## ■ Contents

Preface	
<i>Avrim Blum</i> .....	0:ix

### Regular Papers

Submodular Secretary Problem with Shortlists	
<i>Shipra Agrawal, Mohammad Shadravan, and Cliff Stein</i> .....	1:1–1:19
Hamiltonian Sparsification and Gap-Simulation	
<i>Dorit Aharonov and Leo Zhou</i> .....	2:1–2:21
On Solving Linear Systems in Sublinear Time	
<i>Alexandr Andoni, Robert Krauthgamer, and Yosef Poghrow</i> .....	3:1–3:19
Placing Conditional Disclosure of Secrets in the Communication Complexity Universe	
<i>Benny Applebaum and Prashant Nalini Vasudevan</i> .....	4:1–4:14
Bitcoin: A Natural Oligopoly	
<i>Nick Arnosti and S. Matthew Weinberg</i> .....	5:1–5:1
A Simple Sublinear-Time Algorithm for Counting Arbitrary Subgraphs via Edge Sampling	
<i>Sepehr Assadi, Michael Kapralov, and Sanjeev Khanna</i> .....	6:1–6:20
Tensor Network Complexity of Multilinear Maps	
<i>Per Austrin, Petteri Kaski, and Kaie Kubjas</i> .....	7:1–7:21
A #SAT Algorithm for Small Constant-Depth Circuits with PTF Gates	
<i>Swapnam Bajpai, Vaibhav Krishan, Deepanshu Kush, Nutan Limaye, and Srikanth Srinivasan</i> .....	8:1–8:20
Small-Set Expansion in Shortcode Graph and the 2-to-2 Conjecture	
<i>Boaz Barak, Pravesh K. Kothari, and David Steurer</i> .....	9:1–9:12
Algorithms, Bounds, and Strategies for Entangled XOR Games	
<i>Adam Bene Watts, Aram W. Harrow, Gurtej Kanwar, and Anand Natarajan</i> .....	10:1–10:18
Testing Local Properties of Arrays	
<i>Omri Ben-Eliezer</i> .....	11:1–11:20
The Complexity of User Retention	
<i>Eli Ben-Sasson and Eden Saig</i> .....	12:1–12:30
Torus Polynomials: An Algebraic Approach to ACC Lower Bounds	
<i>Abhishek Bhrushundi, Kaave Hosseini, Shachar Lovett, and Sankeerth Rao</i> .....	13:1–13:16
Almost Envy-Free Allocations with Connected Bundles	
<i>Vittorio Bilò, Ioannis Caragiannis, Michele Flammini, Ayumi Igarashi, Gianpiero Monaco, Dominik Peters, Cosimo Vinci, and William S. Zwickler</i> .....	14:1–14:21

10th Innovations in Theoretical Computer Science (ITCS 2019).

## ■ Preface

The papers in this volume were presented at the 10th Innovations in Theoretical Computer Science (ITCS 2019) conference. The conference was held at UC San Diego in San Diego, CA, USA, January 10-12, 2019, and co-located with SODA 2019. ITCS seeks to promote research that carries a strong conceptual message, for instance, introducing a new concept or model, opening a new line of inquiry within traditional or cross-interdisciplinary areas, introducing new techniques, or making novel connections between existing areas and ideas. The conference format is single-session and aims to promote the exchange of ideas between different areas of theoretical computer science and with other disciplines. The call for papers welcomed all submissions, whether aligned with current theory of computation research directions or deviating from them. A record 202 submissions were received. Of these, the program committee selected 66 papers. I would like to thank the authors of all submissions, whether accepted or not, for their interest in ITCS.

The program committee consisted of 39 members (plus the chair): Scott Aaronson, UT Austin; Eric Blais, Waterloo; Jeremiah Blocki, Purdue; Simina Branzei, Purdue; Bernard Chazelle, Princeton University; Amit Daniely, Hebrew University; Sanjoy Dasgupta, UC San Diego; Zeev Dvir, Princeton University; Uriel Feige, Weizmann; Michal Feldman, Tel-Aviv University; Rong Ge, Duke; Venkatesan Guruswami, CMU; Moritz Hardt, UC Berkeley; Russell Impagliazzo, UC San Diego; Brendan Juba, Washington University St Louis; Varun Kanade, University of Oxford; Eyal Kushilevitz, Technion; Yingyu Liang, University of Wisconsin - Madison; Shachar Lovett, UC San Diego; Sepideh Mahabadi, TTIC; Yishay Mansour, Tel-Aviv University; Rafael Pass, Cornell University; Sofya Raskhodnikova, Boston University; Dana Ron, Tel-Aviv University; Ron Rothblum, Technion; Aviad Rubinfeld, Stanford University; Aaron Sidford, Stanford University; Yaron Singer, Harvard University; Mohit Singh, Georgia Tech; Adam Smith, Boston University; Jacob Steinhardt, UC Berkeley; Madhur Tulsiani, TTIC; Vinod Vaikuntanathan, MIT; Thomas Vidick, Caltech; Matt Weinberg, Princeton University; Ryan Williams, MIT; Mary Wootters, Stanford University; Mihalis Yannakakis, Columbia University; Shengyu Zhang, CUHK and Tencent. I wish to express my heartfelt thanks to them for agreeing to join the committee as well as for investing a great deal of time and effort to evaluate the submissions. I am also grateful to the many subreviewers who assisted with the reviewing process. The local organizer was Shachar Lovett from UC San Diego. I would like to thank him very much for his service. I'm also grateful to Umesh Vazirani, chair of the ITCS Steering Committee, and to Thomas Vidick, who helped with the website among other things. Finally, I would like to thank all the presenters and the audience at ITCS for making ITCS a wonderful experience.

## Abstract

---

In submodular  $k$ -secretary problem, the goal is to select  $k$  items in a randomly ordered input so as to maximize the expected value of a given monotone submodular function on the set of selected items. In this paper, we introduce a relaxation of this problem, which we refer to as submodular  $k$ -secretary problem with shortlists. In the proposed problem setting, the algorithm is allowed to choose more than  $k$  items as part of a shortlist. Then, after seeing the entire input, the algorithm can choose a subset of size  $k$  from the bigger set of items in the shortlist. We are interested in understanding to what extent this relaxation can improve the achievable competitive ratio for the submodular  $k$ -secretary problem. In particular, using an  $O(k)$  sized shortlist, can an online algorithm achieve a competitive ratio close to the best achievable offline approximation factor for this problem? We answer this question affirmatively by giving a polynomial time algorithm that achieves a  $1 - 1/e - \epsilon - O(k^{-1})$  competitive ratio for any constant  $\epsilon > 0$ , using a shortlist of size  $\eta_\epsilon(k) = O(k)$ . This is especially surprising considering that the best known competitive ratio (in polynomial time) for the submodular  $k$ -secretary problem is  $(1/e - O(k^{-1/2}))(1 - 1/e)$  [20].

The proposed algorithm also has significant implications for another important problem of submodular function maximization under random order streaming model and  $k$ -cardinality constraint. We show that our algorithm can be implemented in the streaming setting using a memory buffer of size  $\eta_\epsilon(k) = O(k)$  to achieve a  $1 - 1/e - \epsilon - O(k^{-1})$  approximation. This result substantially improves upon [28], which achieved the previously best known approximation factor of  $1/2 + 8 \times 10^{-14}$  using  $O(k \log k)$  memory; and closely matches the known upper bound for this problem [24].

## 1 Introduction

In the classic *secretary problem*,  $n$  items appear in random order. We know  $n$ , but don't know the value of an item until it appears. Once an item arrives, we have to irrevocably and immediately decide whether or not to select it. Only one item is allowed to be selected, and the objective is to select the most valuable item, or perhaps to maximize the expected value of the selected item [11, 15, 23]. It is well known that the optimal policy is to observe the first  $n/e$  items without making any selection and then select the first item whose value is larger than the value of the best item in the first  $n/e$  items [11]. This algorithm, given by [11], is asymptotically optimal, and hires the best secretary with probability at least  $1/e$ . Hence it is also  $1/e$ -competitive for the expected value of the chosen item, and it can be shown that no algorithm can beat  $1/e$ -competitive ratio in expectation.

Many variants and generalizations of the secretary problem have been studied in the literature, see e.g., [3, 32, 30, 33, 21, 4]. [21, 4] introduced a multiple choice secretary problem, where the goal is to select  $k$  items in a randomly ordered input so as to maximize the *sum* of their values; and [21] gave an algorithm with an asymptotic competitive ratio of  $1 - O(1/\sqrt{k})$ . Thus as  $k \rightarrow \infty$ , the competitive ratio approaches 1. Recent literature studied several generalizations of this setting to multidimensional knapsacks [26], and proposed algorithms for which the expected online solution approaches the best offline solution as the knapsack sizes become large (e.g., [13, 10, 2]).

In another variant of multiple-choice secretary problem, [6] and [16] introduce the *submodular  $k$ -secretary problem*. In this secretary problem, the algorithm again selects  $k$  items, but the value of the selected items is given by a monotone submodular function  $f$ . The algorithm has value oracle access to the function, i.e., for any given set  $T$ , an algorithm can query an oracle to find its value  $f(T)$  [31]. The algorithm can select at most  $k$  items,  $a_1 \cdots, a_k$ , from a randomly ordered sequence of  $n$  items. The goal is to maximize  $f(\{a_1, \dots, a_k\})$ . Currently, the best result for this setting is due to [20], who achieve a  $1/e$ -competitive ratio in exponential time, or  $\frac{1}{e}(1 - \frac{1}{e})$  in polynomial time. In this case, the offline problem is NP-hard and hard-to approximate beyond the factor of  $1 - 1/e$  achieved by the greedy algorithm [27]. However, it is unclear if a competitive ratio of  $1 - 1/e$  can be achieved by an online algorithm for the submodular  $k$ -secretary problem even when  $k$  is large.

### Our model: secretary problem with shortlists

In this paper, we consider a relaxation of the secretary problem where the algorithm is allowed to select a *shortlist* of items that is larger than the number of items that ultimately need to be selected. That is, in a multiple-choice secretary problem with cardinality constraint  $k$ , the algorithm is allowed to choose more than  $k$  items as part of a shortlist. Then, after seeing the entire input, the algorithm can choose a subset of size  $k$  from the bigger set of items in the shortlist.

This new model is motivated by some practical applications of secretary problems, such as hiring (or assignment problems), where in some cases it may be possible to tentatively accept a larger number of candidates (or requests), while deferring the choice of the final  $k$ -selections to after all the candidates have been seen. Since there may be a penalty for declining candidates who were part of the shortlist, one would prefer that the shortlist is not much larger than  $k$ .

Another important motivation is theoretical: we wish to understand to what extent this relaxation of the secretary problem can improve the achievable competitive ratio. This question is in the spirit of several other methods of analysis that allow an online algorithm to have additional power, such as *resource augmentation* [18, 29].

The potential of this relaxation is illustrated by the basic secretary problem, where the aim is to select the item of maximum value among randomly ordered inputs. There, it is not difficult to show that if an algorithm picks every item that is better than the items seen so far, the true maximum will be found, while the expected number of items picked under randomly ordered inputs will be  $O(\log n)$ . Further, we show that this approach can be easily modified to get the maximum with  $1 - \epsilon$  probability while picking at most  $O(\ln(1/\epsilon))$  items for any constant  $\epsilon > 0$ . Thus, with just a constant sized shortlist, we can break the  $1/e$  barrier for the secretary problem and achieve a competitive ratio that is arbitrarily close to 1.

Motivated by this observation, we ask if a similar improvement can be achieved by relaxing the submodular  $k$ -secretary problem to allow a shortlist. That is, instead of choosing  $k$  items, the algorithm is allowed to choose  $\eta(k)$  items as part of a shortlist, for some function  $\eta$ ; and at the end of all inputs, the algorithm chooses  $k$  items from the  $\eta(k)$  selected items. Then, what is the relationship between  $\eta(\cdot)$  and the competitive ratio for this problem? Can we achieve a solution close to the best offline solution when  $\eta(k)$  is not much bigger than  $k$ , for example when  $\eta(k) = \theta(k)$ ?

In this paper, we answer this question affirmatively by giving a polynomial time algorithm that achieves  $1 - 1/e - \epsilon - O(k^{-1})$  competitive ratio for the submodular  $k$ -secretary problem using a shortlist of size  $\eta(k) = O(k)$ . This is surprising since  $1 - 1/e$  is the best achievable approximation (in polynomial time) for the offline problem. Further, for some special cases of submodular functions, we demonstrate that an  $O(1)$  shortlist allows us to achieve a  $1 - \epsilon$  competitive ratio. These results demonstrate the power of (small) shortlists for closing the gap between online and offline (polynomial time) algorithms.

We also discuss connections of secretary problem with shortlists to the related streaming settings. While a streaming algorithm does not qualify as an online algorithm (even when a shortlist is allowed), we show that our algorithm can in fact be implemented in a streaming setting to use  $\eta(k) = O(k)$  memory buffer; and our results significantly improve the available results for the submodular random order streaming problem.

## 1.1 Problem Definition

We now give a more formal definition. Items from a set  $\mathcal{U} = \{a_1, a_2, \dots, a_n\}$  (pool of items) arrive in a uniformly random order over  $n$  sequential rounds. The set  $\mathcal{U}$  is a priori fixed but unknown to the algorithm, and the total number of items  $n$  is known to the algorithm. In each round, the algorithm irrevocably decides whether to add the arriving item to a *shortlist*  $A$  or not. The algorithm's value at the end of  $n$  rounds is given by

$$\text{ALG} = \mathbb{E}[\max_{S \subseteq A, |S| \leq k} f(S)]$$

where  $f(\cdot)$  is a monotone submodular function. The algorithm has value oracle access to this function. The optimal offline utility is given by

$$\text{OPT} := f(S^*), \text{ where } S^* = \arg \max_{S \subseteq [n], |S| \leq k} f(S).$$

We say that an algorithm for this problem achieves a competitive ratio  $c$  using shortlist of size  $\eta(k)$ , if at the end of  $n$  rounds,  $|A| \leq \eta(k)$  and  $\frac{\text{ALG}}{\text{OPT}} \geq c$ .

Given the shortlist  $A$ , since the problem of computing the solution  $\arg \max_{S \subseteq A, |S| \leq k} f(S)$  can itself be computationally intensive, our algorithm will also track and output a subset  $A^* \subseteq A, |A^*| \leq k$ . We will lower bound the competitive ratio by bounding  $\frac{f(A^*)}{f(S^*)}$ .

The above problem definition has connections to some existing problems studied in the literature. The well-studied online submodular  $k$ -secretary problem described earlier is obtained from the above definition by setting  $\eta(k) = k$ , i.e., it is same as the case when no extra items can be selected as part of a shortlist. Another related problem is *submodular random order streaming problem* studied in [28]. In that problem, items from a set  $\mathcal{U}$  arrive online in random order and the algorithm aims to select a subset  $S \subseteq \mathcal{U}$ ,  $|S| \leq k$  in order to maximize  $f(S)$ . The streaming algorithm is allowed to maintain a *buffer* of size  $\eta(k) \geq k$ . However, the streaming problem is distinct from the submodular  $k$ -secretary problem with shortlists in several important ways. On one hand, since an item previously selected in the memory buffer can be discarded and replaced by a new items, a memory buffer of size  $\eta(k)$  does not imply a shortlist of size at most  $\eta(k)$ . On the other hand, in the secretary setting, we are allowed to memorize/store more than  $\eta(k)$  items without adding them to the shortlist. Thus an algorithm for submodular  $k$ -secretary problem with shortlist of size  $\eta(k)$  may potentially use a buffer of size larger than  $\eta(k)$ . Our algorithms, as described in the paper, do use a large buffer. But we will show those algorithms can in fact be implemented to use only  $\eta(k) = O(k)$  buffer, thus obtaining matching results for the streaming problem.

## 1.2 Our Results

Our main contribution is an online algorithm for the submodular  $k$ -secretary problem with shortlists that, for any constant  $\epsilon > 0$ , achieves a competitive ratio of  $1 - \frac{1}{e} - \epsilon - O(\frac{1}{k})$  with  $\eta(k) = O(k)$ . Note that for submodular  $k$ -secretary problem there is an upper bound of  $1 - 1/e$  on the achievable approximation factor, even in the offline setting, and this upper bound applies to our problem for arbitrary size  $\eta(\cdot)$  of shortlists. On the other hand for online monotone submodular  $k$ -secretary problem, i.e., when  $\eta(k) = k$ , the best competitive ratio achieved in the literature is  $1/e - O(k^{-1/2})$  [20]. Remarkably, with only an  $O(k)$  size shortlist, our online algorithm is able to achieve a competitive ratio that is arbitrarily close to the offline upper bound of  $1 - 1/e$ .

In the theorem statements below, big-Oh notation  $O(\cdot)$  is used to represent asymptotic behavior with respect to  $k$  and  $n$ . We assume the standard value oracle model: the only access to the submodular function is through a black box returning  $f(S)$  for a given set  $S$ , and each such query can be done in  $O(1)$  time.

► **Theorem 1.** *For any constant  $\epsilon > 0$ , there exists an online algorithm (Algorithm 2) for the submodular  $k$ -secretary problem with shortlists that achieves a competitive ratio of  $1 - \frac{1}{e} - \epsilon - O(\frac{1}{k})$ , with shortlist of size  $\eta_\epsilon(k) = O(k)$ . Here,  $\eta_\epsilon(k) = O(2^{\text{poly}(1/\epsilon)} k)$ .*

Specifically, we have  $\eta_\epsilon(k) = c \frac{\log(1/\epsilon)}{\epsilon^2} \left( \frac{1}{\epsilon^6} \frac{\log(1/\epsilon)}{\epsilon^4 \log(1/\epsilon)} \right) k$  for some constant  $c$ .

Further, we give an efficient implementation of Algorithm 2 that uses a memory buffer of size at most  $\eta_\epsilon(k)$  to get the following result for the problem of *submodular random order streaming problem* described in the previous section.

► **Theorem 2.** *For any constant  $\epsilon \in (0, 1)$ , there exists an algorithm for the submodular random order streaming problem that achieves  $1 - \frac{1}{e} - \epsilon - O(\frac{1}{k})$  approximation to  $OPT$  while using a memory buffer of size at most  $\eta_\epsilon(k) = O(k)$ . Also, the number of objective function evaluations for each item, amortized over  $n$  items, is  $O(1 + \frac{k^2}{n})$ .*

The above result significantly improves over the state-of-the-art results in random order streaming model [28], which are an approximation ratio of  $\frac{1}{2} + 8 \times 10^{-14}$  using a memory of size  $O(k \log k)$ . In addition it closely matches the known upper bound for this problem [24].

In [24], the authors demonstrate the existence of a monotone submodular function  $f$  such that any constant-pass algorithm that finds a  $(1+\epsilon)(1-1/k)^k$  approximation with probability at least 0.99 requires  $\Omega(n/k^2)$  space in random order streaming model.

Also note from Theorem 2 that our algorithm can be implemented with running time linear in  $n$ , the size of the input ( $O(n+k^2)$  time to be precise). This is significant as, until recently, it was not known if there exists a linear time algorithm achieving a  $1-1/e-\epsilon$  approximation even for the offline monotone submodular maximization problem under cardinality constraint [25]. Another interesting aspect of our algorithm is that it is highly parallel. Even though the decision for each arriving item may take time that is exponential in  $1/\epsilon$  (roughly  $\eta_\epsilon(k)/k$ ), it can be readily parallelized among multiple (as many as  $\eta_\epsilon(k)/k$ ) processors.

It is natural to ask whether these shortlists are, in fact, too powerful. Maybe they could actually allow us to always match the best offline algorithm. We give a negative result in this direction and show that even if we have unlimited computation power, for any function  $\eta(k) = o(n)$ , we can get no better than  $7/8$ -competitive algorithm using a shortlist of size  $\eta(k)$ . Note that with unlimited computational power, the offline problem can be solved exactly. This result demonstrates that having a shortlist does not make the online problem too easy - even with a shortlist (of size  $o(n)$ ) there is an information theoretic gap between the online and offline problem.

► **Theorem 3.** *No online algorithm (even with unlimited computational power) can achieve a competitive ratio better than  $7/8 + o(1)$  for the submodular  $k$ -secretary problem with shortlists, while using a shortlist of size  $\eta(k) = o(n)$ .*

Finally, for some special cases of monotone submodular functions, we can asymptotically approach the optimal solution. The first one is the family of functions we call  $m$ -submodular. A function  $f$  is  $m$ -submodular if it is submodular and there exists a submodular function  $F$  such that for all  $S$ :

$$f(S) = \max_{T \subseteq S, |T| \leq m} F(T).$$

► **Theorem 4.** *If  $f$  is an  $m$ -submodular function, there exists an online algorithm for the submodular  $k$ -secretary problem with shortlists that achieves a competitive ratio of  $1-\epsilon$  with shortlist of size  $\eta_{\epsilon,m}(k) = O(1)$ . Here,  $\eta_{\epsilon,m}(k) = (2m+3) \ln(2/\epsilon)$ .*

A proof of Theorem 4 along with the relevant algorithm appear in the full version [1].

Another special case is monotone submodular functions  $f$  satisfying the following property:  $f(\{a_1, \dots, a_i + \alpha, \dots, a_k\}) \geq f(\{a_1, \dots, a_i, \dots, a_k\})$ , for any  $\alpha > 0$  and  $1 \leq i \leq k$ . We can show that the algorithm by [21] asymptotically approaches optimal solution for such functions, but we omit the details.

### 1.3 Comparison to related work

We compare our results (Theorem 1 and Theorem 2) to the best known results for *submodular  $k$ -secretary problem* and *submodular random order streaming problem*, respectively.

The best known algorithm so far for submodular  $k$ -secretary problem is by [20], with asymptotic competitive ratio of  $1/e - O(k^{-1/2})$ . In their algorithm, after observing each element, they use an oracle to compute optimal offline solution on the elements seen so far. Therefore it requires exponential time in  $n$ . The best competitive ratio that they can get in polynomial time is  $\frac{1}{e}(1 - \frac{1}{e}) - O(k^{-1/2})$ . In comparison, by using a shortlist of size  $O(k)$  our

■ **Table 1** submodular  $k$ -secretary problem settings.

	#selections	Comp ratio	Running time	Comp ratio in poly( $n$ )
[20]	$k$	$1/e - O(k^{-1/2})$	$exp(n)$	$\frac{1}{e}(1 - 1/e)$
this	$O_\epsilon(k)$	$1 - 1/e - \epsilon - O(1/k)$	$O_\epsilon(n)$	$1 - 1/e - \epsilon - O(1/k)$

■ **Table 2** submodular random order streaming problem.

	Memory size	Approximation ratio	Running time	update time
[17]	$O(k)$	0.19	$O(n)$	$O(1)$
[28]	$O(k \log k)$	$1/2 + 8 \times 10^{-14}$	$O(n \log k)$	$O(\log k)$
[5]	$O(\frac{1}{\epsilon} k \log k)$	$1/2 - \epsilon$	$poly(n, k, 1/\epsilon)$	$O(\frac{1}{\epsilon} \log k)$
this	$O_\epsilon(k)$	$1 - 1/e - \epsilon - O(1/k)$	$O_\epsilon(n + k^2)$	amortized $O_\epsilon(1 + \frac{k^2}{n})$

(polynomial time) algorithm achieves a competitive ratio of  $1 - \frac{1}{e} - \epsilon - O(k^{-1})$ . In addition to substantially improving the above-mentioned result for submodular  $k$ -secretary problem, this closely matches the best possible offline approximation ratio of  $1 - 1/e$  in polynomial time. Further, our algorithm is linear time. Table 1 summarizes this comparison. Here,  $O_\epsilon(\cdot)$  hides the dependence on the constant  $\epsilon$ . The hidden constant in  $O_\epsilon(\cdot)$  is  $c \frac{\log(1/\epsilon)}{\epsilon^2} \left( \frac{1}{\epsilon^6} \log(1/\epsilon) \right)^{\frac{1}{\epsilon^4} \log(1/\epsilon)}$  for some absolute constant  $c$ .

In the streaming setting, [9] provided a single pass streaming algorithm for monotone submodular function maximization under  $k$ -cardinality constraint, that achieves a 0.25 approximation under adversarial ordering of input. Their algorithm requires  $O(1)$  function evaluations per arriving item and  $O(k)$  memory. The currently best known approximation under adversarial order streaming model is by [5], who achieve a  $1/2 - \epsilon$  approximation with a memory of size  $O(\frac{1}{\epsilon} k \log k)$ . There is an  $1/2 + o(1)$  upper bound on the competitive ratio achievable by any streaming algorithm for submodular maximization that only queries the value of the submodular function on feasible sets (i.e., sets of cardinality at most  $k$ ) while using  $o(n)$  memory [28].

[17] initiated the study of submodular random order streaming problem. Their algorithm uses  $O(k)$  memory and a total of  $n$  function evaluations to achieve 0.19 approximation. The state of the art result in the random order input model is due to [28] who achieve a  $1/2 + 8 \times 10^{-14}$  approximation, while using a memory buffer of size  $O(k \log k)$ .

Table 2 provides a detailed comparison of our result in Theorem 2 to the above-mentioned results for submodular random order streaming problem, showing that our algorithm substantially improves the existing results for most aspects of the problem.

There is also a line of work studying the online variant of the submodular welfare maximization problem (e.g., [22, 7, 19]). In this problem, the items arrive online, and each arriving item should be allocated to one of  $m$  agents with a submodular valuation functions  $w_i(S_i)$  where  $S_i$  is the subset of items allocated to  $i$ -th agent). The goal is to partition the arriving items into  $m$  sets to be allocated to  $m$  agents, so that the sum of valuations over all agents is maximized. This setting is incomparable with the submodular  $k$ -secretary problem setting considered here.

## 1.4 Organization

The rest of the paper is organized as follows. Section 2 describes our main algorithm (Algorithm 2) for the submodular  $k$ -secretary problem with shortlists, and demonstrates that its shortlist size is bounded by  $\eta_\epsilon(k) = O(k)$ . In Section 3, we analyze the competitive ratio

of this algorithm to prove Theorem 1. In Section 4, we provide an alternate implementation of Algorithm 2 that uses a memory buffer of size at most  $\eta_\epsilon(k)$ , in order to prove Theorem 2. Finally, in Section 5, we provide a proof of our impossibility result stated in Theorem 3. The proof of Theorem 4 along with the relevant algorithm can be found in the full version [1].

## 2 Algorithm description

Before giving our algorithm for submodular  $k$ -secretary problem with shortlists, we describe a simple technique for (classic) secretary problem with shortlists that achieves a  $1 - \delta$  competitive ratio using shortlists of size logarithmic in  $1/\delta$ . Recall that in the secretary problem, the aim is to select an item with expected value close to the maximum among a pool of items  $I = (a_1, \dots, a_N)$  arriving sequentially in a uniformly random order. We will consider the variant with shortlists, where we now want to pick a shortlist which contains an item with expected value close to the maximum. We propose the following simple algorithm. For the first  $n\delta/2$  rounds, don't add any items to the shortlist, but just keep track of the maximum value seen so far. For all subsequent rounds, for any arriving item  $i$  that has a value  $a_i$  greater than or equal to the maximum value seen so far, add it to the shortlist if number of items added so far is less than or equal to  $L = 4 \ln(2/\delta)$ . This algorithm is summarized as Algorithm 1. Clearly, for constant  $\delta$ , this algorithm uses a shortlist of size  $L = O(1)$ . Further, under a uniform random ordering of input, we can show that the maximum value item will be part of the shortlist with probability  $1 - \delta$ . (See Proposition 25 in Section 3.)

There are two main difficulties in extending this idea to the submodular  $k$ -secretary problem with shortlists. First, instead of one item, here we aim to select a set  $S$  of  $k$  items using an  $O(k)$  length shortlist. Second, the contribution of each new item  $i$  to the objective value, as given by the submodular function  $f$ , depends on the set of items selected so far.

The first main concept we introduce to handle these difficulties is that of dividing the input into sequential blocks that we refer to as  $(\alpha, \beta)$  windows. Below is the precise construction of  $(\alpha, \beta)$  windows, for any positive integers  $\alpha$  and  $\beta$ , such that  $k/\alpha$  is an integer.

We use a set of random variables  $X_1, \dots, X_m$  defined in the following way. Throw  $n$  balls into  $m$  bins uniformly at random. Then set  $X_j$  to be the number of balls in the  $j$ th bin. We call the resulting  $X_j$ 's a  $(n, m)$ -ball-bin random set.

---

**Algorithm 2** Algorithm for submodular  $k$ -secretary with shortlist.
 

---

- 1: Inputs: set  $\bar{I} = \{\bar{a}_1, \dots, \bar{a}_n\}$  of  $n$  items arriving sequentially, submodular function  $f$ , parameter  $\epsilon \in (0, 1]$ .
  - 2: Initialize:  $S_0 \leftarrow \emptyset, R_0 \leftarrow \emptyset, A \leftarrow \emptyset, A^* \leftarrow \emptyset$ , constants  $\alpha \geq 1, \beta \geq 1$  which depend on the constant  $\epsilon$ .
  - 3: Divide indices  $\{1, \dots, n\}$  into  $(\alpha, \beta)$  windows as prescribed by Definition 5.
  - 4: **for** window  $w = 1, \dots, k/\alpha$  **do**
  - 5:     **for** every slot  $s_j$  in window  $w, j = 1, \dots, \alpha\beta$  **do**
  - 6:         Concurrently for all subsequences of previous slots  $\tau \subseteq \{s_1, \dots, s_{j-1}\}$  of length  $|\tau| < \alpha$  in window  $w$ , call the online algorithm in Algorithm 1 with the following inputs:
    - number of items  $N = |s_j| + 1, \delta = \frac{\epsilon}{2}$ , and
    - item values  $I = (a_0, a_1, \dots, a_{N-1})$ , with
 
$$a_0 := \max_{x \in R_{1, \dots, w-1}} \Delta(x | S_{1, \dots, w-1} \cup \gamma(\tau))$$

$$a_\ell := \Delta(s_j(\ell) | S_{1, \dots, w-1} \cup \gamma(\tau)), \forall \ell = 1, \dots, N-1$$
 where  $s_j(\ell)$  denotes the  $\ell^{\text{th}}$  item in the slot  $s_j$ .
  - 7:         Let  $A_j(\tau)$  be the shortlist returned by Algorithm 1 for slot  $j$  and subsequence  $\tau$ .  
 Add all items except the dummy item 0 to the shortlist  $A$ . Let's  $A(j) = \bigcup_{\tau} A_j(\tau)$ .  
 That is,
 
$$A \leftarrow A \cup (A(j) \cap s_j)$$
  - 8:     **end for**
  - 9:     After seeing all items in window  $w$ , compute  $R_w, S_w$  as defined in (3) and (4) respectively.
  - 10:      $A^* \leftarrow A^* \cup (S_w \cap A)$
  - 11: **end for**
  - 12: return  $A, A^*$ .
- 

► **Definition 5** ( $(\alpha, \beta)$  windows). Let  $X_1, \dots, X_{k\beta}$  be a  $(n, k\beta)$ -ball-bin random set. Divide the indices  $\{1, \dots, n\}$  into  $k\beta$  slots, where the  $j$ -th slot,  $s_j$ , consists of  $X_j$  consecutive indices in the natural way, that is, slot 1 contains the first  $X_1$  indices, slot 2 contains the next  $X_2$  indices, etc. Next, we define  $k/\alpha$  windows, where window  $w$  consists of  $\alpha\beta$  consecutive slots, in the same manner as we assigned slots.

Thus, the  $q^{\text{th}}$  slot is composed of indices  $\{\ell, \dots, r\}$ , where  $\ell = X_1 + \dots + X_{q-1} + 1$  and  $r = X_1 + \dots + X_q$ . Further, if the ordered the input is  $\bar{a}_1, \dots, \bar{a}_n$ , then we say that the items inside the slot  $s_q$  are  $\bar{a}_\ell, \bar{a}_{\ell+1}, \dots, \bar{a}_r$ . To reduce notation, when clear from context, we will use  $s_q$  and  $w$  to also indicate the *set of items* in the slot  $s_q$  and window  $w$  respectively.

When  $\alpha$  and  $\beta$  are large enough constants, some useful properties can be obtained from the construction of these windows and slots. First, roughly  $\alpha$  items from the optimal set  $S^*$  are likely to lie in each of these windows; and further, it is unlikely that two items from  $S^*$  will appear in the same slot. (These statements will be made more precise in the analysis where precise setting of  $\alpha, \beta$  in terms of  $\epsilon$  will be provided.) Consequently, our algorithm can focus on identifying a constant number (roughly  $\alpha$ ) of optimal items from each of these windows, with at most one item coming from each of the  $\alpha\beta$  slots in a window. The core of our algorithm is a subroutine that accomplishes this task in an online manner using a shortlist of constant size in each window.

To implement this task, we use a greedy selection method that considers all possible  $\alpha$  sized subsequences of the  $\alpha\beta$  slots in a window, and aims to identify the subsequence that maximizes the increment over the ‘best’ items identified so far. More precisely, for any subsequence  $\tau = (s_1, \dots, s_\ell)$  of the  $\alpha\beta$  slots in window  $w$ , we define a ‘greedy’ subsequence  $\gamma(\tau)$  of items as:

$$\gamma(\tau) := \{i_1, \dots, i_\ell\} \quad (1)$$

where

$$i_j := \arg \max_{i \in s_j \cup R_{1, \dots, w-1}} f(S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\} \cup \{i\}) - f(S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\}). \quad (2)$$

In (2) and in the rest of the paper, we use shorthand  $S_{1, \dots, w}$  to denote  $S_1 \cup \dots \cup S_w$ , and  $R_{1, \dots, w}$  to denote  $R_1 \cup \dots \cup R_w$ , etc. We also will take unions of subsequences, which we interpret as the union of the elements in the subsequences. Here  $R_w$  is defined to be the union of all greedy subsequences of length  $\alpha$ , and  $S_w$  to be the best subsequence among those. That is,

$$R_w = \cup_{\tau: |\tau|=\alpha} \gamma(\tau) \quad (3)$$

and

$$S_w = \gamma(\tau^*), \quad (4)$$

where

$$\tau^* := \arg \max_{\tau: |\tau|=\alpha} f(S_{1, \dots, w-1} \cup \gamma(\tau)) - f(S_{1, \dots, w-1}). \quad (5)$$

Note that  $i_j$  (refer to (2)) can be set as either an item in slot  $s_j$  or an item *from a previous greedy subsequence* in  $R_1 \cup \dots \cup R_{w-1}$ . The significance of the latter relaxation will become clear in the analysis.

As such, identifying the sets  $R_w$  and  $S_w$  involves looking forward in a slot  $s_j$  to find the best item (according to the given criterion in (2)) among all the items in the slot. To obtain an online implementation of this procedure, we use an online subroutine that employs the algorithm (Algorithm 1) for the basic secretary problem with shortlists described earlier. This online procedure will result in selection of a set  $H_w$  potentially larger than  $R_w$ , while ensuring that each element from  $R_w$  is part of  $H_w$  with a high probability  $1 - \delta$  at the cost of adding extra  $\log(1/\delta)$  items to the shortlist. Note that  $R_w$  and  $S_w$  can be computed *exactly* at the end of window  $w$ .

Algorithm 2 summarizes the overall structure of our algorithm. In the algorithm, for any item  $i$  and set  $V$ , we define  $\Delta_f(i|V) := f(V \cup \{i\}) - f(V)$ .

The algorithm returns both the shortlist  $A$  which we show to be of size  $O(k)$  in the following proposition, as well as a set  $A^* = \cup_w (S_w \cap A)$  of size at most  $k$  to compete with  $S^*$ . In the next section, we will show that  $\mathbb{E}[f(A^*)] \geq (1 - \frac{1}{e} - \epsilon - O(\frac{1}{k}))f(S^*)$  to provide a bound on the competitive ratio of this algorithm.

► **Proposition 6.** *Given  $k, n$ , and any constant  $\alpha, \beta$  and  $\epsilon$ , the size of shortlist  $A$  selected by Algorithm 2 is of size at most  $4k\beta \binom{\alpha\beta}{\alpha} \log(2/\epsilon) = O(k)$ .*

**Proof.** For each window  $w = 1, \dots, k/\alpha$ , and for each of the  $\alpha\beta$  slots in this window, lines 6 through 7 in Algorithm 2 runs Algorithm 1 for  $\binom{\alpha\beta}{\alpha}$  times (for all  $\alpha$  length subsequences). By construction of Algorithm 1, for each run it will add at most  $L \leq 4 \log(2/\epsilon)$  items to the shortlist. Therefore, over all windows, Algorithm 2 adds at most  $\frac{k}{\alpha} \times \alpha\beta \binom{\alpha\beta}{\alpha} L = O(k)$  items to the shortlist. ◀

### 3 Bounding the competitive ratio (Proof of Theorem 1)

In this section we show that for any  $\epsilon \in (0, 1)$ , Algorithm 2 with an appropriate choice of constants  $\alpha, \beta$ , achieves the competitive ratio claimed in Theorem 1 for the submodular  $k$ -secretary problem with shortlists.

Recall the following notation defined in the previous section. For any collection of sets  $V_1, \dots, V_\ell$ , we use  $V_{1, \dots, \ell}$  to denote  $V_1 \cup \dots \cup V_\ell$ . Also, recall that for any item  $i$  and set  $V$ , we denote  $\Delta_f(i|V) := f(V \cup \{i\}) - f(V)$ .

#### Proof overview

The proof is divided into two parts. We first show a lower bound on the ratio  $\mathbb{E}[f(\cup_w S_w)]/\text{OPT}$  in Proposition 24, where  $S_w$  is the subset of items as defined in (4) for every window  $w$ . Later in Proposition 27, we use the said bound to derive a lower bound on the ratio  $\mathbb{E}[f(A^*)]/\text{OPT}$ , where  $A^* = A \cap (\cup_w S_w)$  is the subset of the shortlist returned by Algorithm 2.

Specifically, in Proposition 24, we provide settings of parameters  $\alpha, \beta$  such that  $\mathbb{E}[f(\cup_w S_w)] \geq (1 - \frac{1}{e} - \frac{\epsilon}{2} - O(\frac{1}{k})) \text{OPT}$ . A central idea in the proof of this result is to show that for every window  $w$ , given  $R_{1, \dots, w-1}$ , the items tracked from the previous windows, any of the  $k$  items from the optimal set  $S^*$  has at least  $\frac{\alpha}{k}$  probability to appear either in window  $w$ , or among the tracked items  $R_{1, \dots, w-1}$ . Further, the items from  $S^*$  that appear in window  $w$ , appear independently, and in a uniformly random slot in this window. (See Lemma 15.) These observations allow us to show that, in each window  $w$ , there exists a subsequence  $\tilde{\tau}_w$  of close to  $\alpha$  slots, such that the greedy sequence of items  $\gamma(\tilde{\tau}_w)$  will be almost “as good as” a randomly chosen sequence of  $\alpha$  items from  $S^*$ . More precisely, denoting  $\gamma(\tilde{\tau}_w) = (i_1, \dots, i_t)$ , in Lemma 19, for all  $j = 1, \dots, t$ , we lower bound the increment in function value  $f(\dots)$  on adding  $i_j$  over the items in  $S_{1, \dots, w-1} \cup i_{1, \dots, j-1}$  as:

$$\begin{aligned} & \mathbb{E}[\Delta_f(i_j | S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\}) | T_{1, \dots, w-1}, i_1, \dots, i_{j-1}] \\ & \geq \frac{1}{k} \left( \left(1 - \frac{\alpha}{k}\right) f(S^*) - f(S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\}) \right). \end{aligned}$$

We then deduce (using standard techniques for the analysis of greedy algorithm for submodular functions) that

$$\begin{aligned} & \mathbb{E} \left[ \left(1 - \frac{\alpha}{k}\right) f(S^*) - f(S_{1, \dots, w-1} \cup \gamma(\tilde{\tau}_w)) \mid S_{1, \dots, w-1} \right] \\ & \leq e^{-t/k} \left( \left(1 - \frac{\alpha}{k}\right) f(S^*) - f(S_{1, \dots, w-1}) \right). \end{aligned}$$

Now, since the length  $t$  of  $\tilde{\tau}_w$  is close to  $\alpha$  (as we show in Lemma 21) and since  $S_w = \gamma(\tau^*)$  with  $\tau^*$  defined as the “best” subsequence of length  $\alpha$  (refer to definition of  $\tau^*$  in (5)), we can show that a similar inequality holds for  $S_w = \gamma(\tau^*)$ , i.e.,

$$\begin{aligned} & \left(1 - \frac{\alpha}{k}\right) f(S^*) - \mathbb{E}[f(S_{1, \dots, w-1} \cup S_w) \mid S_{1, \dots, w-1}] \\ & \leq e^{-\alpha/k} (1 - \delta') \left( \left(1 - \frac{\alpha}{k}\right) f(S^*) - f(S_{1, \dots, w-1}) \right), \end{aligned}$$

where  $\delta' \in (0, 1)$  depends on the setting of  $\alpha, \beta$ . (See Lemma 23.) Then repeatedly applying this inequality for  $w = 1, \dots, k/\alpha$ , and setting  $\delta, \alpha, \beta$  appropriately in terms of  $\epsilon$ , we can obtain  $\mathbb{E}[f(S_{1, \dots, w})] \geq (1 - \frac{1}{e} - \frac{\epsilon}{2} - \frac{1}{k}) f(S^*)$ , completing the proof of Proposition 24.

However, a remaining difficulty is that while the algorithm keeps a track of the set  $S_w$  for every window  $w$ , it may not have been able to add all the items in  $S_w$  to the shortlist  $A$  during the online processing of the inputs in that window. In the proof of Proposition 27, we show that in fact the

algorithm will add most of the items in  $\cup_w S_w$  to the shortlist. More precisely, we show that given that an item  $i$  is in  $S_w$ , it will be in shortlist  $A$  with probability  $1 - \delta$ , where  $\delta$  is the parameter used while calling Algorithm 1 in Algorithm 2. Therefore, using properties of submodular functions it follows that with  $\delta = \epsilon/2$ ,  $\mathbb{E}[f(A^*)] = \mathbb{E}[f(\cup_w S_w \cap A)] \geq (1 - \frac{\epsilon}{2})\mathbb{E}[f(\cup_w S_w)]$  (see Proposition 27). Combining this with the lower bound  $\frac{\mathbb{E}[f(\cup_w S_w)]}{\text{OPT}} \geq (1 - \frac{1}{e} - \frac{\epsilon}{2} - O(\frac{1}{k}))$  proven in Proposition 24, we complete the proof of competitive ratio bound stated in Theorem 1.

### 3.1 Preliminaries

The following properties of submodular functions are well known (e.g., see [8, 12, 14]).

► **Lemma 7.** *Given a monotone submodular function  $f$ , and subsets  $A, B$  in the domain of  $f$ , we use  $\Delta_f(A|B)$  to denote  $f(A \cup B) - f(B)$ . For any set  $A$  and  $B$ ,  $\Delta_f(A|B) \leq \sum_{a \in A \setminus B} \Delta_f(a|B)$ .*

► **Lemma 8.** *Denote by  $A(p)$  a random subset of  $A$  where each element has a probability at least  $p$  to appear in  $A$  (not necessarily independently). Then  $\mathbb{E}[f(A(p))] \geq (1 - p)f(\emptyset) + (p)f(A)$ .*

We will use the following well known deviation inequality for martingales (or supermartingales/submartingales).

► **Lemma 9 (Azuma-Hoeffding inequality).** *Suppose  $\{X_k : k = 0, 1, 2, 3, \dots\}$  is a martingale (or super-martingale) and  $|X_k - X_{k-1}| < c_k$ , almost surely. Then for all positive integers  $N$  and all positive reals  $r$ ,*

$$P(X_N - X_0 \geq r) \leq \exp\left(\frac{-r^2}{2 \sum_{k=1}^N c_k^2}\right).$$

And symmetrically (when  $X_k$  is a sub-martingale):

$$P(X_N - X_0 \leq -r) \leq \exp\left(\frac{-r^2}{2 \sum_{k=1}^N c_k^2}\right).$$

► **Lemma 10 (Chernoff bound for Bernoulli r.v.).** *Let  $X = \sum_{i=1}^N X_i$ , where  $X_i = 1$  with probability  $p_i$  and  $X_i = 0$  with probability  $1 - p_i$ , and all  $X_i$  are independent. Let  $\mu = \mathbb{E}(X) = \sum_{i=1}^N p_i$ . Then,*

$$P(X \geq (1 + \delta)\mu) \leq e^{-\delta^2 \mu / (2 + \delta)}$$

for all  $\delta > 0$ , and

$$P(X \leq (1 - \delta)\mu) \leq e^{-\delta^2 \mu / 2}$$

for all  $\delta \in (0, 1)$ .

### 3.2 Some useful properties of $(\alpha, \beta)$ windows

All the proofs in this section are omitted and are provided in the full version [1].

We first prove some useful properties of  $(\alpha, \beta)$  windows defined in Definition 5 and used in Algorithm 2. The first observation is that every item will appear uniformly at random in one of the  $k\beta$  slots in  $(\alpha, \beta)$  windows.

► **Definition 11.** For each item  $e \in \bar{I}$ , define  $Y_e \in [k\beta]$  as the random variable indicating the slot in which  $e$  appears. We call vector  $Y \in [k\beta]^n$  a *configuration*.

► **Lemma 12.** *Random variables  $\{Y_e\}_{e \in \bar{I}}$  are i.i.d. with uniform distribution on all  $k\beta$  slots.*

This follows from the uniform random order of arrivals, and the use of the balls in bins process to determine the number of items in a slot during the construction of  $(\alpha, \beta)$  windows.

Next, we make some observations about the probability of assignment of items in  $S^*$  to the slots in a window  $w$ , given the sets  $R_{1, \dots, w-1}, S_{1, \dots, w-1}$  (refer to (3), (4) for definition of these sets). To aid analysis, we define the following new random variable  $T_w$  that will track all the useful information from a window  $w$ .

► **Definition 13.** Define  $T_w := \{(\tau, \gamma(\tau))\}_\tau$ , for all  $\alpha$ -length subsequences  $\tau = (s_1, \dots, s_\alpha)$  of the  $\alpha\beta$  slots in window  $w$ . Here,  $\gamma(\tau)$  is a sequence of items as defined in (1). Also define  $\text{Supp}(T_{1, \dots, w}) := \{e | e \in \gamma(\tau) \text{ for some } (\tau, \gamma(\tau)) \in T_{1, \dots, w}\}$  (Note that  $\text{Supp}(T_{1, \dots, w}) = R_{1, \dots, w}$ ).

► **Lemma 14.** For any window  $w \in [W]$ ,  $T_{1, \dots, w}$  and  $S_{1, \dots, w}$  are independent of the ordering of elements within any slot, and are determined by the configuration  $Y$ .

Following the above lemma, given a configuration  $Y$ , we will some times use the notation  $T_{1, \dots, w}(Y)$  and  $S_{1, \dots, w}(Y)$  to make this mapping explicit.

► **Lemma 15.** For any item  $i \in S^*$ , window  $w \in \{1, \dots, W\}$ , and slot  $s$  in window  $w$ , define

$$p_{is} := \Pr(i \in s \cup \text{Supp}(T) | T_{1, \dots, w-1} = T). \quad (6)$$

Then, for any pair of slots  $s', s''$  in windows  $w, w+1, \dots, W$ ,

$$p_{is'} = p_{is''} \geq \frac{1}{k\beta}. \quad (7)$$

► **Lemma 16.** For any window  $w$ ,  $i, j \in S^*$ ,  $i \neq j$  and  $s, s' \in w$ , the random variables  $\mathbf{1}(Y_i = s | T_{1, \dots, w-1} = T)$  and  $\mathbf{1}(Y_j = s' | T_{1, \dots, w-1} = T)$  are independent. That is, given  $T_{1, \dots, w-1} = T$ , items  $i, j \in S^*$ ,  $i \neq j$  appear in any slot  $s$  in  $w$  independently.

### 3.3 Bounding $\mathbb{E}[f(\cup_w S_w)]/\text{OPT}$

In this section, we use the observations from the previous sections to show the existence of a random subsequence of slots  $\tilde{\tau}_w$  of window  $w$  such that we can lower bound  $f(S_{1, \dots, w-1} \cup \gamma(\tilde{\tau}_w)) - f(S_{1, \dots, w-1})$  in terms of  $\text{OPT} - f(S_{1, \dots, w-1})$ . This will be used to lower bound increment  $\Delta_f(S_w | S_{1, \dots, w-1}) = f(S_{1, \dots, w-1} \cup \gamma(\tau^*)) - f(S_{1, \dots, w-1})$  in every window.

► **Definition 17** ( $Z_s$  and  $\tilde{\gamma}_w$ ). Create sets of items  $Z_s, \forall s \in w$  as follows: for every slot  $s$ , add every item from  $i \in S^* \cap s$  independently with probability  $\frac{1}{k\beta p_{is}}$  to  $Z_s$ . Then, for every item  $i \in S^* \cap \text{Supp}(T)$ , with probability  $\alpha/k$ , add  $i$  to  $Z_s$  for a randomly chosen slot  $s$  in  $w$ . Define subsequence  $\tilde{\tau}_w$  as the sequence of slots with  $Z_s \neq \emptyset$ .

► **Lemma 18.** Given any  $T_{1, \dots, w-1} = T$ , for any slot  $s$  in window  $w$ , all  $i, i' \in S^*$ ,  $i \neq i'$  will appear in  $Z_s$  independently with probability  $\frac{1}{k\beta}$ . Also, given  $T$ , for every  $i \in S^*$ , the probability to appear in  $Z_s$  is equal for all slots  $s$  in window  $w$ . Further, each  $i \in S^*$  occurs in  $Z_s$  for at most one slot  $s$ .

**Proof.** First consider  $i \in S^* \cap \text{Supp}(T)$ . Then,  $\Pr(i \in Z_s | T) = \frac{\alpha}{k} \times \frac{1}{\alpha\beta} = \frac{1}{k\beta}$  by construction. Also, the event  $i \in Z_s | T$  is independent from  $i' \in Z_s | T$  for any  $i' \in S^*$  as  $i$  and  $i'$  are independently assigned to a  $Z_s$  in construction. Further, items in  $S^* \cap \text{Supp}(T)$  are assigned with equal probability to slots in window  $w$ .

Now, consider  $i \in S^*$ ,  $i \notin \text{Supp}(T)$ . Then, for all slots  $s$  in window  $w$ ,

$$\Pr(i \in Z_s | T) = \Pr(Y_i = s | T) \frac{1}{p_{is} k\beta} = p_{is} \times \frac{1}{p_{is} k\beta} = \frac{1}{k\beta},$$

where  $p_{is}$  is defined in (6). We used that  $p_{is} = \Pr(Y_i = s | T)$  for  $i \notin \text{Supp}(T)$ . Independence of events  $i \in Z_s | T$  for items in  $S^* \setminus \text{Supp}(T)$  follows from Lemma 16, which ensures  $Y_i = s | T$  and  $Y_j = s' | T$  are independent for  $i \neq j$ ; and from independent selection among items with  $Y_i = s$  into  $Z_s$ .

The fact that every  $i \in S^*$  occurs in at most one  $Z_s$  follows from construction:  $i$  is assigned to  $Z_s$  of only one slot if  $i \in \text{Supp}(T)$ ; and for  $i \notin \text{Supp}(T)$ , it can only appear in  $Z_s$  if  $i$  appears in slot  $s$ . ◀

► **Lemma 19.** Given the sequence  $\tilde{\tau}_w = (s_1, \dots, s_t)$  defined in Definition 17, let  $\gamma(\tilde{\tau}_s) = (i_1, \dots, i_t)$ , with  $\gamma(\cdot)$  as defined in (1). Then, for all  $j = 1, \dots, t$ ,

$$\begin{aligned} & \mathbb{E}[\Delta_f(i_j | S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\}) | T_{1, \dots, w-1}, i_1, \dots, i_{j-1}] \\ & \geq \frac{1}{k} \left( \left(1 - \frac{\alpha}{k}\right) f(S^*) - f(S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\}) \right). \end{aligned}$$

**Proof.** For any slot  $s'$  in window  $w$ , let  $\{s : s \succ_w s'\}$  denote all the slots that appear after  $s'$  in the sequence of slots in window  $w$ .

Now, using Lemma 18, for any slot  $s$  such that  $s \succ_w s_{j-1}$ , we have that the random variables  $\mathbf{1}(i \in Z_s | Z_{s_1} \cup \dots \cup Z_{s_{j-1}})$  are i.i.d. for all  $i \in S^* \setminus \{Z_{s_1} \cup \dots \cup Z_{s_{j-1}}\}$ . Next, we show that the probabilities  $\Pr(i \in Z_{s_j} | Z_{s_1} \cup \dots \cup Z_{s_{j-1}})$  are identical for all  $i \in S^* \setminus \{Z_{s_1} \cup \dots \cup Z_{s_{j-1}}\}$ :

$$\begin{aligned} & \Pr(i \in Z_{s_j} | Z_{s_1} \cup \dots \cup Z_{s_{j-1}}) \\ &= \sum_{s: s \succ_w s_{j-1}} \Pr(i \in Z_s, s = s_j | Z_{s_1} \cup \dots \cup Z_{s_{j-1}}) \\ &= \sum_{s: s \succ_w s_{j-1}} \Pr(i \in Z_s | s = s_j, Z_{s_1} \cup \dots \cup Z_{s_{j-1}}) \Pr(s = s_j | Z_{s_1} \cup \dots \cup Z_{s_{j-1}}). \end{aligned}$$

Now, from Lemma 18, the probability  $\Pr(i \in Z_s | s = s_j, Z_{s_1} \cup \dots \cup Z_{s_{j-1}})$  must be identical for all  $i \notin Z_{s_1} \cup \dots \cup Z_{s_{j-1}}$ . Therefore, from above we have that for all  $i, i' \in S^* \setminus \{Z_{s_1} \cup \dots \cup Z_{s_{j-1}}\}$ ,

$$\Pr(i \in Z_{s_j} | Z_{s_1} \cup \dots \cup Z_{s_{j-1}}) = \Pr(i' \in Z_{s_j} | Z_{s_1} \cup \dots \cup Z_{s_{j-1}}) \geq \frac{1}{k}. \quad (8)$$

The lower bound of  $1/k$  followed from the fact that at least one of the items from  $S^* \setminus \{Z_{s_1} \cup \dots \cup Z_{s_{j-1}}\}$  must appear in  $Z_{s_j}$  for  $s_j$  to be included in  $\tilde{\tau}_w$ . Thus, each of these probabilities is at least  $1/k$ . In other words, if an item is randomly picked from  $Z_{s_j}$ , it will be  $i$  with probability at least  $1/k$ , for all  $i \in S^* \setminus \{Z_{s_1} \cup \dots \cup Z_{s_{j-1}}\}$ .

Now, by definition of  $\gamma(\cdot)$  (refer to (1)),  $i_j$  is chosen greedily to maximize the increment  $\Delta_f(i | S_{1, \dots, w-1} \cup i_{1, \dots, s-1})$  over all  $i \in s_j \cup \text{Supp}(T_{1, \dots, w-1}) \supseteq Z_{s_j}$ . Therefore, we can lower bound the increment provided by  $i_j$  by that provided by a randomly picked item from  $Z_{s_j}$ . By using monotonicity of  $f$ ,

$$\begin{aligned} & \mathbb{E}[\Delta_f(i_j | S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\}) | T_{1, \dots, w-1} = T, i_1, \dots, i_{j-1}] \\ \text{(by (8))} & \geq \frac{1}{k} \mathbb{E} \left[ \sum_{i \in S^* \setminus \{Z_1, \dots, Z_{s_{j-1}}\}} \mathbb{E}[\Delta_f(i | S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\}) | T, i_1, \dots, i_{j-1}] \right] \\ \text{(by Lemma 7)} & \geq \frac{1}{k} \mathbb{E} [ (f(S^* \setminus \{Z_1, \dots, Z_{s_{j-1}}\}) - f(S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\})) | T ] \\ & \geq \frac{1}{k} \mathbb{E} [ (f(S^* \setminus \cup_{s' \in w} Z_{s'}) - f(S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\})) | T ] \\ \text{(by Lemma 18 and 8)} & \geq \frac{1}{k} \left( \left(1 - \frac{\alpha}{k}\right) f(S^*) - f(S_{1, \dots, w-1} \cup \{i_1, \dots, i_{j-1}\}) \right) \end{aligned}$$

The last inequality uses the observation from Lemma 18 that given  $T$ , every  $i \in S^*$  appears in  $\cup_{s' \in w} Z_{s'}$  independently with probability  $\alpha/k$ , so that every  $i \in S^*$  appears in  $S^* \setminus \cup_{s' \in w} Z_{s'}$  independently with probability  $1 - \frac{\alpha}{k}$ ; along with Lemma 8 for submodular function  $f$ .  $\blacktriangleleft$

Using standard techniques for the analysis of greedy algorithm, the following corollary of the previous lemma can be derived: given any  $T_{1, \dots, w-1} = T$ :

**► Lemma 20.**

$$\mathbb{E} \left[ \left(1 - \frac{\alpha}{k}\right) f(S^*) - f(S_{1, \dots, w-1} \cup \gamma(\tilde{\tau}_w)) | T \right] \leq \mathbb{E} \left[ e^{-\frac{|\tilde{\tau}_w|}{k}} | T \right] \left( \left(1 - \frac{\alpha}{k}\right) f(S^*) - f(S_{1, \dots, w-1}) \right).$$

**Proof.** Let  $\pi_0 = (1 - \frac{\alpha}{k})f(S^*) - \mathbb{E}[f(S_{1, \dots, w-1}) | T_{1, \dots, w-1} = T]$ , and for  $j \geq 1$ ,

$$\pi_j := \left(1 - \frac{\alpha}{k}\right) f(S^*) - \mathbb{E}[f(S_{1, \dots, w-1} \cup \{i_1, \dots, i_j\}) | T_{1, \dots, w-1} = T, i_1, \dots, i_{j-1}],$$

Then, subtracting and adding  $(1 - \frac{\alpha}{k})f(S^*)$  from the left hand side of the previous lemma, and taking expectation conditional on  $T_{1, \dots, w-1} = T, i_1, \dots, i_{j-2}$ , we get

$$-\mathbb{E}[\pi_j | T, i_1, \dots, i_{j-2}] + \pi_{j-1} \geq \frac{1}{k} \pi_{j-1}$$

## 1:14 Submodular Secretary Problem with Shortlists

which implies

$$\mathbb{E}[\pi_j | T, i_1, \dots, i_{j-2}] \leq \left(1 - \frac{1}{k}\right) \pi_{j-1} \leq \left(1 - \frac{1}{k}\right)^j \pi_0 .$$

By the martingale stopping theorem, this implies:

$$\mathbb{E}[\pi_t | T] \leq \mathbb{E} \left[ \left(1 - \frac{1}{k}\right)^t | T \right] \pi_0 \leq \mathbb{E} [e^{-t/k} | T] \pi_0$$

where stopping time  $t = |\tilde{\tau}_w|$ . ( $t = |\tilde{\tau}_w| \leq \alpha\beta$  is bounded, therefore, the martingale stopping theorem can be applied). ◀

Next, we compare  $\gamma(\tilde{\tau}_w)$  to  $S_w = \gamma(\tau^*)$ . Here,  $\tau^*$  was defined as the ‘best’ greedy subsequence of length  $\alpha$  (refer to (4) and (5)). To compare it with  $\tilde{\tau}_w$ , we need a bound on size of  $\tilde{\tau}_w$ .

► **Lemma 21.** *For any real  $\delta \in (0, 1)$ , and if  $k \geq \alpha\beta$ ,  $\alpha \geq 8 \log(\beta)$  and  $\beta \geq 8$ , then given any  $T_{1, \dots, w-1} = T$ ,*

$$(1 - \delta) \left(1 - \frac{4}{\beta}\right) \alpha \leq |\tilde{\tau}_w| \leq (1 + \delta) \alpha,$$

with probability at least  $1 - \exp(-\frac{\delta^2 \alpha}{8\beta})$ .

**Proof.** Appears in the full version. ◀

► **Lemma 22 (Corollary of Lemma 21).** *For any real  $\delta' \in (0, 1)$ , if parameters  $k, \alpha, \beta$  satisfy  $k \geq \alpha\beta$ ,  $\beta \geq \frac{8}{(\delta')^2}$ ,  $\alpha \geq 8\beta^2 \log(1/\delta')$ , then given any  $T_{1, \dots, w-1} = T$ , with probability at least  $1 - \delta' e^{-\alpha/k}$ ,*

$$|\tilde{\tau}_w| \geq (1 - \delta') \alpha .$$

► **Lemma 23.** *For any real  $\delta' \in (0, 1)$ , if parameters  $k, \alpha, \beta$  satisfy  $k \geq \alpha\beta$ ,  $\beta \geq \frac{8}{(\delta')^2}$ ,  $\alpha \geq 8\beta^2 \log(1/\delta')$ , then*

$$\mathbb{E} \left[ \frac{k - \alpha}{k} OPT - f(S_{1, \dots, w}) | T_{1, \dots, w-1} \right] \leq (1 - \delta') e^{-\alpha/k} \left( \frac{k - \alpha}{k} OPT - f(S_{1, \dots, w-1}) \right) .$$

**Proof.** The lemma follows from substituting Lemma 22 in Lemma 20. ◀

Now, we can deduce the following proposition.

► **Proposition 24.** *For any real  $\delta' \in (0, 1)$ , if parameters  $k, \alpha, \beta$  satisfy  $k \geq \alpha\beta$ ,  $\beta \geq \frac{8}{(\delta')^2}$ ,  $\alpha \geq 8\beta^2 \log(1/\delta')$ , then the set  $S_{1, \dots, W}$  tracked by Algorithm 2 satisfies*

$$\mathbb{E}[f(S_{1, \dots, W})] \geq (1 - \delta')^2 (1 - 1/e) OPT.$$

**Proof.** By multiplying the inequality Lemma 23 from  $w = 1, \dots, W$ , where  $W = k/\alpha$ , we get

$$\mathbb{E}[f(S_{1, \dots, W})] \geq (1 - \delta') (1 - 1/e) \left(1 - \frac{\alpha}{k}\right) OPT.$$

Then, using  $1 - \frac{\alpha}{k} \geq 1 - \delta'$  because  $k \geq \alpha\beta \geq \frac{\alpha}{\delta'}$ , we obtain the desired statement. ◀

### 3.4 Bounding $\mathbb{E}[f(A^*)]/OPT$

Here, we compare  $f(S_{1, \dots, W})$  to  $f(A^*)$ , where  $A^* = S_{1, \dots, W} \cap A$ , with  $A$  being the shortlist returned by Algorithm 2. The main difference between the two sets is that in construction of shortlist  $A$ , Algorithm 1 is being used to compute the argmax in the definition of  $\gamma(\tau)$ , in an online manner. This argmax may not be computed exactly, so that some items from  $S_{1, \dots, W}$  may not be part of the shortlist  $A$ . We use the following guarantee for Algorithm 1 to bound the probability of this event.

► **Proposition 25.** *For any  $\delta \in (0, 1)$ , and input  $I = (a_1, \dots, a_N)$ , Algorithm 1 returns  $A^* = \max(a_1, \dots, a_N)$  with probability  $(1 - \delta)$ .*

The proof of the above proposition appears in the full version. Intuitively, it follows from the observation that if we select every item that improves the maximum of items seen so far, we would have selected  $\log(N)$  items in expectation. The exact proof involves showing that on waiting  $n\delta/2$  steps and then selecting maximum of every item that improves the maximum of items seen so far, we miss the maximum item with at most  $\delta$  probability, and select at most  $O(\log(1/\delta))$  items with probability  $1 - \delta$ .

► **Lemma 26.** *Let  $A$  be the shortlist returned by Algorithm 2, and  $\delta$  is the parameter used to call Algorithm 1 in Algorithm 2. Then, for given configuration  $Y$ , for any item  $a$  and window  $w$ , we have*

$$\Pr(a \in A | Y, a \in S_{1, \dots, w}) \geq 1 - \delta.$$

**Proof.** From Lemma 14 by conditioning on  $Y$ , the set  $S_{1, \dots, w}$  is determined. Now if  $a \in S_{1, \dots, w}$ , then for some slot  $s_j$  in an  $\alpha$  length subsequence  $\tau$  of some window  $w$ , we must have

$$a = \arg \max_{i \in s_j \cup R_{1, \dots, w-1}} f(S_{1, \dots, w-1} \cup \gamma(\tau) \cup \{i\}) - f(S_{1, \dots, w-1} \cup \gamma(\tau)).$$

Let  $w'$  be the first such window,  $\tau', s_{j'}$  be the corresponding subsequence and slot. Then, it must be true that

$$a = \arg \max_{i \in s_{j'}} f(S_{1, \dots, w'-1} \cup \gamma(\tau') \cup \{i\}) - f(S_{1, \dots, w'-1} \cup \gamma(\tau')).$$

(Note that the argmax in above is not defined on  $R_{1, \dots, w'-1}$ ). The configuration  $Y$  only determines the set of items in the items in slot  $s_{j'}$ , the items in  $s_{j'}$  are still randomly ordered (refer to Lemma 14). Therefore, from Proposition 25, with probability  $1 - \delta$ ,  $a$  will be added to the shortlist  $A_{j'}(\tau')$  by Algorithm 1. Thus  $a \in A \supseteq A_{j'}(\tau')$  with probability at least  $1 - \delta$ . ◀

► **Proposition 27.**

$$\mathbb{E}[f(A^*)] := \mathbb{E}[f(S_{1, \dots, w} \cap A)] \geq (1 - \frac{\epsilon}{2})\mathbb{E}[f(S_{1, \dots, w})]$$

where  $A^* := S_{1, \dots, w} \cap A$  is the size  $k$  subset of shortlist  $A$  returned by Algorithm 2.

**Proof.** From the previous lemma, given any configuration  $Y$ , we have that each item of  $S_{1, \dots, w}$  is in  $A$  with probability at least  $1 - \delta$ , where  $\delta = \epsilon/2$  in Algorithm 2. Therefore using Lemma 8, the expected value of  $f(S_{1, \dots, w} \cap A)$  is at least  $(1 - \delta)\mathbb{E}[f(S_{1, \dots, w})]$ . ◀

## Proof of Theorem 1

Now, we can show that Algorithm 2 provides the results claimed in Theorem 1 for appropriate settings of  $\alpha, \beta$  in terms of  $\epsilon$ . Specifically for  $\delta' = \epsilon/4$ , set  $\alpha, \beta$  as smallest integers satisfying  $\beta \geq \frac{8}{(\delta')^2}, \alpha \geq 8\beta^2 \log(1/\delta')$ . Then, using Proposition 24 and Proposition 27, for  $k \geq \alpha\beta$  we obtain:

$$\mathbb{E}[f(A^*)] \geq (1 - \frac{\epsilon}{2})(1 - \delta')^2(1 - 1/e)\text{OPT} \geq (1 - \epsilon)(1 - 1/e)\text{OPT}.$$

This implies a lower bound of  $1 - \epsilon - 1/e - \alpha\beta/k = 1 - \epsilon - 1/e - O(1/k)$  on the competitive ratio. The  $O(k)$  bound on the size of the shortlist was demonstrated in Proposition 6.

## 4 Streaming (Proof of Theorem 2)

In this section, we show that Algorithm 2 can be implemented in a way that it uses a memory buffer of size at most  $\eta(k) = O(k)$ ; and the number of objective function evaluations for each arriving item is  $O(1 + \frac{k^2}{n})$ . This will allow us to obtain Theorem 2 as a corollary of Theorem 1.

In the current description of Algorithm 2, there are several steps in which the algorithm potentially needs to store  $O(n)$  previously seen items in order to compute the relevant quantities. First, in Step 6, in order to be able to compute  $\gamma(\tau)$  for all less than  $\alpha$  length subsequences  $\tau$  of slots  $s_1, \dots, s_{j-1}$ , the algorithm should have stored all the items that arrived in the slots  $s_1, \dots, s_{j-1}$ . However, this

memory requirement can be reduced by a small modification of the algorithm, so that at the end of iteration  $j - 1$ , the algorithm has already computed  $\gamma(\tau)$  for all such  $\tau$ , and stored them to be used in iteration  $j$ . In fact, this can be implemented in a memory efficient manner, in the following way. For every subsequence  $\tau$  of slots  $s_1, \dots, s_{j-1}$  of length  $< \alpha$ , consider prefix  $\tau' = \tau \setminus s_{j-1}$ . Assume  $\gamma(\tau')$  is available from iteration  $j - 2$ . If  $\tau' = \tau$ , then  $\gamma(\tau) = \gamma(\tau')$ . Otherwise, in Step 6 of iteration  $j - 1$ , the algorithm must have considered the subsequence  $\tau'$  while going through all subsequences of length less than  $\alpha$  of slots  $s_1, \dots, s_{j-2}$ . Now, modify the implementation of Step 6 so that the algorithm also tracks the (true) maximum  $M_{j-1}(\tau')$  of  $a_0, a_1, \dots, a_N$  for each  $\tau'$ . Then,  $\gamma(\tau)$  can be obtained by extending  $\gamma(\tau')$  by  $M_{j-1}(\tau')$ , i.e.,  $\gamma(\tau) = \{\gamma(\tau'), M_{j-1}(\tau')\}$ . Thus, at the end of iteration  $j - 1$ ,  $\gamma(\tau)$  would have been computed for all subsequences  $\tau$  relevant for iteration  $j$ , and so on. In order to store these  $\gamma(\tau)$  for every subsequence  $\tau$  (of at most  $\alpha$  slots from  $\alpha\beta$  slots), we require a memory buffer of size at most  $\alpha^2 \binom{\alpha\beta}{\alpha} = O(1)$ .

Secondly, across windows and slots, the algorithm keeps track of  $R_w, S_w, w = 1, \dots, k/\alpha$  where  $W = k/\alpha$ . In the current description of Algorithm 2, these sets are computed after seeing all the items in window  $w$  in Step 9. Thus, all the items arriving in that window would be needed to be stored in order to compute them, requiring  $O(n)$  memory buffer. However, the alternate implementation discussed in the previous paragraph reduces this memory requirement to  $O(k)$  as well. Using the above implementation, at the end of iteration  $\alpha\beta$  for the last slot  $s_{\alpha\beta}$  in window  $w$ , we would have computed and stored  $\gamma(\tau)$  for all the subsequences  $\tau$  of length  $\alpha$  of slots  $s_1, \dots, s_{\alpha\beta}$ .  $R_w$  is simply defined as union of all items in  $\gamma(\tau)$  over all such  $\tau$  (refer to (3)). And,  $S_w = \gamma(\tau^*)$  for the best subsequence  $\tau^*$  among these subsequences (refer to (4)). Thus, computing  $R_w$  and  $S_w$  does not require any additional memory buffer. Storing  $R_w$  and  $S_w$  for all windows requires a buffer of size at most  $\sum_w |R_w| + |S_w| = \frac{k}{\alpha} \times \alpha \binom{\alpha\beta}{\alpha} + k = O(k)$ . Therefore, the total buffer required to implement Algorithm 2 is of size  $O(k)$ .

Finally, let's bound the number of objective function evaluations for each arriving item. Each arriving item is processed in Step 6, where objective function is evaluated twice for each subsequence to compute the corresponding  $a_i$ . Since there are at most  $\binom{\alpha\beta}{\alpha}$  subsequences  $\tau$  for which this quantity is computed, the total number of times this computation is performed is bounded by  $2 \binom{\alpha\beta}{\alpha} = O(1)$ . For each  $\tau$ , we also compute  $a_0$  in the beginning of the slot. Computing  $a_0$  for each  $\tau$  involves taking max over all items in  $R_{1, \dots, w-1}$ , and requires  $2|R_{1, \dots, w-1}| \leq 2k \binom{\alpha\beta}{\alpha}$  evaluations of the objective function. Due to this computation, in the worst-case, the update time for an item can be  $2k \binom{\alpha\beta}{\alpha}^2 + 2 \binom{\alpha\beta}{\alpha} = O(k)$ . However, since  $a_0$  is computed *once* in the beginning of the slot for each  $\tau$ , the total update time over all items is bounded by  $2k \binom{\alpha\beta}{\alpha}^2 \times k\beta + \binom{\alpha\beta}{\alpha} \times n = O(k^2 + n)$ . Therefore the amortized update time for each item is  $O(1 + \frac{k^2}{n})$ . This concludes the proof of Theorem 2.

