional expansion is crucial - for example in Anari et al's breakthrough proof of the fast convergence of the basis exchange walk [4] and thus showed an algorithm that samples a basis of a matroid. This result started a wave of sampling results that use high dimensional expanders [7, 3, 2] to name a few examples. This result relies heavily on fast convergence of high dimensional random walks on one-sided expanders (As they show that that the basis exchange corresponds to a down-up walk on the top dimension of a one-sided high dimensional expander). In this work we present, to our knowledge, the first result to show a fine grained analysis of the random walk operator in one-sided local spectral expanders.

Replacing eigendecomposition

Previous fine grained analysis of high dimensional random walks relied on finding approximate eigendecomposition of the high dimensional random walk. We present a new approach to finding a fine grained understanding of the high dimensioanl random walks: bootstrapping an understanding of the expansion of random walks on the vertices of the complex. We show that, if the expansion of these random walks beat the expansion of high dimensional random walks on the vertices of local structures[1], we can bootstrap it into a *fine grained* understanding of higher dimensional random walks.

Unification of the High order random walk theorem and the Tricking down theorem

In order to perform our fine grained analysis of the higher dimensional random walk operators we develop a new bootstrapping framework. This new framework is fairly generic and seems to be of independent interest as it can be used to prove another central theorem in the theory of high dimensional expansion, namely the trickling down theorem [16]. We comment that prior to this work these two important theorems were obtained by different proof techniques.

Before we can state our results more formally, we have to define the high dimensional analogs of expander graphs as graphs do not posses high dimensions. This high dimensional object is called a "simplicial complex" and is defined as:

▶ **Definition 1** (Simplicial complex). *A set X is a* simplicial complex *if it is closed downwards meaning that if $\sigma \in X$ and $\tau \subseteq \sigma$ then $\tau \in X$. We call members of X the* faces *of X.*

[1] Specifically, high dimensional random walks on the vertices of the links of vertices.

Simplicial complexes can be thought of as hyper-graphs with closure property (i.e. every subset of a hyper-edge is a hyper-edge). We are interested in higher dimensions and therefore it would be useful to define the dimension of these higher dimensional objects:

▶ **Definition 2** (Dimension). *Let X be a simplicial complex and let $\sigma \in X$ be a face of X. Define the dimension of σ to be $\dim(\sigma) = |\sigma| - 1$. We also denote the set of all faces of dimension i in X as $X(i)$. Also define the dimension of the complex X as $\dim(X) = \max_{\sigma \in X}\{\dim(\sigma)\}$. Note that there is a single (-1)-dimensional face - the empty face.*

Of particular interest are simplicial complexes whose maximal faces are of the same dimension, defined below:

▶ **Definition 3** (Pure simplicial complex). *A simplicial complex X is a* pure simplicial complex *if every face $\sigma \in X$ is contained in some $(\dim(X))$-dimensional face.*

Throughout this paper we will assume that every simplicial complex is pure. In most cases we will be interested in weighted pure simplicial complexes. In weighted pure simplicial complexes the top dimensional faces are weighted and the weight of the rest of the faces follows from there as described here:

▶ **Definition 4** (Weight). *Let X be a pure d-dimensional simplicial complex. Define its weight function $\mathrm{w} : X \to [0,1]$ to be a function such that:*

- $\sum_{\sigma \in X(d)} \mathrm{w}(X) = 1$
- *For every face τ of dimension $i < d$ it holds that $\mathrm{w}(\tau) = \frac{1}{\binom{d+1}{i+1}} \sum_{\substack{\sigma \in X(d) \\ \tau \subseteq \sigma}} \mathrm{w}(\sigma)$.*

It is important to note that we think of unweighted complex as complexes that satisfy $\forall \sigma \in X(d) : \mathrm{w}(\sigma) = \frac{1}{|X(d)|}$. While the top dimensional faces of unweighted complexes all have the same weight, the same cannot be said for lower dimensional faces.

It is also important to note that the sum of weights in every dimension is exactly 1 and therefore for every k the weight function can, and at times will, be thought of as a distribution on $X(k)$.

One key property of high dimensional expanders is that they exhibit *local to global* phenomena. These phenomena are at the main interest of this paper. It is therefore useful to consider local views of the simplicial complex which we define as follows:

▶ **Definition 5** (Link). *Let X be a simplicial complex and $\sigma \in X$ be a face of X. Define the* link *of σ in X as $X_\sigma = \{\tau \setminus \sigma | \sigma \subseteq \tau\}$. It is easy to see that the link of any face is a simplicial complex.*

The weight of faces in the links is induced by the weights of the faces in the original complex. Specifically, we denote by w_σ the weight function in the link of $\sigma \in X(i)$ and it holds that $\forall \tau \in X_\sigma(j) : \mathrm{w}_\sigma(\tau) = \frac{\mathrm{w}(\tau \cup \sigma)}{\binom{i+j+2}{i+1}\mathrm{w}(\sigma)}$. Generally speaking, the local to global phenomena are ways to derive properties of the entire complex by only looking at local views (i.e. links).

Another important substructure of a simplicial complex is its skeletons

▶ **Definition 6** (Skeleton). *Let (X, w) be a weighted pure d-dimensional simplicial complex and let $i \leq d$. Define the i-skeleton of X as the following weighted simplicial complex:*

$$X^{(i)} = \{\sigma \in X | \dim \sigma \leq i\}$$

With the original weight function.

In many cases we will think of the 1-skeleton of a simplicial complex as a graph. In addition, it is important to note that even if the original complex is unweighted, the skeletons of said complex might be.

We are now ready to define a high dimensional expander[2].

▶ **Definition 7** (Local spectral expander). *A pure d-dimensional simplicial complex X is a λ-local spectral expander[3] if for every face σ of dimension at most $d-2$ it holds that $X_\sigma^{(1)}$ is a λ-spectral expander[4]. Note that this includes $\sigma = \emptyset$, i.e. the entire complex.*

Much like graphs, simplicial complexes also support random walks. In graphs, the random walks are of the form vertex-edge-vertex - the walk might move between two vertices if they are connected by an edge. The high dimensional analogue of these random walks travel between two k-dimensional faces if they are part of a common $(k+1)$-dimensional face. Our particular random walk of interest is the higher dimensional analogue of the non-lazy random walk, defined as follows:

▶ **Definition 8** (Non-lazy up-down operator informal, for formal see 24). *Define the k-dimensional non-lazy up-down random walk, $(M')_k^+$ as the k dimensional analogue of the non-lazy random walk on the vertices of a graph: A walk that moves between two k-dimensional faces if they are contained in a $(k+1)$-dimensional face and never stays in place.*

We are going to improve our understanding of how these higher dimensional random walks apply to structured states. These states correspond to another natural structure on high dimensional expanders called cochains that is defined as follows:

▶ **Definition 9** (Cochains). *Let X be a pure d-dimensional simplicial complex. For $-1 \leq k \leq d$ define a k-dimensional cochain F to be any function from $X(k)$ to $\mathbb{R}$. We also denote by $C^k(X;\mathbb{R})$ the set of all k-dimensional cochains.*

We are going to be interested in ways of viewing the cochains in the links of the complex. For now we will only introduce one such way. Namely localization:

▶ **Definition 10** (Localization). *Let X be a pure d-dimensional simplicial complex, k, i be dimensions such that $i < k$ and $F \in C^k(X;\mathbb{R})$. Also let $\sigma \in X(i)$. Define the localization of F to σ to be:*

$$F_\sigma(\tau) = F(\sigma \cup \tau).$$

We note that there is a very natural inner product defined on the cochains of a simplicial complex, defined as follows:

▶ **Definition 11** (Inner product). *Let X be a pure d-dimensional simplicial complex and let $F, G \in C^k(X;\mathbb{R})$. Define the inner product of F and G to be:*

$$\langle F, G \rangle = \sum_{\sigma \in X(k)} \mathrm{w}(\sigma) F(\sigma) G(\sigma).$$

[2] There is no singular definition of high dimensional expander but in this paper we only use the algebraic definition - local spectral expansion.

[3] Much like one dimensional expanders, in high dimensions there is also notion of one-sided vs. two-sided local spectral expansion. The definition we use throughout the paper is that of *one*-sided local spectral expander. The difference being that in two-sided local spectral expander the underlying graph of every link is a two-sided expander rather than a one-sided expander.

[4] The complexes are weighted and therefore their expansion property is defined as the second largest eigenvalue of the non-lazy random walk. A random walk that walks from a face to one of its neighbours with probability equal to the proportion between the weight of the edge that connects them and the sum of the weights of the edges that include said vertex.

1.1 Main Results

In this paper we present a state of the art analysis the high dimensional analogue of the non-lazy random walk. We are specifically interested in going beyond Alev and Lau's worst case result [1, Theorem 1.5] and relate the structure of the cochain to its expansion. Specifically, we define:

▶ **Definition 12** (i-level cochain, informal. For formal see Definition 29)**.** *A cochain F is an i-level cochain with respect to localization if for every $\sigma \in X(i-1)$ it holds that $\langle F_\sigma, \mathbb{1} \rangle = 0$.*[5]

Previously the best analysis of high dimensional random walk was due to Alev and Lau [1, Theorem 1.5] who showed that:

▶ **Theorem 13** (Alev and Lau [1], restated)**.** *Let X be a pure d-dimensioanl high dimensional expander. Define $\gamma_i = \max_{\sigma \in X(i)} \{\lambda_2(X_\sigma)\}$. For any dimension k and any k-dimensional 0-level cochain F it holds that:*

$$\left\langle (M')_k^+ F, F \right\rangle \leq \left(1 - \frac{1}{k+1} \prod_{j=-1}^{k-2} (1-\gamma_i)\right) \|F\|^2.$$

We show that this result can be vastly improved for structured cochains. Specifically, we show the following decomposition of the high dimensional random walks:

▶ **Theorem 14** (Fine grained analysis of high dimensional random walks, Informal. For formal see Theorem 54)**.** *Let $F \in C^k(X; \mathbb{R})$ and let $F_0, \cdots, F_k$ be an orthogonal decomposition of F such that F_i is an i-level cochain and $F = \sum_{i=0}^{k} F_i$. In addition, let $\gamma_i = \max_{\sigma \in X(i)} \{\lambda_2(X_\sigma)\}$ (Where $\lambda_2(X_\sigma)$ is the second largest eigenvalue of the underlying graph of X_σ) then:*

$$\left\langle (M')_k^+ F, F \right\rangle \leq \sum_{i=0}^{k} \left(1 - \frac{1}{k-i+1} \prod_{j=i-1}^{k-1} (1-\gamma_j)\right) \|F_i\|^2.$$

Cases where we improve upon previous results

In the worst case (i.e. no assumption is made on the structure of F) our result matches that of Alev and Lau. In cases where the cochain is structured, however, our Theorem yields strictly better results than what was previously known. We also give some examples of families of structured cochains on which our result is *strictly better* than the result of Alev and Lau - Specifically, we show two families of cochains that are highly structured: The first is a set of cochains associated with a different form of high dimensional expansion, the minimal cochains and the second is the indicator function of a balanced set of faces (for more information see the full version).

Comparison with other known decompositions

Similar decompositions of the high dimensional random walks were already known for two-sided high dimensional expanders [8, 15]. These decomposition relied on finding approximate eigenspaces of the walk operator. Unlike the case in two-sided high dimensional expanders,

[5] We note that every j-dimensional i-level cochain corresponds to a cochain in the i^{th} dimension that has been "lifted" up to the j^{th} dimension. A more formal version of this statement can be found in Lemma 53.

in one-sided high dimensional expanders the eigenspaces of the high dimensional random walks are not currently understood, even approximately. We do, however, understand the expansion of key random walks on the 0-dimensional cochains. We follow this by showing that if this expansion is strong enough (i.e. these random walks converge fast enough) we can boost it to all levels and get a decomposition theorem without eigendecomposition. In order to apply our bootstrapping method we have to show that the expansion of the aforementioned 0-dimensional cochains "beats" the expansion of cochains of higher levels. Note that the decomposition achieved by our bootstrapping theorem differs from the decomposition known in two-sided expanders in one *crucial* way: In our decomposition the level functions are *not* approximate eigenfunctions. Moreover, applying the non-lazy up-down random walk operator to any one of them yields a cochain that is *not* orthogonal to many of the other F_js. This allows us to sidestep a major technical barrier in previous works as we do not rely on the existence of an eigendecomposition of the walk operator (or even an approximate decomposition of that operator). Note that many results that use local spectral expanders, such as their usage in proving the existence of cosystolic expanders, agreement testing, locally testable codes and more only require one application of the walk operator and thus we believe that our result will prove to be influential with regards to these fields.

Our main tool for proving the decomposition of high dimensional random walks is a bootstrapping theorem that reduces decomposition of higher dimensional random walk to an understanding of highly structured cochains (for example cochains that correlate with 0-dimensional cochains). The bootstrapping theorem is fairly general and thus we bring a special case of it here:

▶ **Theorem 15** (Bootstrapping theorem, informal. For formal see Theorem 34). *Let X be a simplicial complex and k be a dimension. Every $F \in C^k(X;\mathbb{R})$ that is orthogonal to the constant functions can be decomposed into $F = \sum_{i=0}^{k} F_i$ such that the cochains F_i are both:*

1. i-level cochains with respect to localization.
2. Orthogonal: *For every $i \neq j$ it holds that F_i is orthogonal to F_j.*

We can use a solution of some recursive formula on 0-level cochains and values $\{\lambda_i\}_{i=0}^{k}$ in order to bootstrap a decomposition of the following form:

$$\left\langle (M')_k^+ F, F \right\rangle = \sum_{i=0}^{k} \lambda_i \left\| F_i \right\|^2.$$

Solving the recursive formula in the bootstrapping theorem requires us to gain some "advantage" for highly structured cochains in the complex. We can therefore view this Theorem as a tool that allows us to bootstrap an advantage we have to a decomposition of the non-lazy random walks.

As we said, our bootstrapping theorem is fairly generic and can also yield the celebrated Oppenheim's trickling down theorem [16, Theorem 4.1]:

▶ **Theorem 16** (Trickling Down, [16]). *Let X be a pure d-dimensional simplicial complex. If it holds that:*

- *For every vertex v: $X_v^{(1)}$ is a λ spectral expander.*
- *X is connected.*

Then it holds that $X^{(1)}$ is a $\frac{\lambda}{1-\lambda}$ spectral expander.

In order to prove the trickling down we use Theorem 15 while defining the i-level cochains differently. For more detail, see Section A.

1.2 Proof Layout

As we mentioned before, we analyze the *non-lazy up-down random walk* - a high dimensional analogue of the non-lazy random walk in graphs. We would like to get a decomposition of the non-lazy random walk operator. In order to do that we decompose the space of cochains to spaces which we term level cochains. Our proof is then comprised of two steps: A bootstrapping Lemma that reduces the problem of decomposing the non-lazy up-down random walk operator to a simple recursive condition about the 0-level cochains and an advantage that allows us to solve said recursive condition. We note that solving the recursive condition is considerably simpler than proving the decomposition directly as the 0-level cochains are very structured objects.

Link viewers

Local-to-global arguments are typically structured by taking a global cochain, decomposing it to local cochains (i.e. cochains on the links of the vertices of the complex) and then using a property of the cochains in the links in order to argue about the original cochain. Two extremely useful ways of decomposing a global cochain to cochains in the links are *restriction* and *localization*. These two methods share many properties, for example:

- They preserve constant functions - Any global constant function is constant locally.
- They are linear - The local view of sum of any two global cochains is the sum of the local views.
- They interact well with the inner product - The expected value of the local inner products of two cochains is their inner product.

We start by identifying these properties and defining a general object that satisfy them called a *link viewer*. A link viewer Λ defines the local view of a cochain F in the link of σ which we denote by $\Lambda_\sigma F$. For the rest of this section, unless stated otherwise, we will think of the *localization link viewer* defined as $\Lambda^\ell_\sigma F = F_\sigma$.

Level cochains

Any link viewer decomposes the space of cochains to subspaces called *i-level cochains*. These spaces are the set of cochains whose expected value is 0 when viewed from any i-dimensional face. We think of these cochains as not correlated with any i-dimensional face. For example, under the localization link viewer the i-level cochains are cochains G that satisfy: $\forall \sigma \in X(i) : \mathbb{E}_{\tau \in X_\sigma(k-i-1)}\left[\Lambda^\ell_\sigma G(\tau)\right] = \mathbb{E}_{\tau \in X_\sigma(k-i-1)}\left[G_\sigma(\tau)\right] = 0$. Note that any i-level cochain is also an $(i-1)$-level cochain and that of F is an i-level cochain then $\Lambda_v F$ is an $(i-1)$-level cochain in the link of every vertex v. It is therefore useful to define *proper level cochains* as well - a proper i-level cochain is an i-level cochain that is orthogonal to every $(i-1)$-level cohain. Every cochain F can be decomposed to $F = \sum_{i=-1}^{p} F_i$ such that every F_i is a proper i-level cochain. This decomposition plays a key role in our proof.

The bootstrapping argument

We can now present our proof for the bootstrapping argument. We assume that the non-lazy up-down random walk expands locally and show that this yields that the non-lazy up-down random walk expands globally. We restrict our attention only to 0-level cochains (which are not necessarily proper) as (-1)-level cochains correspond to the trivial eigenvalue in which we are not interested. Let $F = \sum_{i=0}^{p} F_i$ be a 0-level cochain. Consider its localization to the links of vertices $\Lambda_v F = \sum_{i=0}^{p} \Lambda_v F_i$. Note that $\sum_{i=1}^{p} \Lambda_v F_i$ is a 0-level cochain in X_v(as the localization to links of vertices of i-level cochains is an $(i-1)$-level cochain). Note that $\Lambda_v F_0$ is *not* a 0-level cochain. We can, however, apply our decomposition theorem to some part of $\Lambda_v F_0$ by decomposing it to two parts:

- A 0-level cochain - $\Lambda_v F_0 - \mathbb{E}\left[\Lambda_v F_0\right]$
- A remainder - $\mathbb{E}\left[\Lambda_v F_0\right]$.

We can therefore apply our decomposition theorem to $\sum_{i=0}^{p} \Lambda_v F_i - \mathbb{E}\left[\Lambda_v F_0\right]$. Note that a key step in this decomposition is that despite the fact that these new localized cochains are *not* orthogonal to each other, they are *all* orthogonal to the constants. This allows us to separate them from the constant part of every localization. All we have left to do is to compensate for the remainder. This is done using the advantage step which we will describe next.

The Advantage

In the advantage step we try to bound the remainder we have left in the bootstrapping stage. The advantage required in order to achieve the random walk decomposition Theorem is done by considering the localization link viewer that showing the following observations:

1. Any 0-level function F_0 is, in a sense, a high dimensional description of some other 0-dimensional cochain $G \in C^0(X;\mathbb{R})$. This is true in the sense that $\|F_0\| = \|G\|$ and $\mathbb{E}\left[\Lambda_v^{\ell} F_0\right] = \left\|M_0^{+k} G\right\|$ where M_0^{+k} is the random walk the applied the up step k times followed by applying the down step k times.
2. There is a connection between the random walk on the underlying graph of the complex and M^{+k}. The key claim we use is that once the random walk has performed its first up step *it can already "see" all the vertices it will ever see* (this is due to the structure of simplicial complexes - if two vertices share a k-dimensional face then by the closure property they also share an edge). Going further up only decreases the probability of staying in place. Therefore M^{+k} is a weighted sum of the underlying graph's non-lazy random walk transition matrix and a lazy component (which corresponds to staying in place). We note that this observation can be generalized to any random walk on k-dimensional faces that "walks through" faces of dimension higher than $2k$.

Using these observations as well as our understanding of the 0-dimensional random walk we obtain the advantage we seek.

2 The Signless Differential and Its Adjoint Operator

One of the key operators induced by any simplicial complex is its *signless differential operator*. The signless differential operator is an averaging operator that accepts a k-dimensional cochain and returns a $(k+1)$-dimensional cochain. We adopt the terminology of [15] and consider repeated application of the signless differential and its adjoint operator.

▶ **Definition 17** (Signless differential). *The signless differential operator* $d_k : C^k(X;\mathbb{R}) \to C^{k+1}(X;\mathbb{R})$ *in the following way:*

$$d_k F(\sigma) = \mathbb{E}_{\tau \in X(k)}\left[F(\tau) | \tau \subseteq \sigma\right] = \sum_{\tau \in \binom{\sigma}{k+1}} \frac{1}{k+2} F(\tau).$$

When the dimension is clear from context it will be omitted from the notation. Also define $d_k^* : C^{k+1}(X;\mathbb{R}) \to C^k(X;\mathbb{R})$ *to be the adjoint operator of* d_k.

▶ Note. The signless differential does not meet the definition of a differential as $d_k d_{k-1} \neq 0$.

▶ **Lemma 18** ([15, Lemma 3.6], [8]). *It holds that:*

$$d_k^* F(\tau) = \mathbb{E}_{\sigma \in X(k+1)} \left[F(\sigma) | \tau \subseteq \sigma\right] = \mathbb{E}_{\sigma \in X_\tau(0)} \left[F_\tau(\sigma)\right].$$

For proof see the full version.

We will be interested in repeated application of the signless differential and its adjoint operator. To that effect it will be useful to present them explicitly. Lemmas 19 and 20 will present repeated applications of these operators explicitly (and the proofs of both Lemmas can be found in the full version of this paper).

▶ **Lemma 19.** *Let F be an i-dimensional cochain. Then:*

$$d_{j-1} \cdots d_i F(\sigma) = \mathbb{E}_{\tau \in X(i)} \left[F(\tau) | \tau \subseteq \sigma\right].$$

▶ **Lemma 20.** *Let F be an i-dimensional cochain. Then:*

$$d_i^* \cdots d_{j-1}^* F(\sigma) = \mathbb{E}_{\tau \in X_\sigma(j-i-1)} \left[F_\sigma(\tau)\right].$$

3 Up-Down and Down-Up Operators

In this section we will present two objects of interest - the up-down and down-up walks. These are natural operators that result from considering a standard walk on the k-dimensional faces of a simplicial complex using the following two steps: A *down step* where, given a k-dimensional face, the walk moves to a $(k-1)$-dimensional face that is contained in it with equal probability. And an *up step* in which, given a k-dimensional face, the walk moves to a $(k+1)$-dimensional face with probability proportional to its weight. Applying the up step followed by the down step yields the up-down walk while applying the down step followed by the up step yields the down-up walk.

▶ **Definition 21** (Up-down and down-up operators). *Let X be a simplicial complex. Then define the up-down random walk to be:*

$$\left[M_k^+\right]_{\sigma,\tau} = \begin{cases} \frac{1}{k+2} & \sigma = \tau \\ \frac{\mathrm{w}_\sigma(\tau \setminus \sigma)}{k+2} & \sigma \cup \tau \in X(k+1) \\ 0 & \textit{Otherwise.} \end{cases}$$

And the down-up random walk to be:

$$\left[M_k^-\right]_{\sigma,\tau} = \begin{cases} \frac{1}{k+1} \sum_{\tau' \in \binom{\sigma}{k}} \mathrm{w}_{\tau'}\left(\sigma \setminus \tau'\right) & \sigma = \tau \\ \frac{1}{k+1} \mathrm{w}_{\sigma \cap \tau}\left(\tau \setminus \sigma\right) & \sigma \cap \tau \in X(k-1) \\ 0 & \textit{Otherwise.} \end{cases}$$

We would now like to present characterization the up-down random walk and the down-up random walk using the signless differential (this characterization had appeared in [15, Corollary 3.7] and is given here for completeness). In order to do that, consider the following Lemma:

▶ **Lemma 22.** *Let X be a simplicial complex, it holds that:*

$$M_k^+ = d_k^* d_k \qquad M_k^- = d_{k-1} d_{k-1}^*.$$

For proof, see the full version of this paper.

We are also going to be interested in applying the signless differential and its adjoint operator multiple times in a row. We will therefore define the k-dimensional i-up-down operator and the k-dimensional i-down-up operator in the following way:

▶ **Definition 23.** *Let M_k^{+i} be the k-dimensional i-up-down operator and M_k^{-i} be the k-dimensional i-down-up operator defined as follows:*

$$M_k^{+i} = d_k^* \cdots d_{k+i-1}^* d_{k+i-1} \cdots d_k \qquad\qquad M_k^{-i} = d_{k-1} \cdots d_{k-i-1} d_{k-i-1}^* \cdots d_{k-1}^*.$$

Recall that the i-up-down operator and the i-down-up operators can be presented explicitly using Lemma 19 and Lemma 20. In addition, note that the i-up-down operator corresponds to applying the up step i times and then applying the down step i times. Likewise the i-down-up operator corresponds to applying the down step i times and then applying the up step i times.

4 The Non-Lazy Walk Operator

Our main object of study is going to be the non-lazy k-dimensional random walk operator. This operator is a generalization of the non-lazy random walk operator in graphs to higher dimensions. In graphs the non-lazy random walk operator moves between two vertices if they have an edge connecting them. The higher dimensional version of this operator is going to be something very similar: It is going to move between two k-faces if there is a $(k+1)$-face that contains both faces.

▶ **Definition 24** (The Non-Lazy k-dimensional Random Walk Operator)**.** *Let X be a pure d-dimensional simplicial complex define the k-dimensional random walk operator to be the following operator:*

$$\left[(M')_k^+\right]_{\sigma,\tau} = \begin{cases} \frac{\mathrm{w}_\sigma(\tau\setminus\sigma)}{k+1} & \sigma\cup\tau\in X(k+1) \\ 0 & \textit{Otherwise.} \end{cases}$$

One can also think of the non-lazy random walk operator as the regular up-down operator with the lazy part removed. Formally:

▶ **Observation 25.** *For every dimension k it holds that $(M')_k^+ = \frac{k+2}{k+1} M_k^+ - \frac{1}{k+1} I$.*

Of specific interest is the 0-dimensional non-lazy up-down operator as it can be used to describe *every* one of the 0-dimensional i-up-down operators. This is because every one of these operators ultimately move between a vertex and its neighbours. The more steps one takes up the complex the more mixed the result is. By that we mean that the non-lazy walk operator has a larger effect on the result. Quantitatively, this can be formulated via the following Lemma.

▶ **Lemma 26.** *It holds that $(M')_0^+ = \frac{i+1}{i} M_0^{+i} - \frac{1}{i} I$.*

For proof, see the full version.

5 Analyzing the Non-Lazy Random Walk Operator

We are now ready to start analyzing the random walk operators. In order to do so we are going to use a *local to global* argument. In order to apply a local to global argument we must understand how to view a cochain through the links. Specifically we will be interested in viewing methods that satisfy the following:

▶ **Definition 27** (Link viewer)**.** *A* link viewer *is any transformation Λ that accepts a face σ and a cochain in X. It then returns a cochain in X_σ. In addition, a link viewer satisfies the following:*

- *For every face σ it holds that Λ_σ is linear.*
- *For every face σ it holds that $\Lambda_\sigma \mathbb{1} = \mathbb{1}$.*
- *For every two cochains F, G and any two faces of the same dimension σ,τ it holds that $\dim(F) - \dim(\Lambda_\sigma F) = \dim(G) - \dim(\Lambda_\tau G)$. In addition, denote the dimensional difference for vertices by $\Delta(\Lambda) = \dim(F) - \dim(\Lambda_v F)$.*
- *Viewing of a cochain in a link is only determined by the cochain and the face for which it is the link (and not the path taken to achieve said view). Formally: For every $\tau \subseteq \sigma \in X$ it holds that $\Lambda_\sigma = \Lambda_{\sigma\setminus\tau}\Lambda_\tau$.*
- *For every dimension i it holds that $\langle F, G\rangle = \mathbb{E}_{\sigma\in X(i)}\left[\langle \Lambda_\sigma F, \Lambda_\sigma G\rangle\right]$.*

Of particular interest are link viewers that view the non-lazy random walk operator in "the right way":

▶ **Definition 28.** *A link viewer respects the non-lazy up-down random walk if for every k:*

$$\left\langle (M')^+_k F, F\right\rangle = \mathbb{E}_{v\in X(0)}\left[\left\langle (M')^+_{k-\Delta(\Lambda)} \Lambda_v F, \Lambda_v F\right\rangle\right].$$

▶ **Definition 29** (i-level cochain)**.** *A cochain F is an i-level cochain with respect to Λ if it holds that $\forall\sigma\in X(i-1) : \langle\Lambda_\sigma F, \mathbb{1}\rangle = 0$.*

When the link viewer is clear from context we will simply refer to them as i-level cochains. Denote the set of i-level j-dimensional cochains in X by $C^j_{\Lambda,i}(X;\mathbb{R})$.

▶ **Lemma 30.** *For every dimension $j \le i$: $C^k_{\Lambda,i}(X;\mathbb{R}) \subseteq C^k_{\Lambda,j}(X;\mathbb{R})$.*

Proof. Let $F \in C^k_{\Lambda,i}(X;\mathbb{R})$ and let σ be a $(j-1)$-dimensional face and note the following:

$$\langle\Lambda_\sigma F, \mathbb{1}\rangle = \mathbb{E}_{\tau\in X_\sigma(i-j)}\left[\langle\Lambda_\tau\Lambda_\sigma F, \Lambda_\tau\mathbb{1}\rangle\right] = \mathbb{E}_{\tau\in X_\sigma(i-j)}\left[\langle\Lambda_{\tau\sigma} F, \mathbb{1}\rangle\right]. = 0$$

Where the last equality is due to the fact that $\sigma\cup\tau$ is an $(i-1)$-dimensional face. ◀

Of particular interest are i-level cochains that are orthogonal to the $(i+1)$-level cochains. We will therefore define the following:

▶ **Definition 31** (Proper i-level cochain)**.** *A cochain F is a proper i-level cochain with respect to Λ if it holds that $F \in C^j_{\Lambda,i}(X;\mathbb{R}) \cap \left(C^j_{\Lambda,i+1}(X;\mathbb{R})\right)^\perp$.*

When the link viewer is clear from context we will simply refer to them as proper i-level cochains. Denote the set of proper i-level j-dimensional cochains in X by $C^j_{\Lambda,\hat{i}}(X;\mathbb{R})$.

Consider the following key property of proper level cochains:

▶ **Lemma 32.** *Let $i < j$ and let F be a proper i-level cochain and G be a proper j-level cochain then $\langle F, G\rangle = 0$.*

Proof. Due to Lemma 30 it holds that G is also a $i+1$ level cochain and thus is orthogonal to G by definition. ◀

Note that considering proper level cochains is one of the key ingredients of this paper. In previous results (For example [15]) instead of considering proper i-level cochains the authors essentially considered cochains in $\left(C^k_{\Lambda,i}(X;\mathbb{R})\right)^\perp$. Using proper level cochains allows us to separate the different levels completely and achieve a proper decomposition. Since analyzing the decomposition with only pure level cochains in mind is hard (as even if F is a level cochain the same cannot be said about $\Lambda_\sigma F$) we resort to first show the following technical theorem.

▶ **Theorem 33** (Bootstrapping Theorem, Technical Version). *Let X be a pure d-dimensional simplicial complex, Λ be a link viewer that respects the non-lazy up-down random walk and for every i let $F_i \in C^k_{\Lambda,i}(X;\mathbb{R})$ and $F = \sum_{i=0}^p F_i$. Denote $r = k - \Delta(\Lambda)$ and suppose that there are values of $\{\lambda_{\sigma,i,j}\}_{\sigma\in X, i\in[d], j\in[d]}$ ($\lambda_{\sigma,i,j}$ is the contraction of an i-level j-dimensional cochain in the link of σ) such that for every $\sigma \in X$ and G_0 a 0-level cochain:*

$$\begin{cases}\lambda_{\sigma,1,k}\left\|G_0\right\|^2+\mathbb{E}_{v\in X_\sigma(0)}\left[\left(1-\lambda_{\sigma\cup\{v\},1,r}\right)\left\|M_r^{-r}\Lambda_v G_0\right\|^2\right]\le\lambda_{\sigma,0,k}\left\|G_0\right\|^2\\ \max_{v\in X_\sigma(0)}\left\{\lambda_{\sigma\cup\{v\},i-1,r}\right\}\le\lambda_{\sigma,i,k}.\end{cases}$$

Then:

$$\left\langle (M')_k^+ F, F\right\rangle \le \sum_{i=0}^{p} \lambda_{\emptyset,i,k}\left\|F_i\right\|^2+\sum_{i=0}^{p}\sum_{\substack{j=1\\ i<j}}^{p} c_{i,j}\left\langle F_i,F_j\right\rangle.$$

For some constants $\{c_{i,j}\}$ and where p is the number of level functions that span the space orthogonal to the constants.

Proof. Let r be the dimension of $\Lambda_\sigma F$. Consider the following:

$$\begin{aligned}\left\langle (M')_k^+ F, F\right\rangle &= \left\langle (M')_k^+ \sum_{i=0}^{p} F_i, \sum_{i=0}^{p} F_i\right\rangle\\ &= \mathbb{E}_{v\in X(0)}\left[\left\langle \Lambda_v\left((M')_r^+\sum_{i=0}^{p}F_i\right),\Lambda_v\left(\sum_{i=0}^{p}F_i\right)\right\rangle\right]\\ &= \mathbb{E}_{v\in X(0)}\left[\left\langle (M')_r^+\sum_{i=0}^{p}\Lambda_vF_i,\sum_{i=0}^{p}\Lambda_vF_i\right\rangle\right]\\ &= \mathbb{E}_{v\in X(0)}\left[\left\langle (M')_r^+\left(I-M_r^{-r}\right)\sum_{i=0}^{p}\Lambda_vF_i,\left(I-M_r^{-r}\right)\sum_{i=0}^{p}\Lambda_vF_i\right\rangle\right] \qquad (1)\\ &\quad+\mathbb{E}_{v\in X(0)}\left[\left\langle (M')_r^+M_r^{-r}\sum_{i=0}^{p}\Lambda_vF_i,M_r^{-r}\sum_{i=0}^{p}\Lambda_vF_i\right\rangle\right]\\ &= \mathbb{E}_{v\in X(0)}\left[\left\langle (M')_r^+\left(I-M_r^{-r}\right)\sum_{i=0}^{p}\Lambda_vF_i,\left(I-M_r^{-r}\right)\sum_{i=0}^{p}\Lambda_vF_i\right\rangle\right]\\ &\quad+\mathbb{E}_{v\in X(0)}\left[\left\|M_r^{-r}\Lambda_vF_0\right\|^2\right].\end{aligned}$$

We will now like to apply our Theorem to the localized cochains in the links. For that, consider the following level cochains:

level	cochain	square of norm
$k-1$	$F^v_{k-1} := \Lambda_v F_k$	$\left\|\Lambda_v F_k\right\|^2$
$\vdots$	$\vdots$	$\vdots$
1	$F^v_1 := \Lambda_v F_2$	$\left\|\Lambda_v F_2\right\|^2$
0	$F^v_0 := \Lambda_v F_1 + \left(I - M_r^{-r}\right)\Lambda_v F_0$	$\left\|\Lambda_v F_1\right\|^2 + \left\|\left(I-M_r^{-r}\right)\Lambda_v F_0\right\|^2 + 2\left\langle \Lambda_v F_1, \Lambda_v F_0\right\rangle$

Note that, by definition, for every $i \geq 2$ it holds that $\Lambda_v F_i \in C^r_{\Lambda,i-1}(X_v;\mathbb{R})$. In addition $\Lambda_v F_1 + (I - M_r^{-r})\Lambda_v F_0 \in C^r_{\Lambda,0}(X_v;\mathbb{R})$. We can therefore apply the Theorem to every link which (after some manipulation of the mixed terms that can be found in the full version) yields that, for every link v, it holds that:

$$\left\langle (M')^{+}_{v,k}\left(I - M_r^{-r}\right)\Lambda_v F, \left(I - M_r^{-r}\right)\Lambda_v F\right\rangle \le \sum_{i=0}^{k-1} \lambda_{v,i,r}\left\|F_i^v\right\|^2 + \sum_{i=0}^{p}\sum_{\substack{j=1\\ i<j}}^{p} c_{i,j}\left\langle F_i^v, F_j^v\right\rangle$$

$$= \sum_{i=0}^{k-1} \lambda_{v,i,r}\left\|\Lambda_v F_i\right\|^2 + \lambda_{v,0,r}\left\|\left(I - M_r^{-r}\right)\Lambda_v F_0\right\|^2 + \sum_{i=0}^{p}\sum_{\substack{j=1\\ i<j}}^{p} c'_{i,j}\left\langle \Lambda_v F_i, \Lambda_v F_j\right\rangle .$$

Combining this with 1 and noting that $\lambda_{\emptyset,i,k} \ge \max_{v\in X(0)}\left\{\lambda_{v,i-1,r}\right\}$ yields that:

$$\begin{aligned}\left\langle (M')^{+}_{k} F, F\right\rangle \le &\sum_{i=1}^{k} \lambda_{\emptyset,i,k}\left\|F_i\right\|^2 \\ &+ \mathbb{E}_{v\in X(0)}\left[\left\|M_r^{-r}\Lambda_v F_0\right\|^2 + \lambda_{v,0,r}\left\|\left(I - M_r^{-r}\right)\Lambda_v F_0\right\|^2\right] \\ &+ \sum_{i=0}^{p}\sum_{\substack{j=1\\ i<j}}^{p} c'_{i,j}\left\langle F_i, F_j\right\rangle .\end{aligned}$$

Therefore all we have to do is prove that:

$$\mathbb{E}_{v\in X(0)}\left[\left\|M_r^{-r}\Lambda_v F_0\right\|^2 + \lambda_{v,0,r}\left\|\left(I - M_r^{-r}\right)\Lambda_v F_0\right\|^2\right] \le \lambda_{\emptyset,0,k}\left\|F_0\right\|^2$$

This follows directly from our choice of λs:

$$\begin{aligned}&\mathbb{E}_{v\in X(0)}\left[\left\|M_r^{-r}\Lambda_v F_0\right\|^2 + \lambda_{v,0,r}\left\|\left(I - M_r^{-r}\right)\Lambda_v F_0\right\|^2\right] \\ &\quad= \mathbb{E}_{v\in X(0)}\left[\left(1 - \lambda_{v,0,r}\right)\left\|M_r^{-r}\Lambda_v F_0\right\|^2 + \lambda_{v,0,r}\left(\left\|M_r^{-r}\Lambda_v F_0\right\|^2 + \left\|\left(I - M_r^{-r}\right)\Lambda_v F_0\right\|^2\right)\right] \\ &\quad= \mathbb{E}_{v\in X(0)}\left[\left(1 - \lambda_{v,0,r}\right)\left\|M_r^{-r}\Lambda_v F_0\right\|^2 + \lambda_{v,0,r}\left\|\Lambda_v F_0\right\|^2\right] \\ &\quad\le \mathbb{E}_{v\in X(0)}\left[\left(1 - \lambda_{v,0,r}\right)\left\|M_r^{-r}\Lambda_v F_0\right\|^2\right] + \lambda_{\emptyset,1,k}\left\|F_0\right\|^2 \le \lambda_{\emptyset,0,k}\left\|F_0\right\|^2 .\end{aligned}$$ ◀

▶ **Theorem 34** (Bootstrapping Theorem). *Let X be a pure d-dimensional simplicial complex, Λ be a link viewer that respects the non-lazy up-down random walk and for every i let $F_i \in C^k_{\Lambda,\hat{i}}\left(X;\mathbb{R}\right)$ be a proper i-level cochain and $F = \sum_{i=0}^{p} F_i$. Denote $r = k - \Delta\left(\Lambda\right)$ and suppose that there are values of $\left\{\lambda_{\sigma,i,j}\right\}_{\sigma\in X, i\in[d], j\in[d]}$ such that for every $\sigma \in X$ and G_0 a 0-level cochain:*

$$\begin{cases}\lambda_{\sigma,1,k}\left\|G_0\right\|^2 + \mathbb{E}_{v\in X_\sigma(0)}\left[\left(1 - \lambda_{\sigma\cup\{v\},1,r}\right)\left\|M_r^{-r}\Lambda_v G_0\right\|^2\right] \le \lambda_{\sigma,0,k}\left\|G_0\right\|^2 \\ \max_{v\in X_\sigma(0)}\left\{\lambda_{\sigma\cup\{v\},i-1,r}\right\} \le \lambda_{\sigma,i,k}\end{cases}$$

Then:

$$\left\langle (M')^{+}_{k} F, F\right\rangle \le \sum_{i=0}^{p} \lambda_{\emptyset,i,k}\left\|F_i\right\|^2 .$$

For some constants $\left\{c_{i,j}\right\}$ and where p is the number of level functions that span the space orthogonal to the constants.

Proof. Note that the difference between this Theorem and Theorem 33 is the choice of F_is. Specifically, in this Theorem the the cochains F_i are chosen to be *proper* i-level cochains. Therefore, due to Lemma 32, they are orthogonal to each other. This allows us to apply Theorem 33 and note that:

$$\left\langle (M')^{+}_{k} F, F\right\rangle \le \sum_{i=0}^{p} \lambda_{\emptyset,i,k}\left\|F_i\right\|^2 + \sum_{i=0}^{p}\sum_{\substack{j=1\\ i<j}}^{p} c''_{i,j}\left\langle F_i, F_j\right\rangle = \sum_{i=0}^{p} \lambda_{\emptyset,i,k}\left\|F_i\right\|^2 .$$ ◀

It is important to note that, unlike the decomposition known in the two-sided case, this decomposition is not a decomposition to approximate eigenfunctions. When applying the walk operator to a level function the result might be spread over multiple levels. Theorem 34 also yields a decomposition to the up-down operator:

▶ **Corollary 35.** *With the same assumptions as Theorem 34 it holds that*

$$\left\langle M_k^+ F, F \right\rangle \leq \sum_{i=0}^{p} \left(\frac{k+1}{k+2} \lambda_{\emptyset,i,k} - \frac{1}{k+1} \right) \|F_i\|^2.$$

Proof. The following holds:

$$\begin{aligned}\left\langle M_k^+ F, F \right\rangle &= \frac{k+2}{k+1} \left\langle \left(M'\right)_k^+ F, F \right\rangle - \frac{1}{k+1} \langle F, F \rangle \\ &\leq \frac{k+2}{k+1} \langle \lambda_{\emptyset,i,k} F, F \rangle - \frac{1}{k+1} \|F\|^2 \ = \ \frac{k+2}{k+1} \lambda_{\emptyset,i,k} \|F\|^2 - \frac{1}{k+1} \|F\|^2 \\ &= \sum_{i=0}^{p} \left(\frac{k+1}{k+2} \lambda_{\emptyset,i,k} - \frac{1}{k+1} \right) \|F_i\|^2.\end{aligned}$$ ◀

We use the bootstrapping theorem in order to show both a fine grained analysis of higher order random walks (for full proof, see Appendix B) and the trickling down theorem (for full proof, see Appendix A).

6 Fine Grained Analysis of High Dimensional Random Walks From the Bootstrapping Theorem

In this short section we will present a shortened version of our fine grained analysis of higher order random walks. For the a more detailed version of this analysis, see Appendix B and the full version of this paper.

We define the localization link viewer in the following way:

▶ **Definition 36** (Localization)**.** *Given a simplicial complex X and a cochain $F \in C^k(X; \mathbb{R})$ define the localization link viewer in the following way $\forall \sigma \in X : \Lambda_\sigma^\ell F = F_\sigma$.*

First, we show that it is indeed a link viewer that respects the non-lazy random walk. We then prove the following:

▶ **Lemma 37.** *Let X be a pure d-dimensional simplicial complex and let $F \in C^k(F; \mathbb{R})$ be a cochain. Then $\langle F, \mathbb{1} \rangle = 0 \Leftrightarrow F \in \ker\left(d_{-1}^* \cdots d_{k-1}^*\right)$.*

We use this observation to gain the following advantage:

▶ **Lemma 38** (The advantage)**.** *Let X be a d dimensional simplicial complex whose 1-skeleton is a γ spectral expander. Also let $F \in C_{\Lambda^\ell,0}^k(X; \mathbb{R})$ then:*

$$\left\| d_0^* \cdots d_{k-1}^* F \right\|^2 \leq \left(1 - \frac{k}{k+1}(1-\gamma) \right) \|F\|^2.$$

For more details on the proof of this Lemma, see Lemma 53.

We then use this advantage together with our bootstrapping theorem in order to show the following:

▶ **Theorem 39** (Random walk decomposition). *Let X be a d-dimensional pure simplicial complex. Also, assume that for every face σ of dimension smaller than $d-2$ it holds that $\lambda_2\left((M')^+_{\sigma,0}\right) \leq \lambda_\sigma$. Denote by $\gamma_{\tau,i} = \max_{\sigma\in X_\tau(i)}(\lambda_\sigma)$. For every set of proper level cochains $F_i \in C^k_{\Lambda^\ell,\hat{i}}(X;\mathbb{R})$ it holds that:*

$$\left\langle (M')^+_k \sum_{i=0}^k F_i, \sum_{i=0}^k F_i \right\rangle \leq \sum_{i=0}^k \left(1 - \frac{1}{k-i+1}\prod_{j=i-1}^{k-1}(1-\gamma_j)\right)\|F_i\|^2.$$

Proof sketch, for full proof see Theorem 54. We will prove this theorem by applying Theorem 34 to the k-dimensional non-lazy random walk operator. We start by noting that the space of k-dimensional cochains that are orthogonal to the constants is comprised of exactly k level functions as the space orthogonal to the constants is exactly $\ker(d_0^* \cdots d_k^*)$.

We prove the rest of this theorem using a recursive argument. First note that for $k=0$ the claim holds trivially as $\left\langle (M')^+_0 F, F\right\rangle \leq \lambda_\sigma \|F\|^2 = \gamma_{-1}\|F\|^2$.

Assume that for every non-empty face σ it holds that $\lambda_{\sigma,i,k} \leq 1 - \frac{1}{k-i+1}\prod_{j=i-1}^{k-1}(1-\gamma_{\sigma,j})$. Note that for every $i \geq 1$:

$$\begin{aligned}\lambda_{\emptyset,i,k} &= \max_{v\in X(0)}\{\lambda_{v,i-1,k-1}\}\\ &\leq \max_{v\in X(0)}\left\{1 - \frac{1}{k-i+1}\prod_{j=i-2}^{k-2}(1-\gamma_{\sigma,j})\right\} \leq 1 - \frac{1}{k-i+1}\prod_{j=i-1}^{k-1}(1-\gamma_{\emptyset,j}).\end{aligned}$$

Consider the left hand side of the recursive formula:

$$\lambda_{\emptyset,1,k}\|F_0\|^2 + \mathbb{E}_{v\in X(0)}\left[(1-\lambda_{\emptyset,1,k})\left\|M^{-(k-1)}_{(k-1)}\Lambda^\ell_v F_0\right\|^2\right] \leq \lambda_{\emptyset,0,k}\|F_0\|. \tag{2}$$

We show that:

$$\begin{aligned}&\lambda_{\emptyset,1,k}\|F_0\|^2 + \mathbb{E}_{v\in X(0)}\left[(1-\lambda_{\emptyset,1,k})\left\|M^{-(k-1)}_{(k-1)}\Lambda^\ell_v F_0\right\|^2\right]\\ &\qquad = \lambda_{\emptyset,1,k}\|F_0\|^2 + (1-\lambda_{\emptyset,1,k})\left\|d_0^*\cdots d_{k-1}^* F_0\right\|^2.\end{aligned}$$

Consider, again, the left hand side of inequality 2 and note that due to Lemma 53 it suffices to solve the following:

$$\lambda_{\emptyset,1,k}\left\|F^{=0}\right\|^2 + (1-\lambda_{\emptyset,1,k})\left(1 - \frac{k}{k+1}(1-\gamma_{-1})\right)\left\|F^{=0}\right\|^2 \leq \lambda_{\emptyset,0,k}\left\|F^{=0}\right\|^2.$$

We show that if we set $\lambda_{\emptyset,0,k} = 1 - \frac{1}{k+1}\prod_{j=-1}^{k-1}(1-\gamma_{\emptyset,j})$ we get that for every face σ and dimensions i,k:

$$\lambda_{\sigma,i,k} \leq 1 - \frac{1}{k-i+1}\prod_{j=i-1}^{k-1}(1-\gamma_{\sigma,j}).$$

Applying Theorem 34 proves the decomposition. ◀

A Trickling Down

Before we present our random walk decomposition Theorem, let us start with a “warm up”: An alternative proof for the trickling down theorem [16] that is based on Theorem 34. We believe that the fact that the main tool presented here can be used to prove the trickling down theorem is of independent interest: it shows that there is a single, local to global argument at the heart of both claims. In the trickling down theorem we are interested in the connection between the 0-dimensional non-lazy random walk on the vertices of a complex and the 0-dimensional non-lazy up-down random walk on the links of the vertices of the complex. It will, therefore, be natural to consider a link viewer that does not incur a decrease in dimension. One such link viewer is the restriction link viewer defined as:

▶ **Definition 40** (Restriction). *Given a simplicial complex X and a cochain $F \in C^k(X;\mathbb{R})$ define the restriction link viewer in the following way: $\forall \sigma \in X : \Lambda^r_\sigma F(\tau) = F_0(\tau)$.*

This link viewer maps the 0-dimensional non-lazy up-down random walk to the 0-dimensional non-lazy up-down on the links of the vertices. We will show that applying Theorem 34 to the restriction link viewer yields the trickling down theorem. However, before applying Theorem 34, we must first show that restriction is indeed a link viewer that respects the non-lazy up-down random walk. We state here that this is indeed the case and leave the proofs of these claims to the full version of this paper.

▶ **Lemma 41.** *The restriction link viewer is a link viewer.*

▶ **Lemma 42.** *The restriction link viewer respects the non-lazy random walk operator.*

▶ **Lemma 43.** *It holds for every vertex v and every cochain $F \in C^0(X;\mathbb{R})$ that:*

$$M^-_{v,0}\Lambda^r_v F_0 = \langle \Lambda^r_v F, \mathbb{1}\rangle_v = \mathbb{E}_{u\in X_v(0)}\left[\Lambda^r_v F(u)\right] = (M')^+_0 F(v)$$

Proof.

$$(M')^+_0 F(v) = \left[(M')^+_0 F\right]_v = \sum_{u\in X(0)} \left[(M')^+_0\right]_{v,u} F(u) = \sum_{\substack{u\in X(0)\\ u\cup v\in X(1)}} \mathrm{w}_v\left(u\setminus v\right) F(u)$$

$$= \sum_{u\in X_v(0)} \mathrm{w}_v\left(u\right)\Lambda^r_v F(u) = \mathbb{E}_{u\in X_v(0)}\left[\Lambda^r_v F(u)\right]. \qquad ◀$$

▶ **Corollary 44** (The advantage). *If X’s 1-skeleton is a λ-spectral expander it holds for every vertex v and every cochain $F \in C^0(X;\mathbb{R})$ that:*

$$\left\|d^*_0\Lambda^r_v F_0\right\| = \left\|M^-_0\Lambda^r_v F_0\right\| \le \lambda^2\left\|F\right\|^2.$$

Proof. Note that the 1-skeleton of X is a λ-spectral expander and $F \in C^0(X;\mathbb{R})$ therefore $\left\|(M')^+_0 F\right\|^2 \le \lambda^2\left\|F\right\|^2$. Combining this with Lemma 43 yields:

$$\left\|M^-_0\Lambda^r_v F_0\right\|^2 = \left\|(M')^+_0 F\right\|^2 = \left\|(M')^+_0 F_0\right\|^2 \le \lambda^2\left\|F_0\right\|^2. \qquad ◀$$

We can now show how applying Theorem 34 to the restriction link viewer yields Oppenheim's trickling down theorem [16, Theorem 4.1].

▶ **Theorem 45** (Trickling Down, restated Theorem 16). *If it holds that:*

- *For every vertex v: X_v is a $\lambda_{v,0,k}$ spectral expander.*
- *X is connected.*

Then it holds that $\lambda_{\emptyset,0,k} = \frac{\lambda_{\emptyset,1,k}}{1-\lambda_{\emptyset,1,k}}$.

Proof. Consider the following:

$$\lambda_{\emptyset,1,k} \left\|F_0\right\|^2 + (1 - \lambda_{\emptyset,1,k})\, \mathbb{E}_{v \in X(0)} \left[\left\|M^{-}_{v,0} \Lambda^{r}_{v} F_0\right\|^2\right] \leq \lambda_{\emptyset,0,k} \left\|F_0\right\|^2 .$$

Using Corollary 44 it suffices to find values of $\lambda_{\sigma,i,j}$ such that:

$$\lambda_{\emptyset,1,k} \left\|F_0\right\|^2 + (1 - \lambda_{\emptyset,1,k}) \lambda^2_{\emptyset,0,k} \left\|F_0\right\|^2 \leq \lambda_{\emptyset,0,k} \left\|F_0\right\|^2 .$$

Therefore solving the following inequality would bound $\lambda_{\emptyset,0,k}$:

$$\lambda_{\emptyset,1,k} + (1 - \lambda_{\emptyset,1,k}) \lambda^2_{\emptyset,0,k} \leq \lambda_{\emptyset,0,k}.$$

Note that picking $\lambda_{\emptyset,0,k} = \frac{\lambda_{\emptyset,1,k}}{1-\lambda_{\emptyset,1,k}}$ satisfies the inequality and thus proves the Theorem. ◀

B Decomposition of the Random Walk Operators

We are now ready to present the random walk decomposition theorem based on Theorem 34. Unlike the tricking down theorem, here the assumption we have is only on the expansion of the no-lazy up-down random walk on the vertices. We will, therefore, be interested in a link viewer that decreases the dimension of the cochain. Namely, the localization link viewer, defined as follows:

▶ **Definition 46** (Localization). *Given a simplicial complex X and a cochain $F \in C^k(X; \mathbb{R})$ define the localization link viewer in the following way: $\forall \sigma \in X : \Lambda^{\ell}_{\sigma} F = F_\sigma$.*

As with the trickling down theorem, we will be interested in applying Theorem 34 to the localization link viewer. We start by proving that the localization link viewer that respects the non-lazy up-down random walk. Full proofs of these claims can be found in the full version of this paper.

▶ **Lemma 47.** *The localization link viewer is a link viewer.*

▶ **Lemma 48.** *The localization link viewer respects the non-lazy random walk operator.*

B.1 Gaining the Advantage

Before we present the exact Lemma we use as the advantage step we should expand our understanding of Λ^{ℓ}'s level functions. We will begin by characterising the space of cochains that are orthogonal to the eigenspace of 1 (i.e. the constant functions).

▶ **Lemma 49.** *Let X be a pure d-dimensional simplicial complex and let $F \in C^k(F; \mathbb{R})$ be a cochain. Then: $\langle F, \mathbb{1} \rangle = 0 \Leftrightarrow F \in \ker\left(d^*_{-1} \cdots d^*_{k-1}\right)$.*

Proof. Note that, due to Lemma 20 it holds that: $\langle F, \mathbb{1} \rangle = \mathbb{E}_{\sigma \in X(k)} [F(\sigma)] = d^*_{-1} \cdots d^*_{k-1}(\emptyset)$. This proves the lemma. ◀

Now that we understand the constant part of a cochain we are ready to move on to understanding cochains of a higher level.

▶ **Lemma 50.** *Let X be a pure d-dimensional simplicial complex, i be a dimension and $F \in C^k(X;\mathbb{R})$ be a cochain. Then: $\forall \sigma \in X(i) : \left\langle \Lambda_\sigma^\ell F, \mathbb{1} \right\rangle_\sigma = 0 \Leftrightarrow F \in \ker\left(d_i^* \cdots d_{k-1}^*\right)$.*

Proof. Using Lemma 20 we prove that:

$$\begin{aligned}\forall \sigma \in X(i) : \left\langle \Lambda_\sigma^\ell F, \mathbb{1} \right\rangle_\sigma &= \sum_{\tau \in X_\sigma(0)} \mathrm{w}_\sigma(\tau) \Lambda_\sigma^\ell F(\tau) \\ &= d_{\sigma,i-1}^* \cdots d_{\sigma,k-2}^* F_\sigma(\emptyset) = \left(d_i^* \cdots d_{k-1}^* F\right)_\sigma(\emptyset) = d_i^* \cdots d_{k-1}^* F(\sigma).\end{aligned}$$

Which proves the Lemma. ◀

▶ **Corollary 51.** *It holds that F is a proper k-dimensional i-level cochain iff $F \in \operatorname{Im}(d_{k-1} \cdots d_i) \cap \ker\left(d_{i-1}^* \cdots d_{k-1}^*\right)$.*

Proof. The Corollary holds due the definition of i-level cochains and Lemma 50. ◀

Note that cochains that pure i-level cochains can be thought of as originating in the i-dimensional faces. For example, for every pure 0-level cochain there is a 0-dimensional cochain G such that $F = d \cdots dG$. We also note that any cochain that is not originated in the vertices can be distributed along the links in the sense that they remain orthogonal to the constants when applying the localization link viewer. We will therefore be interested in the cochains that originated in the vertices (as these are exactly the cochains which the local perspective seems to miss). Specifically, we show that the following hold:

▶ **Lemma 52.** *Let F be a k-dimensional proper 0-level cochain then there exists $F^{=0} \in C^0(X;\mathbb{R})$ such that:*

1. $d_{-1}^* F^{=0} = 0$
2. $\|F\|^2 = \left\|F^{=0}\right\|^2$
3. $\left\|d_0^* \cdots d_{k-1}^* F\right\|^2 = \left\|d_{k-1} \cdots d_0 F^{=0}\right\|^2$

The proof of this Lemma can be found in the full version of this paper.

We are now ready to present the advantage we use:

▶ **Lemma 53** (The advantage). *Let X be a d dimensional simplicial complex whose 1-skeleton is a γ spectral expander. Also let $F \in C_{\Lambda^\ell,0}^k(X;\mathbb{R})$ then:*

$$\left\|d_0^* \cdots d_{k-1}^* F\right\|^2 \leq \left(1 - \frac{k}{k+1}(1-\gamma)\right) \|F\|^2$$

Proof. Let F_0 be the projection of F into $C_{\Lambda^\ell,0}^k(X;\mathbb{R}) \cap \left(C_{\Lambda^\ell,1}^k(X;\mathbb{R})\right)^\perp$. Due to Lemma 50 it holds that for every dimension i that $C_{\Lambda^\ell,i}^k(X;\mathbb{R}) = \ker\left(d_{i-1}^* \cdots d_{k-1}^*\right)$ and therefore $F_0 \in \operatorname{Im}(d_{k-1} \cdots d_0) \cap \ker\left(d_{-1}^* \cdots d_{k-1}^*\right)$. We can therefore use Lemma 52 to find $F^{=0}$ such that:

1. $d_{-1}^* F^{=0} = 0$
2. $\|F_0\|^2 = \left\|F^{=0}\right\|^2$
3. $\left\|d_0^* \cdots d_{k-1}^* F_0\right\|^2 = \left\|d_{k-1} \cdots d_0 F^{=0}\right\|^2$

Due to Lemma 26 it holds that:

$$M_0^{+k} = \frac{k}{k+1}\left(M'\right)_0^+ + \frac{1}{k+1} I$$

And therefore:

$$\begin{aligned}
&\left\|d_{k-1}\cdots d_0 F^{=0}\right\|^2 = \left\langle d_{k-1}\cdots d_0 F^{=0}, d_{k-1}\cdots d_0 F^{=0}\right\rangle = \left\langle M_0^{+k} F^{=0}, F^{=0}\right\rangle = \\
&= \left\langle \left(\frac{k}{k+1}\left(M'\right)_0^+ - \frac{1}{k+1} I\right) F^{=0}, F^{=0}\right\rangle = \\
&= \frac{k}{k+1}\left\langle \left(M'\right)_0^+ F^{=0}, F^{=0}\right\rangle + \frac{1}{k+1}\left\langle F^{=0}, F^{=0}\right\rangle \le \\
&\le \left(\frac{k}{k+1}\gamma + \frac{1}{k+1}\right)\left\|F^{=0}\right\|^2 = \\
&= \left(\frac{k}{k+1}\gamma - \frac{k}{k+1} + 1\right)\left\|F^{=0}\right\|^2 = \\
&\qquad = \left(1 - \frac{k}{k+1}\left(1-\gamma\right)\right)\left\|F^{=0}\right\|^2 = \left(1 - \frac{k}{k+1}\left(1-\gamma\right)\right)\left\|F_0\right\|^2
\end{aligned}$$

And thus:

$$\begin{aligned}
\left\|d_0^* \cdots d_{k-1}^* F\right\|^2 &= \left\|d_{k-1}\cdots d_0 F_0\right\|^2 \\
&\le \left(1 - \frac{k}{k+1}\left(1-\gamma\right)\right)\left\|F_0\right\|^2 \le \left(1 - \frac{k}{k+1}\left(1-\gamma\right)\right)\left\|F\right\|^2 .
\end{aligned}$$

◀

B.2 Decomposing the Random Walk Operators

Now that we have developed the tools we need, we can move on to strengthening the result of Alev and Lau [1] by showing a decomposition of the random walk operators. We will do so by applying Theorem 34 to the localization link viewer:

▶ **Theorem 54** (Random walk decomposition). *Let X be a d-dimensional pure simplicial complex. Also, assume that for every face σ of dimension smaller than $d-2$ it holds that $\lambda_2\left(\left(M'\right)_{\sigma,0}^+\right) \le \lambda_\sigma$. Denote by $\gamma_{\tau,i} = \max_{\sigma\in X_\tau(i)}\left(\lambda_\sigma\right)$. For every set of proper level cochains $F_i \in C^k_{\Lambda^\ell,\hat{i}}\left(X;\mathbb{R}\right)$ it holds that:*

$$\left\langle \left(M'\right)_k^+ \sum_{i=0}^{k} F_i, \sum_{i=0}^{k} F_i\right\rangle \le \sum_{i=0}^{k}\left(1 - \frac{1}{k-i+1}\prod_{j=i-1}^{k-1}\left(1-\gamma_j\right)\right)\left\|F_i\right\|^2.$$

Proof. We will prove this theorem by applying Theorem 34 to the k-dimensional non-lazy random walk operator. We start by noting that the space of k-dimensional cochains that are orthogonal to the constants is comprised of exactly k level functions as the space orthogonal to the constants is exactly $\ker\left(d_0^*\cdots d_k^*\right)$.

We prove the rest of this theorem using a recursive argument. First note that for $k=0$ the claim holds trivially as:

$$\left\langle \left(M'\right)_0^+ F, F\right\rangle \le \lambda_\sigma \left\|F\right\|^2 = \gamma_{-1}\left\|F\right\|^2 .$$

Assume that for every non-empty face σ it holds that $\lambda_{\sigma,i,k} \le 1 - \frac{1}{k-i+1}\prod_{j=i-1}^{k-1}\left(1-\gamma_{\sigma,j}\right)$ and note that for every $i \ge 1$:

$$\begin{aligned}\lambda_{\emptyset,i,k} &= \max_{v\in X(0)}\left\{\lambda_{v,i-1,k-1}\right\}\\ &\leq \max_{v\in X(0)}\left\{1-\frac{1}{k-i+1}\prod_{j=i-2}^{k-2}\left(1-\gamma_{\sigma,j}\right)\right\} \;\leq\; 1-\frac{1}{k-i+1}\prod_{j=i-1}^{k-1}\left(1-\gamma_{\emptyset,j}\right).\end{aligned}$$

Consider the left hand side of the recursive formula:

$$\lambda_{\emptyset,1,k}\left\|F_0\right\|^2+\mathbb{E}_{v\in X(0)}\left[\left(1-\lambda_{\emptyset,1,k}\right)\left\|M_{(k-1)}^{-(k-1)}\Lambda_v^{\ell}F_0\right\|^2\right]\leq\lambda_{\emptyset,0,k}\left\|F_0\right\|. \tag{3}$$

And note that:

$$\begin{aligned}&\lambda_{\emptyset,1,k}\left\|F_0\right\|^2+\mathbb{E}_{v\in X(0)}\left[\left(1-\lambda_{\emptyset,1,k}\right)\left\|M_{(k-1)}^{-(k-1)}\Lambda_v^{\ell}F_0\right\|^2\right]\\ &\qquad=\lambda_{\emptyset,1,k}\left\|F_0\right\|^2+\mathbb{E}_{v\in X(0)}\left[\left(1-\lambda_{\emptyset,1,k}\right)\left\|d_{-1}^*\cdots d_{k-2}^*\Lambda_v^{\ell}F_0\right\|^2\right]\\ &\qquad=\lambda_{\emptyset,1,k}\left\|F_0\right\|^2+\mathbb{E}_{v\in X(0)}\left[\left(1-\lambda_{\emptyset,1,k}\right)\left\|\Lambda_v^{\ell}d_0^*\cdots d_{k-1}^*F_0\right\|^2\right]\\ &\qquad=\lambda_{\emptyset,1,k}\left\|F_0\right\|^2+\left(1-\lambda_{\emptyset,1,k}\right)\left\|d_0^*\cdots d_{k-1}^*F_0\right\|^2.\end{aligned}$$

Consider, again, the left hand side of inequality 3 and note that due to Lemma 53 it suffices to solve the following:

$$\begin{aligned}&\lambda_{\emptyset,1,k}\left\|F^{=0}\right\|^2+\left(1-\lambda_{\emptyset,1,k}\right)\left(1-\frac{k}{k+1}\left(1-\gamma_{-1}\right)\right)\left\|F^{=0}\right\|^2\leq\lambda_{\emptyset,0,k}\left\|F^{=0}\right\|^2\\ &\lambda_{\emptyset,1,k}+\left(1-\lambda_{\emptyset,1,k}\right)\left(1-\frac{k}{k+1}\left(1-\gamma_{-1}\right)\right)\leq\lambda_{\emptyset,0,k}\\ &\qquad\qquad\frac{k}{k+1}\left(1-\gamma_{-1}\right)\lambda_{\emptyset,1,k}+\left(1-\frac{k}{k+1}\left(1-\gamma_{-1}\right)\right)\leq\lambda_{\emptyset,0,k}.\end{aligned}$$

Consider the following:

$$\begin{aligned}&\frac{k}{k+1}\left(1-\gamma_{-1}\right)\lambda_{\emptyset,1,k}+\left(1-\frac{k}{k+1}\left(1-\gamma_{-1}\right)\right)\\ &\qquad\leq\frac{k}{k+1}\left(1-\gamma_{-1}\right)\left(1-\frac{1}{k}\prod_{j=0}^{k-1}\left(1-\gamma_{\emptyset,j}\right)\right)+1-\frac{k}{k+1}\left(1-\gamma_{-1}\right)\\ &\qquad=\frac{k}{k+1}\left(1-\gamma_{-1}\right)-\frac{1}{k+1}\prod_{j=-1}^{k-1}\left(1-\gamma_{\emptyset,j}\right)+1-\frac{k}{k+1}\left(1-\gamma_{-1}\right)\\ &\qquad=1-\frac{1}{k+1}\prod_{j=-1}^{k-1}\left(1-\gamma_{\emptyset,j}\right).\end{aligned}$$

Thus if we set:

$$\lambda_{\emptyset,0,k}=1-\frac{1}{k+1}\prod_{j=-1}^{k-1}\left(1-\gamma_{\emptyset,j}\right).$$

We get that for every face σ and dimensions i, k:

$$\lambda_{\sigma,i,k}\leq 1-\frac{1}{k-i+1}\prod_{j=i-1}^{k-1}\left(1-\gamma_{\sigma,j}\right).$$

Applying Theorem 34 proves the decomposition. ◀

Note that the decomposition presented in Theorem 54 is the first decomposition theorem to offer a proper (i.e. not approximate) decomposition of the k-dimensional random walk whose components are orthogonal to each other.

A Deterministic Construction of a Large Distance Code from the Wozencraft Ensemble

Venkatesan Guruswami
Department of EECS, University of California, Berkeley, CA, USA

Shilun Li
Department of Mathematics, University of California, Berkeley, CA, USA

Abstract

We present an explicit construction of a sequence of rate 1/2 Wozencraft ensemble codes (over any fixed finite field $\mathbb{F}_q$) that achieve minimum distance $\Omega(\sqrt{k})$ where k is the message length. The coefficients of the Wozencraft ensemble codes are constructed using Sidon Sets and the cyclic structure of $\mathbb{F}_{q^k}$ where $k+1$ is prime with q a primitive root modulo $k+1$. Assuming Artin's conjecture, there are infinitely many such k for any prime power q.

1 Introduction

The explicit construction of binary error-correcting codes with a rate vs. distance trade-off approaching that of random constructions, i.e., the so-called Gilbert-Varshamov (GV) bound, remains an outstanding challenge in coding theory and combinatorics.

For large n, a random binary linear code of rate $R \in (0,1)$, defined for example as the column span of a random matrix $G \in \mathbb{F}_2^{n \times Rn}$, has relative distance $h^{-1}(1-R)$ with high probability, where $h^{-1}(\cdot)$ is the inverse of the binary entropy function. There is a similar GV bound $h_q^{-1}(1-R)$, involving the q-ary entropy function, for codes over other finite fields $\mathbb{F}_q$.

While explicit constructions meeting the GV bound remain elusive[1], there are known derandomizations showing that codes drawn randomly from much smaller, structured ensembles can also achieve the GV bound. One of the most classical and famous such ensemble is the Wozencraft ensemble, which consists of codes $C_{\mathrm{WE}}^{\alpha} = \{(x, \alpha x) : x \in \mathbb{F}_{q^k}\}$ as α varies over nonzero elements of the field $\mathbb{F}_{q^k}$, and one uses some fixed basis to express elements of $\mathbb{F}_{q^k}$ as length k vectors over $\mathbb{F}_q$. Note that each code C_{WE}^{α} has rate 1/2. The construction of Wozencraft ensemble codes C_{WE}^{α} first appeared in a paper by Massey [13], who attributed the discovery of these codes to John M. Wozencraft.

[1] Ta-Shma [19] recently constructed explicit binary codes near the GV bound for low rates. The codes have distance $\frac{1-\epsilon}{2}$ and rate $\Omega(\epsilon^{2+o(1)})$ which is asymptotically close to the rate $\Omega(\epsilon^2)$ guaranteed by the GV bound.

It is a standard exercise to show that for most choices of α, the code C^{α}_{WE} has distance close to $h_q^{-1}(1/2)$ and thus achieves the GV bound. Puncturing the Wozencraft ensemble gives codes of higher rates that also meet the GV bound. The property of the Wozencraft ensemble and its punctured variants behind this phenomenon is that every nonzero word appears as a codeword in an equal number of codes in the ensemble (if it appears in any code of the ensemble at all).

Using this property, Justesen [10] in 1972 gave the first strongly explicit asymptotically good binary linear codes, by concatenating an outer Reed–Solomon code with different inner codes drawn from the Wozencraft ensemble for different positions of the Reed-Solomon code. The Justesen construction achieves a trade-off between rate vs. distance called the Zyablov bound for rates at least 0.3. There are variants of Wozencraft codes which give Zyablov-bound-achieving codes for lower rates as well (see Section 5). In recent years, Wozencraft ensemble codes have also found other varied uses, for example in constructing covering codes of small block length [14] and write-once-memory codes [16, 17].

Given that for most α, the code C^{α}_{WE} meets the GV bound, it is a natural question whether one can find an explicit α for which the code has good distance (even if it doesn't quite meet the GV bound). Gaborit and Zemor [8] showed that it suffices to consider random α in a subset of size $\approx q^k/k$ and used it to show the existence of linear codes which are a factor k larger in terms of size than the Gilbert-Varshamov bound (such a result was shown earlier for general codes in [9]).

However, it remains an outstanding challenge to find some α in deterministic poly(k) time for which C^{α}_{WE} has distance $\Omega(k)$. This question is relatively well-known, eg. it received mention in a blog post by Dick Lipton [12], but has resisted progress. To the best of our knowledge, even an explicit α for which C^{α}_{WE} has distance $k^{\Omega(1)}$ was not known.

For certain structured fields $\mathbb{F}_{q^k}$ (of which there are an infinite family under Artin's conjecture), we give an explicit construction of $\alpha \in \mathbb{F}_{q^k}$ for which C^{α}_{WE} has distance $\Omega(\sqrt{k})$. We also give an explicit puncturing of these codes to achieve any desired rate $r < 1$, and $\Omega_r(\sqrt{k})$ distance (the constant in the $\Omega()$ depends on r). Our theorems are informally stated below.

▶ **Theorem 1** (Informal). *Fix a field $\mathbb{F}_q$ and consider an integer k such that $k+1$ is prime and q is a primitive root modulo $k+1$. There exist $\alpha^* \in \mathbb{F}_{q^k}$ which can be constructed in deterministic poly(k) time such that:*

- *$C^{\alpha^*}_{WE}$ has distance $\Omega(\sqrt{k})$.*
- *For any $r > \frac{1}{2}$, there is an explicit puncturing of $C^{\alpha^*}_{WE}$ with rate at least r and distance $\Omega_r(\sqrt{k})$.*

Please refer to Theorem 7 and Theorem 17 for construction of α^* and choice of puncturing.

2 Preliminaries

Throughout this paper, we will assume the alphabet has size q, where q is a prime power. Furthermore, we will assume k' is a prime such that q is a primitive root modulo k'. Assuming Artin's conjecture, such k' exists infinitely often at sufficiently high density and can be efficiently found in deterministic poly(k') time.

Denote $k = k'-1$ for ease of notation. Let $p(x) = 1+x+x^2+\ldots+x^{k'-1}$ be the cyclotomic polynomial which is irreducible over $\mathbb{F}_q$ (see Proposition 3). Note that $\mathbb{F}_q[x]/(p(x)) \cong \mathbb{F}_{q^k}$ for the extension field $\mathbb{F}_q[x]/(p(x))$ and we will fix the representation of $\mathbb{F}_{q^k}$ as polynomials in x of degree less than k, with operations performed modulo $p(x)$. We will fix the $\mathbb{F}_q$-linear isomorphism $\varphi : \mathbb{F}_{q^k} \to \mathbb{F}_q^k$ that maps a polynomial of degree less than k to its coefficient vector. That is, $\varphi(\sum_{i=0}^{k-1} a_i x^i) = (a_0, a_1, \ldots, a_{k-1})$. For $\alpha \in \mathbb{F}_{q^k}$, define $\mathrm{wt}(\alpha)$ to be the Hamming weight of $\varphi(\alpha)$.

The Wozencraft ensemble is a classic family of codes defined as follows.

▶ **Definition 2.** *For $\alpha \in \mathbb{F}_{q^k}$, the* ***Wozencraft ensemble code*** *C_{WE}^{α} parameterized by α is given by*

$$C_{WE}^{\alpha} = \{(\varphi(x), \varphi(\alpha x)) : x \in \mathbb{F}_{q^k}\} \ .$$

Note that C_{WE}^{α} is an $\mathbb{F}_q$-linear code of rate $1/2$.

▶ **Proposition 3.** *If k' is a prime such that q is a primitive root modulo k', then $p(x) = \sum_{i=0}^{k'-1} x^i$ is an irreducible polynomial of degree $k' - 1$ in $\mathbb{F}_q[x]$.*

Proof. Since q is a primitive root modulo k', $d = k' - 1$ is the smallest integer satisfying $q^d \equiv 1 \bmod k'$. Note that a field extension $\mathbb{F}_{q^d}$ of $\mathbb{F}_q$ contains a primitive k'-th root of unity ζ if and only if $k' | q^d - 1$, i.e., $q^d \equiv 1 \bmod k'$. So $\mathbb{F}_{q^{k'-1}}$ is the smallest field extension of $\mathbb{F}_q$ containing ζ and the mimimal polynomial of ζ has degree $k' - 1$. Since $p = \sum_{i=0}^{k'-1} x^i$ is a degree $k' - 1$ polynomial such that $p(\zeta) = 0$, p is the minimal polynomial of ζ and thus irreducible. ◀

We will use Sidon sets [18, 1] to construct the parameter α for C_{WE}^{α}.

▶ **Definition 4.** *A* ***Sidon set*** *is a set of integers $A = \{a_1, \ldots, a_d\}$ where $a_1 < a_2 < \ldots < a_d$ such that for all $i, j, k, l \in [d]$ with $i \neq j$ and $k \neq l$,*

$$a_i - a_j = a_k - a_l \iff i = k \text{ and } j = l.$$

A ***Sidon set modulo n*** *is a* ***Sidon set*** *such that for all $i, j, k, l \in [d]$ with $i \neq j$ and $k \neq l$,*

$$a_i - a_j \equiv a_k - a_l \pmod{n} \iff i = k \text{ and } j = l.$$

Size d of the Sidon set A is referred to as its ***order*** *and $a_d - a_1$ as its* ***length.***

▶ Remark 5. For any Sidon set with order d and length m, the $\binom{d}{2}$ distances between each pair of points need to be distinct. So $m \geq \binom{d}{2}$ and this gives a trivial upper bound $d \leq \sqrt{2m}$. This upper bound on d can be improved to $d \leq \sqrt{m} + O(m^{1/4})$ [7] and further to $d \leq \sqrt{m} + m^{1/4} + 1$ [11]. On the other hand, the maximal d given m satisfies $d \geq \sqrt{m} - O(m^{5/16})$ [7] but it is believed that we can have $d > \sqrt{m}$ [6].

We will introduce the Bose-Chowla construction of Sidon sets [4, 3].

▶ **Theorem 6** (Bose-Chowla, [4]). *Let p be a power of a prime, g be a primitive root in $\mathbb{F}_{p^2}$. Then the sequence of p integers*

$$A = \{i \in [p^2 - 2] : g^i + g^{pi} = 1\}$$

forms a Sidon set modulo $p^2 - 1$.

This construction of Sidon set has order $d = p$ and length at most $m(d) = p^2 - 2$. They are asymptotically optimal in the sense that $\lim_{d\to\infty} \sqrt{m(d)}/d = 1$. Given p, such construction can be done in $O(p^2)$ time by fixing $s = 1$ and finding a primitive root g via naive search. We will later define our parameter α to be $\sum_{a \in A} x^a$ where A is a Sidon set and show that C_{WE}^{α} has good distance.

3 Rate 1/2 Construction

In this section, we will give explicit construction of rate 1/2 Wozencraft ensemble codes with minimum distance $\Omega(\sqrt{k})$ using Sidon sets. To begin, we provide an intuitive explanation for the natural occurrence of Sidon sets in this specific context. Subsequently, we proceed with the analysis of the minimum distance of our construction.

3.1 Motivation

Fix a set of indices $A \subseteq [k]$ and an element $\alpha = \sum_{a\in A} x^a \in \mathbb{F}_{q^k}$ with coefficients either 0 or 1. Take any $y = \sum_{s\in S} b_s x^s$ where S is the set of non-zero indices of the coefficients of y, so $b_s \neq 0$ for all $s \in S$. To establish a lower bound on $\Delta(C^{\alpha}_{\mathrm{WE}})$, we would like show a lower bound on the weight of the product $\alpha y \in \mathbb{F}_{q^k}$ for any y. To simplify the analysis, we consider a ring extension of $\mathbb{F}_{q^k}$ (described in Section 3.2), in which the coefficient c_j in front of x^j of the product αy can be expressed as $c_j = \sum_{a\in A, s\in S} \mathbf{1}\{a + s \equiv j \pmod{k'}\} b_s$. We would like to establish a lower bound on the number of non-zero coefficients $c_j \neq 0$, which would transform into a lower bound on the weight of αy in $\mathbb{F}_{q^k}$. It is sufficient to demonstrate the existence of numerous choices of j satisfying $j \equiv a+s \pmod{k'}$ for a unique combination of a and s. In this case, c_j corresponds to the sum of one non-zero element and is therefore non-zero. To ensure there are an abundance of such choices for j with this uniqueness property, it is desirable to minimize collisions of the form $a + s \equiv a' + s' \pmod{k'}$ where $a, a' \in A$ and $s, s' \in S$. Since S can be selected adversarially with respect to A, it is advantageous to have $(a - a') \mod k'$ be unique, which is exactly the property of Sidon sets modulo k'. The result of this construction is stated formally as follows, where the proof is propounded to Section 3.2:

▶ **Theorem 7.** *Let d be the largest prime smaller than $\sqrt{k}$ and let $A = \{a_1, \ldots, a_d\}$ be a Bose-Chowla Sidon set with order d. Define $\alpha^* = \sum_{a\in A} x^a \in \mathbb{F}_{q^k}$. Then $\Delta(C^{\alpha^*}_{WE}) \geq d = \Omega(\sqrt{k})$.*

▶ Remark 8. Since there exists a prime between $[\frac{1}{2}\sqrt{k}, \sqrt{k}]$ by Bertrand–Chebyshev theorem [5], d can be found efficiently via naive search and $d \geq \frac{1}{2}\sqrt{k}$. Moreover, Baker, Harman and Pintz [2] showed that there exists a prime in the interval $[\sqrt{k} - k^{0.27}, \sqrt{k},]$ for k sufficiently large. So $d = (1 - o(1))\sqrt{k}$ and the constructed code $C^{\alpha^*}_{\mathrm{WE}}$ has distance asymptotically $\Delta(C^{\alpha^*}_{\mathrm{WE}}) \geq (1 - o(1))\sqrt{k}$ as $k \to \infty$.

It is also worthwhile to note that when $a + s \equiv j \pmod{k'}$ holds for more than one pair of (a, s), c_j may still be non-zero as it is a sum of multiple non-zero elements. In fact, for α with large weight, it is common that αy has substantial weight yet few choices of j satisfy the uniqueness property. One possible approach to improving the construction of A involves analyzing scenarios where $j \equiv a + s \pmod{k'}$ for multiple pairs of (a, s).

3.2 Proof of Theorem 7

To analyze the minimum distance of C^{α}_{WE}, it is helpful to define the ring $R = \mathbb{F}_q[x]/(x^{k'} - 1)$, which consists of polynomials of degree less than $k' = k + 1$. We can identify $\mathbb{F}_{q^k} \cong R/(p)$ by the map sending $f \in R$ to $(f \mod p) \in \mathbb{F}_{q^k}$. In addition, we can consider $\mathbb{F}_{q^k} \subseteq R$ and extend φ to the $\mathbb{F}_q$-linear map $\widetilde{\varphi} : R \to \mathbb{F}_q^{k'}$ mapping polynomials of degree less than k' to its coefficient vector. Define $\widetilde{\mathrm{wt}}(f)$ to be the Hamming weight of $\widetilde{\varphi}(f)$ for any $f \in R$. The following lemma gives the relationship between $\widetilde{\mathrm{wt}}(f)$ and $\mathrm{wt}(f \mod p)$.

▶ **Lemma 9.** *For any $f \in R$, $\mathrm{wt}(f \mod p) \geq \min\{\widetilde{\mathrm{wt}}(f), k - \widetilde{\mathrm{wt}}(f)\}$.*

Proof. For any $f \in R$, let us write $f = \sum_{i=0}^{k} b_i x^i$. Then

$$f \bmod p = f - b_k p = \sum_{i=0}^{k-1} (b_i - b_k) x^i.$$

If $b_k = 0$, then $\mathrm{wt}(f \bmod p) = \widetilde{\mathrm{wt}}(f)$; if $b_k \neq 0$, then

$$\mathrm{wt}(f \bmod p) = |\{i : b_i \neq b_k\}| \geq k - \widetilde{\mathrm{wt}}(f).$$

So $\mathrm{wt}(f \bmod p) \geq \min\{\widetilde{\mathrm{wt}}(f), k - \widetilde{\mathrm{wt}}(f)\}$. ◀

▶ **Lemma 10.** *Given $\alpha \in \mathbb{F}_{q^k} \subseteq R$, suppose that for every $y \in R$ with $\widetilde{\mathrm{wt}}(y) \leq c(k)$ the condition*

$$c(k) - \widetilde{\mathrm{wt}}(y) \leq \widetilde{\mathrm{wt}}(\alpha y) \leq k - \Big(c(k) - \widetilde{\mathrm{wt}}(y)\Big)$$

holds, where the product αy is taken in R. Then $\Delta(C_{WE}^{\alpha}) \geq c(k)$, where $\Delta(C_{WE}^{\alpha})$ denotes the distance of the code C_{WE}^{α}.

Proof. Take any non-zero $y \in \mathbb{F}_{q^k} \subseteq R$. Its corresponding codeword $C_{\mathrm{WE}}^{\alpha}(y) = (\varphi(y), \varphi(\alpha y \bmod p))$ has Hamming weight $\mathrm{wt}(y) + \mathrm{wt}(\alpha y \bmod p)$. By Lemma 9, the above condition implies

$$\mathrm{wt}(y) + \mathrm{wt}(\alpha y \bmod p) \geq \widetilde{\mathrm{wt}}(y) + \min\{\widetilde{\mathrm{wt}}(\alpha y), k - \widetilde{\mathrm{wt}}(\alpha y)\} \geq c(k).$$

Since C_{WE}^{α} is a linear code, $\Delta(C_{\mathrm{WE}}^{\alpha}) \geq c(k)$. ◀

We can now prove Theorem 7 by showing that α^* satisfies the condition of Lemma 10 with $c(k) = d$.

Proof of Theorem 7. Note that α is an element of $\mathbb{F}_{q^k}$ since it has degree at most $k-2$ by construction. Let us check that the condition of Lemma 10 indeed holds for $\alpha^* = \sum_{a \in A} x^a$ and $c(k) = d$. For any $y \in R$ with $\widetilde{\mathrm{wt}}(y) = w$, we can write $y = \sum_{i=1}^{w} b_{s_i} x^{s_i}$ where $b_{s_i} \neq 0$ for all $1 \leq i \leq w$. We will denote $S = \{s_1, \ldots, s_w\} \subseteq [k']$ the set non-zero coefficient indices of y, where we define $[k'] = \{0, \ldots, k'-1 = k\}$. The coefficients of the product $\alpha^* y = \sum_{j=0}^{k} c_j x^j$ are given by

$$c_j = \sum_{\substack{a \in A \\ s \in S}} \mathbf{1}\{a + s \equiv j \pmod{k'}\} b_s.$$

This motivates us to define the shifted set

$$(j - A)_k = \{(j - a_1) \bmod k', \ldots, (j - a_d) \bmod k'\}$$

which gives us

$$c_j = \sum_{s \in (j-A)_k \cap S} b_s.$$

We will denote by

$$J_m = \{j \in [k'] : |(j - A)_k \cap S| = m\}$$

the indices j such that $|(j-A)_k \cap S|$ has size m. It is evident that if $(j-A)_k \cap S = \emptyset$ then $c_j = 0$, and if $|(j-A)_k \cap S| = 1$ then $c_j \neq 0$. So

$$|J_1| \leq \widetilde{\mathrm{wt}}(\alpha^* y) \leq k - |J_0|.$$

Looking at the conditions of Lemma 10, it would be sufficient to take $c(k)$ such that

$$c(k) - w \leq \min\{|J_0|, |J_1|\}$$

for all w. We make the following claims on lower bounds of $|J_0|$ and $|J_1|$ which will be proven in Section 3.3.

▷ Claim 11. J_1 has size at least $wd - w(w-1)$.

▷ Claim 12. J_0 has size at least $k - wd$.

Assuming the claims, it suffices to take $c(k)$ such that

$$\begin{aligned} c(k) &\leq \min_{1 \leq w \leq c(k)} wd - w(w-1) + w = \min\{d+1, (d-c(k)+2)c(k)\}, \\ c(k) &\leq \min_{1 \leq w \leq c(k)} k - wd + w = k - (d-1)c(k). \end{aligned}$$

Solving the two inequalities, it suffices to take $c(k) \leq d$. So $\alpha^* = \sum_{a \in A} x^a$, $c(k) = d$ satisfy the condition of Lemma 10. ◀

3.3 Proofs of Claim 11 and Claim 12

To show a lower bound on $|J_1|$, it is desired that the sets $J_2, .., J_w$ are small. The following lemma gives an upper bound on the sizes of $J_2, .., J_w$:

▶ **Lemma 13.** *The sets $J_2, \ldots, J_w$ defined in the proof of Theorem 7 satisfy:*

$$\sum_{m=2}^{w} (m-1)|J_m| \leq \sum_{m=2}^{w} \binom{m}{2} |J_m| \leq 2\binom{w}{2} = w(w-1).$$

Proof. It is evident that the first inequality holds. Let us now show that for any two distinct $s, s' \in S$, we have $\{s, s'\} \subseteq (j-A)_k$ for at most two choices of j. Take any distinct pair $s, s' \in S$. Without loss of generality, assume $s < s'$. Suppose $\{s, s'\} \subseteq (j-A)_k$, then we can write $s \equiv j - a_l \pmod{k'}$ and $s' \equiv j - a_{l'} \pmod{k'}$ for some $l, l' \in [d]$. Then $a_l - a_{l'} \equiv s' - s \pmod{k'}$. So

$$a_l - a_{l'} = \begin{cases} s' - s & \text{if } l > l', \\ s' - s - k' & \text{if } l < l'. \end{cases}$$

In both cases, by definition of Sidon sets, l, l' are uniquely determined. Thus $j \equiv a_l + s$ is also uniquely determined.

For any $j_m \in J_m$, $|(j_m - A) \cap S| = m$ so there are $\binom{m}{2}$ distinct pairs $\{s, s'\} \subseteq (j_m - A)_k$. So the total count of such distinct pairs for all $j \in \cup_{m=2}^{w} J_m$ is $\sum_{m=2}^{w} \binom{m}{2} |J_m|$, which must not exceed $2\binom{w}{2}$ since each pair can only occur in $(j-A)_k$ for two choices of j. This gives

$$\sum_{m=2}^{w} \binom{m}{2} |J_m| \leq 2\binom{w}{2} = w(w-1)$$

which completes the proof. ◀

We can now obtain a lower bound on the size of J_1.

▷ Claim. J_1 has size at least $wd - w(w-1)$.

Proof. For each $s \in S$, there are $|A| = d$ number of j such that $s \in (j - A)_k$. When $w = 1$, the lemma holds as $|J_1| = d$. When $w \geq 2$, $|J_1|$ equals $|S|d = wd$ minus the times we overcount:

$$|J_1| = wd - \sum_{m=2}^{w} (m-1)|J_m|.$$

The proof is complete via the bound of Lemma 13:

$$|J_1| = wd - \sum_{m=2}^{w} (m-1)|J_m| \geq wd - w(w-1). \qquad \lhd$$

▷ Claim. J_0 has size at least $k - wd$.

Proof. For any $s \in S$, there are $|A| = d$ values of $j \in [k']$ such that $s \in (j - A)_k$. So there are at most $|S|d = wd$ indices j such that $|(j - A)_k \cap S| > 0$. ◁

4 Higher Rate Construction

In the last section, we gave an explicit construction of rate 1/2 Wozencraft ensemble code $C_{\mathrm{WE}}^{\alpha^*}$ achieving minimum distance $\Omega(\sqrt{k})$. In this section, we will show that appropriate puncturing of $C_{\mathrm{WE}}^{\alpha^*}$ will give us codes of rates $r \in (1/2, 1)$ and minimum distance at least $\Omega\left(\left(1 - \sqrt{2 - \frac{1}{r}}\right)\sqrt{k}\right)$.

▶ **Definition 14.** *Let $C_{WE}^{\alpha,r}$ be the rate r punctured code given by removing the last $(2 - \frac{1}{r})k$ message bits of each codeword in C_{WE}^{α}.*

Let φ_r denote the map sending any polynomial f to the first $(\frac{1}{r} - 1)k$ least significant coefficients. Let $\mathrm{wt}_r(f)$ denote the Hamming weight of $\varphi_r(f)$.

▶ **Lemma 15.** *For any $f \in R$, $\mathrm{wt}_r(f \bmod p) \geq \min\{\mathrm{wt}_r(f), (\frac{1}{r} - 1)k - \mathrm{wt}_r(f)\}$.*

Proof. Writing $f = \sum_{i=0}^{k} b_i x^i$, we have

$$f \bmod p = f - b_k p = \sum_{i=0}^{k-1} (b_i - b_k) x^i.$$

If $b_k = 0$, then $\mathrm{wt}_r(f \bmod p) = \mathrm{wt}_r(f)$; if $b_k \neq 0$, then

$$\mathrm{wt}_r(f \bmod p) = \left|\left\{i \in [(\frac{1}{r} - 1)k] \mid b_i \neq b_k\right\}\right| \geq (\frac{1}{r} - 1)k - \mathrm{wt}_r(f).$$

So $\mathrm{wt}_r(f \bmod p) \geq \min\{\mathrm{wt}_r(f), (\frac{1}{r} - 1)k - \mathrm{wt}_r(f)\}$. ◀

▶ **Lemma 16.** *Let $\alpha \in \mathbb{F}_{q^k} \subseteq R$. Suppose for every $y \in R$ with $\widetilde{\mathrm{wt}}(y) \leq c(k)$ the condition*

$$c(k) - \widetilde{\mathrm{wt}}(y) \leq \mathrm{wt}_r(\alpha y) \leq (\frac{1}{r} - 1)k - \left(c(k) - \widetilde{\mathrm{wt}}(y)\right)$$

holds, where the product αy is taken in R. Then $\Delta(C_{WE}^{\alpha,r}) \geq c(k)$.

Proof. Take any non-zero $y \in \mathbb{F}_{q^k} \subseteq R$. Its corresponding codeword $C_{\mathrm{WE}}^{\alpha,r}(y) = (\varphi(y), \varphi_r(\alpha y \bmod p))$ has hamming weight $\mathrm{wt}(y) + \mathrm{wt}_r(\alpha y \bmod p)$. By Lemma 15, the above condition implies

$$\mathrm{wt}(y) + \mathrm{wt}(\alpha y \bmod p) \geq \widetilde{\mathrm{wt}}(y) + \min\{\mathrm{wt}_r(\alpha y), (\frac{1}{r} - 1)k - \mathrm{wt}_r(\alpha y)\} \geq c(k).$$

Since $C_{\mathrm{WE}}^{\alpha,r}$ is a linear code, $\Delta(C_{\mathrm{WE}}^{\alpha,r}) \geq c(k)$. ◀

The following theorem establishes a lower bound on the minimum distance of the punctured code $C_{\mathrm{WE}}^{\alpha^*,r}$ with α^* constructed using Sidon sets as outlined in Theorem 7.

▶ **Theorem 17.** *For any rate $r > 1/2$, using the construction of α^* by Theorem 7, the condition of Lemma 16 is satisfied with $c(k) = \Omega\left(\left(1 - \sqrt{2 - \frac{1}{r}}\right)\sqrt{k}\right)$. Thus the punctured code $C_{WE}^{\alpha^*,r}$ has minimum distance at least $\Omega\left(\left(1 - \sqrt{2 - \frac{1}{r}}\right)\sqrt{k}\right)$.*

The proof is omitted[2] since it follows a similar outline as the proof of Theorem 7. We present two claims similar to Claim 11 and Claim 12 that substantiate this argument. For any $y = \sum_{s \in S} b_s x^s$ with weight $|S| = w$, denote $J_m^r = \{j \in [(\frac{1}{r} - 1)k] : |(j - A)_k \cap S| = m\}$ the non-punctured indices j such that $|(j - A)_k \cap S|$ has size m, where A is the Sidon set in the construction of α^*. Then analogous to Claim 11 and Claim 12, we can lower bound the size of J_1^r and J_2^r:

▷ Claim 18. J_1^r has size at least $w\left(\left(1 - \sqrt{(2 - \frac{1}{r})} - o(1)\right)\sqrt{k} - (2 - \frac{1}{r})^{\frac{1}{4}} k^{\frac{1}{4}} - 1\right) - w^2$.

▷ Claim 19. J_0^r has size at least $(\frac{1}{r} - 1)k - w\left(\sqrt{(\frac{1}{r} - 1)k} + (\frac{1}{r} - 1)^{\frac{1}{4}} k^{\frac{1}{4}} + 1\right)$.

To justify the claims, we will require the following theorem by Lindström [11] which bounds the order of any Sidon set via its length.

▶ **Theorem 20** (Lindström [11]). *For any Sidon set with length m, the order is at most $\sqrt{m} + m^{1/4} + 1$.*

The key observation is that for any $s \in S$, the shifted set $(s + A)_k$ is a Sidon set. Moreover, it is partitioned into two parts after puncturing: the remaining part $(s + A)_k \cap [(\frac{1}{r} - 1)k]$ and the removed part $(s + A)_k \cap ([k'] \setminus [(\frac{1}{r} - 1)k])$, where each part is itself a Sidon set. Applying Theorem 20 to the two parts and recalling that $|A| = (1 - o(1))\sqrt{k}$ by Remark 8, we can then obtain the results described in Claim 18 and Claim 19.

5 Open Questions

It is well known that Wozencraft ensemble codes C_{WE}^{α} satisfy the Gilbert-Varshamov bound for most α. Concretely,

$$\lim_{k \to \infty} \Pr_{\alpha \in S} [\Delta(C_{\mathrm{WE}}^{\alpha}) \geq d(k)] = 1,$$

where $S = \mathbb{F}_{q^k}^*$, $d(k) = \left(h_q^{-1}(\frac{1}{2}) - \epsilon\right) \cdot 2k$ with h_q the q-ary entropy function and $\epsilon > 0$ chosen arbitrarily. In this paper, we have proposed a construction of $S = \{\alpha^*\}$ such that the equation above holds with $d(k) = \Omega(\sqrt{k})$. It is of natural interest to reduce the size of the

[2] The proof appears in detail in the full version of the paper posted at https://arxiv.org/abs/2305.02484.

ensemble and find $S, d(k)$ satisfying the equation above with $|S|$ small and $d(k)$ large. For example, can one construct S such that the equation above is satisfied via $|S| = O(2^{o(k)})$ and $d(k) = \Omega(k)$, or $|S| = \text{poly}(k)$ and $d(k) = \Omega(k^c)$ with $c > \frac{1}{2}$? In addition, are there any barriers to such constructions, as in, would such constructions imply progress on some other explicit construction challenge?

In 1973, Weldon [20] proposed an ensemble of codes, a code that generalizes Wozencraft ensemble codes. The Weldon ensemble was used by him, and later Shen [15], to construct explicit concatenated codes achieving the Zyablov bound for rates less than 0.3, thus improving upon Justesen codes [10] for low rates. Weldon codes[3] of rate $1/(t+1)$ are indexed by $\alpha_1, \alpha_2, \ldots, \alpha_t \in \mathbb{F}_{q^k}$ and defined as

$$C_{\text{WE}}^{\alpha_1,\ldots,\alpha_t} = (\varphi(x), \varphi(\alpha_1 x), \ldots, \varphi(\alpha_t x)).$$

For some fixed $t > 2$, can one find explicit α_i's where the distance of $C_{\text{WE}}^{\alpha_1,\ldots,\alpha_t}$ is asymptotically larger than $\sqrt{k}$?

NP-Hardness of Almost Coloring Almost 3-Colorable Graphs

Abstract

A graph $G = (V, E)$ is said to be (k, δ) almost colorable if there is a subset of vertices $V' \subseteq V$ of size at least $(1 - \delta)|V|$ such that the induced subgraph of G on V' is k-colorable. We prove that for all k, there exists $\delta > 0$ such for all $\varepsilon > 0$, given a graph G it is NP-hard (under randomized reductions) to distinguish between:

1. Yes case: G is $(3, \varepsilon)$ almost colorable.
2. No case: G is not (k, δ) almost colorable.

This improves upon an earlier result of Khot et al. [16], who showed a weaker result wherein in the "yes case" the graph is $(4, \varepsilon)$ almost colorable.

1 Introduction

The graph coloring problem is one of the most basic combinatorial optimization problems studied in theoretical computer science. A graph $G = (V, E)$ is *k-colorable* if there exists a vertex coloring $\mathsf{col}\colon V \to \{1, \ldots, k\}$ such that for each edge $e = (u, v) \in E$, it holds that $\mathsf{col}(u) \neq \mathsf{col}(v)$. The chromatic number of G, denoted by $\chi(G)$, is defined to be the smallest integer k so that G is k-colorable. What is the computational complexity of finding the chromatic number of a graph?

It has long been known that computing the chromatic number of a graph is NP-hard [10]. Using the PCP theorem, one can improve this result and show that even approximating the chromatic number of a graph (within any constant factor) is NP-hard [12]. Thus, the next natural question to ask is how hard is it to find somewhat efficient coloring of a graph, provided that a very efficient one exists. Specifically, given a $k \in \mathbb{N}$, what is the smallest k' such that given a k-colorable graph, one may efficiently color it using k'?

As the case of $k = 2$ is the 2-coloring problem which is known to be in P, the first interesting case to consider is that of $k = 3$. Despite significant effort, the best unconditional result along these lines, due to [2], asserts that such graphs are NP-hard to color using 5 colors. In terms of conditional results, based on Khot's 2-to-2 Games Conjecture (with perfect completeness) [13], Dinur et al. [7] proved that it is NP-hard to C-color 4-colorable graphs for all $C > 0$. This result was recently improved by Guruswami and Sandeep [8], who showed that it is NP-hard to C-color 3-colorable graphs for any $C > 0$.[1] The gap between the ratios known to be hard and those known to be efficiently achievable is huge: on the algorithmic front, the state of the art result (due to [11]) asserts that one may efficiently find an $n^{0.2-\varepsilon}$-coloring of a given 3-colorable graph, where n is the number of vertices of the graph and $\varepsilon > 0$ is an absolute constant.

Due to the lack of progress towards unconditional hardness results for the graph coloring problem, one is motivated to consider relaxations of the problem that are easier to work with that still capture its essence. Most relevant to us is the almost coloring relaxation. Here, we say a graph $G = (V, E)$ is (k, δ) almost colorable if there exists a subset of vertices $V' \subseteq V$ with $|V'| \geqslant (1-\delta)|V|$ such that the induced subgraph of G on V' is k-colorable. That is, that the graph $G' = (V', E')$, where $E' = \{e = (u, v) \mid u, v \in V'\}$, is k-colorable. With regards to this notion, based on the hardness of 2-to-2 Games with imperfect completeness [15, 6, 5, 16], one can show that almost coloring almost 4-colorable graphs is NP-hard with any constant number of colors. More specifically, using ideas from [7], one can show that for all $\varepsilon, \delta > 0$, given a graph $G = (V, E)$, it is NP-hard to distinguish between:

1. Yes case: G is $(4, \varepsilon)$ almost colorable.
2. No case: G does not contain an independent set of fractional size δ.

In particular, it is NP-hard to $(k, 1-\varepsilon)$ almost color a given $(4, \varepsilon)$ almost colorable graph. We remark that the "independent set" conclusion in the no case is in fact stronger, and one often manages to achieve it via the typical style of PCP reductions for coloring problems.

The distinction between 3-coloring and 4-coloring may seem minor at first glance. This distinction hides within it a technical barrier related to the difference between Unique-Games and 2-to-2 Games. Indeed, the only type of problems that seem to facilitate results for 3-coloring are Unique-Games [7] (which inherently lack perfect completeness) and a certain variant of 2-to-2 games called Rich 2-to-2 Games [4, 3]. Both problems are conjectured to be NP-hard, but the proof of this assertion seems out of reach of current techniques. Using standard 2-to-2 Games, which are now known to be NP-hard (with imperfect completeness), there seem to have been fundamental difficulties beyond 4-colorable graphs.

Recently, Guruswami and Sandeep [8] observed that there there are transformations from the algebraic CSPs world [17] (which date back to [9]) that reduce the chromatic number of a graph from 4 to 3. Using these ideas, and combining them with the reduction of [7], Guruswami and Sandeep managed to prove the aforementioned conditional result, asserting that assuming the d-to-d conjecture of Khot with perfect completeness, it is NP-hard to C-color a given 3-colorable graph, for all constants $C > 0$. We remark that interestingly their reduction fails to establish the stronger "independent set" type conclusion in the no case.

The main result of this paper is that while this reduction does not preserve the independent set conclusion, it does preserve the intermediate, strictly weaker conclusion of almost coloring. More precisely, we use these ideas to get an (unconditional) NP-hardness result regarding almost coloring almost 3-colorable graphs with a constant number of colors. Specifically, we prove:

► **Theorem 1.** *For all $k \in \mathbb{N}$, there exists $\delta > 0$ such that for all $\varepsilon > 0$, given a graph $G = (V, E)$ it is NP-hard (under randomized reductions) to distinguish between:*

1. *Yes case: G is $(3, \varepsilon)$ almost colorable.*
2. *No case: G is not (k, δ) almost colorable.*

[1] In fact, for the result of Guruswami et al./ it suffices to assume that the d-to-d Games Conjecture of Khot [13] holds for some constant $d \in \mathbb{N}$.

Proof Idea

While the reduction of Guruswami and Sandeep [8] does not preserve the notion of almost coloring for all graphs, it turns out that it does so for bounded degree graphs. Indeed, this is the main insight behind the proof of Theorem 1. Thus, our proof of Theorem 1 starts with a hard instance of 2-to-2 Games with imperfect completeness and uses the reduction of [7] to establish hardness of almost coloring almost 4-colorable graphs for instances with certain regularity properties. We then use random sparsification to further reduce such instances to instances with bounded maximal degree. Finally, we use line-graph based reductions as in [8] to reduce this problem to the problem of almost coloring almost 3-colorable graphs.

We remark that just like in the result of Guruswami and Sandeep, our result also fails to establish the stronger "independent set" type conclusion in the no case. Indeed, strengthening Theorem 1 in that manner would automatically improve upon the best known hardness of approximation result for Vertex Cover, which is a long standing challenge. Currently, it is known that it is NP-hard to approximate the size of the smallest vertex cover of a graph within factor $\sqrt{2}-\varepsilon$ for all $\varepsilon > 0$, and an "independent-set"-type strengthening of Theorem 1 would improve this factor to $3/2-\varepsilon$, for all $\varepsilon > 0$. While we do not know how to prove such strengthening, we believe it may be doable and discuss such a possibility in Section 4.

2 Preliminaries

In this section, we present a few notions that will be necessary in the proof of Theorem 1.

2.1 Induced Coloring and Constraint Satisfaction Problems

For an integer $k \in \mathbb{N}$, the k-induced coloring of a graph G is the fractional size of the largest induced subgraph of G which is k-colorable. More precisely:

▶ **Definition 2.** *For a graph $G = (V, E)$, the induced-coloring $\mathsf{iCol}_k(G)$ is the fractional size of the largest induced subgraph that is k-colorable. That is, it is the maximum of $|V'| / |V|$ among all induced sub-graphs (V', E') of G that are k-colorable.*

According to this notation, the fact that a graph G is (k, δ) almost colorable is equivalent to $\mathsf{iCol}_k(G) \geqslant 1-\delta$. Next, we define the label cover problem, followed by the definition of a specific type of label cover instances called 2-to-2 Games.

▶ **Definition 3.** *An instance of Label Cover $\Psi = (G, \Sigma, \Phi)$ consists of a graph $G = (V, E)$, a finite alphabet Σ and a collection of constraints $\Phi = \{\Phi_e\}_{e\in E}$ one for each edge of G. The constraint on an edge $e \in E$ specifies tuples $\Phi_e \subseteq \Sigma \times \Sigma$ that are deemed satisfactory.*

Given an instance of label cover Ψ, the goal is to find an assignment $A\colon V \to \Sigma$ satisfying as many of the constraints as possible. Here, we say A satisfies the constraint on an edge $e = (u, v) \in E$ if $(A(u), A(v)) \in \Phi_e$. We denote by $\mathsf{sat}(\Psi)$ the maximum fraction of constraints that are satisfied in Ψ by any assignment A. We will mostly be interested in a specific type of label cover instances, known as 2-to-2 instances, in which the constraints take a special form.

▶ **Definition 4.** *A label cover instance $(G = (V, E), \Phi, 2R)$ is called a 2-to-2 Games instance if for every edge $e = (u, v) \in E$, the constraint Φ_e is of the form $\cup_{i=1}^{R} A_i \times B_i$, where $\{A_i\}_{i=1}^{R}$ and $\{B_i\}_{i=1}^{R}$ are two partitions of Σ into sets of size 2. Equivalently, the constraint Φ_e takes the form*

$$\left\{(i,j) \in \{1,\ldots,2R\} \;\middle|\; (\pi^{-1}(i), \sigma^{-1}(j)) \in \{(2k,2k),(2k,2k+1),(2k+1,2k),(2k+1,2k+1)\}\right\}$$

for some permutations $\pi, \sigma : [2R] \to [2R]$.

Typically, given a 2-to-2 Games instances Ψ, the goal is to find an assignment to the vertices satisfying as many of the constraints as possible. For our purposes, it will be useful for define a variation of this parameter denoted by $\mathsf{iSat}(\Psi)$.

▶ **Definition 5.** *For an integer $m \in \mathbb{N}$ and a 2-to-2 Games instance $\Psi = (G = (V, E), \Sigma, \Phi)$, we define $\mathsf{iSat}(\Psi)$ to be the fractional size of the largest $V' \subseteq V$ for which there is an assignment $A\colon V' \to \Sigma$ satisfying all of the constraints of Ψ inside V'.*

2.2 Fourier Analysis

Our reduction requires a few basic notions from discrete Fourier analysis which we present next. We refer the reader to [19] for a more thorough presentation.

2.2.1 The Fourier Decomposition over Product Spaces

Let $q \in \mathbb{N}$ be an integer, and denote $[q] = \{0, 1, \ldots, q-1\}$. We will consider the product space $L_2([q]^n, \mu)$ where μ is the uniform measure over $[q]^n$ and the inner product between $f, g\colon [q]^n \to \mathbb{R}$ is defined as

$$\langle f, g \rangle = \mathop{\mathbb{E}}_{x\sim\mu}[f(x)g(x)].$$

We may pick an orthonormal basis $\alpha_0, \ldots, \alpha_{q-1}\colon [q] \to \mathbb{R}$ of $L_2([q], \mu)$ so that $\alpha_0 \equiv 1$, and we do so canonically. Given this basis, we may tensorize it to get an orthonormal basis of $L_2([q]^n, \mu)$ as $\{\alpha_{j_1,\ldots,j_n}\}_{j_1,\ldots,j_n\in[q]}$ where $\alpha_{j_1,\ldots,j_n}$ is defined as

$$\alpha_{j_1,\ldots,j_n}(x_1, \ldots, x_n) = \prod_{i=1}^{n} \alpha_{j_i}(x_i).$$

Given the orthonormal basis $\{\alpha_{\vec{j}}\}_{\vec{j}\in[q]^n}$, we may decompose any $f\colon [q]^n \to \mathbb{R}$ as a linear combination of the basis functions, and the coefficients in this linear combination are given by the Fourier coefficients:

▶ **Definition 6.** *For $f\colon [q]^n \to \mathbb{R}$ and $\vec{j} \in [q]^n$, we define $\hat{f}(\vec{j}) \overset{def}{=} \left\langle f, \alpha_{\vec{j}} \right\rangle$.*

Also, given $\vec{j} \in [q]^n$, we define the degree of $\vec{j}$, $\mathsf{deg}(\vec{j})$, to be the number of indices $i = 1, \ldots, n$ such that $j_i \neq 0$. We define the action of a permutation on a function:

▶ **Definition 7.** *For a permutation $\pi\colon [n] \to [n]$ and a function $f\colon [q]^n \to \mathbb{R}$, we define $f^\pi\colon [q]^n \to \mathbb{R}$ by $f^\pi(x_1, \ldots, x_n) \overset{def}{=} f(x_{\pi(1)}, \ldots, x_{\pi(n)}) = f(x^\pi)$.*

2.2.2 Low Degree Influences and a Corollary of the Invariance Principle

Our analysis requires the notion of low degree influences, which is defined in terms of the Fourier coefficients of a function f in the following way:

▶ **Definition 8.** *For a function $f\colon [q]^n \to \mathbb{R}$, a coordinate $i = 1, \ldots, n$ and an integer d, the degree d influence of i on f is defined as*

$$I_i^{\leqslant d}[f] \overset{def}{=} \sum_{\substack{\vec{j}\in[q]^n \\ \vec{j}_i\neq 0, \mathsf{deg}(\vec{j})\leqslant d}} \hat{f}^2(\vec{j}).$$

The following well known fact asserts that the number of coordinates with significant low degree influence is relatively small.

▶ **Fact 9.** *For a function $f\colon [q]^n \to \mathbb{R}$ with $\|f\|_2 \leqslant 1$ and $\tau > 0$, the number of coordinates $i = 1, \dots, n$ with $I_i^{\leqslant d}[f] \geqslant \tau$ is at most $\frac{d}{\tau}$.*

In the reduction from 2-to-2 Games to 4-coloring we will have functions operating on the space $[q^2]^n$, and we will want to sometimes view it as $[q]^{2n}$. To do so, we will use the natural identification between $[q]^2$ and $[q^2]$ and thus define an identification between the spaces $[q^2]^n$ and $[q]^{2n}$ in the following way:

▶ **Definition 10.** *For $x = (x_1, \dots, x_{2n}) \in [q]^{2n}$, we denote $\overline{x} \overset{def}{=} ((x_1, x_2), \dots, (x_{2n-1}, x_{2n})) \in [q^2]^n$.*

Thus, given a function $f\colon [q]^{2n} \to \mathbb{R}$, one may consider the function $\overline{f}\colon [q^2]^n \to \mathbb{R}$ defined by the natural identification above as:

$$\overline{f}((x_1, x_2), \dots, (x_{2n-1}, x_{2n})) = f(x_1, \dots, x_{2n}).$$

The following facts from [7] will be used in the analysis of our reduction. The first claim related low-degree influences of f and of $\overline{f}$:

▷ Claim 11. For a function $f\colon [q]^{2n} \to \mathbb{R}$, a coordinate $1 \leqslant i \leqslant n$ and a degree parameter d, we have that

$$I_i^{\leqslant d}[\overline{f}] \leqslant I_{2i-1}^{\leqslant 2d}[f] + I_{2i}^{\leqslant 2d}[f].$$

Next, we need a corollary of the invariance principle which is also used in [7], and towards this end, we define the parameter $\Gamma_\rho(\mu, \tau)$:

▶ **Definition 12.** *Let Φ be the cumulative distribution function of $\mathcal{N}(0,1)$. We denote*

$$\Gamma_\rho(\mu, \tau) \overset{def}{=} \Pr\left[X \leqslant \Phi^{-1}(\mu) \wedge Y \geqslant \Phi^{-1}(1-\tau)\right],$$

where (X, Y) are ρ-correlated Gaussian random variables. If $\mu = \tau$, we write $\Gamma_\rho(\mu)$, we also omit ρ when clear from context.

Asymptotics for the value $\Gamma_\rho(\mu, \tau)$ exist (and are not too hard to establish), however, we will only require the fact that $\Gamma_\rho(\varepsilon)$ is a positive constant for all $\rho < 1$ and $\varepsilon > 0$. With the parameter $\Gamma_\rho(\mu, \tau)$ in hand, we now state the corollary of the invariance principle necessary for our analysis which can also be found in [7].

▶ **Theorem 13.** *Let $q \in \mathbb{N}$ be an integer and let T be a connected symmetric Markov chain on $[q]$, with eigenvalues $\lambda_0 = 1 \geqslant \ldots \geqslant \lambda_{q-1}$. If $\rho := \max(|\lambda_1|, |\lambda_{q-1}|) < 1$, then for any $\mu, \tau > 0$ there exist $\delta > 0$ and $d \in \mathbb{N}$, for which the following holds. For all functions $f, g\colon [q]^n \to [0,1]$, if $\mathbb{E}[f] \geqslant \mu, \mathbb{E}[g] \geqslant \tau$, and $\langle f, T^{\otimes n} g\rangle \leqslant \frac{1}{2}\Gamma_\rho(\mu, \tau)$, then there exists a coordinate $i = 1, \dots, n$ such that $I_i^{\leqslant d}[f], I_i^{\leqslant d}[g] \geqslant \delta$.*

2.2.3 A Markov Chain on $[4]^2$

We end this section with the following claim due to [7] establishing the existence of a Markov chain on $[4]^2$ with certain properties:

▷ Claim 14. There exists a connected symmetric Markov chain T on $\{0,1,2,3\}^2$ with $\max(|\lambda_1|, |\lambda_{q-1}|) < 1$, such that if $T((x_1, x_2) \leftrightarrow (y_1, y_2)) > 0$ then $\{x_1, x_2\} \cap \{y_1, y_2\} = \emptyset$.

3 Hardness of Almost Coloring Almost 3-Colorable Graphs

3.1 The Starting Point: 2-to-2 Games

The starting point of our reduction is the hardness of 2-to-2 Games with imperfect completeness [15, 6, 5, 16] (see [18, 14] for an exposition). Specifically, we will use the following formulation:

▶ **Theorem 15.** *For all $s, \eta > 0$, given a 2-to-2 Games instance Ψ, it is NP-hard to distinguish between:*

- *YES case:* $\mathsf{iSat}(\Psi) \geqslant 1 - \eta$.
- *NO case:* $\mathsf{sat}(\Psi) \leqslant s$.

Additionally, in both the Yes and No cases, the graph G underlying Ψ satisfies the following regularity property: for all $\varepsilon \leqslant \beta \leqslant 1$, any set $S \subseteq V$ of fractional size β contains at least $\Omega(\beta^2)$ fraction of the edges of G.

3.2 A Reduction from 2-to-2 Games to Almost 4-Coloring

In this section, we apply the reduction of [7] on instances from Theorem 15 to get the following hardness result for almost 4-coloring:

▶ **Theorem 16.** *For all $\varepsilon, \eta > 0$, given an edge weighted graph $G = (V, E, w)$, it is NP-hard to distinguish between:*

- *Yes case:* $\mathsf{iCol}_4(G) \geqslant 1 - \eta$
- *No case: any set $S \subseteq V$ of fractional size at least ε contains edges of total weight of at least $\Omega\left(\varepsilon^2 \Gamma_\rho(\varepsilon/2)\right)$, where $\rho \in (0, 1)$ is an absolute constant.*

Proof. Let $\Psi = (G = (V, E), \Sigma, \Phi)$ be a 2-to-2 Games instances from Theorem 15 with completeness $1 - \eta$ and soundness $s > 0$, and let T be the Markov chain from Claim 14. Without loss of generality, we assume that the alphabet Σ is $[2R]$, where $2R = |\Sigma|$. Below, when we write Γ, we mean $\Gamma = \Gamma_\rho$ where ρ is the absolute constant from Claim 14.

We construct a graph $G = (V', E')$ by replacing each vertex $u \in V$ by a block of vertices $\{u\} \times \{0, 1, 2, 3\}^{2R}$, denoted by $B[u]$. Thus, $V' = \bigcup_{u \in V} B[u]$. As for the edges of H, for an edge $\{u, v\} \in E$ in G with a 2-to-2 constraint described by the permutations $\pi, \sigma \in S_{2R}$, we add an edge between (u, x) and (v, y) if $T^{\otimes R}(\overline{x^\pi} \leftrightarrow \overline{y^\sigma}) > 0$, in which case we assign the edge the weight $\frac{1}{|E|} T^{\otimes R}(\overline{x^\pi} \leftrightarrow \overline{y^\sigma})$.

Completeness. If $\mathsf{iSat}(\Psi) \geqslant 1 - \eta$, then there is $S \subseteq V$ of fractional size $1 - \eta$ and a assignment $c \colon S \to [2R]$, satisfying all constraints within S. For each $u \in S$ we assign the block $B[u]$ by $A(u, x) = x_{c(u)}$, and note that this assignment forms a 4-coloring of $\bigcup_{u \in S} B[u]$. Thus, $\mathsf{iCol}_4(G') \geqslant 1 - \eta$.

Soundness. Assume towards contradiction that there is a set of vertices $S' \subseteq V'$ of fractional size ε that contains less than $c\varepsilon^2\Gamma(\varepsilon/2)$ of the edges (weighted), where $c > 0$ is an absolute constant to be determined. Define

$$S \overset{def}{=} \left\{ v \in V \;\middle|\; |B[v] \cap S'| \geqslant \frac{\varepsilon}{2} |B[v]| \right\}.$$

By an averaging argument we have that $|S| \geqslant \frac{\varepsilon}{2} |V|$, and for each $v \in S$ we define $f_v \colon \{0, 1, 2, 3\}^{2R} \to \{0, 1\}$ by $f_v(x) = 1_{(v,x) \in S}$. Thus, $\mathbb{E}[f_v] = \frac{|B[v] \cap S'|}{|B[v]|} \geqslant \frac{\varepsilon}{2}$ for all $v \in S$.

By the regularity condition on Ψ, the set S contains at least $\alpha\varepsilon^2$ fraction of the edges of Ψ, where $\alpha > 0$ is an absolute constant. Fix $u, v \in S$ between which there is an edge and let π, σ be the permutations defining the constraint on it. Note that the weight of edges between the block of u and the block of v is proportional to $\langle \overline{f_u^{\pi^{-1}}}, T^{\otimes R}\overline{f_v^{\sigma^{-1}}}\rangle$. Thus, as the total weight edges covered by S' is at most $c\varepsilon^2\Gamma(\varepsilon/2)$, it follows that for at least half of the edges (u, v) inside S we have that

$$\langle \overline{f_u^{\pi^{-1}}}, T^{\otimes R}\overline{f_v^{\sigma^{-1}}}\rangle \leqslant \frac{2c\varepsilon^2\Gamma(\varepsilon/2)}{\alpha\varepsilon^2} < \frac{1}{2}\Gamma(\varepsilon/2)$$

where we used the fact that c is sufficiently small. We refer to such edges (u, v) as good.

Fix a good edge (u, v). Applying Theorem 13 we find $d \in \mathbb{N}$ and $\delta > 0$ depending only on ε, such that there is $i \in \{1, \dots, R\}$ for which $I_i^{\leqslant d}[\overline{f_u^{\pi^{-1}}}] \geqslant \delta, I_i^{\leqslant d}[\overline{f_v^{\sigma^{-1}}}] \geqslant \delta$. Using Claim 11 we conclude that

$$I_{\pi(2i-1)}^{\leqslant 2d}[f_u] + I_{\pi(2i)}^{\leqslant 2d}[f_u] = I_{2i-1}^{\leqslant 2d}[f_u^{\pi^{-1}}] + I_{2i}^{\leqslant 2d}[f_u^{\pi^{-1}}] \geqslant I_i^{\leqslant d}[\overline{f_u^{\pi^{-1}}}] \geqslant \delta,$$

$$I_{\sigma(2i-1)}^{\leqslant 2d}[f_v] + I_{\sigma(2i)}^{\leqslant 2d}[f_v] = I_{2i-1}^{\leqslant 2d}[f_v^{\sigma^{-1}}] + I_{2i}^{\leqslant 2d}[f_v^{\sigma^{-1}}] \geqslant I_i^{\leqslant d}[\overline{f_v^{\sigma^{-1}}}] \geqslant \delta.$$

Taking $\mathsf{List}[u] = \left\{ i \in \{1, \dots, R\} \,\middle|\, I_i^{\leqslant 2d}[f_u] \geqslant \frac{\delta}{2} \right\}$, we conclude that for each good edge (u, v) it holds that the lists $\mathsf{List}[u]$ and $\mathsf{List}[v]$ contain a pair of assignments satisfying the constraint on (u, v). Also, by Fact 9 the size of each one of these lists is at most $\frac{4d}{\delta}$. Thus, if we choose for each $u \in S$ a label from $\mathsf{List}[u]$ uniformly at random, then we get an assignment that satisfies at least $\frac{\delta}{4d}$ of the good edges in expectation. Therefore, in expectation, it satisfies at least $\Omega(\varepsilon^2\delta/d)$ of the constraints of Ψ. In particular, there exists an assignment to Ψ satisfying at least $\Omega(\varepsilon^2\delta/d)$ of the constraints in it, and this is a contradiction provided that the soundness parameter s is sufficiently small. ◀

3.3 Sparsification: Hardness of Almost 4-coloring on Bounded Degree Graphs

In this section, we start with instances produced from Theorem 16, and reduce them to unweighted graph instances in which the maximal degree is bounded. To do so, we apply the random sparsification technique from [1]. More precisely, we show the following result:

▶ **Theorem 17.** *For all $\varepsilon, \eta > 0$, given a graph $G = (V, E)$ it is NP-hard under randomized reductions to distinguish between:*

- *Yes case:* $\mathsf{iCol}_4(G) \geqslant 1 - \eta$
- *No case: G has no independent set of size $\varepsilon |V|$.*

Moreover, the maximal degree of a vertex in G is at most $O\left(\frac{1}{\varepsilon^2\Gamma(\varepsilon/2))}\right)$.

Proof. Let $(G = (V, E), w)$ be a weighted graph as in Theorem 16, and construct a graph $G' = (V', E')$ in the following way:

Step 1: reduce the average degree and remove weight. Let $d^{-1} = C^{-1} \cdot \varepsilon^2\Gamma(\varepsilon/2)$ for a large absolute constant $C > 0$ to be determined. Independently sample dn edges from G (allowing repetitions), with probabilities proportional to the weights and include them, unweighted, in the graph G'.

Completeness. It is clear that $\mathsf{iCol}_4(G') \geqslant \mathsf{iCol}_4(G)$ as G' is a subgraph of G.

Soundness. Let $S \subseteq V$ be a set of fractional size ε, and recall that it contained at least $c\varepsilon^2\Gamma(\varepsilon/2)$ of the total weight, for some $c > 0$. Thus, the probability that S is an independent set in G' is at most

$$\left(1 - c\varepsilon^2\Gamma(\varepsilon/2)\right)^{dn} \leqslant e^{-c\varepsilon^2\Gamma(\varepsilon/2)dn} \leqslant e^{-ncC} \leqslant 2^{-2n}$$

for sufficiently large $C > 0$. As there are at most 2^n distinct such sets S, it follows from the union bound that the probability at least one of them is an independent set is at most $2^n \cdot 2^{-2n} \leqslant 2^{-n}$.

Step 2: Average to maximal degree. After step 1 the average degree is at most $2d$. We remove from G' vertices with degree higher than $4d$. By Markov's inequality, at most half of the vertices are removed. Consequently, if an almost coloring for $1 - \eta$ of the vertices existed, the same coloring colors at least $1 - 2\eta$ of the vertices. Similarly, if the largest independent set had fractional size at most ε, after removing vertices, no independent set has a fractional size larger than 2ε. ◀

3.4 Decreasing the Chromatic number

The final step in our proof is to apply a transformation on instances from Theorem 17 that reduces the almost coloring number in the "yes case" to 3, while keeping the soundness in the form of almost coloring. Toward this end, we use the *directed line graph*. The line graph was shown by [9, 20] to reduce the chromatic number (to be roughly logarithmic in the chromatic number of the original graph). This fact was used in [17, 8] to get hardness results for 3-colorable graphs. We also use this property of the line graph. For our purposes though, we show that a stronger guarantee can be made so long as the original graph has a bounded degree.

▶ **Definition 18.** *For a digraph $G = (V, E)$, the directed line graph of G, denoted by $\delta(G) = (V', E')$, is defined in the following way:*

- *The vertices are $V' = E(G)$, the (directed) edges of the original graph G.*
- *The edges are any pair of edges of G that shares a vertex, namely:*

$$E' = \{((u, v), (v, w)) \mid (u, v), (v, w) \in E(G)\}.$$

Applying the line-graph twice is denoted by $\delta^2(G) \overset{def}{=} \delta(\delta(G))$.

We use the following properties of the line graph. The first two lemmas address the completeness of the reduction.

▶ **Lemma 19.** *If G is 4-colorable, then $\chi(\delta^2(G)) \leqslant 3$.*

Proof. Given a 4-coloring $c : V \to \{0, 1, 2, 3\}$ of G, we can color $\delta^2(G)$ in the following way: for every vertex $((i, j), (j, k))$, if $c(j) \in \{0, 1, 2\}$ we will assign the color $c(j)$. Otherwise, we will assign any color in $\{0, 1, 2\} \setminus \{c(i), c(k)\}$. ◀

Next, we show that if G has bounded degree and a large induced subgraph which is 4-colorable, then $\delta^2(G)$ is almost 3-colorable.

▶ **Lemma 20.** *For a directed graph $G = (V, E)$ with bounded degree d, if $\mathsf{iCol}_4(G) \geqslant 1 - \eta$, then $\mathsf{iCol}_3(\delta^2(G)) \geqslant 1 - 6d^2\eta$.*

Proof. Since $\mathsf{iCol}_4(G) \geqslant 1-\eta$, there exists an induced subgraph H of G, where $|V(H)| \geqslant (1-\eta)\,|V(G)|$ and $\chi(H) \leqslant 4$. By Lemma 19 we get that $\delta^2(H)$ is 3-colorable. Therefore, it suffices to bound the fractional number of vertices of $\delta^2(G)$ that are not vertices of $\delta^2(H)$.

The set $V(\delta^2(G)) \setminus V(\delta^2(H))$ contains vertices of the form $((u,v),(v,w))$ when $\{u,v,w\} \not\subseteq V(H)$. The fractional size of $V(G)\setminus V(H)$ in $V(G)$ is at most η, and for each vertex $v \in V(G)$, there exists at most $3d^2$ vertices in $V(\delta^2(G))$ that include v. Therefore, at most $|V(G)|\,3d^2\eta$ of the vertices are not inside $V(\delta^2(H))$, which implies that $\left|V(\delta^2 H)\right| \geqslant (1-6d^2)\left|V(\delta^2 G)\right|$ and so $\mathsf{iCol}_3(\delta^2(G)) \geqslant 1-6d^2\eta$. ◀

The next lemma addresses the soundness of the reduction:

▶ **Lemma 21.** *Let $G=(V,E)$ be a directed graph with a maximal degree of at most d. Then*

$$\mathsf{iCol}_{\lfloor \log(Q)\rfloor}(\delta(G)) \leqslant \frac{d-1}{d} + \frac{\mathsf{iCol}_Q(G)}{d}.$$

Proof. For $S \subseteq V(\delta G) = E(G)$ and a partial $t = \lfloor \log(Q) \rfloor$ coloring $c\colon S \to [t]$, we can construct the following partial coloring of G. Let $H \subseteq V(G)$ be the set of vertices u such that $(u,v) \in S$ for all neighbours v of u in G. Define $f\colon H \to P([t])$ by

$$f(u) = \{c((u,v)) \mid (u,v) \in E(G)\}.$$

The function above is indeed a valid partial coloring, since for each $(u,v) \in E(G)$, such that u,v are both colored, $c((u,v)) \in f(u)$ and $c((u,v)) \notin f(v)$. This partial coloring has at most Q colors, since $|\mathcal{P}([t])| = 2^t \leqslant 2^{\log(Q)} = Q$.

Finally, by definition, we must have that $|H| \leqslant \mathsf{iCol}_Q(G)\,|V|$. On the other hand, if the size of S is denoted by $1-\eta$, then we have that H contains at least $(1-d\eta)\,|V|$ vertices. It follows that $1-d\eta \leqslant \mathsf{iCol}_Q(G)$, and so $\eta \geqslant \frac{1-\mathsf{iCol}_Q(G)}{d}$. ◀

We are now ready to complete the proof of Theorem 1, restated below:

▶ **Theorem 22.** *For all $k \in \mathbb{N}$ there is $\delta = \delta(k) < 1$ such that the following holds for all $\eta > 0$. Given an undirected graph $G=(V,E)$, it is NP-hard (under randomized reductions) to distinguish between:*

- *Yes case:* $\mathsf{iCol}_3(G) \geqslant 1-\eta$
- *No case:* $\mathsf{iCol}_k(G) \leqslant 1-\delta$

Moreover, the problem is NP-hard on instances with bounded degrees (depending only on k).

Proof. We start with a graph G from Theorem 17 with sufficiently small parameters, construct $\delta^2(G)$, and replace the directed edges with undirected ones. Let d be the bound on the maximal degree of G.

Completeness. If $\mathsf{iCol}_4(G) \geqslant 1-\eta$, then by Lemma 20 $\mathsf{iCol}_3(\delta^2(G)) \geqslant 1-6d^2\eta$, which is at least $1-\sqrt{\eta}$ provided η is small enough (recall that d only depends on the soundness parameter ε in Theorem 17).

Soundness. Suppose that the largest independent set in G has fractional size at most $1/Q$. By Lemma 21 we get that $\mathsf{iCol}_{\lfloor \log(Q/2)\rfloor}(\delta G) \leqslant \frac{2d-1}{2d} + \frac{1}{4d}$. Note that the maximum degree in $\delta(G)$ is at most $4d$, so applying Lemma 21 on $\delta(G)$ we get that

$$\mathsf{iCol}_{\lfloor \log(\lfloor \log(Q/2)\rfloor)\rfloor}(\delta^2(G)) \leqslant \frac{4d-1}{4d} + \frac{4d-1}{16d^2} = 1 - \frac{1}{16d^2}.$$ ◀

4 Discussion

As discussed in the introduction, we believe that it may be possible to improve Theorem 1 so that in the "no case", the graph does not contain an independent set of fractional size ε. More precisely, we believe that the following conjecture should hold:

▶ **Conjecture 23.** *For all $\varepsilon, \eta > 0$, given an undirected graph $G = (V, E)$, it is NP-hard to distinguish between:*

- *Yes case:* $\mathsf{iCol}_3(G) \geqslant 1 - \eta$
- *No case: G does not contain an independent size of fractional size ε.*

If true, Conjecture 23 would be a significant result in our opinion. To start with, it immediately implies an improvement on the best known hardness of approximation result for Vertex Cover (to factor $3/2 - \varepsilon$ for all $\varepsilon > 0$, where the state of the art NP-hardness result stands at $\sqrt{2} - \varepsilon$). Below, we show that a strong enough form of Theorem 1 in which δ is a sufficiently large function of k (more specifically, $\delta \geqslant 2^{-o(k)}$) implies that Conjecture 23 holds. We remark that unfortunately, in our proof $\delta = 2^{2^{-k^{O(1)}}}$, which is quantitatively not strong enough to conclude Conjecture 23.

▶ **Definition 24.** *Given a graph $G = (V, E)$ and $t \in \mathbb{N}$, define $G[t] = (V[t], E[t])$ as:*

- *The vertices are $(a_1, \ldots, a_t) \in V^t$.*
- *There is an edge between $A = (a_1, \ldots, a_t)$ and $B = (b_1, \ldots, b_t)$, if we can move from A to B by replacing one vertex with one of his neighbors.*

$$(b_1, \ldots, b_t) = (a_1, \ldots, a_{i-1}, u, a_{i+1} \ldots, a_t).$$

The following claim shows that the transformation from G to $G[t]$ has an amplification-type effect:

▷ Claim 25. If $\mathsf{iCol}_Q(G) \leqslant 1 - (1 - c)^Q$, then for all $\varepsilon > 0$, there exists $t = t(Q, \varepsilon)$ such that $G[t]$ has no independent set of size $c + \varepsilon$.

Proof. Fix t. For an independent set $I \subseteq V[t]$ we define

$$\mathsf{est}_I(v) := \frac{|\{(a_1, \ldots, a_{t-1}, v) \in V[t]\} \cap I|}{|\{(a_1, \ldots, a_{t-1}, v) \in V[t]\}|}$$

For any independent set I and $v \in V$, it holds that $\mathsf{est}_I(v) \leqslant \mathrm{IS}(G[t-1])$, where $\mathrm{IS}(G)$ denotes the fractional size of the largest IS in G. This holds since $\{(a_1, \ldots, a_{t-1}) \mid (a_1, \ldots, a_{t-1}, v) \in I\}$ is an IS in $G[t-1]$. It also follows that $\mathrm{IS}(G[1]) \geqslant \mathrm{IS}(G[2]) \geqslant \mathrm{IS}(G[3]) \geqslant \ldots$ (as $\mathbb{E}_v\left[\mathsf{est}(v)\right] = |I|/|V[t]|$).

Let $\rho > 0$ be a parameter. Since $\mathrm{IS}(G[1]) \geqslant \mathrm{IS}(G[2]) \geqslant \mathrm{IS}(G[3]) \geqslant \ldots$, there exists $t \leqslant \lceil 1/\rho^2 \rceil + 1$, for which $\mathrm{IS}(G[t-1]) - \mathrm{IS}(G[t]) \leqslant \rho^2$. Fixing a maximal independent $I \subseteq V[t]$, it holds that $\mathsf{est}_I(v) \leqslant \mathrm{IS}(G[t]) + \rho^2$ for all $v \in V$. By Markov's inequality, for at most $\rho|V|$ vertices of G, $\mathsf{est}_I(v) < \mathrm{IS}(G[t]) - \rho$. We say a vertex $v \in V$ is good if $\mathsf{est}_I(v) \geqslant \mathrm{IS}(G[t]) - \rho$.

Sampling $a_1, \ldots, a_{t-1} \in V$ uniformly and taking $\{u \mid (a_1, \ldots, a_{t-1}, u) \in I\}$ Q times, we get Q independent sets, which is a partial Q-coloring. For a good vertex v, the probability that it is included in one of the Q samples is at least

$$1 - (1 - \mathsf{est}_I(v))^Q \geqslant 1 - (1 - \mathrm{IS}(G[t]) + \rho)^Q,$$

so the expected fractional size of such Q coloring is at least:

$$(1-\rho)\Big(1-(1-\mathrm{IS}(G[t])+\rho)^{Q}\Big)\,|V|\,.$$

As this must be smaller than $\mathsf{iCol}_Q(G) \leqslant 1-(1-c)^Q$, it follows that $\mathrm{IS}(G[t]) \leqslant c+O(\rho)$, and the proof is concluded for small enough ρ. ◁

▶ **Corollary 26.** *If $\delta(Q) > \frac{1}{2^{o(Q)}}$ in Theorem 22, then Conjecture 23 holds.*

Proof. Start with a graph $G=(V,E)$ from Theorem 22 and take $G[t]$ for sufficiently large t. If $\mathsf{iCol}_3(G) \geqslant 1-\eta$ and $S \subseteq V$ is a set of fractional size at least $1-\eta$ such that the induced subgraph on S is 3-colorable, then we may color S^t by $(a_1,\dots,a_t) \to \sum_{i=1}^{t} c(a_i) \pmod 3$, when $c : S \to \{0,1,2\}$ is a 3-coloring of S.