## 5 Impossibility Result (Proof of Theorem 3)

In this section we provide an upper bound showing the following:

► **Theorem 3.** *No online algorithm (even with unlimited computational power) can achieve a competitive ratio better than  $7/8 + o(1)$  for the submodular  $k$ -secretary problem with shortlists, while using a shortlist of size  $\eta(k) = o(n)$ .*

In the following proof, for simplicity of notation, we prove the desired bound for submodular  $(k + 1)$ -secretary problem. For any given  $n, k$ , we construct a set of instances of the submodular  $(k + 1)$ -secretary problem with shortlists such that any online algorithm that uses a shortlist of size  $\eta(k + 1)$  will have competitive ratio of at most  $\frac{7}{8} + \frac{\eta(k+1)}{2n}$  on a randomly selected instance from this set.

First, we define a monotone submodular function  $f$  as follows. The ground set consists of  $\frac{n}{2k} + n - 1$  items. There are two types of items,  $C$  and  $D$ , with  $L := n/2k$  items of type  $C$  and  $n - 1$  items of type  $D$ . We define  $f(\phi) := 0$ ,  $f(\{c\}) := k$  for  $c \in C$ , and  $f(\{d\}) := 1$  for all  $d \in D$ . Also there is a collection of  $L$  disjoint sets  $T_\ell = \{c^\ell, d_1^\ell, \dots, d_k^\ell\}$ ,  $\ell = 1, 2, \dots, L$ , such that  $c^\ell \in C$  and  $d_j^\ell \in D$ . We define  $f(T_\ell) := 2k$  for all  $\ell = 1, \dots, L$ . Now, let

$$g(t) := k + \frac{k}{2} + \dots + \frac{k}{2^{i-1}} + \frac{(t - ik)}{2^i},$$

where  $i = \lfloor t/k \rfloor$ . It is easy to see that  $g$  is a monotone submodular function.

Now, define  $f$  on the remaining subsets of the ground set as follows. For all  $S$  with  $|S| \geq 1$ ,

- $|S \cap C| \geq 2 \implies f(S) := 2k + 1$
- $|S \cap C| = 0 \implies f(S) := 1 + g(|S| - 1)$
- $|S \cap C| = 1 \implies S \cap C = \{c^\ell\}$  for some  $\ell \in [L] \implies$

$$f(S) := \min\{2k + 1, k + \frac{1}{2}g(|S| - 1) + \frac{k'}{2^{i+1}}\},$$

where  $k' = |S \cap \{d_1^\ell, \dots, d_k^\ell\}|$ ,  $i = \lfloor (|S| - 1)/k \rfloor$ .

Observe that since  $g(k) = k$ , for any such subset  $S$  of size at most  $k + 1$ , we have  $f(S) \leq k + \frac{k}{2} + \frac{k}{2} = 2k$ .

► **Lemma 28.**  *$f$  is a monotone submodular function.*

Now, denote  $D^\ell := T^\ell \cap D = \{d_1^\ell, \dots, d_k^\ell\}$  for  $\ell = 1, 2, \dots, L$ . Also, let  $D' = D \setminus (\bigcup_{\ell=1}^L D^\ell)$ . Now define  $L$  input instances  $\{I_\ell\}_{\ell=1, \dots, L}$ , each of size  $n$ , as follows. For any arbitrary subset  $\bar{D} \subseteq D'$  of size  $n - Lk - 1$ , define  $I_\ell = \bigcup_{i=1, \dots, L} D^i \cup \bar{D} \cup \{c^\ell\}$ , for  $\ell = 1, \dots, L$ . Thus, for instance  $I_\ell$ , the the optimal  $k + 1$  subset is  $T^\ell$  with value  $f(T^\ell) = 2k$ .

Now consider any algorithm for the submodular secretary problem with shortlists and cardinality constraint  $k + 1$ . We denote by  $Alg$  the set of  $\eta(k + 1)$  items selected by the algorithm as part of the shortlist. Let  $\bar{I}$  denote an instance chosen uniformly at random from  $I_\ell, \ell = 1, \dots, L$ . Let  $\pi$  denote a random ordering of  $n$  items in  $\bar{I}$ . We denote by random variable  $(\bar{I}, \pi)$  the randomly ordered input instance to the algorithm. Also we denote by  $\bar{T}, \bar{D}$  and  $\bar{c}$ , the corresponding  $T^\ell, D^\ell$  and  $c^\ell$ .

Now we claim

► **Lemma 29.**  $\mathbb{E}_{(\bar{I}, \pi)}[|Alg \cap \bar{D}|] \leq k/2 + \eta(k + 1)/L$ .

**Proof.** Appears in the full version [1]. ◀

Now on input  $\bar{I}$ , if the algorithm doesn't select  $\bar{c}$  as part of shortlist  $Alg$ , then by definition of  $f$  for sets that do not contain any item of type  $C$ , we have

$$f(A^*) := \max_{S \subseteq Alg: |S| \leq k+1} f(S) \leq 1 + g(k) < k + 2.$$

Otherwise, if algorithm selects  $\bar{c}$ , then by definition of  $f$ ,

$$f(A^*) := \max_{S \subseteq Alg: |S| \leq k+1} f(S) \leq \max_{S \subseteq Alg \setminus (\bar{D} \cup \{\bar{c}\}): |S| \leq k - |Alg \cap \bar{D}|} f(S \cup \bar{D} \cup \{\bar{c}\}) = k + \frac{k}{2} + \frac{1}{2}|Alg \cap \bar{D}|,$$

and therefore by lemma 29

$$\mathbb{E}[f(A^*)] \leq k + \frac{k}{2} + \frac{k}{4} + \frac{\eta(k + 1)}{2L} = \frac{7k}{4} + \frac{k\eta(k + 1)}{n}.$$

Since the optimal is equal to  $\mathbb{E}[f(\bar{T})] = 2k$ , the competitive ratio is upper bounded by

$$\frac{7}{8} + \frac{\eta(k + 1)}{2n}.$$

This proves a competitive ratio upper bound of  $\frac{7}{8} + o(1)$  when  $\eta(k + 1) = o(n)$ , to complete the proof of Theorem 3.

## Abstract

Analog quantum simulation – simulation of one Hamiltonian by another – is one of the major goals in the noisy intermediate-scale quantum computation (NISQ) era, and has many applications in quantum complexity. We initiate the rigorous study of the physical resources required for such simulations, where we focus on the task of *Hamiltonian sparsification*. The goal is to find a simulating Hamiltonian  $\tilde{H}$  whose underlying interaction graph has bounded degree (this is called *degree-reduction*) or much fewer edges than that of the original Hamiltonian  $H$  (this is called *dilution*). We set this study in a relaxed framework for analog simulations that we call *gap-simulation*, where  $\tilde{H}$  is only required to simulate the groundstate(s) and spectral gap of  $H$  instead of its full spectrum, and we believe it is of independent interest.

Our main result is a proof that in stark contrast to the classical setting, general degree-reduction is *impossible* in the quantum world, even under our relaxed notion of gap-simulation. The impossibility proof relies on devising counterexample Hamiltonians and applying a strengthened variant of Hastings-Koma decay of correlations theorem. We also show a complementary result where degree-reduction is possible when the strength of interactions is allowed to grow polynomially. Furthermore, we prove the impossibility of the related sparsification task of generic Hamiltonian dilution, under a computational hardness assumption. We also clarify the (currently weak) implications of our results to the question of quantum PCP. Our work provides basic answers to many of the “first questions” one would ask about Hamiltonian sparsification and gap-simulation; we hope this serves as a good starting point for future research of these topics.

## 1 Introduction

A major theme in quantum computation is the idea of *analog quantum simulation*. This is the task of simulating one Hamiltonian  $H$  by another Hamiltonian  $\tilde{H}$ , which might be more readily or easily implemented. In fact, this goal was identified as a main motivation for realizing quantum computers as early as 1981 by Feynman[37], with the idea that such analog quantum simulations can shed light on properties of physical quantum systems that are hard to simulate efficiently on classical computers. Cirac and Zoller [26] further developed this idea, and explained that such simulators are likely to be achievable well before fully fault-tolerant quantum computation [4, 48, 46] becomes practical, which might take a long time. While fault-tolerant quantum computers when realized can be used to apply *digital* quantum simulations [52] (where a quantum *circuit* simulates the time-evolution  $e^{-iHt}$  under a local Hamiltonian  $H$ ), *analog* quantum simulations are more accessible for near-term experiments because they do not require full-fledged quantum computer. Many groups are designing implementations in a variety of experimental platforms[59, 19, 18, 12, 42, 38], and we have recently witnessed some experiments in intermediate-sized quantum systems in regimes where classical simulations are difficult [17, 64, 44]. It has been argued that analog quantum simulation constitutes one of the more interesting challenges in the *noisy intermediate-scale quantum computing* (NISQ) era [55].

Beyond their natural physical applications, analog simulations of Hamiltonians are also very important for quantum complexity theory. For example, in the theory of quantum NP, one is often interested in *reducing* problems defined by one class of Hamiltonians to another (e.g. [47, 8, 22, 27, 45]). These reductions are often derived using *perturbative gadgets* (e.g. [45, 54, 21, 43, 24, 25]). Moreover, analog Hamiltonian simulators might also be useful for the design of Hamiltonian-based quantum algorithms, such as adiabatic algorithm [35] and QAOA [36]. In those settings, it is often desirable to tailor the Hamiltonians being used, while maintaining the properties essential for the algorithm.

In this paper, we initiate the rigorous study of the minimal resources required to simulate a given target Hamiltonian, and ask: When can we simulate a Hamiltonian  $H$  by another  $\tilde{H}$  that is *simpler*, easier, or more economic to implement? Of course, this vaguely stated question can take several forms if made more rigorous; here we focus on a natural goal which we loosely call *Hamiltonian sparsification*, which aims to simplify the *interaction graph* of the Hamiltonian. For a 2-local  $n$ -qubit Hamiltonian  $H$ , the interaction graph has  $n$  vertices, with edges connecting any pairs of qubits that participate in a local term in  $H$ . For a  $k$ -local Hamiltonian, we consider an interaction *hypergraph*, where each term acting on  $k$  qubits is represented by a hyperedge. A generic  $k$ -local Hamiltonian has  $\Theta(n^k)$  edges, and  $\Theta(n^{k-1})$  degree per vertex. Roughly speaking, Hamiltonian sparsification aims to simulate a Hamiltonian using another whose interaction graph is more “economic”, e.g., it has less edges (we refer to this as *dilution*) or its degree is bounded (we refer to this as *degree-reduction*).

Hamiltonian sparsification has several important motivations. First, it can help physicists tackle the immense hurdles they face when trying to realize Hamiltonians in the lab. In addition, in many settings in quantum complexity, such as in the study of quantum PCP [3] and recent approaches to the area law question [7], simulating a Hamiltonian by one with constant degree or fewer edges is a potentially important primitive. Indeed, sparsification is used ubiquitously in classical computer science, in a variety of applications; we mention two important ones. The first, graph sparsification (and more generally, matrix sparsification) is a central tool in matrix algorithms [61, 62, 60, 15]. Famously, Ref. [14] proved that any graph can be replaced by another which is sparse (namely, has small degree on average),

such that their Laplacian matrices are spectrally similar. Another common application of sparsification in classical computer science is *degree-reduction* (DR), used in the study of local Constraint Satisfaction Problems (CSPs) and PCPs [32]. We believe that this natural and basic notion deserves to be studied in the quantum context as well, and might have interesting applications beyond those we can foresee today.

### 1.1 Gap-Simulations: Simulating only the low-lying part of the spectrum

Before embarking on the study of Hamiltonian sparsification, we first need an appropriate definition of analog simulation. The study of analog Hamiltonian simulation was set on rigorous footing in a recent work by Cubitt, Montanaro, and Piddock [27]; their definition refines that of Bravyi and Hastings [22], and it roughly goes as follows: A given Hamiltonian  $H$  is simulated by “encoding” its full spectrum into the low-lying part of the spectrum of  $\tilde{H}$  acting on a larger Hilbert space. When  $\tilde{H}$  is implemented, then the low-lying part of its spectrum can be used to derive properties and information about the original Hamiltonian  $H$ . For obvious reasons, we will refer to this definition as *full-spectrum simulation*. In Ref. [27], the notion of *universal* Hamiltonians was defined and studied: these are families of Hamiltonians which are capable of performing full-spectrum simulations of *any* given Hamiltonian, albeit generally with exponential overhead in energy.

While this strong notion of *full-spectrum simulation* is necessary for simulating all dynamical properties of a system, it is common in physics that one is only interested in the properties of the low-energy states and, particularly, the groundstates. In addition, the spectral gap separating the groundstates from the rest of the spectrum is an intimately related quantity that is usually physically important. For example, the groundstates encode exotic quantum behaviors such as topological order, and the spectral gap protects them [63, 50]. Also, they are used together to define quantum phases of matter and characterize phase transitions [56, 28]. Moreover, both are the main objects of interest in quantum computational complexity: In quantum adiabatic algorithms [35], the goal is to prepare a groundstate of a problem Hamiltonian, and the spectral gap governs the efficiency of the process. In quantum NP theory [8], only the groundstate(s) of the Hamiltonian matters as it is the witness for the problem. The spectral gap also determines the temperature of a thermal equilibrium (Gibbs) state that can be used to approximate the groundstate. Hence, we believe that a natural and minimal notion of analog Hamiltonian simulation, which is still meaningful for many physical contexts, should require that both the space of groundstates and the spectral gap above it be preserved.

Therefore, we suggest to consider sparsification, or more generally Hamiltonian simulation, using this minimal notion, which we formally define as *gap-simulation*. To the best of our knowledge, despite its naturalness, this relaxed notion of Hamiltonian simulation was not formally defined and rigorously studied previously in the quantum complexity literature.

A Hamiltonian  $\tilde{H}$  is said to *gap-simulate*  $H$  if it mimics the groundstate(s) and the spectral gap of  $H$ ; no constraints are imposed on the excited part of the spectrum. To provide a sensible definition requires some care, since in the quantum world we can allow inaccuracies and entanglement to an ancilla. We provide two versions of the definition: In the weaker one (Definition 3), the groundspace is mimicked *faithfully*, i.e. the *support* of any groundstate of  $\tilde{H}$ , when reduced to the original Hilbert space, is close to the groundspace of  $H$ . However, this definition does not require quantum *coherence* within the groundspace be maintained. Such coherence is guaranteed by our stronger definition (Definition 2), in which all superpositions within the groundspace are simulated. The extent to which the gap-simulation is incoherent (or unfaithful) is quantified via a small constant  $\epsilon$  (or  $\delta$ ). It

seems that the coherent notion is the “correct” one for most quantum applications, though the weaker one might also be useful in certain contexts (see Sec. 5). We mention that here, like in Ref. [22, 27], we allow encoding of the qubits. Typically, we consider “localized” encodings, though this is not explicitly required in the definition.

To set the stage, some basic results about the framework are provided: We show in Lemma 4 that for Hamiltonians with unique groundstates, our two definitions of gap-simulations coincide. Moreover, both coherent and incoherent gap-simulation definitions are shown to be stable under compositions (Lemma 6).

How does the gap-simulation framework compare with the stricter definitions of full-spectrum simulations developed in Ref. [22, 27]? In Sec. 2.1.1, this connection is discussed formally; roughly, our definition is indeed a relaxed version of full-spectrum simulations whose spectral error is smaller than the spectral gap, up to varying restrictions about encoding (Lemma 8). We choose to work here with the more relaxed definition of gap-simulation, since impossibility results for a weaker definition are of course stronger. More generally, it seems that this framework is an important and relevant one to consider in physics and quantum complexity contexts. Being less demanding, gap-simulation is likely achievable in certain cases where full-spectrum simulation is difficult or even impossible.

## 1.2 Main Results

Equipped with this framework of Hamiltonian sparsification via gap-simulations, we ask: When are sparsifications possible in the quantum world? It is conceivable that, like in the analogous classical settings mentioned above [32, 15], they ought to be always possible. The main result of in this paper (Theorem 11) shows that in stark contrast to the classical setting, both coherent and incoherent degree-reductions are not generally possible in the quantum world, even if one uses the relaxed notion of gap-simulation. This impossibility phenomenon is due to the existence of many-body entanglement in some quantum groundstates; we show, using a strengthened version of Hastings-Koma decay of correlation theorem [41], that there exist local Hamiltonians whose groundstates cannot be coherently mapped into the groundspace of a gapped Hamiltonian with constant degree and bounded interaction strength. Though one might suspect this is a consequence of degeneracy in the groundspace, we show that it holds even in the case of a unique groundstate. We believe this is a surprising and curious phenomenon, which demonstrates the richness in the subject, and highlights the difference in the resources required for classical versus quantum Hamiltonian simulation.

This impossibility result on degree-reduction is essentially tight, as we provide a complementary result (Theorem 13) based on a somewhat sophisticated application of the circuit-to-Hamiltonian construction, stating that degree-reduction becomes possible for any local Hamiltonian with non-negligible spectral gap, when polynomially large overhead in interaction strength is allowed.

We also study a related important sparsification task: dilution. While our main result of Theorem 11 is an information-theoretic result that rules out *existence* of degree-reducers regardless of computational power, we are unable to provide such a strong result in the case of dilution. Information-theoretically, we can only rule out dilution with perfect (or inverse-polynomially close to perfect) coherence (Theorem 15). Nevertheless, we are able to prove impossibility of any efficient classical algorithm to find diluters with constant unfaithfulness, for generic (even classical) Hamiltonians (Theorem 16). The proof of this theorem (relying on Ref. [29]) works under the assumption that  $\text{coNP} \not\subseteq \text{NP/poly}$  (alternatively, the polynomial hierarchy does not collapse to its third level). Although generic constructive dilution is ruled out by our Theorem 16, the question of existence of diluters for general Hamiltonian, with bounded or large interaction strengths, remains open.

The paper provides quite a few further results complementing the above-mentioned main contributions. These build on ideas in classical PCP reductions and perturbative gadgets. In addition, the ideas studied here are strongly reminiscent of questions arising in the context of the major open problem of quantum PCP [3]. We clarify this connection and provide some preliminary results along those lines.

We believe that the study of the resources required for Hamiltonian simulations in various contexts, as well as the framework of gap-simulation, are of potential deep interest for physics as well as quantum complexity. The questions raised touch upon a variety of important challenges, from quantum simulations, to algorithm design, to quantum PCP and NP reductions, to physical implementations on near-term quantum processors, and more. Their study might also shed light on questions in many-body physics, by developing tools to construct “equivalent” Hamiltonians, from the point of view of the study of groundstate physics. The discussion in Sec. 5 includes a more detailed list of some of the open questions and implications.

### 1.3 Overview

In Sec. 2, we set the stage by providing definitions of gap-simulation and sparsification, and proving basic facts about this new framework. In Sec. 3, we state our results formally. Subsequently, Sec. 4 provides elaborated and intuitive proof sketches, and Sec. 5 provides further discussion. All technical proofs are deferred to the extended version [1].

## 2 Definition of the Framework: Setting the Stage

### 2.1 Gap-Simulations of Hamiltonians

We restrict our attention to  $k$ -local Hamiltonians  $H = \sum_{i=1}^M H_i$  acting on  $n$  qudits (with internal states  $\{|0\rangle, \dots, |d-1\rangle\}$ ), where each term  $H_i$  acts nontrivially on a (distinct) subset of at most  $k$  qudits. We denote  $\lambda_j(X)$  as the  $j$ -th lowest eigenvalue of  $X$ , and  $\|X\|$  as the spectral norm of  $X$ . In addition, for any Hermitian projector  $P$ , we denote  $P^\perp \equiv \mathbb{1} - P$ , and  $|\psi\rangle \in P \iff P|\psi\rangle = |\psi\rangle$ .

► **Definition 1** (groundspace, energy spread and gap). Consider a family of  $n$ -qudit Hamiltonians  $\{H_{(n)}\}_{n=1}^\infty$ . Let  $E_n^g = \lambda_1(H_{(n)})$ , and suppose  $P_{(n)}$  is a Hermitian projector onto the subspace of eigenstates of  $H_{(n)}$  with energy  $\leq E_n^g + w_n\gamma_n$ , for some  $\gamma_n > 0$ ,  $0 \leq w_n < 1$ , such that

$$\begin{aligned} [H_{(n)}, P_{(n)}] &= 0, & \|P_{(n)}(H_{(n)} - E_n^g)P_{(n)}\| &\leq w_n\gamma_n, \\ \text{and } \lambda_j(P_{(n)}^\perp(H_{(n)} - E_n^g)P_{(n)}^\perp + \gamma_n P_{(n)}) &\geq \gamma_n & \forall j. \end{aligned} \tag{1}$$

We call the subspace onto which  $P_{(n)}$  projects a *quasi-groundspace*,  $w_n$  its *energy spread*, and  $\gamma_n$  its *quasi-spectral gap*. When we choose  $w_n = 0$  and  $\gamma_n = \min_j \{\lambda_j(H_{(n)}) - E_n^g : \lambda_j(H_{(n)}) \neq E_n^g\}$ , we call the quasi-groundspace that  $P_{(n)}$  projects onto simply *the groundspace* of  $H_{(n)}$ , and  $\gamma_n$  *the spectral gap* of  $H_{(n)}$ . Let  $w_\infty = \sup_n w_n$  and  $\gamma_\infty = \inf_n \gamma_n$ . If  $\gamma_\infty > 0$  and  $w_\infty < 1$ , we say  $\{H_{(n)}\}_{n=1}^\infty$  is *spectrally gapped*.

Below, we omit the subscript  $n$  in  $H_{(n)}$ , referring to a single  $H$ , with the usual implicit understanding that we consider families of Hamiltonians, where  $n \rightarrow \infty$ . All explicit Hamiltonians we gap-simulate here have  $w_n = 0$ , but Definition 1 is more general and allows  $w_n > 0$ , so that it can capture situations with slightly perturbed groundstates (or when simulating a larger low-energy part of the spectrum). We now define Hamiltonian gap-simulation, visualized in Fig. 1:

■ **Figure 1** Visualizing gap-simulation of Hamiltonian  $H$  with quasi-groundspace projector  $P$  by  $\tilde{H}$ . If  $\|\tilde{P} - V(P \otimes P_{\text{anc}})V^\dagger\| \leq \epsilon$ , for some isometry  $V$ , then this is a coherent gap-simulation with  $\epsilon$ -incoherence. If  $\|\tilde{P} - V(P \otimes \mathbb{1}_{\text{anc}})V^\dagger\tilde{P}\| \leq \delta$ , then this is an incoherent but faithful gap-simulation with  $\delta$ -unfaithfulness.

► **Definition 2** (gap-simulation of Hamiltonian). Let  $H$  and  $\tilde{H}$  be two Hamiltonians, defined on Hilbert spaces  $\mathcal{H}$  and  $\tilde{\mathcal{H}}$  respectively, where  $\tilde{\mathcal{H}}$ . Let  $V : \mathcal{H} \otimes \mathcal{H}_{\text{anc}} \rightarrow \tilde{\mathcal{H}}$  be an isometry ( $V^\dagger V = \mathbb{1}$ ), where  $\mathcal{H}_{\text{anc}}$  is some ancilla Hilbert space. Denote  $\tilde{E}^g \equiv \lambda_1(\tilde{H})$ . Per Definition 1, let  $P$  be a quasi-groundspace projector of  $H$ ,  $\gamma$  its quasi-spectral gap. We say that  $\tilde{H}$  *gap-simulates*  $(H, P)$  with *encoding*  $V$ , *incoherence*  $\epsilon \geq 0$  and *energy spread*  $0 \leq \tilde{w} < 1$  if the following conditions are both satisfied:

1. There exists a Hermitian projector  $\tilde{P}$  onto a subspace of eigenstates of  $\tilde{H}$  such that

$$[\tilde{H}, \tilde{P}] = 0, \quad \|\tilde{P}(\tilde{H} - \tilde{E}^g)\tilde{P}\| \leq \tilde{w}\gamma, \quad \text{and} \quad \lambda_j(\tilde{P}^\perp(\tilde{H} - \tilde{E}^g)\tilde{P}^\perp + \gamma\tilde{P}) \geq \gamma \quad \forall j. \quad (2)$$

I.e.,  $\tilde{P}$  projects onto a quasi-groundspace of  $\tilde{H}$  with quasi-spectral gap not smaller than that of  $P$  in  $H$ , and energy spread  $\tilde{w}$ .

2. There exists a Hermitian projector  $P_{\text{anc}}$  acting on  $\mathcal{H}_{\text{anc}}$ , so that

$$[\text{bounded incoherence}] \quad \|\tilde{P} - V(P \otimes P_{\text{anc}})V^\dagger\| \leq \epsilon. \quad (3)$$

When  $P$  projects onto the groundspace of  $H$ , rather than a quasi-groundspace, we usually do not mention  $P$  explicitly, and simply say that  $\tilde{H}$  *gap-simulates*  $H$ .

Requiring  $\epsilon$  from Eq. (3) be small ensures that *coherence* in the groundspace is maintained by the gap-simulation. This is illustrated by considering a Hamiltonian  $H$  with two orthogonal groundstates  $|g_1\rangle$  and  $|g_2\rangle$ . The condition of Eq. (3) essentially says that for any coherent superposition  $|g\rangle = c_1|g_1\rangle + c_2|g_2\rangle$ , and a state  $|a\rangle \in P_{\text{anc}}$  on the ancilla, there exists a groundstate of  $\tilde{H}$  that looks like  $|\tilde{g}\rangle = V(|g\rangle \otimes |a\rangle) + \mathcal{O}(\epsilon)$ . Moreover, any groundstate of  $\tilde{H}$  could be written in this form. This would preserve the expectation value of any observable in the groundspace, i.e.  $\langle g|\hat{\sigma}|g\rangle \approx \langle \tilde{g}|V\hat{\sigma}V^\dagger|\tilde{g}\rangle + \mathcal{O}(\epsilon)$ . In contrast, one can consider an alternative situation where the groundspace of a simulator  $\tilde{H}$  is spanned by states of the form  $|\tilde{g}'_i\rangle \approx V(|g_i\rangle \otimes |a_i\rangle)$ , where  $\langle a_i|a_j\rangle \ll 1$ . This situation remains interesting, as finding a groundstate  $|\tilde{g}'_i\rangle$  of  $\tilde{H}$  reveals information about a groundstate of  $H$  by decoding:  $|g_i\rangle\langle g_i| \approx \text{Tr}_{\text{anc}}(V^\dagger|\tilde{g}'_i\rangle\langle\tilde{g}'_i|V)$ . However, the coherence among groundstates is destroyed, since  $|g\rangle = |g_1\rangle + |g_2\rangle$  is mapped to  $|\tilde{g}'\rangle \approx V(|g_1\rangle \otimes |a_1\rangle + |g_2\rangle \otimes |a_2\rangle)$ , and observables such as  $\hat{\sigma} = |g_1\rangle\langle g_2|$  are not preserved:  $\langle g|\hat{\sigma}|g\rangle \not\approx \langle \tilde{g}'|V\hat{\sigma}V^\dagger|\tilde{g}'\rangle$ .

Although coherence seems important to maintain in most quantum settings, we also define *incoherent* gap-simulation, which may be relevant in some situations (see discussion in Sec. 5).

► **Definition 3** (incoherent gap-simulation). Consider two Hamiltonians  $H$  and  $\tilde{H}$ ,  $P$  a quasi-groundspace projector of  $H$ , and  $V$  some isometry in the same setting as in Definition 2. We say that  $\tilde{H}$  *incoherently gap-simulates*  $(H, P)$  with encoding  $V$ , unfaithfulness  $\delta \geq 0$  and energy spread  $0 \leq \tilde{w} < 1$  if it satisfies the first condition of Definition 2 and, instead of the second condition of Eq. (3),

$$[\text{bounded unfaithfulness}] \quad \|\tilde{P} - V(P \otimes \mathbf{1}_{\text{anc}})V^\dagger \tilde{P}\| \leq \delta. \quad (4)$$

Again, when  $P$  projects onto the groundspace of  $H$ , we simply say  $\tilde{H}$  *incoherently gap-simulates*  $H$ .

Small unfaithfulness essentially means that the *support* of the vectors in the groundspace of  $\tilde{H}$  is roughly contained in a subspace spanned by encoding the groundspace of  $H$  with some ancilla.

It is easy to see that small incoherence implies small unfaithfulness, namely  $\delta \leq 2\epsilon$  [1]. However, small unfaithfulness is a strictly weaker condition than small incoherence; we will see an example in Prop. 17. Importantly, when  $H$  has a *unique* groundstate, the two notions are equivalent up to a constant (the proof of this fact is surprisingly not trivial; see Sec. 4.2):

► **Lemma 4** (incoherent gap-simulation is coherent when groundstate is unique). *Suppose  $H$  has a unique groundstate, with groundspace projector  $P = |g\rangle\langle g|$ . If  $\tilde{H}$  incoherently gap-simulates  $H$  with unfaithfulness  $\delta < 1$ , then it also gap-simulates  $H$  with incoherence  $\epsilon \leq \sqrt{2\delta}/\sqrt{1-\delta^2}$ .*

While we do not explicitly restrict the form of encoding  $V$  in the above definitions, we need to specify them for the impossibility proofs, where we will consider localized encoding:

► **Definition 5** (localized encoding). Consider a (possibly incoherent) gap-simulation of  $H$  by  $\tilde{H}$  encoded by an isometry  $V : \mathcal{H} \otimes \mathcal{H}_{\text{anc}} \rightarrow \tilde{\mathcal{H}}$ . Let  $\mathcal{H} \otimes \mathcal{H}_{\text{anc}} = [\bigotimes_{i=1}^n (\mathcal{H}_i \otimes \mathcal{A}_i)] \otimes \mathcal{A}_E$ , where  $\mathcal{H}_i$  is the  $i$ -th qudit in  $H$ ,  $\mathcal{A}_i$  is its associated ancilla subsystem, and  $\mathcal{A}_E$  contains the remaining ancillas; also let  $\tilde{\mathcal{H}} = \bigotimes_{i=1}^m \tilde{\mathcal{H}}_i$ ,  $m \geq n$ . We say  $V$  is a *localized encoding* if either of the following is true:

1.  $V = [\bigotimes_{i=1}^n V_i] \otimes V_E$ , where  $V_i : \mathcal{H}_i \otimes \mathcal{A}_i \rightarrow \tilde{\mathcal{H}}_i$  is an isometry, and  $\tilde{\mathcal{H}}_i$  consists of  $O(1)$  qudits in  $\tilde{H}$  for  $i = 1, \dots, n$ . Also,  $V_E : \mathcal{A}_E \rightarrow \bigotimes_{i=n+1}^m \tilde{\mathcal{H}}_i$  is an isometry.
2.  $V$  is a constant-depth quantum circuit:  $V = \prod_{a=1}^D U_a$ , where  $D = O(1)$ ,  $U_a = \bigotimes_{\mu} U_{a,\mu}$ , and  $U_{a,\mu}$  is a unitary operator acting on  $O(1)$  number of qudits.

We say  $V$  is an  $\eta$ -*localized encoding* if there is a localized encoding  $V_L$  such that  $\|V - V_L\| \leq \eta$ .

In addition to constant-depth quantum circuits, any quantum error-correcting code where each logical qudit is encoded as  $O(1)$  qudits is also a localized encoding. Note it is easy to see that if a gap-simulation has  $\eta$ -localized encoding  $V$  and incoherence  $\epsilon$  (or unfaithfulness  $\delta$ ), it is also a gap-simulation with localized encoding  $V_L$  and incoherence  $\epsilon' \leq \epsilon + 2\eta$  (or unfaithfulness  $\delta' \leq \delta + 2\eta$ ). Hence, we usually restrict our attention to fully localized encoding in the remainder of the paper.

It is also fairly straightforward to show that compositions of gap-simulation behave intuitively:

► **Lemma 6** (Composition). *Suppose  $H_1$  (incoherently) gap-simulates  $(H_0, P_0)$  with encoding  $V_1$ , incoherence  $\epsilon_1$  (or unfaithfulness  $\delta_1$ ), energy spread  $\tilde{w}_1$ , and a corresponding quasi-groundspace projector  $P_1$ . Also suppose  $H_2$  (incoherently) gap-simulates  $(H_1, P_1)$  with encoding  $V_2$ , incoherence  $\epsilon_2$  (or unfaithfulness  $\delta_2$ ), and energy spread  $\tilde{w}_2$ . Then  $H_2$  (incoherently) gap-simulates  $(H_0, P_0)$  with encoding  $V_2(V_1 \otimes \mathbf{1}_{\text{anc},1})$ , incoherence  $\leq \epsilon_2 + \epsilon_1$  (or unfaithfulness  $\leq 2\delta_2 + \delta_1$ ), and energy spread  $\tilde{w}_2$ .*

### 2.1.1 Comparison of gap-simulation to full-spectrum simulation

To formally compare gap-simulations to full-spectrum simulations of Hamiltonians, we use the following well-motivated definition of full-spectrum simulation developed by Ref. [27]:

► **Definition 7** (Full-spectrum simulation, adapted from Definition 1 of [27]). A Hamiltonian  $\tilde{H}$  *full-spectrum-simulates* a Hamiltonian  $H$  to precision  $(\eta, \xi)$  below an energy cut-off  $\Delta$  if there exists an encoding  $\mathcal{E}(H) = V(H \otimes P + \bar{H} \otimes Q)V^\dagger$ , where  $V$  is an isometry,  $P$  and  $Q$  are mutually orthogonal projectors, such that

1. There exists an encoding  $\tilde{\mathcal{E}}(H) = \tilde{V}(H \otimes P + \bar{H} \otimes Q)\tilde{V}^\dagger$  such that  $\|\tilde{V} - V\| \leq \eta$  and  $\tilde{\mathcal{E}}(\mathbb{1}) = P_{\leq \Delta(\tilde{H})}$ ;
2.  $\|\tilde{H}_{\leq \Delta} - \tilde{\mathcal{E}}(H)\| \leq \xi$ .

Here,  $P_{\leq \Delta(\tilde{H})}$  projects onto eigenstates of  $\tilde{H}$  with eigenvalues  $\leq \Delta$ , and  $\tilde{H}_{\leq \Delta} = \tilde{H}P_{\leq \Delta(\tilde{H})}$ .

The appearance of  $\bar{H}$ , the complex-conjugate of  $H$ , is necessary to allow for encoding of complex Hamiltonians into real ones. Note that for any real-valued Hamiltonian  $H$ , we can simply write  $\mathcal{E}(H) = V(H \otimes P_{\text{anc}})V^\dagger$ , where  $P_{\text{anc}} = P + Q$  is a projector since  $P$  and  $Q$  are orthogonal.

In the main definition used by Ref. [27], they have also motivated a natural restriction that the encoding should be *local*. Specifically, their restriction to “local encoding” requires that  $V = \bigotimes_i V_i$  for some isometries  $V_i$  each acting on at most one qudit from  $H$ ; moreover,  $P$  and  $Q$  are locally orthogonal projectors, in the sense that there are projectors  $P_i \perp Q_i$  acting on the same qudits as  $V_i$  where  $P_i P = P$  and  $Q_i Q = Q$ . We note that our localized encodings per Definition 5 is somewhat different than this notion of “local encoding”. For example, constant-depth circuit qualifies as a localized encoding but not a “local encoding”, due to the possibility of overlaps between supports of encoded qubits (and hence  $V$  cannot be written in tensor-product form). On the other hand, Ref. [27] does not place any explicit restriction on the size of the support of each encoded qubit in their definition. Nevertheless, the specific encodings utilized for simulating general spin-Hamiltonians by universal Hamiltonians in [27] all have  $O(1)$ -sized supports, and thus also qualify as localized encodings.

It is not difficult to show that full-spectrum simulation by Definition 7 with sufficiently small precision ( $\xi \ll (1-w)\gamma$ ) implies a coherent gap-simulation by our Definition 2, if we restrict to encodings of the form  $\mathcal{E}(H) = V(H \otimes P_{\text{anc}})V^\dagger$ . This restriction of the encoding format simplifies the comparison, and has no loss of generality when considering real-valued Hamiltonians.

► **Lemma 8** (Full-spectrum simulation implies coherent gap-simulation). *Let  $H$  be a Hamiltonian that has a quasi-groundspace projector  $P$  with quasi-spectral gap  $\gamma$  and energy spread  $w \leq 1/2$ . Suppose  $\tilde{H}$  full-spectrum-simulates  $H$  to precision  $(\eta, \xi)$  according to Definition 7 with encoding  $\mathcal{E}(H) = V(H \otimes P_{\text{anc}})V^\dagger$ , such that  $\xi \leq (1-w)\gamma/8$ . Then  $\tilde{H}' = \frac{4}{3}\tilde{H}$  gap-simulates  $(H, P)$  with encoding  $V$ , incoherence  $\epsilon \leq 32\xi/\gamma + 2\eta$ , and energy spread  $\tilde{w} \leq (w + 2\xi/\gamma)/(1 - 2\xi/\gamma)$ , per Definition 2.*

## 2.2 Hamiltonian Sparsification: Degree-Reduction and Dilution

We define here the set of parameters of interest when considering minimizing resources in gap-simulations:

1.  $k$  – locality of individual Hamiltonian term; typically  $O(1)$  in physical systems, but we parametrize it to allow minimization, as well as to allow  $O(\log^a n)$ -local Hamiltonians, for some constant  $a$ .

2.  $r$  – maximum degree of Hamiltonian, the main objective in degree-reduction.
3.  $M$  – number of terms in the Hamiltonian, the main objective in dilution.
4.  $J$  – the interaction strength of individual Hamiltonian terms. This is typically restricted to  $O(1)$  in physical systems, but allowing it to grow with  $n$  leads to more possibilities of gap-simulators. Equivalently, a gap-simulator with  $J$  growing with  $n$  can be converted to one that simulates the original Hamiltonian but has a vanishing gap if we restrict to bounded-strength Hamiltonian terms.
5.  $\epsilon$  and  $\delta$  – incoherence  $\epsilon$  and unfaithfulness  $\delta$  that capture how well the Hamiltonian gap-simulates the original Hamiltonian in terms of groundspace projectors.
6.  $\tilde{w}$  – energy spread in the gap-simulator Hamiltonian; allowing it to be different from the original Hamiltonian gives more freedom in gap-simulations.

We will use the notation of  $[r, M, J]$ -gap-simulator to indicate that the maximum degree is  $r$ , the number of local terms is  $M$ , and for each term  $\tilde{H}_i$  we have  $\|\tilde{H}_i\| \leq J$ . We define:

► **Definition 9** (Degree-reduction (DR) and dilution). Let  $\tilde{H}$  be a  $k$ -local  $[r, M, J]$ -gap-simulator of  $H$  with  $\epsilon$ -incoherence (or  $\delta$ -unfaithfulness) and energy spread  $\tilde{w}$ . Additionally suppose  $H = \sum_{i=1}^{M_0} H_i$  is a sum of  $M_0 = M_0(n)$  terms, each of which is  $O(1)$ -local. Then

- We call  $\tilde{H}$  an  $[r, M, J]$ -degree-reducer of  $H$  if  $r = O(1)$ .
- We call  $\tilde{H}$  an  $[r, M, J]$ -diluter of  $H$  if  $M = o(M_0(n))$ .

We also call any degree-reducer or diluter of  $H$  a *sparsifier* of  $H$ .

### 3 Results

Our impossibility results are based on two families of 2-local  $n$  qubits Hamiltonians, which can both be expressed in terms of the collective angular momentum operator  $\mathcal{J}_\alpha = \sum_{i=1}^n \sigma_\alpha^{(i)}/2$  for  $\alpha \in \{x, y, z\}$ , where  $\sigma_\alpha^i$  are the standard Pauli matrices.

► **Example A** (degenerate groundstates).

$$H_A = \left(\mathcal{J}_z + \frac{n}{2}\right) \left(\mathcal{J}_z + \frac{n}{2} - 1\right) = \frac{1}{4} \sum_{i < j}^n (1 - \sigma_z^{(i)}) \otimes (1 - \sigma_z^{(j)}) = \sum_{i < j}^n |1\rangle\langle 1|^{(i)} \otimes |1\rangle\langle 1|^{(j)}. \quad (5)$$

There are  $M_0(n) = \frac{1}{2}n(n-1)$  terms in  $H_A$ , and each qubit has degree  $n-1$ . The terms in  $H_A$  mutually commute, and its groundspace is spanned by the following  $n+1$  zero-energy orthonormal states that have  $\mathcal{J}_z = -n/2$  or  $\mathcal{J}_z = -n/2 + 1$ :

$$GS(H_A) = \text{span}\{|00 \cdots 00\rangle, |00 \cdots 01\rangle, |00 \cdots 10\rangle, \dots, |10 \cdots 00\rangle\}. \quad (6)$$

If we consider a qubit in  $|1\rangle$  to be an “excitation,” the groundstates are states with one or zero “excitations.” Observe that  $w_n = 0$  and  $\gamma_n = 1$ , independent of  $n$ ; the system is thus spectrally gapped.

► **Example B** (unique groundstate). In this example we require that  $n$  is even,  $n = 2s$ :

$$\begin{aligned} H_B &= \mathcal{J}_z^2 - \frac{1}{2}\vec{\mathcal{J}}^2 + b_n = \frac{1}{2}(\mathcal{J}_z^2 - \mathcal{J}_x^2 - \mathcal{J}_y^2) + b_n \\ &= \frac{1}{4} \sum_{i < j}^n (\sigma_z^{(i)} \sigma_z^{(j)} - \sigma_x^{(i)} \sigma_x^{(j)} - \sigma_y^{(i)} \sigma_y^{(j)}) - \frac{n}{8} + b_n \end{aligned} \quad (7)$$

where  $b_n \equiv \frac{1}{8}n(n+2)$  is a constant chosen so that  $\lambda_1(H_B) = 0$ . Similarly to  $H_A$ , this Hamiltonian has  $M_0(n) = \frac{1}{2}n(n-1)$  2-local terms, and each qubit has degree  $n-1$ . Since  $[\tilde{\mathcal{J}}^2, \mathcal{J}_z] = 0$ , the eigenstates of  $H_B$  can be written in eigenbasis of both  $\tilde{\mathcal{J}}^2$  and  $\mathcal{J}_z$ . As  $\mathcal{J}_\alpha$  are spin- $s$  angular momentum operators,  $\mathcal{J}_z^2$  has eigenvalues  $\{0, 1, 2^2, \dots, s^2\}$  and  $\tilde{\mathcal{J}}^2$  has eigenvalues  $\{s(s+1), (s-1)s, \dots, 6, 2, 0\}$ . The groundstate of  $H_B$  is thus a state that has minimal  $\mathcal{J}_z^2 = 0$  and maximal total angular momentum  $\mathcal{J} = s = \frac{n}{2}$ . This is a unique state, which is known as a Dicke state [30]:

$$|g_B\rangle = |\mathcal{J} = \frac{n}{2}; \mathcal{J}_z = 0\rangle = \binom{n}{n/2}^{-1/2} \sum_{|\{i : x_i = 1\}| = n/2} |x_1 \cdots x_n\rangle. \quad (8)$$

where the state can be explicitly written as a symmetric superposition of all strings  $x$  with Hamming weight  $h(x) = |\{i : x_i = 1\}| = n/2$ . This groundstate  $|g_B\rangle$  has energy 0. Meanwhile, all other eigenstates must have energy at least 1. Thus, the system is spectrally gapped with energy spread  $w_n = 0$  and  $\gamma_n = 1$ .

It turns out that these deceptively simple examples form a challenge for Hamiltonian sparsification.

### 3.1 Limitations on Degree-Reduction

For didactic reasons, we start by ruling out generic *perfectly coherent* DR. This is done by showing that such DR is impossible for  $H_A$ .

► **Lemma 10** (Impossibility of generic 0-incoherence DR). *There does not exist any  $k$ -local Hamiltonian  $\tilde{H}_A$  that is an  $[o(n/k), M, J]$ -degree-reducer of the  $n$ -qubit Hamiltonian  $H_A$  with localized encoding, 0-incoherence, and energy spread  $\tilde{w} < 1/2$ , regardless of number of terms  $M$  or interaction strength  $J$ .*

A closer inspection of the proof implies a trade-off between  $\epsilon$  and  $J$ , from which it follows that if  $J = O(1)$  then generic DR is impossible even if we allow  $\epsilon$  which is inverse polynomially small (see exact statement in extended version [1]). We note that this result in fact rules out any improvement of the degree for  $H_A$ , to some sub-linear degree.

However, perfect (or even inverse-polynomially close to perfect) coherence is a rather strong requirement. Indeed, by improving our proof techniques, we manage to improve our results for  $H_A$  to show impossibility even for constant coherence. Moreover, by devising another Hamiltonian with a unique groundstate,  $H_B$ , and proving such an impossibility result also for this Hamiltonian, we arrive at the following theorem. Our main result is a strong impossibility result, ruling out generic DR with *constant unfaithfulness* (and consequently, also constant incoherence).

► **Theorem 11** (Main: Impossibility of constant coherence (faithfulness) DR for  $H_A$  ( $H_B$ )). *For sufficiently small constants  $\epsilon \geq 0$  ( $\delta \geq 0$ ) and  $\tilde{w} \geq 0$ , there exists system size  $n_0$  where for any  $n \geq n_0$ , there is no  $O(1)$ -local  $[O(1), M, O(1)]$ -degree-reducer of the  $n$ -qubit Hamiltonian  $H_A$  ( $H_B$ ) with localized encoding,  $\epsilon$ -incoherence ( $\delta$ -unfaithfulness), and energy spread  $\tilde{w}$ , for any number of Hamiltonian terms  $M$ .*

We deduce that generic quantum DR, with even constant unfaithfulness, is impossible. This stands in striking contrast to the classical setting. It is well known that classical DR is possible for all CSPs in the context of PCP reductions[32]. This construction easily translates to a 0-unfaithfulness degree-reducer for any *classical* local Hamiltonian:

► **Proposition 12** (Incoherent DR of classical Hamiltonians). *Consider an  $n$ -qudit  $k$ -local classical Hamiltonian  $H = \sum_{S \subset \{1, \dots, n\}} C_S$ , where each  $C_S : \{z_i : i \in S\} \rightarrow [0, 1]$  is a function of  $d$ -ary strings of length  $|S| \leq k$  representing states of qudits in  $S$ . Let the number of terms in  $H$  be  $M_0 = |\{S\}| = O(n^k)$ . Then there is a  $k$ -local  $[3, O(kM_0), O(1)]$ -degree-reducer of  $H$  with 0-unfaithfulness, energy spread  $\tilde{w} = 0$ , and trivial encoding  $V = \mathbb{1}$ .*

This demonstrates a large difference between the quantum and classical settings in the context of Hamiltonian sparsification. Characterizing which quantum Hamiltonians can be degree-reduced (with bounded interaction strength), either coherently or just faithfully, remains open.

The impossibility of DR by Theorem 11, which heavily relies on the interaction strength  $J$  being a constant, is essentially tight. We prove this in a complementary result showing that degree-reduction is possible when  $J$  is allowed to grow polynomially for any local Hamiltonian whose spectral gap closes slower than some polynomial (which is the case of interest for gap-simulation):

► **Theorem 13** (Coherent DR with polynomial interaction strength). *Suppose  $H$  is an  $O(1)$ -local Hamiltonian with a quasi-groundspace projector  $P$ , which has quasi-spectral gap  $\gamma = \Omega(1/\text{poly}(n))$  and energy spread  $w$ . Also assume  $\|H\| = O(\text{poly}(n))$ . Then for any  $\epsilon > 0$ , one can construct an  $O(1)$ -local  $[O(1), O(\text{poly}(n)/\epsilon^2), O(\text{poly}(n, \epsilon^{-1}))]$ -degree-reducer of  $H$  with incoherence  $\epsilon$ , energy spread  $w + O(1/\text{poly}(n))$ , and trivial encoding.*

The proof is constructive: we map any given Hamiltonian to the quantum phase-estimation circuit, make the circuit sparse with new ancilla qudits and swap gates, and transform it back to a Hamiltonian using Kitaev's circuit-to-Hamiltonian construction [47]. Some innovations are required to ensure coherence within the groundspace isn't destroyed. For the most general local Hamiltonian whose spectral gap may close exponentially (or possibly even faster, see e.g. [2]), we can show that coherent DR is possible with interaction strength that scales exponentially with inverse gap and incoherence:

► **Theorem 14** (Coherent DR with exponential interaction strength). *Let  $H$  be an  $n$ -qubit  $O(1)$ -local Hamiltonian with  $M_0$  terms, each with bounded norm. Suppose  $H$  has quasi-spectral gap  $\gamma$  and energy spread  $w$ . For any  $\epsilon > 0$ , one can construct a 2-local  $[O(1), O(M_0), O((\gamma\epsilon)^{-\text{poly}(n)})]$ -degree-reducer of  $H$  with incoherence  $\epsilon$ , energy spread  $w + \mathcal{O}(\epsilon)$ , and trivial encoding.*

The proof uses a construction from perturbative gadgets, and is similar to other results in the Hamiltonian simulation literature [54, 27]. Due to significantly more resource required compared to Theorem 13, this construction is only useful in situations where we want to preserve some extremely small spectral gap.

### 3.2 Limitations on Dilution

For perfect or near-perfect dilution, we can prove a similar impossibility result to Lemma 10:

► **Theorem 15** (Impossibility of generic 0-incoherence dilution). *There does not exist any  $k$ -local Hamiltonian  $\tilde{H}_A$  that is an  $[r, o(n^2/k^2), J]$ -diluter of the  $n$ -qubit Hamiltonian  $H_A$  with localized encoding, 0-incoherence, and energy spread  $\tilde{w} < 1/2$ , regardless of degree  $r$  or interaction strength  $J$ .*

Similar to Lemma 10, this in fact holds even if we allow inverse polynomial incoherence [1]; and like above, this seems to be a rather weak impossibility result since requiring inverse polynomial incoherence may be too strong in many situations. Can we strengthen this to rule

out dilution with constant incoherence? The proof technique in Theorem 11 does not apply for dilution, since it relies on the decay of correlation between *distant* nodes in the interaction graph of  $\tilde{H}$  (see Sec. 4.1). On the other hand, a diluter  $\tilde{H}$  can have unbounded degree, and hence constant diameter, e.g. the star graph. Nevertheless, under a computational hardness assumption, no efficient classical *algorithm* for generic constant-unfaithfulness dilution exists, even for all  $k$ -local *classical* Hamiltonians:

► **Theorem 16** (Impossibility of dilution algorithm for classical Hamiltonians). *If  $\text{coNP} \not\subseteq \text{NP/poly}$ , then for any  $\xi > 0$ ,  $\delta < 1/\sqrt{2}$ ,  $\tilde{w} \leq 1/2$ , there is no classical algorithm that given a  $k$ -local  $n$ -qubit classical Hamiltonian  $H$ , runs in  $O(\text{poly}(n))$  time to find an  $[r, O(n^{k-\xi}), J]$ -diluter of  $H$  with  $\delta$ -unfaithfulness, energy spread  $\tilde{w}$ , and any encoding  $V$  that has an  $O(n^{k-\xi})$ -bit description. This holds for any  $r$  and  $J$ .*

The above result rules out general (constructive) dilution even when the Hamiltonians are classical. For specific cases, however, dilution is possible. Our  $H_A$  (which is also a classical Hamiltonian) provides such an example, for which we can achieve dilution even with 0-unfaithfulness, in the incoherent setting:

► **Proposition 17** (0-unfaithfulness incoherent dilution and DR for  $H_A$ ). *There is a 3-local incoherent  $[2, n-1, 1]$ -diluter of  $H_A$  with 0-unfaithfulness, energy spread  $\tilde{w} = 0$ , and trivial encoding. This is also an incoherent  $[2, n-1, 1]$ -degree-reducer of  $H_A$ .*

Furthermore, combining ideas from the construction in Proposition 17 and Theorem 13, we can show that coherent dilution of  $H_A$  with polynomial interaction strength is also possible:

► **Proposition 18** (Coherent dilution and DR for  $H_A$  with polynomial interaction strength). *There is a 6-local  $[6, O(n/\epsilon^2), O(\text{poly}(n, \epsilon^{-1}))]$ -diluter of  $H_A$  with  $\epsilon$ -incoherence, energy spread  $\tilde{w} = 0$ , and trivial encoding. This is also a  $[6, O(n/\epsilon^2), O(\text{poly}(n, \epsilon^{-1}))]$ -degree-reducer of  $H_A$ .*

Note since Theorem 16 rules out constructive dilution regardless of interaction strength  $J$ , we cannot hope to prove an analogue of Theorem 13 or 14 to build coherent diluters for generic Hamiltonians, even allowing arbitrarily large interaction strength. Nevertheless, it remains an interesting open question to characterize Hamiltonians for which diluters exist, whether coherent or incoherent, with constant or large interaction strengths.

### 3.3 Connection to Quantum PCP

It might appear that our results rule out quantum degree-reduction (DR) in the context of quantum PCP (which would add to existing results [23, 5, 11, 20, 40, 6] ruling out quantum generalizations of other parts of Dinur’s PCP proof [32]). However, our results in this context (detailed in extended version[1]) currently have rather weak implications towards such a statement. The catch is that despite the apparent similarity, our gap-simulating DR is a very different notion from DR transformations used in the context of classical and quantum PCP. Gap-simulation seeks the *existence* of a Hamiltonian  $\tilde{H}$  that reproduces the properties of the groundstate(s) and *spectral gap* of an input Hamiltonian  $H$ . On the other hand, a qPCP reduction is an *algorithm* that given  $H$ , it is merely required to output some  $\tilde{H}$ , such that if the groundstate energy of  $H$  is small (or large), then so is the groundstate energy of  $\tilde{H}$ ; in other words, qPCP preserves the *promise gap*. Notice that such a  $\tilde{H}$  always *exists*, and the difficulty in qPCP reductions is to generate  $\tilde{H}$  efficiently, without knowing the groundstate energy of  $H$ . Thus, we cannot hope for an information-theoretical impossibility result (as in Theorem 11 and 15) in the qPCP setting without further restriction on the output.

To circumvent this issue, we generalize to the quantum world a natural requirement, which seems to hold in the classical world for all known PCP reductions, namely that the reduction is *constructive*: roughly, it implies a mapping on not only the CSPs (Hamiltonians) but also individual assignments (states) [16, 33]. Specifically, we require that the reduction from  $H$  to  $\tilde{H}$  preserves groundstate properties in the similar sense as gap-simulation does, and maps excited states of  $H$  (above the promise gap) to high-energy states  $\tilde{H}$ . Under this restriction, we prove that degree-reduction and dilution for quantum PCP with near-perfect coherence is impossible:

► **Theorem 19** (Limitation on qPCP-DR and qPCP-dilution (rough)). *There is no “constructive” qPCP reduction that works to degree-reduce or dilute the Hamiltonian  $H_A$  with localized encoding, if we require small incoherence  $\epsilon$  relative to the energy of the output Hamiltonian  $\tilde{H}_A$ , namely,  $\epsilon \leq o(\|\tilde{H}_A\|^{-1/2})$ .*

The proof of Theorem 19 approximately follows that of impossibility results of Lemma 10 and Theorem 15 for sparsification with close-to-perfect coherence. Unfortunately, as we explain in Sec. 4.1, strengthening these results to prove impossibility for constant error (the regime of interest for qPCP), as is done in Theorem 11, seems to require another new idea.

## 4 Proofs Overview

### 4.1 Proof Sketch for Main Theorem 11 (and related results: Theorem 15, 19 and Lemma 10)

We start with the idea underlying the impossibility of degree-reduction and dilution with (close to) perfect coherence (Lemma 10 and Theorem 15), which we refer to as “contradiction-by-energy”. For simplicity, let’s first examine the case of gap-simulation without encoding. Consider all pairs of original qubits  $(i, j)$ . The groundstates of  $H_A$  include basis states with zero or one excitations (namely, 1’s), but not 2-excitation states. Importantly, the groundstates can be obtained from the 2-excitation state by *local* operations  $\sigma_x^{(i)}$  and  $\sigma_x^{(j)}$ . Assuming the gap-simulator  $\tilde{H}_A$  of  $H_A$  does not interact the qubits  $(i, j)$ , we can express the energy of the 2-excitation state as a linear combination of the energy of 0- and 1-excitation states, up to an error of  $\mathcal{O}(\tilde{w})$  and  $\mathcal{O}(\epsilon\|\tilde{H}_A\|)$ , using the fact that we can commute  $\sigma_x^{(i)}$  and  $\sigma_x^{(j)}$  through independent parts of  $\tilde{H}_A$ . If we assume  $\tilde{w}$  is small and  $\epsilon = 0$ , the energy of the 2-excitation state cannot be distinguished from these groundstates. Thus any gap-simulator  $\tilde{H}_A$  must directly interact all pairs of qubits, which easily proves the impossibility without encoding. We can also see that if  $\epsilon > 0$ , then DR and dilution remain impossible if  $\|\tilde{H}_A\| \leq O(\epsilon^{-1})$ , e.g. when  $\epsilon$  is polynomially small. This impossibility easily extends to localized encoding, where each original qubit is encoded into  $O(1)$  qudits in the gap-simulator Hamiltonian either independently or via some constant-depth circuit. In both cases, the required  $\Omega(n)$  degree and  $\Omega(n^2)$  interaction terms implied for the non-encoded version translate to the same requirements for the encoded version up to a constant factor, proving Lemma 10 and Theorem 15.

We now explain the proof of Theorem 11 that rules out degree-reduction even with constant incoherence. Let us first consider the statement for  $H_A$  with constant  $\epsilon$  incoherence. The challenge is that the contradiction-by-energy trick used in the proof of Lemma 10 and Theorem 15 does not work for  $\epsilon = \Theta(1)$  incoherence. The problem is that the error in energy is of the order of  $\mathcal{O}(\epsilon\|\tilde{H}_A\|)$ ; this is too large for constant  $\epsilon$ , and does not allow one to distinguish the energy of ground and excited states. Instead of contradiction-by-energy, we derive a contradiction using the groundspace correlations between qubits  $(i, j)$ , where  $\epsilon$ -incoherence

only induces an error of  $\mathcal{O}(\epsilon)$ . Since  $H_A$  is gapped, then any degree-reducer Hamiltonian  $\tilde{H}_A$  of  $H_A$  must be gapped (while allowing some small energy spread  $\tilde{w}$ ) by Definition 2. We can therefore apply a result (strengthened to accommodate non-vanishing energy spread [1]) of Hastings-Koma [41] stating that groundspace correlation decays exponentially with the distance on the graph where  $\tilde{H}_A$  is embedded. Since we assume bounded degree, we can find a pair  $(i, j)$  among the original  $n$  qubits such that their supports  $(S_i, S_j)$  after a localized encoding are  $\Omega(\log n)$  distance apart, with respect to the graph metric. Hence, their correlation  $\langle V \sigma_x^{(i)} \sigma_x^{(j)} V^\dagger \rangle$  in the groundspace of  $\tilde{H}_A$  must decay as  $e^{-\Omega(\log n)} = O(1/\text{poly}(n))$ . Contradiction is achieved by the fact that for any pair of original qubits  $(i, j)$ , the groundspace of  $\tilde{H}_A$  contains a state of the form  $V(|0_i 1_j\rangle + |1_i 0_j\rangle) |0^{n-2}, \text{rest}\rangle + \mathcal{O}(\epsilon)$ , which has correlation at least  $\langle V \sigma_x^{(i)} \sigma_x^{(j)} V^\dagger \rangle = 1 - \mathcal{O}(\epsilon)$ . For sufficiently small  $\epsilon$  and  $\tilde{w}$ , this constant correlation from the latter lower bound contradicts the  $O(1/\text{poly}(n))$  upper bound from the Hastings-Koma result.

The second part of Theorem 11 proves impossibility of incoherent DR for  $H_B$  with  $\delta$ -unfaithfulness. Since  $H_B$  has a unique groundstate that can be shown to have constant correlation between any pair of original qubits  $(i, j)$ , we can apply the same argument above for  $H_A$  and show a contradiction with the Hastings-Koma's vanishing upper bound of  $O(1/\text{poly}(n))$  for small  $\delta$  and  $\tilde{w}$ .

We now remark how these impossibility proofs can be extended to the context of quantum PCP. The contradiction-by-energy idea in Lemma 10 and Theorem 15 can indeed be generalized in this context. Under a reasonable restriction on the reduction – namely that the energy of non-satisfying assignments (frustrated or excited states) after the mapping is lower bounded by the promise gap – degree-reduction or dilution for quantum PCP is not generally possible with close-to-perfect (namely inverse polynomial) coherence (Theorem 19). However, this impossibility proof would not work when constant incoherence is allowed. To move to contradiction-by-correlation as in Theorem 11, we need to use some form of Hastings-Koma, which requires a spectral gap in  $\tilde{H}$ . Thus, more innovation is needed as it may be an unnecessarily strong requirement for quantum PCP to preserve the spectral gap.

## 4.2 Overview of Remaining Proofs

**Proof sketch: Equivalence between coherent and incoherent gap-simulations for unique groundstates (Lemma 4).** We want to show that incoherent gap-simulation implies coherent gap-simulation, in the case of unique groundstate of the original Hamiltonian  $H$ . A naïve approach using the small error per groundstate of the gap-simulator will not work due to possible degeneracy in the groundspace of the simulator  $\tilde{H}$ ; this (possibly exponential) degeneracy could add an unwanted exponential factor. Hence, we explicitly construct the subspace on which the ancilla qubits should be projected by  $P_{\text{anc}}$ . The main observation is that since faithful gap-simulation implies that any state in the groundspace of  $\tilde{H}$  must be close to the space spanned by this  $P_{\text{anc}}$ , the dimensions of  $P_{\text{anc}}$  and the groundspace of  $\tilde{H}$  must be the same. A sequence of simple arguments then allows us to derive a bound on the incoherence of any state (i.e., its norm after the incoherence operator in Eq. (3) is applied).

**Proof sketch: DR of any classical Hamiltonian (Proposition 12).** Here we follow the standard classical DR (as in [32]) in which each variable (of degree  $d$ ) is replaced by  $d$  variables, and a ring of equality constraints on these variables is added to ensure they are the same. The proof that this satisfies our gap-simulation definition is straightforward.

**Proof sketch: Coherent DR of any Hamiltonian with  $\Omega(1/\text{poly}(n))$  spectral gap using polynomial interaction strength (Theorem 13).**

The construction is based on mapping the quantum phase estimation (PE) circuit [53] to a Hamiltonian, using a modified version of Kitaev’s circuit-to-Hamiltonian construction [47]. The PE circuit can write the energy of any eigenstate of a given  $H$  in an ancilla register, up to polynomial precision using polynomial overhead. The degree of the Hamiltonian is reduced by “sparsifying” the circuit before converting to the Hamiltonian. To repair the incoherence due to different histories, we run the circuit backwards, removing entanglement between the ancilla and the original register. To achieve  $\epsilon$ -incoherence, we add  $O(\text{poly}(n)/\epsilon^2)$  identity gates to the end of the circuit. The eigenvalue structure of the original Hamiltonian  $H$  is restored by imposing energy penalties on the energy bit-string written on the ancilla by the PE circuit. This yields a full-spectrum simulation of  $H$ , which also implies a gap-simulation of  $H$ .

**Proof sketch: Impossibility of generic dilution algorithm (Theorem 16).**

Ref. [29] shows that under the assumption  $\text{coNP} \not\subseteq \text{NP/poly}$ , there is no poly-time algorithm to “compress” vertex-cover problems on  $n$ -vertex  $k$ -uniform hypergraphs and decide the problem by communicating  $O(n^{k-\xi})$  bits for any  $\xi > 0$  to a computationally unbounded oracle. Suppose towards a contradiction that  $\mathcal{A}$  is a poly-time algorithm to dilute any  $k$ -local classical Hamiltonian; we use it to derive a compression algorithm for vertex cover. To this end,  $\mathcal{A}$  is given a classical  $k$ -local Hamiltonian  $H$  encoding a vertex cover problem;  $\mathcal{A}$  produces the diluter  $\tilde{H}$  with  $O(n^{k-2\xi})$  terms and some encoding  $V$  described by  $O(n^{k-2\xi})$  bits. Using Green’s function perturbation theory, we show that  $\tilde{H}$  can be written using only  $\log(n)$ -bit precision as  $\tilde{H}'$  with  $O(1)$  error in the quasi-groundspace (even accounting for degeneracy). We then communicate  $(\tilde{H}', V)$  to the oracle by sending  $O(n^{k-2\xi} \log n) = O(n^{k-\xi})$  bits. The oracle then uses any groundstate of  $\tilde{H}'$ , which has large overlap with groundstates of  $H$  for small  $\delta$  and high precision, to decide the vertex cover problem and transmit back the answer.

**Proof sketch: Incoherent dilution and DR of  $H_A$  (Proposition 17).**

We use here the usual translation of a classical circuit to a CSP:  $n - 1$  qubits in a tree structure are used to simulate counting of the number of 1s among the original qubits, and the CSP checks the correctness of this (local) computation. The “history” of the computation is written on the ancilla qubits. Since different strings have different such histories, the construction is incoherent.

**Proof sketch: Coherent dilution and DR of  $H_A$  with polynomial interaction strength (Proposition 18).**

We improve upon the construction in Prop. 17 and Theorem 13 to obtain a coherent diluter of  $H_A$  with polynomial interaction strength. The key is an  $O(n)$ -length circuit similar to that of Prop. 17 with a circuit that counts the number of 1s in the same tree geometry. Using the same tricks in Theorem 13 to uncompute computational histories and add identity gates at the end, we show that this leads to a coherent gap-simulator of  $H_A$  with  $\epsilon$ -incoherence and  $O(n/\epsilon^2)$  terms.

**Proof sketch: Coherent DR for any Hamiltonian using exponential or larger interaction strength (Theorem 14).**

In order to provide generic coherent degree-reduction for any local Hamiltonian without restriction on the spectral gap  $\gamma$ , we first show that perturbative gadgets [45, 54] can be used for gap-simulation. The proofs make use of Green’s function machinery to bound incoherence  $\epsilon$ , which can be made small after every application of the gadgets using interactions of strength  $O(\text{poly}(n)/(\gamma\epsilon)^{O(1)})$ . This allows us to construct a

degree-reducer for any  $k$ -local Hamiltonian by a sequence of perturbative gadget applications. In the first part of the sequence, we reduce the locality of individual Hamiltonian terms to 3-local via  $O(\log k)$  serial applications of subdivision gadgets [54], and each 3-local term is further reduced to 2-local via “3-to-2-local” gadgets [54]. Then, each original qubit is isolated from each other by subdivision gadgets so that they only interact with  $O(n^{k-1})$  ancilla qubits that mediate interactions. Finally, applying fork gadgets [54] in  $O(\log n)$  iterations allows us to reduce maximum degree of these original qubits to 6, generating our desired degree-reducer. It is this last part that causes the exponential blow-up in the interaction strength relative to  $\gamma\epsilon$ , so as to maintain the gap-simulation.

**Proof sketch: Generalized Hastings-Koma.** In Ref. [41], Hastings and Koma proved the exponential decay of correlations in the quasi-groundspace of a Hamiltonian  $H$  consisting of finite-range (or exponentially decaying) interactions between particles embedded on a graph. They assume that the system is spectrally gapped, and has vanishing energy spread as the system size  $n \rightarrow \infty$ . Their proof is based on the relationship between the correlation  $\langle \sigma^{(i)} \sigma^{(j)} \rangle$  they want to upper bound, and the commutator  $\langle [e^{-iHt} \sigma^{(i)} e^{iHt}, \sigma^{(j)}] \rangle$ . By applying the Lieb-Robinson bound [51] on the latter, and integrating out the time  $t$ , they show that under the above conditions, the correlations between operators acting on particles  $i$  and  $j$  decay exponentially with the graph-theoretic distance between the particles. For application to the gap-simulation framework, we need to generalize their result to cases where the energy spread is not assumed to vanish with the system size. This is done by a careful modification of their proofs where we optimize the bounds and integration parameters so that errors due to the non-zero energy spread are suppressed.

## 5 Discussion and outlook

We have initiated the rigorous research of resources required for analog simulations of Hamiltonians, and proved unexpected impossibility results for Hamiltonian sparsification. Instead of working with full-spectrum simulations [22, 27], we use a new, relaxed definition of gap-simulation that is motivated by minimal requirements in physics. We note that impossibility results proven in a relaxed framework are of course stronger.

It would be very interesting to improve our understanding of the new framework of gap-simulations presented here, and clarify its applicability. As a start, it will be illuminating to find applications of gap-simulations in cases where full-spectrum simulations as in Ref. [22, 27] are unknown or difficult to achieve. For example, our Prop. 18 achieves dilution of  $H_A$  with gap-simulation, but we do not know how to do so with full-spectrum simulation. Such simulations can enable experimental studies of these physical systems, by reducing resources required for analog simulations. Moreover, in many-body quantum physics, tools to construct “equivalent” Hamiltonians that preserve groundstate properties are of great utility. In this context, the study of gap-simulations can potentially lead to better understanding of universal behaviors in quantum phases of matter, which are characterized only by groundstate physics [56]. Another possible application of gap-simulators may be in the design of Hamiltonian-based quantum algorithms. In adiabatic algorithms [35], it is well known that the higher parts of the spectrum of the final and initial Hamiltonians can significantly affect the adiabatic gap [34, 31, 13]; gap-simulating these final and initial Hamiltonians by others will not affect the final groundstate, and can sometimes dramatically improve on the gap along the adiabatic path. Gap-simulations may also be a useful tool for tailoring the Hamiltonians used in other Hamiltonian-based algorithms such as QAOA [36].

We note that incoherent but faithful gap-simulations can be very interesting despite the apparent violation of the quantum requirement for coherence. For example, in adiabatic algorithms [35], we only want to arrive at one of the solutions (groundstates) to a quantum constraint satisfaction problem. In addition, in quantum NP [8], one is interested only in whether a certain eigenvalue *exists*, and not in the preservation of the entire groundspace. However, in the context of quantum simulation and many-body physics, maintaining coherence seems to be crucial for transporting all the physical properties of the groundspace. One would also expect maintaining coherence to be important when gap-simulating a subsystem (perhaps in an unknown state) of a larger system.

We remark that our framework deliberately avoids requiring that the eigenvalue structure of the spectrum be maintained even in its low-lying part, so as to provide a minimal but still interesting definition. Indeed, when simulating the groundspace, or a quasi-groundspace with small energy spread, this structure is not important. Nevertheless, one can imagine an intermediate definition, in which full-spectrum simulation is too strong, but the structure of a significant portion of the lower part of the spectrum matters. It might be interesting to extend the framework of gap-simulations to allow for such intermediate cases in which, for example, Gibbs states at low (but not extremely low) temperatures are faithfully simulated.

A plethora of open questions arise in the context of sparsification. First, it will be very interesting to find more examples where degree-reduction and/or dilution are possible, or are helpful from the perspective of physical implementations. Assuming bounded interaction strength, which is generally a limitation of physical systems, can we rigorously characterize which Hamiltonians can be coherently (or incoherently) degree-reduced? Of course, similar questions can be asked about dilution. It will also be interesting to consider saving other resources such as the dimensionality of the particles, which would be a generalization of alphabet-reductions from the context of PCP to Hamiltonian sparsification.

Our results on the impossibility of dilution are weaker than those for DR. Can we strengthen these to stronger information-theoretical results, by finding a quantum Hamiltonian for whom a diluter does not *exist* with constant incoherence, or even constant unfaithfulness?

We mention here that the classical graph sparsification results of Ref. [14, 15] can be viewed as dilution of a graph while approximately maintaining its spectrum. These results have been generalized to the matrix setting in Ref. [58]; however, this generalization does not seem to be useful in the context of diluting the interaction graph of a local Hamiltonian. The result of Ref. [58] shows that for sums of  $d \times d$  positive Hermitian matrices,  $O(d)$  matrices are sufficient to reproduce the spectral properties to good approximation, improving over Chernoff-like bounds [10]. While this in principle allows one to approximate a sum of terms by a sum of fewer terms, the required number of terms grows as  $d = 2^{\Omega(n)}$  for quantum Hamiltonians on  $n$  qubits, and is thus irrelevant in our context.

Improving the *geometry* of the simulators is another important task that is relevant for applications of Hamiltonian sparsification to physical implementations. Ref. [49] has devised a method of converting the NP-complete Ising model Hamiltonian ( $H = \sum_{ij} J_{ij} \sigma_z^{(i)} \sigma_z^{(j)} + \sum_i h_i \sigma_z^{(i)}$ ) on  $n$  qubits to a new Hamiltonian on  $O(n^2)$  qubits with interactions embedded on a 2D lattice, and sharing the same low-energy spectrum. Their construction encodes each edge  $\sigma_z^{(i)} \sigma_z^{(j)}$  as a new qubit, and corresponds to an incoherent degree-reducer, where the new groundstates are non-locally encoded version of the original states. Our Prop. 12 also provides incoherent DR of these Hamiltonians, and without encoding, but the geometry is not in 2D; it will be interesting to improve our Prop. 12 as well as our other positive Theorems 13 and 14 to hold using a spatially local  $\tilde{H}$ . We note that if we allow the overhead of polynomial interaction strength, then it should be straightforward to extend the circuit-to-Hamiltonian

construction in Theorem 13 for analog simulations of local Hamiltonians on a 2D lattice, by ordering the gates in a snake-like fashion on the lattice similar to Ref. [54, 9]. Identifying situations where DR in 2D with bounded interaction strength is possible remains an open question.

A different take on the geometry question is to seek gap-simulators which use a single (or few) ancilla qubits that strongly interact with the rest. This may be relevant for physical systems such as neutral atoms with Rydberg blockade [57], where an atom in a highly excited level may have a much larger interaction radius, while no two atoms can be excited in each other's vicinity.

Can we improve our results about quantum PCP, and show impossibility of qPCP-DR with constant incoherence? This would make our impossibility results interesting also in the qPCP context, as they would imply impossibility of DR in the qPCP regime of constant error, under a rather natural restriction on the qPCP reduction. This would complement existing impossibility results on various avenues towards qPCP [23, 5, 11, 20, 40, 6, 3]. Nevertheless, it seems that proving such a result might require a significantly further extension of Hastings-Koma, which may be of interest on its own.

Finally, we mention a possibly interesting variant of gap-simulation, which we call *weak* gap-simulation (see details in extended version[1]). Here, the groundspace is simulated in an *excited* eigenspace of the simulating Hamiltonian, spectrally gapped from above and below, rather than in its groundspace. This can be useful in the context of Floquet Hamiltonian engineering in periodically driven quantum systems, where eigenvalues are meaningful only up to a period, and thus a spectral gap in the middle of the spectrum is analogous to a spectral gap above the groundspace [39]. We are able to show how to weakly gap-simulate  $H_A$  to provide dilution with *constant* incoherence and *bounded* interaction strength – a task which we currently do not know how to do using “standard” gap-simulation. It remains open whether one can show stronger possibility results under weak gap-simulation. If not, can the impossibility results presented here be extended to the weak-gap-simulation setting? This might require an even stronger extension of Hastings-Koma's theorem.

Overall, we hope that the framework, tools, and results presented here will lead to progress in understanding the possibilities and limitations in simulating Hamiltonians by other Hamiltonians – an idea that brings the notion of *reduction* from classical computer science into the quantum realm, and constitutes one of the most important contributions of the field of quantum computational complexity to physics.

## Abstract

We study *sublinear* algorithms that solve linear systems locally. In the classical version of this problem the input is a matrix  $S \in \mathbb{R}^{n \times n}$  and a vector  $b \in \mathbb{R}^n$  in the range of  $S$ , and the goal is to output  $x \in \mathbb{R}^n$  satisfying  $Sx = b$ . For the case when the matrix  $S$  is symmetric diagonally dominant (SDD), the breakthrough algorithm of Spielman and Teng [STOC 2004] approximately solves this problem in near-linear time (in the input size which is the number of non-zeros in  $S$ ), and subsequent papers have further simplified, improved, and generalized the algorithms for this setting.

Here we focus on computing one (or a few) coordinates of  $x$ , which potentially allows for sublinear algorithms. Formally, given an index  $u \in [n]$  together with  $S$  and  $b$  as above, the goal is to output an approximation  $\hat{x}_u$  for  $x_u^*$ , where  $x^*$  is a fixed solution to  $Sx = b$ .

Our results show that there is a qualitative gap between SDD matrices and the more general class of positive semidefinite (PSD) matrices. For SDD matrices, we develop an algorithm that approximates a single coordinate  $x_u$  in time that is polylogarithmic in  $n$ , provided that  $S$  is sparse and has a small condition number (e.g., Laplacian of an expander graph). The approximation guarantee is additive  $|\hat{x}_u - x_u^*| \leq \epsilon \|x^*\|_\infty$  for accuracy parameter  $\epsilon > 0$ . We further prove that the condition-number assumption is necessary and tight.

In contrast to the SDD matrices, we prove that for certain PSD matrices  $S$ , the running time must be at least polynomial in  $n$  (for the same additive approximation), even if  $S$  has bounded sparsity and condition number.

**2012 ACM Subject Classification** Theory of computation → Streaming, sublinear and near linear time algorithms

**Keywords and phrases** Linear systems, Laplacian solver, Sublinear time, Randomized linear algebra

## 1 Introduction

Solving linear systems is a fundamental problem in many areas. A basic version of the problem has as input a matrix  $A \in \mathbb{R}^{n \times n}$  and a vector  $b \in \mathbb{R}^n$ , and the goal is to find  $x \in \mathbb{R}^n$  such that  $Ax = b$ . The fastest known algorithm for general  $A$  is by a reduction to matrix multiplication, and takes  $O(n^\omega)$  time, where  $\omega < 2.373$  [19] is the matrix multiplication exponent. When  $A$  is sparse, one can do better (by applying the conjugate gradient method to the equivalent positive semidefinite (PSD) system  $A^\top Ax = A^\top b$ , see for example [32]), namely,  $O(mn)$  time where  $m = \text{nnz}(A)$  is the number of non-zeros in  $A$ . This  $O(mn)$  bound for exact solvers assumes exact arithmetic, and in practice, one seeks fast approximate solvers.

One interesting subclass of PSD matrices is that of symmetric diagonally dominant (SDD) matrices.<sup>3</sup> Many applications require solving linear systems in SDD matrices, and most notably their subclass of graph-Laplacian matrices, see e.g. [32, 36, 14]. Solving SDD linear systems received a lot of attention in the past decade after the breakthrough result by Spielman and Teng in 2004 [31], showing that a linear system in SDD matrix  $S$  can be solved approximately in near-linear time  $O(m \log^{O(1)} n \log \frac{1}{\epsilon})$ , where  $m = \text{nnz}(S)$  and  $\epsilon > 0$  is an accuracy parameter. A series of improvements led to the state-of-the-art SDD solver of Cohen et al. [14] that runs in near-linear time  $O(m \sqrt{\log n} (\log \log n)^{O(1)} \log \frac{1}{\epsilon})$ . Recent improvements extend to connection Laplacians [24]. Obtaining similar results for all PSD matrices remains a major open question.

Motivated by fast linear-system solvers in alternative models, here we study which linear systems can be solved in *sublinear time*. We can hope for such sublinear times if only one (or a few) coordinates of the solution  $x \in \mathbb{R}^n$  are sought. Formally, given a matrix  $S \in \mathbb{R}^{n \times n}$ , a vector  $b \in \mathbb{R}^n$ , and an index  $u \in [n]$ , we want to approximate the coordinate  $x_u$  of a solution  $x \in \mathbb{R}^n$  to the linear system  $Sx = b$  (assume for now the solution is unique), and we want the running time to be *sublinear in  $n$* .

Our main contribution is a *qualitative separation* between the class of SDD matrices and the larger class of PSD matrices, as follows. For well-conditioned SDD matrices  $S$ , we develop a (randomized) algorithm that approximates a single coordinate  $x_u$  fast – in  $\text{polylog}(n)$  time. In contrast, for some well-conditioned PSD (but not SDD) matrices  $S$ , we show that the same task requires  $n^{\Omega(1)}$  time. In addition, we justify the dependence on the condition number.

Our study is partly motivated by the advent of *quantum* algorithms that solve linear systems in sublinear time, which were introduced in [20], and subsequently improved in [2, 11], and meanwhile used for a number of (quantum) machine learning algorithms (see, e.g., the survey [15]). In particular, the model in [20] considers a system  $Ax = b$  given: (1) oracle access to entries of  $A$  (including fast access to the  $j$ -th non-zero entry in the  $i$ -th row), and (2) a fast black-box procedure to prepare a quantum state  $|b\rangle = \sum_i \frac{b_i|i\rangle}{\|\sum_i b_i|i\rangle\|}$ . Then, if the matrix  $A$  has condition number  $\kappa$ , at most  $d$  non-zeros per row/column, and  $\|A\| = 1$ , their quantum algorithm runs in time  $\text{poly}(\kappa, d, 1/\epsilon)$ , and outputs a quantum state  $|\hat{x}\rangle$  within  $\ell_2$ -distance  $\epsilon$  from  $|x\rangle = \frac{\sum_i x_i|i\rangle}{\|\sum_i x_i|i\rangle\|}$ . The runtime was later improved in [11] to depend logarithmically on  $1/\epsilon$ . (The original goal of [20] was different – to output a “classical” value, a linear combination of  $|x\rangle$  – and for this goal the improved dependence on  $1/\epsilon$  is not possible unless  $BQP = PP$ .) These quantum sublinear-time algorithms raise the question whether there are analogous classical algorithms for the same problems; for example, a very recent success story is a classical algorithm [35] for a certain variant of recommendation

<sup>3</sup> A symmetric matrix  $S \in \mathbb{R}^{n \times n}$  is called SDD if  $S_{ii} \geq \sum_{j \neq i} |S_{ij}|$  for all  $i \in [n]$ .

systems, inspired by an earlier quantum algorithm [22]. Our lower bound precludes a classical analogue to the aforementioned linear-system solver, which works for all matrices  $A$  and in particular for PSD ones.

**Problem Formulation.** To formalize the problem, we need to address a common issue for linear systems – they may be underdetermined and thus have many solutions  $x$ , which is a nuisance when solving for a single coordinate. We require that the algorithm approximates a single solution  $x^*$ , in the sense that invoking the algorithm with different indices  $u \in [n]$  will output coordinates that are all consistent with one “global” solution. This formulation follows the concept of Local Computation Algorithms, see Section 1.3.

Our formal requirement is thus as follows. Given a matrix  $S \in \mathbb{R}^{n \times n}$ , a vector  $b \in \mathbb{R}^n$  in the range (column space) of  $S$ , and an accuracy parameter  $\epsilon > 0$ , there exists  $x^* \in \mathbb{R}^n$  satisfying  $Sx^* = b$ , such that upon query  $u \in [n]$  the (randomized) algorithm outputs  $\hat{x}_u$  that satisfies

$$\forall u \in [n], \quad \Pr \left[ |\hat{x}_u - x_u^*| \leq \epsilon \|x^*\|_\infty \right] \geq \frac{3}{4}. \quad (1)$$

This guarantee corresponds (modulo amplification of the success probability) to reporting a solution  $\hat{x} \in \mathbb{R}^n$  with  $\|\hat{x} - x^*\|_\infty \leq \epsilon \|x^*\|_\infty$ . We remark that the guarantee in [31] is different, that  $\|\hat{x} - x^*\|_S \leq \epsilon \|x^*\|_S$  where  $\|y\|_S \stackrel{\text{def}}{=} \sqrt{y^\top S y}$ , see also Section 1.4.

**Basic Notation.** Given a (possibly edge-weighted) undirected graph  $G = (V, E)$ , we assume for convenience  $V = [n]$ . Its Laplacian is the matrix  $L_G \stackrel{\text{def}}{=} D - A \in \mathbb{R}^{n \times n}$ , where  $A$  is the (weighted) adjacency matrix of  $G$ , and  $D$  is the diagonal matrix of (weighted) degrees in  $G$ . It is well-known that all Laplacians are SDD matrices, which in turn are always PSD.

The *sparsity* of a matrix is the maximum number of non-zero entries in a single row/column. The *condition number* of a PSD matrix  $S$ , denoted  $\kappa(S)$ , is the ratio between its largest and smallest non-zero eigenvalues.<sup>4</sup> For example, for the Laplacian  $L_G$  of a connected  $d$ -regular graph  $G$ , let  $\mu_1 \leq \dots \leq \mu_n$  denote its eigenvalues, then the condition number is  $\kappa(L_G) = \Theta(\frac{d}{\mu_2})$ . This follows from two well-known facts, that  $\mu_n \in [d, 2d]$ , and that  $\mu_2 > \mu_1 = 0$  if  $G$  is connected ( $\mu_2$  is called the spectral gap). Throughout,  $\|A\|$  denotes the spectral norm of a matrix  $A$ , and  $A^+$  denotes the Moore-Penrose pseudo-inverse of  $A$ .<sup>5</sup>

## 1.1 Our Results

Below we describe our results, which include both algorithms and lower bounds. First, we present a polylogarithmic-time algorithm for the simpler case of Laplacian matrices, and then we generalize it to all SDD matrices. We further prove two lower bounds, which show that our algorithms cannot be substantially improved to handle more general inputs or to run faster. The first lower bound shows that general PSD matrices require polynomial time, thereby showing a strong separation from the SDD case. The second one shows that our SDD algorithm’s dependence on the condition number is necessary and in fact near-tight.

<sup>4</sup> Our definition is in line with the standard one, for a general matrix  $A$ , which uses singular values instead of eigenvalues. If  $A$  is singular, one could alternatively define  $\kappa(A) = \infty$ , which would only make the problem easier (say to bound performance in terms of  $\kappa$ ), see e.g. [32].

<sup>5</sup> For a PSD matrix  $A \in \mathbb{R}^{n \times n}$ , let its eigen-decomposition be  $A = \sum_{i=1}^n \lambda_i u_i u_i^\top$ , then the Moore-Penrose pseudo-inverse of  $A$  is  $A^+ = \sum_{i: \lambda_i > 0} \frac{1}{\lambda_i} u_i u_i^\top$ .

**Algorithm for Laplacian matrices.** We first present our simpler algorithm for linear systems in Laplacians with a bounded condition number.

► **Theorem 1.1** (Laplacian Solver, see Section 2). *There exists a randomized algorithm, that given input  $\langle G, b, u, \epsilon, \bar{\kappa} \rangle$ , where*

- $G = (V, E)$  is a connected  $d$ -regular graph given as an adjacency list,
- $b \in \mathbb{R}^n$  is in the range of  $L_G$  (equivalently, orthogonal to the all-ones vector),
- $u \in [n]$ ,  $\epsilon > 0$ , and
- $\bar{\kappa} \geq 1$  is an upper bound on the condition number  $\kappa(L_G)$ ,

*the algorithm outputs  $\hat{x}_u \in \mathbb{R}$  with the following guarantee. Letting  $x^* = L_G^+ b$ , we have*

$$\forall u \in [n], \quad \Pr \left[ |\hat{x}_u - x_u^*| \leq \epsilon \cdot \|x^*\|_\infty \right] \geq 1 - \frac{1}{s},$$

*and the algorithm runs in time  $O(d\epsilon^{-2}s^3 \log s)$ , for suitable  $s = \Theta(\bar{\kappa} \log(\epsilon^{-1} \bar{\kappa} n))$ .*

A few extensions of the theorem follow easily from our proof. First, if the algorithm is given also an upper bound  $B_{up}$  on  $\|b\|_0$ , then the expression for  $s$  can be refined by replacing  $n$  with  $B_{up} \leq n$ . Second, we can improve the running time to  $O(\epsilon^{-2}s^3 \log s)$  whenever the representation of  $G$  allows to sample a uniformly random neighbor of a vertex in constant time. Third, the algorithm has an (essentially) cubic dependence on the condition number  $\kappa(L_G)$ , which can be improved to quadratic if we allow a preprocessing of  $G$  (or, equivalently if we only count the number of probes into  $b$ ). Later we show that this quadratic dependence is *near-optimal*.

**Algorithm for SDD matrices.** We further design an algorithm for SDD matrices with bounded condition number. The formal statement, which appears in Theorem 3.1, is a natural generalization of Theorem 1.1 with two differences. One difference is that a natural solution to the system  $Sx = b$  is  $x = S^+ b$ , but our method requires  $S$  to have normalized diagonal entries, and thus we aim at another solution  $x^*$ , constructed as follows. Define

$$D \stackrel{\text{def}}{=} \text{diag}(S_{11}, \dots, S_{nn}) \quad \text{and} \quad \tilde{S} \stackrel{\text{def}}{=} D^{-1/2} S D^{-1/2}, \tag{2}$$

then our linear system can be written as  $\tilde{S}(D^{1/2}x) = D^{-1/2}b$ , which has a solution

$$x^* \stackrel{\text{def}}{=} D^{-1/2} \tilde{S}^+ D^{-1/2} b, \tag{3}$$

which is expressed using the pseudo-inverse of  $\tilde{S}$  rather than of  $S$ .

A second difference is that Theorem 3.1 makes no assumptions about the multiplicity of the eigenvalue 0 of  $\tilde{S}$ , e.g., if  $S$  is a graph Laplacian, then the graph need not be connected. The assumptions needed to achieve a polylogarithmic time, beyond  $\tilde{S}$  having a bounded condition number,<sup>6</sup> are only that a random “neighbor” in the graph corresponding to  $S$  can be sampled quickly, and that  $\frac{\max_{i \in [n]} D_{ii}}{\min_{i \in [n]} D_{ii}} \leq \text{poly}(n)$ , which holds if  $S$  has polynomially-bounded entries.

**Lower Bound for PSD matrices.** Our first lower bound shows that the above guarantees cannot be obtained for a general PSD matrix, even if we are allowed to preprocess the matrix  $S$ , and only count probes into  $b$ . The proof employs a PSD matrix  $S$  that is invertible (i.e., positive definite), in which case the linear system  $Sx = b$  has a unique solution  $x = S^{-1}b$ .

---

<sup>6</sup> We cannot phrase our requirements in terms of  $\kappa(S)$ , because we are not aware of a non-trivial relationship between it and  $\kappa(\tilde{S})$ .

► **Theorem 1.2** (Lower Bound for PSD Systems, see Section 4). *For every large enough  $n$ , there exists an invertible PSD matrix  $S \in \mathbb{R}^{n \times n}$  with uniformly bounded sparsity  $d = O(1)$  and condition number  $\kappa(S) \leq 3$ , and a distinguished index  $u \in [n]$ , which satisfy the following. Every randomized algorithm that, given as input  $b \in \mathbb{R}^n$ , outputs  $\hat{x}_u$  satisfying*

$$\Pr \left[ |\hat{x}_u - x_u^*| \leq \frac{1}{5} \|x^*\|_\infty \right] \geq \frac{6}{7},$$

where  $x^* = S^{-1}b$ , must probe  $n^{\Omega(1/d^2)}$  coordinates of  $b$  (in the worst case).

**Dependence on Condition Number.** The second lower bound shows that our SDD algorithm has a *near-optimal* dependence on the condition number of  $S$ , even if we are allowed to preprocess the matrix  $S$ , and only count probes into  $b$ . The lower bound holds even for Laplacian matrices. Here and throughout, we use  $\tilde{O}(f)$  to hide polylogarithmic factors in  $f$  or in the input size, i.e., it stands for  $O(f \log^{O(1)}(f+n))$ , and similarly for  $\tilde{\Omega}(f)$ .

► **Theorem 1.3** (Lower Bound for Laplacian Systems). *For every large enough  $n$  and  $k \leq O(n^{1/2}/\log n)$ , there exist an unweighted graph  $G = ([n], E)$  with maximum degree 4 and whose Laplacian  $L_G$  has condition number  $\kappa(L_G) = O(k)$ , and a distinguished edge  $(u, v)$  in  $G$ , which satisfy the following. Every randomized algorithm that, given input  $b$  in the range of  $L_G$ , succeeds with probability  $2/3$  to approximate  $x_u - x_v$  within additive error  $\epsilon \|x^*\|$  for  $\epsilon = \Theta(1/\log n)$  and any solution  $x^* \in \mathbb{R}^n$  for  $L_G x = b$ , must probe  $\tilde{\Omega}(k^2)$  coordinates of  $b$  (in the worst case).*

The proof of this result is omitted here but appears in the full version.

**Applications.** An example application of our algorithmic results is computing the effective resistance between a pair of vertices  $u, v$  in a graph  $G$  (given  $u, v$  and  $G$  as input). It is well known that the effective resistance, denoted  $R_{\text{eff}}(u, v)$ , can be expressed as  $x_u - x_v$ , where  $x$  solves  $L_G x = e_u - e_v$ . The spectral-sparsification algorithm of Spielman and Srivastava [33] relies on a near-linear time algorithm (that they devise) for approximating the effective resistances of all edges in  $G$ . For unweighted graphs, there is also a faster algorithm [25] that runs in time  $\tilde{O}(n)$ , which is sublinear in the number of edges, and approximates effective resistances within a larger factor  $\text{polylog}(n)$ . In a  $d$ -regular expander  $G$ , it is the effective resistance of every vertex pair is  $\Theta(1/d)$ , and in this case our algorithm from Theorem 1.1 can quickly compute, for any single pair, an arbitrarily good approximation (factor  $1+\epsilon$ ). Indeed, observe that we can use  $B_{up} = 2$ , hence the running time is  $O(\frac{1}{\epsilon^2} \text{polylog}(\frac{1}{\epsilon}))$ , independently of  $n$ . The additive accuracy is  $\epsilon \|x\|_\infty$ , where  $x \in \mathbb{R}^n$  represents the vertex potentials when imposing a unit of current from  $u$  to  $v$ , or equivalently, imposing a potential difference  $R_{\text{eff}}(u, v)$  between  $u$  and  $v$ , which implies that every  $x_i \in [x_u, x_v]$ . By considering a solution with  $x_u = 0$  we get  $\|x\|_\infty = x_u - x_v = R_{\text{eff}}(u, v)$ , and thus with high probability, the output actually achieves a multiplicative guarantee  $\hat{R}_{\text{eff}}(u, v) \in (1 \pm \epsilon) R_{\text{eff}}(u, v)$ .

## 1.2 Technical Outline

**Algorithms.** Our basic technique relies on a classic idea of von Neumann and Ulam [18, 38] for estimating a matrix inverse by a power series; see Section 1.3 for a discussion of related work. Our starting point is the identity

$$\forall X \in \mathbb{R}^{n \times n}, \|X\| < 1, \quad (I - X)^{-1} = \sum_{t=0}^{\infty} X^t.$$

(Recall that  $\|X\|$  denotes the spectral norm of a matrix  $X$ .) Now given a Laplacian  $L = L_G$  of a  $d$ -regular graph  $G$ , observe that  $\frac{1}{d}L = I - \frac{1}{d}A$ , where  $A$  is the adjacency matrix of  $G$ . Assume for a moment that  $\|\frac{1}{d}A\| < 1$ ; then by the above identity,  $(\frac{1}{d}L)^{-1} = (I - \frac{1}{d}A)^{-1} = \sum_{t=0}^{\infty} (\frac{1}{d}A)^t$ , and the solution of the linear system  $Lx = b$  would be  $x^* = L^{-1}b = \frac{1}{d} \sum_{t=0}^{\infty} (\frac{1}{d}A)^t b$ . The point is that the summands decay exponentially because  $\|(\frac{1}{d}A)^t b\|_2 \leq \|(\frac{1}{d}A)^t\| \cdot \|b\|_2 \leq \|(\frac{1}{d}A)\|^t \cdot \|b\|_2$ . Therefore, we can estimate  $x_u^*$  using the first  $t_0$  terms, i.e.,  $\hat{x}_u = e_u^\top \frac{1}{d} \sum_{t=0}^{t_0} (\frac{1}{d}A)^t b$ , where  $t_0$  is logarithmic (with base  $\|\frac{1}{d}A\|^{-1} > 1$ ). In order to compute each term  $e_u^\top \frac{1}{d} (\frac{1}{d}A)^t b$ , observe that  $e_u^\top (\frac{1}{d}A)^t e_w$  is exactly the probability that a random walk of length  $t$  starting at  $u$  will end at vertex  $w$ . Thus, if we perform a random walk of length  $t$  starting at  $u$ , and let  $z$  be its (random) end vertex, then

$$\mathbb{E}[b_z] = \sum_{w \in V} e_u^\top (\frac{1}{d}A)^t e_w b_w = e_u^\top (\frac{1}{d}A)^t b.$$

If we perform several random walks (specifically,  $\text{poly}(t_0, \frac{1}{\epsilon})$  walk suffice), average the resulting  $b_z$ 's, and then multiply by  $\frac{1}{d}$ , then with high probability, we will obtain a good approximation to  $e_u^\top \frac{1}{d} (\frac{1}{d}A)^t b$ .

As a matter of fact, we have a non-strict inequality  $\|\frac{1}{d}A\| \leq 1$ , because of the all-ones vector  $\vec{1} \in \mathbb{R}^n$ . Nevertheless, we can still get a meaningful result if all eigenvalues of  $A$  except for the largest one are smaller than  $d$  (equivalently, the graph  $G$  is connected). First, we get rid of any negative eigenvalues by the standard trick of considering  $(dI + A)/2$  instead of  $A$ , which is equivalent to adding  $d$  self-loops at every vertex. Second, we may assume  $b$  is orthogonal to  $\vec{1}$  (otherwise the linear system has no solution), and while the linear system  $Lx = b$  has infinitely many solutions, we estimate the specific solution  $x^* \stackrel{\text{def}}{=} L^+ b$  (recall  $L$  is PSD) by  $\frac{1}{d} \sum_{t=0}^{t_0} (\frac{1}{d}A)^t b$ . Indeed, the idealized analysis above still applies by restricting all our calculations to the subspace orthogonal to  $\vec{1}$ . This is carried out in Theorem 1.1.

To generalize the above approach to SDD matrices, we face three issues. First, due to the irregularity of general SDD matrices, it is harder to properly define the equivalent random walk matrix. We resolve this by normalizing the SDD matrix  $S$  into  $\tilde{S}$  defined in (2), and solving the equivalent (normalized) system  $\tilde{S}(D^{1/2}x) = D^{-1/2}b$ . Second, general SDD matrices can have *positive* off-diagonal elements, in contrast to Laplacians. To address this, we interpret such entries as negative-weight edges, and employ random walks that “remember” the signs of the traversed edges. Third, diagonal elements may strictly dominate their row, which we address by terminating the random walk early with some positive probability.

**Lower Bound: Polynomial Time for PSD Matrices.** We first discuss our lower bound for PSD matrices, which is one of the main contributions of our work. It exhibits a family of matrices  $S$  for which estimating a coordinate  $x_u^*$  of the solution  $x^* = S^{-1}b$  requires  $n^{\Omega(1)}$  probes into the input  $b$ .

Without the sparsity constraint on  $S$ , one can deduce such a lower bound via a reduction from the communication complexity of the *Vector in Subspace Problem* (VSP), in which Alice has an  $n/2$ -dimensional subspace  $H \subset \mathbb{R}^n$ , Bob has a vector  $b \in \mathbb{R}^n$ , and their goal is to determine whether  $b \in H$  or  $b \in H^\perp$ . The randomized communication complexity of this promise problem is between  $\Omega(n^{1/3})$  [23] and  $O(\sqrt{n})$  [28] (while for quantum communication it is  $O(\log n)$ ). To reduce this problem to linear-system solvers, let  $P_H \in \mathbb{R}^{n \times n}$  be the projection operator onto the subspace  $H$ , and set  $S = I + P_H$ . Consider the system  $Sx = b$ , and notice that Alice knows  $S$  and Bob knows  $b$ . It is easy to see that the unique solution  $x^*$  is either  $b$  or  $\frac{1}{2}b$ , depending on whether  $b \in H^\perp$  or  $b \in H$ . Alice and Bob could use a solver that makes few probes to  $b$ , as follows. Bob would pick an index  $u \in [n]$  that maximizes

$|b_u|$  (and thus also  $|x_u|$ ), and send it to Alice. She would then apply the solver, asking Bob for only a few entries of  $b$ , to estimate  $x_u$  within additive error  $\frac{1}{2}\|x\|_\infty$ , which suffices to distinguish the two cases. This matrix  $S$  is PSD with condition number  $\kappa(S) \leq 2$ . However, it is dense.

We thus revert to a different approach of proving it from basic principles. Our high-level idea is to take a  $2d$ -regular expander and assign to its edges random signs ( $\pm 1$ ) that are balanced everywhere, namely, at every vertex the incident edges are split evenly between positive and negative. The signed adjacency matrix  $A \in \{-1, 0, +1\}^{n \times n}$  should have spectral norm  $\mu \stackrel{\text{def}}{=} \|A\| = O(\sqrt{d})$ , and then instead of the (signed) Laplacian  $L = (2d)I - A$ , we consider  $S = 2\mu I - A$ , which is PSD with condition number  $\kappa(S) \leq 3$ , as well as invertible and sparse. Now following arguments similar to our algorithm, we can write  $S^{-1}$  as a power series of the matrix  $A$ , and express coordinate  $x_u^*$  of the solution  $x^* = S^{-1}b$  via  $\mathbb{E}_z[b_z]$  where  $z$  is the (random) end vertex of a random walk that starts at  $u$  and its length is bounded by some  $t_0$  (performed in the “signed” graph corresponding to  $A$ ). Now if the graph around  $u$  looks like a tree (e.g., it has high girth), then not-too-long walks are highly symmetric and easy to count. We now let  $b_v$  be non-zero only at vertices  $v$  at distance exactly  $t_0$  from  $u$ , and for these vertices set  $b_v \in \{+1, -1\}$  at random but with a small bias  $\delta$  towards one of the values. Some calculations show that  $\text{sgn}(\mathbb{E}_z[b_z])$ , and consequently  $\text{sgn}(x_u^*)$ , will be according to our bias (with high probability), however discovering this  $\text{sgn}(x_u^*)$  via probes to  $b$  is essentially the problem of learning a biased coin, which requires  $\Omega(\delta^{-2})$  coin observations. An additional technical obstacle is to bound  $\|x^*\|_\infty$ , so that we can argue that an  $\frac{1}{5}\|x^*\|_\infty$ -additive error to  $x_u^*$  will not change its sign. Overall, we show we can set  $t_0 = \Omega(\log_d n)$  and  $\delta \approx ((2d - 1)^{t_0})^{-1/2}$ , thus concluding that the algorithm must observe  $\Omega(\delta^{-2}) = n^{\Omega(1)}$  entries of  $b$ .

It is instructive to ask where in the above argument is it crucial to have  $\mu = O(\sqrt{d})$ , because if it were valid also for  $\mu = d$ , then it would hold also for the SDD matrix  $S = 2\mu I - A$ , and contradict our own algorithm for SDD matrices. The answer is that  $\mu \ll 2d$  is required to bound  $\|x^*\|_\infty$  in Lemma 4.8.

**Lower Bound: Quadratic Dependence on Condition Number.** We now outline the ideas to prove the  $\tilde{\Omega}(\kappa^2)$  lower bound even for Laplacian systems with condition number  $\kappa$ . First, it is relatively straightforward to prove that a *linear* dependence on the condition number is necessary. Indeed, consider a dumbbell graph, namely, two 3-regular expanders connected by a bridge edge  $(u, v)$ , and suppose one need to estimate  $x_u^* - x_v^*$ . For input  $b = e_i - e_j$ , the value of  $x_u^* - x_v^*$  is non-zero iff vertices  $i, j$  are on opposite sides of the bridge, and determining the latter requires  $\Omega(n)$  probes into  $b$ . Since this graph has condition number  $O(n)$ , we obtain an  $\Omega(\kappa)$  lower bound.

The quadratic lower bound requires both a different graph and a different vector  $b$ . We use the following graph  $G$  with condition number  $O(k)$ : take two 3-regular expanders and connect them with  $n/k$  “bridge edges”. The vector  $b \in \{-1, +1\}^n$  is *dense* and in particular it is either: 1) balanced, i.e.,  $\sum b_i$  on each expander is zero; or 2) unbalanced, i.e., each  $b_i \in \{+1, -1\}$  at random with a bias  $p \approx 1/k$  towards  $+1$  on the first expander, and towards  $-1$  on the second one. Now, as above, it is simple to prove that: 1) in the balanced case, the average of  $x_u^* - x_v^*$  over all bridge edges  $(u, v)$  must be zero; and 2) in the unbalanced case, the same average must be  $\Omega(1)$ . The main challenge is that the actual values might differ from the average – e.g., even in the balanced case, each bridge edge  $(u, v)$  will likely have non-zero value of  $x_u^* - x_v^*$ . Nonetheless, we manage to prove an upper bound on the maximum value of  $|x_u^* - x_v^*|$  over all edges  $(u, v)$  (as in the previous lower bound, we need to bound  $\|x^*\|_\infty$  as well). For the latter, we need to again analyze  $\mathbb{E}_z[b_z]$  where  $z$  is the end vertex of a random walk of some fixed length  $i \geq 1$  starting from  $u$  in the graph  $G$ . Since

the vector  $b$  is not symmetric over the graph  $G$ , a direct analysis seems hard – instead we estimate  $\mathbb{E}_z[b_z]$  via a coupling of such walks in  $G$  with random walks in an expander, which is amenable to a direct analysis.

### 1.3 Related Work

The idea of approximating the inverse  $(I - X)^{-1} = \sum_{t=0}^{\infty} X^t$  (for  $\|X\| < 1$ ) by random walks dates back to von Neumann and Ulam [18, 38]. While we approximate each power  $X^t$  by separate random walks of length  $t$  and truncate the tail (powers above some  $t_0$ ), their method employs random walks whose length is random and whose expectation gives exactly the infinite sum, achieved by assigning some probability to terminate the walk at each step, and weighting the contributions of the walks accordingly (to correct the expectation).

The idea of approximating a generalized inverse  $L^*$  of  $L = dI - A$  by the truncated series  $\frac{1}{d} \sum_{t=0}^{t_0} (\frac{1}{d}A)^t$  on directions that are orthogonal to the all-ones vector was recently used by Doron, Le Gall, and Ta-Shma [16] to show that  $L^*$  can be approximated in probabilistic log-space. However, since they wanted to output  $L^*$  explicitly, they could not ignore the all-ones direction and they needed to relate  $L^*$  to  $\frac{1}{d} \sum_{t=0}^{\infty} (\frac{1}{d}A)^t$  by “peeling off” the all-ones direction, inverting using the infinite sum formula, and then adding back the all-ones direction.

The idea of estimating powers of a normalized adjacency matrix  $\frac{1}{d}A$  (or more generally, a stochastic matrix) by performing random walks is well known, and was used also in [16] mentioned above, and in [17]. Chung and Simpson [12] used it in a context that is related to ours, of solving a Laplacian system  $L_G x = b$ , but with a boundary condition, namely, a constraint that  $x_i = b_i$  for all  $i$  in the support of  $b$ . Their algorithm solves for a subset of the coordinates  $W \subseteq V$ , i.e., it approximates  $x|_W$  (the restriction of  $x$  to coordinates in  $W$ ) where  $x$  solves  $Lx = b$  under the boundary condition. They relate the solution  $x$  to the Dirichlet heat-kernel PageRank vector, which in turn is related to an infinite power series of a transition matrix (specifically, to  $f^\top e^{-t(I-P_W)} = e^{-t} f^\top \sum_{k=0}^{\infty} \frac{t^k}{k!} P_W^k$  where  $P_W$  is the transition matrix of the graph induced by  $W$ ,  $t \in \mathbb{R}$ , and  $f \in \mathbb{R}^{|W|}$ ), and their algorithm uses random walks to approximate the not-too-large powers of the transition matrix, proving that the remainder of the infinite sum is small enough.

Recently, Shyamkumar, Banerjee and Lofgren [30] considered a related matrix-power problem, where the input is a matrix  $A \in \mathbb{R}^{n \times n}$ , a power  $\ell \in \mathbb{N}$ , a vector  $z \in \mathbb{R}^n$ , and an index  $u \in [n]$ , and the goal is to compute coordinate  $u$  of  $A^\ell z$ . They devised for this problem a sublinear (in  $\text{nnz}(A)$ ) algorithm, under some bounded-norm conditions and assuming  $u \in [n]$  is uniformly random. Their algorithm relies, in part, on von Neumann and Ulam’s technique of computing matrix powers using random walks, but of prescribed length. It can be shown that approximately solving positive definite systems for a particular coordinate is reducible to the matrix-power problem.<sup>7</sup> However, in contrast to our results, their expected running time is polynomial in the input size, namely  $\text{nnz}(A)^{2/3}$ , and holds only for a random  $u \in [n]$ .

**Comparison with PageRank.** An example application of our results is computing quickly the PageRank (defined in [8]) of a single node in an undirected  $d$ -regular graph. Recall that the PageRank vector of an  $n$ -vertex graph with associated transition matrix  $P$  is the solution

<sup>7</sup> Let  $Ax = b$  be a linear system where  $A$  is positive definite. Let  $\lambda$  be the largest eigenvalue of  $A$ . Let  $A' \stackrel{\text{def}}{=} \frac{1}{2\lambda}A$  and  $b' \stackrel{\text{def}}{=} \frac{1}{2\lambda}b$ . Consider the equivalent system  $(I - (I - A'))x = b'$ . As the eigenvalues of  $A'$  are in  $(0, 1/2]$ , the eigenvalues of  $I - A'$  are in  $[1/2, 1)$ . Thus, the solution to the linear system is given by  $x = (I - (I - A'))^{-1}b' = \sum_{t=0}^{\infty} (I - A')^t b'$ . Therefore, we can approximate  $x_u$  by truncating the infinite sum at some  $t_0$  and approximating each power  $t < t_0$  by the algorithm for the matrix-power problem.

to the linear system  $x = \frac{1-\alpha}{n}\vec{1} + \alpha Px$ , where  $0 < \alpha < 1$  is a given parameter. In personalized PageRank, one replaces  $\frac{1}{n}\vec{1}$  (the uniform distribution) with some  $b \in \mathbb{R}^n$ , e.g., a standard basis vector. Equivalently,  $x$  solves the system  $Sx = \frac{1-\alpha}{n}\vec{1}$  where  $S = I - \alpha P$  is an SDD matrix with 1's on the diagonal. As all eigenvalues of  $P$  are of magnitude at most 1 (recall  $P$  is a transition matrix), all eigenvalues of  $I - \tilde{S} = I - S = \alpha P$  are of magnitude at most  $\alpha$ , and the running time guaranteed by Theorem 3.1 is logarithmic (with base  $\frac{2}{\alpha+1}$ ).

Algorithms for the PageRank model were studied extensively, and usually consider arbitrary (and even directed) graphs. In particular, the sublinear algorithms of [7] approximate the PageRank of a vertex using  $\tilde{O}(n^{2/3})$  queries, or using  $\tilde{O}((n\Delta)^{1/2})$  queries when the maximum degree is  $\Delta$ . Another example is the heavy-hitters algorithm of [6], which reports all vertices whose approximate PageRank exceeds a threshold  $T$  in sublinear time  $\tilde{O}(1/\Delta)$ , when PageRanks are viewed as probabilities and sum to 1. Other work explores connections to other graph problems, including for instance using PageRank algorithms to approximate effective resistances [13], the PageRank vector itself, and computing sparse cuts [4].

**Local Algorithms.** Our algorithms in Theorems 1.1 and 3.1 are *local* in the sense that they query a small portion of their input, usually around the input vertex, when viewed as graph algorithms. Local algorithms for graph problems were studied in several contexts, like graph partitioning [31, 5], Web analysis [10, 3], and distributed computing [34]. Rubinfeld, Tamir, Vardi, and Xie [29] introduced a formal concept of *Local Computation Algorithms* that requires consistency between the local outputs of multiple executions (namely, these local outputs must all agree with a single global solution). As explained earlier, our problem formulation (1) follows this consistency requirement.

## 1.4 Future Work

One may study alternative ways of defining the problem of solving a linear system in sublinear time, in particular if the algorithm can access  $b$  in a different way. For example, similarly to assumptions and guarantees in [35], the goal may be to produce an  $\ell_2$ -sample from the solution  $x$  (i.e., report a random index in  $[n]$  such that the probability of each coordinate  $i \in [n]$  is proportional to  $x_i^2$ ) assuming oracle access to an  $\ell_2$ -sampler from  $b \in \mathbb{R}^n$ , i.e., use an  $\ell_2$ -sampler for  $b$  to construct an  $\ell_2$ -sampler for  $x$ . Another version of the problem may ask to produce heavy hitters in  $x$ , assuming, say,<sup>8</sup> heavy hitters in  $b$  (which may be useful for the PageRank application). We leave these extensions as interesting open questions, focusing here on the classical access mode to  $b$ , via queries to its coordinates.

Another variation one may consider is to bound the error using a norm other than  $\ell_\infty$ , like  $\|y\|_S \stackrel{\text{def}}{=} \sqrt{y^\top S y}$  used in [31]. For example, if  $S$  is the Laplacian of a  $d$ -regular expander and  $y$  is orthogonal to the all-ones vector, then  $\|y\|_S = \Theta(\sqrt{d}\|y\|_2)$ , which might exceed  $\|y\|_\infty$  significantly even for constant  $d$ . Nevertheless, our requirement  $\|\hat{x} - x^*\|_\infty \leq \epsilon\|x^*\|_\infty$  is generally incomparable to  $\|\hat{x} - x^*\|_2 \leq \epsilon\|x^*\|_2$ .

## 2 Laplacian Solver (for Regular Graphs)

In this section we shall prove Theorem 1.1. The ensuing description deals mostly with a slightly simplified scenario, where the algorithm is given not one but two vertices  $u, v \in [n]$ , and returns an approximation  $\hat{\delta}_{u,v}$  to  $x_u - x_v$  with a slightly different error bound, see

<sup>8</sup> This kind of oracle seems necessary even when  $S = I$ .

---

**Algorithm 1** Solve-Linear-Laplacian.

---

**input** :  $d$ -regular graph  $G$ ; vector  $b$ ;  $\|b\|_0$ ; vertices  $u, v$ ; accuracy parameter  $\epsilon$ ; and  $\mu_2$

**output**: estimate  $\hat{\delta}_{u,v}$  for  $x_u - x_v$

- 1 set  $s = \frac{\log(2\sqrt{2}\epsilon^{-1} \frac{d}{\mu_2} \sqrt{\|b\|_0})}{\log(\frac{d}{d-\mu_2})}$  and  $\ell = O((\frac{\epsilon}{4s})^{-2} \log s)$
  - 2 **for**  $t = 0, 1, \dots, s - 1$  **do**
  - 3     Perform  $\ell$  independent random walks of length  $t$  starting at  $u$ , and let  $u_1^{(t)}, \dots, u_\ell^{(t)}$  be their end vertices. Independently, perform  $\ell$  independent random walks of length  $t$  starting at  $v$ , and let  $v_1^{(t)}, \dots, v_\ell^{(t)}$  be their end vertices.
  - 4     set  $\hat{\delta}_{u,v}^{(t)} = \frac{1}{\ell} \sum_{i \in [\ell]} (b_{u_i^{(t)}} - b_{v_i^{(t)}})$
  - 5 **return**  $\hat{\delta}_{u,v} = \frac{1}{d} \sum_{t=0}^{s-1} \hat{\delta}_{u,v}^{(t)}$
- 

Theorem 2.5 for the precise statement. The advantage is that if  $G$  is connected, all solutions  $x$  give rise to a unique value for  $x_u - x_v$ . We will then explain the modifications required to prove Theorem 1.1 (which actually follows also from our more general Theorem 3.1).

Let  $G = (V = [n], E)$  be a connected  $d$ -regular graph with adjacency matrix  $A \in \mathbb{R}^{n \times n}$ . Let the eigenvalues of  $A$  be  $d = \lambda_1 > \lambda_2 \geq \dots \geq \lambda_n$ , and let their associated orthonormal eigenvectors be  $u_1, \dots, u_n$ . Then  $u_1 = \frac{1}{\sqrt{n}} \cdot \vec{1} \in \mathbb{R}^n$ , and we can write  $A = U\Lambda U^\top$  where  $U = [u_1 \ u_2 \ \dots \ u_n]$  is unitary and  $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$ . For  $u, v \in [n]$ , let  $\chi_{u,v} \stackrel{\text{def}}{=} e_u - e_v$  where  $e_i$  is the  $i$ -th standard basis vector. Then the Laplacian of  $G$  is given by

$$L \stackrel{\text{def}}{=} \sum_{uv \in E} \chi_{u,v} \chi_{u,v}^\top = dI - A = U(dI - \Lambda)U^\top.$$

Observe that  $L$  does not depend on the orientation of each edge  $uv$ , and that  $\mu_2 \stackrel{\text{def}}{=} d - \lambda_2$  is the smallest non-zero eigenvalue of  $L$ . The Moore-Penrose pseudo-inverse of  $L$  is

$$L^+ \stackrel{\text{def}}{=} U \cdot \text{diag}(0, (d - \lambda_2)^{-1}, \dots, (d - \lambda_n)^{-1}) \cdot U^\top.$$

We assume henceforth that all eigenvalues of  $A$  are non-negative. At the end of the proof, we will remove this assumption (by adding self-loops).

The idea behind the next fact is that  $L = d(I - \frac{1}{d}A)$ , and  $\frac{1}{d}A$  has norm strictly smaller than one when operating on the subspace that is orthogonal to the all-ones vector, and hence, the formula  $(I - X)^{-1} = \sum_{t=0}^{\infty} X^t$  for  $\|X\| < 1$  is applicable for the span of  $\{u_2, \dots, u_n\}$ .

► **Fact 2.1.** For every  $x \in \mathbb{R}^n$  that is orthogonal to the all-ones vector,  $L^+x = \frac{1}{d} \sum_{t=0}^{\infty} (\frac{1}{d}A)^t x$ .

**Proof.** It suffices to prove the claim for each of  $u_2, \dots, u_n$  as the fact will then follow by linearity. Fix  $i \in \{2, \dots, n\}$ . Then since  $|\frac{\lambda_i}{d}| < 1$ ,

$$\sum_{t=0}^{\infty} \left(\frac{1}{d}A\right)^t u_i = \sum_{t=0}^{\infty} \left(\frac{\lambda_i}{d}\right)^t u_i = \frac{1}{1 - \frac{\lambda_i}{d}} u_i = \frac{d}{d - \lambda_i} u_i = dL^+ u_i. \quad \blacktriangleleft$$

We now describe an algorithm that on input  $b \in \mathbb{R}^n$  that is orthogonal to the all-ones vector, and two vertices  $u \neq v \in [n]$ , returns an approximation  $\hat{\delta}_{u,v}$  to  $x_u - x_v$ , where  $x$  solves  $Lx = b$ . As  $G$  is connected, the null space of  $L$  is equal to  $\text{span}\{\vec{1}\}$  and hence  $x_u - x_v$  is uniquely defined, and can be written as  $x_u - x_v = \chi_{u,v}^\top L^+ b$ .

► **Claim 2.2.** For  $b$  that is orthogonal to the all-ones vector and  $s = \frac{\log(2\sqrt{2}\epsilon^{-1} \frac{d}{\mu_2} \sqrt{\|b\|_0})}{\log(\frac{d}{d-\mu_2})}$ ,  
 $|\chi_{u,v}^\top L^+ b - \chi_{u,v}^\top \frac{1}{d} \sum_{t=0}^{s-1} (\frac{1}{d} A)^t b| \leq \frac{\epsilon}{2d} \|b\|_\infty$ .

**Proof.** Using Fact 2.1,

$$\chi_{u,v}^\top L^+ b - \chi_{u,v}^\top \frac{1}{d} \sum_{t=0}^{s-1} (\frac{1}{d} A)^t b = \chi_{u,v}^\top \frac{1}{d} \sum_{t=s}^{\infty} (\frac{1}{d} A)^t b,$$

and thus

$$|\chi_{u,v}^\top L^+ b - \chi_{u,v}^\top \frac{1}{d} \sum_{t=0}^{s-1} (\frac{1}{d} A)^t b| \leq \|\chi_{u,v}^\top\|_2 \cdot \left\| \frac{1}{d} \sum_{t=s}^{\infty} (\frac{1}{d} A)^t b \right\|_2.$$

We know that  $\|\chi_{u,v}^\top\|_2 = \sqrt{2}$ , so it remains to bound  $\left\| \frac{1}{d} \sum_{t=s}^{\infty} (\frac{1}{d} A)^t b \right\|_2$ . Decomposing  $b = \sum_{i=2}^n c_i u_i$  we get that  $\sum_{i=2}^n c_i^2 = \|b\|_2^2$  and

$$\sum_{t=s}^{\infty} (\frac{1}{d} A)^t b = \sum_{i=2}^n c_i u_i \sum_{t=s}^{\infty} \left(\frac{\lambda_i}{d}\right)^t = \sum_{i=2}^n \frac{(\frac{\lambda_i}{d})^s}{1 - \frac{\lambda_i}{d}} c_i u_i = d \sum_{i=2}^n \frac{(\frac{\lambda_i}{d})^s}{d - \lambda_i} c_i u_i.$$

Hence,

$$\left\| \frac{1}{d} \sum_{t=s}^{\infty} (\frac{1}{d} A)^t b \right\|_2^2 = \sum_{i=2}^n \left( \frac{(\frac{\lambda_i}{d})^s}{d - \lambda_i} \right)^2 c_i^2 \|u_i\|_2^2 \leq \left( \frac{(\frac{\lambda_2}{d})^s}{d - \lambda_2} \right)^2 \sum_{i=2}^n c_i^2 = \left( \frac{(1 - \frac{\mu_2}{d})^s}{\mu_2} \right)^2 \|b\|_2^2,$$

where the first equality is because the  $u_i$ 's are orthogonal. Altogether,

$$|\chi_{u,v}^\top L^+ b - \chi_{u,v}^\top \frac{1}{d} \sum_{t=0}^{s-1} (\frac{1}{d} A)^t b| \leq \sqrt{2} \frac{(1 - \frac{\mu_2}{d})^s}{\mu_2} \|b\|_2 \leq \sqrt{2} \frac{(1 - \frac{\mu_2}{d})^s}{\mu_2} \sqrt{\|b\|_0} \cdot \|b\|_\infty = \frac{\epsilon}{2d} \|b\|_\infty,$$

as claimed. ◀

► **Claim 2.3.**  $\Pr \left[ |\hat{\delta}_{u,v} - \chi_{u,v}^\top \frac{1}{d} \sum_{t=0}^{s-1} (\frac{1}{d} A)^t b| > \frac{\epsilon}{2d} \|b\|_\infty \right] \leq \frac{1}{s}$ .

**Proof.** Observe that  $e_u^\top (\frac{1}{d} A)^t$  is a probability vector over  $V$ , and  $e_u^\top (\frac{1}{d} A)^t e_w$  is exactly the probability that a random walk of length  $t$  starting at  $u$  will end at  $w$ . Thus, for every  $t \in \{0, 1, \dots, s-1\}$  and  $i \in [l]$ , we have

$$\mathbb{E}[b_{u_i^{(t)}}] = \sum_{w \in [n]} e_u^\top (\frac{1}{d} A)^t e_w b_w = e_u^\top (\frac{1}{d} A)^t b,$$

and similarly  $\mathbb{E}[b_{v_i^{(t)}}] = e_v^\top (\frac{1}{d} A)^t b$ . By a union bound over Hoeffding bounds, with probability at least  $1 - \frac{1}{s}$ , for every  $t \in \{0, 1, \dots, s-1\}$ , we have  $|\frac{1}{\ell} \sum_{i \in [l]} b_{u_i^{(t)}} - e_u^\top (\frac{1}{d} A)^t b| \leq \frac{\epsilon}{4s} \|b\|_\infty$  and  $|\frac{1}{\ell} \sum_{i \in [l]} b_{v_i^{(t)}} - e_v^\top (\frac{1}{d} A)^t b| \leq \frac{\epsilon}{4s} \|b\|_\infty$ . Recalling that  $\hat{\delta}_{u,v} = \frac{1}{d} \sum_{t=0}^{s-1} \frac{1}{\ell} \sum_{i \in [l]} (b_{u_i^{(t)}} - b_{v_i^{(t)}})$ , with probability at least  $1 - \frac{1}{s}$  we have  $|\hat{\delta}_{u,v} - \chi_{u,v}^\top \frac{1}{d} \sum_{t=0}^{s-1} (\frac{1}{d} A)^t b| \leq \frac{\epsilon}{2d} \|b\|_\infty$ , as claimed. ◀

Combining Claim 2.2 and Claim 2.3 we get that (with probability  $1 - \frac{1}{s}$ )  $|\hat{\delta}_{u,v} - \chi_{u,v}^\top L^+ b| \leq \frac{\epsilon}{d} \|b\|_\infty$ . Now, as  $x$  solves  $Lx = b$ , for every  $i \in [n]$  we have  $\sum_{j \in N(i)} (x_i - x_j) = b_i$  where  $N(i)$  is the set of neighbors  $\{j : ij \in E\}$ , which implies that for some neighbor  $j$  of  $i$ , it holds that  $|x_i - x_j| \geq \frac{|b_i|}{d}$ . Therefore,  $\max_{ij \in E} |x_i - x_j| \geq \frac{1}{d} \|b\|_\infty$ . We conclude that  $|\hat{\delta}_{u,v} - \chi_{u,v}^\top L^+ b| \leq \epsilon \cdot \max_{ij \in E} |x_i - x_j|$ . We now turn to the running time of Algorithm 1,

### 3:12 On Solving Linear Systems in Sublinear Time

which is dominated by the time it takes to perform the random walks. There are  $2s \cdot \ell$  random walks in total. The random walks do not need to be independent for different values of  $t$  (as we applied a union bound over the different  $t$ ), we can extend, at each iteration  $t$ , the  $2\ell$  respective random walks constructed at iteration  $t-1$  by an extra step in time  $O(d)$  (recall we assume  $G$  is given as an adjacency list), obtaining a total runtime  $O(s \cdot \ell \cdot d) = O(d\epsilon^{-2}s^3 \log s)$ . To simplify the expression for  $s$ , we need the following bound.

► **Fact 2.4.** For all  $\delta \in (0, 1)$ ,  $\frac{1}{\ln(1-\delta)^{-1}} \leq \frac{1}{\delta}$ .

**Proof.** We need to show that  $\delta \leq \ln(1-\delta)^{-1}$ , or equivalently,  $e^{-\delta} \geq 1-\delta$ , which is well known. ◀

Applying Fact 2.4 to  $\delta = \frac{\mu_2}{d}$ , we have  $s \leq \frac{d}{\mu_2} \log(2\sqrt{2}\epsilon^{-1} \frac{d}{\mu_2} \sqrt{\|b\|_0})$ , and conclude the following.

► **Theorem 2.5.** Given an adjacency list of a connected  $d$ -regular  $n$ -vertex graph  $G$ , a vector  $b \in \mathbb{R}^n$  that is orthogonal to the all-ones vector, vertices  $u, v \in [n]$ , and scalars  $\|b\|_0$ ,  $\epsilon > 0$ , and  $\mu_2 = d - \lambda_2 > 0$ , Algorithm 1 outputs  $\hat{\delta}_{u,v} \in \mathbb{R}$  satisfying

$$\Pr \left[ \left| \hat{\delta}_{u,v} - \chi_{u,v}^\top L^+ b \right| \leq \epsilon \cdot \max_{ij \in E} |x_i - x_j| \right] \geq 1 - \frac{1}{s},$$

in time  $O(d\epsilon^{-2}s^3 \log s)$  for  $s = O(\frac{d}{\mu_2} \log(\epsilon^{-1} \frac{d}{\mu_2} \|b\|_0))$ .

► **Remark.** If we allow preprocessing of  $G$ , the runtime of Algorithm 1 can be reduced to  $O(\epsilon^{-2}s^2)$ , as follows. At the preprocessing phase, compute  $(\frac{1}{d}A)^t$  for all powers  $t \leq s$ . Then, instead of approximating  $e_u^\top (\frac{1}{d}A)^t b$  for all powers  $t \leq s$ , sample a uniform  $t \in \{0, 1, \dots, s\}$ , and then, in  $O(1)$  time (because the probability vector is precomputed, see [37]), sample  $z \in [n]$  based on the probability vector  $e_u^\top (\frac{1}{d}A)^t$ , and finally, output  $\frac{s+1}{d} b_z$ . The expectation of the output is  $\frac{1}{d} \sum_{t=0}^s (\frac{1}{d}A)^t b$ . As for concentration, since the output is in  $[-\frac{s+1}{d} \cdot \|b\|_\infty, \frac{s+1}{d} \cdot \|b\|_\infty]$ , by the Hoeffding bound,  $O(\epsilon^{-2}s^2)$  many repetitions suffice to obtain (with constant probability) an approximation with additive error  $\frac{\epsilon}{2d} \|b\|_\infty$  (as in Claim 2.3).

We still need to show how to remove the assumption that  $A$  has no negative eigenvalues. Given an adjacency matrix  $A$  which might have negative eigenvalues, consider the PSD matrix  $A' = A + dI$ , which is the adjacency matrix of the  $2d$ -regular graph  $G'$  obtained from  $G$  by adding  $d$  self-loops to each vertex. Observe that  $A' = U(\Lambda + dI)U^\top$  and we can write  $L = dI - A = (2dI - A')$ , and thus, similarly to Fact 2.1,  $L^+ x = \frac{1}{2d} \sum_{t=0}^{\infty} (\frac{1}{2d}A')^t x$ , for  $x \in \mathbb{R}^n$  that is orthogonal to the all-ones vector. Therefore, if we use  $A'$  (which is PSD) to guide Algorithm 1's random walks (i.e., at each step of a walk, with probability 1/2 the walk stays put and with probability 1/2 it moves to a uniform neighbor in  $G$ ) and apply Claims 2.2 and 2.3 (which apply even when  $A$  has self-loops), an estimate  $\hat{\delta}_{u,v}$  satisfying with high probability  $|\frac{1}{2}\hat{\delta}_{u,v} - \chi_{u,v}^\top L^+ b| \leq \epsilon \max_{ij \in E} |x_i - x_j|$  is obtained. When running Algorithm 1 on  $G'$ , the term  $s$  evaluates to  $O(\frac{2d}{2d - (\lambda_2 + d)} \log(\epsilon^{-1} \frac{2d}{2d - (\lambda_2 + d)} \|b\|_0)) = O(\frac{d}{\mu_2} \log(\epsilon^{-1} \frac{d}{\mu_2} \|b\|_0))$ , thus, leaving the guarantee of Theorem 2.5 intact (up to constant factors).

**Proof of Theorem 1.1.** The theorem follows by a simple modifications to the analysis above. Observe that the analysis in Claims 2.2 and 2.3 holds also when replacing  $\mu_2$  by a lower bound on  $\mu_2$ , which in turn is easy to derive from the upper bound  $\bar{\kappa}$  given in the input and  $d$  given as part of input  $G$ . Similarly,  $\|b\|_0$  can be replaced by an upper bound  $B_{up} \geq \|b\|_0$ .

To handle one vertex  $u \in [n]$  instead of two vertices  $u, v \in [n]$ , ignore the part dealing with  $v$  in Algorithm 1, and modify the analysis in the two aforementioned claims to use  $e_u$  instead of  $\chi_{u,v}$ . The error bound obtained from combining these lemmas is  $\frac{\epsilon}{d} \|b\|_\infty$ , but since each  $|b_i| = |\sum_j L_{ij} x_j| \leq \sum_j |L_{ij}| \cdot \|x\|_\infty = 2d \|x\|_\infty$ , we can bound the error by  $\frac{\epsilon}{d} \|b\|_\infty \leq 2\epsilon \|x\|_\infty$ . ◀

### 3 An SDD Solver

In this section we prove the following theorem for solving linear systems in SDD matrices. To generalize from Laplacians of regular graphs to SDD matrices, we face several issues as described in Section 1.2. We use the notation defined in (2)-(3).

► **Theorem 3.1** (SDD Solver). *There exists a randomized algorithm, that given input  $\langle S, b, u, \epsilon, \bar{\lambda}_{up} \rangle$ , where*

- $S \in \mathbb{R}^{n \times n}$  is an SDD matrix,
- $b \in \mathbb{R}^n$  is in the range of  $S$  (equivalently, orthogonal to the kernel of  $S$ ),
- $u \in [n]$ ,  $\epsilon > 0$ , and
- $\bar{\kappa} \geq 1$  is an upper bound on the condition number  $\kappa(\tilde{S})$ ,

*this algorithm outputs  $\hat{x}_u \in \mathbb{R}$  with the following guarantee. Suppose  $x^*$  is the solution for  $Sx = b$  given in (3), then*

$$\forall u \in [n], \quad \Pr \left[ |\hat{x}_u - x_u^*| \leq \epsilon \|x^*\|_\infty \right] \geq 1 - \frac{1}{s}$$

*for suitable  $s = O(\bar{\kappa} \log(\epsilon^{-1} \bar{\kappa} \|b\|_0 \cdot \frac{\max_{i \in [n]} D_{ii}}{\min_{i \in [n]} D_{ii}}))$ . The algorithm runs in time  $O(f \epsilon^{-2} s^3 \log s)$ , where  $f$  is the time to make a step in a random walk in the weighted graph formed by the non-zeros of  $S$ .*

Due to space constraints, the proof is omitted from this version.

### 4 Lower Bound for PSD Matrices

In this section we prove Theorem 1.2. The entire proof relies on a  $d$ -regular  $n$ -vertex graph  $G_1$ , such that (i) its girth is  $\Omega(\log_d n)$ ; and (ii) its adjacency matrix  $A_1$  has eigenvalues  $\lambda_1 \geq \dots \geq \lambda_n$  that satisfy  $\max\{|\lambda_2|, |\lambda_n|\} \leq \frac{1}{4}d^{2/3}$  (this bound is somewhat arbitrary, chosen to simplify the exposition). We actually need such a graph to exist for infinitely many  $n$ , with  $d$  bounded uniformly (as  $n$  grows). Such graphs are indeed known, for example the Ramanujan graphs constructed by Lubotzky, Philips and Sarnak [26] and by Margulis [27] for the case where  $d - 1$  is a prime, have eigenvalue upper bound  $2\sqrt{d-1}$  and girth lower bound  $(4/3 - o(1)) \log_{d-1} n$  (see e.g. [21]).

In what follows, let  $G_2$  be a certain isomorphic copy of  $G_1$  (i.e., obtained from  $G_1$  by permuting the vertices, as explained below). It will be convenient to assume that  $G_1$  and  $G_2$  have the *same* vertex set, which we denote by  $V$ , as then we can consider the multi-graph obtained by their edge union, denoted  $G_1 \cup G_2$ . Denoting the adjacency matrix of each  $G_i$  by  $A_i$ , the adjacency matrix of their edge union  $G_1 \cup G_2$  is simply  $A_1 + A_2$ . We can similarly view  $A_1 - A_2$  as the adjacency matrix of the same graph, except that now the edges are signed – those from  $G_1$  are positive, and those from  $G_2$  are negative.

The proof of the theorem will follow easily from the three propositions below. Proposition 4.1 provides combinatorial, girth-like, information about  $G_1 \cup G_2$ . Proposition 4.2 provides spectral information, like the condition number, about  $A_1 - A_2$ . These two propositions are proved by straightforward arguments, and the heart of the argument is in Proposition 4.3. This proposition constructs a PSD linear system based on  $A_1 - A_2$ , for which we can show that recovering a specific coordinate of the solution  $x$ , even approximately, requires many probes to  $b$ . Due to space constraints, the proof of the next proposition is omitted from this version.

► **Proposition 4.1.** *Let  $G_1$  be as above and fix a vertex  $\hat{w} \in V$ . Then there exists an isomorphic copy  $G_2$  of  $G_1$  (on the same vertex set), such that in their edge-union  $G_1 \cup G_2$ , the neighborhood of  $\hat{w}$  of radius  $r_{\text{tree}} \stackrel{\text{def}}{=} 0.2 \log_{4d} n$  is a  $2d$ -regular tree.*

► **Proposition 4.2.** *Let  $A_1, A_2$  be the adjacency matrices described above, and let  $\mu \stackrel{\text{def}}{=} 2\|A_1 - A_2\|$ . Then  $\mu \leq \frac{1}{2}d^{2/3}$ , and the matrix  $M \stackrel{\text{def}}{=} \mu I + A_1 - A_2 \in \mathbb{R}^{n \times n}$  is PSD with all its eigenvalues in the range  $[\frac{1}{2}\mu, \frac{3}{2}\mu]$ . Thus,  $M$  is invertible and has condition number  $\kappa(M) \leq 3$ .*

**Proof.** By the triangle inequality,  $\mu/2 = \|A_1 - A_2\| \leq \|A_1 - dI\| + \|(A_2 - dI)\| \leq 2 \max\{|\lambda_2|, |\lambda_n|\} \leq \frac{1}{2}d^{2/3}$ . The eigenvalues of  $A_1 - A_2$  are in the range  $[-\frac{1}{2}\mu, \frac{1}{2}\mu]$ , and thus those of  $M$  are in the range  $[\frac{1}{2}\mu, \frac{3}{2}\mu]$ . ◀

► **Proposition 4.3** (Proved in Section 4.1). *Let the graphs  $G_1, G_2$  be according to Proposition 4.1, let  $M \stackrel{\text{def}}{=} \mu I + A_1 - A_2 \in \mathbb{R}^{n \times n}$  as above, and fix  $r \leq r_{\text{tree}}/d^2$ . Then every randomized algorithm that, given input  $b \in \{-1, 0, +1\}^n$ , succeeds with probability at least  $6/7$  to approximate coordinate  $x_{\hat{w}}$  of  $x = M^{-1}b$  within additive error at most  $\frac{1}{5}\|x\|_\infty$ , must probe  $d^{\Omega(r)}$  entries from  $b \in \mathbb{R}^n$ , even when  $b$  is supported only on vertices at distance  $r$  from  $\hat{w}$  (in  $G_1 \cup G_2$ ).*

We can now prove Theorem 1.2 using the above 3 propositions. Let  $G_1, G_2, A_1, A_2$  and  $M$  be as required for these propositions, and fix  $r = r_{\text{tree}}/d^2$ . Let  $S \stackrel{\text{def}}{=} M$  and observe that it has the sparsity and condition number required for Theorem 1.2, and let the distinguished index be  $u \stackrel{\text{def}}{=} \hat{w}$ . Now consider a randomized algorithm that, given an input  $b \in \mathbb{R}^n$ , estimates coordinate  $x_u^*$  of  $x^* = S^{-1}b$ , or in other words, coordinate  $x_{\hat{w}}$  of  $x = M^{-1}b$ . We can then apply Proposition 4.3 and deduce that this algorithm must probe  $b \in \mathbb{R}^n$  in

$$d^{\Omega(r)} \geq d^{\Omega((\log_{4d} n)/d^2)} \geq n^{\Omega(1/d^2)}$$

entries, which proves Theorem 1.2.

#### 4.1 Proof of Proposition 4.3

Let  $V_k \subset V$  be the set of vertices at distance exactly  $k$  from  $\hat{w}$  in the edge-union graph  $G_1 \cup G_2$ . By Proposition 4.1, we can view the radius- $r_{\text{tree}}$  neighborhood of  $\hat{w}$  as a tree rooted at  $\hat{w}$ . In particular, for all  $k \leq r_{\text{tree}}$  we have  $|V_k| = 2d(2d-1)^{k-1}$ . For each vertex  $v \in V_k$ , let  $s_v \in \{\pm 1\}$  be the value of entry  $(\hat{w}, v)$  in  $(A_2 - A_1)^k$ , i.e., the product of the signs along the unique length- $k$  walk from  $\hat{w}$  to  $v$  in  $A_2 - A_1$  (i.e., the shortest path in  $G_1 \cup G_2$ ).

Now generate a random  $b \in \{-1, 0, +1\}^n$  as follows. First pick an arbitrary signal  $\sigma \in \{\pm 1\}$ ; then use it to choose for each  $v \in V_r$ , a random  $b_v \in \{\pm 1\}$  with a small bias  $\delta > 0$  (determined below) towards  $\sigma s_v \in \{\pm 1\}$ , i.e.,

$$\mathbb{E}[b_v | \sigma] = \left(\frac{1}{2} + \frac{\delta}{2}\right)\sigma s_v + \left(\frac{1}{2} - \frac{\delta}{2}\right)(-\sigma s_v) = \delta \sigma s_v.$$

Observe that  $\mathbb{E}[s_v b_v | \sigma] = s_v(\delta \sigma s_v) = \delta \sigma$ , which means that  $s_v b_v$  has a small bias towards the signal  $\sigma$ . Finally, let all other entries be 0, i.e.,  $b_v = 0$  for  $v \notin V_r$ . Observe that  $\|b\|_2^2 = |\text{supp}(b)| = |V_r|$  and  $\mathbb{E}[\sigma \sum_{v \in V_r} s_v b_v | \sigma] = \delta |V_r|$ . We set the bias to be

$$\delta \stackrel{\text{def}}{=} C(r^2 \log d) |V_r|^{-1/3} \tag{4}$$

for a sufficiently large constant  $C > 0$ . Notice that  $\{s_v\}_{v \in V_r}$  have fixed values known to the algorithm, hence observing  $b_v$  (by probing this entry of  $b$ ) is information-theoretically equivalent to observing  $s_v b_v$ .

The next lemma is standard and follows easily from Yao’s minimax principle, together with a bound on the total-variation distance between two Binomial distributions, with biases  $\frac{1}{2} + \delta$  and  $\frac{1}{2} - \delta$ , see e.g. [9, Fact D.1.3] or [1, Eqn. (2.15)].

► **Lemma 4.4.** *Every randomized algorithm that, with probability at least  $1/2 + \gamma$  for  $\gamma \in (0, 1/2)$ , recovers an unknown signal  $\sigma \in \{\pm 1\}$  from  $b_1, b_2, \dots \in \{\pm 1\}$ , each set independently to  $\sigma$  or  $-\sigma$  with bias  $\delta > 0$ , must probe at least  $\Omega(\delta^{-2}\gamma^2)$  entries of  $b$ .*

Thus, all probabilities from this point onward are computed over the randomness of  $b$ . We proceed to analyze  $x_{\hat{w}}$ , aiming to show that it can be used to recover  $\sigma$ , namely, that with high probability  $\text{sgn}(x_{\hat{w}}) = \sigma$ . Later we will bound  $\|x\|_\infty$  aiming to show a similar conclusion for  $x_{\hat{w}} \pm \frac{1}{5}\|x\|_\infty$ . For convenience, denote  $B \stackrel{\text{def}}{=} \frac{A_2 - A_1}{\mu}$ , hence  $\|B\| = \frac{\mu/2}{\mu} = \frac{1}{2}$  and

$$M^{-1} = (\mu(I - \frac{A_2 - A_1}{\mu}))^{-1} = \mu^{-1} \sum_{i \geq 0} B^i,$$

and since  $B$  is symmetric, for every vertex  $u \in V$  (including  $\hat{w}$ ),

$$x_u = \langle e_u, M^{-1}b \rangle = \mu^{-1} \sum_{i \geq 0} \langle e_u, B^i b \rangle = \mu^{-1} \sum_{i \geq 0} b^\top B^i e_u. \quad (5)$$

Each summand  $b^\top B^i e_u$  can be viewed as the summation, over all length- $i$  walks from vertex  $u$ , of the coordinate  $b_v$  corresponding to the walk’s end-vertex  $v$ , multiplied by  $\mu^{-i}$  and by the product of the signs of  $A_2 - A_1$  along the walk. We can restrict the summation to walks ending at vertices  $v \in V_r$ , as otherwise  $b_v = 0$ .