The soundness follows from Claim 25. ◀

Abstract

We study the problem of extracting randomness from somewhere-random sources, and related combinatorial phenomena: partition analogues of Shearer's lemma on projections.

A somewhere-random source is a tuple $(X_1, \ldots, X_t)$ of (possibly correlated) $\{0,1\}^n$-valued random variables X_i where for some unknown $i \in [t]$, X_i is guaranteed to be uniformly distributed. An *extracting merger* is a seeded device that takes a somewhere-random source as input and outputs nearly uniform random bits. We study the seed-length needed for extracting mergers with constant t and constant error.

Since a somewhere-random source has min-entropy at least n, a standard extractor can also serve as an extracting merger. Our goal is to understand whether the further structure of being somewhere-random rather than just having high entropy enables smaller seed-length, and towards this we show:

- Just like in the case of standard extractors, seedless extracting mergers with even just one output bit do not exist.
- Unlike the case of standard extractors, it *is* possible to have extracting mergers that output a constant number of bits using only constant seed. Furthermore, a random choice of merger does not work for this purpose!
- Nevertheless, just like in the case of standard extractors, an extracting merger which gets most of the entropy out (namely, having $\Omega(n)$ output bits) must have $\Omega(\log n)$ seed. This is the main technical result of our work, and is proved by a second-moment strengthening of the graph-theoretic approach of Radhakrishnan and Ta-Shma to extractors.

All this is in contrast to the status for condensing mergers (where the output is only required to have high min-entropy), whose seed-length/output-length tradeoffs can all be fully explained by using standard condensers.

Inspired by such considerations, we also formulate a new and basic class of problems in combinatorics: partition analogues of Shearer's lemma. We show basic results in this direction; in particular, we prove that in any partition of the 3-dimensional cube $[0,1]^3$ into two parts, one of the parts has an axis parallel 2-dimensional projection of area at least 3/4.

1 Introduction

We study the problem of extracting randomness from somewhere-random sources, and related combinatorial phenomena: partition analogues of Shearer's lemma on projections. For the (completely self-contained) combinatorics, see Section 1.2, Section 6 and Section 7.

A t-part somewhere-random source is a tuple $(X_1, \dots, X_t)$ of (possibly correlated) $\{0,1\}^n$-valued random variables X_i, where some unknown X_i is guaranteed to be uniformly distributed. We will take t to be constant and n growing throughout this paper. A *merger* is a seeded device that takes a somewhere-random source and purifies its randomness. Mergers have been extensively studied in the theory of extractors, and have played an important role in their development. In fact, there were at least 3 distinct points in the history of extractors [19, 15, 7] when the best known explicit extractor constructions were based on new advances in explicit merger constructions.

An important observation is that t-part somewhere-random sources are special cases of sources with (min) entropy rate $1/t$. Thus any randomness purifying device (such as an extractor, condenser or disperser) that can give guarantees when fed a source with entropy rate at least $1/t$ is automatically some kind of merger for t-part somewhere-random sources.

In the literature, mergers have only been studied in the *condensing* regime: where their output is required to have high entropy rate (rather than requiring the output to be near-uniform). It turns out that information-theoretically, condensing mergers are completely overshadowed by classical condensers. A condenser is a seeded device that takes in a source with sufficient entropy rate and outputs a random variable with high entropy rate. Thus a condenser that can operate on sources with entropy rate $1/t$ is automatically a condensing merger for t-part somewhere-random sources. It turns out that whatever parameter ranges are achievable by condensing mergers can be completely explained by condensers.

In this paper, we study mergers in the *extracting* regime: where their output is required to be near-uniform. Our main result is a characterization of the seed-length needed for such extracting mergers. Unlike the tragic case of condensing mergers and their relationship with condensers, extracting mergers are able to step out of the shadow of extractors, and carve a niche, albeit small, for themselves.

We also study extracting multimergers, where more random variables out of the given tuple of random variables are required to be uniform and independent. This leads us to a number of interesting combinatorial / geometric questions, for which we give some new and basic combinatorial theorems (such as a partition analogue of Shearer's lemma on projections of a set in a product space).

1.1 Overview of results

Our results are best viewed in contrast to the situation with classical extractors and condensers. An extractor takes a source with some min-entropy and an independent uniform seed, and outputs a nearly-uniform distributed random variable. A condenser takes a source with some min-entropy and an independent uniform seed, and outputs a source with higher min-entropy-rate.

Both extractors and condensers are functions of the form:

$$F : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m,$$

where d is the "seed-length" and m is the "output-length".

Consider a random source $\mathbf{X}$ that is $\{0,1\}^n$-valued and has entropy rate $1/t$ (which means that its min-entropy is $\geq n/t$).

In the case of extractors, for $(1-\epsilon)$-fraction of $j \in \{0,1\}^d$, the output $F(\mathbf{X}, j)$ is required to be ϵ-close in statistical distance to the uniform distribution over $\{0,1\}^m$. In the case of condensers, for $(1-\epsilon)$-fraction of $j \in \{0,1\}^d$, the output $F(\mathbf{X}, j)$ is required to be ϵ-close in statistical distance to some $\{0,1\}^m$-valued random variable with min-entropy $\geq k'$.

Extractors and condensers are qualitatively very different from the point of view of seed-length. We summarize their salient features below:

- There are no seedless extractors or condensers.
- There are condensers with **constant** seed-length $d = O(\log \frac{1}{\epsilon})$ which are **lossless** (we can take k' as large as $\frac{n}{t} + d$), provided $m > k' + \Omega(\log \frac{1}{\epsilon})$.
- The seed-length required for an extractor to extract one bit of entropy from a random source $(\{0,1\}^n)^t$ is $\log n + 2\log \frac{1}{\epsilon} + O(1)$. Furthermore, this seed-length suffices to extract almost all the entropy out of the source.

A merger takes in a t-part somewhere-random source (which is a special case of a source with entropy rate $\frac{1}{t}$) and an independent uniform seed, and outputs a source with purer randomness. This naturally creates two kinds of mergers - condensing mergers and extracting mergers. To the best of our knowledge, only condensing mergers have been studied in the literature, and the (non-constructive) existence results for condensing mergers all follow from the existence results for condensers mentioned above.

Let $E : (\{0,1\}^n)^t \times \{0,1\}^d \to \{0,1\}^m$ be an extracting merger, namely its output is guaranteed to be ϵ-close to uniform on $\{0,1\}^m$ whenever given a t-part somewhere-random source as input.

▶ **Theorem A** (Informal). *We have the following:*

- *There are no seedless extracting mergers, even with output length* 1.
- *There are extracting mergers with* **constant** *seed length $O(\log \frac{1}{\epsilon})$, which can output a constant number of nearly-uniform bits.*
- *Nevertheless, if the seed length required for an extracting merger to extract almost all (or even a constant fraction) the entropy out of a somewhere-random source is $\Theta(\log n)$.*

The first item is trivial. The second item is also not difficult, but it already gives a taste of why things are different with extracting mergers. Indeed, randomly-chosen functions are not extracting mergers. The third item in the above theorem is our main technical result. It is proved by a second-moment strengthening of the graph-theoretic approach of Radhakrishnan and Ta-Shma to extractors.

1.2 Projections of partitions

Our study of these questions about randomness extraction leads us to formulate and make progress on a new and natural combinatorial question: the partition analogue of the Shearer/Loomis-Whitney inequalities on volumes of projections. These questions arise when we consider the problem of extracting randomness from t-part s-where random sources (where s out of the t parts of the source are uniform and independent). We call devices that do this *extracting multimergers*. For the rest of this subsection we only focus on the combinatorial aspect.

Let A be an "nice" subset of the solid cube $[0,1]^3$ with (Lebesgue) volume α. Consider the three axis-parallel 2-dimensional projections: $\Pi_{XY}(A)$, $\Pi_{YZ}(A)$, $\Pi_{XZ}(A)$. The Shearer/Loomis-Whitney inequality [5, 14] implies that at least one of these three projections has area at least $\alpha^{2/3}$. This is tight, as witnessed by the case where A is a cube of side-length $\alpha^{1/3}$ (and this is roughly the only such example).

Now consider the following partition variant: Let A, B be "nice" subsets of $[0,1]^3$ that partition $[0,1]^3$. Consider the six axis-parallel 2-dimensional projections of these two sets: $\Pi_{XY}(A)$, $\Pi_{YZ}(A)$, $\Pi_{XZ}(A)$ and $\Pi_{XY}(B)$, $\Pi_{YZ}(B)$, $\Pi_{XZ}(B)$. How large can we guarantee that one of them is?

Using the previous inequality and the fact that at least one of A, B has volume at least $1/2$, we get that one of these six 2-dimensional projections has area at least $(1/2)^{2/3} \geq 0.6299$. For this bound to be tight, we would need both A and B to have volume $1/2$, and both A and B to be tight examples for the Shearer/Loomis-Whitney inequality. This would require us to be able to cover $[0,1]^3$ by two cubes of volume $1/2$ – which is clearly impossible. This suggests that there should be a better bound!

We show, using a delicate study of the sections of the cube and some seemingly lucky inequalities, a tight bound for this problem.

▶ **Theorem B** (Informal). *Let A, B be "nice" subsets of $[0,1]^3$ that partition $[0,1]^3$. Then at least one of the six 2-dimensional projections*

$$\Pi_{XY}(A), \Pi_{YZ}(A), \Pi_{XZ}(A), \Pi_{XY}(B), \Pi_{YZ}(B), \Pi_{XZ}(B),$$

has area at least $3/4$.

Such "projections of partitions" questions can be formulated in great generality, and apart from Theorem B (whose proof we find very interesting), we also make some general observations and make some slightly non-trivial progress. We think these are very natural combinatorial questions worthy of further study. Beyond having connections to mergers, these questions turn out to be related to the KKL and BKKKL theorems/conjectures [12, 2, 10, 9] on influences of Boolean functions on the solid cube $[0,1]^n$. For example, Theorem B implies that any 3-variable Boolean function $f : [0,1]^3 \to \{0,1\}$ has some variable and some bit b such that the "influence towards b" of that variable is at least $1/4$, and this is tight.

Another application of such results is to partition analogues of the Kruskal-Katona theorem. For example, Theorem B implies that for any partition of $\binom{[n]}{3}$ into two parts, one of the two parts has shadow with size at least $\left(\frac{3}{4} - o(1)\right)\binom{n}{2}$.

1.3 Related work

Mergers were introduced by Ta-Shma [19] in his thesis, and were used to construct state-of-the-art extractors at the time (these were condensing mergers). Later, [15] proposed a new condensing merger construction based on taking random linear combinations of vectors over finite fields, and used it in their construction of the first extractors optimal upto constant factors. This analysis was greatly improved by Dvir [6] through his solution to the finite field Kakeya conjecture. Subsequently, [8, 7] defined a higher degree polynomial variant of the [15] merger, and by developing the ideas from [6], were able to construct improved (constant seed) mergers and state-of-the-art extractors. Subsequently [20] showed how to get analogous explicit constructions of condensers (subsuming the [7] condensing mergers) by improving the [11] condensers.

Another interesting constant seed condensing merger is by [18], which was constructed on the way to multi-source extractors.

Our lower bounds for the seed length of extracting mergers are proved by developing ideas from the paper of Radhakrishnan and Ta-Shma [17]. A recent beautiful proof of [1] also achieved a similar result to [17] in a much cleaner way, but we were not able to adapt this approach to our setting.

Other papers relevant to the study of multimergers are related to resilient functions [3, 4, 16].

Finally, our combinatorial results are related to the KKL and BKKKL theorems/conjectures [12, 2, 10, 9] on influences of Boolean functions on the solid cube $[0,1]^n$.

1.4 Organization

We give the basic definitions of extracting mergers and extracting multimergers in Section 2. In Section 3 we start with a simple proof that seedless mergers do not exist. This is followed by showing the existence of mergers and multimergers in the extracting regime with constant seed-length. We prove our lower bound on the seed length of extracting mergers in Section 4, which culminates in Theorem 9. In Section 5 we explore the connection between *seedless* extracting mergers and projections of partition questions. Section 6 is devoted to proving Theorem 17, our (optimal) lower bound on partitioning the unit cube into 2 parts, and Section 7 is devoted to partitions of the cube into 3 parts.

2 Sources and Mergers

▶ **Definition 1** (k-source). *For any k, we say that a random variable X is a k-source if for all x, $\Pr[X = x] \leq 2^{-k}$*

2.1 Somewhere and s-where Random Sources

▶ **Definition 2** (Somewhere-Random Source). *For a domain D, a tuple $\mathbf{X} = (X_1, \ldots, X_t)$ of jointly distributed D-valued random variables is called a t-part somewhere random source if for some $i \in [t]$, the distribution of X_i is uniform over D.*

▶ **Definition 3** (s-where Random Source). *For a domain D and an integer $s > 0$, a tuple $\mathbf{X} = (X_1, \ldots, X_t)$ of jointly distributed D-valued random variables is called a t-part s-where random source if for some distinct $i_1, \ldots, i_s \in [t]$, the joint distribution of $(X_{i_1}, X_{i_2}, \ldots, X_{i_s})$ is uniform over D^s.*

2.2 Extracting Mergers and Multimergers

▶ **Definition 4** (Extracting Mergers). *Let n, t, d, m be integers, and let $\epsilon > 0$.*

A function $E : (\{0,1\}^n)^t \times \{0,1\}^d \to \{0,1\}^m$ is called an $\boldsymbol{(n, t, d, m, \epsilon)}$***-extracting merger*** *if the following holds.*

Suppose $\mathbf{X} = (X_1, \ldots, X_t)$ is a somewhere-random source where each X_i is $\{0,1\}^n$-valued. Then for at least $(1-\epsilon)$-fraction of $j \in \{0,1\}^d$, the distribution of:

$$Z = E(\mathbf{X}, j),$$

is ϵ-close to the uniform distribution on $\{0,1\}^m$.

We will sometimes refer to these as ϵ-extracting mergers (since n, d, t, m are related to the shape of E).

▶ **Definition 5** (Extracting Multimergers). *Let n, t, s, d, m be integers, and let $\epsilon > 0$.*

A function $E : (\{0,1\}^n)^t \times \{0,1\}^d \to \{0,1\}^m$ is called an $\boldsymbol{(n, d, t, m, \epsilon, s)}$***-extracting multimerger*** *if the following holds.*

Suppose $\mathbf{X} = (X_1, \ldots, X_t)$ *is an* s*-where random source where each* X_i *is* $\{0,1\}^n$*-valued. Then for at least* $(1-\epsilon)$*-fraction of* $j \in \{0,1\}^d$*, the distribution of:*

$$Z = E(\mathbf{X}, j),$$

is ϵ*-close to the uniform distribution on* $\{0,1\}^m$*.*

We will sometimes refer to these as (ϵ, s)-extracting multimergers (since n, d, t, m are related to the shape of E).

Observe that the $s = 1$ case in the above definition corresponds to extracting mergers.

Note on the definitions

In all our definitions, we chose to define the "strong" versions (where the output bits are required to be independent of the seed) for simplicity. In fact, our existence result for mergers is for the strong version, and our impossibility result is for the weak version.

3 Simple results about extracting mergers

For the rest of this paper, we only talk about *extracting* (not condensing) mergers and multimergers.

3.1 Seedless Mergers do not exist

We begin with the simple observation that there are no seedless extracting mergers.

▶ **Theorem 6** (There are no seedless mergers). *Let* n *be an integer and* $\varepsilon < 1/2$*. There does not exist a function* $M : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ *that is an* ε*-merger.*

Proof. Fix an $\varepsilon < 1/2$. Assume for the sake of contradiction there exists an ε-merger $M : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$.

In particular, this means for *every* function $f : \{0,1\}^n \to \{0,1\}^n$, when X is distributed uniformly over $\{0,1\}^n$, the distribution of $M(X, f(X))$ is ε-close to uniform on $\{0,1\}$ – and in particular, it has full support on $\{0,1\}$. We will now demonstrate a function $g : \{0,1\}^n \to \{0,1\}^n$ such that $M(g(Y), Y)$ is constant for uniformly distributed Y, thus contradicting the merger assumption.

Fix any $y \in \{0,1\}^n$. Consider the constant function $f_y : \{0,1\}^n \to \{0,1\}^n$ given by $f_y(x) = y$ for all x. By our hypothesis above, the distribution of $M(X, f_y(X))$ has full support $\{0,1\}$. Thus there exists $x \in \{0,1\}^n$ such that $M(x, y) = 0$. Pick one such x and call it $g(x)$.

Thus we have $M(g(y), y) = 0$ for all $y \in \{0,1\}^n$. We conclude that for uniform $Y \in \{0,1\}^n$, $M(g(Y), Y) = 0$, which is the desired contradiction. ◀

3.2 Extracting mergers with constant seed exist

We now show that constant seed extracting mergers with constant output length exist. While the proof is quite simple, it is interesting because (1) constant seed extractors do not exist, (2) a random choice of $E : (\{0,1\}^n)^t \times \{0,1\}^d \to \{0,1\}^m$ does not give a constant seed extracting mergers, and most importantly (3) as we will later see, the seed length still needs to be superconstant to produce a superconstant number of output bits, as we will see in the next section.

▶ **Theorem 7.** *Let n, t be integers and $\epsilon > 0$.*
Then for any integer $m \leq n$, setting:

$$d = \log m + \log(t-1) + 2\log\frac{1}{\epsilon} + O(1),$$

there exists a function $E : (\{0,1\}^n)^t \times \{0,1\}^d \to \{0,1\}^m$ that is an ε-extracting merger.

Thus with $O(\log t + \log \frac{1}{\epsilon})$ bits of seed, we can extract $\mathrm{poly}(\frac{1}{\epsilon})$ bits out.

Proof. We want to get an extracting merger $E((x_1, \dots, x_t), j)$, where the $x_i \in \{0,1\}^n$ and $j \in \{0,1\}^d$.

The nature of a somewhere-random source is that applying a truncation to each element of the source yields a smaller somewhere-random source. The idea of our extracting merger is to truncate our somewhere-random source, and to then apply a standard seeded extractor to the entire truncated source. The truncation makes the instance size smaller, enabling us to use a reduced seed length in the extractor.

We truncate each x_i to the first m bits, thus obtaining $x'_1, \dots, x'_t \in \{0,1\}^m$.

We can verify that our truncation to the first m bits produces a source $(X'_1, \dots, X'_t)$ of length mt and min-entropy m. By the standard result on existence of extractors (See Theorem 6.14 in [21]), there exists a strong (m, ϵ)-extractor $Ext_0 : \{0,1\}^{mt} \times \{0,1\}^d \to \{0,1\}^m$ with seed length $d = \log m + \log(t-1) + 2\log\frac{1}{\epsilon} + O(1)$.

We can thus define the function $E : (\{0,1\}^n)^t \times \{0,1\}^d \to \{0,1\}^m$:

$$E((x_1, \dots, x_t), j) = Ext_0((x'_1, \dots, x'_t), j).$$

Observe that the function E is an ϵ-extracting merger that uses a seed j of length d and outputs m bits as required. ◀

In contrast, a random $E : (\{0,1\}^n)^t \times \{0,1\}^d \to \{0,1\}$ is not an extracting merger at all! To see this, it suffices to fix $t = 2$. If E is chosen at random, then for every $j \in \{0,1\}^d$ and $x \in \{0,1\}^n$, it is very likely that there exists a $y \in \{0,1\}^n$ such that $E((x,y),j) = 0$. Define $f_j : \{0,1\}^n \to \{0,1\}^n$ by $f_j(x) =$ any such y. Then for every $j \in \{0,1\}^d$, $E(X, f_j(X), j)$ is constant when X is picked uniformly at random, showing that E is not a merger.

3.3 Extracting Multimergers

Using the same idea, we also get interesting multimergers.

▶ **Theorem 8.** *Let n, t, s be integers with $s < t$, and $\epsilon > 0$. Then for any integer $a \leq n$, setting $m = s \cdot a$ and:*

$$d = \log a + \ 2\log\frac{1}{\epsilon} + \log(t-s) + \Omega(1),$$

there exists a function $E : (\{0,1\}^n)^t \times \{0,1\}^d \to \{0,1\}^m$ that is an (ε, s)-extracting multimerger.

Taking for example $s = t-1$ and $a = \mathrm{poly}\left(\frac{1}{\epsilon}\right) \ll n$, we get that by investing $O(\log\frac{1}{\epsilon})$ bits of seed, we can extract $\mathrm{poly}\left(\frac{1}{\epsilon}\right) \cdot t$ bits of randomness from any t-part $(t-1)$-where random source $\mathbf{X} \in (\{0,1\}^n)^t$.

In this setting of parameters, the seed length does not even depend on t, and we could take t to be growing superconstantly while preserving constant seed-length.

3.4 Seedless Multimergers

Our final observation of this section is that for multimergers with large t and where s is a large fraction of t, seedless multimergers with small error *do* exist. Indeed, if $s = t - 1$, and we define $E : (\{0,1\}^n)^t \to \{0,1\}$ by

$$E(x_1, \ldots, x_t) = Maj(x_{11}, x_{21}, \ldots, x_{t1}),$$

it is easy to see that E is a seedless $(\epsilon, t-1)$-multimerger for $\epsilon = O(\frac{1}{\sqrt{t}})$. Replacing E with any resilient function gives other examples of seedless multimergers (including with larger output size).

Investigation of this phenomenon leads us to the projections of partitions question, and we explicitly give the connection and some results about it in a later section. Nevertheless, this seems like the tip of an iceberg.

4 Mergers with large output need large seed

In this section we show a lower bound on the seed-length for 2-source extracting mergers, essentially showing that the dependence of the seed-length for extracting mergers in Theorem 7 on m and ϵ is tight.

▶ **Theorem 9.** *Let $\epsilon < 1/40$. Let $E : (\{0,1\}^n)^2 \times \{0,1\}^d \to \{0,1\}^m$ be a ε-extracting merger. Then for $\epsilon \geq 2^{-\Omega(m)}$, we have:*

$$d \geq \log m + \log \frac{1}{\epsilon} - O(1).$$

and for $\epsilon < 2^{-\Omega(m)}$, we have:

$$d \geq \Omega(m).$$

For the proof of this theorem, the representation of the inputs and output of E in terms of bits is a distraction. So, letting $N = 2^n$, $D = 2^d$, $M = 2^m$ and identifying $\{0,1\}^n, \{0,1\}^d, \{0,1\}^m$ with $[N], [D], [M]$ respectively, we will view E as a function $E : [N]^2 \times [D] \to [M]$.

Recalling the ϵ-extracting merger property, we have that E is such that whenever X, Y are jointly distributed $[N]$-valued random variables, with at least one of them uniformly distributed, and J is picked uniformly from $[D]$ and independently of (X, Y), then the distribution of $E((X,Y), J)$ is ϵ-close to the uniform distribution on $[M]$.

We will show that for $\epsilon \geq M^{-\Omega(1)}$, we have:

$$D \geq \Omega\left(\frac{1}{\epsilon} \log M\right),$$

and for $\epsilon < M^{-\Omega(1)}$, we have:

$$D \geq \Omega\left(M^{\Omega(1)}\right).$$

Our proof is based on the following idea. Consider a uniformly random subset $S \subseteq [M]$ of size λM. For each $y \in [N]$, we look for an x such that for all $j \in [D]$, $E(x,y,j) \notin S$. If there is such an x, then we define $g(y) = x$. If such an x exists for most y, then for uniformly chosen $Y \in [N], J \in [D]$, we have $\Pr_{Y,J}[E(g(Y), Y, J) \in S] \ll \lambda - \epsilon$, contradicting the merger property. Thus for most S, for many y there is no such x; namely, for most S, for many y, for all x, there is some j, such that $E(x, y, j) \in S$. For this to happen for even one y turns out to be very abnormal, and we derive our lower bound on D by digging into its structure. This part uses a second moment variation of the Radhakrishnan-TaShma [17] approach to extractor lower bounds.

4.1 Abnormal conductors

A map $C : [N] \times [D] \to [M]$ is called a conductor (this is a general term capturing the shape of seeded extractors and seeded condensers). We will also view this as a bipartite multigraph with $[N]$ on the left, $[M]$ on the right and D labelled edges coming out of every left vertex.

If C is chosen at random, then for most $S \subseteq [M]$ of size λM and most $x \in [N]$, we expect about λ fraction of the edges coming out of x to land in S. But we do not expect that this will happen for *all* x! When C is chosen at random, then for most S there will be some $x \in [N]$ for which a very small ($\ll \lambda$) fraction of edges coming out of x lie in S. We capture this with the following definition.

▶ **Definition 10.** *Let $C : [N] \times [D] \to [M]$ be a conductor. Let S be a subset of $[M]$.*

We say the vertex $x \in [N]$ totally misses *S (under C) if*

$$|\{j \in [D] \mid C(x, j) \in S\}| = 0.$$

We say the vertex $x \in [N]$ mostly misses *S (under C) if*

$$|\{j \in [D] \mid C(x, j) \in S\}| < \frac{1}{2}\frac{|S|}{M}D.$$

▶ **Definition 11** (Abnormal conductors)**.** *Let $C : [N] \times [D] \to [M]$ be a conductor.*

We say that C is (γ, λ)-abnormal if

$$\Pr_{S \in \binom{[M]}{\lambda M}}[\exists x \in [N] \text{ s.t. } x \text{ mostly misses } S] < 1 - \gamma.$$

▶ **Lemma 12** (Extracting mergers contain abnormal conductors)**.** *Suppose $0 < \gamma < \frac{\lambda}{2} - \epsilon$. Suppose $E : [N]^2 \times [D] \to [M]$ is an ϵ-extracting merger. For $y \in [N]$, let $E_y : [N] \times [D] \to [M]$ be the function $E(\cdot, y, \cdot)$. Then for some $y \in [N]$, E_y is (γ, λ)-abnormal.*

Proof. Suppose not; namely that for all $y \in [N]$, we have that E_y is not (γ, λ)-abnormal.

Pick $S \in \binom{[M]}{\lambda M}$ uniformly at random.

Let B_y be the event that there exists some $x \in [N]$ that mostly misses S under E_y.

By our assumption, $\Pr[B_y] \geq 1 - \gamma$. So the expected number of y for which B_y happens is at least $(1 - \gamma)N$.

Thus there exists some particular choice of S for which B_y happens for at least $(1 - \gamma)N$ many ys. Call this choice S_0. Define $f : [N] \to [N]$ by defining $f(y)$ as follows:

$$f(y) = \begin{cases} \text{any } x \text{ that mostly misses } S_0 \text{ under } E_y & B_y \text{ happened,} \\ \text{arbitrary} & B_y \text{ did not happen.} \end{cases}$$

Then

$$\Pr_{Y \in [N], J \in [D]}[E(f(Y), Y, J) \in S_0] < \frac{\lambda}{2}(1 - \gamma) + \gamma < \lambda - \epsilon.$$

But $|S_0| = \lambda M$, and thus we get a contradiction to the ϵ-extracting merger property of E. This completes the proof. ◀

4.2 The structure of abnormal conductors

The previous lemma gave us a y for which E_y is abnormal. We now use show that abnormal conductors are very structured, and thus get a lower bound on D.

▶ **Lemma 13.** *Let $C : [N] \times [D] \to [M]$ be a (γ, λ)-abnormal conductor. Suppose $10\epsilon < \lambda < \frac{1}{2}$. Suppose that for $X \in [N]$ and $J \in [D]$ picked uniformly and independently, $C(X, J)$ is ϵ-close to the uniform distribution on $[M]$. Then*

$$D \geq \min \left\{ \Omega\left(\frac{1}{\lambda}\log(\lambda\gamma M)\right), \Omega\left((\lambda\gamma M)^{1/4}\right) \right\}.$$

Proof. We begin with a pruning phase to remove the high degree vertices from the right side. At first reading, it will be helpful to consider the case where $B = \emptyset$.

Let $\beta = \frac{\lambda}{5} - \epsilon$. Note that the average right degree is ND/M. Define the set of high-degree right vertices by:

$$B = \{z \in [M] \mid \text{ there are at least } \frac{1}{\beta}\frac{ND}{M} \text{ edges to } z\}.$$

Thus $|B| \leq \beta M$. By the hypothesis on $C(X, J)$, we have

$$\Pr_{X \in [N], J \in [D]}[C(X, J) \in B] \leq \beta + \epsilon.$$

Let G be the set of all vertices on the left that do not have too many edges to B; namely:

$$G = \{x \in [N] \mid x \text{ has at most } 2(\beta + \epsilon)D \text{ edges to } B\ \}.$$

Then $|G| \geq N/2$.

Now pick $S \in \binom{[M]}{\lambda M}$ uniformly at random. If there is a vertex $x \in G$ that totally misses $S \setminus B$, then by choice of G:

$$|\{j \mid C(x, j) \in S\}| \leq 2(\beta + \epsilon)D < \frac{1}{2}\lambda D,$$

namely, x mostly misses S.

By our hypothesis on the abnormality of C, the existence of such an x cannot happen too often. Thus:

$$\Pr_S[\exists x \in G \mid x \text{ totally misses } S \setminus B] < 1 - \gamma. \tag{1}$$

For each $x \in G$, let A_x be the event that x totally misses $S \setminus B$ under C.

We are interested in the event that some $x \in G$ totally misses $S \setminus B$, namely, the event $\bigvee_{x \in G} A_x$.

Observe that[1]

$$\Pr[A_x] \geq \frac{\binom{M-D}{\lambda M}}{\binom{M}{\lambda M}} \geq e^{-4\lambda D} =: p.$$

Define $A = \sum_{x \in G} A_x$. Then $\mathbf{E}[A] \geq |G|p$.

[1] Here we use the observation that $(1 - \frac{D}{(1-\lambda)M}) < e^{-\frac{2D}{(1-\lambda)M}} < e^{-4D/M}$, which follows from the fact that $1 - x < e^{-2x}$ for $x < 1/2$.

By the second moment method, we have:

$$\Pr[A=0] \leq \frac{\mathbf{Var}[A]}{\mathbf{E}[A]^2}.$$

But Equation (1) tells us that $\Pr[A=0] > \gamma$.
Thus $\mathbf{Var}[A] \geq \gamma \mathbf{E}[A]^2 \geq \gamma \cdot p^2 |G|^2$.
We now extract some structure from this.
We have:

$$\mathbf{Var}[A] = \sum_{x,x' \in G} \left(\Pr[A_x \wedge A_{x'}] - \Pr[A_x]\Pr[A_{x'}] \right).$$

Two simple observations about this expression:

- Each term in the sum above is at most 1.
- Furthermore, if x, x' have no common neighbors in $[M] \setminus B$, then the corresponding term of the sum above is ≤ 0. Indeed, if $U_x, U_{x'} \subseteq [M] \setminus B$ are the neighborhoods of x and x' in $[M] \setminus B$, and if they are disjoint, then:

$$\Pr[A_x] = \frac{\binom{M-|U_x|}{\lambda M}}{\binom{M}{\lambda M}},$$

$$\Pr[A_{x'}] = \frac{\binom{M-|U_{x'}|}{\lambda M}}{\binom{M}{\lambda M}},$$

$$\Pr[A_x \wedge A_{x'}] = \frac{\binom{M-|U_x \cup U_{x'}|}{\lambda M}}{\binom{M}{\lambda M}} = \frac{\binom{M-|U_x|-|U_{x'}|}{\lambda M}}{\binom{M}{\lambda M}}.$$

So

$$\frac{\Pr[A_x \wedge A_{x'}]}{\Pr[A_x]\Pr[A_{x'}]} = \prod_{i=0}^{\lambda M-1} \frac{(M-i)\cdot(M-|U_x|-|U_{x'}|-i)}{(M-|U_x|-i)\cdot(M-|U_{x'}|-i)} \leq 1.$$

Combining the largeness of $\mathbf{Var}[A]$ with these two observations tells us that there are many $x, x' \in G$ which have a common neighbor in $[M] \setminus B$. Specifically:

$$\gamma p^2 |G|^2 \leq \mathbf{Var}[A] \leq \sum_{x,x' \in G} \mathbf{1}[x, x' \text{ have a common neighbor in } [M] \setminus B].$$

Thus there are at least $\gamma p^2 |G|^2 \geq \frac{1}{4}\gamma p^2 N^2$ pairs x, x' from G that have a common neighbor in $[M] \setminus B$.

Now the initial pruning we did will help us. Since all the vertices in $[M] \setminus B$ have degree at most $\frac{1}{\beta}\frac{ND}{M}$, we can bound the number of such pairs x, x'. For every vertex $x \in G$, there are at most $D \cdot \frac{1}{\beta}\frac{ND}{M}$ vertices x' such that x and x' share a common neighbor in $[M] \setminus B$. Thus the total number of pairs x, x' from G that have a common neighbor in $[M] \setminus B$ is at most

$$N \cdot D \cdot \frac{1}{\beta}\frac{ND}{M} = \frac{1}{\beta}\frac{D^2}{M}N^2.$$

Thus $\frac{1}{4}\gamma p^2 \leq \frac{1}{\beta}\frac{D^2}{M}$. Since $p = e^{-4\lambda D}$, we get:

$$M \leq \frac{4}{\gamma\beta} D^2 e^{8\lambda D}.$$

This means that either $D \geq \Omega\left((\gamma\beta M)^{1/4}\right) = \Omega\left((\gamma\lambda M)^{1/4}\right)$, or else:

$$D \geq \Omega\left(\frac{1}{\lambda}\log(\gamma\beta M)\right) \geq \Omega\left(\frac{1}{\lambda}\log(\gamma\lambda M)\right).$$ ◀

4.3 Putting everything together

We now prove Theorem 9.

Proof. Let $E : [N]^2 \times [D] \to [M]$ be an ϵ-extracting merger.

Set $\lambda = 20\epsilon$ and $\gamma = \epsilon$. Lemma 12 tells us that there is some $y := y_0$ for which E_y is (λ, γ)-abnormal.

Now, since E is ϵ-extracting, we have that $E_y(X, J) = E(X, y, J)$ is ϵ-close to the uniform distribution on $[M]$ for uniform and independent $X \in [N]$ and $J \in [D]$. Thus Lemma 13 tells us that

$$D \geq \min\left\{\Omega\left(\frac{1}{\epsilon}\log(\epsilon^2 M)\right), \Omega\left((\epsilon^2 M)^{1/4}\right)\right\}$$

.

If $\epsilon \geq \frac{1}{M^{1/10}}$, then the first expression is smaller and

$$D \geq \Omega(\frac{1}{\epsilon}\log M),$$

and if $\epsilon < \frac{1}{M^{1/10}}$, then E is also a $\frac{1}{M^{1/10}}$-extracting merger, and thus using the above lower bound for $\frac{1}{M^{1/10}}$ in place of ϵ, we get that:

$$D \geq M^{\Omega(1)}.$$ ◀

5 Seedless Extracting Multimergers and Projections of Partitions

In this section, we study seedless multimergers. Here our understanding is far from complete, and we suggest many directions for research.

We begin by observing a connection between seedless multimergers and a very natural and clean geometric question: how do we partition the unit cube $[0, 1]^t$ into c parts to ensure that all s-dimensional axis-parallel projections of all parts are small? We then prove some interesting positive and negative results about special cases of this general question. We conclude by collecting a number of observations and questions about this natural partitioning problem.

5.1 Seedless Multimergers with 1 bit output

In Section 3.1 we have already seen that there are no seedless mergers (i.e., with $s = 1$). We now look into seedless multimergers.

Let us consider the simplest nontrivial situation: $t = 3$ and $s = 2$, and $m = 1$ (we only try to extract 1 bit of randomness), with n big. Suppose a given function $E : (\{0, 1\}^n)^3 \to \{0, 1\}$ is known to be a (ϵ, s)-multimerger. For convenience, we identify $\{0, 1\}^n$ with $[N]$, for $N = 2^n$.

By the multimerger property, for every function $f : [N]^2 \to [N]$, the distribution of $E(X, Y, f(X, Y))$ should be ϵ-close to uniform. Let

$$P_{XY,0} = \{(x, y) \in [N]^2 : \exists z \mid E(x, y, z) = 0\}.$$

Notice that this is the projection of $E^{-1}(0)$ to two coordinates.

If $P_{XY,0}$ is bigger than $\frac{1+\epsilon}{2}N^2$, then we can violate the multimerger property: we define $f : [N]^2 \to [N]$ by $f(x, y) = z$, if any, such that $E(x, y, z) = 0$". Then $E(X, Y, f(X, Y))$ for uniform and independent $X, Y \in [N]$ is ϵ-far from uniform.

We have a similar observation for all the other two dimensional projections, and also for the set $E^{-1}(1)$. Thus if a seedless one-bit output multimerger for 3-part 2-where random sources exists, then there is a partition of $[N]^3$ into 2 parts such that each part has all its 2-dimensional axis parallel projections have size at most $\frac{1+\epsilon}{2}N^2$.

The connection also goes in reverse. Suppose we have a partition A, B of $[N]^3$ for which each part has all its 2-dimensional axis parallel projections with size at most $\frac{1+\epsilon}{2}N^2$. Let $E : [N]^3 \to \{0,1\}$ be the unique function with $E^{-1}(0) = A$ and $E^{-1}(1) = B$. Suppose (X, Y, Z) is an $[N]^3$-valued random variable that is 2-where random. Then we claim that $E(X, Y, Z)$ is ϵ-close to the uniform distribution. Indeed, if (X, Y) is uniformly distributed over $[N]^2$ (the cases of (Y, Z) and (X, Z) being uniformly distributed are similar), then:

$$\begin{aligned}
\Pr[E(X,Y,Z) = 0] &\le \Pr_{X,Y}[\exists z \in [N] \text{ s.t. } E(X,Y,z) = 0] \\
&\le \Pr_{X,Y}[\exists z \in [N] \text{ s.t. } (X,Y,z) \in A] \\
&\le \frac{|\Pi_{XY}(A)|}{N^2} \\
&\le \frac{1+\epsilon}{2}, \\
\Pr[E(X,Y,Z) = 1] &\le \Pr_{X,Y}[\exists z \in [N] \text{ s.t. } E(X,Y,z) = 1] \\
&\le \Pr_{X,Y}[\exists z \in [N] \text{ s.t. } (X,Y,z) \in B] \\
&\le \frac{|\Pi_{XY}(B)|}{N^2} \\
&\le \frac{1+\epsilon}{2},
\end{aligned}$$

which implies the desired ϵ-closeness to uniform of $E(X, Y, Z)$.

The exact same argument applies to general t, s. We record this below.

▶ **Theorem 14.** *Let $N = 2^n$. There exists a seedless $(n, d, t, m, \epsilon, s)$-multimerger if and only if there is a partition of $[N]^t$ into two sets A, B such that for every subset $U \subseteq [t]$ of size s, the projections $\Pi_U(A)$ and $\Pi_U(B)$ onto the coordinates U are of size at most $\frac{1+\epsilon}{2}N^s$.*

Motivated by this, we consider general projections of partitions questions, where the set $[N]^t$ is partitioned into c parts, and we seek to minimize the maximum s-dimensional axis parallel projection of all the parts[2].

As noted in the introduction, there is a basic bound for this problem that comes from Shearer's lemma. It says that there is a lower bound of $\left(\frac{1}{c}\right)^{s/t} N^s$ on the size of some projection. This bound is usually not tight – but it sometimes is! Whenever c is a perfect t'th power, then this bound is tight, and is realized by a partition into product sets. But for other c this kind of partition does not work, and very interesting questions ensue. In particular, we would like to highlight the case of N gigantic, and $c = \text{poly}(t)$ (so that c is clearly not a perfect t'th power).

Here is one observation that gives a flavor of what happens for large t and s. When c is a constant, and $s = t - o(\sqrt{t})$, there is a partition so that all s-dimensional projections of size $\frac{1}{c} + o(1)$. This comes by considering suitable threshold partitions. Extensions of this are related to the BKKKL [2, 10] conjectures on low influence functions.

[2] For $c > 2$, the problem of getting such partitions with c parts is somewhat related to the problem of multimergers with $\log_2(c)$ bit output, but the connection is not as tight as for the case of $c = 2$

This question is also equivalent to a problem in the continuous domain about open covers of $[0,1]^t$. Here we want to minimize the maximum s-dimensional projection size when we cover $[0,1]^t$ by c open sets.

In the following sections, we discuss two results on partitioning in three dimensions. For the first result, we get (to our surprise!) the tight bound for partitioning the cube into two parts. For the second result, we get nontrivial bounds (both upper and lower) for partitioning the cube into three parts.

Apology

These questions are more naturally phrased as questions about covers rather than partitions. However we stick to the partition language because of the particular sequence of events that led us to these problems.

6 Partitioning the 3-dimensional cube into two parts

In this section, we prove a tight bound on the largest 2 dimensional axis parallel projection of a part when partitioning $[0,1]^3$ into 2 parts.

Let $\pi_{XY}, \pi_{YZ}, \pi_{XZ} : [0,1]^3 \to [0,1]^2$ be the 2-dimensional projection maps.

The following example gives a nice partitioning with small projections.

▶ **Definition 15** (Majority Partitioning Scheme). *We define the function $MAJ_3 : [0,1]^3 \to \{0,1\}$ as*

$$MAJ_3(x,y,z) = Maj(x_1,y_1,z_1)$$

where Maj denotes the Majority function on 3 bits, and where x_1, y_1, z_1 denote the indicator variables for whether $x > 1/2$, $y > 1/2$, $z > 1/2$ respectively.

We refer to the partition naturally induced by the output of MAJ_3 on the input space $[0,1]^3$ i.e. $\{MAJ_3^{-1}(0), MAJ_3^{-1}(1)\}$, as the Majority Partitioning Scheme.

We next record the observation tha all 2-dimensional axis-parallel projections of all parts in the majority partitioning scheme on $[N]^3$ are of size at most $\frac{3}{4}N^2$, which is stated in the following lemma:

▶ **Lemma 16** (Majority Partitions Optimally). *Every 2-dimensional projection of every partition in the majority partitioning scheme MAJ_3 on $[0,1]^3$ is of size at most $\frac{3}{4}$.*

In the other direction, we first prove a lower bound on projection sizes for a discrete version of the problem.

Let N be a large positive integer. We reuse notation and let $\pi_{XY}, \pi_{YZ}, \pi_{XZ} : [N]^3 \to [N]^2$ be the 2-dimensional projection maps.

▶ **Theorem 17.** *Let $A, B \subseteq [N]^3$ be a partition.*

Then one of the six 2-dimensional projections of A and B

$$\pi_{XY}(A), \pi_{YZ}(A), \pi_{XZ}(A), \pi_{XY}(B), \pi_{YZ}(B), \pi_{XZ}(B)$$

has size at least $\frac{3}{4}N^2$.

Proof of Theorem 17 can be found in the appendix.

By a simple discretization argument, we get the following corollary:

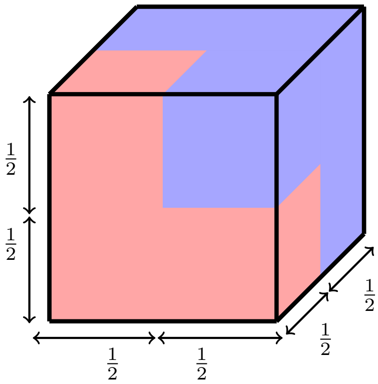

Figure 1 Majority Partitioning of the cube into 2 parts, where the partitioned sets are coloured in red and blue. Observe that *all* projections of the red set and the blue set are of equal size $\frac{3}{4}$, and Theorem 17 implies this partitioning is optimal.

▶ **Corollary 18.** *Any cover of* $[0,1]^3$ *by two open sets* A, B *has one of the following 6 sets:*

$$\Pi_{XY}(A), \Pi_{YZ}(A), \Pi_{XZ}(A), \Pi_{XY}(B), \Pi_{YZ}(B), \Pi_{XZ}(B)$$

having area at least $3/4$.

Thus we get that MAJ_3 is an *optimal* partition for partitioning $[N]^3$ into two parts.

7 Partitioning the 3-dimensional cube into three parts

In this section we study the case of partitioning the 3 dimensional cube $[0,1]^3$ into 3 parts.

We begin with a nice partition of $[0,1]^3$ into 3 parts so that each part has small 2-dimensional axis-parallel projections.

▶ **Definition 19** (Golden Ratio Partitioning Scheme). *Let u be the positive root of $x^2 + x = 1$. We define the function $GR_3 : [0,1]^3 \to \{0,1,2\}$ as*

$$GR_3(x,y,z) = \begin{cases} 0, & |x| > u, |y| > u \\ 1, & |x| \le u, |y| \le u, |z| \le \frac{1}{2} \\ 2, & \textit{otherwise.} \end{cases}$$

We refer to the partition into 3 parts naturally induced by the output of GR_3 on the input space $[0,1]^3$ i.e. $\{GR_3^{-1}(0), GR_3^{-1}(1), GR_3^{-1}(2)\}$, as the golden ratio partitioning scheme.

▶ **Lemma 20** (Golden Ratio Partitioning Bound). *Every 2-dimensional projection of every partition in the golden ratio partitioning scheme GR_3 on $[0,1]^3$ is of size $u \le 0.619$.*

We do not know if this is the optimal partition into 3 parts. For the rest of this section, we prove the best lower bound that we know. As in the previous section, we do this via an analogous discrete problem.

Let $\eta_0 \approx 0.5264$ be the real number $\in [0.5, 1.0]$ satisfying:

$$(2 - 3\eta_0) \cdot \left(2 - 2\sqrt{1 - \eta_0}\right) + (3\eta_0 - 1) = \frac{1}{6}(4 - \eta_0).$$

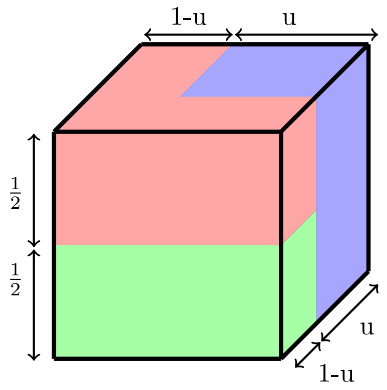

Figure 2 Golden Ratio Partitioning of the cube into 3 parts, where the partitioned sets are coloured in red, green and blue. The green and red parts are just translates of each other. Here u is the positive root of $x^2 + x = 1$.

▶ **Theorem 21.** *Let $A, B, C \subseteq [N]^3$ be a 3-partition of $[N]^3$. Then one of the nine 2-dimensional projections of A, B and C, i.e.,*
$\Pi_{XY}(A), \Pi_{XY}(B), \Pi_{XY}(C), \Pi_{YZ}(A), \Pi_{YZ}(B), \Pi_{YZ}(C), \Pi_{XZ}(A), \Pi_{XZ}(B), \Pi_{XZ}(C)$ *has size at least $\eta_0 N^2$.*

Proof of Theorem 21 can be found in the appendix.

This gives us a corresponding result about covers of $[0, 1]^3$ with 3 open sets.

▶ **Corollary 22.** *Any cover of $[0, 1]^3$ by three open sets A, B, C has one of the following 9 sets:*

$$\Pi_{XY}(A), \Pi_{YZ}(A), \Pi_{XZ}(A), \Pi_{XY}(B), \Pi_{YZ}(B), \Pi_{XZ}(B), \Pi_{XY}(C), \Pi_{YZ}(C), \Pi_{XZ}(C)$$

having area at least η_0.

A Appendix

▶ **Theorem 23** (Restatement of Theorem 17)**.** *Let $A, B \subseteq [N]^3$ be a partition. Then one of the six 2-dimensional projections of A and B*

$$\pi_{XY}(A), \pi_{YZ}(A), \pi_{XZ}(A), \pi_{XY}(B), \pi_{YZ}(B), \pi_{XZ}(B)$$

has size at least $\frac{3}{4}N^2$.

Proof. Suppose $\pi_{XY}(A)$ and $\pi_{XY}(B)$ are both at most $\frac{3}{4}N^2$.

Fix $z \in [N]$. Let us consider the slice $S_z = [N]^2 \times \{z\}$, and focus on the X and Y projections of the sets $A \cap S_z$ and $B \cap S_z$ (so four projections in all, each being a subset of $[N]$).

Define[3]:

$$A_{Xz} = \{x \mid \forall y \in [N], (x, y, z) \in A\}.$$

[3] If A, B was merely a cover of $[N]^3$ rather than a partition, the correct definition would be

$$A_{Xz} = \{x \mid \nexists y \in [N] \text{ s.t. } (x, y, z) \in B\},$$

etc, and the rest of the proof would remain the same.

$B_{Xz} = \{x \mid \forall y \in [N], (x,y,z) \in B\}$.

$A_{Yz} = \{y \mid \forall x \in [N], (x,y,z) \in A\}$.

$B_{Yz} = \{y \mid \forall x \in [N], (x,y,z) \in B\}$.

Let $\alpha_{Xz}, \beta_{Xz}, \alpha_{Yz}, \beta_{Yz} \in [0,1]$ be their fractional sizes (= size divided by N).
Then we have the following:

- $A_{Xz} \cap B_{Xz} = \emptyset$ and $A_{Yz} \cap B_{Yz} = \emptyset$. Thus:

$$\alpha_{Xz} + \beta_{Xz} \leq 1, \tag{2}$$
$$\alpha_{Yz} + \beta_{Yz} \leq 1. \tag{3}$$

- $((A_{Xz} \times [N]) \cup ([N] \times A_{Yz})) \subseteq \pi_{XY}(A)$.
This is because any $(x,y) \in (A_{Xz} \times [N])$ has $(x,y,z) \in A$, and thus $(x,y) \in \pi_{XY}(A)$.
The fractional size of the left hand side is $1 - (1-\alpha_{Xz})(1-\alpha_{Yz})$, and the fractional size of the right hand side is $\leq 3/4$.
This gives us (after applying the AM-GM inequality[4]):

$$\alpha_{Xz} + \alpha_{Yz} \leq 1. \tag{4}$$

- Similarly,

$$((B_{Xz} \times [N]) \cup ([N] \times B_{Yz})) \subseteq \pi_{XY}(B),$$

$$\beta_{Xz} + \beta_{Yz} \leq 1. \tag{5}$$

- At most one of A_{Xz}, B_{Yz} can be nonempty, and at most one of $A_{Yz}, B_{X,z}$ can be nonempty. This is because $x \in A_{Xz}$ and $y \in B_{Yz}$ imply that $(x,y,z) \in A$ and $(x,y,z) \in B$ respectively. Thus at most one of α_{Xz}, β_{Yz}, and at most one of α_{Yz}, β_{Xz} can be nonzero.

Putting everything together, we get that only two of the four numbers $\alpha_{Xz}, \beta_{Xz}, \alpha_{Yz}, \beta_{Yz}$ can be nonzero, and furthermore, the sum of those two is bounded above by 1.

Therefore, for each $z \in [N]$,

$$\alpha_{Xz} + \beta_{Xz} + \alpha_{Yz} + \beta_{Yz} \leq 1.$$

Averaging in z, we get that

$$\mathbf{E}_z[\alpha_{Xz} + \beta_{Xz} + \alpha_{Yz} + \beta_{Yz}] \leq 1,$$

and thus one of the four numbers:

$$\mathbf{E}_z[\alpha_{Xz}], \mathbf{E}_z[\beta_{Xz}], \mathbf{E}_z[\alpha_{Yz}], \mathbf{E}_z[\beta_{Yz}]$$

is at most 1/4.

Finally, observe that $(1 - \mathbf{E}_z[\alpha_{Xz}])$ is the fractional size of $\pi_{XZ}(B)$ (and similarly for the other three numbers), and so one of the four projections

$$\pi_{XZ}(B), \pi_{XZ}(A), \pi_{YZ}(B), \pi_{YZ}(A)$$

has size at least $\frac{3}{4}N^2$. ◀

[4] For any non-negative real numbers x and y, $\sqrt{x \cdot y} \leq \frac{x+y}{2}$

▶ **Theorem 24** (Restatement of Theorem 21). *Let $A, B, C \subseteq [N]^3$ be a 3-partition of $[N]^3$. Then one of the nine 2-dimensional projections of A, B and C, i.e.,*

$\Pi_{XY}(A), \Pi_{XY}(B), \Pi_{XY}(C), \Pi_{YZ}(A), \Pi_{YZ}(B), \Pi_{YZ}(C), \Pi_{XZ}(A), \Pi_{XZ}(B), \Pi_{XZ}(C)$ *has size at least* $\eta_0 N^2$.

Before embarking on the proof of Theorem 21, we note down a simple set intersection lemma that will be useful.

▶ **Lemma 25** (Set intersection inequality). *Suppose U, V, W be arbitrary sets which have union equal to T.*

Then

$$|U| + |V| + |W| \geq 2|T| - (|U \setminus (V \cup W)| + |V \setminus (W \cup U)| + |W \setminus (U \cup V)|) + |U \cap V \cap W|.$$

This lemma gives a way to get a lower bound on the average size of three sets U, V, W that cover a set T by first proving an upper bound on the sizes of the "unique" parts $U \setminus (V \cup W), V \setminus (U \cup W), W \setminus (U \cup V)$. The proof is simple and omitted.

We now prove Theorem 21.

Proof. Consider any partition A, B and C of $[N]^3$ into 3 parts. Suppose $\Pi_{XY}(A)$, $\Pi_{XY}(B)$ and $\Pi_{XY}(C)$ are at most η_0. (If not we are done).

Fix $z \in [N]$.

Our first step is to consider the slice $S_z = [N]^2 \times \{z\}$, and focus on the X and Y projections of the 3 sets $A \cap S_z, B \cap S_z, C \cap S_z$ (so six projections in all, each being a subset of $[N]$).

Define:

$$A_{Xz} = \{x \in [N] \mid \exists y \in [N] \text{ s.t. } (x, y, z) \in A\}.$$

$$B_{Xz} = \{x \in [N] \mid \exists y \in [N] \text{ s.t. } (x, y, z) \in B\}.$$

$$C_{Xz} = \{x \in [N] \mid \exists y \in [N] \text{ s.t. } (x, y, z) \in C\}.$$

$$A_{Yz} = \{y \in [N] \mid \exists x \in [N] \text{ s.t. } (x, y, z) \in A\}.$$

$$B_{Yz} = \{y \in [N] \mid \exists x \in [N] \text{ s.t. } (x, y, z) \in B\}.$$

$$C_{Yz} = \{y \in [N] \mid \exists x \in [N] \text{ s.t. } (x, y, z) \in C\}.$$

Note that:

$$A_{Xz} \cup B_{Xz} \cup C_{Xz} = [N]$$

$$A_{Yz} \cup B_{Yz} \cup C_{Yz} = [N]$$

since A, B, C is a partition of $[N]^3$.

Next we identify the "pure" parts of these projections, defined below:

$$\widetilde{A}_{Xz} = A_{Xz} \setminus (B_{Xz} \cup C_{Xz})$$

$$\widetilde{B}_{Xz} = B_{Xz} \setminus (C_{Xz} \cup A_{Xz})$$

$$\widetilde{C}_{Xz} = C_{Xz} \setminus (A_{Xz} \cup B_{Xz})$$

$$\widetilde{A}_{Yz} = A_{Yz} \setminus (B_{Yz} \cup C_{Yz})$$

$$\widetilde{B}_{Yz} = B_{Yz} \setminus (C_{Yz} \cup A_{Yz})$$

$$\widetilde{C}_{Yz} = C_{Yz} \setminus (A_{Yz} \cup B_{Yz})$$

Furthermore, we have:

$$\{x \mid \Pi^{-1}_{XZ}(x, z) \subseteq A\} \subseteq \widetilde{A}_{Xz}$$

and five similar containments for $\widetilde{B}_{Xz}, \widetilde{C}_{Xz}, \widetilde{A}_{Yz}, \widetilde{B}_{Yz}, \widetilde{C}_{Yz}$.

Let $\widetilde{\alpha}_{Xz}, \widetilde{\beta}_{Xz}, \widetilde{\gamma}_{Xz}, \widetilde{\alpha}_{Yz}, \widetilde{\beta}_{Yz}, \widetilde{\gamma}_{Yz} \in [0, 1]$ be their fractional sizes.

Note that since the corresponding sets are disjoint, we have:

$$\widetilde{\alpha}_{Xz} + \widetilde{\beta}_{Xz} + \widetilde{\gamma}_{Xz} \le 1 \tag{6}$$

$$\widetilde{\alpha}_{Yz} + \widetilde{\beta}_{Yz} + \widetilde{\gamma}_{Zz} \le 1 \tag{7}$$

▶ **Lemma 26.** *For any $z \in [N]$, out of the 6 variables $\widetilde{\alpha}_{Xz}, \widetilde{\beta}_{Xz}, \widetilde{\gamma}_{Xz}, \widetilde{\alpha}_{Yz}, \widetilde{\beta}_{Yz}, \widetilde{\gamma}_{Yz}$, let H be the set of those variables that are nonzero. Then H is a subset of at least one of the following sets of variables:*

$$\{\widetilde{\alpha}_{Xz}, \widetilde{\alpha}_{Yz}\}, \{\widetilde{\beta}_{Xz}, \widetilde{\beta}_{Yz}\}, \{\widetilde{\gamma}_{Xz}, \widetilde{\gamma}_{Yz}\}, \{\widetilde{\alpha}_{Xz}, \widetilde{\beta}_{Xz}, \widetilde{\gamma}_{Xz}\}, \{\widetilde{\alpha}_{Yz}, \widetilde{\beta}_{Yz}, \widetilde{\gamma}_{Yz}\}$$

Proof. It is a consequence of the easy observation that $\widetilde{\alpha}_{Xz}$ and $\widetilde{\beta}_{Yz}$ cannot both be nonzero (and 5 similar easy observations). ◀

Let

$$\delta_{Xz} = \begin{cases} 1 & \widetilde{\alpha}_{Yz}, \widetilde{\beta}_{Yz}, \widetilde{\gamma}_{Yz} > 0 \\ 0 & \text{otherwise} \end{cases}.$$

$$\delta_{Yz} = \begin{cases} 1 & \widetilde{\alpha}_{Xz}, \widetilde{\beta}_{Xz}, \widetilde{\gamma}_{Xz} > 0 \\ 0 & \text{otherwise} \end{cases}.$$

Note that δ_{Xz} depends on the projections in the Y direction (and vice versa). The reason for this definition is the following observation: if $\delta_{Xz} = 1$, then we have

$$A_{Xz} \cap B_{Xz} \cap C_{Xz} = A_{Xz} = B_{Xz} = C_{Xz} = [N], \tag{8}$$

and similarly, if $\delta_{Yz} = 1$, then we have

$$A_{Yz} \cap B_{Yz} \cap C_{Yz} = A_{Yz} = B_{Yz} = C_{Yz} = [N], \tag{9}$$

which is something that our set intersection lemma can exploit.

Define

$$\lambda_{Xz} = \widetilde{\alpha}_{Xz} + \widetilde{\beta}_{Xz} + \widetilde{\gamma}_{Xz} - \delta_{Xz},$$

$$\lambda_{Yz} = \widetilde{\alpha}_{Yz} + \widetilde{\beta}_{Yz} + \widetilde{\gamma}_{Yz} - \delta_{Yz}.$$

$$\lambda_z = \lambda_{Xz} + \lambda_{Yz}.$$

Note that by Equations (6), (7), for all z,

$$\lambda_{Xz} \le 1. \tag{10}$$

$$\lambda_{Yz} \le 1. \tag{11}$$

By the set intersection lemma,

$$|A_{Xz}| + |B_{Xz}| + |C_{Xz}| \geq 2N - \left(|\widetilde{A}_{Xz}| + |\widetilde{B}_{Xz}| + |\widetilde{C}_{Xz}|\right) + |A_{Xz} \cap B_{Xz} \cap C_{Xz}|$$
$$\geq (2 - \lambda_{Xz})N$$

Similarly,

$$|A_{Yz}| + |B_{Yz}| + |C_{Yz}| \geq (2 - \lambda_{Yz})N$$

Summing over $z \in [N]$ and adding these two equations, we get:

$$\Pi_{XZ}(A) + \Pi_{XZ}(B) + \Pi_{XZ}(C) \geq (2 - \mathbf{E}_z[\lambda_{Xz}])\, N^2, \tag{12}$$
$$\Pi_{YZ}(A) + \Pi_{YZ}(B) + \Pi_{YZ}(C) \geq (2 - \mathbf{E}_z[\lambda_{Yz}])\, N^2, \tag{13}$$
$$\Pi_{XZ}(A) + \Pi_{XZ}(B) + \Pi_{XZ}(C) + \Pi_{YZ}(A) + \Pi_{YZ}(B) + \Pi_{YZ}(C) \geq (4 - \mathbf{E}_z[\lambda_z])\, N^2. \tag{14}$$

Our goal is now to get an upper bound on $\mathbf{E}_z[\lambda_z]$.

To get our main result, we will show that $\mathbf{E}_z[\lambda_z] \leq \lambda^* := 4 - 6\eta_0 \approx 0.856$ (or else we find a large projection in some other way). This will show that one of the 6 projections on the left hand side is at least $\eta_0 N^2$, as desired.

If we just want to get a projection of size $\geq \frac{1}{2}N^2$, then it suffices to show that $\lambda^* \leq 1$, and this turns out to be simpler.

Towards that end, we define α_X to be the fraction of x for which $\{x\} \times [N] \subseteq \Pi_{XY}(A)$. Similarly define $\alpha_Y, \beta_X, \beta_Y, \gamma_X, \gamma_Y$.

Note that since $\widetilde{A}_{Xz} \times [N] \times \{z\} \subseteq A$, we have:

$$\alpha_{Xz} \leq \alpha_X,$$

and 5 similar inequalities.

Note that $\alpha_X \leq \eta$, and 5 similar inequalities.

Define $u : [0,1] \to [0,2]$ by:

$$u(a) = 2 - 2\sqrt{1-a}.$$

Using the argument used to arrive at Equation (4) (by the AM-GM inequality), we have

$$\widetilde{\alpha}_{Xz} + \widetilde{\alpha}_{Yz} \leq u(\eta_0) \qquad (\text{ and thus } \alpha_X + \alpha_Y \leq u(\eta_0)\ ).$$

and 2 similar pairs of inequalities.

Let $g_X = \max\{\alpha_X + \beta_X, \beta_X + \gamma_X, \alpha_X + \gamma_X\}$., similarly q_Y.

By the inequalities above, we have: $g_X + g_Y \leq 2\eta_0 + u(\eta_0)$.

Now let $q_X = \Pr_{z \in [n]}[\text{exactly two of } \alpha_{Xz}, \beta_{Xz}, \gamma_{Xz} \text{ are nonzero}]$, similarly define q_Y.

$$q = \Pr_{z \in [n]}[\text{at most one of } \alpha_{Xz}, \beta_{Xz}, \gamma_{Xz} \text{ and at most one of } \alpha_{Yz}, \beta_{Yz}, \gamma_{Yz} \text{ is nonzero}]$$

We are now in a position to state a key lemma which will prove our lower bound:

▶ **Lemma 27.**

$$\mathbf{E}_z[\lambda_z] \leq q \cdot u(\eta_0) + q_X \cdot \min(g_X, 1) + q_Y \cdot \min(g_Y, 1)).$$

Proof. Let $z \in [N]$. We take cases on which of the 6 numbers $\widetilde{\alpha}_{Xz}, \widetilde{\beta}_{Xz}, \widetilde{\gamma}_{Xz}, \widetilde{\alpha}_{Yz}, \widetilde{\beta}_{Yz}, \widetilde{\gamma}_{Yz}$ are nonzero. By Lemma 26, there only a few cases to consider.

- If the first three numbers are nonzero or the second three numbers are nonzero, then λ_z is nonpositive because the sum of those three is at most 1 (by Equations (6), (7), and $\delta_{Xz} = 1$ or $\delta_{Yz} = 1$.
- If exactly two of the first three numbers are nonzero, then λ_z is at most $\min(g_X, 1)$. This happens for q_X fraction of the z's.
- If exactly two of the second three numbers are nonzero, then λ_z is at most $\min(g_Y, 1)$. This happens for q_Y fraction of the z's
- If at most one of the first three numbers and at most one of the second three numbers is nonzero, then λ_z is at most $2 - 2\sqrt{1-\eta_0}$. This happens for q fraction of the z's. ◀

Now $q+q_X+q_Y \leq 1$. At this point, we already see that $\mathbf{E}_z[\lambda_z] \leq 1$ (since $u(\eta_0) \approx 0.6237 \leq 1$), and this gives us the result that some projection has size at least $\frac{1}{2}N^2$.

To get our improved bound of $\eta_0 N^2$, we need one more idea.

▶ **Lemma 28.** $q_X + \mathbf{E}_z[\lambda_{Yz}] \leq 1$ *and* $q_Y + \mathbf{E}_z[\lambda_{Xz}] \leq 1$

Proof. We prove the first inequality, the second being similar. q_X is the fraction of z for which exactly two of $\{\widetilde{\alpha}_{Xz}, \widetilde{\beta}_{Xz}, \widetilde{\gamma}_{Xz}\}$ are nonzero. For such a z, we have $\widetilde{\alpha}_{Yz} = \widetilde{\beta}_{Yz} = \widetilde{\gamma}_{Yz} = \delta_{Yz} = 0$, and thus $\lambda_{Yz} = 0$. Along with Equations (10), (11), this completes the proof. ◀

By Equation (12), if $\mathbf{E}_z[\lambda_{Xz}]$ is at most $2 - 3\eta_0$, then we get a projection onto the XZ plane of size at least $\eta_0 N^2$, and we are done. Similarly, by Equation (13), if $\mathbf{E}_z[\lambda_{Yz}]$ is at most $2 - 3\eta_0$, then we get a projection onto the YZ plane of size at least $\eta_0 N^2$, and we are done. Thus we may assume that both $\mathbf{E}_z[\lambda_{Xz}]$ and $\mathbf{E}_z[\lambda_{Yz}]$ are at least $2 - 3\eta_0$.

By the previous lemma, we thus get that $q_X, q_Y \leq 3\eta_0 - 1$. Summarizing everything we know: $g_X + g_Y \leq 2\eta_0 + u(\eta_0)$, $q_X, q_Y \leq 3\eta_0 - 1$. and $q + q_X + q_Y \leq 1$. Under these constraints, we claim that: $q \cdot u(\eta_0) + q_X \cdot \min(g_X, 1) + q_Y \cdot \min(g_Y, 1) \leq \lambda^*$. By inspection, we see that the LHS is maximized when:

$$g_X = 1, q_X = 3\eta_0 - 1, q = 1 - q_X = 2 - 3\eta_0,$$

which makes it evaluate to:

$$(2 - 3\eta_0) \cdot u(\eta_0) + (3\eta_0 - 1) = \frac{1}{6}(4 - \eta_0) = \lambda^*,$$

where the first equality is the defining equation of η_0, and the second equality is the definition of λ^*. This completes the proof. ◀

Rapid Mixing of Global Markov Chains via Spectral Independence: The Unbounded Degree Case

Antonio Blanca
Pennsylvania State University, University Park, PA, USA

Xusheng Zhang
Pennsylvania State University, University Park, PA, USA

Abstract

We consider spin systems on general n-vertex graphs of unbounded degree and explore the effects of spectral independence on the rate of convergence to equilibrium of global Markov chains. Spectral independence is a novel way of quantifying the decay of correlations in spin system models, which has significantly advanced the study of Markov chains for spin systems. We prove that whenever spectral independence holds, the popular Swendsen–Wang dynamics for the q-state ferromagnetic Potts model on graphs of maximum degree Δ, where Δ is allowed to grow with n, converges in $O((\Delta \log n)^c)$ steps where $c > 0$ is a constant independent of Δ and n. We also show a similar mixing time bound for the block dynamics of general spin systems, again assuming that spectral independence holds. Finally, for *monotone* spin systems such as the Ising model and the hardcore model on bipartite graphs, we show that spectral independence implies that the mixing time of the systematic scan dynamics is $O(\Delta^c \log n)$ for a constant $c > 0$ independent of Δ and n. Systematic scan dynamics are widely popular but are notoriously difficult to analyze. This result implies optimal $O(\log n)$ mixing time bounds for any systematic scan dynamics of the ferromagnetic Ising model on general graphs up to the tree uniqueness threshold. Our main technical contribution is an improved factorization of the entropy functional: this is the common starting point for all our proofs. Specifically, we establish the so-called k-partite factorization of entropy with a constant that depends polynomially on the maximum degree of the graph.

1 Introduction

Spectral independence is a powerful new approach for quantifying the decay of correlations in spin system models. Initially introduced in [4], this condition has revolutionized the study of Markov chains for spin systems. In a series of important and recent contributions, spectral independence has been shown to be instrumental in determining the convergence rate of the Glauber dynamics, the simple single-site update Markov chain that updates the spin at a randomly chosen vertex in each step.

The first efforts in this series (see [4, 24, 25]) showed that spectral independence implies optimal $O(n \log n)$ mixing of the Glauber dynamics on n-vertex graphs of bounded degree for general spin systems. The unbounded degree case was studied in [20, 19, 3, 44], while [6]

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

explored the effects of this condition on the speed of convergence of global Markov chains (i.e., Markov chains that update the spins of a large number of vertices in each step) in the bounded degree setting. Research exploring the applications of spectral independence is ongoing. We contribute to this line of work by investigating how spectral independence affects the speed of convergence of *global Markov chains* for general spin systems on graphs of unbounded degree.

A *spin system* is defined on a graph $G = (V, E)$. There is a set $\mathcal{S} = \{1, \dots, q\}$ of spins or colors, and configurations are assignments of spin values from $\mathcal{S}$ to each vertex of G. The probability of a configuration $\sigma \in \mathcal{S}^V$ is given by the Gibbs distribution:

$$\mu(\sigma) = \frac{e^{-H(\sigma)}}{Z}, \tag{1}$$

where the normalizing factor Z is known as the partition function, and the Hamiltonian $H : \mathcal{S}^V \to \mathbb{R}$ contains terms that depend on the spin values at each vertex (a "vertex potential" or "external field") and at each pair of adjacent vertices (an "edge potential"); see Definition 24. A widely studied spin system, and one that we will pay close attention to in this paper, is the ferromagnetic Potts model, where for a real parameter $\beta > 0$, associated with inverse temperature in physical applications, the Hamiltonian is given by:

$$H(\sigma) = -\beta \sum_{\{u,v\}\in E} \mathbb{1}(\sigma_u = \sigma_v).$$

The classical ferromagnetic Ising model corresponds to the $q = 2$ case. (In this variant of the Potts model, the Hamiltonian only includes edge potentials, and there is no external field.) We shall use μ_{Ising} and μ_{Potts} for the Gibbs distributions corresponding to the Ising and Potts models. Other well-known, well-studied spin systems include uniform proper colorings and the hardcore model.

Spin systems provide a robust framework for studying interacting systems of simple elements and have a wide range of applications in computer science, statistical physics, and other fields. In such applications, generating samples from the Gibbs distribution (1) is a fundamental computational task and one in which Markov chain-based algorithms have been quite successful. A long line of work dating back to the 1980s relates the speed of convergence of Markov chains to various forms of decay of correlations in the model. Spectral independence, defined next, captures the decay of correlations in a novel way.

Roughly speaking, spectral independence holds when the spectral norm of a "pairwise" influence matrix is bounded. To formally define it, let us begin by introducing some notations. Let $\Omega \subseteq \mathcal{S}^V$ be the support of μ: the set of configurations σ such that $\mu(\sigma) > 0$. A *pinning* τ on a subset of vertices $\Lambda \subseteq V$ is a fixed partial configuration on Λ; i.e., a spin assignment from $\mathcal{S}^\Lambda$ to the vertices of Λ. For a pinning τ on $\Lambda \subseteq V$ and $U \subseteq V \setminus \Lambda$, we let $\Omega_U^\tau = \{\sigma_U \in \mathcal{S}^U : \mu(\sigma_U \mid \sigma_\Lambda = \tau) > 0\}$ be the set of partial configurations on U that are consistent with the pinning τ. We write $\Omega_u^\tau = \Omega_{\{u\}}^\tau$ if u is a single vertex. Let

$$\mathcal{P}^\tau := \{(u, s) : u \notin \Lambda, s \in \Omega_u^\tau\}$$

denote the set of consistent vertex-spin pairs in $\Omega_{V\setminus\Lambda}^\tau$ under μ. For each $\Lambda \subseteq V$ and pinning τ on Λ, we define the *signed pairwise influence matrix* $\Psi_\mu^\tau \in \mathbb{R}^{\mathcal{P}^\tau \times \mathcal{P}^\tau}$ to be the matrix with entries:

$$\Psi_\mu^\tau((u, a), (v, b)) = \mu(\sigma_v = b \mid \sigma_u = a, \sigma_\Lambda = \tau) - \mu(\sigma_v = b \mid \sigma_\Lambda = \tau)$$

for $u \neq v$, and $\Psi_\mu^\tau((u, a), (u, b)) = 0$ otherwise.

▶ **Definition 1** (Spectral Independence). *A distribution μ satisfies η-*spectral independence *if for every subset of vertices $\Lambda \subseteq V$ and every pinning $\tau \in \Omega_\Lambda$, the largest eigenvalue of the signed pairwise influence matrix Ψ_μ^τ, denoted $\lambda_1(\Psi_\mu^\tau)$, satisfies $\lambda_1(\Psi_\mu^\tau) \leq \eta$.*

There are several definitions of spectral independence in the literature; we use here the one from [22].

We show that spectral independence implies new upper bounds on the mixing time of several well-studied global Markov chains in the case where the maximum degree Δ of the underlying graph $G = (V, E)$ is unbounded; i.e., $\Delta \to \infty$ with n. The mixing time is defined as the number of steps required for a Markov chain to reach a distribution close in total variation distance to its stationary distribution, assuming a worst possible starting state; a formal definition is given in Section 2. The global Markov chains we consider include the Swendsen–Wang dynamics for the ferromagnetic q-state Potts, the systematic scan dynamics for monotone spin systems, and the block dynamics for general spin systems. These three dynamics are among the most popular and well-studied global Markov chains and present certain advantages (e.g., faster convergence and amenability to parallelization) to the Glauber dynamics.

1.1 The Swendsen–Wang dynamics

A canonical example of a global Markov chain is the Swendsen–Wang (SW) dynamics for the ferromagnetic q-state Potts model. The SW dynamics transitions from a configuration σ_t to σ_{t+1} by:

1. For each edge $e = \{u, v\} \in E$, if $\sigma_t(u) = \sigma_t(v)$, independently include e in the set A_t with probability $p = 1 - e^{-\beta}$;
2. Then, independently for each connected component $\mathcal{C}$ in (V, A_t), draw a spin $s \in \{1, \dots, q\}$ uniformly at random and set $\sigma_{t+1}(v) = s$ for all $v \in \mathcal{C}$.

The SW dynamics is ergodic and reversible with respect to μ_{Potts} and thus converges to it. This Markov chain originated in the late 1980s [53] as an alternative to the Glauber dynamics, which mixes exponentially slowly at low temperatures (large β). The SW dynamics bypasses key barriers that cause the slowdown of the Glauber dynamics at low temperatures. For the Ising model ($q = 2$), for instance, it was recently shown to converge in poly(n) steps on any n-vertex graph for any value of $\beta > 0$ [39]. (The conjectured mixing time is $\Theta(n^{1/4})$, but we seem to be far from proving such a conjecture.) For $q \geq 3$, on the other hand, the SW dynamics can converge exponentially slowly at certain "intermediate" temperatures regimes corresponding to first-order phase transitions; see [38, 15, 36, 37, 26].

Recently, η-spectral independence (with $\eta = O(1)$) was shown to imply that the mixing time of the SW dynamics is $O(\log n)$ on graphs of maximum degree $\Delta = O(1)$, i.e., bounded degree graphs [6]. This mixing time bound is optimal since the SW dynamics requires $\Omega(\log n)$ steps to mix in some cases where η and Δ are both $O(1)$ [7, 9]. However, it does not extend to the unbounded degree setting since the constant factor hidden by the big-O notation depends exponentially on the maximum degree Δ; this is the case even when $\eta = O(1)$ and $\beta\Delta = O(1)$. Our first result provides a mixing time bound that depends only polynomially on Δ.

▶ **Theorem 2.** *Let $q \geq 2$, $\beta > 0$, $\eta > 0$ and $\Delta \geq 3$. Suppose $G = (V, E)$ is an n-vertex graph of maximum degree Δ. Let μ_{Potts} be the Gibbs distribution of the q-state ferromagnetic Potts model on G with parameter β. If μ_{Potts} is η-spectrally independent with $\eta = O(1)$ and $\beta\Delta = O(1)$, then there exists a constant $c > 0$ such that the mixing time of the SW dynamics satisfies $T_{mix}(P_{SW}) = O\big((\Delta \log n)^c\big)$.*

The constant c has a near linear dependency on η and $\beta\Delta$; a more precise statement of Theorem 2 with a precise expression for c is given in Theorem 11.

Despite the expectation that the SW dynamics mixes in $O(\log n)$ steps in weakly correlated systems (i.e., when $\beta\Delta$ is small), proving sub-linear upper bounds on its mixing time has been difficult. Recently, various forms of decay of correlation (e.g., strong spatial mixing, entropy mixing, and spectral independence) have been used to obtain $O(\log n)$ bounds for the mixing time of the SW dynamics on cubes of the integer lattice graph $\mathbb{Z}^d$, regular trees, and general graphs of bounded degree (see [7, 9, 6]). However, for graphs of large degree, i.e., with $\Delta \to \infty$ with n, the only sub-linear mixing time bounds known either hold for the very distinctive mean-field model, where G is the complete graph [35, 11], or hold for very small values of β; i.e., $\beta \lesssim 1/(3\Delta)$ [43]. Our results provide new sub-linear mixing time bounds for graph families of sub-linear maximum degree, provided $\eta = O(1)$ and $\beta\Delta = O(1)$. These last two conditions go hand-in-hand: in all known cases where $\eta = O(1)$, we also have $\beta\Delta = O(1)$.

On graphs of degree at most Δ, η-spectral independence is supposed to hold with $\eta = O(1)$ whenever $\beta < \beta_u(q,\Delta)$, where $\beta_u(q,\Delta)$ is the threshold for the uniqueness/non-uniqueness phase transition on Δ-regular trees. This has been confirmed for the Ising model ($q = 2$) but not for the Potts model. Specifically, for the ferromagnetic Ising model, we have $\beta_u(2,\Delta) = \ln \frac{\Delta}{\Delta-2}$, and when $\beta \le (1-\delta)\beta_u(2,\Delta)$ for some $\delta \in (0,1)$, μ_{Ising} is η-spectrally independent with $\eta = O(1/\delta)$; see [24, 25]. In contrast, for the ferromagnetic Potts model with $q \ge 3$, there is no closed-form expression for $\beta_u(q,\Delta)$ (it is defined as the threshold value where an equation starts to have a double root), and for graphs of unbounded degree η-spectral independence is only known to hold when $\beta \le \frac{2(1-\delta)}{\Delta}$. As a result, we obtain the following corollary of Theorem 2.

► **Corollary 3.** *Let $\delta \in (0,1)$, $\Delta \ge 3$. Suppose that either $q = 2$ and $\beta < (1-\delta)\beta_u(2,\Delta)$, or $q \ge 3$ and $\beta \le \frac{2(1-\delta)}{\Delta}$. Then, there exists a constant $c = c(\delta) > 0$ such that the mixing time of the SW dynamics for the q-state ferromagnetic Potts model on any n-vertex graph of maximum degree Δ satisfies $T_{mix}(P_{SW}) = O\big((\Delta \log n)^c\big)$.*

We mention that other conditions known to imply spectral independence (e.g., those in [14]) are not well-suited for the unbounded degree setting since under those conditions, the best known bound for η depends polynomially on Δ. For another application of Theorem 2, see Section 3.3.1 where we provide a bound on the mixing of the SW dynamics on random graphs.

We comment briefly on our proof approach for Theorem 2. A mixing time bound for the SW dynamics can be deduced from the so-called *edge-spin* factorization of the entropy functional introduced in [7]. It was noted there that this factorization, in turn, follows from a different factorization of entropy known as *k-partite factorization*, or KPF. Spectral independence is known to imply KPF but with a loss of a multiplicative constant that depends exponentially on the maximum degree of the graph. Our proof of Theorem 2 follows this existing framework, but pays closer attention to establishing KPF with an optimized constant with a better dependence on the model parameters. This is done through a multi-scale analysis of the entropy functional; in each scale, we apply spectral independence to achieve a tighter KPF condition. Our new results for KPF not only hold for the Potts model, but also for a general class of spin systems, and we use it to establish new mixing time bounds for the systematic scan dynamics and block dynamics.

1.2 The systematic scan dynamics

Our next contribution pertains the *systematic scan dynamics*, which is a family of Markov chains closely related to the Glauber dynamics in the sense that updates occur at single vertices sequentially. The key difference is that the vertex updates happen according to a predetermined ordering ϕ of the vertices instead of at random vertices. These dynamics offer practical advantages since there is no need to randomly select vertices at each step, thereby reducing computation time.

There is a folklore belief that the mixing time of the systematic scan dynamics (properly scaled) is closely related to that of the Glauber dynamics. However, analyzing this type of dynamics has proven very challenging (see, e.g., [28, 41, 30, 29, 49, 40, 8]), and the best general condition under which the systematic scan dynamics is known to be optimally mixing is a Dobrushin-type condition due to Dyer, Goldberg, and Jerrum [30]. The new developments on Markov chain mixing stemming from spectral independence have not yet provided new results for this dynamics, even for the bounded degree case where much progress has already been made. We show that spectral independence implies optimal mixing of the systematic scan dynamics for *monotone* spin systems with *bounded marginals*; we define both of these notions next.

▶ **Definition 4** (Monotone spin system). *In a monotone system, there is a linear ordering of the spins at each vertex which induces a partial order $\preceq_q$ over the state space. A spin system is* monotone *with respect to the partial order $\preceq_q$ if for every $\Lambda \subseteq V$ and every pair of pinnings $\tau_1 \succeq_q \tau_2$ on $V \setminus \Lambda$, the conditional distribution $\mu(\cdot \mid \sigma_\Lambda = \tau_1)$ stochastically dominates $\mu(\cdot \mid \sigma_\Lambda = \tau_2)$.*

Canonical examples of monotone spin systems include the ferromagnetic Ising model and the hardcore model on bipartite graphs. As in earlier work (see [24, 25, 6]), our bounds on the mixing time will depend on a lower bound on the marginal probability of any vertex-spin pair. This is formalized as follows.

▶ **Definition 5** (Bounded marginals). *The distribution μ is said to be b-*marginally bounded *if for every $\Lambda \subseteq V$ and pinning $\tau \in \Omega_\Lambda$, and each $(v, s) \in \mathcal{P}^\tau$, we have $\mu(\sigma_v = s \mid \sigma_\Lambda = \tau) \geq b$.*

Before stating our result for the systematic scan dynamics of b-marginally bounded monotone spin systems, we note that this Markov chain updates in a single step each vertex once in the order prescribed by ϕ. Under a minimal assumption on the spin system (the same one required to ensure the ergodicity of the Glauber dynamics), the systematic scan dynamics is ergodic. Specifically, when the spin system is totally-connected (see Definition 25), the systematic scan dynamics is ergodic. Moreover, the systematic scan dynamics is not necessarily reversible with respect to μ, so, as in earlier works, we work with the symmetrized version of the dynamics in which, in each step, the vertices are updated according to ϕ first, and subsequently in the reverse order of ϕ. The resulting dynamics, which we denote by P_ϕ, is reversible with respect to μ. Our main result for the systematic scan dynamics is the following.

▶ **Theorem 6.** *Let $b > 0$, $\eta > 0$, and $\Delta \geq 3$. Suppose $G = (V, E)$ is an n-vertex graph of maximum degree Δ. Let μ be the distribution of a totally-connected monotone spin system on G. If μ is η-spectrally independent and b-marginally bounded, then for any ordering ϕ,*

$$T_{mix}(P_\phi) = \left(\frac{e^2\Delta}{b}\right)^{9+4\lceil \frac{2\eta}{b} \rceil} \cdot O(\log n).$$

The bound in this theorem is tight: for a particular ordering ϕ, we prove an $\Omega(\log n)$ mixing time lower bound that applies to settings where Δ, b and η are all $\Theta(1)$; see Lemma 26.

We present next several interesting consequences of Theorem 6. First, we obtain the following corollary using the known results about spectral independence for the ferromagnetic Ising model.

▶ **Corollary 7.** *Let $\delta \in (0,1), \Delta \geq 3$ and $0 < \beta < (1-\delta)\beta_u(2,\Delta)$. Suppose $G = (V,E)$ is an n-vertex graph of maximum degree Δ. For any ordering ϕ of the vertices of G, the mixing time of P_ϕ for the Ising model on G with parameter β satisfies $T_{mix}(P_\phi) = O(\log n)$.*

The constant hidden by the big-O notation is an absolute constant that depends only on the constant δ, even when Δ depends on n. This result, compared to the earlier conditions in [28, 41, 30], extends the parameter regime where the $O(\log n)$ mixing time bound applies; in fact, the parameter regime in Corollary 7 is tight, as the systematic scan dynamics undergoes an exponential slowdown when $\beta > \beta_u(2,\Delta)$ [49]. We also derive analogous results for the hardcore model on bipartite graphs; see Section 4.1.

Our next application concerns the specific but relevant case where the underlying graph is an n-vertex cube of the integer lattice graph $\mathbb{Z}^d$. In this context, it was proved in [8] that all systematic scan dynamics converge in $O(\log n(\log\log n)^2)$ steps whenever a well-known condition known as *strong spatial mixing (SSM)* holds. A pertinent open question is whether SSM implies spectral independence. In fact, spectral independence is often proved by adapting earlier arguments for establishing SSM (see, e.g., [4, 24]). Recently, it was proved in [23] that SSM on trees implies spectral independence on large-girth graphs. We show that for *general* spin systems on $\mathbb{Z}^d$, SSM implies η-spectral independence with $\eta = O(1)$.

▶ **Lemma 8.** *For a spin system on a d-dimensional cube $V \subseteq \mathbb{Z}^d$, SSM implies η-spectral independence, where $\eta = O(1)$.*

The formal definition of SSM is given later in Section 4. Lemma 8 does not assume monotonicity for the spin system and could be of independent interest. An interesting consequence of this lemma, when combined with Theorem 6 is the following.

▶ **Corollary 9.** *Let $d \geq 2$. For a b-marginally bounded monotone spin system on a d-dimensional cube $V \subseteq \mathbb{Z}^d$, SSM implies that the mixing time of any systematic scan P_ϕ is $O(\log n)$.*

For the ferromagnetic Ising model on $\mathbb{Z}^2$, SSM is known to hold for all $\beta < \beta_c(2) = \ln(1+\sqrt{2})$ (see [17, 45, 2, 5]), so by Corollary 9 we deduce that when $\beta < \beta_c(2)$, the mixing time of any systematic scan P_ϕ on an n-vertex square box of $\mathbb{Z}^2$ is $O(\log n)$; note that $\beta_c(2) > \beta_u(2,2d)$, the corresponding tree uniqueness threshold.

We comment briefly on the techniques used to establish our results for the systematic scan dynamics. Our starting point is again the k-partite factorization of entropy (KPF). Our improved bounds for KPF imply that a global Markov chain that updates a random independent set of vertices in each step is rapidly mixing. We then use the censoring technique from [34, 10] to relate the mixing time of this Markov chain to that of the systematic scan dynamics. To establish Lemma 8, we use SSM to construct a contractive coupling for a particular Markov chain. Our Markov chain is similar to the one from [31], but modified to update rectangles instead of balls, and thus match the variant of SSM that holds up to the critical threshold for the Ising model on $\mathbb{Z}^2$. This contractive coupling is then used to establish spectral independence using the machinery from [6].

1.3 The block dynamics

Our final result concerns a family of Markov chains known as the *block dynamics*. They are a natural generalization of the Glauber dynamics where a random subset of vertices (instead of a random vertex) is updated in each step. More precisely, let $\mathcal{B} := \{B_1, \dots, B_K\}$ be a collection of subsets of vertices (called blocks) such that $V = \cup_{i=1}^K B_i$. Let α be a distribution over $\mathcal{B}$. The *(heat-bath) block dynamics* with respect to $(\mathcal{B}, \alpha)$ is the Markov chain that, in each step, given a spin configuration σ_t, selects $B_i \in \mathcal{B}$ according to the distribution α and updates the configuration on B_i with a sample from the $\mu(\cdot \mid \sigma_t(V \setminus B_i))$; that is, from the conditional distribution on B_i given the spins of σ_t in $V \setminus B_i$. We denote this Markov chain (and its transition matrix) by $P_{\mathcal{B},\alpha}$. When the B_i's are each single vertices, and α is a uniform distribution over the blocks in $\mathcal{B}$, we obtain the Glauber dynamics. Our result for the mixing time of the block dynamics is the following.

▶ **Theorem 10.** *Let $b > 0$, $\eta > 0$ and $\Delta \geq 3$. Suppose $G = (V, E)$ is an n-vertex graph of maximum degree Δ. Let μ be a Gibbs distribution of a totally-connected spin system on G. Let $\mathcal{B} := \{B_1, \dots, B_K\}$ be any collection of blocks such that $V = \cup_{i=1}^K B_i$, and let α be a distribution over $\mathcal{B}$. If μ is η-spectrally independent and b-marginally bounded, then there exists a constant $C > 0$ such that the mixing time of block dynamics $P_{\mathcal{B},\alpha}$ satisfies:*

$$T_{mix}(P_{\mathcal{B},\alpha}) = O\Big(\alpha_{min}^{-1} \cdot \Big(\frac{C\Delta \log n \log\log n}{b^7}\Big)^{2+\lceil \frac{2\eta}{b} \rceil}\Big),$$

where $\alpha_{min} = \min_{v \in V} \sum_{B \in \mathcal{B}} \alpha_B$.

Previous results for the block dynamics only apply to the bounded degree case [9, 17, 6], so Theorem 10 provides the first bounds for its mixing time in the unbounded degree setting.

Organization. The rest of the paper is organized as follows. In Section 2, we provide a number of definitions and background results. In Sections 3 and 4, we provide proof sketches for our results for the SW dynamics and the systematic scan dynamics; that is, Theorems 2 and 6, respectively. Some of our proofs are deferred to the full version of the paper [12].

2 Mixing times and modified log-Sobolev inequalities

Let P be an irreducible and aperiodic (i.e., ergodic) Markov chain with state space Ω and stationary distribution μ. Let us assume that P is reversible with respect to μ, and let

$$d(t) := \max_{x \in \Omega} \|P^t(x, \cdot) - \mu\|_{TV} := \max_{x \in \Omega} \max_{A \subseteq \Omega} |P^t(x, A) - \mu(A)|,$$

where $P^t(x, \cdot)$ denotes the distribution of the chain at time t assuming $x \in \Omega$ as the starting state; $\|\cdot\|_{TV}$ denotes the total variation distance. Note that with a slight abuse of notation we use P for both the Markov chain and its transition matrix. For $\varepsilon > 0$, let

$$T_{mix}(P, \varepsilon) := \min\{t > 0 : d(t) \leq \varepsilon\},$$

and the *mixing time of* P is defined as $T_{mix}(P) = T_{mix}(P, 1/4)$.

For functions $f, g : \Omega \to \mathbb{R}$, the *Dirichlet form* of a reversible Markov chain P with stationary distribution μ is defined as

$$\mathcal{E}_P(f, g) = \langle f, (I - P)g \rangle_\mu = \frac{1}{2} \sum_{x, y \in \Omega} \mu(x)P(x, y)(f(x) - f(y))(g(x) - g(y)),$$

where $\langle f, g \rangle_\mu := \sum_{x \in \Omega} f(x)g(x)\mu(x)$.

The spectrum of the ergodic and reversible Markov chain P is real, and we let $1 = \lambda_1 > \lambda_2 \geq \cdots \geq \lambda_{|\Omega|} \geq -1$ denote its eigenvalues. The (absolute) spectral gap of P is defined by $\mathrm{GAP}(P) = 1 - \max\{|\lambda_2|, |\lambda_{|\Omega|}|\}$. When P is positive semidefinite, we have

$$\mathrm{GAP}(P) = 1 - \lambda_2 = \inf\left\{\frac{\mathcal{E}_P(f,f)}{\langle f,f\rangle_\mu} \mid f : \Omega \to \mathbb{R}, \langle f,f\rangle_\mu \neq 0\right\}.$$

For P reversible and ergodic, we have the following standard comparison between the spectral gap and the mixing time

$$T_{mix}(P,\varepsilon) = \frac{1}{\mathrm{GAP}(P)} \cdot \log\big(\frac{1}{\varepsilon\mu_{min}}\big), \tag{2}$$

where $\mu_{min} := \min_{x\in\Omega} \mu(x)$.

The expected value of a function $f : \Omega \to \mathbb{R}_{\geq 0}$ with respect to μ is defined as $\mathrm{E}_\mu[f] = \sum_{x\in\Omega} f(x)\mu(x)$. Similarly, the entropy of the function with respect to μ is given by

$$\mathrm{Ent}_\mu(f) := \mathrm{E}_\mu\Big[f \log \frac{f}{\mathrm{E}_\mu[f]}\Big] = \mathrm{E}_\mu[f \log f] - \mathrm{E}_\mu[f \log(\mathrm{E}_\mu[f])].$$

We say that the Markov chain P satisfies a *modified log-Sobolev inequality* (MLSI) with constant ρ if for every function $f : \Omega \to \mathbb{R}_{\geq 0}$,

$$\rho \cdot \mathrm{Ent}_\mu(f) \leq \mathcal{E}_P(f, \log f).$$

The smallest ρ satisfying the inequality above is called the *modified log-Sobolev constant* of P and is denoted by $\rho(P)$. A well-known general relationship (see [27, 13]) shows that

$$\frac{1 - 2\mu_{min}}{\log(1/\mu_{min} - 1)}\mathrm{GAP}(P) \leq \rho(P) \leq 2\mathrm{GAP}(P). \tag{3}$$

For distributions μ and ν over Ω, the relative entropy of ν with respect to μ, denoted as $\mathcal{H}(\nu \mid \mu)$, is defined as $\mathcal{H}(\nu \mid \mu) := \sum_{x\in\Omega} \nu(x) \log \frac{\nu(x)}{\mu(x)}$. A Markov chain P with stationary distribution μ is said to satisfy discrete *relative entropy decay* with rate $r > 0$ if for all distributions ν:

$$\mathcal{H}(\nu P \mid \mu) \leq (1 - r)\mathcal{H}(\nu \mid \mu). \tag{4}$$

It is a standard fact (see, e.g., Lemma 2.4 in [7]) that when (4) holds, then $\rho(P) \geq r$, and

$$T_{mix}(P,\varepsilon) \leq \frac{1}{r} \cdot \Big(\log\log\big(\frac{1}{\mu_{min}}\big) + \log\big(\frac{1}{2\varepsilon}\big)\Big). \tag{5}$$

3 Swendsen-Wang dynamics on general graphs

In this section, we consider the SW dynamics for the q-state ferromagnetic Potts models on general graphs. In particular, we establish Theorem 2 from the introduction, which is a direct corollary of the following more general result.

▶ **Theorem 11.** *Let $q \geq 2$, $\beta > 0$, $\eta > 0$, $b > 0$, $\Delta \geq 3$, and $\chi \geq 2$. Suppose $G = (V,E)$ is an n-vertex graph of maximum degree Δ and chromatic number χ. Let μ_{Potts} be the Gibbs distribution of the q-state ferromagnetic Potts model on G with parameter β. If μ_{Potts} is η-spectrally independent and b-marginally bounded, then there exists a universal constant $C > 1$ such that the modified log-Sobolev constant of the SW dynamics satisfies:*

$$\rho(P_{SW}) = \Omega\left(\frac{b^{7+6\kappa}}{\chi\cdot(C\Delta\log n)^{\kappa}\cdot(\log\log n)^{\kappa+1}}\right),$$

where $\kappa = 1 + \lceil\frac{2\eta}{b}\rceil$, *and*

$$T_{mix}(P_{SW}) = O\big(b^{-(7+6\kappa)}\cdot\chi\cdot(C\Delta\log n)^{\kappa}(\log\log n)^{\kappa+1}\cdot\log n\big).$$

Theorem 2 follows from this theorem by noting that $\chi\leq\Delta$ and that under the assumptions $\eta = O(1)$ and $\beta\Delta = O(1)$, we have $b = O(1)$ and $\kappa = O(1)$.

▶ Remark 12. When Δ is small, i.e., $\Delta = o(\log n)$, we can obtain slightly better bounds on $\rho(P_{SW})$ and $T_{mix}(P_{SW})$ and replace the $(C\Delta\log n\cdot\log\log n)^{\kappa}$ factor by a factor of $(C\Delta)^{6+4\lceil\frac{2\eta}{b}\rceil}$. This result is included in the full version of this paper [12].

Before proving Theorem 11, we provide a number of definitions and required background results in Section 3.1. We then sketch the proof of Theorem 11 in Sections 3.2 and include some applications of this result in Section 3.3.

3.1 Factorization of entropy

We present next several factorizations of the entropy functional $\mathrm{Ent}_{\mu}(f)$, which are instrumental in establishing the decay of the relative entropy for the SW dynamics. We introduce some useful notations first. For a pinning τ in $V\setminus\Lambda$ (i.e., $\tau\in\Omega_{V\setminus\Lambda}$), we let $\mu^{\tau}_{\Lambda}(\cdot) := \mu(\cdot\mid\sigma_{V\setminus\Lambda}=\tau)$. Given a function $f:\Omega\to\mathbb{R}_{\geq 0}$, subsets of vertices $B\subseteq\Lambda\subset V$, and $\tau\in\Omega_{V\setminus\Lambda}$, the function $f^{\tau}_{B}:\Omega^{\tau}_{B}\to\mathbb{R}_{\geq 0}$ is defined by:

$$f^{\tau}_{B}(\sigma) = \mathrm{E}_{\xi\sim\mu^{\tau}_{\Lambda\setminus B}}[f(\tau\cup\xi\cup\sigma)].$$

If $B=\Lambda$, we often write f^{τ} for f^{τ}_{B}, and if $\tau=\emptyset$, then we use f_B for f^{τ}_{B}. We use $\mathrm{Ent}^{\tau}_{B}(f^{\tau})$ to denote $\mathrm{Ent}_{\mu^{\tau}_{B}}(f^{\tau})$, and if the pinning τ on $V\setminus B$ is from a distribution π over $\Omega_{V\setminus B}$, we use $\mathrm{E}_{\tau\sim\pi}[\mathrm{Ent}^{\tau}_{B}(f^{\tau})]$ to denote the expected value of the function f on S over the random pinning τ.

Various forms of entropy factorization arise from bounding $\mathrm{Ent}_{\mu}(f)$ by different (weighted) sums of restricted entropies of the function f. The first one we introduced, is the so-called *ℓ-uniform block factorization of entropy* of *ℓ-UBF*. For an integer $\ell\leq n$, ℓ-UBF holds for μ with constant C_{UBF} if for all functions $f:\Omega\to\mathbb{R}_{\geq 0}$,

$$\frac{\ell}{n}\cdot\mathrm{Ent}_{\mu}(f)\leq C_{\mathrm{UBF}}\cdot\frac{1}{\binom{n}{\ell}}\sum_{S\in\binom{V}{\ell}}\mathrm{E}_{\tau\sim\mu_{V\setminus S}}\left[\mathrm{Ent}^{\tau}_{S}(f^{\tau})\right], \tag{6}$$

where $\binom{V}{\ell}$ denotes the collection of all subsets of V of size ℓ. An important special case is when $\ell=1$, in which case (6) is called *approximate tensorization of entropy (AT)*; this special case has been quite useful for establishing optimal mixing time bounds for the Glauber dynamics in various settings (see, e.g., [47, 16, 18, 46]). The following result will be useful for us.

▶ **Theorem 13** ([25, 6]). *Let b and η be fixed. For $\theta\in(0,1)$ and $n\geq\frac{2}{\theta}(\frac{4\eta}{b^2}+1)$, the following holds. If the Gibbs distribution μ of a spin system on an n-vertex graph is η-spectrally independent and b-marginally bounded, then $\lceil\theta n\rceil$-UBF holds with $C_{\mathrm{UBF}} = (e/\theta)^{\lceil\frac{2\eta}{b}\rceil}$. In addition, if $\theta < b^2/(12\Delta)$, then:*

$$\mathrm{Ent}_{\mu}(f)\leq C_{\mathrm{UBF}}\cdot\frac{18}{b^5\theta}\sum_{i=1}^{n}\mathrm{E}_{\tau\sim\mu_{V\setminus\{i\}}}\left[\mathrm{Ent}^{\tau}_{i}(f^{\tau})\right].$$

Note that the inequality in the theorem corresponds to AT with constant $C_{\mathrm{AT}} = C_{\mathrm{UBF}} \cdot \frac{18}{b^5\theta}$.

Another useful notion is *k-partite factorization of entropy* or KPF. Let $U_1, \dots, U_k$ be k disjoint independent sets of V such that $\bigcup_{i=1}^k U_i = V$. We say μ satisfies KPF with constant C_{KPF} if for all functions $f : \Omega \to \mathbb{R}_{\geq 0}$,

$$\mathrm{Ent}_\mu(f) \leq C_{\mathrm{KPF}} \sum_{i=1}^{k} \mathrm{E}_{\tau \sim \mu_{V \setminus U_i}} \left[\mathrm{Ent}_{U_i}^{\tau}(f^\tau)\right].$$

KPF was introduced in [6], where it was used to analyze global Markov chains. The interplay between KPF and UBF is intriguing and is further explored in this paper.

3.2 Proof of main result for the SW dynamics: Theorem 11

The main technical contribution in the proof of Theorem 11 is establishing KPF with a better (i.e., smaller) constant C_{KPF}. As in [6], KPF is then used to derive an improved "edge-spin" factorization of entropy which is known to imply the desired bounds on the modified log-Sobolev constant and on the mixing time of the SW dynamics.

▶ **Theorem 14.** *For a b-marginally bounded Gibbs distribution μ that satisfies η-spectral independence on an n-vertex graph $G = (V, E)$ of maximum degree Δ, if b and η are constants independent of Δ and n, and $\Delta \in [3, \frac{b^4 n}{10e(4\eta+b^2)}]$, then there exists an absolute constant $c > 0$ such that k-partite factorization of entropy holds for μ with constant $C_{\mathrm{KPF}} = (\Delta \log n)^c$. Specifically, for a set of k disjoint independent sets $V_1, \dots, V_k$ such that $\bigcup_{j=1}^k V_j = V$,*

$$\mathrm{Ent}_\mu(f) \leq 54 \cdot \frac{e^{13\kappa}}{b^{5+6\kappa}} \cdot (\Delta \log n)^{\kappa} \cdot (\log\log n)^{1+\kappa} \sum_{j=1}^{k} \mathrm{E}_{\tau \sim \mu_{V \setminus V_j}} [\mathrm{Ent}_{V_j}^{\tau}(f^\tau)], \tag{7}$$

where $\kappa = 1 + \lceil \frac{2\eta}{b} \rceil$. Moreover, if $\Delta^2 \leq \frac{b^4 n}{10e(4\eta+b^2)}$, then the following also holds

$$\mathrm{Ent}_\mu(f) \leq 72 \cdot \frac{e^{8\kappa}}{b^{5+4\kappa}} \cdot \Delta^{2+4\kappa} \sum_{j=1}^{k} \mathrm{E}_{\tau \sim \mu_{V \setminus V_j}} [\mathrm{Ent}_{V_j}^{\tau}(f^\tau)]. \tag{8}$$

This Theorem is proved in the full version [12].

▶ Remark 15. Let $\mathcal{B} = \{B_1, \dots, B_k\}$ be a collection of disjoint independent sets such that $V = \bigcup_{i=1}^k B_i$. The independent set dynamics $P_{\mathcal{B}}$ is a heat-bath block dynamics w.r.t. $\mathcal{B}$ and a uniform distribution over $\mathcal{B}$. If μ satisfies k-partite factorization of entropy with C_{KPF}, then $P_{\mathcal{B}}$ satisfies a relative entropy decay with rate $r \geq 1/(k \cdot C_{\mathrm{KPF}})$.

As mentioned, KPF was first studied in [6]; the constant proved there was

$$C_{\mathrm{KPF}} = b^{O(\Delta)} \cdot (b\Delta)^{O(\eta/b)},$$

so our new bound improves the dependence on Δ from exponential to polynomial.

With KPF on hand, the next step in the proof of Theorem 11 relies on the so-called edge-spin factorization of entropy. Let $\Omega_J := \Omega \times \{0,1\}^E$ be the set of joint configurations (σ, A) corresponding to pairs of a spin configuration $\sigma \in \Omega$ and an *edge configuration* (a subset of edges in a graph) $A \subseteq E$. For a q-state Potts model μ_{Potts} with parameter $p = 1 - e^{-\beta}$, we use ν to denote the *Edwards-Sokal* measure on Ω_J given by

$$\nu(\sigma, A) := \frac{1}{Z_J}(1-p)^{|E|-|A|} p^{|A|} \mathbf{1}(\sigma \sim A),$$

where $\sigma \sim A$ is the event that every edge in A has its two endpoints with the same spin in σ, and $Z_J := \sum_{(A,\sigma)\in\Omega_J}(1-p)^{|E|-|A|}p^{|A|}\mathbf{1}(\sigma \sim A)$ is a normalizing constant. Let $\nu(\cdot \mid \sigma)$ and $\nu(\cdot \mid A)$ denote the conditional measures obtained from ν by fixing the spin configuration to be σ or fixing the edge configuration to be A respectively. For a function $f : \Omega_J \to \mathbb{R}_{\geq 0}$, let $f^\sigma : \{0,1\}^{|E|} \to \mathbb{R}_{\geq 0}$ be the function given by $f^\sigma(A) = f(\sigma \cup A)$, and let $f^A : \Omega \to \mathbb{R}_{\geq 0}$ be the function given by $f^A(\sigma) = f(\sigma \cup A)$. We say that *edge-spin factorization of entropy* holds with constant C_{ES} if for all functions $f : \Omega_J \to \mathbb{R}_{\geq 0}$,

$$\mathrm{Ent}_\nu(f) \leq C_{\mathrm{ES}}\left(\mathrm{E}_{(\sigma,A)\sim\nu}\left[\mathrm{Ent}_{A\sim\nu(\cdot|\sigma)}(f^\sigma)\right] + \mathrm{E}_{(\sigma,A)\sim\nu}\left[\mathrm{Ent}_{\sigma\sim\nu(\cdot|A)}(f^A)\right]\right). \tag{9}$$

The following result from [6] will be useful for us.

▶ **Lemma 16** (Theorem 6.1 [6]). *Suppose the q-state ferromagnetic Potts model with parameter β on a graph G of maximum degree is $\Delta \geq 3$ satisfies KPF with constant C_{KPF}. Then, the edge-spin factorization of entropy holds with constant $C_{\mathrm{ES}} = O(\beta\Delta k e^{\beta\Delta}) \cdot C_{\mathrm{KPF}}$.*

The final ingredient in the proof of Theorem 11 is the following.

▶ **Lemma 17** (Lemma 1.8 [7]). *Suppose edge-spin factorization of entropy holds with constant C_{ES}. Then, the SW dynamics P_{SW} satisfies the relative entropy decay with rate $\Omega\left(\frac{1}{C_{\mathrm{ES}}}\right)$.*

We are now ready to prove Theorem 11. Since Theorem 14 requires an upper bound on the maximum degree Δ, when $\Delta = \Omega(n)$ we use a crude comparison argument to obtain a polynomial bound for the modified log-Sobolev constant and mixing time of the SW dynamics.

Proof of Theorem 11. First, we assume $\Delta \in [3, \frac{b^4 n}{10e(4\eta+b^2)}]$. By Theorem 14, μ_{Potts} satisfies χ-partite factorization of entropy with constant

$$C_{\mathrm{KPF}} = (\Delta \log n)^\kappa (\log\log n)^{1+\kappa} \cdot O\left(\frac{e^{13\kappa}}{b^{5+6\kappa}}\right).$$

It follows from Lemma 16 and Lemma 17 that the SW dynamics satisfies (4) with

$$r = \Omega\left(\frac{b^{5+6\kappa}}{\chi\beta\Delta e^{\beta\Delta}\cdot(\Delta\log n)^\kappa(\log\log n)^{1+\kappa}\cdot e^{13\kappa}}\right).$$

Note that $b \leq q^{-1}e^{-\beta\Delta}$, and so $\beta\Delta e^{\beta\Delta} \leq e^{2\beta\Delta} \leq b^{-2}$. Therefore, the mixing time bound follows from (5).

Next, let us consider the case when $\Delta = \Omega(n)$. In this case, it suffices to provide a $1/\mathrm{poly}(n)$ lower bound on the modified log-Sobolev constant of the SW dynamics, which can be obtained in a straightforward manner using the known bounds for the Potts Glauber dynamics and the comparison technology from [8].

Recall that $P_{\mathcal{B}}$ is the independent set dynamics; that is, the block dynamics with respect to a collection of disjoint independent sets $\{B_1, \ldots, B_k\}$; see Remark 15. From Theorem 3.2 in [32], we know that $\mathrm{GAP}(P_{GD}) \geq n^{-(2\eta+1)}$, where P_{GD} denotes the Potts Glauber dynamics. Since $\mathcal{E}_{P_{GD}}(f,f) \leq \mathcal{E}_{P_{\mathcal{B}}}(f,f)$ for any function f, it follows that $\mathrm{GAP}(P_{\mathcal{B}}) \geq n^{-(2\eta+1)}$. In addition, the comparison inequalities from [8] imply that

$$\mathrm{GAP}(P_{SW}) \geq \mathrm{GAP}(P_{\mathcal{B}}) \cdot \min_{i=1,\ldots,k}\ \min_{\tau\in\Omega_{V\setminus B_i}}\ \min_{v\in B_i} \mathrm{GAP}(P_v^\tau),$$

where P_v^τ is the transition matrix for the update at vertex v, with τ as the fixed boundary condition, that adds each monochromatic edge between v and its neighbors independently with probability $p := 1 - e^{-\beta}$, and assigns a new random spin to v only if no edge is added. From a simple coupling argument it follows that for any $v \in B_i$, $\mathrm{GAP}(P_v^\tau) \geq (1-p)^\Delta = e^{-\beta\Delta} \geq qb$. Thus, $\mathrm{GAP}(P_{SW}) \geq n^{-(2\eta+1)}qb$, and $\rho(P_{SW}) = \Omega(n^{-(2\eta+2)}b)$ by (3). The mixing time bound follows from (2). ◀

3.3 Applications of Theorem 11

In this section, we prove Corollary 3 from the introduction and present another application of Theorem 11 concerning the SW dynamics on a random graph generated from the classical Erdős-Rényi $G(n,p)$ model. For this, we first define Dobrushin's influence matrix.

▶ **Definition 18.** *The* Dobrushin influence matrix $A \in \mathbb{R}^{n\times n}$ *is defined by* $A(u,u) = 0$ *and for* $u \neq v$*,*

$$A(u,v) = \max_{(\sigma,\tau)\in S_{u,v}} d_{TV}(\mu_v(\cdot \mid \sigma), \mu_v(\cdot \mid \tau)),$$

where $S_{u,v}$ *contains the set of all pairs of partial configurations* (σ,τ) *in* $\Omega_{V\setminus\{v\}}$ *that can only disagree at* u*, namely,* $\sigma_w = \tau_w$ *if* $w \neq u$*.*

It is known that an upper bound on the spectral norm of A implies spectral independence. In particular, we have the following result from [6].

▶ **Proposition 19** (Theorem 1.13, [6]). *If the Dobrushin influence matrix* A *of a distribution* μ *satisfies* $\|A\| \leq 1-\varepsilon$ *for some* $\varepsilon > 0$*, then* μ *is spectral independent with constant* $\eta = 2/\varepsilon$*.*

For the ferromagnetic Ising model, $\beta_u(\Delta) := \ln \frac{\Delta}{\Delta-2}$ corresponds to the threshold value of the parameter β for the uniqueness/non-uniqueness phase transition on the Δ-regular tree. For the anti-ferromagnetic Ising model, the phase transition occurs at $\bar{\beta}_u(\Delta) := -\ln\frac{\Delta}{\Delta-2}$. If $\bar{\beta}_u(\Delta)(1-\delta) < \beta < \beta_u(\Delta)(1-\delta)$, we say the Ising model satisfies the *δ-uniqueness condition*. On a bounded degree graph, $\|A\| \leq 1-\delta$ for the Ising model is a strictly stronger condition than δ-uniqueness condition. However, due to the observation made in [3], if $\Delta \to \infty$, the two conditions are roughly equivalent.

▶ **Proposition 20.** *The Ising model with parameter* $\bar{\beta}_u(\Delta)(1-\delta) < \beta < \beta_u(\Delta)(1-\delta)$ *and* $\Delta \to \infty$ *satisfies* $\|A\| \leq 1-\delta/2$*.*

This proposition is proved in the full version [12]; we show next that Corollary 3 follows from Theorem 11. For this, we first restate the corollary in a more precise manner.

▶ **Corollary 21.** *Let* $\delta \in (0,1)$ *and* $\Delta \geq 3$*. For the ferromagnetic Ising model with* $\beta \leq (1-\delta)\beta_u(\Delta)$ *on any graph* G *of maximum degree* Δ *and chromatic number* χ*, or for the ferromagnetic* q*-state Potts model with* $q \geq 3$ *and* $\beta \leq \frac{2(1-\delta)}{\Delta}$ *on the same graph, the mixing time of the SW dynamics satisfies*

$$T_{mix}(P_{SW}) = O\big(\chi \cdot \Delta^{\kappa} \cdot (\log n \log\log n)^{1+\kappa}\big),$$

where $\kappa = 1 + \lceil \frac{4qe^2}{\delta} \rceil$*.*

Proof. If $\Delta = O(1)$, then the corollary was proved in a stronger form in [6]. Thus, we assume $\Delta \to \infty$.

We first show spectral independence. Let $q = 2$. Under the δ-uniqueness condition $0 < \beta < (1-\delta)\beta_u(\Delta)$, by Proposition 20 and Proposition 19, the Ising model μ_{Ising} satisfies $(4/\delta)$-spectral independence. For the q-state Potts model with $q \geq 3$, the Dobrushin influence matrix corresponding to μ_{Potts} satisfies $\|A\| \leq \frac{1}{2}\beta\Delta$; see proof of Theorem 2.13 in [54]. Thus, if $\beta \leq \frac{2(1-\delta)}{\Delta}$, then $\|A\| \leq 1-\delta$, and by Proposition 19, μ_{Potts} satisfies $(2/\delta)$-spectral independence.

Letting $N(v)$ denote the neighborhood of v, and noting that for any configuration η on $N(v)$ we have $\mu(\sigma_v = c \mid \sigma_{N(v)} = \eta) \geq 1/(qe^2)$, we deduce that μ_{Potts} and μ_{Ising} are both $(1/(qe^2))$-marginally bounded. Therefore, by noting that $\kappa = 1 + \lceil \frac{4qe^2}{\delta} \rceil$ is a constant that only depends on δ, the mixing time bound follows from Theorem 11

$$T_{mix}(P_{SW}) = O\big(b^{-(7+6\kappa)} \cdot \chi \cdot (C\Delta \log n)^{\kappa} (\log\log n)^{\kappa+1} \cdot \log n\big) = O\big(\chi \cdot \Delta^{\kappa} \cdot (\log n \log\log n)^{1+\kappa}\big),$$

as desired. ◀

3.3.1 The SW dynamics on random graphs

As another application of Theorem 11, we consider the SW dynamics on a random graph generated from the classical $G(n, \frac{d}{n})$ model in which each edge is included independently with probability $p = d/n$; we consider the case where d is a constant independent of n. In this setting, while a typical graph has $\tilde{O}(n)$ edges, its maximum degree is of order $\Theta(\frac{\log n}{\log\log n})$ with high probability. Our results imply that the SW dynamics has polylogarithmic mixing on this type of graph provided β is small enough.

▶ **Corollary 22.** *Let $\delta \in (0,1)$ and $d \in \mathbb{R}_{\geq 0}$ be constants independent of n. Suppose that $G \sim G(n, d/n)$ and G has maximum degree Δ. For the ferromagnetic Ising model with parameter $\beta < (1-\delta)\beta_u(\Delta)$ on G or the ferromagnetic q-Potts model with $q \geq 2$ and $\beta \leq \frac{2(1-\delta)}{\Delta}$ on the same graph, the SW dynamics has $(\log n)^{3+2\lceil \frac{4qe^2}{\delta} \rceil} \cdot O(\log\log n)$ mixing time, with high probability over the choice of the random graph G.*

Corollary 22 is established using Corollary 21 and the following fact about random graphs. The full proof is provided in the full version [12].

▶ **Proposition 23** ([1]). *Let $G \sim G(n, \frac{d}{n})$ for a fixed $d \in \mathbb{R}_{\geq 0}$, and let χ be the chromatic number of G. With high probability over the choice of G, $\chi = k_d$ or $\chi = k_d + 1$, where k_d is the smallest integer k such that $d < 2k \log k$.*

4 Systematic scan dynamics

In this section, we study the systematic scan dynamics for general spin systems, which we define next.

▶ **Definition 24** (Spin system). *Let $G = (V, E)$ be a graph and $\mathcal{S} = \{1, \dots, q\}$ a set of spins. Let $\Omega \subseteq \mathcal{S}^V$ be the set of possible spin configurations on G. We write σ_v for the spin assigned to v by σ. Given a configuration $\sigma \in \Omega$ and a subset Λ of V, we write $\sigma_\Lambda \in \mathcal{S}^\Lambda$ for the configuration of σ restricted to Λ. For a subset of vertices $\Lambda \subseteq V$, a* boundary condition *τ is an assignment of spins to (some) vertices in outer vertex boundary $\partial\Lambda \subseteq V \setminus \Lambda$ of Λ; namely, $\tau : (\partial\Lambda)_\tau \to \mathcal{S}$, with $(\partial\Lambda)_\tau \subseteq \partial\Lambda$. Note that a boundary condition is simply a pinning of a subset of vertices identified as being in the boundary of G. Given a boundary condition $\tau : (\partial V)_\tau \to \mathcal{S}$, the* Hamiltonian *$H : \Omega \to \mathbb{R}$ of a spin system is defined as*

$$H(\sigma) = -\sum_{\{v,u\} \in E} K(\sigma_v, \sigma_u) - \sum_{\{v,u\} \in E : u \in V, v \in (\partial V)_\tau} K(\sigma_v, \tau_v) - \sum_{v \in V} U(\sigma_v), \tag{10}$$

where $K : \mathcal{S} \times \mathcal{S} \to \mathbb{R}$ and $U : \mathcal{S} \to \mathbb{R}$ are respectively the symmetric edge interaction potential function *and the* spin potential function *of the system. The* Gibbs distribution *of a spin system with Hamiltonian H is defined as*

$$\mu(\sigma) = \frac{1}{Z_H} e^{-H(\sigma)},$$

where $Z_H := \sum_{\sigma \in \Omega} e^{-H(\sigma)}$. We use Ω for the set of configurations σ satisfying $\mu(\sigma) > 0$.

The Potts model, as defined in the introduction, corresponds to the spin system with $q \geq 2$, $K(x,y) = \beta \cdot \mathbb{1}(x = y)$, and $U(\sigma_v) = 0$ for all $v \in V$. In this section, we focus on the ferromagnetic Ising model where $\beta > 0$ and $\mathcal{S} = \{-1, +1\}$. Another important spin system is the hardcore model that can be defined by setting $\mathcal{S} = \{1, 0\}$, $K(x,y) = \infty$ if $x = y = 1$ and $K(x,y) = 0$ otherwise, and $U(x) = \mathbb{1}(x = 1) \cdot \ln \lambda$, where $\lambda > 0$ is referred to as the *fugacity* parameter of the model.

We restrict attention to *totally-connected* spin systems, as this ensures that the Glauber dynamics, the systematic scan dynamics, and the block dynamics are all irreducible Markov chains (and thus ergodic).

▶ **Definition 25.** *For a subset $\mathcal{C}_U$ of partial configurations on $U \subseteq V$, let $H[\mathcal{C}_U] = (\mathcal{C}_U, E[\mathcal{C}_U])$ be the induced subgraph where $E[\mathcal{C}_U]$ consists of all pairs of configurations on $\mathcal{C}_U$ that differ at exactly one vertex. We say that $\mathcal{C}_U$ is connected when $H[\mathcal{C}_U]$ is connected. For a pinning τ on $\Lambda \subseteq V$, we say $\Omega^\tau_{V\setminus\Lambda}$ is connected if $H[\Omega^\tau_{V\setminus\Lambda}]$ is connected. A distribution μ over $\mathcal{S}^V$ is* totally-connected *if for every $\Lambda \subseteq V$ and every pinning τ on Λ, $\Omega^\tau_{V\setminus\Lambda}$ is connected.*

Given an ordering $\phi = [v_1, \dots, v_n]$ of the vertices, a systematic scan dynamics performs heat-bath updates on $v_1, \dots, v_n$ sequentially in this order. Recall that a heat-bath update on v_i simply means the replacement of the spin on v_i by a new spin assignment generated according to the conditional distribution in v_i given the configuration in $V \setminus \{v_i\}$. Let $P_i \in \mathbb{R}^{|\Omega|\times|\Omega|}$ be the transition matrix corresponding to a heat-bath update on the vertex v_i. The transition matrix of the systematic scan dynamics for the ordering ϕ can be written as $\mathcal{S}_\phi := P_n \dots P_1$. In general, $\mathcal{S}_\phi$ is not reversible, so as in earlier works we work with the symmetrized version of the scan dynamics that updates the spins in the order ϕ and in addition updates the spins in the reverse order of ϕ [33, 48]. The transition matrix of the symmetrized systematic scan dynamics can then be written as

$$P_\phi := \prod_{i=1}^{n} P_i \prod_{i=0}^{n-1} P_{n-i}.$$

Henceforth, we only consider the symmetrized version of the dynamics. Since P_ϕ is a symmetrized product of reversible transition matrices, one can straightforwardly verify its reversibility with respect to μ; its ergodicity follows from the assumption that the spin system is totally-connected (see Definition 25).

We show tight mixing time bounds for P_ϕ for monotone spin systems (see Definition 4). Our main result for the systematic scan dynamics is Theorem 6 from the introduction; its proof is included in the full version of this paper [12]. We complement Theorem 6 with a lower bound for the mixing time of systematic scan dynamics for a particular ordering ϕ. Specifically, on a bipartite graph $G = (V_E \cup V_O, E)$, an *even-odd scan dynamics P_{EOE}* is a systematic scan dynamics with respect to an ordering ϕ such that v_e appears before v_o in ϕ for all $v_e \in V_E$ and $v_o \in V_O$. In other words,

$$P_\phi = \prod_{i:v_i\in V_E} P_i \prod_{i:v_i\in V_O} P_i \prod_{i:v_i\in V_O} P_i \prod_{i:v_i\in V_E} P_i.$$

The above expression is well-defined without specifying the ordering in which the vertices in V_E and V_O are updated since the updates commute.

▶ **Lemma 26.** *Let Δ be a constant and let G be an n-vertex connected bipartite graph with maximum degree Δ. The even-odd scan dynamics P_{EOE} for the ferromagnetic Ising model on G has mixing time $T_{mix}(P_{EOE}) = \Omega(\log n)$.*

The lower bound in Lemma 26 is proved in the full version of this paper [12] using the machinery from [42] and the fact that even-odd scan dynamics does not propagate disagreements quickly (under a standard coupling). Our proof can thus be extended to other scan orderings that propagate disagreements slowly; however, there are orderings that do propagate disagreements quickly (think of a box in $\mathbb{Z}^2$ with the vertices sorted in a "spiral" from the boundary of the box to its center). For this type of ordering, the technique does not provide the $\Omega(\log n)$ lower bound. In addition, while we focus on the ferromagnetic Ising model to ensure clarity in the proof, the established lower bound is expected to apply to a broader class of spin systems.

4.1 Applications of Theorem 6

We discuss next some applications of Theorem 6. As a first application, we can establish *optimal* mixing for the systematic scan dynamics on the ferromagnetic Ising model under the δ-uniqueness condition, improving the best known results that hold under the Dobrushin-type conditions [51, 28, 41]. This result was stated in Corollary 7 in the introduction and is proved next. For this, we recall that under δ-uniqueness condition, the Ising distribution μ_{Ising} satisfies spectral independence and the bounded marginals condition.

▶ **Proposition 27** ([24, 25])**.** *The ferromagnetic Ising model with parameter β such that $\bar{\beta}_u(\Delta)(1-\delta) < \beta < \beta_u(\Delta)(1-\delta)$ is $O(1/\delta)$-spectrally independent and b-marginally bounded with $b = O(1)$.*

Proof of Corollary 7. We fix $\delta \in (0,1)$ and first assume that Δ is a constant. By Proposition 27, the ferromagnetic Ising model with parameter $\beta < (1-\delta)\beta_u(\Delta)$ satisfies η-spectral independence and b-bounded marginals, where $\eta = O(1/\delta)$ and b is a constant. Since the ferromagnetic Ising model is a monotone system, it follows from Theorem 6 that $T_{mix} = O(\log n)$ for any ordering ϕ.

Now, when $\Delta \to \infty$ as $n \to \infty$, by Proposition 20, the Dobrushin's influence matrix A of ferromagnetic Ising model satisfies that $\|A\| \leq 1 - \delta/2$. Under this assumption, it is known that $T_{mix} = O(\log n)$ for any ordering ϕ; see [41]. ◀

We can similarly show mixing time bound for the systematic scan dynamics of the hardcore model on bipartite graphs under δ-uniqueness condition.

▶ **Corollary 28.** *Let $\delta \in (0,1)$ be a constant. Suppose G is an n-vertex bipartite graph of maximum degree $\Delta \geq 3$. For the hardcore model on G with fugacity λ such that $0 < \lambda < (1-\delta)\lambda_u(\Delta)$, where $\lambda_u(\Delta) = \frac{(\Delta-1)^{\Delta-1}}{(\Delta-2)^{\Delta}}$ is the tree uniqueness threshold on the Δ-regular tree, the systematic scan with respect to any ordering ϕ satisfies*

$$T_{mix}(P_\phi) = \Delta^{O(1/\delta)} \cdot O(\log n).$$

Proof of Corollary 28. The hardcore model on a bipartite graph $(V_1 \cup V_2, E)$ with fugacity $0 < \lambda < (1-\delta)\lambda_u(\Delta)$ is monotone, and [25, 3, 21] show that it satisfies $O(1/\delta)$-spectral independence and the $O(\lambda)$-bounded marginals condition. Theorem 6 then implies $\Delta^{O(1/\delta)} \cdot O(\log n)$ mixing of systematic scan for any ordering. ◀

We consider next the application of Theorem 6 to the special case where the underlying graph is a cube of the d-dimensional lattice graph $\mathbb{Z}^d$. We show that strong spatial mixing implies optimal $O(\log n)$ mixing of any systematic scan dynamics. Previously, under the same type of condition, [8] gave an $O(\log n(\log\log n)^2)$ mixing time bound for arbitrary orderings, and an $O(\log n)$ mixing time bound for a special class of scans that (deterministically) propagate disagreements slowly under the standard identity coupling. We first provide the definition of our SSM condition.

▶ **Definition 29.** *We say a spin system μ on $\mathbb{Z}^d$ satisfies the* strong spatial mixing (SSM) *condition if there exist constants $\alpha, \gamma, L > 0$ such that for every d-dimensional rectangle $\Lambda \subset \mathbb{Z}^d$ of side length between L and $2L$ and every subset $B \subset \Lambda$, with any pair (τ, τ') of boundary configurations on $\partial\Lambda$ that only differ at a vertex u, we have*

$$\|\mu_B^\tau(\cdot) - \mu_B^{\tau'}(\cdot)\|_{TV} \leq \gamma \cdot \exp(-\alpha \cdot dist(u, B)),$$

where $dist(\cdot,\cdot)$ denotes graph distance.

The definition above differs from other variants of SSM in the literature (e.g., [31, 8, 45]) in that Λ has been restricted to "regular enough" rectangles. In particular, our variant of SSM is easier to satisfy than those in [31, 45] but more restricting than the one in [8] (that only considers squares). Nevertheless, it follows from [17, 45, 2, 5] that for the ferromagnetic Ising model, this form of SSM holds up to a critical threshold temperature $\beta < \beta_c(2) = \ln(1 + \sqrt{2})$ on $\mathbb{Z}^2$.

Corollary 9 from the introduction states that for b-marginally bounded monotone spin system on d-dimensional cubes $V \subseteq \mathbb{Z}^d$, SSM implies that the mixing time of any systematic scan P_ϕ is $O(\log n)$. As mentioned there, this result in turn implies that any systematic scan dynamics for the ferromagnetic Ising model is mixing in $O(\log n)$ steps on boxes of $\mathbb{Z}^2$ when $\beta < \beta_c(2)$. Another interesting consequence of Corollary 9 is that we obtain $O(\log n)$ mixing time for any systematic scan dynamics P_ϕ for the hardcore model on $\mathbb{Z}^2$ when $\lambda < 2.538$, which is the best known condition for ensuring SSM [52, 50].

Our proof of Corollary 9 relies on Lemma 8 that is restated below. The proof of Lemma 8 is provided in the full version of this paper [12]. Remarkably, Lemma 8 generalizes beyond monotone systems and may be of independent interests.

▶ **Lemma 8.** *For a spin system on a d-dimensional cube $V \subseteq \mathbb{Z}^d$, SSM implies η-spectral independence, where $\eta = O(1)$.*

Proof of Corollary 9. Assume a monotone spin system satisfies SSM condition. Then the spin system satisfies η-spectral independence, where $\eta = O(1)$ by Lemma 8. By noting that $\Delta = 2^d$ the corollary follows from Theorem 6. ◀

Abstract

We derive a sufficient condition for a sparse random matrix with given numbers of non-zero entries in the rows and columns having full row rank. Inspired by low-density parity check codes, the family of random matrices that we investigate is very general and encompasses both matrices over finite fields and $\{0, 1\}$-matrices over the rationals. The proof combines statistical physics-inspired coupling techniques with local limit arguments.

1 Introduction

1.1 Background and motivation

While "continuous" random matrices such as, for example, a random $n \times n$-matrix with independent Gaussian entries have full rank almost surely for trivial reasons, the rank problem for random combinatorial matrices with entries drawn from discrete distributions poses deep mathematical challenges. In the 1960s Komlós, among the first to study this type of problem, proved that a random $n \times n$-matrix with independent ±1-entries has full rational rank with high probability [24]. An obvious lower bound on the singularity probability is the probability $2^{-n+o(n)}$ that two rows or columns coincide. The conjecture that this lower bound is tight inspired an impressive line of work (e.g., [23, 33]), which culminated in Tikhomirov's proof of the conjecture [34].

By comparison to the case of dense random matrices, relatively little is known about the sparse case where the average number of non-zero entries per row or column is bounded. Moreover, techniques developed for dense random matrices such as large deviations inequalities or Littlewood-Offord arguments do not easily carry over to the sparse case. Yet sparse random matrices are of key interest in computer science. Prominent applications include low-density parity check codes [32], data compression [1, 36] and hashing [16].

One of the first full rank theorems for sparse random matrices came in the guise of a random constraint satisfaction problem. Specifically, in the random k-XORSAT problem we form a random Boolean formula over n variables with m independent XOR-clauses of length k. The question is for what clause densities m/n such a random formula admits an (XOR-)satisfying assignment. Because Boolean XOR is equivalent to addition over the field $\mathbb{F}_2$, this question boils down to determining the threshold m/n up to which a random $m \times n$-matrix over $\mathbb{F}_2$ with precisely k ones per row has full row rank. For the case $k = 3$ this problem was solved by Dubois and Mandler [18] in 2002. Remarkably, the case of general k was solved only more than ten years later by Pittel and Sorkin [31]. Both proofs depend on delicate and technically demanding moment computations.

The contribution of the present paper is a sufficient condition for a sparse random combinatorial matrix to have full row rank. We derive this sufficient condition within the framework of a very general model of random matrices that hails from coding theory [32]. As a very special case this general result encompasses the random k-XORSAT problem. But in addition, we obtain a range of other important special cases such as matrices in which the number of non-zero entries per row or column follows a power law. In fact, the sufficient condition that we obtain is essentially necessary, too. The proof of the main result is based on a novel combination of statistical physics-inspired coupling arguments and local limit theorem techniques. These methods are conceptually more powerful than the method of moments as there exist concrete instances of the present random matrix model where the matrix provably has full rank even though the method of moments fails spectacularly.

1.2 Results

The random matrix model that we investigate allows to control the number of non-zero entries in the rows and columns. The model is identical to the type of model used to construct low-density parity check codes [9, 32]. Specifically, let $\boldsymbol{d} \geq 0$, $\boldsymbol{k} \geq 3$ be independent integer-valued random variables such that $\mathbb{E}[\boldsymbol{d}^{2+\eta}] + \mathbb{E}\left[\boldsymbol{k}^{2+\eta}\right] < \infty$ for an arbitrarily small $\eta > 0$. Let $(\boldsymbol{d}_i, \boldsymbol{k}_i)_{i \geq 1}$ be independent copies of $(\boldsymbol{d}, \boldsymbol{k})$ and set $d = \mathbb{E}[\boldsymbol{d}], k = \mathbb{E}[\boldsymbol{k}]$. Furthermore, let $\mathfrak{d}$ and $\mathfrak{k}$ be the greatest common divisors of the support of $\boldsymbol{d}$ and $\boldsymbol{k}$, respectively. Finally, let $n > 0$ be a large integer divisible by $\mathfrak{k}$ and let $\boldsymbol{m} \sim \mathrm{Po}(dn/k)$ be independent of $(\boldsymbol{d}_i, \boldsymbol{k}_i)_{i \geq 1}$. These definitions ensure that the event

$$\sum_{i=1}^{n} \boldsymbol{d}_i = \sum_{j=1}^{\boldsymbol{m}} \boldsymbol{k}_j \tag{1.1}$$

occurs with probability $\Omega(n^{-1/2})$ [9, Proposition 1.7]. Hence, assuming (1.1) occurs, let $\mathbb{G} = \mathbb{G}_n(\boldsymbol{d}, \boldsymbol{k})$ be a simple random bipartite graph on a set $\{a_1 \ldots, a_{\boldsymbol{m}}\}$ of *check nodes* and a set $\{x_1, \ldots, x_n\}$ of *variable nodes* such that the degree of a_i equals $\boldsymbol{k}_i$ and the degree of x_j equals $\boldsymbol{d}_j$ for all i, j. Adopting coding terminology, we refer to $\mathbb{G}$ as the *Tanner graph.* We need to assume that the second moment is bounded so that the *Tanner graph* is locally finite. The random graph $\mathbb{G}$ naturally induces a $\{0, 1\}$-matrix, namely the $\boldsymbol{m} \times n$-biadjacency matrix $\mathbb{B} = \mathbb{B}(\mathbb{G})$ of the bipartite graph. Explicitly,

$$\mathbb{B}_{ij} = \mathbb{1}\{a_i x_j \in E(\mathbb{G})\} \qquad\qquad (1 \leq i \leq \boldsymbol{m},\ 1 \leq i \leq n).$$

Let

$$D(z) = \sum_{\ell=0}^{\infty} \mathbb{P}\left[\boldsymbol{d} = \ell\right] z^{\ell} \qquad \text{and} \qquad K(z) = \sum_{\ell=0}^{\infty} \mathbb{P}\left[\boldsymbol{k} = \ell\right] z^{\ell}$$

be the probability generating functions of $\boldsymbol{d}$ and $\boldsymbol{k}$. Since $\mathbb{E}[\boldsymbol{d}^2] + \mathbb{E}[\boldsymbol{k}^2] < \infty$, the function

$$\Phi : [0,1] \to \mathbb{R}, \qquad z \mapsto D\left(1 - K'(z)/k\right) - \frac{d}{k}\left(1 - K(z) - (1-z)K'(z)\right) \tag{1.2}$$

is well-defined. The following result renders a sufficient condition for $\mathbb{B}$ to have full row rank.

▶ **Theorem 1.** *If*

$$\Phi(z) < \Phi(0) \qquad \textit{for all } 0 < z \leq 1, \tag{1.3}$$

then $\mathbb{B}$ has full rational row rank w.h.p.

Theorem 1 is a direct consequence of a significantly stronger result on matrices over finite fields. Specifically, suppose that $q \geq 2$ is a prime power, let $\mathbb{F}_q$ signify the field with q elements and let $\boldsymbol{\chi}$ be a random variable that takes values in $\mathbb{F}_q^* = \mathbb{F}_q \setminus \{0\}$. Let $(\boldsymbol{\chi}_{i,j})_{i,j \geq 1}$ be independent copies of $\boldsymbol{\chi}$. Finally, let $\mathbb{A} = \mathbb{A}_n(\boldsymbol{d}, \boldsymbol{k}, \boldsymbol{\chi})$ be the $\boldsymbol{m} \times n$-matrix with entries

$$\mathbb{A}_{i,j} = \mathbb{1}\left\{a_i x_j \in E(\mathbb{G})\right\} \cdot \boldsymbol{\chi}_{i,j} \in \mathbb{F}_q.$$

Hence, the i-th row of $\mathbb{A}$ contains $\boldsymbol{k}_i$ non-zero entries and the j-th column contains $\boldsymbol{d}_j$ non-zero entries.