► **Lemma 4.5.** *For every vertex  $u \in V$  (including  $\hat{w}$ ),*

$$\sum_{i \geq 2r \log \mu} \left| b^\top B^i e_u \right| \leq \frac{1}{4} \mu^{-2r} \cdot \delta |V_r|.$$

**Proof of Lemma 4.5.** For each  $i$ , we have by Cauchy-Schwartz  $|b^\top B^i e_u| \leq \|b\|_2 \cdot \|B\|_2^i \leq |V_r|^{1/2} \cdot 2^{-i}$ , and then by our choice of the bias  $\delta$  in (4),

$$\sum_{i \geq 2r \log \mu} |b^\top B^i e_u| \leq |V_r|^{1/2} \sum_{i \geq 2r \log \mu} 2^{-i} \leq (|V_r| \cdot \delta / 8) \cdot 2\mu^{-2r}. \quad \blacktriangleleft$$

Recall that by Proposition 4.1, the neighborhood of  $\hat{w}$  of radius  $r_{\text{tree}}$  is a tree, and view it as a tree rooted at  $\hat{w}$ . For a vertex  $u$  in this tree, let  $S_u$  be the set of all vertices  $v \in V_r$  that are descendants of  $u$ ; for example,  $S_{\hat{w}} = V_r$ , and if the distance of  $u$  from  $\hat{w}$  is greater than  $r$  then  $S_u = \emptyset$ . Define a random variable  $Z_u \stackrel{\text{def}}{=} \sum_{v \in S_u} s_v b_v$ , whose expectation is

$$\mathbb{E}[Z_u] = \sum_{v \in S_u} \mathbb{E}[s_v b_v \mid \sigma] = |S_u| \cdot \delta \sigma.$$

► **Lemma 4.6.** *With probability at least  $6/7$ ,*

$$\forall 0 \leq k \leq r, \forall u \in V_k, \quad |Z_u - \mathbb{E}[Z_u]| \leq O\left(\sqrt{|S_u|} \cdot \ln(3|V_k|)\right). \quad (6)$$

We remark that the constant 3 is somewhat arbitrary but needed to make sure the righthand-side is positive even for  $k = 0$  (as  $|V_0| = 1$ ). In addition, applying (6) to  $\hat{w} \in V_0$  yields, by our choice of the bias  $\delta$  in (4),

$$|Z_{\hat{w}} - \mathbb{E}[Z_{\hat{w}}]| \leq O\left(\sqrt{|V_r|} \cdot \ln(3|V_r|)\right) \leq \frac{1}{4} \delta |V_r|. \quad (7)$$

### 3:16 On Solving Linear Systems in Sublinear Time

**Proof of Lemma 4.6.** Fix  $0 \leq k \leq r$  and  $u \in V_k$ . By Hoeffding's inequality, for every  $c > 0$ ,

$$\begin{aligned} \Pr \left[ |Z_u - \mathbb{E}[Z_u]| \geq c\sqrt{|S_u| \ln(3|V_k|)} \right] &\leq e^{-2c^2|S_u| \ln(3|V_k|)/(4|S_u|)} \\ &\leq e^{-(c^2/2) \ln(3|V_k|)} = (3|V_k|)^{-c^2/2}. \end{aligned}$$

By a union bound over all  $u \in V_0 \cup \dots \cup V_r$ ,

$$\Pr \left[ \exists u, |Z_u - \mathbb{E}[Z_u]| \geq c\sqrt{|S_u| \ln(3|V_k|)} \right] \leq \sum_{k=0}^r |V_k| \cdot (3|V_k|)^{-c^2/2} = \frac{1}{3} \sum_{k=0}^r (3|V_k|)^{1-c^2/2}.$$

For all  $c \geq 2$  this series is decreasing geometrically, because  $|V_k|$  grows at least by a factor of  $2d - 1 \geq 5$ , and thus the sum is dominated by its first term. By choosing  $c$  to be an appropriate constant, the first term (and the entire sum) can be made arbitrarily small. ◀

We assume henceforth that the event described in Lemma 4.6 occurs. Let  $W_i$  be the set of all walks of length  $i$  that start at  $\hat{w}$  and end (at some vertex) in  $V_r$ , i.e., at distance exactly  $r$  from  $\hat{w}$ . To simplify notation (later), define

$$Q \stackrel{\text{def}}{=} \sum_{i=r}^{5r \log \mu} \mu^{-i} |W_i|.$$

We make two remarks. First, we can equivalently start the summation from  $i = 0$ , because  $W_i = \emptyset$  for all  $i < r$ . Second, the range of  $i$  here complements the one in Lemma 4.5, except that the constant 5 here is intentionally bigger than the 2 there, creating a slack needed at the very end of the proof.

► **Lemma 4.7.** *If the event in Lemma 4.6 occurs, then*

$$x_{\hat{w}} \in (\sigma \pm \frac{1}{2})\delta \cdot \mu^{-1}Q,$$

and thus  $\text{sgn}(x_{\hat{w}}) = \sigma$  (i.e., recovers the signal).

**Proof of Lemma 4.7.** We would like to employ (5) and the interpretation of  $b^\top B^i e_{\hat{w}}$  via walks of length  $i$ . To this end, fix  $0 \leq i \leq 5r \log \mu$ . Observe that  $i \leq r_{\text{tree}}$ , hence a walk of length  $i$  from  $\hat{w}$  is entirely contained in the  $2d$ -regular tree formed by the neighborhood of  $\hat{w}$  of radius  $r_{\text{tree}}$ . Each such walk contributes to  $b^\top B^i e_{\hat{w}}$  the value  $b_v$  at the walk's end vertex  $v$ , multiplied by all the signs seen along the walk. We make two observations. First, we can restrict attention to end vertices  $v \in V_r$  (and in particular  $i \geq r$ ), because otherwise  $b_v = 0$  and the contribution is 0. Second, because it is a tree, every edge along the shortest path between  $\hat{w}$  and  $v$  (the start and end vertices) is traversed by the walk an odd number of times, and every other edge is traversed an even number of times. Hence, the product of the signs along the walk equals the product along that shortest path, which is exactly  $s_v$ . By symmetry, the number of walks ending at each  $v \in V_r$  is the same, namely,  $\frac{|W_i|}{|V_r|}$ , and thus

$$b^\top B^i e_{\hat{w}} = \sum_{v \in V_r} \frac{|W_i|}{|V_r|} \mu^{-i} s_v b_v = \frac{Z_{\hat{w}}}{|V_r|} \cdot \mu^{-i} |W_i|. \quad (8)$$

Assuming the event in Lemma 4.6 occurs, we have  $Z_{\hat{w}} \in (\delta\sigma|S_{\hat{w}}| \pm \frac{1}{4}\delta|V_r|) = (1 \pm \frac{1}{4})\sigma\delta|V_r|$ , and therefore (recall terms for  $i < r$  have zero contribution)

$$\sum_{i=0}^{5r \log \mu} b^\top B^i e_{\hat{w}} \in \sum_{i=r}^{5r \log \mu} (1 \pm \frac{1}{4})\sigma\delta \cdot \mu^{-i} |W_i| = (1 \pm \frac{1}{4})\sigma\delta \cdot Q.$$

For the range of  $i > 5r \log \mu$ , we can use Lemma 4.5 and the obvious  $|W_r| = |V_r|$  to derive

$$\left| \sum_{i > 5r \log \mu} b^\top B^i e_{\hat{w}} \right| \leq \sum_{i > 5r \log \mu} \left| b^\top B^i e_{\hat{w}} \right| \leq \frac{1}{4} \mu^{-2r} \cdot \delta |V_r| \leq \frac{1}{4} \delta Q.$$

Altogether, plugging into (5) we obtain

$$\mu \cdot x_{\hat{w}} = \sum_{i \geq 0} b^\top B^i e_{\hat{w}} \in \sum_{i=0}^{5r \log \mu} (1 \pm \frac{1}{4}) \sigma \delta \cdot Q \pm \frac{1}{4} \delta \cdot Q = (1 \pm \frac{1}{2}) \sigma \delta \cdot Q,$$

which proves the lemma because  $\sigma \in \{\pm 1\}$ . ◀

► **Lemma 4.8.** *If the event in Lemma 4.6 occurs, then*

$$\|x\|_\infty \leq 2\delta \cdot \mu^{-1} Q.$$

The proof of this lemma is omitted here but appears in the full version.

We can now complete the proof of Proposition 4.3. By Lemma 4.6, with probability at least  $6/7$  the event described therein occurs. Assume this is the case and consider an estimate  $\hat{x}_{\hat{w}}$  for  $x_{\hat{w}}$  that has additive error at most  $\epsilon \|x\|_\infty$  for  $\epsilon \leq \frac{1}{5}$ . By Lemma 4.7 we have  $x_{\hat{w}} \in (\sigma \pm \frac{1}{2}) \delta \cdot \mu^{-1} Q$ , and by Lemma 4.8 we have  $\|x\|_\infty \leq 2\delta \cdot \mu^{-1} Q$ . Altogether

$$\hat{x}_{\hat{w}} \in x_{\hat{w}} \pm \frac{1}{5} \|x\|_\infty \subseteq (\sigma \pm \frac{1}{2} \pm \frac{2}{5}) \delta \cdot \mu^{-1} Q,$$

which implies that  $\text{sgn}(x_{\hat{w}}) = \sigma$ .

Now consider a randomized algorithm for estimating  $x_{\hat{w}}$ , and whose output  $\hat{x}_{\hat{w}}$  satisfies the above additive bound with probability at least  $6/7$ . We can use this estimation algorithm to recover the signal  $\sigma$ , by simply reporting the sign of its estimate, namely  $\text{sgn}(x_{\hat{w}})$ . This recovery does not require additional probes to  $b$ , and by a union bound, it succeeds (in recovering  $\sigma$ ) with probability at least  $5/7$ . But by Lemma 4.4, such a recovery algorithm, and in particular the algorithm for estimating  $x_{\hat{w}}$ , must probe  $b$  in at least

$$\Omega(\delta^{-2}) \geq \Omega\left(|V_r|^{2/3} / (r^4 \log^2 d)\right) \geq \Omega\left((2d-1)^{2r/3} / (r^4 \log^2 d)\right) \geq d^{\Omega(r)}$$

entries, which proves Proposition 4.3.

## Abstract

---

In the *conditional disclosure of secrets* (CDS) problem (Gertner et al., J. Comput. Syst. Sci., 2000) Alice and Bob, who hold  $n$ -bit inputs  $x$  and  $y$  respectively, wish to release a common secret  $z$  to Carol (who knows both  $x$  and  $y$ ) if and only if the input  $(x, y)$  satisfies some predefined predicate  $f$ . Alice and Bob are allowed to send a single message to Carol which may depend on their inputs and some shared randomness, and the goal is to minimize the communication complexity while providing information-theoretic security.

Despite the growing interest in this model, very few lower-bounds are known. In this paper, we relate the CDS complexity of a predicate  $f$  to its communication complexity under various communication games. For several basic predicates our results yield tight, or almost tight, lower-bounds of  $\Omega(n)$  or  $\Omega(n^{1-\epsilon})$ , providing an exponential improvement over previous logarithmic lower-bounds.

We also define new communication complexity classes that correspond to different variants of the CDS model and study the relations between them and their complements. Notably, we show that allowing for imperfect correctness can significantly reduce communication – a seemingly new phenomenon in the context of information-theoretic cryptography. Finally, our results show that proving explicit super-logarithmic lower-bounds for imperfect CDS protocols is a necessary step towards proving explicit lower-bounds against the class AM, or even  $AM \cap \text{coAM}$  – a well known open problem in the theory of communication complexity. Thus imperfect CDS forms a new minimal class which is placed just beyond the boundaries of the “civilized” part of the communication complexity world for which explicit lower-bounds are known.

## 1 Introduction

Understanding the communication complexity of information-theoretically secure protocols is a fundamental research problem. Despite much effort, we have very little understanding of the communication complexity of even simple cryptographic tasks, and for most models, there are exponentially large gaps between the best known upper-bounds and the best known lower-bounds. In an attempt to simplify the problem, one may try to focus on the most basic settings with a minimal non-trivial number of players (say two or three) and the simplest possible communication pattern (e.g., single message protocols). Different cryptographic tasks have been studied in this minimal setting, including secure computation [17], and non-interactive zero-knowledge proofs [23]. In this paper we will focus on what seems to be the simplest task in this model: *Conditional Disclosure of Secrets* (CDS) [20].<sup>3</sup>

### Conditional Disclosure of Secrets

Consider a pair of computationally unbounded parties, Alice and Bob, each holding an input,  $x \in \mathcal{X}$  and  $y \in \mathcal{Y}$  respectively, to some public predicate  $f : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$ . Alice and Bob also hold a joint secret  $z$  (say a single bit) and have access to a joint source of randomness  $r \stackrel{R}{\leftarrow} \mathcal{R}$ . The parties wish to disclose the secret  $z$  to a third party, Carol, if and only if the predicate  $f(x, y)$  evaluates to 1. To this end, Alice and Bob should each send a single message  $a = a(x, z; r)$  and  $b = b(y, z; r)$  to Carol. Based on the transcript  $(a, b)$  and the inputs  $(x, y)$ , Carol should be able to recover the secret  $z$  if and only if  $f(x, y) = 1$ . (Note that Carol is assumed to know  $x$  and  $y$ .) That is, we require two properties:

- *Correctness*: There exists a deterministic decoder algorithm  $\text{Dec}$  that recovers  $z$  from  $(x, y, a, b)$  with high probability whenever  $x, y$  is a 1-input (i.e.,  $f(x, y) = 1$ );
- *Privacy*: For every fixed 0-input  $(x, y)$  (for which the predicate evaluates to 0), regardless of the value of the secret  $z$ , the joint distribution of the transcript  $(a, b)$ , induced by a choice of the shared randomness, is statistically close (up to some small deviation error) to some canonical distribution  $\text{Sim}(x, y)$ .

The main complexity measure of CDS protocols is their communication complexity which is taken to be the total bit-length of the messages  $a$  and  $b$ . (See Figure 1 for a schematic view and Section A for formal definitions.)

Apart from being a natural basic notion, CDS has turned out to be a useful primitive with various applications in the context of private information retrieval (PIR) [20], secure multiparty computation [1, 25], secret sharing schemes [14, 15, 36, 31, 11, 2, 29], and attribute-based encryption [7, 37]. Correspondingly, the communication complexity of CDS was extensively studied in the last few years.

<sup>3</sup> While we do not wish to define the notions from [17] and [23], let us just mention that the complexity of a function in these two models upper-bounds the complexity in the CDS model [20, 5]. In this sense, CDS may be considered as being simpler.

■ **Figure 1** Schematic of a CDS protocol.

## Upper bounds

On the positive side, it is known that the CDS complexity of a predicate  $f$  is at most linear in the formula complexity of  $f$  [20]. This result was extended to other (presumably stronger) computational models such as (arithmetic) branching programs [26], and (arithmetic) span programs [5]. The latter paper also shows that the CDS complexity of  $f$  is at most linear in the complexity of any zero-information Arthur Merlin (ZAM) protocol for  $f$ . (The ZAM model, introduced by [23], adds a zero-knowledge property to the standard AM communication complexity model.)<sup>4</sup> In a recent breakthrough, Liu, Vaikuntanathan and Wee [30] showed that the CDS complexity of any predicate  $f : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  over  $n$ -bit inputs is at most  $2^{\tilde{O}(\sqrt{n})}$ , improving over the exponential upper-bound of  $O(2^{n/2})$  from [10]. Applebaum et al. [3] showed that when the secret is very long (exponential in the size of the domain of the predicate) the overhead per each bit of  $z$  can be reduced to  $O(n)$ ; a constant-rate solution (in which the total communication is  $O(|z|)$ ) was recently given in [2].

## The quest for lower bounds

On the lower-bound front much less is known. While we have tight lower bounds for restricted forms of CDS (e.g., when the computations are restricted to linear functions [19, 9, 12]), only few, relatively weak, lower-bounds are known for general CDS. It is important to note that an insecure solution to the problem has a communication cost of 1 bit! (Let Alice send the secret in the clear regardless of her input.) Hence, any super-constant lower-bound is, in a sense, non-trivial. Indeed, unlike the case of standard communication games for which communication lower-bounds are based on the correctness properties of the protocol, the challenge here is to somehow capture the additional cost of *privacy*.

The first super-constant lower-bound was proved by Gay, Kerenidis, and Wee [19].

► **Theorem 1** ([19]). *For every predicate  $f : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$ ,*

$$\text{CDS}(f) \geq \Omega(\log(\text{R}_{A \rightarrow B}(f) + \text{R}_{B \rightarrow A}(f))),$$

where  $\text{R}_{A \rightarrow B}(f)$  denotes the one-way randomized communication complexity of  $f$ , and  $\text{CDS}(f)$  denotes the minimal communication complexity of a CDS protocol for  $f$  with privacy and correctness error of 0.1.<sup>5</sup>

<sup>4</sup> The theorem of [5] actually relates the communication and randomness complexity of CDS for  $f$  to the randomness and communication complexity of a ZAM protocol for the complement of  $f$ . However, using our results in this paper one can conclude that the CDS communication of  $f$  is at most linear in the ZAM communication of  $f$ .

<sup>5</sup> The theorem was originally proved for perfect CDS, however, the proof generalizes to the imperfect case (see [3]).

For  $n$ -bits predicates, Theorem 1 leads, at best, to a logarithmic lower-bound of  $\Omega(\log n)$ . Applebaum *et al.* [3] showed that this bound is essentially tight: There are (partial) functions whose randomized communication complexity is exponentially larger than their CDS complexity. They also proved a linear  $n$ -bit lower-bound for a random (non-explicit)  $n$ -bit predicate  $f : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ . An explicit version of this result was proved by [4].

► **Theorem 2** ([4]). *For every non-degenerate predicate<sup>6</sup>  $f : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$  whose largest 0-monochromatic rectangle is of size at most  $L$ ,*

$$\text{pCDS}(f) \geq \log \frac{|f^{-1}(0)|}{L} - \log \frac{|\mathcal{X} \times \mathcal{Y}|}{|f^{-1}(0)|} - 1 = 2 \log |f^{-1}(0)| - \log |\mathcal{X}| - \log |\mathcal{Y}| - \log L - 1,$$

where  $\text{pCDS}(f)$  denotes the minimal communication complexity of a CDS protocol for  $f$  with perfect privacy and perfect correctness.

The theorem is effective for predicates whose communication matrix is rich in zeroes, and at the same time avoids large zero-monochromatic rectangles. In particular, for mod-2 inner product over  $n$ -bit inputs, we get a tight lower-bound of  $n - O(1)$  and for Set-Intersection a lower-bound of  $\Omega(n)$ . Unfortunately, the theorem is not robust to errors, leaving the imperfect CDS complexity of these predicates wide open. Moreover, for many basic predicates the theorem does not even give logarithmic bounds either due to the lack of many zeroes (e.g., the Not-Equal predicate) or due to the existence of huge zero-rectangles (e.g., the Greater-Than predicate).

## This paper

Theorems 1 and 2 provide a very partial picture, and fall short of proving meaningful and robust lower-bounds for many basic predicates, such as Not-equal, Greater-Than, Intersection, and Index.<sup>7</sup> We believe that a full understanding of these simple cases is necessary for the more ambitious goal of proving stronger lower bounds. Our goal in this paper is to remedy the situation by providing new lower-bound techniques. Specifically, we enrich our lower-bound toolbox by relating the CDS complexity of a function to its communication complexity under various communication games. Our results provide simple, yet effective, ways to leverage privacy to construct communication protocols. They lead to new lower-bounds for perfect and imperfect CDS protocols, and allow us to establish new results regarding the relations between different variants of the CDS model.

## 2 Our Contribution

### 2.1 Perfectly-correct CDS and coNP Games

Our first theorem relates the complexity of any perfectly-correct CDS protocol for  $f$  to the non-deterministic communication complexity of  $f$ 's complement.

► **Theorem 3.** *For every predicate  $f : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$ ,*

$$\text{pcCDS}(f) \geq \Omega(\text{coNP}(f)) - O(\log(n)),$$

where  $n$  denotes the total input length of  $f$ , and  $\text{pcCDS}(f)$  denotes the minimal communication complexity of a CDS protocol for  $f$  with perfect correctness and privacy error of 0.1.

<sup>6</sup> A predicate is non-degenerate if for every fixing of  $x \in \mathcal{X}$  the residual function  $f(x, \cdot)$  is not the constant zero function.

<sup>7</sup> Apart of being basic examples, these predicates are motivated by some of the applications of CDS.

**Proof idea**

To prove the theorem, we first show that the coNP complexity is upper-bounded by the randomness complexity of the CDS, and then prove that one can always assume that the randomness complexity is comparable to the communication complexity via a new sparsification lemma (similar to that of Newman [33]). The first part relies on the following simple observation: In order to convince Alice and Bob that  $f(x, y)$  evaluates to zero it suffices to prove that the joint distribution of the CDS messages for zero-secret,  $(a(x, z = 0; r), b(y, z = 0; r))$ , induced by a random choice of  $r$ , and the joint distribution of the messages for one-secret  $(a(x, z = 1; r), b(y, z = 1; r))$ , are *not disjoint*. A prover can prove this statement by sending to Alice and Bob a pair of strings  $r_0$  and  $r_1$  for which  $(a(x, z = 0; r_0), b(y, z = 0; r_0))$  equals to  $(a(x, z = 1; r_1), b(y, z = 1; r_1))$ . (See full version [6] for details.)

Despite its simplicity, this theorem is quite powerful. In particular, ignoring the constants in the Omega-notation and the logarithmic loss, the bound provided by Theorem 3 subsumes the lower-bound of Theorem 2 from [4]. Indeed, the latter lower-bound is at most the logarithm of the ratio between the zero-mass of  $f$  and its largest zero-monochromatic rectangle – a quantity that cannot be larger than the non-deterministic communication complexity of the complement of  $f$  (i.e.,  $\text{coNP}(f)$ ). Moreover, our new theorem can be applied to predicates that have only few zero entries or to predicates with huge zero-rectangles, for which Theorem 2 becomes meaningless. For example, by plugging-in classical coNP lower-bounds, we settle the complexity of the not-equal predicate with respect to perfectly correct CDS protocols.

► **Corollary 4.** *Let  $\text{NEQ}_n : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  denote the not-equal predicate which evaluates to 1 if and only if  $x \neq y$ . Then,*

$$\text{pcCDS}(\text{NEQ}_n) \geq \Omega(n).$$

Similar tight linear lower-bounds can be obtained for the pcCDS complexity of the Greater-Than predicate, the Set-Intersection predicate, and the Inner-Product predicate. Previously, we had no super-logarithmic lower bounds that tolerate privacy error. (As already mentioned, for Greater-Than and  $\text{NEQ}_n$ , we did not have such bounds even for perfect CDS protocols.)

**pcCDS is not closed under complement**

Interestingly, the *equality* function  $\text{EQ}_n$  has a very succinct perfect CDS protocol: Use the shared randomness to sample a pair-wise independent hash function  $h : \{0, 1\}^n \rightarrow \{0, 1\}$ , and let Alice output  $h(x)$  and Bob output  $h(y) \oplus z$ . The protocol has a minimal communication complexity of 2 and randomness complexity of  $O(n)$ . (The latter can be reduced to  $O(\log n)$  by using an almost pair-wise independent hash function and settling for a constant privacy error.) This yields a strong separation between the complexity of a predicate and its complement with respect to perfectly-correct perfectly-private CDS protocols (pCDS).

► **Corollary 5.**  *$\text{pCDS}(\text{EQ}_n) = 2$  whereas  $\text{pCDS}(\text{NEQ}_n) \geq \text{pcCDS}(\text{NEQ}_n) \geq \Omega(n)$ . In particular, the classes pCDS and pcCDS are not closed under complement.<sup>8</sup>*

Transformations from CDS protocols for  $f$  to its complement were studied in [3]. The resulting protocols either introduce a privacy error or suffer from a communication overhead that grows polynomially with the randomness complexity of the original protocol. The  $\text{NEQ}_n$  example shows that at least one of these losses is inherent.

<sup>8</sup> We follow the standard communication complexity terminology and write pCDS to denote the class of predicates that admit a pCDS protocol whose complexity is polylogarithmic in the input length. A similar convention will be used throughout the paper for all other variants of the CDS model.

### The benefit of decoding errors

The results of [3] (together with our randomness sparsification lemma) show that imperfect CDS is closed under complement. This general result leads to a polylogarithmic CDS protocol for  $\text{NEQ}_n$  with imperfect privacy and imperfect correctness, providing a surprising separation between general imperfect CDS protocols and ones which have perfect correctness. In fact, it is not hard to directly design a CDS protocol for  $\text{NEQ}_n$  with *constant communication*, *perfect privacy*, and constant correctness error. (See the full version [6] for a more general statement.) This leads to the following stronger separation.

► **Corollary 6.** *There is an  $n$ -bit predicate  $f$  for which  $\text{pcCDS}(f) = \Omega(n)$  and  $\text{ppCDS}(f) = O(1)$ , where  $\text{ppCDS}(f)$  denotes the minimal communication complexity of a CDS protocol for  $f$  with perfect privacy and correctness error of 0.1. In particular,*

$$\text{ppCDS} \not\subseteq \text{pcCDS}.$$

As pointed to us by Hoteck Wee, Corollary 6 provides a rare example for an information-theoretic secure protocol that can significantly benefit from a small correctness error. This phenomena seems new in the context of information-theoretic secure cryptography, and is worth further exploration.<sup>9</sup>

## 2.2 Perfectly-Private CDS and PP Games

Our next goal is to lower-bound the complexity of CDS protocols with correctness errors. We begin with the case of perfectly private protocols.

► **Theorem 7.** *For every predicate  $f : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$ ,*

$$\text{ppCDS}(f) \geq \Omega(\text{PP}(f)) - O(\log(n)),$$

where  $n$  denotes the total input length of  $f$ , and  $\text{ppCDS}(f)$  denotes the minimal communication complexity of a CDS protocol for  $f$  with perfect privacy and correctness error of 0.1.

The complexity measure  $\text{PP}(f)$  essentially corresponds to the sum of the communication complexity and number of private random bits used by a communication protocol that computes  $f$  correctly with probability more than  $1/2$ , where shared randomness is not allowed. (See the full version [6] for a formal definition.) The discrepancy method implies that the PP complexity of the mod-2 inner-product predicate  $\text{IP}_n$  is  $\Omega(n)$  (cf. [28]) and so we get the following.

► **Corollary 8.** *Let  $\text{IP}_n : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  denote the inner-product predicate on  $n$ -bit inputs. Then,*

$$\text{ppCDS}(\text{IP}_n) \geq \Omega(n).$$

This is the first linear lower-bound on CDS with imperfect correctness. (Previous arguments fail to achieve such a result even for a non-explicit predicate.)

---

<sup>9</sup> Compare this, for example, to Shannon's classical lower-bound for perfectly-secure one-time symmetric encryption [35] in which a constant decryption error has a minor effect on the key/ciphertext length [16].

**Proof idea**

In order to prove Theorem 7, we turn a ppCDS protocol into a PP protocol. Loosely speaking, the idea is to construct a randomized protocol that accepts the input  $(x, y)$  based on collisions between random CDS transcripts that correspond to a zero-secret and random CDS transcripts that correspond to a one-secret. This idea, which was employed in the query setting by [13], leads to the desired result. (Details appear in the full version [6].)

**2.3 Imperfect CDS, Interactive Proofs, and Zero Knowledge**

We move on to the most general case of imperfect CDS protocols with both constant privacy error and correctness error. We show that the complexity of such protocols is at least polynomial in the AM communication complexity of  $f$ . (The latter class is the communication complexity analogue of Arthur-Merlin proofs.)

► **Theorem 9.** *There exists some universal constant  $c > 0$ , such that for any Boolean function  $f$  it holds that*

$$\text{CDS}(f) \geq \text{AM}(f)^c - \text{polylog}(n),$$

where  $n$  denotes the total input length of  $f$ , and  $\text{CDS}(f)$  denotes the minimal communication complexity of a CDS protocol for  $f$  with correctness and privacy errors of 0.1.

Since (imperfect) CDS is closed under complement (by [3, Theorem 2] and [6, Lemma 1]), it holds that  $\text{CDS}(f) \leq \text{poly}(\text{CDS}(f))$ , and so we conclude the following.

► **Corollary 10.** *There exists some universal constant  $c > 0$ , such that for any Boolean function  $f$  it holds that*

$$\text{CDS}(f) \geq \max(\text{AM}(f), \text{coAM}(f))^c - \text{polylog}(n),$$

where  $n$  denotes the total input length of  $f$ .

**Explicit CDS lower-bounds?**

Corollary 10 can be used to show that the CDS complexity of most  $n$ -bit predicates must be at least polynomial in  $n$ , even when the protocol is imperfect. Unfortunately, it falls short of providing explicit lower-bounds; Finding an explicit function outside  $\text{AM} \cap \text{coAM}$  is a central open problem in the theory of communication complexity. In fact,  $\text{AM} \cap \text{coAM}$  forms a minimal class for which no explicit lower-bounds are known [24]. Corollary 10 places CDS as a weaker (and perhaps more accessible) target for explicit lower-bounds.

**Proof idea**

To prove Theorem 9 we show that a CDS protocol can be transformed into a constant-round private-coins interactive-proof. Then, we note that, just like in the computational setting, such interactive proofs can be converted to an AM protocol with polynomial overhead [8, 22].<sup>10</sup> The first step is obtained by imitating the standard interactive proof of Graph Nonisomorphism [21]. Indeed, the AM protocol constructed in Theorem 9 turns out to satisfy a *statistical zero-knowledge* property; That is, the view of Alice and Bob can be simulated via a low complexity 2-party randomized protocol. (See the full version [6] for details.)

<sup>10</sup>This reduction has a polynomial dependency in the randomness. In order to avoid such an overhead in the final statement, we prove a randomness sparsification lemma for constant-round interactive protocols. This requires some care due to the use of private coins.

### CDS vs. SZK

Recall that, by definition, a CDS protocol yields a (distributed mapping) from the input  $(x, y)$  and the secret  $z$  to a distribution  $D_z$  over the transcript  $(a, b)$  such that the distributions,  $D_0$  and  $D_1$ , are either statistically-close or statistically-far depending on the value of  $f(x, y)$ . This resembles the Statistical Difference problem [34], which is known to be complete for the computational complexity class SZK (consisting of problems that have interactive proofs that are statistically zero-knowledge). One may therefore hope to prove that in the communication complexity setting CDS complexity is characterized by SZK complexity. As already mentioned, Theorem 9 actually shows that  $\text{CDS} \subseteq \text{SZK}$ , however, we do not know whether the reverse direction holds. Roughly speaking, such a result faces two obstacles. Firstly, the completeness result from [34] has an overhead that depends on the randomness complexity of the protocol, and we do not know how to get rid of this dependency. (In particular, it is not clear how to prove a proper sparsification lemma for SZK without sacrificing the zero-knowledge property.) Secondly, even if the randomness complexity is small, we do not know how to obtain a CDS protocol without allowing some interaction between Alice and Bob. Indeed, in the full version [6] we show that  $\text{SZK}' \subseteq \text{CDS}'$  where the “prime” version of SZK charges randomness towards the total complexity and the “prime” version of CDS allows short interaction between Alice and Bob. The problem of proving that  $\text{SZK} \subseteq \text{CDS}$  (and therefore  $\text{SZK} = \text{CDS}$ ) remains as an interesting open problem.

The results described so far are summarised in Figure 2, which shows the relationship between perfect and imperfect CDS and various measures from communication complexity. In Table 1, we list the current state of knowledge of the various CDS complexities of a number of commonly studied predicates. (See Section 3.)

## 2.4 Asymmetry in CDS and One-Way Communication

We shift gears, and turn to study the communication tradeoffs between Alice’s and Bob’s messages. Suppose that Alice’s message is restricted to a short string of length  $t_A$ . Can we prove that Bob’s message must be very long? We prove such tradeoffs based on the one-way randomized communication complexity of  $f$ .

► **Theorem 11.** *In any perfectly correct 0.1-private CDS protocol for  $f$  in which Alice and Bob communicate  $t_A$  and  $t_B$  bits respectively and the total input length of the function is  $n$ , it holds that:*

$$2^{t_A}(t_A + t_B + \log n) \geq \Omega(R_{B \rightarrow A}(f)).$$

(In fact, the result holds even if one considers one-way randomized protocols that err only over zero inputs.) Recall that Theorem 1 (which is from [19]) shows that the total communication complexity  $t_A + t_B$  is at least logarithmic in  $(R_{A \rightarrow B}(f) + R_{B \rightarrow A}(f))$ , which is tight for some predicates [3]. Theorem 11 provides a more accurate picture. If the total communication complexity is dominated by  $t_A$ , then one gets a logarithmic bound, similar to Theorem 1; however, when  $t_A$  is small (e.g., constant), we get a strong linear lower-bound of

$$t_B = \Omega(R_{B \rightarrow A}(f)) - O(\log n).$$

In fact, when  $R_{B \rightarrow A}(f) = \Omega(n)$ , for any constant  $\alpha < 1$  if  $t_A \leq \alpha \log n$  then

$$t_B = \Omega(n^{1-\alpha}).$$

Concretely, consider the  $\text{Index}_n$  predicate in which Bob holds an  $n$ -bit database  $x \in \{0, 1\}^n$  and Alice holds an index  $i \in [n]$  (encoded as a string of length  $\log n$ ) and the output is the  $i$ -th bit of  $x$ . Since  $R_{B \rightarrow A}(\text{Index}_n) = \Omega(n)$  [27] we get:

► **Corollary 12.** *In any perfectly correct 0.1-private CDS protocol for  $\text{Index}_n$  in which Alice communicates at most  $\alpha \log n + O(1)$  bits for some constant  $0 \leq \alpha < 1$ , the database owner, Bob, must communicate at least  $\Omega(n^{1-\alpha})$  bits.*

Similar results can be obtained for predicates like Greater-Than, Set-Disjointness and Set-Intersection, based on classical lower-bounds for randomized one-way communication complexity (cf. [32, 27]).

The  $\text{Index}_n$  predicate plays an important role in CDS constructions and applications. First, it is complete for CDS in the sense that any  $n$ -bit predicate can be reduced to  $\text{Index}_N$  for  $N = 2^n$ . Indeed, the best known general CDS protocols were obtained by improving the pCDS complexity of  $\text{Index}$  [30]. In addition, a CDS for the index function can be viewed as a one-time version of the well-studied notion of *Broadcast Encryption*, and the lower-bound of Corollary 12 becomes especially appealing under this framework. Details follow.

### Broadcast Encryption [18]

Suppose that we have a single sender and  $n$  receivers. The sender has a private encryption key  $r$  and each receiver  $i \in [n]$  has its own private decryption key  $k_i$ . All the keys were collectively generated and distributed in an offline phase. In an online phase, the sender gets a message  $z$  together with a public list of authorized users  $y \subseteq [n]$ , represented by an  $n$ -bit characteristic vector. The sender should broadcast a ciphertext  $b = b(y, z; r)$  to all the receivers (who also know  $y$ ) so that an *authorized* receiver will be able to decrypt the ciphertext, and an unauthorized (computationally unbounded) receiver will learn nothing about the message  $z$ . The goal is to minimize the length of the ciphertext  $b$ , and the length of the keys  $k_i$ .

Information-theoretic one-time secure Broadcast Encryption turns to be equivalent to the CDS problem with respect to the  $\text{Index}_n$  predicate: Identify the ciphertext with Bob's message  $b = b(y, z; r)$  and the  $i$ -th key with Alice's message  $a(i; r)$ .<sup>11</sup> The problem can be solved with  $n$ -bit ciphertext and 1-bit keys, and with 1-bit ciphertext and  $n$ -bit keys. In fact, [19] showed that one can smoothly get any tradeoff as long as the product of the ciphertext length and the key length is  $n$ . Corollary 12 shows that when the key-length is sub-logarithmic the ciphertext must be almost linear, confirming a conjecture of Wee [38].

### Proof idea (of Theorem 11)

The idea is to let Bob send to Alice a pair of random strings  $r_0$  and  $r_1$  that are mapped to the same Bob's message  $b$  under the zero-secret and under the one-secret respectively. Alice then uses the string  $r_z$  and the secret  $z$  to compute a corresponding message  $a_z$ , and accepts if the zero message  $a_0$  equals to the one message  $a_1$ . Perfect correctness guarantees that Alice will never err on 0-inputs. We further show that, when  $f(x, y) = 1$ , Alice accepts with probability which is at least inverse-exponential in her message length (up to a loss that is proportional to the privacy error of the protocol). See the full version [6] for details.

<sup>11</sup> Here we assume that we have a CDS in which only Bob holds the secret. However, any CDS can be transformed into this form with an additional communication cost of  $O(|z|) = O(1)$ .

■ **Table 1** The CDS complexity of some simple functions. By definition, an upper-bound in the leftmost column (pCDS) implies an upper-bound in all other columns, and a lower-bound in the rightmost column (CDS) implies a lower-bound in all other columns. All the linear upper-bounds for pCDS follow from the fact that all of these predicates can be computed by a linear-size formula. The logarithmic lower-bounds for CDS follow from Theorem 1 (and the fact that the corresponding predicates have linear randomized one-way communication complexity.) The linear lower-bounds for pcCDS and ppCDS follow from Theorems 3 and 7 respectively.

Predicate	pCDS	pcCDS	ppCDS	CDS
Equality	$\Theta(1)$	$\Theta(1)$	$\Theta(1)$	$\Theta(1)$
Non-Equality	$\Theta(n)$	$\Theta(n)$	$\Theta(1)$	$\Theta(1)$
Inner-Product	$\Theta(n)$	$\Theta(n)$	$\Theta(n)$	$O(n) \ \& \ \Omega(\log n)$
Greater-Than	$\Theta(n)$	$\Theta(n)$	$O(n) \ \& \ \Omega(\log n)$	$O(n) \ \& \ \Omega(\log n)$
Set-Intersection	$\Theta(n)$	$\Theta(n)$	$O(n) \ \& \ \Omega(\log n)$	$O(n) \ \& \ \Omega(\log n)$
Set-Disjointness	$O(n) \ \& \ \Omega(\log n)$	$O(n) \ \& \ \Omega(\log n)$	$O(n) \ \& \ \Omega(\log n)$	$O(n) \ \& \ \Omega(\log n)$

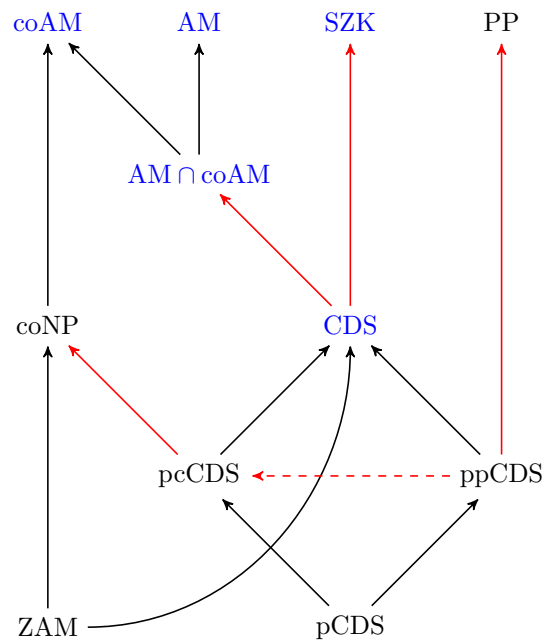

### 3 Conclusion and Open Questions

In this paper we studied the relations between CDS protocols and standard communication complexity games. We established new connections between CDS communication complexity (with perfect and imperfect privacy and correctness) to well-known communication complexity measures for non-deterministic protocols, randomized unbounded-error protocols, and one-way protocols. This leads to new CDS bounds for various simple functions. These results are summarized in Figure 2 and Table 1.

We end by listing the immediate interesting questions left open following our work.

1. Prove an explicit polynomial lower-bound on (imperfect) CDS complexity. (A natural candidate would be Inner-Product.)
2. Our current ppCDS lower-bounds are based on PP complexity, which corresponds to discrepancy. Can we derive such bounds on weaker, easier-to-establish, properties? In particular, can we prove non-trivial ppCDS lower-bounds for predicates that have low randomized bounded-error communication complexity like Greater-Than?
3. Unlike all the other communication complexity measures considered here, CDS complexity is not necessarily upper-bounded by the length of the inputs. But we have no super-linear (or even linear with a large constant factor) lower-bounds for even perfect CDS protocols. Can any of the existing lower-bound techniques from communication complexity be used to obtain such bounds?
4. If not, can this difficulty be explained, perhaps by relating the problem of proving such lower bounds for CDS to more well-studied problems that are still unsolved?
5. Following the paradigm of lifting query complexity lower bounds to the communication setting, is there a natural query complexity measure that can be lifted to CDS complexity?
6. One simple predicate that has eluded all our bounds is Set-Disjointness, for which the best (imperfect) CDS protocol we know has  $O(n)$  complexity, and the best lower bound we can prove, even for perfect CDS, is  $\Omega(\log(n))$ . Are either of these tight?

■ **Figure 2** As is standard, we use the name of a complexity measure to also denote the class of functions with  $\text{polylog}(n)$  complexity under the measure. For classes  $C_1$  and  $C_2$ , a solid arrow  $C_1 \rightarrow C_2$  indicates that  $C_1 \subseteq C_2$ , and a dashed arrow  $C_1 \dashrightarrow C_2$  indicates that  $C_1 \not\subseteq C_2$ . Red arrows indicate new results from this paper. Blue text indicates classes for which explicit bounds are not known.

## A Formal Setup

For a finite set  $A$  we write  $a \stackrel{R}{\leftarrow} A$  to denote a random variable which is sampled uniformly from  $A$ . The *statistical distance* between two discrete random variables,  $X$  and  $Y$ , denoted by  $\Delta(X; Y)$  is defined by  $\Delta(X; Y) := \frac{1}{2} \sum_z |\Pr[X = z] - \Pr[Y = z]|$ . We will also use statistical distance for probability distributions, where for a probability distribution  $D$  the value  $\Pr[D = z]$  is defined to be  $D(z)$ .

► **Definition 13** (CDS). Let  $f : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$  be a predicate. Let  $F_A : \mathcal{X} \times \mathcal{Z} \times \mathcal{R} \rightarrow \mathcal{T}_A$  and  $F_B : \mathcal{Y} \times \mathcal{Z} \times \mathcal{R} \rightarrow \mathcal{T}_B$  be deterministic encoding algorithms, where  $\mathcal{Z}$  is the *secret domain*. Then, the pair  $(F_A, F_B)$  is a CDS scheme for  $f$  with *correctness error*  $c$  and *privacy error*  $s$  if the function  $F(x, y, z, r) = (F_A(x, z, r), F_B(y, z, r))$  that corresponds to the joint computation of  $F_A$  and  $F_B$  on a common  $z$  and  $r$ , satisfies the following properties:

1. ( $c$ -Correctness) There exists a deterministic algorithm  $\text{Dec}$ , called a *decoder*, such that for every 1-input  $(x, y)$  of  $f$  and any secret  $z \in \mathcal{Z}$  we have that:

$$\Pr_{r \stackrel{R}{\leftarrow} \mathcal{R}} [\text{Dec}(x, y, F(x, y, z, r)) \neq z] \leq c$$

2. ( $s$ -Privacy) There exists a randomized simulator  $\text{Sim}$  such that for every 0-input  $(x, y)$  of  $f$ , every secret  $z \in \mathcal{Z}$ , and uniformly chosen randomness  $r \stackrel{R}{\leftarrow} \mathcal{R}$  the following holds:

$$\Delta(\text{Sim}(x, y) ; F(x, y, z, r)) \leq s.$$

The *communication complexity* of the CDS protocol is  $(\log |\mathcal{T}_A| + \log |\mathcal{T}_B|)$  and its *randomness complexity* is  $\log |\mathcal{R}|$ . If  $c$  and  $s$  are zeros, such a CDS scheme is called *perfect*.

## Abstract

Although Bitcoin was intended to be a decentralized digital currency, in practice, mining power is quite concentrated. This fact is a persistent source of concern for the Bitcoin community.

We provide an explanation using a simple model to capture miners' incentives to invest in equipment. In our model,  $n$  miners compete for a prize of fixed size. Each miner chooses an investment  $q_i$ , incurring cost  $c_i q_i$ , and then receives reward  $\frac{q_i^\alpha}{\sum_j q_j^\alpha}$ , for some  $\alpha \geq 1$ . When  $c_i = c_j$  for all  $i, j$ , and  $\alpha = 1$ , there is a unique equilibrium where all miners invest equally. However, we prove that under seemingly mild deviations from this model, equilibrium outcomes become drastically more centralized. In particular,

- When costs are asymmetric, if miner  $i$  chooses to invest, then miner  $j$  has market share at least  $1 - \frac{c_j}{c_i}$ . That is, if miner  $j$  has costs that are (e.g.) 20% lower than those of miner  $i$ , then miner  $j$  must control at least 20% of the *total* mining power.
- In the presence of economies of scale ( $\alpha > 1$ ), every market participant has a market share of at least  $1 - \frac{1}{\alpha}$ , implying that the market features at most  $\frac{\alpha}{\alpha-1}$  miners in total.

We discuss the implications of our results for the future design of cryptocurrencies. In particular, our work further motivates the study of protocols that minimize “orphaned” blocks, proof-of-stake protocols, and incentive compatible protocols.

## Abstract

In the subgraph counting problem, we are given a (large) input graph  $G(V, E)$  and a (small) target graph  $H$  (e.g., a triangle); the goal is to estimate the number of occurrences of  $H$  in  $G$ . Our focus here is on designing *sublinear-time* algorithms for approximately computing number of occurrences of  $H$  in  $G$  in the setting where the algorithm is given *query access* to  $G$ . This problem has been studied in several recent papers which primarily focused on specific families of graphs  $H$  such as triangles, cliques, and stars. However, not much is known about approximate counting of arbitrary graphs  $H$  in the literature. This is in sharp contrast to the closely related subgraph enumeration problem that has received significant attention in the database community as the database join problem. The AGM bound shows that the maximum number of occurrences of any arbitrary subgraph  $H$  in a graph  $G$  with  $m$  edges is  $O(m^{\rho(H)})$ , where  $\rho(H)$  is the *fractional edge-cover* of  $H$ , and enumeration algorithms with matching runtime are known for any  $H$ .

We bridge this gap between subgraph counting and subgraph enumeration by designing a simple sublinear-time algorithm that can estimate the number of occurrences of any arbitrary graph  $H$  in  $G$ , denoted by  $\#H$ , to within a  $(1 \pm \varepsilon)$ -approximation with high probability in  $O(\frac{m^{\rho(H)}}{\#H}) \cdot \text{poly}(\log n, 1/\varepsilon)$  time. Our algorithm is allowed the standard set of queries for general graphs, namely degree queries, pair queries and neighbor queries, plus an additional edge-sample query that returns an edge chosen uniformly at random. The performance of our algorithm matches those of Eden *et al.* [FOCS 2015, STOC 2018] for counting triangles and cliques and extend them to all choices of subgraph  $H$  under the additional assumption of edge-sample queries.

## 1 Introduction

Counting (small) subgraphs in massive graphs is a fundamental algorithmic problem, with a wide range of applications in bioinformatics, social network analysis, spam detection and graph databases (see, e.g. [36, 8, 11]). In social network analysis, the ratio of the number of triangles in a network to the number of length 2 paths (known as the clustering coefficient) as well as subgraph counts for larger subgraphs  $H$  have been proposed as important metrics for analyzing massive networks [42]. Similarly, motif counting are popular method for analyzing protein-protein interaction networks in bioinformatics (e.g., [36]). In this paper we consider designing efficient algorithms for this task.

Formally, we consider the following problem: Given a (large) graph  $G(V, E)$  with  $m$  edges and a (small) subgraph  $H(V_H, E_H)$  (e.g., a triangle) and a precision parameter  $\varepsilon \in (0, 1)$ , output a  $(1 \pm \varepsilon)$ -approximation to the number of occurrences of  $H$  in  $G$ . Our goal is to design an algorithm that runs in time *sublinear* in the number  $m$  of edges of  $G$ , and in particular makes a sublinear number of the following types of queries to the graph  $G$ :

- **Degree query  $v$** : the degree  $d_v$  of any vertex  $v \in V$ ;
- **Neighbor query  $(v, i)$** : what vertex is the  $i$ -th neighbor of the vertex  $v \in V$  for  $i \leq d_v$ ;
- **Pair query  $(u, v)$** : test for pair of vertices  $u, v \in V$ , whether or not  $(u, v)$  belongs to  $E$ .
- **Edge-sample query**: sample an edge  $e$  uniformly at random from  $E$ .

The first three queries are the standard baseline queries (see Chapter 10 of Goldreich's book [23]) assumed by nearly all sublinear time algorithms for counting small subgraphs such as triangles or cliques [16, 18] (see [25] for the necessity of using pair queries for counting subgraphs beside stars). The last query is somewhat less standard but is also considered in the literature prior to our work, for example in [2] for counting stars in sublinear time, and in [19] in the context of lower bounds for subgraph counting problems.

### 1.1 Our Contributions

For the sake of clarity, we suppress any dependencies on the approximation parameter  $\varepsilon$ ,  $\log n$ -terms, and the size of graph  $H$ , using the  $O^*(\cdot)$  notation. Our results are parameterized by the *fractional edge-cover number* of the subgraph  $H$  (see Section 3 for the formal definition). Our goal in this paper is to approximately compute the number of occurrences  $\#H$  of  $H$  in  $G$ , formally defined as number of subgraphs  $H'$  of  $G$  such that  $H$  and  $H'$  are isomorphic.

► **Theorem 1.** *There exists a randomized algorithm that given  $\varepsilon \in (0, 1)$ , a subgraph  $H$ , and a query access to the input graph  $G$ , with high probability outputs a  $(1 \pm \varepsilon)$  approximation to the number of occurrences of  $H$  in  $G$ , denoted by  $\#H$ , using:*

$$O^*\left(\min\left\{m, \frac{m^{\rho(H)}}{\#H}\right\}\right) \text{ queries and } O^*\left(\frac{m^{\rho(H)}}{\#H}\right) \text{ time.}$$

*The algorithm uses degree, neighbor, pair, and edge-sample queries.*

Since the fractional edge-cover number of any  $k$ -clique  $K_k$  is  $k/2$ , as a corollary of Theorem 1, we obtain sublinear algorithms for counting triangles, and in general  $k$ -cliques using

$$O^*\left(\min\left\{m, \frac{m\sqrt{m}}{\#K_3}\right\}\right) \text{ and } O^*\left(\min\left\{m, \frac{m^{k/2}}{\#K_k}\right\}\right),$$

queries respectively. These bounds match the previous results of Eden *et al.* [16, 18] modulo an additive term of  $O^*\left(\frac{n}{(\#K_3)^{1/3}}\right)$  for triangles in [16] and  $O^*\left(\frac{n}{(\#K_k)^{1/k}}\right)$  for arbitrary cliques

in [18] which is needed in the absence of edge-sample queries that are not used by [16, 18]. Our bounds settle a conjecture of Eden and Rosenbaum [19] in the affirmative by showing that one can avoid the aforementioned additive terms depending on  $n$  in query complexity by allowing edge-sample queries. We now elaborate more on different aspects of Theorem 1.

**AGM Bound and Database Joins.** The problem of *enumerating* all occurrences of a graph  $H$  in a graph  $G$  and, more generally, the database join problem, has been considered extensively in the literature. A fundamental question here is that given a database with  $m$  entries (e.g. a graph  $G$  with  $m$  edges) and a conjunctive query  $H$  (e.g. a small graph  $H$ ), what is the maximum possible size of the output of the query (e.g., number of occurrences of  $H$  in  $G$ )? The AGM bound of Atserias, Grohe and Marx [5] provides a tight upper bound of  $m^{\rho(H)}$  (up to constant factors), where  $\rho(H)$  is the fractional edge cover of  $H$ . The AGM bound applies to databases with several relations, and the fractional edge cover in question is weighted according to the sizes of the different relations. A similar bound on the number of occurrences of a hypergraph  $H$  inside a hypergraph  $G$  with  $m$  hyperedges was proved earlier by Friedgut and Kahn [22], and the bound for graphs is due to Alon [3]. Recent work of Ngo et al. [37] gave algorithms for evaluating database joins in time bounded by worst case output size for a database with the same number of entries. When instantiated for the subgraph enumeration problem, their result gives an algorithm for enumerating all occurrences of  $H$  in a graph  $G$  with  $m$  edges in time  $O(m^{\rho(H)})$ .

Our Theorem 1 is directly motivated by the connection between subgraph counting and subgraph enumeration problems and the AGM bound. In particular, Theorem 1 provides a natural analogue of AGM bound for estimation algorithms by stating that if the number of occurrences  $H$  is  $\#H \leq m^{\rho(H)}$ , then a  $(1 \pm \varepsilon)$ -approximation to  $\#H$  can be obtained in  $O^*(\frac{m^{\rho(H)}}{\#H})$  time. Additionally, as we show in Section 4.3, Theorem 1 can be easily extended to the more general problem of database join size estimation (for binary relations). This problem corresponds to a subgraph counting problem in which the graphs  $G$  and  $H$  are both *edge-colored* and our goal is to count the number of copies of  $H$  in  $G$  with the same colors on edges. Our algorithm can solve this problem also in  $O^*(\frac{m^{\rho(H)}}{\#H_c})$  time where  $\#H_c$  denotes the number of copies of  $H$  with the same colors in  $G$ .

**Optimality of Our Bounds.** Our algorithm in Theorem 1 is optimal from different points of view. Firstly, by a lower bound of [19] (building on [16, 18]), the bounds achieved by our algorithm when  $H$  is any  $k$ -clique is optimal among all algorithms with the same query access (including the edge-sample query). In Theorem 15, we further prove a lower bound showing that for *odd cycles* as well, the bounds achieved by Theorem 1 are optimal. These results hence suggest that Theorem 1 is *existentially optimal*: there exists several natural choices for  $H$  such that Theorem 1 achieves the optimal bounds. However, there also exist choices of  $H$  for which the bounds in Theorem 1 are suboptimal. In particular, Aliakbarpour *et al.* [2] presented an algorithm for estimating occurrences of any star  $S_\ell$  for  $\ell \geq 1$  using  $O^*(\frac{m}{(\#S_\ell)^{1/\ell}})$  queries in our query model (including edge-sample queries) which is always at least as good as our bound in Theorem 1, but potentially can be better. On the other hand, in the full version of the paper [4], we show that our current algorithm, with almost no further modification, in fact achieves this stronger bound *using a different analysis*.

Additionally, as we pointed out before, our algorithm can solve the more general database join size estimation for binary relations, or equivalently the subgraph counting problem with colors on edges. In Theorem 16, we prove that for this more general problem, our algorithm in Theorem 1 indeed achieves optimal bounds for *all choices* of the subgraph  $H$ .

**Edge-Sample Queries.** The edge-sample query that we assume is not part of the standard access model for sublinear algorithms, namely the “general graph” query model (see, e.g. [32]). Nonetheless, we find allowing for this query “natural” owing to the following factors:

*Theoretical implementation.* Edge sampling queries can be implemented with an  $\tilde{O}(n/\sqrt{m})$  multiplicative overhead in query and time using the recent result of [20], or with an  $O(n)$  additive preprocessing time (which is still sublinear in  $m$ ) by querying degrees of all vertices. Hence, we can focus on designing algorithms by allowing these queries and later replacing them by either of the above implementations in a black-box way at a certain additional cost.

*Practical implementation.* Edge sampling is a common practice in analyzing social networks [34, 33] or biological networks [1]. Another scenario when random edge sampling is possible is when we can access a random location of the memory that is used to store the graph. To quote [2]: “because edges normally take most of the space for storing graphs, an access to a random memory location where the adjacency list is stored, would readily give a random edge.” Hence, assuming edge sampling queries can be considered valid in many scenarios.

*Understanding the power of random edge queries.* Edge sampling is a critical component of various sublinear time algorithms for graph estimation [16, 17, 2, 18, 20]. However, except for [2] that also assumed edge-sample queries, all these other algorithms employ different workarounds to these queries. As we show in this paper, decoupling these workarounds from the rest of the algorithm by allowing edge-sample queries results in considerably simpler and more general algorithms for subgraph counting and is hence worth studying on its own. We also mention that studying the power of edge-sample queries has been cast as an open question in [19] as well.

**Applications to Streaming Algorithms.** Subgraph counting is also one of the most studied problems in the graph streaming model (see, e.g. [6, 28, 10, 31, 9, 27, 41, 35, 13, 7] and references therein). In this model, the edges of the input graph are presented one by one in a stream; the algorithm makes a single or a small number of passes over the stream and outputs the answer after the last pass. The goal here is to minimize the memory used by the algorithm (similar-in-spirit to minimizing the query complexity in the query model).

Our algorithm in Theorem 1 can be directly adapted to the streaming model, resulting in an algorithm for subgraph counting that makes  $O(1)$  passes over the stream and uses a memory of size  $O^*\left(\min\left\{m, \frac{m^{\rho(H)}}{\#H}\right\}\right)$ . For the case of counting triangles and cliques, the space complexity of our algorithm matches the best known algorithms of McGregor *et al.* [35] and Bera and Chakrabarti [7] which are known to be optimal [7]. To the best of our knowledge, the only previous streaming algorithms for counting arbitrary subgraphs  $H$  are those of Kane *et al.* [31] and Bera and Chakrabarti [7] that use, respectively, one pass and  $O^*\left(\frac{m^{2 \cdot |E(H)|}}{(\#H)^2}\right)$  space, and two passes and  $O^*\left(\frac{m^{\beta(H)}}{\#H}\right)$  space, where  $\beta(H)$  is the *integral* edge-cover number of  $H$ . As  $\rho(H) \leq \beta(H) \leq |E(H)|$  by definition and  $\#H \leq m^{\rho(H)}$  by AGM bound, the space complexity of our algorithm is always at least as good as the ones in [31, 7] but potentially can be much smaller.

## 1.2 Main Ideas in Our Algorithm

Our starting point is the AGM bound which implies that the number of “potential copies” of  $H$  in  $G$  is at most  $m^{\rho(H)}$ . Our goal of estimating  $\#H$  then translates to counting how many of these potential copies form an actual copy of  $H$  in  $G$ . A standard approach at this point is the *Monte Carlo method*: sample a potential copy of  $H$  in  $G$  *uniformly at random*

and check whether it forms an actual copy of  $H$  or not; a simple exercise in concentration inequalities then implies that we only need  $O(\frac{m^{\rho(H)}}{\#H})$  many *independent* samples to get a good estimate of  $\#H$ .

This approach however immediately runs into a technical difficulty. Given only a query access to  $G$ , it is not at all clear how to sample a potential copy of  $H$  from the list of all potential copies. Our first task is then to design a procedure for sampling potential copies of  $H$  from  $G$ . In order to do so, we again consider the AGM bound and the optimal fractional edge-cover that is used to derive this bound. We first prove a simple structural result that states that an optimal fractional edge-cover of  $H$  can be supported only on edges that form a disjoint union of *odd cycles* and *stars* (in  $H$ ). This allows us to decompose  $H$  into a collection of odd cycles and stars and treat any arbitrary subgraph  $H$  as a collection of these simpler subgraphs that are suitably connected together.

The above decomposition reduces the task of sampling a potential copy of  $H$  to sampling a collection of odd cycles and stars. Sampling an odd cycle  $C_{2k+1}$  on  $2k+1$  edges is as follows: sample  $k$  edges  $e_1, \dots, e_k$  uniformly at random from  $G$ ; pick one of the endpoints of  $e_1$  and sample a vertex  $v$  from the neighborhood of this endpoint uniformly at random. With some additional care, one can show that the tuple  $(e_1, \dots, e_k, v)$  sampled here is enough to identify an odd cycle of length  $2k+1$  uniquely. To sample a star  $C_\ell$  with  $\ell$  petals, we sample a vertex  $v$  from  $G$  with probability proportional to its degree (by sampling a random edge and picking one of the two endpoints uniformly), and then sample  $\ell$  vertices  $w_1, \dots, w_\ell$  from the neighborhood of  $v$ . Again, with some care, this allows us to sample a potential copy of a star  $S_\ell$ . We remark that these sampling procedures are related to sampling triangles in [16] and stars in [2]. Finally, to sample a potential copy of  $H$ , we simply sample all its odd cycles and stars in the decomposition using the method above. We should note right away that this however does *not* result in a uniformly at random sample of potential copies of  $H$  as various parameters of the graph  $G$ , in particular degrees of vertices, alter the probability of sampling each potential copy.

The next and paramount step is then how to use the samples above to estimate the value of  $\#H$ . Obtaining an unbiased estimator of  $\#H$  based on these samples is not hard as we can identify the probability each potential copy is sampled with in this process (which is a function of degrees of vertices of the potential copy in  $G$ ) and reweigh each sample accordingly. Nevertheless, the variance of a vanilla variant of this sampling and reweighing approach is quite large for our purpose. To fix this, we use an idea similar to that of [16] for counting triangles: sample a “partial” potential copy of  $H$  first and fix it; sample *multiple* “extensions” of this partial potential copy to a complete potential copy and use the average of estimates based on each extension to reduce the variance. More concretely, this translates to sampling multiple copies of the first cycle for the decomposition and for each sampled cycle, recursively sampling multiple copies of the remainder of  $H$  as specified by the decomposition. A careful analysis of this recursive process – which is the main technical part of the paper – allows us to bound the variance of the estimator by  $O(m^{\rho(H)} \cdot (\#H))$ . Repeating such an estimator  $O(\frac{m^{\rho(H)}}{\#H})$  times independently and taking the average value then gives us a  $(1 \pm \varepsilon)$ -approximation to  $\#H$  by a simple application of Chebyshev’s inequality.

### 1.3 Further Related Work

In addition to the previous work in [16, 18, 2] that are already discussed above, sublinear-time algorithms for estimating subgraph counts and related parameters such as average degree and degree distribution moments have also been studied in [21, 24, 25, 17]. Similarly, sublinear-

time algorithms are also studied for estimating other graph parameters such as weight of the minimum spanning tree [15, 12, 14] or size of a maximum matching or a minimum vertex cover [40, 38, 43, 26, 39] (this is by no means a comprehensive summary of previous results).

Subgraph counting has also been studied extensively in the graph streaming model (see, e.g. [6, 28, 10, 31, 9, 27, 41, 35, 13, 7, 30, 29] and references therein). In this model, the edges of the input graph are presented one by one in a stream; the algorithm makes a single or a small number of passes over the stream and outputs the answer after the last pass. The goal in this model is to minimize the memory used by the algorithm similar-in-spirit to minimizing the query complexity in our query model. However, the streaming algorithms typically require reading the entire graph in the stream which is different from our goal in sublinear-time algorithms.

## 2 Preliminaries

**Notation.** For any integer  $t \geq 1$ , we let  $[t] := \{1, \dots, t\}$ . For any event  $\mathcal{E}$ ,  $\mathbb{I}(\mathcal{E}) \in \{0, 1\}$  is an indicator denoting whether  $\mathcal{E}$  happened or not. For a graph  $G(V, E)$ ,  $V(G) := V$  denotes the vertices and  $E(G) := E$  denotes the edges. For a vertex  $v \in V$ ,  $N(v)$  denotes the neighbors of  $v$ , and  $d_v := |N(v)|$  denotes the degree of  $v$ .

To any edge  $e = \{u, v\}$  in  $G$ , we assign two directed edges  $\vec{e}_1 = (u, v)$  and  $\vec{e}_2 = (v, u)$  called the directed copies of  $e$  and let  $\vec{E}$  be the set of all these directed edges. We also fix a total ordering  $\prec$  on vertices whereby for any two vertices  $u, v \in V$ ,  $u \prec v$  iff  $d_u < d_v$ , or  $d_u = d_v$  and  $u$  appears before  $v$  in the lexicographic order. To avoid confusion, we use letters  $a, b$  and  $c$  to denote the vertices in the subgraph  $H$ , and letters  $u, v$  and  $w$  to denote the vertices of  $G$ .

We use the following standard variant of Chebyshev's inequality.

► **Proposition 2.** For any random variable  $X$  and integer  $t \geq 1$ ,  $\Pr(|X - \mathbb{E}[X]| \geq t) \leq \frac{\text{Var}[X]}{t^2}$ .

We also recall the law of total variance that states the for two random variables  $X$  and  $Y$ ,

$$\text{Var}[Y] = \mathbb{E}_x(\text{Var}[Y | X = x]) + \text{Var}_x[\mathbb{E}[Y | X = x]]. \quad (1)$$

**Assumption on Size of Subgraph  $H$ .** Throughout the paper, we assume that the size of the subgraph  $H$  is a fixed constant independent of the size of the graph  $G$  and hence we suppress the dependency on size of  $H$  in various bounds in our analysis using  $O$ -notation.

## 3 A Graph Decomposition Using Fractional Edge-Covers

In this section, we give a simple decomposition of the subgraph  $H$  using fractional edge-covers. We start by defining fractional edge-covers formally (see also Figure 1).

► **Definition 3 (Fractional Edge-Cover Number).** A fractional edge-cover of  $H(V_H, E_H)$  is a mapping  $\psi : E_H \rightarrow [0, 1]$  such that for each vertex  $a \in V_H$ ,  $\sum_{e \in E_H, a \in e} \psi(e) \geq 1$ . The fractional edge-cover number  $\rho(H)$  of  $H$  is the minimum value of  $\sum_{e \in E_H} \psi(e)$  among all fractional edge-covers  $\psi$ .

■ **Figure 1** Illustration of the our decomposition for  $H$  based on fractional edge-covers.

The fractional edge-cover number of a graph can be computed by the following LP:

$$\begin{aligned} \rho(H) &= \text{minimize} && \sum_{e \in E(H)} x_e \\ &\text{subject to} && \sum_{e \in E_H: a \in e} x_e \geq 1 \text{ for all vertices } a \in V(H). \end{aligned} \quad (2)$$

The following lemma is the key to our decomposition. The proof is based on standard ideas in linear programming and is postponed to the full version of the paper [4].

► **Lemma 4.** *Any subgraph  $H$  admits an optimal fractional edge-cover  $x^*$  such that the support of  $x^*$ , denoted by  $\text{SUPP}(x^*)$ , is a collection of vertex-disjoint odd cycles and star graphs, and,*

1. *for every odd cycle  $C \in \text{SUPP}(x^*)$ ,  $x_e^* = 1/2$  for all  $e \in C$ ;*
2. *for every edge  $e \in \text{SUPP}(x^*)$  that does not belong to any odd cycle,  $x_e = 1$ .*

### 3.1 The Decomposition

We now present the decomposition of  $H$  using Lemma 4. Let  $x^*$  be an optimal fractional edge-cover in Lemma 4 and let  $\mathcal{C}_1, \dots, \mathcal{C}_o$  be the odd-cycles in the support of  $x^*$  and  $\mathcal{S}_1, \dots, \mathcal{S}_s$  be the stars. We define  $\mathcal{D}(H) := \{\mathcal{C}_1, \dots, \mathcal{C}_o, \mathcal{S}_1, \dots, \mathcal{S}_s\}$  as the decomposition of  $H$  (see Figure 1 for an illustration).

For every  $i \in [o]$ , let the length of the odd cycle  $\mathcal{C}_i$  be  $2k_i + 1$  (i.e.,  $\mathcal{C}_i = C_{2k_i+1}$ ); we define  $\rho_i^C := k_i + 1/2$ . Similarly, for every  $j \in [s]$ , let the number of petals in  $\mathcal{S}_j$  be  $\ell_j$  (i.e.,  $\mathcal{S}_j = S_{\ell_j}$ ); we define  $\rho_j^S := \ell_j$ . By Lemma 4,

$$\rho(H) = \sum_{i=1}^o \rho_i^C + \sum_{j=1}^s \rho_j^S. \quad (3)$$

Recall that by AGM bound, the total number of copies of  $H$  possible in  $G$  is  $m^{\rho(H)}$ . We also use the following simple lemma which is a direct corollary of the AGM bound.

► **Lemma 5.** *Let  $I := \{i_1, \dots, i_o\}$  and  $J := \{j_1, \dots, j_s\}$  be subsets of  $[o]$  and  $[s]$ , respectively. Suppose  $\tilde{H}$  is the subgraph of  $H$  on vertices of the odd cycles  $\mathcal{C}_{i_1}, \dots, \mathcal{C}_{i_o}$  and stars  $\mathcal{S}_{j_1}, \dots, \mathcal{S}_{j_s}$ . Then the total number of copies of  $\tilde{H}$  in  $G$  is at most  $m^{\rho(\tilde{H})}$  for  $\rho(\tilde{H}) \leq \sum_{i \in I} \rho_i^C + \sum_{j \in J} \rho_j^S$ .*

**Proof.** Let  $x^*$  denote the optimal value of LP (2) in  $\mathcal{D}(H)$ . Define  $y^*$  as the projection of  $x^*$  to edges present in  $\tilde{H}$ . It is easy to see that  $y^*$  is a feasible solution for LP (2) of  $\tilde{H}$  with value  $\sum_{i \in I} \rho_i^C + \sum_{j \in J} \rho_j^S$ . The lemma now follows from AGM bound for  $\tilde{H}$ . ◀

### 3.2 Profiles of Cycles, Stars, and Subgraphs

We conclude this section by specifying the representation of the potential occurrences of the subgraph  $H$  in  $G$  based on the decomposition  $\mathcal{D}(H)$ .

*Odd cycles:* We represent a potential occurrence of an odd cycle  $C_{2k+1}$  in  $G$  as follows. Let  $\mathbf{e} = (\vec{e}_1, \dots, \vec{e}_k) \in \vec{E}^k$  be an ordered tuple of  $k$  directed copies of edges in  $G$  and suppose  $\vec{e}_i := (u_i, v_i)$  for all  $i \in [k]$ . Define  $u_{\mathbf{e}}^* = u_1$  and let  $w$  be any vertex in  $N(u_{\mathbf{e}}^*)$ . We refer to any such collection  $(\mathbf{e}, w)$  as a *profile* of  $C_{2k+1}$  in  $G$ . We say that “the profile  $(\mathbf{e}, w)$  forms a cycle  $C_{2k+1}$  in  $G$ ” iff (i)  $u_1$  is the smallest vertex on the cycle according to  $\prec$ , (ii)  $v_1 \prec w$ , and (iii) the edges  $(u_1, v_1), (v_1, u_2), \dots, (u_k, v_k), (v_k, w), (w, u_1)$  all exist in  $G$  and hence there is a copy of  $C_{2k+1}$  on vertices  $\{u_1, v_1, u_2, v_2, \dots, u_k, v_k, w\}$  in  $G$ . Note that under this definition and our definition of  $\#C_{2k+1}$ , each copy of  $C_{2k+1}$  correspond to exactly one profile  $(\mathbf{e}, w)$  and vice versa. As such,

$$\#C_{2k+1} = \sum_{\mathbf{e} \in \vec{E}^k} \sum_{w \in N(u_{\mathbf{e}}^*)} \mathbb{I}\left((\mathbf{e}, w) \text{ forms a cycle } C_{2k+1} \text{ in } G\right). \quad (4)$$

*Stars:* We represent a potential occurrence of a star  $S_\ell$  in  $G$  by  $(v, \mathbf{w})$  where  $v$  is the center of the star and  $\mathbf{w} = (w_1, \dots, w_\ell)$  are the  $\ell$  petals. We refer to  $(v, \mathbf{w})$  as a *profile* of  $S_\ell$  in  $G$ . We say that “the profile  $(v, \mathbf{w})$  forms a star  $S_\ell$  in  $G$ ” iff (i)  $|\mathbf{w}| > 1$ , or (ii)  $(\ell = 1)$   $|\mathbf{w}| = 1$  and  $v \prec w_1$ ; in both cases there is a copy of  $S_\ell$  on vertices  $v, w_1, \dots, w_\ell$ . Under this definition, each copy of  $S_\ell$  corresponds to exactly one profile  $(v, \mathbf{w})$ . As such,

$$\#S_\ell = \sum_{v \in V} \sum_{\mathbf{w} \in N(v)^\ell} \mathbb{I}\left((v, \mathbf{w}) \text{ forms a star } S_\ell \text{ in } G\right). \quad (5)$$

*Arbitrary subgraphs:* We represent a potential occurrence of  $H$  in  $G$  by an  $(o + s)$ -tuple  $\mathbf{R} := ((\mathbf{e}_1, \mathbf{w}_1), \dots, (\mathbf{e}_o, \mathbf{w}_o), (v_1, \mathbf{w}_1), \dots, (v_s, \mathbf{w}_s))$  where  $(\mathbf{e}_i, \mathbf{w}_i)$  is a profile of the cycle  $C_i$  in  $\mathcal{D}(H)$  and  $(v_j, \mathbf{w}_j)$  is a profile of the star  $S_j$ . We refer to  $\mathbf{R}$  as a *profile* of  $H$  and say that “the profile  $\mathbf{R}$  forms a copy of  $H$  in  $G$ ” iff (i) each profile forms a corresponding copy of  $C_i$  or  $S_j$  in  $\mathcal{D}(H)$ , and (ii) the remaining edges of  $H$  between vertices specified by  $\mathbf{R}$  all are present in  $G$  (note that by definition of the decomposition  $\mathcal{D}(H)$ , all vertices of  $H$  are specified by  $\mathbf{R}$ ). As such,

$$\#H = \sum_{\mathbf{R}} \mathbb{I}\left(\mathbf{R} \text{ forms a copy of } H \text{ in } G\right) \cdot f(H), \quad (6)$$

for a fixed constant  $f(H)$  depending only on  $H$  as defined below. Let  $\pi : V_H \rightarrow V_H$  be an automorphism of  $H$ . Let  $C_1, \dots, C_o, S_1, \dots, S_s$  denote the cycles and stars in the decomposition of  $H$ . We say that  $\pi$  is decomposition preserving if for every  $i = 1, \dots, o$  cycle  $C_i$  is mapped to a cycle of the same length and for every  $i = 1, \dots, s$  star  $S_i$  is mapped to a star with the same number of petals. Let the number of decomposition preserving automorphisms of  $H$  be denoted by  $Z$ , and define  $f(H) = 1/Z$ . Define the quantity  $\widetilde{\#H} := \sum_{\mathbf{R}} \mathbb{I}\left(\mathbf{R} \text{ forms a copy of } H \text{ in } G\right)$  which is equal to  $\#H$  modulo the scaling factor of  $f(H)$ . It is immediate that estimating  $\#H$  and  $\widetilde{\#H}$  are equivalent to each other and hence in the rest of the paper, with a slight abuse of notation, we use  $\#H$  and  $\widetilde{\#H}$  interchangeably.

## 4 A Sublinear-Time Algorithm for Subgraph Counting

We now present our sublinear time algorithm for approximately counting number of any given arbitrary subgraph  $H$  in an underlying graph  $G$  and prove Theorem 1. The main component of our algorithm is an unbiased estimator random variable for  $\#H$  with low

variance. The algorithm in Theorem 1 is then obtained by simply repeating this unbiased estimator in parallel enough number of times (based on the variance) and outputting the average value of these estimators.

#### 4.1 A Low-variance Unbiased Estimator for $\#H$

We present a low-variance unbiased estimator for  $\#H$  in this section. Our algorithm is a sampling based algorithm. In the following, we first introduce two separate subroutines for sampling odd cycles (**odd-cycle-sampler**) and stars (**star-sampler**), and then use these components in conjunction with the decomposition we introduced in Section 3, to present our full algorithm. We should right away clarify that **odd-cycle-sampler** and **star-sampler** are not exactly sampling a cycle or a star, but rather sampling a set of vertices and edges (in a non-uniform way) that can potentially form a cycle or star in  $G$ , i.e., they sample a profile of these subgraphs defined in Section 3.2.

##### The odd-cycle-sampler Algorithm

We start with the following algorithm for sampling an odd cycle  $C_{2k+1}$  for some  $k \geq 1$ . This algorithm outputs a simple data structure, named the *cycle-sampler tree*, that provides a convenient representation of the samples taken by our algorithm (see Definition 6 immediately after the description of the algorithm). This data structure can be easily avoided when designing a cycle counting algorithm, but will be quite useful for reasoning about the recursive structure of our sampling algorithm for general graphs  $H$ .

---

**Algorithm 1** `odd-cycle-sampler`( $G, C_{2k+1}$ ).

---

1. Sample  $k$  directed edges  $e := (\vec{e}_1, \dots, \vec{e}_k)$  uniformly at random (with replacement) from  $G$  with the constraint that for  $\vec{e}_1 = (u_1, v_1)$ ,  $u_1 \prec v_1$ .
  2. Let  $u_e^* := u_1$  and let  $d_e^* := d_{u_e^*}$ .
  3. For  $i = 1$  to  $t_e := \lceil d_e^* / \sqrt{m} \rceil$ : Sample a vertex  $w_i$  uniformly at random from  $N(u_e^*)$ .
  4. Let  $w := (w_1, \dots, w_{t_e})$ . Return the cycle-sampler tree  $\mathcal{T}(e, w)$  (see Definition 6).
- 

► **Definition 6** (Cycle-Sampler Tree). The cycle-sampler tree  $\mathcal{T}(e, w)$  for the tuple  $(e, w)$  sampled by `odd-cycle-sampler`( $G, C_{2k+1}$ ) is the following 2-level tree  $\mathcal{T}$ :

- Each node  $\alpha$  of the tree contains two attributes:  $\text{label}[\alpha]$  which consists of some of the edges and vertices in  $(e, w)$ , and an integer  $\text{value}[\alpha]$ .
- For the root  $\alpha_r$  of  $\mathcal{T}$ ,  $\text{label}[\alpha_r] := e$  and  $\text{value}[\alpha_r] := (2m)^k / 2$ . ( $\text{value}[\alpha_r]$  is equal to the inverse of the probability that  $e$  is sampled by `odd-cycle-sampler`).
- The root  $\alpha_r$  has  $t_e$  child-nodes in  $\mathcal{T}$  for a parameter  $t_e = \lceil d_e^* / \sqrt{m} \rceil$  (consistent with line 3 of `odd-cycle-sampler`( $G, C_{2k+1}$ ) above).
- For the  $i$ -th child-node  $\alpha_i$  of root,  $i \in [t_e]$ ,  $\text{label}[\alpha_i] := w_i$  and  $\text{value}[\alpha_i] := d_e^*$  ( $\text{value}[\alpha_i]$  is equal to the inverse of the probability that  $w_i$  is sampled by `odd-cycle-sampler`, conditioned on  $e$  being sampled).

Moreover, for each root-to-leaf path  $\mathcal{P}_i := (\alpha_r, \alpha_i)$  (for  $i \in [t_e]$ ), define  $\text{label}[\mathcal{P}_i] := \text{label}[\alpha_r] \cup \text{label}[\alpha_i]$  and  $\text{value}[\mathcal{P}_i] := \text{value}[\alpha_r] \cdot \text{value}[\alpha_i]$  ( $\text{label}[\mathcal{P}_i]$  is a profile of the cycle  $C_{2k+1}$  as defined in Section 3.2).

`odd-cycle-sampler` can be implemented in our query model by using  $k$  edge-sample queries (and picking the correct direction for  $e_1$  based on  $\prec$  and one of the two directions uniformly at random for the other edges) in Line (1), two degree queries in Line (2), and one neighbor query in Line (3). This results in  $O(k)$  queries in total for one iteration of the for-loop in Line (3). As such, the total query complexity of `odd-cycle-sampler` is  $O(t_e)$  (recall that  $k$  is a constant). It is also straightforward to verify that we can compute the cycle-sampler tree  $\mathcal{T}$  of an execution of `odd-cycle-sampler` with no further queries and in  $O(t_e)$  time. We bound the query complexity of this algorithm by bounding the expected number of iterations in the for-loop. The proof is postponed to the full version [4].

► **Lemma 7.** *For the parameter  $t_e$  in Line (3) of `odd-cycle-sampler`,  $\mathbb{E}[t_e] = O(1)$ .*

We now define a process for estimating the number of odd cycles in a graph using the information stored in the cycle-sampler tree and the `odd-cycle-sampler` algorithm. While we do not use this process in a black-box way in our main algorithm, abstracting it out makes the analysis of our main algorithm simpler to follow and more transparent, and serves as a warm-up for our main algorithm.

**Warm-up: An Estimator for Odd Cycles.** Let  $\mathcal{T} := \text{odd-cycle-sampler}(G, C_{2k+1})$  be the output of an invocation of `odd-cycle-sampler`. Note that the cycle-sampler tree  $\mathcal{T}$  is a random variable depending on the randomness of `odd-cycle-sampler`. We define the random variable  $X_i$  such that  $X_i := \text{label}[\mathcal{P}_i]$  for the  $i$ -th root-to-leaf path iff  $\text{label}[\mathcal{P}_i]$  forms a copy of  $C_{2k+1}$  in  $G$  and otherwise  $X_i := 0$  (according to the definition of Section 3). We further define  $Y := \frac{1}{t_e} \cdot \sum_{i=1}^{t_e} X_i$  (note that  $t_e$  is also a random variable). Our estimator algorithm can compute the value of these random variables using the information stored in the tree  $\mathcal{T}$  plus additional  $O(k) = O(1)$  queries for each of the  $t_e$  root-to-leaf path  $\mathcal{P}_i$  to detect whether  $(e, w_i)$  forms a copy of  $H$  or not. Thus, the query complexity and runtime of the estimator is still  $O(t_e)$  (which in expectation is  $O(1)$  by Lemma 7). The expectation and variance of the estimator can be bounded as follows (the proof is in the full version [4]).

► **Lemma 8.** *For the random variable  $Y$  associated with `odd-cycle-sampler`( $G, C_{2k+1}$ ),*

$$\mathbb{E}[Y] = (\#C_{2k+1}), \quad \text{Var}[Y] \leq (2m)^k \sqrt{m} \cdot \mathbb{E}[Y].$$

## The star-sampler Algorithm

We now give an algorithm for sampling a star  $S_\ell$  with  $\ell$  petals. Similar to `odd-cycle-sampler`, this algorithm also outputs a simple data structure, named the *star-sampler tree*, that provides a convenient representation of the samples taken by our algorithm (see Definition 9, immediately after the description of the algorithm). This data structure can be easily avoided when designing a star counting algorithm, but will be quite useful for reasoning about the recursive structure of our sampling algorithm for general graphs  $H$ .

► **Definition 9 (Star-Sampler Tree).** The star-sampler tree  $\mathcal{T}(v, \mathbf{w})$  for the tuple  $(v, \mathbf{w})$  sampled by `star-sampler`( $G, S_\ell$ ) is the following 2-level tree  $\mathcal{T}$  (with the same attributes as in Definition 6) with only two nodes:

- For the root  $\alpha_r$  of  $\mathcal{T}$ ,  $\text{label}[\alpha_r] := v$  and  $\text{value}[\alpha_r] := 2m/d_v$ .  
( $\text{value}[\alpha_r]$  is equal to the inverse of the probability that  $v$  is sampled by `star-sampler`).
- The root  $\alpha_r$  has exactly one child-node  $\alpha_l$  in  $\mathcal{T}$  with  $\text{label}[\alpha_l] = \mathbf{w} = (w_1, \dots, w_\ell)$  and  $\text{value}[\alpha_l] = \binom{d_v}{\ell}$ .  
( $\text{value}[\alpha_l]$  is equal to the inverse of the probability that  $\mathbf{w}$  is sampled by `star-sampler`, conditioned on  $v$  being sampled).

---

**Algorithm 2** `star-sampler`( $G, S_\ell$ ).

---

1. Sample a vertex  $v \in V$  chosen with probability proportional to its degree in  $G$  (i.e., for any vertex  $u \in V$ ,  $\Pr(u \text{ is chosen as the vertex } v) = d_u/2m$ ).
  2. Sample  $\ell$  vertices  $\mathbf{w} := (w_1, \dots, w_\ell)$  from  $N(v)$  uniformly at random (without replacement).
  3. Return the star-sampler tree  $\mathcal{T}(v, \mathbf{w})$  (see Definition 9).
- 

Moreover, for the root-to-leaf path  $\mathcal{P} := (\alpha_r, \alpha_\ell)$ , we define  $\text{label}[\mathcal{P}] := \text{label}[\alpha_r] \cup \text{label}[\alpha_\ell]$  and  $\text{value}[\mathcal{P}] := \text{value}[\alpha_r] \cdot \text{value}[\alpha_\ell]$ . ( $\text{label}[\mathcal{P}]$  is a representation of the star  $S_\ell$  as defined in Section 3.2).

`star-sampler` can be implemented in our query model by using one edge-sample query in Line (1) and then picking one of the endpoints uniformly at random, a degree query to determine the degree of  $v$ , and  $\ell$  neighbor queries in Line (2), resulting in  $O(\ell)$  queries in total. It is also straightforward to verify that we can compute the star-sampler tree  $\mathcal{T}$  of an execution of `star-sampler` with no further queries and in  $O(1)$  time.

We again define a process for estimating the number of stars in a graph using the information stored in the star-sampler tree and the `star-sampler` algorithm, as a warm-up to our main result in the next section.

**Warm-up: An Estimator for Stars.** The star-sampler tree  $\mathcal{T}$  is a random variable depending on the randomness of `star-sampler`. We define the random variable  $X$  such that  $X := \text{value}[\mathcal{P}]$  for the root-to-leaf path of  $\mathcal{T}$  iff  $\text{label}[\mathcal{P}]$  forms a copy of  $S_\ell$  in  $G$  and otherwise  $X := 0$ . Our estimator algorithm can compute the value of this random variable using only the information stored in the tree  $\mathcal{T}$  with no further queries to the graph (by simply checking if all  $w_i$ 's in  $\mathbf{w}$  are distinct). As such, the query complexity and runtime of the estimator algorithm is still  $O(1)$ . The proof of the following lemma is postponed to the full version [4].

► **Lemma 10.** *For the random variable  $X$  associated with `star-sampler`( $G, S_\ell$ ),*

$$\mathbb{E}[X] = (\#S_\ell), \quad \text{Var}[X] \leq 2m^\ell \cdot \mathbb{E}[X].$$

## The Estimator Algorithm for Arbitrary Subgraphs

We now present our main estimator for the number of occurrences of an arbitrary subgraph  $H$  in  $G$ , denoted by  $(\#H)$ . Recall the decomposition  $\mathcal{D}(H) := \{\mathcal{C}_1, \dots, \mathcal{C}_o, \mathcal{S}_1, \dots, \mathcal{S}_s\}$  of  $H$  introduced in Section 3. Our algorithm creates a *subgraph-sampler tree*  $\mathcal{T}$  (a generalization of cycle-sampler and star-sampler trees in Definitions 6 and 9) and use it to estimate  $(\#H)$ . We define the subgraph-sampler tree  $\mathcal{T}$  and the algorithm `subgraph-sampler`( $G, H$ ) that creates it simultaneously:

**Subgraph-Sampler Tree.** The subgraph-sampler tree  $\mathcal{T}$  is a  $z$ -level tree for  $z := (2o + 2s)$  returned by `subgraph-sampler`( $G, H$ ). The algorithm constructs  $\mathcal{T}$  as follows.

*Sampling Odd Cycles.* In `subgraph-sampler`( $G, H$ ), we run `odd-cycle-sampler`( $G, \mathcal{C}_1$ ) and initiate  $\mathcal{T}$  to be its output cycle-sampler tree. For every (current) leaf-node  $\alpha$  of  $\mathcal{T}$ , we run `odd-cycle-sampler`( $G, \mathcal{C}_2$ ) *independently* to obtain a cycle-sampler tree  $\mathcal{T}_\alpha$  (we say that  $\alpha$  *started* the sampling of  $\mathcal{T}_\alpha$ ). We then extend the tree  $\mathcal{T}$  with two new layers by connecting each leaf-node  $\alpha$  to the root of  $\mathcal{T}_\alpha$  that started its sampling. This creates a

4-level tree  $\mathcal{T}$ . We continue like this for  $o$  steps, each time appending the tree obtained by `odd-cycle-sampler`( $G, \mathcal{C}_j$ ) for  $j \in [o]$ , to the (previous) leaf-node that started this sampling. This results in a  $(2o)$ -level tree. Note that the nodes in the tree  $\mathcal{T}$  can have different degrees as the number of leaf-nodes in the cycle-sampler tree is not necessarily the same always (not even for two different trees associated with one single  $\mathcal{C}_j$  through different calls to `odd-cycle-sampler`( $G, \mathcal{C}_j$ )).

*Sampling Stars.* Once we iterated over all odd cycles of  $\mathcal{D}(H)$ , we switch to processing stars  $\mathcal{S}_1, \dots, \mathcal{S}_s$ . The approach is identical to the previous part. Let  $\alpha$  be a (current) leaf-node of  $\mathcal{T}$ . We run `star-sampler`( $G, \mathcal{S}_1$ ) to obtain a star-sampler tree  $\mathcal{T}_\alpha$  and connect  $\alpha$  to  $\mathcal{T}_\alpha$  to extend the levels of tree by 2 more. We continue like this for  $s$  steps, each time appending the tree obtained by `star-sampler`( $G, \mathcal{S}_j$ ) for  $j \in [s]$ , to the (former) leaf-node that started this sampling. This results in a  $z$ -level tree  $\mathcal{T}$ . Note that all nodes added when sampling stars have exactly one child-node (except for the leaf-nodes) as by Definition 9, star-sampler trees always contain only two nodes.

*Labels and Values.* Each node  $\alpha$  of  $\mathcal{T}$  is again given two attributes, `label`[ $\alpha$ ] and `value`[ $\alpha$ ], which are defined to be exactly the same attributes in the corresponding cycle-sampler or star-sampler tree that was used to define these nodes (recall that each node of  $\mathcal{T}$  is “copied” from a node in either a cycle-sampler or a star-sampler tree). Finally, for each root-to-leaf path  $\mathcal{P}$  in  $\mathcal{T}$ , we define `label`[ $\mathcal{P}$ ] :=  $\bigcup_{\alpha \in \mathcal{P}} \text{label}[\alpha]$  and `value`[ $\mathcal{P}$ ] :=  $\prod_{\alpha \in \mathcal{P}} \text{value}[\alpha]$ . In particular, `label`[ $\mathcal{P}$ ] :=  $((e_1, w_1), \dots, (e_o, w_o), (v_1, \mathbf{w}_1), \dots, (v_s, \mathbf{w}_s))$  by definition of labels of cycle-sampler and star-sampler trees. As such `label`[ $\mathcal{P}$ ] is a representation of the subgraph  $H$  as defined in Section 3.2. By making  $O(1)$  additional pair-queries to query all the remaining edges of this representation of  $H$  we determine if `label`[ $\mathcal{P}$ ] forms a copy of  $H$ .

This concludes the description of `subgraph-sampler`( $G, H$ ) and its output subgraph-sampler tree  $\mathcal{T}$ . We bound the query complexity of the algorithm in the following lemma (the proof is postponed to the full version [4]).

► **Lemma 11.** *The expected query complexity/ running time of `subgraph-sampler` is  $O(1)$ .*

We are now ready to present our estimator algorithm using `subgraph-sampler` and the subgraph-sampler tree  $\mathcal{T}$  it outputs.

**An Estimator for Arbitrary Subgraphs.** Note that as before the subgraph-sampler tree  $\mathcal{T}$  itself is a random variable depending on the randomness of `subgraph-sampler`. For any root-to-leaf path  $\mathcal{P}_i := \alpha_1, \dots, \alpha_z$  of  $\mathcal{T}$ , we define the random variable  $X_i$  such that  $X_i := \text{value}[\mathcal{P}_i]$  iff `label`[ $\mathcal{P}_i$ ] forms a copy of  $H$  in  $G$  and otherwise  $X_i := 0$ . We further define  $Y := (\frac{1}{t} \sum_{i=1}^t X_i)$ , where  $t$  is the number of leaf-nodes of  $\mathcal{T}$  (which itself is a random variable). These random variables can all be computed from  $\mathcal{T}$  and `subgraph-sampler` with at most  $O(1)$  further pair-queries per each root-to-leaf path  $\mathcal{P}$  of the tree to determine if indeed `label`[ $\mathcal{P}$ ] forms a copy of  $H$  in  $G$  or not. As such, query complexity and runtime of this algorithm is proportional to `subgraph-sampler` (which in expectation is  $O(1)$  by Lemma 11). In the following two lemmas, we show that  $Y$  is a low-variance unbiased estimator of  $(\#H)$ .

**Notation.** For any node  $\alpha$  in  $\mathcal{T}$ , we use  $\mathcal{T}_\alpha$  to denote the sub-tree of  $\mathcal{T}$  rooted at  $\alpha$ . For a leaf-node  $\alpha$ , we define a random variable  $Y_\alpha$  which is `value`[ $\alpha$ ] iff for the root-to-leaf path  $\mathcal{P}$  ending in  $\alpha$ , `label`[ $\mathcal{P}$ ] forms a copy of  $H$  in  $G$  and otherwise  $Y_\alpha$  is 0. For an internal node  $\alpha$  in  $\mathcal{T}$  with  $t$  child-nodes  $\alpha_1, \dots, \alpha_t$ , we define  $Y_\alpha = \text{value}[\alpha] \cdot (\frac{1}{t} \cdot \sum_{i=1}^t Y_i)$ . It is easy to verify that  $Y_{\alpha_r}$  for the root  $\alpha_r$  of  $\mathcal{T}$  is the same as the estimator random variable  $Y$  defined earlier. Furthermore, for a node  $\alpha$  in level  $\ell$  of  $\mathcal{T}$ , we define  $\mathbf{L}_\alpha := (\text{label}[\alpha_1], \text{label}[\alpha_2], \dots, \text{label}[\alpha_{\ell-1}])$ , where  $\alpha_1, \dots, \alpha_{\ell-1}$  forms the path from the root of  $\mathcal{T}$  to the parent of  $\alpha$ .

We analyze the expected value and the variance of the estimator.

► **Lemma 12.** *For  $Y$  in  $\text{subgraph-sampler}(G, H)$ ,  $\mathbb{E}[Y] = (\#H)$ .*

**Proof.** We prove this inductively by showing that for any node  $\alpha$  in an *odd layer* of  $\mathcal{T}$ ,  $\mathbb{E}[Y_\alpha \mid \mathbf{L}_\alpha] = (\#H \mid \mathbf{L}_\alpha)$ , where  $(\#H \mid \mathbf{L}_\alpha)$  denotes the number of copies of  $H$  in  $G$  that contain the vertices and edges specified by  $\mathbf{L}_\alpha$  (according to the decomposition  $\mathcal{D}(H)$ ).  $\mathbb{E}[Y_\alpha \mid \mathbf{L}_\alpha]$  measures the value of  $Y_\alpha$  after we fix the rest of the tree  $\mathcal{T}$  and let the sub-tree  $\mathcal{T}_\alpha$  be chosen randomly as in  $\text{subgraph-sampler}$ .

The base case of the induction, i.e., for vertices in the last odd layer of  $\mathcal{T}$  follows exactly as in the proofs of Lemmas 8 and 10 (as will also become evident shortly) and hence we do not repeat it here. We now prove the induction hypothesis. Fix a vertex  $\alpha$  in an odd layer  $\ell$ . We consider two cases based on whether  $\ell < 2o$  (hence  $\alpha$  is root of a cycle-sampler tree) or  $\ell > 2o$  (hence  $\alpha$  is root of a star-sampler tree).

**Case of  $\ell < 2o$ .** In this case, the sub-tree  $\mathcal{T}_\alpha$  in the next two levels is a cycle-sampler tree,

$$\begin{aligned} \mathbb{E}[Y_\alpha \mid \mathbf{L}_\alpha] &= \sum_e \Pr(\text{label}[\alpha] = e) \cdot \text{value}[\alpha] \cdot \left( \frac{1}{t_e} \sum_{i=1}^{t_e} \mathbb{E}[Y_{\alpha_i} \mid \mathbf{L}_\alpha, e] \right) \\ &\hspace{15em} \text{(here, } \alpha_i \text{'s are child-nodes of } \alpha \text{)} \\ &= \sum_e \frac{1}{t_e} \sum_{i=1}^{t_e} \mathbb{E}[Y_{\alpha_i} \mid \mathbf{L}_\alpha, e] \\ &\hspace{15em} \text{(as by definition, } \text{value}[\alpha] = \Pr(\text{label}[\alpha] = e)^{-1} \text{)} \end{aligned}$$

Note that each  $\alpha_i$  has exactly one child-node, denoted by  $\beta_i$ . As such,

$$\begin{aligned} \mathbb{E}[Y_\alpha \mid \mathbf{L}_\alpha] &= \sum_e \frac{1}{t_e} \sum_{i=1}^{t_e} \mathbb{E}[Y_{\alpha_i} \mid \mathbf{L}_\alpha, e] \\ &= \sum_e \frac{1}{t_e} \sum_{i=1}^{t_e} \sum_w \Pr(\text{label}[\alpha_i] = w) \cdot \text{value}[\alpha_i] \cdot \mathbb{E}[Y_{\beta_i} \mid \mathbf{L}_\alpha, e, w] \\ &= \sum_e \frac{1}{t_e} \sum_{i=1}^{t_e} \sum_w \mathbb{E}[Y_{\beta_i} \mid \mathbf{L}_{\beta_i}] \\ &\hspace{10em} \text{(by definition } \text{value}[\alpha_i] = \Pr(\text{label}[\alpha_i] = w)^{-1} \text{ and } \mathbf{L}_{\beta_i} = \mathbf{L}_\alpha, (e, w) \text{)} \\ &= \sum_e \frac{1}{t_e} \sum_{i=1}^{t_e} \sum_w (\#H \mid \mathbf{L}_{\beta_i}) = \sum_e \frac{1}{t_e} \sum_{i=1}^{t_e} \sum_w (\#H \mid \mathbf{L}_\alpha, (e, w)) \\ &\hspace{10em} \text{(by induction hypothesis for odd-layer nodes } \beta_i \text{'s)} \\ &= \sum_e \sum_w (\#H \mid \mathbf{L}_\alpha, (e, w)) = (\#H \mid \mathbf{L}_\alpha). \end{aligned}$$

This concludes the proof of induction hypothesis in this case.

**Case of  $\ell > 2o$ .** In this case, the sub-tree  $\mathcal{T}_\alpha$  in the next two levels is a star-sampler tree.

By the same analogy made in the proof of the previous part and Lemma 8, the proof of this part also follows directly from the proof of Lemma 10 for star-sampler trees.

We can now finalize the proof of Lemma 12, by noting that for the root  $\alpha_r$  of  $\mathcal{T}$ ,  $\mathbf{L}_{\alpha_r}$  is the empty-set and hence,  $\mathbb{E}[Y] = \mathbb{E}[Y_{\alpha_r} \mid \mathbf{L}_{\alpha_r}]$ , which by induction is equal to  $(\#H)$ . ◀

► **Lemma 13.** For  $Y$  in  $\text{subgraph-sampler}(G, H)$ ,  $\text{Var}[Y] = O(m^{\rho(H)}) \cdot \mathbb{E}[Y]$ .

**Proof.** We bound  $\text{Var}[Y]$  using a similar inductive proof as in Lemma 12. Recall the parameters  $\rho_1^C, \dots, \rho_o^C$  and  $\rho_1^S, \dots, \rho_s^S$  associated respectively with the cycles  $\mathcal{C}_1, \dots, \mathcal{C}_o$  and stars  $\mathcal{S}_1, \dots, \mathcal{S}_s$  of the decomposition  $\mathcal{D}(H)$ . For simplicity of notation, for any  $i \in [o + s]$ , we define  $\rho_{i+}$  as follows:

$$\text{for all } i \leq o, \rho_{i+} := \sum_{j=i}^o \rho_j^C + \sum_{j=1}^s \rho_j^S, \quad \text{for all } o < i \leq o + s, \rho_{i+} := \sum_{j=i-o}^s \rho_j^S.$$

We inductively show that, for any node  $\alpha$  in an *odd layer*  $2\ell - 1$  of  $\mathcal{T}$ ,

$$\text{Var}[Y_\alpha \mid \mathbf{L}_\alpha] \leq 2^{2z-2\ell} \cdot m^{\rho_{\ell+}} \cdot (\#H \mid \mathbf{L}_\alpha),$$

where  $(\#H \mid \mathbf{L}_\alpha)$  denotes the number of copies of  $H$  in  $G$  that contain the vertices and edges specified by  $\mathbf{L}_\alpha$  (according to the decomposition  $\mathcal{D}(H)$ ).

The induction is from the leaf-nodes of the tree to the root. The base case of the induction, i.e., for vertices in the last odd layer of  $\mathcal{T}$  follows exactly as in the proofs of Lemmas 8 and 10 (as will also become evident shortly) and hence we do not repeat it here. We now prove the induction hypothesis. Fix a vertex  $\alpha$  in an odd layer  $2\ell - 1$ . We consider two cases based on whether  $\ell \leq o$  (hence  $\alpha$  is root of a cycle-sampler tree) or  $\ell > o$  (hence  $\alpha$  is root of a star-sampler tree).

**Case of  $\ell \leq o$ .** In this case, the sub-tree  $\mathcal{T}_\alpha$  in the next two levels is a cycle-sampler tree corresponding to the odd cycle  $\mathcal{C}_\ell$  of  $\mathcal{D}(H)$ . Let the number of edges in  $\mathcal{C}_\ell$  be  $(2k + 1)$  (i.e.,  $\mathcal{C}_\ell = \mathcal{C}_{2k+1}$ ) Let  $e$  denote the label of the  $\alpha$ . By the law of total variance in Eq. (1)

$$\text{Var}[Y_\alpha \mid \mathbf{L}_\alpha] = \mathbb{E}[\text{Var}[Y_\alpha \mid e] \mid \mathbf{L}_\alpha] + \text{Var}[\mathbb{E}[Y_\alpha \mid e] \mid \mathbf{L}_\alpha]. \quad (7)$$

We start by bounding the second term in Eq. (7) which is easier. By the inductive proof of Lemma 12, we also have,  $\mathbb{E}[Y_\alpha \mid \mathbf{L}_\alpha, e] = (\#H \mid \mathbf{L}_\alpha, e)$ . As such,

$$\begin{aligned} \text{Var}[\mathbb{E}[Y_\alpha \mid e] \mid \mathbf{L}_\alpha] &= \text{Var}[(\#H \mid \mathbf{L}_\alpha, e) \mid \mathbf{L}_\alpha] \leq \mathbb{E}[(\#H \mid \mathbf{L}_\alpha, e)^2 \mid \mathbf{L}_\alpha] \\ &= \sum_e \Pr(\text{label}[\alpha] = e) \cdot (\#H \mid \mathbf{L}_\alpha, e)^2 = \frac{1}{m^k} \sum_e (\#H \mid \mathbf{L}_\alpha, e)^2 \\ &\quad (\Pr(\text{label}[\alpha] = e) = 1/m^k \text{ by definition of odd-cycle-sampler}) \\ &\leq \frac{1}{m^k} \left( \sum_e (\#H \mid \mathbf{L}_\alpha, e) \right)^2 = \frac{1}{m^k} (\#H \mid \mathbf{L}_\alpha)^2 \\ &\leq m^{\rho_{\ell+}} \cdot (\#H \mid \mathbf{L}_\alpha). \end{aligned} \quad (8)$$

The reason behind the last equality is that  $(\#H \mid \mathbf{L}_\alpha)$  is at most equal to the number of copies of the subgraph of  $H$  consisting of  $\mathcal{C}_\ell, \dots, \mathcal{C}_o, \mathcal{S}_1, \dots, \mathcal{S}_s$ , which by Lemma 5 is at most  $m^{\rho_{\ell+}}$  by definition of  $\rho_{\ell+}$ . We now bound the first and the main term in Eq. (7),

$$\begin{aligned} \mathbb{E}[\text{Var}[Y_\alpha \mid e] \mid \mathbf{L}_\alpha] &= \sum_e \Pr(\text{label}[\alpha] = e) \cdot \text{Var}[Y_\alpha \mid e, \mathbf{L}_\alpha] \\ &= \sum_e \frac{1}{m^k} \cdot m^{2k} \cdot \frac{1}{t_e^2} \cdot \sum_{i=1}^{t_e} \text{Var}[Y_{\alpha_i} \mid e, \mathbf{L}_\alpha], \end{aligned}$$

(here  $\alpha_i$ 's are child-nodes of  $\alpha$ )

where the final equality holds because  $Y_{\alpha_i}$ 's are independent conditioned on  $\mathbf{e}, \mathbf{L}_\alpha$  and since  $Y_\alpha$  is by definition  $m^k$  times the average of  $Y_{\alpha_i}$ 's. Moreover, note that distribution of all  $Y_{\alpha_i}$ 's are the same. Hence, by canceling the terms,

$$\mathbb{E}[\text{Var}[Y_\alpha | \mathbf{e}] | \mathbf{L}_\alpha] = m^k \cdot \sum_{\mathbf{e}} \frac{1}{t_{\mathbf{e}}} \cdot \text{Var}[Y_{\alpha_1} | \mathbf{e}, \mathbf{L}_\alpha], \quad (9)$$

We thus only need to bound  $\text{Var}[Y_{\alpha_1} | \mathbf{e}, \mathbf{L}_\alpha]$ . Recall that  $\alpha_1$  corresponds to a leaf-node in a cycle-sampler tree and hence its label is a vertex  $w$  from the neighborhood of  $u_{\mathbf{e}}^*$  as defined in `odd-cycle-sampler`. We again use the law of total variance in Eq. (1) to obtain,

$$\text{Var}[Y_{\alpha_1} | \mathbf{e}, \mathbf{L}_\alpha] = \mathbb{E}[\text{Var}[Y_{\alpha_1} | w] | \mathbf{e}, \mathbf{L}_\alpha] + \text{Var}[\mathbb{E}[Y_{\alpha_1} | w] | \mathbf{e}, \mathbf{L}_\alpha] \quad (10)$$

For the first term,

$$\begin{aligned} \mathbb{E}[\text{Var}[Y_{\alpha_1} | w] | \mathbf{e}, \mathbf{L}_\alpha] &= \sum_{w \in N(u_{\mathbf{e}}^*)} \Pr(\text{label}[\alpha_1] = w) \cdot \text{Var}[Y_{\alpha_1} | w, \mathbf{e}, \mathbf{L}_\alpha] \\ &= \sum_w \frac{1}{d_{\mathbf{e}}^*} \cdot (d_{\mathbf{e}}^*)^2 \cdot \text{Var}[Y_{\beta_1} | w, \mathbf{e}, \mathbf{L}_\alpha], \end{aligned}$$

where  $\beta_1$  is the unique child-node of  $\alpha_1$  and so  $Y_{\alpha_1} = \text{value}[\alpha_1] \cdot Y_{\beta_1}$ , while conditioned on  $\mathbf{e}$ ,  $\text{value}[\alpha_1] = d_{\mathbf{e}}^*$ . Moreover, as  $\mathbf{L}_{\beta_1} = (\mathbf{L}_\alpha, \mathbf{e}, w)$ , and by canceling the terms,

$$\begin{aligned} \mathbb{E}[\text{Var}[Y_{\alpha_1} | w] | \mathbf{e}, \mathbf{L}_\alpha] &= \sum_w d_{\mathbf{e}}^* \cdot \text{Var}[Y_{\beta_1} | \mathbf{L}_{\beta_1}] \\ &\leq \sum_w d_{\mathbf{e}}^* \cdot 2^{2z-2\ell-2} \cdot m^{\rho(\ell+1)+} \cdot (\#H | \mathbf{L}_{\beta_1}), \end{aligned} \quad (11)$$

where the inequality is by induction hypothesis for the odd-level node  $\beta_1$ . We now bound the second term in Eq. (10) as follows,

$$\begin{aligned} \text{Var}[\mathbb{E}[Y_{\alpha_1} | w] | \mathbf{e}, \mathbf{L}_\alpha] &\leq \mathbb{E}\left[\left(\mathbb{E}[Y_{\alpha_1} | w]\right)^2 | \mathbf{e}, \mathbf{L}_\alpha\right] \\ &= \sum_w \Pr(\text{label}[\alpha_1] = w) \cdot \left(\mathbb{E}[Y_{\alpha_1} | w, \mathbf{e}, \mathbf{L}_\alpha]\right)^2 \\ &= \sum_w \frac{1}{d_{\mathbf{e}}^*} \cdot (d_{\mathbf{e}}^*)^2 \cdot \left(\mathbb{E}[Y_{\beta_1} | w, \mathbf{e}, \mathbf{L}_\alpha]\right)^2 \\ &= \sum_w d_{\mathbf{e}}^* \cdot \left(\mathbb{E}[Y_{\beta_1} | \mathbf{L}_{\beta_1}]\right)^2 = \sum_w d_{\mathbf{e}}^* \cdot (\#H | \mathbf{L}_{\beta_1})^2 \\ &\leq \sum_w d_{\mathbf{e}}^* \cdot m^{\rho(\ell+1)+} \cdot (\#H | \mathbf{L}_{\beta_1}). \end{aligned} \quad (12)$$

Here, the second to last equality holds by the inductive proof of Lemma 12, and the last equality is because  $(\#H | \mathbf{L}_{\beta_1}) \leq m^{\rho(\ell+1)+}$  by Lemma 5, as  $(\#H | \mathbf{L}_{\beta_1})$  is at most equal to the total number of copies of a subgraph of  $H$  on  $\mathcal{C}_{\ell+1}, \dots, \mathcal{C}_o, \mathcal{S}_1, \dots, \mathcal{S}_s$  (and by definition of  $\rho_{(\ell+1)+}$ ). We now plug in Eq. (11) and Eq. (12) in Eq. (10),

$$\text{Var}[Y_{\alpha_1} | \mathbf{e}, \mathbf{L}_\alpha] \leq \sum_w d_{\mathbf{e}}^* \cdot (2^{2z-2\ell-2} \cdot m^{\rho(\ell+1)+} \cdot (\#H | \mathbf{L}_{\beta_1}) + m^{\rho(\ell+1)+} \cdot (\#H | \mathbf{L}_{\beta_1})).$$

We now in turn plug this in Eq. (9),

$$\begin{aligned}
& \mathbb{E} [\text{Var} [Y_\alpha \mid e] \mid \mathbf{L}_\alpha] \\
& \leq m^k \sum_e \frac{1}{t_e} \sum_w d_e^* \cdot (2^{2z-2\ell-2} \cdot m^{\rho(\ell+1)+} \cdot (\#H \mid \mathbf{L}_{\beta_1}) + m^{\rho(\ell+1)+} \cdot (\#H \mid \mathbf{L}_{\beta_1})) \\
& \leq m^k \sqrt{m} \cdot \sum_e \sum_w 2^{2z-2\ell-1} \cdot m^{\rho(\ell+1)+} \cdot (\#H \mid \mathbf{L}_{\beta_1}) \quad (\text{as } t_e \geq d_e^*/\sqrt{m}) \\
& \leq 2^{2z-2\ell-1} \cdot m^{\rho_{\ell+}} \cdot \sum_e \sum_w (\#H \mid \mathbf{L}_{\beta_1}) \\
& \quad (\text{as } \rho_\ell^C = k + 1/2 \text{ and } \rho_{\ell+} = \rho_\ell^C + \rho_{(\ell+1)+} \text{ by definition}) \\
& = 2^{2z-2\ell-1} \cdot m^{\rho_{\ell+}} \cdot (\#H \mid \mathbf{L}_\alpha). \quad (\text{as } \mathbf{L}_{\beta_1} = (\mathbf{L}_\alpha, e, w))
\end{aligned}$$

Finally, by plugging in this and Eq. (8) in Eq. (7),

$$\begin{aligned}
\text{Var} [Y_\alpha \mid \mathbf{L}_\alpha] &= 2^{2z-2\ell-1} \cdot m^{\rho_{\ell+}} \cdot (\#H \mid \mathbf{L}_\alpha) + m^{\rho_{\ell+}} \cdot (\#H \mid \mathbf{L}_\alpha) \\
&\leq 2^{2z-2\ell} \cdot m^{\rho_{\ell+}} \cdot (\#H \mid \mathbf{L}_\alpha),
\end{aligned}$$

finalizing the proof of induction step in this case. We again remark that this proof closely followed the proof for the variance of the estimator for cycle-sampler tree in Lemma 8.

**Case of  $\ell > o$ .** In this case, the sub-tree  $\mathcal{T}_\alpha$  in the next two levels is a star-sampler tree. By the same analogy made in the proof of the previous case and Lemma 8, the proof of this part also follows the proof of Lemma 10 for star-sampler trees. We hence omit the details.

To conclude, we have that  $\text{Var} [Y] = \text{Var} [Y_{\alpha_r} \mid \mathbf{L}_{\alpha_r}] = O(m^{\rho(H)} \cdot (\#H)) = O(m^{\rho(H)}) \cdot \mathbb{E} [Y]$  as  $Y = Y_{\alpha_r}$  for the root  $\alpha_r$  of  $\mathcal{T}$ ,  $\mathbf{L}_{\alpha_r} = \emptyset$ ,  $(\#H) = \mathbb{E} [Y]$  by Lemma 12, and  $z = O(1)$ .  $\blacktriangleleft$

## 4.2 An Algorithm for Estimating Occurrences of Arbitrary Subgraphs

We now use our estimator algorithm from the previous section to design our algorithm for estimating the occurrences of an arbitrary subgraph  $H$  in  $G$ . In the following theorem, we assume that the algorithm has knowledge of  $m$  and also a lower bound on the value of  $\#H$ ; these assumptions can be lifted easily as we describe afterwards.

**► Theorem 14.** *There exists a sublinear time algorithm that uses degree, neighbor, pair, and edge sample queries and given a precision parameter  $\varepsilon \in (0, 1)$ , an explicit access to a constant-size graph  $H(V_H, E_H)$ , a query access to the input graph  $G(V, E)$ , the number of edges  $m$  in  $G$ , and a lower bound  $h \leq \#H$ , with high probability outputs a  $(1 \pm \varepsilon)$ -approximation to  $\#H$  using  $O\left(\min\left\{m, \frac{m^{\rho(H)}}{h} \cdot \frac{\log n}{\varepsilon^2}\right\}\right)$  queries and  $O\left(\frac{m^{\rho(H)}}{h} \cdot \frac{\log n}{\varepsilon^2}\right)$  time, in the worst-case.*

**Proof.** Fix a sufficiently large constant  $c > 0$ . We run `subgraph-sampler`( $G, H$ ) for  $k := \frac{c \cdot m^{\rho(H)}}{\varepsilon^2 \cdot h}$  time independently in parallel to obtain estimates  $Y_1, \dots, Y_k$  and let  $Z := \frac{1}{k} \sum_{i=1}^k Y_i$ . By Lemma 12,  $\mathbb{E} [Z] = (\#H)$ . Since  $Y_i$ 's are independent, we also have

$$\text{Var} [Z] = \frac{1}{k^2} \sum_{i=1}^k \text{Var} [Y_i] \leq \frac{1}{k} \cdot O(m^{\rho(H)}) \cdot \mathbb{E} [Z] \leq \frac{\varepsilon^2}{10} \cdot \mathbb{E} [Z]^2,$$

by Lemma 13, and by choosing the constant  $c$  sufficiently larger than the constant in the  $O$ -notation of this lemma, together with the fact that  $h \leq (\#H) = \mathbb{E} [Z]$ . By Chebyshev's inequality (Proposition 2),  $\Pr(|Z - \mathbb{E} [Z]| \geq \varepsilon \cdot \mathbb{E} [Z]) \leq \frac{\text{Var} [Z]}{\varepsilon^2 \cdot \mathbb{E} [Z]^2} \leq \frac{1}{10}$ , by the bound above on the variance. This means that with probability 0.9, this algorithm outputs a  $(1 \pm \varepsilon)$ -approximation of  $\#H$ . Moreover, the expected query complexity and running time of this

algorithm is  $O(k)$  by Lemma 11, which is  $O(\frac{m^{\rho(H)}}{\varepsilon^2})$  (if  $k \geq m$ , we simply query all edges of the graph and solve the problem using an offline enumeration algorithm). To extend this result to a high probability bound and also making the guarantee of query complexity and run-time in the worst-case, we simply run this algorithm  $O(\log n)$  times in parallel and stop each execution that uses more than 10 times queries than the expectation. ◀

The algorithm in Theorem 14 assumes the knowledge of  $h$  which is a lower bound on  $(\#H)$ . However, this assumption can be easily removed by making a geometric search on  $h$  starting from  $m^{\rho(H)}/2$  which is (approximately) the largest value for  $(\#H)$  all the way down to 1 in factors of 2, and stopping the search once the estimates returned for a guess of  $h$  became consistent with  $h$  itself. This only increases the query complexity and runtime of the algorithm by polylog( $n$ ) factors. As this part is quite standard, we omit the details and instead refer the interested reader to [16, 18]. This concludes the proof of our main result in Theorem 1 from the introduction.

### 4.3 Extension to the Database Join Size Estimation Problem

The database join size estimation for binary relations can be modeled by the subgraph estimation problem where the subgraph  $H$  and the underlying graph  $G$  are additionally *edge-colored* and we are only interested in counting the copies of  $H$  in  $G$  with matching colors on the edges. In this abstraction, the edges of the graph  $G$  correspond to the entries of the database, and the color of edges determine the relation of the entry.

We formalize this variant of the subgraph counting problem in the following. In the *colorful* subgraph estimation problem, we are given a subgraph  $H(V_H, E_H)$  with a coloring function  $c_H : E_H \rightarrow \mathbb{N}$  and query access to a graph  $G(V, E)$  along with a coloring function  $c_G : E \rightarrow \mathbb{N}$ . The set of allowed queries to  $G$  contains the degree queries, pair queries, neighbor queries, and edge-sample queries as before, with a simple change that whenever we query an edge (through the last three types of queries), the color of the edge according to  $c_G$  is also revealed to the algorithm. Our goal is to estimate the number of copies of  $H$  in  $G$  with matching colors, i.e., the *colorful* copies of  $H$ .

It is immediate to verify that our algorithm in this section can be directly applied to the colorful subgraph estimation problem with the only difference that when testing whether a subgraph forms a copy of  $H$  in  $G$ , we in fact check whether this subgraph forms a colorful copy of  $H$  in  $G$  instead. The analysis of this new algorithm is exactly as in the case of the original algorithm with the only difference that we switch the parameter  $\#H$  to  $\#H_c$  that only counts the number of copies of  $H$  with the same colors in  $G$ . To summarize, we obtain an algorithm with  $O^*(\frac{m^{\rho(H)}}{\#H_c})$  query and time complexity for the colorful subgraph counting problem, which can in turn solves the database join size estimation problem for binary relations.

## 5 Lower Bounds

We present two lower bounds that demonstrate the optimality of Theorem 1 in different scenarios. Our first lower bound establishes tight bounds for counting *odd cycles*.

► **Theorem 15.** *For any  $k \geq 1$ , any algorithm  $\mathcal{A}$  that can output any multiplicative-approximation to the number of copies of the odd cycle  $C_{2k+1}$  in a given graph  $G(V, E)$  with probability at least  $2/3$  requires  $\Omega(\frac{m^{k+\frac{1}{2}}}{\#C_{2k+1}})$  queries to  $G$ .*

Theorem 15 implies that in addition to cliques (that were previously proved [19]; see also [16, 18]), our algorithm in Theorem 1 also achieve optimal bounds for odd cycles.

Our next lower bound targets the more general problem of database join size estimation for which we argued that our Theorem 1 continues to hold. We show that for this more general problem, our algorithm in Theorem 1 is in fact optimal for all choices of subgraph  $H$ .

► **Theorem 16.** *For any subgraph  $H(V_H, E_H)$  which contains at least one edge, suppose  $\mathcal{A}$  is an algorithm for the colorful subgraph estimation problem that given  $H$ , a coloring  $c_H : E_H \rightarrow \mathbb{N}$ , and query access to  $G(V, E)$  with  $m$  edges and coloring function  $c_G : E \rightarrow \mathbb{N}$ , can output a multiplicative-approximation to the number of colorful copies of  $H$  in  $G$  with probability at least  $2/3$ . Then,  $\mathcal{A}$  requires  $\Omega(\frac{m^{p(H)}}{\#H_c})$  queries, where  $\#H_c$  is the number of colorful copies of  $H$  in  $G$ . The lower bound continues to hold even if the number of colors used by  $c_H$  and  $c_G$  is at most two.*

The proofs of Theorems 15 and 16 are postponed to the full version of the paper [4].

## Abstract

We study *tensor networks* as a model of arithmetic computation for evaluating multilinear maps. These capture any algorithm based on low border rank tensor decompositions, such as  $O(n^{\omega+\epsilon})$  time matrix multiplication, and in addition many other algorithms such as  $O(n \log n)$  time discrete Fourier transform and  $O^*(2^n)$  time for computing the permanent of a matrix. However tensor networks sometimes yield faster algorithms than those that follow from low-rank decompositions. For instance the fastest known  $O(n^{(\omega+\epsilon)t})$  time algorithms for counting  $3t$ -cliques can be implemented with tensor networks, even though the underlying tensor has border rank  $n^{3t}$  for all  $t \geq 2$ . For counting homomorphisms of a general pattern graph  $P$  into a host graph on  $n$  vertices we obtain an upper bound of  $O(n^{(\omega+\epsilon) \text{bw}(P)/2})$  where  $\text{bw}(P)$  is the branchwidth of  $P$ . This essentially matches the bound for counting cliques, and yields small improvements over previous algorithms for many choices of  $P$ .

While powerful, the model still has limitations, and we are able to show a number of unconditional lower bounds for various multilinear maps, including:

- (a) an  $\Omega(n^{\text{bw}(P)})$  time lower bound for counting homomorphisms from  $P$  to an  $n$ -vertex graph, matching the upper bound if  $\omega = 2$ . In particular for  $P$  a  $v$ -clique this yields an  $\Omega(n^{\lceil 2v/3 \rceil})$  time lower bound for counting  $v$ -cliques, and for  $P$  a  $k$ -uniform  $v$ -hyperclique we obtain an  $\Omega(n^v)$  time lower bound for  $k \geq 3$ , ruling out tensor networks as an approach to obtaining non-trivial algorithms for hyperclique counting and the Max-3-CSP problem.
- (b) an  $\Omega(2^{0.918n})$  time lower bound for the permanent of an  $n \times n$  matrix.

## 1 Introduction

One of the cornerstones of the theory of computation is the study of efficient algorithms:

For a function  $f$ , how much time is required to evaluate  $f$  on given inputs?

Answering this question for almost any specific  $f$  is well beyond reach of contemporary tools. For example, it is theoretically possible that canonical NP-complete problems, such as the Circuit Satisfiability problem, can be solved in linear time whereas they are widely believed to require super-polynomial (or somewhat less widely, exponential) time [34, 35, 36]. The main reason for this barrier to quantitative understanding is that it is very hard to prove lower bounds for explicit functions in general models of computation such as circuits or Turing machines. This situation withstanding, a more modest program to advance our understanding of computation is to study restricted models that for many  $f$  are simultaneously

- (i) general enough to capture the fastest-known algorithms for  $f$ , and
- (ii) restricted enough to admit proofs of strong *unconditional* time lower bounds for  $f$ .

There is a substantial body of work that fits under this program, ranging from the study of low-depth or otherwise restricted circuits (see e.g. [7], Ch. 14) to models of algorithm-design principles such as greedy algorithms, backtracking, or dynamic programming [3, 27], to linear or semidefinite programming relaxations for hard optimization problems [51].

**Multilinear maps.** One class of functions  $f$  that are of substantial importance is the family of  $\ell$ -linear maps (*multilinear maps*) from  $\ell$  input vector spaces to an output vector space.<sup>1</sup> Examples range from maps of known near-linear-time complexity in the input size, such as the discrete Fourier transform [24, 72], to maps without known polynomial-time-complexity algorithms, such as the permanent of a matrix [64, 70]. Beyond motivation in numerical multilinear algebra and its applications, recent advances in the study of fine-grained algorithm design and complexity have highlighted the fundamental role of algebraic methods in the fastest-known algorithm designs across a broad range of tasks from graph problems, such as all-pairs shortest paths and  $k$ -clique, to parsing and constraint satisfaction problems, such as maximum satisfiability and graph coloring [2, 11, 13, 30, 37, 54, 75, 76].

In this paper, we study the *arithmetic complexity* of evaluating a multilinear map, that is, the number of operations (scalar additions, subtractions, and multiplications) needed to evaluate the map. To set up a baseline, a generic  $\ell$ -linear map from  $\ell$  vector spaces of dimension  $n$  to a scalar requires  $\Omega(n^\ell)$  scalars to represent the map directly using combinations of basis vectors. Given this complexity of a direct explicit representation, it is a fundamental problem to seek less costly representations, along with associated efficient algorithms that work on the chosen representation.

We propose the systematic study of *tensor networks* on hypergraphs as a framework for fast evaluation of multilinear maps, and show a number of upper and lower bounds on the computational power of tensor networks in the spirit of (i) and (ii) above.

**Tensor networks.** Tensor networks have a long and rich history which can be traced as far back as 19<sup>th</sup>-century studies in invariant theory due to Cayley [20, 21], Clebsch [22], Clifford [23], Sylvester [69], and Kempe [40, 41]. Tensor networks are extensively deployed in applications from pure mathematics and theoretical physics [39, 47, 48, 49, 57, 58, 61, 65] to computational physics and chemistry [56, 59, 67]. In theoretical computer science, they appear in various guises including, for example, in the Holant framework [71, 18, 17], in the study of

<sup>1</sup> Multilinear maps with  $\ell = 1$  are called *linear*,  $\ell = 2$  *bilinear*,  $\ell = 3$  *trilinear*, and so forth.

probabilistic graphical models [45, 62], in the study of parallel programming [66], in the study of quantum computing [6], and in the study of arithmetic complexity [8, 19, 26]. Tensor contraction is also emerging as a basic computational primitive in computer hardware [31, 53]. (We refer to the full version of this paper a more detailed discussion.) As the precise definitions are somewhat technical, let us start with a few simple motivating examples and then state our results, with the understanding that precise definitions appear in Section 3.

In our setting, a tensor network is a hypergraph in which the vertices are tensors and the hyperedges are called *modes*. Each mode that is incident to a tensor defines a “dimension” for indexing the entries of the tensor – for example, a matrix is a tensor that is incident to two modes, one mode for the rows of the matrix, and the other mode for the columns of the matrix. A network may be simplified by a sequence of *contractions*, where each contraction takes a subset of tensors and replaces it with a single tensor whose entries are obtained as generalized inner products of the entries of the tensors being contracted.

As a first example of these concepts, let us consider the task of multiplying two matrices,  $A$  and  $B$ . More specifically, let  $A$  be a matrix with rows indexed by mode  $i$  and columns indexed by mode  $k$ , and let  $B$  be a matrix with rows indexed by mode  $k$  and columns indexed by mode  $j$ . We may represent the multiplication task as the tensor network depicted on the left in (1). The result of contracting  $A$  and  $B$  is a new matrix with rows indexed by  $i$  and columns indexed by  $j$ , where the entry at each position  $(i, j)$  is  $\sum_k A_{ik}B_{kj}$ . If the three index sets all have size  $n$ , then computing  $A \cdot B$  by contracting them in such a direct manner uses  $\Theta(n^3)$  operations. To obtain faster matrix multiplication, we can rewrite the bare-bones network on the left in (1) using a low-rank decomposition of the matrix multiplication tensor. For example, Strassen’s decomposition [68] of  $2 \times 2$  matrix multiplication can be represented using the second network in (1). Note that the index  $i$  used by  $A$  and the result has been separated into two distinct indices  $i$  and  $i'$ , and similarly for  $j$  and  $k$ .

$$\begin{aligned}
 & \text{Network 1: } \begin{array}{c} i \\ \downarrow \\ \boxed{A} \\ \downarrow k \\ \boxed{B} \\ \downarrow j \end{array} \quad \begin{array}{c} i \downarrow j \\ \downarrow \\ \boxed{\gamma} \\ \downarrow e \\ \begin{array}{cc} \boxed{\alpha} & \boxed{\beta} \\ \downarrow i' \downarrow k' & \downarrow k' \downarrow j' \\ \boxed{A} & \boxed{B} \end{array} \end{array} \quad \begin{array}{l} \gamma = \begin{bmatrix} 1 & 0 & 0 & 1 & -1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & 0 & 0 \\ 1 & -1 & 1 & 0 & 0 & 1 & 0 \end{bmatrix} \\ \alpha = \begin{bmatrix} 1 & 0 & 1 & 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 1 & 0 & 1 & 0 & 0 & -1 \end{bmatrix} \\ \beta = \begin{bmatrix} 1 & 1 & 0 & -1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & -1 & 0 & 1 & 0 & 1 \end{bmatrix} \end{array} \quad (1)
 \end{aligned}$$

We can *execute* the network by successively contracting groups of vertices. In (2) we see the process of successively contracting pairs of tensors in a carefully chosen order, until only a single tensor – the result of the computation – remains. Such an execution can be naturally represented by a rooted binary tree, as shown on the right in (2), where the tensors of the network form the leaves, and each internal node represents the result of contracting its two children. To summarize, a tensor-network algorithm is specified by providing (a) a tensor network that when contracted yields the desired result, and (b) an execution tree indicating the order in which to contract tensors in the network.

The *cost* of performing one of the contractions in an execution is the product of the lengths of the modes used by any tensor involved in the contraction. This simply measures (up to a constant factor) the number of arithmetic operations (additions/multiplications) used to compute the result by a direct, naïve computation that does not depend on the values of the tensors. For example, the contraction of  $\alpha$  and  $A$  in the first step of (2) has cost 28 because it involves the three modes  $i'$  (length 2),  $k$  (length 2) and  $\ell$  (length 7).

We observe that cost is data-oblivious – the tensor  $\alpha$  is fixed with many zero-entries but these entries still contribute to the cost. Indeed, in many cases there may be faster ways of evaluating a contraction than to evaluate it naively, and just like we saw above, this can often be dealt with by rewriting the network appropriately. For instance, consider now the multiplication of two  $2^k \times 2^k$  matrices. Because the family of matrix multiplication tensors is closed under Kronecker products, this operation may be computed by a tensor network like the one shown in (3) (depicting the case  $k = 5$ ), where  $\alpha$ ,  $\beta$  and  $\gamma$  are as in (2). The rows/columns of the matrices are now indexed by  $k$ -tuples of bits. The execution of this network contracts one  $\alpha/\beta/\gamma$  tensor at a time, which lets us keep the cost low. For example, the first contraction of  $A$  with the first  $\alpha$  block has a cost of  $2^k \cdot 2^k \cdot 7$ , and results in a tensor of size  $2^{k-1} \times 2^{k-1} \times 7$ , then the next contraction has a cost of  $2^{k-1} \cdot 2^{k-1} \cdot 7^2$  and produces a result of size  $2^{k-2} \times 2^{k-2} \times 7 \times 7$ , and so on, until the contraction with the last  $\alpha$  block which has a cost of  $2 \cdot 2 \cdot 7^k = O(7^k)$ , and all the contractions in the execution have cost bounded by this, meaning that we get a total running time of  $O(k7^k) = O(N^{\log_2 7} \log N)$  for  $N \times N$  matrices.<sup>2</sup>

This type of argument can capture any algorithm based on a low-rank decomposition of the underlying tensor of the multilinear map, and indeed, this enables  $O(n^\omega)$ -time<sup>3</sup> matrix multiplication using tensor networks. Beyond simple low-rank decompositions, which always give rise to “star-like” networks as in (3), there are many interesting algorithms that can be captured using networks with a more complicated topology. For instance, many maps of substantial importance have a layered structure that decomposes the map to a sequence of elementary maps. A canonical example is the discrete Fourier transform (DFT), which for a smooth composite order such as  $2^k$ , can be decomposed into a fast Fourier transform (FFT) that consists of a sequence of  $k$  transforms of order 2 interleaved with diagonal-matrix multiplications of twiddle factors [24, 72].

<sup>2</sup> In fact, a more careful analysis gives running time  $O(N^{\log_2 7})$ .  
<sup>3</sup> Throughout the paper,  $\omega = \omega(\mathbb{F})$  denotes the infimum over all  $e$  such that the arithmetic complexity of multiplying two  $n \times n$  matrices is  $O(n^e)$ . While the value of  $\omega$  may depend on the underlying field  $\mathbb{F}$ , we tacitly ignore this, since the field is fixed throughout the paper. For all fields it is known that  $2 \leq \omega < 2.3728639$  [50, 73].

## 1.1 Our results

Starting with motivation (i) and seeking to express existing fastest-known algorithms as executions of tensor networks by a sequence of contractions, we show upper bounds for a number of natural problems. Beyond standard linear settings such as the FFT, not only do tensor networks realize classical bilinear settings such as Abelian group algebra products and fast matrix multiplication algorithms based on low tensor rank, they are powerful enough to capture a substantial number of higher-linearity applications, including Ryser's algorithm for matrix permanent [64], and the *Kruskal operator* [43, 46], which underlies realization of rank-decompositions for tensor rank [44] and current fastest algorithms for detecting outlier correlations [38].

One problem for which tensor networks turn out to be particularly useful is counting homomorphisms from a fixed pattern graph  $P$  to a large host graph  $G$  on  $n$  vertices. The most well-studied such problem is when  $P$  is a  $k$ -clique. For this problem, the currently fastest algorithm runs in time roughly  $O(n^{\omega^{k/3}})$  (with variations in the exponent depending on  $k \bmod 3$ ) [54, 30]. For general  $P$ , it is known that the problem can be solved in  $O(n^{\text{tw}(P)+1})$  time [28], where  $\text{tw}(P)$  is the treewidth of  $P$ . We show that tensor networks can solve the problem in  $O(n^{(\omega+\epsilon)\text{bw}(P)/2})$  time, where  $\text{bw}(P)$  is the *branchwidth* of  $P$ . For  $P$  a  $k$ -clique we have  $\text{bw}(P) = \lceil 2k/3 \rceil$  so this almost recovers the  $O(n^{\omega^{k/3}})$  running time, and in this case we can slightly improve the running time to recover the  $O(n^{\omega^{\lfloor k/3 \rfloor + (k \bmod 3)}}$ ) time of Nešetřil and Poljak [54]. In the case of general  $P$ , this improves on the treewidth-based bound for graphs with  $\text{bw}(P) \leq 2(\text{tw}(P) + 1)/\omega$  (and in particular if  $\omega = 2$  it is always as fast as the treewidth-based bound, ignoring the  $\epsilon$ ). By recent results of Curticapean, Dell, and Marx [25], fast algorithms for homomorphism-counting can be used to obtain fast algorithms for counting subgraphs of  $G$  isomorphic to  $P$ , and in some cases our new branchwidth-based bound leads to an improvement; for example, for counting paths of lengths of length 7, 8 or 9, we get a running time of  $O(n^{3\omega/2+\epsilon}) < O(n^{3.56})$  compared to  $O(n^4)$  using the treewidth-based bound, whereas for very long paths it is not clear whether we would need  $\omega = 2$  in order for these bound to improve on the treewidth-based bound. Previous work that combines branch decompositions and fast matrix multiplication includes Dorn [29] and Bodlaender *et al.* [15].

Further applications captured by tensor networks are the set covering and set partitioning frameworks via fast zeta and Möbius transforms that underlie the current fastest algorithms for graph coloring [13] and its generalizations such as computing the Tutte polynomial [10, 11]. To summarize, we have the following compendium theorem of upper bound results.

► **Theorem 1.1.** *We have the following upper bounds on arithmetic complexity via tensor networks:*

1.  $O(n^{\omega+\epsilon})$  for the matrix multiplication map of two  $n \times n$  matrices.
2.  $O(n^{(\omega+\epsilon)\lfloor v/3 \rfloor + (v \bmod 3)})$  for counting  $v$ -cliques in an  $n$ -vertex graph.
3.  $O(n^{(\omega+\epsilon)\text{bw}(P)/2})$  for counting homomorphisms of a fixed pattern (hyper)graph  $P$  into a (hyper)graph on  $n$  vertices.
4.  $O(\max(n^{\lceil \ell/2 \rceil(\omega+\epsilon-1)r}, n^{2\lceil \ell/2 \rceil r^{\omega+\epsilon-2}}))$  for the Kruskal operator of  $\ell$  matrices of shape  $n \times r$ .
5.  $O(2^k k)$  for the discrete Fourier transforms for the Abelian groups  $\mathbb{Z}_{2^k}$  and  $\mathbb{Z}_2^k$ .
6.  $O(2^k k)$  for group algebra products on  $\mathbb{F}[\mathbb{Z}_{2^k}]$  and  $\mathbb{F}[\mathbb{Z}_2^k]$  when 2 is unit in  $\mathbb{F}$ .
7.  $O(2^k k)$  for the semigroup algebra product on  $\mathbb{F}[\{0, 1\}^k, \subseteq, \cap, \cup]$ .
8.  $O(2^n n)$  for the permanent of an  $n \times n$  matrix.

Above  $\epsilon > 0$  is an arbitrary constant.

Perhaps the most interesting application above is the  $v$ -clique problem, which suggests that one should seek to pursue generalizations to  $v$ -vertex hypercliques of  $\binom{v}{k}$  hyperedges with  $v > k \geq 3$ . Indeed, subgraph counting is a problem that has received substantial interest over the years (e.g. [37, 54, 5, 4, 30, 12, 14, 77, 74, 33, 32, 55, 42, 25]), but progress in the particular case of  $v$ -clique has been stuck to the extent that the problem has attracted notoriety as a hardness assumption in fine-grained complexity [1, 2]. Beyond the study of cliques, hypercliques, and subgraph counting, nontrivial algorithms for such forms would have immediate applicability, for example, in the study of maximum constraint satisfaction problems (Max-CSP) for constraints of width  $k \geq 3$ ; cf. Williams [75] for the case  $k = 2$ . One of the main goals of our subsequent lower bounds is to rule out tensor networks as a candidate to yield improved algorithms in this setting.

Turning from upper bounds to lower bounds and motivation (ii), tensor networks are restricted enough to enable nontrivial lower bounds for many multilinear maps. To begin with, an immediate limitation of tensor networks is that all the intermediate results during the execution of a network are multilinear, and the execution of a network can be simulated by a multilinear circuit. Raz [60] shows that multilinear formulas cannot compute the determinant of an  $n \times n$  matrix in a polynomial number of operations in  $n$ , even though polynomial-size general circuits are known for the determinant (cf. [9, 16, 63]).

It turns out that considerably stronger lower bounds can be shown for tensor networks. In particular, we establish essentially tight lower bounds (subject to the assumption  $\omega = 2$ ) for arithmetic complexity via tensor networks of  $P$ -homomorphism counting and the Kruskal operator. Furthermore, we rule out the possibility of any nontrivial algorithm designs via tensor networks for counting cliques in hypergraphs. The following theorem collects our main lower-bound results, and should be contrasted with the upper bounds in Theorem 1.1.

► **Theorem 1.2.** *We have the following lower bounds on arithmetic complexity via tensor networks:*

1.  $\Omega(n^{\text{bw}(P)})$  for the multilinear form corresponding to  $P$ -homomorphism counting. In particular, this yields a lower bound of  $\Omega(n^{\lceil 2v/3 \rceil})$  for counting cliques of size  $v$ , and a lower bound of  $\Omega(n^v)$  for counting hypercliques of size  $v$ .
2.  $\Omega(\max(n^\ell, n^{\lceil \ell/2 \rceil} r))$  for the Kruskal operator of  $\ell$  matrices of shape  $n \times r$ .
3.  $\Omega(\binom{n}{\lfloor n/3 \rfloor})$  for the determinant or permanent of an  $n \times n$  matrix.

We remark that [52] independently showed that the border rank of the  $v$ -hyperclique tensor is  $\Omega(n^v)$ ; our  $\Omega(n^v)$  lower bound for tensor networks strengthens that. One may wonder about the gap between the bounds of  $\Omega(\binom{n}{\lfloor n/3 \rfloor})$  and  $O(2^n n)$  for the permanent. As we explain below, our lower bound methods are inherently rank-based and cannot go beyond  $\binom{n}{\lfloor n/3 \rfloor}$ . A curious point is that it is not immediately clear whether tensor networks can even achieve  $O^*(2^n)$  time for the determinant, and we do not know whether or not this is possible.

## 1.2 Overview of proof ideas

As a running example in this overview, we consider the 6-linear forms  $A : \mathbb{F}^{[n] \times [n]} \times \mathbb{F}^{[n] \times [n]} \times \dots \times \mathbb{F}^{[n] \times [n]} \rightarrow \mathbb{F}$  taking as input 6 matrices of size  $n \times n$ , defined by

$$A(X^{(1)}, X^{(2)}, X^{(3)}, X^{(4)}, X^{(5)}, X^{(6)}) = \sum_{i,j,k,\ell \in [n]} X_{ij}^{(1)} X_{ik}^{(2)} X_{il}^{(3)} X_{jk}^{(4)} X_{j\ell}^{(5)} X_{k\ell}^{(6)}. \quad (4)$$

If  $\chi$  is the adjacency matrix of a loopless graph  $G$ , then  $A(\chi, \chi, \chi, \chi, \chi, \chi)$  counts the number of 4-cliques in the graph. Associated with  $A$  is the 6-tensor  $T(A)$  of size  $n^2 \times n^2 \times \dots \times n^2$ ,

where each of the 6 modes is indexed by a pair  $(i, j) \in [n] \times [n]$ , and the value at a given position is the coefficient of the corresponding term in  $A$ . Concretely,

$$T(A)_{i_1 j_1, i_2 k_2, i_3 \ell_3, j_4 k_4, j_5 \ell_5, k_6 \ell_6} = \begin{cases} 1 & \text{if } i_1 = i_2 = i_3, j_1 = j_4 = j_5, k_2 = k_4 = k_6 \wedge \ell_3 = \ell_5 = \ell_6, \\ 0 & \text{otherwise.} \end{cases}$$

**Upper bounds.** Most, but not all, of the families of multilinear maps we consider are closed under taking Kronecker products. For instance, consider the 4-clique counting form (4) for an  $n$ -vertex graph and its associated tensor  $T(A)$ . Then for any  $k \geq 1$ , the tensor associated with the 4-clique counting form in  $n^k$ -vertex graphs is  $T(A)^{\otimes k}$ , the  $k$ -fold Kronecker product of  $T(A)$  with itself. We write  $A^{\otimes k}$  for the associated map. With this in mind, it is natural to seek general constructions that, given an efficient evaluation of some map  $A$ , yields an efficient evaluation of  $A^{\otimes k}$ .

We give such a construction, and show that the cost of the best tensor network execution for  $A^{\otimes k}$  is essentially submultiplicative in a quantity that we call the *amortized cost* of an execution. For tensors of order at most 3, the notion of amortized cost essentially captures the rank of  $T(A)$ , but for higher-order tensors, the amortized cost may be significantly smaller than the rank. Roughly speaking, the amortized cost of a step in an execution of a map  $A$  is: (i) equal to the normal cost if the operation involves the contraction of two tensors that both depend on some input variables of  $A$ , but (ii) equal to the size of the result if only one of the tensors involved in the contraction depends on the input variables of  $A$ . A precise definition appears in Section 4. Our general upper bound for the cost of  $A^{\otimes k}$  can, somewhat informally, be stated as follows.

► **Theorem 1.3** (Submultiplicativity of cost, informal statement). *If a multilinear map  $A$  has a tensor network execution consisting of  $s$  steps, each with cost at most  $c$  and amortized cost at most  $a$ , then  $A^{\otimes k}$  has a tensor network execution consisting of at most  $k \cdot s$  steps, each with cost at most  $a^{k-1} \cdot c$ .*

An immediate corollary of this is that we can capture any algorithm for  $A^{\otimes k}$  based on a low-rank decomposition of  $T(A)$  (Corollary 4.2). For example, this implies that tensor networks can multiply  $n \times n$  matrices in  $O(n^{\omega+\epsilon})$  time.

However, returning to our running example form (4), as we explain below the tensor  $T(A)$  has rank  $n^4$ , meaning that Corollary 4.2 only yields a trivial upper bound. This is where the full generality of Theorem 1.3 comes in. Consider the form (4) for graphs on some constant number  $n_0$  of vertices. As it turns out, we can design a network and an associated execution for this form, depicted in (5) and explained in more detail in the full version of this paper, with an execution of cost  $n_0^{2e+3}$  and amortized cost  $n_0^{e+1}$ , where  $n_0^e$  is the rank of the tensor associated with  $n_0 \times n_0$  matrix multiplication. Picking  $n_0$  to be a large enough constant so that  $e$  is approximately  $\omega$ , and letting  $k$  be such that  $n$  is approximately  $n_0^k$ , we obtain via Theorem 1.3 an  $O(n^{\omega+\epsilon+1})$  time upper bound for (4).

**Lower bounds.** Just like many other arithmetic complexity lower bounds, our lower bounds boil down to establishing lower bounds on the rank of certain matrices.

To establish a lower bound on the *rank* of  $T(A)$ , we *flatten* it to a matrix and analyze the rank of that matrix. There are  $2^5$  possible bipartitions of the set of 6 modes of  $T(A)$ , and the lower bound on the rank of  $T(A)$  that we obtain is the maximum of the ranks of the resulting matrices. Using this method it is easy to establish that for our example form (4), the rank of  $T(A) = n^4$ . That this is an upper bound follows from (4), and that it is a lower bound follows by considering the bipartition taking variables  $X^{(1)}$  and  $X^{(6)}$  as row indices, and the other 4 variables as column indices. The resulting  $n^4 \times n^8$  matrix has full rank.

Tensor networks are more versatile and can be more efficient than low-rank decompositions of  $T(A)$ . Nevertheless, we show limitations on this versatility. In particular we show that every tensor network execution for  $A$  induces a tree in which the leaves are the inputs of  $A$  and all internal vertices have degree 3. We call this a *socket tree*. Each edge in a socket tree induces a bipartition of the variables and our key technical lemma is to show that for each such bipartition, the rank of the corresponding flattening of  $T(A)$  is a lower bound on the cost of the execution that gave rise to the tree. Thus, to obtain a lower bound for the cost of a specific execution, we consider the maximum rank obtained over all edges of the corresponding socket tree, and to lower bound the cost of every tensor network execution, we minimize this quantity over all possible socket trees. We refer to the resulting quantity as the *socket width* of  $A$ , denoted  $w(A)$  (formal definition appears in Section 5). Our general lower bound can thus be phrased as follows, where  $c(A)$  denotes the minimum cost of a tensor network for evaluating  $A$  (formal definition appears in Section 3).