▶ **Theorem 2.** *If q and $\mathfrak{d}$ are coprime and* (1.3) *is satisfied, then $\mathbb{A}$ has full row rank over $\mathbb{F}_q$ w.h.p.*

Theorem 1 follows from Theorem 2 and a few lines of linear algebra.

The sufficient condition (1.3) is quite close to being necessary, too. Indeed, the *normalised* rank of $\mathbb{A}$ (and $\mathbb{B}$) can be expressed in terms of the function Φ as follows [9, Theorem 1.1]:

$$\frac{\mathrm{rk}(\mathbb{A})}{n} \xrightarrow{n \to \infty} 1 - \max_{z \in [0,1]} \Phi(z) \qquad \text{in probability.} \tag{1.4}$$

Since $\boldsymbol{k} \geq 3$, the definition (1.2) ensures that $\Phi(0) = 1 - d/k$ and thus $n\Phi(0) \sim n - \boldsymbol{m}$ w.h.p. Hence, (1.4) implies that $\mathrm{rk}(\mathbb{A}) \leq \boldsymbol{m} - \Omega(n)$ w.h.p. unless $\Phi(z)$ attains its maximum at $z = 0$. In other words, $\mathbb{A}$ has full row rank *only if* $\Phi(z) \leq \Phi(0)$ for all $0 < z \leq 1$. Indeed, in Section 1.3 we will discover examples that require a strict inequality as in (1.3). The condition that q and $\mathfrak{d}$ be coprime is generally necessary as well, as we will see in Example 8 below.

▶ Remark 3. We emphasise that (1.4) does not guarantee that $\mathbb{A}$ has full row rank w.h.p. even if (1.3) is satisfied. In fact, due to the normalisation on the l.h.s., (1.4) only implies that $\mathrm{rk}(\mathbb{A}) = \boldsymbol{m} - o(n)$ w.h.p., rather than the far stronger statement that $\mathrm{rk}(\mathbb{A}) = \boldsymbol{m}$ w.h.p. delivered by Theorem 2.

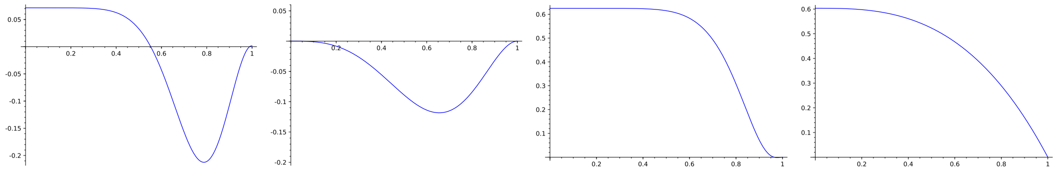

Figure 1 From left to right: the shape of Φ for Examples 4–7.

1.3 Examples

To illustrate the power of Theorems 1 and 2 we consider a few instructive special cases of distributions $\boldsymbol{d}, \boldsymbol{k}, \boldsymbol{\chi}$.

▶ **Example 4** (random k-XORSAT)**.** In random k-XORSAT we are handed a number of independent random constraints c_i of the type $c_i = y_{i1}$ XOR $\cdots$ XOR y_{ik} where each literal y_{ij} is either one of n available Boolean variables $x_1, \ldots, x_n$ or a negation $\neg x_1, \ldots, \neg x_n$. The goal to determine the maximum number of random constraints can be satisfied simultaneously w.h.p. Because Boolean XOR comes down to addition over $\mathbb{F}_2$ and since the clauses are drawn independently, XOR-satisfiability can be rephrased as the full rank problem for the random matrix $\mathbb{A}$ over $\mathbb{F}_q$ with $q = 2$, $\boldsymbol{k} = k$ fixed to a deterministic value and $\boldsymbol{d} \sim \mathrm{Po}(d)$ a Poisson variable. Hence, the generating functions of $\boldsymbol{d}, \boldsymbol{k}$ read $D(z) = \exp(d(z-1))$ and $K(z) = z^k$ and $\Phi_{d,k}(z) = \exp(-dz^{k-1}) - \frac{d}{k}\left(1 - kz^{k-1} + (k-1)z^k\right)$. Thus, Theorem 2 implies that for a given $k \geq 3$ the threshold of d up to which random k-XORSAT is satisfiable w.h.p. equals the largest d such that

$$\Phi_{d,k}(z) < \Phi_{d,k}(0) = 1 - d/k \qquad \text{for all } 0 < z \leq 1. \tag{1.5}$$

A few lines of calculus verify that (1.5) matches the formulas for the k-XORSAT threshold derived by combinatorial methods tailored to this specific case [18, 31]. Theorem 2 also encompasses the generalisations of XORSAT to other finite fields $\mathbb{F}_q$ from [5, 21].

▶ **Example 5** (identical distributions)**.** An interesting scenario arises when $\boldsymbol{d}, \boldsymbol{k}$ are identically distributed. For example, suppose that $\mathbb{P}[\boldsymbol{d} = 3] = \mathbb{P}[\boldsymbol{d} = 4] = \mathbb{P}[\boldsymbol{k} = 3] = \mathbb{P}[\boldsymbol{k} = 4] = 1/2$. Thus, $D(z) = K(z) = (z^3 + z^4)/2$. The resulting $\Phi(z)$ attains two identical maxima, namely $\Phi(0) = \Phi(1) = 0$. Since $\boldsymbol{k}_i, \boldsymbol{d}_i$ are chosen independently subject only to (1.1), the probability that $\mathbb{A}$ has more rows than columns works out to be $1/2 + o(1)$. As a consequence, $\mathbb{A}$ cannot have full row rank w.h.p. This shows that the condition that 0 be the *unique* maximiser of $\Phi(x)$ is generally necessary.

▶ **Example 6** (fixed $\boldsymbol{d}, \boldsymbol{k}$)**.** Suppose that both $\boldsymbol{d} = d, \boldsymbol{k} = k \geq 3$ are constants rather than genuinely random. Then $\Phi(z) = (1 - z^{k-1})^d - \frac{d}{k}(1 - kz^{k-1} + (k-1)z^k)$. Clearly, $\mathbb{A}$ cannot have full row rank unless $d \leq k$, while Theorem 2 implies that $\mathbb{A}$ has full row rank w.h.p. if $d < k$. This result was previously established via the second moment method [30]. But in the critical case $d = k$ the function $\Phi(z)$ attains its identical maxima at $z = 0$ and $z = 1$. Specifically, $0 = \Phi(0) = \Phi(1) > \Phi(z)$ for all $0 < z < 1$. Hence, Theorem 2 does not cover this special case. Nonetheless, Huang [22] and Mészáros [29] proved that the random $\{0, 1\}$-matrix $\mathbb{B}$ has full rational rank w.h.p. The proof is based on a delicate moment computation in combination with a precise local expansion via the Laplace method. However, numerical evidence indicates that the corresponding "d-regular" random matrix $\mathbb{A}$ over a finite field fails to have full rank w.h.p.

▶ **Example 7** (power laws). Let $\mathbb{P}(\boldsymbol{d} = \ell) \propto \ell^{-\alpha}$ for some $\alpha > 3$ and $\boldsymbol{k} = k \geq 3$. Thus,

$$D(z) = \frac{1}{\zeta(\alpha)} \sum_{\ell=1}^{\infty} \frac{z^\ell}{\ell^\alpha}, \quad K(z) = z^k,$$
$$\Phi(z) = D\left(1 - z^{k-1}\right) - \frac{\zeta^{-1}(\alpha)\zeta(\alpha-1)}{k}\left(1 - kz^{k-1} + (k-1)z^k\right)$$

and it can be verified that $\Phi'(z) < 0$ for all $z \in (0,1)$. Hence, (1.3) is always satisfied and Theorems 1 and 2 show that $\mathbb{A}, \mathbb{B}$ have full row rank.

▶ **Example 8** (zero row sums). Theorem 2 requires the assumption that q and the g.c.d. $\mathfrak{d}$ of the support of $\boldsymbol{d}$ be coprime. This assumption is indeed necessary. To see this, consider the case that $q = 2$, $\boldsymbol{\chi} = 1$, $\boldsymbol{d} = 4$ and $\boldsymbol{k} = 8$ deterministically. Then the rows of $\mathbb{A}$ always sum to zero. Hence, $\mathbb{A}$ cannot have full row rank.

2 Proof Strategy

The proof of the main theorem (Theorem 2) substantially extends the techniques behind the asymptotic rank formula (1.4) from [9]. As one key additional ingredient we require a new method to count "equitable" vectors in the kernel of $\mathbb{A}$, i.e., vectors in which each element of $\mathbb{F}_q$ occurs with frequency $1/q + o(1)$. This part of the proof, which involves the asymptotic enumeration of lattice points that satisfy certain arithmetic conditions, hinges on local limit techniques and algebraic arguments, specifically the identification of suitable bases of $\mathbb{Z}$-modules generate by lattice points. This argument generalises techniques that were also used in the study of adjacency matrices of random d-regular graphs [22, 29].

To motivate the proof strategy we first go down the "classical" path of the method of moments. We will discover where this proof strategy gets stuck and then work our way around the obstacle by means of physics-inspired coupling arguments. In statistical physics jargon, the moment calculation amounts to an "annealed" analysis. In a nutshell, the issue with such analyses is that unlikely events can render outsized contributions to moments of exponentially large random variables such as the number of vectors in the kernel of $\mathbb{A}$. Once we see where such large deviations hazards lurk, we will be able to replace the "annealed" strategy by a "quenched" approach that sidesteps these large deviations effects.

2.1 The method of moments

By extension of random k-XORSAT from Example 4, the full rank problem for the random matrix $\mathbb{A}$ over $\mathbb{F}_q$ can be viewed as a random constraint satisfaction problem. Specifically, choose a vector $\boldsymbol{y} \in \mathbb{F}_q^{\boldsymbol{m}}$ uniformly independently of $\mathbb{A}$. Then a solution to our random CSP is just a solution $x \in \mathbb{F}_q^n$ to the linear system $\mathbb{A}x = \boldsymbol{y}$. Thus, together with the corresponding entry of $\boldsymbol{y}$ each of the $\boldsymbol{m}$ rows of $\mathbb{A}$ induces a constraint.

Since the early 2000s the default method for approaching random CSPs has been the second moment method [2, 3]. Indeed, one of the first contributions to this line of work was the aforementioned work of Dubois and Mandler on random 3-XORSAT [18], which corresponds to the special case $q = 2$, $\boldsymbol{k} = 3$, $\boldsymbol{d} = \mathrm{Po}(d)$. A natural first stab at the full rank problem therefore appears to be to run the second moment routine on the number $\boldsymbol{Z} = \boldsymbol{Z}(\mathbb{A}, \boldsymbol{y})$ of solutions to $\mathbb{A}x = \boldsymbol{y}$. But clearly, to have any chance of success we need to condition on the degrees of the variable and check nodes, and a few more innocent pieces of information. Formally, let $\mathfrak{A}$ be the σ-algebra generated by $\boldsymbol{m}, (\boldsymbol{k}_i)_{i\geq1}, (\boldsymbol{d}_i)_{i\geq1}$ and by the numbers $\boldsymbol{m}(\chi_1, \ldots, \chi_\ell)$ of rows with non-zero entries $\chi_1, \ldots, \chi_\ell \in \mathbb{F}_q^*$. Let us write $\mathbb{P}_{\mathfrak{A}} = \mathbb{P}[\,\cdot \mid \mathfrak{A}]$ and $\mathbb{E}_{\mathfrak{A}} = \mathbb{E}[\,\cdot \mid \mathfrak{A}]$ for the conditional probability and expectation given $\mathfrak{A}$.

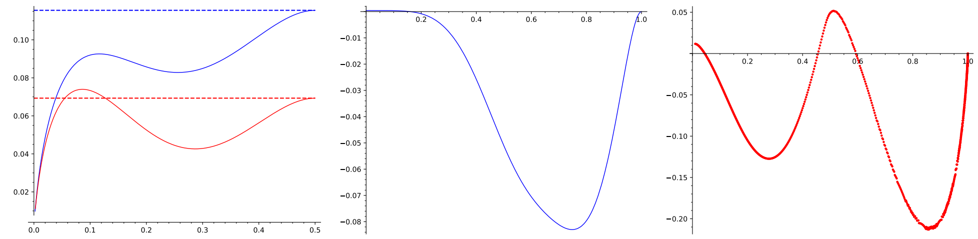

Figure 2 *Left:* the r.h.s. of (2.6) for $d = 2.5$ (blue) and $d = 2.7$ (red) in the interval $[0, \frac{1}{2}]$. *Middle:* the function $\Phi(z)$ from Example 9. *Right:* numerical lower bound on the moment formula from Example 9.

Since $\boldsymbol{y}$ is independent of $\mathbb{A}$, for any fixed $x \in \mathbb{F}_q^n$ the event $\mathbb{A}x = \boldsymbol{y}$ has probability $q^{-\boldsymbol{m}}$. As there are q^n choices of x, linearity of expectation yields

$$\mathbb{E}_{\mathfrak{A}}[\boldsymbol{Z}] = q^{n-\boldsymbol{m}}. \tag{2.1}$$

For the second moment method to succeed we need to verify that $\mathbb{E}_{\mathfrak{A}}[\boldsymbol{Z}^2] \sim \mathbb{E}_{\mathfrak{A}}[\boldsymbol{Z}]^2$. Then Chebyshev's inequality yields $\boldsymbol{Z} \sim \mathbb{E}_{\mathfrak{A}}[\boldsymbol{Z}]$ w.h.p., and thus $\mathbb{A}x = \boldsymbol{y}$ has a solution w.h.p., provided that $n \le \boldsymbol{m}$. This fact, in turn, would imply that $\mathbb{A}$ has full row rank w.h.p.; for if it were the case that $\operatorname{rk}\mathbb{A} < \boldsymbol{m}$, then the linear system $\mathbb{A}x = \boldsymbol{y}$ would fail to have a solution with probability at least $1/q$.

Concerning the computation of $\mathbb{E}_{\mathfrak{A}}[\boldsymbol{Z}^2]$, because the set of solutions is either empty or a translation of the kernel, we obtain

$$\begin{aligned}\mathbb{E}_{\mathfrak{A}}[\boldsymbol{Z}^2] &= \sum_{\sigma,\tau\in\mathbb{F}_q^n} \mathbb{P}_{\mathfrak{A}}\left[\mathbb{A}\sigma = \mathbb{A}\tau = \boldsymbol{y}\right] = \sum_{\sigma,\tau\in\mathbb{F}_q^n} \mathbb{P}_{\mathfrak{A}}\left[\mathbb{A}\sigma = \boldsymbol{y}\right] \mathbb{P}_{\mathfrak{A}}\left[\sigma - \tau \in \ker\mathbb{A}\right] \\ &= \mathbb{E}_{\mathfrak{A}}\left[\boldsymbol{Z}\right] \mathbb{E}_{\mathfrak{A}}\left[|\ker\mathbb{A}|\right].\end{aligned} \tag{2.2}$$

Hence, we are left to calculate $\mathbb{E}_{\mathfrak{A}}\left[|\ker\mathbb{A}|\right]$.

Unlike in the case (2.1) of the first moment of $\boldsymbol{Z}$, the probability of belonging to the kernel of $\mathbb{A}$ is not the same for all $x \in \mathbb{F}_q^n$. Indeed, as an extreme example, the zero vector always belongs to the kernel. By contrast, depending on $\boldsymbol{d}, \boldsymbol{k}$ and q there may be vectors that cannot possibly belong to the kernel for divisibility reasons; e.g., if $\boldsymbol{k} = 3$ and $q = 2$, then the all-ones vector cannot lie in $\ker\mathbb{A}$.

Hence, we need to tread carefully. In order to calculate the expected size of the kernel we need to discriminate vectors x according to the number $n_\ell(s)$ of variable nodes of a given degree ℓ that take a specific value $s \in \mathbb{F}_q$. Further, given the $n_\ell(s)$ we need to know the numbers $m_{\chi_1,\ldots,\chi_\ell}(s_1,\ldots,s_\ell)$ of rows with non-zero entries $\chi_1,\ldots,\chi_\ell$ whose neighbouring variable nodes in $\mathbb{G}$ receive values $s_1,\ldots,s_\ell$. Since given $\mathfrak{A}$ the matching of the variable and check nodes remains random given their degrees, the ensuing contribution to the first moment works out to be

$$\begin{aligned}\Xi(n_\ell(s), m_{\chi_1,\ldots,\chi_\ell}(s_1,\ldots,s_\ell))_{\ell,s,s_1,\ldots,s_\ell} &= \sum_{s\in\mathbb{F}_q} \mathbb{E}\left[(\boldsymbol{d}-1)n_{\boldsymbol{d}}(s)\log\frac{n_{\boldsymbol{d}}(s)}{n}\right] \\ -\frac{d}{k}\mathbb{E}&\left[\sum_{\sigma_1,\ldots,\sigma_{\boldsymbol{k}}\in\mathbb{F}_q} \mathbb{1}\left\{\boldsymbol{\chi}\perp\sigma\right\} m_{\boldsymbol{\chi}_{1,1},\ldots,\boldsymbol{\chi}_{1,\boldsymbol{k}}}(\sigma_1,\ldots,\sigma_{\boldsymbol{k}}) \log\frac{m_{\boldsymbol{\chi}_{1,1},\ldots,\boldsymbol{\chi}_{1,\boldsymbol{k}}}(\sigma_1,\ldots,\sigma_{\boldsymbol{k}})}{\boldsymbol{m}}\right].\end{aligned} \tag{2.3}$$

Then

$$\mathbb{E}_{\mathfrak{A}}|\ker\mathbb{A}| = \exp\left[\max_{n_\ell(s),m_{\chi_1,\ldots,\chi_\ell}(s_1,\ldots,s_\ell)} \Xi(n_\ell(s), m_{\chi_1,\ldots,\chi_\ell}(s_1,\ldots,s_\ell)) + o(n)\right]. \tag{2.4}$$

Hence, in order to compute the expected kernel size we should maximise the fairly impressive formula (2.3) over a potentially *very* large range of parameters $n_\ell(s)$, $m_{\chi_1,\ldots,\chi_\ell}(s_1,\ldots,s_\ell)$. The choice of these parameters is subject to the constraint that for every value $s \in \mathbb{F}_q$ the number of occurrences of s counted from the side of the check nodes must equal the number of occurrences viewd from the variable side. This leads to the equations

$$\mathbb{E}[\boldsymbol{d}n_{\boldsymbol{d}}(s)] = \mathbb{E}\left[\sum_{\sigma_1,\ldots,\sigma_{\boldsymbol{k}}\in\mathbb{F}_q} \boldsymbol{k}\mathbb{1}\left\{\sigma_1 = s\right\}\mathbb{1}\left\{\boldsymbol{\chi}\perp\sigma\right\} m_{\boldsymbol{\chi}_{1,1},\ldots,\boldsymbol{\chi}_{1,\boldsymbol{k}}}(\sigma_1,\ldots,\sigma_{\boldsymbol{k}})\right] \forall s \in \mathbb{F}_q.$$

Taking these constraints into account, we can transform (2.4) into a Lagrangian optimisation problem whose only variables are the $n_\ell(s)$, $s \in \mathbb{F}_q$, $\ell \in \mathrm{supp}\boldsymbol{d}$. A somewhat delicate application of the Laplace method then shows that $\mathbb{E}_{\mathfrak{A}}[|\ker\mathbb{A}|] = O(q^{n-\boldsymbol{m}})$, i.e., that the second moment method "nearly works", if and only if the maximum of (2.3) is attained at the "equitable" solution

$$n_\ell(s) \sim n\mathbb{P}\left[\boldsymbol{d} = \ell\right]/q \qquad \text{for all } s \in \mathbb{F}_q,\ \ell \in \mathrm{supp}\boldsymbol{d}. \tag{2.5}$$

Unfortunately, we have no idea how to solve the optimisation problem (2.4) in any generality. Worse, even if we knew how to tackle this optimisation task, that would still not suffice to prove Theorem 2. Indeed, the plain moment calculation fails even for random 3-XORSAT, i.e., the case $q = 2$, $\boldsymbol{k} = 3$ constant and $\boldsymbol{d} = \mathrm{Po}(d)$. In this case the second moment calculation reduces to the one-dimensional optimisation problem

$$\log \mathbb{E}_{\mathfrak{A}}|\ker\mathbb{A}| \sim n \cdot \max_{z\in[0,1]} -z\log z - (1-z)\log(1-z) + \frac{\boldsymbol{m}}{n}\log\frac{1+(1-2z)^3}{2} \quad \text{(cf. [18])}. \tag{2.6}$$

At $z = 1/2$ the r.h.s. of (2.6) simplifies to $(n - \boldsymbol{m})\log 2$, and thus $\mathbb{E}_{\mathfrak{A}}|\ker\mathbb{A}| = 2^{n-\boldsymbol{m}}$ matches the first moment (2.1). But if the maximum (2.6) is attained at $z \neq 1/2$, then $\mathbb{E}_{\mathfrak{A}}|\ker\mathbb{A}| \gg 2^{n-\boldsymbol{m}}$ and the second moment method fails. Figure 2 displays (2.6) for $d = 2.5$ and $d = 2.7$. While for $d = 2.5$ the function takes its maximum at $z = 1/2$, for $d = 2.7$ the maximum is attained at $z \approx 0.085$. However, the actual random 3-XORSAT threshold is $d \approx 2.75$ [18]. Thus, method of moments fails short of the real threshold.

The reason for this is that rare events are apt to boost the *expected* number of vectors in the kernel. This is precisely what happens in random k-XORSAT. The rare event in question is a fluctuation of the density of the *2-core* $\mathbb{G}^{(2)}$ of the Tanner graph, which is obtained by iteratively removing any variable nodes of degree at most one along with their unique adjacent check node if the variable degree equals one. Dubois and Mandler therefore pinpointed the 3-XORSAT threshold by applying the second moment method to the minor $\mathbb{A}^{(2)}$ induced by $\mathbb{G}^{(2)}$ while conditioning on the 2-core having its typical size and density. However, even in random k-XORSAT with $k > 3$ the ensuing optimisation problem (2.3) is anything but straightforward, as witnessed by the work of Pittel and Sorkin [31]. Furthermore, increasing the size of the field to $q > 2$ boosts the number of variables involved, which adds further significant challenges to the optimisation problem; even the case $q = 3$ turns out to be essentially intractable [21]. Finally, for general $\boldsymbol{d}, \boldsymbol{k}$ and q it is far from clear what the "relevant" variables would be that are responsible for any large deviations effects. Inspecting a few examples of degree distributions $\boldsymbol{d}, \boldsymbol{k}$ reveals that conditioning on the size and density of the 2-core will not generally suffice.

The upshot is that the second moment method hardly seems like a promising path towards Theorem 2. But we learned that we basically need to get a handle on the typical size of the kernel of $\mathbb{A}$. Specifically, if we could prove that typical vectors in the kernel are nearly equitable in the sense that all elements $s \in \mathbb{F}_q$ occur about n/q times, then we could conceivably derive the desired bound $|\ker\mathbb{A}| \leq q^{n-\boldsymbol{m}}$ w.h.p.

▶ **Example 9** (failure of the moment method). To underscore the issue with the method of moments, consider the random variables $\boldsymbol{d}, \boldsymbol{k}$ with generating functions $D(z) = 0.889z^3 + 0.111z^{21}$ and $K(z) = z^5$ and set $q = 101$. The resulting function $\Phi(z)$ (just barely) attains its unique maximum at $z = 1$. Hence, Theorem 2 shows that $\mathbb{A}$ has full row rank w.h.p. However, the moment formula (2.4) fails to attain its global maximum at the uniform solution; hence, the method of moments provably fails on this example, even though the 2-core $\mathbb{G}^{(2)}$ coincides with the entire original Tanner graph $\mathbb{G}$. Indeed, Figure 2 displays $\Phi(z)$ (middle) along with a numerical *lower* bound on the moment formula (right). The parameter on the horizontal axis of the right plot corresponds to the fraction variable occurrences set to zero. Hence, a necessary condition for the method of moments to succeed is that the maximum value be attained at $1/q$, which clearly is not the case.

2.2 Quenched analysis

Informed by this discussion, we are thus going to seize upon a different set of techniques to show that typical kernel vectors are essentially equitable. To be precise, let $\boldsymbol{x}_{\mathbb{A}} = (\boldsymbol{x}_{\mathbb{A},i})_{i\in[n]} \in \mathbb{F}_q^n$ be a random vector from the kernel of $\mathbb{A}$. We would like to show that for a given random matrix $\mathbb{A}$, such a random vector $\boldsymbol{x}_{\mathbb{A}} \in \ker \mathbb{A}$ is equitable w.h.p. In physics jargon, such a direct investigation of random solutions to a typical random combinatorial problem instance (in contrast to a moment calculation) is termed a *quenched analysis*. The fundamental merit of such a conditional (or quenched) analysis is that we may condition on the matrix $\mathbb{A}$ being *typical*; hence, we do not need to take very unlikely outcomes of $\mathbb{A}$ into consideration. By contrast, in the moment computations that we sketched in Section 2.1 we average over *all* possible outcomes of $\mathbb{A}$, including pathological cases that for some reason possess excessively large kernels.

The cornerstone of the quenched analysis will be to prove that w.h.p. over the choice of $\mathbb{A}$ the event

$$\mathfrak{O} = \left\{ \sum_{\sigma,\tau\in\mathbb{F}_q} \sum_{i,j=1}^{n} \left|\mathbb{P}\left[\boldsymbol{x}_{\mathbb{A},i} = \sigma,\ \boldsymbol{x}_{\mathbb{A},j} = \tau \mid \mathbb{A}\right] - q^{-2}\right| = o(n^2) \right\} \tag{2.7}$$

occurs. In words, $\mathfrak{O}$ asks that for any two field elements $\sigma, \tau \in \mathbb{F}_q$ for most pairs $1 \le i, j \le n$ the probability that the i-th entry $\boldsymbol{x}_{\mathbb{A},i}$ of a random kernel vector $\boldsymbol{x}_{\mathbb{A}}$ equals σ while the j-th entry $\boldsymbol{x}_{\mathbb{A},j}$ equals τ is about q^{-2}. Thus, for most choices of the indices i, j the pair $(\boldsymbol{x}_{\mathbb{A},i}, \boldsymbol{x}_{\mathbb{A},j}) \in \mathbb{F}_q^2$ is approximately uniformly distributed. Together with Chebyshev's inequality, this implies that a random vector $\boldsymbol{x}_{\mathbb{A}} \in \ker \mathbb{A}$ is equitable w.h.p. In fact, if $\mathfrak{O}$ occurs then even the degree-weighted empirical distribution of the entries of a typical $\boldsymbol{x}_{\mathbb{A}}$ is asymptotically uniform w.h.p., i.e., w.h.p. over the choice of $\boldsymbol{x}_{\mathbb{A}}$ we have

$$\sum_{i=1}^{n} \boldsymbol{d}_i \mathbb{1}\{\boldsymbol{x}_{\mathbb{A}} = \tau\} \sim q^{-1} \sum_{i=1}^{n} \boldsymbol{d}_i \qquad \text{for all } \tau \in \mathbb{F}_q. \tag{2.8}$$

Thus, the thrust behind considering the event $\mathfrak{O}$ is to accomplish just what we failed to accomplish via the moment computation: to show that the dominant contribution to the kernel comes from approximately equitable vectors.

Apart from showing that $\mathbb{A} \in \mathfrak{O}$ w.h.p., the following proposition also shows that the first moment formula (2.1) remains true on $\mathfrak{O}$.

▶ **Proposition 10.** *Under the assumptions of Theorem 2 we have* $\mathbb{P}\left[\mathbb{A} \in \mathfrak{O}\right] \sim 1$ *and*

$$\mathbb{E}_{\mathfrak{A}}\left[\boldsymbol{Z} \cdot \mathbb{1}\left\{\mathbb{A} \in \mathfrak{O}\right\}\right] \sim \mathbb{E}_{\mathfrak{A}}\left[\boldsymbol{Z}\right] \sim q^{n-\boldsymbol{m}}. \tag{2.9}$$

Before we elaborate on the proof of Proposition 10 in Section 2.3, we remark that the second moment method "works" once we condition on the event $\mathfrak{O}$. Indeed, the estimate (2.8), which is valid on $\mathfrak{O}$ w.h.p., demonstrates that once we condition on $\mathfrak{O}$, the dominant contribution to (2.3) comes from approximately uniform choices of $n_{\boldsymbol{d}}(s)$ as in (2.5). Due to the concavity of the entropy function, (2.5) implies that the optimal choices of the check variables $m_{\chi_1,\ldots,\chi_\ell}$ are asymptotically uniform as well, subject to the obvious linear constraint. Explicitly, the optimal $m_{\chi_1,\ldots,\chi_\ell}$ read

$$m_{\chi_1,\ldots,\chi_\ell}(s_1,\ldots,s_\ell) \sim \mathbb{1}\{s_1\chi_1+\cdots+s_\ell\chi_\ell=0\}q^{1-\ell}\boldsymbol{m}\mathbb{P}\left[\boldsymbol{k}=\ell\right]\prod_{i=1}^{\ell}\mathbb{P}\left[\boldsymbol{\chi}=\chi_i\right]. \tag{2.10}$$

Expanding (2.3) around (2.5) and (2.10), one could derive the bound $\mathbb{E}_{\mathfrak{A}}\left[\boldsymbol{Z}^2\cdot\mathbb{1}\left\{\mathbb{A}\in\mathfrak{O}\right\}\right] = O(\mathbb{E}_{\mathfrak{A}}\left[\boldsymbol{Z}\right])^2$ via a routine application of the Laplace method. However, to prove Theorem 2 we actually require the following more precise estimate.

▶ **Proposition 11.** *Under the assumptions of Theorem 2 we have*

$$\mathbb{E}_{\mathfrak{A}}\left[\boldsymbol{Z}^2\cdot\mathbb{1}\left\{\mathbb{A}\in\mathfrak{O}\right\}\right] \sim \mathbb{E}_{\mathfrak{A}}\left[\boldsymbol{Z}\right]^2. \tag{2.11}$$

The key challenge towards the proof the (2.11) is to obtain asymptotic equality, rather than the weaker bound $\mathbb{E}_{\mathfrak{A}}\left[\boldsymbol{Z}^2\cdot\mathbb{1}\left\{\mathbb{A}\in\mathfrak{O}\right\}\right] = O(\mathbb{E}_{\mathfrak{A}}\left[\boldsymbol{Z}\right]^2)$. This requires a meticulous expansion of the second moment around the equitable solution, which involves the detailed analysis of the lattices generated by integer vectors that encode conceivable values of the variables from (2.3). We are going to outline this analysis in Section 2.4. But first let us observe that Theorem 2 follows from Propositions 10 and 11 easily.

Proof of Theorem 2. The assumption (1.3) implies that $1-d/k=\Phi(0)>\Phi(1)=0$. Since $\boldsymbol{m}=\mathrm{Po}(dn/k)$, we thus obtain $n-\boldsymbol{m}=\Omega(n)$ w.h.p. Therefore, (2.9) implies that $\mathbb{E}_{\mathfrak{A}}\left[\boldsymbol{Z}\cdot\mathbb{1}\left\{\mathbb{A}\in\mathfrak{O}\right\}\right]\sim q^{n-\boldsymbol{m}}=q^{\Omega(n)}$ w.h.p. Hence, (2.11) implies together with Chebyshev's inequality that $\boldsymbol{Z}\geq\boldsymbol{Z}\mathbb{1}\{\mathbb{A}\in\mathfrak{O}\}=q^{\Omega(n)}$ w.h.p. Consequently, the random linear system $\mathbb{A}x=\boldsymbol{y}$ has a solution w.h.p., which implies that $\mathrm{rk}\,\mathbb{A}=\boldsymbol{m}$ w.h.p. ◀

2.3 Proof of Proposition 10: typical kernel vectors

The asymptotic rank formula (1.4) provides our point of departure toward the proof of Proposition 10. The basic idea is to show that (1.4) could not possibly be correct unless $\mathbb{A}\in\mathfrak{O}$ w.h.p. However, at closer inspection it turns out we cannot just apply (1.4) as is. Instead, we need to derive the analogue of (1.4) for a slightly enhanced random matrix from scratch.

Specifically, for an integer $t\geq 0$ obtain $\mathbb{A}_{[t]}$ from $\mathbb{A}$ by adding t more rows that each contain precisely three non-zero entries. The positions of these non-zero entries are chosen uniformly, mutually independently and independently of $\mathbb{A}$. The non-zero entries themselves are independent copies of $\boldsymbol{\chi}$. For this enhanced matrix we derive the following upper bound on its asymptotic rank.

▶ **Proposition 12.** *If* (1.3) *is satisfied then there exists* $\delta_0=\delta_0(\boldsymbol{d},\boldsymbol{k})>0$ *such that for all* $0<\delta<\delta_0$ *we have*

$$\limsup_{n\to\infty}\frac{1}{n}\mathbb{E}[\mathrm{nul}\,\mathbb{A}_{[\lfloor\delta n\rfloor]}]\leq 1-\frac{d}{k}-\delta. \tag{2.12}$$

The proof of Proposition 12 relies on the so-called “Aizenman-Sims-Starr scheme” [4], a coupling argument inspired by spin glass theory that also constituted the cornerstone of the derivation of (1.4) in [9]. That said, a subtle modification of this argument is necessary to accommodate the additional ternary equations. A vital assumption towards the proof of Proposition 12 is that the function Φ from (1.2) attains its *unique* global max at $z = 0$. In fact, the proof of Proposition 12 is the only place where the uniqueness of the maximiser is required.

How does Proposition 10 follow from Proposition 12? Assuming (1.3), we obtain from (1.4) that

$$\frac{1}{n}\operatorname{nul}\mathbb{A} \sim 1 - \frac{d}{k} \qquad \text{w.h.p.} \tag{2.13}$$

Now suppose that we add $\lfloor \delta n \rfloor$ extra ternary rows to $\mathbb{A}$ to obtain $\mathbb{A}_{[\lfloor \delta n \rfloor]}$. Comparing (2.12) and (2.13), we conclude that all but $o(n)$ of these extra rows decrease the nullity by one. Indeed, adding a single row cannot decrease the nullity by more than one, and routine arguments show that $\operatorname{nul}\mathbb{A}_{[\lfloor \delta n \rfloor]}$ concentrates about its expectation.

But a drop in nullity of $\delta n + o(n)$ w.h.p. is conceivable only if $\mathbb{A} \in \mathfrak{O}$ w.h.p. To see this, let us contemplate the kernel of a general $M \times N$ matrix A over $\mathbb{F}_q$ for a brief moment. Draw $\boldsymbol{x}_A = (\boldsymbol{x}_{A,i})_{i \in [N]} \in \ker A$ uniformly at random. For any given coordinate $\boldsymbol{x}_{A,i}$, $i \in [N]$ there are two possible scenarios: either $\boldsymbol{x}_{A,i} = 0$ with probability one, or $\boldsymbol{x}_{A,i}$ is uniformly distributed over $\mathbb{F}_q$. To see this, consider a basis $\zeta_1, \ldots, \zeta_h$ of the kernel of A. Then we can sample $\boldsymbol{x}_A$ by just multiplying each ζ_j with a random scalar $\boldsymbol{z}_j \in \mathbb{F}_q$ and summing up: $\boldsymbol{x}_A = \boldsymbol{z}_1\zeta_1 + \cdots + \boldsymbol{z}_h\zeta_h$. If the i-th coordinate of all ζ_j is zero, then $\boldsymbol{x}_{A,i} = 0$ deterministically; otherwise $\boldsymbol{x}_{A,i}$ is a sum of uniformly random elements of $\mathbb{F}_q$, and thus uniformly random itself. It therefore makes sense to call coordinate i *frozen* if $x_i = 0$ for all $x \in \ker A$, and unfrozen otherwise. Let $\mathfrak{F}(A)$ be the set of frozen coordinates.

If $\mathbb{A}$ had many frozen coordinates then adding an extra random row with three non-zero entries could hardly decrease the nullity w.h.p. For if all three non-zero coordinates fall into the frozen set, then we get the new equation “for free”, i.e., $\operatorname{nul}\mathbb{A}_{[1]} = \operatorname{nul}\mathbb{A}$. Thus, Proposition 12 implies that $|\mathfrak{F}(\mathbb{A})| = o(n)$ w.h.p. We conclude that $\boldsymbol{x}_{\mathbb{A},i}$ is uniformly distributed over $\mathbb{F}_q$ for all but $o(n)$ coordinates $i \in [n]$. However, this does not yet imply that $\boldsymbol{x}_{\mathbb{A},i}$, $\boldsymbol{x}_{\mathbb{A},j}$ are independent for most i, j, as required by $\mathfrak{O}$. Yet a slightly more careful deliberation based on linear algebra and the “pinning lemma” [9, Proposition 2.4] shows that $\mathbb{A} \in \mathfrak{O}$ w.h.p.

2.4 Proof of Proposition 11: expansion around the equitable solution

We prove Proposition 11 by way of expanding (2.3) carefully around the uniform distribution (2.5). Recall that once the $n_\ell(s)$ are set to the equitable solution (2.5), the optimal check variables $m_{\chi_1,\ldots,\chi_\ell}(s_1, \ldots, s_\ell)$ are given by (2.10). This observation by itself now suffices to conclude without (much) further ado that

$$\mathbb{E}_{\mathfrak{A}}[\boldsymbol{Z}^2 \cdot \mathbb{1}\{\mathbb{A} \in \mathfrak{O}\}] = O\left(\mathbb{E}_{\mathfrak{A}}[\boldsymbol{Z} \cdot \mathbb{1}\{\mathbb{A} \in \mathfrak{O}\}]^2\right). \tag{2.14}$$

The challenge is to sharpen this estimate so as to obtain the asymptotic equality claimed in (2.11). In his work on adjacency matrices of random regular graphs, Huang [22] actually faced a similar issue (with $\boldsymbol{d} = \boldsymbol{k}$ constant and q a prime number). To prove Proposition 11 we need to cope with the (significantly) more general situation of arbitrary $\boldsymbol{d}, \boldsymbol{k}$ and prime powers q. This improvement actually constitutes one of the main technical obstacles that we need to surmount toward the proof of Theorem 2.

The issue is that in order to eliminate the constant factor hidden in the $O(\,\cdot\,)$ in (2.14) we need to carefully consider divisibility properties that make it possible or impossible for a vector $x \in \mathbb{F}_q^n$ to belong to the kernel. These questions depend not only on the degree distributions $\boldsymbol{d}, \boldsymbol{k}$ but also on q and the distribution $\boldsymbol{\chi}$ of the non-zero entries. Hence, to estimate the kernel size precisely we need to crystallise the conceivable frequencies of field elements that may lead to solutions. Specifically, for an integer $\ell \geq 3$ and $\chi_1, \ldots, \chi_\ell \in \mathbb{F}_q \setminus \{0\}$ let

$$\mathcal{S}_q(\chi_1, \ldots, \chi_\ell) = \left\{ \sigma \in \mathbb{F}_q^\ell : \sum_{i=1}^{\ell} \chi_i \sigma_i = 0 \right\} \tag{2.15}$$

comprise all solutions to a linear equation with coefficients $\chi_1, \ldots, \chi_{k_0} \in \mathbb{F}_q$. Furthermore, for each $\sigma \in \mathcal{S}_q(\chi_1, \ldots, \chi_\ell)$ we define the vector

$$\hat{\sigma} = \left(\sum_{i=1}^{\ell} \mathbb{1}\left\{ \sigma_i = s \right\} \right)_{s \in \mathbb{F}_q \setminus \{0\}} \in \mathbb{Z}^{\mathbb{F}_q \setminus \{0\}} \tag{2.16}$$

to track the frequencies with which the various non-zero field elements appear. Moreover, let

$$\mathfrak{M}_q(\chi_1, \ldots, \chi_\ell) \subseteq \mathbb{Z}^{\mathbb{F}_q \setminus \{0\}}$$

be the $\mathbb{Z}$-module generated by the frequency vectors $\hat{\sigma}$ for $\sigma \in \mathcal{S}_q(\chi_1, \ldots, \chi_\ell)$. Thus, $\mathfrak{M}_q(\chi_1, \ldots, \chi_\ell) \subseteq \mathbb{Z}^{\mathbb{F}_q \setminus \{0\}}$ captures all conceivable frequency vectors of solutions σ to $\sum_{i=1}^{\ell} \chi_i \sigma_i$.

Depending on the coefficients $\chi_1, \ldots, \chi_\ell$, the module $\mathfrak{M}_q(\chi_1, \ldots, \chi_\ell)$ may be a proper submodule of the integer lattice $\mathbb{Z}^{\mathbb{F}_q \setminus \{0\}}$. For example, in the case $q = \ell = 3$ and $\chi_1 = \chi_2 = \chi_3 = 1$ the module $\mathfrak{M}_3(1,1,1)$ constitutes the sub-lattice spanned by $\binom{1}{1}$ and $\binom{0}{3}$, which is a proper sub-lattice of $\mathbb{Z}^2$. The following proposition characterises the lattice spanned by the frequency vectors for general $\chi_1, \ldots, \chi_\ell$. The determinant formula that the proposition provides shows that $\mathfrak{M}_q(\chi_1, \ldots, \chi_\ell)$ is a proper sub-module iff all the coefficients $\chi_1, \ldots, \chi_\ell$ coincide.

▶ **Proposition 13.** *Let $q \geq 2$ be a prime power, $\ell \geq 3$ and let $\chi_1, \ldots, \chi_\ell \in \mathbb{F}_q \setminus \{0\}$. Then $\mathfrak{M}_q(\chi_1, \ldots, \chi_\ell)$ has a basis $\mathfrak{b}_1, \ldots, \mathfrak{b}_{q-1}$ of non-negative integer vectors with $\|\mathfrak{b}_i\|_1 \leq 3$ for all $1 \leq i \leq q-1$ such that*

$$\det\left(\mathfrak{b}_1 \ \cdots \ \mathfrak{b}_{q-1} \right) = q^{\mathbb{1}\{\chi_1 = \cdots = \chi_\ell\}}.$$

A vital feature of Proposition 13 is that the module basis consists of non-negative integer vectors with small ℓ_1-norm. In effect, the basis vectors are "combinatorially meaningful" towards our purpose of counting solutions. Perhaps surprisingly, the proof of Proposition 13 turns out to be rather delicate, with details depending on whether q is a prime or a prime power, among other things.

In addition to the subgrid constraints imposed by the linear equations themselves, we need to take another divisibility condition into account. Indeed, for any assignment $\sigma \in \mathbb{F}_q^n$ of values to variables the frequencies of the various field elements $s \in \mathbb{F}_q$ are divisible by the g.c.d. $\mathfrak{d}$ of $\operatorname{supp}(\boldsymbol{d})$, i.e.

$$\mathfrak{d} \mid \sum_{i=1}^{n} \boldsymbol{d}_i \mathbb{1}\left\{ \sigma_i = s \right\} \qquad \text{for all } s \in \mathbb{F}_q. \tag{2.17}$$

Thus, to compute the expected kernel size we need to study the intersection of the subgrid (2.17) with the grid spanned by the frequency vectors $\hat{\sigma}$ for $\sigma \in \mathcal{S}_q(\boldsymbol{\chi}_{1,1}, \ldots, \boldsymbol{\chi}_{1,\boldsymbol{k}})$. Specifically, in order to derive Proposition 11 from Proposition 13 we need to estimate the number of vectors $\sigma \in \mathbb{F}_q^n$ represented by each grid point and calculate the ensuing satisfiability probability. This argument combines the Laplace method with local limit techniques.

3 Discussion

While there is a substantial body of work on dense random matrices where the average number of non-zero entries per row/column diverges or even is linear in the size of the matrix (e.g., [6, 7, 14, 15, 23, 24, 33, 34]), far less is known about sparse random matrices. The aim of this paper has been to determine sufficient (as well as necessary) conditions for a sparse random matrix to have *full* row rank. To this end we drew upon some of the elements of prior work on the *asymptotic* rank of random matrices [5, 9], specifically the formula (1.4). In particular, the proof of Proposition 12 adapts and extends the Aizenman-Sims-Starr scheme from [9]. Additionally, the expansion around the centre employs some of the techniques developed in the study of satisfiability thresholds, particularly the extensive use of local limit theorems [12, 11]. These also played a role in prior work on the adjacency matrices of random d-regular graphs [22, 29].

A principal new proof ingredient is the asymptotically precise analysis of the moment formula (2.3) for general $\boldsymbol{d}, \boldsymbol{k}, q$ around the equitable solution by means of the study of the sub-grids of the integer lattice induced by the constraints. This issue that was absent in the prior literature on variations on random k-XORSAT [5, 9, 13] and on other random constraint satisfaction problems [12, 11]. That said, in the study of the random regular matrix from Example 6 Huang [22] faced a similar issue in the special case $\boldsymbol{d} = \boldsymbol{k}$ constant and $\boldsymbol{\chi} = 1$ deterministically. Proposition 13, whose proof is based on a combinatorial investigation of lattices in the general case, constitutes a considerable generalisation of this case. A further new feature of the proof of Proposition 13 is the explicit ℓ_1-bound on the basis vectors, which greatly facilitates the proof of Theorem 2.

Satisfiability thresholds of random constraint satisfaction problems have been studied extensively in the statistical physics literature via a non-rigorous technique called the “cavity method”. The cavity method comes in two installments: the simpler “replica symmetric ansatz” associated with the Belief Propagation message passing scheme, and the more intricate “replica symmetry breaking ansatz”. The proof of Theorem 2 demonstrates that the former renders the correct prediction as to the satisfiability threshold of random linear equations. By contrast, in quite a few problems, notoriously random k-SAT, replica symmetry breaking occurs [10, 17], requiring a substantially different proof strategy.

A natural question is whether the methods presented in this work can be extended to the adjacency matrices of random graphs. Apart from the aforementioned works regarding the regular case [22, 29] and the work of Bordenave, Lelarge and Salez [8], an exciting recent contribution by Glasgow, Kwan, Sah and Sawhney deals with the precise connection between the matching number and the rank [20]. By contrast to the present work, these contributions rely on local weak convergence and/or Littlewood-Offord techniques; see also [19]. Furthermore, recently the methods from [9] were extended to obtain a rank formula for the adjacency matrices of Erdös-Rényi graphs over arbitrary fields [35]. In fact, the consideration of general fields reveals new phenomena, as was already discovered in some of the earlier literature [6, 7, 25, 26, 27, 28].

Tighter $\mathrm{MA}/1$ Circuit Lower Bounds from Verifier Efficient PCPs for PSPACE

Joshua Cook

Dana Moshkovitz
Department of Computer Science, University of Texas Austin, TX, USA

Abstract

We prove that for some constant $a > 1$, for all $k \leq a$,

$$\mathbf{MATIME}[n^{k+o(1)}]/1 \not\subset \mathbf{SIZE}[O(n^k)],$$

for some specific $o(1)$ function. This is a super linear polynomial circuit lower bound.

Previously, Santhanam [29] showed that there exists a constant $c > 1$ such that for all $k > 1$:

$$\mathbf{MATIME}[n^{ck}]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

Inherently to Santhanam's proof, c is a large constant and there is no upper bound on c. Using ideas from Murray and Williams [26], one can show for all $k > 1$:

$$\mathbf{MATIME}[n^{10k^2}]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

To prove this result, we construct the first **PCP** for $\mathbf{SPACE}[n]$ with quasi-linear verifier time: our **PCP** has a $\tilde{O}(n)$ time verifier, $\tilde{O}(n)$ space prover, $O(\log(n))$ queries, and polynomial alphabet size. Prior to this work, **PCP**s for $\mathbf{SPACE}[O(n)]$ had verifiers that run in $\Omega(n^2)$ time. This **PCP** also proves that **NE** has **MIP** verifiers which run in time $\tilde{O}(n)$.

1 Introduction

Some of the most fundamental problems in complexity theory are proving circuit lower bounds for uniform complexity classes. One such conjecture is that **NP** does not have polynomial size circuits, which is a strong version of $\mathbf{P} \neq \mathbf{NP}$. Very little is known on such lower bounds. In particular, there are no known proofs that **NEXP** does not have polynomial sized circuits! However, there are some closely related results that could be loosely seen as relaxations.

One can strengthen **NP** slightly by giving the non-deterministic algorithm access to randomness, as well as an extra bit of trusted advice. This gives the complexity class $\mathbf{MA}/1$. We can weaken polynomial sized circuits to circuits of fixed polynomial size: $\mathbf{SIZE}[n^k]$ for constant k.

Santhanam [29] proved that for any constant k, $\mathbf{MA}/1 \nsubseteq \mathbf{SIZE}[n^k]$. The $\mathbf{MA}/1$ algorithm runs in time n^{ck} for a large $c > 1$. In fact, inherently to Santhanam's proof, there is no upper bound on c (We will explain why when we describe Santhanam's proof in Section 1.2.1). One can use ideas from Murray and Williams [26] to get, for some explicit c with $2 < c < 10$, the result $\mathbf{MATIME}[n^{ck^2}]/1 \not\subset \mathbf{SIZE}[n^k]$.

The goal of this paper is to prove a fine grained separation of $\mathbf{MA}/1$ from fixed polynomial size circuits, namely,

$$\mathbf{MATIME}[n^{k+o(1)}]/1 \not\subset \mathbf{SIZE}[n^k].$$

We believe that the gold standard for separations should be fine grained separations. Fine grained separations are necessary for key results in complexity theory, e.g., Williams' program (See, e.g., [33]) and optimal derandomization [14].

Some fine grained separations are known, namely, hierarchy theorems that show that giving algorithms more time allows them to solve more problems [18, 11]. Hierarchy theorems are known for many complexity classes. While no hierarchy theorems are known for $\mathbf{MA}$, they are known for $\mathbf{MA}/1$. Fortnow, Santhanam, and Trevisan showed that $\mathbf{MA}$ with a small amount of advice can solve more problems when given more time [16]. Van Melkebeek and Pervyshev showed that for any $1 < b < d$, $\mathbf{MATIME}[n^b]/1 \subsetneq \mathbf{MATIME}[n^d]/1$ [32]. In particular, they imply that even $\mathbf{MATIME}[n^{2k}]/1$ is much larger than $\mathbf{MATIME}[n^{k+o(1)}]/1$.

1.1 Results

In this work, we give a fine grained separation for $\mathbf{MA}/1$ and $\mathbf{SIZE}[n^k]$. We show that for at least some $k > 1$, there is an $\mathbf{MA}$ protocol with one bit of advice whose verifier has time almost n^k such that any circuit solving the same problem also requires size n^k. Formally:

▶ **Theorem 1** (Fine Grained $\mathbf{MA}$ Lower Bound)**.** *There exists a constant $a > 1$, such that for all $k < a$, for some $f(n) = o(1)$,*

$$\mathbf{MATIME}[O(n^{k+f(n)})]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

We stress that we give **super linear** polynomial lower bounds. Our result holds for some k *strictly* greater than 1, even though we don't know which k. This result removes the large polynomial factor in the gap between the $\mathbf{MA}/1$ time and the circuit size in Santhanam's result. It may be the case that a is small, like $a = 1.0001$. But in that case, we get the following result for all k:

▶ **Theorem 2** ($\mathbf{MA}$ Lower Bound for Small a)**.** *If the a from Theorem 1 is finite, then for all $k > 0$, for some $f(n) = o(1)$,*

$$\mathbf{MATIME}[O(n^{ak+f(n)})]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

This gives us a win-win scenario: if a is large, we get a strong result for a large range of k, but if a is small we get a similar result for all k.

When we describe our proof we will explain why we only get separations for $k < a$ for an (unknown) $a > 1$ and not for all $k > 1$. For now we would like to stress that: (1) under plausible complexity assumptions the upper bound a is in fact super-constant in n; (2) even the case of a constant $a > 1$ as promised in our theorem is highly interesting, since it is unknown how to prove that $\mathbf{NP} \nsubseteq \mathbf{SIZE}[n^k]$ for *any* $k > 1$.

Santhanam's original proof uses an interactive protocol for $\mathbf{PSPACE}$. To prove our circuit lower bound, we replace the interactive protocol with a new, more efficient $\mathbf{PCP}$.

To get our fine grained results, we need a **PCP** for space $S = O(n)$ and time $T = 2^{O(n)}$ algorithms, where the verifier simultaneously has $\tilde{O}(n)$ time and $\mathbf{poly}(\log(n))$ many queries. Further, the **PCP** needs a prover that can compute any bit of the proof in $\tilde{O}(n)$ space. Notably, we do not need any bounds on the proof length.

The **PCP** given by Babai, Fortnow, and Lund in their proof that **MIP** = **NEXP** [4] required $\Omega(\log(T))$ queries, while we want $O(\log(\log(T)))$ queries.

Holmgren and Rothblum in their work on delegated computation [20] improved on the BFL **PCP** in several ways that can[1] be used to give a **PCP** with verifier time $\tilde{O}(n+\log(T))$. Unfortunately, it still requires $\Omega(\log(T))$ queries.

Ben-Sasson, Goldreich, Harsha, Sudan, and Vadhan [5] gave a **PCP** that uses a constant number of queries, but has verifier time $\mathbf{poly}(\log(T))$, while we need $\tilde{O}(n+\log(T))$ verifier time. Similar results were given by subsequent work [23, 8, 6].

The small space requirement for the prover is achieved by Holmgren and Rothblum [20]. In some **PCP**s, like the **PCP** in Ben-Sasson, Chiesa, Genkin, and Tromer's work on the concrete efficiency of **PCP**s [6], the prover requires space $\Omega(T)$. In contrast, our result needs prover space $\tilde{O}(S+n)$.

A sufficiently efficient **PCP** was not known, so we construct a new **PCP**.

▶ **Theorem 3** (Verifier Efficient **PCP**). *Let $S, T = \Omega(n)$ be functions, and L be any language computed by a simultaneous time T and space S algorithm. Let $\delta \in (0, 1/2)$ be a constant. Then there is a* **PCP** *for L with:*

1. *Verifier time $\tilde{O}(n+\log(T))$.*
2. *Query time $\tilde{O}(\log(T))$.*
3. *$O(\log(n)+\log(\log(T)))$ queries.*
4. *Alphabet Σ with $\log(|\Sigma|) = O(\log(\log(T)))$.*
5. *Log of proof length $\tilde{O}(\log(T))$.*
6. *Prover space $\tilde{O}(S)$.*
7. *Perfect completeness and soundness δ.*

We believe we can achieve a similar verifier time, query time and prover space while also achieving constant number of queries and alphabet size. We do not need these improvements for our main result, so we only prove this simpler result.

Only our prover requires the space bound for its efficient computation. If we remove this space limitation, we get a similar **PCP** for nondeterministic algorithms.

▶ **Theorem 4** (Verifier Efficient **PCP** for Nondeterministic Algorithms). *Let $T = \Omega(n)$, $\delta \in (0, 1/2)$ be a constant, and $L \in \mathbf{NTIME}[T]$. Then there is a* **PCP** *for L with:*

1. *Verifier time $\tilde{O}(n+\log(T))$.*
2. *Query time $\tilde{O}(\log(T))$.*
3. *$O(\log(n)+\log(\log(T)))$ queries.*
4. *Alphabet Σ with $\log(|\Sigma|) = O(\log(\log(T)))$.*
5. *Log of proof length $\tilde{O}(\log(T))$.*
6. *Perfect completeness and soundness δ.*

An immediate corollary of Theorem 4 is a more fine grained equivalence between **MIP** and **NEXP**.

[1] The **PCP** constructed by Holmgren and Rothblum was built to have no signalling soundness and has many steps that take longer than $\tilde{O}(\log(T))$ time to compute. Still, the basic elements of of their **PCP** needed for a standard **PCP** are computable in $\tilde{O}(n+\log(T))$ time.

▶ **Corollary 5** (Fine Grained Equivalence of $\mathbf{MIP} = \mathbf{NEXP}$)**.** *For any time constructable function $p(n) = \Omega(n)$, language $L \in \mathbf{NTIME}[2^{\tilde{O}(p(n))}]$ if and only if there is a two prover, one round* **MIP** *protocol for L whose verifier runs in time $\tilde{O}(p(n))$.*

Note this equivalence implies a hierarchy theorem for **MIP** since there are hierarchy theorems for **NTIME** [11, 30, 34, 15].

A special case is **MIP** protocols for **NE**.

▶ **Corollary 6** (**NE** Has Quasi-linear Time Verifiers)**.** *For any language $L \in$* **NE***, there is a two prover, one round* **MIP** *protocol for L whose verifier runs in time $\tilde{O}(n)$.*
Note this verifier time is nearly optimal since the verifier requires linear time to read its entire input.

All previous **PCP**s fail to achieve such an efficient **MIP** verifier. If the original **PCP** makes $\Omega(n)$ queries of size $\Omega(n)$, then it takes $\Omega(n^2)$ time to send the queries even if we allow more provers. And all previous **PCP**s with fewer queries require verifier time $\Omega(n^2)$ to either verify the response or compute the queries.

1.2 Proof Idea

1.2.1 MA Lower Bounds Using PCP

We first review Santhanam's original proof.

Santhanam's original result uses the fact that if $\mathbf{PSPACE} \subset \mathbf{P/poly}$, then $\mathbf{PSPACE} = \mathbf{MA}$. This follows from the famous result that $\mathbf{IP} = \mathbf{PSPACE}$ [31, 22]. The idea is that if $\mathbf{PSPACE} \subset \mathbf{P/poly}$, then an **MA** protocol can guess a circuit computing any problem in **PSPACE**. The prover in the interactive protocol for **PSPACE** is also computable in **PSPACE**. So to solve any **PSPACE** problem in **MA**, the **MA** protocol first guesses the circuit for a prover, then simulates the verifier using the circuit we guessed as the prover.

Using this, Santhanam's original proof then considered two cases: either $\mathbf{PSPACE} \subset \mathbf{P/poly}$, or $\mathbf{PSPACE} \not\subset \mathbf{P/poly}$.

If $\mathbf{PSPACE} \subset \mathbf{P/poly}$, then we already know $\mathbf{PSPACE} = \mathbf{MA}$. Now we just need a problem not computable by a size n^k circuit. But there is a straightforward algorithm that exhaustively finds a circuit of size larger than n^k that computes a function that cannot be computed by a smaller circuit. In fact, such an algorithm only requires space $\tilde{O}(n^k)$. So $\mathbf{PSPACE} \not\subset \mathbf{SIZE}[n^k]$. In this case, $\mathbf{PSPACE} = \mathbf{MA}$, so $\mathbf{MA} \not\subset \mathbf{SIZE}[n^k]$.

If $\mathbf{PSPACE} \not\subset \mathbf{P/poly}$, then we know a hard problem that is not in $\mathbf{SIZE}[n^k]$, namely any **PSPACE** complete problem. Let us take a **PSPACE** complete, downward self reducible language, Y. Now Y may be too hard for **MA** to solve, but if we give it enough padding, eventually the padded version of Y will be computable by size n^k circuits. But for this amount of padding, **MA** can pull the same trick it does in the $\mathbf{PSPACE} \subset \mathbf{P/poly}$ case. Namely, guess a circuit for Y and then simulate the **IP** protocol for Y. For some **PSPACE** complete Y, the language itself is its proof and this works. The trick is to use just the right amount of padding so it requires circuits of at least size n^k, but not much larger. Santhanam uses the single bit of advice in a clever way to figure out when there is just the right amount of padding.

In either case, the time of this protocol is roughly the time of the verifier in the **IP** protocol, plus the size of the prover circuit times the number of times the prover is queried.

There are two reasons the **MA** protocol could take polynomially more time than the size of the circuits it wants to compute in the case $\mathbf{PSPACE} \subset \mathbf{P/poly}$. One is that the **IP** from the original Santhanam result has polynomial verifier time and a polynomial time interaction with the prover, making the verifier in the $\mathbf{MA}/1$ protocol take polynomially longer than the circuit complexity of the problem being solved. By using a **PCP**, we get better results. The other is that the prover circuit complexity could be large, depending on the circuit size required for **PSPACE** (could be any polynomial when **PSPACE** $\subset$ **P/poly**). This is the reason there is no upper bound on the polynomial run time of the **MA**/1 protocol in Santhanam's proof. To avoid this issue we consider a finer case analysis.

We break the problem into three cases. For some **SPACE**$[O(n)]$ complete language, X, we have one[2] of the following:

1. $X \notin$ **P/poly**.
2. $X \in$ **SIZE**$[n^{1+o(1)}]$.
3. $X \in$ **SIZE**$[n^{a+o(1)}] \setminus$ **SIZE**$[n^{a-o(1)}]$ for some $a > 1$.

The original proof only used the two cases $X \notin$ **P/poly** and $X \in$ **P/poly**. The case where $X \notin$ **P/poly** is completely unchanged. Note that this is the plausible case, and here there is no constant upper bound a on k.

If $X \in$ **P/poly**, we use our efficient **PCP**, Theorem 3, instead of the **IP** Santhanam uses. With this substitution, the case where $X \in$ **SIZE**$[n^{1+o(1)}]$ is almost unchanged from the original proof. By separating this into it's own case, we get tight bounds for all k in this case.

If $X \in$ **SIZE**$[n^{a+o(1)}] \setminus$ **SIZE**$[n^{a-o(1)}]$ for some $a > 1$, then we use the same padding technique we use if $X \notin$ **P/poly**, just using our new **PCP**. In this case, we can only do this if for some $k < a$, we are trying to show **MATIME**$[n^{k+o(1)}]/1 \not\subset$ **SIZE**$[n^{k-o(1)}]$. This is the case where a is finite, but in this case, we can use Santhanam's argument using our **PCP** to get Theorem 2.

To see why $k > a$ poses a difficulty, suppose **SPACE**$[O(n)] \not\subseteq$ **SIZE**$[o(n^2)]$, but **SPACE**$[O(n^2)] \subseteq$ **SIZE**$[O(n^2)]$. Then to get a language requiring size n^3 circuits, we need to use a space n^3 algorithm. But the prover for a space n^3 language is a language running on an input with length n^3, and using space linear in its input length. Thus we may need a size $(n^3)^2 = n^6$ circuit for our prover. So the verifier takes time at least n^6 to even read the prover circuit, thus can't run in time n^3. See Item 2 in our open problems for further explanation.

▶ Remark 7. We note our verifier in Theorem 1 is a RAM machine, *not* a standard Turing Machine. This is because we know how to efficiently simulate a circuit on a RAM machine, but not on a standard Turing Machine.

1.2.2 Verifier Efficient PCP

Now we explain the **PCP** we actually use in the **MA** protocol. We start with a **PCP** similar to [20] and [4] that we refer to as our base **PCP**. This **PCP** has a verifier that runs in time $\tilde{O}(n + \log(T))$ and uses $O(\log(T))$ queries. To reduce the number of queries, we use **PCP** composition [3, 7, 13, 25, 12].

To perform **PCP** composition, we need a robust **PCP**. Loosely, a robust **PCP** is a **PCP** so that when $x \notin L$, for any proof, most sets of queries to that proof return not only a rejected response, but a response that is far from any accepted response. To make our base **PCP** robust, we use the aggregation through curves technique [2]. Now we briefly explain how to use aggregation through curves to convert our base **PCP** into a robust **PCP**.

An honest proof for our base **PCP** is a single low degree polynomial. Suppose our base **PCP** has q queries. To make our **PCP** robust, we first choose the randomness for the base **PCP**, and another random point in the **PCP** proof. Then we find the degree q curve that

[2] This is a trichotomy in an asymptotic sense: for every constant a, either $X \in$ **SIZE**$[O(n^a)]$ or it is not. See Section 3.5 for details.

goes through all these points. Then we check if the proof, restricted to this curve, is a low degree polynomial, and whether the base **PCP** would have accepted on this input. Since a low degree polynomial is an error correcting code, this gives robustness.

One concern one might have with this robust **PCP** is that it actually requires $\Omega(\log(T)^2)$ queries. We don't need to actually calculate all of these query locations. Since we reduce the actual number of queries with **PCP** composition, we only need to be able to calculate any individual query location quickly. To find these query locations requires us to compute a point on the degree q curve going through each of our q points our base **PCP** queries plus a random point. In our base **PCP**, $q = O(\log(T))$ and our proof has dimension $O(\log(T))$. So the naive way to compute this curve is to calculate each coordinate independently, which would take time $\tilde{O}(\log(T)^2)$.

To efficiently compute low degree curves through points, or to extrapolate a function going through those points, we introduce the concept of time extrapolatable functions.

▶ **Definition 8** (Extrapolatability). *For any $n, q, t > 0$, and field $\mathbb{F}$, we call $Q : [q] \to \mathbb{F}^n$ "t extrapolatable" (or time t extrapolatable) if there is a time t algorithm taking any $v \in \mathbb{F}^q$, that outputs*

$$\sum_{i \in [q]} v_i Q(i).$$

Equivalently, if we think of Q as outputting the columns of a matrix, then we say Q is time t extrapolatable if one can multiply a vector with it in time t. An important property of extrapolatable functions is that an extrapolation of an extrapolatable function can be computed efficiently. This is where it gets its name.

Our base **PCP** is just a sum check and a few point checks. Each of these are time $\tilde{O}(\log(T))$ extrapolatable. Our robust **PCP** only queries locations easily computable given the extrapolation of our base **PCP** query locations. Extrapolations of extrapolatable functions are easy to compute, so we can easily compute the query locations of the robust **PCP**.

We also introduce the concept an extrapolatable **PCP** (**ePCP**) as one where an honest proof is a low degree polynomial, and the query locations after fixing a choice of randomness are extrapolatable. We show that any **ePCP** can be extended into a robust **PCP** where the query locations of that robust **PCP** can be computed efficiently.

1.3 Generalization And Sharpness

We actually prove a stronger result than Theorem 1 that is sharp. First, our **MA** protocol is input oblivious: the message from Merlin is just a program for computing a **PSPACE** complete language and doesn't depend on the specific input, just its length. Second, the hardness is against the model used in Merlin's message. We used circuits, but we can describe a randomized algorithm directly to save some polynomial factors.

We define input oblivious Merlin-Arthur time, **OMATIME**, the same way as Fortnow, Santhanam, and Williams [17]. Input oblivious Merlin-Arthur are languages solvable with untrusted advice, where the advice only depends on the input length. In our case, Merlin gets to send a long, untrusted message for every input length, and Arthur also gets a single bit of trusted advice. Note that Santhanam's original proof implicitly also uses input oblivious **MA**.

The main property of circuits we use is that a randomized algorithm can efficiently simulate it. We can instead use $\mathbf{BPTIME}[n^k]/n^k$, that is, randomized algorithms running in time n^k with description length n^k. This uses the same model of computation as our verifier, allowing it to more efficiently simulate **OMATIME**.

Using **OMATIME** instead of **MATIME** and **BPTIME** instead of **SIZE**, we can follow the same proof as our main result to show:

▶ **Theorem 9** (**OMATIME** Lower Bound Against **BPTIME**). *There exists constant $a > 1$, such that for all $k < a$, for some $f(n) = o(1)$,*

$$\mathbf{OMATIME}[O(n^{k+f(n)})]/1 \not\subset \mathbf{BPTIME}[O(n^k)]/O(n^k).$$

This result is tight in the sense that for any function $f(n)$, we have

$$\mathbf{OMATIME}[f(n)]/1 \subseteq \mathbf{BPTIME}[O(f(n))]/(f(n)+1).$$

To get stronger results, we need to use nondeterminism that depends on the input. So one could say our result is less about the power of nondeterminism, and more about the power of trusted versus untrusted advice. Specifically: trusting advice doesn't always buy (much) time in the randomized setting, as long as we have *some* trusted advice.

Let us briefly outline what would need to change in our main proof to prove Theorem 9, and justify why those changes would work.

First we need to make a class of randomized programs that act more like circuits. Consider the class of programs, $\mathcal{C}$, that contain randomized algorithms that work only a specific input length. For any $C \in \mathcal{C}$, we say $C(x)$ is the random variable that simulates C on input x for time $|C|$, and outputs what C does if C terminates in time $|C|$, and outputs 0 otherwise. See that $\mathcal{C}$ behaves like circuits in the following important ways:

1. Given a program $C \in \mathcal{C}$, a randomized algorithm can calculate the random variable $C(x)$ in time $O(|C|)$.
2. For any function $f(n)$ and language $L \in \mathbf{BPTIME}[f(n)]/f(n)$, for every n, there is a $C_n \in \mathcal{C}$ such that $|C_n| = O(f(n))$ and with high probability $C_n(x) = 1_{x \in L}$.

A few notes on using $\mathcal{C}$ in our proof, as opposed to circuits.

1. First, see that $\mathbf{SPACE}[O(n^k)] \not\subseteq \mathbf{BPTIME}[o(n^k)]/o(n^k)$. This follows using the same exhaustive search type algorithm used for $\mathbf{SIZE}[o(n^k)]$.
   For any polynomial n^k, there is a deterministic program, A, with length $O(n^k)$ running in time $O(n^k)$, but is not computable with high probability by any program $C \in \mathcal{C}$ with length $o(n^k)$. This follows from a simple counting argument: length n^k deterministic programs contain more than $2^{\alpha n^k}$ functions for some constant α (just use some lookup table), while there are only $2^{\alpha n^k}$ length αn^k programs.
   Such an A can still be found by exhaustive search in space $O(n^k)$, since given $C \in \mathcal{C}$, we can space efficiently check every choice of randomness and calculate majority. This gives us that
   $$\mathbf{SPACE}[O(n^k)] \not\subseteq \mathbf{BPTIME}[o(n^k)]/o(n^k).$$
2. Given that $L \in \mathbf{BPTIME}[f(n)]/f(n)$, then for any n, there is some advice (notably, a program $C_n \in \mathcal{C}$ with size $|C_n| \leq f(n)$) such that a randomized algorithm given that advice can compute whether $x \in L$ with probability $1 - \epsilon$ in time $O(f(n)\log(\frac{1}{\epsilon}))$.
   This allows our verifier to efficiently compute a $\mathbf{SPACE}[O(n)]$ complete problem, L, in time nearly $f(n)$ if $L \in \mathbf{BPTIME}[f(n)]/f(n)$, given correct advice.
3. We also note that for some programs $C \in \mathcal{C}$, for some inputs x, our program C evaluated on x may answer one or zero with very close to half probability. That is, the syntax of $\mathcal{C}$ does not only give bounded error randomized algorithms, just a randomized algorithm. This is not an issue, because in the completeness case, there will be a program C that does have bounded error the prover should provide. And in the soundness case, the soundness of our **PCP** holds against any multi-prover strategy, even a randomized strategy. So no program provided will convince the verifier with high probability.

Finally, see that in all cases of our proof, Arthur only asks Merlin for a program computing some $\mathbf{SPACE}[O(n)]$ complete problem. This advice does not depend on the specific input, only on the input size.

2 Preliminaries

We assume some familiarity with basic complexity theory. See Arora and Barak's book for background [1]. In this paper, by algorithm, we mean algorithm on a RAM machine, and by circuit, we mean a fan in 2 circuit with unbounded depth. A randomized algorithm is a deterministic algorithm with an extra input for randomness. We will assume in this paper that all time and space bounds for algorithms are sufficiently easily computable.

Now recall that **MA** is the complexity class of problems with polynomial sized certificates that can be verified with bounded error by a randomized, polynomial time algorithm. This is like **NP** with a randomized verifier. Then we define **MATIME** in an analogous way to **NTIME**. Our results have perfect completeness, so we only define **MATIME** with perfect completeness.

▶ **Definition 10** ($\mathbf{MATIME}/1$). *For any function $f : \mathbb{N} \to \mathbb{N}$, define $\mathbf{MATIME}[f(n)]/1$ as the set of languages, L, such that there is a function $b : \mathbb{N} \to \{0,1\}$ and a time $f(n)$ randomized algorithm M taking four inputs, an input x, a random input r, a witness w, and an advice bit such that*

Completeness *If $x \in L$ and $n = |x|$, then there exists w with $|w| \leq f(n)$ such that*

$$\Pr_r[M(x, r, w, b(n)) = 1] = 1.$$

Soundness *If $x \notin L$ and $n = |x|$, then for every w,*

$$\Pr_r[M(x, r, w, b(n)) = 1] < 1/2.$$

We let **SIZE** denote the class of languages with circuits of a given size.

▶ **Definition 11** (**SIZE**). *For any function $f : \mathbb{N} \to \mathbb{N}$, $\mathbf{SIZE}[f(n)]$ is the class of languages, L, where for each input length n, there is a circuit of size $f(n)$ with n inputs computing L for inputs of length n.*

Further, $\mathbf{SIZE}[O(f(n))]$ is the class of languages, L, such that for some $g(n) = O(f(n))$, we have $L \in \mathbf{SIZE}[g(n)]$. Similarly for $\mathbf{SIZE}[o(f(n))]$.

In this paper, we will focus on time and space efficient, non-adaptive **PCP**s with perfect completeness. Because we need to pay close attention to the amount of time it takes to make a single query to the proof, we separate the algorithm for producing queries, Q, from the algorithm for verifying the response, V. We also separate the function that gives all the query locations for a choice of randomness, I, from the algorithm that gives a single one of those query locations, Q.

So at a high level, a **PCP** protocol does the following:

1. Chooses a common random string, r.
2. Runs query function Q with randomness r for $q(n)$ many times to get all query locations, I.
3. Looks up all query locations, I, into a provided proof, π, to get proof window π_I.
4. Runs verifier V with randomness r and proof window π_I and outputs if V accepts.

Now we formally define a **PCP**.

▶ **Definition 12** (**PCP**). *We say that a language L has a non-adaptive* **PCP**, *A, with perfect completeness if there exists verifier V, prover P, index function I, and query function Q, such that, for some alphabet Σ, $\delta \in [0,1]$, and functions $r, l, q : \mathbb{N} \to \mathbb{N}$:*

1. *I takes 2 inputs, an input of length n and randomness of length $r(n)$, and outputs an element of $[l(n)]^{q(n)}$. That is, I outputs $q(n)$ indexes in a length $l(n)$ string,*
2. *Q is an algorithm with three inputs, an input x of length n, randomness r of length $r(n)$, and an index $i \in [q(n)]$ and outputs an element of $[l(n)]$ such that $Q(x, r, i) = I(x, r)_i$.*
3. *V is an algorithm with three inputs, an input of length n, randomness of length $r(n)$, and $q(n)$ symbols from Σ, and outputs either accept or reject.*
4. *P is an algorithm that takes two inputs, an input of length n, and an index $i \in [l(n)]$, and outputs a symbol from Σ.*

Completeness *If $x \in L$ and $n = |x|$, then there exists $\pi^x \in \Sigma^{l(n)}$ such that*

$$\Pr_r[V(x, r, \pi^x_{I(x,r)}) = 1] = 1,$$

and for every $i \in [l(n)]$, $P(x, i) = \pi^x_i$.
Soundness *If $x \notin L$ then for every π',*

$$\Pr_r[V(x, r, \pi'_{I(x,r)}) = 1] \leq \delta.$$

Then we also say:

1. *A has proof length $l(n)$.*
2. *A has alphabet Σ.*
3. *A has soundness δ.*
4. *A uses $q(n)$ queries.*
5. *A uses $r(n)$ bits of randomness.*
6. *If V runs in time $t(n)$, A has verifier time $t(n)$.*
7. *If V runs in space $s(n)$, A has verifier space $s(n)$.*
8. *If P runs in space $s'(n)$, A has prover space $s'(n)$.*
9. *If Q is computable in time $t'(n)$, A has query time $t'(n)$.*

3 Efficient PCP To Fine Grained Lower Bounds

We only give a detailed sketch here. The full version of our paper is available at [9].

Our analysis depends on the circuit complexity of some **PSPACE** complete problem. So we start by choosing a **SPACE**$[O(n)]$ complete problem. We use a version of `SPACE TMSAT` (on page 83 of [1]).

▶ **Definition 13** (Specific Problem). *`SPACE TMSAT` is the language*

$$\{(M, x, 1^n, 0^*) : \text{Turing machine } M \text{ accepts } x \text{ using at most } n \text{ space.}\}$$

Note: `SPACE TMSAT` $\in$ **SPACE**$[O(n)]$ and `SPACE TMSAT` is **SPACE**$[O(n)]$ complete. The 0^* is just there to make it explicit the language is paddable. In particular, this means that the circuit complexity of `SPACE TMSAT` is non-decreasing.

▶ **Lemma 14** (`SPACE TMSAT` Circuit Complexity is Non-Decreasing). *If $A'(n)$ is the size of the minimum circuit solving `SPACE TMSAT` for inputs of length n, then $A'(n)$ is non-decreasing.*

Proof. Let C be the circuit of size $A'(n+1)$ solving `SPACE TMSAT` for length $n+1$ inputs. Then to get a circuit for length n inputs, use C with an extra 0 hard coded into the last input. The resulting circuit will be at most the size of C and solve length n inputs. Thus $A'(n+1) \geq A'(n)$. ◀

Then using Theorem 3, we can get a **PCP** for `SPACE TMSAT` by setting $T = 2^{O(n)}$ and $S = O(n)$. This can be turned into a **PCP** with a binary alphabet by replacing every query for a symbol in Σ with $O(\log(n))$ queries to the individual bits of that symbol.

▶ **Corollary 15** (**PCP** for `SPACE TMSAT`)**.** *There is a* **PCP** *for* `SPACE TMSAT` *with:*

1. *Verifier time* $\tilde{O}(n)$*.*
2. *Query time* $\tilde{O}(n)$*.*
3. $\mathbf{poly}(\log(n))$ *queries.*
4. *Binary alphabet.*
5. *Log of proof length* $\tilde{O}(n)$*.*
6. *Prover space* $\tilde{O}(n)$*.*
7. *Soundness* $1/2$ *and perfect completeness.*

We prove three different **MATIME**/1 lower bounds that are based on three different hard problems. Different ones work better in different parameter regimes. After constructing them all, we show we always fall into some range of parameters so that we can get the lower bounds of Theorem 1.

3.1 Implicitly Encoding Advice in Input Length

In each of our cases, we will use advice to find the size of some prover circuit. To do this, we implicitly encode a number in the input length. If that implicitly encoded number describes the size, our advice bit will be 1. Otherwise, the advice bit is 0.

For any input length $n \in \mathbb{N}$, for some $l \in \mathbb{N}$, we have $n \in [2^l, 2^{l+1})$. For such an l, there is some $m \in \mathbb{N}$ such that $n = 2^l + m$. This m, or equivalently this l, is our implicitly encoded number. Because we will use this decomposition a lot, we will explicitly define some functions that perform this decomposition.

▶ **Definition 16** (Implicit Encoding In Input)**.** *For natural* $n \geq 1$*, let* $l \geq 0$ *be an integer so that* $n \in [2^l, 2^{l+1})$*, and* $m \geq 0$ *be an integer so that* $n = 2^l + m$*. Then define* $\mu(n) = m$ *and* $\rho(n) = l$*.*

There is a simple interpretation of this $m = \mu(n)$ and $l = \rho(n)$ in terms of the binary representation of n. You can think of l as the length of the binary number, and m the binary number after the top bit is removed.

3.2 SPACE TMSAT not in P/poly

In this case, we follow the proof in the original work [29] where **PSPACE** $\not\subset$ **P/poly**. We present the same arguments here with more precise parameters.

When **PSPACE** $\not\subset$ **P/poly**, the circuit complexity of `SPACE TMSAT` for different input sizes could change drastically and in a way that may be hard to analyze. This is an issue because the **PCP** for `SPACE TMSAT` needs a prover with a longer input than the input being verified, thus might require a much larger circuit.

Instead, we use a downward self reducible **PSPACE** complete language. Specifically, a language that has a sound interactive protocol with queries the same length as its input and whose prover is the language itself. We cite the result from Lemma 11 in [29]:

▶ **Lemma 17** (Same Size, Self Proving **PSPACE** Complete Language)**.** *There is a* **PSPACE**-*complete language Y and a probabilistic polynomial-time oracle Turing machine M such that for any input x:*

1. *M only asks its oracle queries of length $|x|$.*
2. *If M is given Y as oracle and $x \in Y$, then M accepts with probability 1.*
3. *If $x \notin Y$, then irrespective of the oracle given to M, M rejects with probability at least $1/2$.*

The important feature of language Y is that for an input x, the prover for x is the same language Y, and queries to the prover have the same length as x. This means Y, and the prover for Y, have the same circuit. Then if $\mathbf{PSPACE} \not\subset \mathbf{P/poly}$, then the polynomial overhead of the proof protocol grows much more slowly than the difficulty of Y. So a padded version of Y can be used as our language in this case. A proof sketch is in Appendix A, full proofs are in the full version [9].

▶ **Lemma 18** (Bound if **PSPACE** does not have Polynomial Sized Circuits)**.** *If* `SPACE TMSAT` $\notin$ **P/poly***, then for any $k > 0$, and some $f(n) = o(1)$:*

$$\mathbf{MATIME}[O(n^{k+f(n)})]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

3.3 SPACE TMSAT in Almost Linear Size

The idea in this case is to use a brute force, small space algorithm that finds a problem not in a fixed polynomial size. In particular, for circuit size $S(n)$, the brute force algorithm uses space $O(S(n))$ to compute some function with minimum circuit size $\Theta(S(n))$. Then we want to simulate the **PCP** from Corollary 15 to prove the output of this algorithm. Since the **PCP** is efficient, the prover for this algorithm does not use much more space than the brute force algorithm itself.

If `SPACE TMSAT` has almost linear sized circuits, the prover doesn't require much larger circuits than the space of the prover. Finally, our **PCP** is efficient, so the time of the **MA** verifier isn't much more than the size of the prover circuit. So the **MA** protocol doesn't require much more time then the size of the circuit it proves the output of.

If `SPACE TMSAT` requires larger circuits, say quadratic circuits, then the size of the prover circuits would be quadratically larger than the input length of the prover. That is, the prover circuit would be quadratically larger than the circuit it is trying to prove. This would give quadratic overhead for the **MA** verifier time over the size of the circuit it verifies. So this construction only works well enough when `SPACE TMSAT` has almost linear sized circuits.

So this gives a proof when `SPACE TMSAT` has almost linear sized circuits. A proof sketch is in Appendix A, full proofs are in the full version [9].

▶ **Lemma 19** (Bound if `SPACE TMSAT` has Size $n^{1+o(1)}$)**.** *If for some $g(n) = o(1)$ and some non-decreasing function $A(n) = n^{1+g(n)}$ we have* `SPACE TMSAT` $\in \mathbf{SIZE}[O(A(n))]$*, then for any $k > 0$, there is an $f(n) = o(1)$ such that:*

$$\mathbf{MATIME}[O(n^{k+f(n)})]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

3.4 SPACE TMSAT in Polynomial Size, but not Almost Linear

This is the "bad" case, where we can't prove the result for every constant k, only for $k < a$. This is the most complicated case, requiring us to both pad the input to get the correct problem difficulty, and use advice to get the size of the circuits for the prover. The idea is to solve `SPACE TMSAT` on a padded version of the input using our **PCP**. So we need the advice to tell us three things:

1. Some m so that SPACE TMSAT on length m inputs requires circuits of size $\omega(n^k)$.
2. Further, we need SPACE TMSAT on length m inputs to require circuits of size near m^a. This keeps the prover from requiring circuits too much larger than SPACE TMSAT on length m inputs does.
3. How big the circuit for the prover in Corollary 15 needs to be.

Similar to the previous cases, this advice will come implicitly from the input length, and the single advice bit will be 1 if and only if the input length encodes valid advice. A skectch is in Appendix A. For full details, see the full version [9].

▶ **Lemma 20** (Bound if SPACE TMSAT has size $n^{a+o(1)}$). *Suppose for some function $h(n)$ with $|h(n)| = o(1)$ and for some constant $a > 1$, for some function $A(n)$ we have $A(n) = n^{a+h(n)}$. Then if $A(n)$ is non-decreasing and we have SPACE TMSAT $\in \mathbf{SIZE}[O(A(n))] \setminus \mathbf{SIZE}[o(A(n))]$, then for any $k < a$, for some $f(n) = o(1)$,*

$$\mathbf{MATIME}[O(n^{k+f(n)})]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

3.5 Altogether

Altogether, these three cases imply Theorem 1. More details can be found in the full version [9].

▶ **Theorem 1** (Fine Grained **MA** Lower Bound). *There exists a constant $a > 1$, such that for all $k < a$, for some $f(n) = o(1)$,*

$$\mathbf{MATIME}[O(n^{k+f(n)})]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

Proof. First, we will find the best polynomial approximation of the circuit complexity of SPACE TMSAT. So define set

$$S = \{a \in \mathbb{R} : \texttt{SPACE TMSAT} \in \mathbf{SIZE}[O(n^a)]\}.$$

If $S = \emptyset$, then there is no constant a such that SPACE TMSAT $\in \mathbf{SIZE}[O(n^a)]$. Then SPACE TMSAT $\notin \mathbf{P/poly}$, so we use Lemma 18.

So suppose $S \neq \emptyset$. One can show that SPACE TMSAT requires linear size circuits since it depends on all inputs. Thus for any $a < 1$, we know that SPACE TMSAT $\notin \mathbf{SIZE}[O(n^a)]$, that is $a \notin S$. So 1 is a lower bound for S.

Then the set S is nonempty and has a lower bound. So S has an infimum, a, so that for any constant $\epsilon > 0$, we have SPACE TMSAT $\in \mathbf{SIZE}[O(n^{a+\epsilon})]$, but SPACE TMSAT $\notin \mathbf{SIZE}[O(n^{a-\epsilon})]$. This implies that for some $h(n)$ with $|h(n)| = o(1)$ and $A(n) = n^{a+h(n)}$ that SPACE TMSAT $\in \mathbf{SIZE}[O(A(n))] \setminus \mathbf{SIZE}[o(A(n))]$.

If $a = 1$, we use Lemma 19. If $a > 1$, we use Lemma 20. ◀

To prove Theorem 2, we use a proof similar to Lemma 19. See the full paper [9] for details.

4 PCP Sketch

We give a brief overview of the **PCP** proof. A full proof is available at [9].

Our overall protocol constructs an extrapolatable **PCP** by observing that a simple BFL style **PCP** is extrapolatable. Then this can be turned into an **rPCP** with an efficient query function. Finally we can compose this with a decodable, BFL style **PCP** with a very fast verifier.

4.1 Extrapolatable PCPs

We start by showing some lemmas about extrapolatability that make the definition easy to work with. Notably, if 2 functions are extrapolatable, so is their concatenation. This allows us to show components of a **PCP** are extrapolatable individually to get an extrapolatable **PCP**.

▶ **Lemma 21** (Extrapolatability Combination). *For integers $n, q, q', t, t' > 0$, and field $\mathbb{F}$, if $p : [q] \to \mathbb{F}^n$ is t extrapolatable, and $p' : [q'] \to \mathbb{F}^n$ is t' extrapolatable, then $g : [q + q'] \to \mathbb{F}^n$ is $O(t + t' + n\log(\mathbb{F}))$ extrapolatable where*

$$g(i) = \begin{cases} p(i) & i \leq q \\ p'(i-q) & i > q \end{cases}.$$

Of course, extrapolatability's main purpose is to allow efficient extrapolation.

▶ **Lemma 22** (Efficient Polynomials From Extrapolatability). *For any $n, q, t > 0$, field $\mathbb{F}$ where $|\mathbb{F}| > q$, and t extrapolatable $Q : [q] \to \mathbb{F}^n$, there is a time $O(t + q\,\mathbf{polylog}(|\mathbb{F}|))$ algorithm computing the value of a degree $q - 1$ polynomial, g, such that for all $i \in [q]$ we have $g(i) = Q(i)$.*

Now we introduce extrapolatable **PCP**s and show they imply robust **PCP**s with fast query functions. Extrapolatable **PCP**s are **PCP**s whose proofs are low degree functions, only require soundness against proofs that are low degree functions, and whose query location function is extrapolatable.

In our notation, the query function Q returns a single query location of the verifier V on a choice of randomness, whereas I returns every query location for a choice of randomness. Query function, Q, needs to be extrapolatable, but index function, I, is more convenient for defining completeness and soundness. See standard **PCP**s, Definition 12, for reference.

▶ **Definition 23** (Extrapolatable **PCP**). *We say a non-adaptive **PCP**, A, for language L with verifier V, prover P, individual query function Q, and index function I is an extrapolatable **PCP** (**ePCP**) if for some m and d:*

1. *For some field $\mathbb{F}$, A uses alphabet $\mathbb{F}$.*
2. *The proof length is $|\mathbb{F}|^m$.*
   That is, any proof, π, can be viewed as a function $\pi : \mathbb{F}^m \to \mathbb{F}$.

Low Degree Completeness *If $x \in L$ and $n = |x|$, then there exists a polynomial $\pi^x : \mathbb{F}^n \to \mathbb{F}$ of degree at most d such that $\Pr_r[V(x, r, \pi^x(I(x, r))) = 1] = 1$, and for every $i \in [l(n)]$, we have $P(x, i) = \pi^x_i$.*

Low Degree Soundness *If $x \notin L$ then for every polynomial $\pi' : \mathbb{F}^n \to \mathbb{F}$ of degree at most d has $\Pr_r[V(x, r, \pi'(I(x, r))) = 1] \leq \delta$.*

Further, we say A has:

1. *Extrapolation time $t(n)$ if for any x, r, the function $Q_{x,r}(i) = Q(x, r, i)$ is time $t(n)$ extrapolatable.*
2. *Degree d and m variables.*
3. *Low degree soundness δ.*
4. *Perfect low degree completeness.*

The main application of an **ePCP** is a convenient primitive in constructing efficient robust **PCP**s (**rPCP**). Robust **PCP**s are a standard primitive in the literature and are commonly used in **PCP** composition [3, 7, 13, 25, 12]. This conversion of **ePCP** to **rPCP** is where all the low degree testing is performed. But low degree test queries are simple lines so are easy to compute. Note that our **rPCP**s constructed from an **ePCP** uses the same proof, so if the **ePCP** prover is efficient, so is the **rPCP** prover. See the full paper [9] for a proof.

▶ **Theorem 24** (**ePCP** gives efficient **rPCP**). *For any language L with an* **ePCP**, *A, with*

1. *Verifier time $t(n)$.*
2. *Verifier space $s(n)$.*
3. *Extrapolation time $t'(n)$.*
4. *Randomness $r(n)$.*
5. *Degree $d(n)$ and $m(n)$ variables.*
6. *$q(n)$ queries.*
7. *Alphabet $\mathbb{F}$ where $|\mathbb{F}| > 10q(n)d(n)$.*
8. *Prover P.*
9. *Low degree soundness 0.1.*
10. *Perfect low degree completeness.*

Language L has an **rPCP**, *B, with*

1. *Verifier time $O(t(n) + |\mathbb{F}|^3\mathbf{polylog}(|\mathbb{F}|))$.*
2. *Verifier space $O(s(n) + \log(|\mathbb{F}|))$.*
3. *Randomness $r(n) + O(m(n)\log(|\mathbb{F}|))$.*
4. *Query time $O(t'(n) + (q(n) + m(n))\mathbf{polylog}(|\mathbb{F}|))$.*
5. *$O(|\mathbb{F}|)$ queries.*
6. *Prover P with perfect completeness.*
7. *Soundness at most 0.99.*

4.2 Constructing our Extrapolatable PCP

Our **ePCP** is a BFL [4] style **PCP**. We start by converting our algorithm into a cellular automata so that it has very uniform, local constraints, similar to the Cook-Levin theorem [10, 21], or what was done in [20]. In particular, the constraints can be described by a simple polynomial of the computation history of the cellular automata.

Then our **ePCP** will ask for a multilinear extension of the computation history, a low degree polynomial encoding the constraint function of that computation history, and a sum check [22] style proof verifying that constraint is always satisfied. Then the verifier just needs to check the computation history is consistent with the input, the constraint polynomial is consistent with the computation history polynomial, and the sum check of the constraint polynomial succeeds. All low degree testing is handled in the conversion from an **ePCP** to an **rPCP**.

Now we verify that a variation on standard sum check [22, 4] is extrapolatable. Since **ePCP**s only need soundness against low degree proofs, our base **ePCP** only needs to perform constantly many queries besides the sum check. So the check sum is the most difficult thing to prove the extrapolatability of.

▶ **Lemma 25** (Sum Check Queries Are Extrapolatable). *For any variable number $n \in \mathbb{N}$, degree $d \in \mathbb{N}$, field $\mathbb{F}$ with $|\mathbb{F}| > \max\{d, n\} + 1$, and randomness r, the query location function, Q_r, used in the sum check protocol for a degree d and n variable function are $O(nd\mathbf{polylog}(|\mathbb{F}|))$ extrapolatable.*

The proof is straightforward and comes from a close observation of the specific sum check query locations.

We need a low space prover to use in our **MA** lower bounds. Creating the computation history itself takes about as much space as the original algorithm. Multilinear extensions can be done straightforwardly in small space if one only needs one symbol, or does not care about time.

▶ **Lemma 26** (Multilinear Extensions Require Low Space). *Suppose function $G : \{0,1\}^n \to \{0,1\}$ is computable in space S. Then the multilinear function g consistent with G on Boolean inputs is computable in space $O(n \log(|\mathbb{F}|) + S)$.*

Similarly, individual symbols from the constraint polynomial can be computed in small space from the multilinear extension of the computation history. The sum check proof is essentially partial linearizations of the constraint polynomial, so can also be done in small space.

4.3 Decodable PCP

After that, we use a similar **PCP** for the decodable inner **PCP** (**dPCP**), and apply a standard robust, decodable **PCP** composition [12]. Essentially only two changes need to be made to get our **dPCP**. First we need to only check consistency of the computation history with the explicit input (and *not* the implicit input). Second, we need to do an additional query to an implicit input to decode from it. This does not require any new tricks.

Finally, we do a standard **PCP** composition of a robust **PCP** with a decodable **PCP** to do query reduction. We note that we can not do the standard trick of having the outer **rPCP** output a circuit that the inner **dPCP** proves the output of as that circuit description would be too large for a verifier to compute. Instead this must be done implicitly, similar to [5]. We also note that to keep the space of the inner **PCP** prover small requires the space of the outer **PCP** prover, the space of the outer query function, *and* the space of the outer **PCP** verifier to be small.

4.4 Fine Grained MIP = NEXP

We note that the low space and deterministic algorithm requirements were only to keep the prover space low. Dropping the prover space requirement and using the same proof gives Theorem 4. Then using Theorem 4, one can use a standard technique to get $\frac{1}{\mathbf{polylog}(n)}$ error, 2 query **PCP**. Combining this with a repetition theorem [28, 19, 27] gives the 2 query, constant error **MIP** stated in Corollary 5.

5 Open Problems

There are several ways we would like to improve the circuit lower bounds.

1. Remove the advice bit.
   We still had to use advice, a limitation from the original Santhanam result. It would be nice if we could get lower bounds on **MA** with no non-uniformity.
2. Prove tight bounds for all k.
   Another limitation of our circuit lower bound is that it does not prove this tight bound for all $k > 1$, just for some k.

The major barrier is in the case that **SPACE**$[n]$ algorithms may require super linear, but polynomial, sized circuits. Then the circuit size required for any given space may change in a strange way. For example, suppose for some $a > 1$

$$\mathbf{SPACE}[n] \subseteq \mathbf{SIZE}[O(n^a)] \setminus \mathbf{SIZE}[o(n^a)].$$

What we would like, but this does not obviously imply, is that for all $b > 1$:

$$\mathbf{SPACE}[n^b] \subseteq \mathbf{SIZE}[O(n^{ab})] \setminus \mathbf{SIZE}[o(n^{ab})].$$

While a padding argument shows $\mathbf{SPACE}[n^b] \subseteq \mathbf{SIZE}[O(n^{ab})]$, it does not show that $\mathbf{SPACE}[n^b] \not\subseteq \mathbf{SIZE}[o(n^{ab})]$.

3. Make lower bound more frequent.
   We only prove that infinitely often this lower bound occurs, but it may have even super exponential gaps between input sizes where the circuit lower bound holds. Murray and Williams [26] gave a refinement of the Santhanam circuit lower bounds, that is incomparable to ours, which gives circuit lower bounds that holds for input lengths only polynomially far apart.
4. Prove exponential lower bounds for **MAEXP**.
   A similar problem is to prove exponential circuit lower bounds for the exponential version of **MA**, known as **MAEXP**. The best circuit lower bounds known for **MAEXP** are “half-exponential” by Miltersen, Vinodchandran, and Watanabe [24]. Loosely, a function is half exponential if that function composed with itself is exponential.

Another open problem is to give a **PCP** whose verifier time matches ours with only quasilinear proof length. Known **PCP**s with proof length $\tilde{O}(T)$ have verifier time $\Omega(n + \log(T)^2)$. We suspect ideas from theorem 2.6 in [5][3] (which extends the results of [7] from **NP** to **NEXP**) may give a **PCP** with verifier time near $\tilde{O}(n + \log(T))$ while giving a proof of length $T^{1+o(1)}$. But it would not have proof length $\tilde{O}(T) = T\mathbf{polylog}(T)$. We stress that close analysis of the verifier time for the **PCP** of [5] has not been performed, and that **PCP** is much more complex than ours.

A MA Circuit Lower Bound Proofs

In this section, we sketch the proofs of the main lemmas of Section 3. Full proofs are available in the full version [9].

▶ **Lemma 18** (Bound if **PSPACE** does not have Polynomial Sized Circuits). *If SPACE TMSAT $\notin$ $\mathbf{P/poly}$, then for any $k > 0$, and some $f(n) = o(1)$:*

$$\mathbf{MATIME}[O(n^{k+f(n)})]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

Proof. The idea is to take length m inputs to Y, pad them up to length n inputs so that Y on length m inputs requires, and has, circuits of size just slightly larger than n^k. Then as long as n grows much faster than m, the overhead of the interactive protocol verifier will be small and we only need to focus on prover overhead, which is around n^k since the circuit for Y is the prover for Y.

First, I claim that, since $Y \notin \mathbf{P/poly}$, for some $g(n) = \omega(1)$, we have $Y \notin \mathbf{SIZE}[O(n^{g(n)})]$. If this was not true, then Y must have circuits of size n^k for some k upper bounding the best choice of $g(n)$.

Now we define our language, W, in $\mathbf{MATIME}[n^{k+f(n)}]/1$ but not in $\mathbf{SIZE}[O(n^k)]$. For any input size, n, using Definition 16, let $m = \mu(n)$ and $l = \rho(n)$. Let our advice bit be 1 if both:

1. Y on length m inputs has circuits with size $n^k \log(n)$. This makes sure there is a fast prover for Y.
2. And Y on length m inputs does not have circuits of size $m^{g(m)}$. This makes sure m grows much more slowly than n.

Then $x \in W$ for some x with $|x| = n$ if and only if the advice bit is 1 and for some $y \in Y$ with $|y| = m$ we have $x = y1^{n-m}$.

Let $a > 0$ be the constant so that the verifier (M in Lemma 17) for Y's interactive protocol runs in time $O(n^a)$. Define the $\mathbf{MA}$ protocol as follows. If the trusted advice bit is one, Merlin gives Arthur a length $n^k \log(n)$ circuit. Then Arthur simulates the interactive protocol for Y on y using the circuit from Merlin as the prover. This protocol runs in time $O(m^a n^k \log(n))$. By assumption we have $m^{g(m)} < n^k \log(n)$, which one can show implies $m < n^{f'(n)}$ for some $f'(n) = o(1)$. Thus the $\mathbf{MA}/1$ protocol runs in time $O(n^{f'(n)} n^k \log(n)^2) = n^{k+f(n)}$ for some $f(n) = o(1)$.

By choice of $g(m)$, for infinitely many m, the second condition is satisfied and $g(m) > k+1$. For such m, the smallest choice of $n = 2^l + m$ where Y on length m inputs has circuits of size $n^k \log(n)$ can not have circuits of size $(n/2)^k \log(n/2)$. For such n, language W does not have circuits of size $O(n^k)$, but does have an $\mathbf{MA}$ protocol running in time $n^{k+f(n)}$. ◀

▶ **Lemma 19** (Bound if `SPACE TMSAT` has Size $n^{1+o(1)}$). *If for some $g(n) = o(1)$ and some non-decreasing function $A(n) = n^{1+g(n)}$ we have `SPACE TMSAT` $\in \mathbf{SIZE}[O(A(n))]$, then for any $k > 0$, there is an $f(n) = o(1)$ such that:*

$$\mathbf{MATIME}[O(n^{k+f(n)})]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

Proof. The proof proceeds in five steps.

1. Find a language $L \in \mathbf{SPACE}[n^k \log(n)^2] \setminus \mathbf{SIZE}[n^k \log(n)/10]$. In particular, for every input length n, language L has circuits of size $n^k \log(n)$ but not $n^k \log(n)/10$.
2. Reduce L to `SPACE TMSAT` and use Corollary 15. In particular, find a circuit, C_n, for the prover in an $\mathbf{MA}$ protocol for L on length n inputs.
3. Define our advice bit to implicitly give an upper bound for the size of C_m for some m within a factor of 2 of n. Then we define W to be length m elements of L, padded to length n.
4. Show that infinitely often the advice bit is 1 and W does not have small circuits.
5. Show that W has an efficient $\mathbf{MA}$ protocol.

With that outline in mind, let us begin the proof.

1. Find a language $L \in \mathbf{SPACE}[n^k \log(n)^2] \setminus \mathbf{SIZE}[n^k \log(n)/10]$.
   From the non-uniform hierarchy (in Arora and Barak [1, Theorem 6.22]), there is a language $L \in \mathbf{SIZE}[n^k \log(n)] \setminus \mathbf{SIZE}[n^k \log(n)/10]$. In particular, for every n, language L on length n has circuits size $n^k \log(n)$ but not size $n^k \log(n)/10$. A brute force search can then find and simulate such a circuit using space $O(n^k \log(n)^2)$.
2. Reduce L to `SPACE TMSAT` and use Corollary 15.
   Since M only uses space $g(n) = \tilde{O}(n^k)$, we know $x \in L$ if and only if $(M, x, 1^{g(n)}, 0) \in$ `SPACE TMSAT`. We know `SPACE TMSAT` on length $\tilde{O}(n^k)$ inputs has a $\mathbf{PCP}$ protocol from Corollary 15 that uses $\mathbf{polylog}(n)$ many length $\tilde{O}(n^k)$ queries to a space $\tilde{O}(n^k)$ prover, P, where each query can be calculated by a time $\tilde{O}(n^k)$ algorithm, Q, and the results from P are verified by a time $\tilde{O}(n^k)$ verifier, V.

Now we reduce the prover P to `SPACE TMSAT` so we can use that `SPACE TMSAT` $\in$ $\mathbf{SIZE}[O(n^{1+g(n)})]$ to get a circuit for P. A length $\tilde{O}(n^k)$ query, q, to P can be converted into a length $\tilde{O}(n^k)$ input, q', for `SPACE TMSAT` by providing the algorithm for P and $\tilde{O}(n^k)$ 1s. Call the circuit for `SPACE TMSAT` on length $|q'|$ inputs C_n. Since `SPACE TMSAT` $\in \mathbf{SIZE}[O(n^{1+g(n)})]$, we know C_n has size $(\tilde{O}(n^k))^{1+g(n)} = n^{k+g'(n)}$ for some $g'(n) = o(1)$.

3. Define our advice bit.

Now an **MA** protocol can guess C_n, but we may not be able to compute how large C_n needs to be. The function $g'(n)$ may be hard to compute. So we use advice.

Let $l = \rho(n)$, $m = 2^l$ and $t = \mu(n)$ so that $n = m + t$. Then let the advice bit be 1 if

a. Circuit C_m has size $m^k 2^t$.

b. For any natural t' less than t, circuit C_m does not have size $m^k 2^{t'}$.

This condition allows us to use the smallest t possible for a given m.

Then $x \in W$ for some x with $|x| = n$ if and only if the advice bit is 1 and for some $y \in$ `SPACE TMSAT` with $|y| = m$ we have $x = y1^{n-m}$.

4. Show W does not have small circuits.

First see that for every large enough l, for $m = 2^l$, there will be one t such that this advice bit is 1. That is for some $t < m$, C_m has size $m^k 2^t$. Otherwise, C_m would have exponential size, but it only has almost linear size. Then for the minimum such t, the advice bit will be one. So infinitely often, the advice bit will be 1.

When the advice bit is 1, the language W on length $n = m + t$ inputs is equal to L on length m inputs. Language L on length m inputs does not have circuits of size $m^k \log(m)/10$. See by choice of m that $2m > n$, so $n^k = o(m^k \log(m)/10)$. Thus infinitely often, W does not have size n^k circuits. Thus $W \notin \mathbf{SIZE}[O(n^k]$.

5. Show W has an efficient **MA** protocol.

If the advice bit is 0, this is trivially true. For $n = 2^l + t$ so that the advice bit is 1 and $m = 2^l$, either

$t = 0$**:** Then C_m has size $n^k = O(m^{k+g'(m)})$.

$t \geq 1$**:** Then C_m has size $m^k 2^t$ but not $m^k 2^{t-1}$. Since C_m does have circuits of size $m^{k+g'(m)}$, we have $m^k 2^t = O(m^{k+g'(m)})$.

In either case, an **MA** protocol can guess C_m with a circuit with size $O(m^{k+g'(m)})$.

Then an **MA** protocol for $x = y1^{n-m}$ and an advice bit of 1 can verify if $y \in L$ by first guessing a circuit for C_m, then using it as the prover in the **PCP** protocol from Corollary 15.

The **MA** verifier needs to calculate $\mathbf{polylog}(m)$ queries with Q, run C_m on each of those queries, and run V on those results. Since C_m has size $O(m^{k+g'(m)})$, and Q and V run in time $\tilde{O}(m^{k+g'(m)})$, calculating all query locations, running C_m on each of those locations, and V on those outputs takes time

$$\begin{aligned} &\mathbf{polylog}(m)(\tilde{O}(m^k) + O(m^{k+g'(m)})) + \tilde{O}(m^k) \\ =&\tilde{O}(m^{k+g'(m)}). \end{aligned}$$

Finally, since $m < n$, for some $f(n) = o(1)$, the **MA** verifier runs in time $n^{k+f(n)}$.

The **MA** protocol is complete and sound since the **PCP** is. Thus

$$W \in \mathbf{MATIME}[O(n^{k+f(n)})]/1. \qquad \blacktriangleleft$$

▶ **Lemma 20** (Bound if `SPACE TMSAT` has size $n^{a+o(1)}$)**.** *Suppose for some function $h(n)$ with $|h(n)| = o(1)$ and for some constant $a > 1$, for some function $A(n)$ we have $A(n) = n^{a+h(n)}$. Then if $A(n)$ is non-decreasing and we have `SPACE TMSAT` $\in \mathbf{SIZE}[O(A(n))] \setminus \mathbf{SIZE}[o(A(n))]$, then for any $k < a$, for some $f(n) = o(1)$,*

$$\mathbf{MATIME}[O(n^{k+f(n)})]/1 \not\subset \mathbf{SIZE}[O(n^k)].$$

Proof. We want to solve a smaller instance of `SPACE TMSAT` that requires circuits of size $n^k \log(n)$, and we also need advice to tell us the size of circuits needed to prove `SPACE TMSAT`. The advice for this will come implicitly from the input length.

For input x of length n, (using ρ and μ from Definition 16) let $l = \rho(n)$, $l' = \rho(\mu(n))$, and $t = \mu(\mu(n))$ so that $n = 2^l + 2^{l'} + t$. We want to solve `SPACE TMSAT` on length $2^{l'}$ inputs, so we let $m := 2^{l'}$. Then $n = 2^l + m + t$ and our language will solve length m inputs for `SPACE TMSAT` using prover circuits of size $(2^l)^k 2^t$. Our advice bit will tell us when 2^l, m and t are appropriate.

So then m is the input length to `SPACE TMSAT` we want to solve, 2^l is how much padding is needed to make length m problems the right difficulty, and $(2^l)^k 2^t$ is the size of the circuits needed for our **PCP** prover.

The proof proceeds in 4 steps.

1. Define circuits C_m that prove `SPACE TMSAT` for length m inputs using our **PCP** and our theorem assumptions on circuits for `SPACE TMSAT`.
2. Define when the advice bit should be 1.
3. Show infinitely often the advice bit is 1 and $W \notin \mathbf{SIZE}[O(n^k)]$.
4. Show that W has an efficient **MA** protocol.

Now following this outline:

1. Define circuits C_m that prove `SPACE TMSAT` for length m inputs.
   Then `SPACE TMSAT` on length m inputs has a **PCP** protocol with verifier time $\tilde{O}(m)$, log of proof length $\tilde{O}(m)$, and prover space $\tilde{O}(m)$. Then the prover for `SPACE TMSAT` on length m inputs can be reduced to a circuit for `SPACE TMSAT` with length $\tilde{O}(m)$ inputs. Then `SPACE TMSAT` on length $\tilde{O}(m)$ inputs has a circuit, C_m, of size at most $\tilde{O}(m)^{a+h(m)}$. So for some $h'(m) = o(1)$, we have $|C_m| \le m^{a+h'(m)}$.
2. Define when the advice bit should be 1.
   Since `SPACE TMSAT` $\notin \mathbf{SIZE}[o(A(n))]$, for some $c_1 > 0$, for some infinite set, U', for all $n' \in U'$, language `SPACE TMSAT` on length n' inputs does not have circuits with size $c_1 A(n')$.
   Let the advice bit be 1 if and only if each of the following hold:
   a. `SPACE TMSAT` on length m inputs does not have circuits with size at most $c_1 A(m/2)$. This restricts us to m where the circuits for `SPACE TMSAT` require size near our upper bound. This limits how much bigger C_m needs to be than the circuits for `SPACE TMSAT` on length m inputs.
   b. `SPACE TMSAT` on length m inputs does not have a circuit with size $(l-1)(2^{l-1})^k$.
   c. `SPACE TMSAT` on length m inputs does have a circuit with size $l(2^l)^k$.
   d. Circuit C_m has size $(2^l)^k 2^t$.
   e. Either $t = 0$, or C_m does not have size $(2^l)^k 2^{t-1}$.
   Then $x \in W$ for some x with $|x| = n$ if and only the advice bit is 1 and for some $y \in$ `SPACE TMSAT` with $|y| = m$ we have $x = y1^{n-m}$.
3. Now we will argue that infinitely often the advice bit is 1 and W does not have circuits with size $O(n^k)$. See the full version [9] for full details. We do this in a few steps:

- First restrict our focus to m large enough and where `SPACE TMSAT` on length m inputs requires circuits of size at least $c_1 A(m/2)$. This will be the set of input lengths, U. Since m can be any power of 2 and A is monotone, as long as A is tight, we can always find an infinite set of $m = 2^{l'}$ such that `SPACE TMSAT` on length m inputs requires circuits of size $A(m/2)$.
- For each $m \in U$, find appropriate l and t.
  Take the smallest l so that `SPACE TMSAT` on length m inputs does have a circuit of size $l(2^l)^k$. Note that $l > l' = \log(m)$, since `SPACE TMSAT` on length m inputs does not have circuits with size $m^k \log(m)$ since $k < a$.
  Let t be the smallest t such that C_m has size $(2^l)^k 2^t$. Since we know C_m has poly sized circuits, we know that some $t < m$ achieves this.
- Now for $n = 2^l + m + t$, the advice bit is 1 and language `SPACE TMSAT` on length n inputs does not have circuits with size $O(n^k)$.

4. Show that

$$W \in \mathbf{MATIME}\left[n^{k+f(n)}\right]/1.$$

If the advice bit is 0, this is trivial. Otherwise, assume for n the advice bit is 1.
When the advice bit is 1, we know C_m has size at most $(2^l)^k 2^t$ and either

$t = 0$: Then C_m has size $(2^l)^k = O(n^k)$.

$t \geq 1$: Then C_m does not have size $(2^l)^k 2^{t-1}$ by choice of t. Circuit C_m has size $m^{a+h'(m)}$. Further, `SPACE TMSAT` on length m inputs does not have circuits with size $c_1 A(m/2)$ since the advice bit is 1, but it does have circuits with size $l(2^l)^k$. Together this implies that

$$\begin{aligned} c_1 A(m/2)\frac{2^{t-1}}{l} &< m^{a+h'(m)} \\ 2^t &< \frac{2}{c_1}\frac{l m^{a+h'(m)}}{A(m/2)}. \end{aligned}$$

Then one can show that $2^t = m^{o(1)}$. So for some $f'(n) = o(1)$ we have $(2^l)^k 2^t = n^{k+f'(n)}$.

The verifier for `SPACE TMSAT` can be simulated in time $\tilde{O}(m)$, and the $\mathbf{poly}(\log(m))$ queries to the prover can be simulated in time

$$\mathbf{poly}(\log(m))S(2^l)2^t = n^{k+f(n)}$$

for some $f(n) = o(1)$. Thus

$$W \in \mathbf{MATIME}\left[n^{k+f(n)}\right]/1.$$

Abstract

We show that the space-bounded Statistical Zero Knowledge classes $\mathsf{SZK}_{\mathsf{L}}$ and $\mathsf{NISZK}_{\mathsf{L}}$ are surprisingly robust, in that the power of the verifier and simulator can be strengthened or weakened without affecting the resulting class. Coupled with other recent characterizations of these classes [4], this can be viewed as lending support to the conjecture that these classes may coincide with the non-space-bounded classes SZK and NISZK, respectively.

1 Introduction

The complexity class SZK (Statistical Zero Knowledge) and its "non-interactive" subclass NISZK have been studied intensively by the research communities in cryptography and computational complexity theory. In [12], a space-bounded version of SZK, denoted $\mathsf{SZK}_{\mathsf{L}}$ was introduced, primarily as a tool for understanding the complexity of estimating the entropy of distributions represented by very simple computational models (such as low-degree polynomials, and NC^0 circuits). There, it was shown that $\mathsf{SZK}_{\mathsf{L}}$ contains many important problems previously known to lie in SZK, such as Graph Isomorphism, Discrete Log, and

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2023).

Decisional Diffie-Hellman. The corresponding "non-interactive" subclass of SZK_L, denoted $\mathsf{NISZK}_\mathsf{L}$, was subsequently introduced in [1], primarily as a tool for clarifying the complexity of computing time-bounded Kolmogorov complexity under very restrictive reducibilities (such as projections). Just as every problem in $\mathsf{SZK} \leq_{\mathrm{tt}}^{\mathsf{AC}^0}$ reduces to problems in NISZK [14], so also every problem in $\mathsf{SZK}_\mathsf{L}{\leq}_{\mathrm{tt}}^{\mathsf{AC}^0}$ reduces to problems in $\mathsf{NISZK}_\mathsf{L}$, and thus $\mathsf{NISZK}_\mathsf{L}$ contains intractable problems if and only if SZK_L does.

Very recently, all of these classes were given surprising new characterizations, in terms of efficient reducibility to the Kolmogorov random strings. Let $\widetilde{R}_K$ be the (undecidable) promise problem $(Y_{\widetilde{R}_K}, N_{\widetilde{R}_K})$ where $Y_{\widetilde{R}_K}$ contains all strings y such that $K(y) \geq |y|/2$ and the NO instances $N_{\widetilde{R}_K}$ consists of those strings y where $K(y) \leq |y|/2 - e(|y|)$ for some approximation error term $e(n)$, where $e(n) = \omega(\log n)$ and $e(n) = n^{o(1)}$.

▶ **Theorem 1** ([4]). *Let A be a decidable promise problem. Then*

- *$A \in \mathsf{NISZK}$ if and only if A is reducible to $\widetilde{R}_K$ by randomized polynomial time reductions.*
- *$A \in \mathsf{NISZK}_L$ if and only if A is reducible to $\widetilde{R}_K$ by randomized AC^0 or logspace reductions.*
- *$A \in \mathsf{SZK}$ if and only if A is reducible to $\widetilde{R}_K$ by randomized polynomial time "Boolean formula" reductions.*
- *$A \in \mathsf{SZK}_L$ if and only if A is reducible to $\widetilde{R}_K$ by randomized logspace "Boolean formula" reductions.*

In all cases, the randomized reductions are restricted to be "honest", so that on inputs of length n all queries are of length $\geq n^\epsilon$.

There are very few natural examples of computational problems A where the class of problems reducible to A via polynomial-time reductions differs (or is conjectured to differ) from the class or problems reducible to A via AC^0 reductions. For example the natural complete problems for NISZK under $\leq_{\mathrm{m}}^{\mathsf{P}}$ reductions remain complete under AC^0 reductions. Thus Theorem 1 gives rise to speculation that NISZK and $\mathsf{NISZK}_\mathsf{L}$ might be equal. (This would also imply that $\mathsf{SZK} = \mathsf{SZK}_\mathsf{L}$.)

This motivates a closer examination of SZK_L and $\mathsf{NISZK}_\mathsf{L}$, to answer questions that have not been addressed by earlier work on these classes.

Our main results are:

1. **The verifier and simulator may be very weak.** $\mathsf{NISZK}_\mathsf{L}$ and SZK_L are defined in terms of three algorithms: (1) A logspace-bounded *verifier*, who interacts with (2) a computationally-unbounded *prover*, following the usual rules of an interactive proof, and (3) a logspace-bounded *simulator*, who ensures the zero-knowledge aspects of the protocol. (More formal definitions are to be found in Section 2.) We show that the verifier and simulator can be restricted to lie in AC^0. Let us explain why this is surprising.

   The proof presented in [1], showing that $\mathsf{EA}_{\mathsf{NC}^0}$ is complete for $\mathsf{NISZK}_\mathsf{L}$, makes it clear that the verifier and simulator can be restricted to lie in $\mathsf{AC}^0[\oplus]$ (as was observed in [24]). But the proof in [1] (and a similar argument in [14]) relies heavily on hashing, and it is known that, although there are families of universal hash functions in $\mathsf{AC}^0[\oplus]$, no such families lie in AC^0 [19]. We provide an alternative construction, which avoids hashing, and allows the verifier and simulator to be very weak indeed.
2. **The verifier and simulator may be somewhat stronger.** The proof presented in [1], showing that $\mathsf{EA}_{\mathsf{NC}^0}$ is complete for $\mathsf{NISZK}_\mathsf{L}$, also makes it clear that the verifier and simulator can be as powerful as $\oplus\mathsf{L}$, without leaving $\mathsf{NISZK}_\mathsf{L}$. This is because the proof relies on the fact that logspace computation lies in the complexity class PREN of functions that have *perfect randomized encodings* [7], and $\oplus\mathsf{L}$ also lies in PREN. Applebaum, Ishai, and Kushilevitz defined PREN and the somewhat larger class SREN (for *statistical*

randomized encodings), in proving that there are one-way functions in SREN if and only if there are one-way functions in NC^0. They also showed that other important classes of functions, such as NL and GapL, are contained in SREN.[1] We initially suspected that $\mathsf{NISZK_L}$ could be characterized using verifiers and simulators computable in GapL (or even in the slightly larger class DET, consisting of problems that are $\leq_T^{\mathsf{NC}^1}$ reducible to GapL), since DET is known to be contained in $\mathsf{NISZK_L}$ [1].[2] However, we were unable to reach that goal.

We were, however, able to show that the simulator and verifier can be as powerful as NL, without making use of the properties of SREN. In fact, we go further in that direction. We define the class PM, consisting of those problems that are $\leq_T^{\mathsf{L}}$-reducible to the Perfect Matching problem. PM contains NL [18], and is not known to lie in (uniform) NC (and it is not known to be contained in SREN). We show that statistical zero knowledge protocols defined using simulators and verifiers that are computable in PM yield only problems in $\mathsf{NISZK_L}$.

3. **The complexity of the simulator is key.** As part of our attempt to characterize $\mathsf{NISZK_L}$ using simulators and verifiers computable in DET, we considered varying the complexity of the simulator and the verifier separately. Among other things, we show that the verifier can be as complex as DET if the simulator is logspace-computable. In most cases of interest, the NISZK class defined with verifier and simulator lying in some complexity class remains unchanged if the rules are changed so that the verifier is significantly stronger or weaker.

We also establish some additional closure properties of $\mathsf{NISZK_L}$ and $\mathsf{SZK_L}$, some of which are required for the characterizations given in [4].

The rest of the paper is organized as follows: Section 3 will show how $\mathsf{NISZK_L}$ can be defined equivalently using an AC^0 verifier and simulator. Section 4 will show that increasing the power of the verifier and simulator to lie in PM does not increase the size of $\mathsf{NISZK_L}$ (where PM is the class of problems (containing NL) that are logspace Turing reducible to Perfect Matching). Section 5 expands the list of problems known to lie in $\mathsf{NISZK_L}$. McKenzie and Cook [20] studied different formulations of the problem of solving linear congruences. These problems are not known to lie in DET, which is the largest well-studied subclass of P known to be contained in $\mathsf{NISZK_L}$. However, these problems are randomly logspace-reducible to DET [8]. We show that $\mathsf{NISZK_L}$ is closed under randomized logspace reductions, and hence show that these problems also reside in $\mathsf{NISZK_L}$. Section 6 shows that the complexity of the simulator is more important than the complexity of the verifier, in non-interactive zero-knowledge protocols. In particular, the verifier can be as powerful as DET, while still defining only problems in $\mathsf{NISZK_L}$. Finally Section 7 will show that $\mathsf{SZK_L}$ is closed under logspace Boolean formula truth-table reductions.

2 Preliminaries

We assume familiarity with basic complexity classes $\mathsf{L}, \mathsf{NL}, \oplus\mathsf{L}$ and P, and circuit complexity classes NC^0 and AC^0. We assume knowledge of m-reducibility (many-one-reducibility) and Turing-reducibility. $\#\mathsf{L}$ is the class of functions that count the number of accepting paths of NL machines, and $\mathsf{GapL} = \{f - g : f, g \in \#\mathsf{L}\}$. The determinant is complete for GapL, and the complexity class DET is the class of languages NC^1-Turing reducible to functions in GapL.

[1] This is not stated explicitly for GapL, but it follows from [17, Theorem 1]. See also [11, Section 4.2].

[2] More precisely, as observed in [3], the Rigid Graph (non-) Isomorphism problem is hard for DET [26], and the Rigid Graph Non-Isomorphism problem is in $\mathsf{NISZK_L}$ [1, Corollary 23].

Many of the problems we consider deal with entropy (also known as Shannon entropy). The *entropy* of a distribution X (denoted $H(X)$) is the expected value of $\log(1/\Pr[X=x])$. Given two distributions X and Y, the *statistical difference* between the two is denoted $\Delta(X,Y)$ and is equal to $\sum_\alpha \big|\Pr[X=\alpha]-\Pr[Y=\alpha]\big|/2$. Equivalently, for finite domains D, $\Delta(X,Y)=\max_{S\subseteq D}\{\big|\Pr_X[S]-\Pr_Y[S]\big|\}$. This quantity is also known as the *total variation distance* between X and Y. The *support* of X, denoted $\mathrm{supp}(X)$, is $\{x : \Pr[X=x]>0\}$.

▶ **Definition 2.** *Promise Problem: a promise problem Π is a pair of disjoint sets (Π_Y, Π_N) (the "YES" and "NO" instances, respectively). A* solution *for Π is any set S such that $\Pi_Y \subseteq S$, and $S \cap \Pi_n = \emptyset$.*

▶ **Definition 3.** *A* branching program *is a directed acyclic graph with a single source and two sinks labeled 1 and 0, respectively. Each non-sink node in the graph is labeled with a variable in $\{x_1,\ldots,x_n\}$ and has two edges leading out of it: one labeled 1 and one labeled 0. A branching program computes a Boolean function f on input $x=x_1\ldots x_n$ by first placing a pebble on the source node. At any time when the pebble is on a node v labeled x_i, the pebble is moved to the (unique) vertex u that is reached by the edge labeled 1 if $x_i=1$ (or by the edge labeled 0 if $x_i=0$). If the pebble eventually reaches the sink labeled b, then $f(x)=b$. Branching programs can also be used to compute functions $f:\{0,1\}^m\to\{0,1\}^n$, by concatenating n branching programs $p_1,\ldots,p_n$, where p_i computes the function $f_i(x)=$ the i-th bit of $f(x)$. For more information on the definitions, backgrounds, and nuances of these complexity classes, circuits, and branching programs, see the text by Vollmer [27].*

▶ **Definition 4** (Non-interactive zero-knowledge proof (NISZK), adapted from [1, 14])**.** *A non-interactive statistical zero-knowledge proof system for a promise problem Π is defined by a pair of deterministic polynomial time machines*[3] *(V,S) (the* verifier *and* simulator*, respectively) and a probabilistic routine P (the* prover*) that is computationally unbounded, together with a polynomial $r(n)$ (which will give the size of the random reference string σ), such that:*

1. *(Completeness): For all $x\in\Pi_Y$, the probability (over random σ, and over the random choices of P) that $V(x,\sigma,P(x,\sigma))$ accepts is at least $1-2^{-O(|x|)}$.*
2. *(Soundness): For all $x\in\Pi_N$, and for every possible prover P', the probability that $V(x,\sigma,P'(x,\sigma))$ accepts is at most $2^{-O(|x|)}$. (Note P' here can be malicious, meaning it can try to fool the verifier)*
3. *(Zero Knowledge): For all $x\in\Pi_Y$, the statistical distance between the following two distributions is bounded by $2^{-|x|}$:*
   a. *Choose $\sigma\leftarrow\{0,1\}^{r(|x|)}$ uniformly random, $p\leftarrow P(x,\sigma)$, and output (p,σ).*
   b. *$S(x,r)$ (where the coins r for S are chosen uniformly at random).*

It is known that changing the definition, to have the error probability in the soundness and completeness conditions and in the simulator's deviation be $\frac{1}{n^{\omega(1)}}$ results in an equivalent definition [1, 14]. (See the comments after [1, Claim 39].) We will occasionally make use of this equivalent formulation, when it is convenient.

NISZK *is the class of promise problems for which there is a non-interactive statistical zero knowledge proof system.*

$\mathsf{NISZK}_{\mathcal{C}}$ *denotes the class of problems in* NISZK *where the verifier V and simulator S lie in complexity class $\mathcal{C}$.*

[3] In prior work on NISZK [14, 1], the verifier and simulator were said to be probabilistic machines. We prefer to be explicit about the random input sequences provided to each machine, and thus the machines can be viewed as deterministic machines taking a sequence of random bits as input.

▶ **Definition 5** (EA and $\mathsf{EA}_{\mathsf{NC}^0}$, [1, 14]). *Consider Boolean circuits $C_X : \{0,1\}^m \to \{0,1\}^n$ representing distribution X. The promise problem* EA *is given by:*

$$\mathsf{EA}_Y := \{(C_X, k) : H(X) > k+1\}$$

$$\mathsf{EA}_N := \{(C_X, k) : H(X) < k-1\}$$

$\mathsf{EA}_{\mathsf{NC}^0}$ *is the variant of* EA *where the distribution C_x is an* NC^0 *circuit with each output bit depending on at most 4 input bits.*

▶ **Definition 6** (SDU and $\mathsf{SDU}_{\mathsf{NC}^0}$). *Consider Boolean circuits $C_X : \{0,1\}^m \to \{0,1\}^n$ representing distributions X. The promise problem* $\mathsf{SDU} = (\mathsf{SDU}_Y, \mathsf{SDU}_N)$ *is given by:*

$$\mathsf{SDU}_Y := \{C_X : \Delta(X, U_n) < 1/n\}$$

$$\mathsf{SDU}_N := \{C_X : \Delta(X, U_n) > 1 - 1/n\}.$$

$\mathsf{SDU}_{\mathsf{NC}^0}$ *is the analogous problem, where the distributions X are represented by* NC^0 *circuits where no output bit depends on more than* four *input bits.*

▶ **Theorem 7** ([1, 4]). $\mathsf{EA}_{\mathsf{NC}^0}$ *and* $\mathsf{SDU}_{\mathsf{NC}^0}$ *are complete for* $\mathsf{NISZK}_\mathsf{L}$. $\mathsf{EA}_{\mathsf{NC}^0}$ *remains complete, even if k is fixed to $k = n-3$.*

▶ **Definition 8** (SD and $\mathsf{SD}_{\mathsf{BP}}$, [12, 25]). *Consider a pair of Boolean circuits $C_1, C_2 : \{0,1\}^m \to \{0,1\}^n$ representing distributions X_1, X_2. The promise problem* SD *is given by:*

$$\mathsf{SD}_Y := \{(C_1, C_2) : \Delta(X_1, X_2) > 2/3\}$$

$$\mathsf{SD}_N := \{(C_1, C_2) : \Delta(X_1, X_2) < 1/3\}.$$

$\mathsf{SD}_{\mathsf{BP}}$ *is the variant of* SD *where the distributions X_1, X_2 are represented by branching programs.*

2.1 Perfect Randomized Encodings

We will make use of the machinery of *perfect randomized encodings* [7].

▶ **Definition 9.** *Let $f : \{0,1\}^n \to \{0,1\}^\ell$ be a function. We say that $\hat{f} : \{0,1\}^n \times \{0,1\}^m \to \{0,1\}^s$ is a perfect randomized encoding of f with blowup b if it is:*

- **Input independent:** *for every $x, x' \in \{0,1\}^n$ such that $f(x) = f(x')$, the random variables $\hat{f}(x, U_m)$ and $\hat{f}(x', U_m)$ are identically distributed.*
- **Output Disjoint:** *for every $x, x' \in \{0,1\}^n$ such that $f(x) \neq f(x')$, $\mathrm{supp}(\hat{f}(x, U_m)) \cap \mathrm{supp}(\hat{f}(x', U_m)) = \emptyset$.*
- **Uniform:** *for every $x \in \{0,1\}^n$ the random variable $\hat{f}(x, U_m)$ is uniform over the set $\mathrm{supp}(\hat{f}(x, U_m))$.*
- **Balanced:** *for every $x, x' \in \{0,1\}^n$ $|\mathrm{supp}(\hat{f}(x, U_m))| = |\mathrm{supp}(\hat{f}(x', U_m))| = b$*

The following property of perfect randomized encodings is established in [12].

▶ **Lemma 10.** *Let $f : \{0,1\}^n \to \{0,1\}^\ell$ be a function and let $\hat{f} : \{0,1\}^n \times \{0,1\}^m \to \{0,1\}^s$ be a perfect randomized encoding of f with blowup b. Then $H(\hat{f}(U_n, U_m)) = H(f(U_n)) + \log b$.*

3 Simulators and Verifiers in AC^0

In this section, we show that $\mathsf{NISZK_L}$ can be defined equivalently using verifiers and simulators that are computable in AC^0. The standard complete problems for NISZK and $\mathsf{NISZK_L}$ take a circuit C as input, where the circuit is viewed as representing a probability distribution X; the goal is to approximate the entropy of X, or to estimate how far X is from the uniform distribution. Earlier work [15, 1, 24] that had presented non-interactive zero-knowledge protocols for these problems had made use of the fact that the verifier could compute hash functions, and thereby convert low-entropy distributions to distributions with small support. But an AC^0 verifier cannot compute hash functions [19].

Our approach is to "delegate" the problem of computing hash functions to a logspace verifier, and then to make use of the uniform encoding of this verifier to obtain the desired distributions via an AC^0 reduction. To this end, we begin by defining a suitably restricted version of $\mathsf{SDU_{NC^0}}$ and show that this restricted version remains complete for $\mathsf{NISZK_L}$ under AC^0 reductions (and even under projections).

With this new complete problem in hand, we provide a $\mathsf{NISZK_{AC^0}}$ protocol for the complete problem, to conclude $\mathsf{NISZK_L} = \mathsf{NISZK_{AC^0}}$.

▶ **Definition 11.** *Consider an* NC^0 *circuit* $C : \{0,1\}^m \to \{0,1\}^n$ *and the probability distribution* X *on* $\{0,1\}^n$ *defined as* $C(U_m)$ *- where* U_m *denotes* m *uniformly random bits. For some fixed* $\epsilon > 0$ *(chosen later in Remark 16), we define:*

$$\mathsf{SDU'}_{\mathsf{NC^0},Y} = \{X : \Delta(C, U_n) < \frac{1}{2^{n^\epsilon}}\}$$

$$\mathsf{SDU'}_{\mathsf{NC^0},N} = \{X : |\operatorname{supp}(X)| \le 2^{n-n^\epsilon}\}$$

We will show that $\mathsf{SDU'_{NC^0}}$ is complete for $\mathsf{NISZK_L}$ under uniform $\le_m^{\mathsf{proj}}$ reductions. In order to do so, we first show that $\mathsf{SDU'_{NC^0}}$ is in $\mathsf{NISZK_L}$ by providing a reduction to $\mathsf{SDU_{NC^0}}$.

▷ Claim 12. $\mathsf{SDU'_{NC^0}} \le_m^{\mathsf{proj}} \mathsf{SDU_{NC^0}}$, and thus $\mathsf{SDU'_{NC^0}} \in \mathsf{NISZK_L}$.

Proof. On a given probability distribution X defined on $\{0,1\}^n$ for $\mathsf{SDU'_{NC^0}}$, we claim that the identity function $f(X) = X$ is a reduction of $\mathsf{SDU'_{NC^0}}$ to $\mathsf{SDU_{NC^0}}$. If X is a YES instance for $\mathsf{SDU'_{NC^0}}$, then $\Delta(X, U_n) < \frac{1}{2^{n^\epsilon}}$, which clearly is a YES instance of $\mathsf{SDU_{NC^0}}$. If X is a NO instance for $\mathsf{SDU'_{NC^0}}$, then $|\operatorname{supp}(X)| \le 2^{n-n^\epsilon}$. Thus, if we let T be the complement of $\operatorname{supp}(X)$, we have that, under the uniform distribution, a string α is in T with probability $\ge 1 - \frac{1}{2^{n^\epsilon}}$, whereas this event has probability zero under X. Thus $\Delta(X, U_n) \ge 1 - \frac{1}{2^{n^\epsilon}}$, easily making it a NO instance of $\mathsf{SDU_{NC^0}}$. ◁

3.1 Hardness for $\mathsf{SDU'_{NC^0}}$

▶ **Theorem 13.** $\mathsf{SDU'_{NC^0}}$ *is hard for* $\mathsf{NISZK_L}$ *under* $\le_m^{\mathsf{proj}}$ *reductions.*

Proof. In order to show that $\mathsf{SDU'_{NC^0}}$ is hard for $\mathsf{NISZK_L}$, we will show that the reduction given in [1] proving the hardness of $\mathsf{SDU_{NC^0}}$ for $\mathsf{NISZK_L}$ actually produces an instance of $\mathsf{SDU'_{NC^0}}$.

Let Π be an arbitrary promise problem in $\mathsf{NISZK_L}$ with proof system (P, V) and simulator S. Let x be an instance of Π. Let $M_x(r)$ denote a machine that simulates $S(x)$ with randomness r to obtain a transcript (σ, p) - if $V(x, \sigma, p)$ accepts then $M_x(r)$ outputs σ; else it outputs $0^{|\sigma|}$. We will assume without loss of generality that $|\sigma| = n^k$ for some constant k.

It was shown in [15, Lemma 3.1] that for the promise problem EA, there is an NISZK protocol with completeness error, soundness error and simulator deviation all bounded from above by 2^{-m} for inputs of length m. Furthermore, as noted in the paragraph before Claim 38 in [1], the proof carries over to show that $\mathsf{EA}_{\mathsf{BP}}$ has an $\mathsf{NISZK}_{\mathsf{L}}$ protocol with the same parameters. Thus, any problem in $\mathsf{NISZK}_{\mathsf{L}}$ can be recognized with exponentially small error parameters by reducing the problem to $\mathsf{EA}_{\mathsf{BP}}$ and then running the above protocol for $\mathsf{EA}_{\mathsf{BP}}$ on that instance. In particular, this holds for $\mathsf{EA}_{\mathsf{NC}^0}$. In what follows, let M_x be the distribution described in the preceding paragraph, assuming that the simulator S and verifier V yield a protocol with these exponentially small error parameters.

▷ Claim 14. If $x \in \Pi_{YES}$ then $\Delta(M_x(r), U_{n^k}) \leq 1/2^{n-1}$. And if $x \in \Pi_{NO}$ then $|\operatorname{supp}(M_x(r))| \leq 2^{n^k - n^{\epsilon k}}$ for $\epsilon < \frac{1}{k}$.

Refer to Appendix A.1 for the proof.

The above claim talks about the distribution $M_x(r)$ where M is a logspace machine. We will instead consider an NC^0 distribution with similar properties that can be constructed using projections. This distribution (denoted by C_x) is a perfect randomized encoding of $M_x(r)$. We make use of the following construction:

▶ **Lemma 15** ([1, Lemma 35]). *There is a function computable in AC^0 (in fact, it can be a projection) that takes as input a branching program Q of size l computing a function f and produces as output a list p_i of NC^0 circuits, where p_i computes the i-th bit of a function $\hat{f}$ that is a perfect randomized encoding of f that has blowup $b = 2^{(\binom{l}{2}-1)2((l-1)^2-1)}$ (and thus the length of $\hat{f}(r) = \log b + |f(r)|$). Each p_i depends on at most four input bits from (x, r) (where r is the sequence of random bits in the randomized encoding).*

The properties of perfect randomized encodings (see Definition 9) imply that the range of $\hat{f}$ (and thus also the range of C_x) can be partitioned into equal sized pieces corresponding to each value of $f(r)$. Thus, let $\alpha_1, \alpha_2, .., \alpha_z$ be the range of $f(r)$, and let $[\alpha] = \{\hat{f}(r, s) : f(r) = \alpha\}$. It follows that $|[\alpha]| = b$. For a given α, and for a given β of length $\log b$ we denote by $\alpha\beta$ the β-th element of $[\alpha]$. Since the simulator S runs in logspace, each bit of $M_x(r)$ can be simulated with a branching program Q_x. Furthermore, it is straightforward to see that there is an AC^0-computable function that takes x as input and produces an encoding of Q_x as output, and it can even be seen that this function can be a projection. Let the list of NC^0 circuits produced from Q_x by the construction of Lemma 15 be denoted C_x.