► **Theorem 1.4.** *For every multilinear map  $A$ , it holds that  $c(A) \geq w(A)$ .*

Indeed, for our running example (4), there are low-width socket trees establishing that  $w(A) \leq n^3$ , see (6). However, that bound is tight: our  $\Omega(n^{\lceil 2 \cdot 4/3 \rceil}) = \Omega(n^3)$  lower bound for the  $\binom{4}{2}$ -linear form (Theorem 1.2) is obtained by proving that  $w(A) \geq n^3$  and appealing to Theorem 1.4.

### 1.3 Organization of this paper

The present conference abstract contains only the key definitions and technical results underlying our main theorems. All the upper and lower bounds for the arithmetic complexity of specific multilinear maps together with their proofs can be found in the full version of this paper. Section 2 recalls preliminaries on tensors and multilinear maps. In Section 3, tensor networks, execution and cost of a tensor network, and cost of a multilinear map are defined. Section 4 presents our main upper-bound result on submultiplicativity of cost. In Section 5, a general lower bound on the cost of evaluating a multilinear map using tensor network is obtained; this lower bound is expressed in terms of the socket-width of a multilinear map.

## 2 Preliminaries on tensors and multilinear maps

This section sets up our notation for tensors and multilinear maps. Throughout the paper  $[n]$  denotes  $\{1, 2, \dots, n\}$  and  $\mathbb{F}$  denotes an arbitrary fixed field. We work with tensors and multilinear maps relative to fixed bases for the respective vector spaces over  $\mathbb{F}$ .

**Modes, indexing, and positions.** We will work with the following convention of positioning individual entries inside a tensor. Let  $E$  be a finite set of *modes*. Associate with each mode  $e \in E$  a finite nonempty *index set*  $J(e)$ . In this case we say that  $E$  is a set of *indexed modes*. The *length* of  $e$  is  $|J(e)|$ . A *position* is an element  $j \in \prod_{e \in E} J(e)$ . Let us write  $J(E) = \prod_{e \in E} J(e)$  for the set of all positions with respect to the indexed modes  $E$ . In the special case that the set of modes  $E$  is empty we define the set of positions  $J(E)$  to consist of a single element.

**Tensors, matrices, vectors, and scalars.** Let  $E$  be a set of indexed modes. A *tensor* with respect to  $E$  is a mapping  $T : J(E) \rightarrow \mathbb{F}$ . Equivalently, we write  $T \in \mathbb{F}^{J(E)}$  to indicate that  $T$  is a tensor with respect to the indexed modes  $E$ . We view the set  $\mathbb{F}^{J(E)}$  of all tensors over  $E$  as a vector space over  $\mathbb{F}$  with addition and scalar multiplication of tensors defined entrywise. We say that  $|E|$  is the *order* of the tensor. A tensor of order zero is called a *scalar*, a tensor of order one is called a *vector*, and a tensor of order two is called a *matrix*. The *volume* of the tensor is  $|J(E)|$ . The tuple  $(|J(e)| : e \in E)$  is the *shape* of the tensor. It is convenient to use the “ $\times$ ”-symbol to punctuate the shape of a tensor; that is, instead of writing, say  $(2, 3, 4)$  for the shape, we write  $2 \times 3 \times 4$ . For a position  $j \in J(E)$  and a tensor  $T \in \mathbb{F}^{J(E)}$ , we say that  $T_j \in \mathbb{F}$  is the *entry* of  $T$  at  $j$ .

A *flattening* of  $T$  induced by a bipartition  $E_1 \cup E_2 = E$  of the modes of  $T$  is a  $|J(E_1)| \times |J(E_2)|$  matrix  $M$  where, for  $j_1 \in J(E_1)$  and  $j_2 \in J(E_2)$  we have  $M_{j_1, j_2} = T_{j_1, j_2}$ . Given two order  $\ell$  tensors  $S \in \mathbb{F}^{[n_1] \times [n_2] \times \dots \times [n_\ell]}$  and  $T \in \mathbb{F}^{[m_1] \times [m_2] \times \dots \times [m_\ell]}$ , their *Kronecker product*  $S \otimes T$  is a tensor in  $\mathbb{F}^{[n_1 m_1] \times [n_2 m_2] \times \dots \times [n_\ell m_\ell]}$  defined by

$$(S \otimes T)_{m_1(i_1-1)+j_1, m_2(i_2-1)+j_2, \dots, m_\ell(i_\ell-1)+j_\ell} = S_{i_1, i_2, \dots, i_\ell} T_{j_1, j_2, \dots, j_\ell}.$$

**Multilinear maps.** Let  $E_1, E_2, \dots, E_\ell, E'$  be pairwise disjoint sets of indexed modes such that  $E_1, E_2, \dots, E_\ell$  are nonempty. A map  $A : \mathbb{F}^{J(E_1)} \times \mathbb{F}^{J(E_2)} \times \dots \times \mathbb{F}^{J(E_\ell)} \rightarrow \mathbb{F}^{J(E')}$  is an  $\ell$ -*linear map* if  $A$  is linear with respect to each of its  $\ell$  inputs individually. In particular, a 1-linear map is a linear map. A multilinear map that gives a scalar output is a *multilinear form*. In particular,  $A$  is a form if and only if  $E'$  is empty.

**The tensors of a multilinear map.** For an  $\ell$ -linear map  $A : \mathbb{F}^{J(E_1)} \times \mathbb{F}^{J(E_2)} \times \dots \times \mathbb{F}^{J(E_\ell)} \rightarrow \mathbb{F}^{J(E')}$ , we define two slightly different tensors  $T(A)$  and  $\hat{T}(A)$ . Both are indexed by  $J(E_1 \cup E_2 \cup \dots \cup E_\ell \cup E')$  and at position  $j_1 j_2 \dots j_\ell j'$  take the value

$$T(A)_{j_1 j_2 \dots j_\ell j'} = \hat{T}(A)_{j_1 j_2 \dots j_\ell j'} = A(e^{(j_1)}, e^{(j_2)}, \dots, e^{(j_\ell)})_{j'},$$

where  $e^{(j_i)} \in \mathbb{F}^{J(E_i)}$  denotes the tensor with a 1 in position  $j_i$  and 0s in all other position. The difference between  $T(A)$  and  $\hat{T}(A)$  is their shape. The shape of  $T(A)$  is  $|J(E_1)| \times |J(E_2)| \times \dots \times |J(E_\ell)| \times |J(E')|$ , except if  $A$  is a form in which case the  $|J(E')|$  part is omitted. Thus  $T(A)$  is of order  $\ell + 1$  (or  $\ell$  if  $A$  is a form). The shape of  $\hat{T}(A)$  is  $(|J(e)| : e \in E_i, i \in [\ell + 1])$ , thus its order is  $|E_1| + |E_2| + \dots + |E_\ell| + |E'|$ .

## 7:10 Tensor Network Complexity of Multilinear Maps

In other words, each mode of  $T(A)$  corresponds to one of the inputs of  $A$ , or the output. These inputs are in turn sets of indexed modes so may contain more “fine-grained” structure, but this information is lost at the level of granularity of  $T(A)$ . When working with tensor networks for evaluating  $A$ , we need to keep track of the fine-grained mode structure because this is in many cases what allows us to construct efficient algorithms, hence in most parts of the paper we are more interested in the tensor  $\hat{T}(A)$  which contains this structure.

On the other hand,  $\hat{T}(A)$  does not contain information about which modes are grouped together to form the inputs and output of  $A$ , and this information is also important. This leads us to the notion of sockets, defined next.

**Sockets.** Let us study the tensor  $\hat{T}(A)$  with respect to the map  $A$ . We say that the modes in  $E_1 \cup E_2 \cup \dots \cup E_\ell$  are the *input* modes of  $\hat{T}(A)$ , and the modes in  $E'$  are the *output* modes of  $\hat{T}(A)$  with respect to  $A$ . Let us say that  $E_1, \dots, E_\ell$  are the *input sockets* of  $\hat{T}(A)$  with respect to  $A$ . Similarly,  $E'$  is the *output socket* in  $\hat{T}(A)$  with respect to  $A$ . In particular, the output socket is empty if and only if  $A$  is a form. To describe a socketing of the modes of a tensor, it is convenient to use parentheses to group a “ $\times$ ”-punctuated shape of a tensor into sockets, see also Section 2.

Let  $\hat{T}$  be a tensor over a set of indexed modes  $E$ . Any tuple  $\mathcal{E} = (E_1, E_2, \dots, E_\ell, E')$  of subsets of  $E$  that partitions  $E$  with  $E_1, E_2, \dots, E_\ell$  nonempty defines an  $\ell$ -linear map  $A_{\mathcal{E}}(\hat{T}) : \mathbb{F}^{J(E_1)} \times \mathbb{F}^{J(E_2)} \times \dots \times \mathbb{F}^{J(E_\ell)} \rightarrow \mathbb{F}^{J(E')}$  with  $\hat{T}(A_{\mathcal{E}}(\hat{T})) = \hat{T}$ . In this case the tuple  $(E_1, E_2, \dots, E_\ell)$  gives the input sockets of  $T$  and  $E'$  is the output socket of  $\hat{T}$  with respect to  $A_{\mathcal{E}}(\hat{T})$ . We thus conclude that two multilinear maps  $A_1, A_2$  may have the same base tensor  $\hat{T}(A_1) = \hat{T}(A_2)$ , and from a tensor  $\hat{T}$  one may obtain different multilinear maps by varying how the modes of  $\hat{T}$  are assigned to input and output sockets.

**The form of a multilinear map.** Let  $A$  be a multilinear map with a nonempty output socket. We can turn  $A$  into a multilinear form  $F(A)$  by turning its output socket into an input socket. Let us say that  $F(A)$  is the *multilinear form* of  $A$ . We also set  $F(A) = A$  when  $A$  is a multilinear form.

### 3 Tensor networks

This section defines tensor networks and the cost of a multilinear map.

**Networks.** A *network* (or *diagram*) consists of a finite set  $V$  of *vertices*, a finite set  $E$  of *hyperedges*, an *incidence relation*  $I \subseteq V \times E$ , and a *boundary*  $B \subseteq E$ . A network is *nondegenerate* if every hyperedge is incident to at least one vertex. In what follows we assume that all networks are nondegenerate. A hyperedge  $e \in E$  is a *loop* if  $e \notin B$  and  $e$  is incident to exactly one vertex.

For a vertex  $v \in V$ , let us write  $I(v) = \{e \in E : (v, e) \in I\}$  for the set of hyperedges incident to  $v$ . Dually, for an hyperedge  $e \in E$ , let us write  $I(e) = \{v \in V : (v, e) \in I\}$  for the set of vertices incident to  $e$ . For a network  $D$ , we write  $V(D)$ ,  $E(D)$ ,  $I(D)$ , and  $B(D)$  to refer to the vertices of  $D$ , the hyperedges of  $D$ , the incidence relation of  $D$ , and the boundary of  $D$ , respectively.

**Induced networks.** For a network  $D$  and a nonempty subset  $W \subseteq V(D)$ , the *induced* network  $D[W]$  consists of the vertices in  $W$  together with the hyperedges of  $D$  that are

incident to at least one vertex in  $W$ ; the boundary of  $D[W]$  consists of all hyperedges that are at the boundary of  $D$  or incident to a vertex outside  $W$ . Formally,

$$\begin{aligned} V(D[W]) &= W, \\ E(D[W]) &= \{e \in E(D) : \exists w \in W \text{ s.t. } (w, e) \in I(D)\}, \\ I(D[W]) &= I(D) \cap (V(D[W]) \times E(D[W])), \\ B(D[W]) &= (B(D) \cap E(D[W])) \cup \{e \in E(D[W]) : \exists v \in V(D) \setminus W \text{ s.t. } (v, e) \in I(D)\}. \end{aligned} \tag{7}$$

For a vertex  $v \in V$ , we abbreviate  $D[v] = D[\{v\}]$ . Note that the boundary of  $D[v]$  consists of all non-loop hyperedges incident to  $v$  in  $D$ .

**Tensor networks.** Let  $D$  be a network. We *index*  $D$  by associating with each hyperedge  $e \in E$  an *index set*  $J(e)$  of size  $\ell(e)$ . Induced networks inherit indexing by restriction. Next we associate with each vertex  $v \in V$  a tensor  $T(v) \in \mathbb{F}^{J(I(v))}$ . We say that  $D$  equipped with the tensors  $(T(v))_{v \in V}$  is a *tensor network*.

The *value* of a tensor network  $D$ , or the tensor *represented by*  $D$ , is a tensor  $T(D) \in \mathbb{F}^{J(B)}$ , defined for all  $i \in J(B)$  by

$$T(D)_i = \sum_{j \in J(E(D) \setminus B)} \prod_{v \in V} T(v)_{ij}. \tag{8}$$

Observe that in (8) the positions  $i$  and  $j$  together identify a unique entry of  $T(v)$  by projection to  $J(I(v))$ . The value of a tensor network with an empty boundary is a scalar.

**Contracting tensors.** Let  $D$  be a tensor network and let  $W \subseteq V(D)$  be a nonempty set of vertices. Let  $w$  be a new element not in  $V$ . We may *contract*  $W$  in  $D$  to obtain a tensor network  $D/W$  by replacing the sub-network  $D[W]$  in  $D$  with the single vertex  $w$  whose associated tensor  $T(w)$  is the tensor represented by  $D[W]$ . Formally,

$$\begin{aligned} V(D/W) &= (V(D) \setminus W) \cup \{w\}, \\ E(D/W) &= E(D) \setminus (E(D[W]) \setminus B(D[W])), \\ I(D/W) &= (I(D) \setminus I(D[W])) \cup \{(w, e) : e \in B(D[W])\}, \\ B(D/W) &= B(D), \\ T(w) &= T(D[W]). \end{aligned} \tag{9}$$

The *cost* of contracting  $W$  in  $D$  is  $c(D, W) = \prod_{e \in E(D[W])} |J(e)|$ . The value of a tensor network is invariant under contraction, i.e., for all nonempty  $W \subseteq V(D)$  it holds that  $T(D) = T(D/W)$ .

**Execution and cost of a tensor network.** To compute the tensor  $T(D)$  from a given tensor network  $D$ , we may proceed by a sequence of contractions on  $D$ . Such a process is called *executing*  $D$ , and the *cost* of  $D$  is the cost of a minimum-cost execution of  $D$ .

More precisely, let  $D = D_0$  be a tensor network with at least one tensor. For  $k = 1, 2, \dots, t$ , select a nonempty subset  $W_{k-1} \subseteq V(D_{k-1})$  such that  $W_{k-1}$  has at least two tensors or consists of a single tensor with a loop. Set  $D_k = D_{k-1}/W_{k-1}$  and observe that the number of tensors and/or modes decreases by at least one in the contraction. Suppose that  $D_t$  is loopless and consists of a single tensor. We say that such a sequence of contractions is an *execution* of  $D$  in  $t$  *steps*. The *cost* of the execution is  $\max_{k=1,2,\dots,t} c(D_{k-1}, W_{k-1})$ . The cost of an execution in zero steps is defined to be 0.

It is immediate that  $D$  has at least one execution and every execution consists of at most  $2|V(D)| - 1$  steps. By invariance under contractions, we have  $T(D_t) = T(D)$ . The *cost*  $c(D)$  of  $D$  is the cost of a minimum-cost execution of  $D$ .

An execution of  $D$  of cost  $c(D)$  immediately translates into an algorithm that computes  $T(D)$  using  $O(c(D)|V(D)|)$  arithmetic operations in  $\mathbb{F}$ , since the contraction step  $D_k = D_{k-1}/W_{k-1}$  takes  $O(c(D_{k-1}, W_{k-1})) \leq c(D)$  time to evaluate, and there are  $O(V(D))$  steps.

► **Lemma 3.1.** *Let  $D$  be a tensor network. There exists a minimum-cost execution of  $D$  such that each contracted set has size at most two. Furthermore, if  $D$  is loopless, we can assume that each contracted set has size exactly two.*

In what follows we restrict to consider loopless  $D$  only. Thus while a general execution may contract arbitrary vertex sets in  $D$  in each step, without loss of generality the minimum-cost execution has the structure of a rooted binary tree, whose leaves are the vertices of the tensor network, and each internal vertex is the tensor obtained by contracting its two children.

**Cost of a multilinear map.** We now define the cost of a multilinear map via the minimum-cost tensor networks (and socketing) for evaluating the map. That is, the cost of a map is defined in terms of the best tensor network that implements the map. More precisely, let

$$A : \mathbb{F}^{J(E_1)} \times \mathbb{F}^{J(E_2)} \times \dots \times \mathbb{F}^{J(E_\ell)} \rightarrow \mathbb{F}^{J(E')}$$

be an  $\ell$ -linear map. Consider the tensor  $\hat{T}(A)$  of  $A$  and the associated input sockets  $E_1, E_2, \dots, E_\ell$  and the output socket  $E'$ . Let  $D^*$  be an arbitrary tensor network such that  $T(D^*) = \hat{T}(A)$  and the boundary satisfies  $B(D^*) = E_1 \cup E_2 \cup \dots \cup E_\ell \cup E'$ . Modify the network  $D^*$  as follows. For each  $k = 1, 2, \dots, \ell$ , introduce a new vertex to  $D^*$ , make the new vertex incident to each of the modes in the input socket  $E_k$ , and associate the new vertex with a tensor  $X^{(k)} \in \mathbb{F}^{J(E_k)}$ . Remove the modes  $E_1 \cup E_2 \cup \dots \cup E_\ell$  from the boundary of  $D^*$ . Let us denote the resulting network by  $D$  and call the introduced  $\ell$  new vertices the *socket vertices* of  $D$ . We observe that  $B(D) = E'$  and  $A(X^{(1)}, X^{(2)}, \dots, X^{(\ell)}) = T(D)$ . Furthermore, the cost  $c(D)$  is independent of the value of  $X^{(k)} \in \mathbb{F}^{J(E_k)}$  for  $k = 1, 2, \dots, \ell$ . We say that  $D$  is a *realization* of  $A$  if it can be obtained from  $A$  by this process, and write  $\mathcal{D}(A)$  for the set of all tensor network realizations  $D$  of  $A$ .

The *cost* of the map  $A$  is  $c(A) = \min_{D \in \mathcal{D}(A)} c(D)$ . This minimum exists since the cost of a tensor network is a nonnegative integer and the family  $\mathcal{D}(A)$  is nonempty.

#### 4 An upper bound via submultiplicativity

This section presents our main tool for proving upper bounds on the cost of a multilinear map that admits representation as a Kronecker power, namely submultiplicativity of an amortized notion of cost under Kroneckerling.

**Kronecker power of a multilinear map.** Let  $E_1, E_2, \dots, E_\ell, E'$  be pairwise disjoint sets of indexed modes such that  $E_1, E_2, \dots, E_\ell$  are nonempty. Let

$$A : \mathbb{F}^{J(E_1)} \times \mathbb{F}^{J(E_2)} \times \dots \times \mathbb{F}^{J(E_\ell)} \rightarrow \mathbb{F}^{J(E')}$$

be an  $\ell$ -linear map. For a positive integer  $k$ , we define the  $\ell$ -linear map  $A^{\otimes k}$  such that its tensor satisfies  $T(A^{\otimes k}) = T(A)^{\otimes k}$ . Then

$$A^{\otimes k} : \mathbb{F}^{J(E_1)^k} \times \mathbb{F}^{J(E_2)^k} \times \dots \times \mathbb{F}^{J(E_\ell)^k} \rightarrow \mathbb{F}^{J(E')^k}.$$

Note that  $T(A^{\otimes k}) = T(A)^{\otimes k}$  is the  $k$ -fold Kronecker product of  $T(A)$  with itself – that is, it has the same order, but the index sets are larger – whereas  $\hat{T}(A^{\otimes k})$  is the  $k$ -fold outer product of  $\hat{T}(A)$  with itself – that is, its index sets have the same sizes, but its order is  $k$  times larger.

**Amortized cost and submultiplicativity.** Let  $D$  be a diagram that realizes  $A$  and let  $\mathcal{T}_D$  be an execution tree for  $D$ . For each internal vertex  $x$  in  $\mathcal{T}_D$  (that is, a vertex obtained by contraction), define the *amortized cost* of  $x$  by splitting into the following three cases:

- (i) if neither of the two subtrees of  $x$  contains a socket vertex, the amortized cost of  $x$  is 1;
- (ii) if exactly one of the subtrees of  $x$ , say, the subtree rooted at  $y$  (where  $x$  and  $y$  are adjacent in  $\mathcal{T}_D$ ), contains at least one socket vertex, the amortized cost of  $x$  is the maximum of the volume of the tensor at  $x$  and the volume of the tensor at  $y$ ;<sup>4</sup>
- (iii) if both of the subtrees of  $x$  contain at least one socket vertex, the amortized cost of  $x$  is the cost of the contraction to obtain  $x$ .

The *amortized cost*  $a(\mathcal{T}_D)$  of  $\mathcal{T}_D$  is the maximum of the amortized costs of the internal vertices of  $\mathcal{T}_D$ . Since the amortized cost of each internal vertex of  $\mathcal{T}_D$  is at most its cost, we have  $a(\mathcal{T}_D) \leq c(\mathcal{T}_D)$ . Furthermore, we observe that the amortized cost of  $x$  in case (ii) above may be strictly less than the cost of the contraction to obtain  $x$ . In particular, in (ii) the amortized cost is defined *not by the cost of the contraction but rather by volume*. This is because in a  $k^{\text{th}}$  Kronecker power we can amortize the cost of the aggregate transformation in case (ii) not with a single contraction but with a sequence of  $k$  contractions. This observation will form the heart of the proof of Theorem 1.3.

Before proceeding with the proof, let us illustrate the key ideas in visual terms. Let us start with the three illustrations in (10).

Suppose the leftmost network in (10) is socketed so that the two modes at the top form the output socket, and the four modes at the bottom form two input sockets so that modes in the same socket are incident to the same vertex. In the middle in (10), we have adjoined two socket vertices to the input sockets to obtain a realization  $D$ . On the right in (10), we display an execution tree  $\mathcal{T}_D$  for  $D$ . Observe that the bottom-most internal vertices of  $\mathcal{T}_D$ , and the top-most internal vertex of  $\mathcal{T}_D$ , have type (ii). The internal vertex in the center has type (iii). (There are no internal vertices of type (i).) Supposing that all the modes have length at least 2, we also observe that the vertices of type (ii) have amortized cost strictly less than their contraction cost.

Let us now consider the  $k^{\text{th}}$  power of (10) visually, for  $k = 4$ :

<sup>4</sup> Here, it is crucial to note that the volume of the other subtree rooted at  $x$ , only containing non-socket vertices, does not contribute directly to the amortized cost of  $x$ .

The leftmost network in (11) depicts the  $k$ -fold outer product of the network on the left in (10) with itself. Observe that we simply take  $k$  copies of the network, but that for the purposes of the visualization we have taken care to draw the  $k$  copies of each mode together for the socketing. In the middle in (11), we have adjoined two socket vertices to the input sockets to obtain a realization  $D^{\otimes k}$  of  $A^{\otimes k}$ . On the right in (11), we display an execution tree  $\mathcal{T}_{D^{\otimes k}}$  for  $D^{\otimes k}$ . Observe how each of the internal vertices of type (ii) in  $\mathcal{T}_D$  gets expanded to a sequence of  $k$  internal vertices in  $\mathcal{T}_{D^{\otimes k}}$ . This transformation from  $\mathcal{T}_D$  to  $\mathcal{T}_{D^{\otimes k}}$  is the gist of the following theorem.

► **Theorem 4.1** (Formal statement of Theorem 1.3). *Let  $D$  be an arbitrary realization of  $A$  and let  $\mathcal{T}_D$  be an arbitrary execution tree for  $D$ . For all positive integers  $k$ , we have*

$$c(A^{\otimes k}) \leq a(\mathcal{T}_D)^{k-1} c(\mathcal{T}_D). \tag{12}$$

Furthermore, this realization of  $A^{\otimes k}$  consists of at most  $k \cdot |V(D)|$  vertices.

**Proof.** Let  $D^*$  be the subnetwork of  $D$  with  $T(D^*) = \hat{T}(A)$ . That is,  $D^*$  is the network induced by all the non-socket vertices of  $D$ . Taking  $k$  disjoint copies of  $D^*$ , we obtain a network whose tensor is  $\hat{T}(A^{\otimes k})$ . Attaching the resulting network to tensors at sockets gives a realization of  $A^{\otimes k}$ . Let us write  $D^{\otimes k}$  for this realization.

To establish (12), it suffices to construct an execution tree  $\mathcal{T}_{D^{\otimes k}}$  for  $D^{\otimes k}$  whose cost satisfies  $c(\mathcal{T}_{D^{\otimes k}}) \leq a(\mathcal{T}_D)^{k-1} c(\mathcal{T}_D)$ . We construct  $\mathcal{T}_{D^{\otimes k}}$  by rewriting  $\mathcal{T}_D$  from leaves towards the root to consider the  $k$  copies of each vertex in  $D^*$ . We start with leaf vertices which are the vertices of  $D^{\otimes k}$ . We split the process into cases (i), (ii), and (iii) as in the definition of amortized cost. Let  $x$  be the internal vertex of  $\mathcal{T}_D$  that we are currently considering.

In case (i), we perform the contraction indicated by  $x$  in each of the  $k$  copies of  $D^*$  in  $D^{\otimes k}$  individually. This creates  $k$  new internal vertices in  $\mathcal{T}_{D^{\otimes k}}$  that are all copies of  $x$ . We set these  $k$  vertices as the vertices that correspond to  $x$  in the subsequent steps. Each of these contractions in  $\mathcal{T}_{D^{\otimes k}}$  has the same cost as the contraction indicated by  $x$  in  $\mathcal{T}_D$ . This cost is less or equal than  $c(\mathcal{T}_D)$ .

In case (ii), let  $y$  be the child of  $x$  in  $\mathcal{T}_D$  such that the subtree rooted at  $y$  contains a socket vertex, and let  $z$  be the other child of  $x$  in  $\mathcal{T}_D$ . There is a single vertex in  $\mathcal{T}_{D^{\otimes k}}$  corresponding to  $y$  and  $k$  identical vertices in  $\mathcal{T}_{D^{\otimes k}}$  corresponding to  $z$ . We contract these  $k$  vertices individually each with the vertex that corresponds to  $y$ . This creates  $k$  new internal vertices in  $\mathcal{T}_{D^{\otimes k}}$ , where we set the topmost vertex as the vertex that corresponds to  $x$  in the subsequent steps. After the  $i$ th step, the corresponding tensor has  $i$  copies of modes of  $x$  and  $k - i$  copies of modes of  $y$ . The cost of the contraction in the  $i$ th step is the cost of contracting  $y$  and  $z$  in  $\mathcal{T}_D$  multiplied by the the volume of  $y$  to the power  $k - i$  and the volume of  $x$  to the power  $i - 1$ . Since the volumes of  $x$  and  $y$  are less than or equal to  $a(\mathcal{T}_D)$ , this cost is less than or equal to  $a(\mathcal{T}_D)^{k-1} c(\mathcal{T}_D)$ .

In case (iii), let  $y$  and  $z$  be the two child vertices of  $x$  in  $\mathcal{T}_D$ . By the structure of the earlier steps, we have that a single vertex in  $D^{\otimes k}$  corresponds to  $y$ , and similarly for  $z$ . We contract these two vertices. This creates one new internal vertex in  $\mathcal{T}_{D^{\otimes k}}$ , which we set as the vertex that corresponds to  $x$  in the subsequent steps. This tensor has  $k$  copies of modes of  $x$ . The cost of this contraction in  $\mathcal{T}_{D^{\otimes k}}$  is the cost of the corresponding contraction in  $\mathcal{T}_D$  to the  $k^{\text{th}}$  power, because both tensors have  $k$  copies of all modes compared to  $y$  and  $z$ . By definition, in case (iii) the amortized cost of contracting  $y$  and  $z$  is the same as the cost of contracting  $y$  and  $z$ . Hence the cost of this contraction in  $\mathcal{T}_{D^{\otimes k}}$  is less or equal than  $a(\mathcal{T}_D)^k \leq a(\mathcal{T}_D)^{k-1} c(\mathcal{T}_D)$ . This rewriting process produces an execution tree  $\mathcal{T}_{D^{\otimes k}}$  for  $D^{\otimes k}$  with  $c(\mathcal{T}_{D^{\otimes k}}) \leq a(\mathcal{T}_D)^{k-1} c(\mathcal{T}_D)$ . ◀

An immediate corollary is that tensor networks can use low rank decompositions of  $T(A)$  to efficiently evaluate  $A^{\otimes k}$ .

► **Corollary 4.2** (Submultiplicativity of low-rank executions). *Let  $A : \mathbb{F}^{J(E_1)} \times \mathbb{F}^{J(E_2)} \times \dots \times \mathbb{F}^{J(E_\ell)} \rightarrow \mathbb{F}^{J(E')}$  be a multilinear map. Define  $m = \max\{|J(E_1)|, |J(E_2)|, \dots, |J(E_\ell)|, |J(E')|\}$  and  $r = \text{rk } T(A)$ . Then  $c(A^{\otimes k}) \leq \max(r, m)^k \min(r, m)$*

**Proof.** By taking a star-like network topology (as in (10)) we get an execution with  $a(\mathcal{T}_D) = \max(r, m)$  and cost  $c(\mathcal{T}_D) = m \cdot r$ . ◀

## 5 A lower bound for the cost of a multilinear map

In this section, we prove a general lower bound on the cost of evaluating a multilinear map using tensor networks, as defined in Section 3. The lower bound is expressed in terms of the *socket-width* of a multilinear map, which we now proceed to define.

Let  $A : \mathbb{F}^{J(E_1)} \times \mathbb{F}^{J(E_2)} \times \dots \times \mathbb{F}^{J(E_\ell)} \rightarrow \mathbb{F}^{J(E')}$  be an  $\ell$ -linear map. A *socket-tree* of  $A$  is a tree  $\mathcal{T}_S$  whose  $\ell + 1$  leaf vertices are the sockets  $E_1, E_2, \dots, E_\ell, E'$  of  $A$  and whose internal vertices all have degree exactly 3. Associate with each edge  $e = \{x_R, x_C\}$  of  $\mathcal{T}_S$  the two subtrees  $\mathcal{T}_S(x_R, e)$  and  $\mathcal{T}_S(x_C, e)$  obtained by removing  $e$ , where  $\mathcal{T}_S(x_R, e)$  is the subtree containing  $x_R$  and  $\mathcal{T}_S(x_C, e)$  is the subtree containing  $x_C$ . Let  $L(x_R, e)$  be the set of leaves in  $\mathcal{T}_S(x_R, e)$  and let  $L(x_C, e)$  be the set of leaves in  $\mathcal{T}_S(x_C, e)$ .

The sets  $L(x_R, e)$  and  $L(x_C, e)$  are both nonempty and together partition the set of sockets. Consider the flattening  $M(\mathcal{T}_S, e)$  of the tensor  $T(A)$  such that the modes in  $L(x_R, e)$  index the rows and the modes in  $L(x_C, e)$  index the columns of  $M(\mathcal{T}_S, e)$ . The *width* of  $\mathcal{T}_S$  at  $e$  is the rank of  $M(\mathcal{T}_S, e)$ , and the *width* of  $\mathcal{T}_S$  is  $w(\mathcal{T}_S) = \max_{e \in E(\mathcal{T}_S)} \text{rk}(M(\mathcal{T}_S, e))$ .

Let us write  $\mathcal{S}(A)$  for the set of all socket-trees of the multilinear form  $A$ . We define the *socket-width* of  $A$  to be  $w(A) = \min_{\mathcal{T}_S \in \mathcal{S}(A)} w(\mathcal{T}_S)$ .

The rest of this section is devoted to proving Theorem 1.4:

► **Theorem 1.4.** *For every multilinear map  $A$ , it holds that  $c(A) \geq w(A)$ .*

First, we prove that without loss of generality, we may restrict our attention to forms.

► **Claim 5.1.** *For any multilinear map  $A$ , it holds that  $c(A) \geq c(F(A))$ .*

**Proof.** We observe that  $A$  and  $F(A)$  satisfy  $\hat{T}(A) = \hat{T}(F(A))$ . Any network  $D \in \mathcal{D}(A)$  can be modified to a network  $D' \in \mathcal{D}(F(A))$  by attaching a tensor  $X' \in \mathbb{F}^{J(E')}$  to the boundary of  $D$ . Let  $D \in \mathcal{D}(A)$  be such that  $c(D) = c(A)$ . The minimum-cost execution of  $D$ , followed by contracting  $T(D)$  and  $X'$ , is an execution of  $D'$ . Its cost is  $c(A)$ , since the cost of contracting  $T(D)$  and  $X'$  is  $\prod_{e \in B(D)} |J(e)|$  and  $\prod_{e \in B(D)} |J(e)| \leq c(A)$ , because the last step of the minimum-cost execution of  $D$  contracted a set  $W$  with all modes  $e \in B(D)$  incident to  $W$ . Thus,  $c(A) \geq c(F(A))$ . ◀

Furthermore,  $w(A) = w(F(A))$  for every multilinear map  $A$ , since  $w(A)$  only depends on the tensor  $T(A)$ , but not on which of its coordinates (if any) is the output. Thus it suffices to prove Theorem 1.4 for multilinear forms, which we now proceed to do.

► **Lemma 5.2.** *For any multilinear form  $F$ , it holds that  $c(F) \geq w(F)$ .*

**Proof.** Let  $D \in \mathcal{D}(F)$  be such that  $c(D) = c(F)$ . It is a tensor network with empty boundary and a socket vertex  $S_i \in V(D)$  for each input socket  $E_i$ , where  $i = 1, 2, \dots, \ell$ . Its tensor is  $T(D) = F(X^{(1)}, X^{(2)}, \dots, X^{(\ell)})$  where  $X^{(i)} = T(S_i)$  for  $i = 1, 2, \dots, \ell$ .

(a) Example of a possible execution tree  $\mathcal{T}_D$ . Given the choice of  $e$  in the corresponding socket tree  $\mathcal{T}_S$  shown on the right there are four possible choices of  $\tilde{e}$ .

(b) The corresponding socket tree  $\mathcal{T}_S$ . The exact choice of  $\tilde{e}$  in  $\mathcal{T}_D$  determines which part of the cut is the  $x_R$  part, and which is the  $x_C$  part.

■ **Figure 1** Illustration of the notation used for the execution and socket trees.

By Lemma 3.1, a minimum-cost execution of  $D$  can be represented by a rooted binary tree  $\mathcal{T}_D$ , where the set of leaves of  $\mathcal{T}_D$  are  $V(D)$  and each inner vertex represents the vertex obtained by contracting its two children. Let  $\mathcal{T}_S$  be the unique socket-tree of  $F$  that is obtained as a topological minor of  $\mathcal{T}_D$ . Slightly abusing the notation, we assume that the leaves of  $\mathcal{T}_S$  are the socket vertices  $S_1, S_2, \dots, S_\ell$  instead of the sockets  $E_1, E_2, \dots, E_\ell$ . To establish the lemma, it suffices to show that  $\mathcal{T}_D$  has cost at least  $w(\mathcal{T}_S)$ , since  $w(\mathcal{T}_S) \geq w(F)$ .

Let  $e = \{x_R, x_C\} \in E(\mathcal{T}_S)$  be an edge of the socket tree  $\mathcal{T}_S$  with  $\text{rk}(M(\mathcal{T}_S, e)) = w(\mathcal{T}_S)$ , and let  $\tilde{e}$  be an edge of the execution tree  $\mathcal{T}_D$  in the subdivision of  $e$  appearing in  $\mathcal{T}_D$ . Without loss of generality we may assume that  $\tilde{e}$  is directed from the part of  $\mathcal{T}_D$  corresponding to  $x_R$  towards the part corresponding to  $x_C$  (if not, simply switch names of  $x_R$  and  $x_C$ ). Define  $S_R = L(x_R, e)$  and  $S_C = L(x_C, e)$ . Let  $W_R \subseteq V(D)$  be the set of non-socket vertices of  $D$  that appear on the same side of  $\tilde{e}$  in  $\mathcal{T}_D$  with socket vertices  $S_R$  and let  $W_C$  be the set of remaining non-socket vertices of  $D$ . See Figure 1 for an illustration of all these definitions. Finally, let  $D' = D/S_R/S_C/W_R/W_C$  be the result of contracting each of these four sets of vertices of  $D$ . For notational convenience, we identify the four vertices of the new network with the four subsets  $S_R, S_C, W_R, W_C$ .

Now, the tensor  $P = T(D'[W_R \cup S_R])$  appears as an intermediate result in the execution  $\mathcal{T}_D$ ,<sup>5</sup> hence the volume of  $P$  is a lower bound on the cost of  $\mathcal{T}_D$ .

We group the modes of  $D'$  incident on  $S_R$  or  $W_R$  as shown in Figure 2:  $E_{SW}$  are all modes in  $D'$  incident exactly upon  $S_R$  and  $W_R$ ,  $E_{WC}$  are all modes incident on  $W_R$  but not on  $S_R$ ,  $E_{SC}$  are all modes incident on  $S_R$  but not  $W_R$ , and finally  $E_{SWC}$  are all modes incident upon  $S_R, W_R$ , and at least one of  $S_C$  or  $W_C$ . Write  $E_S = E_{SW} \cup E_{SC} \cup E_{SWC}$  for the modes incident on  $S_R$ , and similarly  $E_C = E_{WC} \cup E_{SC} \cup E_{SWC}$  for all modes incident upon at least one of  $S_R/W_R$  and at least one of  $S_C/W_C$ . Note that  $|J(E_C)|$  is precisely the volume of  $P$  which we aim to lower bound.

Define a matrix  $A \in \mathbb{F}^{J(E_S)} \times \mathbb{F}^{J(E_C)}$  as follows. We identify its row indices  $i \in J(E_S)$  as being triples  $i = (i_{SW}, i_{SC}, i_{SWC}) \in J(E_{SW}) \times J(E_{SC}) \times J(E_{SWC})$  and similarly its column indices  $j \in J(E_C)$  are triples  $j = (j_{SC}, j_{WC}, j_{SWC}) \in J(E_{SC}) \times J(E_{WC}) \times J(E_{SWC})$ . Then

<sup>5</sup> Note that the same is not true for the tensor  $T(D'[W_C \cup S_C])$ .

■ **Figure 2** Illustration of  $D'$ . We group the modes of  $D'$  based on how they connect  $S_R$ ,  $S_C$ , and the “ $C$  part” of  $D'$ .

the entries of  $A$  are

$$A_{(i_{SW}, i_{SC}, i_{SWC}), (j_{SC}, j_{WC}, j_{SWC})} = \begin{cases} T(D'[W_R])_{i_{SW}, j_{WC}, j_{SWC}} & \text{if } i_{SC} = j_{SC} \wedge i_{SWC} = j_{SWC}, \\ 0 & \text{otherwise,} \end{cases}$$

In the case when  $E_S = E_{SW}$  (i.e., all modes incident on  $S_R$  connect only to  $W_R$ ),  $A$  is simply a flattening of  $T(D'[W_R])$ . Recall that  $T(D'[S_R]) \in \prod_{e \in E_S} \mathbb{F}^{J(e)}$ . Then for every  $j = (j_{SC}, j_{WC}, j_{SWC}) \in J(E_C)$ , we have

$$\begin{aligned} \sum_{i \in J(E_S)} A_{i,j} T(D'[S_R])_i &= \sum_{i_{SW} \in J(E_{SW})} A_{(i_{SW}, j_{SC}, j_{SWC}), j} T(D'[S_R])_{i_{SW}, j_{SC}, j_{SWC}} \\ &= \sum_{i_{SW}} T(D'[W_R])_{i_{SW}, j_{WC}, j_{SWC}} T(D'[S_R])_{i_{SW}, j_{SC}, j_{SWC}} \\ &= P_{j_{SC}, j_{WC}, j_{SWC}} = P_j \end{aligned}$$

(recall that  $P$  is the contraction of  $T(D'[W_R])$  and  $T(D'[S_R])$ ). Viewing  $T(D'[S_R])$  as a row vector in  $\mathbb{F}^{J(E_S)}$  we see that  $P$  is the vector-matrix product  $P = T(D'[S_R]) \cdot A \in \mathbb{F}^{J(E_C)}$ .

Symmetrically, for the other half of  $D'$ , we can write  $Q = T(D'[W_C \cup S_C])$  as a matrix-vector product  $Q = B \cdot T(D'[S_C]) \in \mathbb{F}^{J(E_C)}$  where  $B$  is a matrix corresponding to  $T(D'[W_S])$  analogously to how  $A$  corresponds to  $T(D'[W_R])$ .

Thus we have  $T(D) = T(D'[S_R]) \cdot A \cdot B \cdot T(D'[S_C])$ . Recall that for each socket vertex  $S_i$  in the original network  $D$ , we have  $T(S_i) = X^{(i)}$ . Denoting  $X_R = T(D'[S_R])$  and  $X_C = T(D'[S_C])$ , we get  $X_R = \bigotimes_{S_i \in S_R} X^{(i)}$  and  $X_C = \bigotimes_{S_i \in S_C} X^{(i)}$ .<sup>6</sup> Hence

$$F(X^{(1)}, X^{(2)}, \dots, X^{(\ell)}) = X_R \cdot A \cdot B \cdot X_C.$$

It follows that  $A \cdot B$  is the flattening of  $T(F)$  to a matrix with rows indexed by the sockets in  $S_R$  and columns indexed by the sockets in  $S_C$ . But this flattening is precisely the matrix  $M(\mathcal{T}_S, e)$ , implying that  $|J(E_C)| \geq \text{rk}(M(\mathcal{T}_S, e)) = w(\mathcal{T}_S)$ , as desired. ◀

<sup>6</sup> These identities use the fact that  $D$  is derived from a *non-degenerate* network  $D^*$  for  $\hat{T}(F)$ . In particular, every mode in the network  $D$  is incident upon at least one non-socket vertex, hence all modes incident upon  $S_R$  are boundary modes in  $D'[S_R]$ , and similarly for  $S_C$ .

## Abstract

We show that there is a zero-error randomized algorithm that, when given a small constant-depth Boolean circuit  $C$  made up of gates that compute constant-degree Polynomial Threshold functions or PTFs (i.e., Boolean functions that compute signs of constant-degree polynomials), counts the number of satisfying assignments to  $C$  in significantly better than brute-force time.

Formally, for any constants  $d, k$ , there is an  $\varepsilon > 0$  such that the zero-error randomized algorithm counts the number of satisfying assignments to a given depth- $d$  circuit  $C$  made up of  $k$ -PTF gates such that  $C$  has size at most  $n^{1+\varepsilon}$ . The algorithm runs in time  $2^{n-n^{\Omega(\varepsilon)}}$ .

Before our result, no algorithm for beating brute-force search was known for counting the number of satisfying assignments even for a single degree- $k$  PTF (which is a depth-1 circuit of linear size).

The main new tool is the use of a learning algorithm for learning degree-1 PTFs (or Linear Threshold Functions) using comparison queries due to Kane, Lovett, Moran and Zhang (FOCS 2017). We show that their ideas fit nicely into a memoization approach that yields the #SAT algorithms.

**2012 ACM Subject Classification** Theory of computation → Circuit complexity

## 1 Introduction

This paper adds to the growing line of work on *circuit-analysis algorithms*, where we are given as input a Boolean circuit  $C$  from a fixed class  $\mathcal{C}$  computing a function  $f : \{-1, 1\}^n \rightarrow \{-1, 1\}$ ,<sup>3</sup> and we are required to compute some parameter of the function  $f$ . A typical example of this is the question of satisfiability, i.e. whether  $f$  is the constant function 1 or not. In this paper, we are interested in computing  $\#SAT(f)$ , which is the number of satisfying assignments of  $f$  (i.e.  $|\{a \in \{-1, 1\}^n \mid f(a) = -1\}|$ ).

Problems of this form can always be solved by “brute-force” in time  $\text{poly}(|C|) \cdot 2^n$  by trying all assignments to  $C$ . The question is can this brute-force algorithm be significantly improved, say to time  $2^n/n^{\omega(1)}$  when  $C$  is small, say  $|C| \leq n^{O(1)}$ .

Such algorithms, intuitively are able to distinguish a small circuit  $C \in \mathcal{C}$  from a “black-box” and hence find some structure in  $C$ . This structure, in turn, is useful in answering other questions about  $\mathcal{C}$ , such as proving lower bounds against the class  $\mathcal{C}$ .<sup>4</sup> There has been a large body of work in this area, a small sample of which can be found in [21, 20, 26, 27]. A striking result of this type was proved by Williams [26] who showed that for many circuit classes  $\mathcal{C}$ , even *co-non-deterministic* satisfiability algorithms running in better than brute-force time yield lower bounds against  $\mathcal{C}$ .

Recently, researchers have also uncovered tight connections between many combinatorial problems and circuit-analysis algorithms, showing that even modest improvements over brute-force search can be used to improve long-standing bounds for these combinatorial problems (see, e.g., [30, 2, 3, 1]). This yields further impetus in improving known circuit-analysis algorithms.

This paper is concerned with #SAT algorithms for constant depth threshold circuits, denoted as  $TC^0$ , which are Boolean circuits where each gate computes a linear threshold function (LTF); an LTF computes a Boolean function which accepts or rejects based on the sign of a (real-valued) linear polynomial evaluated on its input. Such circuits are surprisingly powerful: for example, they can perform all integer arithmetic efficiently [4, 9], and are at the frontier of our current lower bound techniques [16, 5].

It is natural, therefore, to try to come up with circuit-analysis algorithms for threshold circuits. Indeed, there has a large body of work in the area (reviewed below), but some extremely simple questions remain open.

An example of such a question is the existence of a better-than-brute-force algorithm for satisfiability of degree- $k$  PTFs where  $k$  is a constant greater than 1. Informally, the question is the following: we are given a degree- $k$  polynomial  $Q(x_1, \dots, x_n)$  in  $n$  Boolean variables and we ask if there is any Boolean assignment  $a \in \{-1, 1\}^n$  to  $x_1, \dots, x_n$  such that  $Q(a) < 0$ . (Note that for a linear polynomial (i.e.  $k = 1$ ), this problem is trivial.)

Surprisingly, no algorithm is known for this problem that is significantly better than  $2^n$  time.<sup>5</sup> In this paper, we solve the stronger counting variant of this problem for any constant-degree PTFs. We start with some definitions and then describe this result.

► **Definition 1** (Polynomial Threshold Functions). A *Polynomial Threshold Function (PTF)* on  $n$  variables of degree- $k$  is a Boolean function  $f : \{-1, 1\}^n \rightarrow \{-1, 1\}$  such that there is

<sup>3</sup> We work with the  $\{-1, 1\}$  basis for Boolean functions, which is by now standard in the literature. (See for instance [18].) Here  $-1$  stands for True and  $1$  stands for False.

<sup>4</sup> This intuition was provided to us by Ryan Williams.

<sup>5</sup> An algorithm was claimed for this problem in the work of Sakai, Seto, Tamaki and Teruyama [22]. Unfortunately, the proof of this claim only works when the weights are suitably small. See Footnote 1 on page 4 of [14].

a degree- $k$  multilinear polynomial  $P(x_1, \dots, x_n) \in \mathbb{R}[x_1, \dots, x_n]$  that, for all  $a \in \{-1, 1\}^n$ , satisfies  $f(a) = \text{sgn}(P(a))$ . (We assume that  $P(a) \neq 0$  for any  $a \in \{-1, 1\}^n$ .)

In such a scenario, we call  $f$  a  $k$ -PTF. In the special case that  $k = 1$ , we call  $f$  a *Linear Threshold function (LTF)*. We also say that the polynomial  $P$  *sign-represents*  $f$ .

When  $P \in \mathbb{Z}[x_1, \dots, x_n]$ , we define the weight of  $P$ , denoted  $w(P)$ , to be the *bit-complexity* of the sum of the absolute values of all the coefficients of  $P$ . In particular, the coefficients of  $P$  are integers in the range  $[-2^{w(P)}, 2^{w(P)}]$ .

We now formally define the #SAT problem for  $k$ -PTFs. Throughout, we assume that  $k$  is a constant and not a part of the input.

► **Definition 2** (#SAT problem for  $k$ -PTFs). The problem is defined as follows.

**Input:** A  $k$ -PTF  $f$ , specified by a degree- $k$  polynomial  $P(x_1, \dots, x_n)$  with integer coefficients.<sup>6</sup>

**Output:** The number of satisfying assignments to  $f$ . That is, the number of  $a \in \{-1, 1\}^n$  such that  $P(a) < 0$ .

We use  $\#SAT(f)$  to denote this output. We say that the input instance has parameters  $(n, M)$  if  $n$  is the number of input variables and  $w(P) \leq M$ .

► **Remark.** An interesting setting of  $M$  is  $\text{poly}(n)$  since any  $k$ -PTF can be represented by an integer polynomial with coefficients of bit-complexity at most  $\tilde{O}(n^k)$  [17]. However, note that our algorithms are even when  $M$  is  $\exp(n^{o(1)})$ , i.e. when the weights are slightly short of doubly exponential in  $n$ .

We give a better-than-brute-force algorithm for #SAT( $k$ -PTF). Formally we prove the following theorem.

► **Theorem 3.** *Fix any constant  $k$ . There is a zero-error randomized algorithm that solves the #SAT problem for  $k$ -PTFs in time  $\text{poly}(n, M) \cdot 2^{n-S}$  where  $S = \tilde{\Omega}(n^{1/(k+1)})$  and  $(n, M)$  are the parameters of the input  $k$ -PTF  $f$ . (The  $\tilde{\Omega}(\cdot)$  hides factors that are inverse polylogarithmic in  $n$ .)*

► **Remark.** An anonymous ITCS 2019 referee pointed out to us that from two results of Williams [25, 28], it follows that satisfiability for 2-PTFs can be solved in  $2^{n-\Omega(\sqrt{n})}$  time. Note that this is better than the runtime of our algorithm. However, the method does not extend to  $k \geq 3$ .

We then extend this result to a powerful model of circuits called  *$k$ -PTF circuits*, where each gate computes a  $k$ -PTF. This model was first studied by Kane, Kabanets and Lu [13] who proved strong average case lower bounds for slightly superlinear-size constant-depth  $k$ -PTF circuits. Using these ideas, Kabanets and Lu [14] were able to give a #SAT algorithm for a restricted class of  $k$ -PTF circuits, where each gate computes a PTF with a subquadratically many, say  $n^{1.99}$ , monomials (while the size remains the same, i.e. slightly superlinear).<sup>7</sup> A reason for this restriction on the PTFs was that they did not have an algorithm to handle even a single degree-2 PTF (which can have  $\Omega(n^2)$  many monomials).

Building on our #SAT algorithm for  $k$ -PTFs and the ideas of [14], we are able to handle general  $k$ -PTF circuits of slightly superlinear size. We state these results formally below.

We first define  $k$ -PTF circuits formally.

<sup>6</sup> It is known [17] that such a representation always exists.

<sup>7</sup> Their result also works for the slightly larger class of PTFs that are subquadratically sparse in the  $\{0, 1\}$ -basis with *no restriction* on degree. Our result can also be stated for the larger class of *polynomially sparse* PTFs, but for the sake of simplicity, we stick to constant-degree PTFs.

► **Definition 4** (*k*-PTF circuits). A *k*-PTF circuit on  $n$  variables is a Boolean circuit on  $n$  variables where each gate  $g$  of fan-in  $m$  computes a fixed *k*-PTF of its  $m$  inputs. The size of the circuit is the *number of wires* in the circuit, and the depth of the circuit is the longest path from an input to the output gate.<sup>8</sup>

The problems we consider is the #SAT problem for *k*-PTF circuits, defined as follows.

► **Definition 5** (#SAT problem for *k*-PTF circuits). The problem is defined as follows.

**Input:** A *k*-PTF circuit  $C$ , where each gate  $g$  is labelled by an integer polynomial that sign-represents the function that is computed by  $g$ .

**Output:** The number of satisfying assignments to  $C$ .

We use #SAT( $C$ ) to denote this output. We say that the input instance has parameters  $(n, s, d, M)$  where  $n$  is the number of input variables,  $s$  is the size of  $C$ ,  $d$  is the depth of  $C$  and  $M$  is the maximum over the weights of the degree- $k$  polynomials specifying the *k*-PTFs in  $C$ . We will say that  $M$  is the weight of  $C$ , denoted by  $w(C)$ .

We now state our result on #SAT for *k*-PTF circuits. The following result implies Theorem 3, but we prove them separately.

► **Theorem 6.** *Fix any constants  $k, d$ . Then the following holds for some constant  $\varepsilon_{k,d} > 0$  depending on  $k, d$ . There is a zero-error randomized algorithm that solves the #SAT problem for *k*-PTF circuits of size at most  $s = n^{1+\varepsilon_{k,d}}$  with probability at least  $1/4$  and outputs ? otherwise. The algorithm runs in time  $\text{poly}(n, M) \cdot 2^{n-S}$ , where  $S = n^{\varepsilon_{k,d}}$  and  $(n, s, d, M)$  are the parameters of the input *k*-PTF circuit.*

**Previous work.** Satisfiability algorithms for  $\text{TC}^0$  have been widely investigated. Impagliazzo, Lovett, Paturi and Schneider [12, 10] give algorithms for checking satisfiability of depth-2 threshold circuits with  $O(n)$  gates. An incomparable result was proved by Williams [29] who obtained algorithms for subexponential-sized circuits from the class  $\text{ACC}^0 \circ \text{LTF}$ , which is a subclass of subexponential  $\text{TC}^0$ .<sup>9</sup> For the special case of *k*-PTFs (and generalizations to sparse PTFs over the  $\{0, 1\}$  basis) with *small weights*, a #SAT algorithm was devised by Sakai et al. [22].<sup>10</sup> The high-level idea of our algorithm is the same as theirs.

For general constant-depth threshold circuits, the first satisfiability algorithm was given by Chen, Santhanam and Srinivasan [7]. In their paper, Chen et al. gave the first average case lower bound for  $\text{TC}^0$  circuits of slightly super linear size  $n^{1+\varepsilon_d}$ , where  $\varepsilon_d$  depends on the depth of the circuit. (These are roughly the strongest size lower bounds we know for general  $\text{TC}^0$  circuits even in the worst case [11].) Using their ideas, they gave the first (zero-error randomized) improvement to brute-force-search for satisfiability algorithms (and indeed even #SAT algorithms) for constant depth  $\text{TC}^0$  circuits of size at most  $n^{1+\varepsilon_d}$ .

The lower bound results of [7] were extended to the much more powerful class of *k*-PTF circuits (of roughly the same size as [7]) by Kane, Kabanets and Lu [13]. In a follow-up paper, Kabanets and Lu [14] considered the satisfiability question for *k*-PTF circuits, and

<sup>8</sup> Note, crucially, that only the fan-in of a gate counts towards its size. So any gate computing a *k*-PTF on  $m$  variables only adds  $m$  to the size of the circuit, though of course the polynomial representing this PTF may have  $\approx m^k$  monomials.

<sup>9</sup>  $\text{ACC}^0 \circ \text{LTF}$  is a subclass of  $\text{TC}^0$  where general threshold gates are allowed only just above the variables. All computations above these gates are one of AND, OR or Modular gates (that count the number of inputs modulo a constant). It is suspected (but not proved) that subexponential-sized  $\text{ACC}^0$  circuits cannot simulate even a single general threshold gate. Hence, it is not clear if the class of subexponential-sized  $\text{ACC}^0 \circ \text{LTF}$  circuits contains even depth-2  $\text{TC}^0$  circuits of linear size.

<sup>10</sup> More specifically, the algorithm of Sakai et al. [22] works as long as the weight of the input polynomial  $P \in \mathbb{Z}[x_1, \dots, x_n]$  is bounded by  $\exp(n^{1-\Omega(1)})$  (or equivalently,  $M \leq O(n^{1-\Omega(1)})$ ).

could resolve this question in the special case that each PTF is subquadratically sparse, i.e. has  $n^{2-\Omega(1)}$  monomials. One of the reasons for this sparsity restriction is that their strategy does not seem to yield a SAT algorithm for a single degree-2 PTF (which is a depth-1 2-PTF circuit of *linear* size).

## 1.1 Proof outline

For simplicity we discuss SAT algorithms instead of #SAT algorithms.

### Satisfiability algorithm for $k$ -PTFs

At a high level, we follow the same strategy as Sakai et al. [22]. Their algorithm uses *memoization*, which is a standard and very useful strategy for satisfiability algorithms (see, e.g. [23]). Let  $\mathcal{C}$  be a circuit class and  $\mathcal{C}_n$  be the subclass of circuits from  $\mathcal{C}$  that have  $n$  variables. Memoization algorithms for  $\mathcal{C}$ -SAT fit into the following two-step template.

- Step 1: Solve by brute-force all instances of  $\mathcal{C}$ -SAT where the input circuit  $C' \in \mathcal{C}_m$  for some suitable  $m \ll n$ . (Typically,  $m = n^\varepsilon$  for some constant  $\varepsilon$ .) Usually this takes  $\exp(m^{O(1)}) \ll 2^n$  time.
- Step 2: On the input  $C \in \mathcal{C}_n$ , set all input variables  $x_{m+1}, \dots, x_n$  to Boolean values and for each such setting, obtain  $C'' \in \mathcal{C}_m$  on  $m$  variables. Typically  $C''$  is a circuit for which we have solved satisfiability in Step 1 and hence by a simple table lookup, we should be able to check if  $C''$  is satisfiable in  $\text{poly}(|C|)$  time. Overall, this takes time  $O^*(2^{n-m}) \ll 2^n$ .

At first sight, this seems perfect for  $k$ -PTFs, since it is a standard result that the number of  $k$ -PTFs on  $m$  variables is at most  $2^{O(m^{k+1})}$  [8]. Thus, Step 1 can be done in  $2^{O(m^{k+1})} \ll 2^n$  time.

For implementing Step 2, we need to ensure that the lookup (for satisfiability for  $k$ -PTFs on  $m$  variables) can be done quickly. Unfortunately how to do this is unclear. The following two ways suggest themselves.

- Store all polynomials  $P' \in \mathbb{Z}[x_1, \dots, x_m]$  with small coefficients. Since every  $k$ -PTF  $f$  can be sign-represented by an integer polynomial with coefficients of size  $2^{\text{poly}(m)}$  [17], this can be done with a table of size  $2^{\text{poly}(m)}$  and in time  $2^{\text{poly}(m)}$ . When the coefficients are small (say of bit-complexity  $\leq n^{o(1)}$ ), then this strategy already yields a #SAT algorithm, as observed by Sakai et al. [22]. Unfortunately, in general, given a restriction  $P'' \in \mathbb{Z}[x_1, \dots, x_m]$  of a polynomial  $P \in \mathbb{Z}[x_1, \dots, x_n]$ , its coefficients can be much larger (say  $2^{\text{poly}(n)}$ ) and it is not clear how to efficiently find a polynomial with small coefficients that sign-represents the same function.
- It is also known that every  $k$ -PTF on  $m$  variables can be uniquely identified by  $\text{poly}(m)$  numbers of bit-complexity  $O(m)$  each [8]: these are called the ‘‘Chow parameters’’ of  $f$ . Again for this representation, it is unclear how to compute efficiently the Chow parameters of the function represented by the restricted polynomial  $P''$ . (Even for an LTF, computing the Chow parameters is as hard as Subset-sum [19].)

The way we solve this problem is by using a beautiful recent result of Kane, Lovett, Moran and Zhang [15], who show that there is a simple decision tree that, when given as input the coefficients of any degree- $k$  polynomial  $P' \in \mathbb{Z}[x_1, \dots, x_m]$ , can determine the sign of the polynomial  $P'$  at all points in  $\{-1, 1\}^m$  using only  $\text{poly}(m)$  queries to the coefficients of  $P$ . Here, each query is a linear inequality on the coefficients of  $P$ ; such a decision tree is called a *linear decision tree*.

Our strategy is to replace Step 1 with the construction of this linear decision tree (which can be done in  $\exp(m^{O(1)})$  time). At each leaf of the linear decision tree, we replace the truth table of the input polynomial  $P'$  by a single bit that indicates whether  $f' = \text{sgn}(P')$  is satisfiable or not.

In Step 2, we simply run this decision tree on our restricted polynomial  $P''$  and obtain the answer to the corresponding satisfiability query in  $\text{poly}(m, w(P''))$  time. Note, crucially, that the height of the linear decision tree implied by [15] construction is  $\text{poly}(m)$  and *independent* of the bit-complexity of the coefficients of the polynomial  $P''$  (which may be as big as  $\text{poly}(n)$  in our algorithm). This concludes the description of the algorithm for  $k$ -PTF.

### Satisfiability algorithm for $k$ -PTF circuits

For  $k$ -PTF circuits, we follow a template set up by the result of Kabanets and Lu [14] on sparse-PTF circuits. We start by describing this template and then describe what is new in our algorithm.

The Kabanets-Lu algorithm is an induction on the depth  $d$  of the circuit (which is a fixed constant). Given as input a depth  $d$   $k$ -PTF circuit  $C$  on  $n$  variables, Kabanets and Lu do the following:

**Depth-reduction:** In [14], it is shown that on a random restriction that sets all *but*  $n^{1-2\beta}$  variables (here, think of  $\beta$  as a small constant, say 0.01) to random Boolean values, the bottom layer of  $C$  simplifies in the following sense.

All but  $t \leq n^\beta$  gates at the bottom layer become *exponentially* biased, i.e. on all but  $\delta = \exp(-n^{\Omega(1)})$  fraction of inputs they are equal to a fixed  $b \in \{-1, 1\}$ . Now, for each such biased gate  $g$ , there is a minority value  $b_g \in \{-1, 1\}$  that it takes on very few inputs. [14] show how to enumerate this small number of inputs in  $\delta \cdot 2^n$  time and check if there is a satisfying assignment among these inputs. Having ascertained that there is no such assignment, we replace these gates by their majority value and there are only  $t$  gates at the bottom layer. At this point, we “guess” the output of these  $t$  “unbiased” gates and for each such guess  $\sigma \in \{-1, 1\}^t$ , we check if there is an assignment that simultaneously satisfies:

- (a) the depth  $d - 1$  circuit  $C'$ , obtained by setting the unbiased gates to the guess  $\sigma$ , is satisfied.
- (b) each unbiased gate  $g_i$  evaluates to the corresponding value  $\sigma_i$ .

**Base case:** Continuing this way, we eventually get to a base case which is an AND of sparse PTFs for which there is a satisfiability algorithm using the polynomial method.

In the above algorithm, there are two steps where subquadratic sparsity is crucially used. The first is the minority assignment enumeration algorithm for PTFs, which uses ideas of Chen and Santhanam [6] to reduce the problem to enumerating biased LTFs, which is easy [7]. The second is the base case, which uses a non-trivial polynomial approximation for LTFs [24]. Neither of these results hold for even degree-2 PTFs in general. To overcome this, we do the following.

**Enumerating minority assignments.** Given a  $k$ -PTF on  $m$  variables that is  $\delta = \exp(-n^{\Omega(1)})$ -close to  $b \in \{-1, 1\}$ , we enumerate its minority assignments as follows. First, we set up a linear decision tree as in the  $k$ -PTF satisfiability algorithm. Then we set all but  $q \approx \log \frac{1}{\delta}$  variables of the PTF. On most such settings, the resulting PTF becomes the constant function and we can check this using the linear decision tree we created earlier. In this setting, there is nothing to do. Otherwise, we brute-force over the remaining variables to find the minority

assignments. Setting parameters suitably, this yields an  $O(\sqrt{\delta} \cdot 2^m)$  time algorithm to find the minority assignments of a  $\delta$ -biased  $k$ -PTF on  $m$  variables.

**Base case.** Here, we make the additional observation (which [14] do not need) that the AND of PTFs that is obtained further is *small* in that it only has slightly superlinear size. Hence, we can apply another random restriction in the style of [14] and using the minority assignment enumeration ideas, reduce it to an AND of a small (say  $n^{0.1}$ ) number of PTFs on  $n^{0.01}$  (say) variables. At this point, we can again run the linear decision tree (in a slightly more generalized form) to check satisfiability.

## 2 A result of Kane, Lovett, Moran, and Zhang [15]

► **Definition 7** (Coefficient vectors.). Fix any  $k, m \geq 1$ . There are exactly  $r = \sum_{i=0}^k \binom{m}{i}$  many multilinear monomials of degree at most  $k$ . Any multilinear polynomial  $P(x_1, \dots, x_m)$  can be identified with a list of the coefficients of its monomials in lexicographic order (say) and hence with some vector  $w \in \mathbb{R}^r$ . We call  $w$  the *coefficient vector* of  $P$  and use  $\text{coeff}_{m,k}(P)$  to denote this vector. When  $m, k$  are clear from context, we will simply use  $\text{coeff}(P)$  instead of  $\text{coeff}_{m,k}(P)$ .

► **Definition 8** (Linear Decision Trees). A *Linear Decision Tree* for a function  $f : \mathbb{R}^r \rightarrow S$  (for some set  $S$ ) is a decision tree where each internal node is labelled by a linear inequality of the form  $\sum_{i=1}^r w_i z_i \geq \theta$  (here  $z_1, \dots, z_n$  denote the input variables). Depending on the answer to this linear inequality, computation proceeds to the left or right child of this node, and this process continues until a leaf is reached, which is labelled with an element of  $S$  that is the output of  $f$  on the given input.

The following construction of linear decision trees due to Kane, Lovett, Moran and Zhang [15] will be crucial for us.

► **Theorem 9.** *There is a randomized algorithm, which on input a positive integer  $r$ , a subset  $H \subseteq \{-1, 1\}^r$ , and an error parameter  $\varepsilon$ , produces a (random) linear decision tree  $T$  of depth  $\Delta = O(r \log r \cdot \log(|H|/\varepsilon))$  that computes a (random) function  $F : \mathbb{R}^r \rightarrow \{-1, 1\}^{|H|} \cup \{?\}$  that has the following properties.*

1. Each linear query has coefficients in  $\{-2, -1, 0, 1, 2\}$ .
2. Given as input any  $w \in \mathbb{R}^r$  such that  $\langle w, a \rangle \neq 0$  for all  $a \in \{-1, 1\}^r$ ,  $F(w)$  is either the truth table of the LTF defined by  $w$  (with constant term 0) on inputs from  $H \subseteq \{-1, 1\}^r$ , or is equal to ?. Further, we have  $\Pr_F[F(w) = ?] \leq \varepsilon$ .

The randomized algorithm runs in time  $2^{O(\Delta)}$ .

► **Remark.** The last statement in the above theorem is not formally stated in [15] but can easily be inferred from their proof and a remark [15, Page 363] on the ‘‘Computational Complexity’’ of their procedure.<sup>11</sup>

We will need a generalization of this theorem for evaluating (tuples of)  $k$ -PTFs. However, it is a simple corollary of this theorem.

► **Corollary 10.** *Fix positive constants  $k$  and  $c$ . Let  $r = \sum_{i=0}^k \binom{m}{i} = \Theta(m^k)$  denote the number of coefficients in a degree- $k$  multilinear polynomial in  $m$  variables. There is a randomized algorithm which on input positive integers  $m$  and  $\ell \leq m^c$  produces a (random)*

<sup>11</sup> We also thank Daniel Kane (personal communication) for telling us about this.

linear decision tree  $T$  of depth  $\Delta = O(\ell \cdot m^{k+1} \log m)$  that computes a (random) function  $F : \mathbb{R}^{r-\ell} \rightarrow \mathbb{N} \cup \{?\}$  that has the following properties.

1. Each linear query has coefficients in  $\{-2, -1, 0, 1, 2\}$ .
2. Given as input any  $\ell$ -tuple of coefficient vectors  $\bar{w} = (\text{coeff}_{m,k}(P_1), \dots, \text{coeff}_{m,k}(P_\ell)) \in \mathbb{R}^{r-\ell}$  such that  $P_i(a) \neq 0$  for all  $a \in \{-1, 1\}^m$ ,  $F(\bar{w})$  is either the number of common satisfying assignments to all the  $k$ -PTFs on  $\{-1, 1\}^m$  sign-represented by  $P_1, \dots, P_\ell$ , or is equal to ?. Further, we have  $\Pr_F[F(\bar{w}) = ?] \leq (1/2)$ .

The randomized algorithm runs in time  $2^{O(\Delta)}$ .

**Proof.** For each  $b \in \{-1, 1\}^m$ , define  $\text{eval}_b \in \{-1, 1\}^r$  to be the vector of all evaluations of multilinear monomials of degree at most  $k$ , taken in lexicographic order, on the input  $b$ . Define  $H \subseteq \{-1, 1\}^r$  to be the set  $\{\text{eval}_b \mid b \in \{-1, 1\}^m\}$ . Clearly,  $|H| \leq 2^m$ . Further, note that given any polynomial  $P(x_1, \dots, x_m)$  of degree at most  $k$ , the truth table of the  $k$ -PTF sign-represented by  $P$  is given by the evaluation of the LTF represented by  $\text{coeff}(P)$  at the points in  $H$ . Our aim, therefore, is to evaluate the LTFs corresponding to  $\text{coeff}(P_1), \dots, \text{coeff}(P_\ell)$  at all the points in  $H$ .

For each  $i$ , we use the randomized algorithm from Theorem 9 to produce a decision tree  $T_i$  that evaluates the Boolean function  $f_i : \{-1, 1\}^m \rightarrow \{-1, 1\}$  sign-represented by  $P_i$  (or equivalently, evaluating the LTF corresponding to  $\text{coeff}(P_i)$  at all points in  $H$ ) with error  $\varepsilon = 1/2\ell$ . Note that  $T_i$  has depth  $O(m^k \log m \cdot \log(2^m/\ell)) = O(m^{k+1} \log m)$  as  $\ell \leq m^c$ . The final tree  $T$  is obtained by simply running  $T_1, \dots, T_\ell$  in order, which is of depth  $O(\ell m^{k+1} \log m)$ . The tree  $T$  outputs the number of common satisfying assignments to all the  $f_i$  if all the  $T_i$ s succeed and ? otherwise. Since each  $T_i$  outputs ? with probability at most  $1/2\ell$ , the tree  $T$  outputs ? with probability at most  $(1/2\ell) \cdot \ell = 1/2$ .

The claim about the running time follows from the analogous claim in Theorem 9 and the fact that the number of common satisfying assignments to all the  $f_i$  can be computed from the truth tables in  $2^{O(m)}$  time. This completes the proof.  $\blacktriangleleft$

### 3 The PTF-SAT algorithm

We are now ready to prove Theorem 3. We first state the algorithm, which follows a standard memoization idea (see, e.g. [23]). We assume that the input is a polynomial  $P \in \mathbb{Z}[x_1, \dots, x_n]$  of degree at most  $k$  that sign-represents a Boolean function  $f$  on  $n$  variables. The parameters of the instance are assumed to be  $(n, M)$ . Set  $m = n^{1/(k+1)} / \log n$ .

#### Algorithm $\mathcal{A}$ .

1. Use  $n_1 = 10n$  independent runs of the algorithm from Corollary 10 with  $\ell = 1$  to construct independent random linear decision trees  $T_1, \dots, T_{n_1}$  such that on any input polynomial  $Q(x_1, \dots, x_m)$  (or more precisely  $\text{coeff}_{m,k}(Q)$ ) of degree at most  $k$  that sign-represents a  $k$ -PTF  $g$  on  $m$  variables, each  $T_i$  computes the number of satisfying assignments to  $g$  with error at most  $1/2$ .
2. Set  $N = 0$ . ( $N$  will ultimately be the number of satisfying assignments to  $f$ .)
3. For each setting  $\sigma \in \{-1, 1\}^{n-m}$  to the variables  $x_{m+1}, \dots, x_n$ , do the following:
  - a. Compute the polynomial  $P_\sigma$  obtained by substituting the variables  $x_{m+1}, \dots, x_n$  accordingly in  $P$ .

- b. Run the decision trees  $T_1, \dots, T_{n_1}$  on  $\text{coeff}(P_\sigma)$  and compute their outputs. If all the outputs are ?, output ?. Otherwise, some  $T_i$  outputs  $N_\sigma$ , the number of satisfying assignments to  $P_\sigma$ . Add this to the current estimate to  $N$ .
4. Output  $N$ .

**Correctness.** It is clear from Corollary 10 and step 3b that algorithm  $\mathcal{A}$  outputs either ? or the correct number of satisfying assignments to  $f$ . Further, we claim that with probability at least  $1 - 1/2^{\Omega(n)}$ , the output is indeed the number of satisfying assignments to  $f$ . To see this, observe that it follows from Corollary 10 that for each setting  $\sigma \in \{-1, 1\}^{n-m}$  to the variables  $x_{m+1}, \dots, x_n$ , each linear decision tree  $T_i$  produced in step 1 errs on  $\text{coeff}(P_\sigma)$  (i.e. outputs ?) with probability at most  $1/2$ . The probability of each  $T_i$  doing so is thus at most  $1/2^{n_1}$ , as they are constructed independently. So the probability that the algorithm fails to determine  $N_\sigma$  is at most  $1/2^{n_1}$ . Finally, taking a union bound over all  $\sigma$ , which are  $2^{n-m}$  in number, we conclude that the probability of algorithm  $\mathcal{A}$  outputting ? is at most  $2^{n-m}/2^{n_1} \leq 1/2^{\Omega(n)}$ .

**Running time.** We show that the running time of algorithm  $\mathcal{A}$  is  $\text{poly}(n, M) \cdot 2^{n-m}$ . First note that by Corollary 10, the construction of a single linear decision tree  $T_i$  takes  $2^{O(\Gamma)}$  time, where  $\Gamma = m^{k+1} \log m$ , and hence, step 1 takes  $n_1 \cdot 2^{O(\Gamma)}$  time. Next, for a setting  $\sigma \in \{-1, 1\}^{n-m}$  to the variables  $x_{m+1}, \dots, x_n$ , computing  $P_\sigma$  and constructing the vector  $\text{coeff}(P_\sigma)$  takes only  $\text{poly}(n, M)$  time. Recall that the depth of each linear decision tree  $T_i$  is  $O(\Gamma)$  and thus, on input vector  $\text{coeff}(P_\sigma)$ , each of whose entries has bit complexity at most  $M$ , it takes time  $O(\Gamma) \cdot \text{poly}(M, n)$  to run all  $T_i$  and obtain the output  $N_\sigma$  or ?. Therefore, step 3 takes  $\text{poly}(n, M) \cdot 2^{n-m}$  time. Finally, the claim about the total running time of algorithm  $\mathcal{A}$  follows at once when we observe that for the setting  $m = n^{1/(k+1)}/\log n$ ,  $\Gamma = o(n/(\log n)^k) = o(n)$ .

## 4 Constant-depth circuits with PTF gates

In this section we give an algorithm for counting the number of satisfying assignment for a  $k$ -PTF circuit of constant depth and slightly superlinear size. We begin with some definitions.

► **Definition 11.** Let  $\delta \leq 1$  be any parameter. Two Boolean functions  $f, g$  are said to be  $\delta$ -close if  $\Pr_x[f(x) \neq g(x)] \leq \delta$ .

A  $k$ -PTF  $f$  specified by a polynomial  $P$  is said to be  $\delta$ -close to an explicit constant if it is  $\delta$ -close to a constant and such a constant can be computed efficiently, i.e.  $\text{poly}(n, M)$ , where  $n$  is the number of variables in  $P$  and  $w(P)$  is at most  $M$ .

► **Definition 12.** For a Boolean function  $f : \{-1, 1\}^n \rightarrow \{-1, 1\}$ , the majority value of  $f$  is the bit value  $b \in \{-1, 1\}$  which maximizes  $\Pr_x[f(x) = b]$  and the bit value  $-b$  is said to be its minority value.

For a Boolean function  $f$  with majority value  $b$ , an assignment  $x \in \{-1, 1\}^n$  is said to be a majority assignment if  $f(x) = b$  and minority assignment otherwise.

► **Definition 13.** Given a  $k$ -PTF  $f$  on  $n$  variables specified by a polynomial  $P$ , a parameter  $m \leq n$  and a partial assignment  $\sigma \in \{-1, 1\}^{n-m}$  on  $n-m$  variables, let  $P_\sigma$  be the polynomial obtained by substituting the variables in  $P$  according to  $\sigma$ . If  $P$  has parameters  $(n, M)$  then  $P_\sigma$  has parameters  $(m, M)$ . For a  $k$ -PTF circuit  $C$ ,  $C_\sigma$  is defined similarly. If  $C$  has parameters  $(n, s, d, M)$  then  $C_\sigma$  has parameters  $(m, s, d, M)$ .

**Outline of the #SAT procedure.** For designing a #SAT algorithm for  $k$ -PTF circuits, we use the generic framework developed by Kabanets and Lu [14] with some crucial modifications.

Given a  $k$ -PTF circuit  $C$  on  $n$  variables of depth  $d$  we want to count the number of satisfying assignments  $a \in \{-1, 1\}^n$  such that  $C(a) = -1$ . We in fact solve a slightly more general problem. Given  $(C, \mathcal{P})$ , where  $C$  is a small  $k$ -PTF circuit of depth  $d$  and  $\mathcal{P}$  is a set of  $k$ -PTF functions, such that  $\sum_{f \in \mathcal{P}} \text{fan-in}(f)$  is small, we count the number of assignments that simultaneously satisfy  $C$  and all the function in  $\mathcal{P}$ .

At the core of the algorithm that solves this problem, Algorithm  $\mathcal{B}$ , is a recursive procedure  $\mathcal{A}_5$ , which works as follows: on inputs  $(C, \mathcal{P})$  it first applies a simplification step that outputs  $\ll 2^n$  instances of the form  $(C', \mathcal{P}')$  such that

- Both  $C'$  and functions in  $\mathcal{P}'$  are on  $m \ll n$  variables.
- The sets of satisfying assignments of these instances “almost” partition the set of satisfying assignments of  $(C, \mathcal{P})$ .
- With all but very small probability the bottom layer of  $C'$  has the following nice structure.
  - At most  $n$  gates are  $\delta$ -biased. We denote this set of gates by  $B$  (as we will simplify them by setting them to the values they are biased towards).
  - At most  $n^{\beta d}$  gates are not  $\delta$ -biased. We denote these gates by  $G$  (as we will simplify them by “guessing” their values).
- There is a small set of satisfying assignments that are not covered by the satisfying assignments of  $(C', \mathcal{P}')$  but we can count these assignments with a brute-force algorithm that does not take too much time.

For each  $C'$  with this nice structure, then we try to use this structure to create  $C''$  which has depth  $d - 1$ . Suppose we reduce the depth as follows:

- Set all the gates in  $B$  to the values that they are biased towards.
- Try all the settings of the values that the gates in  $G$  can take, thereby from  $C'$  creating possibly  $2^{n^{\beta d}}$  instances  $(C'', \mathcal{P}')$ .

$(C'', \mathcal{P}')$  now is an instance where  $C''$  has depth  $d - 1$ . Unfortunately, by simply setting biased gates to the values they are biased towards, we may miss out on the minority assignments to these gates which could eventually satisfy  $C'$ . We design a subroutine  $\mathcal{A}_3$  to precisely handle this issue, i.e. to keep track of the number of minority assignments, say  $N_{C'}$ . This part of our algorithm is completely different from that of [14], which only works for subquadratically sparse PTFs.

Once  $\mathcal{A}_3$  has computed  $N_{C'}$ , i.e. the number of satisfying assignments among the minority assignments, we now need to only count the number of satisfying assignments among the rest of the assignments.

To achieve this we use an idea similar to that in [7, 14], which involves appending  $\mathcal{P}'$  with a few more  $k$ -PTFs (this forces the biased gates to their majority values). This gives say a set  $\tilde{\mathcal{P}}'$ . Similarly, while setting gates in  $G$  to their guessed values, we again use the same idea to ensure that we are counting satisfying assignments consistent with the guessed values, once again updating  $\tilde{\mathcal{P}}'$  to a new set  $\mathcal{P}''$ . This creates instances of the form  $(C'', \mathcal{P}'')$ , where the depth of  $C''$  is  $d - 1$ .

This way, we iteratively decrease the depth of the circuit by 1. Finally, we have instances  $(C'', \mathcal{P}'')$  such that the depth of  $C''$  is 1, i.e. it is a single  $k$ -PTF, say  $h$ . At this stage we solve #SAT( $\tilde{C}$ ), where  $\tilde{C} = h \wedge \bigwedge_{f \in \mathcal{P}''} f$ . This is handled in a subroutine  $\mathcal{A}_4$ . Here too our algorithm differs significantly from [14].

In what follows we will prove Theorem 6. In order to do so, we will set up various subroutines  $\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3, \mathcal{A}_4, \mathcal{A}_5$  designed to accomplish certain tasks and combine them together at the end to finally design algorithm  $\mathcal{B}$  for the #SAT problem for  $k$ -PTF circuits.

$\mathcal{A}_1$  will be an oracle, used in other routines, which will compute number of common satisfying assignments for small AND of PTFs on few variables (using the same idea as in the algorithm for #SAT for  $k$ -PTFs).  $\mathcal{A}_2$  will be a simplification step, which will allow us to argue about some structure in the circuit (this algorithm is from [14]). It will make many gates at the bottom of the circuit  $\delta$ -close to a constant, thus simplifying it.  $\mathcal{A}_3$  will be used to count minority satisfying assignments for a bunch of  $\delta$ -biased PTFs, i.e. assignments which cause at least one of the PTFs to evaluate to its minority value.  $\mathcal{A}_4$  will be a general base of case of our algorithm, which will count satisfying assignments for AND of superlinear many PTFs, by first using  $\mathcal{A}_2$  to simplify the circuit, then reducing it to the case of small AND of PTFs and then using  $\mathcal{A}_1$ .  $\mathcal{A}_5$  will be a recursive procedure, which will use  $\mathcal{A}_2$  to first simplify the circuit, and then convert it into a circuit of lower depth, finally making a recursive call on the simplified circuit.

**Parameter setting.** Let  $d$  be a constant. Let  $A, B$  be two fixed absolute large constants. Let  $\zeta = \min(1, A/2Bk^2)$ . For each  $2 \leq i \leq d$ , let  $\beta_i = A \cdot \varepsilon_i$  and  $\varepsilon_i = (\frac{\zeta}{10A(k+1)})^i$ . Choose  $\beta_1 = 1/10$  and  $\varepsilon_1 = 1/10A$ .

**Oracle access to a subroutine.** Let  $\mathcal{A}_1(n', s, f_1, \dots, f_s)$  denote a subroutine with the following specification. Here,  $n$  is the number of variables in the original input circuit.

**Input:** AND of  $k$ -PTFs, say  $f_1, \dots, f_s$  specified by polynomials  $P_1, \dots, P_s$  respectively, such that  $s \leq n^{0.1}$  and for each  $i \in [s]$ ,  $f_i$  is defined over  $n' \leq n^{1/(2(k+1))}$  variables and  $w(P_i) \leq M$ .

**Output:**  $\#\{a \in \{-1, 1\}^{n'} \mid \forall i \in [s], P_i(a) = -1\}$ .

In what follows, we will assume that we have access to the above subroutine  $\mathcal{A}_1$ . We will set up such an oracle and show that it answers any call to it in time  $\text{poly}(n, M)$  in Section 4.5.

#### 4.1 Simplification of a $k$ -PTF circuit

For any  $1 > \varepsilon \gg (\log n)^{-1}$ , let  $\beta = A\varepsilon$  and  $\delta = \exp(-n^{\beta/B \cdot k^2})$ , where  $A$  and  $B$  are constants. Note that it is these constants  $A, B$  we use in the parameter settings paragraph above. Let  $\mathcal{A}_2(C, d, n, M)$  be the following subroutine.

**Input:**  $k$ -PTF circuit  $C$  of depth  $d$  on  $n$  variables with size  $n^{1+\varepsilon}$  and weight  $M$ .

**Output:** A decision tree  $T_{DT}$  of depth  $n - n^{1-2\beta}$  such that for a uniformly random leaf  $\sigma \in \{-1, 1\}^{n-n^{1-2\beta}}$  it outputs a *good* circuit  $C_\sigma$  with probability  $1 - \exp(-n^\varepsilon)$ , where  $C_\sigma$  is called good if its bottom layer has the following structure:

- there are at most  $n$  gates which are  $\delta$ -close to an explicit constant. Let  $B_\sigma$  denote this set of gates.
- there are at most  $n^\beta$  gates that are not  $\delta$ -close to an explicit constant. Let us denote this set of gates by  $G_\sigma$ .

In [14], such a subroutine  $\mathcal{A}_2(C, d, n, M)$  was designed. Specifically, they proved the following theorem.

► **Theorem 14** (Kabanets and Lu [14]). *There is a zero-error randomized algorithm  $\mathcal{A}_2(C, d, n, M)$  that runs in time  $\text{poly}(n, M) \cdot O(2^{n-n^{1-2\beta}})$  and outputs a decision tree as described above with probability at least  $1 - 1/2^{10n}$  (and outputs ? otherwise). Moreover, given a good  $C_\sigma$ , there is a deterministic algorithm that runs in time  $\text{poly}(n, M)$  which computes  $B_\sigma$  and  $G_\sigma$ .*

► **Remark.** In [14], it is easy to see that the probability of outputting ? is at most  $1/2$ . To bring down this probability to  $1/2^{10n}$ , we run their procedure in parallel  $10n$  times, and output the first tree that is output by the algorithm. The probability that no such tree is output is  $1/2^{10n}$ .

► **Remark.** In designing the above subroutine in [14], they consider a more general class of polynomially sparse-PTF circuits (i.e. each gate computes a PTF with polynomially many monomials) as opposed to the  $k$ -PTF circuits we consider here. Under this weaker assumption, they get that  $\delta = \exp(-n^{\Omega(\beta^3)})$ . However, by redoing their analysis for degree  $k$ -PTFs, it is easy to see that  $\delta$  could be set to  $\exp(-n^{\beta/B \cdot k^2})$  for some constant  $B$ . Under this setting of  $\delta$ , we get exactly the same guarantees. In this sense, the above theorem statement is a slight restatement of [14, Theorem 3.11].

## 4.2 Enumerating the minority assignments

We now design an algorithm  $\mathcal{A}_3(m, \ell, \delta, g_1, \dots, g_\ell)$ , which has the following behaviour.

**Input:** parameters  $m \leq n, \ell, \delta$  such that  $\delta \in [\exp(-m^{1/10(k+1)}), 1]$ ,  $\ell \leq m^2$ ,  $k$ -PTFs  $g_1, g_2, \dots, g_\ell$  specified by polynomials  $P_1, \dots, P_\ell$  on  $m$  variables  $(x_1, \dots, x_m)$  each of weight at most  $M$  and which are  $\delta$ -close to  $-1$ .

**Oracle access to:**  $\mathcal{A}_1$ .

**Output:**  $a \in \{-1, 1\}^m$  such that  $\exists i \in [\ell]$  for which  $P_i(a) > 0$ .

► **Lemma 15.** *There is a deterministic algorithm  $\mathcal{A}_3(m, \ell, \delta, g_1, \dots, g_\ell)$  as specified above that runs in time  $\text{poly}(m, M) \cdot \sqrt{\delta} \cdot 2^m$ .*

**Proof.** We start with the description of the algorithm.

$\mathcal{A}_3(m, \ell, \delta, g_1, \dots, g_\ell)$ .

1. Set  $q = \frac{1}{2} \log \frac{1}{\delta} \leq \frac{m}{2}$  and let  $\mathcal{N} = \emptyset$ . ( $\mathcal{N}$  will eventually be the collection of minority assignments i.e. all  $a \in \{-1, 1\}^m$  such that  $\exists i \in [\ell]$  for which  $P_i(a) > 0$ .)
2. For each setting  $\rho \in \{-1, 1\}^{m-q}$  to the variables  $x_{q+1}, \dots, x_m$ , do the following:
  - a. Construct the restricted polynomials  $P_{1,\rho}, \dots, P_{\ell,\rho}$ . Let  $g_{i,\rho} = \text{sgn}(P_{i,\rho})$  for  $i \in [\ell]$ .
  - b. Using oracle  $\mathcal{A}_1(q, 1, -g_{i,\rho})$ , check for each  $i \in [\ell]$  if  $g_{i,\rho}$  is the constant function  $-1$  by checking if the output of the oracle on the input  $-g_{i,\rho}$  is zero.
  - c. If there is an  $i \in [\ell]$  such that  $g_{i,\rho}$  is not the constant function  $-1$ , try all possible assignments  $\chi$  to the remaining  $q$  variables  $x_1, \dots, x_q$ . This way, enumerate all assignments  $b = (\chi, \rho)$  to  $x_1, \dots, x_m$  for which there is an  $i \in [\ell]$  such that  $P_i(b) > 0$ . Add such an assignment to the collection  $\mathcal{N}$ .
3. Output  $\mathcal{N}$ .

**Correctness.** If  $a \in \{-1, 1\}^m$  is a minority assignment (i.e.  $\exists i_0 \in [\ell]$  so that  $P_{i_0}(a) < 0$ ) and if  $a = (\chi, \rho)$  where  $\rho$  is an assignment to the last  $m - q$  variables, and  $\chi$  to the first  $q$ ,  $a$  will get added to  $\mathcal{N}$  in the loop of step 2 corresponding to  $\rho$  and that of  $\chi$  in step 2c, because of  $i_0$  being a witness. Conversely, observe that we only add to the collection  $\mathcal{N}$  when we encounter a minority assignment.

**Running time.** For each setting  $\rho \in \{-1, 1\}^{m-q}$  to the variables  $x_{q+1}, \dots, x_m$ , step 2a takes  $\text{poly}(m, M)$  time and step 2b takes  $O(\ell) = O(m^2)$  time and so combined, they take only  $\text{poly}(m, M)$  time. Let  $\mathcal{T}$  be the set consisting of all assignments  $\rho$  to the last  $m - q$  variables such that the algorithm enters the loop described in step 2c i.e.

$$\mathcal{T} = \{\rho \in \{-1, 1\}^{m-q} \mid \exists i \in [\ell] : g_{i,\rho} \text{ is not the constant function } -1\}$$

and let  $\mathcal{T}^c$  denote its complement. Also note that for a  $\rho \in \mathcal{T}$ , enumeration of minority assignments in step 2c takes  $2^q \cdot \ell \cdot \text{poly}(m, M)$  time. Therefore, we can bound the total running time by

$$\text{poly}(m, M)(2^q \cdot |\mathcal{T}| + |\mathcal{T}^c|).$$

Next, we claim that the size of  $\mathcal{T}$  is small:

► **Lemma 16.**  $|\mathcal{T}| \leq \ell \cdot \sqrt{\delta} \cdot 2^{m-q}$ .

**Proof.** We define for  $i \in [\ell]$ ,  $\mathcal{T}_i = \{\rho \in \{-1, 1\}^{m-q} \mid g_{i,\rho} \text{ is not the constant function } -1\}$ . By the union bound, it is sufficient to show that  $|\mathcal{T}_i| \leq \sqrt{\delta} \cdot 2^{m-q}$  for a fixed  $i \in [\ell]$ . Let  $D_m$  denote the uniform distribution on  $\{-1, 1\}^m$  i.e. on all possible assignments to the variables  $x_1, \dots, x_m$ . Then from the definition of  $\delta$ -closeness, we know

$$\Pr_{a \sim D_m} [g_i(a) = 1] \leq \delta.$$

Writing LHS in the following way, we have

$$\mathbf{E}_{\rho \sim D_{m-q}} \left[ \Pr_{\chi \sim D_q} [g_{i,\rho}(\chi) = 1] \right] \leq \delta$$

where  $D_{m-q}$  and  $D_q$  denote uniform distributions on assignments to the last  $m-q$  variables and the first  $q$  variables respectively. By Markov's inequality,

$$\Pr_{\rho \sim D_{m-q}} \left[ \Pr_{\chi \sim D_q} [g_{i,\rho}(\chi) = 1] \geq \sqrt{\delta} \right] \leq \sqrt{\delta}$$

Consider a  $\rho$  for which this event does not occur i.e. for which  $\Pr_{\chi \sim D_q} [g_{i,\rho}(\chi) = 1] < \sqrt{\delta}$ . For such a  $\rho$ ,  $g_{i,\rho}$  has only  $2^q = 1/\sqrt{\delta}$  many inputs and therefore,  $g_{i,\rho}$  must be the constant function  $-1$ . Thus, we conclude that

$$\Pr_{\rho \sim D_{m-q}} [g_{i,\rho} \text{ is not the constant function } -1] \leq \sqrt{\delta}$$

or in other words,  $|\mathcal{T}_i| \leq \sqrt{\delta} \cdot 2^{m-q}$ . ◀

Finally, by using the trivial bound  $|\mathcal{T}^c| \leq 2^{m-q}$  and the above claim, we obtain a total running time of  $\text{poly}(m, M) \cdot \sqrt{\delta} \cdot 2^m$  and this concludes the proof of the lemma. ◀

### 4.3 #SAT for AND of $k$ -PTFs

We design an algorithm  $\mathcal{A}_4(n, M, g_1, \dots, g_\tau)$  with the following functionality.

**Input:** A set of  $k$ -PTFs  $g_1, \dots, g_\tau$  specified by polynomials  $P_1, \dots, P_\tau$  on  $n$  variables such that  $w(p_i) \leq M$  for each  $i \in [\tau]$  and  $\sum_{i \in [\tau]} \text{fan-in}(g_i) \leq n^{1+\epsilon_1}$ .

**Output:**  $\#\{a \in \{-1, 1\}^n \mid \forall i \in [\tau], P_i(a) < 0\}$ .

### 4.3.1 The details of the algorithm

$\mathcal{A}_4(\mathbf{n}, \mathbf{M}, \mathbf{g}_1, \dots, \mathbf{g}_\tau)$ .

1. Let  $m = n^\alpha$  for  $\alpha = \frac{\zeta \varepsilon_1}{2(k+1)}$ . Let  $C$  denote the AND of  $g_1, \dots, g_\tau$ .
2. Run  $\mathcal{A}_2(C, 2, n, M)$  to obtain the decision tree  $T_{DT}$ . Initialize  $N$  to 0.
3. For each leaf  $\sigma$  of  $T_{DT}$ , do the following:
  - (A) If  $C_\sigma$  is not *good*, count the number of satisfying assignments for  $C_\sigma$  by brute-force and add to  $N$ .
  - (B) If  $C_\sigma$  is *good*, do the following:
    - (i)  $C_\sigma$  is now an AND of PTFs in  $B_\sigma$  and  $G_\sigma$ , over  $n' = n^{1-2\beta_1}$  variables, where all PTFs in  $B_\sigma$  are  $\delta$ -close to an explicit constant, where  $\delta = \exp(-n^{\beta_1/B \cdot k^2})$ . Moreover,  $|B_\sigma| \leq n, |G_\sigma| \leq n^{\beta_1}$ .  
Let  $B_\sigma = \{h_1, \dots, h_\ell\}$  be specified by  $Q_1, \dots, Q_\ell$ .  
Suppose for  $i \in [\ell]$ ,  $h_i$  is close to  $a_i \in \{-1, 1\}$ . Then let  $Q'_i = -a_i \cdot Q_i$  and  $h'_i = \text{sgn}(Q'_i)$ . Let  $B'_\sigma = \{Q'_1, \dots, Q'_\ell\}$ .
    - (ii) For each restriction  $\rho : \{x_{m+1}, \dots, x_{n'}\} \rightarrow \{-1, 1\}$ , do the following:
      - (a) Check if there exists  $h' \in B'_\sigma$  such that  $h'_\rho$  is not the constant function  $-1$  using  $\mathcal{A}_1(m, 1, h'_\rho)$ .
      - (b) If such an  $h' \in B'_\sigma$  exists, then count the number of satisfying assignments for  $C_{\sigma\rho}$  by brute-force and add to  $N$ .
      - (c) If the above does not hold, we have established that for each  $h_i \in B_\sigma$ ,  $h_{i,\rho}$  is the constant function  $a_i$ . If  $\exists i \in [\ell]$  such that  $a_i = 1$ , it means  $C_{\sigma\rho}$  is also a constant 1. Then simply halt. Else set each  $h_i$  to  $a_i$ .  
Thus,  $C_{\sigma\rho}$  has been reduced to an AND of  $n^{\beta_1}$  many PTFs over  $m$  variables. Call this set  $G'_{\sigma\rho}$ , use  $\mathcal{A}_1(m, n^{\beta_1}, G'_{\sigma\rho})$  to calculate the number of satisfying assignments and add the output to  $N$ .
4. Finally, output  $N$ .

### 4.3.2 The correctness argument and running time analysis

► **Lemma 17.**  $\mathcal{A}_4$  is a zero-error randomized algorithm that counts the number of satisfying assignments correctly. Further,  $\mathcal{A}_4$  runs in time  $\text{poly}(n, M) \cdot 2^{n-n^\alpha}$  and outputs the right answer with probability at least  $1/2$  (and outputs ? otherwise).

**Proof.**

**Correctness.** For a leaf  $\sigma$  of  $T_{DT}$ , when  $C_\sigma$  is not *good*, we simply use brute-force, which is guaranteed to be correct. Otherwise,

- If  $h'_\rho$  not the constant function  $-1$  for some  $h' \in B'_\sigma$ , then we again use brute-force, which is guaranteed to work correctly.
- Otherwise, for each  $h' \in B'_\sigma$ ,  $h'_\rho$  is the constant function  $-1$ . Here we only need to consider the satisfying assignments for the gates in  $G_{\sigma\rho}$ . For this we use  $\mathcal{A}_1$ , that works correctly by assumption.

Further, we need to ensure that the parameters that we call  $\mathcal{A}_1$  on, are valid. To see this, observe that  $m = n^\alpha \leq n^{1/(2(k+1))}$  because of the setting of  $\alpha$  and further, we have  $n^{\beta_1} \leq n^{0.1}$ .

Finally, the claim about the error probability follows from the error probability of  $\mathcal{A}_2$  (Theorem 14).

**Running Time.** The time taken for constructing  $T_{DT}$  is  $O^*(2^{n-n^{1-2\beta_1}})$ , by Theorem 14. For a leaf  $\sigma$  of  $T_{DT}$ , we know that step 3A is executed with probability at most  $2^{-n^{\varepsilon_1}}$ . The total time for running step 3A is thus  $O^*(2^{n-n^{\varepsilon_1}})$ . We know that the oracle  $\mathcal{A}_1$  answers

calls in  $\text{poly}(n, M)$  time. Hence, the total time for running step 3(B)iiia is  $O^*(2^{n-n^\alpha})$ . Next, note that if step 3(B)iiib is executed, then all PTFs in  $B_\sigma$  are  $\delta$ -close to  $-1$ . So, the number of times it runs is at most  $\delta \cdot 2^{n^\ell}$ . Therefore, the total time for running step 3(B)iiib is  $O^*(2^{n+n^\alpha-n^{\beta_1/Bk^2}})$ . Similar to the analysis of step 3(B)iiia, the total time for running step 3(B)iiic is also  $O^*(2^{n-n^\alpha})$ .

Summing them up, we conclude that total running time is  $O^*(2^{n-n^\alpha})$ , as due to our choice of various parameters,  $n - n^\alpha$  is the dominating power of 2. This completes the proof.  $\blacktriangleleft$

#### 4.4 #SAT for larger depth $k$ -PTF circuits

Let  $C$  be a  $k$ -PTF circuit of depth  $d \geq 1$  on  $n$  variables and let  $\mathcal{P}$  be a set of  $k$ -PTFs  $g_1, \dots, g_\tau$ , which are specified by  $n$ -variate polynomials  $P_1, \dots, P_\tau$ . Let  $\#\text{SAT}(C, \mathcal{P})$  denote  $\#\{a \in \{-1, 1\}^n \mid C(a) < 0 \text{ and } \forall i \in [\tau], P_i(a) < 0\}$ . We now specify our depth-reduction algorithm  $\mathcal{A}_5(n, d, M, n^{1+\varepsilon_d}, C, \mathcal{P})$ .

**Input:**  $(C, \mathcal{P})$  as follows:

- $k$ -PTF circuit  $C$  with parameters  $(n, n^{1+\varepsilon_d}, d, M)$ .
- a set  $\mathcal{P}$  of  $k$ -PTFs  $g_1, \dots, g_\tau$  on  $n$  variables, which are specified by polynomials  $P_1, \dots, P_\tau$  such that  $\sum_{i=1}^\tau \text{fan-in}(g_i) \leq n^{1+\varepsilon_d}$  and for each  $i \in [\tau]$ ,  $w(P_i) \leq M$ .

**Oracle access to:**  $\mathcal{A}_1, \mathcal{A}_4$ .

**Output:**  $\#\text{SAT}(C, \mathcal{P})$ .

We start by describing the algorithm.

##### 4.4.1 The details of the algorithm

Let `count` be a global counter initialized to 0 before the execution of the algorithm.

**$\mathcal{A}_5(n, d, M, n^{1+\varepsilon_d}, C, \mathcal{P})$ .**

1. If  $d = 1$ , output  $\mathcal{A}_4(n, M, \{C\} \cup \mathcal{P})$  and halt.
2. Run  $\mathcal{A}_2(C, d, n, M)$ , which gives us a  $\text{T}_{\text{DT}}$ .
3. For each leaf  $\sigma \in \{-1, 1\}^{n-n^{1-2\beta_d}}$  of  $\text{T}_{\text{DT}}$ . (If not, output ?.)
  - a. For each  $i \in [\tau]$  compute  $P_{i,\sigma}$ , the polynomial obtained by substituting  $\sigma$  in its variables. Let  $\mathcal{P}_\sigma = \{P_{1,\sigma}, \dots, P_{\tau,\sigma}\}$ .
  - b. Obtain  $C_\sigma$ . If  $C_\sigma$  is not a good circuit, then brute-force to find the number of satisfying assignments of  $(C_\sigma, \mathcal{P}_\sigma)$ , say  $N_\sigma$ , and set `count` = `count` +  $N_\sigma$ .
  - c. If  $C_\sigma$  is good then obtain  $B_\sigma$  and  $G_\sigma$ .
  - d. Let  $B_\sigma = \{h_1, \dots, h_\ell\}$  be specified by  $Q_1, \dots, Q_\ell$ . We know that each  $h \in B_\sigma$  is  $\delta$ -close to an explicit constant, for  $\delta = \exp(-n^{\beta_d/Bk^2})$ . Suppose for  $i \in [\ell]$ ,  $h_i$  is close to  $a_i \in \{-1, 1\}$ . Then let  $Q'_i = -a_i \cdot Q_i$  and  $h'_i = \text{sgn}(Q'_i)$ . Let  $B'_\sigma = \{Q'_1, \dots, Q'_\ell\}$ .
  - e. Run  $\mathcal{A}_3(n^{1-2\beta_d}, \ell, \delta, h'_1, \dots, h'_\ell)$  to obtain the set  $\mathcal{N}_\sigma$  of all the minority assignments of  $B_\sigma$ . (Note that this uses oracle access to  $\mathcal{A}_1$ .)  
for each  $a \in \mathcal{N}_\sigma$ , if  $((C(a) < 0) \text{ AND } (\forall i \in [\ell], P_i(a) < 0))$ , then `count` = `count` + 1.
  - f. Let  $G_\sigma = \{f_1, \dots, f_t\}$  be specified by polynomials  $R_1, \dots, R_t$ . We know that  $t \leq n^{\beta_d}$ . For each  $b \in \{-1, 1\}^t$ ,
    - i. Let  $R'_i = -b_i \cdot R_i$  for  $i \in [t]$ . Let  $G'_{\sigma,b} = \{R'_1, \dots, R'_t\}$ .
    - ii. Let  $C_{\sigma,b}$  be the circuit obtained from  $C_\sigma$  by replacing each  $h_i$  by  $a_i$   $1 \leq i \leq \ell$  and each  $f_j$  by  $b_j$  for  $1 \leq j \leq t$ .

- iii.  $\mathcal{P}_{\sigma,b} = \mathcal{P}_{\sigma} \cup B'_{\sigma} \cup G'_{\sigma,b}$ .
- iv. If  $d > 2$  then run  $\mathcal{A}_5(n^{1-2\beta_d}, d-1, M, n^{1+\varepsilon_d}, C_{\sigma,b}, \mathcal{P}_{\sigma,b})$   $n_1 = 10n$  times and let  $N_{\sigma}$  be the output of the first run that does not output ?. Set  $\text{count} = \text{count} + N_{\sigma}$ . (If all runs of  $\mathcal{A}_5$  output ?, then output ?.)
- v. If  $d = 2$  then run  $\mathcal{A}_4(n^{1-2\beta_d}, M, C_{\sigma,b} \cup \mathcal{P}_{\sigma,b})$   $n_1 = 10n$  times and let  $N_{\sigma}$  be the output of the first run that does not output ?. Set  $\text{count} = \text{count} + N_{\sigma}$ . (If all runs of  $\mathcal{A}_5$  output ?, then output ?.)

4. Output  $\text{count}$ .

#### 4.4.2 The correctness argument and running time analysis

► **Lemma 18.** *The algorithm  $\mathcal{A}_5$  described above is a zero-error randomized algorithm which on input  $(C, \mathcal{P})$  as described above, correctly  $\#SAT(C, \mathcal{P})$ . Moreover, the algorithm outputs the correct answer (and not ?) with probability at least  $1/2$ . Finally,  $\mathcal{A}_5(n, d, M, n^{1+\varepsilon_d}, C, \emptyset)$  runs in time  $\text{poly}(n, M) \cdot 2^{n - n^{\zeta\varepsilon_d/2(k+1)}}$ , where parameters  $\varepsilon_d, \zeta$  are as defined at the beginning of Section 4.*

**Proof.** We argue correctness by induction on the depth  $d$  of the circuit  $C$ .

Clearly, if  $d = 1$ , correctness follows from the correctness of algorithm  $\mathcal{A}_4$ . This takes care of the base case.

If  $d \geq 2$ , we argue first that if the algorithm does not output ?, then it does output  $\#SAT(C, \mathcal{P})$  correctly. Assume that the algorithm  $\mathcal{A}_2$  outputs a decision tree  $T_{DT}$  as required (otherwise, the algorithm outputs ? and we are done). Now, it is sufficient to argue that for each  $\sigma$ , the number of satisfying assignments to  $(C_{\sigma}, \mathcal{P}_{\sigma})$  is computed correctly (if the algorithm does not output ?).

Fix any  $\sigma$ . If  $C_{\sigma}$  is not a good circuit, then the algorithm uses brute-force to compute  $\#SAT(C_{\sigma}, \mathcal{P}_{\sigma})$  which yields the right answer. So we may assume that  $C_{\sigma}$  is indeed good.

Now, the satisfying assignments to  $(C_{\sigma}, \mathcal{P}_{\sigma})$  break into two kinds: those that are minority assignments to the set  $B_{\sigma}$  and those that are majority assignments to  $B_{\sigma}$ . The former set is enumerated in Step 3e (correctly by our analysis of  $\mathcal{A}_3$ ) and hence we count all these assignments in this step.

Finally, we claim that the satisfying assignments to  $(C_{\sigma}, \mathcal{P}_{\sigma})$  that are majority assignments of all gates in  $B_{\sigma}$  are counted in Step 3f. To see this, note that each such assignment  $a \in \{-1, 1\}^{n^{1-2\beta_d}}$  forces the gates in  $G_{\sigma}$  to some values  $b_1, \dots, b_t \in \{-1, 1\}$ . Note that for each such  $b \in \{-1, 1\}^t$ , these assignments are exactly the satisfying assignments of the pair  $(C_{\sigma,b}, \mathcal{P}_{\sigma,b})$  as defined in the algorithm. In particular, the number satisfying assignments to  $(C_{\sigma}, \mathcal{P}_{\sigma})$  that are majority assignments of all gates in  $B_{\sigma}$  can be written as

$$\sum_{b \in \{-1, 1\}^t} \#SAT(C_{\sigma,b}, \mathcal{P}_{\sigma,b}).$$

We now want to apply the induction hypothesis to argue that all the terms in the sum are computed correctly. To do this, we need to argue that the size of  $C_{\sigma,b}$  and the total fan-in of the gates in  $\mathcal{P}_{\sigma,b}$  are bounded as required (note that the total size of  $C$  remains the same, while the total fan-in of  $\mathcal{P}$  increases by the total fan-in of the gates in  $B'_{\sigma} \cup G'_{\sigma,b}$  which is at most  $n^{1+\varepsilon_d}$ ). It can be checked that this boils down to the following two inequalities

$$n^{(1-2\beta_d)(1+\varepsilon_d-1)} \geq n^{1+\varepsilon_d} \quad \text{and} \quad n^{(1-2\beta_d)(1+\varepsilon_d-1)} \leq 2n^{1+\varepsilon_d}$$

both of which are easily verified for our choice of parameters (for large enough  $n$ ). Thus, by the induction hypothesis, all the terms in the sum are computed correctly (unless we get ?). Hence, the output of the algorithm is correct by induction.

Now, we analyze the probability of error. If  $d = 1$ , the probability of error is at most  $1/2$  by the analysis of  $\mathcal{A}_4$ . If  $d > 2$ , we get an error if either  $\mathcal{A}_2$  outputs  $?$  or there is some  $\sigma$  such that the corresponding runs of  $\mathcal{A}_5$  or  $\mathcal{A}_4$  output  $?$ . The probability of each is at most  $1/2^{10n}$ . Taking a union bound over at most  $2^n$  many  $\sigma$ , we see that the probability of error is at most  $1/2^{\Omega(n)} \leq 1/2$ .

Finally, we analyze the running time. Define  $\mathcal{T}(n, d, M)$  to be the running time of the algorithm on a pair  $(C, \mathcal{P})$  as specified in the input description above. We need the following claim.

► **Lemma 19.**  $\mathcal{T}(n, d, M) \leq \text{poly}(n, M) \cdot 2^{n-n^{\zeta \varepsilon_d/2(k+1)}}$ .

To see the above, we argue by induction. The case  $d = 1$  follows from the running time of  $\mathcal{A}_4$ . Further from the description of the algorithm, we get the following inequality for  $d \geq 2$ .

$$\mathcal{T}(n, d, M) \leq \text{poly}(n, M) \cdot (2^{n-n^{1-2\beta_d}} + 2^{n-n^{\varepsilon_d}} + 2^{n-\frac{1}{2} \cdot n^{-\beta_d/(Bk^2)}} + 2^{n-n^{(1-2\beta_d)\zeta \varepsilon_d-1/2(k+1)}}) \quad (1)$$

The first term above accounts for the running time of  $\mathcal{A}_2$  and all steps other Steps 3b, 3e and 3f. The second term accounts for the brute force search in Step 3b since there are only a  $2^{-n^{\varepsilon_d}}$  fraction of  $\sigma$  where it is performed. The third term accounts for the minority enumeration algorithm in Step 3e (running time follows from the running time of that algorithm). The last term is the running time of Step 3f and follows from the induction hypothesis.

It suffices to argue that each term in the RHS of (1) can be bounded by  $2^{n-n^{\zeta \varepsilon_d/2(k+1)}}$ . This is an easy verification from our choice of parameters and left to the reader. This concludes the proof. ◀

## 4.5 Putting it together

In this subsection, we complete the proof of Theorem 6 using the aforementioned subroutines. We also need to describe the subroutine  $\mathcal{A}_1$ , which is critical for all the other subroutines. We shall do so *inside* our final algorithm for the #SAT problem for  $k$ -PTF circuits, algorithm  $\mathcal{B}$ . Recall that  $\mathcal{A}_1$  has the following specifications:

**Input:** AND of  $k$ -PTFs, say  $f_1, \dots, f_s$  specified by polynomials  $P_1, \dots, P_s$  respectively, such that  $s \leq n^{0.1}$  and for each  $i \in [s]$ ,  $f_i$  is defined over  $n' \leq n^{1/(2(k+1))}$  variables and  $w(P_i) \leq M$ .

**Output:**  $\#\{a \in \{-1, 1\}^{n'} \mid \forall i \in [s], f_i(a) = -1\}$ .

We are now ready to complete the proof of Theorem 6. Suppose  $C$  is the input  $k$ -PTF circuit with parameters  $(n, n^{1+\varepsilon_d}, d, M)$ . On these input parameters  $(C, n, n^{1+\varepsilon_d}, d, k, M)$ , we finally have the following algorithm for the #SAT problem for  $k$ -PTF circuits:

**$\mathcal{B}(C, n, n^{1+\varepsilon_d}, d, k, M)$ .**

1. (*Oracle Construction Step*) Construct the oracle  $\mathcal{A}_1$  as follows. Use  $n_1 = 10n$  independent runs of the algorithm from Corollary 10, with  $\ell$  chosen to be  $n^{0.1}$  and  $m$  to be  $n^{1/2(k+1)}$ , to construct independent random linear decision trees  $T_1, \dots, T_{n_1}$  such that on any input  $\bar{w} = (\text{coeff}_{m,k}(Q_1), \dots, \text{coeff}_{m,k}(Q_\ell)) \in \mathbb{R}^{r \cdot \ell}$  (where  $Q_i$ s are polynomials of degree at most  $k$  that sign-represent  $k$ -PTFs  $g_i$ , each on  $m$  variables), each  $T_i$  computes the number of common satisfying assignments to  $g_1, \dots, g_\ell$  with error at most  $1/2$ .
2. Run  $\mathcal{A}_5(n, d, M, n^{1+\varepsilon_d}, C, \emptyset)$ . For an internal call to  $\mathcal{A}_1$ , say on parameters  $(n', s, f_1, \dots, f_s)$  where  $n' \leq m$  and  $s \leq \ell$ , do the following:

- a. Run each  $T_i$  on the input  $\bar{w} = (\text{coeff}_{n',k}(P_1), \dots, \text{coeff}_{n',k}(P_s)) \in \mathbb{R}^{r \cdot s}$ . (We expand out the coefficient vectors with dummy variables so that they depend on exactly  $m$  variables. Similarly, using some dummy polynomials, we can assume that there are exactly  $\ell$  polynomials.)
- b. If some  $T_i$  outputs the number of common satisfying assignments to  $f_1, \dots, f_s$ , then output that. Otherwise, if all  $T_i$  output ?, then output ?.

► **Lemma 20.** *The construction of the zero-error randomized oracle  $\mathcal{A}_1$  in the above algorithm takes  $2^{O(n^{0.6})}$  time. Once constructed, the oracle  $\mathcal{A}_1$  answers any call (with the correct parameters) in  $\text{poly}(n, M)$  time with error at most  $1/2^{10n}$ .*

**Proof.**

**Correctness.** It is clear from Corollary 10 that algorithm  $\mathcal{A}_1$  outputs either ? or the correct number of common satisfying assignments to  $f_1, \dots, f_s$ . Further, as the  $T_i$ s in step 1 are constructed independently, it follows that with probability at least  $1 - 1/2^{10n}$ , the algorithm indeed outputs the number of common satisfying assignments to  $f_1, \dots, f_s$ .

**Running Time.** Substituting the parameters  $\ell = n^{0.1}$  and  $m = n^{1/(2(k+1))}$  in Corollary 10, we see that the construction of  $\mathcal{A}_1$  (step 1) takes  $n_1 \cdot 2^{n^{0.6}}$  time. Also, the claimed running time of answering a call follows upon observing that steps 2a and 2b combined take only  $\text{poly}(n, M)$  time to execute. ◀

With the correctness of  $\mathcal{A}_1$  now firmly established, we finally argue the correctness and running time of algorithm  $\mathcal{B}$ .

**Correctness.** The correctness of  $\mathcal{B}$  follows from that of  $\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3, \mathcal{A}_4$ , and  $\mathcal{A}_5$  (see Lemma 20, Theorem 14, Lemmas 15, 17, and 18 respectively). Furthermore, if the algorithm  $\mathcal{A}_1$  is assumed to have no error at all, then from the analysis of  $\mathcal{A}_5$ , we see that the probability of error in  $\mathcal{B}$  is at most  $1/2$ . However, as algorithm  $\mathcal{A}_1$  is itself randomized, we still need to bound the probability that any of the calls made to  $\mathcal{A}_1$  produce an undesirable output (i.e. an output of ?). To this end, first note that as the running time of  $\mathcal{A}_5$  is bounded by  $2^n$ , the number of calls to  $\mathcal{A}_1$  is also bounded by  $2^n$ . But by Theorem 14 and Lemma 20, the probability of  $\mathcal{A}_1$  outputting ? is bounded by  $1/2^{10n}$ . Therefore, by the union bound, algorithm  $\mathcal{B}$  correctly outputs the number of satisfying assignments to the input circuit  $C$  with probability at least  $1/2 - 1/2^{\Omega(n)} \geq 1/4$ .

**Running Time.** By Lemma 18 and 20, the running time of  $\mathcal{B}$  will be  $2^{O(n^{0.6})} + \text{poly}(n, M) \cdot 2^{n - n^{\zeta \varepsilon_d / 2(k+1)}}$ . Thus, the final running time is  $\text{poly}(n, M) \cdot 2^{n-S}$  where  $S = n^{\zeta \varepsilon_d / 2(k+1)}$  and where  $\varepsilon_d > 0$  is a constant depending only on  $k$  and  $d$ . Setting  $\varepsilon_{k,d} = \zeta \varepsilon_d / 2(k+1)$  gives the statement of Theorem 6.

## Abstract

Dinur, Khot, Kindler, Minzer and Safra (2016) recently showed that the (imperfect completeness variant of) Khot’s 2 to 2 games conjecture follows from a combinatorial hypothesis about the soundness of a certain “Grassmanian agreement tester”. In this work, we show that soundness of Grassmannian agreement tester follows from a conjecture we call the “Shortcode Expansion Hypothesis” characterizing the non-expanding sets of the degree-two Short code graph. We also show the latter conjecture is equivalent to a characterization of the non-expanding sets in the Grassman graph, as hypothesized by a follow-up paper of Dinur et al. (2017).

Following our work, Khot, Minzer and Safra (2018) proved the “Shortcode Expansion Hypothesis”. Combining their proof with our result and the reduction of Dinur et al. (2016), completes the proof of the 2 to 2 conjecture with imperfect completeness. We believe that the Shortcode graph provides a useful view of both the hypothesis and the reduction, and might be suitable for obtaining new hardness reductions.

## 1 Introduction

In [5], Subhash Khot put forward a family of variants of Unique Games Conjectures. A binary constraint  $P(x_1, x_2)$  where  $x_i$ s take values in alphabet  $\Sigma$  is said to be  $d$ -to- $d$  if for every value to  $x_1$ , there are exactly  $d$  values for  $x_2$  that satisfy  $P$  and vice versa. For any  $d$ ,

<sup>2</sup> Supported by Schmidt foundation fellowship and NSF CCF-1412958.

the “ $d$ -to- $d$  games conjecture” roughly says that for every  $\epsilon > 0$ , there is some finite alphabet  $\Sigma$  such that it is NP-hard to distinguish, given a constraint satisfaction problem with  $d$ -to- $d$  constraints, whether it is possible to satisfy at least  $1 - \epsilon$  fraction of the constraints, or if every assignment satisfies at most  $\epsilon$  fraction of the constraints.<sup>3</sup> The case of  $d = 1$  corresponds to the more famous *Unique Games Conjecture*, but until recently there was no constant  $d$  for which the corresponding  $d$ -to- $d$  conjecture was known to be true.

Dinur, Khot, Kindler, Minzer, and Safra [3], building on ideas of Khot, Minzer and Safra [6], recently initiated an approach towards proving the 2-to-2 conjecture, based on a certain combinatorial hypothesis positing the soundness of the “Grassmann Agreement Test”. In this work we show that their hypothesis follows from a certain natural hypothesis characterizing the structure of non-expanding sets in the degree two Short code graph [2]. Following our work, Khot, Minzer and Safra [7] proved the latter hypothesis thus completing the proof of the 2-to-2 games conjecture. This has several implications to hardness of approximation including improving on the NP-hardness of approximation for Vertex Cover along with a host of other improved NP-hardness results. Perhaps more importantly, this also gives a strong evidence for the truth of the Unique Games Conjecture itself. We defer to [3, 4, 7] for a detailed discussion on the importance of the 2-to-2 games conjecture, as well as the reduction of this conjecture to showing the soundness of the Grassmann agreement tester.

## 1.1 Our Results

Our main result reduces the task of proving the “Grassmann Agreement Hypothesis” of Dinur, Khot, Kindler, Minzer and Safra [3, Hypothesis 3.6] to characterizing the structure of non-expanding sets in the associated Grassmann graph.

- We show that the Grassmann Agreement Hypothesis [3, Hypothesis 3.6] follows from the Grassmann Expansion Hypothesis [4, Hypothesis 1.7].
- We describe the related Shortcode test and the associated agreement and expansion hypothesis and relate them to the Grassmann versions above.

The above, combined with the work of [3, 7], suffices to prove the 2-to-2 conjecture. However we note that it is possible to directly obtain a proof of the 2-to-2 conjecture (see the recent exposition at [1]) using the “Shortcode Expansion Hypothesis” without going through the Grassmann graph at all. We think the Short code view provides a natural way to understand the reduction and suggests potential extensions, see Section 1.6.

## 1.2 Grassmann Graph and DKKMS Consistency Test

To state our results formally, we need to define the Grassman and Short code graphs, which we now do. The Grassmann graph  $\mathcal{G}(\ell, n)$  with parameters  $\ell, n$  has vertices given by all  $\ell$ -dimensional subspaces (denoted by  $\mathcal{V}_\ell$ ) of  $\mathbb{F}_2^n$ . Two subspaces  $V, V'$  of  $\mathbb{F}_2^n$  have an edge between them if  $\dim(V \cap V') = \ell - 1$ .

Let  $\text{LIN}(\mathbb{F}_2^n)$  be the set of all linear functions  $\mathbb{F}_2^n \rightarrow \mathbb{F}_2$ . For every  $f \in \text{LIN}(\mathbb{F}_2^n)$ , let  $F_f$  be the map that assigns to every  $V \in \mathcal{V}_\ell$ ,  $F_f(V) = f|_V$  the restriction of the linear function  $f$  to the subspace  $V$ . Let  $\text{LIN}(\ell, n) = \{F_f \mid f \in \text{LIN}(\mathbb{F}_2^n)\}$  be the set of all such maps.

The Grassmann Consistency test is a two-query test for  $\text{LIN}(\ell, n)$  described below:

---

<sup>3</sup> For  $d > 1$ , the conjectures are often stated in their *perfect completeness variant*, where we replace  $1 - \epsilon$  with 1 in the first case. In this work (as well as all the line of works following [6]), we refer to the imperfect completeness version as stated above.

————— **Test 1: Grassmann Consistency Test** —————

**Given:** a map  $F$  from  $\mathcal{V}_\ell \rightarrow \text{LIN}(\mathbb{F}_2^\ell)$  that maps any  $V \in \mathcal{V}_\ell$  to  $F(V)$  a linear function on  $V$ .

**Operation:**

1. Pick an edge  $(V, V')$  of  $\mathcal{G}(\ell, n)$  uniformly at random.
2. Receive  $F(V), F(V') \in \text{LIN}(\ell, n)$ .
3. Accept if  $F(V)_{V \cap V'} = F(V')_{V \cap V'}$  otherwise reject.

It is easy to see the following completeness of the Grassmann graph test.

► **Fact 1 (Completeness).** *Suppose  $F \in \text{LIN}(\ell, n)$ . Then,  $F$  passes the Grassman Consistency test with probability 1.*

The DKKMS hypothesis conjectures a precise version of soundness of the Grassmann Consistency Test.

► **Hypothesis 2 (DKKMS Soundness Hypothesis).** *For every  $\delta > 0$ , there exists  $\epsilon > 0$ , and an integer  $r > 0$  such that following holds for sufficiently large  $n \gg \ell$ .*

*Let  $F : \mathcal{V}_\ell \rightarrow \text{LIN}(\mathbb{F}_2^\ell)$  such that  $\Pr_{(V, V') \sim \mathcal{G}(\ell, n)}[F(V)_{V \cap V'} = F(V')_{V \cap V'}] \geq \delta$ . Then, there exist subspaces  $Q, W \subseteq \mathbb{F}_2^n$  of dimensions  $r$  and  $n - r$  respectively and an  $f \in \text{LIN}(\mathbb{F}_2^n)$  such that*

$$\Pr_{V \sim \mathcal{V}_\ell, Q \subseteq V \subseteq W} [F(V) = f_V] \geq \epsilon.$$

### 1.3 Shortcode Graph and Consistency Test

We now define the closely related *Degree 2 Shortcode* graph and an immediate analog of the Grassmann consistency test on this graph. For parameters  $\ell, n$  as before, the vertices of the degree 2 Short code graph  $\mathcal{S}_{\ell, n}$  are elements of  $\text{Mat}_{\ell, n}$ , that is, all matrices on  $\mathbb{F}_2$  with dimensions  $\ell \times n$ . Two vertices  $M_1$  and  $M_2$  have an edge between them if  $M_1 - M_2$  is a rank 1 matrix over the field  $\mathbb{F}_2$ . The 2 query codeword test on this graph is entirely analogous to the one above for the Grassmann graph:

————— **Test 2: Degree 2 Shortcode Consistency Test** —————

**Given:** a map  $F$  from  $\text{Mat}_{\ell, n} \rightarrow \mathbb{F}_2^\ell$ .

**Operation:**

1. Pick  $M_1 \sim \text{Mat}_{\ell, n}$  and a rank 1 matrix  $ab^\top$  for vectors  $a \in \mathbb{F}_2^\ell, b \in \mathbb{F}_2^n$  all uniformly at random from their respective domains. Let  $M_2 = M_1 + ab^\top$ .
2. Receive  $F(M_1), F(M_2) \in \mathbb{F}_2^\ell$ .
3. Accept if  $F(M_2) \in \{F(M_1), F(M_1) + a\}$ .

Just as the Grassmann consistency test, the above Short code consistency test is a “2-to-2” constraint and the following completeness is easy to establish.

► **Fact 3 (Completeness).** *Let  $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^\ell$  be any affine linear function. Let  $F = F_f : \text{Mat}_{\ell, n} \rightarrow \mathbb{F}_2^\ell$  be the map that evaluates  $f$  on each row the input matrix. Then,  $F$  passes the Short code consistency test with probability 1.*

The analogous soundness hypothesis can now be stated as:

► **Hypothesis 4** (Degree 2 Shortcode Soundness Hypothesis). *For every  $\delta > 0$ , there exists  $\epsilon > 0$ , and an integer  $r > 0$  such that following holds for sufficiently large  $n \gg \ell$ .*

*Let  $F : \text{Mat}_{\ell,n} \rightarrow \mathbb{F}_2^\ell$  such that  $\Pr_{M \sim \text{Mat}_{\ell,n}, a \sim \mathbb{F}_2^\ell, b \sim \mathbb{F}_2^n} [F(M + ab^\top) \in \{F(M), F(M) + a\}] \geq \delta$ . Then, there exists linear constraints  $(q_i, t_i)$  and  $(r_i, s_i)$  for  $i \leq r$  and a  $z \in \mathbb{F}_2^n, u \in \mathbb{F}_2^\ell$  such that*

$$\Pr_{M \sim \text{Mat}_{\ell,n}} [F(M) = Mz + u \mid Mq_i = t_i, r_i^\top M = s_i \ \forall i \leq r] \geq \epsilon.$$

## 1.4 Soundness vs Small-Set Expansion in Grassmann/Shortcode Graphs

Recall that for a regular graph  $G$ , the expansion of a set  $S$  of vertices is the probability that a random walk beginning at a uniformly random vertex in  $S$  steps out of  $S$ . That is,  $\Phi_G(S) = \Pr_{v \sim S, v' \sim v} [v' \notin S]$ .

The DKKMS Soundness Hypothesis implies a natural characterization small non-expanding sets in  $\mathcal{G}(\ell, n)$  noted below as Hypothesis 6. Similarly, the degree 2 Short code soundness hypothesis implies a natural characterization of non-expanding sets in  $\mathcal{S}_{\ell,n}$ . We include a brief overview of the argument here and refer the reader to the more extensive commentary in Section 1.3 of [3] for further details.

Suppose  $A_1, A_2, \dots, A_r$  are “non-expanding” sets that cover a constant fraction of vertices in  $\mathcal{G}(\ell, n)$ . We construct a labeling strategy  $F$  by choosing  $r$  uniformly random linear functions  $f_i : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$  and setting  $F(V) = f_i$  if  $V \sim A_i$  and  $F(V)$  is a random linear function otherwise. Clearly,  $F$  doesn’t agree with a single linear function on significantly more than  $1/r$  fraction of the vertices in  $\mathcal{V}_\ell$ . On the other hand, if  $A_i$ s are sufficiently non-expanding, then, a random edge will lie inside one of the  $A_i$ s with a non-trivially large probability and thus  $F$  will satisfy the Grassmann consistency test. In this, case, we will hope that there are subspaces  $Q, W$  of constant dimension and co-dimension, respectively such that restricting to subspaces  $V \in \mathcal{V}_\ell(Q, W)$  (where  $\mathcal{V}_\ell(Q, W)$  is the subset  $V \in \mathcal{V}_\ell$  such that  $V \subseteq W$ ) implies that  $F(V) = f_V$  for some fixed global linear function  $f$ . This can happen in the above example for  $F$  only if there are  $Q, W$  as above such that one of the  $\frac{|A_i \cap \mathcal{V}_\ell(Q, W)|}{|\mathcal{V}_\ell(Q, W)|}$  is  $\Omega(1)$  (i.e. independent of  $\ell, n$ ). Thus, Hypothesis 2 forces that the non-expanding sets  $A_i$  to be “structured” (in the sense of having a large density inside  $\mathcal{V}_\ell(Q, W)$  for some  $Q, W$  of constant dimension and co-dimension, respectively.) This can be interpreted as saying that the non-expansion of any set of vertices in  $\mathcal{G}(\ell, n)$  can be “explained” away by a more than typical density in one of the canonical non-expanding sets (i.e., those that contain a subspace  $Q$  and are contained inside a subspace  $W$  of constant dimension and co-dimension, respectively.)

To formally state the Grassmann Expansion Hypothesis, we define the special non-expanding sets (referred to as “zoom-in” and “zoom-outs” in [4]):

► **Definition 5** (Nice Sets in Grassmann Graph). A subset  $S \subseteq \mathcal{V}_\ell$  of vertices in  $\mathcal{G}(\ell, n)$  is said to be  $r$ -nice if there are subspace  $Q, W$  of  $\mathbb{F}_2^n$  of dimension and co-dimension  $r_1, r_2$  respectively such that  $r_1 + r_2 = r$  and  $S = \{V \subseteq \mathcal{V}_\ell \mid Q \subseteq V \subseteq W\}$ .

► **Hypothesis 6** (Grassmann Expansion Hypothesis). *For every  $\eta > 0$ , there exists  $\delta, r$  depending only on  $\eta$  such that if  $S \subseteq \mathcal{V}_\ell$  satisfies  $\Phi_{\mathcal{G}(\ell,n)}(S) < \eta$ , then, there are subspaces  $Q, W$  over  $\mathbb{F}_2^n$  of dimension and co-dimension  $r_1, r_2$  satisfying  $r_1 + r_2 \leq r$  respectively, such that  $\Pr_{V: Q \subseteq V \subseteq W} [V \in S] \geq \delta$ .*

Analogously, we can define nice sets in the degree 2 Short code graph and state the expansion hypothesis. We call  $Q$ , a *right* affine subspace of matrices in  $\text{Mat}_{\ell,n}$  if there are pairs  $(q_i, t_i)$  and every  $M \in Q$  satisfies  $Mq_i = t_i$ . We define a *left* affine subspace analogously.

► **Definition 7** (Nice Sets in Degree 2 Shortcode Graph). A subset  $S \subseteq \mathcal{S}_{\ell,n}$  is said to be  $r$ -nice if it is an intersection of a left and right affine subspace in  $\text{Mat}_{\ell,n}$  with sum of the dimensions  $r$ .

► **Hypothesis 8** (Shortcode Expansion Hypothesis). For every  $\eta > 0$ , there exist  $\delta, r$  depending only on  $\eta$  such that for every subset  $S \subseteq \text{Mat}_{\ell,n}$ , if  $\Pr_{M \sim S, a \sim \mathbb{F}_2^\ell, b \sim \mathbb{F}_2^n} [M + ab^\top \in S] \geq \eta$ , then, there exists an  $r$ -nice set  $\mathcal{T} \subseteq \mathcal{S}_{\ell,n}$  such that  $|S \cap \mathcal{T}| \geq \delta |\mathcal{T}|$ .

While Hypotheses 2 and 4 posit soundness of a specific “code-word consistency” test associated with the Grassmann/Shortcode graphs, Hypotheses 6 and 8 ask for a purely graph theoretic property: a characterization of non-expanding sets in  $\mathcal{G}(\ell, n)$  and  $\mathcal{S}_{\ell,n}$ . As such, it appears easier to attack and [3] thus suggested understanding the structure of non-expanding sets in  $\mathcal{G}(\ell, n)$  as a natural first step. As we show in this note, proving Hypothesis 8 is in fact enough to show Hypothesis 2. In a follow up work [7], this result was used in to complete the proof of the DKKMS soundness hypothesis.

## 1.5 Our Results

We are now ready to state our main results formally.

First, we show that the soundness of the Short code consistency test follows from the expansion hypothesis for the Short code graph.

► **Theorem 9.** *The degree 2 Shortcode Expansion Hypothesis 8 implies the Degree 2 Shortcode Soundness Hypothesis 4.*

Second, we show that the soundness hypothesis for the Short code consistency test implies the soundness hypothesis for the Grassmann consistency test. This reduces the DKKMS soundness hypothesis to establishing the expansion hypothesis for the Shortcode graph.

► **Theorem 10.** *The degree 2 Shortcode Soundness Hypothesis implies the Grassmann Soundness Hypothesis 2.*

Finally, we relate the expansion hypothesis of the Grassmann graph to the expansion hypothesis for the degree 2 Short code graph.

► **Theorem 11.** *The Grassmann Expansion Hypothesis (Hypothesis 6) is equivalent to the Shortcode Expansion Hypothesis (Hypothesis 8).*

## 1.6 Discussion

Working with the Short code consistency test (and consequently, the Short code expansion hypothesis) makes an approach to proving Hypothesis 2 somewhat more tractable. This is because unlike the Grassmann graph, Degree 2 Short code graph is a Cayley graph on  $\text{Mat}_{\ell,n}$  under the group operation of  $\mathbb{F}_2$ -addition with the set of all rank 1 matrices forming the set of generators. Thus studying expansion of sets of vertices can be approached via powerful methods from Fourier analysis. Indeed, this is the route taken by the recent breakthrough [7] that proves the Short code expansion hypothesis and completes the proof of the 2-to-2 games conjecture (with imperfect completeness).

Perhaps equally importantly, the Short code consistency test suggests immediate extensions (*higher degree Short code graphs*) that provide a natural path to proving the Unique Games Conjecture. We discuss this approach here.

First, the Grassmann/Short code consistency tests as stated above are “2-to-2” tests. That is, for any reply for the first query, there are two admissible replies for the other query.

However, it is simple to modify the tests and make them *unique* or “1-to-1” at the cost of making the completeness  $1/2$  instead of  $1$ . For concreteness, we describe this simple modification below.

**Test 3: Unique Degree 2 Shortcode Consistency Test**

**Given:** a map  $F$  from  $\text{Mat}_{\ell,n} \rightarrow \mathbb{F}_2^\ell$ .

**Operation:**

1. Pick  $M_1 \sim \text{Mat}_{\ell,n}$  and a rank 1 matrix  $ab^\top$  for vectors  $a \in \mathbb{F}_2^\ell$ ,  $b \in \mathbb{F}_2^n$  all uniformly at random from their respective domains. Let  $M_2 = M_1 + ab^\top$ .
2. Receive  $F(M_1), F(M_2) \in \mathbb{F}_2^\ell$ .
3. Accept if  $F(M_2) = F(M_1)$ .

**Test 4: Unique Degree 3 Shortcode Consistency Test**

**Given:** a map  $F$  from  $\text{Ten}_{\ell,m,n} \rightarrow \mathbb{F}_2^\ell$ .

**Operation:**

1. Pick  $T_1 \sim \text{Ten}_{\ell,m,n}$  and a rank 1 tensor  $a \otimes b \otimes c$  for vectors  $a \in \mathbb{F}_2^\ell$ ,  $b \in \mathbb{F}_2^m$  and  $c \in \mathbb{F}_2^n$  all uniformly at random from their respective domains. Let  $T_2 = T_1 + a \otimes b \otimes c$ .
2. Receive  $F(T_1), F(T_2) \in \mathbb{F}_2^\ell$ .
3. Accept if  $F(T_2) = F(T_1)$ .

It is easy to check that the any strategy that passes the 2-to-2 test can be modified to obtain a success probability of  $1/2$  in passing the “unique” test above (see proof of Lemma 14 below). This is one of the several ways that the NP hardness of “2-to-2” games implies the NP hardness of  $(1/2, \epsilon)$ -unique games - that is, distinguishing between instances where at least  $1/2$  the constraints are satisfiable from those where at most  $\epsilon$  fraction of constraints are satisfiable.

A natural strategy, thus, to try to show NP hardness of  $(1 - \epsilon, \epsilon)$ -unique games is to use some variant of the Short code consistency test above that has completeness  $1 - \epsilon$  instead of  $1/2$ . Indeed, the degree 2 Short code consistency test suggests natural analogs with higher completeness - by moving to higher degree Short code graphs. For concreteness, consider the following test on degree 3 Short code graphs, where it is easy to argue a completeness of  $3/4$ .

Let  $\text{Ten}_{\ell,m,n}$  be the set of all  $\ell \times m \times n$  tensors over  $\mathbb{F}_2$ . Recall that a rank 1 tensor is defined by 3 vectors  $a \in \mathbb{F}_2^\ell$ ,  $b \in \mathbb{F}_2^m$  and  $c \in \mathbb{F}_2^n$  and can be written as  $a \otimes b \otimes c$ .

To see why there’s a natural analog of the strategy in case of the degree 2 Short code consistency test that gives a completeness of  $3/4$ , we show:

► **Lemma 12 (Completeness).** *Let  $y \in \mathbb{F}_2^m$  and  $z \in \mathbb{F}_2^n$ . Let  $F_f : \text{Ten}_{\ell,m,n} \rightarrow \mathbb{F}_2^\ell$  be the map that assigns to any tensor  $T$ , the value  $F_f(T)_i = \sum_{j,k} T(i, j, k)y_j z_k$ . Then,  $F_f$  passes the test with probability  $3/4$ .*

**Proof.** Let  $T, T'$  be such that  $T - T'$  is rank 1 tensor. Then,  $F_f$  passes the test only if  $F_f(T - T') = 0$ . If  $T - T' = a \otimes b \otimes c$ , then  $F_f(T - T') = \langle b, y \rangle \cdot \langle c, z \rangle a$ . Since  $b, c$  are independently chosen in the test, the probability that  $F_f(T - T') = 0$  is  $3/4$ . ◀

Thus, the degree 3 Short code consistency test gives a natural analog of the degree 2 Short code consistency test with higher completeness. Indeed, degree  $r$  version gives a test with completeness of  $1 - 2^{-r}$  as expected. One can also frame expansion hypotheses similar to the ones for the degree 2 case that posit a characterization of the non-expanding sets in higher degree Short code graphs.

While our current efforts to compose this test with the “outer-PCP” in order to get a reduction to Unique Games problem (with higher completeness) have not succeeded, it seems a natural avenue for launching an attack on the UGC.<sup>4</sup>

## 2 Small-Set-Expansion vs Soundness

In this section, we establish that the inverse Short code hypothesis (Hypothesis 8) implies the soundness of the degree 2 Short code consistency test 4.

### From 2-to-2 to Unique Tests

For the sake of exposition, it will be easier to work with Test 1.6, the “unique” version of the degree 2 Short code consistency test. Thus, we restate the soundness hypothesis for Test 1.6 and show that it is enough to establish Hypothesis 4.

► **Hypothesis 13** (Soundness of Test 1.6). *For every  $\eta > 0$ , there exists  $\delta > 0$ , and an integer  $r > 0$  such that following holds for sufficiently large  $n \gg \ell$ .*

*Let  $F : \text{Mat}_{\ell,n} \rightarrow \mathbb{F}_2^\ell$  such that  $\Pr_{M \sim \text{Mat}_{\ell,n}, a \sim \mathbb{F}_2^\ell, b \sim \mathbb{F}_2^n} [F(M + ab^\top) = F(M)] \geq \eta$ . Then, there exists linear constraints  $(q_i, t_i)$  and  $(r_i, s_i)$  for  $i \leq r$  and a  $z \in \mathbb{F}_2^n, u \in \mathbb{F}_2^\ell$  such that*

$$\Pr_{M \sim \text{Mat}_{\ell,n}} [F(M) = Mz + u \mid Mq_i = t_i, r_i^\top M = s_i \forall i \leq r] \geq \delta.$$

We first show that Hypothesis 13 implies Hypothesis 4.

► **Lemma 14.** *Hypothesis 13 implies Hypothesis 4.*

**Proof.** Let  $F$  be the labeling strategy for Test 1.3. We will first obtain a good labeling strategy for Test 1.6 by modifying  $F$  slightly.

Choose  $h$  uniformly at random from  $\mathbb{F}_2^n$ . For any  $M \in \text{Mat}_{\ell,n}$ , let  $G(M) = F(M) + Mh$ . We claim that if  $F$  passes the Test 1.3 with probability  $\eta$ , then  $G$  passes Test 1.6 with probability at least  $\eta/2$ .

To see this, take any  $M, M'$  such that  $M \sim M'$  in  $\mathcal{S}_{\ell,n}$ . That is,  $M - M' = ab^\top$  for vectors  $a, b$ . We will argue that  $G(M) = G(M')$  with probability  $1/2$ . This will imply that in expectation over the choice of  $h$ ,  $G$  satisfies at least  $1/2$  the constraints satisfied by  $F$  in Test 1.3 completing the proof.

This is simple to see: since  $F$  passes the test,  $F(M) = F(M')$  or  $F(M) - F(M') = a$ . WLOG, say the first happens. Observe that  $G$  passes the unique test on  $M, M'$  if  $F(M) + Mh = F(M') + M'h$  or  $F(M) - F(M') = (M - M')h = \langle b, h \rangle a$ . Since  $F(M) = F(M')$ ,  $G$  thus passes if  $\langle b, h \rangle = 0$  which happens with probability  $1/2$ . ◀

<sup>4</sup> There are indeed very serious obstacles that must be overcome before carrying this out. Specifically, the reduction of [3] uses a careful interplay between *smoothness* properties of the outer PCP and *efficiency* or “blow up” properties of the test (i.e., the number of potential queries by the verifier as a function of the number of honest strategies). The tensor based test has too much of a blowup to be able to be simply “plugged in” in the outer PCP used by [3].

### Expansion to Soundness

We will now show that Hypothesis 8 implies Hypothesis 13. This completes the proof of Theorem 9. A similar argument can be used to directly establish that Hypothesis 6 implies Hypothesis 2. We do not include it here explicitly. Instead, we relate the expansion and soundness hypothesis for the degree 2 Short code test to the analogs for the Grassmann test as we believe this could shed light on showing expansion hypotheses for higher degree Short code tests discussed in the next section.

► **Lemma 15.** *Hypothesis 8 implies Hypothesis 13.*

**Proof.** Let  $F$  be the labeling function as in the assumption in Hypothesis 13. Then, we know that  $\Pr_{M \sim \text{Mat}_{\ell,n}, a \sim \mathbb{F}_2^\ell, b \sim \mathbb{F}_2^n} [F(M) = F(M + ab^\top)] \geq \eta$ . For any  $z \in \{0, 1\}^\ell$ , let  $S_z$  be the set of all matrices  $M$  with  $F(M) = z$ . Then, by an averaging argument, there must be a  $z \in \{0, 1\}^\ell$  such that  $\Pr_{M \sim S_z, a \sim \mathbb{F}_2^\ell, b \sim \mathbb{F}_2^n} [M + ab^\top \in S_z] \geq \eta$ .

Apply Hypothesis 8 to  $S_z$  to obtain  $r$ -nice subset  $Q$  of  $\text{Mat}_{\ell,n}$  such that  $|Q \cap S_z| \geq \delta|Q|$ . Let  $Mq = t$  be an affine constraint satisfied by every  $M \in Q$ . Consider the affine linear strategy  $H : \text{Mat}_{\ell,n} \rightarrow \mathbb{F}_2^\ell$  that maps any  $M$  to  $H(M) = Mq + t + z$ . Observe that for every  $M \in Q$ ,  $H(M) = z$  by this choice. As a result, when  $M \sim M'$  are such that  $M, M' \subseteq Q$ ,  $\Pr[H(M) = H(M')] \geq \delta$ . Thus,  $H$  is the “decoded” strategy that satisfies the requirements of Hypothesis 13 as required. This completes the proof. ◀

## 3 Relating Grassmann Graphs to Degree 2 Shortcode Graphs

In this section, we show a formal relationship between the Grassmann and the degree 2 Shortcode tests. In particular, we will prove Theorems 10 and 11.