We show that this distribution C_x is an instance of $\mathsf{SDU'}_{\mathsf{NC}^0}$ if $x \in \Pi$. For $x \in \Pi_{YES}$, we have $\Delta(M_x(r), U_{n^k}) \leq 1/2^{n-1}$, and we want to show $\Delta(C_x(r), U_{\log b + n^k}) \leq 1/2^{n-1}$. Thus it will suffice to observe that $\Delta(M_x(r), U_{n^k}) = \Delta(C_x(r), U_{\log b + n^k}) \leq 1/2^{n-1}$.

To see this, note that

$$\Delta(C_x(r), U_{\log b + n^k}) = \sum_{\alpha\beta} \Big| \Pr[C_x = \alpha\beta] - \frac{1}{2^{n^k + b}} \Big|/2 = \sum_{\beta} \sum_{\alpha} \Big| \Pr[M_x = \alpha] \frac{1}{2^b} - \frac{1}{2^b} \frac{1}{2^{n^k}} \Big|/2$$

$$= \sum_{\alpha} \Big| \Pr[M_x = \alpha] - \frac{1}{2^{n^k}} \Big|/2 = \Delta(M_x(r), \mathcal{U}_{n^k}).$$

Thus, for $x \in \Pi_{YES}$, C_x is a YES instance for $\mathsf{SDU'}_{\mathsf{NC}^0}$.

For $x \in \Pi_{NO}$, Claim 14 shows that $|\operatorname{supp}(M_x(r))| \leq 2^{n^k - n}$. Since the NC^0 circuit C_x is a perfect randomized encoding of $M_x(r)$, we have that the support of C_x for $x \in \Pi_{NO}$ is bounded from above by $b \times 2^{n^k - n}$ Note that $\log b$ is polynomial in n; let $q(n) = \log b$. Let $r(n)$ denote the length of the output of C; $r(n) = q(n) + n^k$. Thus the size of $\operatorname{supp}(C_x) \leq 2^{n^k - n + q(n)} = 2^{r(n) - n} < 2^{r(n) - r(n)^{\epsilon}}$ (if $1/\epsilon$ is chosen to be greater than the degree of r), and hence C_x is a NO instance for $\mathsf{SDU'}_{\mathsf{NC}^0}$. ◀

▶ Remark 16. Here is how we pick ϵ in the definition of $\mathsf{SDU'}_{\mathsf{NC}^0}$. $\mathsf{SDU}_{\mathsf{NC}^0}$ is in $\mathsf{NISZK}_\mathsf{L}$ via some simulator and verifier, where the error parameters are exponentially small, and the shared reference strings σ have length n^k on inputs of length n. Now we pick $\epsilon > 0$ so that $\epsilon < 1/k$ (as in Claim 14) and also $1/\epsilon$ is greater than the degree of r (as in the last sentence of the proof of Theorem 13).

3.2 $\mathsf{NISZK}_{\mathsf{AC}^0}$ protocol for $\mathsf{SDU'}_{\mathsf{NC}^0}$ on input X represented by circuit C

3.2.1 Non Interactive proof system

1. Let C take inputs of length m and produce outputs of length n, and let σ be the reference string of length n.
2. If there is no r such that $C(r) = \sigma$, then the prover sends $\perp$. Otherwise, the prover picks an element r uniformly at random from $p \sim \{r | C(r) = \sigma\}$ and sends it to the verifier.
3. V accepts iff $C(r) = \sigma$. (Since C is an NC^0 circuit, this can be accomplished in AC^0 – this step can not be accomplished in NC^0 since it depends on all of the bits of σ.)

3.2.2 Simulator for $\mathsf{SDU'}_{\mathsf{NC}^0}$ proof system, on input X represented by circuit C

1. Pick a random s of length m and compute $\gamma = C(s)$.
2. Output (s, γ).

3.3 Proofs of Zero Knowledge, Completeness and Soundness

- **Completenss:** Suppose $X \in \mathsf{SDU'}_{\mathsf{NC}^0,Y}$, then $\Delta(X, U_n) < \frac{1}{2^{n^\epsilon}}$. This implies $|\operatorname{supp}(X)| > 2^n(1 - \frac{1}{2^{n^\epsilon}})$, which immediately implies that the verifier accepts with high probability.
- **Soundness:** Suppose $X \in \mathsf{SDU'}_{\mathsf{NC}^0,N}$, we note that whenever $\sigma \notin \operatorname{supp}(X)$, no prover can make the verifier accept. If $X \in \mathsf{SDU'}_{\mathsf{NC}^0,N}$, the probability that $\sigma \notin \operatorname{supp}(X)$ is greater than $1 - \frac{1}{2^{n^\epsilon}}$.
- **Statistical Zero-Knowledge:** Refer to Appendix A.2 for proof. ⌟

4 Simulator and Verifier in PM

In this section, we show that $\mathsf{NISZK}_\mathsf{L}$ can be defined equivalently using verifiers and simulators that lie in the class PM of problems that logspace-Turing reduce to Perfect Matching. (PM is not known to lie in (uniform) NC.) That is, we can increase the computational power of the simulator and the verifier from L to PM without affecting the power of noninteractive statistical zero knowledge protocols.

The Perfect Matching problem is the well-known problem of deciding, given an undirected graph G with $2n$ vertices, if there is a set of n edges covering all of the vertices. We define a corresponding complexity class PM as follows:

$$\mathsf{PM} := \{A : A \leq_T^L \text{Perfect Matching}\}$$

It is known that $\mathsf{NL} \subseteq \mathsf{PM}$ [18].

Our argument proceeds by first observing[4] that $\mathsf{NISZK}_\mathsf{L} = \mathsf{NISZK}_{\oplus\mathsf{L}}$, and then making use of the details of the argument that Perfect Matching is in $\oplus\mathsf{L/poly}$ [6].

[4] This equality was previously observed in [24].

▶ **Proposition 17.** $\mathsf{NISZK}_{\oplus\mathsf{L}} = \mathsf{NISZK}_{\mathsf{L}}$

Proof. It suffices to show $\mathsf{NISZK}_{\oplus\mathsf{L}} \subseteq \mathsf{NISZK}_{\mathsf{L}}$. We do this by showing that the problem $\mathsf{EA}_{\mathsf{NC}^0}$ is hard for $\mathsf{NISZK}_{\oplus\mathsf{L}}$; this suffices since $\mathsf{EA}_{\mathsf{NC}^0}$ is complete for $\mathsf{NISZK}_{\mathsf{L}}$. The proof of [1, Theorem 26] (showing that $\mathsf{EA}_{\mathsf{NC}^0}$ is complete for $\mathsf{NISZK}_{\mathsf{L}}$ involves (a) building a branching program to simulate a logspace computation called M_x that is constructed from a logspace-computable simulator and verifier, and (b) constructing an NC^0-computable perfect randomized encoding of M_x, using the fact that $\mathsf{L} \subset \mathcal{PREN}$, where $\mathcal{PREN}$ is the class defined in [7], consisting of all problems with perfect randomized encodings. But Theorem 4.18 in [7] shows the stronger result that $\oplus\mathsf{L}$ lies in $\mathcal{PREN}$, and hence the argument of [1, Theorem 26] carries over immediately, to reduce any problem in $\mathsf{NISZK}_{\oplus\mathsf{L}}$ to $\mathsf{EA}_{\mathsf{NC}^0}$ (by modifying step (a), to build a *parity* branching program for M_x that is constructed from a $\oplus\mathsf{L}$ simulator and verifier). ◀

We also rely on the following lemma:

▶ **Lemma 18** (Adapted from [6, Section 3] and [21, Section 4]). *Let $W = (w_1, w_2, \cdots, w_{n^{k+3}})$ be a sequence of n^{k+3} weight functions, where each $w_i : [\binom{n}{2}] \to [4n^2]$ is a distinct weight assignment to edges in n-vertex graphs. Let (G, w_i) denote the result of weighting the edges of G using weight assignment w_i. Then there is a function f in* GapL*, such that, if (G, w_i) has a unique perfect matching of weight j, then $f(G, W, i, j) \in \{1, -1\}$, and if G has no perfect matching, then for* every *(W, i, j), it holds that $f(G, W, i, j) = 0$. Furthermore, if W is chosen uniformly at random, then with probability $\geq 1 - 2^{-n^k}$, for* <u>*each*</u> *n-vertex graph G:*

- *If G has no perfect matching then $\forall i \forall j$ $f(G, W, i, j) = 0$.*
- *If G has a perfect matching then $\exists i$ such that (G, w_i) has a unique minimum-weight matching, and hence $\exists i \exists j$ $f(G, W, i, j) \in \{1, -1\}$.*

Thus if we define $g(G, W)$ to be $1 - \Pi_{i,j}(1 - f(G, W, i, j)^2)$, we have that $g \in$ GapL *and with probability $\geq 1 - 2^{-n^k}$ (for randomly-chosen W), $g(G, W) = 1$ if G has a perfect matching, and $g(G, W) = 0$ otherwise.*

Note that this lemma is saying that most W constitute a good "advice string", in the sense that $g(G, W)$ provides the correct answer to the question "Does G have a perfect matching?" for every graph G with n vertices.

▶ **Corollary 19.** *For every language $A \in$* PM *there is a language $B \in \oplus\mathsf{L}$ such that, if $x \in A$, then $\Pr_{W \leftarrow [4n^2]^{n^5}}[(x, W) \in B] \geq 1 - 2^{-n^2}$, and if $x \notin A$, then $\Pr_{W \leftarrow [4n^2]^{n^5}}[(x, W) \in B] \leq 2^{-n^2}$.*

Refer to Appendix A.3 for proof.

▶ **Theorem 20.** $\mathsf{NISZK}_{\mathsf{L}} = \mathsf{NISZK}_{\mathsf{PM}}$

Proof. We show that $\mathsf{NISZK}_{\mathsf{PM}} \subseteq \mathsf{NISZK}_{\oplus\mathsf{L}}$, and then appeal to Proposition 17.

Let Π be an arbitrary problem in $\mathsf{NISZK}_{\mathsf{PM}}$, and let (S, P, V) be the PM simulator, prover, and verifier for Π, respectively. Let S' and V' be the $\oplus\mathsf{L}$ languages that are probabilistic realizations of S, V, respectively, guaranteed by Corollary 19. We now define a $\mathsf{NISZK}_{\mathsf{L}}$ protocol (S'', P'', V'') for Π.

On input x with shared randomness σW, the prover P'' sends the same message $p = P(x, \sigma)$ as the original prover sends. The verifier V'', returns the value of $V'((x, \sigma, p), W)$, which with high probability is equal to $V(x, \sigma, p)$. The simulator S'', given as input x and random sequence rW, executes $S'((x, r, i), W)$ for each bit position i to obtain a bit that (with high probability) is equal to the i^{th} bit of $S(x, r)$, which is a string of the form (σ, p), and outputs $(\sigma W, p)$.

Now we will analyze the properties of (S'', P'', V''):

- **Completeness:** Suppose $x \in \Pi_Y$, then $\Pr_\sigma[V(x, \sigma, P(x, \sigma)) = 1] \geq 1 - 2^{-O(n)}$. Since $\forall y \in \{0,1\}^n : \Pr_W[V(y) = V'(y, W)] \geq 1 - 2^{-n^k}$ we have:

$$\Pr_{\sigma W}[V'((x, \sigma, P''(x, \sigma)), W) = 1] \geq [1 - 2^{-O(n)}][1 - 2^{-n^k}] = 1 - 2^{-O(n)}$$

- **Soundness:** Suppose $x \in \Pi_N$, then $\Pr_\sigma[\forall p : V(x, \sigma, p) = 0] \geq 1 - 2^{-O(n)}$. Since $\forall y \in \{0,1\}^n : \Pr_W[V(y) = V'(y, W)] \geq 1 - 2^{-n^k}$, we have:

$$\Pr_{\sigma W}[\forall p : V'((x, \sigma, p), W) = 0] \geq [1 - 2^{-O(n)}][1 - 2^{-n^k}] = 1 - 2^{-O(n)}$$

- **Statistical Zero-Knowledge:** Suppose $x \in \Pi_Y$. Let S^* denote the distribution on strings of the form (σ, p) that $S(x, r)$ produces, where r is uniformly generated, and let P^* denote the distribution on strings given by $(\sigma, P(x, \sigma))$ where σ is chosen uniformly at random. Similarly, let S''^* denote the distribution on strings of the form $(\sigma W, p)$ that $S''(x, rW)$ produces, where r and W are chosen uniformly, and let P''^* be the distribution given by $(\sigma W, P''(x, \sigma W))$. Let $A = \{(\sigma W, p) : \exists i \exists r\ S(x, r)_i \neq S'((x, r, i), W)\}$.
Since $\Pr_W[\forall i \forall r : S(x, r)_i = S'((x, r, i), W)] \geq 1 - 2^{-O(n)}$ we have:

$$\begin{aligned}
\Delta(S''^*, P''^*) &= \frac{1}{2} \sum_{(\sigma W, p)} \left| \Pr[S''^* = (\sigma W, p)] - \Pr[P''^* = (\sigma W, p)] \right| \\
&\leq \frac{1}{2}(2^{-O(n)} + \sum_{(\sigma W, p) \in \overline{A}} \left| \Pr[S''^* = (\sigma W, p)] - \Pr[P''^* = (\sigma W, p)]) \right| \\
&= \frac{1}{2}(2^{-O(n)} + \sum_{(\sigma W, p) \in \overline{A}} \left| \Pr[S^* = (\sigma, p)] - \Pr[P^* = (\sigma, p)] \right| \Pr[W]) \\
&\leq 2^{-O(n)} + \sum_W \Pr[W] \frac{1}{2} \sum_{(\sigma, p)} \left| \Pr[S^* = (\sigma, p)] - \Pr[P^* = (\sigma, p)] \right| \\
&= 2^{-O(n)} + \Delta(S^*, P^*) = 2^{-O(n)}
\end{aligned}$$

Therefore (S'', P'', V'') is a $\mathsf{NISZK}_{\oplus\mathsf{L}}$ protocol deciding Π. ◀

5 Additional problems in $\mathsf{NISZK_L}$

In this section, we give additional examples of problems in P that lie in $\mathsf{NISZK_L}$. These problems are not known to lie in (uniform) NC. Our main tool is to show that $\mathsf{NISZK_L}$ is closed under a class of randomized reductions.

The following definition is from [4]:

▶ **Definition 21.** *A promise problem $A = (Y, N)$ is $\leq_m^{\mathsf{BPL}}$-reducible to $B = (Y', N')$ with threshold θ if there is a logspace-computable function f and there is a polynomial p such that*

- *$x \in Y$ implies $\Pr_{r \in \{0,1\}^{p(|x|)}}[f(x, r) \in Y'] \geq \theta$.*
- *$x \in N$ implies $\Pr_{r \in \{0,1\}^{p(|x|)}}[f(x, r) \in N'] \geq \theta$.*

Note, in particular, that the logspace machine computing the reduction has two-way access to the random bits r; this is consistent with the model of probabilistic logspace that is used in defining $\mathsf{NISZK_L}$.

▶ **Theorem 22.** $\mathsf{NISZK_L}$ *is closed under $\leq_m^{\mathsf{BPL}}$ reductions with threshold $1 - \frac{1}{n^{\omega(1)}}$.*

Proof. Let $\Pi \leq_{\mathrm{m}}^{\mathsf{BPL}} \mathsf{EA}_{\mathsf{NC}^0}$, via logspace-computable function f. Let (S_1, V_1, P_1) be the $\mathsf{NISZK_L}$ proof system for $\mathsf{EA}_{\mathsf{NC}^0}$.

Algorithm 1 Simulator $S(x, r\sigma')$.

```
(σ, p) ← S_1(f(x, σ'), r);
return ((σ, σ'), p);
```

Algorithm 2 Verifier $V(x, (\sigma, \sigma'), p)$.

```
return V_1((f(x, σ'), σ, p))
```

Algorithm 3 Prover $P(x, (\sigma, \sigma'))$.

```
return P_1((f(x, σ'), σ));
```

We now claim that (S, P, V) is a $\mathsf{NISZK_L}$ protocol for Π.

It is apparent that S and V are computable in logspace. We just need to go through completeness, soundness, and statistical zero-knowledge of this protocol.

- **Completeness:** Suppose x is YES instance of Π. Then with probability $1 - \frac{1}{n^{\omega(1)}}$ (over randomness of σ'): $f(x, \sigma')$ is a YES instance of $\mathsf{EA}_{\mathsf{NC}^0}$. Thus for a randomly chosen σ:

$$\Pr[V_1(f(x,\sigma'), \sigma, P_1(f(x,\sigma'), \sigma)) = 1] \geq 1 - \frac{1}{n^{\omega(1)}}$$

- **Soundness:** Suppose x is NO instance of Π. Then with probability $1 - \frac{1}{n^{\omega(1)}}$ (over randomness of σ'): $f(x, \sigma')$ is a NO instance of $\mathsf{EA}_{\mathsf{NC}^0}$. Thus for a randomly chosen σ:

$$\Pr[V_1(f(x,\sigma'), \sigma, P_1(f(x,\sigma'), \sigma)) = 0] \geq 1 - \frac{1}{n^{\omega(1)}}$$

- **Statistical Zero-Knowledge:** If x is a YES instance, $f(x, \sigma')$ is a YES instance of $\mathsf{EA}_{\mathsf{NC}^0}$ with probability close to 1. For any YES instance y of $\mathsf{EA}_{\mathsf{NC}^0}$, the distribution given by S_1 on input y is exponentially close the the distribution on transcripts (σ, p) induced by (V_1, P_1) on input y. Thus the distribution on $(\sigma\sigma', p)$ induced by (V, P) has distance at most $\frac{1}{n^{\omega(1)}}$ from the distribution produced by S on input x. The claim now follows by the comments regarding error probabilities in Definition 4. ◀

McKenzie and Cook [20] defined and studied the problems LCON, LCONX and $\mathsf{LCONNULL}$. LCON is the problem of determining if a system of linear congruences over the integers mod q has a solution. LCONX is the problem of finding a solution, if one exists, and $\mathsf{LCONNULL}$ is the problem of computing a spanning set for the null space of the system.

These problems are known to lie in uniform NC^3 [20], but are not known to lie in uniform NC^2, although Arvind and Vijayaraghavan showed that there is a set B in $\mathsf{L}^{\mathsf{GapL}} \subseteq \mathsf{DET} \subseteq \mathsf{NC}^2$ such that $x \in \mathsf{LCON}$ if and only if $(x, W) \in B$, where W is a randomly-chosen weight function [8]. (The probability of error is exponentially small.) The mapping $x \mapsto (x, W)$ is clearly a $\leq_{\mathrm{m}}^{\mathsf{BPL}}$ reduction. Since $\mathsf{DET} \subseteq \mathsf{NISZK_L}$ [1], it follows that

$$\mathsf{LCON} \in \mathsf{NISZK_L}$$

The arguments in [8] carry over to LCONX and $\mathsf{LCONNULL}$ as well.

▶ **Corollary 23.** $\mathsf{LCON} \in \mathsf{NISZK_L}$. $\mathsf{LCONX} \in \mathsf{NISZK_L}$. $\mathsf{LCONNULL} \in \mathsf{NISZK_L}$.

6 Varying the Power of the Verifier

In this section, we show that the computational complexity of the simulator is more important than the computational complexity of the verifier, in non-interactive protocols. The results in this section were motivated by our attempts to show that $\mathsf{NISZK}_\mathsf{L} = \mathsf{NISZK}_\mathsf{DET}$. Although we were unable to reach this goal, we were able to show that the verifier could be as powerful as DET, if the simulator was restricted to be no more powerful than NL. The general approach here is to replace a powerful verifier with a weaker verifier, by requiring the prover to provide a proof to convince a weak verifier that the more powerful verifier would accept.

We define $\mathsf{NISZK}_{A,B}$ as the class of problems with a NISZK protocol where the simulator is in A and the verifier is in B (and hence $\mathsf{NISZK}_A = \mathsf{NISZK}_{A,A}$). We will consider the case where $A \subseteq B \subseteq \mathsf{NISZK}_A$ and A, B are both classes of functions that are closed under composition.

▶ **Theorem 24.** $\mathsf{NISZK}_{A,B} = \mathsf{NISZK}_A$

Proof. Let Π be an arbitrary promise problem in $\mathsf{NISZK}_{A,B}$ with (S_1, V_1, P_1) being the A simulator, B verifier, and prover for Π's proof system, where the reference string has length $p_1(|x|)$ and the prover's messages have length $q_1(|x|)$. Since $V_1 \in B \subseteq \mathsf{NISZK}_A$, $L(V_1)$ has a proof system (S_2, V_2, P_2), where the reference string has length $p_2(|x|)$ and the prover's messages have length $q_2(|x|)$.

Then Π has the following NISZK_A proof system:

Algorithm 4 Simulator $S(x, r_1, r_2)$.

```
Data: $x \in \Pi_{Yes} \cup \Pi_{No}$
$(\sigma, p) \leftarrow S_1(x, r_1)$;
$(\sigma', p') \leftarrow S_2((x, \sigma, p), r_2)$;
return $((\sigma, \sigma'), (p, p'))$;
```

Algorithm 5 Verifier $V(x, (\sigma, \sigma'), (p, p'))$.

```
return $V_2((x, \sigma, p), \sigma', p')$
```

Algorithm 6 Prover $P(x, \sigma\sigma')$.

```
Data: $x \in \Pi_{Yes} \cup \Pi_{No}, \sigma \in \{0,1\}^{p_1(|x|)}, \sigma' \in \{0,1\}^{p_2(|x|)}$
if $x \in \Pi_{Yes}$ then
    $p \leftarrow P_1(x, \sigma)$;
    $p' \leftarrow P_2((x, \sigma, p), \sigma')$;
    return $(p, p')$;
else
    return $\perp, \perp$;
end
```

- **Correctness:** Suppose $x \in \Pi_{Yes}$, then given random σ, with probability $(1 - \frac{1}{2^{O(|x|)}})$: $(x, \sigma, P_1(x, \sigma)) \in L(V_1)$ which means with probability $(1 - \frac{1}{2^{O(|x|+p_1(|x|)+|p|)}})$ it holds that $((x, \sigma, p), \sigma', P_2(x, \sigma, P_1(x, \sigma)) \in L(V_2)$. So the probability that V accepts is at least:
$$(1 - \frac{1}{2^{O(|x|)}})(1 - \frac{1}{2^{O(|x|+p_1(|x|)+q_1(|x|))}}) = 1 - \frac{1}{2^{O(|x|)}}$$
- **Soundness:** Suppose $x \in \Pi_N$. When given a random σ, we have that with probability less than $\frac{1}{2^{O(|x|)}}$: $\exists p$ such that $(x, \sigma, p) \in L(V_1)$. For $(x, \sigma, p) \notin L(V_1)$, the probability that there is a p such that $((x, \sigma, p), \sigma', p') \in L(V_2)$ is at most $\frac{1}{2^{O(|x|+p_1(|x|)+|p|)}}$ (given random σ'). So the probability that V rejects is at least:
$$(1 - \frac{1}{2^{O(|x|)}})(1 - \frac{1}{2^{O(|x|+p(|x|)+|p|)}}) = 1 - \frac{1}{2^{O(|x|)}}$$

- **Statistical Zero-Knowledge:** Refer to the full version [2]. ◀

▶ **Corollary 25.** $\mathsf{NISZK_L} = \mathsf{NISZK_{AC^0}} = \mathsf{NISZK_{AC^0,DET}} = \mathsf{NISZK_{NL,DET}}$

The proof of Theorem 24 did not make use of the condition that the verifier is at least as powerful as the simulator. Thus, maintaining the condition that $A \subseteq B \subseteq \mathsf{NISZK}_A$, we also have the following corollary:

▶ **Corollary 26.** $\mathsf{NISZK}_B = \mathsf{NISZK}_{B,A}$

▶ **Corollary 27.** $\mathsf{NISZK}_{A,B} \subseteq \mathsf{NISZK}_{B,A}$

▶ **Corollary 28.** $\mathsf{NISZK_{DET}} = \mathsf{NISZK_{DET,AC^0}}$

7 $\mathsf{SZK_L}$ closure under $\leq^{\mathsf{L}}_{\mathrm{bf-tt}}$ reductions

Although our focus in this paper has been on $\mathsf{NISZK_L}$, in this section we report on a closure property of the closely-related class $\mathsf{SZK_L}$.

The authors of [12], after defining the class $\mathsf{SZK_L}$, wrote:

> We also mention that all the known closure and equivalence properties of SZK (e.g. closure under complement [22], equivalence between honest and dishonest verifiers [15], and equivalence between public and private coins [22]) also hold for the class $\mathsf{SZK_L}$.

In this section, we consider a variant of a closure property of SZK (closure under $\leq^{\mathsf{P}}_{\mathrm{bf-tt}}$ [25]), and show that it also holds[5] for $\mathsf{SZK_L}$. Although our proof follows the general approach of the proof of [25, Theorem 4.9], there are some technicalities with showing that certain computations can be accomplished in logspace (and for dealing with distributions represented by branching programs instead of circuits) that require proof. (The characterization of $\mathsf{SZK_L}$ in terms of reducibility to the Kolmogorov-random strings presented in [4] relies on this closure property.)

▶ **Definition 29** (From [25, Definition 4.7]). *For a promise problem* Π*, the characteristic function of* Π *is the map* $\mathcal{X}_\Pi : \{0,1\}^* \to \{0,1,*\}$ *given by*

$$\mathcal{X}_\Pi(x) = \begin{cases} 1 & \textit{if } x \in \Pi_{Yes}, \\ 0 & \textit{if } x \in \Pi_{No}, \\ * & \textit{otherwise.} \end{cases}$$

▶ **Definition 30.** *Logspace Boolean formula truth-table reduction* ($\leq^{\mathsf{L}}_{\mathrm{bf-tt}}$ *reduction): We say a promise problem* Π ***logspace Boolean formula truth-table reduces*** *to* Γ *if there exists a logspace-computable function* f*, which on input* x *produces a tuple* $(y_1, \ldots, y_m)$ *and a Boolean formula* ϕ *(with* m *input gates) such that:*

$$x \in \Pi_{Yes} \implies \phi(\mathcal{X}_\Gamma(y_1), \ldots, \mathcal{X}_\Gamma(y_m)) = 1$$

$$x \in \Pi_{No} \implies \phi(\mathcal{X}_\Gamma(y_1), \ldots, \mathcal{X}_\Gamma(y_m)) = 0$$

[5] We observe that open questions about closure properties of NISZK also translate to open questions about $\mathsf{NISZK_L}$. NISZK is not known to be closed under union [23], and neither is $\mathsf{NISZK_L}$. Neither is known to be closed under complementation. Both are closed under conjunctive logspace-truth-table reductions.

We begin by proving a logspace analogue of a result from [25], used to make statistically close pairs of distributions closer and statistically far pairs of distributions farther.

▶ **Lemma 31** (Polarization Lemma, adapted from [25, Lemma 3.3]). *There is a logspace-computable function that takes a triple $(P_1, P_2, 1^k)$, where P_1 and P_2 are branching programs, and outputs a pair of branching programs (Q_1, Q_2) such that:*

$$\Delta(P_1, P_2) < \frac{1}{3} \implies \Delta(Q_1, Q_2) < 2^{-k}$$

$$\Delta(P_1, P_2) > \frac{2}{3} \implies \Delta(Q_1, Q_2) > 1 - 2^{-k}$$

To prove this, we adapt the same method as in [25] and alternate two different procedures, one to drive pairs with large statistical distance closer to 1, and one to drive distributions with small statistical distance closer to 0. The following lemma will do the former:

▶ **Lemma 32** (Direct Product Lemma, from [25, Lemma 3.4]). *Let X and Y be distributions such that $\Delta(X, Y) = \epsilon$. Then for all k,*

$$k\epsilon \geq \Delta(\otimes^k X, \otimes^k Y) \geq 1 - 2\exp(-k\epsilon^2/2)$$

The proof of this statement follows from [25]. To use this for Lemma 31, we note that a branching program for $\otimes^k P$ can easily be created in logspace from a branching program P by simply copying and concatenating k independent copies of P together.

We now introduce a lemma to push close distributions closer:

▶ **Lemma 33** (XOR Lemma, adapted from [25, Lemma 3.5]). *There is a logspace-computable function that maps a triple $(P_0, P_1, 1^k)$, where P_0 and P_1 are branching programs, to a pair of branching programs (Q_0, Q_1) such that $\Delta(Q_0, Q_1) = \Delta(P_0, P_1)^k$. Specifically, Q_0 and Q_1 are defined as follows:*

$$Q_0 = \bigotimes_{i \in [k]} P_{y_i} : y \leftarrow_R \{y \in \{0,1\}^k : \oplus_{i \in [k]} y_i = 0\}$$

$$Q_1 = \bigotimes_{i \in [k]} P_{y_i} : y \leftarrow_R \{y \in \{0,1\}^k : \oplus_{i \in [k]} y_i = 1\}$$

Refer to Appendix A.4 for proof. We now have the tools to prove Lemma 31.

Proof of Lemma 31. From [25, Section 3.2], we know that we can polarize $(P_0, P_1, 1^k)$ by:

- Letting $l = \lceil \log_{4/3} 6k \rceil$, $j = 3^{l-1}$
- Applying Lemma 33 to $(P_0, P_1, 1^l)$ to get (P_0', P_1')
- Applying Lemma 32: $P_0'' = \otimes^j P_0'$, $P_1'' = \otimes^j P_1'$
- Applying Lemma 33 to $(P_0'', P_1'', 1^k)$ to get (Q_0, Q_1)

Each step is computable in logspace, and since logspace is closed under composition, this completes our proof. ◀

We also mention the following lemma, which will be useful in evaluating the Boolean formula given by the $\leq^{\mathsf{L}}_{\mathrm{bf-tt}}$ reduction.

▶ **Lemma 34.** *There is a function in NC^1 that takes as input a Boolean formula ϕ (with m input bits) and produces as output an equivalent formula ψ with the following properties:*

1. *The depth of ψ is $O(\log m)$.*
2. *ψ is a tree with alternating levels of AND and OR gates.*

3. *The tree's non-leaf structure is always the same for a fixed input length.*
4. *All NOT gates are located just before the leaves.*

Refer to Appendix A.5 for proof.

▶ **Theorem 35.** $\mathsf{SZK_L}$ *is closed under* $\leq^{\mathsf{L}}_{\mathrm{bf-tt}}$ *reductions.*

To begin the proof of this theorem, we first note that as in the proof of [25, Lemma 4.10], given two $\mathsf{SD_{BP}}$ pairs, we can create a new pair which is in $\mathsf{SD}_{\mathsf{BP},No}$ if both of the original two pairs are (which we will use to compute ANDs of queries.) We can also compute in logspace the OR query for two queries by creating a pair $(P_1 \otimes S_1, P_2 \otimes S_2)$. We prove that these operations produce an output with the correct statistical difference with the following two claims:

▷ Claim 36. $\{(y_1, y_2) | \mathcal{X}_{\mathsf{SD_{BP}}}(y_1) \vee \mathcal{X}_{\mathsf{SD_{BP}}}(y_2) = 1\} \leq^{\mathsf{L}}_{\mathrm{m}} \mathsf{SD_{BP}}$.

▷ Claim 37. $\{(y_1, y_2) | \mathcal{X}_{\mathsf{SD_{BP}}}(y_1) \wedge \mathcal{X}_{\mathsf{SD_{BP}}}(y_2) = 1\} \leq^{\mathsf{L}}_{\mathrm{m}} \mathsf{SD_{BP}}$.

Refer to Appendix A.6 and Appendix A.7 for the construction and proof. Crucially we note that the construction still retains a 2/3 completeness and 1/3 soundness bound.

Proof of Theorem 35. Now suppose that we are given a promise problem Π such that $\Pi \leq^{\mathsf{L}}_{\mathrm{bf-tt}} \mathsf{SD_{BP}}$. We want to show $\Pi \leq^{\mathsf{L}}_{\mathrm{m}} \mathsf{SD_{BP}}$, which by $\mathsf{SZK_L}$'s closure under $\leq^{\mathsf{L}}_{\mathrm{m}}$ reductions implies $\Pi \in \mathsf{SZK_L}$.

We follow the steps below on input x to create an $\mathsf{SD_{BP}}$ instance (F_0, F_1) which is in $\mathsf{SD}_{\mathsf{BP},Y}$ if $x \in \Pi_Y$:

1. Run the L machine for the $\leq^{\mathsf{L}}_{\mathrm{bf-tt}}$ reduction on x to get queries $(q_1, \ldots, q_m)$ and the formula ϕ.
2. Build ψ from ϕ using Lemma 34. Replace negated queries $\neg q_i$ with the query produced by the reduction from $\mathsf{SD}_{\mathsf{BP},Y}$ to $\mathsf{SD}_{\mathsf{BP},N}$ on q_i, and then apply Lemma 31 (the Polarization Lemma) with $k = n$ on these queries to get $(y_1, \ldots, y_k)$. Pad the output bits of each branching program so each branching program has m output bits.
3. Build the template tree T. At the leaf level, for each variable in ψ, we will plug in the corresponding query y_i. By Lemma 34 the tree is full.
4. Given x and designated output position j of F_0 or F_1, there is a logspace computation which finds the original output bit from $y_1 \ldots y_m$ that bit j was copied from. This machine traverses down the template tree from the output bit and records the following:
   - The node that the computation is currently at on the template tree, with the path taken depending on j.
   - The position of the random bits used to decide which path to take when we reach nodes corresponding to AND.

   This takes $O(\log m)$ space. We can use this algorithm to copy and compute each output bit of F_0 and F_1, creating (F_0, F_1) in logspace.

For step 4, we give an algorithm $\mathsf{Eval}(x, j, \psi, y_1, \ldots, y_m)$ to compute the jth output bit of F_0 or F_1 on x, for a formula ψ satisfying the properties of Lemma 34, a list of $\mathsf{SD_{BP}}$ queries $(y_1, \ldots, y_m)$, and j. Without loss of generality, we lay out the algorithm to compute only $F_0(x)$.

Outline of $\mathsf{Eval}(x, j, \psi, y_1, \ldots, y_m)$:

The idea is to compute the jth output bit of F_0 by recursively calculating which query output bit it was copied from. To do this, first notice that the AND and OR operations produce branching programs where each output bit is copied from exactly one output bit of one of the query branching programs, so composing these operations together tells us that every output bit in F_0 is copied from exactly one output bit from one query. By Lemma 34 and our AND and OR operations preserving the number of output bits, we also have that if every BP has l output bits, F_0 will have $2^a l = |\psi| l$ output bits, where a is the depth of ψ. This can be used to recursively calculate which query the jth bit is from: for an OR gate, divide the output bits into fourths, and decide which fourth the jth bit falls into (with each fourth corresponding to one BP, or two fourths corresponding to a subtree.) For an AND gate, divide the output into fourths, decide which fourth the jth bit falls into, and then use the 4 random bits for the XOR operation to compute which fourth corresponds to which branching programs (2 fourths will correspond to 1 BP or subtree, and the other 2 fourths will correspond to the 2 BPs from the other subtree.) If j is updated recursively, then at the query level, we can directly return the j'th output bit. This can be done in logspace, requiring a logspace path of "lefts" and "rights" to track the current gate, logspace to record and update j', logspace to compute $2^a l$ at each level, and logspace to compute which subtree/query the output bit comes from at each level.

The resulting BP will be two distributions that will be in $\mathsf{SD}_{\mathsf{BP},Y} \iff x \in \Pi_Y$. By this process $\Pi \leq^{\mathsf{L}}_{\mathrm{m}} \mathsf{SD}_{\mathsf{BP}}$. ◀

A Appendix

This appendix contains some proofs that were moved from the main part of the paper, due to space limitations.

A.1 Proof of Claim 14

Proof. For $x \in \Pi_{YES}$, claim 38 of [1] shows that $\Delta(M_x(r), U_{n^k}) \leq 1/2^{n-1}$, establishing the first part of the claim.

For $x \in \Pi_{NO}$, from the soundness guarantee of the $\mathsf{NISZK_L}$ protocol for $\mathsf{EA_{NC^0}}$, we know that, for at least a $1 - \frac{1}{2^n}$ fraction of the shared reference strings $\sigma \in \{0,1\}^{n^k}$, there is no message p that the prover can send that will cause V to accept. Thus there are at most $2^{n^k - n}$ outputs of $M_x(r)$ other than 0^{n^k}. For $\epsilon < \frac{1}{k}$, we have $|\operatorname{supp}(M_x(r))| \leq 2^{n^k - n^{\epsilon k}}$. $\lhd$

A.2 Proof of Statistical Zero-Knowledge in Section 3.3

Proof. Suppose $X \in \mathsf{SDU'}_{\mathsf{NC^0},Y}$. Recall that $\sigma \sim \{0,1\}^n$, $s \sim \{0,1\}^m$, $p \sim \{r : C(r) = \sigma\}$ and $\gamma = C(s)$. In order to provide an upper bound on $\Delta((p,\sigma),(s,\gamma))$, we consider the element wise probability of each distribution and show that for $X \in \mathsf{SDU'}_{\mathsf{NC^0},Y}$ the claim holds. For $a \in \{0,1\}^m$ and $b \in \{0,1\}^n$ we have:

$$\Delta((p,\sigma),(s,\gamma)) = \sum_{(a,b)} \frac{1}{2} \left|\Pr[(p,\sigma) = (a,b)] - \Pr[(s,\gamma) = (a,b)]\right|$$

Let us consider an element $b \in \{0,1\}^n$. Let $A_b = \{a_1, a_2, .., a_{k_b}\}$ be the pre-images of b under C i.e. for $1 \leq i \leq k_b$ it holds that $C(a_i) = b$. Let $\beta_b = \Pr_{y \sim U_m}[C(y) = b]$. Then $k_b 2^{-m} = \beta_b$ (since exactly k_b elements of $\{0,1\}^m$ are mapped to b under C). Let $B = \{b | \neg\exists y : C(y) = b\}$. Since $\Delta(C(U_m), U_n) \leq \frac{1}{2^{n^\epsilon}}$, it follows that $\frac{|B|}{2^m} \leq \frac{1}{2^{n^\epsilon}}$. We have:

$$\begin{aligned}
\Delta((p,\sigma),(s,\gamma)) &= \sum_{(a,b)} \frac{1}{2}(|\Pr[(p,\sigma) = (a,b)] - \Pr[(s,\gamma) = (a,b)]|) \\
&= \frac{1}{2} \sum_{(a,b):b \in B} |\Pr[(p,\sigma) = (a,b)] - \Pr[(s,\gamma) = (a,b)]| \\
&\quad + \frac{1}{2} \sum_{(a,b):b \notin B} |\Pr[(p,\sigma) = (a,b)] - \Pr[(s,\gamma) = (a,b)]|
\end{aligned}$$

For (a,b) satisfying $b \in B$, we have $\Pr[(s,\gamma) = (a,b)] = \Pr[(p,\sigma) = (a,b)] = 0$. For $b \notin B$ and a satisfying $C(a) \neq b$ we again have $\Pr[(s,\gamma) = (a,b)] = \Pr[(p,\sigma) = (a,b)] = 0$. For $(a,b) : C(a) = b$ we have $\Pr[(s,\gamma) = (a,b)] = 2^{-m}$ since $s \sim U_m$ and picking s fixes b. We also have $\Pr[(p,\sigma) = (a,b)] = \frac{2^{-n}}{k_b}$ since $\sigma \sim U_n$ and then the prover picks p uniformly from A_b. This gives us

$$\begin{aligned}
\Delta((p,\sigma),(s,\gamma)) &= \frac{1}{2} \sum_{(a,b):C(a)=b} \left|2^{-m} - \frac{2^{-n}}{k_b}\right| \\
&= \frac{1}{2} \sum_{(a,b):C(a)=b} \left|2^{-m} - \frac{2^{-m-n}}{\beta_b}\right| \\
&= \frac{1}{2} \sum_{(a,b):C(a)=b} \frac{2^{-m}}{\beta_b} \left|\beta_b - 2^{-n}\right| \\
&\leq \frac{1}{2} \sum_{(a,b):C(a)=b} \left|\beta_b - 2^{-n}\right| = \Delta(C(U_m), U_n) \leq \frac{1}{2^{n^\epsilon}}
\end{aligned}$$

where the first inequality holds since $\beta_b \geq 2^{-m}$ whenever $\beta_b \neq 0$. Thus we have :

$$\Delta((p,\sigma),(s,\gamma)) = O(\frac{1}{2^{n^\epsilon}}).$$ ◀

A.3 Proof of Corollary 19

Proof. Let A be in PM, where there is a logspace oracle machine M accepting A with an oracle P for Perfect Matching. We may assume without loss of generality that all queries made by M on inputs of length n have the same number of vertices $p(n)$. This is because G has a perfect matching iff $G \cup \{x_1 - y_1, x_2 - y_2, ..., x_k - y_k\}$ has a perfect matching. (I.e., we can "pad" the queries, to make them all the same length.)

Let $C = \{(G, W) : g(G, W) \equiv 1 \bmod 2\}$, where g is the function from Lemma 18. Clearly, $C \in \oplus\mathsf{L}$. Now, a logspace oracle machine with input (x, W) and oracle C can simulate the computation of M^P on x; each time M poses the query "Is $G \in P$", instead we ask if $(G, W) \in C$. Then with high probability (over the random choice of W) all of the queries will be answered correctly and hence this routine will accept if and only if $x \in A$, by Lemma 18. Let B be the language accepted by this logspace oracle machine. We see that $B \in \mathsf{L}^C \subseteq \mathsf{L}^{\oplus\mathsf{L}} = \oplus\mathsf{L}$, where the last equality is from [16]. ◀

A.4 Proof of Lemma 33

Proof. The proof that $\Delta(Q_0, Q_1) = \Delta(P_0, P_1)^k$ follows from [25, Proposition 3.6]. To finish proving this lemma, we show a logspace-computable mapping between $(P_0, P_1, 1^k)$ and (Q_0, Q_1).

Let ℓ and w be the max length and width between P_0 and P_1. We describe the structure of Q_0, with Q_1 differing in a small step: to begin with, Q_0 reads the $k-1$ random bits $y_1, \ldots, y_{k-1}$. For each of the random bits, it can pick the correct of two different branches, one having P_0 built in at the end and the other having P_1. We will read y_1, branch to P_0 or P_1 (and output the distribution accordingly), then unconditionally branch to reading y_2 and repeat until we reach y_{k-1} and branch to P_0 or P_1. We then unconditionally branch to y_1 and start computing the parity, and at the end we will be able to decide the value of y_k which will allow us to branch to the final copy of P_0 or P_1.

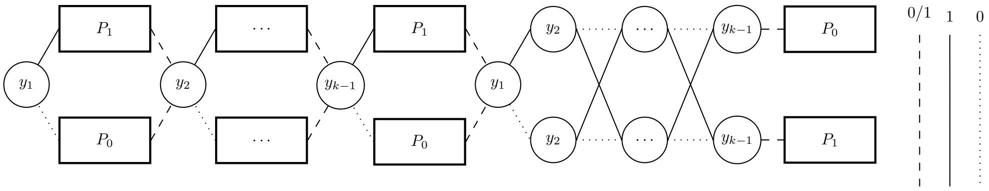

Figure 1 Branching program for Q_0 of Lemma 33.

Creating (Q_0, Q_1) can be done in logspace, requiring logspace to create the section to compute y_k and logspace to copy the independent copies of P_0 and P_1. ◀

A.5 Proof of Lemma 34

Proof. Although this lemma does not seem to have appeared explicitly in the literature, it is known to researchers, and is closely related to results in [13] (see Theorems 5.6 and 6.3, and Lemma 3.3) and in [5] (see Lemma 5). Alternatively, one can derive this by using the fact that the Boolean formula evaluation problem lies in NC^1 [9, 10], and thus there is an alternating Turing machine M running in $O(\log n)$ time that takes as input a Boolean formula ψ and an assignment α to the variables of ψ, and returns $\psi(\alpha)$. We may assume without loss of generality that M alternates between existential and universal states at each step, and that M runs for exactly $c \log n$ steps on each path (for some constant c), and that M accesses its input (via the address tape that is part of the alternating Turing machine model) only at a halting step, and that M records the sequence of states that it has visited along the current path in the current configuration. Thus the configuration graph of M, on inputs of length n, corresponds to a formula of $O(\log n)$ depth having the desired structure, and this formula can be constructed in NC^1. Given a formula ϕ, an NC^1 machine can thus build this formula, and hardwire in the bits that correspond to the description of ϕ, and identify the remaining input variables (corresponding to M reading the bits of α) with the variables of ϕ. The resulting formula is equivalent to ϕ and satisfies the conditions of the lemma. ◀

A.6 Proof of Claim 36

Proof. Let $y_1 = (A_1, B_1)$ and $y_2 = (A_2, B_2)$. Let $p > 0$ be a parameter, where we are guaranteed that:

$$(A_i, B_i) \in \mathsf{SD}_{\mathsf{BP},Y} \implies \Delta(A_i, B_i) > 1 - p$$

$$(A_i, B_i) \in \mathsf{SD}_{\mathsf{BP},N} \implies \Delta(A_i, B_i) < p$$

Then consider:

$$y = (A_1 \otimes A_2, B_1 \otimes B_2)$$

Let us analyze the Yes and No instance of $\mathcal{X}_{\mathsf{SD}_{\mathsf{BP}}}(y_1) \vee \mathcal{X}_{\mathsf{SD}_{\mathsf{BP}}}(y_2)$:

- YES: $\Delta(A_1 \otimes A_2, B_1 \otimes B_2) \geq \max\{\Delta(A_1 \otimes B_2, B_1 \otimes B_2), \Delta(B_1 \otimes A_2, B_1 \otimes B_2)\} = \max\{\Delta(A_1, B_1), \Delta(A_2, B_2)\} > 1 - p$.
- NO: $\Delta(A_1 \otimes A_2, B_1 \otimes B_2) \leq \Delta(A_1, B_1) + \Delta(A_2, B_2) < 2p$.

The second equality is from [25, Fact 2.3]. ◁

In our Boolean formula, we will have only $d = O(\log m)$ depth, so we have this OR operation for at most $\frac{d+1}{2}$ levels (and the soundness gap doubles at every level). Since $p = \frac{1}{2^m}$ at the beginning, the gap (for NO instance) will be upper bounded at the end by:

$$< 2^{\frac{d+1}{2}} \frac{1}{2^m} = \frac{m^{O(1)}}{2^m} < 1/3.$$

A.7 Proof of Claim 37

Proof. Let $y_1 = (A_1, B_1)$ and $y_2 = (A_2, B_2)$. Let $p > 0$ be a parameter, where we are guaranteed that:

$$(A_i, B_i) \in \mathsf{SD}_{\mathsf{BP},Y} \implies \Delta(A_i, B_i) > 1 - p$$

$$(A_i, B_i) \in \mathsf{SD}_{\mathsf{BP},N} \implies \Delta(A_i, B_i) < p$$

We can construct a pair of BPs $y = (A, B)$ whose statistical difference is exactly

$$\Delta(A_1, B_1) \cdot \Delta(A_2, B_2)$$

The pair (A, B) we construct is analogous to (Q_0, Q_1) in Lemma 33, and can be created in logspace with 2 random bits b_0, b_1. We have $A = (A_1, A_2)$ if $b_0 = 0$ and $A = (B_1, B_2)$ if $b_0 = 1$, while $B = (A_1, B_2)$ if b_2 is 0 and (A_2, B_1) if $b_1 = 1$.

Let us analyze the Yes and No instance of $\mathcal{X}_{\mathsf{SD}_{\mathsf{BP}}}(y_1) \wedge \mathcal{X}_{\mathsf{SD}_{\mathsf{BP}}}(y_2)$:

- YES: $\Delta(A_1, B_1) \cdot \Delta(A_2, B_2) > (1-p)^2$.
- NO: $\Delta(A_1, B_1) \cdot \Delta(A_2, B_2) \leq \max\{\Delta(A_1, B_1), \Delta(A_2, B_2)\} < p$. ◁

In our Boolean formula we will have only $d = O(\log m)$ depth, so we have this AND operation for at most $\frac{d+1}{2}$ levels (and the completeness gap squares itself at every level). Since $p = \frac{1}{2^m}$ at the beginning, the gap (for YES instance) will be lower bounded at the end by:

$$> (1 - \frac{1}{2^m})^{2^{\frac{d+1}{2}}} = (1 - \frac{1}{2^m})^{m^{O(1)}} > (1 - \frac{1}{2^m})^{2^m/m} \approx (\frac{1}{e})^{1/m} > \frac{2}{3}.$$

On Constructing Spanners from Random Gaussian Projections

Abstract

Graph sketching is a powerful paradigm for analyzing graph structure via linear measurements introduced by Ahn, Guha, and McGregor (SODA'12) that has since found numerous applications in streaming, distributed computing, and massively parallel algorithms, among others. Graph sketching has proven to be quite successful for various problems such as connectivity, minimum spanning trees, edge or vertex connectivity, and cut or spectral sparsifiers. Yet, the problem of approximating shortest path metric of a graph, and specifically computing a spanner, is notably missing from the list of successes. This has turned the status of this fundamental problem into one of the most longstanding open questions in this area.

We present a partial explanation of this lack of success by proving a strong lower bound for a *large family of graph sketching algorithms* that encompasses prior work on spanners and many (but importantly not also all) related cut-based problems mentioned above. Our lower bound matches the algorithmic bounds of the recent result of Filtser, Kapralov, and Nouri (SODA'21), up to lower order terms, for constructing spanners via the same graph sketching family. This establishes near-optimality of these bounds, at least restricted to this family of graph sketching techniques, and makes progress on a conjecture posed in this latter work.

1 Introduction

Analyzing structure of different objects via random linear projections, also known as *sketching*, is a fundamental paradigm that arise in various contexts. Canonical examples of this approach include dimensionality reduction results such as Johnson-Lindenstrauss lemma [25], sparse recovery results in compressed sensing [16], approximation algorithms for large matrices [40, 41], or various sketches for statistical estimation such as AMS sketch [4], count sketch [12], or count-min sketch [14] in data streams.

A pioneering work of [1] initiated *graph sketching* that considers this paradigm for graphs. A graph sketching algorithm samples a sketching matrix A from a fixed distribution, independent of the input graph G, and compute $A \cdot R(G)$ where R is a suitable representation of G chosen by the algorithm designer, say, its adjacency matrix, Laplacian, or (signed) edge-incidence matrix. The algorithm then uses $A \cdot R(G)$, referred to as the *sketch*, to (approximately) discover properties of G with no further access to G, e.g., to determine

whether or not G is connected. Assuming one can design a sketching matrix A with "few" rows, this approach leads to sketches that can be stored and updated efficiently and be used to recover fundamental properties of G.

The linearity of the sketches and the natural "composability" guarantee that comes with it makes graph sketching a versatile tool in many applications. For instance, graph sketching is the de facto method of algorithm design for *dynamic streaming* algorithms that process a graph specified via a sequence of edge insertions and deletions; see, e.g. [1, 2, 30, 6, 31, 21]. Graph sketching works seamlessly in this model as linearity of sketches allows one to update them easily after each update in the stream. It is even known that this method is universal for dynamic streams under certain (strong) assumptions on length of the stream [35, 3] (see also [28] for necessity of these assumptions). Another model that has benefited greatly from graph sketching is that of *distributed sketching* (a.k.a. simultaneous communication model or broadcast congested clique) wherein every vertex is a processor that sees only edges incident on the vertex and its task is to communicate a small message, simultaneously with other vertices, that allows a referee to solve the problem; see, e.g. [10, 1, 2, 11, 37, 7, 42]. Finally, graph sketching has also been a powerful tool for designing distributed or massively parallel algorithms; see, e.g. [1, 2, 24, 22, 38, 27, 20, 21].

All these considerations have turned graph sketching into a highly attractive solution concept in the last decade since their introduction in [1]. We now have efficient sketches, that often match existentially optimal bounds up to poly-log factors[1], for various fundamental problems such as connectivity [1], minimum spanning trees [1], edge connectivity [1], vertex connectivity [23], cut sparsifiers [2], spectral sparsifiers [30, 31], graph coloring [5], densest subgraph [36], and others.

Graph sketching for spanners

We study graph sketching for the problem of computing *spanners* that (approximately) preserve the shortest path metric of the input graph. Formally,

▶ **Definition 1.** *A subgraph H of a graph $G = (V, E)$ is a d-spanner of G for some integer $d \geq 1$, called the* <u>*stretch*</u> *of the spanner, if for every pair $u, v \in V$ one has*

$$dist_G(u, v) \leq dist_H(u, v) \leq d \cdot dist_G(u, v),$$

where $dist_*(\cdot, \cdot)$ stands for the shortest path metric of the corresponding graph.

For every integer $k \geq 1$, every n-vertex graph $G = (V, E)$ admits a $(2k - 1)$-spanner with only $O(n^{1+1/k})$ edges which is also existentially optimal under the widely-believed Erdős Girth Conjecture. For instance, every graph admits an $O(\log n)$-spanner on $O(n)$ edges.

Spanners are notably absent from the list of successes in graph sketching. Indeed, despite the significant attention given to sketching spanners, see, e.g., [2, 34, 20, 21, 17], until very recently, it was not even known whether an $o(n)$-spanner can be recovered via sketches of $O(n)$ size. The work of [21] made the first progress on this problem in nearly a decade by presenting an $O(n^{2/3})$-spanner using sketches of $\widetilde{O}(n)$ size[2], or more generally a d-spanner using sketches of size $\widetilde{O}(n^2/d^{3/2})$. But such bounds are still quite far from existential bounds on spanners dictated by the girth conjecture. Yet, no non-trivial lower bounds are known for

[1] For instance, sketches of size $O(n \log^3 n)$ for spanning forests of n-vertex graphs [1] compared to existential bound of $\Omega(n \log n)$ bits to store the spanning forest.

[2] We use $\widetilde{O}(\cdot)$ and $\widetilde{\Omega}(\cdot)$ notation to hide poly-log factors.

this problem[3], beside the work of [37] (see also [42]) that proves that finding *any* spanning tree requires sketches of size $\Omega(n \log^3 n)$ bits (namely, a lower bound for any spanner of finite stretch).

The lack of progress on understanding graph sketching for spanners have also been consequential in other computing models that use graph sketching as their primary tool, most notably, the dynamic streaming model. Indeed, complexity of spanners has been a tantalizing open question in the dynamic streaming model already since its introduction in [1] (for insertion-only streams, optimal algorithms that essentially match existential bounds under Erdős girth conjecture have been known since the introduction of the model itself in [18]; see, also [9, 19]).

This state-of-affairs raises the following question: *What is the best stretch-vs-size tradeoff possible for constructing spanners via graph sketching?* We make progress on this longstanding open question by proving a nearly-tight lower bound for a large family of graph sketching algorithms that encompasses prior work on spanners in [21] and most other closely related problems.

1.1 Our Contribution

We prove **a lower bound on the size of a special case yet general family of sketches for graph spanners**. This family, that shall be defined shortly, contains the prior sketching algorithm of [21] for graph spanners – our lower bound matches their bound up to lower order terms and is thus **nearly-optimal**. In addition, this family also contains many prior sketching algorithms for "cut-based" problems such as connectivity [1], vertex connectivity [23], and spectral sparsifiers [30] (and thus also cut sparsifiers). We now elaborate more on our results, starting with the definition of our sketches, which we call *random Gaussian sketches.*

Random Gaussian sketches

To date, the main success of graph sketching has been for *cut-based* problems [1, 2, 30, 23]. These sketches all work by encoding a graph G as its $\binom{n}{2} \times n$ *signed edge-incidence matrix* $B(G)$ (see Section 3.1) and then apply a sketching matrix A with few rows on the left to obtain the sketch $A \cdot B(G)$. The power of these sketches comes from surprisingly powerful cancellations that the use of the signed edge incidence matrix enables. In addition, the sketching matrix A of in these approaches implements a *sparse recovery* scheme on carefully chosen random subgraphs of the input graphs (e.g. uniformly random subgraphs of the input graph in the case of connectivity [1], cut sparsifiers [2], or spectral sparsifiers [30], and sampled vertex induced subgraphs in the case of spanners [21]).

To give a concrete example, let us consider the AGM sketches [1] for finding spanning forests. For any graph $G = (V, E)$ and any set of vertices $S \subseteq V$, adding up the columns of $B(G)$ corresponding to vertices in S, i.e., $\sum_{v \in S} B(G)^v$ gives us a vector with non-zero entries corresponding to edges of the cut $(S, V \setminus S)$. The linearity of matrix A then allows us to obtain

$$A \cdot \left(\sum_{v \in S} B(G)^v \right) = \sum_{v \in S} A \cdot B(G)^v,$$

[3] This state-of-affairs is in sharp contrast with another widely-studied problem of finding large matchings which is also absent from the list of successes in graph sketching; for the matching problem, *asymptotically tight* lower bounds which are much stronger than existential bounds are known; see [6, 15, 8].

for a cut S specified in the recovery phase. The sketching matrix A itself is an ℓ_0-sampler sketch that samples a non-zero entry of a vector v given $A \cdot v$ (see [26, 32]). An ℓ_0-sampler sketch is typically implemented via a simple sparse recovery sketch combined with a sampling matrix that samples the edges of the graph at $O(\log n)$ geometrically decreasing rates. Combined with the above approach, we can thus sample an edge from any cut of the graph specified in the recovery phase. The algorithm of [1] heavily builds on this subroutine by implementing Borůvka's algorithm for growing connected components via using these sketches to find an outgoing edge from each component in each step.

In this paper, we focus on this family of sketches where the sparse recovery scheme is implemented using *random Gaussian projections*. This means that each *row* of the sketching matrix is of the type $g \cdot S$ where S is an $\binom{n}{2} \times \binom{n}{2}$-dimensional diagonal sampling matrix – where $S_{(u,v),(u,v)} = 1$ iff (u,v) is sampled – and g is an $\binom{n}{2}$-dimensional vector of independent Gaussian variables:

$$\begin{bmatrix} \quad g \quad \end{bmatrix}_{1\times\binom{n}{2}} \times \begin{bmatrix} \\ \quad S \quad \\ \\ \end{bmatrix}_{\binom{n}{2}\times\binom{n}{2}} \times \begin{bmatrix} \\ B(G) \\ \\ \end{bmatrix}_{\binom{n}{2}\times n} = \begin{bmatrix} \; g \cdot S \cdot B(G) \; \end{bmatrix}_{1\times n}.$$

The entire sketch is obtained by taking s such rows where sampling matrices can be correlated but Gaussian vectors are independent. The recovery algorithm is given sampling matrices and the sketch but *not* Gaussian variables. We refer to s as the *dimension* of the sketch (thus size of the sketch is $O(s \cdot n)$). See Section 3.1 for formal definitions.

General "power" of random Gaussian sketches? In Appendix A, we show this family of sketches can implement many (but importantly *not* all) prior cut-based sketching algorithms in [1, 30, 23], and most importantly the spanner sketch of [21]. But we also point out that these sketches are *not* universal and one can easily construct problems where the power of these sketches does not match general sketching algorithms[4]. Perhaps more importantly, we assume that the recovery algorithm of these sketches is *oblivious* to the Gaussian vectors used in the sketching matrix which means that the recovery algorithm has a *partial* knowledge of the sketching matrix. A particular shortcoming of this is that while these sketches handle the "main" source of cancelations enabled by edge-incidence matrix, they do *not* handle a "secondary" source of cancelation: to obtain sketches of subgraphs of the input by generating the sketching matrix again at the recovery phase, apply it on some recovered part of the input, and subtract it from the original sketch (this approach is used in the edge connectivity and cut sparsifier sketch of [2] – although we note that random Gaussian sketches can recover a cut sparsifier by instead implementing the algorithm of [30]). We thus see the merit of study of this family as arguably the "most natural" candidate for finding spanners, given their past successes for closely related problems.

Our result

We prove a near-optimal lower bound on the dimension of random Gaussian sketches for constructing spanners, or even returning the distance of two fixed vertices (see also Theorem 5).

[4] Consider recovering the induced subgraph of the input on the first $\sqrt{n}$ vertices. A sparse recovery algorithm that spends $O(\sqrt{n})$ bits per each of these $\sqrt{n}$ vertices gives a sketch of size $O(n)$ for this problem. However, any random Gaussian sketch requires a dimension of $\Theta(\sqrt{n})$ that *cannot* be amortized over all vertices, leading to a sketch of size $O(n^{3/2})$ instead.

▶ **Result 1.** *Any random Gaussian sketch for constructing a d-spanner with constant probability of success requires dimension $\Omega(n^{1-o(1)}/d^{3/2})$, or put differently, any random Gaussian sketch of dimension s can only achieve a stretch of $\Omega((n/s)^{2/3-o(1)})$. The lower bound applies even to the problem of approximating the distance of two fixed vertices.*

Our lower bounds in Result 1 matches algorithmic bounds of [21] up to the $n^{o(1)}$ term for computing spanners via graph sketching (whose sketches fit the framework of random Gaussian sketches) for all stretch d. This establishes the optimality of these bounds at least among this popular family of graph sketching algorithms. We note that [21] conjectured optimality of their algorithmic bounds among *all* graph sketching techniques; our bounds in Result 1 makes partial progress towards settling this conjecture.

Before moving on, we note that for the case when dimension $s = \text{polylog}(n)$, corresponding to sketches of size $\widetilde{O}(n)$, Result 1 implies a lower bound of $n^{2/3-o(1)}$ on the stretch; this should be contrasted with the $O(\log n)$ bound of existential results on the stretch of spanners with $O(n)$ edges, suggesting that computing spanner is much harder using graph sketching (specifically via random Gaussian sketches) compared to existential bounds and arbitrary algorithms. Finally, the lower bound holds even for the algorithmically easier problem of simply estimating distance of two fixed vertices in the graph, as opposed to recovering the entire shortest path metric via a spanner.

Our techniques

We consider a family of hard instances that form a random chain of cliques of size (n/d) with diameter d, and a single edge e^* that connects two vertices at distance $\Theta(d)$ together (see Figure 1). It is easy to see that such e^* should belong to every $o(d)$-spanner of the graph and we prove that no random Gaussian sketch of "small" dimension can recover e^*. The proof is through analyzing how much a *single* random Gaussian projection can reveal information about e^*, or a bit more formally, the KL-divergence between the resulting sketches of two neighboring graphs that only differ on e^*. The rest follows by summing up this information across the s projections.

To prove the bound for a single projection, we use properties of Gaussian variables and KL-divergence to bound the information revealed about the edge e^* by the *effective resistance* of the *sampled* subgraph of the input after applying the sampling matrix. We prove that the distribution of our input, combined with a *hierarchical expander decomposition* of all edges of sampling matrix, implies that the sampled subgraph of the input form a chain of *expanders* (with proper lower bounds on both expansion and minimum degree). This step requires analyzing expansion of vertex-sampled subgraphs of an expander which can be of independent interest. Lastly, we bound the effective resistance of the edge e^* in this chain of expanders by exhibiting a proper *electrical flow* in the graph using properties of expanders.

Related work

In a recent independent work Chen, Khanna and Li [13] showed, similarly to our work, a lower bound matching the sketching dimension of [21] for linear sketches that can support *continuous* weight updates (as opposed to sketches that are only required to work for unweighted graphs). Thus, from the perspective of the ultimate result, the lower bound of [13] is incomparable to ours. Their lower bound works for more general sketches than ours (although still not universal), but assumes that these sketches work in the continuous weight update model; our lower bound assumes a special sketch structure, but works in the mode standard setting of unweighted graphs. There is quite a bit of overlap in techniques: both papers use expander decompositions and prove that expanders are preserved under vertex sampling (but the actual proofs of the corresponding lemmas are different).

2 Preliminaries

Notation

We use $\mathcal{N}(\mu, \sigma)$ to denote the Gaussian distribution with mean μ and variance σ^2. For any distributions P and Q, $\mathbb{D}(P \mid\mid Q)$ denotes the *KL-divergence* of P from Q and $\|P - Q\|_{\text{tvd}}$ is the *total variation distance* between P and Q.

For a graph $G = (V, E)$ on n vertices, we use $d_1, \ldots, d_n$ to denote the degrees of vertices in G. For any sets of vertices $S, T \subseteq V$, $E(S, T)$ denotes the set of edges between S and T and $\text{vol}_G(S) := \sum_{v \in S} d_v$ denotes the *volume* of S (we drop the subscript when clear). The *conductance* of G is defined as

$$\varphi(G) := \min_{S \subseteq V} \frac{|E(S, V \setminus S)|}{\min\{\text{vol}(S), \text{vol}(V \setminus S)\}}.$$

We say that G is a *φ-expander* if its conductance is at least φ.

For a graph G, $\mathbf{A}$ is the *adjacency matrix*, $\mathbf{D}$ is the *degree diagonal matrix*, $\mathbf{B}$ is the *signed edge-incidence matrix*, $\mathbf{L}$ is the *Laplacian matrix*, and $\widetilde{\mathbf{L}}$ is the *normalized Laplacian matrix*. The *spectral gap* of G is defined as the second smallest eigenvalue of $\widetilde{\mathbf{L}}$ which is related to the conductance via Cheeger's inequality. Finally, $R^G_{\text{eff}}(u, v)$ denotes the *effective resistance* between u, v when treating edges of G as resistors with unit resistance.

We also use the following (variant of) expander decomposition that bounds the minimum degree of resulting expanders. The proof is a simple modification of standard decompositions, e.g. in [29, 39].

▶ **Proposition 2.** *Let $G = (V, E)$ be any graph on n vertices and m edges, and $\varepsilon \in (0, 1/2)$ and $d_{\min} \geq 1$ be parameters. The vertices of G can be partitioned into subgraphs $H_1, \ldots, H_k$ such that:*

(i) *Each H_i is an ε-expander with minimum degree $d_{\min}$;*

(ii) *At most $8\varepsilon \cdot m \log n + n \cdot d_{\min}$ edges E_0 of G do not belong to any subgraph $\{H_i\}_{i \in [k]}$.*

3 Main Result

We formalize Result 1 in this section. We start by defining the sketching model, using random Gaussian projections, that we study. We then present our lower bound for constructing spanners (and in general preserving shortest path metric) using these sketches. Finally, we give the proof outline of this result here and postpone the proof of its main ingredients to the subsequent sections.

3.1 Random Gaussian Projections and Sketches

For an n-vertex graph $G = (V, E)$, its **signed edge-incidence** matrix is an $\binom{n}{2} \times n$-dimensional matrix $\mathbf{B} = \mathbf{B}(G)$ defined as follows:

- Each column corresponds to a vertex v and each row corresponds to a pair of vertices (u, w);
- The entry $\mathbf{B}_{(u,w),v}$ is either $+1$ if (u, w) is an edge in G and $v = u$, -1 if (u, w) is an edge in G and $v = w$, and 0 otherwise.

Note that for any edge $e = (u, v)$ of G, the corresponding row (u, v) in $\mathbf{B}$ has exactly one $+1$ at column u, one -1 at column v, and is otherwise 0. A row (u, v) of $\mathbf{B}$ which does not have a corresponding edge in G is the all-0 row.

Our sketches are based on taking random Gaussian projections of matrix $\mathbf{B}$, which roughly speaking correspond to sampling edge of G (using any sampling scheme oblivious to the graph), and multiply a Gaussian vector with signed edge-incidence matrix of the resulting graph. Formally,

▶ **Definition 3.** *Let $G = (V, E)$ be an n-vertex graph and consider the following:*

(i) **Sampling matrix:** *Let $\mathbf{S}$ be a $\binom{n}{2} \times \binom{n}{2}$-dimensional* diagonal *matrix with 0-1-values on the diagonal. Notice that the matrix $\mathbf{S} \cdot \mathbf{B}(G)$ is the edge-incidence matrix of the subgraph of G obtained by picking only those edges of G that their corresponding (diagonal) value in $\mathbf{S}$ is 1.*

(ii) **Gaussian projection:** *Let $\mathbf{g}$ be a $\binom{n}{2}$-dimensional vector of Gaussian random variables, where each entry is sampled independently from $\mathcal{N}(0, 1)$.*

A **random Gaussian projection** *of G with respect to $\mathbf{S}$ is an n-dimensional vector obtained by sampling $\mathbf{g} \sim \mathcal{N}(0, 1)^{\binom{n}{2}}$, and returning $\boldsymbol{p} := \mathbf{g} \cdot \mathbf{S} \cdot \mathbf{B}(G)$.*

Using Definition 3, we can define the sketches we focus on as follows.

▶ **Definition 4.** *Let Π be a problem defined on n-vertex graphs $G = (V, E)$. A* ***random Gaussian sketch*** *for Π is defined via the following pair:*

(i) **Sketching matrices:** *A distribution $\mathcal{D}^{\mathtt{smpl}}$ on s-tuples of sampling matrices for some $s \geq 1$.*

(ii) **Recovery algorithm:** *An algorithm that given s sampling matrices $\mathcal{S} = (\mathbf{S}_1, \ldots, \mathbf{S}_s) \sim \mathcal{D}^{\mathtt{smpl}}$ and s random Gaussian projection $\mathcal{P} = (\boldsymbol{p}_1, \ldots, \boldsymbol{p}_s)$ of any graph G with respect to these sampling matrices, returns a solution to $\Pi(G)$.*

We refer to s as the dimension of the sketch (note that a sketch of dimension s has size $O(s \cdot n)$).

A random Gaussian sketch for a graph G then consists of sampling the sketching matrices $\mathcal{S}$ from $\mathcal{D}^{\mathtt{smpl}}$ (independent of G), receiving random Gaussian projections $\mathcal{P}$, and running the recovery algorithm on $(\mathcal{S}, \mathcal{P})$ to return the solution.

We emphasize that in Definition 4, the recovery algorithm is given the sketching matrices used for random Gaussian projections explicitly, but is *not* given the Gaussian vectors themselves.

We note that our formalization of random Gaussian sketches is new to this paper, albeit it has been used implicitly in prior algorithmic results for in graph sketching literature. In Appendix A, we elaborate more on this connection and point out that how these sketches can be used to solve many of the canonical problems in graph sketching literature such as connectivity, minimum spanning tree, cut or spectral sparsifiers, and most closely related to ours, spanners. But we also emphasize that these sketches are *not* universal – see the discussion on the power of these sketches in Section 1.1.

3.2 The Lower Bound

The following is the formalization of Result 1 that we prove.

▶ **Theorem 5.** *For any absolute constant $\delta \in (0, 1)$, and integers $n \geq 1$ and $1 \leq d \leq n^{2/3-\delta}$, any random Gaussian sketch (Definition 4) that outputs a d-spanner of every given n-vertex graph G with probability at least $2/3$ has dimension (i.e., number of rows)*

$$\Omega(\frac{n^{1-\delta}}{d^{3/2}}).$$

Moreover, the lower bound continues to hold even if the algorithm is only required to answer the shortest path distance *between two* prespecified *vertices up to a factor of d.*

Theorem 5 can alternatively be seen as proving that any random Gaussian sketch of dimension s can only achieve a stretch of

$$\Omega((\frac{n}{s})^{2/3-\delta}),$$

for any constant $\delta > 0$. In light of the result of [21], the bounds obtained in Theorem 5 are optimal, up to $n^{o(1)}$-factors, for the entire range of dimension s or stretch d. In particular, Theorem 5 implies that to obtain a $n^{2/3-\Omega(1)}$-spanner, one needs random Gaussian sketches of dimension $n^{\Omega(1)}$. This makes progress on a conjecture of [21] that stated the same bounds for *arbitrary* sketches.

Finally, we also mention that Theorem 5 works even for the problem wherein we are given two vertices a and b of the graph, and our goal is to simply determine the distance of a and b in the graph using the sketches. This problem is algorithmically easier than finding a spanner of the graph in that firstly, we do not need to pick subset of edges of the graph G and can preserve the shortest path metric in any desired way, and secondly that we only need to maintain the distance between two vertices and not all pairs. Yet, effectively the entirety of our effort is to prove the result for spanners already and we get this stronger lower bound almost for free using standard ideas.

In the rest of this section, we first present a hard input distribution used to establish Theorem 5. We then state our main technical lemma that bounds the information revealed by a single random Gaussian projection on the graphs sampled from this distribution and show how this lemma easily implies the theorem. The next subsection then includes the proof outline of this technical lemma, whose main ingredients are postponed to the next sections.

3.3 A Hard Input Distribution

For any sufficiently large $n, d > 0$, we define a hard distribution $\mu = \mu(n, d)$ over n-vertex graphs. For simplicity, we prove the lower bound for $(d/2)$-spanners instead – reparameterizing d then implies the same asymptotic lower bound for exact d-spanners as well (see Figure 1).

Distribution $\boldsymbol{\mu(n, d)}$. A hard input distribution for $(d/2)$-spanners of n-vertex graphs.

1. Partition the vertices V into d groups $V_1, \ldots, V_d$: each $v \in V$ is sent to one of the groups chosen uniformly at random.
2. Let G be a graph obtained by placing a clique on each $V_i \cup V_{i+1}$ for $i \in [d-1]$.
3. Sample a pair of vertices $(u^*, v^*) \in \binom{V}{2}$ independently and return the graph $G + e^*$ for $e^* = (u^*, v^*)$.

In the following, we use $\mathbf{B} = \mathbf{B}(G)$ to the denote the signed edge-incidence matrix of G; we also use $\mathbf{B}(e^*)$ as the edge-incidence matrix of the n-vertex graph consisting of the single edge $e^* = (u^*, v^*)$. We emphasize that the final graph output by the distribution is $G + e^*$ (this notation will be make the latter parts of the proof cleaner).

We first establish a straightforward property of graphs sampled from μ in context of spanners.

▶ **Lemma 6.** *With constant probability over the choice of $(G, e^*) \sim \mu(n, d)$, every $(d/2)$-spanner of $G + e^*$ contains the edge $e^* = (u^*, v^*)$.*

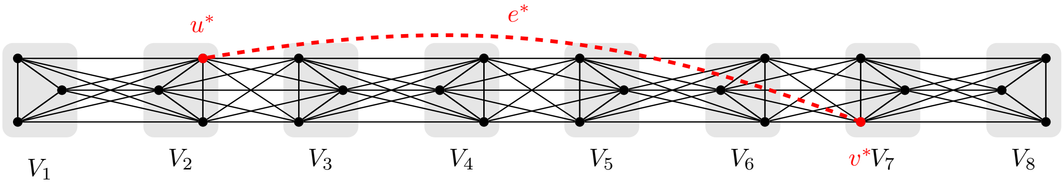

Figure 1 An illustration of $\mu = \mu(n, d)$ for $n = 24$ and $d = 8$. Any 4-spanner of G contains e^*.

Proof. For a graph G and pairs (u^*, v^*) sampled from $\mu(n, d)$,

$$\Pr_{u^*,v^*}\left(dist_G(u^*, v^*) > d/2\right) = \frac{1}{d^2} \cdot \left(O(d) + \sum_{i=1}^{d} |d/2 - i|\right) > \frac{1}{5},$$

where the equality holds since when $u^* \in V_1$, v^* can be in $V_{d/2+2}, \ldots, V_d$, when $u^* \in V_2$, v^* can be in $V_{d/2+3}, \ldots, V_d$, and so on ($O(d)$ handles the differences of even or odd choices of d and $d/2$).

Moreover, whenever the distance of u^*, v^* in G is more than $d/2$, any $(d/2)$-spanner of $G + e^*$ should contain the edge e^*, as otherwise the distance between u^* and v^* in the spanner will be more than $d/2$ times their distance in $G + e^*$, violating the bound on the stretch of the spanner. ◀

The following lemma is the main technical contribution of our work. Roughly speaking, this lemma bounds the "information" that can be learned about the edge e^* in μ using a *single* sub-sampled Gaussian projection of a graph sampled from μ.

▶ **Lemma 7.** *Let* $\mathbf{S}$ *be any sampling matrix and consider a single random Gaussian projection with respect to* $\mathbf{S}$*. For* (G, e^*) *sampled from* $\mu = \mu(n, d)$*,*

$$\mathop{\mathbb{E}}_{G,e^*}\left[\min\{1, \mathbb{D}_{\mathbf{g}}(\mathbf{g}\cdot\mathbf{S}\cdot\mathbf{B}(G) \mid\mid \mathbf{g}\cdot\mathbf{S}\cdot(\mathbf{B}(G) + \mathbf{B}(e^*)))\}\right] = O(\frac{d^{3/2}}{n^{1-\delta}}),$$

for any constant $\delta > 0$*, where the KL-divergence is taken only over the Gaussian variables.*

Before getting to the proof of Lemma 7, we show that it implies Theorem 5 immediately.

Proof of Theorem 5 (assuming Lemma 7). Let $(\mathcal{D}^{\mathtt{smpl}}, \mathcal{A})$ be any sub-sampled Gaussian sketch of dimension $s \geq 1$ for recovering a $(d/2)$-spanner. Consider a distribution μ' on n-vertex graphs defined as follows:

- Distribution μ': Sample (G, e^*) from μ and $\theta \in \{0, 1\}$ uniformly at random; if $\theta = 0$, return G, otherwise return $G + e^*$.

Let G' be a graph sampled from μ'. Suppose we sample $\mathcal{S} = (\mathbf{S}_1, \ldots, \mathbf{S}_s)$ from $\mathcal{D}^{\mathtt{smpl}}$ and receive sub-sampled Gaussian projections $\mathcal{P} = (\boldsymbol{p}_1, \ldots, \boldsymbol{p}_s)$ where for every $i \in [s]$, $\boldsymbol{p}_i = \mathbf{g}_i \cdot \mathbf{S}_i \cdot \mathbf{B}(G')$ for a Gaussian vector $\mathbf{g}_i$. Additionally, suppose we are even given $(\mathcal{S}, G, e^*)$, and thus the only unknown information is whether or not $e^* \in G'$ also, i.e., whether $\theta = 1$ or not. This way, we can run $\mathcal{A}$, using $\mathcal{S}, \mathcal{P}$ as input, to obtain a $(d/2)$-spanner of G': if e^* belongs to this spanner, we declare e^* is in G' and otherwise we say it is not. By Lemma 6, we are going to be able to determine the value of θ with probability $1/2 + \Theta(1)$. This implies that over the distribution μ',

$$\|[(\mathcal{S}, G, e^*, \mathcal{P}) \mid \theta = 0] - [(\mathcal{S}, G, e^*, \mathcal{P}) \mid \theta = 1]\|_{\mathrm{tvd}} = \Omega(1), \tag{1}$$

as otherwise, we cannot estimate the value of θ with probability better than $1/2 + o(1)$ given our input $(\mathcal{S}, G, e^*, \mathcal{P})$ which is sampled from either $\mu' \mid \theta = 0$ or $\mu' \mid \theta = 1$. We now have,

$$\text{LHS of Eq (1)} \leq \mathop{\mathbb{E}}_{(\mathcal{S},G,e^*)} \|[\mathcal{P} \mid \theta = 0, \mathcal{S}, G, e^*] - [\mathcal{P} \mid \theta = 1, \mathcal{S}, G, e^*]\|_{\text{tvd}}$$

(as the distribution of $(\mathcal{S}, G, e^*)$ is the same under both $\theta = 0$ and $\theta = 1$)

$$\leq \sqrt{\mathop{\mathbb{E}}_{(\mathcal{S},G,e^*)} \min\{1, \mathbb{D}(\mathcal{P} \mid \theta = 0, \mathcal{S}, G, e^* \mid\mid \mathcal{P} \mid \theta = 1, \mathcal{S}, G, e^*)\}}$$

(by Pinsker's inequality, the fact that TVD is bounded by 1, and concavity of $\sqrt{\cdot}$)

$$= \sqrt{\mathop{\mathbb{E}}_{(\mathcal{S},G,e^*)} \left[\min\{1, \sum_{i=1}^{s} \mathbb{D}(\boldsymbol{p}_i \mid \theta = 0, \mathcal{S}, G, e^* \mid\mid \boldsymbol{p}_i \mid \theta = 1, \mathcal{S}, G, e^*)\}\right]}$$

(by chain rule of KL-divergence as $\boldsymbol{p}_i$'s are now only function of $\mathbf{g}_i$'s and so are independent)

$$\leq \sqrt{\sum_{i=1}^{s} \mathop{\mathbb{E}}_{(\mathcal{S},G,e^*)} \left[\min\{1, \mathbb{D}(\boldsymbol{p}_i \mid \theta = 0, \mathcal{S}, G, e^* \mid\mid \boldsymbol{p}_i \mid \theta = 1, \mathcal{S}, G, e^*)\}\right]}$$

(we can take min inside the summation to get an upper bound)

$$= \sqrt{\sum_{i=1}^{s} \mathop{\mathbb{E}}_{(\mathbf{S}_i,G,e^*)} \left[\min\{1, \mathbb{D}(\boldsymbol{p}_i \mid \theta = 0, \mathbf{S}_i, G, e^* \mid\mid \boldsymbol{p}_i \mid \theta = 1, \mathbf{S}_i, G, e^*)\}\right]}$$

(as $\boldsymbol{p}_i$ is only a function of $\mathbf{S}_i$ conditioned on G, e^*)

$$= \sqrt{\sum_{i=1}^{s} \mathop{\mathbb{E}}_{(\mathbf{S}_i,G,e^*)\sim\mu} \min\{1, \mathbb{D}_{\mathbf{g}_i}(\mathbf{g}_i \cdot \mathbf{S}_i \cdot \mathbf{B}(G) \mid\mid \mathbf{g}_i \cdot \mathbf{S}_i \cdot (\mathbf{B}(G) + \mathbf{B}(e^*)))\}},$$

where the last equality is because input graph G' in μ' is G when $\theta = 0$ and $G + e^*$ when $\theta = 1$, and distribution of $(\mathbf{S}_i, G, e^*, \mathbf{g}_i)$ is the same under μ and μ'.

Now given that $\mathbf{S}_i \perp (G, e^*)$ in μ, each term in the RHS above is the same quantity upper bounded in Lemma 7. Thus, combining Eq (1), the above equation, and Lemma 7, we get that

$$\Omega(1) = \|[(\mathcal{S}, G, e^*, \mathcal{P}) \mid \theta = 0] - [(\mathcal{S}, G, e^*, \mathcal{P}) \mid \theta = 1]\|_{\text{tvd}} \leq \sqrt{s \cdot O(\frac{d^{3/2}}{n^{1-\delta}})},$$

which implies that $s = \Omega(n^{1-\delta}/d^{3/2})$ as desired. This implies the first part of Theorem 5.

The proof of the second part follows almost immediately from the above argument as follows. Consider the following distribution:

- Distribution μ'': Sample (G', e^*, θ) from μ'. Add two new vertices a and b to the graph and add edges (a, u^*) and (v^*, b) to the graph as well.

Let G'' be a graph sampled from μ''. Consider the distance between a and b in G'': if $\theta = 1$ in the sampled G', distance of a and b is 3, otherwise, if $\theta = 0$, by the same argument as Lemma 6, the distance between a and b is more than $(d/2)$ with constant probability. This means that if our algorithm could simply estimate the distance of a and b to within a factor of $(d/6)$, it can determine the value of θ with probability $1/2 + \Theta(1)$.

Now if we further give u^*, v^*, and the Gaussian variables on all edges incident to a or b to the recovery algorithm, what the algorithm knows becomes the sketches of $G'' \setminus \{a, b\}$ (by simply subtracting the corresponding Gaussians). Since the Gaussians revealed are independent of the sketch of $G'' \setminus \{a, b\}$, the same exact argument as the first part now implies that the same lower bound of $s = \Omega(d^{3/2}/n^{1-\delta})$ on the sketch dimension. Given that the number of vertices in G'' is $n + 2$, and by re-parameterizing d with a constant factor, we obtain the desired lower bound. This concludes the proof of Theorem 5. ◀

3.4 Proof Outline of Lemma 7

We now present the proof outline of Lemma 7, postponing the proof of its two main ingredients to the next two sections. For convenience, we restate Lemma 7 below.

▶ **Lemma** (Restatement of Lemma 7). *Let* $\mathbf{S}$ *be any sampling matrix and consider a single random Gaussian projection with respect to* $\mathbf{S}$*. For* (G, e^*) *sampled from* $\mu = \mu(n, d)$*,*

$$\mathop{\mathbb{E}}_{G,e^*}\left[\min\{1, \mathbb{D}_{\mathbf{g}}(\mathbf{g}\cdot\mathbf{S}\cdot\mathbf{B}(G) \mid\mid \mathbf{g}\cdot\mathbf{S}\cdot(\mathbf{B}(G)+\mathbf{B}(e^*)))\}\right] = O(\frac{d^{3/2}}{n^{1-\delta}}),$$

for any constant $\delta > 0$*, where the KL-divergence is taken only over the Gaussian variables.*

To continue, we define the following notation for the sampling matrix $\mathbf{S}$:

- *graph*$(\mathbf{S})$: the graph on V containing all edges $e \in \binom{V}{2}$ where $\mathbf{S}_{e,e} = 1$.
- $m(\mathbf{S})$: the number of *edges* in *graph*$(\mathbf{S})$.
- $G(\mathbf{S})$: the subgraph of G on edges that belong to *graph*$(\mathbf{S})$, i.e., $G(\mathbf{S}) := G \cap \mathit{graph}(\mathbf{S})$. Note that this way we have, $\mathbf{B}(G(\mathbf{S})) = \mathbf{S}\cdot\mathbf{B}(G)$ and $\mathbf{B}(G(\mathbf{S})+e^*) = \mathbf{S}\cdot(\mathbf{B}(G)+\mathbf{B}(e^*))$.

Ingredient one: from KL-divergence to effective resistances

The first key step of the proof of Lemma 7 is to relate the KL-divergence term of Lemma 7 to *effective resistance* of the edge e^* in the underlying sampled graph. Formally,

▶ **Lemma 8.** *For any sampling matrix* $\mathbf{S}$*, any fixed* G*, and any pair of vertices* $e = (u, v) \in \binom{V}{2}$*,*

$$\min\{1, \mathbb{D}_{\mathbf{g}}(\mathbf{g}\cdot\mathbf{S}\cdot\mathbf{B}(G) \mid\mid \mathbf{g}\cdot\mathbf{S}\cdot(\mathbf{B}(G)+\mathbf{B}(e)))\} \leq 2\cdot R_{\text{eff}}^{G(\mathbf{S})+e}(u, v).$$

We will apply Lemma 8 to the choice of edge $e^* = e$ whenever e^* belongs to *graph*$(\mathbf{S})$, i.e., when e^* is sampled by the sampling matrix $\mathbf{S}$. To prove Lemma 8, we first calculate the KL-divergence between two high-dimensional Gaussians in terms of their covariance matrices. Then we observe that the covariance matrix of $\mathbf{g}\cdot\mathbf{S}\cdot\mathbf{B}(G)$ is simply the *Laplacian matrix* of $G(\mathbf{S})$. The lemma is proved by plugging in the Laplacian matrices of $G(\mathbf{S})$ and $G(\mathbf{S}) + e$, and applying the connection between effective resistance and Laplacian matrix. The proof is provided in the full version.

Ingredient two: bounding effective resistances via expanders

Our strategy is now to bound the effective resistance of the edge e^* in $G(\mathbf{S}) + e^*$. To do so, we will identify a "good"-*expander* subgraph H of the *graph*$(\mathbf{S})$ that contains the edge e^*, and then primarily focus on the edges of H that appear in $G(\mathbf{S})$ to bound the effective resistance of e^* also. The following lemma is the heart of the proof.

▶ **Lemma 9.** *For any sampling matrix* $\mathbf{S}$*, suppose* H *is any subgraph of graph*$(\mathbf{S})$ *which is an* ε*-expander with min-degree* D *for some* $\varepsilon > 0$ *and* $D \geq (\varepsilon^{-8}\cdot n^{\delta})\cdot d$ *for a constant* $\delta > 0$*. For any edge* $e = (u, v) \in H$*,*

$$\mathop{\mathbb{E}}_{G}\left[R_{\text{eff}}^{G(\mathbf{S})+e}(u, v)\right] = O(\varepsilon^{-4})\cdot\left(\frac{d}{D} + \frac{d^3}{D^2}\right).$$

We will use a hierarchical expander decomposition of *graph*$(\mathbf{S})$ to identify an expander that contains the edge e^* and then apply Lemma 9 to this expander and edge e^*. To prove Lemma 9, we first observe that adding edges to a graph could only decrease the effective resistance, and thus, it suffices to study the effective resistance of (u, v) in $G \cap H$. Note that $G \cap H$ randomly partitions the vertices into d sets, and only keeps the edges of H with endpoints in the same set or adjacent sets. We then show that because H is an expander with large min-degree, $G \cap H$ restricted to any two adjacent sets must also be an expander with large min-degree with high probability. Hence, $G \cap H$ looks like a "chain of expanders" (which we call *a balanced path of expanders*), where adjacent expanders have a constant fraction overlap. Finally, we show that since $G \cap H$ overall is well-connected, if we place a unit electric flow from u to v, the flow will be well-spread across the graph. Most edges have a small current, i.e., a low potential difference. Therefore, it allows us to argue that the potential difference between u and v is also small, i.e., the effective resistance between u and v is small. The detailed proof is provided in the full version.

Putting everything together

We now put these two ingredients together to prove Lemma 7. In order to be able to apply our second tool in Lemma 9, we need a *hierarchical* expander decomposition of *graph*$(\mathbf{S})$, which shows that the edge e^* is "more likely" to land in "better" expanders of *graph*$(\mathbf{S})$ for the purpose of Lemma 9 – here, "better" means an expander with a higher minimum degree (the parameter in Lemma 9 that governs the final bound).

▶ **Lemma 10.** *For every $t \geq 1$, we can partition edges of graph$(\mathbf{S})$ into t sets $E_1(\mathbf{S}), \ldots, E_t(\mathbf{S})$ such that:*

(i) *For any $i \leq t$, define $m_i(\mathbf{S}) := |E_i(\mathbf{S})|$; then, $m_1(\mathbf{S}) \leq m(\mathbf{S})$ and $m_{i+1}(\mathbf{S}) \leq m_i(\mathbf{S})/2$.*

(ii) *For any $i < t$, there is some $k_i \geq 1$ such that edges in $E_i(\mathbf{S})$ can be partitioned into ε-expanders $H^i_1, \ldots, H^i_{k_i}$ with minimum degree at least D_i for parameters*[5]

$$\varepsilon := \frac{1}{36 \log n} \quad \textit{and} \quad D_i \geq \frac{m_i(\mathbf{S})}{36n}.$$

Proof. For simplicity of exposition, we drop $(\mathbf{S})$ when denoting $E_i(\mathbf{S})$'s in the following. We construct $E_1, \ldots, E_t$ inductively using an auxiliary set of edges $F_0, \ldots, F_t$. Start with F_0 being the set of all edges in *graph*$(\mathbf{S})$ and for $i = 1$ to t do:

1) Apply the expander decomposition of Proposition 2 to F_{i-1} with parameters

$$\varepsilon = \frac{1}{36 \log n} \quad \text{and} \quad d_{\min} = D_i = \frac{|F_{i-1}|}{36n},$$

to get ε-expanders $H^i_1, \ldots, H^i_{k_i}$ each with minimum degree at least D_i.

2) Let E_i be the union of edges assigned to the expanders in the decomposition of Proposition 2 in the previous step, and F_i be the leftover edges. Continue to iteration $i + 1$.

We argue that $|F_i| \leq |F_{i-1}|/4$ for all $i \leq t$. For $i > 0$, we have that $|F_i|$ is the number of leftover edges of the decomposition and thus by Proposition 2,

$$|F_i| \leq 8\varepsilon \cdot |F_{i-1}| \cdot \log n + n \cdot D_i = \frac{8\,|F_{i-1}|}{36} + \frac{|F_{i-1}|}{36} = \frac{|F_{i-1}|}{4}.$$

Now firstly, $E_i = F_{i-1} \setminus F_i$ and so by the above bound, $|E_i| \geq 2\,|F_i|$. At the same time, $E_{i+1} \subseteq F_i$ for and thus $|E_i| \geq 2\,|E_{i+1}|$. This proves the first part.

Secondly, we get property (ii) of the lemma by the choice of $\varepsilon = 1/36 \log n$ in the decomposition and since $D_i = |F_{i-1}|/36n \geq |E_i|/36n$ as $E_i \subseteq F_{i-1}$. ◀

[5] Notice that the edges $E_t(\mathbf{S})$ admit no such type of expander decomposition in our partitioning.

We now have all the tools needed to prove Lemma 7. For the rest of the proof, we fix a partitioning $(E_1(\mathbf{S}), \ldots, E_t(\mathbf{S}))$ of $graph(\mathbf{S})$ using Lemma 10 for some $t \geq 1$ such that:

$$t \text{ is the } \underline{\text{largest}} \text{ index where:} \quad m_{t-1}(\mathbf{S}) \geq n^{1+\delta} \cdot d^{3/2}, \tag{2}$$

where $\delta > 0$ is the absolute constant in Lemma 7. This means that for every $e \in E_i(\mathbf{S})$ for $i < t$, the edge e belongs to some ε-expander H^i_j for $j \in [k_i]$ with min-degree D_i such that,

$$\varepsilon = \frac{1}{36 \log n} \qquad \text{and} \qquad D_i \geq \frac{m_i(\mathbf{S})}{36n}. \tag{3}$$

This also implies that $D_i \geq (1/36) \cdot d^{3/2} \cdot n^{\delta} \geq (\varepsilon^{-10} \cdot n^{\delta'}) \cdot d$ for some absolute constant $\delta' > 0$ which allows us to apply Lemma 9 to each expander H^i_j in the proof.

We now have,

$$\begin{aligned}
\text{LHS of Lemma 7} &= \mathop{\mathbb{E}}_{G,e^*}\Big[\min\{1, \mathbb{D}_{\mathbf{g}}(\mathbf{g}\cdot\mathbf{S}\cdot\mathbf{B}(G) \mid\mid \mathbf{g}\cdot\mathbf{S}\cdot(\mathbf{B}(G)+\mathbf{B}(e^*)))\}\Big] \\
&= \sum_{e \in graph(\mathbf{S})} \Pr(e^* = e) \cdot \mathop{\mathbb{E}}_{G \mid e^* = e}\Big[\min\{1, \mathbb{D}_{\mathbf{g}}(\mathbf{g}\cdot\mathbf{S}\cdot\mathbf{B}(G) \mid\mid \mathbf{g}\cdot\mathbf{S}\cdot(\mathbf{B}(G)+\mathbf{B}(e^*)))\}\Big] \\
&\qquad \text{(whenever } e^* \notin graph(\mathbf{S})\text{, both terms of the KL-divergence will be the same and thus it will be 0)} \\
&= \sum_{i=1}^{t} \sum_{e \in E_i(\mathbf{S})} \Pr(e^* = e) \cdot \mathop{\mathbb{E}}_{G}\Big[\min\{1, \mathbb{D}_{\mathbf{g}}(\mathbf{g}\cdot\mathbf{S}\cdot\mathbf{B}(G) \mid\mid \mathbf{g}\cdot\mathbf{S}\cdot(\mathbf{B}(G)+\mathbf{B}(e^*)))\}\Big] \\
&\qquad \text{(by the partitioning of edges of } graph(\mathbf{S}) \text{ and since } G \perp e^* \text{ in } \mu) \\
&= \frac{1}{\binom{n}{2}} \sum_{i=1}^{t} \sum_{e \in E_i(\mathbf{S})} \Big[\min\{1, \mathbb{D}_{\mathbf{g}}(\mathbf{g}\cdot\mathbf{S}\cdot\mathbf{B}(G) \mid\mid \mathbf{g}\cdot\mathbf{S}\cdot(\mathbf{B}(G)+\mathbf{B}(e)))\}\Big] \\
&\qquad \text{(as the marginal distribution of } e^* \text{ is uniform over } \tbinom{V}{2} \text{ and we conditioned on } e^* = e) \\
&\leq \frac{m_t(\mathbf{S})}{\binom{n}{2}} + \frac{1}{\binom{n}{2}} \cdot \sum_{i=1}^{t-1} \sum_{e=(u,v) \in E_i(\mathbf{S})} \mathop{\mathbb{E}}_{G}\Big[2 \cdot R_{\text{eff}}^{G(\mathbf{S})+e}(u,v)\Big] \\
&\qquad \text{(using the trivial upper bound of 1 for } E_t(\mathbf{S}) \text{ and Lemma 8 for } E_1(\mathbf{S}), \ldots, E_{t-1}(\mathbf{S})) \\
&= \frac{m_t(\mathbf{S})}{\binom{n}{2}} + \frac{2}{\binom{n}{2}} \cdot \sum_{i=1}^{t-1} \sum_{j=1}^{k_i} \sum_{e=(u,v) \in H^i_j} \mathop{\mathbb{E}}_{G}\Big[R_{\text{eff}}^{G(\mathbf{S})+e}(u,v)\Big] \\
&\qquad \text{(as each } E_i(\mathbf{S}) \text{ for } i < t \text{ is partitioned into expanders } H^i_1, \ldots, H^i_{k_i} \text{ by Lemma 10)} \\
&= \frac{m_t(\mathbf{S})}{\binom{n}{2}} + \frac{2}{\binom{n}{2}} \cdot \sum_{i=1}^{t-1} \sum_{j=1}^{k_i} \sum_{e=(u,v) \in H^i_j} O(\varepsilon^{-4}) \cdot \Big(\frac{d}{D_i} + \frac{d^3}{D_i^2}\Big) \\
&\qquad \text{(by Lemma 9 as each } H^i_j \text{ is an } \varepsilon\text{-expander with min-degree } D_i \text{ (and by Eq (3) we can use the lemma))} \\
&= \frac{m_t(\mathbf{S})}{\binom{n}{2}} + \frac{2}{\binom{n}{2}} \cdot \sum_{i=1}^{t-1} m_i(\mathbf{S}) \cdot O(\log^4 n) \cdot \Big(\frac{d \cdot n}{m_i(\mathbf{S})} + \frac{d^3 \cdot n^2}{m_i(\mathbf{S})^2}\Big) \\
&\qquad \text{(as } \varepsilon = \Theta(1/\log n) \text{ and } D_i \geq m_i(\mathbf{S})/12n \text{ by Eq (3) and } H^i_1, \ldots, H^i_{k_i} \text{ have } m_i(\mathbf{S}) \text{ edges in total)} \\
&= \frac{m_t(\mathbf{S})}{\binom{n}{2}} + O(\log^5 n \cdot \frac{d}{n}) + O(\log^4 n) \cdot \frac{d^3}{m_{t-1}(\mathbf{S})} \\
&\qquad \text{(as } m_i(\mathbf{S})\text{'s decrease (at least) by a geometric series and } t = O(\log n) \text{ by Lemma 10)} \\
&\leq \frac{n^{1+\delta} \cdot d^{3/2}}{\binom{n}{2}} + O(\log^5 n \cdot \frac{d}{n}) + O(\log^4 n) \cdot \frac{d^3}{n^{1+\delta} \cdot d^{3/2}} \qquad \text{(by the choice of } t \text{ in Eq (2))} \\
&= O(\frac{d^{3/2}}{n^{1-\delta}}).
\end{aligned}$$

This concludes the proof of Lemma 7. Due to page limits, we omit the proof of Lemma 8 and Lemma 9 here. They can be found in the full version.

A Implementing Prior Work Via Random Gaussian Sketches

We now outline implementations of existing works on graph sketching in our model.

A.1 ℓ_0-samplers and connectivity sketches

Recall that in the ℓ_0-sampling problem one needs to design a sketching matrix A such that for every $x \in \mathbb{R}^n$ one can recover a uniformly random element of x from Ax (to within total variation distance δ) or output FAIL (with failure probability bounded by δ)[6]. We outline a construction of an ℓ_0-sampler in our model, i.e. where every rows of the sketch A is of the form $g \cdot S$, where S is an arbitrary matrix with zeros and ones on the diagonal and zeros on off-diagonal entries (S is known to the decoder) and g is a vector with i.i.d. unit variance Gaussian entries (g is not known to the decoder). Note that our ℓ_0-sampler only needs to work for vectors x whose entries are in $\{-1, 0, +1\}$, as this is the case in all applications of graph sketching.

We first recall the construction of a basic ℓ_0 sampler (see [26] for a space-optimal construction). For integer j between 0 and $\lceil \log_2 n \rceil$ let $x^j \in \mathbb{R}^n$ denote the restriction of x^j to elements of a subset of the universe $[n]$ that includes every element independently with probability 2^{-j}. There exists j^* such that with constant probability x^j contains exactly one nonzero. To determine the value of j^* or conclude that such an index does not exist, it suffices to estimate the ℓ_2^2 norm of x to within a $1 \pm 1/3$ factor, for example (since nonzero entries of x equal 1 in absolute value). The latter can be achieved (with at most inverse polynomial failure probability) by averaging squared dot products of $O(\log n)$ independent Gaussian vectors with x^j, which is allowed by our model. Note that here the decoder indeed does not need to know the Gaussian vectors, as required. If j^* exists, one must recover the identity of the nonzero element. The typical way to do it is to compute the dot product of x^{j^*} with the vector whose i-th coordinate equals i, for every $i \in [n]$. This is not available in our model. To replace this approach, for every $j = 0, \ldots, \lceil \log_2 n \rceil$ and $b = 0, \ldots, \lceil \log_2 n \rceil$ approximate the ℓ_2^2 norm of the vector x^j restricted to the set of elements in $[n]$ that have 1 in the b-th position in their binary representation using $O(\log n)$ dot products with i.i.d. Gaussians. This allows one to read off the binary representation of the nonzero in x^{j^*}, and therefore yields an ℓ_0 sampler.

Graph connectivity and spanning trees

Since an ℓ_0-sampler is the only sketch used by the connectivity sketch of [1], it follows that a spanning forest of the input graph can be recovered by a sketch that fits our model and has a polylogarithmic number of rows.

[6] Note that these two parameters appear differently in the space complexity of ℓ_0-sampling, and are therefore treated separately in works that obtain optimal space bounds for ℓ_0-samplers [1]. We set both parameters to δ for simplicity.

Approximate vertex connectivity

The result of [23] uses the spanning tree sketch of [1] black box (the sketch is applied to random vertex induced subgraphs) to approximate vertex connectivity. Since the sketch of [1] can be implemented in our model, as described above, the result of [23] also can.

A.2 ℓ_2-heavy hitters, spectral sparsifiers and spanners

Recall that in the φ-heavy hitters problem in ℓ_2 one needs to design a sketching matrix A such that for every $x \in \mathbb{R}^n$ one can recover a list of elements $L \subseteq [n]$ such that every $i \in [n]$ satisfying $x_i^2 \geq \varphi\|x\|_2^2$ belongs to L and no $i \in [n]$ with $x_i^2 < c\varphi\|x\|_2^2$ for a constant $c > 0$ belongs to L.

A basic ℓ_2 heavy hitters sketch works by first hashing elements of $[n]$ to $B \approx 1/\varphi$ buckets, i.e. effectively defining x^b for $b \in [B]$ to be the restriction of x to bucket b, and computing the sum of elements of x^b with random signs. In our model we can replace the random signs with random Gaussians, so that the resulting dot product is Gaussian with variance $\|x^b\|_2^2$. Fixing any $j \in [n]$ and letting b denote the bucket that j hashes to we get that a single hashing can be used to obtain an estimate of its absolute value that is correct up to constant factor and an additive $O(1/\sqrt{B})\|x\|_2$ term with probability[7] at least 9/10. We can now repeat the estimator $O(\log n)$ times and include in L elements that are estimated as larger than a $c'\varphi\|x\|_2$ for a sufficiently small constant $c' > 0$ in absolute value. Therefore, setting $B = O(1/\varphi)$ achieves the required bounds. This yields an ℓ_2-heavy hitters sketch with decoding time nearly linear in the size n of the universe. The decoding time can be improved to $(1/\varphi) \cdot \mathrm{poly}(\log n)$ using a bit-encoding approach similar to the one from Section A.1 above.

Spectral sparsifiers and spanners

Spectral sparsification sketches [30, 33, 31] require graph connectivity sketches, which we already implemented in Section A.1, as well as ℓ_2-heavy hitters sketches, and therefore can also be implemented in our model. Non-adaptive sketching algorithms for spanner construction [21] rely on spectral sparsification sketches that are applied to vertex-induced subgraphs of the input graph. Thus, these sketches can also be implemented in our model with at most a polylogarithmic loss in the number of rows.

[7] We use the fact that the dot product of x^b with a random Gaussian vector will be distributed as $g_j x_j + N(0, \|x^b_{-j}\|_2^2)$, and $|g_j|$ is at least a constant with probability at least 9/10. Here x_j^b stands for the vector obtained from x^b by zeroing out entry j.

Evaluating Stability in Massive Social Networks: Efficient Streaming Algorithms for Structural Balance

Abstract

Structural balance theory studies stability in networks. Given a n-vertex complete graph $G = (V, E)$ whose edges are labeled positive or negative, the graph is considered *balanced* if every triangle either consists of three positive edges (three mutual "friends"), or one positive edge and two negative edges (two "friends" with a common "enemy"). From a computational perspective, structural balance turns out to be a special case of correlation clustering with the number of clusters at most two. The two main algorithmic problems of interest are: (i) detecting whether a given graph is balanced, or (ii) finding a partition that approximates the *frustration index*, i.e., the minimum number of edge flips that turn the graph balanced.

We study these problems in the streaming model where edges are given one by one and focus on *memory efficiency*. We provide randomized single-pass algorithms for: (i) determining whether an input graph is balanced with $O(\log n)$ memory, and (ii) finding a partition that induces a $(1+\varepsilon)$-approximation to the frustration index with $O(n \cdot \operatorname{polylog}(n))$ memory. We further provide several new lower bounds, complementing different aspects of our algorithms such as the need for randomization or approximation.

To obtain our main results, we develop a method using pseudorandom generators (PRGs) to sample edges between independently-chosen *vertices* in graph streaming. Furthermore, our algorithm that approximates the frustration index improves the running time of the state-of-the-art correlation clustering with two clusters (Giotis-Guruswami algorithm [SODA 2006]) from $n^{O(1/\varepsilon^2)}$ to $O(n^2 \log^3 n/\varepsilon^2 + n \log n \cdot (1/\varepsilon)^{O(1/\varepsilon^4)})$ time for $(1+\varepsilon)$-approximation. These results may be of independent interest.

1 Introduction

Structural balance theory [21, 30, 35, 36] arises in the study of social relationships with positive and negative relations. Positive links describe friendship/agreement and negative links describe antagonism/disagreement. The theory dates back to work by Heider [35]. It describes the stability of relations among three individuals – only two kinds of triangles are stable: the ones where all three ties are positive, indicating mutual friendship; and the ones with two negative ties and one positive tie, describing the folklore that "the enemy of your enemy is your friend." A network that is far from being balanced (i.e., with many unstable triangles) accumulates stress which may lead to major re-arrangements of edges.

The structural balance theory appears in many application areas such as international relations [7, 43], biological networks [29, 38], portfolio analysis in financial networks [33], Ising model [14] in statistical physics, and online social media and opinion formation, dynamics, and evolution [6, 48–50] which bears itself on, for example, Facebook [47] and Twitter [40, 51].

One fundamental question is to understand whether a network is close to being balanced or not. In a *complete signed* graph where each pair of vertices is labeled positive or negative – the focus of our study – , the *Cartwright-Harary Theorem* [21, 32] states that every balanced network must have the nodes partitioned into (at most) two "camps", inside each of which the edges are all positive and between them the edges are negative. For graphs that are not balanced, a natural measure to characterize its distance from total balance is the *frustration index*, defined as the minimum number of edges whose negation of signs results in balance [1, 8, 34, 53]. These questions can be distilled into the following algorithmic problems (see Problem 1 and Problem 2 for the formal definitions):

- **Structural Balance Testing**: Given a complete signed graph G, decide whether or not it is balanced, namely, does not contain any imbalanced triangle.
- **Frustration-minimizing Partition**: Given a complete signed graph G, find a partition of vertices into two camps such that the minimum number of sign flips on the edges is required for the resulting graph to be balanced.

The problems we consider are closely related to (min-disagreement) *correlation clustering* where the goal is to partition the graph into clusters, so as to minimize the total number of negative edges inside clusters and positive edges across the clusters [5, 13, 24, 25, 28, 31], except that structural balance enforces the number of clusters to be two. Structural balance testing is straightforward to solve in $O(n^2)$ time on n-vertex graphs: place an arbitrary vertex and all its positive neighbors on one side of the bi-partition L, and its negative neighbors on the other side R, and then verify. On the other hand, the classical work by Giotis and Guruswami [31] on correlation clustering with two clusters implies the NP-hardness of the frustration-minimizing partition. It further provides a PTAS with running time $n^{O(1/\varepsilon^2)} + n \cdot (1/\varepsilon)^{O(1/\varepsilon^4)}$ for $(1+\varepsilon)$-approximation of this problem. To our knowledge, this is the state of the art for structural balance testing and frustration-minimizing partition.

Prior work primarily focused on *running time* of algorithms and assume *unrestricted access* to the entire graph. In many modern applications of large-scale networks, however, there are many other considerations to take into account. For instance, the algorithms may only have **limited access** to and a **memory** much smaller than the input. One of the most popular models capturing the above scenario is the **graph streaming model**. In this model, the edges arrive one after another and the algorithm needs to process this stream "on-the-fly" with limited memory. The algorithm is allowed to make one or multiple passes over the stream, and the memory is usually substianlly smaller than the (worst-case) input size, i.e. $\Theta(n^2)$. We focus on the single-pass setting and ask the following motivating question: *How well can we solve structural balance testing and frustration-minimizing partition problems in the single-pass graph streaming setting?*

The golden spots for streaming algorithms are (i) the polylog(n) memory regime, which is polynomial to the memory that is necessary to represent a single edge, and (ii) the $\widetilde{O}(n) := O(n \cdot \text{polylog}(n))$ memory regime – often referred to as the *semi-streaming* model. We study structural balance in the graph streaming model in these parameter regimes.

1.1 Our Contributions

Structural balance testing. One way of testing structural balance of G is to check whether the 2-lift of G associated with its edge signing is connected. Computing the 2-lift can be done on-the-fly, and testing connectivity in the streaming model can be done with $O(n \log n)$ space. This is already a quadratic improvement over the trivial algorithm with $O(n^2)$ space, and it is also known that graph connectivity requires $\Omega(n \log n)$ space in the streaming model. Is this also the limit for structural balance testing? Our first result is a simple algebraic algorithm, which stems from testing for complete bipartiteness of negative edges, that uses *exponentially improved* space complexity. In the full version, we also provide a companion algorithm that, while more complicated to describe, is combinatorial and introduces a technique that partially derandomizes a vertex sketch we use where hash functions with limited-independence alone do not suffice.

▶ **Result 1** (Informal statement of Theorem 2)**.** *There is a single-pass randomized algorithm that given a complete signed graph G in a graph stream, tests whether G is balanced with probability at least $\frac{99}{100}$ using $O(\log n)$ space.*

Result 1 shows that structural balance testing can be done with high space efficiency – note that $\Theta(\log n)$ space is necessary to simply write down a single edge. As we elaborate later, our algorithms in Result 1 are *sketching-based* algorithms that are randomized and crucially use the fact that each edge of the graph appears precisely once in the stream. We further complement our algorithms with two new lower bounds (Propositions 10 and 11) that show the necessity of both conditions for obtaining any $o(n)$-space algorithm for this problem. Additionally, a standard $\Omega(n \log n)$ space lower bound for input graphs that are not necessarily complete via a reduction from bipartiteness testing can be shown (see the full version); the generalized problem and the $o(n)$ space regime are thus incompatible.

Frustration-minimizing partition. Outputting the solution to frustration-minimizing partition already requires $\Omega(n)$ space, thus, as is standard, we focus on semi-streaming algorithms for this problem. One can use *cut sparsifiers* and a variant of an argument by [3] (for correlation clustering) to obtain an algorithm with $\widetilde{O}(n/\varepsilon^2)$ space that can return the "frustration value" of any bi-partition of vertices to within a $(1 \pm \varepsilon)$ factor. By enumerating over all bi-partitions, then, we can find the frustration-minimizing one up to a $(1 + \varepsilon)$-approximation. The problem with this approach is that the resulting algorithm takes exponential time (to enumerate all bi-partitions), which is quite prohibitive, especially in large graphs[1].

[1] This scenario is not uncommon in the streaming model. For instance, the Tournament Feedback Arc Set problem admits an "easy" exponential-time $(1 + \varepsilon)$-approximation semi-streaming algorithm [22] that was improved very recently by [16] to a PTAS albeit with $O(\log n)$ passes over the stream; see [15] for another example.

To bypass this challenge, we present a "streamified" version of the correlation clustering algorithm with two clusters of [31] (henceforth, the Giotis-Guruswami algorithm); namely, an approach that allows us to collect just enough information from the stream to *weakly* simulate (meaning not entirely faithfully) the Giotis-Guruswami algorithm in polynomial time at the end of the stream.

▶ **Result 2** (Informal statement of Theorem 7)**.** *There is a single-pass randomized algorithm that given a complete signed graph in a graph stream, with high probability*[a] *finds a partition of vertices with frustration value at most* $(1+\varepsilon)$ *factor of the frustration index using* $\widetilde{O}(n/\varepsilon^2)$ *space and polynomial (in* n *but not* ε*) time.*

[a] Here, and throughout, with high probability means with probability at least $1 - 1/n$.

Result 2 gives an efficient semi-streaming algorithm for $(1 + \varepsilon)$-approximation of the frustration-minimizing partition problem, which is NP-hard to solve exactly. We further show (Proposition 13) that even if we allow the streaming algorithm to use exponential (or more) time, solving this problem exactly requires $\Omega(n^2)$ space (the same as storing the entire input). This fully rules out any non-trivial streaming algorithms for solving this problem exactly.

There is still one missing piece in obtaining "truly efficient" semi-streaming algorithms for our problem. As stated earlier, the Giotis-Guruswami algorithm that Result 2 builds on has running time (roughly) $n^{O(1/\varepsilon^2)}$ even ignoring any streaming aspects[2], which makes this algorithm quite impractical. Our final contribution remedies this state of affairs. By building on our weak simulation of the Giotis-Guruswami algorithm in Result 2, we design an improved offline (non-streaming) algorithm for frustration-minimizing partition with nearly-linear running time for any fixed $\varepsilon > 0$ (note that the input is of size $\Theta(n^2)$ in this problem over a complete signed graph).

▶ **Result 3** (Informal statement of Theorem 9)**.** *There is a randomized (classical) algorithm that given a complete signed graph, with high probability, finds a partition of vertices with frustration value at most* $(1+\varepsilon)$ *factor of the frustration index in* $\widetilde{O}(n^2/\varepsilon^2 + n\cdot(1/\varepsilon)^{O(1/\varepsilon^4)})$ *time.*

Result 3 presents the first improvement after two decades over the Giotis-Guruswami algorithm for frustration-minimizing partition and correlation clustering with two fixed clusters *outside of graph streaming models*, which can be of independent interest. Moreover, the algorithm in Result 3 can also be used in Result 2, improving the running time to nearly-linear for any constant $\varepsilon > 0$ in the semi-streaming model.

Our algorithmic results combined with our new lower bounds (in Section 5) collectively complete the picture of streaming and efficient algorithms for structural balance testing and frustration-minimizing partition problems.

1.2 Our Techniques

Structural balance testing. The lower bounds in Propositions 10 and 11 show that any $o(n)$-space algorithm for testing structural balance has to be randomized and, more importantly, uses the fact that it sees the sign between every pair of vertices *exactly once*. This motivates

[2] A simple modification of the Giotis-Guruswami algorithm and a slightly more careful analysis actually reduces the running time of their algorithm to roughly $O(n^{100} + n \cdot (1/\varepsilon)^{O(1/\varepsilon^4)})$ (see the analysis in Section 4). While this is faster than the original $n^{O(1/\varepsilon^2)}$ bound, it is still quite far from being practical.

us to consider *sketching-based* algorithms that are based on collecting aggregate statistics of large subsets of edges in the graph when seeing them in the stream (without having to store explicit information). We proceed by proving the following structural result (stated informally): (i) In any balanced graph, for any set S of *odd* size, there is an *even* number of pairs of vertices in S with a negative sign (easy direction); (ii) Conversely, in any unbalanced graph, a constant fraction of odd-size sets S (of certain cardinality) have an *odd* number of negatively-signed pairs inside (hard direction).

This result naturally suggests the following algorithm (stated with some oversimplification): sample an odd-size set S of vertices uniformly at random at the beginning of the stream and count the number of negative edges in the stream with both endpoints in S. In the balanced case, this number will be even, while in the unbalanced case, it has a non-trivial chance of being odd.

There is a serious challenge in making this strategy work: determining S and therefrom which edges should be counted requires $\Omega(n)$ space to *store the random bits.* We surmount this by observing that the function for the parity of "$-$" edges in a sampled set S can be viewed as a *degree-2 polynomial* with one variable per vertex. As such, we turn from sampling vertices to using PRGs for low-degree polynomials based on sums of small bias generators so that $O(\log(n))$ truly random bits and $O(\log(n))$ extra space suffice to generate pseudorandom bits whose 0-set on the polynomial is in proportion with that of truly random bits. In the full version, we also give an alternative combinatorial algorithm (in contrast with the abovestated algebraic algorithm) which is interesting in its own right, especially from a techniques standpoint.

Frustration-minimizing partition. Our algorithm in Result 2 is obtained via "streamifying" the Giotis-Guruswami algorithm [31]. Their algorithm considers the high versus low frustration index cases separately where the high frustration index scenario means at least a constant fraction of all pairs needs to flip sign. Among these, the first part has a simple solution in [31] which already lends itself to a semi-streaming algorithm immediately. Our main technical ingredient in Result 2 lies in addressing the low frustration index case. For simplicity of exposition, in the following, we assume ε is a constant.

The Giotis-Guruswami algorithm in the low frustration index case is as follows. Sample $O(\log n)$ vertices S and enumerate all $n^{O(1)}$ bi-partitions of S. Then, for every bi-partition (S_L, S_R), perform a *merging* operation followed by a *switching* operation: In merging, every vertex $v \in V \setminus S$ is assigned in parallel to the side of (S_L, S_R) that creates less frustration for v, i.e., the number of negative edges of v to this side plus its positive edges to the opposing side is minimized. Let (L, R) be the resulting bi-partition of vertices. In switching, each vertex $v \in V$ in parallel is re-assigned to the side of (L, R) with the least frustration. The analysis of [31] is as follows: for the bi-partition (S_L, S_R) of S that is consistent with the optimal solution, (i) after merging, most vertices are in the "correct" side of (L, R) already, namely, they are consistent with the optimal bi-partition, and (ii) after switching, the vertices already consistent with the optimal solution do not change side, and the rest of vertices are moved to the side that only induce a small additive cost. The key reasoning behind both steps is that in the low frustration-index case, most vertices have a "clear" preference toward which side of the optimal bi-partition they should reside.

To simulate the Giotis-Guruswami algorithm via a semi-streaming algorithm, we can sample the set S at the beginning of the stream and store all $\widetilde{O}(n)$ edges incident on it during the stream. The merging phase can now be easily implemented as it relies only on the edges connected to S. The switching phase, on the other hand, requires checking *every* edge in the graph and thus cannot be faithfully implemented in $o(n^2)$ space. We instead develop a way to *approximately* implement this step, by sampling $O(\log n)$ edges per vertex and using them to estimate the frustration of each vertex in the switching phase. This allows us to still classify the majority of vertices the same as that of the Giotis-Guruswami algorithm except for the ones with no clear preference between bi-partitions of the optimal solution. An extra argument here ensures that this step does not increase the cost too much and this new solution is still a $(1+\varepsilon)$-approximation, leading to our semi-streaming algorithm.

The ideas above also allow us to significantly improve the *running time* of the Giotis-Guruswami algorithm even outside of graph streaming models. The most time-consuming step of that algorithm is the need to enumerate all bi-partitions of the sampled set S of size $O(\log n)$. We preface the sampling step of the set S by sampling a smaller set T of size only $O(\log \log n)$, enumerate only over $(\log n)^{O(1)}$ bi-partitions of T, and use those to find an *approximate* optimal bi-partition of the set S. We then follow a similar strategy as above to simulate the Giotis-Guruswami algorithm, by showing that even though the bi-partition of the set S is no longer truly optimal, the extra error occurred by the approximation, does *not* propagate too much in the merging and switching step – in other words, these operations are "robust" enough to handle even an approximately optimal bi-partition of S, not a truly optimal one.

Lower Bounds. Most of our lower bounds are based on reductions from known problems in communication complexity such as Index or Equality. The exception is our lower bound in Proposition 11 which shows that, perhaps counter-intuitively, when a stream contains copies of an edge more than once, solving structural balance testing becomes impossible in $o(n)$ space. We show this lower bound by presenting a new *3-party* communication problem which is a mixture of the Index and Set Intersection problems. Roughly speaking, in this new problem, we also provide the information about the hidden index of the Index problem to *all* players, but in a way that to find this index, they will need to solve an instance of the Set Intersection problem. We then borrow an idea from [9, 10] that allows us to argue that a low-communication protocol cannot even change the distribution of the hidden index by much. We then combine this with standard information-theoretic arguments to show that the Index problem the players need to solve remains hard as the distribution of its hidden index has not been altered too much.

1.3 Related Work

By slightly relaxing structural balance to allow triangles with three negative ties as in [30], the frustration-minimizing partitions becomes fully equivalent to the correlation clustering problem (without any constraint on the number of clusters). More recently, motivated by similar considerations as in our paper, there has been a flurry of results on this problem in modern models of computation such as sublinear-time, streaming, or massively parallel algorithms [3, 11, 17, 18, 26, 27]. In particular, for the single-pass streaming setting, the very recent state-of-the-art result by [23] obtains a $(3+\varepsilon)$-approximation correlation clustering in $O(n/\varepsilon)$ space and polynomial time. Our result shows that we can obtain a better approximation when the number of clusters is two. Furthermore, [18] independently observes a $(1+\varepsilon)$-approximation algorithm for correlation clustering in exponential time using cut sparsifiers, which is similar to our observation in Lemma 8.

In a general graph (not necessarily complete), structural balance means that all cycles must contain an even number of negative edges. The problem of minimizing frustration index, phrased in the literature as the Balanced Subgraph problem [37], is MaxSNP-hard [45, 52] and even NP-hard to approximate within any constant factor assuming Khot's Unique Games Conjecture [39]. On the positive side, this problem admits a polynomial time $O(\sqrt{\log n})$-approximation [2] and an $O(\log k)$-approximation [12] when the frustration index is k. Readers can refer to [37] for further details about applications in practice. None of these algorithms consider space constraints or the streaming setting.

2 Preliminaries

Notation. Throughout, we use $G = (V, E = E^+ \cup E^-)$ to denote a complete signed graph with $|V| = n$ vertices, where E^+ is the set of "+" edges and E^- is the set of "−" edges. We further use $G^+ = (V, E^+)$ and $G^- = (V, E^-)$ to denote the graph restricted to the "+" and "−" edges. Note that E^+ and E^- are always disjoint and $|E^+ \cup E^-| = \binom{n}{2}$. For any set $S \subseteq V$ of vertices, $G[S]$ denotes the induced subgraph of G on S.

For two sets of vertices S, $T \subset V$, we use $E(S,T)$ to denote the set of edges (both "+" and "−") with one endpoint in S and the other in T. Analogously, we use $E(v,S)$ to denote the set of edges (both "+" and "−") with one endpoint v and the other in S. Furthermore, $E^+(S,T)$ (resp. $E^-(S,T)$) refers to the set of "+" (resp. "−") edges with one endpoint in S and the other in T, and $E^+(v,S)$ (resp. $E^-(v,S)$) refers to the set of "+" (resp. "−") edges with one endpoint v and the other in S. In particular, $N^+(S) = E^+(S, V \setminus S)$ and similarly, $N^+(v) = E^+(v,V)$ ($N^-(S)$ and $N^-(v)$ defined in the same manner).

When the context involves more than one graph (say G and H), we add a subscript to make the notation clear as to which graph is being referred to (for example, $E_G(S,T)$ and $E_H(S,T)$).

2.1 Problem Definition

In this paper, we consider (strong) structural balance. A complete signed graph $G = (V, E^+ \cup E^-)$ is said to exhibit structural balance property (in short, is balanced) if every triangle has an even number of "−" edges. An equivalent characterization of structural balance shown in [21] is that there exists a bi-partition of the vertices into S and T, $S \cap T = \emptyset$ and $S \cup T = V$, such that every edge with both endpoints in S (or T) is labelled "+", and every edge connecting S to T is labelled "−". Inspired by this, the notion of frustration index [1, 34, 53] captures how far a graph is from structural balance.

▶ **Definition 1** (Frustration Index). *Let $G = (V, E^+ \cup E^-)$ be a complete signed graph, and let (L, R) be a bi-partition of V. Then the* frustration *of G with respect to L, R is*

$$\mathsf{frust}(G,\ L, R) = \left|E^+(L,R)\right| + \left|E^-(L)\right| + \left|E^-(R)\right|.$$

When the context is clear, we use the notation $\mathsf{frust}(G,\ L)$ instead of $\mathsf{frust}(G,\ L, R)$. The frustration index *$\mathsf{frust}(G)$ is the minimum of $\mathsf{frust}(G,\ L, R)$ over all possible bi-partitions (L, R) of V.*

Frustration can be equivalently defined using "disagreement" notation:

$$\mathsf{frust}(G,\ L, R) = \frac{1}{2} \sum_{v \in V} \mathsf{Dis}(v, L, R).$$

We use $\mathsf{Dis}(v, S, T)$ to count the disagreement of edges incident to v with respect to S, T. For example, when $v \in S$, we have $\mathsf{Dis}(v, S, T) = |E^-(v, S)| + |E^+(v, T)|$. When $T = V \setminus S$, we may write $\mathsf{Dis}(v, S)$ instead of $\mathsf{Dis}(v, S, V \setminus S)$.

Now we are ready to formally define our problems.

▶ **Problem 1** (Structural Balance Testing). *Given a complete signed graph $G = (V, E^+ \cup E^-)$, decide if there is a partition (L, R) of V such that*

- *If $(u, v) \in E^+$, then u and v are both contained in L or both contained in R;*
- *If $(u, v) \in E^-$, then either u is in L and v is in R, or vice versa.*

In other words, the answer is "YES" if and only if the graph is balanced.

▶ **Problem 2** (Frustration-minimizing Partition). *Given a complete signed graph $G = (V, E^+ \cup E^-)$, find a partition (L^*, R^*) of V such that*

$$(L^*, R^*) = \arg\min_{\substack{(L,R): \\ L \cup R = V \\ L \cap R = \{\}}} \mathsf{frust}(G,\, L, R).$$

In other words, the partition (L^*, R^*) minimizes the frustration.

3 Structural Balance Testing in Logarithmic Space

We formally present our main algorithm for structural balance testing (Problem 1) – a randomized algorithm that uses only $O(\log n)$ bits and returns whether the graph is balanced with high (constant) probability.

▶ **Theorem 2** (Formalization of Result 1). *There is a randomized single-pass algorithm* BalanceTester *that solves Problem 1 with $O(\log n)$ bits of space and the following guarantees:*

- *If input graph G is balanced,* BalanceTester *always outputs* Balanced*;*
- *If input graph G is not balanced,* BalanceTester *outputs* NotBalanced *with probability at least $\frac{99}{100}$.*

A few remarks on Theorem 2 are in order. First, it is not hard to design a deterministic algorithm that uses $\tilde{O}(n)$ space to test whether the graph is balanced – for completeness, such an algorithm can be found in the full version of this paper. However, by our lower bound in Proposition 10, any single-pass streaming algorithm for structural balance testing with $o(n)$ memory has to be randomized. Furthermore, we remark that the $O(\log n)$ memory is asymptotically optimal since it is the number of bits that is necessary to store even a single edge. Finally, since the error is one-sided, we can boost the success probability to $1 - \frac{1}{n}$ by running the algorithm $O(\log n)$ times, which results in $O(\log^2 n)$ overall space complexity.

We now proceed to the design and analysis of our algorithm. In what follows, we assume our graph contains at least $n \geq 3$ vertices, as the structural balance is always satisfied otherwise.

3.1 A Sample-and-Test Lemma for "$-$" Edges

The idea behind our algorithm starts as follows. If we focus on "$-$" edges, our task can be framed as testing if the graph $G^- = (V, E^-)$ is a *complete bipartite graph*. To this end, observe that if we sample a set S of an odd number of vertices, and count the number of "$-$" edges in $G[S]$, the parity will always be even when G^- is complete bipartite. With a slightly more involved analysis, we can show that if G^- is not complete bipartite, then by sampling S uniformly at random, the number of "$-$" edges in $G[S]$ is odd with constant probability. As such, we can use the parity of such a counter as a signal of the structural balance of the graph.

We now formalize the above intuition. In particular, in the following lemma, we design the S-sampler and state its properties.

▶ **Lemma 3** (S-sampler Lemma). *For a given complete signed graph $G = (V, E)$, let $S \subseteq V$ be a subset of vertices sampled with the following $\underline{S\text{-sampler}}$:*

1. *Pick a fixed vertex v_n arbitrarily.*
2. *Sample each vertex in $v \in V \setminus \{v_n\}$ independently with probability $\frac{1}{2}$ to get S'.*
3. *If $|S'|$ is odd, let $S = S'$; otherwise, let $S = S' \cup \{v_n\}$.*

Then, the following statements are true:

1. *If G is balanced, the induced subgraph $G[S]$ always has an even number of "$-$" edges;*
2. *If G is not balanced, the induced subgraph $G[S]$ has an odd number of "$-$" edges with probability at least $\frac{1}{4}$, over the randomness of sampling S.*

The main idea to prove Lemma 3 is by observing that the parity of "$-$" edges counted by our S-sampler is in fact captured by a *degree-2* polynomial over $\mathbb{F}_2$. The observation can be formalized as the following lemma.

▶ **Lemma 4.** *Let $X_i \in \{0, 1\}$ be the indicator random variable for whether vertex v_i is sampled by S-sampler. Define the following polynomial with $(n-1)$ variables over $\mathbb{F}_2$:*

$$P^*(X) = \sum_{\substack{i,j<n \\ (v_i,v_j)\in E^-}} X_i X_j + \sum_{\substack{i<n \\ (v_i,v_n)\in E^-}} X_i \left(1 + \sum_{j=1}^{n-1} X_j\right). \tag{1}$$

Then, the polynomial $P^*(X) = |E^-(G[S])|$ over $\mathbb{F}_2$, which is the parity of number of negative edges induced by the sample set S.

Proof. Note that Eq (1) is essentially obtained by substituting $X_n = 1 + \sum_{j=1}^{n-1} X_j$, and counting a "$-$" edge (v_i, v_j) if both v_i and v_j are sampled. If the number of sampled vertices other than v_n is odd, we have $\sum_{j=1}^{n-1} X_j = 1$, which implies $X_n = 0$ over $\mathbb{F}_2$; otherwise, if the number of sample vertices other than v_n is even, we have $\sum_{j=1}^{n-1} X_j = 0$, which implies $X_n = 1$ over $\mathbb{F}_2$. Therefore, the polynomial P^* exactly captures the sampling process of the S-sampler. Finally, if the total number of "$-$" edges is odd, the polynomial P^* evaluates to 1, and vice versa. ◀

As we will see shortly, Lemma 4 is also crucial to run our *streaming* algorithm for the S-sampler by storing limited number of random bits. To show that the S-sampler gives a useful signal for whether the graph is balanced, we show that the polynomial P^* in Eq (1) gives a useful signal. We first show that P^* is identically 0 if and only if G is balanced.

▶ **Lemma 5.** *The polynomial P^* in Eq (1) is identically 0 if and only if G is balanced.*

Proof. Suppose first that G is balanced. Then either G^- is empty, or it is a complete bipartite graph. Let S be the sample from S-sampler. In the first case, the number of "$-$" edges in $G[S]$ is always 0. In the second case, let L and R be the bi-partition of G^-, and let $A = L \cap S$ and $B = R \cap S$. The number of "$-$" edges in $G[S]$ is $|A| \cdot |B|$, which is an even number since one of $|A|$ and $|B|$ is even (recall that $|S|$ is odd). By Lemma 4, P^* is thus identically 0 when G is balanced.

Suppose, on the other hand, that G is not balanced. Then there is a triangle (v_i, v_j, v_k) with an odd number of "$-$" edges. If $i, j, k \neq n$, setting $X_i = X_j = X_k = 1$ and $X_\ell = 0$ for $\ell \neq i, j, k$ yields $P^*(X) = 1$. If on the other hand, say, $k = n$, then setting $X_i = X_j = 1$ and $X_\ell = 0$ for $\ell \neq i, j$ yields $P^*(X) = 1$. Hence P^* is not identically 0 when G is not balanced. ◀

Next, we give a lemma on the *fraction* of assignments that are non-zero on the polynomial P^*, which gives us a lower bound for the success probability to capture an odd number of "$-$" edges when G is imbalanced. We note that the lemma is standard in the coding theory community (e.g. [46]), but we state a proof here for completeness.

▶ **Lemma 6.** *Let $P(x_1, x_2, \ldots, x_n)$ be a polynomial over $\mathbb{F}_2$ with degree at most 2. If P is not identically 0, then there is a set X, with cardinality at least 2^{n-2}, such that $x \in X$ implies $P(x) = 1$.*

Proof. We may assume that P is multilinear since $\bar{P}(x) = P(x)$ for all $x \in \{0,1\}^n$, where $\bar{P}$ is the linearization of P (i.e. all monomials of the form x_i^2 are replaced with x_i).

If P is of degree 1 or less, the claim holds by using the Schwartz-Zippel lemma.Suppose then that P is of degree 2. Up to a reordering of variables, $x_{n-1}x_n$ is a term of P with coefficient 1. Let a be a fixed assignment of x_k to $\{0,1\}$ for all $k \in [n-2]$. Then $P(a, x_{n-1}, x_n)$ is a multilinear degree 2 polynomial $Q(x_{n-1}, x_n)$ with the term $x_{n-1}x_n$ having coefficient 1. Checking over all 8 possible polynomials that Q may take, we see that each of them has at least one assignment a' of x_{n-1}, x_n to $\{0,1\}$ such that $Q(a') = 1$. This completes the proof since there are 2^{n-2} possible assignments a. ◀

Finalizing the proof of Lemma 3. By Lemma 4 and Lemma 5, if G is balanced, the polynomial P^* is identically 0, which means the S-sampler always finds an even number of "$-$" edges. Otherwise, if G is not balanced, P^* is not 0. Therefore, by Lemma 6, the S-sampler finds an odd number of "$-$" edges with probability at least $\frac{1}{4}$. ◀

By Lemma 3, to test the structural balance of a complete signed graph, it suffices to implement the S-sampler and count the number of negative edges. However, while the counter takes $O(\log n)$ space, it is not immediately clear how the S-sampler can be implemented with a small space in the streaming setting. In particular, since we need to sample each vertex *independently*, the trivial solution requires $\Omega(n)$ memory to store the random bits (for each vertex). We address this issue in the next step.

3.2 Simulating the S-sampler in Streaming with $O(\log n)$ Space

We tackle this issue by using the fact that our S-sampler is a degree-2 polynomial (Lemma 4). We may consequently use a PRG that fools degree-2 polynomials (see [20, 41, 44] for constructions). More concretely, there exists a PRG that takes $O(\log n)$ truly random bits, and generates n pseudorandom bits with $O(\log n)$ extra space per bit so that a degree-2 polynomial cannot distinguish a truly random input from a pseudorandom input to within a small constant error.

Using this, we design an $O(\log n)$-memory algorithm as follows.

A streaming algorithm to test structural balance.

- Run 100 independent copies of the following S-sampler simulation:
  1. Maintain $O(\log n)$ truly random bits and a counter.
  2. For each arriving "$-$" edge $(u, v) \in E^-$:
     a. Generate the pseudorandom bits for vertices u and v (name the bits X_u and X_v) with a PRG for degree 2 polynomials with $\varepsilon = \frac{1}{20}$ (see [20, 41, 44]).
     b. If both $X_u = 1$ and $X_v = 1$, increase the counter by 1.
  3. By the end of the stream, if the parity of the counter is odd, return 1; otherwise, return 0.
- If any of the copies of S-sampler simulation returns 1, report Not Balanced; otherwise, report Balanced.

Analysis of the space complexity. The truly random bits and the counter take $O(\log n)$ bits of space. Furthermore, for each "$-$" edge, the PRG generates the pseudorandom bits for X_u and X_v with $O(\log n)$ bits of extra space since $\varepsilon = \frac{1}{20}$. The space for this purpose can be re-used across different edges. Each copy of the S-sampler simulation therefore takes $O(\log n)$ space to implement. Finally, since we run 100 independent copies in parallel, the final algorithm take $O(\log n)$ space.

Analysis of correctness. By Lemma 3, if the graph is balanced, the S-sampler simulation always returns 0. On the other hand, if the graph is imbalanced and we sample with truly random bits U_{n-1}, it holds from Lemma 3 that $\Pr(P^*(U_{n-1}) = 1) \geq \frac{1}{4}$ since P^* is a valid implementation of the S-sampler. By the guarantees of the PRG $g : \{0,1\}^{O(\log n) \to (n-1)}$, we have

$$|\Pr(P^*(g(U_\ell)) = 1) - \Pr(P^*(U_{n-1}) = 1)| \leq \frac{1}{20},$$

where U_ℓ are $O(\log n)$ truly random bits, the seed for the PRG. We hence have $\Pr(P^*(g(U_l)) = 1) \geq \frac{1}{4} - \frac{1}{20} = \frac{1}{5}$. As such, the probability for no copy to return 1 is at most $(\frac{4}{5})^{100} < \frac{1}{100}$, as desired.

4 Semi-streaming Frustration-minimizing Partition in Poly-Time

In this section, we consider Problem 2 of finding, in the semi-streaming model, a partition of a complete signed graph that is as close to structurally balanced as possible. More specifically, we want to divide the set of vertices into two parts and minimize the number of "$-$" edges contained in either part and "$+$" edges connecting the two parts.

Giotis and Guruswami [31] showed that Problem 2 is NP-hard. In the streaming setting, we show that any algorithm that gives the exact optimal frustration-minimizing partition (or computes the optimal frustration index) requires $\Omega(n^2)$ memory (see Proposition 13). In view of this, we settle for finding a partition that approximates one which is as close to structurally balanced as possible. This section shows how to adapt the correlation clustering algorithm with two clusters in [31] to the semi-streaming model. We leave the technical details to the full version of the paper and, here, highlight the ingredients that make up the following result.

▶ **Theorem 7** (Formalization of Result 2). *There is an algorithm that, given a complete signed graph $G = (V, E^+ \cup E^-)$ and $\varepsilon \in (0,1)$, with high probability finds a partition (L, R) of V where*

$$\mathsf{frust}(G,\, L) \leq (1+\varepsilon) \cdot \mathsf{frust}(G).$$

Moreover, the algorithm uses $O\Big(n \cdot \frac{\log^4(n/\varepsilon)}{\varepsilon^6}\Big)$ space, a single pass over the stream and has running time of $O\Big((\frac{n}{\varepsilon})^2 \cdot \log^3 n + n \log n \cdot (\frac{1}{\varepsilon})^{O(\varepsilon^{-4})}\Big)$.

4.1 Evaluating Frustration

The first key ingredient is a tool for determining $\mathsf{frust}(G,\, L)$ for an arbitrary $L \subseteq V$, subject to the memory constraints of the semi-streaming setting. We turn to the idea of cut sparsifiers (see [4, 19, 42]), which store a sparse representation of G which approximately answers the cut queries for all $S \subseteq V$: what is the size of $E(S, V \setminus S)$?

▶ **Lemma 8.** *Let $G = (V, E^+ \cup E^-)$ be a complete signed graph. There is a single-pass streaming algorithm using $O\big(n \log^3 n/\varepsilon^2\big)$ space and $O\big(n^2 \log^2 n\big)$ time that, for any $\varepsilon \in (0,1)$, with high probability produces an oracle that, when given $L \subseteq V$, returns $\mathsf{frust}_\varepsilon(G,\, L)$ in $O\big(n \log n/\varepsilon^2\big)$ time where*

$$(1-\varepsilon)\mathsf{frust}(G,\, L) \leq \mathsf{frust}_\varepsilon(G,\, L) \leq (1+\varepsilon)\mathsf{frust}(G,\, L).$$

Our construction of the "frustration sparsifier" in Lemma 8 follows from a standard application of cut sparsifiers, and the fact that the portion of frustration contributed to by the "−" edges in each side can be estimated indirectly by looking at "+" edges crossing the cut.

Frustration Sparsifier for $G = (V, E^+ \cup E^-)$ and $\varepsilon \in (0,1)$:

- Let $H = (V, E_H, w_H)$ be an $\frac{\varepsilon}{2}$ cut sparsifier for $G' = (V, E^+)$.
- Return $\mathsf{frust}_\varepsilon(G,\, \cdot)$ which, when given $L \subseteq V$, computes

$$\underbrace{w_H(L, V \setminus L)}_{\approx |E^+(L, V \setminus L)|} + \underbrace{|E^-| - (|L| \cdot |V \setminus L| - w_H(L, V \setminus L))}_{\approx |E^-(L)| + |E^-(V \setminus L)|}.$$

The proof of Lemma 8 can be found in the full version of this paper.

Observe as an aside that frustration sparsifiers alone give us a single-pass algorithm that uses $\widetilde{O}(n)$ space which, however, runs in exponential time: construct a frustration sparsifier with parameter ε, enumerate over all partitions of V, and return the one which gives the smallest estimated frustration.

4.2 A Polynomial Time Algorithm: Streamification of Giotis-Guruswami Algorithm

The next key ingredient is a simulation of the Giotis-Guruswami algorithm [31]. For the remainder of this section, let $\mathsf{frust}(G) = \gamma n^2$ where γ is not necessarily a constant. We are particularly interested in the case when $\gamma \leq \varepsilon/100^4$, which is the case of the Giotis-Guruswami algorithm which is non-trivial to simulate.

When there is no constraint on space usage, the Giotis-Guruswami algorithm works by sampling $\Theta(\log n)$ vertices (called the sample S) and trying every partition (S_L, S_R) of S. S_L and S_R are taken to be subsets of L and R respectively, where (L, R) is a partition of V. For each such partition (S_L, S_R), there should be a clear local choice for whether a vertex v should be assigned to L or to R by choosing the smaller of $\mathsf{Dis}(v, S_L + v, S_R)$[3] and $\mathsf{Dis}(v, S_L, S_R + v)$ respectively; we do this for all unsampled vertices, and refer to this step of the algorithm as MERGING. The algorithm then tries to further refine the solution quality by marking each vertex that improves the frustration when moved from L to R or vice versa, keeping every other vertex fixed. All marked vertices are then moved to the other part. The process of marking vertices and moving them after all have been marked is referred to as the SWITCHING step.

As it turns out, the correctness of the Giotis-Guruswami algorithm still holds with a small error introduced by graph sparsification. This is crucial as it allows us to design space efficient streaming algorithms by simply maintaining a cut sparsifier during the stream, and performing the Giotis-Guruswami procedure in the end. More concretely, only once the sparse representations of the input stream have been obtained (i.e. a single pass over the stream has been completed), do we then start iterating over every partition (S_L, S_R) of S, and in each iteration MERGING, SWITCHING, and storing the best resulting (L, R) seen so far. MERGING is easily ported to the streaming setting; we just need to store the $\Theta(n \log n)$ edges incident to S. The way SWITCHING is adapted, on the other hand, is less trivial; we store a sparse representation of the input graph by sampling $\Theta\big((1/\varepsilon^2)\log n\big)$ neighbors for each vertex. Finally, determining the (approximate) best partition seen through all iterations can be done by using a frustration sparsifier.

```
**Streamification of [31]** for $G = (V, E^+ \cup E^-)$ and $\varepsilon \in (0,1)$, when $\gamma \lessapprox \varepsilon$:
1. Sample $100 \log n$ vertices uniformly at random. Call this set $S$.
2. Sample $100^3 \cdot \frac{\log n}{\varepsilon^2}$ vertices uniformly at random for each vertex $v$. Call these sets $N_v$.
3. Read through the stream of (signed) edges and
   - Store edges incident to $S$. Call this graph $G_S$.
   - Store edges joining $v$ and $N_v$ for all $v$. Call this graph $G_N$.
   - Store $\mathsf{frust}_{\varepsilon/10}(G, \cdot)$, a frustration sparsifier of $G$.
4. For every partition $(S_L, S_R)$ of $S$
   (Merging)
      For every $v \in V \setminus S$, assign $v$ to $L$ if $\mathsf{Dis}_{G_S}(v, S_L + v, S_R) < \mathsf{Dis}_{G_S}(v, S_L, S_R + v)$, and $R$ otherwise.
      $S_L$ is assigned to $L$ and $S_R$ is assigned to $R$.
   (Switching)
      Mark $v \in L$ if $\mathsf{Dis}_{G_N}(v, L + v, R - v) > \mathsf{Dis}_{G_N}(v, L - v, R + v)$ and mark $v \in R$ similarly (flip the inequality).
      Switch assignments of all marked vertices from $L$ to $R$ or vice versa.
    Keep $(L, R)$ if $\mathsf{frust}_{\varepsilon/10}(G, L)$ is the smallest seen so far.
5. Return $(L, R)$.
```

[3] In this section, we use the following notation: For any set S and any vertex v, $S + v$ denotes $S \cup \{v\}$ and $S - v$ denotes $S \setminus \{v\}$.

The roles of MERGING and SWITCHING are roughly explained as follows. When (S_L, S_R) is congruent with how S would be partitioned in an optimal solution, MERGING assigns most vertices to L and R in the same way they would have been assigned in said optimal solution. These vertices do not change assignment when SWITCHING. The remaining vertices may have lots of disagreement with their current assignment in spite of having lots of agreement with S_L or S_R. SWITCHING rectifies this, minimizing the disagreement of these vertices with a large number of vertices (the ones that stay put, mentioned earlier).

We leave the proofs to the full version of the paper. Suffice to say, the core technical work here is in the analysis showing that weakly simulating SWITCHING in the way we have still yields a correct algorithm.

4.3 Looking at Exponentially Fewer Candidate Partitions

Observe that the first two ingredients yield an algorithm with $\Theta(n^{101})$ running time, where the inefficiency stems from having to iterate over all partitions of a sample of size $100 \log n$. The last key ingredient completes Theorem 7 by instead iterating over all partitions of a sample of size $100 \log \log n$, building from this a partition of size $O(\log n)$ via an independent sample (we call this step MINI-MERGING), and thereafter running MERGING and SWITCHING.

This gives us Theorem 7, and also Theorem 9 by running the algorithm in an offline setting regardless of it being a streaming algorithm.

▶ **Theorem 9** (Formalization of Result 3). *There is a randomized algorithm that, given a complete signed graph $G = (V, E^+ \cup E^-)$, and for any $\varepsilon \in (0, 1)$, with high probability returns a partition (L, R) of V where*

$$\mathsf{frust}(G, L) \leq (1 + \varepsilon) \cdot \mathsf{frust}(G).$$

Moreover, the algorithm has runtime $O\left(\frac{n^2 \log^3 n}{\varepsilon^2} + n \log n \cdot (1/\varepsilon)^{O\left(\varepsilon^{-4}\right)}\right)$.

To the best of our knowledge, this is the first algorithm for Problem 2 and 2-correlation clustering that is nearly-linear in the input. A little more formalism is supplied in Appendix A, but much of the details are left to the full version of the paper.

5 Space Lower Bounds

In this section, we state space lower bounds that complement our algorithmic results.

- Any p-pass deterministic streaming algorithm solving Problem 1 requires $\Omega\left(\frac{n}{p}\right)$ space.
- Any single-pass randomized algorithm solving Problem 1 on a complete signed multi-graph, where edges are allowed to repeat twice, requires $\Omega(n)$ space.
- Any single-pass randomized streaming algorithm solving Problem 2 *exactly*, or that outputs the *exact* frustration index, requires $\Omega\left(n^2\right)$ space.

Combined with our upper bounds in Theorem 2 and Theorem 7, our results convey the following message: (i). It is possible to test structural balance with a very high space efficiency by taking advantage of the arrive-once inputs and randomness, and both aspects are *necessary*; and (ii). It is possible to achieve a $(1 + \varepsilon)$-approximation in $\tilde{O}(n)$ space and polynomial time for any constant ε. In contrast, the exact solution requires almost all the input to be stored.

5.1 Structural Balance Testing by Deterministic Algorithms

We first present space lower bound for deterministic streaming algorithms. The formal statement of the lower bound is as follows.

▶ **Proposition 10.** *Any deterministic p-pass algorithm for Problem 1 requires $\Omega\left(\frac{n}{p}\right)$ bits of space. In particular, any deterministic single-pass algorithm requires $\Omega(n)$ bits of space.*

The proof of our deterministic lower bound uses a reduction from EQUALITY, which is known to require $\Omega\left(\frac{n}{p}\right)$ bits of communication over p rounds. More can be found in the full version.

5.2 Structural Balance Testing by Randomized Algorithms with Multi-edges

The second lower bound is the most interesting from a technical standpoint. It shows that we need to use $\Omega(n)$ space if the inputs are complete signed graphs with multi-edges. We assume that the signs of the multi-edges between the same pair of vertices are *consistent*: if e_1 between (u, v) is "+", a second edge e_2 between (u, v) also has to be "+". The definition of structural balance still holds by checking one of the edges between each vertex pair.

The formal statement of our lower bound is as follows.

▶ **Proposition 11.** *Any single-pass streaming algorithm that correctly tests structural balance with probability at least $\frac{99}{100}$ on complete signed multi-graphs with sign-consistent multi-edges has to use a memory of $\Omega(n)$ bits.*

On the high level, the plan to prove Proposition 11 is a reduction from INDEX. The standard INDEX problem is described as follows: Alice holds a string $x \in \{0, 1\}^N$, Bob holds an index $i^* \in [N]$, and the two players want to learn the value of x_{i^*}.

In a first attempt at a reduction, the two players are initially given $2N + 2$ vertices, with each bit x_j corresponding to two vertices u_j and v_j and two special vertices s and t. Alice creates two empty sets A and B, and for each input bit x_j, $j \in [N]$, Alice puts u_j to A and v_j to B if $x_j = 0$, and v_j to A and u_j to B if $x_j = 1$. Then, for every vertex except u_{i^*} and v_{i^*}[4], Alice adds "+" edges from s to the vertices in A and from t to vertices in B. Furthermore, for each pair of vertices *both inside* A or B, Alice adds a "+" edge; and for vertex pairs such that $u \in A$ and $v \in B$, Alice adds a "−" edge. On the other end, Bob completes the graph by adding "+" edges to (s, u_{i^*}) and (t, v_{i^*}) and "−" edges to (s, v_{i^*}) and (t, u_{i^*}). Now, if $x_{i^*} = 0$, the resulting graph is balanced; otherwise, the graph is unbalanced since v_{i^*} is in A.

While the plan sounds nice, it does *not* work. Careful readers may have already found the problem: Alice does *not* know which vertices correspond to u_{i^*} and v_{i^*}; and if she somehow infers it, the problem becomes easy as she can output x_{i^*} without any communication. As such, for the above idea to work, we need to somehow "hide" the index to the holder of the string, but give them the ability to create graphs that leave everything but x_{i^*}.

To the above end, we introduce the following version of Leave-One INDEX.

▶ **Problem 3** (Leave-One INDEX). *Consider a communication problem between 3 players, namely Alice, Bob, and Charlie. Both Alice and Bob hold the same string $x \in \{0, 1\}^N$, and Charlie holds an index $i^* \in [N]$. Furthermore, Alice holds $S \subset [N]$ and Bob holds $T \subset [N]$, such that $S \cup T = [N] \setminus \{i^*\}$. The communication goes in the order of Alice, Bob and Charlie, and the players want to output x_{i^*}.*

[4] The construction is in fact not possible as we will see in the next paragraph; it is here to explain the intuition.

The sets of S and T create some "flexibility" for Alice and Bob to infer the index. Indeed, if $S \cap T = \emptyset$, the problem becomes easy as Bob can learn Alice's bits from a message that simply encodes which bits are missing[5]. Nevertheless, we prove (see Appendix B) that the worst-case communication complexity of the Leave-One INDEX problem is still $\Omega(N)$. The formal lower bound is as follows.

▶ **Lemma 12.** *Any (possibly randomized) one-way communication protocol for the Leave-One INDEX defined in Problem 3 that outputs x_{i^*} correctly with probability at least $\frac{99}{100}$ requires $\Omega(N)$ bits of communication.*

Figure 1 shows how Alice, Bob, and Charlie can use the previously mentioned (wrong) idea to get a (now) correct reduction of Leave-One Index to testing structural balance, where the multi-edges occur from the intersection $S \cap T$ of Alice's and Bob's sets.

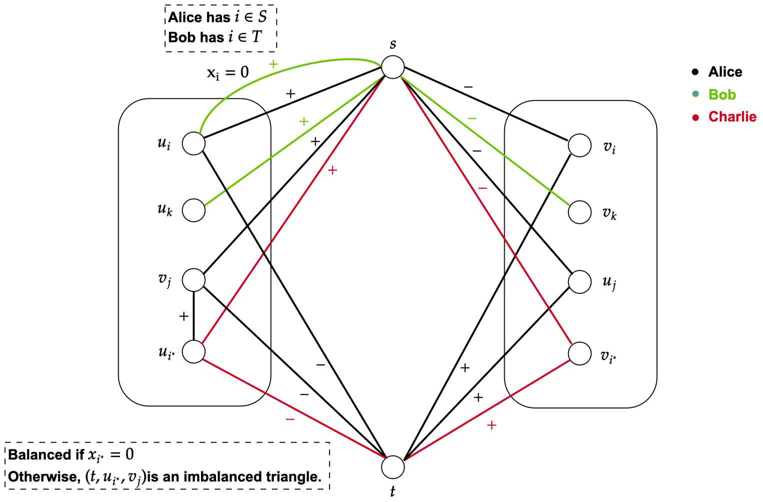

Figure 1 An illustration of the reduction from Leave-One Index.

5.3 Frustration-minimizing Partition by Exact Algorithms

Finally, we show that any single-pass streaming algorithm that solves the frustration index *exactly* has to store almost the entire graph.

▶ **Proposition 13.** *Any single-pass streaming algorithm that solves Problem 2 exactly or returns the optimal frustration index value requires $\Omega(n^2)$ bits of space.*

Proposition 13 goes through communication complexity again. This time, our reduction is from INDEX (a matrix variant thereof) which is hard under the one-way communication regime. Details are to be found in the full version.

[5] In particular, there is a simple protocol with 1 bit of communication when $S \cap T = \emptyset$: Alice takes XOR of all bits in $x[S]$, and send it to Bob. Bob takes XOR of all bits in $x[T]$ he will learn the XOR of $x[S \cup T]$. Bob then compares the XOR of x vs. the XOR of all bits in $x[S \cup T]$ to learn x_{i^*}

A Offline Solution to Problem 2 (More Details)

Here we present an offline algorithm for solving Problem 2 when $\gamma < \varepsilon/100^4$ (which is an important part leading to Theorem 9), which can be transferred to the semi-streaming setting with superficial modification.

```
Nearly-Linear Time EPTAS solving Problem 2 for $G = (V, E^+ \cup E^-)$ and $\varepsilon \in (0,1)$, when $\gamma < \varepsilon/100^4$:
1. Sample $2000 \log n$ vertices uniformly at random from $V$. Call this set $S$ and let
   $G_S = (V, E(S) \cup E(S, V \setminus S))$.
2. Sample $100 \log \log n$ vertices uniformly at random from $S$. Call this set $S'$, the
   seed-set, and let $G_{S'} = (V, E(S') \cup E(S', V \setminus S'))$.
3. Sample $100^3 \cdot \frac{\log n}{\varepsilon^2}$ vertices uniformly at random for each vertex $v$. Call these sets
   $N_v$ and let $G_N = (V, \bigcup_v E(v, N_v))$.
4. Construct $\mathsf{frust}_{\varepsilon/10}(G, \cdot)$, a frustration sparsifier of $G$.
5. For every partition $(S'_L, S'_R)$ of $S'$
   (Mini-merging on $S'$)
      For every $v \in S \backslash S'$, assign $v$ to $S_L$ if $\mathsf{Dis}_{G_{S'}}(v, S'_L + v, S'_R) < \mathsf{Dis}_{G_{S'}}(v, S'_L, S'_R + v)$,
      and $S_R$ otherwise.
      $S'_L$ is assigned to $S_L$ and $S'_R$ is assigned to $S_R$.
   (Merging on $S$)
      For every $v \in V \setminus S$, assign $v$ to $L$ if $\mathsf{Dis}_{G_S}(v, S_L + v, S_R) < \mathsf{Dis}_{G_S}(v, S_L, S_R + v)$,
      and $R$ otherwise.
      $S_L$ is assigned to $L$ and $S_R$ is assigned to $R$.
   (Switching)
      Mark $v \in L$ if $\mathsf{Dis}_{G_N}(v, L + v, R - v) > \mathsf{Dis}_{G_N}(v, L - v, R + v)$ and mark $v \in R$
      similarly (flip the inequality).
      Switch assignments of all marked vertices from $L$ to $R$ or vice versa.
    Keep $(L, R)$ if $\mathsf{frust}_{\varepsilon/10}(G, L)$ is the smallest seen so far.
6. Return $(L, R)$.
```

B Proof of Lemma 12

In the proof of the communication complexity for the standard INDEX problem, the intuition is that the first player (Alice) has no knowledge of i^* other than knowing it is uniformly distributed (in the particular hard distribution). As such, the problem can only be solved if a sufficiently large number of bits are communicated. However, in the Leave-One INDEX problem (Problem 3), the first two players (Alice and Bob) might be able to learn where exactly i^* is by comparing their sets of indices S and T. In Problem 3, by the promise that $i^* \notin T$, Bob can learn the distribution of i^* better than uniform even without communication.

Our plan to prove Lemma 12 is to conduct a case analysis on whether the communication between Alice and Bob somehow "solves" the problem. To be precise, we separate the cases based on whether Alice's message significantly changes the distribution of i^* from Bob's perspective. If such a case happens, then we can use a result from [10] to show that the communication between *Alice and Bob* has to be $\Omega(\varepsilon^2 N)$. On the other hand, if the message from Alice does *not* tell Bob a lot about the distribution of i^*, a large number of bits are still required for the communication between *Bob and Charlie* since there are constant fraction of coordinates where i^* still looks almost uniform. The latter bound cannot be obtained directly by a reduction since i^* is already not uniform from Bob's perspective. Nevertheless, we can adapt the information-theoretic proof for INDEX to get the desired lower bound in a standard manner.

We now formalize the above intuition. Let $\Pi_{A,B}$ be the random variable for the message between Alice and Bob, and $\Pi_{B,C}$ be the random variable for the message between Bob and Charlie. Furthermore, let X be the random variable for the string being held by Alice and Bob, and let I be the random variable for i^*. For the choice of the set T, we use T' to denote the realization. Conditioning on the first message $\Pi_{A,B} = \pi_{A,B}$ and Bob's local inputs X, T, we let $I^B := I \mid X, T, \Pi_{A,B}$ be the random variable for i^* from *Bob's internal perspective after message* $\pi_{A,B}$. We slightly abuse notation and let these random variables also represent their distributions.

As promised, the first case we are going to show is the communication lower bound between Alice and Bob if the distribution of i^* that Bob learns is ε-far from his *prior* knowledge. Formally, we define the notation of ε-learn as follows.

▶ **Definition 14.** *Let $\pi_{A,B}$ be the message of a randomized one-way communication protocol. We say that Bob ε-learns i^* if after the message $\pi_{A,B}$, in expectation, the distribution of i^* from Bob's perspective is more than ε-far from the distribution he knows from his own input in the total variation distance, i.e.*

$$\mathbb{E}[\|I \mid \Pi_{A,B}, X, T - I \mid X, T\|_{\mathrm{TVD}}] > \varepsilon,$$

where the expectation is over the randomness of X, T and $\Pi_{A,B}$.

The notion of ε-learn was first developed by [9,10]. As such, we can prove a communication lower bound for Bob to ε-learn i^*.

▶ **Lemma 15.** *Any such protocol $\pi_{A,B}$ for Bob to ε-learn i^* has to use $\Omega\big(\varepsilon^2 \cdot N\big)$ bits of communication between Alice and Bob.*

Proof. We prove the lemma by a direct reduction from [10], which address the set intersection problem. The definition of the problem and the communication complexity is as follows.

▶ **Proposition 16** ([10]). *The Set-Intersection is a two-player game between Alice and Bob. The two players are given $A \subseteq [m]$ and $B \subseteq [m]$, respectively, with the promise that there exists a unique element e^* such that $e^* = A \cap B$. The goal is to find the target element e^* after one-way communication. Let E be the distribution of e^*, it is known that any communication protocol that achieves*

$$\mathbb{E}[\|E \mid \Pi, B - E \mid B\|_{\mathrm{TVD}}] > \varepsilon$$

has to use a communication of $\Omega\big(\varepsilon^2 m\big)$ bits, where the expectation is over the randomness of B and the protocol's randomness Π. In particular, the communication lower bound applies to the following distribution.

A hard distribution for Set-Intersection.

- *Sample two* disjoint *sets of coordinates A' and B' of size $N/4 - 1$ each uniformly at random from $[N]$.*
- *Sample an element e^* uniformly at random from $[N] \setminus (A' \cup B')$, and let $A := A' \cup \{e^*\}$, $B := B' \cup \{e^*\}$.*

The result of Proposition 16 can be generalized to back-and-forth communication if we allow Alice *or* Bob to ε-learn the distribution. However, for the purpose of our reduction, the one-way version suffices. The reduction from Set-Intersection to the communication between Alice and Bob in Lemma 12 is as follows.

Inputs: Alice holds $A \subseteq [m]$, Bob holds $B \subseteq [m]$, $A \cap B = e^*$.

A communication protocol PROT for Lemma 12 that ε-learns the index i^* as in Lemma 15.

1. Alice creates a set $S' = [m] \setminus A$.
2. Bob creates a set $T' = [m] \setminus B$.
3. Alice runs PROT, sends to Bob. Bob uses the distribution for i^* as the distribution for e^*.

To prove the correctness of the reduction, we only need to show that a). S' and T' are valid inputs for PROT and b). $i^* = e^*$. It is straightforward to verify these conditions: we know that an element is *not* covered by $S' \cup T'$ if and only if *both* A and B cover it, which is exactly e^*. Therefore, the desired lower bound is established. ◀

Lemma 15 implies that with $o(N)$ bits of communication it is impossible for Bob to gain knowledge of the distribution of I that is significantly different from what he already knows. We now observe that with the input X and T, and conditioning on Alice's message does *not* significantly change Bob's distribution, Bob's distribution of I is close to uniform on the $[N] \setminus T$ coordinates.

▷ Claim 17. Conditioning on the event that Bob does *not* ε-learn i^*, the distribution of i^* that Bob learns from T and Alice's message $\pi_{A,B}$ is at most ε-far from uniform in expectation over the supports of $[N] \setminus T$, i.e.,

$$\mathop{\mathbb{E}}_{T,\Pi_{A,B}} [\|I \mid T, \Pi_{A,B} - U([N] \setminus T)\|_{\mathrm{TVD}}] \leq \varepsilon.$$

Proof. We first show that without Alice's message, the distribution I of Bob restricted to $[N] \setminus T$ is uniform. This is a simple observation: with the promise that $i^* \notin T$, Bob can safely discard all coordinates therein. Since the string x is *independent* of i^*, Bob does not learn anything from x. As such, Bob's distribution remains *uniform* on the $[N] \setminus T$ coordinates.

We now condition on the fact that Bob does not ε learn i^*. As such, there is

$$\begin{aligned}
&\mathop{\mathbb{E}}_{X,T,\Pi_{A,B}} [\|I \mid X, T, \Pi_{A,B} - U([N] \setminus T)\|_{\mathrm{TVD}}] \\
&\leq \mathop{\mathbb{E}}_{X,T,\Pi_{A,B}} \left[\|I \mid X, T - U([N] \setminus T)\|_{\mathrm{TVD}} + \|I^B - I \mid X, T\|_{\mathrm{TVD}}\right] \qquad \text{(triangle inequality)} \\
&\leq \mathop{\mathbb{E}}_{X,T,\Pi_{A,B}} [0 + \|I \mid \Pi_{A,B}, X, T - I \mid X, T\|_{\mathrm{TVD}}] \leq \varepsilon,
\end{aligned}$$

where the last inequality directly comes from our assumption of no ε-learning.

Finally, note that the choice of i^* is independent of X (whether or not conditioning on $\Pi_{A,B}$). Therefore, we have

$$\begin{aligned}
&\mathop{\mathbb{E}}_{X,T,\Pi_{A,B}} [\|I \mid X, T, \Pi_{A,B} - U([N] \setminus T)\|_{\mathrm{TVD}}] \\
&= \mathop{\mathbb{E}}_{T,\Pi_{A,B}} [\|I \mid T, \Pi_{A,B} - U([N] \setminus T)\|_{\mathrm{TVD}}] \\
&\leq \varepsilon,
\end{aligned}$$

as desired. ◁

We now use the result of Claim 17 to prove the communication complexity conditioning on Bob does not ε-learn i^*. To continue, we insist that the distribution T where T' is sampled from always produces size-t sets. As such, we can establish the following lemma.

▶ **Lemma 18.** *Suppose the players sample from a distribution T to ensure the size of the set given to Bob is always t. Conditioning on the event that Bob does* not *ε-learn i^*, any communication protocol such that Charlie correctly outputs x_{i^*} with probability at least $1 - \delta$ requires at least $(1 - H_2(\delta) - 2\varepsilon) \cdot (N - t)$ bits of communication.*

On a high level, the proof of Lemma 18 uses a strategy that is similar to the information-theoretic proof of INDEX, but it controls the entropy on the coordinates outside T. The sketch of the proof is as follows. By Fano's inequality, for Charlie to output x_{i^*} correctly with probability at least $1-\delta$, there has to be $\mathbb{H}(X_I \mid \Pi_{A,B}, \Pi_{B,C}, T, I) \leq H_2(\delta)$. Using Claim 17, we can prove that if Bob does *not* ε-learn i^*, the "uncertainty" of X_I – measured by the entropy – is still comparable to the entropy of X_I restricted to the $[N] \setminus T$ coordinates, i.e.,

$$\mathbb{H}(X_I \mid \Pi_{A,B}, \Pi_{B,C}, T, I) \geq \frac{1}{N-t} \cdot \mathbb{H}\big(X_{[N]\setminus T} \mid \Pi_{A,B}, \Pi_{B,C}, T\big) - 2\varepsilon.$$

Therefore, we can apply Fano's inequality to lower bound the mutual information between $X_{[N]\setminus T}$ and the information revealed by the protocol, i.e., $(\Pi_{A,B}, \Pi_{B,C})$, which in turn gives us the lower bound on the number of bits to communicate. We leave the proof of Lemma 18 to the full version.

Finalizing the proof of Lemma 12. For completeness, we construct the hard distribution of Problem 3 as follows.

A hard distribution for Problem 3.

1. Sample A and B according to the hard distribution for Set-Intersection prescribed in Proposition 16.
2. Let $S = [N] \setminus A$, and $T = [N] \setminus B$. Sample X from $\{0,1\}^N$ uniformly at random.
3. Give (X, S) to Alice, (X, T) to Bob, and i^* to Charlie.

Observe that in the above distribution, for any choice of T', there is $t = |T'| = \frac{3}{4} \cdot N$. Furthermore, it agrees with the hard distribution of Proposition 16 through the reduction in Lemma 15.

If Bob ε-learns i^* for $\varepsilon = \frac{1}{100}$, then the communication lower bound is already $\Omega\big(N^2\big)$ (by Lemma 15). Therefore, we condition on the case when Bob does *not* (1/100)-learns i^*. As such, let us conditioning on the event that $\mathbb{E}\big[\|I^B - I \mid X, T\|_{\mathrm{TVD}}\big] \leq \frac{1}{100}$; and by Lemma 18, to make up the success probability of $\frac{99}{100}$, the protocol needs to send a message of length at least $(1 - H_2(\frac{1}{100}) - 2/100) \cdot (N - t) = \Omega(N)$ bits, as desired. ◀

How to Make Your Approximation Algorithm Private: A Black-Box Differentially-Private Transformation for Tunable Approximation Algorithms of Functions with Low Sensitivity

Abstract

We develop a framework for efficiently transforming certain approximation algorithms into differentially-private variants, in a black-box manner. Specifically, our results focus on algorithms A that output an approximation to a function f of the form $(1-\alpha)f(x)-\kappa \leq A(x) \leq (1+\alpha)f(x)+\kappa$, where $\kappa \in \mathbb{R}_{\geq 0}$ denotes additive error and $\alpha \in [0,1)$ denotes multiplicative error can be"tuned" to small-enough values while incurring only a polynomial blowup in the running time/space. We show that such algorithms can be made differentially private without sacrificing accuracy, as long as the function f has small "global sensitivity". We achieve these results by applying the "smooth sensitivity" framework developed by Nissim, Raskhodnikova, and Smith (STOC 2007).

Our framework naturally applies to transform non-private FPRAS and FPTAS algorithms into ε-differentially private approximation algorithms where the former case requires an additional postprocessing step. We apply our framework in the context of sublinear-time and sublinear-space algorithms, while preserving the nature of the algorithm in meaningful ranges of the parameters. Our results include the first (to the best of our knowledge) ε-edge differentially-private sublinear-time algorithm for estimating the number of triangles, the number of connected components, and the weight of a minimum spanning tree of a graph whose accuracy holds with high probability. In the area of streaming algorithms, our results include ε-DP algorithms for estimating L_p-norms, distinct elements, and weighted minimum spanning tree for both insertion-only and turnstile streams. Our transformation also provides a private version of the smooth histogram framework, which is commonly used for converting streaming algorithms into sliding window variants, and achieves a multiplicative approximation to many problems, such as estimating L_p-norms, distinct elements, and the length of the longest increasing subsequence.

1 Introduction

Approximation algorithms are often used to efficiently approximate a function $f : \mathcal{D} \to \mathbb{R}^+$ in settings where resource constraints prevent us from computing the function exactly. For example, problems such as Knapsack are NP-Hard and, unless $\mathsf{P} = \mathsf{NP}$, do not admit a polynomial time solution. However, the Knapsack problem admits a fully polynomial time approximation scheme (FPTAS) i.e., for any $\alpha > 0$ there is a deterministic algorithm, running in time $\text{poly}(n, 1/\alpha)$, which outputs a solution that is guaranteed to be be nearly as good (up to multiplicative factor $1 \pm \alpha$) as the optimal solution. As a second example, even if the problem is computationally tractable it may still be the case that the input dataset $D \in \mathcal{D}$ is extremely large, making it infeasible to load the entire dataset into RAM, or impractical to execute a linear time algorithm. To remedy such shortcomings, models such as sublinear-space and sublinear-time algorithms have been proposed. For example, one may want to estimate frequencies of elements that appear in a stream of n elements up to a multiplicative $1 \pm \alpha$ factor, while using only poly $\left(\log n, \frac{1}{\alpha}\right)$ memory cells. Or, one may want to estimate the number of connected components of a dense graph on n vertices up to (relative) additive error κ by only inspecting $\text{poly}(\log n, \frac{1}{\kappa})$ many edges.

In addition to time and space efficiency, user privacy is another important consideration in contexts where the input to our function f is sensitive user data. Differential privacy (DP) [20, 22] is a rigorous mathematical concept that gives provable guarantees on what it means for an algorithm to preserve the privacy of individual information in the input dataset. Informally, a randomized function computed on a dataset D is *differentially private* if the distribution of the function's output does not change significantly with the presence or absence of an individual data point. Thus, a natural goal is to develop efficient differentially private algorithms to approximate functions/queries of interest.

One general way to preserve differential privacy is to add noise scaled to the global sensitivity Δ_f of our function f, i.e., the maximum amount $|f(D) - f(D')|$ that the answer could change by modifying a single record in our dataset D to obtain a new dataset D'. This general approach yields efficient and accurate approximations for f as long as we have an efficient algorithm to compute f *exactly* and the global sensitivity of f is sufficiently small. However, in some resource-constrained settings, we may need to use an approximation algorithm $\mathcal{A}_f$ instead of evaluating f exactly. Unfortunately, the mechanism that computes $\mathcal{A}_f(D)$ and then adds noise scaled to the global sensitivity Δ_f of our function f is not necessarily differentially private. In particular, even if we are guaranteed that $|\mathcal{A}_f(D) - f(D)| \le \alpha f(D)$ we might still have $|\mathcal{A}_f(D) - \mathcal{A}_f(D')| \ge 2\alpha f(D) \gg \Delta_f$ for neighboring datasets D and D', e.g., suppose $\mathcal{A}_f(D) = (1 + \alpha) f(D)$ and $\mathcal{A}_f(D') = (1 - \alpha) f(D')$. Thus, the global sensitivity of $\mathcal{A}_f$ can be quite large and adding noise proportional to $\Delta_{\mathcal{A}_f}$ would prevent us from providing meaningful accuracy guarantees. This raises a natural question: Suppose that our function f admits an accurate (but not necessarily resource-efficient) differentially private approximation algorithm and that f also admits an efficient (but not necessarily private) approximation algorithm. Is it necessarily the case that there is also an equally efficient differentially private approximation algorithm?

Unfortunately, a result of [36, 18] suggests that the answer to the previous question may be no. Suppose our dataset D consists of n users $x_1, \ldots, x_n$ with n binary attributes i.e., $x_i \in \{0, 1\}^n$. Consider the function $f(D)$ that computes all of the one-way marginals i.e.,

$f(D) = \langle \frac{1}{n} \sum_{i=1}^{n} x_i[j] \rangle_{j=1}^{n} \in \mathbb{R}^n$. In particular, there is a non-private sublinear time algorithm that samples $\mathcal{O}(\log n)$ users and (with high probability) outputs a good approximation to *all* n one-way marginals. However, if we require that our algorithm satisfy pure, i.e, ε-differential privacy (resp. approximate, i.e., (ε, δ)-differential privacy) then we need to look at *at least* $\Omega(n/\varepsilon)$ (resp. $\Omega(\sqrt{n \log(1/\delta)})$) samples [36, 18]. In light of this, we pose the following general questions:

What are sufficient conditions for an approximation algorithm to be made differentially private?

Can an approximation algorithm be made differentially private in an efficient black-box manner?

Over the years, many differentially private approximation algorithms have been developed for problems in optimization, machine learning, and distribution testing (see for e.g., [35, 1, 30, 34]), in a somewhat ad-hoc manner. Often, these results give a differentially private algorithm for that specific problem and do not easily generalize to give differentially private algorithms for a large class of problems. A general framework for developing differentially private approximation algorithms for a large class of problems is desirable as this would not only make DP approximation algorithms more easily accessible to non-DP experts, but more importantly, it would shed light on what kinds of algorithms are more amenable to differential privacy. Furthermore, a framework that uses the underlying approximation algorithm as a *black-box* is desirable as this avoids the need to (re)design, (re)analyze, and (re)implement the new differentially private versions of these approximation algorithms. We emphasize that this type of framework has been well-studied for *computing* functions privately by calibrating noise proportional to their global or smooth sensitivity [23, 41] (see Section A for more discussion).

Our work makes partial progress towards answering these general questions. In particular, we give an efficient black-box framework for converting a non-private approximation algorithm $\mathcal{A}_f$ with tunable accuracy parameters into a differentially private approximation algorithm $\mathcal{A}'_f$ with reasonable accuracy guarantees as long as the global sensitivity Δ_f of the function f being approximated is sufficiently low. For the case when $\mathcal{A}_f$ is deterministic, we achieve a pure ε-differentially private approximation algorithm via a direct transformation, and when $\mathcal{A}_f$ is randomized, i.e., has a small failure probability, we achieve ε-differential privacy by first applying a transformation that gives a (ε, δ)-differentially private algorithm and then apply a postprocessing step to achieve ε-differentially privacy. For example, suppose that for any $\alpha > 0$ our algorithm $\mathcal{A}_f$, taking α and our dataset D as input, provides the guarantee that $|\mathcal{A}_f(D) - f(D)| \leq \alpha f(D)$ e.g., any FPTAS algorithm would satisfy our tunable accuracy requirement. In such a case, for any $\alpha > 0$ we can transform our non-private algorithm $\mathcal{A}_f$ into a differentially private version with multiplicative error α and small additive error term which (necessarily) comes from the noise that we added. Intuitively, we exploit the fact that we can run $\mathcal{A}_f$ with an even smaller accuracy parameter $\rho \ll \alpha$ which can be tuned to ensure that the smooth sensitivity of our algorithm is sufficiently small. Our same general framework still applies if we allow that the approximation algorithm $\mathcal{A}_f$ has a small additive error term i.e., $|\mathcal{A}_f(D) - f(D)| \leq \alpha f(D) + \kappa$. If $\mathcal{A}_f(D)$ is only guaranteed to output a good approximation (i.e., $|\mathcal{A}_f(D) - f(D)| \leq \alpha f(D) + \kappa$) with probability $1 - \delta/2$ (e.g., an FPRAS algorithm would satisfy this requirement with additive error $\kappa = 0$) then our framework achieves ε-differential privacy by first obtaining an approximate (ε, δ)-differential privacy algorithm and then a postprocessing step. In cases where the approximation algorithm is not tunably accurate our black-box framework does not necessarily apply[1]. For example, the best known approximation algorithms for vertex cover achieve the guarantee $f(G) \leq \mathcal{A}_f(G) \leq 2f(G)$ i.e., because there is no way to control the smooth sensitivity of our approximation algorithm.

1.1 Our Contributions

We introduce a generic black-box framework for converting certain approximation algorithms for a function $f : \mathcal{D} \to \mathbb{R}^+$ into a differentially private approximation algorithm using smooth sensitivity [41]. We first introduce a definition for *tunable* approximation algorithms used throughout our paper, and then present our main results for the DP framework, and then give new differentially private algorithms for a variety of approximation algorithms obtained via this unifying framework. We refer to our full version [11] for missing details.

▶ **Definition 1** ((α, κ, δ)-approximation). *An algorithm $\mathcal{A}_f$ is a (α, κ, δ)-approximation for f if for every $D \in \mathcal{D}$ with probability at least $1 - \delta$, we have that $(1 - \alpha)f(D) - \kappa \leq \mathcal{A}_f(D) \leq (1 + \alpha)f(D) + \kappa$.*

We may abuse notation and omit the failure probability δ parameter in the above definition, if it is clear from the context. Some algorithms $\mathcal{A}_f$ may take the approximation parameters $\alpha, \kappa, \delta \geq 0$ as input[2].

▶ **Definition 2** (tunable approximation). *$\mathcal{A}_f(D, \alpha, \kappa, \delta)$ provides a tunable approximation of f if for every $\alpha, \kappa, \delta \geq 0$ the algorithm $\mathcal{A}_f(\cdot, \alpha, \kappa, \delta)$ obtained by hardcoding α, κ and δ is a (α, κ, δ)-approximation for f.*
When the parameters α, κ, δ are clear from the context, we may abuse notation and just write $\mathcal{A}_f(D)$. For a tunable approximation algorithm we will use $R(n, \alpha, \kappa, \delta)$ to denote the amount of a particular resource used by the algorithm. The resources we consider in this work include time, space and query complexity of the algorithm (depending on the model) which we denote by $T(\cdot, \cdot, \cdot, \cdot)$, $S(\cdot, \cdot, \cdot, \cdot)$, and $Q(\cdot, \cdot, \cdot, \cdot)$ respectively.

As a concrete example any FPTAS algorithm $\mathcal{A}_f$ for f would be a tunable approximation for f with running time $T(n, \alpha, \kappa, \delta) = \text{poly}(n, 1/\alpha)$ for any $\alpha > 0$ and any $\kappa, \delta \geq 0$ – an FPTAS has no additive error ($\kappa = 0$) and zero failure probability ($\delta = 0$). Similarly a FPRAS algorithm would be a tunable approximation with running time $T(n, \alpha, \kappa, \delta) = \text{poly}(n, \alpha, \log(1/\delta))$ for any $\alpha, \delta > 0$ and any $\kappa \geq 0$ – an FPRAS also has no additive error ($\kappa = 0$).

General Framework for Approximation Algorithms. Our main result gives a framework for converting any existing non-DP algorithm $\mathcal{A}_f$ that provides an (α, κ, δ)-approximation of f into an ε-DP algorithm $\mathcal{A}''_f$ in the following manner: (1) Apply Algorithm 1 to obtain an (ε, δ)-DP algorithm $\mathcal{A}'_f$ that achieves an $(\alpha', \kappa', \delta')$-approximation (see Theorem 3), (2) Apply a postprocessing step on the output of $\mathcal{A}'_f$ outlined in Theorem 5 to achieve an ε-DP algorithm $\mathcal{A}''_f$ with the same accuracy guarantees as $\mathcal{A}'_f$ barring an additive error of $o(1)$. We emphasize that $\mathcal{A}_f$ is a tunable approximation, in other words, $\mathcal{A}_f$ takes the parameters (α, κ, δ) as input.

[1] One could still apply our black-box transformation. However, the accuracy guarantees would be degraded and we would only achieve (ε, δ)-differential privacy for sufficiently large values of $\varepsilon, \delta > 0$ which depend on the approximation error parameter α.

[2] We allow that $\alpha = \kappa = \delta = 0$ in which case $\mathcal{A}_f$ can simply compute f exactly – whether or not this computation is efficient.

▶ **Theorem 3** ((ε, δ)-privacy). *Suppose that $\mathcal{A}_f$ is a tunable approximation of $f : \mathcal{D} \to \mathbb{R}^+$. Then for all $\varepsilon > 0$, $\delta = \delta(n) > 0$*[3]*, $\alpha \geq 0$ and $\kappa \geq 0$, there is an algorithm $\mathcal{A}'_f$ such that*

(1) *(Privacy) $\mathcal{A}'_f$ is (ε, δ')-differentially private where $\delta' = \delta(1 + \exp(\varepsilon/2))$.*

(2) *(Accuracy) For all $D \in \mathcal{D}$, and $0 < \gamma$, with probability $1 - \delta - \exp(-\gamma)$,*

$$(1-\alpha')f(D) - \kappa' - \frac{2\Delta_f}{\varepsilon} \cdot \gamma \leq \mathcal{A}'_f(D) \leq (1+\alpha')f(D) + \kappa' + \frac{2\Delta_f}{\varepsilon} \cdot \gamma$$

where $\alpha' = \frac{\alpha(\varepsilon+16\gamma)}{12\log(4/\delta)}$, $\kappa' = \kappa\left(\frac{2\gamma\alpha}{3\log(4/\delta)} + \frac{8\gamma}{\varepsilon} + 1\right)$, and $\Delta_f := \max_{D,D' \in \mathcal{D}, D \sim D'} \|f(D) - f(D')\|_1$.

(3) *(Resource) $\mathcal{A}'_f$ uses $R\left(n, \frac{\varepsilon\alpha}{\log(4/\delta)}, \kappa, \delta\right)$ resource, where $R(\cdot,\cdot,\cdot,\cdot)$ is the resource used by $\mathcal{A}_f$.*

We illustrate the utility of Theorem 3 with specific parameters – if we have a non-private algorithm $\mathcal{A}_f$ that guarantees an $(\alpha, 0, \delta)$-approximation, then for constant ε, $\delta = \frac{1}{n^c}$ and $\gamma = c\log(n)$, we see that the DP algorithm $\mathcal{A}_f$ achieves an $\left(\alpha(1+o(1)), \mathcal{O}\left(\frac{\Delta_f \log(n)}{\varepsilon}\right), \frac{1}{n^c}\right)$-approximation. We typically use these parameters for δ, γ in our applications for streaming and sublinear-time algorithms.

Our reduction in Theorem 3 is quite simple – we describe the associated Algorithm 1 below.

Algorithm 1 (ε, δ)-differentially private framework $\mathcal{A}'_f$ for tunable approximation algorithm $\mathcal{A}_f$.

```
Input: Input set $D$, accuracy parameters $\alpha \in (0,1)$ and $\kappa$, DP parameter $\varepsilon$, DP failure
    probability $\delta \in (0,1)$, approx. algorithm $\mathcal{A}_f$.
1: Let $x_A := \mathcal{A}_f(D, \rho, \tau, \delta/2)$, where $\rho := \left(\frac{\varepsilon\alpha}{12\log(4/\delta)}\right)$, and $\tau := \kappa$.
2: return $x_A + X$ where $X \sim \mathsf{Lap}\left(\frac{2(4\rho x_A + 4\tau + \Delta_f)}{\varepsilon}\right)$
```

Note that in Algorithm 1, we leave our additive parameter κ as is when running $\mathcal{A}_f$, but we still choose to define $\tau := \kappa$. This is because depending on the problem, and the accuracy/efficiency guarantees desired, we can set τ to be a tuned version of κ (for e.g., we set $\tau := \kappa/\log(n)$ for the problem of estimating the number of connected components).

▶ Remark 4. We also note that, even if the failure probability $\delta > 0$ of $\mathcal{A}_f$ is non-negligible, that we can always boost the success probability by running $\mathcal{A}_f(D)$ multiple times and computing the median over all outputs. Even if the error rate $0 < \delta < 1/2$ is a constant we can always reduce the failure probability to a lower target $0 < \delta' \ll \delta$ while increasing the running time by a multiplicative factor $O(\log(1/\delta'))$. In particular, we can set δ' to be a negligible function of n such as $\delta' = n^{-\log n}$ whilst only incurring a $\mathcal{O}\left(\log^2 n\right)$ blowup in our running time.

We stress that we can only apply Theorem 3 to existing non-DP algorithms $\mathcal{A}_f$ that give an approximation guarantee of the form $(1-\alpha)f(D) - \kappa \leq \mathcal{A}_f \leq (1+\alpha)f(D) + \kappa$. For example, we cannot apply Theorem 3 to obtain an (ε, δ)-DP algorithm for estimating the minimum vertex cover size in sublinear time. This is because the non-DP sublinear-time algorithm $\mathcal{A}_{vc}$ has an approximation guarantee of the form $2VC(G) - \kappa n \leq \mathcal{A}_{vc} \leq 2VC(G) + \kappa n$. On the other hand, we can use our DP framework to obtain an (ε, δ)-DP algorithm for obtaining a

[3] typically we set $\delta = \text{negl}(n)$ or $\delta = n^{-c}$ for some constant $c > 0$. In particular $\delta(n)$ may approach zero as $n \to \infty$.

$(0, \kappa n, \delta)$-approximation of the maximum matching size in sublinear time (see full version for details [11]). Intriguingly, both the minimum vertex cover size and the maximum matching size algorithms use the same underlying strategy of estimating a greedy maximal matching in a local fashion, but since they return different estimators based on the objective and we can only use our framework as a black-box, we cannot apply our framework to the former while we can still apply it to the latter.

Finally, by applying a post-processing step described below, we show how to obtain an ε-DP algorithm from the (ε, δ)-DP algorithm obtained in Theorem 3. Importantly, the accuracy guarantee of the resulting ε-DP algorithm only differs by a small additive factor of $1/(KM)$, where $M = \max_D f(D)$ is the maximum possible output value, e.g., $M \le n^3$ for triangle counting and $K > 0$. Moreover for negligible δ, the accuracy guarantee of the resulting pure DP algorithm still holds with high probability.

▶ **Theorem 5.** *Let $M = \max_D f(D)$ and let parameter $K > 0$. If $\mathcal{A}'_f(D)$ is (ε, δ)-DP algorithm with accuracy guarantee $(1-\alpha)f(D) - \kappa \le \mathcal{A}_f(D) \le (1+\alpha)f(D) + \kappa$ holding with probability $1 - \eta$ then there exists an algorithm $\mathcal{A}''_f(D)$ which is ε-DP with accuracy guarantee $(1-\alpha)f(D) - \kappa - \frac{1}{KM} \le \mathcal{A}_f(D) \le (1+\alpha)f(D) + \kappa + \frac{1}{KM}$ with probability at least $1 - \eta - p$ where $p = \frac{\delta K(M+1)}{e^\varepsilon - 1 + \delta K(M+1)}$.*

Our second result is an analogous framework for converting any existing deterministic non-DP approximation algorithm $\mathcal{A}_f$ that provides an $(\alpha, \kappa, 0)$-approximation of f into an ε-DP algorithm $\mathcal{A}'_f$.

▶ **Theorem 6** (ε-privacy)**.** *Suppose that $\mathcal{A}_f$ is a deterministic tunable approximation of $f : \mathcal{D} \to \mathbb{R}^+$.Then for all $\varepsilon > 0$, $\alpha \ge 0$ and $\kappa \ge 0$, there is an algorithm $\mathcal{A}'_f$ such that*

(1) *(Privacy) $\mathcal{A}'_f$ is ε-differentially private.*

(2) *(Accuracy) For all $D \in \mathcal{D}$, we have that with probability $\ge 9/10$,*

$$(1-\alpha')f(D) - \kappa' - \frac{7\Delta_f}{\varepsilon} \le \mathcal{A}'_f(D) \le (1+\alpha')f(D) + \kappa' + \frac{7\Delta_f}{\varepsilon}$$

where $\alpha' := \alpha C_1(\varepsilon + C_2\gamma)$, $\kappa' := \kappa C_3(\alpha + \frac{C_4}{\varepsilon})$ for some constants $C_1, C_2, C_3, C_4 > 0$ and $\Delta_f := \max_{D, D' \in \mathcal{D}, D \sim D'} \|f(D) - f(D')\|_1$.

(3) *(Resource) $\mathcal{A}'_f$ uses $R\left(n, \frac{\varepsilon\alpha}{36}, \kappa\right)$ resource, where $R(\cdot, \cdot, \cdot)$ is the resource used by $\mathcal{A}_f$.*

DP Sublinear-time Results. We use Theorem 3 in conjunction with Theorem 5 in a black-box manner to obtain pure differentially-private sublinear time algorithms for several problems (see Table 1 for a summary).

In many models of sublinear-time computation the efficiency of the algorithm is measured in the number of queries made to the input, rather than the time complexity of the algorithm. It is often the case that the two are polynomially related, but there are instances in which the actual time complexity of the algorithm may be exponentially larger than the query complexity, in terms of the approximation factor. Nevertheless, in these instances too, the literature uses time and query complexity interchangeably. This is because the sublinear-time model assumes restricted or expensive access to the input, while further computation on local machines with the answers obtained from queries is considered to be cheap. We use query complexity for the sake of clarity.

We note that in the sublinear-time literature, the approximation parameters α, κ are usually considered to be a constant, but the analyses for most of these theorems hold for $\alpha = \alpha(n), \kappa = \kappa(n) \in (0, 1)$, where n is the input size.

Here we do not explicitly define the sublinear model (or the queries allowed) for each problem.For a graph G we denote the number of vertices as n, the number of edges as m, and the average degree of the graph as $\bar{d}$.

Typically, the accuracy guarantees of the non-DP results are presented with probability at least 2/3 – in order to apply our framework, we apply the median trick (see Remark 4) to boost the probability of success to $1 - \delta$. For simplicity of comparing our results, for any constant $c > 0$, we set $\delta := 1/n^c$ in the sequel.

We give the first (to the best of our knowledge) ε-DP sublinear time algorithm for estimating the number of triangles, connected components, and the weight of a minimum spanning tree whose accuracy guarantees hold with high probability.

For estimating the average degree of a graph, in recent work, [10] gave a pure ε-DP algorithm that achieves an $(\alpha, 0)$-approximation – a crucial observation is that their analysis only holds under the assumption that the average degree is at least one i.e., $\bar{d} \geq 1$ (see full version [11] for details). In this work, we remove the need for this assumption in the DP setting, by directly applying our black-box DP transformation to the original algorithm of [33] which works substantially better whenever we have $m = \omega(n)$ edges.

For estimating the maximum matching size in a graph, although [10] gave an ε-DP algorithm for estimating the maximum matching size that achieves a 2-multiplicative factor and κn additive factor, they left the task of finding an $(0, \kappa n)$-approximation in the DP setting as an open problem. In this work, we partially resolve this problem by presenting an ε-DP algorithm that gives a $(0, \mathcal{O}\left(\frac{\kappa n}{\varepsilon}\right))$-approximation of the maximum matching size. Crucially, our resulting analysis cannot guarantee that the added Laplace noise will be small with high probability, but only guarantees this will be the case with *constant probability.* This problem highlights a limitation of our black-box DP framework – if the non-DP algorithm that we want to apply our DP transformation on has a time/space/query complexity that has an exponential dependence on the approximation parameters then the resulting DP algorithm that achieves a similar approximation guarantee with high probability may be highly inefficient in terms of time/space/query complexity.

We also show how to apply our DP framework to an algorithm estimating the distance to bipartiteness in dense graphs [31, 3], which is accurate with probability $1 - o(1)$. The same reduction can be similarly applied to other natural properties that enjoy the feature that they admit distance-estimation algorithms with $\mathrm{poly}(1/\kappa)$ query complexity, where κ is the additive (normalized) error. For example, in the fundamental results of [32] an efficient distance approximation algorithm for the maximum k-cut problem, and thus k-colorability is presented. [27], also based on results from [6], generalizes these properties to the notion of "semi-homogeneous partition properties" and show efficient distance estimation algorithms for properties such as Induced P_3-freeness, induced P_4-freeness, and chordality.[4]

DP Streaming Results. We also apply our framework given by Theorem 3 and Theorem 5 to obtain differentially-private streaming algorithms for many fundamental problems, i.e., see Table 2 and Table 3. We remark that while the accuracy guarantees of our resulting algorithms may be surpassed by recent works studying these problems on an individual basis, our applications are black-box reductions that avoid individual utility and privacy analysis of each non-private streaming algorithm, which can be heavily involved and quite non-trivial, e.g., [40, 9, 43, 17, 46, 13].

In the streaming model, elements of an underlying dataset arrive one-by-one and the goal is to compute or approximate some predetermined function on the dataset using space that is sublinear in the size of the dataset. Our reductions also have wide applications to various archetypes of data stream models, which we now discuss. In insertion-only streams, the updates of the stream increment the underlying dataset, such as adding edges to a graph, adding terms to a sequence, or increasing the coordinates of a frequency vector. In turnstile (or dynamic) streams, the updates of the stream can both increase and decrease (or insert and delete) elements of the underlying dataset. Finally, in the sliding window model, only the W most recent updates of the data stream define the underlying dataset. Both the turnstile streaming model and the sliding window model are generalizations of insertion-only streams, and our framework has implications in all three models.

We first show that our framework can be applied to existing non-private dynamic algorithms for weighted minimum spanning tree, L_p norm estimation for $p \geq 1$ (and also F_p moment estimation for $0 < p < 1$), and distinct elements estimation. Thus using our framework, we essentially get private dynamic algorithms for these problems for free (in terms of correctness, not optimality). Since the dynamic streaming model generalizes the insertion-only streaming model, we also obtain private streaming algorithms in the insertion-only model as well. We summarize these results in Table 2.

We then apply our framework in Theorem 3 to the sliding window model. To that end, we first recall that given a $(\alpha, 0)$-approximation algorithm for the insertion-only streaming model, the smooth histogram framework [14] provides a transformation that obtains a $(\alpha, 0)$-approximation algorithm in the sliding window model for a "smooth" function. Although there are problems that are known to not be smooth, e.g., [15, 12, 16, 25, 37], the smooth histogram framework does provide a $(\alpha, 0)$-approximation to many important problems, such as counting, longest increasing subsequence, L_p norm estimation for $p \geq 1$ (and also F_p moment estimation for $0 < p < 1$), and distinct elements estimation. We remark that

[4] In general, distance estimation is closely related to tolerant testing [42], and for dense graph properties it is known that if a property is testable with a number of queries of the form $f(\kappa)$, then they admit a distance estimator [28] with an exponential blowup in $\frac{1}{\kappa}$ in the query complexity. Hence, in its general form the query complexity of estimating the distance to "hereditary" graph properties is a tower of exponential of height $\mathrm{poly}(1/\kappa)$ [4].

if we tried to apply the non-private smooth histogram framework to a DP insertion-only streaming algorithm, this might preserve privacy by post-processing, but may significantly increase the error in terms of accuracy. On the other hand, our framework avoids these issues and achieves private analogs of these algorithms in the sliding window model without compromising utility. We summarize our results for the sliding window model in Table 3. We note that in recent work, [26] give a generalized smooth histogram approach to convert a DP continual release streaming algorithm into a sliding window algorithm in the continual release setting. We focus on the one-shot streaming setting in our work.

1.2 Our Techniques

Given a tunable (α, κ, δ)-approximation algorithm $\mathcal{A}_f$ for the function $f : \mathcal{D} \to \mathbb{R}^+$, our goal is to obtain a differentially private approximation algorithm that achieves a target $(\alpha', \kappa', \delta')$-approximation of f where α', κ' are in terms of α, κ.

Warm-up: When $\mathcal{A}_f$ is deterministic and only has multiplicative error. For simplicity, let us first consider an $(\alpha, 0, 0)$-approximation algorithm $\mathcal{A}_f$, in other words, $\mathcal{A}_f$ *always* outputs a value such that $(1-\alpha)f(D) \leq \mathcal{A}_f(D) \leq (1+\alpha)f(D)$. Since we want to make $\mathcal{A}_f$ differentially private, intuitively, we need to add noise to the output of $\mathcal{A}_f$. The local sensitivity of $\mathcal{A}_f$ at D (i.e., $LS_{\mathcal{A}_f}(D) = \max_{D' \sim D} |\mathcal{A}_f(D) - \mathcal{A}_f(D')|$) is upper bounded by $2\alpha f(D) + \Delta_f$. Since Δ_f is small and we can tune α to be arbitrarily small, it is tempting to think that we can just add noise proportional to $2\alpha f(D) + \Delta_f$. Unfortunately, scaling noise proportional to local sensitivity is not necessarily private. On the other hand we could ensure privacy by scaling noise proportional to the global sensitivity (i.e., $\max_{D \in \mathcal{D}} LS_{\mathcal{A}_f}(D) \leq \max_{D \in \mathcal{D}} 2\alpha f(D) + \Delta_f$)

but noise will likely be too large to obtain meaningful accuracy guarantees. We adopt the strategy of adding noise proportional to the smooth sensitivity [41] of $\mathcal{A}_f$ instead. In particular, [41] observed that if we can find a "sufficiently smooth" function $S_f(D) \geq LS_{\mathcal{A}_f}(D)$ upper bounding the local sensitivity of $\mathcal{A}_f$ then we can preserve privacy by computing $\mathcal{A}_f(D)$ and adding noise scaled according to $S_f(D)$.

We can show that the function $S_f(D) = 4\alpha\mathcal{A}_f(D) + \Delta_f$ is a β-smooth upper bound on the local sensitivity of $\mathcal{A}_f$ for $\beta = 6\alpha$ where S_f is β-smooth if $S_f(D) \leq e^{\beta} S_f(D')$ for all pairs of neighboring datasets $D \sim D'$. To achieve privacy using the smooth sensitivity framework we need to ensure that β is sufficiently small relative to our privacy parameters ε and δ (if applicable). For example, we can achieve $\left(\varepsilon, \delta\left(1 + \exp\left(\frac{\varepsilon}{2}\right)\right)\right)$-differential privacy by adding Laplace Noise scaled by $\frac{2S_f(D)}{\varepsilon}$, but only if S_f is β-smooth for $\beta \leq \frac{\varepsilon}{2\ln(2/\delta)}$. For pure differential privacy we require that $\beta < \frac{\varepsilon}{2(\lambda+1)}$ where λ is a parameter of the noise distribution – smaller λ implies higher variance.

If we want to ensure that the output is accurate, we also need to ensure that the calibrated noise with $S_f(D)$ is small e.g., $o(f(D)) + \mathcal{O}(\Delta_f)$. Note that by definition since $S_f(D) = 4\alpha\mathcal{A}_f(D) + \Delta_f$, and we add noise proportional $S_f(D)$, we expect that the noise added may be $> \alpha f(D)$. Thus, in order to address this challenge, our basic strategy is to run the original (non-private) approximation algorithm $\mathcal{A}_f$ with *tuned* error factors e.g., we decrease α by a multiplicative factor of $\frac{\varepsilon}{\ln(n)}$, let $\rho := \frac{\varepsilon\alpha}{\ln(n)}$. Since we are now running $\mathcal{A}_f(D, \rho, 0, 0)$, we have that the function $S_f(D) = 4\rho\mathcal{A}_f(D) + \Delta_f$ is a β-smooth upper bound on the local sensitivity of the algorithm $\mathcal{A}_f(\cdot, \rho, 0, 0)$. Assuming the global sensitivity Δ_f is small, we can now show that w.h.p. the noise sampled proportional to $S_f(D)$ is at most $\alpha f(D) + O(\Delta_f/\varepsilon)$ thus resulting in an ε-differentially private algorithm with reasonable accuracy.

By tuning the parameter α we actually accomplish two useful properties (1. accuracy) we decrease both the local sensitivity and our smooth upper bound $S_f(D)$ which reduces the magnitude of the noise that we add, and (2. privacy) we achieve β-smoothness for increasingly small values of β so that the required condition $\beta \leq \frac{\varepsilon}{2\ln(2/\delta)}$ (or $\beta < \frac{\varepsilon}{2(\lambda+1)}$) can be satisfied if we want to scale noise according to $S_f(D)$.

Extending to deterministic $\mathcal{A}_f$ with multiplicative and additive error. More generally, if we have an $(\alpha, \kappa, 0)$-approximation algorithm $\mathcal{A}_f$ then we can show that $S_f(D) = 4\alpha\mathcal{A}_f(D) + \Delta_f + 4\tau$ is a β-smooth upper bound on the local sensitivity of $\mathcal{A}_f$ with $\beta = 6\alpha$ (see Lemma 14). In particular, note that the additive error term κ does not adversely impact smoothness. Thus, we can achieve pure differentially privacy by tuning α such that $6\alpha < \beta < \frac{\varepsilon}{2(\lambda+1)}$ and scaling our noise according to $S_f(D)$ (see Lemma 15). We can also obtain stronger accuracy guarantees by relaxing the requirement for pure DP and tuning α such that $6\alpha \leq \beta \leq \frac{\varepsilon}{2\ln(2/\delta)}$ so that we can sample our noise from the Laplace distribution which has strong concentration guarantees.

When $\mathcal{A}_f$ is randomized. The remaining challenge is to handle randomized approximation algorithms $\mathcal{A}_f$ which are only guaranteed to output a good approximation with high probability i.e., with non-zero probability $\delta > 0$ the algorithm is allowed to output an arbitrarily bad approximation. In particular, let us consider an (α, κ, δ)-approximation algorithm $\mathcal{A}_f$. For any possible input D we are always guaranteed that with probability $\geq 1 - \delta$ the algorithm $\mathcal{A}_f(D)$ outputs a good approximation $(1 - \alpha)f(D) \leq \mathcal{A}_f(D) \leq (1 + \alpha)f(D)$. Unfortunately, the function $S_f(D) = 4\alpha\mathcal{A}_f(D) + \Delta_f + 4\kappa$ is no longer guaranteed to be a β-smooth upper bound on the local sensitivity of $\mathcal{A}_f$ since $\mathcal{A}_f$ may sometimes output a value outside the specified approximation bounds.

In order to address this challenge, we define a function $g_f(D)$ that matches $\mathcal{A}_f(D)$ with probability at least $1-\delta/2$ and is *always* guaranteed to output a good approximation. We emphasize that $g_f(D)$ may not be efficiently computable, but it is well-defined and only used for the purpose of analysis. More specifically, we set $g_f(D) = \mathcal{A}_f(D)$ as long as $(1-\alpha)f(D) - \kappa \leq \mathcal{A}_f(D) \leq (1+\alpha)f(D) + \kappa$. If $\mathcal{A}_f(D) > (1+\alpha)f(D)$, then we define $g_f(D) := (1+\alpha)f(D)$, similarly, if $\mathcal{A}_f(D) < (1-\alpha)f(D)$, then we define $g_f(D) := (1-\alpha)f(D) + \kappa$. Observe that we are always guaranteed that $(1-\alpha)f(D) - \kappa \leq g_f(D) \leq (1+\alpha)f(D) + \kappa$. Thus, $S_f(D) = 4\alpha g_f(D) + \Delta_f + 4\tau$ is a $\beta = 6\alpha$-smooth upper bound on the local sensitivity of g_f (see Lemma 8). As long as $6\alpha \leq \beta \leq \frac{\varepsilon}{2\ln(2/\delta)}$ we could preserve $\left(\varepsilon, \delta\left(1+\exp\left(\frac{\varepsilon}{2}\right)\right)\right)$-differential privacy by outputting $g_f(D)$ plus Laplace Noise scaled by $\frac{8\alpha g_f(D)+\Delta_f+8\tau}{\varepsilon}$ i.e., scaled according to our β-smooth upper bound on the local sensitivity of g_f. Unfortunately, the function g_f may not be efficiently computable. Thus, we substitute g_f for $\mathcal{A}_f$ and instead output $\mathcal{A}_f(D)$ plus Laplace noise scaled according to $\frac{8\alpha\mathcal{A}_f(D)+\Delta_f+8\tau}{\varepsilon}$. While $4\alpha\mathcal{A}_f(D) + \Delta_f + 4\tau$ is not necessarily a β-smooth upper bound on the local sensitivity of $\mathcal{A}$, the key point is that the latter (efficiently computable) procedure is equivalent to the former (differentially private) procedure as long as $g_f(D) = A_f(D)$ which happens as long as $\mathcal{A}_f$ outputs a good approximation i.e., except with probability $\delta/2$. Thus, we can apply a hybrid argument to argue that the final efficiently computable algorithm is $\left(\varepsilon, \frac{\delta}{2} + \delta\left(1+\exp\left(\frac{\varepsilon}{2}\right)\right)\right)$-differential privacy (see Lemma 10). In order to ensure accuracy, we use the same strategy as before, i.e., we run $\mathcal{A}_f(D, \rho, \tau, \delta/2)$, where $\rho \leq \frac{\varepsilon\alpha}{\log(1/\delta)}$. Sampling noise proportional to $S_f(D)$ (where $S_f(D)$ is now defined in terms of ρ), and absorbing the failure probability of algorithm $\mathcal{A}_f$ into the DP failure probability term δ, results in an approximate differentially private algorithm. Finally applying the postprocessing step results in a pure differentially private algorithm. We refer to the full proofs (Section 2) for additional details.

Applications. We give some intuition on how we apply Theorem 3 to various applications by choosing appropriate parameters. Recall that with probability $1-\delta-\exp(-\gamma)$, $\mathcal{A}'_f$ outputs $(1-\alpha')f(D) - \kappa' - \frac{2\Delta_f}{\varepsilon}\cdot\gamma \leq \mathcal{A}'_f(D) \leq (1+\alpha')f(D) + \kappa' + \frac{2\Delta_f}{\varepsilon}\cdot\gamma$, where $\alpha' = \frac{\alpha(\varepsilon+16\gamma)}{12\log(4/\delta)}$, and $\kappa' = \kappa\left(\frac{2\gamma\alpha}{3\log(4/\delta)} + \frac{8\gamma}{\varepsilon} + 1\right)$ with a time/space/query complexity blow-up incurred by running the original algorithm $\mathcal{A}_f$ with multiplicative accuracy parameter $\rho = \frac{\varepsilon\alpha}{\log(4/\delta)}$. First, observe that if the original algorithm $\mathcal{A}_f$ has time/space/query complexity with a dependence on $\mathrm{poly}(\frac{1}{\alpha})$, then the resulting time/space/query complexities for $\mathcal{A}'_f$ will still have a polynomial dependence, i.e., $\mathrm{poly}(\frac{\log(4/\delta)}{\alpha})$ – this naturally leads to FPRAS or FPTAS applications, as well as other classes of approximation algorithms like sublinear time or space. On the otherhand, if the time/space/query complexity of $\mathcal{A}_f$ has a non-polynomial dependence on $1/\alpha$, e.g., $\exp(\frac{1}{\alpha})$, then since δ is typically $\mathsf{negl}(n)$ or $\frac{1}{n^c}$ for $c > 0$, the resulting DP algorithm $\mathcal{A}'_f$ could have much worse time/space/query-guarantees with respect to n, e.g., in an extreme case if we set $\delta = 2^{-\mathrm{poly}(n)}$ then $\rho = \Omega(\mathrm{poly}(n)/\alpha)$ and we could incur a $\exp(\frac{\mathrm{poly}(n)}{\alpha})$ multiplicative overhead in the running time. It is worth noting that one could optionally reduce the additive error term κ' for $\mathcal{A}'_f$ by reducing the error term κ for $\mathcal{A}$.

We further emphasize this trade-off between obtaining small failure probability bounds and the accuracy or resource guarantees. Consider the following two examples – (Example 1) if we set the probability of failure, i.e., $\exp(-\gamma) = \delta = \frac{1}{n^c}$ for any $c > 0$, then the resulting approximation parameters are roughly $\alpha' = \alpha(1+o(1))$, and $\kappa' = \kappa(\alpha + \frac{\log(n)}{\varepsilon} + 1)$[5], and

[5] In the applications we consider the original (non-private) approximation algorithm typically has only multiplicative or only additive error and not both. In particular, we typically either have $\alpha > 0$ and $\kappa = 0$ or $\kappa > 0$ and $\alpha = 0$, but not the case where $\alpha > 0$ and $\kappa > 0$. Considering the case when $\kappa \neq 0$, and $\alpha = 0$, we (roughly) have $\kappa' = \kappa(\frac{\log(n)}{\varepsilon} + 1)$.

the additional error term depending on global sensitivity is roughly $\frac{\Delta_f \log(n)}{\varepsilon}$. We incur a time/space overhead by running $\mathcal{A}_f$ with multiplicative accuracy parameter $\rho = \Omega(\varepsilon\alpha/\log n)$ instead of α. (Example 2) if we set the probability of failure, i.e., $\exp(-\gamma) = \delta = \frac{1}{n^{\log\log(n)}} - \mathsf{negl}(n)$, then α' remains the same as before, and now $\kappa' = \kappa(\alpha + \frac{\log(n)\log\log(n)}{\varepsilon} + 1)$, but the additional error term depending on global sensitivity becomes $\frac{\Delta_f \log(n)\log\log(n)}{\varepsilon}$. In this latter case we incur time or space overhead by running $\mathcal{A}_f$ with multiplicative accuracy parameter $\rho = \Omega\left(\frac{\varepsilon\alpha}{\log n \log\log n}\right)$ – to reduce the $\kappa' \log n \log\log n$ error term it could be useful to run $\mathcal{A}_f$ with additive error parameter $\frac{\kappa}{\log n \log\log n}$ which may incur additional time or space overhead. Thus these two examples illustrate how, as we decrease the failure probability, the accuracy and resource (time/space in this case) guarantees become worse. See full version [11] for applications to sublinear time and streaming algorithms.

2 General Transformation for Approximation Algorithms

In this section, we formally define our black-box differentially private transformation for (randomized) approximation algorithms. Given a tunable approximation (see Definition 2) algorithm of f, call it $\mathcal{A}_f$, that outputs an (α, κ, δ)-approximation, our framework for randomized algorithms involves two steps – (1) Apply Algorithm 1 to $\mathcal{A}_f$ to obtain an (ε, δ)-DP algorithm $\mathcal{A}'_f$ with accuracy guarantees outlined in Theorem 3 (2) Apply postprocessing step to the output of $\mathcal{A}'_f$ to obtain an ε-DP algorithm (see Theorem 5).

We first prove Theorem 3 that provides theoretical guarantees for algorithm $\mathcal{A}'_f$ (Algorithm 1). This is our main contribution as the postprocessing step to obtain pure DP applies a folkore result.

Observe that even for the case when the original algorithm $\mathcal{A}_f$ gives an $(\alpha, 0, \delta)$-approximation of f (i.e., $\kappa = 0$), the resulting DP algorithm $\mathcal{A}'_f$ will still have an additive error, this additive error is inherent due to the requirement of adding Laplace noise to preserve DP. We emphasize that the Laplace noise added to the output of algorithm $\mathcal{A}_f$ depends on the global sensitivity of the function f, therefore, we can only get meaningful DP approximation algorithms using this transformation for functions with low global sensitivity.

Proof of Theorem 3. $\mathcal{A}'_f$ is defined in Algorithm 1 – it first runs $\mathcal{A}_f(D, \rho, \kappa, \delta/2)$ where $\rho := \frac{\varepsilon\alpha}{12\log(4/\delta)}$ and then adds Laplace Noise. Thus, the resource used by $\mathcal{A}'_f$ is $R(n, \rho, \kappa, \delta)$. The privacy guarantee follows from Lemma 10, and the accuracy guarantee follows from Lemma 12. ◀

▶ Remark 7. When $\mathcal{A}_f$ is a PRAS, by definition, the output of $\mathcal{A}_f$ is an $(\alpha, 0, \delta)$-approximation of f running in time $T(n, \alpha, 0, \delta) = \text{poly}(n, 1/\alpha, \log(1/\delta))$. Applying Theorem 3 with negligible $\delta = n^{-\log n}$ and $\gamma = \log^2 n$ for any $\alpha' > 0$ we obtain a private $\left(\alpha', O\left(\frac{\Delta_f}{\varepsilon \log^2 n}\right), 2n^{-\log n}\right)$-approximation with polynomial running time $\text{poly}(n, 1/\varepsilon, 1/\alpha')$.

▶ **Lemma 8.** *Let $0 < \rho < 1/2$. Suppose that $\mathcal{A}_f$ outputs a (ρ, τ, δ)-approximation of a function $f : \mathcal{D} \to \mathbb{R}^+$ with global sensitivity Δ_f. Let $\mathcal{A}_{f,R}$ denote a deterministic run of $\mathcal{A}$ using a fixed set of random coins R. Define function $g_{f,R}$ by*

$$g_{f,R}(D) = \begin{cases} \mathcal{A}_{f,R}(D) & \textit{if } (1-\rho)f(D) - \tau \leq \mathcal{A}_{f,R}(D) \leq (1+\rho)f(D) + \tau \\ (1-\rho)f(D) - \tau & \textit{if } \mathcal{A}_{f,R}(D) < (1-\rho)f(D) - \tau \\ (1+\rho)f(D) + \tau & \textit{if } \mathcal{A}_{f,R}(D) > (1+\rho)f(D) + \tau \end{cases}$$

Then the function $S_f(D) = 4\rho g_{f,R}(D) + 4\tau + \Delta_f$ is a β-smooth upper bound for $g_{f,R}$ where $\beta \geq 6\rho$.

Proof. Fix an arbitrary set of random coin tosses R. We frequently use the fact that $(1-\rho)f(D) - \tau \le g_{f,R}(D) \le (1+\rho)f(D) + \tau$. We also note that since $0 \le \rho < 1/2$, we have that $\frac{1}{2}f(D) - \tau \le g_{f,R}(D) \le 2f(D) + \tau$.

First, we show that Condition 1 of Definition 24 holds. Without loss of generality, we assume $f(D) \ge f(D')$, where D' is any neighboring input. Then:

$$
\begin{aligned}
LS_{g_{f,R}}(D) &= \max_{D':D\sim D'} \|g_{f,R}(D) - g_{f,R}(D')\| \\
&\le \|(1+\rho)f(D) + \tau - (1-\rho)f(D') + \tau\| \\
&\le \rho\|f(D) + f(D')\| + 2\tau + \Delta_f \\
&\le 2\rho f(D) + 2\tau + \Delta_f \\
&\le 4\rho g_{f,R}(D) + 2\rho\tau + 2\tau + \Delta_f && \text{as } \frac{1}{2}f(D) - \tau \le g_{f,R}(D) \\
&\le 4\rho g_{f,R}(D) + 4\tau + \Delta_f \\
&= S_f(D)
\end{aligned}
$$

Next, we show that Condition 2 of Definition 24 holds below. We have:

$$
\begin{aligned}
S_f(D) &= 4\rho g_{f,R}(D) + 4\tau + \Delta_f \\
&\le 4\rho\,(1+\rho)\,f(D) + 4\rho\tau + 4\tau + \Delta_f && \text{by def of } g_{f,R} \\
&\le 4\rho\,(1+\rho)\,(\Delta_f + f(D')) + 4\rho\tau + 4\tau + \Delta_f && \text{since } D \sim D' \\
&\le 4\rho(1+\rho)f(D') + (4\rho(1+\rho)+1)\Delta_f + 4\rho\tau + 4\tau \\
&\le 4\rho\frac{(1+\rho)}{1-\rho}(g_{f,R}(D') + \tau) + (1+6\rho)\Delta_f + 4\rho\tau + 4\tau && \text{by def of } g_{f,R} \\
&\le 4\rho(1+\rho)(1+2\rho)(g_{f,R}(D') + \tau) + (1+6\rho)\Delta_f + 4\rho\tau + 4\tau \\
&\le 4\rho(1+\rho)(1+2\rho)g_{f,R}(D') + 12\rho\tau + (1+6\rho)\Delta_f + 4\rho\tau + 4\tau \\
&\le 4\rho(1+\rho)(1+2\rho)g_{f,R}(D') + (1+6\rho)(\Delta_f + 4\tau) \\
&\le 4\rho(1+4\rho)g_{f,R}(D') + (1+6\rho)(\Delta_f + 4\tau) \\
&\le (1+6\rho)(4\rho g_{f,R}(D') + \Delta_f + 4\tau) \\
&\le e^{6\rho}\cdot(4\rho g_{f,R}(D') + \Delta_f + 4\tau) = e^{\beta}S_f(D'),
\end{aligned}
$$

where $\beta \ge 6\rho$. ◀

▶ Remark 9. As a special case if we have a $(0,\kappa,0)$-approximation algorithm $\mathcal{A}_f$ (i.e., no multiplicative error, zero failure probability) then applying Lemma 8 yields the smooth upper bound $S_f(D) = 4\tau + \Delta_f$. We observe that this smooth upper bound is independent of D and, therefore, S_f is just an upper bound on the global sensitivity of g_f. Furthermore, in this special case we are guaranteed that $\mathcal{A}_f(D) = g_f(D)$ with probability 1. Thus, in this special case, we can achieve pure ε-DP by computing $\mathcal{A}_f(D)$ and adding Laplace noise proportional to S_f.
If we have a $(0,\kappa,\delta)$-approximation algorithm for $\delta \ne 0$ then we still have $S_f(D) = 4\tau + \Delta_f$ which means that $S_f(D)$ is an upper bound on the global sensitivity of g_f. However, computing $\mathcal{A}_f(D)$ and adding Laplace noise proportional to S_f does not necessarily yield a pure DP algorithm since we may have $\Delta_f(D) \ne \mathcal{A}_f(D)$ with non-zero probability δ. If we have $(\alpha,\kappa,0)$-approximation algorithm $\mathcal{A}_f$, and $\alpha \ne 0$, since $S_f(D) = 4\rho\mathcal{A}_f(D) + 4\tau + \Delta_f$ still depends on the input D. However, we can still achieve DP using Theorem 6.

Applying Lemma 8 to the theorem calibrating noise to smooth bounds on the smooth sensitivity [41] we show that the Algorithm 1 preserves privacy below.

▶ **Lemma 10** (Privacy). *Algorithm 1 is (ε, δ')-differentially private where $\delta' = \delta(1+\exp(\varepsilon/2))$.*

Proof. Consider a modification of Algorithm 1, call it Algorithm 1' where instead of computing $\mathcal{A}_f(D, \rho, \tau, \delta/2)$ we instead sample the random coins R that $\mathcal{A}_f$ would have used and replace the value $\mathcal{A}_f(D, \rho, \tau, \delta/2; R)$ (which we denote as $\mathcal{A}_{f,R}(D)$ in the sequel) with $g_{f,R}(D)$.The function $g_{f,R}$ may not be efficiently computable, but we only use Algorithm 1' for the purpose of analysis. We first observe that by Lemma 8, for any $\beta \geq 6\rho$ the function $S_f(D) = 4\rho g_{f,R}(D) + 4\tau + \Delta_f$ is a β-smooth upper bound on the sensitivity of $g_{f,R}$. Thus, by Theorem 25, it is sufficient to set $\rho := \frac{\varepsilon\alpha}{12\log(4/\delta)}$ for $6\rho \leq \beta \leq \frac{\varepsilon}{2\ln(\frac{4}{\delta})}$ and add noise proportional to $\mathsf{Lap}\left(\frac{2S_f(D)}{\varepsilon}\right) = \mathsf{Lap}\left(\frac{2(4\rho g_{f,R}(D)+4\tau+\Delta_f)}{\varepsilon}\right)$ to preserve $(\varepsilon, \delta/2)$-privacy of Algorithm 1'.

Since $g_{f,R}(D)$ is $\mathcal{A}_{f,R}(D)$ except with probability $\delta/2$, Algorithm 1 is identical to Algorithm 1' except with probability $\delta/2$. Thus, this shows that Algorithm 1 is (ε, δ)-private. ◀

▶ **Fact 11.** *If $Y \sim \mathsf{Lap}(b)$, then $\Pr[|Y| \geq \ell \cdot b] = \exp(-\ell)$.*

▶ **Lemma 12** (Accuracy). *For all $\gamma > 0$, with probability $1 - \exp(-\gamma) - \delta$,*

$$\big(1 - \rho(1 + \frac{16\gamma}{\varepsilon})\big)f(D) - \tau\big(\frac{8\gamma\rho}{\varepsilon} + \frac{8\gamma}{\varepsilon} + 1\big) - \frac{2\Delta_f\gamma}{\varepsilon} \leq \mathcal{A}'(D) \leq \big(1 + \rho(1 + \frac{16\gamma}{\varepsilon})\big)f(D)$$
$$+ \tau\big(\frac{8\gamma\rho}{\varepsilon} + \frac{8\gamma}{\varepsilon} + 1\big) + \frac{2\Delta_f\gamma}{\varepsilon}.$$

Proof. First, using Fact 11, for any $\gamma > 0$, we have that,

$$\mathbf{Pr}\left[|X| \geq \frac{2(4\rho\mathcal{A}(D) + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma\right] = \exp(-\gamma)$$

$\mathcal{A}_f$ is a $(\rho, \tau, \delta/2)$-approximation of f so for any $D \in \mathcal{D}$, we have that $\mathcal{A}_f(D) \leq (1+\rho)f(D)+\tau$ with probability $1-\delta/2$. Since $0 < \rho < 1/2$ we have $(1+\rho)f(D)+\tau \leq 2f(D)+\tau$. Therefore, by a union bound,

$$\Pr\big[\big(\mathcal{A}_f(D) > (1+\rho)f(D) + \tau\big) \vee \big(\mathcal{A}_f(D) < (1-\rho)f(D) - \tau\big) \vee \big(|X|$$
$$\geq \frac{2(4\rho\mathcal{A}_f(D) + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma\big)\big] \leq \delta/2 + \exp(-\gamma)$$

Thus, with probability $1 - \exp(-\gamma) - \delta/2$, we have that

$$(1-\rho)f(D) - \tau \leq \mathcal{A}_f(D) \leq (1+\rho)f(D) + \tau \leq 2f(D) + \tau \tag{1}$$

and

$$|X| < \frac{2(4\rho\mathcal{A}_f(D) + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma \tag{2}$$

By plugging in Eq. 1 into Eq. 2, we have that with probability $1 - \exp(-\gamma) - \delta/2$,

$$|X| < \frac{2(4\rho(2f(D) + \tau) + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma$$

Overall, this means that with probability $1 - \exp(-\gamma) - \delta/2$,

$$(1-\rho)f(D) - \tau - \frac{2(4\rho(2f(D) + \tau) + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma \leq \mathcal{A}'_f(D)$$
$$\leq (1+\rho)f(D) + \tau + \frac{2(4\rho(2f(D) + \tau) + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma$$

Grouping the like terms together gives the theorem statement. ◀

▶ **Theorem 5.** *Let $M = \max_D f(D)$ and let parameter $K > 0$. If $\mathcal{A}'_f(D)$ is (ε,δ)-DP algorithm with accuracy guarantee $(1-\alpha)f(D)-\kappa \le \mathcal{A}_f(D) \le (1+\alpha)f(D)+\kappa$ holding with probability $1-\eta$ then there exists an algorithm $\mathcal{A}''_f(D)$ which is ε-DP with accuracy guarantee $(1-\alpha)f(D)-\kappa-\frac{1}{KM} \le \mathcal{A}_f(D) \le (1+\alpha)f(D)+\kappa+\frac{1}{KM}$ with probability at least $1-\eta-p$ where $p = \frac{\delta K(M+1)}{e^{\varepsilon}-1+\delta K(M+1)}$.*

The proof of Theorem 5 is in Appendix D. At a high level our idea is to define $\mathcal{A}'_f(D) = \frac{\lceil K\mathcal{A}_f(D)\rceil}{KM}$. The rounding step introduces a small additive error term $\le \frac{1}{KM}$ and ensures that $\mathcal{A}'_f(D)$ now has bounded range $|\mathcal{R}| \le (M+1)K$. Since $\mathcal{A}'_f$ has bounded range we can apply a folklore result (see Theorem 19) to transform this (ε,δ)-DP algorithm into an ε-DP algorithm.

2.1 Achieving Pure DP for Approximation Algorithms with Zero Failure Probability

In this section we show how one can achieve pure differential privacy ($\delta = 0$) when we have a tunable $(\alpha,\kappa,0)$-approximation algorithm. The basic framework is the same except that we use the Cauchy distribution instead of Laplace when applying the Smooth Sensitivity framework – see Theorem 25. Since we assume $\delta = 0$ in this section we will sometimes simplify notation and write $T(n,\alpha,\kappa)$ (resp. $S(n,\alpha,\kappa)$) instead of $T(n,\alpha,\kappa,0)$ (resp. $S(n,\alpha,\kappa,0)$). We move the proofs in this section to Appendix C.

Algorithm 2 ε-differentially private framework for tunable deterministic approximation algorithms.

```
Input: Input set $D$, accuracy parameter $\alpha \in (0,1)$, differential privacy parameter $\varepsilon$, approx.
    algorithm $\mathcal{A}_f$.
Let $x_A := \mathcal{A}_f(D,\rho,\tau,0)$ where $\rho := \frac{\varepsilon\alpha}{36}$ and $\tau := \kappa$.
return $x_A + X$ where $X \sim \mathsf{C}\left(\frac{6(4\rho x_A+\Delta_f)}{\varepsilon}\right)$
```

▶ Remark 13. When $\mathcal{A}_f$ is a PTAS, by definition, the output of $\mathcal{A}_f$ is an $(\alpha,0,0)$-approximation of f running in time $T(n,\alpha,0) = \mathrm{poly}(n,1/\alpha)$. Applying Theorem 6 with for any $\alpha > 0$ we obtain a private $\left(\alpha, O\left(\frac{\Delta_f}{\varepsilon}\right), 9/10\right)$-approximation with polynomial running time $\mathrm{poly}(n,1/\varepsilon,1/\alpha)$.

▶ **Lemma 14.** *Suppose that $\mathcal{A}_f$ outputs a $(\rho,\tau,0)$-approximation where $0 < \rho < 1/2$ of a function $f : \mathcal{D} \to \mathbb{R}^+$ with global sensitivity Δ_f. Then the function $S_f(D) = 4\rho\mathcal{A}_f(D) + 4\tau + \Delta_f$ is a β-smooth upper bound for $\mathcal{A}_f$ where $\beta \ge 6\rho$.*

The proof remains the same as in Lemma 8. Applying Lemma 14 to the theorem calibrating noise to smooth bounds on the smooth sensitivity [41] we show that the Algorithm 2 preserves privacy below.

▶ **Lemma 15.** *Algorithm 2 is ε-differentially private.*

▶ **Lemma 16.** *For all $\gamma > 6.5$, with probability at least $9/10$,*

$$\left(1-\rho\left(1+\frac{48\gamma}{\varepsilon}\right)\right)f(D) - \frac{24(\rho+1)\gamma\tau}{\varepsilon} - \frac{6\Delta_f}{\varepsilon}\cdot\gamma \le \mathcal{A}'_f(D)$$
$$\le \left(1+\rho\left(1+\frac{48\gamma}{\varepsilon}\right)\right)f(D) + \frac{24(\rho+1)\gamma\tau}{\varepsilon} + \frac{6\Delta_f}{\varepsilon}\cdot\gamma$$

▶ Remark 17. For simplicity, we have chosen to sample from the standard cauchy distribution $\lambda = 2$, more generally, if we sample noise with density $h(z) \propto \frac{1}{1+|z|^\lambda}$, where $\lambda = c$, then with probability $1 - \delta$, $\gamma = \frac{1}{\delta^{1/c}}$ in Lemma 16.

Application to the Knapsack Problem. As a fun example we consider the knapsack problem. The knapsack problem is well known to be NP-Hard, but also admits an FPTAS. To define an instance of the knapsack problem we have a maximum weight capacity W for the knapsack and n items each with a value $v_{max} \geq v_i \geq 0$ and a weight $w_i \geq 0$. The goal is to find a subset $S \subseteq [n]$ of items to put in the knapsack maximizing the total value $v(S) = \sum_{i \in S} v_i$ subject to the constraint that the total weight $w(S) = \sum_{i \in S} w_i$ does not exceed our capacity i.e., $w(S) \leq W$.

For the purpose of this illustration let's fix the capacity W and weights $w_1, \ldots, w_n$ and let $f(v_1, \ldots, v_n)$ denote the value of the optimal knapsack solution given values $v_1, \ldots, v_n$. Let's say that two knapsack instances $(W, v_1, \ldots, v_n, w_1, \ldots, w_n)$ and $(W, v'_1, \ldots, v'_n, w_1, \ldots, w_n)$ are neighbors if $\sum_i \| v_i - v'_i| \leq 1$. Thus, we are viewing the exact value of each item as sensitive and the goal of differential privacy is to prevent an attacker from inferring these sensitive values exactly. Observe that the global sensitivity of f is upper bounded by $\Delta_f \leq \max_{v \sim v'} \max_{S \subseteq [n]} |v(S) - v'(S)| \leq 1$[6].

Since there is an FPTAS algorithm for Knapsack we can find a non-private approximation algorithm $\mathcal{A}_f(\vec{v}, \alpha, \kappa = 0)$ running in time $T(n, \alpha) = \text{poly}(n, 1/\alpha)$. If we apply Theorem 6 then for any target α' our ε-DP algorithm $\mathcal{A}'_f$ runs in time $\text{poly}(n, 1/\varepsilon, 1/\alpha)$ and solves Knapsack with additive error $\mathcal{O}(1/\varepsilon)$ and multiplicative error α' with probability at least 9/10. If we don't require pure DP then we can also apply Theorem 3 then for any target α' our algorithm $\mathcal{A}'_f$ runs in time $\text{poly}(n, 1/\varepsilon, 1/\alpha, \log(1/\delta))$ and solves Knapsack with probability at least $1 - \delta - \exp(-\gamma)$ with additive error at most $\mathcal{O}(\gamma/\varepsilon)$ and multiplicative error α'.

3 Conclusion and Open Questions

In this work, we introduce a general framework for transforming a non-private approximation algorithm into a differentially private approximation algorithm. We show specific applications of our framework for sublinear time and sublinear space algorithms. Although our framework applies to a large variety of problems and settings, it does incur a small penalty in both runtime and space for achieving differential privacy. A natural question is whether these losses are necessary for a general black-box framework and what are sufficient conditions for achieving a black-box reduction.

It also seems possible that our framework could provide a method for achieving differentially private algorithms when the important resource is not runtime, number of queries, or space. For example, in distributed algorithms, it is often desired to achieve sublinear communication while in learning/testing, it is often desired to achieve sublinear query complexity. We believe that exploring the limits and capabilities of our framework in those settings would be a natural future direction of work.

[6] We could also define neighboring knapsack instances such that we can completely replace the value of any item i.e., v and v' are neighbors if there exists some index $i \in [n]$ such that $v_i \neq v'_i$ and $v_j = v'_j$ for all $j \neq i$. However, in this case we can we would have large global sensitivity $\Delta_f = v_{max}$. Thus, we won't be able to design an accurate differentially private approximation even if we are willing to solve the NP-Hard knapsack problem exactly.

A Related Work

One of the first differentially private frameworks for computing general functions was introduced by [23] which released functions with additive noise, where the noise is calibrated according to the *global sensitivity* of the function f. This framework was generalized by [41], to handle functions which might have a high global sensitivity but are usually less sensitive in practice. The framework allows the release of functions with instance-specific noise, where the noise that is added is not just determined by f but by the input dataset as well. The noise magnitude calibrated is according to the *smooth sensitivity* of f on the input dataset which is a smooth upper bound on the *local sensitivity* of f on an input dataset. The smooth sensitivity of a function may be hard to compute, therefore in the same work, [41] give a generic method called the *sample and aggregate* method that bypasses the explicit computation of the smooth sensitivity of the function and works even when the function is given as a black-box. [21] suggested a framework called *Propose-Test-Release* to release statistical estimators with additive noise where the noise is calibrated according to the *local sensitivity* of the estimator. Note that adding noise proportional to the local sensitivity of a function with respect to an input set usually does not preserve privacy, but their approach first proposes a bound on the local sensitivity and privately tests whether this bound holds for the specific input set, and then releases the noisy response to the query.

In the context of developing differentially private frameworks for approximation algorithms, [10] formally introduced the notion of *coupled global sensitivity* of a randomized algorithm, which gives an analogous framework as that of the global sensitivity framework [23], but for randomized approximation algorithms instead of deterministic functions. In this framework, one can run a non-private randomized approximation algorithm $\mathcal{A}_f(D)$ on the dataset, and privacy is obtained by adding noise proportional to the coupled global sensitivity of $\mathcal{A}_f$. More formally, the coupled global sensitivity measures the worst-case L_1-sensitivity of the outputs of a randomized algorithm $\mathcal{A}_f$ on neighboring inputs over a minimum coupling of the internal coin tosses of $\mathcal{A}_f$.

In independent work, Tetek [45] also explores the problem of transforming randomized approximation algorithms into (pure) differentially private approximation algorithms. In contrast to our results Tetek's transformation [45] assumes that the error of the original approximation algorithm either has small subexponential diameter or bounded mean error – assumptions that would not apply generically to every (tunable) approximation algorithm. Assuming subexponential error their work shows that it is possible to achieve ε-DP by adding Laplace Noise yielding accuracy guarantees that hold with high probability. However, the assumption of the error being subexponential is quite strong and does not often hold for many randomized approximation algorithms. While assuming bounded mean error is a weaker assumption on the error of the non-private randomized algorithm, however the DP noise is sampled from the Pareto distribution, which has polynomial tail bounds. This leads to accuracy guarantees which only hold with constant probability. Note that applying the median trick commonly used to amplify success probability in the non-private literature adversely affects the privacy budget and is thus not desirable. In contrast, our transformation applies generically to any (tunably) accurate approximation algorithm and we achieve accuracy guarantees that hold with high probability for the same problems studied in their paper. Finally, we correct an outdated claim[7] from the comparison to our work detailed in [45] that says that we only achieve approximate privacy. We can achieve *pure* DP algorithms by applying a postprocessing step to the output of our transformation as outlined in Theorem 5.

B Preliminaries

We use the notation $\tilde{\mathcal{O}}\left(f(n)\right)$ to mean $f(n) \cdot \text{polylog}(f(n))$. We define datasets D and D' as *neighboring*, denoted as $D \sim D'$, if removing or adding one point in D results in D'; alternatively, if changing one data point in D results in D'.

[7] A prior version of the paper achieved pure DP, but that transformation (Theorem 1.5) only applied to deterministic tunable approximation algorithms

▶ **Definition 18** (Differential privacy). *[22] An algorithm $\mathcal{A}$ is (ε, δ)-DP if for every pair of neighboring datasets $D \sim D'$, and for all sets $\mathcal{S}$ of possible outputs, we have that $\Pr[\mathcal{A}(D) \in \mathcal{S}] \le e^{\varepsilon} \Pr[\mathcal{A}(D') \in \mathcal{S}] + \delta$. When $\delta = 0$ we simply say that the algorithm is ε-DP.*

Given an (ε, δ)-DP algorithm, one can obtain an ε-DP algorithm under certain conditions outlined below. We include the proof for completeness in Appendix D.

▶ **Theorem 19** (Approximate DP to Pure DP). *Let $\mathcal{A} : \mathcal{D} \to \mathcal{R}$. If $\mathcal{A}$ is an (ε, δ)-DP algorithm such that $\delta \le \frac{(e^{\varepsilon}-1)p}{|\mathcal{R}|(1-p)}$ then there is an algorithm $\mathcal{A}'$ such that $\mathcal{A}'$ is ε-DP defined in the following manner.*

$$\mathcal{A}'(D) = \begin{cases} \mathcal{A}(D) & \textit{with probability } 1-p \\ \mathsf{random}(\mathcal{R}) & \textit{with probability } p \end{cases}$$

where $\mathcal{R}$ is the range of $\mathcal{A}_f$.

We define the distributions we will use to sample additive noise from below.

▶ **Definition 20** (Laplace distribution). *We say a random variable X is drawn from a Laplace distribution with mean μ and scale $b > 0$ if the probability density function of X at x is $\frac{1}{2b} \exp\left(-\frac{|x-\mu|}{b}\right)$. We use the notation $X \sim \mathsf{Lap}(b)$ to denote that X is drawn from the Laplace distribution with scale b and mean $\mu = 0$.*

▶ **Definition 21** (Cauchy distribution). *We say a random variable X is drawn from a Cauchy distribution with location parameter x_0 and scale $b > 0$ if the probability density function of X at x is $\frac{1}{\pi b}\left(\frac{b^2}{(x-x_0)^2+b^2}\right)$. We use the notation $X \sim \mathsf{C}(b)$ to denote that X is drawn from the Cauchy distribution with scale b and location parameter $x_0 = 0$.*

We formally define the concept of global sensitivity which is a worst-case notion of sensitivity for deterministic functions below.

▶ **Definition 22** (Global sensitivity). *The global sensitivity of a function $f : \mathcal{D} \to \mathbb{R}^d$ is defined by*

$$\Delta_f = \max_{D,D' \in \mathcal{D}, D \sim D'} \|f(D) - f(D')\|_1.$$

We define the notion of local sensitivity for a fixed input, which can be much smaller than the global sensitivity, but in general, adding noise calibrated according to the local sensitivity does not preserve DP.

▶ **Definition 23** (Local sensitivity). *For $f : \mathcal{D} \to \mathbb{R}$ and $D \in \mathcal{D}$, the local sensitivity of f at D is defined as*

$$LS_f(D) = \max_{D' : D \sim D'} \|f(D) - f(D')\|_1.$$

Note: if $f : \mathcal{D} \times \mathcal{R} \to \mathbb{R}$ is a randomized function which, in addition to a dataset $D \in \mathcal{D}$ takes random coins $r \in \mathcal{R}$ as input we simply define $LS_f(D) = \max_{r \in \mathcal{R}} LS_{f_r}$ where $f_r(D) \doteq f(D; r)$.

In order to add instance-specific noise, we define the notions of β-smooth upper bound which is a smooth upper bound on the local sensitivity.

▶ **Definition 24** (Smooth upper bound on local sensitivity). *For $\beta > 0$, a function $S : \mathcal{D} \to \mathbb{R}$ is a β-smooth upper bound on the local sensitivity of $f : \mathcal{D} \to \mathbb{R}$ if*

(1) *For all $D \in \mathcal{D}$, we have $S(D) \geq LS_f(D)$.*

(2) *For all $D, D' \in \mathcal{D}$ with $\|D - D'\|_1 = 1$, we have $S(D) \leq e^\beta \cdot S(D')$.*

Finally, although one cannot add noise calibrated with local sensitivity, one can add noise proportional to a β-smooth upper bound on the local sensitivity as follows.

▶ **Theorem 25** (Corollary 2.4 in [41]). *Let $f : \mathcal{D} \to \mathbb{R}$ and $S : \mathcal{D} \to \mathbb{R}$ be a β-smooth upper bound on the local sensitivity of f.*

(1) *If $\beta \leq \frac{\varepsilon}{2(\lambda+1)}$ and $\lambda > 1$, the algorithm $D \to f(D) + \frac{2(\lambda+1)S(D)}{\varepsilon} \cdot \eta$, where η is sampled from the distribution with density $h(z) \propto \frac{1}{1+|z|^\lambda}$, is ε-differentially private.*

(2) *If $\beta \leq \frac{\varepsilon}{2\ln(2/\delta)}$ and $\delta \in (0,1)$, then the algorithm $D \to f(D) + \frac{2S(D)}{\varepsilon} \cdot \eta$ where $\eta \sim \mathsf{Lap}(1)$ is (ε, δ')-differentially private for $\delta' = \delta\left(1 + \exp\left(\frac{\varepsilon}{2}\right)\right)$*[8].

C Proofs of Section 2.1

Proof of Theorem 6.

Proof. $\mathcal{A}'_f$ is defined in Algorithm 2 – we first run $\mathcal{A}_f(D, \rho, \kappa)$ where $\rho := \frac{\varepsilon\alpha}{36}$ and then we add noise proportional to the standard Cauchy distribution. Thus, the resource used will be $R(n, \rho, \kappa)$.

The privacy guarantee follows from Lemma 15, and the accuracy guarantee follows from Lemma 16. ◀

Proof of Lemma 15

Proof. We first observe that by Lemma 14, $S_f(D) = 4\mathcal{A}_f(D) + 4\tau + \Delta_f$ is a β-smooth upper bound for $\mathcal{A}_f$. Recall that $\rho := \frac{\varepsilon\alpha}{36}$, thus we can apply Theorem 25 (with $\lambda = 2$) where $6\rho \leq \beta \leq \frac{\varepsilon}{6}$ and conclude that it is sufficient to add noise proportional to $\mathsf{C}\left(\frac{2(2+1)S_f(x)}{\varepsilon}\right) = \mathsf{C}\left(\frac{6(4\rho\mathcal{A}_f(D)+4\tau+\Delta_f)}{\varepsilon}\right)$ to preserve ε-privacy.
◀

▶ **Fact 26.** *If $Y \sim \mathsf{C}(x; 0, b)$, then $\Pr[|Y| \geq \ell b] = 1 - \frac{2\tan^{-1}(\ell)}{\pi}$.*

Proof of Lemma 16.

Proof. First, we invoke Fact 26 below,

$$\Pr\left[|X| \geq \frac{6(4\rho\mathcal{A}_f(D) + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma\right] = 1 - \frac{2\tan^{-1}(\gamma)}{\pi} \leq \frac{1}{10}$$

where the final inequality comes from using the fact that $\gamma > 6.5$. In other words, with probability $\geq 9/10$,

$$|X| \leq \frac{6(4\rho\mathcal{A}_f(D) + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma \tag{3}$$

$\mathcal{A}_f$ is a $(\rho, \tau, 0)$-approximation of f so for any $D \in \mathcal{D}$, we have that $\mathcal{A}_f(D) \leq (1+\rho)f(D) + \tau$. Since $0 < \rho < 1/2$ we have $(1+\rho)f(D) + \tau \leq 2f(D) + \tau$.

[8] These bounds differ slightly from those listed in the original paper (Corollary 2.4 in [41]). We confirmed with the authors in private communication that δ should be multiplied by $(1 + \exp(\varepsilon/2))$.

By plugging in the relation $\mathcal{A}_f(D) \leq 2f(D) + \tau$ into Eq. 3, we have that with probability at least $9/10$,

$$|X| \leq \frac{6(8\rho f(D) + 4\rho\tau + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma$$

Thus with probability at least $9/10$,

$$(1-\rho)f(D) - \tau - \frac{6(8\rho f(D) + 4\rho\tau + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma \leq \mathcal{A}'_f(D)$$
$$\leq (1+\rho)f(D) + \tau + \frac{6(8\rho f(D) + 4\rho\tau + 4\tau + \Delta_f)}{\varepsilon} \cdot \gamma$$

Rearranging the like terms together in the above expression completes the proof. ◀

D Proof of Approximate DP to Pure DP transformation

▶ **Theorem 5.** *Let $M = \max_D f(D)$ and let parameter $K > 0$. If $\mathcal{A}'_f(D)$ is (ε, δ)-DP algorithm with accuracy guarantee $(1-\alpha)f(D) - \kappa \leq \mathcal{A}_f(D) \leq (1+\alpha)f(D) + \kappa$ holding with probability $1-\eta$ then there exists an algorithm $\mathcal{A}''_f(D)$ which is ε-DP with accuracy guarantee $(1-\alpha)f(D) - \kappa - \frac{1}{KM} \leq \mathcal{A}_f(D) \leq (1+\alpha)f(D) + \kappa + \frac{1}{KM}$ with probability at least $1-\eta-p$ where $p = \frac{\delta K(M+1)}{e^\varepsilon - 1 + \delta K(M+1)}$.*

Proof. Note that WLOG we can assume that $\mathcal{A}_f(D)$ outputs a value between 0 and M since we can always truncate the output to this range – this operation preserves privacy by postprocessing and does not adversely affect accuracy. For some $K > 0$, define algorithm $\mathcal{A}''_f(D)$ as outputting $\frac{\lceil K\mathcal{A}_f(D)\rceil}{KM}$. Observe that $\mathcal{A}''_f$ is (ε, δ)-DP by postprocessing and the accuracy guarantee of $\mathcal{A}''_f$ is almost identical to that of $\mathcal{A}_f$ since by definition $|\mathcal{A}''_f(D) - \mathcal{A}_f(D)| < \frac{1}{KM}$. By post-processing we can ensure that the range $\mathcal{R}$ of $\mathcal{A}''_f(D)$ is small $|\mathcal{R}| = (M+1)K$ since $\mathcal{R} = \{\frac{i}{KM} : 0 \leq i \leq KM\}$. Thus, we can pick p such that $\delta \leq \frac{(e^\varepsilon - 1)p}{|\mathcal{R}|(1-p)}$ and apply a folklore theorem (see Theorem 19) to transform our (ε, δ)-DP algorithm $\mathcal{A}''_f(D)$ to an ε-DP algorithm $\mathcal{A}'_f(D)$ in the following manner:

$$\mathcal{A}'_f(D) = \begin{cases} \mathcal{A}''_f(D) & \text{with probability } 1-p \\ \mathsf{random}(\mathcal{R}) & \text{with probability } p \end{cases}$$

By combining the accuracy guarantees of $\mathcal{A}_f$ and $\mathcal{A}''_f$ we see that with probability $1-\eta-p$, we have that $(1-\alpha)f(D) - \kappa - \frac{1}{KM} \leq \mathcal{A}_f(D) \leq (1+\alpha)f(D) + \kappa + \frac{1}{KM}$ where $p = \frac{\delta K(M+1)}{e^\varepsilon - 1 + \delta K(M+1)}$ as claimed. ◀

▶ **Theorem 19** (Approximate DP to Pure DP). *Let $\mathcal{A} : \mathcal{D} \to \mathcal{R}$. If $\mathcal{A}$ is an (ε, δ)-DP algorithm such that $\delta \leq \frac{(e^\varepsilon - 1)p}{|\mathcal{R}|(1-p)}$ then there is an algorithm $\mathcal{A}'$ such that $\mathcal{A}'$ is ε-DP defined in the following manner.*

$$\mathcal{A}'(D) = \begin{cases} \mathcal{A}(D) & \textit{with probability } 1-p \\ \mathsf{random}(\mathcal{R}) & \textit{with probability } p \end{cases}$$

where $\mathcal{R}$ is the range of $\mathcal{A}_f$.

Proof. Recall that we define $\mathcal{A}'$ as follows:

$$\mathcal{A}'(D) = \begin{cases} \mathcal{A}(D) & \text{with probability } 1-p \\ \mathsf{random}(\mathcal{R}) & \text{with probability } p \end{cases}$$

Let $D, D' \in \mathcal{D}$ be neighboring databases and fix output $y \in \mathcal{R}$. We first give a general claim regarding the probability of $\mathcal{A}'(D) = y$ in terms of the $\Pr[\mathcal{A}(D) = y]$.

▷ Claim 27. For $D \in \mathcal{D}$,

$$\Pr[\mathcal{A}'(D) = y] = \Pr[\mathcal{A}(D) = y]\,(1-p) + \frac{p}{|\mathcal{R}|}$$

Now we need to show that $\Pr[\mathcal{A}'(D) = y] \le e^{\varepsilon} \Pr[\mathcal{A}'(D') = y]$.

$$\begin{aligned}
&\Pr[\mathcal{A}'(D) = y] \\
&= \Pr[\mathcal{A}(D) = y]\,(1-p) + \frac{p}{|\mathcal{R}|} \\
&\le (1-p)\,(e^{\varepsilon} \Pr[\mathcal{A}(D') = y] + \delta) + \frac{p}{|\mathcal{R}|} \\
&\le e^{\varepsilon} \Pr[\mathcal{A}(D') = y]\,(1-p) + \delta\,(1-p) + \frac{p}{|R|} && (4) \\
&= e^{\varepsilon}(\Pr[\mathcal{A}'(D') = y] - \frac{p}{|\mathcal{R}|}) + \delta\,(1-p) + \frac{p}{|\mathcal{R}|} && (5) \\
&\le e^{\varepsilon} \Pr[\mathcal{A}'(D') = y] + \delta\,(1-p) + \frac{p}{|\mathcal{R}|}(1-e^{\varepsilon}) \\
&\le e^{\varepsilon} \Pr[\mathcal{A}'(D') = y] && (6)
\end{aligned}$$

The transition 4 to 5 follows from the observation that $\Pr[\mathcal{A}'(D') = y] = (1-p) \Pr[\mathcal{A}(D') = y] + \frac{p}{|\mathcal{R}|}$ and therefore, $(1-p) \Pr[\mathcal{A}(D') = y] = \Pr[\mathcal{A}'(D') = y] - \frac{p}{|\mathcal{R}|}$. The last equation 6 follows because $\delta \le \frac{(e^{\varepsilon}-1)p}{|\mathcal{R}|(1-p)}$ and thus

$$\delta\,(1-p) + \frac{p}{|\mathcal{R}|}(1-e^{\varepsilon}) \le 0 \;.$$ ◀

Fast Decoding of Explicit Almost Optimal ε-Balanced q-Ary Codes And Fast Approximation of Expanding k-CSPs

Fernando Granha Jeronimo ✉
Institute for Advanced Study, Princeton, NJ, USA

Abstract

Good codes over an alphabet of constant size q can approach but not surpass distance $1 - 1/q$. This makes the use of q-ary codes a necessity in some applications, and much work has been devoted to the case of constant alphabet q. In the large distance regime, namely, distance $1 - 1/q - \varepsilon$ for small $\varepsilon > 0$, the Gilbert–Varshamov (GV) bound asserts that rate $\Omega_q(\varepsilon^2)$ is achievable whereas the q-ary MRRW bound gives a rate upper bound of $O_q(\varepsilon^2 \log(1/\varepsilon))$. In this sense, the GV bound is almost optimal in this regime. Prior to this work there was no known explicit and efficiently decodable q-ary codes near the GV bound, in this large distance regime, for any constant $q \geq 3$.

We design an $\widetilde{O}_{\varepsilon,q}(N)$ time decoder for explicit (expander based) families of linear codes $\mathcal{C}_{N,q,\varepsilon} \subseteq \mathbb{F}_q^N$ of distance $(1-1/q)(1-\varepsilon)$ and rate $\Omega_q(\varepsilon^{2+o(1)})$, for any desired $\varepsilon > 0$ and any constant prime q, namely, almost optimal in this regime. These codes are ε-balanced,i.e., for every non-zero codeword, the frequency of each symbol lies in the interval $[1/q - \varepsilon, 1/q + \varepsilon]$. A key ingredient of the q-ary decoder is a new near-linear time approximation algorithm for linear equations (k-LIN) over $\mathbb{Z}_q$ on expanding hypergraphs, in particular, those naturally arising in the decoding of these codes.

We also investigate k-CSPs on expanding hypergraphs in more generality. We show that special trade-offs available for k-LIN over $\mathbb{Z}_q$ hold for linear equations over a finite group. To handle general finite groups, we design a new matrix version of weak regularity for expanding hypergraphs. We also obtain a near-linear time approximation algorithm for general expanding k-CSPs over q-ary alphabet. This later algorithm runs in time $\widetilde{O}_{k,q}(m + n)$, where m is the number of constraints and n is the number of variables. This improves the previous best running time of $O(n^{\Theta_{k,q}(1)})$ by a Sum-of-Squares based algorithm of [AJT, 2019] (in the expanding regular case).

We obtain our results by generalizing the framework of [JST, 2021] based on weak regularity decomposition for expanding hypergraphs. This framework was originally designed for binary k-XOR with the goal of providing near-linear time decoder for explicit binary codes, near the GV bound, from the breakthrough work of Ta-Shma [STOC, 2017]. The explicit families of codes over prime $\mathbb{F}_q$ are based on suitable instatiations of the Jalan–Moshkovitz (Abelian) generalization of Ta-Shma's distance amplification procedure.

1 Introduction

Codes over small alphabet sizes have attracted a lot of effort in coding theory [17]. There is now a vast theory about them, but important mysteries remain. One very natural alphabet is the binary alphabet, which has a myriad of uses and applications. However, it also comes with an important limitation, namely, a family of good binary codes cannot[1] surpass distance 1/2. By using a q-ary alphabet, a family of good codes can approach distance $1 - 1/q$ but not surpass it. This makes the use of q-ary codes a necessity whenever larger distances are needed. Working towards explicit and efficiently decodable codes with optimal trade-offs between rate and distance has been a challenging but fruitful guiding goal in coding theory.

In the large distance case, namely, distances are of the form $1 - 1/q - \varepsilon$ for small values of $\varepsilon > 0$, the Gilbert–Varshamov (GV) bound [13, 36] asserts that rate $\Omega_q(\varepsilon^2)$ is achievable whereas the q-ary version of McEliece, Rodemich, Rumsey and Welch (MRRW) [26] gives an impossibility upper of $O_q(\varepsilon^2 \log(1/\varepsilon))$. This means that the GV bound is nearly optimal in this regime of constant alphabet size q and large distance. To the best of our knowledge, in this regime, (prior to this work) no explicit and efficiently decodable families of q-ary codes near the GV bound were known for any $q \geq 3$.

Two widely used approaches in the construction of q-ary codes for small q are based on code concatenation [11] and on algebraic geometry (AG) constructions [30, 34]. Using code concatenation, it is possible to obtain explicit constructions achieving the suboptimal Zyablov bound trade-off between rate and distance, which gives a rate of $\Omega_q(\varepsilon^3)$. Some explicit families of AG codes are celebrated for beating the GV bound in some specific parameter regimes, e.g., the seminal work of Tsfasman, Vlădut and Zink[2] [35] or the (non-linear) construction of Elkies [9]. This surprising phenomenon of explicit AG codes beating random codes cannot happen in a major way in the large distance and constant alphabet regime since the GV bound is nearly optimal. Furthermore, known explicit constructions of linear AG codes are far from the GV bound for large distances and constant q. Another drawback of several explicit families of good AG codes is that known decoders can take much longer than linear time in the blocklength [27].

On a more combinatorial side, in a breakthrough work using expander graphs, Ta-Shma [31] gave the first explicit construction of binary codes of distance $1/2 - \varepsilon$ and rate $\Omega(\varepsilon^{2+o(1)})$, namely, near the Gilbert–Varshamov bound. A polynomial time decoder for these binary codes was first given in [23] followed by a near-linear time decoder in [24]. Subsequently, Jalan and Moshkovitz [22] extended Ta-Shma's analysis [31] to handle (in particular) codes over larger alphabets[3]. Suitable instantiations of [22] imply explicit codes over prime $\mathbb{F}_q$ of distance $1 - 1/q - \varepsilon$ with rate $\Omega_q(\varepsilon^{2+o_q(1)})$, namely, again near the (q-ary) GV bound for constant q.

Motivated by the above situation, we design a near-linear time decoder for explicit families of q-ary codes of distance $(1 - 1/q)(1 - \varepsilon)$ and rate $\Omega(\varepsilon^{2+o_q(1)})$ for any constant prime q, namely, near the GV bound in the large distance regime. More precisely, our main result is as follows (answering a question from [22]).

[1] This is a consequence of the Plotkin bound.

[2] More precisely, the TVZ bound [35] establishes a rate of $r \geq 1 - \delta - 1/(\sqrt{q} - 1)$ with respect to the relative distance δ.

[3] More precisely, [22] analyzed the (scalar) Abelian case of Ta-Shma's amplification.

▶ **Theorem 1** (Main I – Near-linear Time Unique Decoding over $\mathbb{F}_q$)**.** *Let q be a prime. For every $\varepsilon > 0$ sufficiently small, there are explicit linear Ta-Shma codes $\mathcal{C}_{N,q,\varepsilon} \subseteq \mathbb{F}_q^N$ for infinitely many values $N \in \mathbb{N}$ with*

(i) *distance at least $(1 - 1/q)(1 - \varepsilon)$ (actually ε-balanced),*

(ii) *rate $\Omega_q(\varepsilon^{2+\alpha})$ where $\alpha = O(1/(\log_2(1/\varepsilon))^{1/6})$, and*

(iii) *an $r(q/\varepsilon) \cdot \tilde{O}(N)$ time randomized unique decoding algorithm that decodes within radius $((1 - 1/q)(1 - \varepsilon))/2$,*

where $r(x) = \exp(\exp(\text{poly}(x)))$.

In fact, we actually prove the following stronger *list* decoding result.

▶ **Theorem 2** (Near-linear time List Decoding over $\mathbb{F}_q$)**.** *Let q be a prime. For every $\varepsilon > 0$ sufficiently small, there are explicit binary linear Ta-Shma codes $\mathcal{C}_{N,q,\varepsilon} \subseteq \mathbb{F}_q^N$ for infinitely many values $N \in \mathbb{N}$ with*

(i) *distance at least $(1 - 1/q)(1 - \varepsilon)$ (actually ε-balanced),*

(ii) *rate $\Omega_q(\varepsilon^{2+\alpha})$ where $\alpha = O(1/(\log_2(1/\varepsilon))^{1/6})$, and*

(iii) *an $r(q/\varepsilon) \cdot \tilde{O}(N)$ time randomized list decoding algorithm that decodes within radius $1 - 1/q - 2^{-\Theta_q((\log_2(1/\varepsilon))^{1/6})}$ and works with high probability,*

where $r(x) = \exp(\exp(\text{poly}(x)))$.

We obtain our results by building on and extending the *binary* decoding framework in [24]. This framework is based on a generalization of the weak regularity decomposition to (sparse) *expanding* hypergraphs that generalizes the seminal work of Frieze and Kannan [12]. The weak regularity decomposition of [24] was then used to approximate *expanding* k-XOR instances naturally arising in the decoding of binary Ta-Shma's codes [31]. Similarly, constraint satisfaction problems (CSPs) will play a key role in our decoder. Here, we also take the opportunity to investigate *expanding* CSPs more broadly.

An instance of a k-CSP is given by a k-uniform (ordered) constraint hypergraph $W \subseteq [n]^k$, where each vertex is associated with a variable taking values in an alphabet of size q and each edge is associated with a constraint involving the variables of its vertices. While even approximating a CSP is NP-hard in general, suitable notions of expansion of the constraint hypergraph allow for efficient approximation algorithms as in [24]. One such notion is *splittability* [2]. Roughly speaking, a τ-splittable collection of tuples for some $\tau \in (0, 1]$ is the higher-order analogue of the second largest singular value of the normalized adjacency matrix of a graph (the smaller the τ the more expanding is the collection). Approximating expanding k-CSPs is at the core of some decoding algorithms for expander based constructions of codes [8, 1, 23, 24, 6].

As mentioned above, approximating expanding k-CSPs will be again at the core of our extension of [24] to more general constraints over larger alphabets. Our new q-ary decoder will need to handle instances of linear equations over the alphabet $\mathbb{Z}_q$, where each equation involves a sum of k variables. This kind of k-CSP is commonly denoted k-LIN over alphabet $\mathbb{Z}_q$. We will see that the special algebraic structure of these linear constraints will allow to obtain some improved parameter trade-offs, which will be explored in the decoding application. More precisely, the expansion (splittability) parameter τ will have no dependence on alphabet size q and only a polynomial dependence on the arity[4] k, and this allows us to obtain better approximation guarantees. Our second result follows.

[4] In the binary case of [24], it was also possible to have a polynomial dependence on the arity k.

▶ **Theorem 3** (Main II)**.** *Let $\mathfrak{I}$ be an instance of MAX k-LIN$_q$ on n variables with alphabet $\mathbb{Z}_q$ and constraints supported on a regular*[5] *collection of tuples $W \subseteq [n]^k$. If W is τ-splittable with $\tau \le \tau_0(k, \delta) := \mathrm{poly}(\delta/k)$, then we can compute an assignment satisfying $\mathsf{OPT} - \delta$ in time $r(q/\tau_0) \cdot \widetilde{O}(|W| + n)$, where $r(x) = \exp(\exp(\mathrm{poly}(x)))$.*

We show that this phenomenon of no dependence of the expansion on the alphabet size q and only polynomial dependence on arity k also occurs for linear equations over a general finite groups $\mathfrak{G}$. Similarly, this leads to better approximation guarantees. To actually implement and obtain this advantage, we will design a new matrix version of the weak regularity decomposition for expanding hypergraphs. Our third result follows.

▶ **Theorem 4** (Main III)**.** *Let $\mathfrak{I}$ be an instance of MAX k-LIN$_{\mathfrak{G}}$ on n variables with alphabet a finite group $\mathfrak{G}$ and constraints supported on a regular collection of tuples $W \subseteq [n]^k$. If W is τ-splittable with $\tau \le \tau_0(k, \delta) := \mathrm{poly}(\delta/k)$, then we can compute an assignment satisfying $\mathsf{OPT} - \delta$ in time $O_{|\mathfrak{G}|,k,\delta}(1) \cdot \mathrm{poly}(|W| + n)$.*

▶ Remark 5. In Theorem 4, we did not attempt to make the running time near-linear in the number of constraints and variables, but it is plausible that it can be done.

We find intriguing this interplay between the type of constraint used in the CSP and the expansion requirement for a given approximation. A natural question is to investigate this interplay for more general constraint types.

In this work, we also investigate how fast we can approximate expanding k-CSPs over q-ary alphabet without making any assumptions on the constraints. We show that k-CSPs can be approximated in near-linear time in the number of constraints and variables, assuming k and q are constants, and provided the constraint hypergraph is sufficiently expanding (splittable). An important caveat of this general case is that the expansion requirements will now depend on both the alphabet size q and arity k in an exponential way (of the form $q^{-O(k)}$).

▶ **Theorem 6.** *Let $\mathfrak{I}$ be an instance of MAX k-CSP on n variables with alphabet $[q]$ and constraints supported on a regular collection of tuples $W \subseteq [n]^k$. If W is τ-splittable with $\tau \le \tau_0(k, q, \delta) := \mathrm{poly}(\delta/(kq^k))$, then we can compute an assignment satisfying $\mathsf{OPT} - \delta$ in time $r(kq/\delta) \cdot \widetilde{O}(|W| + n)$, where $r(x) = \exp(\exp(\exp(\mathrm{poly}(x))))$.*

We obtain the above result via a reduction to the "binary" weak regularity in [24] in a somewhat similar fashion to [10]. Even though it is not hard to make this connection, we think it is worth stating it since this result may be more broadly applicable. Moreover, for fixed arity k and alphabet size q, this improves the running time in the expanding regime of the Sum-of-Squares based algorithm in [2] and also the expanding regime[6] of earlier results 2-CSPs [5, 18, 19, 28].

For comparison, we recall the expanding regime[7] of [2] below.

▶ **Theorem 7** (Sum-of-Squares [2])**.** *Let $\mathfrak{I}$ be an instance of MAX k-CSP on n variables with alphabet $[q]$ and constraints supported $W \subseteq [n]^k$. If W is τ-splittable with $\tau \le \tau_0(k, q, \delta) := \mathrm{poly}(\delta/k) \cdot q^{-k}$, then we can compute an assignment satisfying $\mathsf{OPT} - \delta$ in time $n^{\mathrm{poly}(1/\tau_0)}$.*

▶ Remark 8. In the new theorem above, we do not attempt to optimize the function $r(x)$.

[5] This is an analog to tuples of a graph being d-vertex regular.

[6] We point out these approaches also consider when the expansion is defective (low threshold rank case). Since we are interested in near-linear running time, we need to focus on the expanding case.

[7] Using the improved analysis of swap walks by Dikstein and Dinur [7].

Related Work. As we mentioned above, our work is an extension of the *binary* framework of [24]. This framework was designed for approximating expanding k-XOR and to give a near-liner time decoding algorithm for the explicit binary codes of Ta-Shma [31], near the GV bound. The first polynomial time decoder for these codes was given in [23] using the Sum-of-Squares semi-definite programming hierarchy and its running time, albeit polynomial, is very far from near-linear in the blocklength.

AG codes are widely used in the study of explicit constructions over constant q-ary alphabets. Some of these constructions achieve very competitive parameter trade-offs (e.g., rate versus distance) if not the best known in several cases. However, explicit and efficiently decodable codes near GV bound for large distances,i.e., $1 - 1/q - \varepsilon$, and constant alphabet size were not known prior to this work. In fact, the first explicit construction only appeared in the breakthrough work of [31] for binary codes using more combinatorial expander based techniques. This absence of explicit construction near the GV bound in this regime means that much is yet to be discovered about this case. We view our near-linear time decoder of prime q-ary codes in this regime as not only reaching previously unattained parameter regimes with an explicit construction, but also offering a more combinatorial perspective among a wealthy of algebraic techniques.

For *non-explicit* families of codes approaching the GV bound, much more is known. Random linear codes achieve this bound, but their decoding is believed to be computationally hard. It is possible to construct more structured ensembles of random codes that allow for efficient decoding in this regime. We have the non-explicit classical Goppa codes. Another important technique is based on Thommesen's [32] technique of concatenation with random inner codes. These Thommesen based ensembles can sometimes approach the GV bound and also allow for efficient decoding [16, 14, 21, 25] and even near-linear time decoding [21, 25].

More recently, Blanc and Doron [6] used the framework in [24] to decode explicit binary codes near the GV bound with improved parameters, where they obtain a polynomial improvement on the $o(1)$ error term of the rate $\Omega(\varepsilon^{2+o(1)})$ (the α in Theorem 1) and also put forward some interesting conjectures towards further improving the rate. It is plausible that their improvement also applies here for q-ary alphabets.

In the constant alphabet case, a different parameter regime that has received much attention is the near-capacity regime [15, 20, 21, 25] of list decoding from radius $1 - r - \varepsilon$ with rate r for small values of $\varepsilon > 0$. This regime can only occur when the alphabet size q is a function of ε. Note that our near GV bound regime is the opposite, we have a fixed constant q and we can take ε arbitrarily small (smaller than some function of q).

Due to space constraints, most of our proofs only appear in the full version of this paper.

2 Proof Strategy

We will now describe our contributions in more detail. Our algorithmic results will be based on extensions of the *binary* weak regularity framework of [24]. Roughly speaking, this framework being a *"low level"* framework gives fine control over its components leading to a near-linear time decoder for Ta-Shma's codes [31] over $\mathbb{F}_2$. This same low level structure means that extensions may require suitable generalizations in several of these components as well technical work to implement them. The extensions to handle codes over prime q-ary alphabet and a matrix version of weak regularity will be no exception.

First, we will recall the weak regularity decomposition of Frieze and Kannan [10] in a more analytic form [33]. We will also first consider its *existential* form and later discuss its algorithmic form. Our setup will be as follows. Let $W \subseteq [n]^k$ be a collection of tuples endowed with the uniform probability measure μ_k. Suppose that we have a function $g\colon W \to \mathbb{C}$ that we want to approximate using a simpler approximating function, which will be made precise below. Further suppose that the quality of approximation will be measured with respect to correlations with a class of test functions $\mathcal{F}$. Given some desired approximation error $\delta > 0$, the goal will be to find a *"simple"* approximator $h \approx g$ such that

$$\max_{f \in \mathcal{F}} \left| \langle g - h, f \rangle_{\mu_k} \right| \ \le \ \delta \,.$$

As an *existential* result, it is well-known that an h of the form $h = \sum_{\ell=1}^{p} c_\ell \cdot f_\ell$ always exists, where c_ℓ's are scalars and the f_ℓ's are functions belonging to $\mathcal{F}$. Furthermore, the number of test functions p is small being at most[8] $O(1/\delta^2)$. This means that h is indeed *"simple"* since it is the sum of a small number of test functions, so h is almost as complex as the test functions it needs to fool.

To motivate the generalizations in the weak regularity framework, we will start the discussion of the important case of linear equations over $\mathbb{Z}_q$ as a motivating example. As mentioned above, approximating k-LIN over $\mathbb{Z}_q$ will be crucial in the near-linear time decoding algorithm for prime q-ary alphabets. For us, an instance $\mathfrak{I}$ of k-LIN is given by a system of linear equations[9]

$$x_{i_1} + \cdots + x_{i_k} \equiv r_w \pmod q \qquad\qquad \forall\ w = (i_1, \ldots, i_k) \in W, \tag{1}$$

where $(r_w)_{w \in W} \in \mathbb{Z}_q^W$ are given RHS coefficients. We will need to model this problem in a way that is amenable to the weak regularity approach. We will also take advantage of the algebraic structure of the constraints to avoid any dependence of the alphabet size q and to have only a mild dependence on the arity k in the expansion the framework will require from W.

"Global" Approximation of Dirac Delta Functions. An elementary property of Fourier analysis over $\mathbb{Z}_q$ is that the Dirac delta function $x \mapsto \mathbf{1}_{[x=y]}$ admits a simple but extremely handy Fourier decomposition which we now recall. Let $\omega = \exp(2\pi\sqrt{-1}/q)$. Using orthogonality of characters, we have

$$\mathbf{1}_{[x=y]} = \mathop{\mathbb{E}}_{a \in \mathbb{Z}_q} \left[\omega^{a(x-y)} \right] .$$

Suppose we have an assignment $b \in \mathbb{Z}_q^n$ to the variables of our system of linear equations $\mathfrak{I}$. Then, the fraction of satisfied constraints, which we denote by $\mathsf{val}(\mathfrak{I}, b)$ and refer as the value of this assignment, can be expressed as

$$\mathsf{val}(\mathfrak{I}, b) := \mathop{\mathbb{E}}_{w=(i_1,\ldots,i_k)\sim\mu_k} \left[\mathbf{1}_{[b_{i_1} + \cdots + b_{i_k} \equiv r_w]} \right] = \mathop{\mathbb{E}}_{w=(i_1,\ldots,i_k)\sim\mu_k} \left[\mathop{\mathbb{E}}_{a \in \mathbb{Z}_q} \left[\omega^{a(b_{i_1} + \cdots + b_{i_k} - r_w)} \right] \right] .$$

This suggests defining q functions one for each $a \in \mathbb{Z}_q$ of the form $g_a\colon W \to \mathbb{C}$ as $g_a(w) := \omega^{a \cdot b_w}$, the *"harmonic"* components. We also endow the space $\mathbb{C}^W$ with the inner product defined by the measure μ_k on W. We will need some additional notation. For $b \in \mathbb{Z}_q^n$, we define the function $\chi_{b,a}$ on $[n]$ as $\chi_{b,a}(i) = \omega^{a \cdot b_i}$. We can now rexpress $\mathsf{val}(\mathfrak{I}, b)$ in terms of its harmonic components as

[8] The ℓ_1-norm of the coefficients is "small", i.e., $\sum_{\ell=1}^{p} |c_\ell|$.

[9] The coefficients of the variables are always taken to be 1 here.

$$\begin{aligned}\mathsf{val}(\mathfrak{I}, b) &= \mathop{\mathbb{E}}_{w=(i_1,\ldots,i_k)\sim\mu_k}\left[\mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\omega^{a(b_{i_1}+\cdots+b_{i_k}-r_w)}\right]\right] \\ &= \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\mathop{\mathbb{E}}_{w=(i_1,\ldots,i_k)\sim\mu_k}\left[\omega^{-a\cdot r_w}\cdot\omega^{a(b_{i_1}+\cdots+b_{i_k})}\right]\right] \\ &= \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\left\langle g_a, \underbrace{\chi_{b,a}\otimes\cdots\otimes\chi_{b,a}}_{k}\right\rangle_{\mu_k}\right] \\ &= \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\left\langle g_a, (\chi_{b,a})^{\otimes k}\right\rangle_{\mu_k}\right].\end{aligned}$$

We can now try to further approximate each g_a using a simpler function h_a that behaves similarly to g_a with respect to functions of the form $f_{b,a} = \chi_{b,a} \otimes \cdots \otimes \chi_{b,a}$ as in the inner product above. We can view functions of form $f_{b,a}$ as tests with respect to which g_a and its simpler approximator have similar correlations. This means that we can model the problem in way amenable to the existential weak regularity framework. For each a, we will consider a (slightly) more general class of test functions $\mathrm{CUT}^{\otimes k}_{\omega,q,a}$ defined as follows

$$\mathrm{CUT}^{\otimes k}_{\omega,q,a} \coloneqq \{\chi_{b^{(1)},a}\otimes\cdots\otimes\chi_{b^{(k)},a} \mid b^{(1)},\ldots,b^{(k)} \subseteq \mathbb{Z}_q^n\}.$$

A simple yet useful remark is that if we can find a decomposition fooling a larger class of test functions, this would suffice since, in particular, it fools the initial class of test.

Suppose that for some $\delta \in (0,1)$ we can find a δ-approximation $h_a = \sum_{\ell=1}^{p_a} c_{a,\ell}\cdot\chi_{b^{(a,\ell,1)},a}\otimes\cdots\otimes\chi_{b^{(a,\ell,k)},a}$ to g_a with respect to a class of test functions, i.e.,

$$\max_{f\in\mathrm{CUT}^{\otimes k}_{\omega,q,a}} \left|\langle g_a - h_a, f\rangle_{\mu_k}\right| \le \delta.$$

By replacing g_a with h_a in the computation of $\mathsf{val}(\mathfrak{I}, b)$ above, we obtain[10]

$$\mathsf{val}(\mathfrak{I}, b) = \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\left\langle g_a, (\chi_{b,a})^{\otimes k}\right\rangle\right] = \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\left\langle h_a, (\chi_{b,a})^{\otimes k}\right\rangle\right] \pm \delta.$$

We will explain how to algorithmically find h_a in near-linear time later. Now, we will argue why having access to weak regularity decomposition greatly simplifies our task of approximating $\mathsf{val}(\mathfrak{I}, b)$ and also later while decoding q-ary codes.

We can simplify the above equation for $\mathsf{val}(\mathfrak{I}, b)$ even further using the assumed expansion (splittability) of W. A suitable version of the expander mixing lemma allows us to pass from the measure μ_k to the product measure $\mu_1^{\otimes k}$, where μ_1 is the uniform measure on $[n]$. More precisely, we can show that if W is sufficiently expanding (depending on δ), then

$$\begin{aligned}\mathsf{val}(\mathfrak{I}, b) = \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\left\langle h_a, (\chi_{b,a})^{\otimes k}\right\rangle_{\mu_k}\right] \pm \delta &= \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\left\langle h_a, (\chi_{b,a})^{\otimes k}\right\rangle_{\mu_1^{\otimes k}}\right] \pm 2\delta \\ &= \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\sum_{\ell=1}^{p_a} c_{a,\ell}\cdot\prod_{j=1}^{k}\left\langle\chi_{b^{(a,\ell,1)},a}, \chi_{b,a}\right\rangle_{\mu_1}\right] \pm 2\delta.\end{aligned}$$

The *low complexity* of the approximator h_a will allow us to simplify the search for an approximately optimal assignment $b \in \mathbb{Z}_q^n$. The expression above reveals that we only need to know the values of

[10] For scalars x, y (real or complex) and real $\delta \in \mathbb{R}^+$, we use the notation $x = y \pm \delta$ if $|x - y| \le \delta$.

$$\left\{ \left\langle \chi_{b^{(a,\ell,j)},a}, \chi_{b,a} \right\rangle_{\mu_1} \right\}_{a \in \mathbb{Z}_q, \ell \in [p_a], j \in [k]} .$$

Luckily, algorithmically, there will be only $O(qk^3/\delta^2)$ such numbers (no dependence on n and only slightly more than the $O(qk/\delta^2)$ from the existential result). Using brute-force search, it is possible to find sufficiently fine and (close to valid) approximations for these numbers.

To make the entire process efficient and near-linear time we still need to say how to find the functions h_a's in near-linear time. As in [24], we will reduce the problem of finding a weak regularity decomposition with respect to a class of k-tensors, in this case the class $\mathrm{CUT}^{\otimes k}_{\omega,q,a}$, to multiple applications of the 2-tensor case (in a sparse regime). To execute this process in near-linear, we will again use the expansion of W to conveniently move to easier to handle product measures (as above). This involves finding a constant factor approximation for the following expression

$$\max_{x,y \in \mathbb{Z}_q^n} \left| \sum_{i,j=1}^{n} \mathsf{A}_{i,j} \cdot \omega^{a \cdot x_i} \cdot \omega^{a \cdot y_j} \right| , \tag{2}$$

This kind of optimization is known as the *Grothendieck problem* and, in this case, it is for roots of unity going beyond the ±1 case of Alon and Naor [3]. In [29], So, Zhang and Ye considered a more restricted version of this problem (with positive semi-definite matrices) known as the *little* Grothendieck problem. We will extend their analysis to the Grothendieck problem building on some ingredients present in their proof. In our application, the matrices A will be sparse with $m \approx n$ non-zero entries and to achieve a near-linear time we will need to find an (additive) approximation to the Grothendieck problem in time $\widetilde{O}(m)$ of Equation (2). This can be done using the fast SDP solver of Arora and Kale [4].

We now explain how the above weak regularity decomposition can be used in decoding of the expander based construction of Ta-Shma's codes [31]. We will see that the decoding problem can be naturally phrased as a k-LIN instance over $\mathbb{Z}_q$, which is a natural q-ary extension of the k-XOR over $\mathbb{Z}_2$ from [1, 23, 24]. First, we briefly describe Ta-Shma's code construction over alphabet $\mathbb{F}_q$, with q prime, as analyzed[11] in [22]. The idea is to start with a good base code $\mathcal{C}_0 \subseteq \mathbb{F}_q^n$ and to use a carefully constructed collection of tuples $W \subseteq [n]^k$ to amplify its distance via the direct-sum encoding. For any $z \in \mathbb{F}_q^n$, recall that its direct-sum encoding is a new word denoted $y = \mathrm{dsum}_W(z)$ in $\mathbb{F}_q^W$ and defined as

$$y_{(i_1,\ldots,i_k)} \;=\; z_{i_1} + \cdots + z_{i_k} \pmod q \qquad\qquad \forall\ (i_1,\ldots,i_k) \in W\,.$$

The direct-sum code $\mathcal{C} = \mathrm{dsum}_W(\mathcal{C}_0)$ is defined as $\mathcal{C} = \{\mathrm{dsum}_W(z) \mid z \in \mathcal{C}_0\}$. Note the similarity of the above equation and the system of linear equations from Equation (1). In the decoding task, we are given a (possibly) corrupted version of $\widetilde{y}$ of some codeword $y = \mathrm{dsum}_W(z) \in \mathcal{C}$, with $z \in \mathcal{C}_0$. We can view $\widetilde{y}$ as defining the RHS coefficients of an instance of k-LIN, namely, $r_W = \widetilde{y}_w$.

Having an instance of k-LIN over $\mathbb{Z}_q$, we can now use weak regularity as described above. For each $a \in \mathbb{Z}_q$, let g_a be the *harmonic* component associated with RHS vector $\widetilde{y}$ (as above). Similarly, we find a weak regularity approximation h_a for each function g_a.

[11] In [22], they considered the more general (scalar) Abelian case.

If the distance $\Delta(\widetilde{y}, \mathrm{dsum}_W(z)) \le (1 - 1/q)(1 - \beta)$ is not too large, we will be able to deduce that some harmonic function h_a "captures" the structure of the codeword z in the following sense. Set $\mathcal{R} = \{\omega^{a \cdot a'} \mid a' \in \mathbb{Z}_q\}$ and let $f_1, \dots, f_r \colon [n] \to \mathcal{R}$ be the functions appearing in the decomposition of h_a. For each tuple $(y_1, \dots, y_r) \in \mathcal{R}^r$, we can consider the set

$$\{x \in [n] \mid f_1(x) = y_1, \dots, f_r(x) = y_r\}.$$

These sets partition[12] the space $[n]$, and we can show that z is approximately constant in most of these parts. In this sense, the low complexity structure of h_a captures the structure of the codeword z. In this last argument, we use that assumption that q is prime[13].

The case of k-LIN over a finite group will also allow for a weak regularity decomposition in a similar spirit as above, where scalar Fourier characters are replaced by larger dimensional representations and "global" approximation of Dirac delta functions are performed. Extending the weak regularity framework to this case will require considering matrix valued functions. The way we model this case is done in the full version and it uses very elementary properties of representation theory. This case again exhibits an interesting interplay between the type of constraints and the requirement on expansion. (The reader who is only interested in decoding can safely ignore this extension and focus on the $\mathbb{Z}_q$ case.)

3 Constraint Types and Alphabets

We explore the role of different types of constraints and corresponding alphabets going beyond the binary k-XOR considered in [24]. For the special case of linear equations over $\mathbb{Z}_q$ or over an arbitrary finite group $\mathfrak{G}$, we will explore the special structure of the constraints and obtain results with improved parameters.

3.1 General CSPs via the Binary Regularity

We will prove our first result for approximating a general expanding k-CSPs over a q-ary alphabet in near-linear time. We obtain this result using the *binary* near-linear time weak regularity decomposition from [24] in a similar way that Frieze and Kannan modeled k-CSPs [10] using regularity. We formalize this (relatively simple) connection since we believe this result may be of independent interest and may find applications elsewhere. Moreover, it also improves the running time of [2] to near-linear time, for fixed k and q, while offering a different approach to approximating general expanding k-CSPs which could be simpler than their Sum-of-Squares based algorithm. We now restate and proceed to prove this result.

▶ **Theorem 6.** *Let $\mathfrak{I}$ be an instance of MAX k-CSP on n variables with alphabet $[q]$ and constraints supported on a regular collection of tuples $W \subseteq [n]^k$. If W is τ-splittable with $\tau \le \tau_0(k, q, \delta) \coloneqq \mathrm{poly}(\delta/(kq^k))$, then we can compute an assignment satisfying $\mathsf{OPT} - \delta$ in time $r(kq/\delta) \cdot \widetilde{O}(|W| + n)$, where $r(x) = \exp(\exp(\exp(\mathrm{poly}(x))))$.*

We will find a weak regularity decomposition with respect to $0/1$ valued test functions $\mathcal{F} = \mathrm{CUT}^{\otimes k}$ where

$$\mathrm{CUT}^{\otimes k} \coloneqq \{\pm \mathbf{1}_{S_1} \otimes \cdots \otimes \mathbf{1}_{S_k} \mid S_1, \dots, S_k \subseteq [n]\}.$$

The near-linear weak regularity decomposition of [24], which we recall below, can handle this class of functions.

[12] Possibly with empty parts.

[13] So that all non-trivial roots of unity are primitive roots. It is plausible that this restriction is not necessary.

▶ **Theorem 9** (Efficient Weak Regularity from [24]). *Let $W \subseteq [n]^k$ be a τ-splittable collection of tuples. Suppose $\mathcal{F}$ is one of $\mathrm{CUT}^{\otimes k}$, $\mathrm{CUT}_{\pm}^{\otimes k}$. Let $\mathcal{R}$ be the domain of the functions in $\mathcal{F}$, when $k = 1$. Let $g \in \mathcal{R}^{W[1]^k}$ be supported on W with $\|g\|_{\mu_k} \leq 1$. For every $\delta > 0$, if $\tau \leq \delta^2/(k^3 \cdot 2^{20})$, then we can find $h = \sum_{\ell=1}^{p} c_\ell \cdot f_\ell$ with $p = O(k^2/\delta^2)$, $c_1, \dots, c_p \in \mathbb{R}$ and functions $f_1, \dots, f_p \in \mathcal{F}$, such that $\|h\|_{\mu_1^{\otimes k}} \leq 2$, $\sum_{\ell=1}^{p} |c_\ell| = O(k/\delta)$ and h is a good approximator to g in the following sense*

$$\max_{f \in \mathcal{F}} \quad \left| \left\langle g - \left(\frac{d}{n}\right)^{k-1} h, f \right\rangle \right| \;\leq\; \delta \cdot |W| \,,$$

where the inner product is over the counting measure on $W[1]^k$. Furthermore, h can be found in $\widetilde{O}(2^{2^{\widetilde{O}(k^2/\delta^2)}} \cdot |W|)$ time.

Having access to a weak regularity decomposition as above makes the task of approximating the value of a CSP instance relatively simple, as we now describe. This is a common feature of weak regularity based arguments,e.g., [10, 28]. Here, we consider both arbitrary arity k and arbitrary alphabet size q.

We will first need some notation. Let $\alpha \in [q]^k$ and define $W_\alpha = \{w \in W \;\mid\; P_w(\alpha) = 1\}$ to be the set of tuples whose predicates P_w are satisfied by on the input α. Let $\mathcal{A}(\mathfrak{I}) = \{\alpha \in [q]^k \;\mid\; W_\alpha \neq \emptyset\}$ be the set of satisfying inputs of at least one predicate of $\mathfrak{I}$.

We will use the following claim which relates the value of an assignment to the structure of the weak regularity decomposition.

▷ Claim 10. Suppose that for every $\alpha \in [q]^k$, we have a weak regularity decomposition h_α, from Theorem 9, of the indicator $\mathbf{1}_{W(\alpha)}$ with error parameter $\delta > 0$ and with respect to the test class $\mathrm{CUT}^{\otimes k}$. Let $b \in [q]^n$ (viewed as an assignment), which induces a partition $T_1 \sqcup \cdots \sqcup T_q$ of $[n]$. Then,

$$\mathsf{val}(\mathfrak{I}, b) \;=\; \sum_{\alpha \in \mathcal{A}} \sum_{\ell=1}^{p_\alpha} c_{\alpha,\ell} \frac{\left|S_1^{\alpha,\ell} \cap T_{\alpha_1}\right|}{n} \cdots \frac{\left|S_k^{\alpha,\ell} \cap T_{\alpha_k}\right|}{n} \;\;\pm\;\; \delta \cdot |\mathcal{A}(\mathfrak{I})| \;.$$

Proof. Let $\mathcal{A} = \mathcal{A}(\mathfrak{I})$. The value of this assignment is

$$\begin{aligned}
\mathsf{val}(\mathfrak{I}, b) \;&=\; \sum_{\alpha \in \mathcal{A}} \left\langle \mathbf{1}_{W_\alpha}, \mathbf{1}_{T_{\alpha_1}} \otimes \cdots \otimes \mathbf{1}_{T_{\alpha_k}} \right\rangle_{\mu_k} \\
&=\; \frac{1}{|W|} \sum_{\alpha \in \mathcal{A}} \left\langle \left(\frac{d}{n}\right)^{k-1} h_\alpha, \mathbf{1}_{T_{\alpha_1}} \otimes \cdots \otimes \mathbf{1}_{T_{\alpha_k}} \right\rangle \;\pm\; \delta \cdot |\mathcal{A}| \\
&=\; \frac{1}{|W|} \sum_{\alpha \in \mathcal{A}} \left\langle \left(\frac{d}{n}\right)^{k-1} \sum_{\ell=1}^{p_\alpha} c_{\alpha,\ell} \cdot \mathbf{1}_{S_1^{\alpha,\ell}} \otimes \cdots \otimes \mathbf{1}_{S_k^{\alpha,\ell}}, \mathbf{1}_{T_{\alpha_1}} \otimes \cdots \otimes \mathbf{1}_{T_{\alpha_k}} \right\rangle \;\pm\; \delta \cdot |\mathcal{A}| \\
&=\; \frac{1}{n^k} \sum_{\alpha \in \mathcal{A}} \sum_{\ell=1}^{p_\alpha} c_{\alpha,\ell} \cdot \left\langle \mathbf{1}_{S_1^{\alpha,\ell}} \otimes \cdots \otimes \mathbf{1}_{S_k^{\alpha,\ell}}, \mathbf{1}_{T_{\alpha_1}} \otimes \cdots \otimes \mathbf{1}_{T_{\alpha_k}} \right\rangle \;\pm\; \delta \cdot |\mathcal{A}| \\
&=\; \sum_{\alpha \in \mathcal{A}} \sum_{\ell=1}^{p_\alpha} c_{\alpha,\ell} \cdot \left\langle \mathbf{1}_{S_1^{\alpha,\ell}}, \mathbf{1}_{T_{\alpha_1}} \right\rangle_{\mu_1} \cdots \left\langle \mathbf{1}_{S_k^{\alpha,\ell}}, \mathbf{1}_{T_{\alpha_k}} \right\rangle_{\mu_1} \;\pm\; \delta \cdot |\mathcal{A}| \\
&=\; \sum_{\alpha \in \mathcal{A}} \sum_{\ell=1}^{p_\alpha} c_{\alpha,\ell} \frac{\left|S_1^{\alpha,\ell} \cap T_{\alpha_1}\right|}{n} \cdots \frac{\left|S_k^{\alpha,\ell} \cap T_{\alpha_k}\right|}{n} \;\pm\; \delta \cdot |\mathcal{A}| \,,
\end{aligned}$$

concluding the proof. ◁

Proof of Theorem 6. Let $\mathfrak{I}$ be an instance of a k-CSP over alphabet $[q]$ supported on a collection of tuples $W \subseteq [n]^k$ and with predicates $(P_w \colon [q]^k \to \{0,1\})_{w \in W}$.

For each $\alpha \in \mathcal{A}(\mathfrak{I})$, we apply the weak regularity decomposition of Theorem 9 to the function $\mathbf{1}_{W_\alpha}$ with error parameter $\delta > 0$ and test class $\mathcal{F} = \mathrm{CUT}^{\otimes k}$. This gives an approximation $h_\alpha = \sum_{\ell=1}^{p_\alpha} c_{\alpha,\ell} \cdot \mathbf{1}_{S_1^{\alpha,\ell}} \otimes \cdots \otimes \mathbf{1}_{S_k^{\alpha,\ell}}$.

A crucial property is that instead of having to know an assignment $b \in [q]^n$, represented as a partition $T_1 \sqcup \cdots \sqcup T_q = [n]$, it is enough to know the values of the following inner products

$$\left\{ \left\langle \mathbf{1}_{S_j^{\alpha,\ell}}, \mathbf{1}_{T_{\alpha_j}} \right\rangle_{\mu_1} \right\}_{\alpha \in \mathcal{A}(\mathfrak{I}), \ell \in [p_\alpha], j \in [k]}$$

The decomposition is *low complexity*, in the sense that there are only a few of these values. However, we cannot take arbitrary values for these inner products since they may be far from *realizable*, i.e., no true assignment $b \in [q]^n$ can give rise to these values even approximately. From the inner products above, we can extract the following class of functions

$$\mathcal{F}' = \left\{ \mathbf{1}_{S_j^{\alpha,\ell}} \right\}_{\alpha \in \mathcal{A}(\mathfrak{I}), \ell \in [p_\alpha], j \in [k]},$$

whose size $r = |\mathcal{F}'| = O(|\mathcal{A}(\mathfrak{I})|\, k^3/\delta^2)$ is independent from n.

Using Claim 10, to be able to approximate $\mathsf{val}(\mathfrak{I}, b)$ within error $\delta' > 0$ we need to choose the error of the weak regularity decomposition[14] to be $\delta = \delta'/(2\,|\mathcal{A}(\mathfrak{I})|)$ In this case, we have $r = O(|\mathcal{A}(\mathfrak{I})|^2\, k^3/(\delta')^2) = O(q^{2k} k^3/(\delta')^2)$ and the τ-splittability parameter of W needs to satisfy $\tau \leq \mathrm{poly}(\delta'/(kq^k))$.

For convenience, label the functions of $\mathcal{F}'$ as $f_1, \dots, f_r$. Their range is the (simple) binary set $\mathcal{R} = \{0,1\}$. We will consider the factor $\mathcal{B}$ defined by the collection $\mathcal{F}'$, which, roughly speaking, is a partition of $[n]$ according to the values of these functions. More precisely, for every tuple $(y_1, \dots, y_r) \in \mathcal{R}^r$ we have a (possibly empty) part (or atom) of the form

$$\{x \in [n] \;\mid\; f_1(x) = y_1, \dots, f_r(x) = y_r\}.$$

In this case, we have at most $\mathcal{R}^r = 2^r$ atoms in the factor. By definition the functions $\mathcal{F}'$ are constant in each of them. An assignment b gives rise to a distribution on $[q]$ in each atom of the factor. Conversely, any approximate distribution on $[q]$ in each atom approximately corresponds to a realizable assignment b.

Let $L = \sum_{\alpha \in \mathcal{A}(\mathfrak{I}), \ell \in [p_\alpha]} |c_{\alpha,\ell}| \leq |\mathcal{A}(\mathfrak{I})|\, O(k/\delta)$. Set $\eta = \delta/(k \cdot L \cdot q)$. We can η-approximate these distributions in ℓ_1-norm on each atom[15]. The number of approximate distributions can be (crudely) bounded as

$$(1/(\eta q))^{\mathcal{R}^r} \leq \exp(\exp(\exp(\mathrm{poly}(qk/\delta')))).$$

With this fine enough discretization of the distributions on each atom, when computing the expression

$$\mathsf{val}(\mathfrak{I}, b) = \sum_{\alpha \in \mathcal{A}} \sum_{\ell=1}^{p_\alpha} c_{\alpha,\ell} \frac{\left|S_1^{\alpha,\ell} \cap T_{\alpha_1}\right|}{n} \cdots \frac{\left|S_k^{\alpha,\ell} \cap T_{\alpha_k}\right|}{n} \;\pm\; \delta \cdot |\mathcal{A}|$$

we incur an additional error of $\delta'/2$. By our choice of δ, the total approximation error is at most δ'. ◀

[14] We can assume without loss of generality that $\mathcal{A}(\mathfrak{I}) \neq \emptyset$ since otherwise the value of the CSP is always zero.

[15] If the atom is too smaller than $1/(\eta q)$, then we can consider all the possible exact distribution.

3.2 Stating the Extended Weak Regularity Framework

We now show how to obtain our main results for linear equations k-LIN over $\mathbb{Z}_q$ in Theorem 3 and over a finite group $\mathfrak{G}$ in Theorem 4.

In the full version, we see that to approximate k-LIN over $\mathbb{Z}_q$ it suffices to find a good weak regularity decomposition with respect to the test functions $\mathcal{F} = \mathrm{CUT}^{\otimes k}_{\omega,q,a}$ defined as follows

$$\mathrm{CUT}^{\otimes k}_{\omega,q,a} \coloneqq \{\chi_{b_1,a} \otimes \cdots \otimes \chi_{b_k,a} \mid b_1, \ldots, b_k \subseteq \mathbb{Z}_q^n\}.$$

In the full version, we will see that to approximate k-LIN over a finite group, it suffices to find a good weak regularity decomposition with respect to the *matrix* valued test functions $\mathcal{F}$ defined as follows

$$\mathrm{CUT}^{\otimes k}_{\rho} \coloneqq \{\rho_{b_1} \otimes \cdots \otimes \rho_{b_k} \mid b_1, \ldots, b_k \in \mathfrak{G}^n\}.$$

It will be more convenient to enlarge the test class $\mathcal{F}$ to unitary valued functions as follows

$$\mathrm{CUT}^{\otimes k}_{\mathbb{U}_{s,k,\delta}} \coloneqq \{f_1 \otimes \cdots \otimes f_k \mid f_1, \ldots, f_k \colon [n] \to \mathbb{U}_{s,k,\delta}\},$$

where $\mathbb{U}_{s,k,\delta}$ will be a fine enough discretization of the matrices[16] $M_s(\mathbb{C})$ of operator norm at most 1.

We will extend the framework to additionally handle the classes of functions $\mathrm{CUT}^{\otimes k}_{\omega,q,a}$ and $\mathrm{CUT}^{\otimes k}_{\mathbb{U}_{s,k,\delta}}$. This is proven in the full version. Let $\mathbb{K}$ be the underlying field which is either $\mathbb{R}$ or $\mathbb{C}$. Our extended framework gives the following efficient algorithmic result.

▶ **Theorem 11** (Efficient Weak Regularity (Extension of [24])). *Let $W \subseteq [n]^k$ be a τ-splittable collection of tuples. Suppose $\mathcal{F}$ is one of $\mathrm{CUT}^{\otimes k}$, $\mathrm{CUT}^{\otimes k}_{\pm}$, $\mathrm{CUT}^{\otimes k}_{\omega,q,a}$, for $q \geq 3$, or $\mathrm{CUT}^{\otimes k}_{\mathbb{U}_{s,k,\delta}}$. Let $\mathcal{R}$ be the domain of the functions in $\mathcal{F}$, when $k = 1$. Let $g \in \mathcal{R}^{W[1]^k}$ be supported on W with $\|g\|_{\mu_k} \leq 1$. For every $\delta > 0$, if $\tau \leq \delta^2/(k^3 \cdot 2^{20})$, then we can find $h = \sum_{\ell=1}^{p} c_\ell \cdot f_\ell$ with $p = O(k^2/\delta^2)$, scalars $c_1, \ldots, c_p \in \mathbb{K}$ and functions $f_1, \ldots, f_p \in \mathcal{F}$, such that $\|h\|_{\mu_1^{\otimes k}} \leq 2$, $\sum_{\ell=1}^{p} |c_\ell| = O(k/\delta)$ and h is a good approximator to g in the following sense*

$$\max_{f \in \mathcal{F}} \quad \left| \left\langle g - \left(\frac{d}{n}\right)^{k-1} h, f \right\rangle \right| \;\leq\; \delta \cdot |W|,$$

where the inner product is over the counting measure on $W[1]^k$. Furthermore, h can be found in $\widetilde{O}(2^{|\mathcal{R}|^{\widetilde{O}(k^2/\delta^2)}} \cdot |W|)$ time in the scalar valued case and in time $\widetilde{O}_{s,k,\delta}(\mathrm{poly}(|W|))$, otherwise.

3.3 Improved Case: k-LIN over $\mathbb{Z}_q$

The goal of this section is to prove Theorem 3 (restated below) assuming the new extended efficient regularity algorithm from Theorem 11.

▶ **Theorem 3** (Main II). *Let $\mathfrak{I}$ be an instance of MAX k-LIN$_q$ on n variables with alphabet $\mathbb{Z}_q$ and constraints supported on a regular*[17] *collection of tuples $W \subseteq [n]^k$. If W is τ-splittable with $\tau \leq \tau_0(k, \delta) \coloneqq \mathrm{poly}(\delta/k)$, then we can compute an assignment satisfying $\mathsf{OPT} - \delta$ in time $r(q/\tau_0) \cdot \widetilde{O}(|W| + n)$, where $r(x) = \exp(\exp(\mathrm{poly}(x)))$.*

[16] We use $M_s(\mathbb{C})$ for the set of $s \times s$ matrices over $\mathbb{C}$.

[17] This is an analog to tuples of a graph being d-vertex regular.

For k-LIN over alphabet $\mathbb{Z}_q$, we are given a collection of equations (each variable appearing with coefficient one) specified as collection of tuples $W \subseteq [n]^k$ and we are given a collection of corresponding RHS $(r_w)_{w\in W} \in \mathbb{Z}_q^W$. The system of linear equations can be written as follows

$$x_{i_1} + \cdots + x_{i_k} \;=\; r_w \pmod q \qquad\qquad \forall\ w = (i_1, \dots, i_k) \in W.$$

Orthogonality of Fourier characters will be crucially used here.

▶ **Fact 12** (Character Orthogonality). *Let ω be a non-trivial q-th root of unit. Then,*

$$\mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}[\omega^a] = 0\,.$$

Orthogonality allows for a convenient way of implementing the Dirac delta function on (the alphabet) $\mathbb{Z}_q$.

▶ **Fact 13.** *Fix $y \in \mathbb{Z}_q$. The indicator function $x \mapsto \mathbf{1}_{[x=y]}$ on $\mathbb{Z}_q$ can be expressed as*

$$\mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\omega^{a(x-y)}\right].$$

We now make precise the argument sketched in the proof strategy of Section 2.

Proof of Theorem 3. Let $\mathfrak{I}$ be an instance of k-LIN over $\mathbb{Z}_q$ with constraints supported on $W \subseteq [n]^k$ and RHS values $\{r_w\}_{w\in W}$. For every $a \in \mathbb{Z}_q$, we define $g_a \colon W \to \mathbb{C}$ as the map $w \in W \mapsto \omega^{a\cdot r_w}$, where $\omega = \exp(2\pi\sqrt{-1}/q)$.

Apply the efficient weak regularity decomposition of Theorem 11 to each g_a using error parameter $\delta > 0$ and test functions $\mathcal{F} = \mathrm{CUT}^{\otimes k}_{\omega,q,a}$. Note that this requires the splittability (expansion) parameter τ of W to satisfy $\tau \le O(\delta^2/k^3)$. We obtain a function $h_a = \sum_{\ell=1}^{p_a} c_{a,\ell}\cdot \chi_{b^{(a,\ell,1)},a} \otimes \cdots \otimes \chi_{b^{(a,\ell,k)},a}$, where $b^{(a,\ell,1)},\dots,b^{(a,\ell,k)} \in \mathbb{Z}_q^n$, for every $a \in \mathbb{Z}_q$ and every $\ell \in [p_a]$. Let $b \in \mathbb{Z}_q^n$ be an assignment to the variables of the system of linear equations. The value of this CSP on input b can be computed as

$$\begin{aligned}
\mathsf{val}(\mathfrak{I}, b) = \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\langle g_a, \chi_{b,a}\otimes\cdots\otimes\chi_{b,a}\rangle_{\mu_k}\right] &= \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\mathop{\mathbb{E}}_{w=(i_1,\dots,i_k)\sim\mu_k}\left[\omega^{-a\cdot r_w}\omega^{a(b_{i_1}+\cdots+b_{i_k})}\right]\right]\\
&= \mathop{\mathbb{E}}_{w=(i_1,\dots,i_k)\sim\mu_k}\left[\mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\omega^{a(b_{i_1}+\cdots+b_{i_k}-r_w)}\right]\right]\\
&= \mathop{\mathbb{E}}_{w=(i_1,\dots,i_k)\sim\mu_k}\left[\mathbf{1}_{[b_{i_1}+\cdots+b_{i_k}=r_w]}\right].
\end{aligned}$$

Using the weak regularity decomposition h_a of each g_a, we obtain

$$\begin{aligned}
\mathsf{val}(\mathfrak{I}, b) &= \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\langle g_a, \chi_{b,a}\otimes\cdots\otimes\chi_{b,a}\rangle_{\mu_k}\right]\\
&= \frac{1}{|W|}\mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\left\langle\left(\frac{d}{n}\right)^{k-1} h_a, \chi_{b,a}\otimes\cdots\otimes\chi_{b,a}\right\rangle\right] \pm \delta\\
&= \frac{1}{n^k}\mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\sum_{\ell=1}^{p_a} c_{a,\ell}\cdot\left\langle \chi_{b^{(a,\ell,1)},a}\otimes\cdots\otimes\chi_{b^{(a,\ell,k)},a}, \chi_{b,a}\otimes\cdots\otimes\chi_{b,a}\right\rangle\right] \pm \delta\\
&= \mathop{\mathbb{E}}_{a\in\mathbb{Z}_q}\left[\sum_{\ell=1}^{p_a} c_{a,\ell}\cdot\left\langle \chi_{b^{(a,\ell,1)},a}, \chi_{b,a}\right\rangle_{\mu_1}\cdots\left\langle \chi_{b^{(a,\ell,k)},a}, \chi_{b,a}\right\rangle_{\mu_1}\right] \pm \delta\,,
\end{aligned}$$

concluding the proof.

Now it suffices to approximate the following values

$$\left\{ \left\langle \chi_{b^{(a,\ell,j)},a}, \chi_{b,a} \right\rangle_{\mu_1} \right\}_{a \in \mathbb{Z}_q, \ell \in [p_a], j \in [k]} ,$$

so that there is always a true assignment $b \in [q]^n$ which gives these values.

To this end, we first define the following collection $\mathcal{F}'$ of functions

$$\mathcal{F}' = \left\{ \chi_{b^{(a,\ell,j)},a} \right\}_{a \in \mathbb{Z}_q, \ell \in [p_a], j \in [k]} .$$

Note that $r = |\mathcal{F}'| = O(qk^3/\delta^2)$. The functions above have range $\mathcal{R} = \{\omega^{a'} \mid a' \in \mathbb{Z}_q\}$. They form a factor $\mathcal{B}$ with at most $|\mathcal{R}|^r$ atoms. By the definition of a factor, the functions $\mathcal{F}'$ are constant in each one of them, so to compute $\left\langle \chi_{b^{(a,\ell,j)},a}, \chi_{b,a} \right\rangle_{\mu_1}$ it suffices to know the distribution of symbols of b in each atom.

Let $L = \sum_{a \in \mathbb{Z}_q, \ell \in [p_a]} |c_{a,\ell}| = O(qk/\delta)$ and set $\eta = \delta/(k \cdot L \cdot q)$. The total number of η-approximate distributions in ℓ_1-norm on each atom can be (crudely) bounded as

$$(1/\eta q)^{|\mathcal{R}|^r} \leq \exp(\exp(\mathrm{poly}(qk/\delta))).$$

Using these distributions, we can approximate

$$\mathsf{val}(\mathfrak{I}, b) \;=\; \mathop{\mathbb{E}}_{a \in \mathbb{Z}_q} \left[\sum_{\ell=1}^{p_a} c_{a,\ell} \cdot \left\langle \chi_{b^{(a,\ell,1)},a}, \chi_{b,a} \right\rangle_{\mu_1} \cdots \left\langle \chi_{b^{(a,\ell,k)},a}, \chi_{b,a} \right\rangle_{\mu_1} \right] \;\pm\; \delta ,$$

incurring an additional error of δ. ◀

Directed Poincaré Inequalities and L^1 Monotonicity Testing of Lipschitz Functions

Renato Ferreira Pinto Jr.
University of Waterloo, Canada

Abstract

We study the connection between directed isoperimetric inequalities and monotonicity testing. In recent years, this connection has unlocked breakthroughs for testing monotonicity of functions defined on discrete domains. Inspired the rich history of isoperimetric inequalities in continuous settings, we propose that studying the relationship between directed isoperimetry and monotonicity in such settings is essential for understanding the full scope of this connection.

Hence, we ask whether directed isoperimetric inequalities hold for functions $f : [0,1]^n \to \mathbb{R}$, and whether this question has implications for monotonicity testing. We answer both questions affirmatively. For Lipschitz functions $f : [0,1]^n \to \mathbb{R}$, we show the inequality $d_1^{\mathsf{mono}}(f) \lesssim \mathbb{E}\left[\|\nabla^- f\|_1\right]$, which upper bounds the L^1 distance to monotonicity of f by a measure of its "directed gradient". A key ingredient in our proof is the *monotone rearrangement* of f, which generalizes the classical "sorting operator" to continuous settings. We use this inequality to give an L^1 monotonicity tester for Lipschitz functions $f : [0,1]^n \to \mathbb{R}$, and this framework also implies similar results for testing real-valued functions on the hypergrid.

1 Introduction

In property testing, algorithms must make a decision about whether a function $f : \Omega \to R$ has some property $\mathcal{P}$, or is *far* (under some distance metric) from having that property, using a small number of queries to f. One of the most well-studied problems in property testing is *monotonicity testing*, the hallmark case being that of testing monotonicity of Boolean functions on the Boolean cube, $f : \{0,1\}^n \to \{0,1\}$. We call f monotone if $f(x) \le f(y)$ whenever $x \preceq y$, i.e. $x_i \le y_i$ for every $i \in [n]$.

A striking trend emerging from this topic of research has been the connection between monotonicity testing and *isoperimetric inequalities*, in particular directed analogues of classical results such as Poincaré and Talagrand inequalities. We preview that the focus of this work is to further explore this connection by establishing directed isoperimetric inequalities for functions $f : [0,1]^n \to \mathbb{R}$ with continuous domain and range, and as an application obtain monotonicity testers in such settings. Before explaining our results, let us briefly summarize the connection between monotonicity testing and directed isoperimetry.

For a function $f : \{0,1\}^n \to \mathbb{R}$, let $d_1^{\mathsf{const}}(f)$ denote its L^1 distance to any constant function $g : \{0,1\}^n \to \mathbb{R}$, and for any point x, define its discrete gradient $\nabla f(x) \in \mathbb{R}^n$ by $(\nabla f(x))_i := f(x^{i\to 1}) - f(x^{i\to 0})$ for each $i \in [n]$, where $x^{i\to b}$ denotes the point x with its i-th coordinate set to b. Then the following inequality[1] is usually called the Poincaré inequality on the Boolean cube (see e.g. [31]): for every $f : \{0,1\}^n \to \{0,1\}$,

$$d_1^{\mathsf{const}}(f) \lesssim \mathbb{E}\left[\|\nabla f\|_1\right] . \tag{1}$$

(Here and going forward, we write $f \lesssim g$ to denote that $f \le cg$ for some universal constant c, and similarly for $f \gtrsim g$. We write $f \approx g$ to denote that $f \lesssim g$ and $g \lesssim f$.)

Now, let $d_1^{\mathsf{mono}}(f)$ denote the L^1 distance from f to any monotone function $g : \{0,1\}^n \to \mathbb{R}$, and for each point x let $\nabla^- f(x)$, which we call the *directed gradient* of f, be given by $\nabla^- f(x) := \min\{\nabla f(x), 0\}$. Then [17] were the first to notice that the main ingredient of the work of [27], who gave a monotonicity tester for Boolean functions on the Boolean cube with query complexity $O(n/\epsilon)$, was the following "directed analogue" of (1)[2]: for every $f : \{0,1\}^n \to \{0,1\}$,

$$d_1^{\mathsf{mono}}(f) \lesssim \mathbb{E}\left[\|\nabla^- f\|_1\right] . \tag{2}$$

The tester of [27] is the "edge tester", which samples edges of the Boolean cube uniformly at random and rejects if any sampled edge violates monotonicity. Inequality (2) shows that, if f is far from monotone, then many edges are violating, so the tester stands good chance of finding one.

In their breakthrough work, [17] gave the first monotonicity tester with $o(n)$ query complexity by showing a directed analogue of Margulis's inequality. This was improved by [20], and eventually the seminal paper of [30] resolved the problem of (nonadaptive) monotonicity testing of Boolean functions on the Boolean cube, up to polylogarithmic factors, by giving a tester with query complexity $\widetilde{O}(\sqrt{n}/\epsilon^2)$. The key ingredient was to show a directed analogue of *Talagrand's inequality.* Talagrand's inequality gives that, for every $f : \{0,1\}^n \to \{0,1\}$,

$$d_1^{\mathsf{const}}(f) \lesssim \mathbb{E}\left[\|\nabla f\|_2\right] .$$

Compared to (1), this replaces the ℓ^1-norm of the gradient with its ℓ^2-norm. [30] showed the natural directed analogue[3] up to polylogarithmic factors, which were later removed by [32]: for every $f : \{0,1\}^n \to \{0,1\}$,

$$d_1^{\mathsf{mono}}(f) \lesssim \mathbb{E}\left[\|\nabla^- f\|_2\right] .$$

Since then, directed isoperimetric inequalities have also unlocked results in monotonicity testing of Boolean functions on the hypergrid [7, 5, 16, 6] (see also [8, 28]) and real-valued functions on the Boolean cube [9].

Our discussion so far has focused on isoperimetric (*Poincaré-type*) inequalities on *discrete* domains. On the other hand, a rich history in geometry and functional analysis, originated in continuous settings, has established an array of isoperimetric inequalities for functions

[1] The left-hand side is usually written $\mathrm{Var}[f]$ instead; for Boolean functions, the two quantities are equivalent up to a constant factor, and writing $d_1^{\mathsf{const}}(f)$ is more consistent with the rest of our presentation.

[2] Typically the left-hand side would be the distance to a *Boolean* monotone function, rather than any real-valued monotone function, but the two quantities are equal; this may be seen via a maximum matching of violating pairs of f, see [26].

[3] In fact, they require a *robust* version of this inequality, but we omit that discussion for simplicity.

defined on continuous domains, as well as an impressive range of connections to topics such as partial differential equations [33], Markov diffusion processes [1], probability theory and concentration of measure [12], optimal transport [15], polynomial approximation [35], among others.

As a motivating starting point, we note that for suitably smooth (Lipschitz) functions $f : [0,1]^n \to \mathbb{R}$, an L^1 Poincaré-type inequality holds [13]:

$$d_1^{\mathsf{const}}(f) \lesssim \mathbb{E}\left[\|\nabla f\|_2\right] . \tag{3}$$

Thus, understanding the full scope of the connection between classical isoperimetric inequalities, their directed counterparts, and monotonicity seems to suggest the study of the continuous setting. In this work, we ask: do *directed* Poincaré-type inequalities hold for functions f with continuous domain and range? And if so, do such inequalities have any implications for monotonicity testing? We answer both questions affirmatively: Lipschitz functions $f : [0,1]^n \to \mathbb{R}$ admit a directed L^1 Poincaré-type inequality (Theorem 1.2), and this inequality implies an upper bound on the query complexity of testing monotonicity of such functions with respect to the L^1 distance (Theorem 1.4). (We view L^1 as the natural distance metric for the continuous setting; see Section 1.3 for a discussion.) This framework also yields results for L^1 testing monotonicity of real-valued functions on the hypergrid $f : [m]^n \to \mathbb{R}$. Our testers are *partial derivative testers*, which naturally generalize the classical *edge testers* [27, 18] to continuous domains.

We now introduce our model, and then summarize our results.

1.1 L^p-testing

Let (Ω, Σ, μ) be a probability space (typically for us, the unit cube or hypergrid with associated uniform probability distribution). Let $R \subseteq \mathbb{R}$ be a range, and $\mathcal{P}$ a property of functions $g : \Omega \to R$. Given a function $f : \Omega \to \mathbb{R}$, we denote the L^p distance of f to property $\mathcal{P}$ by $d_p(f, \mathcal{P}) := \inf_{g \in \mathcal{P}} d_p(f, g)$, where $d_p(f, g) := \mathop{\mathbb{E}}_{x \sim \mu}\left[|f(x) - g(x)|^p\right]^{1/p}$. For fixed domain Ω, we write $d_p^{\mathsf{const}}(f)$ for the L^p distance of f to the property of constant functions, and $d_p^{\mathsf{mono}}(f)$ for the L^p distance of f to the property of monotone functions. (See Definition 2.2 for a formal definition contemplating e.g. the required measurability and integrability assumptions.)

▶ **Definition 1.1** (L^p-testers). *Let $p \geq 1$. For probability space (Ω, Σ, μ), range $R \subseteq \mathbb{R}$, property $\mathcal{P} \subseteq L^p(\Omega, \mu)$ of functions $g : \Omega \to R$, and proximity parameter $\epsilon > 0$, we say that randomized algorithm A is an L^p*-tester for $\mathcal{P}$ *with query complexity q if, given* oracle access *to an unknown input function $f : \Omega \to R \in L^p(\Omega, \mu)$, A makes at most q oracle queries and 1) accepts with probability at least $2/3$ if $f \in \mathcal{P}$; 2) rejects with probability at least $2/3$ if $d_p(f, \mathcal{P}) > \epsilon$.*

We say that A has *one-sided error* if it accepts functions $f \in \mathcal{P}$ with probability 1, otherwise we say it has *two-sided error*. It is *nonadaptive* if it decides all of its queries in advance (i.e. before seeing output from the oracle), and otherwise it is *adaptive*. We consider two types of oracle:

Value oracle: Given point $x \in \Omega$, this oracle outputs the value $f(x)$.

Directional derivative oracle: Given point $x \in \Omega$ and vector $v \in \mathbb{R}^n$, this oracle outputs the derivative of f along v at point x, given by $\frac{\partial f}{\partial v}(x) = v \cdot \nabla f(x)$, as long as f is differentiable at x. Otherwise, it outputs a special symbol $\perp$.

A directional derivative oracle is weaker than a full first-order oracle, which would return the entire gradient [14], and it seems to us like a reasonable model for the high-dimensional setting; for example, obtaining the full gradient costs n queries, rather than a single query. This type of oracle has also been studied in optimization research, e.g. see [21]. For our applications, only the *sign* of the result will matter, in which case we remark that, for sufficiently smooth functions (say, functions with bounded second derivatives) each directional derivative query may be simulated using two value queries on sufficiently close together points.

Our definition (with value oracle) coincides with that of [4] when the range is $R = [0, 1]$. On the other hand, for general R, we keep the distance metric unmodified, whereas [4] normalize it by the magnitude of R. Intuitively, we seek testers that are efficient even when f may take large values as the dimension n grows; see Section 1.3.3 for more details.

1.2 Results and main ideas

1.2.1 Directed Poincaré-type inequalities

Our first result is a directed Poincaré inequality for Lipschitz functions $f : [0, 1]^n \to \mathbb{R}$, which may be seen as the continuous analogue of inequality (2) of [27].

▶ **Theorem 1.2.** *Let $f : [0, 1]^n \to \mathbb{R}$ be a Lipschitz function with monotone rearrangement f^*. Then*

$$d_1^{\mathsf{mono}}(f) \approx \mathbb{E}\left[|f - f^*|\right] \lesssim \mathbb{E}\left[\|\nabla^- f\|_1\right] . \tag{4}$$

As hinted in the statement, a crucial tool for this result is the *monotone rearrangement* f^* of f. We construct f^* by a sequence of axis-aligned rearrangements $R_1, \dots, R_n$; each R_i is the *non-symmetric monotone rearrangement* operator along dimension i, which naturally generalizes the *sorting* operator of [27] to the continuous case. For each coordinate $i \in [n]$, the operator R_i takes f into an equimeasurable function $R_i f$ that is monotone in the i-th coordinate, at a "cost" $\mathbb{E}\left[|f - R_i f|\right]$ that is upper bounded by $\mathbb{E}\left[|\partial_i^- f|\right]$, where $\partial_i^- f := (\nabla^- f)_i$ is the directed partial derivative along the i-th coordinate. We show that each application R_i can only decrease the "cost" associated with further applications R_j, so that the total cost of obtaining f^* (i.e. the LHS of (4)) may be upper bounded, via the triangle inequality, by the sum of all directed partial derivatives, i.e. the RHS of (4).

A technically simpler version of this argument also yields a directed Poincaré inequality for real-valued functions on the hypergrid. We also note that Theorems 1.2 and 1.3 are both tight up to constant factors.

▶ **Theorem 1.3.** *Let $f : [m]^n \to \mathbb{R}$ and let f^* be its monotone rearrangement. Then*

$$d_1^{\mathsf{mono}}(f) \approx \mathbb{E}\left[|f - f^*|\right] \lesssim m\mathbb{E}\left[\|\nabla^- f\|_1\right] .$$

Table 1 places our results in the context of existing classical and directed inequalities. In that table and going forward, for any $p, q \geq 1$ we call the inequalities

$$d_p^{\mathsf{const}}(f)^p \lesssim \mathbb{E}\left[\|\nabla f\|_q^p\right] \qquad \text{and} \qquad d_p^{\mathsf{mono}}(f)^p \lesssim \mathbb{E}\left[\|\nabla^- f\|_q^p\right]$$

a *classical* and *directed* (L^p, ℓ^q)*-Poincaré inequality*, respectively. Note that the L^p notation refers to the space in which we take norms, while ℓ^q refers to the geometry in which we measure gradients. In this paper, we focus on the L^1 inequalities.

Table 1 Classical and directed Poincaré-type inequalities on discrete and continuous domains. Cells marked with * indicate inequalities that follow from another entry in the table.

Setting Inequality		Discrete		Continuous
		$\{0,1\}^n \to \{0,1\}$	$\{0,1\}^n \to \mathbb{R}$	$[0,1]^n \to \mathbb{R}$
(L^1, ℓ^1)-Poincaré	$d_1^{\mathsf{const}}(f) \lesssim \mathbb{E}\left[\|\nabla f\|_1\right]$	* [34]	* [34]	* [13]
	$d_1^{\mathsf{mono}}(f) \lesssim \mathbb{E}\left[\|\nabla^- f\|_1\right]$	[27]	Theorem 1.3	Theorem 1.2
(L^1, ℓ^2)-Poincaré	$d_1^{\mathsf{const}}(f) \lesssim \mathbb{E}\left[\|\nabla f\|_2\right]$	* [34]	[34]	[13]
	$d_1^{\mathsf{mono}}(f) \lesssim \mathbb{E}\left[\|\nabla^- f\|_2\right]$	[30]	?	Conjecture 1.8

We also note that we have ignored in our discussion the issues of *robust* inequalities, which seem essential for some of the testing applications (see [30]), and the distinction between *inner* and *outer boundary*, whereby some inequalities on Boolean f may be made stronger by setting $\nabla f(x) = 0$ when $f(x) = 0$ (see e.g. [34]). We refer the reader to the original works for the strongest version of each inequality and a detailed treatment of these issues.

1.2.2 Testing monotonicity on the unit cube and hypergrid

Equipped with the results above, we give a monotonicity tester for Lipschitz functions $f : [0,1]^n \to \mathbb{R}$, and the same technique yields a tester for functions on the hypergrid as well. The testers are parameterized by an upper bound L on the best Lipschitz constant of f in ℓ^1 geometry, which we denote $\mathsf{Lip}_1(f)$ (see Definition 2.1 for a formal definition).

Both of our testers are *partial derivative testers.* These are algorithms which only have access to a directional derivative oracle and, moreover, their queries are promised to be axis-aligned vectors. In the discrete case, these are usually called *edge testers* [27, 18].

▶ **Theorem 1.4.** *There is a nonadaptive partial derivative L^1 monotonicity tester for Lipschitz functions $f : [0,1]^n \to \mathbb{R}$ satisfying $\mathsf{Lip}_1(f) \leq L$ with query complexity $O\left(\frac{nL}{\epsilon}\right)$ and one-sided error.*

Similarly, there is a nonadaptive partial derivative L^1 monotonicity tester for functions $f : [m]^n$ satisfying $\mathsf{Lip}_1(f) \leq L$ with query complexity $O\left(\frac{nmL}{\epsilon}\right)$ and one-sided error.

The testers work by sampling points x and coordinates $i \in [n]$ uniformly at random, and using directional derivative queries to reject if $\partial_i^- f(x) < 0$. Their correctness is shown using Theorems 1.2 and 1.3, which imply that, when f is ϵ-far from monotone in L^1-distance, the total magnitude of its negative partial derivatives must be large – and since each partial derivative is at most L by assumption, the values $\partial_i^- f(x)$ must be strictly negative in a set of large measure, which the tester stands good chance of hitting with the given query complexity.

1.2.3 Testing monotonicity on the line

The results above, linking a Poincaré-type inequality with a monotonicity tester that uses partial derivative queries and has linear dependence on n, seem to suggest a close parallel with the case of the edge tester on the Boolean cube [27, 18]. On the other hand, we also show a strong separation between Hamming and L^1 testing. Focusing on the simpler problem of monotonicity testing *on the line*, we show that the tight query complexity of L^1 monotonicity testing Lipschitz functions grows with the square root of the size of the (continuous or discrete) domain:

▶ **Theorem 1.5.** *There exist nonadaptive L^1 monotonicity testers for Lipschitz functions $f : [0, m] \to \mathbb{R}$ and $f : [m] \to \mathbb{R}$ satisfying $\mathsf{Lip}_1(f) \le L$ with query complexity $\widetilde{O}\left(\sqrt{mL/\epsilon}\right)$. The testers use value queries and have one-sided error.*

This result (along with the near-tight lower bounds in Section 1.2.4) is in contrast with the case of Hamming testing functions $f : [m] \to \mathbb{R}$, which has sample complexity $\Theta(\log m)$ [23, 25, 11, 2]. Intuitively, this difference arises because a Lipschitz function may violate monotonicity with rate of change L, so the area under the curve may grow quadratically on violating regions. The proof is in fact a reduction to the Hamming case, using the Lipschitz assumption to establish a connection between the L^1 and Hamming distances to monotonicity.

1.2.4 Lower bounds

We give two types of lower bounds: under no assumptions about the tester and for constant n, we show that the dependence of Theorem 1.4 on L/ϵ is close to optimal[4]. We give stronger bounds for the special case of partial derivative testers (such as the ones from Theorem 1.4), essentially showing that our analysis of the partial derivative tester is tight.

▶ **Theorem 1.6.** *Let n be a constant. Any L^1 monotonicity tester (with two-sided error, and adaptive value and directional derivative queries) for Lipschitz functions $f : [0,1]^n \to \mathbb{R}$ satisfying $\mathsf{Lip}_1(f) \le L$ requires at least $\Omega\left((L/\epsilon)^{\frac{n}{n+1}}\right)$ queries.*

Similarly, any L^1 monotonicity tester (with two-sided error and adaptive queries) for functions $f : [m]^n \to \mathbb{R}$ satisfying $\mathsf{Lip}_1(f) \le L$ requires at least $\Omega\left(\min\left\{(mL/\epsilon)^{\frac{n}{n+1}}, m^n\right\}\right)$ queries.

Notice that the bounds above cannot be improved beyond logarithmic factors, due to the upper bounds for the line in Theorem 1.5. It also follows that adaptivity (essentially) does not help with L^1 monotonicity testing on the line, matching the situation for Hamming testing [25, 19, 2].

Theorem 1.6 is obtained via a “hole” construction, which hides a non-monotone region of f inside an ℓ^1-ball B of radius r. We choose r such the violations of monotonicity inside B are large enough to make f ϵ-far from monotone, but at the same time, the ball B is hard to find using few queries. However, this construction has poor dependence on n.

To lower bound the query complexity of partial derivative testers with better dependence on n, we employ a simpler “step” construction, which essentially chooses a coordinate i and hides a small negative-slope region on every line along coordinate i. These functions are far from monotone, but a partial derivative tester must correctly guess both i and the negative-slope region to detect them. We conclude that Theorem 1.4 is optimal for partial derivative testers on the unit cube, and optimal for edge testers on the hypergrid for constant ϵ and L:

▶ **Theorem 1.7.** *Any partial derivative L^1 monotonicity tester for Lipschitz functions $f : [0,1]^n \to \mathbb{R}$ satisfying $\mathsf{Lip}_1(f) \le L$ (with two-sided error and adaptive queries) requires at least $\Omega(nL/\epsilon)$ queries.*

[4] Note that one may always multiply the input values by $1/L$ to reduce the problem to the case with Lipschitz constant 1 and proximity parameter ϵ/L, so this is the right ratio to look at.

Table 2 Query complexity bounds for testing monotonicity on the unit cube and hypergrid. Upper bounds are for nonadaptive (n.a.) algorithms with one-sided error (1-s.), and lower bounds are for adaptive algorithms with two-sided error, unless stated otherwise. For L^1-testing, the upper bounds derived from prior works (*) are specialized to the Lipschitz case by us; see the full version of the paper for details. Our lower bounds hold either for constant (const.) n, or for partial derivative testers (p.d.t.).

Domain	**Hamming testing** $f : \Omega \to \mathbb{R}$	L^1**-testing** (prior works) $f : \Omega \to \mathbb{R}$, $\mathsf{Lip}_1(f) \leq L$	L^1**-testing** (this work) $f : \Omega \to \mathbb{R}$, $\mathsf{Lip}_1(f) \leq L$
$\Omega = [0,1]^n$	Infeasible	$\widetilde{O}\left(\frac{n^2 L}{\epsilon}\right)$ (*) [4]	$O\left(\frac{nL}{\epsilon}\right)$ p.d.t.
		–	$\Omega\left(\left(\frac{L}{\epsilon}\right)^{\frac{n}{n+1}}\right)$ const. n $\Omega\left(\frac{nL}{\epsilon}\right)$ p.d.t.
$\Omega = [m]^n$	$O\left(\frac{n \log m}{\epsilon}\right)$ [18]	$\widetilde{O}\left(\frac{n^2 mL}{\epsilon}\right)$ (*) [4]	$O\left(\frac{nmL}{\epsilon}\right)$ p.d.t.
	$\Omega\left(\frac{n \log(m) - \log(1/\epsilon)}{\epsilon}\right)$ [19]	$\widetilde{\Omega}\left(\frac{L}{\epsilon}\right)$ n.a. 1-s. [4] $\Omega(n \log m)$ n.a. [11]	$\Omega\left(\left(\frac{mL}{\epsilon}\right)^{\frac{n}{n+1}}\right)$ const. n $\Omega(nm)$ p.d.t.

For sufficiently small constant ϵ and constant L, any partial derivative L^1 monotonicity tester for functions $f : [m]^n \to \mathbb{R}$ satisfying $\mathsf{Lip}_1(f) \leq L$ *(with two-sided error and adaptive queries) requires at least $\Omega(nm)$ queries.*

Table 2 summarizes our upper and lower bounds for testing monotonicity on the unit cube and hypergrid, along with the analogous Hamming testing results for intuition and bounds for L^1 testing from prior works. See Section 1.3.3 and the full version of the paper for a discussion and details of how prior works imply the results in that table, since to our knowledge the problem of L^1 monotonicity testing parameterized by the Lipschitz constant has not been explicitly studied before.

1.3 Discussion and open questions

1.3.1 Stronger directed Poincaré inequalities?

Classical Poincaré inequalities are usually of the ℓ^2 form, which seems natural e.g. due to basis independence. On the other hand, in the directed setting, the weaker ℓ^1 inequalities (as in [27] and Theorems 1.2 and 1.3) have more straightforward proofs than ℓ^2 counterparts such as [30]. A perhaps related observation is that monotonicity is *not* a basis-independent concept, since it is defined in terms of the standard basis. It is not obvious whether directed ℓ^2 inequalities ought to hold in every (real-valued, continuous) setting. Nevertheless, in light of the parallels and context established thus far, we are hopeful that such an equality does hold. Otherwise, we believe that the reason should be illuminating. For now, we conjecture:

▶ **Conjecture 1.8.** *For every Lipschitz function $f : [0,1]^n \to \mathbb{R}$, it holds that*

$$d_1^{\mathsf{mono}}(f) \lesssim \mathbb{E}\left[\|\nabla^- f\|_2\right] .$$

Accordingly, we also ask whether an L^1 tester with $O(\sqrt{n})$ complexity exists, presumably with a dependence on the $\mathsf{Lip}_2(f)$ constant rather than $\mathsf{Lip}_1(f)$ since ℓ^2 is the relevant geometry above.

1.3.2 Query complexity bounds

Our lower bounds either have weak dependence on n, or only apply to a specific family of algorithms (partial derivative testers). Previous works have established tester-independent lower bounds with strong dependence on n by using reductions from communication complexity [10, 11], whose translation to the continuous setting is not obvious[5], by reduction to comparison-based testers [19], whose connection to L^1 testing setting seems less immediate, or directly via a careful construction [2]. We believe that finding strong tester-independent lower bounds for L^1 testing Lipschitz functions on the unit cube is an interesting direction for further study.

We also remark that even a tight lower bound matching Theorem 1.4 may not rule out testers with better dependence on n if, for example, such a tester were parameterized by $\mathsf{Lip}_2(f)$, which can be a factor of $\sqrt{n}$ larger than $\mathsf{Lip}_1(f)$. We view the possibility of better testers on the unit cube, or otherwise a conceptual separation with [30], as an exciting direction for future work.

1.3.3 Relation to prior work on L^p-testing

[4] initiated the systematic study of L^p-testing and, most relevant to the present work, established the first (and, to our knowledge, only) results on L^p testing of the monotonicity property, on the hypergrid and on the discrete line. While our models are broadly compatible, a subtle but crucial distinction must be explained.

[4] focused their exposition on the case of functions $f : \Omega \to [0, 1]$, and in this regime, L^1 testing can only be easier than Hamming testing, which they show via a reduction based on Boolean threshold functions. On the other hand, for functions with other ranges, say $f : \Omega \to [a, b]$, their definition normalizes the notion of distance by a factor of $\frac{1}{b-a}$. In our terminology, letting $r := b - a$ and $g := f/r$, it follows that $d_1(g) = d_1(f)/r$, so testing f with proximity parameter ϵ reduces to testing g with proximity parameter ϵ/r. For Hamming testers with query complexity that depends linearly on $1/\epsilon$, this amounts to paying a factor of r in the reduction to the Boolean case[6]. This loss is indeed necessary, because by the same reasoning, testing g with proximity parameter ϵ reduces to testing f with proximity parameter $r\epsilon$. Therefore the problems of testing f with proximity parameter ϵ and testing f/r with proximity parameter ϵ/r have the same query complexity.

In this work, we do not normalize the distance metric by r; we would like to handle functions f that may take large values as the dimension n grows, as long as f satisfies a Lipschitz assumption, and our goal is to beat the query complexity afforded by the reduction to the Boolean case. We derive these benchmarks by assuming that the input f is Lipschitz, and inferring an upper bound on r based on the Lipschitz constant and the size of the domain. Combined with the hypergrid tester of [4] and a discretization argument for the unit cube inspired by [8, 28], we establish benchmarks for our testing problem. See the full version of the paper for further details.

With the discussion above in mind, it is instructive to return to Table 2. We note that our upper bounds have polynomially smaller dependence on n than the benchmarks, suggesting that our use of the Lipschitz assumption – via the directed Poincaré inequalities

[5] Note that there is no obvious reduction from testing on the hypergrid to testing on the unit cube – one idea is to simulate the unit cube tester on a multilinear interpolation of the function defined on the hypergrid, but the challenge is that simulating each query to the unit cube naively requires an exponential number of queries to the hypergrid.

[6] This factor can also be tracked explicitly in the characterization of the L^1 distance to monotonicity of [4]: it arises in Lemmas 2.1 and 2.2, where an integral from 0 to 1 must be changed to an integral from a to b, so the best threshold function is only guaranteed to be ϵ/r-far from monotone.

in Theorems 1.2 and 1.3 – exploits useful structure underlying the monotonicity testing problem (whereas the benchmark testers must work for every function with bounded range, not only the Lipschitz ones). Our lower bounds introduce an almost-linear dependence on the hypergrid length m; intuitively, this dependence is not implied by the previous bounds in [4, 11] because those construct the violations of monotonicity via Boolean functions, whereas our constructions exploit the fact that a Lipschitz function can "keep growing" along a given direction, which exacerbates the L^1 distance to monotonicity in the region where that happens. Our lower bounds for partial derivative testers show that the analysis of our algorithms is essentially tight, so new (upper or lower bound) ideas are required to establish the optimal query complexity for arbitrary testers.

On the choice of L^1 distance and Lipschitz assumption

We briefly motivate our choice of distance metric and Lipschitz assumption. For continuous range and domain, well-known counterexamples rule out testing with respect to Hamming distance: given any tester with finite query complexity, a monotone function may be made far from monotone by arbitrarily small, hard to detect perturbations. Testing against L^1 distance is then a natural choice, since this metric takes into account the magnitude of the change required to make a function monotone ([4] also discuss connections with learning and approximation theory). However, an arbitrarily small region of the input may still have disproportionate effect on the L^1 distance if the function is arbitrary, so again testing is infeasible. Lipschitz continuity seems like a natural enough assumption which, combined with the choice of L^1 distance, makes the problem tractable. Another benefit is that Lipschitz functions are differentiable almost everywhere by Rademacher's theorem, so the gradient is well-defined almost everywhere, which enables the connection with Poincaré-type inequalities.

Organization

Section 2 introduces definitions and notation. In Section 3 we prove our directed Poincaré inequality on the unit cube, and in Section 4 we give our L^1 monotonicity tester for this domain. The analogous versions for the discrete case of the hypergrid, as well as the proofs of our results for testing on the line (Section 1.2.3) and lower bounds (Section 1.2.4) may be found in the full version of the paper.

2 Preliminaries

For integer $m \geq 1$, we write $[m]$ to denote the set $\{i \in \mathbb{Z} : 1 \leq i \leq m\}$. For any $c \in \mathbb{R}$, we write c^+ for $\max\{0, c\}$ and c^- for $-\min\{0, c\}$. We denote the closure of an open set $B \subset \mathbb{R}^n$ by $\overline{B}$.

For a measure space (Ω, Σ, ν) and measurable function $f : \Omega \to \mathbb{R}$, we write $\int_\Omega f \, \mathrm{d}\nu$ for the Lebesgue integral of f over this space. Then for $p \geq 1$, the space $L_p(\Omega, \nu)$ is the set of measurable functions f such that $|f|^p$ is Lebesgue integrable, i.e. $\int_\Omega |f|^p \, \mathrm{d}\nu < \infty$, and we write the L^p norm of such functions as $\|f\|_{L^p} = \|f\|_{L^p(\nu)} = \left(\int_\Omega |f|^p \, \mathrm{d}\nu\right)^{1/p}$. We will write ν to denote the Lebesgue measure on $\mathbb{R}^n$ (the dimension n being clear from context), and simply write $L^p(\Omega)$ for $L^p(\Omega, \nu)$; we will reserve μ for the special case of probability measures.

2.1 Lipschitz functions and L^p distance

We first define Lipschitz functions with respect to a choice of ℓ^p geometry.

▶ **Definition 2.1.** *Let $p \geq 1$. We say that $f : \Omega \to \mathbb{R}$ is* (ℓ^p, L)-Lipschitz *if, for every $x, y \in \Omega$, $|f(x) - f(y)| \leq L\|x - y\|_p$. We say that f is Lipschitz if it is (ℓ^p, L)-Lipschitz for any L (in which case this also holds for any other choice of ℓ^q), and in this case we denote by $\mathsf{Lip}_p(f)$ the best possible Lipschitz constant:*

$$\mathsf{Lip}_p(f) := \inf_L \{f \text{ is } (\ell^p, L)\text{-Lipschitz}\} .$$

It follows that $\mathsf{Lip}_p(f) \leq \mathsf{Lip}_q(f)$ for $p \leq q$.

We now formally define L^p distances, completing the definition of L^p-testers from Section 1.1.

▶ **Definition 2.2** (L^p-distance)**.** *Let $p \geq 1$, let $R \subseteq \mathbb{R}$, and let (Ω, Σ, μ) be a probability space. For a property $\mathcal{P} \subseteq L^p(\Omega, \mu)$ of functions $g : \Omega \to R$ and function $f : \Omega \to R \in L^p(\Omega, \mu)$, we define the distance from f to $\mathcal{P}$ as $d_p(f, \mathcal{P}) := \inf_{g \in \mathcal{P}} d_p(f, g)$, where*

$$d_p(f, g) := \|f - g\|_{L^p(\mu)} = \mathop{\mathbb{E}}_{x \sim \mu} [|f(x) - g(x)|^p]^{1/p} .$$

For $p = 0$, we slightly abuse notation and, taking $0^0 = 0$, write $d_0(f, g)$ for the Hamming distance between f and g weighted by μ (and $\mathcal{P}$ may be any set of measurable functions on (Ω, Σ, μ)).

In our applications, we will always take μ to be the uniform distribution over Ω[7]. As a shorthand, when (Ω, Σ, μ) is understood from the context and $R = \mathbb{R}$, we will write

1. $d_p^{\mathsf{const}}(f) := d_p(f, \mathcal{P}^{\mathsf{const}})$ where $\mathcal{P}^{\mathsf{const}} := \{f : \Omega \to \mathbb{R} \in L^p(\Omega, \mu) : f = c, c \in \mathbb{R}\}$; and
2. $d_p^{\mathsf{mono}}(f) := d_p(f, \mathcal{P}^{\mathsf{mono}})$ where $\mathcal{P}^{\mathsf{mono}} := \{f : \Omega \to \mathbb{R} \in L^p(\Omega, \mu) : f \text{ is monotone}\}$.

Going forward, we will also use the shorthand $d_p(f) := d_p^{\mathsf{mono}}(f)$.

2.2 Directed partial derivatives and gradients

Let B be an open subset of $\mathbb{R}^n$, and let $f : B \to \mathbb{R}$ be Lipschitz. Then by Rademacher's theorem f is differentiable almost everywhere in B. For each $x \in B$ where f is differentiable, let $\nabla f(x) = (\partial_1 f(x), \ldots, \partial_n f(x))$ denote its gradient, where $\partial_i f(x)$ is the partial derivative of f along the i-th coordinate at x. Then, let $\partial_i^- := \min\{0, \partial_i\}$, i.e. for every x where f is differentiable we have $\partial_i^- f(x) = -(\partial_i f(x))^-$. We call ∂_i^- the *directed partial derivative* operator in direction i. Then we define the *directed gradient* operator by $\nabla^- := (\partial_1^-, \ldots, \partial_n^-)$, again defined on every point x where f is differentiable.

3 Directed Poincaré inequalities for Lipschitz functions

In this section, we establish Theorem 1.2. We start with the one-dimensional case, i.e. functions on the line, and then generalize to higher dimensions. See the full version of the paper for the discrete case of the hypergrid.

3.1 One-dimensional case

Let $m > 0$, let $I := (0, m)$, and let $f : \overline{I} \to \mathbb{R}$ be a measurable function. We wish to show that $\|f - f^*\|_{L^1} \lesssim m \|\partial^- f\|_{L^1}$, where f^* is the monotone rearrangement of f. We first introduce the monotone rearrangement, and then show this inequality using an elementary calculus argument.

[7] More precisely: when $\Omega = [0, 1]^n$, μ will be the Lebesgue measure on Ω (with associated σ-algebra Σ).

3.1.1 Monotone rearrangement

Here, we introduce the (non-symmetric, non-decreasing) monotone rearrangement of a one-dimensional function. We follow the definition of [29], with the slight modification that we are interested in the *non-decreasing* rearrangement, whereas most of the literature usually favours the non-increasing rearrangement. The difference is purely syntactic, and our choice more conveniently matches the convention in the monotonicity testing literature. Up to this choice, our definition also agrees with that of [3, Chapter 2], and we refer the reader to these two texts for a comprehensive treatment.

We define the (lower) *level sets* of $f : \overline{I} \to \mathbb{R}$ as the sets

$$\overline{I}_c := \left\{x \in \overline{I} : f(x) \leq c\right\}$$

for all $c \in \mathbb{R}$. For nonempty measurable $S \subset \mathbb{R}$ of finite measure, the *rearrangement* of S is the set

$$S^* := [0, \nu(S)]$$

(recall that ν stands for the Lebesgue measure here), and we define $\emptyset^* := \emptyset$. For a level set $\overline{I}_c$, we write $\overline{I}_c^*$ to mean $\left(\overline{I}_c\right)^*$.

▶ **Definition 3.1.** *The* monotone rearrangement *of f is the function $f^* : \overline{I} \to \mathbb{R}$ given by*

$$f^*(x) := \inf \left\{c \in \mathbb{R} : x \in \overline{I}_c^*\right\} . \tag{5}$$

Note that f^* is always a non-decreasing function.

We note two well-known properties of the monotone rearrangement: equimeasurability and order preservation. Two functions f, g are called *equimeasurable* if $\nu\{f \geq c\} = \nu\{g \geq c\}$ for every $c \in \mathbb{R}$. A mapping $u \mapsto u^*$ is called *order preserving* if $f(x) \leq g(x)$ for all $x \in \overline{I}$ implies $f^*(x) \leq g^*(x)$ for all $x \in \overline{I}$. See [3, Chapter 2, Proposition 1.7] for a proof of the following:

▶ **Fact 3.2.** *Let $f : \overline{I} \to \mathbb{R}$ be a measurable function. Then f and f^* are equimeasurable.*

▶ **Fact 3.3.** *The mapping $f \mapsto f^*$ is order preserving.*

3.1.2 Absolutely continuous functions and the one-dimensional Poincaré inequality

Let $f : \overline{I} \to \mathbb{R}$ be absolutely continuous. It follows that f has a derivative ∂f almost everywhere (i.e. outside a set of measure zero), $\partial f \in L^1(I)$ (i.e. its derivative is Lebesgue integrable), and

$$f(x) = f(0) + \int_0^x \partial f(t)\,\mathrm{d}t$$

for all $x \in \overline{I}$. It also follows that $\partial^- f \in L^1(I)$.

We may now show our one-dimensional inequality:

▶ **Lemma 3.4.** *Let $f : \overline{I} \to \mathbb{R}$ be absolutely continuous. Then $\|f - f^*\|_{L^1} \leq 2m \|\partial^- f\|_{L^1}$.*

Proof. Let $S := \{x \in \overline{I} : f^*(x) > f(x)\}$, and note that S is a measurable set because f, f^* are measurable functions (the latter by Fact 3.2). Moreover, since f and f^* are equimeasurable (by the same result), we have $\int f \,\mathrm{d}\nu = \int f^* \,\mathrm{d}\nu$ and therefore

$$\begin{aligned} \|f - f^*\|_{L^1} &= \int_I |f - f^*| \,\mathrm{d}\nu = \int_S (f^* - f)\,\mathrm{d}\nu + \int_{I\setminus S} (f - f^*)\,\mathrm{d}\nu \\ &= \int_S (f^* - f)\,\mathrm{d}\nu + \left(\int_I (f - f^*)\,\mathrm{d}\nu - \int_S (f - f^*)\,\mathrm{d}\nu\right) = 2\int_S (f^* - f)\,\mathrm{d}\nu\,. \end{aligned}$$

Hence our goal is to show that

$$\int_S (f^* - f)\,\mathrm{d}\nu \le m \left\|\partial^- f\right\|_{L^1}\,.$$

Let $x \in \overline{I}$. We claim that there exists $x' \in [0,x]$ such that $f(x') \ge f^*(x)$. Suppose this is not the case. Then since f is continuous on $[0,x]$, by the extreme value theorem it attains its maximum and therefore there exists $c < f^*(x)$ such that $f(y) \le c$ for all $y \in [0,x]$. Thus $[0,x] \subseteq \overline{I}_c$, so $\nu\left(\overline{I}_c\right) \ge x$ and hence $x \in \overline{I}_c^*$. Then, by Definition 3.1, $f^*(x) \le c < f^*(x)$, a contradiction. Thus the claim is proved.

Now, let $x \in S$ and fix some $x' \in [0,x]$ such that $f(x') \ge f^*(x)$. Since f is absolutely continuous, we have

$$f^*(x) - f(x) \le f(x') - f(x) = -\int_{x'}^{x} \partial f(t)\,\mathrm{d}t \le -\int_0^m \partial^- f(t)\,\mathrm{d}t = \left\|\partial^- f\right\|_{L^1}\,.$$

The result follows by applying this estimate to all x:

$$\int_S (f^* - f)\,\mathrm{d}\nu \le \int_S \left\|\partial^- f\right\|_{L^1} \mathrm{d}\nu = \nu(S)\left\|\partial^- f\right\|_{L^1} \le m\left\|\partial^- f\right\|_{L^1}\,. \qquad ◀$$

3.2 Multidimensional case

Although we ultimately only require an inequality on the unit cube $[0,1]^n$, we will first work in slightly more generality and consider functions defined on a *box* in $\mathbb{R}^n$, defined below. This approach makes some of the steps more transparent, and also gives intuition for the discrete case of the hypergrid.

▶ **Definition 3.5.** *Let $a \in \mathbb{R}^n_{>0}$. The* box of size a *is the closure $\overline{B} \subset \mathbb{R}^n$ of $B = (0,a_1) \times \cdots \times (0,a_n)$.*

Going forward, $\overline{B} \subset \mathbb{R}^n$ will always denote such a box.

Notation

For $x \in \mathbb{R}^n$, $y \in \mathbb{R}$ and $i \in [n]$, we will use the notation x^{-i} to denote the vector in $\mathbb{R}^{[n]\setminus\{i\}}$ obtained by removing the i-th coordinate from x (note that the indexing is not changed), and we will write (x^{-i}, y) as a shorthand for the vector $(x_1, \dots, x_{i-1}, y, x_{i+1}, \dots, x_n) \in \mathbb{R}^n$. We will also write x^{-i} directly to denote any vector in $\mathbb{R}^{[n]\setminus\{i\}}$. For function $f : \overline{B} \to \mathbb{R}$ and $x^{-i} \in \mathbb{R}^{[n]\setminus\{i\}}$, we will write $f_{x^{-i}}$ for the function given by $f_{x^{-i}}(y) = f(x^{-i}, y)$ for all $(x^{-i}, y) \in \overline{B}$. For any set $D \in \mathbb{R}^n$, we will denote by D^{-i} the projection $\{x^{-i} : x \in D\}$, and extend this notation in the natural way to more indices, e.g. D^{-i-j}.

▶ **Definition 3.6** (Rearrangement in direction i)**.** *Let $f : \overline{B} \to \mathbb{R}$ be a measurable function and let $i \in [n]$. The* rearrangement of f in direction i *is the function $R_i f : \overline{B} \to \mathbb{R}$ given by*

$$(R_i f)_{x^{-i}} := (f_{x^{-i}})^* \tag{6}$$

for all $x^{-i} \in \left(\overline{B}\right)^{-i}$. We call each R_i the rearrangement operator in direction i.

We may put (6) in words as follows: on each line in direction i determined by point x^{-i}, the restriction of $R_i f$ to that line is the monotone rearrangement of the restriction of f to that line.

▶ **Proposition 3.7.** *Let $\overline{B}$ be the box of size $a \in \mathbb{R}^n$, and let $f : \overline{B} \to \mathbb{R}$ be Lipschitz continuous. Then for each $i \in [n]$,*

$$\left\| f - R_i f \right\|_{L^1} \le 2a_i \left\| \partial_i^- f \right\|_{L^1} .$$

Proof. Since f is Lipschitz continuous, each $f_{x^{-i}} : [0, a_i] \to \mathbb{R}$ is Lipschitz continuous and *a fortiori* absolutely continuous. The result follows from Lemma 3.4, using Tonelli's theorem to choose the order of integration. ◀

A key ingredient in our multidimensional argument is that the rearrangement operator preserves Lipschitz continuity:

▶ **Lemma 3.8** ([29, Lemma 2.12])**.** *If $f : \overline{B} \to \mathbb{R}$ is Lipschitz continuous (with Lipschitz constant L), then $R_i f$ is Lipschitz continuous (with Lipschitz constant $2L$).*

We are now ready to define the (multidimensional) monotone rearrangement f^*:

▶ **Definition 3.9.** *Let $f : \overline{B} \to \mathbb{R}$ be a measurable function. The* monotone rearrangement *of f is the function*

$$f^* := R_n R_{n-1} \cdots R_1 f .$$

We first show that f^* is indeed a monotone function:

▶ **Proposition 3.10.** *Let $f : \overline{B} \to \mathbb{R}$ be Lipschitz continuous. Then f^* is monotone.*

Proof. Say that $g : \overline{B} \to \mathbb{R}$ is *monotone in direction i* if $g_{x^{-i}}$ is non-decreasing for all $x^{-i} \in \left(\overline{B}\right)^{-i}$. Then g is monotone if and only if it is monotone in direction i for every $i \in [n]$. Note that $R_i f$ is monotone in direction i by definition of monotone rearrangement. Therefore, it suffices to prove that if f is monotone in direction j, then $R_i f$ is also monotone in direction j.

Suppose f is monotone in direction j, and suppose $i < j$ without loss of generality. Let $a \in \mathbb{R}^n$ be the size of B. Let $x^{-j} \in \left(\overline{B}\right)^{-j}$ and $0 \le y_1 < y_2 \le a_j$, so that $(x^{-j}, y_1), (x^{-j}, y_2) \in \overline{B}$. We need to show that $(R_i f)(x^{-j}, y_1) \le (R_i f)(x^{-j}, y_2)$. Let $\overline{I}_i := [0, a_i]$. For each $k \in \{1, 2\}$, let $g_k : \overline{I}_i \to \mathbb{R}$ be given by

$$g_k(z) := f(x_1, \dots, x_{i-1}, z, x_{i+1}, \dots, x_{j-1}, y_k, x_{j+1}, \dots, x_n) .$$

Note that

$$g_k^*(z) = (R_i f)(x_1, \dots, x_{i-1}, z, x_{i+1}, \dots, x_{j-1}, y_k, x_{j+1}, \dots, x_n)$$

for every $z \in \overline{I}_i$, and therefore our goal is to show that $g_1^*(x_i) \le g_2^*(x_i)$. But f being monotone in direction j means that $g_1(z) \le g_2(z)$ for all $z \in \overline{I}_i$, so by the order preserving property (Fact 3.3) of the monotone rearrangement we get that $g_1^*(x_i) \le g_2^*(x_i)$, concluding the proof. ◀

It is well-known that the monotone rearrangement is a non-expansive operator. Actually a stronger fact holds, as we note below.

▶ **Proposition 3.11** ([22]). *Let $m > 0$ and let $f, g \in L^1[0,m]$. Then f^*, g^* satisfy*

$$\int_{[0,m]} (f^* - g^*)^- \,\mathrm{d}\nu \leq \int_{[0,m]} (f - g)^- \,\mathrm{d}\nu$$

and

$$\int_{[0,m]} |f^* - g^*| \,\mathrm{d}\nu \leq \int_{[0,m]} |f - g| \,\mathrm{d}\nu \,.$$

The result above is stated for functions on the interval. Taking the integral over the box B and repeating for each operator R_i yields the non-expansiveness of our monotone rearrangement operator, as also noted by [29]:

▶ **Corollary 3.12.** *Let $f, g \in L^1(\overline{B})$. Then $\|f^* - g^*\|_{L^1} \leq \|f - g\|_{L^1}$.*

We show that the rearrangement operator can only make the norm of the directed partial derivatives smaller, i.e. decrease the violations of monotonicity, which is the key step in this proof.

▶ **Proposition 3.13.** *Let $f : \overline{B} \to \mathbb{R}$ be Lipschitz continuous and let $i, j \in [n]$. Then $\left\|\partial_j^-(R_i f)\right\|_{L^1} \leq \left\|\partial_j^- f\right\|_{L^1}$.*

Proof. We may assume that $i \neq j$, since otherwise the LHS is zero. We will use the following convention for variables names: $w \in \mathbb{R}^n$ will denote points in B; $z \in \mathbb{R}^{[n]\setminus\{i,j\}}$ will denote points in B^{-i-j}; $x \in \mathbb{R}$ will denote points in $(0, a_i)$ (indexing the i-th dimension); and $y \in \mathbb{R}$ will denote points in $(0, a_j)$ (indexing the j-th dimension). For each $i \in [n]$, let e_i denote the i-th basis vector.

Since f is Lipschitz, so is $R_i f$ by Lemma 3.8. By Rademacher's theorem, these functions are differentiable almost everywhere. Therefore, let $D \subseteq B$ be a measurable set such that f and $R_i f$ are differentiable in D and $\nu(D) = \nu(B)$. We have

$$\begin{aligned}
\left\|\partial_j^-(R_i f)\right\|_{L^1} &= \int_D \left|\partial_j^-(R_i f)\right| \mathrm{d}\nu = \int_D \left[\lim_{h\to 0}\left(\frac{(R_i f)(w + he_j) - (R_i f)(w)}{h}\right)^-\right] \mathrm{d}\nu(w) \\
&\overset{(BC1)}{=} \lim_{h\to 0}\int_D \left(\frac{(R_i f)(w + he_j) - (R_i f)(w)}{h}\right)^- \mathrm{d}\nu(w) \\
&\overset{(D1)}{=} \lim_{h\to 0}\int_B \left(\frac{(R_i f)(w + he_j) - (R_i f)(w)}{h}\right)^- \mathrm{d}\nu(w) \\
&\overset{(T1)}{=} \lim_{h\to 0}\int_{B^{-i-j}}\int_{(0,a_j)}\int_{(0,a_i)} \left(\frac{(R_i f)(z, y+h, x) - (R_i f)(z, y, x)}{h}\right)^- \mathrm{d}\nu(x)\,\mathrm{d}\nu(y)\,\mathrm{d}\nu(z) \\
&\leq \lim_{h\to 0}\int_{B^{-i-j}}\int_{(0,a_j)}\int_{(0,a_i)} \left(\frac{f(z, y+h, x) - f(z, y, x)}{h}\right)^- \mathrm{d}\nu(x)\,\mathrm{d}\nu(y)\,\mathrm{d}\nu(z) \\
&\overset{(T2)}{=} \lim_{h\to 0}\int_B \left(\frac{f(w + he_j) - f(w)}{h}\right)^- \mathrm{d}\nu(w) \\
&\overset{(D2)}{=} \lim_{h\to 0}\int_D \left(\frac{f(w + he_j) - f(w)}{h}\right)^- \mathrm{d}\nu(w) \\
&\overset{(BC2)}{=} \int_D \left[\lim_{h\to 0}\left(\frac{f(w + he_j) - f(w)}{h}\right)^-\right] \mathrm{d}\nu(w) = \int_D \left|\partial_j^- f\right| \mathrm{d}\nu = \left\|\partial_j^- f\right\|_{L^1} \,.
\end{aligned}$$

Equalities (BC1) and (BC2) hold by the bounded convergence theorem, which applies because the difference quotients are uniformly bounded by the Lipschitz constants of $R_i f$ and f (respectively), and because $R_i f$ and f are differentiable in D (which gives pointwise convergence of the limits). Equalities (D1) and (D2) hold again by the uniform boundedness of the difference quotients, along with the fact that $\nu(B \setminus D) = 0$. Equalities (T1) and (T2) hold by Tonelli's theorem. Finally, the inequality holds by Proposition 3.11, since $(R_i f)(z, y+h, \cdot)$ is the monotone rearrangement of $f(z, y+h, \cdot)$ and $(R_i f)(z, y, \cdot)$ is the monotone rearrangement of $f(z, y, \cdot)$. ◀

We are now ready to prove our directed (L^1, ℓ^1)-Poincaré inequality.

▶ **Theorem 3.14.** *Let B be the box of size $a \in \mathbb{R}^n$ and let $f : \overline{B} \to \mathbb{R}$ be Lipschitz continuous. Then*

$$\|f - f^*\|_{L^1} \le 2 \sum_{i=1}^{n} a_i \left\|\partial_i^- f\right\|_{L^1} .$$

Proof. We have

$$\begin{aligned}
\|f - f^*\|_{L^1} &\le \sum_{i=1}^{n} \|R_{i-1} \cdots R_1 f - R_i \cdots R_1 f\|_{L^1} && \text{(Triangle inequality)} \\
&\le 2 \sum_{i=1}^{n} a_i \left\|\partial_i^- (R_{i-1} \cdots R_1 f)\right\|_{L^1} && \text{(Lemma 3.8 and Proposition 3.7)} \\
&\le 2 \sum_{i=1}^{n} a_i \left\|\partial_i^- f\right\|_{L^1} && \text{(Lemma 3.8 and Proposition 3.13)} .
\end{aligned}$$

◀

Setting $B = (0,1)^n$ yields the inequality portion of Theorem 1.2:

▶ **Corollary 3.15.** *Let $B = (0,1)^n$ and let $f : \overline{B} \to \mathbb{R}$ be Lipschitz continuous. Then*

$$\mathbb{E}\left[|f - f^*|\right] = \|f - f^*\|_{L^1} \le 2 \int_B \|\nabla^- f\|_1 \, \mathrm{d}\nu = 2\mathbb{E}\left[\|\nabla^- f\|_1\right] .$$

To complete the proof of Theorem 1.2, we need to show that $d_1(f) \approx \mathbb{E}\left[|f - f^*|\right]$, i.e. that the monotone rearrangement is "essentially optimal" as a target monotone function for f. The inequality $d_1(f) \le \mathbb{E}\left[|f - f^*|\right]$ is clear from the fact that f^* is monotone. The inequality in the other direction follows from the non-expansiveness of the rearrangement operator, with essentially the same proof as that of [30] for the Boolean cube:

▶ **Proposition 3.16.** *Let $f : [0,1]^n \to \mathbb{R}$ be Lipschitz continuous. Then $\mathbb{E}\left[|f - f^*|\right] \le 2d_1(f)$.*

Proof. Let $g \in L^1([0,1]^n)$ be any monotone function. It follows that $g^* = g$. By Corollary 3.12, we have that $\|f^* - g^*\|_{L^1} \le \|f - g\|_{L^1}$. Using the triangle inequality, we obtain

$$\|f - f^*\|_{L^1} \le \|f - g\|_{L^1} + \|g - f^*\|_{L^1} = \|f - g\|_{L^1} + \|f^* - g^*\|_{L^1} \le 2\|f - g\|_{L^1} .$$

The claim follows by taking the infimum over the choice of g. ◀

To check that Corollary 3.15 is tight up to constant factors, it suffices to take the linear function $f : [0,1]^n \to \mathbb{R}$ given by $f(x) = 1 - x_1$ for all $x \in [0,1]^n$. Then f^* is given by $f^*(x) = x_1$, so $\mathbb{E}\left[f - f^*\right] = 1/2$ while $\mathbb{E}\left[\|\nabla^- f\|_1\right] = 1$, as needed.

Algorithm 1 L^1 monotonicity tester for Lipschitz functions using partial derivative queries.

```
    Input: Partial derivative oracle access to Lipschitz function $f : [0,1]^n \to \mathbb{R}$.
    Output: Accept if $f$ is monotone, reject if $d_1(f) > \epsilon$.
    Requirement: $\mathsf{Lip}_1(f) \le L$.
  procedure PartialDerivativeTester($f, L, \epsilon$)
      repeat $\Theta(nL/\epsilon)$ times
          Sample $x \in [0,1]^n$ uniformly at random.
          Sample $i \in [n]$ uniformly at random.

4 Application to monotonicity testing

In this section, we use the directed Poincaré inequality on the unit cube to show that the natural partial derivative tester attains the upper bound from Theorem 1.4. As noted in the introduction, we refer to the full version of the paper for the case of the hypergrid.

The tester is given in Algorithm 1. It is clear that this algorithm is a nonadaptive partial derivative tester, and that it always accepts monotone functions. It suffices to show that it rejects with good probability when $d_1(f) > \epsilon$.

▶ **Lemma 4.1.** *Let $f : [0,1]^n \to \mathbb{R}$ be a Lipschitz function satisfying $\mathsf{Lip}_1(f) \le L$. Suppose $d_1(f) > \epsilon$. Then Algorithm 1 rejects with probability at least $2/3$.*

Proof. Let $D \subseteq [0,1]^n$ be a measurable set such that f is differentiable on D and $\mu(D) = 1$, which exists by Rademacher's theorem. For each $i \in [n]$, let $S_i := \{x \in D : \partial_i f(x) < 0\}$. A standard argument gives that each $S_i \subset \mathbb{R}^n$ is a measurable set. We claim that

$$\sum_{i=1}^{n} \mu(S_i) > \frac{\epsilon}{2L} .$$

Suppose this is not the case. By the Lipschitz continuity of f, we have that $|\partial_i f(x)| \le L$ for every $x \in D$ and $i \in [n]$, and therefore

$$2 \sum_{i=1}^{n} \mathbb{E}\left[\left|\partial_i^- f\right|\right] \le 2L \sum_{i=1}^{n} \mu(S_i) \le \epsilon .$$

On the other hand, the assumption that $d_1(f) > \epsilon$ and Corollary 3.15 yield

$$\epsilon < \mathbb{E}\left[|f - f^*|\right] \le 2\mathbb{E}\left[\|\nabla^- f\|_1\right] = 2 \sum_{i=1}^{n} \mathbb{E}\left[\left|\partial_i^- f\right|\right] ,$$

a contradiction. Therefore the claim holds.

Now, the probability that one iteration of the tester rejects is the probability that $x \in S_i$ when x and i are sampled uniformly at random. This probability is

$$\mathbb{P}\left[\text{Iteration rejects}\right] = \sum_{j=1}^{n} \mathbb{P}_i\left[i = j\right] \mathbb{P}_x\left[x \in S_j\right] = \sum_{j=1}^{n} \frac{1}{n} \cdot \mu(S_j) > \frac{\epsilon}{2nL} .$$

Thus $\Theta\left(\frac{nL}{\epsilon}\right)$ iterations suffice to reject with high constant probability. ◀

Abstract

In classical statistics and distribution testing, it is often assumed that elements can be sampled exactly from some distribution $\mathcal{P}$, and that when an element x is sampled, the probability $\mathcal{P}(x)$ of sampling x is also known. In this setting, recent work in distribution testing has shown that many algorithms are robust in the sense that they still produce correct output if the elements are drawn from any distribution $\mathcal{Q}$ that is sufficiently close to $\mathcal{P}$. This phenomenon raises interesting questions: under what conditions is a "noisy" distribution $\mathcal{Q}$ sufficient, and what is the algorithmic cost of coping with this noise?

In this paper, we investigate these questions for the problem of estimating the sum of a multiset of N real values $x_1, \ldots, x_N$. This problem is well-studied in the statistical literature in the case $\mathcal{P} = \mathcal{Q}$, where the Hansen-Hurwitz estimator [Annals of Mathematical Statistics, 1943] is frequently used. We assume that for some (known) distribution $\mathcal{P}$, values are sampled from a distribution $\mathcal{Q}$ that is pointwise close to $\mathcal{P}$. That is, there is a parameter $\gamma < 1$ such that for all x_i, $(1-\gamma)\mathcal{P}(i) \leq \mathcal{Q}(i) \leq (1+\gamma)\mathcal{P}(i)$. For every positive integer k we define an estimator ζ_k for $\mu = \sum_i x_i$ whose bias is proportional to γ^k (where our ζ_1 reduces to the classical Hansen-Hurwitz estimator). As a special case, we show that if $\mathcal{Q}$ is pointwise γ-close to uniform and all $x_i \in \{0, 1\}$, for any $\varepsilon > 0$, we can estimate μ to within additive error εN using $m = \Theta(N^{1-\frac{1}{k}} / \varepsilon^{2/k})$ samples, where $k = \lceil (\lg \varepsilon)/(\lg \gamma) \rceil$. We then show that this sample complexity is essentially optimal. Interestingly, our upper and lower bounds show that the sample complexity need not vary uniformly with the desired error parameter ε: for some values of ε, perturbations in its value have no asymptotic effect on the sample complexity, while for other values, any decrease in its value results in an asymptotically larger sample complexity.

1 Introduction

Consider the following simple problem. Let us have values $x_i \in \{0,1\}$ for $i \in [N]$ and assume we may sample i from a distribution $\mathcal{Q}$ that is pointwise γ-close to uniform (see Definition 2). It is easy to obtain an additive $\pm\gamma N$ approximation of the number of $1's$. But is it possible to get a better approximation using a number of samples that is sub-linear in N? We answer this question positively. Specifically, we solve a more general sum estimation problem, with the above problem being the simplest application. Additionally, we derive lower bounds showing that for a wide range of parameters, the sample complexity of our algorithm is asymptotically tight.

In full generality, estimating the sum of a (multi)set of numbers is a fundamental problem in statistics, and the problem plays an important role in the design of efficient algorithms for large datasets. The basic problem can be formulated as follows: given a multiset of N elements, $S = \{x_1, x_2, \ldots, x_N\}$, compute an estimate of the sum $\mu = \sum_{i\in[N]} x_i$.

Assume that the values x_i can be sampled according to some probability distribution $\mathcal{Q}$ over S (equivalently, over $[N]$). The classical work of Hansen and Hurwitz [12] examines the setting in which, when an element $x \in S$ is sampled, the probability $\mathcal{Q}(x)$ can be determined. They introduce the Hansen-Hurwitz estimator defined by

$$\mu_{\text{HH}} = \frac{1}{m}\sum_{j=1}^{m} \frac{X_j}{\mathcal{Q}(X_j)} \tag{1}$$

where $X_1, X_2, \ldots, X_m$ are samples taken from the distribution $\mathcal{Q}$. This estimator has been used extensively (though often implicitly) in sublinear algorithms [5, 20, 1, 14]. Hansen and Hurwitz prove that (1) is an accurate estimator of μ via the following theorem:

▶ **Theorem 1** (Hansen & Hurwitz, 1943 [12]). *The value μ_{HH} is an unbiased estimator of the sum μ (i.e., $\mathrm{E}(\mu_{HH}) = \mu$) and its variance is*

$$\mathrm{Var}[\mu_{HH}] = \frac{1}{m}\sum_{i=1}^{N} \mathcal{Q}(i)\left(\frac{x_i}{\mathcal{Q}(i)} - \mu\right)^2. \tag{2}$$

Theorem 1 can be applied to obtain probabilistic guarantees for estimating μ via sampling. For example, if one wishes to compute a $1\pm\varepsilon$ multiplicative estimate of μ with probability $1-\delta$, by Chebyshev's inequality, it suffices to take m sufficiently large that $\mathrm{Var}[\mu_{\text{HH}}]/(\varepsilon^2\mu^2) < \delta$.

In practice, it may however be unreasonable to assume that the probability distribution from which elements are sampled is known precisely. For example, the underlying process generating the samples may be noisy or may induce some underlying bias. We model this situation by assuming that the true sampling distribution $\mathcal{Q}$ is close to some known distribution $\mathcal{P}$. When an element x is sampled, the probability $\mathcal{P}(x)$ can be determined, but not the true probability $\mathcal{Q}(x)$. We assume that $\mathcal{Q}$ is *pointwise close* to $\mathcal{P}$ in the following sense. The assumption of pointwise closeness turns out to be necessary (as compared to weaker notions of closeness); see the discussion on page 4.

▶ **Definition 2.** *Let $\mathcal{P}$ and $\mathcal{Q}$ be probability distributions over a (multi)set S. Then for any $\gamma < 1$, we say that $\mathcal{Q}$ is* pointwise γ-close *to $\mathcal{P}$ if for every $x \in S$, we have*

$$(1-\gamma)\mathcal{P}(x) \le \mathcal{Q}(x) \le (1+\gamma)\mathcal{P}(x). \tag{3}$$

Given the situation above, one can apply the Hansen-Hurwitz estimator (1) with the known distribution $\mathcal{P}$ in place of the true sample distribution $\mathcal{Q}$. We define the *positive sum*, μ_+ to be

$$\mu_+ = \sum_{x \in S} |x| \,. \tag{4}$$

It is straightforward to show that the resulting estimator has bias at most $\gamma\mu_+$, and its variance increases by a factor of $1 + O(\gamma)$. However, the parameter γ may be too large to guarantee the desired error in the estimate of μ. For the above problem of estimating the sum of 0-1 values, this would lead to error of γN, while we want error of εN for $\varepsilon < \gamma$.[1]

Our setting is closely related to recent work in distribution testing. For example, it has been noted that many algorithms that rely on a probability oracle are “robust” in the sense that we may do distribution testing to within ε if the oracle’s answers have relative error of, say, $1 \pm \varepsilon/3$ [18, 3]. Our work goes further in the sense that our estimators work also in the setting when the error in the oracle’s answers is greater than the desired error parameter ε. Specifically, our goal is to characterize the (sample) complexity of a task as a function of the oracle error parameter γ and a desired approximation parameter ε. This can also be seen as a generalization of the learning-augmented distribution testing setting where γ is assumed to be constant [6].

1.1 Our Contributions

In this paper, our goal is to estimate the sum $\mu = \sum_{i=1}^{N} x_i$ with an error that is strictly less than the bias $\gamma\mu_+$ (Equation (4)) guaranteed by μ_{HH}. Specifically, given a desired error parameter ε with $0 < \varepsilon < \gamma$, we wish to estimate μ with bias close to $\varepsilon\mu_+$. In our setting, for each sample we are given a random index $i \in [N]$ drawn from the unknown distribution $\mathcal{Q}$, along with the value x_i and our estimate $\mathcal{P}(i)$ of the true probability $\mathcal{Q}(i)$. We introduce a family of estimators $\zeta_1, \zeta_2, \ldots$, where each ζ_k has bias at most $\gamma^k\mu_+$. To motivate the construction of ζ_k, we first re-write the Hansen-Hurwitz estimator in terms of the frequency vector of samples from S. Specifically, if $X_1, X_2, \ldots, X_m$ are the sampled elements, define the frequency vector $Y = (Y_1, Y_2, \ldots, Y_N)$ by

$$Y_i = |\{j : X_j = i\}| \,.$$

We define the estimator

$$\xi_1 = \frac{1}{m} \sum_{i=1}^{N} Y_i \cdot \frac{x_i}{\mathcal{P}(i)} .$$

Note that this estimator can be efficiently implemented, as the items that have not been sampled contribute 0 to the sum. We may thus implement this in time linear in the sample complexity, and do not need to take $O(N)$ time.

In the case where $\mathcal{P} = \mathcal{Q}$, ξ_1 is equivalent to the Hansen-Hurwitz estimator μ_{HH}. More generally, $\mathcal{Q}$ is pointwise γ-close to $\mathcal{P}$, and ξ_1 has bias at most $\gamma\mu_+$.

The estimator ξ_1 can be generalized as follows. Rather than sampling individual elements, we can examine h-wise collisions between samples, where an *h-wise collision* consists of h samples resulting in the same outcome.

[1] It is possible to get tighter bounds if parameterizing also by the sum, but for simplicity, we choose to parameterize the error only by N, ε, and γ.

▶ **Definition 3.** *For any positive integer h, we define the h-*wise collision estimator *ξ_h of $\mu = \sum_i x_i$ to be*

$$\xi_h = \frac{1}{\binom{m}{h}} \sum_{i=1}^{N} \binom{Y_i}{h} \frac{x_i}{(\mathcal{P}(i))^h}. \tag{5}$$

We note that $\binom{Y_i}{h}$ gives the number of h-wise collisions involving the value $X_j = i$. It is straightforward to show that when $\mathcal{Q} = \mathcal{P}$, all ξ_h are unbiased estimators for μ, and that ξ_h has bias $O(h\gamma\mu_+)$ when $\mathcal{Q}$ is pointwise γ-close to $\mathcal{P}$.

Individually, the estimators $\xi_1, \xi_2, \ldots$ are no better than $\xi_1 = \mu_{\mathrm{HH}}$ in terms of bias and variance. As we will show, however, for any positive integer k, a suitable linear combination of the ξ_i can be chosen such that the coefficients of γ^j in the bias cancel out for $j < k$. The resulting estimator then has bias $\leq \gamma^k \mu_+$.

▶ **Definition 4.** *For each positive integer k, we define the* bias reducing estimator of order *k, ζ_k, to be*

$$\zeta_k = \sum_{h=1}^{k} (-1)^{h+1} \binom{k}{h} \xi_h = \sum_{h=1}^{k} (-1)^{h+1} \frac{\binom{k}{h}}{\binom{m}{h}} \sum_{i \in [N]} \binom{Y_i}{h} \frac{x_i}{(\mathcal{P}(i))^h}. \tag{6}$$

▶ **Example 5.** In order to give some intuition about the expression (6), consider the case where $\mathcal{P}$ is the uniform distribution and $k = 2$. Define α_i to be such that $\mathcal{Q}(i) = (1 + \alpha_i)\mathcal{P}(i)$. Note that $|\alpha_i| \leq \gamma$ because $\mathcal{Q}$ is assumed to be pointwise γ-close to uniform. By a simple calculation, we have that $\mathrm{E}[\xi_1] = \sum_{i=1}^{N} (1 + \alpha_i) x_i$ and $\mathrm{E}[\xi_2] = \sum_{i=1}^{N} (1 + \alpha_i)^2 x_i = (1 + 2\alpha_i + \alpha_i^2) x_i$. Therefore, it holds that[2]

$$\mathrm{E}[\zeta_2] = \mathrm{E}[2\xi_1 - \xi_2] = \sum_{i=1}^{N} 2(1+\alpha_i)x_i - (1+2\alpha_i+\alpha_i^2)x_i = \sum_{i=1}^{n} (1+\alpha_i^2)x_i \subseteq \mu \pm \sum_{i=1}^{n} \alpha_i^2 |x_i| \subseteq \mu \pm \gamma^2 \mu_+.$$

This proves that the bias of the estimator is at most $\gamma^2 \mu_+$. Similarly, one can show that the bias of the estimator above is $\leq \gamma^k \mu_+$. We prove this in Section 2.

▶ **Theorem 6** (Bias portion of Theorem 10)**.** *Supoose $\mathcal{P}$ and $\mathcal{Q}$ are probability distributions over $[N]$ with $\mathcal{Q}$ pointwise γ-close to $\mathcal{P}$. Let ζ_k be defined as in (6). Then*

$$|\mathrm{E}[\zeta_k - \mu]| \leq \gamma^k \mu_+.$$

In particular, if $x_i \geq 0$ for all i, then ζ_k has bias at most $\gamma^k \mu$.

This theorem shows that ζ_k reduces the bias to γ^k compared to the bias γ for the Hansen-Hurwitz estimator (equivalent to ζ_1). Theorem 10 additionally bounds the variance of ζ_k, which is required for our applications.

We apply Theorem 6 (or more specifically, Theorem 10) to obtain our main algorithmic results. Our goal is as follows: given sample access to some $\mathcal{Q}$ that is pointwise γ-close to $\mathcal{P}$ and a desired error parameter ε, estimate μ with error ε using as few samples as possible. To this end, we employ a two-stage estimation technique (see Algorithm 2). In the first stage, we use the 1-wise collision estimator ξ_1 (i.e., the Hansen-Horwitz estimator) to obtain a coarse estimate of μ. Then, the second stage refines this estimate by applying the bias reducing estimator ζ_k with an appropriately chosen k. Specifically, we show the following:

[2] The first of the two inclusions is not tight in that the absolute value in $|x_i|$ is not necessary, but it becomes necessary for odd values of k.

▶ **Theorem 7** (Special case of Theorem 10). *Define $n = \max_i 1/\mathcal{P}(i)$.*[3] *Suppose $\mathcal{Q}$ is pointwise γ-close to $\mathcal{P}$, and let $\mathrm{Var}_{\mathrm{HH}}$ be defined as*

$$\mathrm{Var}_{\mathrm{HH}} = \frac{1}{N^2}\sum_{i=1}^{N} \mathcal{Q}(i)\left(\frac{x_i}{\mathcal{Q}(i)} - \mu\right)^2. \tag{7}$$

That is, $\mathrm{Var}_{\mathrm{HH}}$ is the variance of the Hansen-Hurwitz estimator for the mean *μ_{HH}/N with sample size $m = 1$ (cf. (Equation 2)). For $\varepsilon_1, \varepsilon_2 > 0$, define $k = \lceil (\log \varepsilon_1)/\log \gamma) \rceil$. Then using*

$$m = O\left(\sqrt[k]{n^{k-1}\varepsilon_2^{-2}\,\mathrm{Var}_{\mathrm{HH}}}\right)$$

independent samples from $\mathcal{Q}$, with probability at least $2/3$, Algorithm 2 produces an estimate $\hat{\mu}$ of $\mu = \sum_i x_i$ with absolute error

$$|\mu - \hat{\mu}| \le \varepsilon_1 \mu_+ + \varepsilon_2.$$

To understand the complexity of this algorithm, we note that when $\mathcal{P} = \mathcal{Q}$, in order to get an error ε_2 the complexity of the Hansen-Hurwitz estimator is $\varepsilon_2^{-2}\,\mathrm{Var}_{\mathrm{HH}}$. The complexity of our algorithm can thus be seen as a weighted geometric average between the complexity of the Hansen-Hurwitz estimator, and n.

As a corollary of Theorem 7, we obtain a solution to the aforementioned problem of estimating a sum of 0-1 values.

▶ **Corollary 8.** *Suppose $\mathcal{Q}$ is pointwise γ-close to the uniform distribution over $[N]$ and $x_i \in [0,1]$ for every $i \in [N]$. For any $\varepsilon > 0$ define $k = \lceil (\log \varepsilon)/\log \gamma \rceil$. Then $m = O(N^{1-1/k}\varepsilon^{-2/k})$ samples are sufficient to obtain an estimate of $\mu = \sum_i x_i$ with additive error εN with probability $2/3$.*

We note that the asymptotic sample complexities in Theorem 7 and Corollary 8 are non-uniform in γ and ε. In the case of Corollary 8, for any fixed postive integer k and constant $\gamma > 0$, if $\varepsilon = \gamma^k$, then $O(N^{1-1/k})$ samples are sufficient to obtain an εN additive estimate. On the other hand, if $\gamma^{k+1} \le \varepsilon < \gamma^k$, then our algorithm uses $O(N^{1-1/(k+1)})$ samples. Our next main result shows that this sample complexity is essentially optimal, and perhaps surprisingly, that the non-uniformity of the sample complexity is unavoidable. Specifically, we show the following lower bound.

▶ **Theorem 9.** *Suppose $x_1, x_2, \ldots, x_N \in \{0,1\}$ and N is a parameter. Then for every positive integer k, there exists a positive constant c_k such that for $\varepsilon \le c_k\gamma^k$, there is a sequence of distributions on $[N]$ that are γ-close to uniform such that the number of samples required to estimate μ within error εN is $\Omega(N^{1-1/(k+1)})$.*

This lower bound matches the upper bound of Corollary 8 for a large range of parameters. When $\gamma \le c_k$ (where c_k is as in the conclusion of the theorem), our algorithm has sample complexity $O(N^{1-1/(k+1)})$ for all $\varepsilon \in [\gamma^{k+1}, \gamma^k)$, while the lower bound shows $\Omega(N^{1-1/(k+1)})$ samples are necessary for all $\varepsilon \in [\gamma^{k+1}, c_k\gamma^k]$. Interestingly, these matching upper and lower bounds show that the asymptotic sample complexity is non-uniform as a let of ε for any fixed (sufficiently small) γ: for every $\varepsilon \in [\gamma^{k+1}, c_k\gamma^k]$, exactly $\Theta(N^{1-1/(k+1)})$ samples are

[3] Note that $N \le n$, where N is the size of the multiset being sampled. In the case where $\mathcal{P}(i) = \Omega(1/N)$ for all i, we have $n = \Theta(N)$. The convention of defining n in this way was previously used in [6].

necessary and sufficient, while for $\varepsilon = \gamma^k$, $\Theta(N^{1-1/k})$ samples are necessary and sufficient. Thus, as a function ε, the sample complexity contains "islands of stability" – intervals in which some perturbations of ε have no effect on the asymptotic sample complexity – while between these intervals, an arbitrarily small (constant) decrease in ε results in a polynomial (in N) increase in the sample complexity.

Discussion and Related Work

Throughout the paper, we assume that the probability distribution $\mathcal{Q}$ from which samples are generated is pointwise close to $\mathcal{P}$ in the sense of Definition 2. Pointwise closeness is a strictly stronger (and less commonly used) distance measure than, for example, total variation distance (i.e., L_1 distance) or other L_p distances. Nonetheless, this relatively strong assumption about the relationship between $\mathcal{P}$ and $\mathcal{Q}$ is necessary in order to obtain any non-trivial guarantee for estimating μ.[4] Algorithms for generating samples with pointwise approximation guarantees have been studied in the context of sublinear time algorithms [10, 18, 8, 7, 6, 20, 9] as well as Markov chains [16, 13]. In the latter case, *uniform mixing time* gives a bound on complexity of obtaining samples with pointwise guarantees. Interestingly, Hermon [13] shows a result that can be viewed as an analogue of our lower bound for Markov chains (specifically random walks on bounded degree graphs). Namely, small perturbations in the transition probabilities of edges can result in an asymptotic increases in the uniform mixing time.

The problem of estimating the sum is well-studied in statistics. Classical estimators for non-uniform sampling probabilities are described by Hansen and Hurwitz [12] and Horvitz and Thompson [15]. Sum estimation in the related setting where we do not know the sampling probabilities but know that they are proportional to the items' values has been studied in [17, 2].

Open problem: Sample correctors for uniform sampling

Finally, we state one interesting open problem. The concept of sample correctors from [4] assumes that we may sample from a distribution that is close to some property, and we want to be able to use it to sample from a distribution even closer to satisfying the property. It is natural to ask if one can use $o(n)$ samples from a distribution pointwise γ-close to uniform and simulate a sample with bias $o(\gamma)$.

1.2 Technical Overview

Upper Bound

The goal is to reduce the bias from γ to γ^k. Now the main observation that guides our construction is the following identity:

$$1 + (-1)^{k+1}\gamma^k = \sum_{h=1}^{k} (-1)^{h+1} \binom{k}{h} (1+\gamma)^h \ . \tag{8}$$

This should be compared to our estimator, $\zeta_k = \sum_{h=1}^{k}(-1)^{h+1}\binom{k}{h}\xi_h$, which clearly mirrors the identity. The reason for this is that the probability of an h-wise collision on position $i \in [N]$ is $\mathcal{Q}(i)^h \approx (1+\gamma)^h \mathcal{P}(i)^h$ in the worst case when $\frac{\mathcal{Q}(i)}{\mathcal{P}(i)} = 1+\gamma$. Hence the expectation of the h-wise collision estimator, ξ_h, is approximately bounded by $(1+\gamma)^h\mu$. This implies that

[4] As an extreme example, consider the case where only a γ-fraction of values x_i are nonzero. If $\mathcal{P}$ is uniform, then $\mathcal{Q}$ can assign zero mass to the nonzero elements, and still be γ-close to $\mathcal{P}$ with respect to total variation distance. Thus, *any* estimator will return a value that is independent of the actual sum.

when we take the expectation of our estimator then the expression reduces to Equation (8) which shows that the bias is reduced to γ^k. Here, we cheated slightly by assuming that the bias is the same for all the positions $i \in [N]$. This is of course not true, but actual calculation reduces to N instances of Equation (8).

The more delicate part of the analysis of our estimator is the bound on the variance. The main difficulty lies in rewriting $\zeta_k - \mathrm{E}[\zeta_k]$ into something manageable. We note that we can write our estimator ζ_k as

$$\zeta_k = \sum_{i\in[N]} x_i \sum_{h=1}^{k} (-1)^{h+1} \frac{\binom{k}{h}}{\binom{m}{h}} \frac{\binom{Y_i}{h}}{(\mathcal{P}(i))^h} \ .$$

We can express the frequency vector Y by random variables as follows: $Y_i = \sum_{j\in[m]}[X_j = i]$. (Here, we use $[X_j = i]$ to denote the indicator random variable of the event $X_j = i$.) This allows us to see that $\binom{Y_i}{h} = \sum_{\substack{I\subseteq[m]\\|I|=h}} \prod_{j\in I}[X_j = i]$. If we now define the polynomials P_i by

$$P_i(\beta_1, \dots, \beta_m) = \sum_{h=1}^{k} (-1)^{h+1} \frac{\binom{k}{h}}{\binom{m}{h}} \frac{1}{(\mathcal{P}(i))^h} \sum_{\substack{I\subseteq[m]\\|I|=h}} \prod_{j\in I} \beta_j \ ,$$

then we can write our estimator as $\zeta_k = \sum_{i\in[N]} x_i P_i([X_1 = i], \dots, [X_m = i])$. We observe that P has degree 1 in each variable so $\mathrm{E}[P_i([X_1 = i], \dots, [X_m = i])] = P_i(\mathcal{Q}(i), \dots, \mathcal{Q}(i))$. Furthermore, it seems reasonable that there should exist polynomials Q_i which have degree 1 in each variable and satisfy $P_i([X_1 = i], \dots, [X_m = i]) - P_i(\mathcal{Q}(i), \dots, \mathcal{Q}(i)) = Q_i([X_1 = i] - \mathcal{Q}(i), \dots, [X_m = i] - \mathcal{Q}(i))$. This will help us in understanding the variance of our final estimator ζ_k by decomposing into variances of the simpler events $[X_1 = i]$. We show that Q_i exist and are defined as follows

$$Q_i(\beta_1, \dots, \beta_m) = (-1)^{k+1} \sum_{h=1}^{k} \frac{\binom{k}{h}}{\binom{m}{h}} \frac{\gamma_i^{k-h}}{(\mathcal{P}(i))^h} \sum_{\substack{I\subseteq[m]\\|I|=h}} \prod_{j\in I} \beta_j$$

So we get that $\zeta_k - \mathrm{E}[\zeta_k] = \sum_{i\in[N]} x_i Q_i([X_1 = i] - \mathcal{Q}(i), \dots, [X_m = i] - \mathcal{Q}(i))$. Since $[X_1 = i] - \mathcal{Q}(i)$ is a zero mean variable and Q_i has degree 1 in each variable, it becomes easy to calculate the variance.

A technical detail that we have not touched upon yet is that if $k \geq 2$ then $\mathrm{Var}[\zeta_k]$ becomes very large if $\mu^2 \gg \mathrm{Var}[\mu_{\mathrm{HH}}]$. The reason is that $\mathrm{Var}[\zeta_k]$ depends on $\sum_{i\in[N]} \mathcal{P}(i) \left(\frac{x_i}{\mathcal{P}(i)}\right)^2 = \mathrm{Var}[\mu_{\mathrm{HH}}] + \mu^2$. Thus, if $\mu^2 \gg \mathrm{Var}[\mu_{\mathrm{HH}}]$ then our variance becomes much larger which is a problem. Now imagine that we already have an estimate, W, of μ. We then set $\bar{x}_i = x_i - \mathcal{P}(i)W$ and make a new estimator $\bar{\zeta}_k$ that uses $\bar{x}_i$ instead of x_i. Then $\bar{\zeta}_k$ will estimate $\mu - W$ so $\bar{\zeta}_k + W$ will be an estimator of μ. The trick is that $\mathrm{Var}[\bar{\zeta}_k]$ depends on $\mathrm{Var}[\mu_{\mathrm{HH}}] + (\mu - W)^2$ so if $W = \mu + O(\sqrt{\mathrm{Var}[\mu_{\mathrm{HH}}]})$ then we will have control over the variance. We can get such estimate, W, by using our estimator for $k = 1$ where there are no issues with variance (i.e., the standard deviation of $W - \mu$ only depends on $\sqrt{\mathrm{Var}[\mu_{\mathrm{HH}}]}$ rather than on μ).

Lower Bound

At a high level, our strategy is to define a reduction from the problem of distinguishing two distributions D_1 and D_2 to the problem of estimating $\mu = \sum_i x_i$. More concretely, for each fixed positive integer k, we define distributions D_1 and D_2 with support sizes n_1 and n_2, respectively, such that:

1. $n_1 = (1 + (\Theta(\gamma))^k)n_2$,
2. D_1 and D_2 are both pointwise γ-close to uniform, and
3. D_1 and D_2 have identical p^{th} frequency moments for $p = 1, 2, \ldots, k$.[5]

We describe a reduction showing that for $N = n_1 + n_2$, $\mathcal{P}$ uniform over $[N]$, and $x_i \in \{0, 1\}$ for all $i \in [N]$, any algorithm that distinguishes $\mu = n_1$ from $\mu = n_2$ can also distinguish D_1 from D_2. We then apply a framework of Raskhodnikova et al. [19], which implies that distinguishing any two distributions whose first k frequency moments are equal requires $\Omega(n^{1-1/(k+1)})$ samples. One difference between our setting and that of [19] is that in our setting, for each sample i we are also given x_i, whereas [19] focuses on support size estimation. However, since the x_i's are 0 or 1-valued, estimating the sum requires us to estimate either the number of x_i's which are 0 or the number of x_i's which are 1. We can apply this observation to reduce the problem to finding two nearly uniform distributions (i.e., both are pointwise γ-close to uniform) that differ in support size by a multiplicative $1 \pm \Theta(\gamma)^k$ factor, yet match in the first k moments.

To do this, we use a combinatorial construction that is inspired by a related lower bound in [6]. For simplicity, we assume that the probability of sampling any fixed item lies in $\{\frac{1}{n}, \frac{1+\gamma}{n}, \ldots, \frac{1+k\gamma}{n}\}$ (while these distributions would only be $k \cdot \gamma$-close to uniform, we can replace γ with γ/k). For the distribution D_1, we assume the number of elements with probability $\frac{1+i\cdot\gamma}{n}$ is a_i, and for the distribution D_2 the number of elements with probability $\frac{1+i\cdot\gamma}{n}$ is b_i. Then, our goal is for the support sizes of D_1 and D_2 (which are $\sum a_i, \sum b_i$, respectively) to differ significantly but for the first k moments to match. This means $\sum a_i$ and $\sum b_i$ differ significantly, but $\sum a_i(1 + i \cdot \gamma)^\ell = \sum b_i(1 + i \cdot \gamma)^\ell$. If we define $c_i := a_i - b_i$ and think of $(1 + i \cdot \gamma)^\ell$ as a degree ℓ polynomial $P(i)$, we want $\sum c_i P(i) = 0$ but $\sum c_i$ to be large (roughly $\gamma^k \cdot n$). Finally, we need to make sure that $\sum a_i, \sum b_i$ are both $\Theta(n)$.

To determine the values of each c_i, we utilize the observation that for any polynomial $P(x)$ of degree less than k, the successive differences, i.e., $P(x) - P(x - 1)$ is a polynomial of degree less than $k - 1$. We can repeatedly take successive differences k times to get a linear combination of $P(0), P(1), \ldots, P(k)$ that equals 0 for any polynomial P of degree less than k. We can therefore set $c_i := a_i - b_i$ to be these linear coefficients. Unfortunately, we will have $\sum c_i = 0$ as well. Instead, we replace c_i with $c'_i := c_i/(1 + i\gamma)$, so that $\sum c'_i \cdot (1 + i \cdot \gamma)^\ell = \sum c_i \cdot (1 + i \cdot \gamma)^{\ell-1} = 0$ for all $1 \le \ell \le k$. However, $\sum c'_i = \sum c_i/(1 + i \cdot \gamma)$ is not expressible as $\sum c_i P(i)$ for a polynomial P of low degree, and will in fact be nonzero, which is exactly what we want. We scale the c'_i terms so that $\sum c'_i = \gamma^k \cdot n$. If we write $a_i = \max(c'_i, 0)$ and $b_i = \max(-c'_i, 0)$, then every a_i and b_i is nonnegative but $a_i - b_i = c'_i$. One can show via some careful combinatorics that after this scaling, $\sum a_i$ and $\sum b_i$ are both $\Theta(n)$, as desired.

2 Sum Estimation

We now give the algorithm for the sum estimation problem. We then state our main result (Theorem 10) as well as the special case for estimating the sum of 0-1 values (Corollary 8) that we discussed in the introduction. We then state and prove Lemma 12 which we then use to prove Theorem 10.

We now state our main theorem. Note that this implies, by a simple substitution, the simpler version mentioned in the introduction as Theorem 7.

[5] Recall that the p^{th} frequency moment of a distribution D is $\sum_x (D(x))^p$.

Algorithm 1 *EstimateSum*(m, k, W).

```
$(X_j)_{j\in[m]} \leftarrow$ take $m$ samples from the distribution $\mathcal{Q}$
For every $i \in [N]$, let $Y_i$ denote the number of times value $i$ was sampled
  $(Y_i = \sum_{j\in[m]}[X_j = i]$ )
For every $h \in [k]$, let $\xi_h$ be the $h$-wise collision estimator
  $(\xi_h = \frac{1}{\binom{m}{h}} \sum_{i=1}^{N} \binom{Y_i}{h} \frac{x_i - \mathcal{P}(i)W}{(\mathcal{P}(i))^h}$ )
return $W + \sum_{h=1}^{k} (-1)^{h+1} \binom{k}{h} \xi_h$
```

Algorithm 2 *ImprovedEstimateSum*(m, t, k).

```
$W \leftarrow EstimateSum(t, 1, 0)$
return $EstimateSum(m, k, W)$
```

▶ **Theorem 10.** *Define $n = \max_i 1/\mathcal{P}(i)$. Suppose $\mathcal{Q}$ is pointwise γ-close to $\mathcal{P}$, and let $\mathrm{Var}_{\mathrm{HH}}$ be the variance of μ_{HH}/N defined in Equation (7). For $\varepsilon_1, \varepsilon_2 > 0$, define $k = \lceil (\lg \varepsilon_1)/\lg \gamma)\rceil$. Then using*

$$m = O\left(\sqrt[k]{n^{k-1}\varepsilon_2^{-2}\,\mathrm{Var}_{\mathrm{HH}}}\right)$$

independent samples from $\mathcal{Q}$, with probability at least $2/3$, Algorithm 2 produces an estimate $\hat{\mu}$ of $\mu = \sum_i x_i$ with absolute error

$$|\mu - \hat{\mu}| \le \varepsilon_1(1+\gamma) \mathop{\mathrm{E}}_{X\sim\mathcal{P}}[|\mathcal{P}(X)^{-1}x_X - \mu|] + \varepsilon_2$$

This theorem implies in a straightforward way a solution to the problem of estimating the sum of 0-1 values that we discussed in the introduction.

▶ **Corollary 11.** *Suppose $\mathcal{Q}$ is pointwise γ-close to the uniform distribution over $[N]$ and $x_i \in \{0,1\}$ for every $i \in [N]$. For any $\varepsilon > 0$ define $k = \lceil (\log \varepsilon)/\log \gamma\rceil$. Then $m = O(n^{1-1/k}\varepsilon^{-2/k})$ samples are sufficient to obtain an estimate of $\mu = \sum_i x_i$ with additive error $\varepsilon(\mu + \sqrt{\mu N})$ with probability $2/3$.*

Before we can prove our main result, we need the following lemma.

▶ **Lemma 12** (Analysis of *EstimateSum*$(m, k, 0)$)**.** *Define $n = \max_i 1/\mathcal{P}(i)$. Let $(x_i)_{i\in[N]}$ be a sequence of numbers and define $\mu = \sum_{i\in[N]} x_i$. Let $\mathcal{P}$ be a probability distribution over $[N]$, and let $\mathcal{Q}$ be another probability distribution over $[N]$ that is pointwise γ-close to $\mathcal{P}$.*

Consider a sequence $(X_j)_{j\in[m]}$ of independent random variables both with distribution $\mathcal{Q}$. Define $Y_i = \sum_{j\in[m]}[X_j = i]$ for every $i \in [N]$. Define

$$\zeta_k = \sum_{h=1}^{k} (-1)^{h+1} \frac{\binom{k}{h}}{\binom{m}{h}} \sum_{i\in[N]} \binom{Y_i}{h} \mathcal{P}(i)^{-h} x_i \; .$$

Then for $k \ge 2$, we get that

$$|\operatorname{E}[\zeta_k] - \mu| \le \gamma^k \sum_{i\in[N]} |x_i| \tag{9}$$

$$\mathrm{Var}[\zeta_k] \le \max\left\{2(1+\gamma)\gamma^{2k-2}k^2 \frac{\sum_{i\in[N]} \mathcal{P}(i)^{-1}x_i^2}{m}, 2^k(1+\gamma)^k k^{3k} \frac{n^{k-1}\sum_{i\in[N]} \mathcal{P}(i)^{-1}x_i^2}{m^k}\right\} , \tag{10}$$

and for $k = 1$, we get that

$$|\operatorname{E}[\zeta_1] - \mu| \leq \gamma \sum_{i \in [N]} |x_i - \mathcal{P}(i)\mu| \tag{11}$$

$$\operatorname{Var}[\zeta_1] \leq (1+\gamma)\frac{\sum_{i \in [N]} \mathcal{P}(i)^{-1}(x_i - \mathcal{P}(i)\mu)^2}{m} \tag{12}$$

We are now ready to prove the main theorem.

Proof of Theorem 10. Let W be an estimate of μ using $\mathit{EstimateSum}(t, 1, 0)$ where $t = O(1 + \gamma^{2k}\varepsilon_2^{-2}\operatorname{Var}_{\mathrm{HH}})$. Using Lemma 12 we get an estimate of the bias and the variance. Now by Chebyshev's inequality, we easily get that $|W - \mu| \leq \gamma \sum_{i \in [N]} \mathcal{P}(i)|\mathcal{P}(i)^{-1}x_i - \mu| + \max\left\{\varepsilon_2/(2\gamma^k), \sqrt{\sum_{i \in [N]} \mathcal{P}(i)(\mathcal{P}(i)^{-1}x_i - \mu)^2}\right\}$ with probability 5/6. We note that $\sum_{i \in [N]} \mathcal{P}(i)|\mathcal{P}(i)^{-1}x_i - \mu| \leq \sqrt{\sum_{i \in [N]} \mathcal{P}(i)(\mathcal{P}(i)^{-1}x_i - \mu)^2}$ since p-norms are increasing. So we also get that $|W - \mu| \leq O(\sqrt{\sum_{i \in [N]} \mathcal{P}(i)(\mathcal{P}(i)^{-1}x_i - \mu)^2})$

Now we calculate ζ using $\mathit{EstimateSum}(m, k, W)$ with $m = O\left(\sqrt[k]{n^{k-1}\varepsilon_2^{-2}\operatorname{Var}_{\mathrm{HH}}}\right)$ so ζ corresponds to $\mathit{ImprovedEstimateSum}(m, t, k)$. We now note that by Lemma 12,

$$\begin{aligned}|(\operatorname{E}[\zeta] - W) - (\mu - W)| &\leq \gamma^k \sum_{i \in [N]} \mathcal{P}(i)|\mathcal{P}(i)^{-1}x_i - W| \\ &\leq \gamma^k|W - \mu| + \gamma^k \sum_{i \in [N]} \mathcal{P}(i)|\mathcal{P}(i)^{-1}x_i - \mu|,\end{aligned}$$

and

$$\begin{aligned}\operatorname{Var}[\zeta] \leq \max\Bigg\{ & 2(1+\gamma)\gamma^{2k-2}k^2\frac{\sum_{i \in [N]} \mathcal{P}(i)(\mathcal{P}(i)^{-1}x_i - W)^2}{m}, \\ & 2^k(1+\gamma)^k k^{3k}\frac{n^{k-1}\sum_{i \in [N]} \mathcal{P}(i)(\mathcal{P}(i)^{-1}x_i - W)^2}{m^k}\Bigg\} \\ = \max\Bigg\{ & 2(1+\gamma)\gamma^{2k-2}k^2\frac{\sum_{i \in [N]} \mathcal{P}(i)(\mathcal{P}(i)^{-1}x_i - \mu)^2 + (W-\mu)^2}{m}, \\ & 2^k(1+\gamma)^k k^{3k}\frac{n^{k-1}\left(\sum_{i \in [N]} \mathcal{P}(i)(\mathcal{P}(i)^{-1}x_i - W)^2 + (W-\mu)^2\right)}{m^k}\Bigg\}\end{aligned}$$

Assuming that

$$|W - \mu| = \gamma \sum_{i \in [N]} \mathcal{P}(i)|\mathcal{P}(i)^{-1}x_i - \mu| + \max\left\{\varepsilon_1/(2\gamma^k), \sqrt{\sum_{i \in [N]} \mathcal{P}(i)(\mathcal{P}(i)^{-1}x_i - \mu)^2}\right\},$$

we get that $|(\operatorname{E}[\zeta] - W) - (\mu - W)| \leq \gamma^k(1+\gamma)\sum_{i \in [N]} \mathcal{P}(i)|\mathcal{P}(i)^{-1}x_i - \mu| + \varepsilon_2/2$. Using that $|W - \mu| \leq O(\sqrt{\sum_{i \in [N]} \mathcal{P}(i)(\mathcal{P}(i)^{-1}x_i - \mu)^2})$ we can then use Chebyshev's inequality to conclude that with probability 5/6

$$|\zeta - \operatorname{E}[\zeta]| \leq \varepsilon_2/2$$

So all in all, with probability at least 2/3 we that $|\zeta - \mu| \leq \varepsilon_1(1+\gamma)\sum_{i \in [N]} \mathcal{P}(i)|\mathcal{P}(i)^{-1}x_i - \mu| + \varepsilon_2$. ◀

3 Lower Bound

In this section, we prove that for a range of parameters – specifically in the setting of Corollary 11 – the sample complexity of our sum estimation algorithm (Algorithm 2) is asymptotically tight.

▶ **Theorem 13.** *Let k be a positive integer and let $\varepsilon < \gamma < 1$ be positive numbers. Suppose A is an algorithm such that for any $v \in \{0,1\}^N$ and any distribution $\mathcal{P}$ over $[N]$ that is pointwise γ-close to uniform, A uses samples from $\mathcal{P}$ and returns an estimate of $\|v\|_1 = \sum_i v_i$ within additive error εN with probability $2/3$. Then there exists c_k with $0 < c_k < 1$ such that if $\varepsilon \leq c_k \gamma^k$ then A requires $\Omega(N^{1-1/(k+1)})$ samples.*

While at a first glance this result might seem contradictory to our upper bound (specifically, Corollary 8), it actually reveals the following interesting phenomena. Notice that in our upper bound, the complexity depends on $k = \lceil (\log \varepsilon)/\log \gamma \rceil$, so that, e.g., for $\varepsilon = \gamma^k$, the complexity is $O(N^{1-\frac{1}{k}})$. Once ε becomes slightly smaller, i.e., $\varepsilon = c\gamma^k$ for c satisfying $\gamma \leq c < 1$, the complexity of our algorithm abruptly jumps to $O(n^{1-\frac{1}{k+1}})$. The lower bound implies that this increase in complexity is unavoidable for sufficiently small c. That is, Theorem 13 states that there exists a (sufficiently small) constant c_k, such that indeed once $\varepsilon = c_k \cdot \gamma^k$, the required number of samples is $\Omega(n^{1-\frac{1}{k+1}})$. Interestingly, for all ε satisfying $\gamma^{k+1} \leq \varepsilon \leq c_k\gamma^k$, the asymptotic complexity of sum estimation is the same; the complexity only varies for ε satisfying $c_k\gamma^k \leq \varepsilon \leq \gamma^k$. Our matching upper and lower bounds demonstrate that the sample complexity's non-uniform dependence on ε is not an artifact, but captures the true complexity of the problem (up to the dependency on $\gamma^{k/2}$ in the numerator of the upper bound). Note that if the conclusion of Theorem 13 held *every* $c < 1$, then this would capture the right dependency on n for *all* possible ranges of γ. Since we only prove the theorem for a sufficiently small c_k, it might be the case that for values ε that are not too much smaller than γ^k, the optimal dependency on N is lower than our stated upper bound. Nonetheless, our upper and lower bounds match (up to constant factors) for all ε satisfying $\gamma^{k+1} \leq \varepsilon \leq c_k\gamma^k$.

As described in Section 1.2, the main technical ingredient in the proof of the theorem is in describing two distributions D_1 and D_2 over ranges $[n_1], [n_2]$, respectively, such that D_1 and D_2 are pointwise γ-close to uniform, $n_1 = (1 + \Theta(\gamma)^k)n_2$, and D_1 and D_2 have matching frequency moments 1 through k. Given these distributions we rely on the framework for proving lower bounds by Raskhodnikova et al. [19], which states that any uniform algorithm that distinguishes two random variables with matching frequency moments 1 through k must perform $\Omega(n^{1-1/(k+1)})$ many samples.

In order to simplify our construction and its analysis, we prove the lower bound for *uniform algorithms*. Here, a uniform algorithm is an algorithm whose output depends only on the "collision statistics" of the samples – i.e., the number of collisions involving each sample, and not the identities of the samples themselves.

▶ **Definition 14** (Uniform algorithm. Definition 3.2 in [19])**.** *An algorithm is* uniform *if it samples indices $i_1, \cdots, i_m$ independently with replacement and its output is uniquely determined by (i) the value of the items x_{i_j} and (ii) the set of collisions, where two indices j and j'* collide *if $i_j = i_{j'}$.*

In particular, a uniform algorithm's output does *not* depend on the sampled indices themselves. The following lemma asserts that our restriction to uniform algorithms is without loss of generality.

▶ **Lemma 15** (cf. Theorem 11.12 in [11]). *Suppose there exists an algorithm A such that for any $v \in \{0,1\}^N$ A uses samples from $\mathcal{P}$ and returns an estimate of $\|v\|_1 = \sum_i v_i$ within additive error εN with probability $2/3$ using s samples in expectation. Then there exists a uniform algorithm A' that achieves the same approximation guarantee using s samples in expectation.*

The proof of Lemma 15 is essentially the same as that of Goldreich's Theorem 11.12 in [11]. The key idea is that $\sum_i v_i$ is a "label invariant" in the sense that it is unaffected by any permutation of the indices of v. Thus, given an algorithm A as in the hypothesis of Lemma 15, we can obtain uniform algorithm A' with the same approximation guarantee by simply choosing a uniformly random permutation of the indices of v, then using the permuted indices of v as inputs for A. See Theorem 11.12 in [11] for details.

Finally, our lower bound argument requires the following result that is a direct consequence of the work of Raskhodnikova et al. [19].

▶ **Theorem 16** (Consequence of Lemma 5.3 and Corollary 5.7 from [19]). *Let D_1 and D_2 be distributions over positive integers $b_1 < \ldots < b_\ell$, that have matching frequency moments 1 through k. Then for any uniform algorithm A with sample complexity s that distinguishes D_1 and D_2 with high constant probability, $s = \Omega(n^{1-1/(k+1)})$.*

Our main argument for the lower bound applies Theorem 16 in conjunction with a reduction from distinguishing D_1 and D_2 to sum estimation. The main technical ingredient is the following lemma, which asserts the existence of suitable distributions D_1 and D_2.

▶ **Lemma 17.** *For every positive integer k and sufficiently large integer n, there exist two distributions D_1, D_2 over $[n_1]$ and $[n_2]$ (respectively) satisfying $n_1 = (1+\Theta(\gamma)^k)n$, and $n_2 = n$ such that $p_{D_j}(i) \in (1 \pm \gamma)\frac{1}{n}$ for $j \in \{1,2\}$ and the following holds. For all $\ell \in \{1, 2, \ldots, k\}$, it holds that*

$$\sum_{i=1}^{n_1} (p_{D_1}(i))^\ell = \sum_{i=1}^{n_2} (p_{D_2}(i))^\ell.$$

In particular, there exists an absolute constant c_k such that for sufficiently large n, $n_2 \geq (1 + c_k\gamma^k)n_1$ and the above conclusion holds.

Before proving the lemma, we show how the lemma implies Theorem 13.

Proof of Theorem 13. The theorem follows from Theorem 16 together with Lemma 17. Let $N = n_1 + n_2$, where $n_1 = (1 + \Theta(\gamma)^k)n_2$ as in the conclusion of Lemma 17, and consider distinguishing between two possible outcomes $\mathcal{O}_1$ and $\mathcal{O}_2$.

In the first outcome $\mathcal{O}_1$, let $S = \{1, 2, \ldots, n_1\} \subseteq [N]$ and $T = \{t_1, \ldots, t_{n_2}\} := [N] \backslash S$. The distribution $\mathcal{Q}$ will be as follows. With exactly $1/2$ probability, we choose S: if so, we then choose a sample $i \sim D_1$, which will be in $[n_1]$, and output i. Otherwise, we choose T: we then choose a sample $i \sim D_2$, which will be in $[n_2]$, and then output t_i. Here, D_1, D_2 are the distributions from Lemma 17. Finally, we let $v_i = 1$ if $i \in S$ and $v_i = 0$ if $i \in T$.

The second outcome $\mathcal{O}_2$ is similar but "flipped". Now, we let $S = \{1, 2, \ldots, n_2\} \subseteq [N]$, and $T = \{t_1, \ldots, t_{n_1}\} := [N] \backslash S$. With exactly $1/2$ probability, we choose S: if so, we then choose a sample $i \sim D_2$, and output i. Otherwise, we choose T: we then choose a sample $i \sim D_1$, and then output t_i. Finally, we let $v_i = 1$ if $i \in S$ and $v_i = 0$ if $i \in T$.

Under $\mathcal{O}_1$, we have that $\sum v_i$ always equals n_1, whereas under $\mathcal{O}_2$, we have that $\sum v_i$ is always n_2. In addition, since both n_1 and n_2 are $\frac{N}{2} \cdot (1 \pm O(\gamma))$, and since D_1 and D_2 are γ-pointwise close to uniform, the distribution $\mathcal{Q}$ that we sample from in either case is $O(\gamma)$-pointwise close to uniform. So, we may assume that $\mathcal{P}$ is uniform over $[N]$ in either case.

Now, assume that there exists a uniform algorithm[6] A that draws samples (i, v_i) either from outcome $\mathcal{O}_1$ or outcome $\mathcal{O}_2$ and with probability at least 2/3, computes an estimate of $\sum_i v_i$ up to additive error $c_k \gamma^k N/5$, where c_k is as in the second conclusion of Lemma 17. Observe that when the error bound on A is satisfied (which occurs with probability at least 2/3), A's output distinguishes scenarios $\mathcal{O}_1$ and $\mathcal{O}_2$.

Finally, we observe that distinguishing $\mathcal{O}_1$ from $\mathcal{O}_2$ is sufficient to distinguish the distributions D_1 and D_2. Indeed, under scenario $\mathcal{O}_1$, the 1-values and sampled from D_1, while the 0-values are sampled from D_2, while the roles are reversed in $\mathcal{O}_2$. Thus, the output of A suffices to distinguish D_1 and D_2. Since A uses s samples in expectation, Theorem 16 and Lemma 17 imply that $s = \Omega(n^{1-1/(k+1)})$, as desired. ◀

We now conclude by proving our main technical lemma.

Proof of Lemma 17. First, we note that

$$\sum_{i=0}^{k}(-1)^i\binom{k}{i}\binom{i}{r} = \sum_{i=r}^{k}(-1)^i\binom{k}{i}\binom{i}{r} = \sum_{i=r}^{k}(-1)^i \cdot \frac{k!}{(k-i)!(i-r)!r!}$$
$$= \sum_{i=r}^{k}(-1)^i \cdot \binom{k}{r}\binom{k-r}{i-r} = (-1)^r\binom{k}{r} \cdot \sum_{j=0}^{k-r}(-1)^j\binom{k-r}{j}.$$

The last line follows by setting $j = i - r$. Now, note that the summation in the last line equals $(1-1)^{k-r} = 0$ if $k > r$, and equals 1 if $k = r$. So, this means that $\sum_{i=0}^{k}(-1)^i\binom{k}{i}\binom{i}{r} = 0$ for all $0 \le r < k$.

Next, note that $\binom{i}{r} = \frac{i(i-1)\cdots(i-r+1)}{r!}$ for all integers $i \ge 0$. This is a degree-r polynomial in i. From this observation, it is well-known that every degree at most $k-1$ polynomial in i can be written as a linear combination of $\binom{i}{0}, \dots, \binom{i}{k-1}$. Therefore, for any polynomial P of degree at most $k-1$, $\sum_{i=0}^{k}(-1)^i\binom{k}{i} \cdot P(i) = 0$.

Now, we let the distribution D_1 have exactly a $\frac{\binom{k}{i}}{2^{k-1}}$ fraction of its mass consisting of items each with probability $\left(1 + \frac{\gamma \cdot i}{k}\right) \cdot \frac{1}{n_0}$, for each *even* integer $0 \le i \le k$. Here, n_0 will be an integer chosen later. Note this means it must have $n_0 \cdot \frac{\binom{k}{i}}{2^{k-1} \cdot (1 + \frac{\gamma \cdot i}{k})}$ points with mass $\left(1 + \frac{\gamma \cdot i}{k}\right) \cdot \frac{1}{n_0}$ for each *even* integer $0 \le i \le k$. Likewise, we let the distribution D_2 have exactly a $\frac{\binom{k}{i}}{2^{k-1}}$ fraction of its mass consisting of items each with probability $\left(1 + \frac{\gamma \cdot i}{k}\right) \cdot \frac{1}{n_0}$, for each *odd* integer $0 \le i \le k$. Note that the total fraction of mass for both D_1 and D_2 is clearly 1.

First, we note that for any $1 \le \ell \le k$,

$$\sum_{i=1}^{n_1}(p_{D_1}(i))^\ell - \sum_{i=1}^{n_1}(p_{D_2}(i))^\ell \tag{13}$$
$$= \sum_{\substack{i=0\\ i \text{ even}}}^{k} n_0 \cdot \frac{\binom{k}{i}}{2^{k-1} \cdot (1 + \frac{\gamma \cdot i}{k})} \cdot \left(\left(1 + \frac{\gamma \cdot i}{k}\right) \cdot \frac{1}{n_0}\right)^\ell \tag{14}$$
$$- \sum_{\substack{i=0\\ i \text{ odd}}}^{k} n_0 \cdot \frac{\binom{k}{i}}{2^{k-1} \cdot (1 + \frac{\gamma \cdot i}{k})} \cdot \left(\left(1 + \frac{\gamma \cdot i}{k}\right) \cdot \frac{1}{n_0}\right)^\ell \tag{15}$$

[6] Again, the assumption that A is uniform is without loss of generality by Lemma 15. For our construction, however, the two scenarios $\mathcal{O}_1$ and $\mathcal{O}_2$ can be distinguished by a non-uniform algorithm using $O(\gamma^k)$ samples. Indeed, the two scenarios are distinguished by seeing any value v_i with $n_2 < i \le n_1$. Following the proof of Lemma 15 (cf. Theorem 11.12 in [11]), the scenarios are indistinguishable to even a non-uniform algorithm we we replace S and T with randomly chosen complementary subsets of $[N]$.

$$= \frac{1}{n_0^{\ell-1} \cdot 2^{k-1}} \cdot \sum_{i=0}^{k} (-1)^i \binom{k}{i} \cdot \left(1 + \frac{\gamma \cdot i}{k}\right)^{\ell-1}. \tag{16}$$

By letting $P(i)$ be the polynomial $\left(1+\frac{\gamma \cdot i}{k}\right)^{\ell-1}$, we have that $P(i)$ has degree at most $k-1$, so this equals 0, as desired.

Finally, we look at the difference $n_1 - n_2$, i.e., the difference in support size between D_1 and D_2. This simply equals

$$\sum_{\substack{i=0 \\ i \text{ even}}}^{k} n_0 \cdot \frac{\binom{k}{i}}{2^{k-1} \cdot (1 + \frac{\gamma \cdot i}{k})} - \sum_{\substack{i=0 \\ i \text{ odd}}}^{k} n_0 \cdot \frac{\binom{k}{i}}{2^{k-1} \cdot (1 + \frac{\gamma \cdot i}{k})} = \frac{n_0}{2^{k-1}} \cdot \sum_{i=0}^{k} (-1)^i \cdot \frac{\binom{k}{i}}{1 + \frac{\gamma}{k} \cdot i}. \tag{17}$$

We now inductively prove (by inducting on $k \ge 1$) that $\sum_{i=0}^{k} (-1)^i \cdot \frac{\binom{k}{i}}{a+\gamma \cdot i} = \frac{k! \cdot \gamma^k}{a(a+\gamma)\cdots(a+k\gamma)}$ for any real numbers a, γ. For $k = 1$, we have that $\sum_{i=0}^{k} (-1)^i \cdot \frac{\binom{k}{i}}{a+\gamma \cdot i} = \frac{1}{a} - \frac{1}{a+\gamma} = \frac{\gamma}{a(a+\gamma)}$. For general k, we can write

$$\sum_{i=0}^{k} (-1)^i \cdot \frac{\binom{k}{i}}{a + \gamma \cdot i} = \sum_{i=0}^{k} (-1)^i \cdot \frac{\binom{k-1}{i-1} + \binom{k-1}{i}}{a + \gamma \cdot i} \tag{18}$$

$$= \sum_{i=0}^{k-1} (-1)^i \cdot \frac{\binom{k-1}{i}}{a + \gamma \cdot i} + \sum_{i=1}^{k} (-1)^i \cdot \frac{\binom{k-1}{i-1}}{a + \gamma \cdot i} \tag{19}$$

$$= \sum_{i=0}^{k-1} (-1)^i \cdot \frac{\binom{k-1}{i}}{a + \gamma \cdot i} - \sum_{j=0}^{k-1} (-1)^j \cdot \frac{\binom{k-1}{j}}{(a + \gamma) + \gamma \cdot j}, \tag{20}$$

where we have set $j = i - 1$. We can now use the inductive hypothesis on $k - 1$ to obtain that this equals

$$\frac{(k-1)! \cdot \gamma^{k-1}}{a(a+\gamma)\cdots(a+(k-1)\gamma)} - \frac{(k-1)! \cdot \gamma^{k-1}}{(a+\gamma)\cdots(a+(k-1)\gamma)(a+k\gamma)} \tag{21}$$

$$= (k-1)! \cdot \gamma^{k-1} \cdot \frac{(a+k\gamma) - a}{a(a+\gamma)\cdots(a+(k-1)\gamma)(a+k\gamma)} \tag{22}$$

$$= k! \cdot \gamma^k \cdot \frac{1}{a(a+\gamma)\cdots(a+(k-1)\gamma)(a+k\gamma)}. \tag{23}$$

Therefore, by setting $a = 1$ and replacing γ with $\gamma' = \gamma/k$, we have that the difference in support size between D_1 and D_2 is

$$\frac{n_0}{2^{k-1}} \cdot \frac{k!}{k^k} \cdot \gamma^k \cdot \frac{1}{(1+\gamma/k)(1+2\gamma/k) \cdot (1+\gamma)}.$$

Assuming that $\gamma \le 1/2$, we can apply Stirling's approximation to obtain that this difference is $n_0 \cdot (\gamma/\Theta(1))^k$.

To finish, we will set n_0 appropriately. Note that we wish for D_2 to have support size exactly n. However, all of the points in D_2 has mass between $\frac{1}{n_0}$ and $\frac{1+\gamma}{n_0}$, which means that the support size n_2 must be between $\frac{n_0}{1+\gamma}$ and n_0. So, we can first set n_0, and then choose $n = n_2$ to be $n_0 \cdot \sum_{i=0, i \text{ odd}}^{k} \frac{\binom{k}{i}}{2^{k-1} \cdot (1+\frac{\gamma \cdot i}{k})}$, which is in the range $\left[\frac{n_0}{1+\gamma}, n_0\right]$, and n_1 to be $n_0 \cdot \sum_{i=0, i \text{ even}}^{k} \frac{\binom{k}{i}}{2^{k-1} \cdot (1+\frac{\gamma \cdot i}{k})}$. Both n_1 and $n = n_2$ are in the range $\left[\frac{n_0}{1+\gamma}, n_0\right]$. Indeed, we will have that $\sum_{i=1}^{n_1} (p_{D_1}(i))^\ell = \sum_{i=1}^{n_2} (p_{D_2}(i))^\ell$, and $n_1 - n_2 = \Theta(\gamma)^k \cdot n_0 = \Theta(\gamma)^k \cdot n$. In addition, because all of the values $p_{D_j}(i)$ are in the range $\left[\frac{1}{n_0}, \frac{1+\gamma}{n_0}\right]$ for both $j = 1$ and $j = 2$, this means that they are also in the range $\left[\frac{1-\gamma}{n}, \frac{1+\gamma}{n}\right]$, as desired. This completes the proof. ◀

A Proof of Lemma 12

Here, we prove the main technical lemma for our sum estimator.

Proof. For each $i \in [N]$ we define γ_i such that $\mathcal{Q}(i) = (1+\gamma_i)\mathcal{P}(i)$. Since we know that $\mathcal{Q}$ is pointwise γ-close to $\mathcal{P}$ then $|\gamma_i| \le \gamma$, and since both $\mathcal{Q}$ and $\mathcal{P}$ are probability distributions then $\sum_{i\in[N]} \gamma_i \mathcal{P}(i) = 0$.

We start by proving the bounds on the expectation, i.e., Equation (9) and Equation (11).

$$\begin{aligned}
\mathrm{E}[\zeta_k] &= \mathrm{E}\left[\sum_{h=1}^{k}(-1)^{h+1}\frac{\binom{k}{h}}{\binom{m}{h}}\sum_{i\in[N]}\binom{Y_i}{h}\mathcal{P}(i)^{-h}x_i\right]\\
&= \sum_{h=1}^{k}(-1)^{h+1}\frac{\binom{k}{h}}{\binom{m}{h}}\sum_{i\in[N]}\mathrm{E}\left[\binom{Y_i}{h}\right]\mathcal{P}(i)^{-h}x_i\ .
\end{aligned}$$

We use the fact that $Y_i = \sum_{j\in[m]}[X_j = i]$ is a sum of 0-1 variables so $\binom{Y_i}{h} = \sum_{I\subseteq[m]:|I|=h}\prod_{j\in I}[X_j = i]$. This implies that $\mathrm{E}\left[\binom{Y_i}{h}\right] = \binom{m}{h}\mathcal{Q}(i)^h = \binom{m}{h}(1+\gamma_i)^h\mathcal{P}(i)^h$. Plugging this in, we get that

$$\begin{aligned}
\mathrm{E}[\zeta_k] &= \sum_{h=1}^{k}(-1)^{h+1}\frac{\binom{k}{h}}{\binom{m}{h}}\sum_{i\in[N]}\binom{m}{h}(1+\gamma_i)^h\mathcal{P}(i)^h\mathcal{P}(i)^{-h}x_i = \sum_{h=1}^{k}(-1)^{h+1}\binom{k}{h}\sum_{i\in[N]}(1+\gamma_i)^h x_i\\
&= \sum_{i\in[N]} x_i\sum_{h=1}^{k}(-1)^{h+1}\binom{k}{h}(1+\gamma_i)^h = \sum_{i\in[N]} x_i\left(1+\sum_{h=0}^{k}(-1)^{h+1}\binom{k}{h}(1+\gamma_i)^h\right)\\
&= \sum_{i\in[N]} x_i\left(1-(1-(1+\gamma_i))^k\right) = \sum_{i\in[N]} x_i\left(1+(-1)^{k+1}\gamma_i^k\right)
\end{aligned}$$

If $k \geq 2$ then we easily see that

$$|\operatorname{E}[\zeta_k] - \mu| = |\sum_{i\in[N]} x_i - \sum_{i\in[N]} x_i(1+(-1)^{k+1}\gamma_i^k)| = |\sum_{i\in[N]} \gamma_i^k x_i| \leq \gamma^k \sum_{i\in[N]} |x_i|$$

For $k = 1$ we will exploit that $\sum_{i\in[N]} \gamma_i \mathcal{P}(i) = 0$.

$$\begin{aligned}|\operatorname{E}[\zeta_1] - \mu| &= |\sum_{i\in[N]} \gamma_i x_i| = |\sum_{i\in[N]} \gamma_i(\mathcal{P}(i)\mu + (x_i - \mathcal{P}(i)\mu))| \\ &= |\sum_{i\in[N]} \gamma_i(x_i - \mathcal{P}(i)\mu)| \leq \gamma \sum_{i\in[N]} |x_i - \mathcal{P}(i)\mu|\end{aligned}$$

Now we will focus on bounding the variance. First we prove Equation (12).

$$\begin{aligned}\operatorname{Var}[\zeta_1] &= \operatorname{E}\left[\left(\frac{1}{m}\sum_{j\in[m]}\sum_{i\in[N]} x_i([X_j = i]\mathcal{P}(i)^{-1} - (1+\gamma_i))\right)^2\right] \\ &= \frac{1}{m^2}\sum_{j\in[m]} \operatorname{E}\left[\left(\sum_{i\in[N]} x_i([X_j = i]\mathcal{P}(i)^{-1} - (1+\gamma_i))\right)^2\right]\end{aligned}$$

We will argue that $\sum_{i\in[N]} x_i([X_j = i]\mathcal{P}(i)^{-1} - (1+\gamma_i)) = \sum_{i\in[N]}(x_i - \mathcal{P}(i)\mu)([X_j = i]\mathcal{P}(i)^{-1} - (1+\gamma_i))$.

$$\begin{aligned}&\sum_{i\in[N]} x_i([X_j = i]\mathcal{P}(i)^{-1} - (1+\gamma_i)) \\ &= \sum_{i\in[N]}(x_i - \mathcal{P}(i)\mu + \mathcal{P}(i)\mu)([X_j = i]\mathcal{P}(i)^{-1} - (1+\gamma_i)) \\ &= \sum_{i\in[N]}(x_i - \mathcal{P}(i)\mu)([X_j = i]\mathcal{P}(i)^{-1} - (1+\gamma_i)) + \mu\sum_{u\in[N]} \mathcal{P}(i)\gamma_i\end{aligned}$$

Now since $\sum_{i\in[N]} \gamma_i \mathcal{P}(i) = 0$ it follows. We can now bound the variance.

$$\begin{aligned}\operatorname{Var}[\zeta_1] &= \frac{1}{m^2}\sum_{j\in[m]} \operatorname{E}\left[\left(\sum_{i\in[N]}(x_i - \mathcal{P}(i)\mu)([X_j = i]\mathcal{P}(i)^{-1} - (1+\gamma_i))\right)^2\right] \\ &\leq \frac{1}{m^2}\sum_{j\in[m]} \operatorname{E}\left[\left(\sum_{i\in[N]} \mathcal{P}(i)^{-1}(x_i - \mathcal{P}(i)\mu)[X_j = i]\right)^2\right] \\ &= \frac{1}{m}\sum_{i\in[N]} \frac{\mathcal{Q}(i)}{\mathcal{P}(i)^2}(x_i - \mathcal{P}(i)\mu)^2 \leq \frac{1+\gamma}{m}\sum_{i\in[N]} \mathcal{P}(i)^{-1}(x_i - \mathcal{P}(i)\mu)^2\end{aligned}$$

Now we just need to focus on the case of $k \geq 2$ and prove Equation (10). For this we need the following lemma for which we defer the proof till Appendix A.

▶ **Lemma 18.** *For all sequences of numbers $(\beta_j)_{j\in[m]}$ and all α the following identity holds:*

$$\sum_{\substack{I\subseteq[m]\\0<|I|\leq k}} (-1)^{|I|+1}\frac{\binom{k}{|I|}}{\binom{m}{|I|}}\left(\prod_{j\in I}\beta_j - (1+\alpha)^h\right) = (-1)^{k+1}\sum_{\substack{I\subseteq[m]\\0<|I|\leq k}} \frac{\binom{k}{|I|}}{\binom{m}{|I|}}\alpha^{k-|I|}\prod_{j\in I}(\beta_j - (1+\alpha))$$

The idea is to use Lemma 18 to prove that

$$\zeta_k - \mathrm{E}[\zeta_k] = \sum_{\substack{I \subseteq [m] \\ 0<|I|\leq k}} \frac{\binom{m-|I|}{k-|I|}}{\binom{m}{k}} \alpha^{k-|I|} \sum_{i \in [N]} x_i \prod_{j \in I} (\mathcal{P}(i)^{-1}[X_j = i] - (1+\gamma_i)) \,. \tag{24}$$

First we use that $\mathrm{E}[\zeta_k] = \sum_{h=1}^{k} (-1)^h \frac{\binom{k}{h}}{\binom{m}{h}} \sum_{i \in [N]} \mathcal{P}(i)^{-h} x_i \, \mathrm{E}\left[\binom{Y_i}{h}\right]$ which allow us to rewrite $\zeta_k - \mathrm{E}[\zeta_k]$.

$$\zeta_k - \mathrm{E}[\zeta_k] = \sum_{h=1}^{k} (-1)^h \frac{\binom{k}{h}}{\binom{m}{h}} \sum_{i \in [N]} \mathcal{P}(i)^{-h} x_i \left(\binom{Y_i}{h} - \mathrm{E}\left[\binom{Y_i}{h}\right] \right)$$

We now again use that $Y_i = \sum_{j \in [m]} [X_j = i]$ is a sum of 0-1 variables so $\binom{Y_i}{h} = \sum_{I \subseteq [m] : |I| = h} \prod_{j \in I} [X_j = i]$ and $\mathrm{E}\left[\binom{Y_i}{h}\right] = \binom{m}{h} (1+\gamma_i)^h \mathcal{P}(i)^h$.

$$\begin{aligned}
&\sum_{h=1}^{k} (-1)^h \frac{\binom{k}{h}}{\binom{m}{h}} \sum_{i \in [N]} \mathcal{P}(i)^{-h} x_i \left(\binom{Y_i}{h} - \mathrm{E}\left[\binom{Y_i}{h}\right] \right) \\
&= \sum_{h=1}^{k} (-1)^h \frac{\binom{k}{h}}{\binom{m}{h}} \sum_{i \in [N]} \mathcal{P}(i)^{-h} x_i \sum_{\substack{I \subseteq [m] \\ |I| = h}} \left(\prod_{j \in I} [X_j = i] - (1+\gamma_i)^h \mathcal{P}(i)^h \right) \\
&= \sum_{i \in [N]} x_i \sum_{h=1}^{k} \sum_{\substack{I \subseteq [m] \\ |I| = h}} (-1)^h \frac{\binom{k}{h}}{\binom{m}{h}} \mathcal{P}(i)^{-h} \left(\prod_{j \in I} [X_j = i] - (1+\gamma_i)^h \mathcal{P}(i)^h \right) \\
&= \sum_{i \in [N]} x_i \sum_{\substack{I \subseteq [m] \\ 0<|I|\leq k}} (-1)^{|I|+1} \frac{\binom{k}{|I|}}{\binom{m}{|I|}} \mathcal{P}(i)^{-h} \left(\prod_{j \in I} [X_j = i] - (1+\gamma_i)^{|I|} \mathcal{P}(i)^{|I|} \right) \\
&= \sum_{i \in [N]} x_i \sum_{\substack{I \subseteq [m] \\ 0<|I|\leq k}} (-1)^{|I|+1} \frac{\binom{k}{|I|}}{\binom{m}{|I|}} \left(\prod_{j \in I} \mathcal{P}(i)^{-1} [X_j = i] - (1+\gamma_i)^{|I|} \right)
\end{aligned}$$

For each $i \in [N]$, the expression $\sum_{\substack{I \subseteq [m] \\ 0<|I|\leq k}} (-1)^{|I|+1} \frac{\binom{k}{|I|}}{\binom{m}{|I|}} \left(\prod_{j \in I} \mathcal{P}(i)^{-1} [X_j = i] - (1+\gamma_i)^{|I|} \right)$ is of the form of Lemma 18. So applying that N times we get that

$$\begin{aligned}
&\sum_{i \in [N]} x_i \sum_{\substack{I \subseteq [m] \\ 0<|I|\leq k}} (-1)^{|I|+1} \frac{\binom{k}{|I|}}{\binom{m}{|I|}} \left(\prod_{j \in I} \mathcal{P}(i)^{-1} [X_j = i] - (1+\gamma_i)^{|I|} \right) \\
&= \sum_{i \in [N]} x_i (-1)^{k+1} \sum_{\substack{I \subseteq [m] \\ 0<|I|\leq k}} \frac{\binom{k}{|I|}}{\binom{m}{|I|}} \gamma_i^{k-|I|} \prod_{j \in I} \left(\mathcal{P}(i)^{-1} [X_j = i] - (1+\gamma_i) \right) \\
&= (-1)^{k+1} \sum_{\substack{I \subseteq [m] \\ 0<|I|\leq k}} \frac{\binom{k}{|I|}}{\binom{m}{|I|}} \sum_{i \in [N]} \gamma_i^{k-|I|} x_i \prod_{j \in I} \left(\mathcal{P}(i)^{-1} [X_j = i] - (1+\gamma_i) \right)
\end{aligned}$$

This shows that Equation (24) is true.

Now let $I_1, I_2 \subseteq [m]$ be two different set of indices with $0 < |I_1|, |I_2| \leq k$. Without loss of generality, we can assume that there exists $h \in I_1 \setminus I_2$.

$$\begin{aligned} T = (&\sum_{i\in[N]} \gamma_i^{k-|I_1|} x_i \prod_{j\in I_1} (\mathcal{P}(i)^{-1}[X_j = i] - (1+\gamma_i))) \\ &\cdot (\sum_{i\in[N]} \gamma_i^{k-|I_2|} x_i \prod_{j\in I_2} (\mathcal{P}(i)^{-1}[X_j = i] - (1+\gamma_i))) \end{aligned}$$

Note that if we multiply this expression out then every term will contain a factor of the form $(\mathcal{P}(i)^{-1}[X_h = s] - (1+\gamma_i))$ for some $s \in [N]$ and where all the other factors are independent of X_h. Since $\mathrm{E}[(\mathcal{P}(i)^{-1}[X_h = s] - (1+\gamma_i))] = 0$ we get that $\mathrm{E}[T] = 0$. This implies that

$$\mathrm{E}[(\zeta_k - \mathrm{E}[\zeta_k])^2] = \sum_{\substack{I\subseteq[m] \\ 0<|I|\leq k}} \left(\frac{\binom{k}{|I|}}{\binom{m}{|I|}}\right)^2 \mathrm{E}[(\sum_{i\in[N]} \gamma_i^{k-|I|} x_i \prod_{j\in I} (\mathcal{P}(i)^{-1}[X_j = i] - (1+\gamma_i)))^2]$$

Let $I \subseteq [N]$ be fixed then

$$\begin{aligned} &\mathrm{E}[(\sum_{i\in[N]} \gamma_i^{k-|I|} x_i \prod_{j\in I} (\mathcal{P}(i)^{-1}[X_j = i] - (1+\gamma_i)))^2] \leq \mathrm{E}[(\sum_{i\in[N]} \gamma_i^{k-|I|} x_i \prod_{j\in I} \mathcal{P}(i)^{-1}[X_j = i])^2] \\ &= \sum_{i\in[N]} \gamma_i^{2k-2|I|} x_i^2 \frac{\mathcal{Q}(i)^{|I|}}{\mathcal{P}(i)^{2|I|}} \leq \gamma^{2k-2|I|} \sum_{i\in[N]} x_i^2 \frac{(1+\gamma_i)^{|I|}}{\mathcal{P}(i)^{|I|}} \end{aligned}$$

Collecting terms we get that

$$\begin{aligned} &\mathrm{E}[(\zeta_k - \mathrm{E}[\zeta_k])^2] \leq \sum_{\substack{I\subseteq[m] \\ 0<|I|\leq k}} \left(\frac{\binom{k}{|I|}}{\binom{m}{|I|}}\right)^2 \gamma^{2k-2|I|} \sum_{i\in[N]} x_i^2 \frac{(1+\gamma_i)^{|I|}}{\mathcal{P}(i)^{|I|}} \\ &= \sum_{h=1}^{k} \frac{\binom{k}{h}^2}{\binom{m}{h}} \gamma^{2k-2h} \sum_{i\in[N]} x_i^2 \frac{(1+\gamma_i)^h}{\mathcal{P}(i)^h} \leq \sum_{h=1}^{k} \frac{\binom{k}{h}^2}{\binom{m}{h}} \gamma^{2k-2h} (1+\gamma)^h \sum_{i\in[N]} \frac{x_i^2}{\mathcal{P}(i)^h} \\ &\leq \sum_{h=1}^{k} \frac{k^{2h}}{\binom{m}{h}} \gamma^{2k-2h} (1+\gamma)^h \sum_{i\in[N]} \frac{x_i^2}{\mathcal{P}(i)^h} \leq \max_{h=1}^{k} \frac{2^h k^{2h}}{\binom{m}{h}} \gamma^{2k-2h} (1+\gamma)^h \sum_{i\in[N]} \frac{x_i^2}{\mathcal{P}(i)^h} \end{aligned}$$

Now we note that for all $i \in [N]$, the map $h \mapsto \frac{2^h k^{2h}}{\binom{m}{h}} \gamma^{2k-2h} (1+\gamma)^h \frac{x_i^2}{\mathcal{P}(i)^h}$ is log-convex since each factor is log-convex. This implies that the map $h \mapsto \frac{2^h k^{2h}}{\binom{m}{h}} \gamma^{2k-2h} (1+\gamma)^h \sum_{i\in[N]} \frac{x_i^2}{\mathcal{P}(i)^h}$ is convex and is thus maximized at the boundary. We then get that

$$\begin{aligned} \mathrm{E}[(\zeta_k - \mathrm{E}[\zeta_k])^2] \leq \max\Big\{&2(1+\gamma)\gamma^{2k-2} k^2 \frac{\sum_{i\in[N]} \mathcal{P}(i)^{-1} x_i^2}{m}, \\ &2^k (1+\gamma)^k k^{3k} \frac{n^{k-1} \sum_{i\in[N]} \mathcal{P}(i)^{-1} x_i^2}{m^k}\Big\} \end{aligned}$$

which finishes the proof of Equation (10). ◀

Finally, we must prove Lemma 18 which will finish the proof of Lemma 12.

▶ **Lemma 19.** *For all sequences of numbers $(\beta_j)_{j\in[m]}$ and all α the following identity holds:*

$$\sum_{\substack{I\subseteq[m] \\ 0<|I|\leq k}} (-1)^{|I|+1} \frac{\binom{k}{|I|}}{\binom{m}{|I|}} \left(\prod_{j\in I} \beta_j - (1+\alpha)^h\right) = (-1)^{k+1} \sum_{\substack{I\subseteq[m] \\ 0<|I|\leq k}} \frac{\binom{k}{|I|}}{\binom{m}{|I|}} \alpha^{k-|I|} \prod_{j\in I} (\beta_j - (1+\alpha))$$

First we need a simple lemma.

▶ **Lemma 19.** *For all sequences of numbers $(\beta_j)_{j\in I}$ and all α the following identity holds:*

$$\prod_{j\in I}\beta_j-(1+\alpha)^{|I|}=\sum_{\emptyset\neq J\subseteq I}(1+\alpha)^{|I|-|J|}\prod_{j\in J}(\beta_j-(1+\alpha))$$

Proof. Let $\beta'_j:=\beta_j-(1+\alpha)$. Then,

$$\begin{aligned}\prod_{j\in I}\beta'_j-(1+\alpha)^{|I|}&=\prod_{j\in I}(\beta'_j+(1+\alpha))-(1+\alpha)^{|I|}\\&=\left[\sum_{J\subseteq I}(1+\alpha)^{|I|-|J|}\prod_{j\in J}\beta'_j\right]-(1+\alpha)^{|I|}\\&=\sum_{\emptyset\neq J\subseteq I}(1+\alpha)^{|I|-|J|}\prod_{j\in J}(\beta_j-(1+\alpha)).\end{aligned}$$ ◀

Proof of Lemma 18. We start by applying Lemma 19

$$\begin{aligned}&\sum_{\substack{I\subseteq[m]\\0<|I|\le k}}(-1)^{|I|+1}\frac{\binom{k}{|I|}}{\binom{m}{|I|}}\left(\prod_{j\in I}\beta_j-(1+\alpha)^h\right)\\&\quad=\sum_{\substack{I\subseteq[m]\\0<|I|\le k}}(-1)^{|I|+1}\frac{\binom{k}{|I|}}{\binom{m}{|I|}}\sum_{\emptyset\neq J\subseteq I}(1+\alpha)^{|I|-|J|}\prod_{j\in J}(\beta_j-(1+\alpha))\end{aligned}$$

We use that $\frac{\binom{k}{|I|}}{\binom{m}{|I|}}=\frac{\binom{m-|I|}{k-|I|}}{\binom{m}{k}}$ which follows from the fact that $\binom{m}{k}\binom{k}{|I|}=\binom{m}{|I|,k-|I|,m-k}=\binom{m}{|I|}\binom{m-|I|}{k-|I|}$.

$$\begin{aligned}&\sum_{\substack{I\subseteq[m]\\0<|I|\le k}}(-1)^{|I|+1}\frac{\binom{k}{|I|}}{\binom{m}{|I|}}\sum_{\emptyset\neq J\subseteq I}(1+\alpha)^{|I|-|J|}\prod_{j\in J}(\beta_j-(1+\alpha))\\&=\sum_{\substack{I\subseteq[m]\\0<|I|\le k}}(-1)^{|I|+1}\frac{\binom{m-|I|}{k-|I|}}{\binom{m}{k}}\sum_{\emptyset\neq J\subseteq I}(1+\alpha)^{|I|-|J|}\prod_{j\in J}(\beta_j-(1+\alpha))\\&=\frac{1}{\binom{m}{k}}\sum_{\substack{J\subseteq[m]\\0<|J|\le k}}\left(\prod_{j\in J}(\beta_j-(1+\alpha))\right)\sum_{\substack{I\subseteq[m]\\J\subseteq I,|I|\le k}}(-1)^{|I|+1}\binom{m-|I|}{k-|I|}(1+\alpha)^{|I|-|J|}\\&=\frac{1}{\binom{m}{k}}\sum_{\substack{J\subseteq[m]\\0<|J|\le k}}\left(\prod_{j\in J}(\beta_j-(1+\alpha))\right)\sum_{h=|J|}^{k}(-1)^{h+1}\binom{m-|J|}{h-|J|}\binom{m-h}{k-h}(1+\alpha)^{h-|J|}\end{aligned}$$

Now we use that $\binom{m-h}{k-h}\binom{m-|J|}{h-|J|} = \binom{m-|J|}{k-h,m-k,h-|J|} = \binom{m-|J|}{k-|J|}\binom{k-|J|}{h-|J|}$.

$$\begin{aligned}
&\frac{1}{\binom{m}{k}} \sum_{\substack{J\subseteq[m]\\0<|J|\le k}} \left(\prod_{j\in J}(\beta_j-(1+\alpha))\right) \sum_{h=|J|}^{k} (-1)^{h+1}\binom{m-|J|}{h-|J|}\binom{m-h}{k-h}(1+\alpha)^{h-|J|}\\
&= \frac{1}{\binom{m}{k}} \sum_{\substack{J\subseteq[m]\\0<|J|\le k}} \left(\prod_{j\in J}(\beta_j-(1+\alpha))\right) \sum_{h=|J|}^{k} (-1)^{h+1}\binom{m-|J|}{k-|J|}\binom{k-|J|}{h-|J|}(1+\alpha)^{h-|J|}\\
&= \frac{1}{\binom{m}{k}} \sum_{\substack{J\subseteq[m]\\0<|J|\le k}} (-1)^{|J|+1}\binom{m-|J|}{k-|J|} \left(\prod_{j\in J}(\beta_j-(1+\alpha))\right) \sum_{h=0}^{k-|J|} (-1)^{h}\binom{k-|J|}{h}(1+\alpha)^{h}\\
&= \frac{1}{\binom{m}{k}} \sum_{\substack{J\subseteq[m]\\0<|J|\le k}} (-1)^{|J|+1}\binom{m-|J|}{k-|J|} \left(\prod_{j\in J}(\beta_j-(1+\alpha))\right) (1-(1+\alpha))^{k-|J|}\\
&= \frac{(-1)^{k+1}}{\binom{m}{k}} \sum_{\substack{J\subseteq[m]\\0<|J|\le k}} \binom{m-|J|}{k-|J|}\alpha^{k-|J|} \left(\prod_{j\in J}(\beta_j-(1+\alpha))\right)
\end{aligned}$$

Finally, we again use that $\frac{\binom{k}{|I|}}{\binom{m}{|I|}} = \frac{\binom{m-|I|}{k-|I|}}{\binom{m}{k}}$ to finish the proof.

$$\begin{aligned}
&\frac{(-1)^{k+1}}{\binom{m}{k}} \sum_{\substack{J\subseteq[m]\\0<|J|\le k}} \binom{m-|J|}{k-|J|}\alpha^{k-|J|} \left(\prod_{j\in J}(\beta_j-(1+\alpha))\right)\\
&\quad = (-1)^{k+1} \sum_{\substack{J\subseteq[m]\\0<|J|\le k}} \frac{\binom{k}{h}}{\binom{m}{h}}\alpha^{k-|J|} \left(\prod_{j\in J}(\beta_j-(1+\alpha))\right)
\end{aligned}$$

Abstract

For any Boolean functions f and g, the question whether $\mathrm{R}(f \circ g) = \widetilde{\Theta}(\mathrm{R}(f) \cdot \mathrm{R}(g))$, is known as the composition question for the randomized query complexity. Similarly, the composition question for the approximate degree asks whether $\widetilde{\deg}(f \circ g) = \widetilde{\Theta}(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))$. These questions are two of the most important and well-studied problems in the field of analysis of Boolean functions, and yet we are far from answering them satisfactorily.

It is known that the measures compose if one assumes various properties of the outer function f (or inner function g). This paper extends the class of outer functions for which R and $\widetilde{\deg}$ compose.

A recent landmark result (Ben-David and Blais, 2020) showed that $\mathrm{R}(f \circ g) = \Omega(\mathrm{noisyR}(f) \cdot \mathrm{R}(g))$. This implies that composition holds whenever $\mathrm{noisyR}(f) = \widetilde{\Theta}(\mathrm{R}(f))$. We show two results:

1. When $\mathrm{R}(f) = \Theta(n)$, then $\mathrm{noisyR}(f) = \Theta(\mathrm{R}(f))$. In other words, composition holds whenever the randomized query complexity of the outer function is full.
2. If R composes with respect to an outer function, then noisyR also composes with respect to the same outer function.

On the other hand, no result of the type $\widetilde{\deg}(f \circ g) = \Omega(M(f) \cdot \widetilde{\deg}(g))$ (for some non-trivial complexity measure $M(\cdot)$) was known to the best of our knowledge. We prove that

$$\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\sqrt{\mathrm{bs}(f)} \cdot \widetilde{\deg}(g)),$$

where $\mathrm{bs}(f)$ is the block sensitivity of f. This implies that $\widetilde{\deg}$ composes when $\widetilde{\deg}(f)$ is asymptotically equal to $\sqrt{\mathrm{bs}(f)}$.

It is already known that both R and $\widetilde{\deg}$ compose when the outer function is symmetric. We also extend these results to weaker notions of symmetry with respect to the outer function.

1 Introduction

For studying the complexity of Boolean functions, a number of simple complexity measures (like decision tree complexity, randomized query complexity, degree, certificate complexity and so on) have been studied over the years. (Refer to the survey [15] for an introduction to complexity measures of Boolean functions.) Understanding how these measures are related to each other [1, 2, 4, 27], and how they behave for various classes of Boolean functions has been a central area of research in complexity theory [34, 23, 42].

A crucial step towards understanding a complexity measure is: how does the complexity measure behave when two Boolean functions are combined to obtain a new function (i.e., what is the relationship between the measure of the resulting function and the measures of the two individual functions) [16, 12, 25, 44]? One particularly natural combination of functions is called *composition*, and it takes a central role in complexity theory.

For any two Boolean functions $f : \{0,1\}^n \to \{0,1\}$ and $g : \{0,1\}^m \to \{0,1\}$, the composed function $f \circ g : \{0,1\}^{nm} \to \{0,1\}$ is defined as the function

$$f \circ g(x_1, \ldots, x_n) = f(g(x_1), \ldots, g(x_n)),$$

where $x_i \in \{0,1\}^m$ for $i \in [n]$. For the function $f \circ g$, the function f is called the outer function and g is called the inner function. See Definition 13 for a natural extension to partial functions.

Let $M(\cdot)$ be a complexity measure of Boolean functions. A central question in complexity theory is the following.

▶ **Question 1** (Composition question for M). *Is the following true for all Boolean functions f and g:*

$$M(f \circ g) = \widetilde{\Theta}(M(f) \cdot M(g))?$$

The notation $\widetilde{\Theta}(\cdot)$ hides poly-logarithmic factors of the arity of the outer function f.

Composition of Boolean functions with respect to different complexity measures is a very important and useful tool in areas like communication complexity, circuit complexity and many more. To take an example, a popular application of composition is to create new functions demonstrating better separations (refer to [33, 44, 3, 25] for some other results of similar flavour).

It is known that the answer to the composition question is in the affirmative for complexity measures like deterministic decision tree complexity [37, 44, 31], degree [44] and quantum query complexity [35, 29, 28]. While it is well understood how several complexity measures behave under composition, there are two important measures (even though well studied) for which this problems remains wide open: randomized query complexity (denoted by R) and approximate degree (denoted by $\widetilde{\deg}$) [38, 33, 3, 39, 17, 40]. (See Definition 30 and Definition 31 for their respective formal definitions.)

For both R and $\widetilde{\deg}$ the upper bound inequality is known, i.e., $\mathrm{R}(f \circ g) = \widetilde{O}(\mathrm{R}(f) \cdot \mathrm{R}(g))$ (folklore) and $\widetilde{\deg}(f \circ g) = O(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))$ [41]. Thus it is enough to prove the lower bound on the complexity of composed function in terms of the individual functions. Most of the attempts to prove this direction of the question have focused on special cases when the outer function has certain special properties[1].

[1] We note that some works have also studied the composition of R and $\widetilde{\deg}$ when the inner functions have special properties, for example, [1, 13, 6, 24, 30, 10].

The initial steps taken towards answering the composition question for R were to show a lower bound by using a weaker measure of outer function than the randomized query complexity. In particular, it was shown that $\mathrm{R}(f \circ g) = \Omega(\mathrm{s}(f) \cdot \mathrm{R}(g))$ [26, 5], where $\mathrm{s}(f)$ is the sensitivity of f (Definition 32). Since $\mathrm{s}(f) = \Theta(\mathrm{R}(f))$ for any symmetric function[2] f, these results show that R composes when the outer function is a symmetric function (like OR, AND, Majority, Parity, etc.). The lower bound was later improved to obtain $\mathrm{R}(f \circ g) = \Omega(\mathrm{fbs}(f) \cdot \mathrm{R}(g))$ [7, 8], where $\mathrm{fbs}(f)$ is the fractional block sensitivity of f (Definition 33).

Unfortunately, at this stage, there could even be a cubic gap between R and fbs; the best known bound is $\mathrm{R}(f) = O(\mathrm{fbs}(f)^3)$ [2]. Given that there are already known Boolean functions with quadratic gap between $\mathrm{fbs}(f)$ and $\mathrm{R}(f)$ (e.g., BKK function [1]), it is natural to consider composition question for randomized query complexity when R is *big* but fbs is *small*. We take a step towards this problem by showing that composition for R holds when the outer function has full randomized query complexity, i.e., $\mathrm{R}(f) = \Theta(n)$, where n is the arity of the outer function f.

For composition of $\widetilde{\deg}$, Sherstov [38] already showed that $\widetilde{\deg}(f \circ g)$ composes when the approximate degree of the outer function f is $\Theta(n)$, where n is the arity of the outer function. Thus approximate degree composes for several symmetric functions (having approximate degree $\Theta(n)$, like Majority and Parity). Though, until recently it was not even clear if $\widetilde{\deg}(\mathsf{OR} \circ \mathsf{AND}) = \Omega(\widetilde{\deg}(\mathsf{OR})\,\widetilde{\deg}(\mathsf{AND}))$ (arguably the simplest of composed functions). OR has approximate degree $O(\sqrt{n})$, and thus the result of [38] does not prove $\widetilde{\deg}$ composition when the outer function is OR (similarly for AND). In a long series of work by [33, 3, 39, 17, 40], the question was finally resolved; it was later generalized to the case when the outer function is symmetric [11].

In contrast to R composition, no lower bound on the approximate degree of composed function is known with a weaker measure on the outer function. It is well known that for any Boolean function f, $\sqrt{\mathrm{s}(f)} \le \sqrt{\mathrm{bs}(f)} = O(\widetilde{\deg}(f))$ [33]. So a natural step towards proving $\widetilde{\deg}$ composition is: prove a lower bound on $\widetilde{\deg}(f \circ g)$ by $\sqrt{\mathrm{bs}(f)} \cdot \widetilde{\deg}(g)$. We show this result by generalizing the approach of [11].

While the techniques used for the composition of R and $\widetilde{\deg}$ are quite different, one can still observe similarities between the classes of outer functions for which the composition of R and $\widetilde{\deg}$ is known to hold respectively. We further expand these similarities, by extending the classes of outer functions for which the composition theorem hold.

2 Our Results and Techniques

It is well-known, by amplification, that $\mathrm{R}(f \circ g) = O(\mathrm{R}(f) \cdot \mathrm{R}(g) \cdot \log \mathrm{R}(f))$. In the case of approximate degree, Shrestov [41] showed that $\widetilde{\deg}(f \circ g) = O(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))$. So, to answer the composition question for R (or $\widetilde{\deg}$), we are only concerned about proving a lower bound on $\mathrm{R}(f \circ g)$ (or $\widetilde{\deg}(f \circ g)$) in terms of $\mathrm{R}(f)$ and $\mathrm{R}(g)$ (or $\widetilde{\deg}(f)$ and $\widetilde{\deg}(g)$) respectively.

We split our results into three parts. In the first part we prove the tight lower bound on $\mathrm{R}(f \circ g)$ when the outer function has full randomized complexity. In the second part we provide a tight lower bound on $\widetilde{\deg}(f \circ g)$ in terms of $\mathrm{bs}(f)$ and $\widetilde{\deg}(g)$. Our results on the lower bound of $\mathrm{R}(f \circ g)$ and $\widetilde{\deg}(f \circ g)$ are summarized in Table 1. Finally, we also prove composition theorems for R and $\widetilde{\deg}$ when the outer functions have a slightly relaxed notion of symmetry.

[2] Functions that depend only on the Hamming weight of their input.

Table 1 Composition of R and $\widetilde{\deg}$ depending on the complexity of the outer function in terms of block-sensitivity and arity.

	In terms of $\mathrm{bs}(f)$	In terms of arity of f
R	$\mathrm{R}(f \circ g) = \widetilde{\Omega}(\mathrm{bs}(f) \cdot \mathrm{R}(g))$ [26]	$\mathrm{R}(f \circ g) = \widetilde{\Omega}(\mathrm{R}(f) \cdot \mathrm{R}(g))$ when $\mathrm{R}(f) = \Theta(n)$ Theorem 2
$\widetilde{\deg}$	$\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\sqrt{\mathrm{bs}(f)} \cdot \widetilde{\deg}(g))$ Theorem 7	$\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))$ when $\widetilde{\deg}(f) = \Theta(n)$ [38]

2.1 Lower bounds on $\mathrm{R}(f \circ g)$ when the outer function has full randomized query complexity

Sherstov [38] proved that $\widetilde{\deg}(f \circ g) = \Omega(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))$ when the approximate degree of the outer function f is $\Theta(n)$, where n is the arity of f. Though, a corresponding result for the case of randomized query complexity was not known. Our main result is to prove the corresponding theorem for randomized query complexity.

▶ **Theorem 2.** *Let f be a partial Boolean function on n-bits such that $\mathrm{R}(f) = \Theta(n)$. Then for all partial functions g, we have*

$$\mathrm{R}(f \circ g) = \Omega(\mathrm{R}(f) \cdot \mathrm{R}(g)).$$

The proof of this theorem is given in Section 4. Notice, since $\mathrm{R}(f \circ g) = O(\mathrm{R}(f) \cdot \mathrm{R}(g) \log \mathrm{R}(f))$ (by error reduction), Theorem 2 says that composition of R holds when the randomized query complexity of the outer function, f, is $\Theta(n)$. Next, we give main ideas behind the proof of the above theorem.

Ideas behind proof of Theorem 2

A crucial complexity measure that we use for the proof of Theorem 2 is called the *noisy randomized query complexity*, first introduced by Ben-David and Blais [9] in order to study randomized query complexity. Noisy randomized query complexity can be seen as a generalization of randomized query complexity where the algorithm can query a bit with any bias and only pays proportionally to the square of the bias in terms of cost (see Definition 16). They give the following characterization of $\mathrm{noisyR}(f)$ (the noisy randomized query complexity of f).

▶ **Theorem 3** (Ben-David and Blais [9])**.** *For all partial functions f on n-bits, we have*

$$\mathrm{noisyR}(f) = \Theta\left(\frac{\mathrm{R}(f \circ \mathrm{GapMaj}_n)}{n}\right), \tag{1}$$

where GapMaj_n is the Gap-Majority function on n bits whose input is promised to have Hamming weight either $(n/2 + 2\sqrt{n})$ (in which case the output is -1) or $(n/2 - 2\sqrt{n})$ (in which case the output is 1).

We want to point out that the arity of f and Gap-Majority is the *same* in Theorem 3. Towards a proof of Theorem 2, we first make the following crucial observation.

▶ **Observation 4.** *Let f be a partial Boolean function on n bits. If $t(n) \geq 1$ is a non-decreasing function of n and*

$$\mathrm{noisyR}(f) = \Omega\left(\frac{\mathrm{R}(f \circ \mathrm{GapMaj}_{t(n)})}{t(n)}\right),$$

then $\mathrm{R}(f \circ g) = \Omega((\mathrm{R}(f) \cdot \mathrm{R}(g))/t(n))$ for all partial functions g.

In particular choosing $t(n)$ to be $(\log n)$, if the outer function f satisfies

$$\mathrm{noisyR}(f) = \Omega\left(\frac{\mathrm{R}(f \circ \mathrm{GapMaj}_{\log n})}{\log n}\right). \tag{2}$$

then the above observation gives $\mathrm{R}(f \circ g) = \Omega((\mathrm{R}(f) \cdot \mathrm{R}(g))/(\log n))$ for all partial functions g.

The Observation 4 allows us to approach the composition question for randomized query complexity in a conceptually fresh manner. The goal of proving that randomized query complexity composes for a function or a class of functions, say upto $(\log n)$-factor, reduces to showing that Equation 2 holds for that function or class of functions for $t(n) = \log n$.

We are able to show that Equation 2 holds for all non-decreasing functions $t(n)$ with a slight overhead.

▶ **Theorem 5.** *Let f be a partial function on n bits and let $t \geq 1$, then* $\mathrm{R}(f \circ \mathrm{GapMaj}_t) = O\left(t \cdot \mathrm{noisyR}(f) + n\right)$.

Notice that this is a generalization of Ben-David and Blais' characterization of noisyR given by Theorem 3 in one direction. To give an idea of the proof, their characterization (Theorem 3) shows that any noisy oracle algorithm for f can be simulated using only two biases, 1 and $1/\sqrt{n}$ (where n is the arity of f), with only constant overhead. We generalize this by showing that the same simulation works with a slight overhead even when the bias $1/\sqrt{n}$ is replaced by a bias $1/\sqrt{t}$, for some $t \geq 1$. A detailed proof the above theorem has been included in the full version of this paper [20].

This seemingly inconsequential generalization allows us to complete the proof of Theorem 2, i.e. if for an n-bit partial function f, $\mathrm{R}(f) = \Theta(n)$, then $\mathrm{R}(f \circ g) = \widetilde{\Theta}(\mathrm{R}(f) \cdot \mathrm{R}(g))$ for all partial functions g (see Section 4 for details).

Furthermore, Theorem 5 even sheds light on *the composition question for* noisyR. A corollary of this theorem is that if R composes with respect to an outer function, then noisyR also composes with respect to the same outer function (see Section 4 for a proof).

▶ **Corollary 6.** *Let f be a partial Boolean function. If* $\mathrm{R}(f \circ g) = \widetilde{\Theta}(\mathrm{R}(f) \cdot \mathrm{R}(g))$ *for all partial functions g then* $\mathrm{noisyR}(f \circ g) = \widetilde{\Theta}(\mathrm{noisyR}(f) \cdot \mathrm{noisyR}(g))$.

2.2 Lower bound on $\widetilde{\deg}(f \circ g)$ in terms of block sensitivity of f and $\widetilde{\deg}(g)$

As discussed in the introduction, the composition question for $\widetilde{\deg}$ is only known to hold when the outer function f is symmetric [11] or has high approximate degree [38]. There are also no known lower bounds on $\widetilde{\deg}(f \circ g)$ in terms of weaker measures of f and $\widetilde{\deg}(g)$. Compare this with the situation with respect to composition of R. It was shown in [26] that $\mathrm{R}(f \circ g) = \Omega(\mathrm{s}(f)\,\mathrm{R}(g))$, where $\mathrm{s}(f)$ denotes the sensitivity of f. This was later strengthened to $\Omega(\mathrm{fbs}(f)\,\mathrm{R}(g))$ [7, 8], where $\mathrm{fbs}(f)$ is the fractional block sensitivity of f.

In this second part we show analogous lower bounds on approximate degree of composed function $f \circ g$. Our main result here is the following.

▶ **Theorem 7.** *For all non-constant (possibly partial)*[3] *Boolean functions* $f : \{0,1\}^n \to \{0,1\}$ *and* $g : \{0,1\}^m \to \{0,1\}$, *we have*

$$\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\sqrt{\mathrm{bs}(f)} \cdot \widetilde{\deg}(g)).$$

[3] For definitions of block sensitivity and approximate degree in the context of partial functions, please see Definitions 32 and 17.

We first note that the above theorem is tight in terms of block sensitivity, i.e., we cannot have $\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\mathrm{bs}(f)^c \cdot \widetilde{\deg}(g))$ for any $c > 1/2$. This is because the OR function over n bits witnesses the tight quadratic separation between $\widetilde{\deg}$ and bs, i.e., $\widetilde{\deg}(\mathsf{OR}_n) = \Theta(\sqrt{n}) = \Theta(\sqrt{\mathrm{bs}(\mathsf{OR}_n)})$ [33].

We also get the following composition theorem as a corollary. It says that the composition for $\widetilde{\deg}$ holds when the outer function has minimal approximate degree with respect to its block sensitivity. Recall, $\widetilde{\deg}(f) = \Omega(\sqrt{\mathrm{bs}(f)})$ [33].

▶ **Corollary 8.** *For all Boolean function $f : \{0,1\}^n \to \{0,1\}$ with $\widetilde{\deg}(f) = \Theta(\sqrt{\mathrm{bs}(f)})$ and for all $g : \{0,1\}^m \to \{0,1\}$, we have $\widetilde{\deg}(f \circ g) = \widetilde{\Theta}(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))$.*

This complements a result of Sherstov [38, Theorem 6.6], which shows that composition of $\widetilde{\deg}$ holds when the outer function has maximal $\widetilde{\deg}$ with respect to its arity.

We further note that Corollary 8 covers new set of composed functions $f \circ g$ for which the composition theorem for $\widetilde{\deg}$ doesn't follow from the known results [11, 38]. For example, consider the Rubinstein function RUB with arity n(see [36] for Definition) as the outer function f. It is clearly not a symmetric function. It also doesn't have high approximate degree, i.e., $\widetilde{\deg}(\mathsf{RUB}) = O(\sqrt{n}\log n)$ (see Lemma A.7 from [20]). Therefore, the composition of $\widetilde{\deg}(\mathsf{RUB} \circ g)$ doesn't follow from the existing results. However, it follows from Corollary 8, since $\mathrm{bs}(\mathsf{RUB}) = \Omega(n)$ and so $\widetilde{\deg}(\mathsf{RUB}) = \widetilde{\Theta}(\sqrt{\mathrm{bs}(\mathsf{RUB})})$.

Another example is the sink function SINK over $\binom{n}{2}$ variables ([22]), which is also not a symmetric function. Furthermore, its approximate degree is $O(\sqrt{n}\log n)$ (Lemma A.7 from [20]). Therefore, the composition of $\widetilde{\deg}(\mathsf{SINK} \circ g)$ also doesn't follow from the existing results. Again, it follows from Corollary 8, since $\mathrm{bs}(\mathsf{SINK}) = \Theta(n)$ (Observation A.4, [20]) and $\widetilde{\deg}(\mathsf{SINK}) = \widetilde{\Theta}(\sqrt{n})$.

Ideas behind proof of Theorem 7

We will first sketch the proof ideas in the case when f and g are total Boolean functions, and then explain how to extend it to partial functions too.

Our starting point is the well known Nisan-Szegedy's embedding of PrOR (see Definition 18) over $\mathrm{bs}(f)$ many bits in a Boolean function f [33]. Carrying out this transformation in $f \circ g$ embeds $\mathsf{PrOR}_{\mathrm{bs}(f)} \circ (g_1, \ldots, g_{\mathrm{bs}(f)})$ into $f \circ g$, where $g_1, \ldots, g_{\mathrm{bs}(f)}$ are different partial functions such that $\widetilde{\mathrm{bdeg}}(g_i) \geq \widetilde{\deg}(g)$ for all $i \in [\mathrm{bs}(f)]$[4]. Since the transformation is just substitutions of variables by constants, we further have

$$\widetilde{\deg}(f \circ g) \geq \widetilde{\mathrm{bdeg}}(\mathsf{PrOR}_{\mathrm{bs}(f)} \circ (g_1, \ldots, g_{\mathrm{bs}(f)})). \tag{3}$$

It now looks like that we can appeal to the composition theorem for PrOR (Theorem 21) [11] to obtain our theorem. However, there is a technical difficulty – Theorem 21 doesn't hold for *different* inner *partial* functions. It only deals with a single total inner function. We therefore generalize the proof of Theorem 21 to obtain the following general version of the composition theorem for PrOR.

▶ **Theorem 9.** *For any partial Boolean functions $g_1, g_2, \ldots, g_n$, we have*

$$\widetilde{\mathrm{bdeg}}\left(\mathsf{PrOR}_n \circ (g_1, g_2, \ldots, g_n)\right) = \Omega\left(\frac{\sqrt{n} \cdot \min_{i=1}^{n} \widetilde{\mathrm{bdeg}}(g_i)}{\log n}\right).$$

[4] $\widetilde{\mathrm{bdeg}}$ is the notion of approximate degree in the context of partial functions. For a formal definition, see Definition 17.

We can now obtain Theorem 7 from Equation (3) and Theorem 9. The proof of Theorem 9 is a generalization of a result due to [11] (see Theorem 21). For lack of space, we present the proof of this theorem in the complete version of this paper [20].

2.3 Composition results when the outer functions has some symmetry

The class of symmetric functions capture many important function like OR, AND, Parity and Majority. Recall that a function is symmetric when the function value only depends on the Hamming weight of the input; in other words, a function is symmetric iff its value on an input remains unchanged even after permuting the bits of the input. As noted earlier, both for R and $\widetilde{\deg}$, composition was known to hold when the outer function was symmetric.

A natural question is, whether one can prove composition theorems when the outer function is *weakly* symmetric (it is symmetric with respect to a weaker notion of symmetry). In this paper we consider one such notion of symmetry – junta-symmetric functions.

▶ **Definition 10** (k-junta symmetric function)**.** *A function $f : \{0,1\}^n \to \{0,1\}$ is called a k-junta symmetric function if there exists a set $\mathcal{J}$ of size k of variables such that the function value depends on assignments to the variables in $\mathcal{J}$ as well as on the Hamming weight of the whole input.*

k-junta symmetric functions can be seen as a mixture of symmetric functions and k-juntas. This class of functions has been considered previously in literature, particularly in [19, 14] where these functions plays a crucial role. [19] even presents multiple characterisations of k-junta symmetric functions for constant k. Note that by definition an arbitrary k-junta (i.e., a function that depend on k variables) is also a k-junta symmetric function, since we can consider the dependence on Hamming weight to be trivial. Thus, this notion loses out on the symmetry of the function considered. We, therefore, consider the class of *strongly* k-junta symmetric functions.

▶ **Definition 11** (Strongly k-junta symmetric function)**.** *A k-junta symmetric function is called strongly k-junta symmetric if every variable is influential. In other words, there exists a setting to the junta variables such that the function value depends on the Hamming weight of the whole input in a non-trivial way.*

We prove that if the outer function is strongly $\sqrt{n}$-junta symmetric ("strongly" indicating that the dependence on the Hamming weight is non-trivial) then $\widetilde{\deg}$ composes. On the other hand, Theorem 2 implies that R composes for any strongly k-junta symmetric functions (as long as $n-k=\Theta(n)$).

▶ **Theorem 12.** *For any strongly k-junta symmetric function $f : \{0,1\}^n \to \{0,1\}$ and any Boolean function $g : \{0,1\}^m \to \{0,1\}$, we have*

- $\widetilde{\deg}(f \circ g) = \widetilde{\Theta}(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))$ *where* $k = O(\sqrt{n})$.
- $\mathrm{R}(f \circ g) = \widetilde{\Theta}(\mathrm{R}(f) \cdot \mathrm{R}(g))$ *where* $n-k=\Theta(n)$.

For the lack of space, the proof of the above theorem is given in Appendix C. Note that if one is able to prove the above theorem for k-junta-symmetric functions (without the requirement of "strongly") for any non-constant k then we would have the full composition theorem.

Organization of the paper

We have formally defined complexity measures and Boolean functions needed for our results in Section 3 and Appendix A. Section 4 contains proofs of our results related to the composition of randomized query complexity (Theorem 2). In Section 5 we give the proof of our result for the composition of approximate degree (Theorem 7). Finally, for the sake of space, the results about the composition of functions with the weak notion of symmetry are in Appendix C.

3 Preliminaries

Notations: We will use $[n]$ to represent the set $\{1, \dots, n\}$. For any (possibly partial) Boolean function $f : \{0,1\}^n \to \{0,1,*\}$ we will denote by $\mathrm{Dom}(f)$ the set $f^{-1}(\{0,1\})$. The arity of f is the number of variables - in this case n. A Boolean function $f : \{0,1\}^n \to \{0,1,*\}$ is said to be total if $\mathrm{Dom}(f) = \{0,1\}^n$. Any function (not otherwise stated) will be a total Boolean function.

For any $x \in \{0,1\}^n$, we will use $|x|$ to denote the number of 1s in x, that is, the Hamming weight of the string x. The string x^i denotes the modified string x with the i-th bit flipped. Similarly, x^B is defined to be the string such that all the bits whose index is contained in the set $B \subseteq [n]$ are flipped in x.

Following is a formal definition of (partial) function composition.

▶ **Definition 13** (Generalized composition of functions). *For any (possibly partial) Boolean function $f : \{0,1\}^n \to \{0,1,*\}$ and n (possibly partial) Boolean functions $g_1, g_2, \dots, g_n$, define the (possibly partial) composed function*

$$f \circ (g_1, g_2, \dots, g_n)(x_1, x_2, \dots, x_n) = f(g_1(x_1), g_2(x_2), \dots, g_n(x_n)),$$

where g_i's can have different arities and, moreover, if $x_i \notin \mathrm{Dom}(g_i)$ for any $i \in [n]$ or the string $(g_1(x_1), g_2(x_2), \dots, g_n(x_n)) \notin \mathrm{Dom}(f)$, then the function $f \circ g$ outputs $*$.

In this paper we use the standard definitions of various complexity measures like randomized query complexity, sensitivity, block-sensitivity, fractional block sensitivity and approximate degree. We present the formal definitions in Appendix A.

3.1 Standard definitions and functions for the composition of R

The function Gap-Majority has played an important role in the study of composition of R.

▶ **Definition 14** (Gap-Majority). *The function $\mathrm{GapMaj}_t : \{0,1\}^t \to \{0,1,*\}$ is a partial function with arity t such that*

$$\mathrm{GapMaj}_t(x) = \begin{cases} 1 & \text{if } |x| = t/2 + 2\sqrt{t}, \\ 0 & \text{if } |x| = t/2 - 2\sqrt{t}, \\ * & \text{otherwise.} \end{cases}$$

It can be shown that $\mathrm{R}(\mathrm{GapMaj}_t) = \Theta(t)$ [9].

In regards to the composition question of R, one of the most significant complexity measures (defined by Ben-David and Blais [9]) is that of noisyR. We first define the noisy oracle model.

▶ **Definition 15** (Noisy Oracle Model and Noisy Oracle Access to a String ([9])). *For $b \in \{0,1\}$, a noisy oracle to b takes a parameter $-1 \leq \gamma \leq 1$ as input and returns a bit b' such that $\Pr[b' = b] = (1+\gamma)/2$. The cost of one such query is γ^2. Each query to noisy oracle returns independent bits.*

For $x = (x_1, \ldots, x_n) \in \{0,1\}^n$, noisy oracle access to x is access to n independent noisy oracles, one for each bit x_i, $i \in [n]$.

Next, we define the noisy oracle model of computation.

▶ **Definition 16** (Noisy Oracle Model of Computation ([9])). *Let $f : \{0,1\}^n \to \{0,1,*\}$ be a partial Boolean function. A* noisyR *query algorithm A computes f if for all $x \in \mathrm{Dom}(f)$, $\Pr[A(x) \neq f(x)] \leq 1/3$, where A is a randomized algorithm given noisy oracle access to x, and the probability is over both noisy oracle calls and the internal randomness of the algorithm A. The cost of the algorithm A for an input x is the sum of the cost of all noisy oracle calls made by A on x, and the cost of A, cost(A), is the maximum cost over all $x \in \mathrm{Dom}(f)$. The* noisyR *randomized query complexity of f, denoted by* $\mathrm{noisyR}(f)$, *is defined as*

$$\mathrm{noisyR}(f) = \min_{A \text{ computes } f} cost(A).$$

Again, 1/3 in the above definition can be replaced by any constant $< 1/2$. If only queries with $\gamma = 1$ are allowed in the noisy query model, then we obtain the usual randomized algorithm for f, thus $\mathrm{noisyR}(f) = O(\mathrm{R}(f))$.

3.2 Standard definitions and functions for the composition of $\widetilde{\deg}$

The definition of $\widetilde{\deg}$ can naturally be extended to partial functions f by restricting the definition to hold only for inputs in $\mathrm{Dom}(f)$, but the approximating polynomial can take arbitrarily large values on points outside the domain. However, for the purpose of understanding the composition of approximate degree of Boolean functions (or even total Boolean functions) one need a measure of approximate degree of partial Boolean functions which is bounded on all the points of the Boolean cube.

▶ **Definition 17** (Bounded approximate degree ($\widetilde{\mathrm{bdeg}}$)). *For a partial Boolean function $f : \{0,1\}^n \to \{0,1,*\}$, the bounded approximate degree of f ($\widetilde{\mathrm{bdeg}}(f)$) is the minimum possible degree of a polynomial p such that*
- $|p(x) - f(x)| \leq 1/3, \quad \forall x \in \mathrm{Dom}(f)$, *and*
- $0 \leq p(x) \leq 1 \quad \forall x \in \{0,1\}^n$.

In other words, we take the minimum possible degree of a polynomial which is bounded for all possible inputs ($p(x) \in [0,1]$ for all $x \in \{0,1\}^n$), and it approximates f in the usual sense over $\mathrm{Dom}(f)$.

Over the years people have tried to study the composition of $\widetilde{\deg}$ with different outer functions. In this context the following restriction of OR is an important partial function:

▶ **Definition 18** (Promise-OR). *Promise-*OR *(denoted by* PrOR_n*) is the function* PrOR_n : $\{0,1\}^n \to \{0,1,*\}$ *such that* $\mathsf{PrOR}_n(x) = 0$ *if* $|x| = 0$, *equals to 1 if* $|x| = 1$, *and* $*$ *otherwise.*

Some useful previous results. We will also be crucially using a few results from prior works in our proofs. The following are a couple of useful results on noisyR.

▶ **Lemma 19** ([9]). *Let f be a non-constant partial Boolean function then* $\mathrm{noisyR}(f) = \Omega(1)$.

▶ **Theorem 20** ([9]). *For all partial functions f and g, $\mathrm{R}(f \circ g) = \Omega(\mathrm{noisyR}(f) \cdot \mathrm{R}(g))$.*

We will also be using the following theorem of [11] regarding the composition question of $\widetilde{\mathrm{bdeg}}$ when the outer function is PrOR_n. Informally, we will call it the Promise-OR composition theorem.

▶ **Theorem 21** ([11]). *For any Boolean function $g : \{0,1\}^m \to \{0,1\}$ we have,*

$$\widetilde{\mathrm{bdeg}}\left(\mathsf{PrOR}_n \circ g\right) = \Omega\left(\sqrt{n} \cdot \widetilde{\deg}(g)/\log n\right).$$

4 Results about composition of R

This section is devoted to the results related to the composition of randomized query complexity. Our main result states that composition of R holds if the outer function has full randomized query complexity (Theorem 2). As mentioned in the proof idea, the proof critically depends on the notion of noisy randomized query complexity and its properties (introduced by Ben-David and Blais [9]).

Recall the definition of noisy randomized query complexity of a function f from Definition 16. As mentioned in the introduction (Theorem 3), Ben-David and Blais [9] proved that

$$\mathrm{noisyR}(f) = \Theta\left(\frac{\mathrm{R}(f \circ \mathrm{GapMaj}_n)}{n}\right), \tag{4}$$

where GapMaj_n is the Gap-Majority function on n bits. Note that Ben-David and Blais proved Equation 4 when the arity of functions f and Gap-Majority is the same. We show that if Equation 4 can be generalized for Gap-Majority functions of arbitrary arity for some outer function f, then randomized query complexity composes for the function f. We restate the following observation from the introduction.

▶ **Observation 4.** *Let f be a partial Boolean function on n bits. If $t(n) \geq 1$ is a non-decreasing function of n and*

$$\mathrm{noisyR}(f) = \Omega\left(\frac{\mathrm{R}(f \circ \mathrm{GapMaj}_{t(n)})}{t(n)}\right),$$

then $\mathrm{R}(f \circ g) = \Omega((\mathrm{R}(f) \cdot \mathrm{R}(g))/t(n))$ for all partial functions g.

Proof. Suppose $\mathrm{noisyR}(f) = \Omega\left(\frac{\mathrm{R}(f \circ \mathrm{GapMaj}_{t(n)})}{t(n)}\right)$, since $\mathrm{R}(f \circ \mathrm{GapMaj}_t) \geq \mathrm{R}(f)$, we have $\mathrm{noisyR}(f) = \Omega(\mathrm{R}(f)/(t(n))$. Theorem 20 implies that a lower bound on noisyR translates to a lower bound on $\mathrm{R}(f \circ g)$. We have,

$$\begin{aligned} \mathrm{R}(f \circ g) &= \Omega(\mathrm{noisyR}(f) \cdot \mathrm{R}(g)) && \text{(Theorem 20)} \\ &= \Omega\left(\frac{\mathrm{R}(f) \cdot \mathrm{R}(g)}{t(n)}\right). \end{aligned}$$ ◀

Observation 4 follows from the above observation by choosing $t(n)$ to be a small function of n.

We restate from Section 1 our generalized characterization of noisyR (i.e., generalization of Equation 4). For a complete proof of Theorem 5 we refer to the full version of this paper [20].

▶ **Theorem 5.** *Let f be a partial function on n bits and let $t \geq 1$, then* $\mathrm{R}(f \circ \mathrm{GapMaj}_t) = O\left(t \cdot \mathrm{noisyR}(f) + n\right)$.

This allows us to show that if for an n-bit partial function f, $\mathrm{R}(f) = \Theta(n)$, then $\mathrm{R}(f \circ g) = \widetilde{\Theta}(\mathrm{R}(f) \cdot \mathrm{R}(g))$ for all partial functions g (Theorem 2).

The proof of Theorem 2 is discussed in Section 4.1. A corollary of this theorem is that if R composes with respect to an outer function, then noisyR also composes with respect to the same outer function (Corollary 6).

We give proof of Theorem 2 in the next section and prove Corollary 6 in Section 4.3. We need the following theorem for these proofs, which lower bounds $R(f \circ g)$ in terms of $R(f)$ and $R(g)$.

▶ **Theorem 22** ([24])**.** *Let f and g be partial functions then* $\mathrm{R}(f \circ g) = \Omega(\mathrm{R}(f) \cdot \sqrt{\mathrm{R}(g)})$.

4.1 Composition for functions with $\mathrm{R}(f) = \Theta(n)$

We restate the theorem below.

▶ **Theorem 2.** *Let f be a partial Boolean function on n-bits such that $\mathrm{R}(f) = \Theta(n)$. Then for all partial functions g, we have*

$$\mathrm{R}(f \circ g) = \Omega(\mathrm{R}(f) \cdot \mathrm{R}(g)).$$

Proof. From Theorem 22 we have a lower bound on the randomized query complexity of $(f \circ \mathrm{GapMaj}_t)$:

$$\mathrm{R}(f \circ \mathrm{GapMaj}_t) = \Omega(\mathrm{R}(f) \cdot \sqrt{t}). \tag{5}$$

On the other hand, Theorem 5 gives an upper bound of $O\left(t \cdot \mathrm{noisyR}(f) + n\right)$ on $\mathrm{R}(f \circ \mathrm{GapMaj}_t)$. Thus, choosing $t = \left(\frac{C \cdot n}{\mathrm{noisyR}(f)}\right)$ for a large enough constant C, we have

$$\mathrm{R}(f) \cdot \sqrt{\frac{n}{\mathrm{noisyR}(f)}} = O\left(\frac{n}{\mathrm{noisyR}(f)} \cdot \mathrm{noisyR}(f) + n\right).$$

This implies that

$$\mathrm{R}(f) = O\left(\sqrt{n \cdot \mathrm{noisyR}(f)}\right). \tag{6}$$

Thus, if $\mathrm{R}(f) = \Theta(n)$, then $\mathrm{noisyR}(f) = \Omega(\mathrm{R}(f))$, which implies composition from Theorem 20. ◀

Notice that Equation 6 is equivalent to the following observation.

▶ **Observation 23.** *Let f be a partial Boolean function on n-bits. Then,* $\mathrm{noisyR}(f) = \Omega\left(\frac{\mathrm{R}(f)^2}{n}\right)$.

When $\mathrm{R}(f) = \Theta(n)$, we have already seen that Observation 23 implies composition of randomized query complexity when the outer function is f.

Though, Observation 23 implies a more general result. When $\mathrm{R}(f)$ is close to n (arity of f), Observation 23 places a limit on the gap between $\mathrm{R}(f)$ and $\mathrm{noisyR}(f)$ (consequently on the violation of composition with outer function being f). These implications are formally discussed in Appendix 4.2.

Another implication of Theorem 2 is that composition of R for an outer function f implies the composition of noisyR for outer function being f (Corollary 6).

4.2 Additional implications of Observation 23

Without loss of generality we can assume $\mathrm{R}(f \circ g) = \Omega(\mathrm{R}(g))$ (note that this is true when f is non-constant).

Ben-David and Blais [9] gave a counterexample for composition, but the arity of the used function was very high compared to the randomized query complexity. They observed that the composition can still be true in the weaker sense:

$$\mathrm{R}(f \circ g) = \Omega\left(\frac{\mathrm{R}(f) \cdot \mathrm{R}(g)}{\log n}\right).$$

Observation 23 shows that a much weaker composition result is true.

▶ **Corollary 24.** *Let f and g be partial functions on n and m bits respectively. If $\mathrm{R}(f \circ g) = \Omega(\mathrm{R}(g))$, then*

$$\mathrm{R}(f \circ g) = \Omega\left(\frac{\mathrm{R}(f) \cdot \mathrm{R}(g)}{\sqrt{n}}\right).$$

Proof.

$$\begin{aligned} \mathrm{R}(f \circ g) &= \Omega(\mathrm{noisyR}(f) \cdot \mathrm{R}(g)) && \text{(Theorem 20)} \\ &= \Omega\left(\frac{\mathrm{R}(f)^2 \cdot \mathrm{R}(g)}{n}\right). && (7) \end{aligned}$$

Where the last equality follows from Observation 23 [5] Now there are two cases:

- **Case 1.** $\mathrm{R}(f) = O(\sqrt{n})$. In this case $\mathrm{R}(f)/\sqrt{n} = O(1)$ and since we assumed $\mathrm{R}(f \circ g) = \Omega(\mathrm{R}(g))$, the claim follows from Equation 7.
- **Case 2.** $\mathrm{R}(f) = \Theta(n^{1/2} \cdot t(n))$ where $t(n)$ is a strictly increasing function of n. Thus,

$$\frac{\mathrm{R}(f)^2 \cdot \mathrm{R}(g)}{n} = \Omega\left(t(n)^2 \cdot \mathrm{R}(g)\right) = \Omega\left(\frac{\mathrm{R}(f) \cdot \mathrm{R}(g)}{\sqrt{n}}\right).$$

Again, the claim follows from Equation 7. ◀

The weaker composition, Corollary 24, implies that if $\mathrm{R}(f)$ and $\mathrm{R}(g)$ are comparable to the arity of these functions, the randomized query complexity of $f \circ g$ is "not far" from the conjectured randomized query complexity $\mathrm{R}(f) \cdot \mathrm{R}(g)$. In other words, if there is a large polynomial separation between $\mathrm{R}(f \circ g)$ and $(\mathrm{R}(f) \cdot \mathrm{R}(g))$, then $\mathrm{R}(f)$ and $\mathrm{R}(g)$ can not be too large.

▶ **Corollary 25.** *Let f and g be partial functions such that f is a function on n-bits and g is a function on $t(n)$-bits where $t(n)$ is a strictly increasing function of n. If $\mathrm{R}(f) = \Theta(n^{\beta})$, $\mathrm{R}(g) = \Theta(n^{\gamma})$ and $\mathrm{R}(f \circ g) = O((\mathrm{R}(f) \cdot \mathrm{R}(g))^{\alpha})$, where $\alpha < 1$ is a constant, then $(1 - \alpha)(\alpha + \beta) < 1/2$.*

Proof. For some constants A and B we have

$$A \cdot \frac{\mathrm{R}(f) \cdot \mathrm{R}(g)}{\sqrt{n}} \leq \mathrm{R}(f \circ g) \leq B \cdot (\mathrm{R}(f) \cdot \mathrm{R}(g))^{\alpha},$$

[5] Sherstov [38] proved that for Boolean functions f and g, $\widetilde{\deg}(f \circ g) = \Omega((\widetilde{\deg}(f)^2 \widetilde{\deg}(g))/n)$. Thus in Equation 7 we prove the same result but in the randomized world.

where the first inequality follows from Corollary 24 and second from assumption. Assigning the values of $\mathrm{R}(f)$ and $\mathrm{R}(g)$ in terms on n we have,

$$\begin{aligned}
&A \cdot n^{\beta+\gamma-1/2} \leq B \cdot n^{\alpha(\beta+\gamma)} \\
&n^{(1-\alpha)(\beta+\gamma)-1/2} \leq \frac{B}{A}.
\end{aligned}$$

which implies, for large enough n, $(1-\alpha)(\beta+\gamma) \leq 1/2$. ◀

A special case of the above corollary is when arity and randomized query complexity of g are superpolynomial in n. In this case a polynomial gap between $\mathrm{R}(f \circ g)$ and $(\mathrm{R}(f) \cdot \mathrm{R}(g))$ is not possible.

4.3 Proof of Corollary 6

First, we need the following lemma which follows from Theorem 5, Theorem 20 and Lemma 19.

▶ **Lemma 26.** *Let f be a partial function on n bits and let $t = \Omega(n)$. Then*

$$\mathrm{noisyR}(f) = \Theta\left(\frac{\mathrm{R}(f \circ \mathrm{GapMaj}_t)}{t}\right).$$

Proof. From Theorem 5 we have for all $t \geq 1$, $\mathrm{R}(f \circ \mathrm{GapMaj}_t) = O(t \cdot \mathrm{noisyR}(f) + n)$. Since we have assumed $t = \Omega(n)$ and $\mathrm{noisyR}(f) = \Omega(1)$ (Lemma 19), we get $\mathrm{R}(f \circ \mathrm{GapMaj}_t) = O(t \cdot \mathrm{noisyR}(f))$. Thus, $\mathrm{noisyR}(f) = \Omega\left(\frac{\mathrm{R}(f \circ \mathrm{GapMaj}_t)}{t}\right)$.

The upper bound $\mathrm{noisyR}(f) = O\left(\frac{\mathrm{R}(f \circ \mathrm{GapMaj}_t)}{t}\right)$ follows from Theorem 20 and the fact that $\mathrm{R}(\mathrm{GapMaj}_t) = \Theta(t)$. ◀

Now we prove that if R composes for f then noisyR composes for that f. For convenience, we recall the statement of the corollary from the introduction.

▶ **Corollary 6.** *Let f be a partial Boolean function. If $\mathrm{R}(f \circ g) = \widetilde{\Theta}(\mathrm{R}(f) \cdot \mathrm{R}(g))$ for all partial functions g then $\mathrm{noisyR}(f \circ g) = \widetilde{\Theta}(\mathrm{noisyR}(f) \cdot \mathrm{noisyR}(g))$.*

Proof. From Theorem 3, we have

$$\mathrm{noisyR}(f \circ g) = \Theta\left(\frac{\mathrm{R}\left((f \circ g) \circ \mathrm{GapMaj}_{mn}\right)}{mn}\right).$$

Since $(f \circ g) \circ h = f \circ (g \circ h)$, the right hand side of the above expression is equal to

$$\Theta\left(\frac{\mathrm{R}\left(f \circ (g \circ \mathrm{GapMaj}_{mn})\right)}{mn}\right).$$

The proof follows from the assumption that R composes and Lemma 26.

$$\begin{aligned}
\mathrm{noisyR}(f \circ g) &= \Theta\left(\frac{\mathrm{R}\left(f\right) \cdot \mathrm{R}\left(g \circ \mathrm{GapMaj}_{mn}\right)}{mn}\right) && \text{(assuming R composes)} \\
&= \Theta\left(\mathrm{R}(f) \cdot \mathrm{noisyR}(g)\right) && \text{(from Lemma 26)} \\
&= \Theta\left(\mathrm{noisyR}(f) \cdot \mathrm{noisyR}(g)\right). && \text{(assuming R composes)}
\end{aligned}$$

5 Composition of approximate degree in terms of block sensitivity

In this section we study the composition question for approximate degree. Recall that the composition question asks: whether for all Boolean functions f and g

$$\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\widetilde{\deg}(f)\,\widetilde{\deg}(g))?$$

Following our discussion from the introduction, we know that the above composition is known to hold for only two sub-classes of outer functions, namely symmetric functions [11] and functions with high approximate degree [38]. It is thus natural to seek weaker lower bounds to make progress towards the composition question. One way to weaken the expression on the right-hand side would be to replace the measure $\widetilde{\deg}(f)$ by a weaker measure (like $\sqrt{\mathrm{s}(f)}$, $\sqrt{\mathrm{bs}(f)}$ or $\sqrt{\mathrm{fbs}(f)}$). Here we will establish one such lower bound of $\sqrt{\mathrm{bs}(f)}\,\widetilde{\deg}(g)$.

We restate our theorem now.

▶ **Theorem 7.** *For all non-constant (possibly partial)*[6] *Boolean functions $f : \{0,1\}^n \to \{0,1\}$ and $g : \{0,1\}^m \to \{0,1\}$, we have*

$$\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\sqrt{\mathrm{bs}(f)} \cdot \widetilde{\deg}(g)).$$

We note that many analogous results are known in the setting of composition of R; see, for example, [26, 7, 8, 13, 6, 24, 10]. To the best of our knowledge, this is the first such result in the setting of $\widetilde{\deg}$. We present only a proof sketch here; most of the technical parts of the proof appear in Appendix B.

Further, we present the sketch of the proof in two parts. For simplicity, in the first part we sketch a proof of the lower bound $\sqrt{\mathrm{s}(f)}\,\widetilde{\deg}(g)$ for total function f, and then in the second part we modify the arguments to obtain Theorem 7.

We begin with a proof sketch for a lower bound of $\sqrt{\mathrm{s}(f)}\,\widetilde{\deg}(g)$. Let $x \in \{0,1\}^n$ be an input having the maximum sensitivity with respect to f, and $S \subseteq [n]$ be the set of sensitive bits at x ($|S| = \mathrm{s}(f)$). Consider the subfunction f' obtained from f by fixing the set of variables *not* in S according to x. By construction, f' is defined over $\mathrm{s}(f)$ many variables and is fully sensitive at the input $x|_S$ given by x restricted to the indices in S. Since f' is a subfunction of f and g is non-constant, we have $\widetilde{\deg}(f \circ g) \geq \widetilde{\deg}(f' \circ g)$.

Notice that f' at the neighbourhood of x, in the Boolean cube, is the partial function PrOR (Definition 18) or its negation. Therefore, we have $\widetilde{\deg}(f \circ g) \geq \widetilde{\deg}(f' \circ g) \geq \widetilde{\mathrm{bdeg}}(\mathsf{PrOR}_{|S|} \circ g)$ (see Definition 17 for a definition of the bounded approximate degree). We can now invoke the composition theorem for PrOR (Theorem 21) [11] to obtain our lower bound:

$$\widetilde{\deg}(f \circ g) \geq \widetilde{\deg}(f' \circ g) \geq \widetilde{\mathrm{bdeg}}(\mathsf{PrOR}_{|S|} \circ g) = \widetilde{\Omega}(\sqrt{\mathrm{s}(f)}\,\widetilde{\deg}(g)).$$

However, there is a technical issue with our argument above. When we claimed that f' looks like a PrOR function we were not quite correct. Technically, it is a Shifted-PrOR function $\mathsf{PrOR}_{|S|}^{x|_S}$, where $\mathsf{PrOR}_n^a(y_1, y_2, \ldots, y_n) := \mathsf{PrOR}_n(y_1 \oplus a_1, y_2 \oplus a_2, \ldots, y_n \oplus a_n)$ for $a \in \{0,1\}^n$. Formally, we have

$$\widetilde{\deg}(f \circ g) \geq \widetilde{\deg}(f' \circ g) \geq \widetilde{\mathrm{bdeg}}(\mathsf{PrOR}_{|S|}^{x|_S} \circ g) = \widetilde{\mathrm{bdeg}}(\mathsf{PrOR}_{|S|} \circ (g_1, \ldots, g_{|S|})), \tag{8}$$

where $g_i = g$ or $\neg g$ depending on the corresponding i-th bit in $x|_S$.

[6] For definitions of block sensitivity and approximate degree in the context of partial functions, please see Definitions 32 and 17.

We, therefore, need a composition theorem for PrOR with *different* inner functions, while Theorem 21 requires that all the inner functions be same. In fact, we would need a more general composition theorem with *different* inner *partial* functions, which we restate below. This generalization is crucially used when dealing with block sensitivity.

▶ **Theorem 9.** *For any partial Boolean functions $g_1, g_2, \ldots, g_n$, we have*

$$\widetilde{\mathrm{bdeg}}\left(\mathsf{PrOR}_n \circ (g_1, g_2, \ldots, g_n)\right) = \Omega\left(\frac{\sqrt{n}\cdot \min_{i=1}^{n} \widetilde{\mathrm{bdeg}}(g_i)}{\log n}\right).$$

The proof of Theorem 9 is a generalization of proof of Theorem 21. For the sake of completeness we have added a proof in the full version of the paper [20].

Now returning to Equation (8) and using Theorem 9, we obtain the desired lower bound:

$$\widetilde{\deg}(f\circ g) \geq \widetilde{\deg}(f'\circ g) \geq \widetilde{\mathrm{bdeg}}(\mathsf{PrOR}_{|S|}^{x|_S}\circ g) = \widetilde{\Omega}(\sqrt{\mathrm{s}(f)}\,\widetilde{\deg}(g)).$$

We are now ready to present the modifications required to improve the lower bound to $\widetilde{\Omega}(\sqrt{\mathrm{bs}(f)}\,\widetilde{\deg}(g))$.

Proof of Theorem 7. Let $b = \mathrm{bs}(f)$ and $a = (a_1, a_2, \ldots, a_n)$ be an input where f achieves the maximum block sensitivity. Further, let $B_1, B_2, \ldots, B_b$ be disjoint minimal sets of variables that achieves the block sensitivity at a, i.e., $f(a) \neq f(a^{B_i})$ for all $i \in [b]$. Recall, a^{B_i} denotes the Boolean string obtained from a by flipping the bits at all the indices given by B_i. Define a partial function $f' : \{0,1\}^n \to \{0,1,*\}$ such that,

$$f'(x) = \begin{cases} 0 & \text{if } x = a, \\ 1 & \text{if } x = a^{B_i}, \text{ for some } i \in [b], \\ * & \text{otherwise.} \end{cases}$$

Note that f contains f' or its negation as a sub function. Thus, $\widetilde{\deg}(f\circ g) \geq \widetilde{\mathrm{bdeg}}(f'\circ g)$.

Since g is non-constant, we can fix the indices *not* in $\bigcup_{i=1}^{b} B_i$ according to a to obtain $f''\circ g$. We would now like to embed PrOR_b over the remaining variables in f''. For this purpose we define the following partial functions: for every $i \in [b]$, let $I_i : \{0,1\}^{B_i} \to \{0,1,*\}$ be such that

$$I_i(x) = \begin{cases} 0 & \text{if } x = a|_{B_i}, \\ 1 & \text{if } x = a^{B_i}|_{B_i}, \\ * & \text{otherwise.} \end{cases}$$

Now observe that $f''\circ g$ can be rewritten as $\mathsf{PrOR}_b \circ (I_1\circ g, \ldots, I_b \circ g)$. We therefore have

$$\begin{aligned} \widetilde{\deg}(f\circ g) \geq \widetilde{\mathrm{bdeg}}(f'\circ g) \geq \widetilde{\mathrm{bdeg}}(f''\circ g) &= \widetilde{\mathrm{bdeg}}(\mathsf{PrOR}_b \circ (I_1\circ g, \ldots, I_b\circ g)) \\ &= \Omega\left(\frac{\sqrt{b}\cdot \min_i \widetilde{\mathrm{bdeg}}(I_i\circ g)}{\log b}\right) = \widetilde{\Omega}\left(\sqrt{b}\cdot \widetilde{\deg}(g)\right), \end{aligned}$$

where the second last equality follows from Theorem 9 and the last equality uses the fact $\widetilde{\mathrm{bdeg}}(I_i\circ g) \geq \widetilde{\deg}(g)$ for all i, which in turn follows from each I_i being non-constant. ◀

We end this section with few final remarks. As a corollary to Theorem 7 we have the following composition for $\widetilde{\deg}$ when the outer function has minimal approximate degree with respect to its block sensitivity.

▶ **Corollary 8.** *For all Boolean function* $f : \{0,1\}^n \to \{0,1\}$ *with* $\widetilde{\deg}(f) = \Theta(\sqrt{\mathrm{bs}(f)})$ *and for all* $g : \{0,1\}^m \to \{0,1\}$*, we have* $\widetilde{\deg}(f \circ g) = \widetilde{\Theta}(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))$*.*

We also note that the set of Boolean functions with $\widetilde{\deg}(f) = \Theta(\sqrt{\mathrm{bs}(f)})$ includes examples of *non-symmetric* functions f with *low* approximate degree. In other words, when such functions are outer function in a composed function then the composition of $\widetilde{\deg}$ doesn't follow from the known results [11, 38]. Such examples are described in Subsection 2.2.

As stated in the introduction, we recall that Theorem 7 is tight in terms of block-sensitivity, i.e., the lower bound can not be improved to $\widetilde{\Omega}(\mathrm{bs}(f)^c \cdot \widetilde{\deg}(g))$ for some $c > 1/2$.

6 Conclusion

While our work makes progress on the composition problem for R and $\widetilde{\deg}$, the main problems of whether $\widetilde{\deg}$ and R composes for any pair of Boolean functions still remains open. In this light, we would like to highlight some questions that can be useful stepping stones towards the main questions.

We showed that the composition question for R is equivalent to the following open question (which is a generalization of Ben-David and Blais [9] result):

▶ **Open question 27.** *Let* $f : \{0,1\}^n \to \{0,1,*\}$ *be a Boolean function. Then, is it true that for arbitrary* t*,* $\mathrm{noisyR}(f) = \Theta\left(\mathrm{R}(f \circ \mathrm{GapMaj}_t)/t\right)$*?*

In case of approximate degree composition, a natural question is whether $\sqrt{\mathrm{bs}(f)}$ can be replaced by some other complexity measures. In this regards we state the following open problems:

▶ **Open question 28.** *For all Boolean functions* f *and* g*, can we prove either of the following:*

- $\widetilde{\deg}(f \circ g) = \Omega(\sqrt{\widetilde{\deg}(f)} \cdot \widetilde{\deg}(g))$*?*
- $\widetilde{\deg}(f \circ g) = \Omega(\sqrt{\mathrm{fbs}(f)} \cdot \widetilde{\deg}(g))$*?*

Recently, in [43, 42, 23, 18, 21], the classes of transitive functions got a lot of attention as natural generalization of the classes of symmetric functions. Can the result for symmetric functions be extended to transitive functions?

▶ **Open question 29.** *Can we prove that* $\widetilde{\deg}$ *and* R *compose when the outer function is transitive?*

A Standard definition of complexity measures

We look at many different complexity measures in the paper, let us start with the formal definition of R and $\widetilde{\deg}$.

▶ **Definition 30** (Randomized query complexity (R))**.** *Let $f : \{0,1\}^n \to \{0,1,*\}$ be a (possibly partial) Boolean function. A randomized query algorithm A computes f if $\forall x \in \mathrm{Dom}(f), \Pr[A(x) \neq f(x)] \leq 1/3$, where the probability is over the internal randomness of the algorithm. The cost of the algorithm A, cost(A), is the number of queries made in the worst case over any input as well as internal randomness. The randomized query complexity of f, denoted by $\mathrm{R}(f)$, is defined as*

$$\mathrm{R}(f) = \min_{A \text{ computes } f} cost(A).$$

▶ **Definition 31** (Approximate degree ($\widetilde{\deg}$))**.** *A polynomial $p : \mathbb{R}^n \to \mathbb{R}$ is said to approximate a Boolean function $f : \{0,1\}^n \to \{0,1\}$ if $|p(x) - f(x)| \leq 1/3, \quad \forall x \in \{0,1\}^n$. The approximate degree of f, $\widetilde{\deg}(f)$, is the minimum possible degree of a polynomial which approximates f.*

Note that the constant $1/3$ in the above definitions can be replaced by any constant strictly smaller than $1/2$ which changes $\widetilde{\deg}(f)$ by only a constant factor.

Other than R and $\widetilde{\deg}$, two important related measures are sensitivity ($\mathrm{s}(f)$) and block sensitivity ($\mathrm{bs}(f)$). While the sensitivity and block sensitivity of a total function is well defined, we note that for the case of partial functions there are at least two valid ways of extending the definition from total functions to partial functions. All our results in this paper will hold for partial functions with the following definitions of sensitivity and block sensitivity.

▶ **Definition 32.** *The sensitivity $\mathrm{s}(f,x)$ of a function $f : \{0,1\} \to \{0,1,*\}$ on x is the maximum number s such that there are indices $i_1, i_2, \ldots, i_s \in [n]$ with $f(x^{i_j}) = 1 - f(x)$, for all $1 \leq j \leq s$. Here x^i is obtained from x by flipping the i^{th} bit. The sensitivity of f is defined to be $\mathrm{s}(f) = \max_{x \in \mathrm{Dom}(f)} \mathrm{s}(f,x)$.*

Similarly, the block sensitivity $\mathrm{bs}(f,x)$ of a function $f : \{0,1\} \to \{0,1,*\}$ on x is the maximum number b such that there are disjoint sets $B_1, B_2, \ldots, B_b \subseteq [n]$ with $f(x^{B_j}) = 1 - f(x)$ for all $1 \leq j \leq b$. Recall x^{B_j} is obtained from x by flipping all bits inside B_j. The block sensitivity of f is defined to be $\mathrm{bs}(f) = \max_{x \in \mathrm{Dom}(f)} \mathrm{bs}(f,x)$.

In the definition of block sensitivity, the constraint that the blocks has to be disjoint can be relaxed by extending the definition to "fractional blocks". This gives the measure of fractional block sensitivity.

▶ **Definition 33.** *The fractional block sensitivity $\mathrm{fbs}(f,x)$ of a function $f : \{0,1\} \to \{0,1,*\}$ on x is the maximum value of $\sum_{j=i}^{b} p_j$ such that there are sets $B_1, B_2, \ldots, B_b \subseteq [n]$ and $p_1, \ldots, p_b \in (0,1]$ satisfying the following two conditions.*

- *For each $1 \leq j \leq b$, $f(x^{B_j}) = 1 - f(x)$, and*
- *For each $1 \leq i \leq n$, $\sum_{j:\, i \in B_j} p_j \leq 1$.*

The fractional block sensitivity of f is defined to be $\mathrm{fbs}(f) = \max_{x \in \mathrm{Dom}(f)} \mathrm{fbs}(f,x)$.

B Approximate degree of Promise-OR composed with different inner functions

In this section we show that the approximate degree composes when the outer function is PrOR and the inner functions are (possibly) different partial functions. The proof is essentially a straightforward generalization of the proof of Theorem 21 [11, Theorem 16 (arXiv version)]. However, for the sake of completeness and reader's convenience, we give an overview of the proof here. We will need some definitions and theorems from [11] which we state now. We start with the definition of a problem called “singleton combinatorial group testing”. It generalizes the combinatorial group testing problem.

▶ **Definition 34** (Singleton CGT). *Let D be the set of all $w \in \{0,1\}^{2^n}$ for which there exists an $x \in \{0,1\}^n$ such that for all $S \subseteq [n]$ satisfying $\sum_{i \in S} x_i \in \{0,1\}$, we have $\sum_{i \in S} x_i = w_S$. Note that for all $w \in D$, the string x is uniquely defined by $x_i = w_{\{i\}}$. Let us denote this string by $x(w)$. we then define the partial function $\mathsf{SCGT}_{2^n} : D \to \{0,1\}^n$ by $\mathsf{SCGT}_{2^n}(w) = x(w)$.*

▶ **Theorem 35** ([11, Theorem 19 (arXiv version)]). *The bounded-error quantum query complexity of SCGT_{2^n} is $\Theta(\sqrt{n})$.*

For a formal Definition of bounded error quantum query complexity we refer the survey by [15]. Before we state the next result that we need from [11] we are defining robustness of a polynomial to input noise.

▶ **Definition 36** (Robustness to input noise). *For any function $f : \{0,1\}^n \to \{0,1,*\}$ we say a polynomial $p : \{0,1\}^n \to \mathrm{R}$ approximately computes f with δ-robustness where $\delta \in [0, \frac{1}{2})$ if for any $x \in \mathrm{Dom}(f)$ and $\Delta \in [-\delta, \delta]^n$, we have $|f(x) - p(\Delta + x)| \leq \frac{1}{3}$.*

Now we are ready to state the next result.

▶ **Theorem 37** ([11, Theorem 17 (arXiv version)]). *For a partial Boolean function f, there exists a bounded multilinear polynomial p of degree $O(\mathsf{Q}(f))$ that approximates f with robustness $\Omega(1/\mathsf{Q}(f)^2)$ where $\mathsf{Q}(f)$ is the bounded error quantum query complexity of the function f.*

We refer [11] for more details about robustness of a polynomial induces by quantum algorithm. We also need the existence of a multilinear robust polynomial for $\mathsf{XOR}_n \circ \mathsf{SCGT}_{2^n}$, which follows from Theorems 35 and 37 above, where $\mathsf{XOR}_n \circ \mathsf{SCGT}_{2^n}$ is the parity of n output bits of SCGT_{2^n}.

▶ **Theorem 38** ([11, Theorem 20 (arXiv version)]). *There is a real polynomial p of degree $O(\sqrt{n})$ over 2^n variables $\{w_S\}_{S \subseteq [n]}$ and a constant $c \geq 10^{-5}$ such that for any input $w \in \{0,1\}^{2^n}$ with $\mathsf{XOR}_n \circ \mathsf{SCGT}_{2^n}(w) \neq *$ and any $\Delta \in [-c/n, c/n]^{2^n}$,*

$$|p(w + \Delta) - \mathsf{XOR}_n \circ \mathsf{SCGT}_{2^n}(w)| \leq 1/3.$$

Furthermore, p is multilinear and for all $w \in \{0,1\}^{2^n}$, $p(w) \in [0,1]$.

We also need the following result of Sherstov that shows composition holds for the approximate degree of the parity of n different functions.

▶ **Theorem 39** ([38, Theorem 5.9]). *For any partial Boolean functions $f_1, \dots, f_n$, we have*

$$\widetilde{\mathrm{bdeg}}(\mathsf{XOR} \circ (f_1, \dots, f_n)) = \Omega\left(\sum_{i=1}^{n} \widetilde{\mathrm{bdeg}}(f_i)\right).$$

Theorem 9 can be proved in the similar line of [11, Theorem 20 (arXiv version)], which we are restating below. For the sake of completeness a detailed proof has been added in the full version of the paper [20].

▶ **Theorem 40.** *For any partial Boolean functions $f_1, f_2, \dots, f_n$, we have*

$$\widetilde{\mathrm{bdeg}}\left(\mathsf{PrOR}_n \circ (f_1, f_2, \dots, f_n)\right) = \Omega\left(\frac{\sqrt{n} \cdot \min_{i=1}^{n} \widetilde{\mathrm{bdeg}}(f_i)}{\log n}\right).$$

Furthermore the following upper bound also holds,

$$\widetilde{\mathrm{bdeg}}\left(\mathsf{PrOR}_n \circ (f_1, f_2, \ldots, f_n)\right) = O\left(\sqrt{n} \cdot \max_{i=1}^{n} \widetilde{\mathrm{bdeg}}(f_i) \cdot \log n\right).$$

We will now use this weak bound to establish nearly optimal bound for the approximate degree of PrOR composed with n different *partial* functions. This will again be a simple generalization of OR composed with different functions [11, Theorem 37]. For the sake of completeness, we work out some of the details.

▶ **Theorem 41.** *For any partial Boolean functions $f_1, f_2, \ldots, f_n$, we have*

$$\widetilde{\mathrm{bdeg}}\left(\mathsf{PrOR}_n \circ (f_1, f_2, \ldots, f_n)\right) = \widetilde{\Theta}\left(\sqrt{\sum_{i=1}^{n} \widetilde{\mathrm{bdeg}}(f_i)^2}\right),$$

when the lcm of $\widetilde{\mathrm{bdeg}}(f_i)^2$ for $i \in [n]$ is $\Theta(\max_i\ \widetilde{\mathrm{bdeg}}(f_i)^2)$.

Proof. As mentioned before, the proof is merely working out the details of [11, Theorem 37] while keeping in mind that we are working with *partial* functions.

Let $F = \mathsf{PrOR}_n \circ (f_1, f_2, \ldots, f_n)$, $d_i = \widetilde{\mathrm{bdeg}}(f_i)^2$ for $i \in [n]$, and ℓ be the lcm of d_i's. Now consider the function $G = \mathsf{PrOR}_\ell \circ F$. From Theorem 40, we have the following bounds on $\widetilde{\mathrm{bdeg}}(G)$ up to constants

$$\frac{\sqrt{\ell} \cdot \widetilde{\mathrm{bdeg}}(F)}{\log \ell} \leq \widetilde{\mathrm{bdeg}}(G) \leq \sqrt{\ell} \cdot \widetilde{\mathrm{bdeg}}(F) \cdot \log \ell. \tag{9}$$

Now using the associativity of PrOR we can rewrite G as

$$G = \mathsf{PrOR}_{n\ell} \circ (\underbrace{f_1, \ldots, f_1}_{\ell \text{ times}}, \ldots, \underbrace{f_n, \ldots, f_n}_{\ell \text{ times}}). \tag{10}$$

Further regrouping f_i's, we can rewrite G as follows

$$G = \mathsf{PrOR}_d \circ (\underbrace{\mathsf{PrOR}_{\ell/d_1} \circ f_1, \ldots, \mathsf{PrOR}_{\ell/d_1} \circ f_1}_{d_1 \text{ times}}, \ldots, \underbrace{\mathsf{PrOR}_{\ell/d_n} \circ f_n, \ldots, \mathsf{PrOR}_{\ell/d_n} \circ f_n}_{d_n \text{ times}}), \tag{11}$$

where $d = \sum_{i=1}^{n} d_i$. Now using Theorem 40 and $\sqrt{d_i} = \widetilde{\mathrm{bdeg}}(f_i)$, we obtain following bounds for $\mathsf{PrOR}_{\ell/d_i} \circ f_i$ (up to constants)

$$\frac{\sqrt{\ell}}{\log(\ell/d_i)} \leq \widetilde{\mathrm{bdeg}}(\mathsf{PrOR}_{\ell/d_i} \circ f_i) \leq \sqrt{\ell} \cdot \log(\ell/d_i). \tag{12}$$

Now consider (11) and using Theorem 40 along with (12), we obtain

$$\frac{\sqrt{d\ell}}{\log d \cdot \log \ell} \leq \widetilde{\mathrm{bdeg}}(G) \leq \sqrt{d\ell} \cdot \log \ell \cdot \log d \tag{13}$$

Now from (13) and (9) it follows

$$\frac{\sqrt{d}}{\log d \cdot \log^2 \ell} \leq \widetilde{\mathrm{bdeg}}(F) \leq \sqrt{d} \cdot \log^2 \ell \cdot \log d.$$ ◀

C Composition theorems for strongly-k-junta symmetric outer functions

In this section we will prove the composition result of $\widetilde{\deg}$ and R when the outer function has some amount of symmetry. Of course, there are various notion of symmetry. Traditionally a function is said to have the maximum amount of symmetry when the function value is invariant under any permutation of the variables. Such functions are called symmetric. Symmetric functions are very well studied in the literature of Boolean function analysis. In the terms of composition theorems of $\widetilde{\deg}$ and R it was proved in [11] and [26] that $\widetilde{\deg}$ and R respectively composes when the outer function is symmetric.

In terms of weaker notions of symmetry there are various possible definitions. In this paper we consider the case of strongly-k-junta symmetric functions. The composition theorem for $\widetilde{\deg}$ when the outer function is strongly-k-junta symmetric (Theorem 12(Part(i)) is presented in Appendix C.1. The proof of the composition theorem for R when the outer function is strongly-k-junta symmetric (Theorem 12(Part(ii)) follows easily from Theorem 2.

▶ **Observation 42.** *For any strongly $k-$junta symmetric function $f : \{0,1\}^n \to \{0,1\}$ and any Boolean function $g : \{0,1\}^m \to \{0,1\}$, we have $\mathrm{R}(f \circ g) = \widetilde{\Omega}(\mathrm{R}(f) \cdot \mathrm{R}(g))$ where $n - k = \Theta(n)$.*

Proof. There exists an assignment of the k-bits such that the resulting function is a non-constant symmetric function on $(n-k)$ bits. Since the sensitivity of the restricted function is $\Omega(n)$, the randomized query complexity is also $\Omega(n)$ (see [32]). Hence, from Theorem 2 the result follows. ◀

C.1 Composition of approximate degree for $\sqrt{n}$-junta symmetric functions

In this section, first, we define Multiplexer Function or Addressing Function that will be useful is the analysis.

▶ **Definition 43** (Multiplexer Function or Addressing Function).
The function MUX : $\{0,1\}^{k+2^k} \to \{0,1\}$ *with input* $(x_0, \ldots, x_{k-1}, y_0, \ldots, y_{2^k-1})$ *outputs the bit* y_t, *where* $t = \sum_{i=0}^{k-1} x_i 2^i$.

A crucial result that we use in the prove of composition theorem of $\widetilde{\deg}$ is the following result from [34].

▶ **Theorem 44** ([34]). *For any non-constant symmetric function $f : \{0,1\}^n \to \{0,1\}$, let k be the closest integer to $n/2$ such that f takes different values on inputs of Hamming weight k and $k+1$. Define,*

$$\gamma(f) = \begin{cases} k & \text{if } k \leq n/2, \\ n-k & \text{otherwise.} \end{cases}$$

Then

$$\widetilde{\deg}(f) = \Theta\left(\sqrt{n(\gamma(f)+1)}\right).$$

Using the result of [34] we prove the following proposition about the approximate degree of a k-junta symmetric function. Recall the multiplexer function from Definition 43.

▶ **Proposition 45.** *For any k-junta symmetric function $f : \{0,1\}^n \to \{0,1\}$, we have $\widetilde{\deg}(f) = \Omega\left(\sqrt{(n-k)\gamma_{\max}}\right)$ and $\widetilde{\deg}(f) = O\left(\max\{k, \sqrt{(n-k)\gamma_{\max}}\}\right)$, where $\gamma_{\max} = \max_{i \in \{0,1\}^k}\{\gamma(f_i)\}$ such that f_i is the symmetric function obtained by restricting the junta variables according to i.*

Proof. Fixing the junta variables in f we obtain a symmetric function on $n-k$ variables with approximate degree $\Omega(\sqrt{(n-k)\gamma_{\max}})$ (Theorem 44), which in turn implies the same lower bound on $\widetilde{\deg}(f)$.

For the upper bound, we obtain an approximating polynomial for f by composing the (exact) polynomial for the multiplexer function $\mathsf{MUX} : \{0,1\}^{k+2^k} \to \{0,1\}$ with the approximating polynomials for different symmetric functions obtained by restricting the k junta variables. Therefore, $\widetilde{\deg}(f) = k + O(\sqrt{(n-k)\gamma_{\max}}) = O\left(\max\{k, \sqrt{(n-k)\gamma_{\max}}\}\right)$. ◀

As mentioned earlier, the composition of $\widetilde{\deg}$ when the outer function is symmetric was proved in [11]. The following is their result that we crucially use in the proof of Theorem 12.

▶ **Theorem 46** ([11])**.** *For any symmetric Boolean function $f : \{0,1\}^n \to \{0,1\}$ and any Boolean function $g : \{0,1\}^m \to \{0,1\}$ we have,*

$$\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))$$

We now present the proof of Part (i) of Theorem 12, that the proof of composition of $\widetilde{\deg}$ when the outer function is strongly-k-junta symmetric.

Proof of Theorem 12(Part (i)). Since f is a strongly-k-junta symmetric function so there exists a setting of the k junta variables such that the resulting function is a non-constant symmetric function. Let f' be the symmetric function obtained by restricting the junta variables of f so that f' is non-constant. Then by Theorem 44 the approximate degree of f' is $\Omega(\sqrt{(n-k)\gamma_{\max}})$. Then clearly we have

$$\widetilde{\deg}(f \circ g) \geq \widetilde{\deg}(f' \circ g) = \widetilde{\Omega}(\widetilde{\deg}(f') \cdot \widetilde{\deg}(g)) = \widetilde{\Omega}(\sqrt{(n-k)\gamma_{\max}} \cdot \widetilde{\deg}(g)), \tag{14}$$

where the first equality follows from Theorem 46. Now from Proposition 45 we know that $\widetilde{\deg}(f) = O(\sqrt{(n-k)\gamma_{\max}})$ if $k = O(\sqrt{(n-k)\gamma_{\max}})$, which is satisfied when $k = O(\sqrt{n})$. Thus from (14) we obtain

$$\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g)).$$ ◀

Sampling from the Random Cluster Model on Random Regular Graphs at All Temperatures via Glauber Dynamics[*]

Department of Computer Science, University of Oxford, UK

Abstract

We consider the performance of Glauber dynamics for the random cluster model with real parameter $q > 1$ and temperature $\beta > 0$. Recent work by Helmuth, Jenssen and Perkins detailed the ordered/disordered transition of the model on random Δ-regular graphs for all sufficiently large q and obtained an efficient sampling algorithm for all temperatures β using cluster expansion methods. Despite this major progress, the performance of natural Markov chains, including Glauber dynamics, is not yet well understood on the random regular graph, partly because of the non-local nature of the model (especially at low temperatures) and partly because of severe bottleneck phenomena that emerge in a window around the ordered/disordered transition.

Nevertheless, it is widely conjectured that the bottleneck phenomena that impede mixing from worst-case starting configurations can be avoided by initialising the chain more judiciously. Our main result establishes this conjecture for all sufficiently large q (with respect to Δ). Specifically, we consider the mixing time of Glauber dynamics initialised from the two extreme configurations, the all-in and all-out, and obtain a pair of fast mixing bounds which cover *all* temperatures β, including in particular the bottleneck window. Our result is inspired by the recent approach of Gheissari and Sinclair for the Ising model who obtained a similar-flavoured mixing-time bound on the random regular graph for sufficiently low temperatures. To cover all temperatures in the RC model, we refine appropriately the structural results of Helmuth, Jenssen and Perkins about the ordered/disordered transition and show spatial mixing properties "within the phase", which are then related to the evolution of the chain.

1 Introduction

For real numbers $q, \beta > 0$ and a graph $G = (V, E)$, the *random cluster model* on G with parameters q and β is a probability distribution on the set $\Omega = \Omega_G$ of all assignments $\mathcal{F} : E \to \{0, 1\}$; we typically refer to assignments in Ω as configurations. For a configuration $\mathcal{F}$, we say that edges mapped to 1 are *in-edges*, and edges mapped to 0 are *out-edges*. We

use $\mathrm{In}(\mathcal{F})$ to denote the set of edges e with $\mathcal{F}(e) = 1$, $\mathrm{Out}(\mathcal{F})$ to denote the set of edges e with $\mathcal{F}(e) = 0$, $|\mathcal{F}|$ for the cardinality of $\mathrm{In}(\mathcal{F})$ and $c(\mathcal{F})$ for the number of connected components in the graph $(V, \mathrm{In}(\mathcal{F}))$. Then, the weight of $\mathcal{F}$ in the RC model is given by $w_G(\mathcal{F}) = q^{c(\mathcal{F})}(e^{\beta} - 1)^{|\mathcal{F}|}$.

For integer values of q, the RC model is closely connected to the (ferromagnetic) Ising/-Potts models; $q = 2$ is the Ising model and $q \geq 3$ is the Potts model whose configurations are all possible assignments of q colours to the vertices of the graph where an assignment σ has weight proportional to $\mathrm{e}^{\beta m(\sigma)}$ with $m(\sigma)$ being the number of monochromatic edges under σ. The RC model is an alternative edge representation of the models (for integer q) that has also been studied extensively in its own right due to its intricate behaviour (see, e.g., [19]).

We will be primarily interested in sampling from the so-called *Gibbs distribution* on Ω induced by these weights, denoted by $\pi_G(\cdot)$, where for a configuration $\mathcal{F}$, $\pi_G(\mathcal{F}) = w_G(\mathcal{F})/Z_G$ where the normalising factor $Z_G = \sum_{\mathcal{F}' \in \Omega_G} w_G(\mathcal{F}')$ is the aggregate sum of weight of all configurations (known as the partition function). We focus on the *Glauber dynamics* which is a classical Markov chain for sampling from Gibbs distributions which is a particularly useful tool for developing approximate sampling algorithms. We will refer to Glauber dynamics for the RC model as the RC dynamics. Roughly, the RC dynamics is a Markov chain $(X_t)_{t \geq 0}$ initialised at some configuration X_0 which evolves by iteratively updating at each step $t \geq 1$ a randomly chosen edge based on whether its endpoints belong to the same component in the graph $(V, \mathrm{In}(X_t))$. The mixing time of the chain is the number of steps to get within total variation distance $\leq 1/4$ from π_G, see Section 2 for details.

Our goal is to obtain a fast algorithm for the RC model using Glauber dynamics on the random regular graph. There are two key obstacles that arise, especially at low temperatures (large β): (i) Glauber dynamics for the RC model has a highly non-local behaviour, and (ii) there are severe bottleneck phenomena and worst case graphs which prohibit a general fast-convergence result, and more generally an efficient algorithm. The random regular graph is a particularly interesting testbed in this front since it exhibits all the relevant phase transition phenomena and has also been used as the main gadget in hardness reductions [15].

To overview the phenomena that are most relevant for us, the following picture was detailed in a remarkable development by Jenssen, Helmuth, and Perkins [22]: for $\Delta \geq 5$ and all sufficiently large q, they established the ordered/disordered transition occurring at some β_c satisfying $\beta_c = (1 + o_q(1))\frac{2 \log q}{\Delta}$ (see also [15] for integer $q \geq 3$).[1] Roughly, for $\beta < \beta_c$ a typical configuration of the model is disordered, whereas for $\beta > \beta_c$ it is ordered: disordered configurations resemble the all-out configuration (in that all components are of size $O(\log n)$) whereas ordered configurations resemble the all-in configuration (where there is a giant component with $\Omega(n)$ vertices). The two types of configurations coexist at $\beta = \beta_c$, i.e., each appears with some probability bounded away from zero. The methods in [22] are based on cluster expansion techniques which also yielded an efficient sampling algorithm at all temperatures $\beta > 0$. This is a surprising algorithmic result given that the coexistence causes multimodality in π_G and severe bottleneck phenomena for Markov chains in a window around β_c; it was shown for instance in [22] that the RC dynamics (and the related non-local Swendsen-Wang dynamics) have exponential mixing time, essentially because of the number of steps needed for the chain to move from ordered to disordered (and vice versa).

These results pose a rather bleak landscape for the RC dynamics; yet, on random regular graphs it is widely conjectured that the multimodality and the associated bottlenecks can be circumvented by initialising the chain more judiciously, in particular at either the all-out

[1] Recent results of Bencs, Borbényi, and Csikvári [1] yield the exact formula $\beta_c = \log \frac{q-2}{(q-1)^{1-2/\Delta} - 1}$ for all $q > 2$ and $\Delta \geq 3$, which was previously only known for integer q [15].

or the all-in configurations (depending on whether $\beta \leq \beta_c$). However the tools available for analysing Markov chains are typically insensitive to the initial configuration, and even more so when working at a critical range of the parameters.

Our main result establishes this conjecture for all $\Delta \geq 5$ and q sufficiently large (conditions which we inherit from [22]). For an integer n such that Δn is even, let $\mathcal{G}_{n,\Delta}$ denote the set of all Δ-regular graphs with n vertices.[2] Throughout, we use $O(1)$ to denote a constant depending on q, β, Δ but independent of n.

▶ **Theorem 1.** *Let $\Delta \geq 5$ be an integer. There exists $C = C(\Delta) > 0$ such that, for all sufficiently large q, the following holds for any $\beta > 0$, w.h.p. over $G \sim \mathcal{G}_{n,\Delta}$.*

1. *For $\beta < \beta_c$, the mixing time of the RC dynamics starting from all-out is $O(n \log n)$.*
2. *For $\beta > \beta_c$, the mixing time of the RC dynamics starting from all-in is $O(n^C)$. For integer q, the mixing time is in fact $O(n \log n)$.*

Note that Theorem 1 implies an $O(n \log n)$ sampling algorithm from the Potts model for all $\beta \neq \beta_c$ (and all sufficiently large q). Intuitively, and as we will see later in more detail, Theorem 1 asserts that the RC dynamics starting from all-in mixes quickly within the set of ordered configurations for $\beta > \beta_c$, and similarly it mixes well within the disordered set of configurations starting from all out when $\beta < \beta_c$. In fact the same is true for $\beta = \beta_c$ and hence the RC dynamics can be used to sample even at criticality, see Remark 12 for details.

Finally, let us note that the RC dynamics can be used analogously to the theorem above to produce a sample within total variation distance ε of π_G for any $\varepsilon \geq \mathrm{e}^{-\Theta(n)}$, by running it for a number of steps which is $\log(1/\varepsilon)$ times the corresponding mixing time bound.[3] The lower bound on the error comes from the total variation distance between π_G and the conditional "ordered" and "disordered" configurations, see Lemma 3.

1.1 Further related work

Our approach to proving Theorem 1 is inspired from a recent paper by Gheissari and Sinclair [16] who established similar flavoured results for the Ising model ($q = 2$) on the random regular graph for large β. To obtain our results for all β, we adapt suitably their notion of "spatial mixing within the phase", see Section 2.2 for details.

Among the results in [16], it was established that Glauber dynamics on the random regular graph, initialised appropriately, mixes in $O(n \log n)$ time when β is sufficiently large.[4] More recently, Gheissari and Sinclair [17] obtained mixing-time bounds for the RC dynamics on the lattice $\mathbb{Z}^d$ under appropriate boundary conditions. They also analyse the mixing time starting from a mixture of the all-in/all-out initialisation. Note that the phase transition on grid lattices is qualitatively different than that of the random regular graph; there, instead of a window/interval of temperatures, the three points β_u, β_u^* and β_c all coincide into a single phase transition point. See also [6, 23] for related algorithmic results on $\mathbb{Z}^d$ using cluster expansion methods.

For the random regular graph, Blanca and Gheissari [4] showed for all integer $\Delta \geq 3$ and real $q \geq 1$ that the mixing time is $O(n \log n)$ provided that $\beta < \beta_u(q, \Delta)$ where β_u is the uniqueness threshold on the tree. A sampling algorithm (not based on MCMC) for

[2] We write $G \sim \mathcal{G}_{n,\Delta}$ to denote a graph in $\mathcal{G}_{n,\Delta}$ chosen uniformly at random, and we say that a property holds w.h.p. for $G \sim \mathcal{G}_{n,\Delta}$ as a shorthand for "with probability $1 - o_n(1)$ over a graph $G \in \mathcal{G}_{n,\Delta}$ chosen uniformly at random.

[3] The standard submultiplicative argument to bootstrap the total-variation distance goes through using the monotonicity of the RC model (to account for the constraint on the initial configuration), see also [25].

[4] Note that, for $q = 2$, an $O(n^{10})$ upper bound for the RC dynamics on any graph G was previously known at all temperatures β by Guo and Jerrum [20] (see also [13]).

$\beta < \beta_c(q,\Delta)$ and $q,\Delta \geq 3$ was designed by Efthymiou [12] (see also [3]), albeit achieving weaker approximation guarantees. Coja-Oghlan et al. [10] showed that, for all integer $q,\Delta \geq 3$ and $\beta \in (\beta_u, \beta'_u)$ the mixing time is $\mathrm{e}^{\Omega(n)}$ where $\beta'_u = \log(1+\frac{q}{\Delta-2}) > \beta_u$ is (conjectured to be) another uniqueness threshold on the tree (see [21, 24]). More generally, for integer $q \geq 3$, the hardness results/techniques of [18, 15] yield that for any $\beta > \beta_c$, there are graphs G where the mixing time of the RC dynamics is $\exp(n^{\Omega(1)})$ and the problem of appoximately sampling on graphs of max-degree Δ becomes #BIS-hard; on the other hand, for $\beta \leq (1-o_{q,\Delta}(1))\beta_c$ it has been shown in [11, 7] that the cluster-expansion technique of [22] yields a sampling algorithm on any max-degree Δ graph.

As a final note, another model of interest where analogous mixing results for Glauber dynamics (initialised appropriately) should be obtainable is for sampling independent sets on random bipartite regular graphs. However, in contrast to the RC/Potts models, the phase transition there is analogous to that of the Ising model, and hence, establishing the relevant spatial mixing properties close to the criticality threshold is likely to require different techniques, see, e.g., [9] for more discussion.

1.2 Independent results of Blanca and Gheissari

In an independent and simultaneous work, Blanca and Gheissari [5] obtain related (but incomparable) results. For $\Delta \geq 3, q \geq 1$ and arbitrarily small $\tau > 0$, they show for sufficiently large β a mixing time bound of $O(n^{1+\tau})$ for the RC dynamics on the random regular graph starting from an arbitrary configuration (and obtain an analogous result for the grid and the Swendsen-Wang dynamics). Our result instead applies to all β for the random regular graph (even the critical window) by taking into consideration the initial configuration; the two papers have different approaches to obtain the main ingredients.

2 Proof of Theorem 1

We start with the formal description of the RC dynamics. Given a graph $G = (V, E)$ and an initial configuration $X_0 : E \to \{0, 1\}$, the RC dynamics on G is a Markov chain $(X_t)_{t\geq 0}$ on the set of configurations Ω_G. Let $p := 1 - \mathrm{e}^{-\beta}$ and $\hat{p} := \frac{p}{(1-p)q+p}$ (note that for $q > 1$ it holds that $\hat{p} \in (p/q, p)$). For $t \geq 0$, to obtain X_{t+1} from X_t:

1. Choose u.a.r. an edge $e \in E$. If e is a cut-edge in the graph $(V, \mathrm{In}(X_t) \cup \{e\})$, set $X_{t+1}(e) = 1$ with probability $\hat{p}$ (and $X_{t+1}(e) = 0$ otherwise). Else, set $X_{t+1}(e) = 1$ with probability p, and $X_{t+1}(e) = 0$ otherwise.
2. Set $X_{t+1}(f) = X_t(f)$ for all $f \in E\backslash\{e\}$.

It is a standard fact that the distribution of X_t converges to the RC distribution π_G. Let $T_{\mathrm{mix}}(G; X_0) = \min_{t\geq 0}\{t \mid \mathrm{dist}_{\mathrm{TV}}(X_t, \pi_G) \leq 1/4\}$ be the number of steps needed to get within total-variation distance $\leq 1/4$ from π_G starting from X_0, and $T_{\mathrm{mix}}(G) = \max_{X_0} T_{\mathrm{mix}}(G; X_0)$ be the mixing time from the worst starting state.

2.1 The ordered and disordered phases on random regular graphs

We review in more detail the ordered/disordered transition, following [22].

▶ **Definition 2.** *For $\Delta \geq 3$, let $\eta = \eta(\Delta) \in (0, 1/2)$ be a small constant (see Definition 17). For $G \in \mathcal{G}_{n,\Delta}$, the* ordered phase *is the set of configurations $\Omega^{\mathrm{ord}} := \{\mathcal{F} \in \Omega : |\mathrm{In}(\mathcal{F})| \geq (1-\eta)|E|\}$, whereas the* disordered phase *is the set $\Omega^{\mathrm{dis}} := \{\mathcal{F} \in \Omega : |\mathrm{In}(\mathcal{F})| \leq \eta|E|\}$. For $q, \beta > 0$, let $\pi^{\mathrm{ord}}_G, \pi^{\mathrm{dis}}_G$ be the conditional distributions of π_G on $\Omega^{\mathrm{ord}}, \Omega^{\mathrm{dis}}$, respectively.*

We will use the following result of Helmuth, Jenssen and Perkins [22, Lemma 9].

▶ **Lemma 3** ([22, Theorem 1]). *Let $\Delta \geq 5$ be an integer. Then, for all sufficiently large q, there exists $\beta_c > 0$ satisfying $\beta_c = (1 + o_q(1))\frac{2\log q}{\Delta}$ such that the following holds for any $\beta > 0$ w.h.p. for $G \sim \mathcal{G}_{n,\Delta}$.*

$$\text{if } \beta < \beta_c \text{, then } \left\|\pi_G - \pi_G^{\mathrm{dis}}\right\|_{\mathrm{TV}} = \mathrm{e}^{-\Omega(n)}; \qquad \text{if } \beta > \beta_c \text{, then } \left\|\pi_G - \pi_G^{\mathrm{ord}}\right\|_{\mathrm{TV}} = \mathrm{e}^{-\Omega(n)}. \tag{1}$$

Moreover, there exists $\zeta = \zeta(\Delta) > 0$ with $\zeta < \eta$ such that

$$\begin{aligned} &\text{for } \beta \leq \beta_c, \quad \pi_G^{\mathrm{dis}}\Big(|\operatorname{In}(\mathcal{F})| \geq \zeta|E|\Big) = \mathrm{e}^{-\Omega(n)}, \qquad \text{and} \\ &\text{for } \beta \geq \beta_c, \quad \pi_G^{\mathrm{ord}}\Big(|\operatorname{In}(\mathcal{F})| \leq (1-\zeta)|E|\Big) = \mathrm{e}^{-\Omega(n)}. \end{aligned} \tag{2}$$

Proof. The claims about the total variation distance are shown in [22, Theorem 1, Items (2), (3), (8)]. Equation (2) shows a bit of slack in the definitions of Ω^{dis} and Ω^{ord} that will be useful later; it follows essentially from the same theorem, we defer the details to Lemma 25 of the full version [14]. ◀

2.2 Main ingredient: Weak spatial mixing within a phase

Let $G = (V, E)$ be a graph. For $v \in V$ and $r \geq 0$, let $B_r(v)$ denote the set of all vertices in V whose distance from v is at most r. Let $\pi = \pi_G$ be the RC distribution on G and let $\pi_{\mathcal{B}_r^+(v)}$ be the conditional distribution of π where all edges in $E\backslash E(B_r(v))$ are "in". We define analogously $\pi_{\mathcal{B}_r^-(v)}$ by conditioning the edges in $E\backslash E(B_r(v))$ to be "out".

▶ **Definition 4.** *Let G be a graph with m edges. Let $q, \beta > 0$ be reals and $r \geq 1$ be an integer. We say that the graph G has* WSM within the ordered phase at radius r *if for every $v \in V(G)$ and every edge e incident to v, $\|\pi_{\mathcal{B}_r^+(v)}(e \mapsto \cdot) - \pi_G^{\mathrm{ord}}(e \mapsto \cdot)\|_{\mathrm{TV}} \leq \frac{1}{100m}$. Analogously, we say that G has* WSM within the disordered phase at radius r *if for every $v \in V(G)$ and every edge e incident to v, $\|\pi_{\mathcal{B}_r^-(v)}(e \mapsto \cdot) - \pi_G^{\mathrm{dis}}(e \mapsto \cdot)\|_{\mathrm{TV}} \leq \frac{1}{100m}$.*

The bulk of our arguments consists of showing the following two theorems.

▶ **Theorem 5.** *Let $\Delta \geq 5$ be an integer. There exists $M = M(\Delta) > 0$ such that for all q sufficiently large, the following holds for any $\beta \geq \beta_c$. W.h.p. over $G \sim \mathcal{G}_{n,\Delta}$, G has WSM within the ordered phase at a radius r which satisfies $r \leq \frac{M}{\beta}\log n$.*

The upper bound on the radius r in terms of $1/\beta$ ensures that we can remove the dependence on β of the mixing time in Theorem 1 (caused by a loose bound on the mixing time on the tree, see Lemma 9 below). For the disordered phase, we have

▶ **Theorem 6.** *For all integer $\Delta \geq 5$, for all q sufficiently large and any $\beta \leq \beta_c$, w.h.p. over $G \sim \mathcal{G}_{n,\Delta}$, G has WSM within the disordered phase at a radius r which satisfies $r \leq \frac{1}{3}\log_{\Delta-1} n$.*

2.3 Second ingredient: Local mixing on tree-like neighbourhoods

We first define a local version of RC dynamics where we perform only updates in a small ball around a vertex. Here, we need to consider the extreme boundary conditions that all vertices outside of the ball belong in distinct components ("free boundary") and where they belong to the same component ("wired boundary"); we will refer to these two chains as the free and wired RC dynamics, respectively. For the random regular graph, these "local-mixing" considerations are strongly connnected to the Δ-regular tree.

Formally, given a graph $G = (V, E)$ and a subset $U \subseteq V$, let $G[U]$ be the induced subgraph of G on U. The tree-excess of a connected graph G is given by $|E| - |V| + 1$. For a vertex v in G and integer $r \geq 0$, let $B_r(v)$ denote the set of vertices at distance at most r from v and $S_r(v)$ those at distance exactly r from v. For $K > 0$, a max-degree Δ graph G is locally K-treelike if for every $v \in V$ and $r \leq \frac{1}{3}\log_{\Delta-1}|V|$, the graph $G[B_r(v)]$ has tree excess $\leq K$.

▶ **Lemma 7** (see, e.g., [16, Lemma 5.8]). *For any integer $\Delta \geq 3$, there is $K > 0$ such that w.h.p. $G \sim G_{n,\Delta}$ is locally K-treelike.*

For a graph G, a vertex ρ in G and an integer $r \geq 1$, the *free RC dynamics* on $B_r(\rho)$ is the RC dynamics where all edges outside of $B_r(\rho)$ are conditioned to be out and only edges of G with both endpoints in $B_r(\rho)$ are updated.

▶ **Lemma 8** ([4, Lemma 6.5]). *Let $\Delta \geq 3$ be an integer, and $q, K > 1$, $\beta > 0$ be reals. There exists $C > 0$ such that the following holds for any Δ-regular graph G and integer $r \geq 1$.*

Suppose that $\rho \in V$ is such that $G[B_r(\rho)]$ is K-treelike. Then, with $n = |B_r(\rho)|$, the mixing time of the free RC dynamics on $B_r(\rho)$ is $\leq Cn\log n$.

To define the wired RC dynamics, for a graph G, a vertex ρ in G and an integer $r \geq 1$, let H be the graph obtained by removing all vertices and edges outside of $B_r(\rho)$, and adding a new vertex v_∞ connected to all vertices in $S_r(\rho)$. The *wired RC dynamics* on $B_r(\rho)$ is the RC dynamics on H where the edges adjacent to v_∞ are conditioned to be in and only edges of G with both endpoints in $B_r(\rho)$ are updated. Denote by $\hat{\pi}_{B_r(\rho)}$ the stationary distribution of the wired RC dynamics. Note that when the graph outside of $B_r(\rho)$ is connected, $\hat{\pi}_{B_r(\rho)}$ induces the same distribution as $\pi_{\mathcal{B}_r^+(\rho)}$.[5]

▶ **Lemma 9.** *Let $\Delta \geq 3$ be an integer, and $q, K > 1$, $\beta > 0$ be reals. There exists $\hat{C} > 0$ such that the following holds for every Δ-regular graph $G = (V, E)$ and any integer $r \geq 1$.*

Suppose that $\rho \in V$ is such that $G[B_r(\rho)]$ is K-treelike. Then, with $n = |B_r(\rho)|$, the mixing time of the wired RC dynamics on $B_r(\rho)$ is $\leq \hat{C}n^3(q^4\mathrm{e}^\beta)^{\Delta r}$.

▶ Remark 10. For integer $q > 1$, the mixing time bound in Lemma 9 can be improved to $O(n\log n)$ using results of [2], see Appendix A.2. in the full version [14] for details.

2.4 Proof of Theorem 1

In this section, we will prove the $\beta > \beta_c$ part of Theorem 1, given below as Theorem 11 for convenience. The proof of the $\beta < \beta_c$ part of Theorem 1 is in Appendix A of the full version [14].

▶ **Theorem 11.** *Let $\Delta \geq 5$ be an integer. Then, for all sufficiently large q, there exists $C = C(q, \Delta)$ such that the following holds w.h.p. for $G \sim \mathcal{G}_{n,\Delta}$. For $\beta > \beta_c$, the mixing time of the RC dynamics starting from all-in is $O(n^C)$. For integer q, the mixing time is in fact $O(n\log n)$.*

Proof of Theorem 11 (Theorem 1(b)). The argument resembles that of [16], a bit of care is required to combine the pieces. Consider $G = (V, E) \sim \mathcal{G}_{n,\Delta}$ with $n = |V|$ and $m = |E|$. Let q be sufficiently large so that both Lemma 3 and Theorem 5 apply; assume also that Lemma 7 applies so that G is locally K-treelike.

[5] More precisely, the weight of a configuration $\mathcal{F} : E(B_r(\rho)) \to \{0,1\}$ in $\hat{\pi}_{B_r(\rho)}$ is proportional to $q^{\hat{c}(\mathcal{F})}(\mathrm{e}^\beta - 1)^{|\mathcal{F}|}$ where $\hat{c}(\mathcal{F})$ denotes the number of components in the graph $(B_r(\rho), \mathrm{In}(F))$ that do not include any of the vertices in $S_r(\rho)$ (since all of these belong to the same component in the wired dynamics and hence contribute just a single extra factor of q).

Consider arbitrary $\beta > \beta_c$ and set $\beta_0 := \log(q^{1.9/\Delta} + 1)$. Since $\beta_c = (1 + o_q(1))\frac{2\log q}{\Delta}$, we have that $\beta \geq \beta_0$ for all sufficiently large q. By Lemma 3, a graph $G = (V, E) \sim \mathcal{G}_{n,\Delta}$ satisfies w.h.p. $\left\|\pi_G - \pi_G^{\mathrm{ord}}\right\|_{\mathrm{TV}} = \mathrm{e}^{-\Omega(n)}$ and $\pi_G^{\mathrm{ord}}\big(|\operatorname{In}(\mathcal{F})| \leq (1-\zeta)|E|\big) = \mathrm{e}^{-\Omega(n)}$. Moreover, by Theorem 5, G has WSM within the ordered phase at radius r for some $r \leq \frac{M}{\beta}\log n$, where $M = M(\Delta) > 0$ is a constant independent of β. Note that by taking q large, we can ensure that β_0 and hence β are at least M so that $r \leq \frac{1}{3}\log_{\Delta-1} n$. Theorem 11 will follow by showing that the mixing time is bounded by $T = O(n^{2+\log W})$, where $W = \Delta^{2M/\beta_0}\mathrm{e}^{M\Delta(\Delta+1)}$ is independent of q, β; for integer q we will show the stronger upper bound $\tilde{T} = O(n\log n)$.

Consider the RC dynamics $(X_t)_{t\geq 0}$ with X_0 being the all-in configuration on the edges. Consider also the "ordered" RC dynamics $\hat{X}_t$ with $\hat{X}_0 \sim \pi_G^{\mathrm{ord}}$ where we reject moves that lead to configurations outside of Ω^{ord}; note that $\hat{X}_t \sim \pi_G^{\mathrm{ord}}$ for all $t \geq 0$. For $t \geq 0$, let $\mathcal{E}_t$ be the event that $\operatorname{In}(\hat{X}_t) \geq (1-\zeta)|E|$ and let $\mathcal{E}_{<t} := \bigcap_{t'=0,\dots,t-1}\mathcal{E}_{t'}$. From Lemma 3 we have that $\pi_G^{\mathrm{ord}}(\mathcal{E}_t) \geq 1 - \mathrm{e}^{-\Omega(n)}$ and hence by a union bound $\pi_G^{\mathrm{ord}}(\mathcal{E}_{<t}) \geq 1 - t\mathrm{e}^{-\Omega(n)}$ as well.

We couple the evolution of X_t and $\hat{X}_t$ using the monotone coupling, i.e., at every step of the two chains choose the same edge e_t to update and use the same uniform number $U_t \in [0, 1]$ to decide whether to include e_t in each of $X_{t+1}, \hat{X}_{t+1}$. Using the monotonicity of the model for $q \geq 1$ (and in particular that $p > \hat{p}$), under the monotone coupling, for all $t \geq 0$ such that $\mathcal{E}_{<t}$ holds (and hence no reject move has happened in $\hat{X}_t$ so far), we have that $\hat{X}_t \leq X_t$ (i.e., $\operatorname{In}(\hat{X}_t) \subseteq \operatorname{In}(X_t)$). To complete the proof, it therefore suffices to show that

$$\Pr(X_T \neq \hat{X}_T) \leq 1/4. \tag{3}$$

Consider an arbitrary time $t \geq 0$. By a union bound, we have that

$$\Pr\left(X_t \neq \hat{X}_t\right) \leq \sum_e \Pr\left(X_t(e) \neq \hat{X}_t(e)\right) \leq m\Pr\left(\overline{\mathcal{E}_{<t}}\right) + \sum_e \Pr\left(X_t(e) \neq \hat{X}_t(e) \mid \mathcal{E}_{<t}\right). \tag{4}$$

Fix an arbitrary edge e incident to some vertex v, and let (X_t^v) be the wired RC dynamics on $G[B_r(v)]$. We couple the evolution of (X_t^v) with that of (X_t) and $(\hat{X}_t)$ using the monotone coupling analogously to above, where in X_t^v we ignore updates of edges outside the ball $G[B_r(v)]$). We have $X_t^v \geq X_t$ for all $t \geq 0$, and hence, conditioned on $\mathcal{E}_{<t}$, we have that $X_t^v \geq X_t \geq \hat{X}_t$. It follows that

$$\begin{aligned}\Pr\left(X_t(e) \neq \hat{X}_t(e) \mid \mathcal{E}_{<t}\right) &= \Pr(X_t(e) = 1 \mid \mathcal{E}_{<t}) - \Pr(\hat{X}_t(e) = 1 \mid \mathcal{E}_{<t})\\ &\leq |\Pr(X_t^v(e) = 1 \mid \mathcal{E}_{<t}) - \Pr(\hat{X}_t(e) = 1 \mid \mathcal{E}_{<t})|.\end{aligned}$$

For any two events A, B, we have $|\Pr(A) - \Pr(A \mid B)| \leq 2\Pr(\overline{B})$, so using this for $B = \mathcal{E}_{<t}$ and A the events $\{X_t^v(e) = 1\}, \{\hat{X}_t(e) = 1\}$, the triangle inequality gives

$$\Pr\left(X_t(e) \neq \hat{X}_t(e) \mid \mathcal{E}_{<t}\right) \leq 4\Pr\left(\overline{\mathcal{E}_{<t}}\right) + |\Pr(X_t^v(e) = 1) - \Pr(\hat{X}_t(e) = 1)|$$

Note that $\Pr(\hat{X}_t(e) = 1) = \pi_G^{\mathrm{ord}}(e \mapsto 1)$, so another application of triangle inequality gives

$$\begin{aligned}\Pr\left(X_t(e) \neq \hat{X}_t(e) \mid \mathcal{E}_{<t}\right) \leq 4\Pr\left(\overline{\mathcal{E}_{<t}}\right) &+ \left|\Pr(X_t^v(e) = 1) - \pi_{\mathcal{B}_r^+(v)}(e \mapsto 1)\right|\\ &+ \left|\pi_{\mathcal{B}_r^+(v)}(e \mapsto 1) - \pi_G^{\mathrm{ord}}(e \mapsto 1)\right|.\end{aligned} \tag{5}$$

Since G has WSM within the ordered phase at radius r, we have that

$$\left|\pi_{\mathcal{B}_r^+(v)}(e \mapsto 1) - \pi_G^{\mathrm{ord}}(e \mapsto 1)\right| \leq 1/(100m). \tag{6}$$

Moreover, let T_v be the mixing time of the wired RC dynamics on $G[B_r(v)]$ and let $N_v = |E(B_r(v))| \le \Delta^{r+1}$. Since $r \le \frac{1}{3}\log_{\Delta-1} n$, $G[B_r(v)]$ is K-treelike, so from Lemma 9, with $\hat{C} = O(1)$ denoting the constant there (and absorbing a couple of factors of Δ into it),

$$T_v \le \hat{C}(N_v)^3(q^4 \mathrm{e}^{\beta})^{\Delta r} \le \hat{C}N_v\Delta^{2r}q^{4\Delta r}\mathrm{e}^{\beta\Delta r} = \hat{C}N_v\Big(\Delta^{2M/\beta}q^{4\Delta M/\beta}\mathrm{e}^{M\Delta}\Big)^{\log n} \le \hat{C}N_v W^{\log n},$$

where in the last inequality we used that $\beta > \beta_0$, $\beta_0 > \frac{1}{\Delta}\log q$ and $W = \Delta^{2M/\beta_0}\mathrm{e}^{M\Delta(\Delta+1)}$. For $T = \Theta(n^{2+\log W})$, we have $T \ge 40T_v\frac{m}{N_v}\log m$, so by Chernoff bounds, with probability $1-\exp(-n^{\Omega(1)})$, we have at least $10T_v \log m$ updates inside $B_r(v)$ among $t = 1,\dots,T$. For integer $k \ge 1$ the distance from stationarity after kT_v steps is at most $(1/4)^k$, we obtain

$$\big|\Pr(X_T^v(e)=1) - \pi_{\mathcal{B}_r^+(v)}(e \mapsto 1)\big| \le \exp(-n^{\Omega(1)}) + \mathrm{e}^{-4\log m} \le 1/m^3. \tag{7}$$

Plugging (6) and (7) into (5) for $t = T$, and then back into (4), we obtain using $\Pr(\overline{\mathcal{E}_{<T}}) \le T\mathrm{e}^{-\Omega(n)}$ that $\Pr(X_T \ne \hat{X}_T) \le 5mT\mathrm{e}^{-\Omega(n)} + m/m^3 + 1/100 \le 1/4$, as needed.

For integer q, to get the improved mixing time bound $O(n\log n)$ in Theorem 11 the reasoning is similar. The main difference is that for integer q, we have that for any vertex v the mixing time T_v is bounded by $T_v = O(N_v \log N_v)$ (cf. Remark 10), and therefore the above argument yields a mixing time upper bound of $O(n(\log n)^2)$. With a bit more care, for $\tilde{T} = \Theta(n\log n)$, we show in Appendix A.3 in the full version [14] using a log-Sobolev inequality that

$$\big|\Pr(X_{\tilde{T}}^v(e)=1) - \pi_{\mathcal{B}_r^+(v)}(e \mapsto 1)\big| \le 1/m^3, \tag{8}$$

which analogously to above yields $\Pr(X_{\tilde{T}} \ne \hat{X}_{\tilde{T}}) \le 1/4$, and hence the desired mixing time bound of $O(n\log n)$ for integer q. ◀

▶ Remark 12. All the ingredients to show the coupling of the RC dynamics starting from all-in with π_G^{ord} (i.e., (3)) work even at criticality, i.e., for $\beta = \beta_c$; a similar observation applies at $\beta = \beta_c$ for π_G^{dis} when starting the RC dynamics from all-out. The difference at criticality is that π_G is a mixture of π_G^{ord} and π_G^{dis}, i.e., to obtain a sample for π_G, one should output a sample for π_G^{ord} with some probability Q and otherwise a sample from π_G^{dis}. The value of Q can be computed in time $\tilde{O}(n^2)$ by approximating the corresponding partition functions, by using, e.g., the algorithms in [22, 8] (or even the RC dynamics itself). See also [22, Theorems 2 & 3] for precise results characterising the distribution of Q; it is shown for example that Q converges to $1/(q+1)$ as q grows large.

3 Proof outline of the WSM within the ordered phase

3.1 Locally tree-like expanders

Analogously to [22], we work a bit more generally with Δ-regular expanders, which are also tree-like. The *expansion profile* of an n-vertex graph $G = (V, E)$ for $\varepsilon > 0$ is given by

$$\phi_G(\varepsilon) := \min_{S\subseteq V;\ 0<|S|\le\varepsilon n} \frac{|E(S, V\backslash S)|}{\Delta|S|}.$$

Then the classes $G_{\Delta,\delta}$ and $\mathcal{G}_{\Delta,\delta,K}$ are as follows.

▶ **Definition 13.** *Let $\Delta \ge 5$ be an integer, and $\delta \in (0, 1/2), K > 0$ be reals. $G_{\Delta,\delta}$ is the class of Δ-regular graphs such that $\phi_G(1/2) \ge 1/10$ and $\phi_G(\delta) \ge 5/9$. $\mathcal{G}_{\Delta,\delta,K}$ is the class of all locally K-treelike graphs $G \in \mathcal{G}_{\Delta,\delta}$.*

We use the following lemma.

▶ **Lemma 14** ([22, Proposition 37]). *Fix $\Delta \geq 5$. There is a constant $\delta \in (0, 1/2)$ such that w.h.p. a uniformly random Δ-regular graph belongs to $\mathcal{G}_{\Delta,\delta}$.*

Lemma 14 and Lemma 7 show that there is also a positive integer K such that, w.h.p, $G \in \mathcal{G}_{\Delta,\delta,K}$. Next we state an important property of expanders from [26].

▶ **Lemma 15** ([26, Lemma 2.3]). *Let $G = (V, E)$ be a regular graph and consider $E' \subseteq E$ with $|E'| \leq \theta|E|$ for some $\theta \in (0, \phi_G(1/2))$. Then $(V, E\backslash E')$ has a component of size at least $(1 - \frac{\theta}{2\phi_G(1/2)})|V|$.*

We use Lemma 15 to establish the existence of a giant component.

▶ **Definition 16.** *The size of a component of a graph is the number of vertices in the component. A* giant component *in an n-vertex graph is a component whose size is greater than $n/2$. Given a graph $G = (V, E)$ and a subset $F \subseteq E$, $G[F]$ denotes the graph (V, F).*

▶ **Definition 17.** *Fix $\Delta \geq 5$. Fix $\delta \in (0, 1/2)$ satisfying Lemma 14. Let $\eta = \min(\delta/5, 1/100)$.*

▶ **Corollary 18.** *Fix integers $\Delta \geq 5$ and $K \geq 0$ and a real number $\delta \in (0, 1/2)$. Let G be a graph in $\mathcal{G}_{\Delta,\delta,K}$ and let $\mathcal{F}$ be a configuration in Ω^{ord} or a partial configuration with $|\operatorname{In}(\mathcal{F})| \geq (1 - \eta)|E|$. Then there is a giant component in $G[\operatorname{In}(\mathcal{F})]$ whose size is at least $(1 - \delta)|V|$.*

Proof. Apply Lemma 15 with $E' = \operatorname{Out}(\mathcal{F})$ and $\theta = \eta = \min(\delta/5, 1/100)$. Note $|\operatorname{Out}(\mathcal{F})| \leq \eta|E|$ and $\phi_G(1/2) \geq 1/10$. Thus the lemma say that $G[\operatorname{In}(\mathcal{F})]$ has a component of size at least $\left(1 - \frac{\delta/5}{2 \cdot 1/10}\right)|V| = (1 - \delta)|V| > |V|/2$. ◀

3.2 Sketch of proof of Theorem 5

Let $\Delta \geq 5$ be an integer. Consider any sufficiently large q and any $\beta \geq \beta_c$. For sufficiently large n, choose a "radius" $r \approx \frac{1}{\beta}\log n$ and let $G = (V, E) \sim \mathcal{G}_{n,\Delta}$. Fix a vertex $v \in V$ and an edge e incident to v. We wish to show, with sufficiently high probability, that $\|\pi_{\mathcal{B}_r^+(v)}(e \mapsto \cdot) - \pi_G^{\text{ord}}(e \mapsto \cdot)\|_{\text{TV}} \leq 1/(100|E|)$.

Our goal is essentially to construct a coupling of $\mathcal{F}^+ \sim \pi_{\mathcal{B}_r^+(v)}$ and $\mathcal{F}^{\text{ord}} \sim \pi^{\text{ord}}$, such that $\Pr(\mathcal{F}^+(e) \neq \mathcal{F}^{\text{ord}}(e))$ is sufficiently small. In order to construct the coupling, we take advantage of the fact that $G[B_r(v)]$ is locally tree-like. In fact, we identify a suitable subgraph of $G[B_r(v)]$ without cycles and restrict the coupling to this subgraph.

Consider a breadth-first search from v in $G[B_r(v)]$. Let T_0 be the rooted tree consisting of all forward edges in this breadth-first search. All other edges in $B_r(v)$ are called "excess edges". W.h.p., since $G \sim \mathcal{G}_{n,\Delta}$, there are at most K excess edges in $B_r(v)$ for some absolute constant $K > 0$. In particular, since G is locally tree-like, we can identify integers r_1 and r_2 satisfying $r \geq r_1 > r_2 \geq 0$ such that $E(B_{r_1}(v)) \setminus E(B_{r_2}(v))$ contains no excess edges and $r_1 - r_2 \geq r/(2K) = \Omega(r)$. The fact that $r_1 - r_2 = \Omega(r)$ ensures that $B_{r_1}(v) \setminus B_{r_2}(v)$ is a sufficiently large subgraph of G, and the coupling focuses on this subgraph.

In order to describe the coupling process we need a small amount of notation. A *partial configuration* $\mathcal{F}$ is a map from the edges of G to the set $\{0, 1, *\}$. In-edges and out-edges (those that are mapped to 1 or to 0) are "revealed" and edges that are mapped to $*$ are "unrevealed". A refinement of a partial configuration is obtained by revealing more edges. We use $\mathcal{F} \subseteq \mathcal{F}'$ to denote the fact that $\mathcal{F}'$ refines $\mathcal{F}$.

In the coupling, we generate a sequence of edge subsets $F_0 \subseteq F_1 \subseteq \cdots \subseteq E$ such that, after iteration i, the edges in F_i are revealed. We also construct two sequences of partial configurations $\mathcal{F}_0^+ \subseteq \mathcal{F}_1^+ \subseteq \cdots \subseteq \mathcal{F}^+$ and $\mathcal{F}_0^{\mathrm{ord}} \subseteq \mathcal{F}_1^{\mathrm{ord}} \subseteq \cdots \subseteq \mathcal{F}^{\mathrm{ord}}$, maintaining the invariant that the revealed edges in $\mathcal{F}_i^{\mathrm{ord}}$ and $\mathcal{F}_i^+$ are exactly the edges in F_i. The coupling will have the crucial property that $\mathcal{F}^{\mathrm{ord}} \sim \pi^{\mathrm{ord}}$ and $\mathcal{F}^+ \sim \pi_{\mathcal{B}_{r_1}^+(v)}$

- The process starts with iteration $i = 0$. The initial set F_0 of revealed edges is all edges except those in $E(B_{r_1}(v))$. In $\mathcal{F}_0^{\mathrm{ord}}$ these revealed edges are sampled from the projection $\pi_{F_0}^{\mathrm{ord}}$ of π^{ord} onto F_0. It is likely that the configuration $\mathcal{F}_0^{\mathrm{ord}}$ has at least $(1-\eta)|E|$ in-edges. If not, then the coupling terminates (unsuccessfully), generating $\mathcal{F}^{\mathrm{ord}}$ and $\mathcal{F}^+$ from the right distributions. We will show that the probability of this unsuccessful termination is low. On the other hand, if $\mathcal{F}_0^{\mathrm{ord}}$ has a least $(1-\eta)|E|$ in-edges, then we are off to a good start. All configurations refining $\mathcal{F}_0^{\mathrm{ord}}$ are in Ω^{ord}, so the projection of π and π^{ord} onto subsequent edges that get revealed are the same (making it easier to continue the coupling). At this point $\mathcal{F}_0^+$ is taken to be the configuration with revealed edges F_0 where all revealed edges are in-edges.
- After iteration $i = 0$, iterations continue with $i = 1, 2, \ldots$ until an edge is revealed whose distance from v is at most r_2 or until the in-edges in $\mathcal{F}_i^{\mathrm{ord}}$ induce a giant component, and this giant component contains all vertices on the boundary of F_i. We will show that it is very unlikely that an edge at distance at most r_2 from v is reached. So it is likely the giant component in $\mathcal{F}_i^{\mathrm{ord}}$ contains all vertices on the boundary of F_i. This is a good situation because the conditional distribution of π, conditioned on refining $\mathcal{F}_i^{\mathrm{ord}}$ and the conditional distribution of $\mathcal{F}^+$, conditioned on refining $\mathcal{F}_i^+$ induce the same distribution on edges incident to v, which enables us to show that $\Pr(\mathcal{F}^+(e) \neq \mathcal{F}^{\mathrm{ord}}(e))$ is sufficiently small.
- The process at iteration $i+1$ is as follows. W_i is taken to be the set of all vertices on the boundary of F_i whose components (induced by the in-edges in $\mathcal{F}_i^{\mathrm{ord}}$) are all small. By "boundary" we mean that vertices in W_i are adjacent to revealed edges, and to unrevealed edges. If W_i is empty, then the coupling finishes. Otherwise, a vertex $w_i \in W_i$ is chosen to be as far from v as possible. The edges in the subtree of T_0 below the parent of w_i are revealed in F_{i+1}.

The main remaining ingredient in the proof is showing that the unsuccessful terminations of the coupling are unlikely. To do this, we use the polymer framework of [22]. (Ordered) polymers are defined using an inductive definition. For a set of edges $A \subseteq E$, let $\mathcal{B}_0(A) = A$, and inductively for $j = 0, 1, 2, \ldots$ define $\mathcal{B}_{j+1}(A)$ to be the set of all edges such that they are either in $\mathcal{B}_j(A)$ or edges that are incident to a vertex that has at least $5\Delta/9$ incident edges in $\mathcal{B}_j(A)$. Let $\mathcal{B}_\infty(A) = \bigcup_{j\in\mathbb{N}} \mathcal{B}_j(A)$. An ordered polymer of a configuration $\mathcal{F}$ is a connected component of $B_\infty(\mathrm{Out}(\mathcal{F}))$. The bulk of the work is to prove the following lemma, which is repeated in the appendix of the full version [14] (with more detail) as Lemma 44.

▶ **Lemma 19.** *Fix $\Delta \geq 5$ and $K, M > 0$. Suppose that $\beta \geq 3M$. Suppose that n is sufficiently large so that $r := \frac{M}{\beta}\log_{\Delta-1} n > K$ and $|B_r(v)| \leq 9\Delta n/200$. Define r_1 as above. Let $\mathcal{F}^{\mathrm{ord}}$ and $\mathcal{F}^+$ be generated by the process. Then at least one of the following conditions holds.*

1. *$\mathcal{F}^{\mathrm{ord}}$ and $\mathcal{F}^+$ agree on the edges that are incident to v.*
2. *$|\mathrm{In}(\mathcal{F}^{\mathrm{ord}}) \setminus E(B_{r_1}(v))| < (1-\eta)|E|$.*
3. *$\mathcal{F}^{\mathrm{ord}}$ contains a polymer of size at least $\frac{r}{400\Delta(1+K)} - 1$.*

To complete the proof of Theorem 5, we show that items 2 and 3 are unlikely. The proof that item 2 is unlikely, Lemma 45 in the full version [14], follows from the slack specified in Equation (2) of Lemma 3. The proof that item 3 is unlikely, Lemma 29 in the full version [14], follows from an analysis on the size of polymers by adapting appropriately the cluster expansion techniques of [22] (a bit of extra work is needed there to capture the $1/\beta$ dependence in the size of the polymer, see [14, Lemma 29] for details).

The proof of WSM for the disordered phase (Theorem 6) follows a similar strategy, the details are given in Appendix D of the full version [14].

Abstract

Range Avoidance (Avoid) is a total search problem where, given a Boolean circuit $\mathsf{C}\colon \{0,1\}^n \to \{0,1\}^m$, $m > n$, the task is to find a $y \in \{0,1\}^m$ outside the range of C. For an integer $k \geq 2$, NC^0_k-Avoid is a special case of Avoid where each output bit of C depends on at most k input bits. While there is a very natural randomized algorithm for Avoid, a deterministic algorithm for the problem would have many interesting consequences. Ren, Santhanam, and Wang (FOCS 2022) and Guruswami, Lyu, and Wang (RANDOM 2022) proved that explicit constructions of functions of high formula complexity, rigid matrices, and optimal linear codes, reduce to NC^0_4-Avoid, thus establishing conditional hardness of the NC^0_4-Avoid problem. On the other hand, NC^0_2-Avoid admits polynomial-time algorithms, leaving the question about the complexity of NC^0_3-Avoid open.

We give the first reduction of an explicit construction question to NC^0_3-Avoid. Specifically, we prove that a polynomial-time algorithm (with an NP oracle) for NC^0_3-Avoid for the case of $m = n + n^{2/3}$ would imply an explicit construction of a rigid matrix, and, thus, a super-linear lower bound on the size of log-depth circuits.

We also give deterministic polynomial-time algorithms for all NC^0_k-Avoid problems for $m \geq n^{k-1}/\log(n)$. Prior work required an NP oracle, and required larger stretch, $m \geq n^{k-1}$.

1 Introduction

The Range Avoidance (Avoid) problem is: given a Boolean circuit $\mathsf{C}\colon \{0,1\}^n \to \{0,1\}^m$ for some *stretch* $m > n$, find an element $y \in \{0,1\}^m$ outside the range of C. By the pigeonhole principle, such a y always exists. This problem was first introduced by Kleinberg, Korten, Mitropolsky, and Papadimitriou [15] as a complete problem for the class APEPP (Abundant Polynomial Empty Pigeonhole Principle). Informally, APEPP contains total search problems where the existence of a solution follows via the union bound (such as Shannon's classical proof that most functions require circuits of exponential size).

Korten [16] proved that a deterministic algorithm for Avoid would imply explicit constructions of objects that are central to the field of computational complexity, and would resolve several long-standing open problems. Such objects include functions of high circuit complexity, rigid matrices, pseudorandom generators, and Ramsey graphs. The key idea is that there is a succinct way to encode all "easy" objects (such as descriptions of functions of low circuit complexity) in the input space of a small circuit that acts as a decoder. Then a solution to the Avoid problem yields a "hard" object (such as a function of high circuit complexity), implying an explicit construction. In fact, the aforementioned works [15, 16] showed that even a deterministic algorithm *with an* NP *oracle* solving Avoid in polynomial time would lead to breakthrough results in complexity theory.

The only known deterministic algorithm for Avoid is the trivial brute force algorithm running in time $2^n \cdot \mathrm{poly}(n, |\mathsf{C}|)$.[1] No better algorithms are known for Avoid even if the algorithm is allowed to use an NP oracle. On the other hand, using both an NP oracle and randomness, one can solve Avoid in polynomial time: Pick a random string $y \in \{0,1\}^m$, and simply check if $y \in \mathrm{Range}(\mathsf{C})$ using the NP oracle. This shows that $\textsc{Avoid} \in \mathsf{FZPP}^{\mathsf{NP}}$, and, using the standard trick of simulating randomness by non-uniformity, $\textsc{Avoid} \in \mathsf{FP}^{\mathsf{NP}}/\mathsf{Poly}$.[2] Interestingly, for the class of polynomial-time algorithms with an NP oracle, the Avoid problem is equally hard for all values of stretch $n + 1 \leq m \leq \mathrm{poly}(n)$ [15].

For a class of circuits $\mathcal{C}$, the $\mathcal{C}$-Avoid problem is a special case of Avoid where each output is computed by a circuit from $\mathcal{C}$. Recent works by Ren, Santhanam, and Wang [19] and Guruswami, Lyu, and Wang [9] proved that efficient algorithms for $\mathcal{C}$-Avoid even for certain simple circuit classes $\mathcal{C}$ would be sufficient for getting various explicit constructions. Later, Chen, Huang, Li, and Ren [6] re-derived the best known lower bounds against ACC^0 circuits from an efficient algorithm for a certain $\mathcal{C}$-Avoid problem. While this suggests that designing efficient algorithms for Avoid problems is a promising approach to various explicit construction questions, the work of Ilango, Li, and Williams [10] proves barriers for designing polynomial time algorithms under certain cryptographic assumptions.

Let NC^1 denote the class of Boolean fan-in-2 circuits of depth $O(\log(n))$, and NC^0_k denote the class of Boolean functions where each output depends on at most k inputs for a constant k. [19] used perfect encodings of [13, 14, 2] to reduce NC^1-Avoid to NC^0_4-Avoid in polynomial time. Consequently, [9] reduced most of the aforementioned explicit constructions in [16] (and several new ones!) to NC^1-Avoid, and, thus, to NC^0_4-Avoid. In particular, polynomial-time *deterministic* algorithms (even with an NP oracle) for NC^0_4-Avoid would now imply breakthrough results in complexity theory.

[9] gave a polynomial-time algorithm solving NC^0_2-Avoid for any stretch $m \geq n + 1$. As mentioned above, NC^0_4-Avoid might be hard to solve efficiently. This leaves the question about the complexity of NC^0_3-Avoid open.

▶ **Open Problem 1** ([9]). *Can we reduce explicit construction problems to solving* NC^0_3*-Avoid? Or can we solve* NC^0_3*-Avoid in polynomial time?*

Unlike the case of the general Avoid problem, NC^0_k-Avoid may be much easier for large

[1] This trivial algorithm is (conditionally) tight for a related problem studied in [15], where the range of C has size much smaller than 2^{n+1}, and is given by a circuit computing a function from $[N]$ to $[M]$. [15] gives a deterministic reduction from SAT on n variables to Avoid for a circuit $\mathsf{C}\colon [2^n] \to [2^n + 2^{o(n)}]$ running in subexponential time. Thus, under the Exponential Time Hypothesis [12, 11], this problem does not admit deterministic (and randomized) algorithms running in time $2^{o(n)}$.

[2] Here, the complexity classes FP, FE, FZPP are simply the functional analogs of the decision classes P, E, ZPP.

values of the stretch m. Indeed, on one hand, NC^0_k-Avoid for small stretch $m = n + o(n)$ is capable of encoding hard explicit construction problems [19, 9]. On the other hand, NC^0_k-Avoid for $m = \Omega(n^k)$ is easily solvable in polynomial time: since the number of distinct functions depending on at most k out of n inputs is $O(n^k)$, every such instance of the problem must have two outputs computing identical functions. Assigning different values to these outputs solves NC^0_k-Avoid.

[9] presented an algorithm solving NC^0_k-Avoid for stretch $m \geq \Omega(n^{k-1})$ in polynomial time with an NP oracle.[3] This improvement on the trivial algorithm suggests a natural question of whether one can solve NC^0_k-Avoid for even smaller values of stretch m.

▶ **Open Problem 2.** *Design a polynomial-time algorithm (with an* NP *oracle) solving* NC^0_k*-Avoid with* n *inputs and stretch* $m = o(n^{k-1})$ *for* $k \geq 3$.

1.1 Our Results

The classical result of Shannon [20] shows that most Boolean functions of n variables require Boolean circuits of exponential size. Despite that, the best known lower bound on the size of a circuit (or even a circuit of logarithmic depth, i.e., NC^1) for a function in P (or even E^{NP}) is $3.1n - o(n)$ proven by Li and Yang [17]. A central problem in circuit complexity is to prove a super-linear lower bound on the number of gates of NC^1 circuits computing an explicit function [22, 3, Frontier 3].

Similarly, for the class of *linear* NC^1 circuits – NC^1 circuits where each gate computes the XOR (or its negation) of its two inputs – no super-linear lower bound on the complexity of an explicit linear map $M \in \mathbb{F}_2^{n\times n}$ is known. The best lower bound against linear circuits is $3n - o(n)$ proven by Chashkin [5].

In our first result (Theorem 9), we answer Open Problem 1 by showing that a polynomial-time algorithm for NC^0_3-Avoid would imply an explicit construction of a map requiring linear NC^1 circuits of super-linear size (thus, demonstrating the hardness of NC^0_3-Avoid).

▶ **Theorem 1.** *An* FP *(resp.* $\mathsf{FP}^{\mathsf{NP}}$*) algorithm for* NC^0_3*-Avoid with stretch* $m = n + O(n^{2/3})$ *implies an explicit construction of a linear map in* FP *(resp.* $\mathsf{FP}^{\mathsf{NP}}$*) that cannot be computed by linear* NC^1 *circuits of size* $o(n \log\log(n))$.

Our proof of Theorem 1 first reduces an explicit construction of a rigid matrix to NC^0_3-Avoid (Theorem 9). A matrix $M \in \mathbb{F}_2^{n\times n}$ is called (r, s)-rigid if it cannot be written as a sum $M = L + S$ of a rank-r matrix L and a matrix S with at most s non-zeros per row. In a seminal work, Valiant [22] introduced an approach for proving super-linear lower bounds on the size of linear NC^1 circuits via matrix rigidity. Valiant proved that an $(\varepsilon n, n^\varepsilon)$-rigid matrix $M \in \mathbb{F}_2^{n\times n}$ for any constant $\varepsilon > 0$ requires linear NC^1 circuits of size $\Omega(n \log\log(n))$. Theorem 1 now follows straightforwardly as a corollary of Theorem 9.

The best known constructions of rigid matrices do not yet achieve the parameters sufficient for Valiant's circuit lower bound. [7, 18, 21] construct an $\left(r, \Omega\left(\frac{n}{r}\log(\frac{n}{r})\right)\right)$-rigid matrix in polynomial time, [8] gives an $\left(r, \Omega\left(\frac{n^2}{r^2\log(n)}\right)\right)$-rigid matrix in time $2^{O(n)}$ for $r \geq \sqrt{n}$, and [1, 4] give $(2^{\varepsilon\log(n)/\log\log(n)}, \Omega(n))$-rigid matrices in polynomial time with an NP oracle. However, even an $\mathsf{FP}^{\mathsf{NP}}$ algorithm for NC^0_3-Avoid with stretch $m = n + n^{12/17-\varepsilon}$ for any constant $\varepsilon > 0$ would already improve on these known constructions of rigid matrices.

[3] The algorithm of [9] does not use the full power of $\mathsf{FP}^{\mathsf{NP}}$: it outputs a hitting set $H \subseteq \{0,1\}^m$ such that for every NC^0_k function C, at least one point $y \in H$ is outside the range of C. Only then the algorithm looks at the input function and finds a solution $y \in H$ using the NP oracle.

In fact, we reduce the problem of constructing explicit rigid matrices to a problem that we call degree-2-Avoid, where each output computes a degree-2 polynomial of the inputs. Following Ren, Santhanam, and Wang's approach [19], this problem can be reduced to NC^0_3-Avoid using the perfect encoding scheme of Applebaum, Ishai, and Kushilevitz [2].[4]

On the algorithmic side, we make partial progress towards resolving Open Problem 2. We first give a simple deterministic polynomial-time algorithm for NC^0_3-Avoid for stretch $m \geq \binom{n}{2}/3 + 2n$ (presented in Appendix A). This algorithm already improves on the best known algorithm for NC^0_3, as it does not use an NP oracle. Then, in Theorem 4 we extend this algorithm to solve NC^0_k-Avoid for all constant k. Recall that the current best algorithms for this problem solve the case where $m \geq \Omega(n^{k-1})$ in polynomial time using an NP oracle [9]. We improve this result in two directions: our algorithm does not use an NP oracle, and it works in polynomial time for stretch $m \geq n^{k-1}/\log(n)$.

▶ **Theorem 2.** *There is a deterministic polynomial-time algorithm that solves the NC^0_k-Avoid problem with n inputs and stretch m for every $k \geq 3$ and $m \geq n^{k-1}/\log(n)$.*

1.2 Proof Overview

1.2.1 Hardness of NC^0_3-Avoid

Valiant [22] proved that linear NC^1 circuits with a linear number of gates can only compute non-rigid linear maps $M \in \mathbb{F}_2^{n\times n}$, i.e., maps M that can be written as a sum $M = Q + S$, where $\operatorname{rank}(Q) \leq \varepsilon n$ and each row of S has at most n^δ ones in it. For the rest of the section, our non-rigid matrices can be written as the sum of a matrix with rank $\leq n/10$ and a matrix with row sparsity at most $n^{0.1}$. Therefore, constructing a rigid matrix would imply a super-linear lower bound on the size of linear NC^1 circuits computing it.

To reduce an explicit construction of an $n \times n$ rigid matrix to solving an instance of NC^0_3-Avoid, we design an NC^0_3 function $f\colon \{0,1\}^{p(n)} \to \{0,1\}^{n^2}$, for some polynomial $p(n) < n^2$, such that for every non-rigid matrix $M \in \{0,1\}^{n\times n}$, there exists $x \in \{0,1\}^{p(n)}$ satisfying $f(x) = M$. Now, any solution $M' \in \{0,1\}^{n\times n}$ to the NC^0_3-Avoid problem for the function f must be a rigid matrix.

Before constructing such an NC^0_3 function f, we first design a function $g\colon \mathbb{F}_2^{n^2/2} \to \mathbb{F}_2^{n^2}$, where each output bit of g is a degree-2 polynomial of the inputs, and the range of g contains all non-rigid matrices. A solution to the degree-2-Avoid problem for the function g would give us a rigid matrix. Following [19], we can then apply a perfect encoding scheme [13, 14, 2] to g, and obtain an NC^0_3 function f, as required (see Lemma 6). Effectively, this reduces solving Avoid on g to solving Avoid on f.

Now we construct a degree-2 function $g\colon \mathbb{F}_2^{n^2/2} \to \mathbb{F}_2^{n^2}$ whose inputs encode all non-rigid matrices, i.e., for every non-rigid matrix M, there is an $x \in \{0,1\}^{n^2/2}$ such that $f(x) = M$. A non-rigid matrix M can be written as $M = LR + S$, where $L, R^T \in \mathbb{F}_2^{n\times n/10}$, and each row of S contains at most $n^{0.1}$ ones. The first $n^2/5$ inputs of the function g will correspond to the elements of L and R. Note that every entry of LR is a degree-2 function of the entries of L and R since it just computes the inner product of a row in L and a column in R. Now, for each $n^{0.1}$-sparse row of S, we show how to encode it using $n^{0.6}$ inputs and a degree 2 function. Repeating this procedure for each row of S will finish the proof.

[4] Ren, Santhanam, and Wang use the following definition of perfect encodings: A function $\widehat{f}$ is a perfect encoding of a function f if there exists a polynomial time algorithm Dec such that for all x, y: $\mathrm{Dec}(y) = f(x) \iff \exists r, y = \widehat{f}(x, r)$.

We interpret the $n^{0.1}$-sparse row with n entries as a $\sqrt{n} \times \sqrt{n}$ matrix A. Since A has at most $n^{0.1}$ non-zero entries, $\operatorname{rank}(A) \leq n^{0.1}$. It can be written as a product $A = BC$ where $B, C^T \in \mathbb{F}_2^{\sqrt{n} \times n^{0.1}}$. Therefore, there is a degree-2 function h that takes as input B, C of size $2n^{0.6}$ and outputs the sparse matrix A.

The presented encoding of s-sparse vectors in $\mathbb{F}_2^n$ is only non-trivial for $s < \sqrt{n}$ (as otherwise the number of inputs of h exceeds the number of outputs). As a result, we cannot encode the entire matrix S as an $n^{1.1}$-sparse vector in $\mathbb{F}_2^{n^2}$. However, for Valiant's approach of proving circuit lower bounds, we can assume that S is $n^{0.1}$-*row* sparse.[5] Thus, we can separately encode each row of S using only $O(n^{0.6})$ inputs to obtain an encoding of S in $O(n^{1.6})$ bits. In Lemma 8, we will demonstrate how to accommodate slightly better sparsity parameter when we are allowed higher (but still constant) degree d for the encoding function.

1.2.2 Simple algorithm for NC_3^0-Avoid

We start with a short description of a simple deterministic polynomial-time algorithm for NC_3^0-Avoid for stretch $m \geq \binom{n}{2}/3 + 2n$ (presented in Appendix A). This algorithm already improves on the best known algorithm for NC_3^0-Avoid, as our algorithm does not use an NP oracle.

If we had a #SAT oracle, then we could solve NC_3^0-Avoid even for stretch $m = n + 1$. Our algorithm would iteratively find constant assignments to each of the first n outputs to minimize the number of inputs that map to the current (partial) output assignments. Throughout our exposition, we say such inputs are *consistent with the (partial) output assignments*. Before we describe our algorithm, it is important to note that we always fix circuit outputs to constant assignments. At each iteration, we would use the #SAT oracle to find the output assignment that reduces the size of the input set by at least half. After fixing the first n outputs, we still have at least $m - n \geq 1$ unassigned outputs, and only one input point $x \in \mathbb{F}_2^n$ that is consistent with the previously assigned output bits. This allows us to find an assignment of the $(n+1)$-th output bit such that the string specified by the output bits lies outside the range of the circuit.

Unfortunately, solving #SAT (even approximately) is hard for this class of multi-output circuits. In the absence of an efficient #SAT algorithm, our algorithm maintains an affine subspace $\mathcal{S}$ that contains all inputs from $\mathbb{F}_2^n$ that are consistent with the current partial assignment ($\mathcal{S}$ may also contain inputs that are not consistent with the current partial assignment). We carefully set output values so that at each iteration, we reduce the dimension of $\mathcal{S}$ by at least one. This way, after $n + 1$ steps we will find a solution to the NC_3^0-Avoid problem. However, our algorithm can only work when the stretch is $m \geq \Omega(n^2)$.

Without loss of generality, we assume that each output reads exactly three input bits. At each iteration the number of currently unassigned outputs is $> \binom{n}{2}/3$. This allows us to find a pair of outputs y_1 and y_2 that share a pair of input variables.[6] Say, $y_1 = f_1(x_1, x_2, x_3)$ and $y_2 = f_2(x_2, x_3, x_4)$. We will find a constant assignment to y_1 and y_2 that reduces the dimension of the affine subspace $\mathcal{S}$.

Note that there are 16 assignments to (x_1, x_2, x_3, x_4) and four different values of (y_1, y_2). Therefore, there is a way to assign $y_1 = c_1, y_2 = c_2$ such that at most four points (x_1, x_2, x_3, x_4) map to these values of the outputs. Note that there always exists a hyperplane H containing

[5] Alternatively, one can argue by Markov's inequality that if a matrix M cannot be written as a sum of rank-r and $n^{0.1}$-*row* sparse matrices, then M also cannot be written as a sum of rank-$2r$ and $rn^{0.1}$-*globally* sparse matrices.

[6] Each output sees 3 pairs of input bits, giving a total of $3m > \binom{n}{2}$ pairs. By the pigeonhole principle, at least one pair of inputs appears in two outputs.

any four points in $\mathbb{F}_2^4$. Let $\mathcal{H}$ be the affine subspace obtained by extending H to all n inputs. Then, $\mathcal{S} \cap \mathcal{H}$ gives us an affine subspace containing all inputs consistent with the assignment $y_1 = c_1, y_2 = c_2$.

If $\mathcal{S} \nsubseteq \mathcal{H}$, then we have an assignment of two outputs that reduces the dimension of our affine subspace as $\dim(\mathcal{S} \cap \mathcal{H}) < \dim(\mathcal{S})$. Otherwise, if $\mathcal{S} \subseteq \mathcal{H}$, then instead of considering all 16 assignments to the inputs (x_1, x_2, x_3, x_4), we can restrict our attention to at most 8 such assignments that belong to H, which makes the problem only easier (as we show in Theorem 16).

1.2.3 Better algorithm for NC_k^0-Avoid

The main bottleneck of this simple algorithm is that it maintains an affine subspace that must contain all consistent inputs. While affine subspaces are easy to work with, they are not expressive enough to accurately describe all inputs that are consistent with an arbitrary partial assignment. In order to improve the previous algorithm, we will maintain a more expressive structure than an affine subspace – a union of affine subspaces. Below we sketch our approach to solving NC_3^0-Avoid with stretch $m \geq \Omega(n^2/\log(n))$. Theorem 4 generalizes this to solving NC_k^0-Avoid problems with stretch $m \geq \Omega(n^{k-1}/\log(n))$ for all values of k.

Again, without loss of generality, we assume that each output depends on exactly three inputs. Consider a bipartite graph, where the left vertices correspond to n inputs, the right vertices correspond to m outputs, and an input-output pair (x_i, y_j) is connected by an edge if the output y_j depends on the input x_i. First we select $t = 3n^2/m$ highest-degree inputs $I = \{x_1, \ldots, x_t\}$. Their neighborhood must contain at least $3n$ distinct outputs $O = \{y_1, \ldots, y_{3n}\}$.[7] Let C be the sub-circuit defined on outputs from O and their corresponding inputs. Now, we will find a $y \in \mathbb{F}_2^{3n}$ outside $\mathrm{Range}(\mathsf{C})$.

First, consider all 2^t assignments to the inputs in $I = \{x_1, \ldots, x_t\}$, resulting in circuits $\mathsf{C}_1, \ldots, \mathsf{C}_{2^t}$. Since every output in O is connected to at least one input from I, fixing an assignment to the inputs I reduces each C_i to an NC_2^0 circuit. In a way, we have reduced NC_3^0-Avoid to an OR of 2^t instances of NC_2^0-Avoid: we need to find a $y \in \{0,1\}^{3n}$ outside the ranges of all the C_i's. For each circuit C_i, we will maintain an affine subspace $\mathcal{S}_i$ containing all inputs consistent with the current partial assignment of the outputs.

Our algorithm works by iteratively fixing the output bits from $\{y_1, \ldots, y_{3n}\}$ such that at each step the total number of points in the (disjoint) union of the affine subspaces $\mathcal{S}_i$ is reduced by a constant factor, eventually making all the subspaces empty. We observe (in Lemma 13) that for any affine subspace $\mathcal{S}_i$, one of the assignments $y_i = 0$ or $y_i = 1$ always reduces the dimension of $\mathcal{S}_i$ by one. Therefore, by picking the "best" assignment $y_i = c$ across all the subspaces $\mathcal{S}_i$, we can reduce the size of the union of such affine subspaces by a constant factor of $4/3$. Repeating this procedure for $\log_{4/3}(2^n) + 1 < 3n$ steps finishes the proof.

1.3 Open Problems

Our work motivates several natural questions about the complexity of NC_3^0-Avoid and degree-2-Avoid. We reduce explicit constructions of rigid matrices to solving degree-2-Avoid, and then NC_3^0-Avoid, with appropriate stretch.

[7] Since the number of outputs is m, and each output has degree 3, the number of edges in the graph is $3m$, and the average degree of an input is $3m/n$. The t highest-degree inputs then have total degree at least $3mt/n$, and must be connected to at least $mt/n = 3n$ distinct outputs.

▶ **Open Problem 3.** *Can other explicit construction questions be reduced to* NC_3^0*-*Avoid *or degree-*2*-*Avoid*?*

Particularly, we suspect that the construction of linear and list-decodable codes with optimal parameters [9] might be good candidates for these reductions.

Using the encoding of [2] in the reduction from degree-2-Avoid to NC_3^0-Avoid almost always decreases the required stretch to $m = n + o(n)$ (as highlighted in Section 3). It would also be interesting to find a more efficient encoding or reduction from degree-2-Avoid to NC_3^0-Avoid. This could potentially increase the stretch for NC_3^0-Avoid required to obtain explicit constructions thereby making the problem easier.

▶ **Open Problem 4.** *Can we construct a more efficient reduction from degree-*2*-*Avoid *to* NC_0^3*-*Avoid*?*

We believe degree-2-Avoid might be of independent interest since it allows for a larger stretch. For example, for improved constructions of rigid matrices, it suffices to solve degree-2-Avoid for super-linear stretch $m \geq n^{12/11-\varepsilon}$ for a constant $\varepsilon > 0$. In fact, degree-2-Avoid is easy to solve when the stretch is $m \geq n^2$. Note that there are at most $\binom{n}{2}$ unique degree-2 monomials on n variables. If $m \geq n^2$, then we can replace each unique monomial with a new variable. As a result, we will have m linear functions in $< m$ variables. We can solve Avoid on this linear function instance by a dimension reduction strategy similar to the one outlined in the previous section.

▶ **Open Problem 5.** *Are there algorithmic techniques to solve degree-*2*-*Avoid *that do not use a reduction to* NC_3^0*-*Avoid*?*

For the NC_3^0-Avoid problem, our algorithm runs in deterministic time $2^{O(n^2/m)}$ for any stretch $m \geq n+1$. In particular, this recovers the exponential-time brute force algorithm for the hardest case of $m = n+1$. It would be interesting to obtain matching conditional lower bounds for deterministic algorithms for NC_3^0-Avoid.

▶ **Open Problem 6.** *Is there a conditional lower bound of* $2^{\Omega(n^2/m)}$ *on the complexity of deterministic algorithms without an* NP *oracle for* NC_3^0*-*Avoid*?*

Finally, it is natural to ask if algorithms with NP oracles can solve NC_3^0-Avoid more efficiently.

▶ **Open Problem 7.** *Do there exist polynomial-time algorithms with* NP *oracles that solve* NC_3^0*-*Avoid *for stretch* $m = o(n^2/\log(n))$*?*

1.4 Structure

The rest of the paper is organized as follows. In Section 2, we give all necessary background material, including a reduction from degree-d-Avoid to NC_{d+1}^0-Avoid in Section 2.3. In Section 3, we reduce the problem of constructing explicit rigid matrices to NC_3^0-Avoid. In Section 4, we give deterministic algorithms solving NC_k^0-Avoid in polynomial time for stretch $m \geq n^{k-1}/\log(n)$. Finally, Appendix A contains an alternative deterministic polynomial-time algorithm for NC_3^0 for the case where stretch $m \geq \Omega(n^2)$.

2 Preliminaries

For every $a \in \mathbb{F}_2^n$ and subspace L of $\mathbb{F}_2^n$, we can define an affine subspace $\mathcal{A} \subseteq \mathbb{F}_2^n$ where $\mathcal{A} = \{a + v \mid v \in L\}$. The dimension of the affine subspace $\dim(\mathcal{A})$ is the same as the dimension of the linear subspace L that defines it. Equivalently, the set of points that lie on a specified set of hyperplanes over $\mathbb{F}_2^n$ also characterize an affine subspace of $\mathbb{F}_2^n$. The hyperplanes can be written as a system of linear equations $Ax = b$, and the dimension of the corresponding affine subspace $\mathcal{A}$ can be calculated as $\dim(\mathcal{A}) = n - \operatorname{rank}(A)$.

The circuits and algorithms in this paper generally work over the boolean hypercube $\{0,1\}^n$. We work with multi-output circuits $\mathsf{C} : \{0,1\}^n \to \{0,1\}^m$ where $m > n$ and m is called the stretch of the circuit. A partial output assignment, $y \in \{0,1,*\}^m$, is a fixing of a subset of the output bits of the circuit to constants. For an input $x \in \{0,1\}^n$ to the circuit, we say x *is consistent with a partial output assignment* $y \in \{0,1,*\}^m$, if $\mathsf{C}(x)$ agrees with y on the fixed bits. When specified, the input (resp. output) space of a circuit might instead be viewed as the vector space $\mathbb{F}_2^n$ (resp. $\mathbb{F}_2^m$) over the finite field $\mathbb{F}_2$.

The complexity classes $\mathsf{FP}, \mathsf{FP}^{\mathsf{NP}}, \mathsf{FE}$, and $\mathsf{FE}^{\mathsf{NP}}$ are classes of search problems analogous to the classes of decision problems $\mathsf{P}, \mathsf{P}^{\mathsf{NP}}, \mathsf{E}$, and E^{NP}. For example, the class FP contains all functions that can be computed by deterministic polynomial-time Turing machines.

2.1 Circuits and Matrix Rigidity

In this paper, we work with circuit classes NC^0_k and NC^1, which we define below.

▶ **Definition 1** (NC Circuits). *The circuit class* NC^i *contains multi-output Boolean circuits on* n *inputs of depth* $O(\log^i(n))$ *where each gate has fan-in* 2*. We are particularly concerned with the following classes of circuits:*

- *For every constant* $k \geq 1$, NC^0_k *is the class of circuits where each output depends on at most* k *inputs.*
- NC^1 *is the class of circuits of depth* $O(\log(n))$ *where all gates have fan-in* 2*.*
- *Linear* NC^1 *circuits are circuits of depth* $O(\log(n))$ *where every gate has fan-in* 2 *and computes an affine function, i.e., the XOR of its two inputs or its negation.*

It is a long-standing open problem in circuit complexity to prove super-linear lower bounds on the size of (linear) NC^1 circuits computing an n-output function from FP or even $\mathsf{FE}^{\mathsf{NP}}$ [22, 3, Frontier 3]. Valiant [22] suggested an approach for proving super-linear lower bounds for linear NC^1 circuits using the notion of matrix rigidity.

▶ **Definition 2** (Matrix Rigidity). *For* $r, s \in \mathbb{Z}^+$*, a matrix* $M \in \mathbb{F}_2^{n\times n}$ *is* (r,s)-rigid *if* M *cannot be written as a sum*

$$M = L + S\,,$$

where $L, S \in \mathbb{F}_2^{n\times n}$*,* L *is low rank, i.e.,* $\operatorname{rank}(L) \leq r$*, and* S *is row sparse, i.e., every row of* S *has at most* s *non-zero entries.*

Valiant [22] proved that a linear operator given by a sufficiently rigid matrix requires linear NC^1 circuits of size at least $\Omega(n \log\log(n))$, but there are still no known constructions of such rigid matrices even in $\mathsf{FE}^{\mathsf{NP}}$.

▶ **Theorem 3** ([22]). *If a family of matrices* $(M_n)_{n\geq 1}$*,* $M_n \in \mathbb{F}^{n\times n}$*, is* $(\varepsilon n, n^{\delta})$*-rigid for constant* $\varepsilon, \delta > 0$*, then the linear map* $x \mapsto Mx$ *requires linear* NC^1 *circuits of size* $\Omega(n \log\log(n))$*.*

2.2 Range Avoidance for Circuits

In the range avoidance problem, given a circuit C with n inputs and m outputs, $m > n$, the goal is to find an m-bit string outside the range of C.

▶ **Definition 3** (Avoid). *In the* Avoid *problem, given a description of a circuit* $\mathsf{C} : \{0,1\}^n \to \{0,1\}^m$ *for* $m > n$*, the task is to find a* $y \in \{0,1\}^m$ *such that* $\forall x \in \{0,1\}^n \colon \mathsf{C}(x) \neq y$*.*

The function $m = m(n)$ is called the *stretch* of the multi-output circuit C. Note that Avoid is a total search problem, i.e., there always exists such a $y \in \{0,1\}^m$ since $m > n$. We focus on a more restricted problem where there is an additional promise that the input circuit C is from a fixed circuit class $\mathcal{C}$.

▶ **Definition 4** ($\mathcal{C}$-Avoid). *In the* $\mathcal{C}$-Avoid *problem, given a description of a circuit* $\mathsf{C} : \{0,1\}^n \to \{0,1\}^m$ *for* $m > n$*, where* $\mathsf{C} \in \mathcal{C}$*, the task is to find a* $y \in \{0,1\}^m$ *such that* $\forall x \in \{0,1\}^n \colon \mathsf{C}(x) \neq y$*.*

In particular, we are concerned with NC^1-Avoid and NC^0_k-Avoid for constant $k \geq 1$. We will also consider the class of functions where each output is a multivariate polynomial of the inputs of degree at most d over $\mathbb{F}_2$.

▶ **Definition 5** (degree-d-Avoid). *In the* degree-d-Avoid *problem, given a description of a function* $\mathsf{C} \colon \mathbb{F}_2^n \to \mathbb{F}_2^m$ *for* $m > n$*, where each output can be computed by a polynomial of degree* $\leq d$ *in the* n *inputs, the task is to find a* $y \in \mathbb{F}_2^m$ *such that* $\forall x \in \mathbb{F}_2^n \colon \mathsf{C}(x) \neq y$*.*

2.3 Low Degree and Low Locality

Perfect randomized encodings were introduced by [2] for various cryptographic applications. We are interested in the following property of perfect encodings: For a Boolean function $f : \{0,1\}^n \to \{0,1\}^m$ and its encoding $\widehat{f} \colon \{0,1\}^{n+\ell} \to \{0,1\}^{m+\ell}$, there exists a polynomial-time decoding algorithm, $\mathrm{Dec} \colon \{0,1\}^{m+\ell} \to \{0,1\}^m$, such that for all $y \in \{0,1\}^{m+\ell}$ and $x \in \{0,1\}^n$ satisfying $\mathrm{Dec}(y) = f(x)$, there exists $r \in \{0,1\}^\ell$ such that $y = \widehat{f}(x,r)$. This property can be used in Avoid reductions as follows. Given a solution to the Avoid problem for the function $\widehat{f}$, i.e., $y \notin \mathrm{Range}(\widehat{f})$, one can find a solution to the Avoid problem for the function f in polynomial time by simply computing $\mathrm{Dec}(y) \notin \mathrm{Range}(f)$.

[2] first encode NC^1 functions as degree-3 functions. Then, they encode every degree-d function as an NC^0_{d+1} function. Composing these two encodings provides an encoding of NC^1 functions in NC^0_4. Using this encoding, [19] provides a polynomial time reduction from NC^1-Avoid to NC^0_4-Avoid. We use only one part of the result from [2]: there is a polynomial time reduction from degree-d-Avoid to NC^0_{d+1}-Avoid. For completeness, we include the proof here.

▶ **Lemma 6.** *Let* $d \geq 2$ *be a constant, and* $f \colon \mathbb{F}_2^n \to \mathbb{F}_2^m$ *be a multi-output function where every output computes a sum of* k *monomials of degree* $\leq d$*. Then there exists a function* $\widehat{f} \colon \{0,1\}^{n+(2k-1)m} \to \{0,1\}^{2km}$ *computed by an* NC^0_{d+1} *circuit and a polynomial time algorithm* $\mathrm{Dec} \colon \{0,1\}^{2km} \to \{0,1\}^m$ *such that for all* x, y*, if* $\mathrm{Dec}(y) = f(x)$*, there exists an* $r \in \{0,1\}^{(2k-1)m}$ *such that* $\widehat{f}(x,r) = y$*.*

Proof. We follow the encoding constructed in [2]. First, we construct an encoding $\widehat{g}$ for each single output function g of f. Let $g(x) = T_1(x) + T_2(x) + \cdots + T_k(x)$ be a single output degree-d function where each $T_i(x)$ is a monomial of degree at most d. Consider the encoding of g, $\widehat{g} : \{0,1\}^n \times \{0,1\}^k \times \{0,1\}^{k-1} \to \{0,1\}^{2k}$ defined as follows

$$\begin{aligned}\widehat{g}(x,r,s) = (T_1(x) - r_1, \quad & T_2(x) - r_2, \quad & \ldots \quad & T_{k-1}(x) - r_{k-1}(x), \quad & T_k(x) - r_k, \\ r_1 - s_1, \quad & s_1 + r_2 - s_2, \quad & \ldots \quad & s_{k-2} + r_{k-1} - s_{k-1}, \quad & s_{k-1} + r_k)\,.\end{aligned}$$

Clearly, each output bit of $\widehat{g}$ can be computed by an NC^0_{d+1} circuit. We define a polynomial-time algorithm $\mathrm{Dec}_{\widehat{g}}\colon \{0,1\}^{2k} \to \{0,1\}$ such that if $\mathrm{Dec}_{\widehat{g}}(y) = g(x)$ then there exist r and s satisfying $\widehat{g}(x,r,s) = y$. Given $y \in \{0,1\}^{2k}$, $\mathrm{Dec}_{\widehat{g}}(y)$ sums up the bits of y modulo 2.

Suppose $\mathrm{Dec}_{\widehat{g}}(y) = g(x)$ for some $x \in \{0,1\}^n$, i.e.,

$$\mathrm{Dec}_{\widehat{g}}(y) = \sum_{j=1}^{2k} y_j = g(x) = \sum_{j=1}^{k} T_j(x)\,. \tag{1}$$

We will now show that there exist r and s such that $\widehat{g}(x,r,s) = y$. For each $j \in [k]$, we set $r_j = T_j(x) - y_j$. We also set $s_1 = r_1 - y_{k+1}$ and sequentially set $s_j = s_{j-1} + r_j - y_{k+j}$ for each $j \in \{2,\dots,k-1\}$. By definition, the first $2k-1$ bits of $\widehat{g}(x,r,s)$ equal the first $2k-1$ bits of y. For the last bit, note that:

$$\begin{aligned} s_{k-1} + r_k &= \sum_{i=1}^{k} r_i - \sum_{i=k+1}^{2k-1} y_i && \text{(by the definition of } s\text{)} \\ &= \sum_{i=1}^{k} T_i(x) - \sum_{i=1}^{2k-1} y_i && \text{(by the definition of } r\text{)} \\ &= y_{2k}\,. && \text{(by Equation (1))} \end{aligned}$$

Therefore, for the constructed r and s, $\widehat{g}(x,r,s) = y$, as required.

Suppose $f(x) = (f_1(x), f_2(x), \dots, f_m(x))$, where each $f_i(x)$ is a sum of at most k monomials of degree $\le d$. Let $\widehat{f_i}$ be the encoding of f_i as defined above. Then our encoding of f is simply a concatenation of the encodings of its individual outputs, $\widehat{f}\colon \{0,1\}^{n+(2k-1)m} \to \{0,1\}^{2km}$, where

$$\widehat{f}(x, r^{(1)}, r^{(2)}, \dots, r^{(m)}, s^{(1)}, s^{(2)}, \dots, s^{(m)}) = (\widehat{f_1}(x, r^{(1)}, s^{(1)}), \dots, \widehat{f_m}(x, r^{(m)}, s^{(m)}))\,. \tag{2}$$

On input $y = (y_1, y_2, \dots, y_m) \in \{0,1\}^{2km}$, the decoding algorithm returns

$$\mathrm{Dec}(y) = (\mathrm{Dec}_{\widehat{f_1}}(y_1), \dots, \mathrm{Dec}_{\widehat{f_m}}(y_m))\,. \tag{3}$$

Suppose $\mathrm{Dec}(y) = f(x)$ for some $x \in \{0,1\}^n$. Then $\mathrm{Dec}_{\widehat{f_i}}(y_i) = f_i(x)$ for all $i \in [m]$. By our proof above, there exists $r^{(i)}$ and $s^{(i)}$ such that $y_i = \widehat{f_i}(x, r^{(i)}, s^{(i)})$ and, thereby,

$$y = (y_1, \dots, y_m) = (\widehat{f_1}(x, r^{(1)}, s^{(1)}), \dots, \widehat{f_m}(x, r^{(m)}, s^{(m)})) = \widehat{f}(x, r^{(1)}, s^{(1)}, \dots, r^{(m)}, s^{(m)})\,.$$

Finally, Dec runs in time $O(mk)$ since it runs m iterations of $\mathrm{Dec}_{\widehat{f_i}}$ for each i, each of which simply computes a sum of $2k$ bits. Since each $\widehat{f_i}$ is in NC^0_{d+1}, so is $\widehat{f}$. ◀

Now, following [19], we conclude that there is a polynomial-time reduction from degree-d-Avoid to NC^0_{d+1}-Avoid.

▶ **Corollary 7.** *For every $d \ge 1$, if there exists an* FP *(resp.* $\mathsf{FP}^{\mathsf{NP}}$*) algorithm for* NC^0_{d+1}*-Avoid, then there exists an* FP *(resp.* $\mathsf{FP}^{\mathsf{NP}}$*) algorithm for degree-$d$-Avoid.*

Proof. Let f be an input to a degree-d-Avoid problem with m output bits. Then, each output bit of f is a sum of at most $k = O(n^d)$ monomials of degree d. Let $\widehat{f}$ be the encoding of f in NC^0_{d+1} guaranteed by Lemma 6. Note that $\widehat{f}\colon \{0,1\}^{n+(2k-1)m} \to \{0,1\}^{2km}$. By the assumption of the Corollary, there is an FP (resp. $\mathsf{FP}^{\mathsf{NP}}$) algorithm that returns a $y \notin \mathrm{Range}(\widehat{f})$. Then, by Lemma 6, $\mathrm{Dec}(y) \notin \mathrm{Range}(f)$ and Dec runs in polynomial time. Therefore, there is an FP (resp. $\mathsf{FP}^{\mathsf{NP}}$) algorithm for degree-$d$-Avoid. ◀

3 Hardness of NC^0_3-Avoid

In this section, we reduce the problem of constructing explicit rigid matrices to the algorithmic task of solving NC^0_3-Avoid. First, in Lemma 8 we give an explicit degree-2 function $f\colon \{0,1\}^k \to \{0,1\}^n$, $k \ll n$, whose range contains all sparse vectors of length n. Note that such a function f must have degree at least 2. Indeed, if f was affine and its range contained all vectors of sparsity at most 1, then its range must have dimension n, and the number of inputs of f would be $k \geq n$.

Next, in Theorem 9, we apply this lemma, together with the reduction from degree-2-Avoid to NC^0_3-Avoid from Lemma 6, to conclude that an efficient algorithm for NC^0_3-Avoid would provide an explicit construction of rigid matrices.

▶ **Lemma 8.** *For every $d \geq 1$ and every polynomial-time computable $s := s(n) < \frac{n^{1-1/d}}{d}$, there exists a polynomial-time computable function $f\colon \mathbb{F}_2^{dsn^{1/d}} \to \mathbb{F}_2^n$ whose range contains all vectors of sparsity at most s, and each output of f is a degree-d polynomial.*

Proof. Let G be an arbitrary d-uniform hypergraph on $\ell = dn^{1/d}$ vertices and n hyperedges (such a graph exists because $\binom{\ell}{d} \geq (\ell/d)^d = n$). Fix an ordering $\{1,\dots,\ell\}$ of the vertices and $\{1,\dots,n\}$ of the edges. Each vertex of G will be labeled by a vector from $\mathbb{F}_2^s$. Our function $f\colon \mathbb{F}_2^{s\ell} \to \mathbb{F}_2^n$ will take as input the labels of the vertices of G and output n elements corresponding to the n hyperedges of G: the ith output is the generalized inner product of the labels of the d vertices in the ith hyperedge. We interpret the input as a matrix $X \in \mathbb{F}_2^{s\times\ell}$, where the jth column $X_j \in \mathbb{F}_2^s$ is the label corresponding to the jth vertex. Suppose the hyperedge i contains the vertices $\{j_1,\dots,j_d\}$ then the ith output is $f_i(X) = \sum_{k=1}^{s} X_{k,j_1}\cdots X_{k,j_d}$. Clearly, f is a degree-d function, it only remains to show that its output contains all vectors of sparsity $\leq s$. For this, we show that for every vector $y \in \mathbb{F}_2^n$ of sparsity $\leq s$, there is an input, i.e., a labeling of the vertices of G, such that f outputs y. Let the s non-zero elements of y correspond to the distinct edges $i_1,\dots,i_s$ in G. For each vertex j in G we set its label $X_j \in \mathbb{F}_2^s$ to be such that $(X_j)_k = 1$ if $j \in i_k$ and $(X_j)_k = 0$ otherwise.

Consider any edge $i = \{j_1,\dots,j_d\}$ and the submatrix $X_{j_1,\dots,j_d}$ of X containing the labels of these vertices connected by i.

- If $i = i_k$ for some $k \in [s]$, then $y_i = 1$. The i_kth row of $X_{j_1,\dots,j_d}$ contains all 1 entries. Furthermore, every other row contains at least one zero. Therefore, $f_i(X) = 1$.
- If $i \neq i_k$ for all $k \in [s]$, then $y_i = 0$ and each row of $X_{j_1,\dots,j_d}$ contains at least one zero. Therefore, $f_i(X) = 0$. ◀

Equipped with Lemma 8, we are ready to show that an efficient algorithm for degree-2-Avoid or NC^0_3-Avoid would imply an explicit construction of rigid matrices.

▶ **Theorem 9.** *For every constant $1/2 \leq \delta \leq 1$, an FP (resp. $\mathsf{FP}^{\mathsf{NP}}$) algorithm for degree-2-Avoid with stretch $m = 2n^{2/(1+\delta)}$ will provide an FP (resp. $\mathsf{FP}^{\mathsf{NP}}$) algorithm for finding an $(n^\delta/10, n^{\delta-1/2}/10)$-rigid matrix.*

Furthermore, for every $1/2 \leq \delta \leq 1$, an FP (resp. $\mathsf{FP}^{\mathsf{NP}}$) algorithm for NC^0_3-Avoid with stretch $m = n + O(n^{2/(2+\delta)})$ will provide an FP (resp. $\mathsf{FP}^{\mathsf{NP}}$) algorithm for finding an $(n^\delta/10, n^{\delta-1/2}/10)$-rigid matrix.

Proof. Let $r = n^\delta/10$ and $s = n^{\delta-1/2}/10$. First, we reduce (in deterministic polynomial time) the problem of finding an (r,s)-rigid matrix to solving degree-2-Avoid for a function $g\colon \mathbb{F}_2^{4rn} \to \mathbb{F}_2^{n^2}$.

Suppose $M \in \mathbb{F}_2^{n\times n}$ is not (r,s)-rigid. Then, M can be written as a sum $M = Q + S$, where $\operatorname{rank}(Q) \leq r$ and S is s-row sparse. Furthermore, $Q = L \cdot R$ for some matrices $L, R^T \in \mathbb{F}_2^{n\times r}$.

We view the input of g as $2rn$ entries of the matrices L and R, and $2sn^{3/2}$ inputs of n copies of the degree-2 function f from Lemma 8 needed to encode the entries of n sparse rows of S. Then the function g simply outputs all n^2 entries of $M = L \cdot R + S$. Note that each output of g computes a dot-product of a row of L and a column of R, and adds a degree-2 output of f. Therefore, we constructed a degree-2 function g whose range contains all non-rigid matrices. A solution to degree-2-Avoid on input g would therefore give an (r,s)-rigid matrix. The number of inputs of g is $n' = 2rn + 2sn^{3/2} = 4rn = 2n^{1+\delta}/5$, and the stretch of the function g is at least $m'(n') \geq 2(n')^{2/(1+\delta)}$. This concludes the proof of the first part of the theorem.

For the second part, we use the polynomial-time reduction from degree-2-Avoid to NC_3^0-Avoid from Lemma 6. By the construction above, we have a degree-2 function $g\colon \mathbb{F}_2^{4rn} \to \mathbb{F}_2^{n^2}$ where each output bit is the sum of at most $t = r + s \leq 2r$ degree-2 monomials. We apply Lemma 6 to reduce Avoid for g to Avoid for an NC_3^0 function $\widehat{g}\colon \{0,1\}^{\widehat{n}} \to \{0,1\}^{\widehat{m}}$, where $\widehat{n} = n' + (2t-1)n^2$ and $\widehat{m} = 2tn^2$. This yields a stretch of $\widehat{m}(\widehat{n}) = \widehat{n} + O(\widehat{n}^{2/(2+\delta)})$ for the function $\widehat{g}$. Therefore, an algorithm for NC_3^0-Avoid for stretch $\widehat{m}(n)$ yields an (r,s)-rigid matrix. ◀

We remark that in the regime $\delta > 1/2$, Theorem 9 would give matrices that for rank n^δ have higher rigidity than all known constructions of rigid matrices in $\mathsf{FP}, \mathsf{FP}^{\mathsf{NP}}$ and $\mathsf{FE}^{\mathsf{NP}}$. Therefore, for every $\varepsilon > 0$, an $\mathsf{FP}^{\mathsf{NP}}$ algorithm for degree-2-Avoid with stretch $n^{12/11-\varepsilon}$ or an $\mathsf{FP}^{\mathsf{NP}}$ algorithm for NC_3^0-Avoid with stretch $n + n^{12/17+\varepsilon}$ would lead to new rigidity lower bounds. Since the regime of $\delta = 1$ in Theorem 9 is sufficient for Valiant's program of proving super-linear lower bounds on the size of linear NC^1 circuits (see Theorem 3), we have the following corollary.

▶ **Corollary 10.** *An* FP *(resp.* $\mathsf{FP}^{\mathsf{NP}}$*) algorithm for degree-2-Avoid with stretch $m = 2n$ or for* NC_3^0*-Avoid with stretch $m = n + O(n^{2/3})$ will provide a linear function in* FP *(resp.* $\mathsf{FP}^{\mathsf{NP}}$*) that cannot be computed by linear* NC^1 *circuits of size $o(n \log\log(n))$.*

4 Algorithms for NC_k^0-Avoid

In this section, we describe polynomial-time algorithms for solving NC_k^0-Avoid with non-trivial stretch. More specifically, we provide an algorithm that runs in time $2^{O(n^{k-1}/m)}\cdot\operatorname{poly}(n)$ when the stretch of the input circuit is at least $m \geq \Omega(n^{k-2})$. First, we describe a useful structural property of NC_k^0 circuits, which follows from the following simple graph-theoretic result.

▶ **Lemma 11.** *For any constants $c \geq 1$ and $k \geq 3$, every k-uniform hypergraph $G = (V,E)$ with n vertices and $m \geq cn^{k-2}$ hyperedges contains a subset of vertices $V' \subseteq V, |V'| \leq cn^{k-1}/m$ and a subset of hyperedges $E' \subseteq E, |E'| \geq cn$ such that each hyperedge in E' contains at least $k-2$ vertices from V'. Furthermore, there is a polynomial-time algorithm that finds such a V' and E'.*

Proof. Consider the following bipartite graph H with vertex set $A \sqcup B$ where $A = \{u_S \mid S \subseteq V, |S| = k-2\}$ is the set of vertices indexed by the $k-2$ sized subsets of V and $B = \{v_e \mid e \in E\}$ is indexed by the edges of G. Furthermore there is an edge (u_S, v_e) in H if $S \subseteq e$, i.e., if all the vertices in S are contained in the hyperedge $e \in E$. Since each hyperedge

e contains k vertices, the degree of each vertex in B is exactly $\binom{k}{k-2}$. Then, the average degree of the vertices in A is $\frac{|B|\binom{k}{k-2}}{|A|} = \frac{m\binom{k}{k-2}}{\binom{n}{k-2}}$. Let $A' \subseteq A$ be the subset of t vertices with highest degree in A and let $N(A')$ be their neighbors in B. Then total degree of vertices in A' is at least $\frac{tm\binom{k}{k-2}}{\binom{n}{k-2}}$. Since each vertex in B has degree $\binom{k}{k-2}$, $|N(A')| \geq \frac{tm\binom{k}{k-2}}{\binom{n}{k-2}\binom{k}{k-2}} = \frac{tm}{\binom{n}{k-2}}$. Therefore, setting $t = \frac{cn\binom{n}{k-2}}{m}$, V' to be the set of $t(k-2) = \frac{cn(k-2)\binom{n}{k-2}}{m} \leq cn^{k-1}/m$ vertices of G contained in the union of the vertex subsets in A', and $E' = N(A')$ completes our proof.

To find V' and E', we first construct the graph H which has polynomial size, and then find the vertices in A' by finding the t vertices in A with maximum degree. It is now straightforward to construct V' from A' and to find $E' = N(A')$. ◀

▶ **Corollary 12.** *For any constants $c \geq 1$ and $k \geq 3$, given an NC^0_k circuit C with n inputs and $m \geq cn^{k-2}$ outputs, there exists a subset of outputs O of size $|O| \geq cn$, and a subset of inputs I of size $|I| \leq cn^{k-1}/m$, such that for every output bit $\mathsf{C}_i \in O$, at least $k-2$ of the input bits feeding into C_i are from I. Furthermore, there is a polynomial-time algorithm that finds such sets I and O.*

Proof. Without loss of generality we assume that each output of C reads exactly k inputs (as if it reads $\ell < k$ inputs, we let it additionally read arbitrary $k - \ell$ inputs and ignore them). Consider the hypergraph where each vertex corresponds to one of the n inputs $\{x_1, \ldots, x_n\}$ of C. Each edge of the hypergraph corresponds to an output C_i, $e_i = \{j \mid \mathsf{C}_i \text{ reads } x_j\}$. Now, we apply Lemma 11 on this hypergraph and set $I = V'$ and $O = E'$. Note that $|I| = |V'| \leq cn^{k-1}/m$ and $|O| = |E'| \geq cn$. ◀

This corollary finds a linear number of output bits O of the circuit that mostly depend on a small number of common input bits I. Our algorithm for NC^0_k-Avoid will "branch" on all possible assignments to the inputs from I. Each such assignment will correspond to an affine subspace $\mathcal{S} \subseteq \mathbb{F}_2^n$ of the input space. Then, our algorithm works by fixing the output bits from O such that the sum of the dimensions of these affine subspaces is significantly reduced at each step, eventually making all subspaces empty. Note that by the guarantee of Corollary 12, after fixing the inputs I, each output from O depends on at most two inputs. Thus, we need an efficient way to reduce the dimension of the affine subspace containing the consistent inputs for the case where output functions depend on at most two inputs. In Lemma 13, we provide such a subroutine AffineReduce (Algorithm 1).

▶ **Lemma 13.** *Let $\mathcal{S} \subseteq \mathbb{F}_2^n$ be an affine subspace, and $f \colon \mathbb{F}_2^n \to \mathbb{F}_2$ be a function that depends on at most two inputs. The algorithm AffineReduce in deterministic polynomial time finds two affine subspaces (or empty sets) $\mathcal{S}_0, \mathcal{S}_1 \subseteq \mathcal{S}$ such that*

(1) *$\forall x \in \mathcal{S}, b \in \mathbb{F}_2$, if $f(x) = b$, then $x \in \mathcal{S}_b$;*

(2) *$|\mathcal{S}_0| + |\mathcal{S}_1| \leq 3|\mathcal{S}|/2$.*

Proof. Without loss of generality we assume that $f(x)$ depends on (a subset of) x_1 and x_2. We will consider three cases depending on the degree of f, and in each case we will find affine subspaces (or empty sets) $\mathcal{S}_0, \mathcal{S}_1 \subseteq \mathcal{S}$ such that at least one of them has dimension strictly smaller than the dimension of $\mathcal{S}$ (or at least one of them is an empty set). This will ensure that $|\mathcal{S}_0| + |\mathcal{S}_1| \leq 3|\mathcal{S}|/2$.

- If $f(x) = c$ for some $c \in \mathbb{F}_2$ is a constant function, then we set $\mathcal{S}_c = \mathcal{S}$ and $\mathcal{S}_{1-c} = \emptyset$. Clearly, $\mathcal{S}_c = \mathcal{S}$ and $\mathcal{S}_{1-c}$ contain all points $x \in \mathcal{S}$ that are consistent with $f(x) = c$ and $f(x) = 1 - c$, respectively.

- If $f(x) = a_1x_1 + a_2x_2 + c$ for some constants $a_1, a_2, c \in \mathbb{F}_2$ is an affine function, then for each $b \in \mathbb{F}_2$ let H_b be the hyperplane defined by $a_1x_1 + a_2x_2 + c = b$, and let $\mathcal{S}_b = \mathcal{S} \cap H_b$. Again, $\mathcal{S} \cap H_b$ contains all the inputs in $\mathcal{S}$ that are consistent with $f(x) = b$. Furthermore, if $\dim(\mathcal{S}_0) = \dim(\mathcal{S})$, then $\mathcal{S} \subseteq H_0$ and $\mathcal{S}_1 = \mathcal{S} \cap H_1 = \emptyset$. Therefore, either $\dim(\mathcal{S}_0) < \dim(\mathcal{S})$ or $\mathcal{S}_1 = \emptyset$.
- If $f(x) = (x_1 + a_1)(x_2 + a_2) + c$ for some constants $a_1, a_2, c \in \mathbb{F}_2$ is a quadratic function, then let $\mathcal{H}$ be the affine subspace defined by $\mathcal{H} = \{x \in \mathbb{F}_2^n \mid x_1 = 1 + a_1, x_2 = 1 + a_2\}$. Consider the affine subspace $\mathcal{S}_{1-c} = \mathcal{S} \cap \mathcal{H}$ which contains all points $x \in \mathcal{S}$ satisfying $f(x) = 1 - c$.
  - If $\dim(\mathcal{S}_{1-c}) < \dim(\mathcal{S})$, then we are done as we can take $\mathcal{S}_c = S$
  - If $\dim(\mathcal{S}_{1-c}) = \dim(\mathcal{S})$, then $\mathcal{S} \subseteq \mathcal{H}$. Then, every point in $\mathcal{S}$ satisfies $f(x) = 1 - c$, thus, setting $\mathcal{S}_{1-c} = \mathcal{S}$ and $\mathcal{S}_c = \emptyset$ completes our construction.

In each case, either $|\mathcal{S}_0| \leq \frac{|\mathcal{S}|}{2}$ or $|\mathcal{S}_1| \leq \frac{|\mathcal{S}|}{2}$. Therefore, $|\mathcal{S}_0| + |\mathcal{S}_1| \leq 3|\mathcal{S}|/2$.

The only computation made by AffineReduce is to compute the dimensions of explicitly given affine subspaces, which can be performed in polynomial time. ◀

Algorithm 1 AffineReduce($\mathcal{S}, f$).

```
Input: Affine subspace $\mathcal{S} \subseteq \mathbb{F}_2^n$, $f\colon \mathbb{F}_2^n \to \mathbb{F}_2$ that may depend only on $x_1$ and $x_2$
Output: $\mathcal{S}_0, \mathcal{S}_1 \subseteq \mathcal{S}$
  if $f(x) = c$ then
      return $\mathcal{S}_c = \mathcal{S}$ and $\mathcal{S}_{1-c} = \emptyset$
  if $f(x) = a_1x_1 + a_2x_2 + c$ then
      For $b \in \mathbb{F}_2$, let $H_b = \{x \in \mathbb{F}_2^n\colon a_1x_1 + a_2x_2 + c = b\}$
      return $\mathcal{S}_0 = \mathcal{S} \cap H_0$ and $\mathcal{S}_1 = \mathcal{S} \cap H_1$
  if $f(x) = (x_1 + a_1)(x_2 + a_2) + c$ then
      Let $\mathcal{H} = \{x \in \mathbb{F}_2^n\colon x_1 = 1 + a_1, x_2 = 1 + a_2\}$
      Let $\mathcal{S}_{1-c} = \mathcal{S} \cap \mathcal{H}$
      if $\dim(\mathcal{S}_{1-c}) < \dim(\mathcal{S})$ then
          return $\mathcal{S}_{1-c}$ and $\mathcal{S}_c = \mathcal{S}$
      else
          return $\mathcal{S}_{1-c}$ and $\mathcal{S}_c = \emptyset$
```

A simple application of AffineReduce recovers a polynomial-time algorithm for NC_2^0-Avoid from [9].

▶ **Corollary 14.** *There is a deterministic polynomial-time algorithm that, given an* NC_2^0 *circuit* $\mathsf{C}\colon \{0,1\}^n \to \{0,1\}^m$, $m \geq n+1$, *finds an element* $y \in \{0,1\}^m, y \notin \mathrm{Range}(\mathsf{C})$.

Proof. At iteration $1 \leq i \leq n+1$, our algorithm will fix the value of the ith output bit y_i. The algorithm also maintains an affine subspace $\mathcal{S} \subseteq \mathbb{F}_2^n$ that contains all inputs $x \in \mathbb{F}_2^n$ consistent with the partial output assignments of $y_1, \ldots, y_i$. By Lemma 13, there exists an assignment $y_i = b$, such that either none of the inputs in $\mathcal{S}_b$ are consistent with y or the dimension of $\mathcal{S} = \mathcal{S}_b$ reduces at least by one. In the former case, we already find our desired output y (we can just set the unassigned bits of y to arbitrary values). Otherwise, after fixing the first n outputs, we have $\dim(\mathcal{S}) = 0$, i.e., $S = \{x\}$ for some $x \in \mathbb{F}_2^n$. Let $b \in \{0,1\}$ be the value of the $(n+1)$th output bit of $\mathsf{C}(x)$. Then setting $y_{n+1} = 1 - b$ produces our desired output y. This algorithm runs in polynomial time since it makes at most n calls to AffineReduce and one call to $\mathsf{C}(x)$. ◀

Finally, equipped with Lemma 13, we are ready to present our main algorithm for NC^0_k-Avoid.

▶ **Theorem 4.** *Given an NC^0_k circuit $\mathsf{C}\colon \{0,1\}^n \to \{0,1\}^m$, where $m \geq 3n^{k-2}$, the algorithm* SubspaceUnion *finds an element $y \in \{0,1\}^m, y \notin \text{Range}(\mathsf{C})$ in deterministic time $2^{O(n^{k-1}/m)} \cdot \text{poly}(n)$.*

Proof. First we apply Corollary 12 with $c = 3$ to the circuit C, and select in polynomial time a subset of inputs $I = \{x_1, \dots, x_t\}$ and a set of outputs $O = \{y_1, y_2, ..., y_{3n}\}$ for $t \leq 3n^{k-1}/m$. This ensures that each y_i has at most two inputs outside of I. For each of the 2^t assignments of the inputs from I, we consider a circuit where the values of these t inputs are fixed. Namely, for $j \in \{0, \dots, 2^t - 1\}$, we fix the inputs in I to the bits in the binary representation of j. Then we restrict the circuit C to the outputs $y_1, \dots, y_{3n}$ and all the inputs that feed them, and obtain a circuit C_j, where each output depends on at most 2 inputs. We'll find a value $y \in \{0,1\}^{3n}$ that no C_j outputs, and this will give us a solution to the original NC^0_k-Avoid instance.

Our algorithm will maintain the following invariant. At the ith iteration of the algorithm after we fix the values of the outputs $y_1, \dots, y_i$, we maintain $\mathcal{U} = \bigcup_{j=0}^{2^t-1} \mathcal{U}_j$, a disjoint union of 2^t affine subspaces, such that all inputs $x \in \mathbb{F}_2^n$ that are consistent with $y_1, \dots, y_i$ belong to $\mathcal{U}$ (and $\mathcal{U}$ may contain points that are inconsistent with $y_1, \dots, y_i$, too).

In the beginning of the algorithm, for every $0 \leq j < 2^t$, we let $\mathcal{U}_j$ be the affine subspace where the inputs in I are fixed to the bits in the binary representation of j. Then $\mathcal{U} = \bigcup_j \mathcal{U}_j = \mathbb{F}_2^n$ is the set of all inputs consistent with our initial empty partial assignment.

At every step i, we will show how to find a constant $b \in \{0,1\}$ such that after fixing $y_i = b$, the size of our disjoint union $|\mathcal{U}|$ reduces by a factor of $4/3$. Therefore, after repeating this procedure for the $3n$ outputs from O, we will have an empty $\mathcal{U}$, and the constructed partial assignment will give us a solution to the NC^0_k-Avoid problem.

At the ith iteration of the algorithm, we have values of outputs $y_1, \dots y_{i-1}$ fixed, and are to fix the value of y_i. We have two choices: either set $y_i = 0$ or set $y_i = 1$. By Lemma 13, we have two affine subspaces (or empty sets) $\mathcal{U}_{j,0}, \mathcal{U}_{j,1} \subseteq \mathcal{U}_j$ containing all inputs $x \in \mathcal{U}_j$ mapping to $y_i = 0$ and $y_i = 1$, respectively. Moreover, Lemma 13 guarantees that $|\mathcal{U}_{j,0}| + |\mathcal{U}_{j,1}| \leq 3|\mathcal{U}_j|/2$. Summing over all $0 \leq j < 2^t$, we get

$$\sum_j |\mathcal{U}_{j,0}| + \sum_j |\mathcal{U}_{j,1}| \leq \sum_j 3|\mathcal{U}_j|/2 = 3|\mathcal{U}|/2\,.$$

Let $b \in \{0,1\}$ be the value minimizing $\sum_j |\mathcal{U}_{j,b}|$. In particular, we have that $\sum_j |\mathcal{U}_{j,b}| \leq 3|\mathcal{U}|/4$. Therefore, setting $y_i = b$ reduces the size of $\mathcal{U}$ at least by a factor of $4/3$. Repeating this procedure $\log_{4/3}(2^n) + 1 \leq 3n$ times will result in a partial assignment to the output bits O with no inputs that map to it.

The algorithm SubspaceUnion maintains 2^t affine subspaces of $\mathbb{F}_2^n$, computes their dimensions and calls the deterministic polynomial-time AffineReduce procedure polynomial number of times. Therefore, this algorithm runs in time $2^t \cdot \text{poly}(n) = 2^{O(n^{k-1}/m)} \cdot \text{poly}(n)$. ◀

We conclude this section with a corollary stating that SubspaceUnion solves NC^0_k-Avoid efficiently for certain non-trivial values of stretch m.

▶ **Corollary 15.** *For any constants $k \geq 3$ and $\varepsilon > 0$, the algorithm* SubspaceUnion *solves NC^0_k-Avoid on n inputs and m outputs in deterministic polynomial and deterministic sub-exponential $2^{O(n^{1-\varepsilon})}$ time for $m \geq n^{k-1}/\log(n)$ and $m \geq n^{k-2+\varepsilon}$, respectively.*

Algorithm 2 SubspaceUnion(C).

```
Input: NC$_k^0$ circuit $\mathsf{C} : \{0,1\}^n \to \{0,1\}^m$, where $m \geq 3n^{k-2}$
Output: $y \in \{0,1\}^m$, $y \notin \mathrm{Range}(\mathsf{C})$
  Find $x_1, \dots, x_t$ and $y_1, \dots, y_{3n}$ via Corollary 12 for $t \leq 3n^{k-1}/m$
  For $0 \leq j < 2^t$, set $\mathcal{U}_j = \{x \in \{0,1\}^n : \sum_{i=1}^t x_i 2^{i-1} = j\}$
  for i=1 to 3n do
      Find function $f$ at $y_i$
      For $0 \leq j < 2^t$, set $\mathcal{U}_{j,0}$,$\mathcal{U}_{j,1} \leftarrow$ AffineReduce($\mathcal{U}_j, f$)
      Find $b \in \{0,1\}$ minimizing $\sum_j |\mathcal{U}_{j,b}|$
      Set $y_i = b$
      For $0 \leq j < 2^t$, set $\mathcal{U}_j = \mathcal{U}_{j,b}$
  Set all remaining $y_k = 0$
  return $y$
```

A An Alternative Algorithm for NC^0_3-Avoid

▶ **Theorem 16.** *Given an NC^0_3 circuit $\mathsf{C} : \{0,1\}^n \to \{0,1\}^m$, where $m \geq \frac{1}{3}\binom{n}{2} + 2n$, the algorithm* OneSubspace *finds an element $y \in \{0,1\}^m, y \notin \mathrm{Range}(\mathsf{C})$ in deterministic polynomial time.*

Proof. The algorithm maintains an affine subspace $\mathcal{S} \subseteq \mathbb{F}_2^n$ over the inputs, and a partial output assignment $y \in \{0,1,*\}^m$ such that $\mathcal{S}$ contains all inputs $x \in \mathbb{F}_2^n$ consistent with y. Initially, $y = (*,\ldots,*)$ and $\mathcal{S} = \mathbb{F}_2^n$. At each iteration, OneSubspace assigns at most two outputs and reduces the dimension of $\mathcal{S}$ by at least 1. After n steps, $\mathcal{S}$ must have dimension 0. Then the algorithm assigns one more output bit, and terminates with an element $y \notin \mathrm{Range}(\mathsf{C})$.

Now, we only need to argue that the algorithm can reduce the dimension of $\mathcal{S}$ in each iteration and that we can perform each step in polynomial time.

First, if there is an output y_1 that depends on at most 2 inputs x_1, x_2, let f be the function computed at that output: $y_1 = f(x_1, x_2)$. By Lemma 13, AffineReduce$(\mathcal{S}, f)$ outputs an affine subspace $\mathcal{S}_b$ of lower dimension $\dim(\mathcal{S}_b) < \dim(\mathcal{S})$, containing all inputs consistent with $y_1 = b$. Thus, in the following we assume that each output depends on exactly 3 inputs.

Since we fix at most 2 bits of the output at each iteration, the number of unassigned outputs m is always greater than $\frac{1}{3}\binom{n}{2}$. Then, there exists a pair of outputs y_1, y_2 that both depend on the same pair of inputs x_2, x_3. Since each output depends on three pairs of inputs, and the number of such pairs is $\binom{n}{2} < 3m$, there must be a pair of inputs that feeds into two outputs. Let x_1, x_4 be the remaining inputs that feed into the outputs y_1, y_2, respectively: $y_1 = f_1(x_1, x_2, x_3), y_2 = f_2(x_2, x_3, x_4)$.

There exist 4 possible values of (y_1, y_2) and at most 16 possible values of the input bits (x_1, x_2, x_3, x_4) appearing in $\mathcal{S}$. Then, there exists a pair of constants $(b_1, b_2) \in \{0,1\}^2$ such that at most 4 different assignments $A \subseteq \{0,1\}^4$ to (x_1, x_2, x_3, x_4) are consistent with the partial assignment $(y_1, y_2) = (b_1, b_2)$. Since $|A| \leq 4$, there is a 3-dimensional affine subspace in $\mathbb{F}_2^4$ that contains all points from A. Therefore, there is a hyperplane $\mathcal{H} \subseteq \mathbb{F}_2^4$ defining this 3-dimensional affine subspace. Extending $\mathcal{H}$ to all n inputs, gives us an affine subspace $\mathcal{H}' = \{x \in \mathbb{F}_2^n : (x_1, x_2, x_3, x_4) \in \mathcal{H}\} \subseteq \mathbb{F}_2^n$ that contains all inputs in $\mathbb{F}_2^n$ consistent with the partial assignment $(y_1, y_2) = (b_1, b_2)$.

If $\mathcal{S} \not\subseteq \mathcal{H}'$, then setting $(y_1, y_2) = (b_1, b_2), \mathcal{S} = \mathcal{S} \cap \mathcal{H}'$ reduces the dimension of the affine subspace $\mathcal{S}$. In the following we assume that $\mathcal{S} \subseteq \mathcal{H}'$.

- Suppose there exists $(c_1, c_2) \in \{0,1\}^2$ such that for all points (x_1, x_2, x_3, x_4) in $\mathcal{H}'$, $(f_1(x_1, x_2, x_3), f_2(x_2, x_3, x_4)) \neq (c_1, c_2)$. Then we can set $(y_1, y_2) = (c_1, c_2)$ and $\mathcal{S} = \emptyset$ as no points in $\mathcal{S} \subseteq \mathcal{H}'$ can output (c_1, c_2). In this case we found a $y \notin \mathrm{Range}(\mathsf{C})$.
- If there are no such assignments, then since $|\mathcal{H}| = 8$, there must exist an assignment $(c_1, c_2) \in \{0,1\}^2$ such that at most two points from $\mathcal{H}$ are consistent with $(y_1, y_2) = (c_1, c_2)$. These (at most) two points form a 0- or 1-dimensional affine subspace $\mathcal{U} \subseteq \mathbb{F}_2^4$, which we extend to all n inputs $\mathcal{U}' = \{x \in \mathbb{F}_2^n : (x_1, x_2, x_3, x_4) \in \mathcal{U}\} \subseteq \mathbb{F}_2^n$.

- If $\mathcal{S} \not\subseteq \mathcal{U}'$, we can set $(y_1, y_2) = (c_1, c_2)$ and $\mathcal{S} = \mathcal{S} \cap \mathcal{U}'$, reducing the dimension of $\mathcal{S}$.
- Otherwise, all inputs in $\mathcal{S} \subseteq \mathcal{U}'$ have $(y_1, y_2) = (c_1, c_2)$, and we can set $(y_1, y_2) = (1 - c_1, c_2)$ to obtain $\mathcal{S} = \emptyset$.

This algorithm performs n iterations, each of which computes dimensions of a constant number of explicitly given affine subspaces in polynomial time. ◀

Abstract

We investigate algorithms for testing whether an image is connected. Given a proximity parameter $\epsilon \in (0,1)$ and query access to a black-and-white image represented by an $n \times n$ matrix of Boolean pixel values, a (1-sided error) connectedness tester accepts if the image is connected and rejects with probability at least 2/3 if the image is ϵ-far from connected. We show that connectedness can be tested nonadaptively with $O(\frac{1}{\epsilon^2})$ queries and adaptively with $O(\frac{1}{\epsilon^{3/2}}\sqrt{\log\frac{1}{\epsilon}})$ queries. The best connectedness tester to date, by Berman, Raskhodnikova, and Yaroslavtsev (STOC 2014) had query complexity $O(\frac{1}{\epsilon^2}\log\frac{1}{\epsilon})$ and was adaptive. We also prove that every nonadaptive, 1-sided error tester for connectedness must make $\Omega(\frac{1}{\epsilon}\log\frac{1}{\epsilon})$ queries.

1 Introduction

Connectedness is one of the most fundamental properties of images [16]. In the context of property testing, it was first studied two decades ago [18], but the query complexity of this property is still unresolved. We improve the algorithms for testing this property and also give the first lower bound on the query complexity of this task.

We focus on black-and-white images. For simplicity, we only consider square images, but everything in this paper can be easily generalized to rectangular images. We represent an image by an $n \times n$ binary matrix M of pixel values, where 0 denotes white and 1 denotes black. To define *connectedness*, we consider *the image graph* G_M of an image M. The vertices of G_M are $\{(i,j) \mid M[i,j] = 1\}$, and two vertices (i,j) and (i',j') are connected by an edge if $|i-i'| + |j-j'| = 1$. In other words, the image graph consists of black pixels connected by the grid lines. The image is *connected* if its image graph is connected.

We study connectedness in the property testing model [20, 11], first considered in the context of images in [18]. A (1-sided error) property tester for connectedness gets query access to the input matrix M. Given a proximity parameter $\epsilon \in (0,1)$, the tester has to accept if M is connected and reject with probability at least 2/3 if M is ϵ-far from connected. An image is ϵ-far from connected if at least an ϵ fraction of pixels have to be changed to make it connected. The tester is *nonadaptive* if it makes all its queries before receiving any answers; otherwise, it is *adaptive*.

In [18], it was shown that connectedness can be tested adaptively with $O(\frac{1}{\epsilon^2}\log^2\frac{1}{\epsilon})$ queries. The adaptive complexity of testing connectedness was later improved to $O(\frac{1}{\epsilon^2}\log\frac{1}{\epsilon})$ in [8].

1.1 Our Results

1.1.1 Connectedness Testers

We give two new algorithms for testing connectedness of images: one adaptive, one nonadaptive. Both improve on the best connectedness tester to date in terms of query complexity. Previously, no nonadaptive testers for connectedness were proposed.

▶ **Theorem 1.1.** *Given a proximity parameter $\epsilon \in (0,1)$, connectedness of $n \times n$ images, where $n > \epsilon^{-2} \cdot 256$, can be ϵ-tested adaptively and with 1-sided error with query and time complexity $O(\frac{1}{\epsilon^{3/2}}\sqrt{\log\frac{1}{\epsilon}})$.*

It can be tested nonadaptively and with 1-sided error with query and time complexity $O(\frac{1}{\epsilon^2})$.

Previous algorithms for testing connectedness of images are modeled on the connectedness tester for bounded-degree graphs by Goldreich and Ron [12]: they pick a uniformly random pixel and adaptively try to find a small connected component by querying its neighbors. As discussed in [18], even though connectedness of an image is defined in terms of the connectedness of the corresponding (degree-4) image graph, these two properties are different because of how the distance is defined. In the bounded-degree graph model, the (absolute) distance between graphs is the number of edges that need to be changed to transform one graph into the other. In contrast, the (absolute) distance between two image graphs is the number of pixels (vertices) on which they differ; in other words, the edge structure of the image graph is fixed, and only vertices can be added or removed to transform one graph into another. However, previous connectedness testers in the image model did not take advantage of the differences.

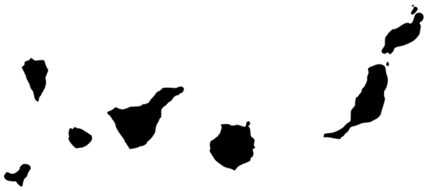

Figure 1 An image M.

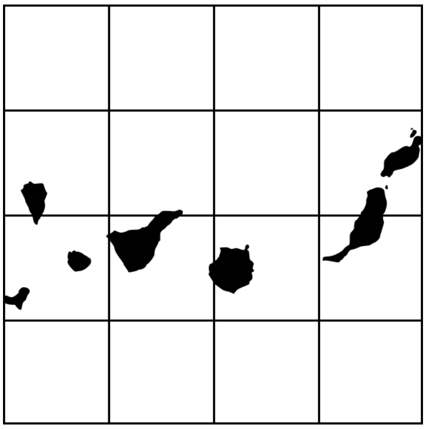

Figure 2 The same image with a grid.

As our starting point, we use an idea from [7] that gave an algorithm for approximating the (relative) distance to the nearest connected image with additive error ϵ with query $O(\frac{1}{\epsilon^4})$ and running time $\exp\left(O\left(\frac{1}{\epsilon}\right)\right)$. They observed that one can modify an image in a small number of pixels by drawing a grid on the image (as shown in Figures 1 and 2). In the resulting image, the distance to connectedness is determined by the properties of individual squares into which the grid lines partition the image.

Our algorithms consider different partitions of the grid (a logarithmic number of partitions in $\frac{1}{\epsilon}$). For each partition, they sample random squares and try to check whether the squares satisfy the following property called *border-connectedness.*

▶ **Definition 1.2** (Border connectedness)**.** *A (sub)image s is* border-connected *if for every black pixel (i, j) of s, the image graph G_s contains a path from (i, j) to a pixel on the border of s. The property* border connectedness, *denoted C', is the set of all border-connected images.*

Our nonadaptive algorithm reads all pixels in each sampled square. Our adaptive algorithm further partitions each square into diamonds, as shown in Figure 4. It queries all pixels on the diamond lattice and then adaptively tries to catch a witness (that is, a small connected component) in one of the diamonds, using the lattice structure. (We could have partitioned into squares again, but partitioning into diamonds makes the proof cleaner and saves a constant factor in the analysis.)

1.1.2 The Lower Bound

We also prove the first nontrivial lower bound for testing connectedness of images. Note that all nontrivial properties have query complexity $\Omega(1/\epsilon)$, even for adaptive testers. In particular, for connectedness, this is the number of queries needed to distinguish between the white image and an image, where we color black a random subset of size ϵn^2 of the set of pixels with both coordinates divisible by 3. By standard arguments, it implies a lower bound of $\Omega(1/\epsilon)$. Some properties of images, such is being a halfplane, can be tested nonadaptively (with 1-sided error) with $O(1/\epsilon)$ queries [5]. We show that it is impossible for connectedness.

▶ **Theorem 1.3.** *Every nonadaptive (1-sided error) ϵ-tester for connectedness of images must query $\Omega(\frac{1}{\epsilon}\log\frac{1}{\epsilon})$ pixels (for some family of images).*

Every 1-sided error tester must catch a witness of disconnectedness in order to reject. This witness could include a connected component completely surrounded by white pixels. The difficulty for proving hardness is that, unlike in the case of finding a witness for disconnectedness of graphs, the algorithm does not have to read the whole connected component. Instead, it is sufficient to find a closed white loop with a black pixel inside it (and another black pixel outside it). As we discussed, it is sufficient for an algorithm to look for witnesses inside relatively small squares (specifically, squares with side length $O(1/\epsilon)$), since adding a grid around such squares, as shown in Figure 2, would change $O(\epsilon n^2)$ pixels. But no matter how you had a witness inside such a square, it can be easily captured with $O(1/\epsilon)$ queries if the border of the square is white.

To overcome this difficulty, we consider a checkerboard-like pattern with white squares replaced by many parallel lines, called *bridges*, with one white (disconnecting) pixel positioned randomly on each bridge. See Figure 5. To catch a white border around a connected component, a tester has to query all disconnecting pixels of at least one square. To make this difficult, we hide the checkerboard pattern inside a randomly positioned *interesting window.* The sizes of interesting windows and their positions are selected so that the tester cannot effectively reuse queries needed to succeed in catching the disconnecting pixels in each interesting window.

1.2 Other Related Work

In addition to [12], connectedness testing and approximating the number of connected components in graphs in sublinear time was explored in [9, 8, 4]. Other property testing tasks studied in the pixel model of images, the model considered in this paper, include testing whether an image is a half-plane [18], convexity [18, 6, 5], and image partitioning properties [13]. Early implementations and applications to vision were provided in [13, 14, 15, 17]. Finally, general classes of matrix properties were investigated, including matrix-poset properties [10], *earthmover resilient* properties [2], *hereditary* properties [1], and classes of matrices that are free of specified patterns [3].

Testing connectedness has also been studied by Ron and Tsur [19] with a different input representation suitable for testing sparse images.

2 Definitions and Notation

We use $[0..n)$ to denote the set of integers $\{0, 1, \ldots, n-1\}$ and $[n]$ to denote $\{1, 2, \ldots, n\}$.

2.1 Image Representation

We represent an image by an $n \times n$ binary matrix M of pixel values, where 0 denotes white and 1 denotes black. The object is a subset of $[0..n)^2$ corresponding to black pixels; namely, $\{(i,j) \mid M[i,j] = 1\}$. The *border of the image* is the set $\{(i,j) \in [0..n)^2 \mid i \in \{0, n-1\}$ or $j \in \{0, n-1\}\}$.

2.2 Property Testing Definitions

A *property* $\mathcal{P}$ is a set of images. The set of connected images is denoted C. The *absolute distance* from an image M to a property $\mathcal{P}$, denoted $Dist(M, \mathcal{P})$, is the smallest number of pixels in M that need to be modified to get an image in $\mathcal{P}$. The (relative) distance between an $n \times n$ image M and a property $\mathcal{P}$ is $dist(M, \mathcal{P}) = Dist(M, \mathcal{P})/n^2$. We say that M is ϵ-far from $\mathcal{P}$ if $dist(M, \mathcal{P}) \geq \epsilon$; otherwise, M is ϵ-close to $\mathcal{P}$.

3 Adaptive and Nonadaptive Property Testers for Connectedness

In this section, we present our testers for connectedness, proving Theorem 1.1. Both testers use the same top-level procedure, described in Algorithm 1. First, it samples random pixels to ensure that a black pixel is found. It will be used later to certify non-connectedness by producing a black pixel and an isolated black component. Then Algorithm 1 considers a logarithmic number of partitions of the image into subimages of the same size. For each partition, it samples a carefully selected number of these subimages and tests them for border connectedness (see Definition 1.2). This is where the two algorithms diverge. The nonadaptive algorithm tests for border connectedness using the subroutine *Exhaustive-Square-Tester* which queries all pixels in the sampled square and determines exactly if the square is border connected. The adaptive algorithm uses subroutine *Diagonal-Square-Tester* (Algorithm 2). If the top-level procedure finds a subimage that violates border connectedness and a black pixel outside that subimage, it rejects; otherwise, it accepts.

To simplify the analysis of the algorithm, we assume[1] that $n-1$ and $1/\epsilon$ are powers of 2. Next, we define terminology used to describe the partitions considered by Algorithm 1.

[1] This assumption can be made w.l.o.g. because if $n \in (2^{i-1}+1, 2^i+1)$ for some i , instead of the original image M we can consider a $(2^i+1) \times (2^i+1)$ image M', which is equal to M on the corresponding coordinates and has white pixels everywhere else. Let $\epsilon' = \epsilon n^2/(2^i+1)^2$. To ϵ-test M for connectedness, it suffices to ϵ'-test M' for connectedness. The resulting tester for M has the desired query complexity because $\epsilon' = \Theta(\epsilon)$. If $\epsilon \in (1/2^j, 1/2^{j-1})$ for some j, to ϵ-test a property $\mathcal{P}$, it suffices to run an ϵ''-test for $\mathcal{P}$ with $\epsilon'' = 1/2^j < \epsilon$.

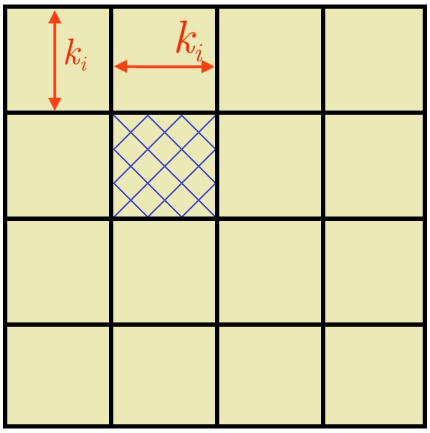

Figure 3 An illustration to Definition 3.1: black lines consist of grid pixels; the 16 yellow $k_i \times k_i$ squares represent squares of S_i. One of the squares includes diagonal lattice pixels from Definition 3.6 that are used in Algorithm 2.

▶ **Definition 3.1** (Grid pixels, squares of different levels, witnesses). *For* $i \in [0..\log \frac{1}{\epsilon})$, *let* $k_i = \frac{4}{\epsilon} \cdot 2^{-i} - 1$. *Call* (x, y) *a* grid pixel of level i *if* $(k_i + 1)|x$ *or* $(k_i + 1)|y$. *For all coordinates* u, v, *which are divisible by* $k_i + 1$, *the* $k_i \times k_i$ *subimage that consists of pixels* $[k_i]^2 + (u, v)$ *is called a* square of level i. *The set of all squares of level* i *is denoted* $\mathcal{S}_i$. Boundary pixels *of a square of level* i *are the pixels of the square which are adjacent to the grid pixels of level* i. *A square of any level that violates property* C' *(see Definition 1.2) is called a* witness.

Algorithm 1 *ϵ-tester* for connectedness.

```
input : parameter $\epsilon \in (0,1)$ ; access to a $n \times n$ binary matrix $M$.
1 Query $\frac{4}{\epsilon}$ pixels uniformly at random with replacement.
2 For $i = 0$ to $\log \frac{1}{\epsilon}$
    (a) Sample $2^{i+3}$ uniformly random squares of level $i$ (see Definition 3.1) with replacement.
    (b) For every sampled square $s$ from Step 2a, let $[k_i]^2 + (u, v)$ be the set of its pixels.
        Run the border-connectedness subroutine with inputs $i, u, v$: if the tester is nonadaptive,
        use Exhaustive-Square-Tester; otherwise use Diagonal-Square-Tester (Algorithm 2).
        If the subroutine rejects and Step 1 detected a black pixel outside $s$, reject.
3 Accept.
```

3.1 Effective Local Cost and the Structural Lemma

In this section, we prove our main structural lemma (Lemma 3.5) used in the analysis of Algorithm 1. It relates the distance to connectedness to the properties of individual squares, defined next.

▶ **Definition 3.2** (Local cost and effective local cost). *For a level* i, *consider a square* $s \in \mathcal{S}_i$. *The* local cost *of* s *is* $lc(s) = Dist(s, C')$. *The* effective local cost *of* s *is* $elc(s) = \min(2k_i, lc(s))$.

Next we state and prove two claims used in the proof of Lemma 3.5.

▷ Claim 3.3. For any square s of level $i \in [0..\log\frac{1}{\epsilon} - 1)$, let $ch(s)$ denote the set of its 4 children (i.e., squares of level $i+1$ inside it). Then $lc(s) \leq elc(s) + \sum_{q \in ch(s)} lc(q)$.

Proof. If $lc(s) \leq 2k_i$ then $elc(s) = lc(s)$. Since all costs are nonnegative, the inequality in Claim 3.3 becomes trivial.

Now assume that $lc(s) > 2k_i$. Then $elc(s) = 2k_i$. We can modify $\sum_{q \in ch(s)} lc(q)$ pixels in s so that all its children satisfy the property C'. (Note that here C' is the set of $k_i \times k_i$ (sub)images.) Then we can make black all pixels of s that partition it into its children, i.e., pixels $\{(x,y) \mid x = \frac{k_i+1}{2} \text{ or } y = \frac{k_i+1}{2}\}$. There are at most $2k_i$ such pixels, and after this modification s will satisfy C'. Hence, $lc(s) \leq elc(s) + \sum_{q \in ch(s)} lc(q)$. ◁

▷ Claim 3.4 (Distance to Border Connectedness). Let s be a $k \times k$ image. Then

$$Dist(s, C') \leq \frac{k^2}{4}.$$

Proof. If s contains at most $\frac{k^2}{4}$ black pixels, we can make all of them white, i.e., modify at most $\frac{k^2}{4}$ pixels and obtain an image that satisfies C'. Now consider an image s with more than $\frac{k^2}{4}$ black pixels, i.e., with less than $\frac{3k^2}{4}$ white pixels. Partition all pixels of s into 3 groups such that group $i \in \{0,1,2\}$ contains all pixels (x,y), where $y \equiv i \pmod 3$. Making all pixels of one group black produces an image that satisfies C'. By averaging, at least one group has less than $\frac{k^2}{4}$ white pixels. Making all these white pixels black results in an image that satisfies C'. This completes the proof. ◁

▶ **Lemma 3.5** (Structural Lemma). *Let M be an $n \times n$ image that is ϵ-far from C. Then the sum of effective local costs of all squares of all levels inside M is at least $\frac{\epsilon n^2}{2}$.*

Proof. To obtain a connected image, we can make all the $\frac{\epsilon n^2}{2}$ grid pixels of level 0 black and modify pixels inside every square of $\mathcal{S}_0$ to ensure it satisfies the property C'. Thus,

$$\sum\nolimits_{s \in \mathcal{S}_0} lc(s) \geq Dist(M, C) - \frac{\epsilon n^2}{2} \geq \frac{\epsilon n^2}{2}.$$

Consequently, it suffices to show that $\sum_{i=0}^{\log\frac{1}{\epsilon}-1} \sum_{s \in \mathcal{S}_i} elc(s) \geq \sum_{s \in \mathcal{S}_0} lc(s)$.

Let s be a square of level i. We use $desc(s,j)$ to denote the set of all squares of level $j \geq i$ inside s. (In particular, $desc(s,i)$ contains only s.) We will prove by induction that for any integer $j \in [i, \log\frac{1}{\epsilon} - 1)$,

$$lc(s) \leq \sum_{h=i}^{j} \sum\nolimits_{q \in desc(s,h)} elc(q) + \sum\nolimits_{q \in desc(s,j+1)} lc(q). \tag{1}$$

For $j = i$ (base case), the inequality in (1) holds since it is equivalent to the statement in Claim 3.3. Assume that (1) holds for $j = m$, that is,

$$lc(s) \leq \sum_{h=i}^{m} \sum\nolimits_{q \in desc(s,h)} elc(q) + \sum\nolimits_{q \in desc(s,m+1)} lc(q).$$

We will prove (1) holds for $j = m+1$. By Claim 3.3,

$$lc(q) \leq elc(q) + \sum\nolimits_{f \in ch(q)} lc(f).$$

Thus,

$$\sum\nolimits_{q\in desc(s,m+1)} lc(q) \le \sum\nolimits_{q\in desc(s,m+1)} elc(q) + \sum\nolimits_{q\in desc(s,m+2)} lc(q)$$

and

$$\begin{aligned} lc(s) &\le \sum_{h=i}^{m} \sum\nolimits_{q\in desc(s,h)} elc(q) + \sum\nolimits_{q\in desc(s,m+1)} lc(q) \\ &\le \sum_{h=i}^{m+1} \sum\nolimits_{q\in desc(s,h)} elc(q) + \sum\nolimits_{q\in desc(s,m+2)} lc(q), \end{aligned}$$

completing the inductive argument.

By (1) applied with $j = \log\frac{1}{\epsilon} - 2$, we get that for every square s of level i,

$$\begin{aligned} lc(s) &\le \sum_{h=i}^{\log\frac{1}{\epsilon}-2} \sum\nolimits_{q\in desc(s,h)} elc(q) + \sum\nolimits_{q\in desc(s,\log\frac{1}{\epsilon}-1)} lc(q) \\ &= \sum_{h=i}^{\log\frac{1}{\epsilon}-1} \sum\nolimits_{q\in desc(s,h)} elc(q), \end{aligned} \tag{2}$$

where the final equality holds because in every square of level $i = \log\frac{1}{\epsilon} - 1$, we have $k_i = 7$, and consequently, by Claim 3.4, the local cost is at most $\frac{7^2}{4} < 2\cdot 7$, i.e., it is equal to the effective local cost of that square.

Summing up (2) for all squares in $\mathcal{S}_0$, we get

$$\sum\nolimits_{s\in\mathcal{S}_0} lc(s) \le \sum\nolimits_{s\in\mathcal{S}_0} \sum\nolimits_{h=i}^{\log\frac{1}{\epsilon}-1} \sum\nolimits_{q\in desc(s,h)} elc(q) = \sum\nolimits_{h=i}^{\log\frac{1}{\epsilon}-1} \sum\nolimits_{s\in\mathcal{S}_i} elc(s),$$

where the last equality is obtained by switching the order of summations and rearranging the second summation in terms of levels. ◀

3.2 Testing Border-Connectedness

In this section, we state and analyze our adaptive border connectedness subroutine after defining the concepts used in it. We state the guarantees of both border connectedness subroutines in Lemma 3.7.

For the adaptive subroutine, we partition the square into diamonds and fences surrounding them, as described in Definition 3.6. The subroutine queries all pixels on the fences and categorizes diamonds into those whose black pixels are potentially connected to the border (set B in Algorithm 2) and those whose black pixels are definitely not (set A in Algorithm 2). Then it tries to find a black pixel in a diamond from set A or (using BFS) an isolated black component in diamonds from set B. Observe that either of the two provides evidence that the square is not border-connected.

▶ **Definition 3.6** (Diagonal lattice pixels, diamonds and fences). *For a fixed value of i, consider a square s in $\mathcal{S}_i$. Let m_i be the largest odd integer less than or equal to $\lceil\sqrt{k_i/\log k_i}\rceil$.* Diagonal lattice pixels *of the square is the set of pixels $L = \{(x,y)\in s \mid m_i|(x+y)$ or $m_i|(x-y)\}$. Let D be a $k_i\times k_i$ image whose pixels with coordinates from $[k_i]^2 - L$ are black and the remaining pixels are white. A set of pixels of the square whose corresponding pixels in D form a connected component is called a* diamond *of the square. A set of all diagonal lattice pixels that have some neighbouring pixel(s) from a particular diamond is called the* fence *of that diamond.*

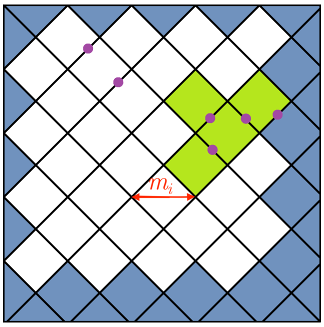

Figure 4 An example of execution of Algorithm 2. Black lines represent lattice pixels. The blue diamonds are included in B because they are adjacent to the border of the square. The purple dots represent black pixels in the lattice. The green diamonds are added to B during the BFS because their fences contain black pixels. The white diamonds remain in A.

Note that lattice pixels are not part of any diamond. Moreover, some diamonds are partial (those that have pixels from the border of the square.)

Algorithm 2 Border-connectedness subroutine *Diagonal-Square-Tester*.

```
input  : parameters $i$, $u$ and $v$; access to an $n \times n$ matrix $M$.
Let $s$ be a square of level $i$ that consists of pixels $[k_i]^2 + (u, v)$ and $m_i$ be the largest odd
  integer less than or equal to $\lceil \sqrt{k_i / \log k_i} \rceil$.
Query all the diagonal lattice pixels of $s$ (see Definition 3.6).
Initialize $B$ to be the set of all diamonds of $s$ that contain a border pixel of $s$. Initialize
  $A$ to be the set of the remaining diamonds of $s$.
While $\exists d_1 \in B$ and $\exists d_2 \in A$ such that $d_1$ and $d_2$ have a black pixel in the common
  portion of their fences, move $d_2$ from $A$ to $B$.
Query $k_i m_i$ pixels in $s$ uniformly at random with replacement.
  (a) If a black pixel from a diamond in $A$ or its fence is discovered, reject.
  (b) If a black pixel from a diamond in $B$ is discovered, pick a natural number $x \in [k_i^2]$ from
      the distribution with the probability mass function $f(j) = \frac{1}{j(j+1)}$ for all $j \in [k_i^2 - 1]$
      and $f(j) = \frac{1}{j}$ for $j = k_i^2$. (Observe that $\Pr(x \geq j) = \frac{1}{j}$ for all $j \in [k_i^2]$.) Starting from
      the black pixel, perform a BFS of its connected component. If the search halted after
      discovering at most $x$ black pixels, none of which are on the border of $s$, reject. Else (if
      $x + 1$ black pixels were found for this component or a black pixel on the border of
      square $s$ is reached) stop the search and proceed with the remaining queried pixels.
Accept.
```

Recall from Definition 3.1 that a witness is a square of one of the levels that violates border-connectedness.

▶ **Lemma 3.7.** *Fix level $i \in [0..\log \frac{1}{\epsilon})$. Let $s \in \mathcal{S}_i$ be a witness that consists of pixels $[k_i]^2 + (u, v)$. A border-connectedness subroutine of Algorithm 1 rejects s with probability at least $\frac{elc(s) \cdot \alpha}{2k_i}$, where $\alpha = 1$ for* Exhaustive-Square-Tester *and $\alpha = 1 - e^{-1}$ for* Diagonal-Square-Tester.

Proof. *Exhaustive-Square-Tester* determines that s is a witness with probability $1 \geq \frac{elc(s)}{2k_i} \cdot 1$.

Now we prove the statement for *Diagonal-Square-Tester*. Let A and B be defined as in Algorithm 2 after Step 3. Let a be the number of black pixels in all the diamonds of the set A and on the fences of those diamonds. Let b be the number of connected components of the image graph that are formed by black pixels in all the diamonds in the set B and in their fences and that contain no pixels on the border of s.

Next, we prove that

$$bm_i + a \geq lc(s) \geq elc(s). \tag{3}$$

We claim that we can connect all b connected components to each other and to the border of the square by modifying at most bm_i pixels. To see this, notice that any two black pixels in the same diamond can be connected to each other by changing less than m_i pixels (by taking any Manhattan-distance shortest path between the two pixels and making it all black). To prove the claim, we can connect the b connected components to the border of the square in the order their diamonds were added to B by the algorithm. The initial diamonds placed in B have at least one pixel on the border of the square, so their connected components can be directly connected to the border (using at most m_i pixels per connected component). Now assume that we already connected to the border all components that have pixels in the diamonds added to B so far. When the algorithm moves some diamond d_2 from A to B, it is done because there is already a diamond d_1 in B such that d_1 and d_2 have a black pixel β in the common portion of their fences. Then β must be already connected to the border. If there are any connected components in d_2 that are not connected to the border yet, we can fix that by connecting them to β (using at most m_i pixels per connected component). We proceed like this until all b connected components of the diamonds that were added to B by the algorithm are connected to the border of the square. At this point, we have changed at most bm_i pixels.

Recall that we have a black pixels in all the diamonds of the set A and on the fences of those diamonds. We make all of them white. After these at most $bm_i + a$ modifications, the square s satisfies C'. Thus, Equation (3) holds.

Observe that for $x \in [0, 1]$,

$$x \geq 1 - e^{-x} \geq x(1 - e^{-1}) > x/2. \tag{4}$$

By (4), the probability that a specific pixel from s is selected by Algorithm 2 in Item b is

$$1 - (1 - 1/k_i^2)^{k_i m_i} \geq 1 - e^{-\frac{k_i m_i}{k_i^2}} > \frac{m_i}{2k_i}.$$

Consider one of the b connected components defined above. Let p be the number of pixels in it. *Diagonal-Square-Tester* finds this component completely if in Step 4b of the subroutine, one of the p pixels from the component is selected and $x \geq p$ is chosen. This happens with probability at least $\frac{1}{p} \cdot \frac{m_i}{2k_i} \cdot p = \frac{m_i}{2k_i}$. The subroutine determines that s is a witness if it finds one of the b connected components or one of the a black pixels considered above. Thus, by (3) and (4), the probability that Algorithm 2 determines that square s is a witness is at least

$$1 - \left(1 - \frac{m_i}{2k_i}\right)^{a+b} \geq 1 - e^{-\frac{m_i(a+b)}{2k_i}} \geq 1 - e^{-\frac{bm_i+a}{2k_i}} \geq 1 - e^{-\frac{elc(s)}{2k_i}} \geq \frac{elc(s)(1 - e^{-1})}{2k_i},$$

completing the proof of Lemma 3.7. ◀

3.3 Proof of Theorem 1.1

In this section, we use Lemmas 3.5 and 3.7 to complete the analysis of our connectedness tester and the proof of Theorem 1.1.

Algorithm 1 always accepts connected images, since it sees no violation of C' in Step 2b. Consider an image M that is ϵ-far from connectedness. For every $i \in [0..\log\frac{1}{\epsilon})$, there are $\frac{n^2}{k_i^2}$ squares in $\mathcal{S}_i$. Let $\mathcal{W}_i$ be the set of all witnesses in $\mathcal{S}_i$. Let s be a square in $\mathcal{W}_i$. The probability that Algorithm 1 chooses s in Step 2a is

$$1-\left(1-\frac{k_i^2}{n^2}\right)^{2^{i+3}} \geq 1-e^{\frac{k_i^2\cdot 2^{i+3}}{n^2}} > \frac{k_i^2\cdot 2^{i+2}}{n^2},$$

where the inequalities follow from (4). By Lemma 3.7, the probability that the algorithm rejects s after choosing it is at least $\alpha\cdot elc(s)/2k_i$. Thus, the probability that the algorithm samples s in Step 2a and then rejects in Step 2b is at least

$$\frac{2^{i+2}k_i\cdot\alpha\cdot elc(s)}{2n^2} \geq \frac{6\alpha\cdot elc(s)}{\epsilon n^2}.$$

Thus, the probability that Algorithm 1 does not catch $s \in \mathcal{W}_i$ as a witness is at most $1-\frac{6\alpha\cdot elc(s)}{\epsilon n^2} \leq e^{-\frac{6\alpha\cdot elc(s)}{\epsilon n^2}}$. The probability that the algorithm does not catch any witness of $\mathcal{W}_i$ is at most

$$P_i = e^{-\frac{6\alpha}{\epsilon n^2}\cdot\sum_{s\in\mathcal{W}_i} elc(s)}.$$

Observe that $elc(s)=0$, for $s \in \mathcal{S}_i - \mathcal{W}_i$. Thus, by Lemma 3.5,

$$\sum_{s\in\mathcal{W}_i} elc(s) = \sum_{s\in\mathcal{S}_i} elc(s) \geq \frac{\epsilon n^2}{2}.$$

By a union bound over all levels, the probability that Algorithm 1 fails to catch any witness is at most

$$\sum\nolimits_{i\in\{0\}\cup[\log(1/\epsilon)]} P_i \leq e^{-\frac{6\alpha}{\epsilon n^2}\cdot\frac{\epsilon n^2}{2}} = e^{-3\alpha}.$$

Therefore, the probability that the algorithm detects at least one witness is at least $1-e^{-3\alpha}$. Since at least an ϵ fraction of pixels in M are black and every square of every level contains at most $\frac{16}{\epsilon^2} < \frac{\epsilon n^2}{2}$ pixels, the probability that Algorithm 1 detects a black pixel outside of that witness in Step 1 is at least $1-(1-\frac{\epsilon}{2})^{\frac{4}{\epsilon}} > 1-e^{-2}$. Thus, for both values of α, the probability that Algorithm 1 rejects M is at least

$$(1-e^{-2})(1-e^{-3\alpha}) \geq 2/3.$$

3.3.1 Query Complexity

We prove that Algorithm 1 has query complexity $O(\frac{1}{\epsilon^2})$ if it uses *Exhaustive-Square-Tester* as a subroutine. Algorithm 1 samples 2^{i+1} squares of level $i \in \{0\}\cup[\log\frac{1}{\epsilon}]$ and, for each sampled square, it calls *Exhaustive-Square-Tester* which makes $(\frac{4}{\epsilon}\cdot 2^{-i}-1)(\frac{4}{\epsilon}\cdot 2^{-i}-1) < \frac{16}{\epsilon^2 2^{2i}}$ queries in each sampled square of level i. Thus, the query complexity of Algorithm 1 is

$$\sum\nolimits_{i=0}^{\log\frac{1}{\epsilon}} 2^{i+1}\cdot\frac{16}{\epsilon^2 2^{2i}} < \sum\nolimits_{i=0}^{\log\frac{1}{\epsilon}} \frac{32}{\epsilon^2 2^{i}} = O\left(\frac{1}{\epsilon^2}\right).$$

When Algorithm 1 uses *Diagonal-Square-Tester*, it queries at most $\frac{2k_i^2}{m_i}$ diagonal lattice pixels inside each square of level i (in Step 1 of the subroutine). After that, in Step 4 of the subroutine, it selects $k_i m_i$ pixels and a number $x \in [k_i^2]$ from the specified distribution and then makes at most $4x$ queries for each selected pixel. Observe that $\mathbb{E}(x) = O(\log k_i)$. Thus, the expected number of queries inside a square of level i is at most $\frac{2k_i^2}{m_i} + k_i m_i \cdot 4 \cdot O(\log k_i) = O(k_i^{3/2}\sqrt{\log k_i})$. The expected total number of queries is $\sum_{i=0}^{\log(1/\epsilon)} O(k_i^{3/2}\sqrt{\log k_i}) \cdot 2^{i+1} = O(\epsilon^{-3/2}\sqrt{\log \frac{1}{\epsilon}})$.

By standard arguments, the adaptive version of Algorithm 1 can be converted to an algorithm that makes asymptotically the same number of queries in the worst case, and has the same accuracy guarantee and running time.

3.3.2 Running Time

The time complexity of Step 1a and Step 2 of Algorithm 1 is $O(\frac{1}{\epsilon})$. Therefore, the total time complexity of Algorithm 1 is $O(\frac{1}{\epsilon})$+time complexity of Step 1b. In Step 1b, Algorithm 1 uses either *Exhaustive-Square-Tester* or *Diagonal-Square-Tester*. Both of them perform a breadth first search within each sampled square. Breadth first search is linear in the sum of the number of edges and the number of nodes of the graph. Every pixel of a sampled square has at most 4 neighboring pixels. Thus, the number of edges in the image graph of every sampled square is linear in the number of pixels inside it and the time complexity of Step 1b is linear in the number of all queried pixels, i.e., $O(\frac{1}{\epsilon^2})$ for *Exhaustive-Square-Tester* and $O(\epsilon^{-3/2}\sqrt{\log(1/\epsilon)})$ for *Diagonal-Square-Tester*. This completes the proof of the theorem.

4 Lower Bound for Testing Connectedness

In this section, we give a lower bound on the query complexity of testing connectedness, proving Theorem 1.3. We use the standard set up of constructing a distribution $\mathcal{N}$ on ϵ-far inputs such that every deterministic nonadaptive algorithm that makes $q \leq \frac{c}{\epsilon}\log\frac{1}{\epsilon}$ queries (for some constant c) has probability of error greater than 1/3. By Yao's Principle [21], it is sufficient to prove Theorem 1.3.

4.1 Construction of $\mathcal{N}$

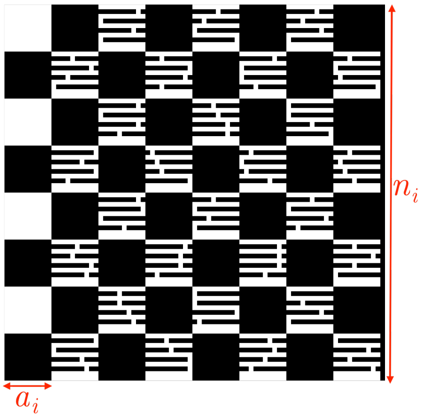

Figure 5 Our construction of $\mathcal{N}$: an interesting window together with a column of black pixels immediately to the right of it. All other pixels in the constructed image are white.

The construction is parameterized by n and the proximity parameter ϵ. It gives a distribution supported on $(n+1)\times(n+1)$ images that are ϵ-far from connectedness. We assume that ϵ is sufficiently small and that $n > \frac{1}{16}(\frac{1}{\epsilon})^{5/8}$. We also assume that n is a power of 2 and $1/\epsilon$ is an even power of 2 and that both of them are sufficiently large, so that all indices in our construction are integer. (See also Footnote 1 for the discussion of integrality issues.) Our construction starts by selecting a *level.* The indices of the levels range from the low index $\ell = \frac{1}{8}\log\frac{1}{\epsilon}$ to the high index $h = \frac{1}{4}\log\frac{1}{\epsilon}$. For all $i \in \{\ell, \ell+1, \dots, h\}$, define $a_i = 2^i$ and $n_i = 16 \cdot \sqrt{\epsilon} \cdot n \cdot a_i = \sqrt{\epsilon} \cdot n \cdot 2^{i+4}$. First, we pick a uniformly random integer $i \in \{\ell, \ell+1, \dots, h\}$. Consider the $n \times n$ image resulting from removing the last row and the last column of the $(n+1)\times(n+1)$ image. We partition this $n \times n$ image into $(\frac{n}{n_i})^2$ squares with side length n_i called *windows of level i*; that is, each window of level i is an $n_i \times n_i$ subimage. We pick one of the windows of level i uniformly at random and call it an *interesting window.* We make the n_i pixels immediately to the right of the interesting window black, representing a vertical black line segment, and all other pixels outside of the interesting window white.

Now we describe how to color the interesting window. See Figure 5 for an illustration. We fill the interesting window with a checkerboard pattern of squares of size $a_i \times a_i$ pixels. Inside each white checkerboard square that is not in the first column, number the rows starting from 0 and make every odd row, excluding the last, fully black, except for one randomly selected pixel for each row. The resulting $\frac{a_i}{2} - 1$ black lines, each containing one white pixel, are called *bridges.* The white pixels on the bridges are called *disconnecting pixels.* We refer to each checkerboard square with the bridges as a *bridge square.*

The intuition behind the construction is the following. Each black checkerboard square is in its own connected component. However, to "catch" this connected component as a witness of disconnectedness, a tester would have to query all the disconnecting pixels in the bridge squares to the left and/or to the right of the black square. Since the positions of the disconnecting pixels are random, it would have to query $\Omega(a_i^2)$ pixels in at least one relevant bridge square. Since the windows are selected at random, the algorithm would have to do it for many windows of each level. The key feature of our construction is that interesting windows of different levels are either disjoint or contained in one another, so potential witnesses for one window can't significantly help with another.

4.2 Analysis of the Construction

We start by showing that all images in the support of $\mathcal{N}$ are far from connected.

▶ **Lemma 4.1.** *Every image in the support of $\mathcal{N}$ is ϵ-far from connected.*

Proof. There are $\frac{(n_i/a_i)^2}{2} = 128\epsilon n^2$ black regions, each one in a separate connected component except for the last $\frac{n_i/a_i}{2} = 8\sqrt{\epsilon}\cdot n$ which are connected by the vertical line. Thus, the image graph has at least $128 \cdot \epsilon n^2 - 8\sqrt{\epsilon}\cdot n$ connected components. Changing one pixel from white to black corresponds to adding a node of degree at most 4 to the image graph. This decreases the number of connected components by at most 3. Removing a pixel decreases the number of connected components by at most 1. Consequently, overall, we need to change at least $\frac{1}{3}(128\epsilon n^2 - 8\sqrt{\epsilon}\cdot n)$ pixels. This is at least ϵn^2 for sufficiently large n; in particular, it holds for $n > \frac{1}{16}(\frac{1}{\epsilon})^{5/8}$, which was our assumption in the beginning of Section 4.1. ◀

Next we show that if the number of queried pixels is small, then every 1-sided error deterministic algorithm detects a violation of connectedness in an image distributed according to $\mathcal{N}$ with insufficiently small probability.

▶ **Lemma 4.2.** *Let M be an image distributed according to $\mathcal{N}$. Fix a deterministic nonadaptive 1-sided error algorithm $\mathcal{A}$ for testing connectedness of images. Let $\mathbf{Q}$ be the set of pixels queried by $\mathcal{A}$ and let $q = |\mathbf{Q}|$. For sufficiently small constant $c > 0$, if $q \le \frac{c}{\epsilon}\log\frac{1}{\epsilon}$, then $\mathcal{A}$ detects a violation of connectedness in M with probability less than $1/3$.*

Proof. We define an event E that must happen in order for the algorithm $\mathcal{A}$ to succeed in finding a witness of disconnectedness in an image distributed according to $\mathcal{N}$. Then we show that the probability of E is too small. To define E, we define a special group of pixels.

▶ **Definition 4.3** (A revealing set and event E)**.** *Let M be an image distributed according to $\mathcal{N}$. The set of all disconnecting pixels from one bridge square of M is called a* revealing set *for the window containing the bridge square. Let E denote the event that $\mathbf{Q}$ contains a revealing set for the interesting window of M.*

Since the tester $\mathcal{A}$ has 1-sided error, it can reject only if it finds a violation of connectedness. In particular, for an image distributed according to $\mathcal{N}$, in order to succeed, it must find a revealing set for the interesting window of the image.

▷ Claim 4.4. If the number of queries $q \le \frac{c}{\epsilon}\log\frac{1}{\epsilon}$ for sufficiently small constant c, then $\Pr[E] < 1/3$.

Proof. An important feature of our construction is that the largest bridge square is smaller than the smallest window. Indeed, the side length of the largest bridge square is $a_h = (\frac{1}{\epsilon})^{1/4}$, whereas the side length of the smallest window is $n_\ell = 16\sqrt{\epsilon}\cdot(\frac{1}{\epsilon})^{1/8}n = 16\epsilon^{3/8}n$. Thus, $a_h < n_\ell$ as long as $n > \frac{1}{16}(\frac{1}{\epsilon})^{5/8}$, as we assumed in the beginning of Section 4.1. The consequence of this feature and the fact that both a_i's and n_i's are powers of 2 is that each bridge square of level i is contained in one window of level j for all levels i and j.

A (potential) bridge square of level $i \in \{\ell, \ell+1, \dots, h\}$ is *covered* if $\mathbf{Q}$ contains at least $a_i^2/8$ pixels from that square. A window of level i is *good* if it contains a covered bridge square of level $j \ge i$; otherwise, it is *bad*. For each good window w, we pick a covered bridge square of the highest level contained in w and call it the covered bridge square *associated with* w. All windows of the same level are associated with different covered bridge squares, because each bridge square is contained in exactly one window of a given level.

Let G be the event that the interesting window in M is good. Then, by the law of total probability,

$$\Pr[E] = \Pr[E \mid G]\cdot\Pr[G] + \Pr[E \mid \overline{G}]\cdot\Pr[\overline{G}] \le \Pr[G] + \Pr[E \mid \overline{G}].$$

Next, we analyze event G. For every level $i \in \{\ell, \ell+1, \dots, h\}$, let g_i be the number of good windows of level i associated with covered bridge squares of level i and let t_i be the total number of good windows of level i. Then $g_h = t_h$ and $g_i = t_i - t_{i+1}$ for all $i \in [\ell, h-1]$. Observe that, for each level $i \in [\ell, h]$, the covered bridge squares associated with the good windows of level i are distinct. By definition, each of them contributes at least $a_i^2/8$ towards $\mathbf{Q}$. Therefore, the number of all pixels in $\mathbf{Q}$ satisfies

$$\begin{aligned} q &\ge \sum_{i=\ell}^{h}\frac{a_i^2 g_i}{8} = \frac{1}{8}\left(\sum_{i=\ell}^{h-1}a_i^2(t_i - t_{i+1}) + a_h^2 t_h\right) = \frac{1}{8}\left(\sum_{i=\ell}^{h-1}4^i(t_i - t_{i+1}) + 4^h t_h\right)\\ &\ge \frac{3}{32}\sum_{i=\ell}^{h}(4^i t_i). \end{aligned} \tag{5}$$

Recall that $q \le \frac{c}{\epsilon}\log\frac{1}{\epsilon}$, that the total number of levels is $h - \ell + 1 = \Theta(\log\frac{1}{\epsilon})$, and that the number of all windows for each level i is $(\frac{n}{n_i})^2 = \Theta(\frac{1}{4^i\epsilon})$. Thus,

$$\begin{aligned}\Pr[G] &= \frac{1}{h-\ell+1}\sum_{i=\ell}^{h}\frac{t_i}{(n/n_i)^2} = \frac{1}{\Theta(\log(\frac{1}{\epsilon}))}\sum_{i=\ell}^{h}(t_i\cdot\Theta(4^i\epsilon)) = \frac{1}{\Theta(\frac{1}{\epsilon}\log(\frac{1}{\epsilon}))}\sum_{i=\ell}^{h}(4^i t_i)\\ &< \frac{q}{\Theta(\frac{1}{\epsilon}\log(\frac{1}{\epsilon}))} < 1/6,\end{aligned}$$

where Equation (5) was used to obtain the first inequality, and the last inequality holds for sufficiently small constant c.

It remains to analyze $\Pr[E \mid \overline{G}]$, that is, the probability of E, given that the interesting window is bad. Consider a bad window of level $i \in \{\ell, \dots, h\}$. It has at most q bridge squares that contain a queried pixel. Consider one of such bridge squares. Recall that this bridge square has $a_i/2 - 1$ bridges. Number these bridges using integers $1, 2, \dots, a_i/2 - 1$. Let x_k denote the number of pixels of $\mathbf{Q}$ on the bridge number $k \in [a_i/2 - 1]$ of the bridge square. Then the probability that this bridge square has a revealing set for the window is

$$\begin{aligned}\prod_{k=1}^{a_i/2-1}\frac{x_k}{a_i} &\le \left(\frac{1}{a_i/2-1}\cdot\sum_{k=1}^{a_i/2-1}\frac{x_k}{a_i}\right)^{a_i/2-1} \le \left(\frac{a_i/8}{a_i/2-1}\right)^{a_i/2-1} \le \left(\frac{1}{2}\right)^{a_i/2-1}\\ &\le 2(\sqrt{2})^{-\sqrt[8]{\frac{1}{\epsilon}}},\end{aligned}$$

where the first inequality follows from the inequality between geometric and arithmetic means, the second inequality holds since $\sum_{k=1}^{a_i/2} x_k < a_i^2/8$, and the third inequality holds since ϵ is sufficiently small and, consequently, we can assume that the minimum value of a_i is at least 4. By a union bound over all bridge squares in this window that contain a query,

$$\Pr[E \mid \overline{G}] \le 2(\sqrt{2})^{-\sqrt[8]{\frac{1}{\epsilon}}}\cdot q \le 2(\sqrt{2})^{-\sqrt[8]{\frac{1}{\epsilon}}}\cdot\frac{c}{\epsilon}\cdot\log\frac{1}{\epsilon} < \frac{1}{6},$$

for sufficiently small ϵ and constant c.

Thus, $\Pr[E] \le \Pr[G] + \Pr[E \mid \overline{G}] < \frac{1}{6} + \frac{1}{6} = \frac{1}{3}$, as claimed. This completes the proof of Claim 4.4. ◁

This concludes the proof of Lemma 4.2. ◀

Theorem 1.3 follows from Lemma 4.2.