### 3.1 A homomorphism from $\mathcal{G}(\ell, n)$ into $\mathcal{S}_{\ell,n}$

Key to the relationship between the two tests is an embedding of the degree 2 Short code graph  $\mathcal{S}_{\ell,n}$  into  $\text{Mat}_{\ell,n-\ell}$ . We describe this embedding first. As justified in the previous section, it is without loss of generality to work with the “unique” versions of both the tests.

To describe the above embedding, we need the notion of *projection* of a subspace of  $\mathbb{F}_2^n$  to a set of coordinates.

► **Definition 16** (Projection of a Subspace). Given a subspace  $V \subseteq \mathbb{F}_2^n$ , the projection of  $V$  to a set of coordinates  $S \subseteq [n]$ , written as  $\text{Proj}_S(V)$  is the subspace of  $\mathbb{F}_2^{|S|}$  defined by taking the vectors obtained by keeping only the coordinates indexed by  $S$  for every vector  $v \in V$ .

Let  $\mathcal{B} \subseteq \mathbb{F}_2^n$  be the set  $n$ -tuples of linearly independent elements of  $\mathbb{F}_2^n$ , i.e. each  $B \in \mathcal{B}$  forms a basis for the vector space  $\mathbb{F}_2^n$ . We will use  $B_0$  to denote the standard basis  $\{e_1, e_2, \dots, e_n\}$ .

We will now describe a class of graph homomorphisms from  $\mathcal{G}(\ell, n)$  into  $\mathcal{S}_{\ell,n-\ell}$ . Each element of this class can be described by a basis  $B$  of  $\mathbb{F}_2^n$ .

For each basis  $B \in \mathcal{B}$ , let  $\mathcal{V}_\ell(B) \subseteq \mathcal{V}_\ell$  be the set of all subspaces  $V \in \mathcal{V}_\ell$  such that the projection of  $V$  to the first  $\ell$  coordinates when written w.r.t. the basis  $B$  is full-dimensional. Our embedding will map each element of  $\mathcal{V}_\ell(B)$  into a distinct element of  $\text{Mat}_{\ell,n}$  such that the edge structure within  $\mathcal{V}_\ell(B)$  in  $\mathcal{G}(\ell, n)$  is preserved under this embedding.

► **Definition 17** (Homomorphism from  $\mathcal{G}(\ell, n)$  into  $\mathcal{S}_{\ell,n}$ ). Let  $\phi = \phi_B : \mathcal{V}_\ell(B) \rightarrow \text{Mat}_{\ell,n-\ell}$  be defined as follows. Write every vector in the  $B$ -basis. For any  $V \in \mathcal{V}_\ell(B)$  and for  $1 \leq i \leq \ell$ , let  $v_i$  be the unique vector in  $V$  such that  $\text{Proj}_{[i]}(v_i) = e_i \in \mathbb{F}_2^\ell$ . We call  $v_1, v_2, \dots, v_\ell$  to be the *canonical basis* for  $V$ .

Define  $\phi(V)$  to be the  $\ell \times (n - \ell)$  matrix with the  $i^{\text{th}}$  row given by the projection of  $v_i$  on the last  $(n - \ell)$  coordinates for each  $1 \leq i \leq \ell$ . When the basis  $B$  is clear from the context, we will omit the subscript and write  $\phi$ .

It is easy to confirm that  $\phi$  is a bijection from  $\mathcal{V}_\ell(B)$  into  $\text{Mat}_{\ell, n}$ . This is because canonical basis for a subspace  $V$  is unique.

Next, we prove some important properties of the homomorphism  $\phi$  that will be useful in the proof of Theorem 10.

First, we show that the map  $\phi$  is indeed a homomorphism as promised and thus, preserves edge structure.

► **Lemma 18** ( $\phi$  is a homomorphism). *For  $\phi = \phi_B$  defined above and any  $V, V' \in \mathcal{V}_\ell(B)$ ,  $V \sim V'$  in  $\mathcal{G}(\ell, n)$  iff  $\phi(V) \sim \phi(V')$  in  $\mathcal{S}_{\ell, n}$ .*

**Proof.** Let  $u \in GF(2)^\ell, v \in GF(2)^{n-\ell}$  be arbitrary non-zero vectors that define a rank 1 matrix  $uv^\top$ . Consider the matrix  $M = M_V + uv^\top$ . Then,  $M \in \text{Mat}_{\ell, n-\ell}$  and thus  $\phi^{-1}(M) = W \in \mathcal{V}_\ell(B)$ . We claim that  $\dim(W \cap V) = \ell - 1$ . Suppose  $b_1, b_2, \dots, b_\ell$  are the rows of  $M_V$ . Then, the rows of  $M$  are given by  $b_i + u_i v$ . Thus,  $W$  is spanned by  $(e_i, b_i + u_i v)$  where  $e_i$  is the  $i^{\text{th}}$  standard basis element on the first  $\ell$  coordinates and the notation  $(e_i, b_i + u_i v)$  indicates the concatenation of the vectors in the ordered pair to get a  $n$  dimensional vector. In particular, every element of  $W$  can be written as  $\sum_{i \leq \ell} \lambda_i (e_i, b_i) + (\sum_{i \leq \ell} \lambda_i u_i) v$  and any such vector is contained in  $V$  if  $(\sum_{i \leq \ell} \lambda_i u_i)$  implying that  $\dim(V \cap W) = \dim(V) - 1 = \ell - 1$ .

On the other hand, let  $V'$  be a subspace in  $\mathcal{V}_\ell(B)$  such that  $V' \sim V$  and let  $M_V$  and  $M_{V'}$  be the matrices obtained via the map  $\phi$ . Then,  $M_V$  and  $M_{V'}$  must differ in at least one row, say, WLOG, the last row of  $M_V$  and  $M_{V'}$  are  $(e_\ell, v)$  and  $(e_\ell, v')$  respectively. Notice that since the vector with  $e_\ell$  in the first  $\ell$  coordinates is unique in  $V, V'$ , neither of  $(e_\ell, v), (e_\ell, v')$  belong to the intersection  $V \cap V'$ . Further, for every vector  $z \in V$ , either  $z$  or  $z + (e_\ell, v)$  must be contained in the intersection  $V \cap V'$  (as the extra linear equation that  $V \cap V'$  satisfies over and above  $V$  is satisfied by exactly one of  $z$  and  $z + (e_\ell, v)$ ). Thus, by letting  $b'_i = b_i + (e_\ell, v) + (e_\ell, v')$  to every one of the canonical basis elements  $b_i$  of  $V$  that are not in  $V \cap V'$ , we get a set of elements that are all 1) contained in  $V'$  2)  $\text{Proj}_{[\ell]} b'_i = e_i$  for every  $i$ . This then has to be the canonical basis of  $M_{V'}$  (by uniqueness of the canonical basis) and further, the corresponding  $M_{V'}$  can be written as  $1_S(w + w')^\top$  where  $S$  is the set of  $i$  such that  $b_i$  is not in  $V \cap V'$ . ◀

Next, we want to argue that expansion of sets is preserved up to constant factors under the map  $\phi$ . Towards this, we first show that  $\mathcal{V}_\ell(B)$  contains a fraction of the vertices of  $\mathcal{G}(\ell, n)$  as we next show.

► **Lemma 19** (Projections of Subspaces). *Let  $V \sim \mathcal{V}_\ell$  for  $\ell \leq \sqrt{n}/2$ . Then,  $\Pr[\dim \text{Proj}_{[\ell]}(V) = \ell] \geq 0.288$  for large enough  $n$  and  $\ell = \omega(1)$ .*

*Further, let  $V \in \mathcal{V}_\ell(B)$  for some  $B$ . Then, at least 1/2 fraction of the neighbors of  $V$  in  $\mathcal{G}(\ell, n)$  are contained in  $\mathcal{V}_\ell(B)$ .*

**Proof.** We can sample a random subspace of  $\ell$  dimension as follows: Choose  $\ell$  uniformly random and independent points from  $GF(2)^n$ . If they are linearly independent, let  $V$  be the subspace spanned by them.

We can estimate the probability that the sampled points are linearly independent as:  $\prod_{i=0}^{\ell-1} (1 - 2^{-n+i}) \geq 1 - 2^{-n} 2^{\ell^2}$ .

Next, we estimate the probability that the projection to first  $\ell$  coordinates of the sampled vectors is linearly independent. By a similar reasoning as above, this probability is at least  $\prod_{i=0}^{\ell-1} (1 - 2^{-\ell+i}) \approx 0.289$  (the limit of this product for large  $\ell$ .)

By a union bound, thus, a random subspace has a full dimensional projection on  $S$  with probability at least  $0.289 - 2^{-n/2}$  for any  $\ell < \sqrt{n}/2$ .

For the remaining part, assume that  $B = B_0$  - the standard basis. Notice that a random neighbor of  $V$  can be sampled as follows: choose a uniformly random basis for  $V$ , say  $v_1, v_2, \dots, v_\ell$ . Replace  $v_\ell$  by a uniformly random vector  $v'_\ell$  outside of  $V$  in  $\mathbb{F}_2^n$ . Since  $V \in \mathcal{V}_\ell(B)$ , the projection of  $V$  to the first  $\ell$  coordinates is linearly independent.  $V'$  would thus satisfy the same property whenever  $v_\ell$  is such that the projection of  $v'_\ell$  to the first  $\ell$  coordinates is not in the span of the projection to the first  $\ell$  coordinates of  $v_1, v_2, \dots, v_{\ell-1}$ . The chance of this happening is exactly  $1/2$ . This completes the proof.  $\blacktriangleleft$

As a consequence of above, we can now obtain that the preimages of non-expanding sets under  $\phi$  are non-expanding in  $\mathcal{G}(\ell, n)$ .

► **Lemma 20.** *Let  $T \subseteq \text{Mat}_{\ell, n}$  be a subset satisfying  $\Pr_{M \sim T, M' \sim M}[M' \in T] = \eta$ . Then,  $\phi^{-1}(T)$  satisfies:  $\Pr_{V \sim \phi^{-1}(T), V' \sim V}[V' \in \phi^{-1}(T)] \geq \eta/2$ .*

**Proof.** Let  $B$  the basis used to construct  $\phi$ . Then,  $\phi(T) \subseteq \mathcal{V}_\ell(B)$ . By Lemma 19,  $1/2$  the neighbors of  $\phi(T)$  are contained in  $\mathcal{V}_\ell(B)$ . By assumption,  $\eta$  fraction of these neighbors are contained inside  $T$ . This finishes the proof.  $\blacktriangleleft$

Via a similar application of Lemma 19, we can establish an appropriate converse.

► **Lemma 21.** *Let  $S \subseteq \mathcal{V}_\ell$  be a subset satisfying  $\Pr_{V \sim S, V' \sim V}[V' \in S] \geq \eta$ . Then, for a uniformly random choice of basis  $B$  for  $\mathbb{F}_2^n$ ,  $\mathbb{E}_B |\phi(S \cap \mathcal{V}_\ell(B))| = \Omega(|S|)$  and  $\Pr_{M, M' \sim \phi(S \cap \mathcal{V}_\ell(B)), M' \sim M}[M' \in \phi(S \cap \mathcal{V}_\ell(B))] \geq \Omega(\eta)$ .*

Finally, we show that  $r$ -nice sets in  $\mathcal{G}(\ell, n)$  get mapped to  $r$ -nice sets in  $\mathcal{S}(\ell, n)$  and vice versa.

► **Lemma 22.** *Let  $S \subseteq \mathcal{V}_\ell$  be an  $r$ -nice set in  $\mathcal{G}(\ell, n)$ . Then,  $\phi_B(S \cap \mathcal{V}_\ell(B))$  is an  $r$ -nice set in  $\mathcal{S}_{\ell, n}$ . Conversely, if  $T \subseteq \text{Mat}_{\ell, n}$  is an  $r$ -nice set in  $\mathcal{S}_{\ell, n}$  then  $\phi^{-1}(T) = Q \cap \mathcal{V}_\ell(B)$  for some  $r$ -nice set  $Q$  in  $\mathcal{G}(\ell, n)$ .*

**Proof.** WLOG, assume that  $B = B_0$ . We will assume that  $S \subseteq \mathcal{V}_\ell$  is the set of all subspaces in  $\mathcal{V}_\ell$  contained in a subspace  $W$  of co-dimension  $r$ . The general case is analogous. Equivalently, if  $w_1, w_2, \dots, w_r$  form a basis for  $W$ , then, for every  $V \in S \cap \mathcal{V}_\ell(B)$  and ever  $v \in V$   $\langle v, w_i \rangle = 0$  for every  $i$ .

Consider the canonical basis  $v_1, v_2, \dots, v_\ell$  for  $V$  - recall that this means that the projection of  $v_i$  to the first  $\ell$  coordinates equal  $e_i$ . Thus, for every  $i$ , we can write  $v_i = (e_i, v'_i)$  for some vectors  $v'_i$  of  $n - \ell$  dimensions.

Then,  $\phi(V)$  is the matrix  $M_V$  with rows  $v'_i$  by our construction. In particular, this means that the  $M_V$  satisfies the constrain:  $M_V \cdot w_i = t_i$  where  $t_i$  is the vector with  $j$ th coordinate equal to  $\langle e_j, w_i \rangle$ . Thus, we have shown that for every  $V \in S$ ,  $\phi(V)$  satisfies a set of  $r$  affine linear equations.

Conversely, observe that if any  $M$  satisfies the affine linear equation  $M_V w_i = t_i$  as above, the set of all  $(e_i, u_i)$  for  $i \leq \ell$  where  $u_i$  is the  $i$ th row of  $M_V$ , must span a subspace in  $S$ . This yields that  $\phi(S \cap \mathcal{V}_\ell(B))$  is an  $r$ -nice set.

The converse follows from entirely similar ideas. Suppose  $T \subseteq \text{Mat}_{\ell, n}$  is an  $r$ -nice set. WLOG, we restrict to the case where  $T$  is the set of all matrices satisfying linear constraints  $M q_i = t_i$  for some choice of  $r$  linearly independent constraints  $(q_i, t_i)$ . Letting  $u_1, u_2, \dots, u_\ell$  be the rows of  $M$ , this implies that every vector  $v$  in the span of  $(e_i, u_i)$  for  $i \leq \ell$  satisfies

the linear equation  $\langle q, v \rangle = 0$  where  $q = (q_i, t_i(1), t_i(2), \dots, t_i(\ell))$ . This immediately yields that  $\phi^{-1}(M)$  is contained in a subspace  $W$  of co-dimension  $r$ . Conversely, it is easy to check that for every subspace  $V$  of dimension  $\ell$  contained in  $W \cap \mathcal{V}_\ell(B)$ ,  $\phi(V)$  satisfies the  $r$  affine linear constraints above.

This completes the proof. ◀

### 3.2 Shortcode Test vs Grassmann Test

We now employ the homomorphism constructed in the previous subsection to relate the soundness and expansion hypothesis in Short code and Grassmann tests.

First, we show that the soundness hypothesis for degree 2 Short code consistency test implies the soundness hypothesis for the Grassmann consistency test and complete the proof of Theorem 10.

► **Lemma 23.** *The degree 2 Short code soundness hypothesis (Hypothesis 13) implies the Grassmann soundness hypothesis (Hypothesis 2).*

**Proof.** Let  $F$  be the assumed labeling strategy in Hypothesis 2. We will construct a labeling strategy for  $\mathcal{S}_{\ell,n}$  from  $G$  so that we can apply the conclusion of 13. We will first choose an embedding of the type we constructed before in order to construct  $G$ .

Let  $B \sim \mathcal{B}$  be chosen uniformly at random and let  $\phi = \phi_B$  as in the previous subsection. For any  $V \in \mathcal{V}_\ell(B)$ , let  $F(V) = f$ , a linear function restricted to  $V$ . Let  $v_1, v_2, \dots, v_\ell$  be the canonical basis for  $V$ , i.e., the projection of  $v_i$  to the first  $\ell$  coordinates (when written in basis  $B$ ) equals  $e_i$  for every  $i$ . Set  $G(\phi(V)) = z$  where  $z_i = f(v_i)$ . Since  $\phi$  is onto, this defines a labeling strategy for all of  $\text{Mat}_{\ell,n}$ .

Next, we claim that if  $F$  passes the Grassmann consistency test with probability  $\eta$  then  $G$  passes the degree 2 Short code consistency test with probability  $\Omega(\eta)$ .

Before going on to the proof of this claim, observe that this completes the proof of the lemma. To see this, we first apply Hypothesis 13 to conclude that there's an  $r$ -nice set  $Q$  in  $\mathcal{S}_{\ell,n}$  and an affine function defined by  $z \in \mathbb{F}_2^{n-\ell}, u \in \mathbb{F}_2^\ell$  such that the labeling strategy  $H(M) = Mz + u$  passes the degree 2 Short code consistency test with probability  $\delta$  for all  $M$  in  $Q$ . It is easy to construct the analogous linear strategy for the Grassmann consistency test: For any  $V \in \mathcal{V}_\ell(B)$  with the canonical basis  $v_1, v_2, \dots, v_\ell$  defined above, set  $f(v_i) = u_i + \langle v_i, z \rangle$ . Extend  $f$  linearly to the span of all such vectors. Finally, extend  $f$  to all vectors by taking any linear extension. From Lemma 19,  $1/2$  the neighbors of vertices in  $\phi^{-1}(Q)$  are contained in  $\mathcal{V}_\ell(B)$ . From Lemma 22,  $\phi^{-1}(Q) = \mathcal{F} \cap \mathcal{V}_\ell(\mathcal{B})$  for some  $r$ -nice set  $\mathcal{F}$  in  $\mathcal{G}(\ell, n)$ . Finally, by an argument similar to the one in Lemma 19,  $|\mathcal{F} \cap \mathcal{V}_\ell(\mathcal{B})| \geq \otimes(|\mathcal{F}|)$  with high probability over the draw of  $B$ . Combining the above three observations yields that  $f$  passes the Grassmann consistency test when restricted to the nice set  $\mathcal{F}$  with probability  $\Omega(\delta)$ .

We now complete the proof of the claim. This follows immediately if we show that for any  $V \sim V'$  chosen from  $\mathcal{V}_\ell(B)$ ,  $\Pr_{V \sim V', V, V' \in \mathcal{V}_\ell(B)}[F(V)|_V = F(V')|_{V'}] \geq 0.07(\eta - 2^{-n+\ell})$ .

Without loss of generality, we assume that  $B$  is the standard basis  $\{e_1, e_2, \dots, e_n\}$ . First, notice that  $\text{Span}\{V \cup V'\}$  is of dimension  $\ell + 1$  for all but  $2^{-n+\ell}$  fraction of pairs  $V \sim V'$ . Thus, we can assume that  $\Pr_{V \sim V' | \dim \text{Span}\{V \cup V'\} = \ell + 1}[F(V)|_V = F(V')|_{V'}] \geq \eta - 2^{-n+\ell}$ .

Let  $C = B^{-1}$ , the basis change matrix corresponding to  $B$  and let  $C_i$  be the  $i^{\text{th}}$  row of  $C$  and let  $C_{[\ell]}$  be the matrix formed by taking the first  $\ell$  rows of  $C$ . Fix  $V \sim V'$  for some  $V, V' \in \mathcal{V}_\ell$ . Assume now that  $\text{Span}\{V \cup V'\}$  is of dimension  $\ell + 1$ . Let  $v_1, v_2, \dots, v_{\ell-1}$  be a basis for  $V \cap V'$ . Let  $V = \{V \cap V' \cup w_1\}$  and  $V' = \{V \cap V' \cup w_2\}$  for some  $w_1, w_2$  that linearly independent of each other and of any vector in  $V \cap V'$ . We estimate the probability that

$V, V' \in \mathcal{V}_\ell(B)$ . Then, this is the probability that  $v_1, v_2, \dots, v_{\ell-1}, w_1, w_2$  are mapped by  $C^{[\ell]}$  into  $a_1, a_2, \dots, a_{\ell-1}, a_\ell, a_{\ell+1}$  respectively, satisfying  $a_\ell, a_{\ell+1} \notin \text{Span}\{a_i \mid i \leq \ell-1\}$ . It is easy to check that the probability of this over the random choice of  $B$  is at least  $0.288 * 1/4 > 0.07$ . This proves the claim.

By taking  $n$  large enough (compared to  $\ell$ ), this probability can be made larger than, say,  $0.06\eta$  (say). This finishes the proof.  $\blacktriangleleft$

Next, we show that the Grassmann Expansion Hypothesis (Hypothesis 6) is equivalent to the Shortcode Expansion Hypothesis (Hypothesis 8) and complete the proof of Theorem 11.

► **Lemma 24.** *The Grassmann Expansion Hypothesis (Hypothesis 6) is equivalent to the Shortcode Expansion Hypothesis (Hypothesis 8).*

**Proof.** First, we show that Hypothesis 6 implies Hypothesis 8.

Let  $S \subseteq \text{Mat}_{\ell,n}$  be such that  $\Pr_{M \sim S, a \in \mathbb{F}_2^\ell, b \in \mathbb{F}_2^n} [M + ab^\top \in S] = \eta$ . Then, by Lemma 20,  $\phi_B^{-1}(S)$  has an expansion of  $\Omega(\eta)$  in  $\mathcal{G}(\ell, n)$ .

Applying the Grassmann expansion hypothesis (Hypothesis 6), we know that there exists a  $r$ -nice set  $\mathcal{F}$  in  $\mathcal{G}(\ell, n)$  such that  $|\mathcal{F} \cap \phi_B^{-\infty}(S)| \geq \delta|\mathcal{F}|$ . Further, since  $\phi_B^{-1}(S) \subseteq \mathcal{V}_\ell(B)$ , we must have:  $|(\mathcal{F} \cap \mathcal{V}_\ell(B)) \cap \phi_B^{-\infty}(S)| \geq \delta|\mathcal{F} \cap \phi_B^{-\infty}(S)|$ . To finish, observe that by Lemma 22,  $\phi(\mathcal{F} \cap \phi_B^{-\infty}(S))$  is an  $r$ -nice set, say  $\mathcal{Q}$  in  $\mathcal{S}_{\ell,n}$ . This, show that  $|S \cap \mathcal{Q}| \geq \delta|\mathcal{Q}|$  completing the proof.

The proof of the other direction, that is, Hypothesis 8 implies Hypothesis 6, is analogous and relies on the use of Lemma 21.  $\blacktriangleleft$

## Abstract

Entangled games are a quantum analog of constraint satisfaction problems and have had important applications to quantum complexity theory, quantum cryptography, and the foundations of quantum mechanics. Given a game, the basic computational problem is to compute its *entangled value*: the supremum success probability attainable by a quantum strategy. We study the complexity of computing the (commuting-operator) entangled value  $\omega^*$  of entangled XOR games with any number of players. Based on a duality theory for systems of operator equations, we introduce necessary and sufficient criteria for an XOR game to have  $\omega^* = 1$ , and use these criteria to derive the following results:

1. An algorithm for symmetric games that decides in polynomial time whether  $\omega^* = 1$  or  $\omega^* < 1$ , a task that was not previously known to be decidable, together with a simple tensor-product strategy that achieves value 1 in the former case. The only previous candidate algorithm for this problem was the Navascués-Pironio-Acín (also known as noncommutative Sum of Squares or ncSoS) hierarchy, but no convergence bounds were known.
2. A family of games with three players and with  $\omega^* < 1$ , where it takes doubly exponential time for the ncSoS algorithm to witness this. By contrast, our algorithm runs in polynomial time.
3. Existence of an unsatisfiable phase for random (non-symmetric) XOR games. We show that there exists a constant  $C_k^{\text{unsat}}$  depending only on the number  $k$  of players, such that a random  $k$ -XOR game over an alphabet of size  $n$  has  $\omega^* < 1$  with high probability when the number of clauses is above  $C_k^{\text{unsat}} n$ .
4. A lower bound of  $\Omega(n \log(n) / \log \log(n))$  on the number of levels in the ncSoS hierarchy required to detect unsatisfiability for most random 3-XOR games. This is in contrast with the classical case where the  $(3n)^{\text{th}}$  level of the sum-of-squares hierarchy is equivalent to brute-force enumeration of all possible solutions.

## 1 Introduction

Constraint satisfaction problems (CSPs) are a fundamental object of study in theoretical computer science. In quantum information theory, there are two natural analogues of CSPs, which both play important roles: local Hamiltonians and (our focus) non-local games. Non-local games originate from Bell’s pioneering 1964 paper, which showed how to test for quantum entanglement in a device with which we can interact only via classical inputs and outputs. In modern language, the tests developed by Bell are games: a referee presents two or more players with classical questions drawn from some distribution and demands answers from them. Each combination of question and answers receives some score and the players cooperate (but may not communicate) to maximize their expected score. These games are interesting because often the players can win the game with a higher probability if they share an entangled quantum state, so a high average score can certify the presence of quantum entanglement. Such tests are not only of scientific interest, but have had wide application to proof systems [8, 19], quantum key distribution [1, 13, 29], delegated computation [26], and randomness generation [10], among others.

To be able to use a nonlocal game as a test for entanglement, it is essential to be able to approximately compute two quantities: the best possible expected score when the players share either classical correlations or entangled states, respectively called the “classical” and “quantum” (or “entangled”) values of the game, and denoted  $\omega$  and  $\omega^*$ . Classically, our understanding of the complexity of computing  $\omega$  rests on the intimate connection between games and CSPs. Indeed, there are several natural ways to map a CSP into a game. Perhaps the most commonly used is the “clause-variable game,” in which a CSP of any arity  $k$  is mapped to a two-player game, where one player is asked for the assignment to a clause of the CSP, and the other for the assignment to a single variable. However, there is another natural yet perhaps less-studied reduction that maps a  $k$ -ary CSP to a  $k$ -player nonlocal game, which moreover is symmetric under exchange of the players. In this reduction, given a CSP with a  $k$ -ary predicate, the referee of the game chooses uniformly at random a single clause, consisting of a  $k$ -tuple of variables and set of accepted assignments. The referee will then ask each of the  $k$  players for the value of one of the  $k$  variables in the clause, and accept if and only if the returned values constitute an accepted assignment to the clause. Classically, a simple convexity argument shows that the players can always stick to *deterministic* strategies, where each question is assigned a fixed answer, and for odd  $k$ ,

it is easy to show that there is a close relation between  $\omega$  and the CSP value: if the CSP has value 1 (i.e. all clauses are satisfiable),  $\omega = 1$ , and if its value is at most  $1 - \delta$ , then  $\omega \leq 1 - \delta/k$ . Hence, thanks to various dichotomy theorems, we have a good understanding of the difficulty of computing  $\omega$  for symmetric games<sup>5</sup>: in some cases, we know a P algorithm, and for most others, we know it is NP-complete. In particular, thanks to [18], this is known even for games where the referee’s acceptance depends only the XOR of single-bit answers from the players. Such games are known as XOR games.

The hardness of computing quantum value  $\omega^*$  is not as well understood, both in terms of upper and lower bounds. We know striking examples of quantum “advantage” (i.e. cases where the quantum value of a game is higher than the classical value), such as a Magic Square game, a game arising from an unsatisfiable CSP which nevertheless has an entangled strategy that succeeds with certainty, and thus quantum value  $\omega^* = 1$ . This advantage is also the main obstacle to our understanding, in that the set of entangled strategies is very rich: the “assignment” to each variable is no longer a value from a discrete set, but a linear operator over a Hilbert space of potentially unbounded dimension. Indeed, if infinite-dimensional entanglement is allowed, then depending on how one implements the requirement of non-communication between the players, one can obtain two different notions of entangled value – the tensor product value  $\omega_{TP}^*$  and the commuting operator value  $\omega_{CO}^*$  – which are not known to be equal.

As a result of the difficulties of unbounded-dimensional entanglement, we can say very little in terms of upper bounds on the complexity of computing either version of  $\omega^*$ , and in fact, it is not known whether even a constant-factor (additive) approximation to either is Turing-computable. For general games, the best we can say is they are recursively enumerable: for  $\omega_{TP}^*$ , there is a straightforward brute-force search over all strategies that in the limit of infinite time converges from below, and for  $\omega_{CO}^*$ , there is an algorithm, called the NPA or ncSoS hierarchy [22, 11], that in the limit of infinite time converges from above, but with no bound on the speed of convergence for either algorithm. On the hardness side, what we know is based on exploiting the CSP-game connection outlined above, but technically this has proved significantly more challenging than in the classical case. For instance, it was shown by Vidick that in the worst case, computing a constant-factor approximation to  $\omega_{TP}^*$  for 3-player XOR games is NP-hard [30], matching the classical hardness of [18], but this required redoing the soundness analysis of a PCP construction in the presence of entanglement. For general (non-XOR) games and tighter approximations we have super-classical hardness results [20, 21, 14]. Moreover, families of games with a “clause-variable” structure have been found for which deciding whether  $\omega^* = 1$  is uncomputable [27]. At the same time, we know that for certain families of games,  $\omega^*$  is easy to compute. Perhaps the best understood case is two-player XOR-games, for which Tsirelson showed that a simple semidefinite program (the lowest level of the ncSoS) exactly computes  $\omega_{CO}^* = \omega_{TP}^*$ , in contrast to the classical case where  $\omega$  for such games is NP-hard to approximate. A second family of games where results are known is XOR games with a maximum of two questions per player, but any number of players. Here there is a classification of all correlations achievable by quantum players, as well as a description of the measurement strategy players use to achieve these correlations. Interestingly, we arrive at the same measurement strategy later in this work through independent techniques.

---

<sup>5</sup> Classically, there are simple reductions from the general case to the symmetric case, but as we discuss below, these fail to preserve completeness in the presence of entanglement.

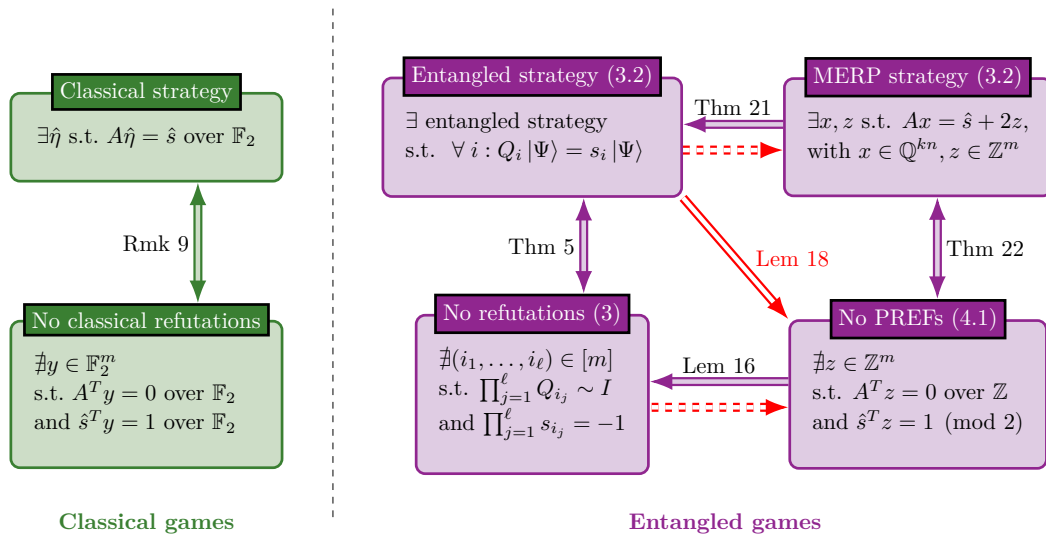

From the preceding results, XOR games emerge as a natural class of games to understand on the road to a full “dichotomy theorem” for quantum games. Classically, XOR games are also convenient to analyze because of their linear structure: a  $k$ -player XOR game represents a CSP whose clauses are linear equations over the finite field  $\mathbb{F}_2$ , each containing  $k$  variables. As a result, classically XOR games are always easy in the “perfect completeness” regime: we can determine whether an XOR game is perfectly satisfiable in polynomial time using Gaussian elimination over  $\mathbb{F}_2$ , even though distinguishing  $\geq 1 - \varepsilon$  satisfiability from  $\leq \frac{1}{2} + \varepsilon$  satisfiability is NP-complete. This linear structure also makes it easy to reason about the classical value of random instances of XOR games using linear algebra. However, this simple linear structure does not capture entangled strategies and neither the Gaussian elimination algorithm for the perfect completeness regime, nor the classical analysis of random instances generalizes easily to the quantum case. Indeed, the undecidability result of [27] applies to the perfect completeness regime for games based on systems of linear equations, though these systems are not over  $\mathbb{F}_2$  and the games are in the two-player “clause-variable” format. Is the perfect completeness regime for quantum XOR games easy, as in the classical case, or hard, as suggested by Slofstra’s results? And what can we say about random instances?

In this work, we make progress on these questions for the subclass of *symmetric* XOR games: those for which the game remains invariant under any permutation of the players. This class of games includes those arising from CSPs via the reduction described above, as well as the hard instances of [30]. Our main results are captured by the following theorem.

► **Theorem 1** (Theorems 14 and 15 in the body). *A symmetric  $k$ -player XOR game has entangled value  $\omega_{CO}^* = \omega_{TP}^* = 1$  if and only if an associated system of linear Diophantine equations has no solution. This condition can be checked in polynomial time, and whenever it is satisfied, the perfect tensor-product strategy can be found in polynomial time. When it is not satisfied, a succinct description of an ncSoS dual certificate that  $\omega^* < 1$  can be found in polynomial time (even though the certificate may be exponentially long).*

We achieve these results by viewing an XOR game as a “non-commuting” generalization of linear systems of equations, in which the expectation of differences between products of operator-valued variables and plus or minus the identity operator are constrained to be zero. We develop a “duality theory” for these systems of operator equations, where the dual certificates of infeasibility correspond to a special class of ncSoS proofs which we call “refutations.” For symmetric games, we show that a dual certificate exists if and only if a certain system of linear Diophantine equations has a solution (which we call a “PREF”). An important feature of our algorithm is that while it is inspired by ncSoS, its performance can be significantly superior: it can detect in polynomial time the existence of an exponentially long ncSoS dual certificate. Indeed, we show (in Theorem 23) a concrete family of games where our algorithm can detect that  $\omega^* < 1$  in time which scales polynomially in the game size  $n$ , whereas ncSoS takes doubly exponential time. We believe this result may be interesting in its own right to those who study the Sum of Squares algorithm, and hope that our techniques inspire further efficient algorithms that “simulate” high levels of SoS. Additionally, by further considering the dual of the system of Diophantine equations we construct, we are able to extract a simple finite-dimensional (and hence tensor product) strategy (which we call “MERP”) that achieves  $\omega_{TP}^* = \omega_{CO}^* = 1$  whenever the system of equations has a solution. A diagram illustrating the dualities we use is given in Figure 1.

Our notion of refutation is similar to the “substitution method” in the prior work of [9], used there to analyze clause-variable style games (there called Binary Constraint System Games) in the perfect-completeness regime. However, the connection we show between refutations and linear Diophantine equations, which is the heart of our efficient algorithm for

**Figure 1** We extend the well-understood duality relation for classical XOR games (left) to a more complex set of dualities characterizing perfect strategies for entangled XOR games (right). The arrows indicate implications, with the red, unfilled arrows holding for symmetric games only. The dashed red arrows follow from the key lemma for symmetric games. Definitions and notation are developed in the remaining sections.

searching over refutations, is new to this work and makes essential use of the properties of symmetric XOR games. We consider it an interesting open question whether our techniques could be adapted to the Binary Constraint System case.

The symmetry condition on the game is important to our analysis, and it is worth going into some detail as it presents an interesting divergence from the classical case. Classically, any game can be symmetrized as follows: for each clause consisting of questions  $(q^{(1)}, \dots, q^{(k)})$  asked to players  $1, \dots, k$ , the referee chooses a random permutation  $\pi$  of  $\{1, \dots, k\}$ , and sends player  $i$  the pair  $(\pi(i), q^{(\pi(i))})$ . Each player  $i$  then follows the same strategy that player  $\pi(i)$  would have used in the original, unsymmetrized game. In the quantum setting, this transformation fails to preserve completeness: for instance, if an entangled strategy for a three-player unsymmetrized game requires players 1 and 2 to share entanglement, in the symmetrized version, a player receiving the index 1 does not know which other player received index 2, and thus does not know who to be entangled with. This can be understood as an instance of the phenomenon of *monogamy*, which distinguishes entanglement from classical correlations. It is an interesting question for future work to extend our methods to the nonsymmetric case.

Furthermore, as alluded to earlier, our algorithm yields an understanding of the typical value of a random symmetric XOR game. Classically, research in this direction draws significantly on insights from statistical mechanics and has proven that there exist sharp satisfiable/unsatisfiable thresholds for random  $k$ -SAT and related games. But these techniques do not carry over to the quantum case. For random classical games, a basic method is to look at the expected number of winning strategies (the “first moment method”) or the variance (the “second moment method”) as we randomize the referee’s payoff function within some family such as random  $k$ -SAT or random  $k$ -XOR. This suffices, for example, to show that random 3-XOR games with  $n$  variables and  $Cn$  clauses are satisfiable with high probability if and only if  $C \lesssim 0.92$  [12]. Since quantum strategies do not form a discrete (or even finite-dimensional)

set, these methods are not possible. Nor is it obvious how to use more refined tools such as Shearer’s Lemma or the Lovász Local Lemma, which address the question of when sets of overlapping constraints can be simultaneously satisfied. Our duality theory enables us to avoid these obstacles by studying refutations, rather than strategies. Refutations are discrete objects and thus are more amenable to combinatorial and probabilistic techniques. Using our techniques we are able to prove that random quantum XOR games have an unsatisfiable phase above a certain clause density.

► **Theorem 2** (Theorem 26 in the body). *For every  $k$ , there exists a constant  $C_k^{unsat}$  depending only on  $k$  such that a random  $k$ -XOR game  $G$  with  $m \geq C_k^{unsat}n$  clauses has value  $\omega^*(G) < 1$  with probability  $1 - o(1)$ .*

In our overall approach in this paper, we were inspired by the work of Grigoriev [17], who studied the power of SoS refutations for random classical XOR games. We view Theorem 2, together with the ncSoS lower bounds of Theorem 23, as a quantum generalization of Grigoriev’s results.

## 2 XOR Games

We begin by defining a  $k$ -XOR game, along with its classical and quantum values.

► **Definition 3.** Define a **clause**  $c = (q, s)$  to be any  $(k + 1)$ -tuple consisting of a **query**  $q \in [n]^k$  and **parity bit**  $s \in \{-1, 1\}$ .

In a  $k$ -XOR game  $G$  associated with a set of clauses  $M$ , a verifier selects a clause  $c_i = (q_i, s_i)$  uniformly at random from  $M$ . For all  $\alpha \in [k]$ , the **question**  $q_i^{(\alpha)}$  is then sent to the  $\alpha$ -th player of the game. Without communicating, the players then each send back a single output  $\in \{-1, 1\}$ , and win the game if their outputs multiply to  $s_i$ .

The GHZ game [16] is a canonical example of a 3-XOR game. It is defined by the clauses (here we use the labels  $\{x, y\}$  for the questions instead of the typical  $\{1, 2\}$ ):

$$G_{GHZ} := \left\{ \begin{array}{l} \left[ \begin{array}{c} x \\ x \\ x \\ +1 \end{array} \right], \left[ \begin{array}{c} y \\ y \\ x \\ -1 \end{array} \right], \left[ \begin{array}{c} y \\ x \\ y \\ -1 \end{array} \right], \left[ \begin{array}{c} x \\ y \\ y \\ -1 \end{array} \right] \end{array} \right\} \begin{array}{l} \leftarrow \text{Player A} \\ \leftarrow \text{Player B} \\ \leftarrow \text{Player C} \\ \leftarrow \text{Desired product} \end{array} \quad . \quad (1)$$

There is a natural reduction from a  $k$ -CSP over  $\mathbb{F}_2$  to a  $k$ -XOR game, based on the isomorphism between the groups  $(\{0, 1\}, +_{\text{mod } 2})$  and  $(\{1, -1\}, \times)$ . The XOR game corresponding to a CSP has clauses defined by picking a clause from the CSP at random, sending each player a question corresponding to a random distinct variable from the CSP clause, then choosing a parity bit by demanding that players’ answers satisfy the CSP. Games constructed from CSPs in this manner are symmetric over permutation of the players, and are therefore called **symmetric games**.

By excluding communication during the game, the classical game tests whether the players have cooperatively solved the CSP before the questioning began. When the players are given access to quantum resources, the game instead probes “quantum solutions” to the CSP, described by measurements of a shared state in some Hilbert space.

The **value** of that game is defined to be the optimal win probability obtained by the players. We distinguish various possible classes of resources that may be made available to the players in executing a strategy, each of which defines a particular type of value.

► **Definition 4.** We define three versions of the value of game  $G$ .

1. The **classical value**  $\omega(G)$  is the value achievable by players using only classical shared information.
2. The **tensor-product value** is the value obtainable by players sharing a quantum state but restricted to making measurements on distinct factors of a tensor-product Hilbert space. Intuitively, this is a no-communication condition described in Hilbert-space language.
3. The **commuting-operator value**<sup>6</sup>  $\omega^*(G)$  is the value obtainable by players making commuting measurements on a shared quantum state. Intuitively, this is a weaker form of the no-communication constraint, permitting states living in non-separable Hilbert spaces.

When a CSP is reduced to an XOR game  $G$ , the classical value roughly corresponds to the fraction of satisfiable constraints, with  $\omega(G) = 1$  if and only if the CSP is satisfiable. Sharing a quantum state may allow the players to provide a quantum solution ( $\omega^* = 1$ ) even when  $\omega \neq 1$ . Famously, the GHZ game is a symmetric game that corresponds to a test of the classically-unsatisfiable, yet quantumly-soluble CSP:

$$x + x + x = 0 \pmod{2} \quad \text{and} \quad x + y + y = 1 \pmod{2}. \quad (2)$$

Games (such as the GHZ game) that satisfy  $\omega < 1$  and  $\omega^* = 1$  are called **pseudo-telepathy games**. Identifying other XOR pseudo-telepathy games is one of the motivating goals of this work.

For a given game, the set of values achievable by tensor-product strategies may not be closed [27]. Whether the closure of this set can differ from the commuting-operator value of the game remains unanswered<sup>7</sup>. In this paper, we focus primarily on a description of the commuting-operator value but in many cases can show that it coincides with the tensor-product value.

### 3 Refutations

A main aim of this paper is to characterize the set of XOR games with commuting-operator value  $\omega^* = 1$ . In the case of  $k = 2$  players, Tsirelson gave an efficient semidefinite program that computes the exact value of  $\omega^*$ ; however, this technique does not generalize easily to  $k \geq 3$  [6, 28]. Furthermore, the potentially unbounded size of the players' resource state makes it impossible to upper bound the value of a game via brute force search over strategies.

To avoid these problems, this work introduces a dual characterization that certifies games with value  $\omega^* < 1$ . This is a natural generalization of a well-understood dual system of equations that certifies games with classical value  $\omega < 1$ , and employs operator language similar to the quantum satisfying assignments for Binary Constraint System games presented in [9]. The dual pictures in both the classical and commuting-operator cases introduce the notion of a “refutation”: intuitively, a sequence of game clauses that together contradict the existence of a value-1 strategy. We show Theorem 5 that refutations are dual to  $\omega^* = 1$ ; our proof can be viewed as a quantum generalization of [17].

<sup>6</sup>  $\omega^*(G)$  is often also referred to as the field-theoretic value of  $G$ .

<sup>7</sup> And hard! For general two-player games this question is known to be equivalent to Connes' embedding conjecture [15].

► **Theorem 5** (Strategy-Refutation Duality). *An XOR game  $G$  has commuting-operator value  $\omega^*(G) = 1$  if and only if it admits no refutations.*

We first take a small detour into the classical duality picture to build intuition and necessary notation (Section 3.1), then describe refutations and outline the proof of duality in the quantum case (Section 3.2).

### 3.1 Classical Strategies and Refutations

Classically, refutations emerge naturally from the linear-algebraic dual to the equations satisfied by a classical value-1 strategy.

For any game, the optimal classical strategy can be specified via a map  $[kn] \rightarrow \{1, -1\}$  giving a deterministic answer to each possible question given to each player. In order to use linear algebraic tools, we exploit the isomorphism  $(\{1, -1\}, \times) \sim (\{0, 1\}, +_{\text{mod } 2})$  and specify a classical strategy via a vector  $\hat{\eta} \in \mathbb{F}_2^{kn}$ . Explicitly:  $\hat{\eta}_{(\alpha-1)n+j} = 0$  if player  $\alpha$  responds to question  $j$  with a 1, and equals 1 if the player responds with a  $-1$ . To clearly specify the player and question, we use the notation

$$\hat{\eta}(\alpha, j) := \hat{\eta}_{(\alpha-1)n+j}.$$

From this point on, we will freely switch back and forth between an additive and a multiplicative representation of strategies, leaving the mapping implicit.

To complete the linear algebraic picture, we also define a vector of desired outputs  $\hat{s}$  and a game matrix  $A$ . The game matrix is defined such that given a strategy vector  $\hat{\eta}$ , the parities of the outputs for each clause are given by the vector  $A\hat{\eta}$ .

► **Definition 6.** Given a  $k$ -XOR game with  $m$  queries and alphabet size  $n$ , the **game matrix**  $A$  is an  $m \times kn$  matrix describing query-player-question incidence, and the length- $m$  **parity bit vector**  $\hat{s} \in \mathbb{F}_2^m$  the desired outputs:

$$A_{i,(\alpha-1)n+j} := \begin{cases} 1 & \text{if } q_i^{(\alpha)} = j \\ 0 & \text{otherwise} \end{cases} \quad \text{and} \quad \hat{s}_i := \begin{cases} 0 & \text{if } s_i = 1 \\ 1 & \text{if } s_i = -1 \end{cases}. \quad (3)$$

An XOR game  $G$  is completely specified by providing the game matrix  $A$  and parity bit vector  $\hat{s}$ , i.e.  $G \sim (A, \hat{s})$ . For example, we translate the GHZ queries into  $A_{GHZ}$  and parity bits into  $\hat{s}_{GHZ}$  by:

$$\implies A_{GHZ} := \left( \begin{array}{c|c|c} (A) & (B) & (C) \\ \hline 1 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 0 \end{array} \right) \quad \text{and} \quad \hat{s}_{GHZ} := \begin{pmatrix} 0 \\ 1 \\ 1 \\ 1 \end{pmatrix}. \quad (4)$$

A linear-algebraic constraint for achieving classical value 1 can then be defined by asking that a strategy exists that outputs the desired  $\hat{s}$ .

► **Definition 7.** The **classical constraint equation** for strategy  $\hat{\eta}$  on game  $G \sim (A, \hat{s})$  is

$$A\hat{\eta} = \hat{s} \quad (\text{over } \mathbb{F}_2). \quad (5)$$

The solutions to (5) are exactly the classical strategies achieving value 1 on game  $G \sim (A, \hat{s})$ . In other words, a game  $G$  has classical value 1 iff (5) has a solution. Gaussian elimination can be used to check for a solution to (5), so we can decide whether a game has  $\omega = 1$  in P. Even so, transforming to the dual picture provides a useful analog to the quantum case.

► **Definition 8.** Define a **classical refutation**  $y \in \mathbb{F}_2^m$  as any vector satisfying the equation dual to (5),

$$\begin{bmatrix} A^T \\ \hat{s}^T \end{bmatrix} y = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \quad (\text{over } \mathbb{F}_2). \quad (6)$$

► **Theorem 9.** *Either a classical refutation  $y$  satisfying (6) or a classical strategy  $\hat{\eta}$  satisfying (5) must exist.*

**Proof.** Immediate from the observation that equations (5) and (6) are dual. ◀

A refutation  $y$  has a direct interpretation as a certificate that  $\omega < 1$ : collecting constraints from clauses  $i$  corresponding to non-zero entries  $y_i$  produces a contradiction to the value-1 hypothesis. To understand this, note that satisfying clause  $i$  requires that the  $i$ th row of (5) is true under strategy  $\hat{\eta}$ ,

$$\begin{aligned} [A\hat{\eta}]_i &= \hat{s}_i \\ \Leftrightarrow \sum_{\alpha} \hat{\eta}(\alpha, q_i^{(\alpha)}) &= \hat{s}_i \pmod{2}. \end{aligned}$$

Summing the value-1 constraints selected by  $y$  (left-multiplication by  $y$ ) produces the desired contradiction when  $y$  satisfies (6),

$$\begin{aligned} \sum_{i:y_i=1} \sum_{\alpha} \hat{\eta}(\alpha, q_i^{(\alpha)}) &= \sum_{i:y_i=1} \hat{s}_i \\ \Leftrightarrow y^T A\hat{\eta} &= y^T \hat{s} \pmod{2} \\ \implies 0 &= 1 \pmod{2}. \end{aligned}$$

This interpretation is key to generalizing refutations to the commuting-operator value of XOR games.

### 3.2 Commuting-Operator Strategies and Refutations

Whereas classical strategies are specified by assigning deterministic output to every player-question pair, commuting-operator strategies are specified by assigning a  $\pm 1$  valued quantum measurement to every player-question pair and fixing some entangled state shared by the players. Each player then executes a commuting-operator strategy by selecting the measurement corresponding to the question they receive, then returning the result of applying it to the shared state.

Using the Naimark dilation theorem, we can restrict the measurements in the players' strategies to be Projection-Valued Measures (PVMs). This is the quantum mechanical analogue of the statement that the optimal classical strategy can be taken to be deterministic. In the case of XOR games, this means the measurements can be chosen to be a pair of projectors  $\{O_1, O_{-1}\}$  that partition the space into two subspaces, corresponding to outputs 1 and  $-1$ . We make this restriction for the remainder of the paper.

All that remains is to enforce the no communication requirement on the quantum players. This is done in one of two possible ways. In tensor product strategies the Hilbert space in which  $|\Psi\rangle$  lives is taken to be separable, with different players' measurements acting on disjoint parts of the state. In commuting-operator strategies no restriction is placed on the Hilbert space, but the Hermitian matrices corresponding to different players' measurements are forced to commute. (These two restrictions are distinct only in the case of an infinite dimensional Hilbert space). In this paper we work exclusively with the commuting-operator definition, though all the explicit strategies we construct are also valid tensor product strategies.

## 10:10 Algorithms, Bounds, and Strategies for Entangled XOR Games

Putting this all together, we can define for any strategy the observables corresponding to the players' measurements.

► **Definition 10.** Given a commuting-operator strategy consisting of measurements  $\{O_1^\alpha(j), O_{-1}^\alpha(j)\}$  for each possible question  $j$  and player  $\alpha$ , define the Hermitian **strategy observable** for player  $\alpha$  upon receiving question  $j$

$$O^\alpha(j) := O_1^\alpha(j) - O_{-1}^\alpha(j). \quad (7)$$

Operators  $O^\alpha(j)$  can equivalently be chosen without reference to particular PVMs by taking any set of Hermitian operators that satisfy the constraints (for all players  $\alpha \neq \beta$  and questions  $j, j'$ )

$$[O^\alpha(j), O^\beta(j')] = 0 \quad (\text{operators held by distinct players commute}) \quad (8a)$$

$$(O^\alpha(j))^2 = I \quad (\text{square identity, enforcing } \pm 1 \text{ eigenvalues}). \quad (8b)$$

This abstract definition of strategy observables will be the one most frequently referenced in the remainder of this paper.

Given Hermitian observables, the condition for commuting-operator strategies to achieve value 1 is an eigenvalue condition, generalizing (5).

► **Definition 11.** For a  $k$ -XOR game  $G$ , define the **commuting-operator constraint equations**:

$$\forall i \in [m] : \quad Q_i |\Psi\rangle = s_i |\Psi\rangle \quad (9)$$

where the **query observable**  $Q_i := \prod_\alpha O^\alpha(q_i^{(\alpha)})$  is the product of all players' observables for the  $i$ th query.

A strategy achieving value  $\omega^* = 1$  must be played on a state  $|\Psi\rangle$  which is an eigenvector of every query observable, with appropriate eigenvalue, to ensure zero probability of outputting an incorrect response to some query. This eigenvalue criterion guarantees that the players win all queries. A game  $G$  therefore has commuting operator value  $\omega^* = 1$  iff there exists some state and strategy observables that satisfy (8) and (9).

While there is an efficient algorithm to solve the classical constraint equations, no such algorithm is known to exist for the commuting-operator constraint equations. Indeed, there is no known upper bound on the dimension of the Hilbert space required to optimally play an entangled game, meaning the search space of the commuting-operator equations is not finite, and the equations themselves may be undecidable. To work around this we develop refutations to characterize the commuting-operator value of XOR games. This technique gives a search space which is still infinite, but is at least discrete, allowing for some progress to be made via combinatorial analysis.

We would like to construct a dual to the commuting-operator constraint equations, meaning a certificate for the unsatisfiability of (9). As there is no immediate analogue to the linear algebraic methods used in the classical case, we instead generalize the view of a refutation as a collection of clauses producing a contradiction (similar to (6)). At a high level, refutations are obtained by multiplying together constraints of the form (9) and applying the known operator identities of (8a) and (8b) to arrive at an equation of the form  $I |\Psi\rangle = -|\Psi\rangle$  which cannot be true for a normalized quantum state.<sup>8</sup>

<sup>8</sup> Importantly, the order in which the constraint equations are multiplied matters, as two distinct commuting-operator strategy observables with the same player label may not commute. Further, the same constraint equation may need to be incorporated multiple times before one can arrive at a contradiction.

To formally define a refutation, we use an equivalence relation between possible strings of strategy observables on the LHS of an equation of the form (9).

► **Definition 12.** Let  $Z_1$  and  $Z_2$  be two operators formed from products of strategy observables. We say  $Z_1$  is equivalent to  $Z_2$ , written  $Z_1 \sim Z_2$ , if  $Z_1 = Z_2$  is an identity for all strategy observables satisfying (8).

Definitions 11 and 12 then allow us to precisely define a (quantum) refutation, analogous to Definition 8. From now on, a “refutation” will be a quantum refutation unless otherwise specified.

► **Definition 13.** Let  $G$  be some  $k$ -XOR game with  $m$  clauses. A **refutation for  $G$**  is defined to be a sequence of clause indices  $(i_1, i_2, \dots, i_\ell) \in [m]^\ell$  satisfying

$$Q_{i_1} Q_{i_2} \dots Q_{i_\ell} \sim I \quad \text{and} \quad s_{i_1} s_{i_2} \dots s_{i_\ell} = -1. \quad (10)$$

Assuming the value-1 hypothesis and combining the  $\ell$  constraint equations satisfying (10) then gives the desired contradiction,  $I|\Psi\rangle = -|\Psi\rangle$ . Whether a product of queries  $Q_{i_1} Q_{i_2} \dots Q_{i_\ell}$  is equivalent to  $I$  can be efficiently checked by collecting each player’s operators using (8a) and repeatedly applying (8b) to greedily cancel operators.

Refutations certify that  $\omega^* < 1$  analogously to the way that classical refutations certify that  $\omega < 1$ . We prove in the full paper that the converse is also true, completing the proof of Theorem 5. The proof of this fact relies on a connection between refutations and the ncSoS hierarchy analogous to a connection made by Grigoriev [17] between classical refutations and the SoS hierarchy. In particular, we show the ncSoS algorithm takes time exponential in the minimum length refutation to prove a game has value  $\omega^* < 1$ . Theorem 5 then follows from completeness of ncSoS.

It is not obvious that one can find refutations more easily than one can find strategies. The remaining results focus primarily on subclasses of XOR games for which we can apply the refutations picture to exactly characterize the games with  $\omega^* = 1$ . In particular, we identify an easily-computed stronger refutation condition that is complete for symmetric games, i.e. those naturally corresponding to CSPs. Subsequently we analyze specific families of games that give bounds on the behavior of ncSoS and insight into the structure of the XOR game landscape.

## 4 Symmetric Games

The refutation technology developed above gives surprisingly powerful results when applied to symmetric games. In particular, we show:

► **Theorem 14.** *Membership in the set of symmetric games with  $\omega^* = 1$  can be efficiently decided via a system of linear Diophantine equations.*

Previously the question of whether symmetric games took value 1 was not known to be decidable. Theorem 14 affirms that it is decidable and in fact in P. We prove the theorem by introducing a simple necessary condition for refutations to exist, then showing the structure of symmetric games ensures this condition is also sufficient for a refutation.

Games that do not satisfy this necessary condition have value  $\omega^* = 1$ . By returning to duality arguments, we further show that they can be played optimally by a simple family of strategies.

► **Theorem 15.** *Any value-1 symmetric game can be played optimally by a single qubit strategy using a GHZ resource state. Furthermore, this strategy can be found in polynomial time.*

#### 4.1 A Necessary Condition for Refutation (PREF)

Any valid refutation involves a product of query observables that cancel to  $I$  via the square identity (8b). Focusing on the strategy observables corresponding to one player, we see every operator at an even depth in the sequence must cancel with one at an odd depth. Given any sequence of query observables we can count the number of copies of  $O^\alpha(j)$  at odd and even depths – if the sequence corresponds to a refutation the counts must be equal. Then for any given game, it is necessary to be able to construct some sequence of queries  $Q_{i_1} \dots Q_{i_\ell}$  satisfying this counting equality (with appropriate parity  $s_{i_1} \dots s_{i_\ell} = -1$ ) in order to construct a true refutation. We call such a sequence a **parity-permuted refutation (PREF)**.

To prove properties of such PREFs, we find it useful to introduce a freer equivalence relation  $\overset{\mathcal{L}}{\sim}$  on strings of queries that allows reordering within the even positions and the odd positions before cancellation (compare to Definition 12). A PREF is then a string of clauses  $(i_1, \dots, i_\ell)$  satisfying  $Q_{i_1} \dots Q_{i_\ell} \overset{\mathcal{L}}{\sim} I$  and the same parity-bit requirement as a regular refutation. In later sections, we carefully define and use a technical version of  $\overset{\mathcal{L}}{\sim}$ , but here simply state that  $\overset{\mathcal{L}}{\sim}$  is a more inclusive equivalence relation than  $\sim$ , which immediately gives Lemma 16.

► **Lemma 16** (Necessary condition for refutation). *If a game  $G$  admits a refutation, it contains a PREF.*

We define **noPREF games** to be those games that do not admit a PREF. These games admit no true refutations by the previous lemma, and so have  $\omega^* = 1$ . Whether or not a game contains a PREF is efficiently decidable by checking for a solution to a linear system of equations. We sketch the algorithm that decides membership, delegating a rigorous proof to the full paper.

► **Lemma 17** (Informal). *Membership in the set of noPREF games can be efficiently decided by a system of linear Diophantine equations.*

**Proof (sketch).** We prove the result by showing that a game  $G \sim (A, \hat{s})$  contains a PREF if and only if there is a solution to the set of equations

$$A^T z = 0 \tag{11}$$

$$\hat{s}^T z = 1 \pmod{2} \tag{12}$$

for some  $z \in \mathbb{Z}^m$ . To prove the forward direction we note that each row of (11) guarantees that a particular player-question pair has equal positive and negative count and (12) ensures the parity bit requirement is met, such that the game  $G$  contains a PREF built by interleaving the multisets of clause indices

$$\mathcal{O} = \{i \text{ with multiplicity } |z_i| \mid \forall i : z_i > 0\} \tag{13a}$$

$$\mathcal{E} = \{i \text{ with multiplicity } |z_i| \mid \forall i : z_i < 0\} \tag{13b}$$

with their elements placed in odd and even positions, respectively. The reverse direction is proved similarly, but requires a technical lemma relating the even and odd clauses of a PREF. Then standard techniques for solving linear Diophantine equations complete the proof. ◀

Symmetric games have additional structure that allows us to prove a stronger statement.

► **Lemma 18** (Informal). *The noPREF characterization is complete for symmetric games. That is, every value 1 symmetric game is in the noPREF set.*

**Proof.** The proof of Lemma 18 is both constructive and purely combinatorial. It involves first showing that symmetric games have enough structure to construct “shuffle gadgets” which let us approximately commute strategy observables past each other. Then, careful application of these shuffle gadgets lets us transform a PREF into a true refutation. The technical proof is presented in the full paper. ◀

Theorem 14 then follows directly from Lemmas 17 and 18 since symmetric games have commuting-operator value 1 if and only if they admit no PREFs and this condition is efficiently checkable.

## 4.2 A Single Qubit Strategy (MERP)

We arrived at the noPREF classification of XOR games by generalizing the classical dual picture to the entangled games case, then finding a simple necessary condition for a dual proof (refutation) to exist. In this section we take the dual of a dual, and give a simple technique to construct a strategy that achieves value 1 for any noPREF game, thus sketching the proof of Theorem 15.

We call the resulting family of strategies **Maximal Entanglement, Relative Phase (MERP)** strategies. These strategies are exactly the class of strategies developed in [31] to optimally solve all games with alphabet size two. They are played on a  $k$  qubit  $GHZ$  state (one qubit per player), and achieve value one if and only if (Theorem 21) there is a solution to the equation

$$A\hat{\theta} = \hat{s} \pmod{2}, \quad \hat{\theta} \in \mathbb{Q}^{kn}.$$

► **Definition 19 (MERP).** Given a  $k$ -XOR game  $G$ , a **MERP strategy** for  $G$  is a tensor-product strategy in which:

1. The  $k$  players share the maximally entangled state

$$|\Psi\rangle = \frac{1}{\sqrt{2}} \left[ |0\rangle^{\otimes k} + |1\rangle^{\otimes k} \right] \tag{14}$$

with player  $\alpha$  having access to the  $\alpha$ -th qubit of the state.

2. Upon receiving question  $j$  from the verifier, player  $\alpha$  rotates his qubit by an angle  $\theta(\alpha, j)$  about the  $Z$  axis, then measures his qubit in the  $X$  basis and sends his observed outcome to the verifier.

Equivalently, we define the states

$$|\theta(\alpha, j)_{\pm}\rangle := \frac{1}{\sqrt{2}} \left[ |0\rangle \pm e^{i\theta(\alpha, j)} |1\rangle \right] \tag{15}$$

and pick strategy observables

$$O^{\alpha}(j) := |\theta(\alpha, j)_{+}\rangle\langle\theta(\alpha, j)_{+}| - |\theta(\alpha, j)_{-}\rangle\langle\theta(\alpha, j)_{-}|. \tag{16}$$

Each  $Z$  rotation executed by the players introduces a relative phase between the  $|0\rangle^{\otimes k}$  and  $|1\rangle^{\otimes k}$  components of the GHZ state, and these relative phases add. The measurement is constructed such that a total relative phase that is an even multiple of  $\pi$  results in overall output 1 while an odd multiple of  $\pi$  results in overall output  $-1$ . Collecting the rotation angles into a strategy vector

$$\hat{\theta}_{(\alpha-1)n+j} := \frac{1}{\pi} \theta(\alpha, j) \tag{17}$$

results in a useful parallel between MERP strategies and classical strategies:

► **Definition 20.** Define the **MERP constraint equations** for game  $G$  by

$$A\hat{\theta} = \hat{s} \pmod{2} \quad (18)$$

► **Theorem 21.** *The value obtained by a MERP strategy is given by*

$$v^{MERP}(G, \hat{\theta}) := \frac{1}{2} + \frac{1}{2m} \left( \sum_{i=1}^m \cos\left(\pi \left[ (A\hat{\theta})_i - \hat{s}_i \right] \right) \right). \quad (19)$$

Consequently, there exists a MERP strategy achieving  $v^{MERP} = 1$  on a game  $G$  iff its MERP constraint equations have a solution over  $\mathbb{Q}$ .

The proof of Theorem 21 is computational. For any game, Theorem 21 indicates that a MERP strategy achieves value 1 if and only if the MERP constraint equation (18) is satisfied. Similarly to the classical case, this can be efficiently checked by Gaussian elimination. Here, however, the underlying field is  $\mathbb{Q}$  as opposed to  $\mathbb{F}_2$ .

Both MERP strategies and PREF specifications are defined by linear systems of equations, over  $\mathbb{Q}$  and  $\mathbb{Z}$  respectively. Remarkably, these systems of equations are dual to each other, in much the same way as classical strategies and refutations. By showing this, we prove Theorem 22.

► **Theorem 22.** *Any game  $G$  admits either a PREF or a MERP strategy with value 1.*

**Proof.** Technical proof in the style of a Theorem of Alternatives presented in the full paper. ◀

Intuitively, this result (coupled with Lemma 18 and Theorem 21) indicates that the power of quantum solutions to noPREF games is equivalent to promoting the underlying field from  $\mathbb{F}_2$  to  $\mathbb{Q}$ . We expect further advantage to be gained from the non-commuting nature of operator-valued solutions in cases where a game admits a PREF but no true refutation. These classes of games are the main subject of future work.

Figure 1 (given in the Introduction) summarizes the new duality relations presented in this paper. We repeat them here. The general quantum duality provides a complex but complete description of games with  $\omega^* = 1$ . The PREF conditions are efficient to compute, but are only *necessary* conditions for constructing commuting-operator refutations, and thus the dual, MERP value 1, holds true for only a subset of all  $\omega^* = 1$  games. We can make a stronger statement about symmetric games: PREFs are both necessary and sufficient for a symmetric game to have a refutation, so the duality ensures MERP achieves value 1 for all symmetric games with  $\omega^* = 1$ .

## 5 ncSoS Bounds and the XOR Landscape

The refutations picture also allows us to give worst and average case bounds on the behavior of ncSoS for XOR games, and construct new families of games with interesting properties.

First, we construct a family of games that have  $\omega^* < 1$ , but are built in such a way that the ncSoS algorithm has a hard time recognizing this. Called Capped GHZ games, games in this family are symmetric and contain PREFs that all are at least exponentially long. The ncSoS algorithm<sup>9</sup> then requires time doubly exponential to prove that these games

<sup>9</sup> Our results imply that in the case of entangled XOR games the ncSoS has runtime within a polynomial factor of a brute force search over refutations up to a certain length.

have commuting-operator value  $< 1$ . This gives a rare example of a problem whose solution requires a superlinear number of levels of ncSoS, and illustrates the distinction between ncSoS and SoS, the latter always terminating after at most a linear number of levels. On the other hand, Lemma 18 tells us the existence of a PREF for this symmetric game indicates  $\omega^* < 1$ , which allows us to solve the same problem in polynomial time. This leads us to prove:

► **Theorem 23.** *There exists a family of 3-XOR games with  $\omega^* < 1$  but for which the minimum refutation length scales exponentially in the number of clauses  $m$  and alphabet size  $n$ . For these games exponentially many levels of ncSoS are needed to witness that  $\omega^* < 1$ .*

**Proof.** An explicit construction of Capped GHZ games presented in the full paper. These are symmetric games designed such that the PREF condition for these games can only be satisfied by sets containing exponentially many clauses. Since any refutation also gives a PREF, this means all refutations have at least exponential length. Finally, as a symmetric game, the existence of a PREF indicates the game has  $\omega^* < 1$ . By the connection between ncSoS and refutations, this means the ncSoS algorithm requires at least exponentially many levels to detect the game has value less than one. ◀

Returning to pseudo-telepathy, we construct a family of games that generalize the GHZ game, termed the Asymptotically Perfect Difference (APD) family. Members are parameterized by scale  $K$ , with the  $K$ -th member having  $k = 2^K - 1$  players. The APD family is designed such that any desired parity bits  $s_i$  can be produced by some strategy (the game is in the noPREF set regardless of the  $s_i$ , so  $\omega^* = 1$  for all  $s_i$ ). On the other hand, a growing fraction of possible assignments of  $s_i$  correspond to low classical value, and the family has perfect difference [4] in the asymptotic limit,  $\lim_{K \rightarrow \infty} 2(\omega^* - \omega) = 1$ . In comparison, there are randomized constructions of families of games whose bias ratio  $\frac{\omega^* - 1/2}{\omega - 1/2}$  diverges for fixed  $k \geq 3$  as  $n \rightarrow \infty$  [25, 4], but these constructions give no guarantee on the difference. Specifically, we prove it is possible to force an upper bound on  $\omega$  in terms of the number of players  $k$  while preserving  $\omega^* = 1$ :

► **Theorem 24.** *There exists a family of  $k$ -XOR games, parametrized by  $K$ , for which  $\omega^*(G(K)) = 1$  and the classical value is bounded by*

$$\frac{1}{2} \leq \omega(G(K)) \leq \frac{1}{2} + \sqrt{\frac{K+1}{2^{K+1}}} \leq \frac{1}{2} + \sqrt{\frac{\log k}{k}}. \quad (20)$$

Quicker asymptotic convergence to difference  $2(\omega^* - \omega) \rightarrow 1$  could be achieved in other ways, for example by the generalized Mermin-GHZ game [2] or by XORing together the answers (aka “XOR repetition”) of other pseudo-telepathy XOR games [5]. Although their bias scales in a weaker way, the APD games have the property that perfect entangled strategies exist for *any* choice of target bit strings  $s$ .

To investigate the incompleteness of the PREF condition, we define an XOR game that contains a PREF, but provably has commuting-operator value 1. This game is solved by a single-qubit strategy employing measurements in the  $X$ ,  $Y$ , and  $Z$  bases. This may be a starting point for stricter necessary criterion, building towards a complete algorithm for deciding the value of entangled XOR games. The existence of this game proves the following theorem.

► **Theorem 25.** *The PREF characterization is incomplete. In particular, there exists an XOR game with six players, alphabet size three, for which the entangled value is 1, but the noPREF condition is unable to detect this.*

Finally, we investigate thresholds in  $\omega^*$  by considering the behavior of randomly generated XOR games with a large number of clauses. We prove Theorem 26, which shows that (much like the classical case) random XOR games become unsatisfiable with high probability when  $m$  is larger than some constant times  $n$ . Previous techniques could show that  $k$ -XOR instances were unsatisfiable only in the “dense” regime, i.e. where  $m \geq \Omega(n^k)$  [24].

► **Theorem 26.** *For every  $k$ , there exists a constant  $C_k^{unsat}$  depending only on  $k$  such that a random  $k$ -XOR game  $G$  with  $m \geq C_k^{unsat}n$  clauses has value  $\omega^*(G) < 1$  with probability  $1 - o(1)$ .*

**Proof.** Explicit construction of a refutation presented in the full paper. ◀

We also investigate the average case performance of ncSoS. We show that random games with a fixed ratio of  $m$  to  $n$  have a minimal length refutation that scales like  $\Omega(n \log(n) / \log(\log(n)))$ , implying that it takes the ncSoS algorithm superexponential time to show that these games have  $\omega^* < 1$  (Theorem 27). These results should be thought of as quantum analogues of Grigoriev’s [17] integrality gap instances for classical XOR games.

► **Theorem 27.** *For any constant  $C$ , the minimum length refutation of a random 3-XOR game with  $m = Cn$  queries on an alphabet of size  $n$  has length at least*

$$\frac{en \log(n)}{8C^2 \log(\log(n))} - o\left(\frac{n \log(n)}{\log(\log(n))}\right) \tag{21}$$

*with probability  $1 - o(1)$  (as  $n \rightarrow \infty$ ). Hence, either  $\omega^* = 1$  or  $\Omega(n \log(n) / \log(\log(n)))$  levels of the ncSoS hierarchy are needed to witness that  $\omega^* < 1$  for such games.*

## 6 Future Work

We see four main directions in which our characterization of non-local XOR games could be extended.

First, our linear algebraic characterization of  $\omega^* = 1$  games is incomplete: there exist games with  $\omega^* = 1$  for which a MERP strategy cannot achieve value 1. We expect a strengthening of the PREF condition may allow us to extend our decidability algorithm to detect these games and develop dual strategies that solve them. Understanding the structure of such games would give further intuition about the behavior of optimal XOR commuting-operator strategies, in particular strategies which may require more entanglement than the simple MERP strategies.

Second, determining whether  $\omega^* = 1$  for nonsymmetric XOR games may be outside P or even undecidable. In the realm of Binary Constraint System (BCS) games, [27] shows that determining whether a general BCS game has perfect value is undecidable. The structural similarity between BCS games and XOR games suggests that perhaps some of the group theoretic techniques of that work could be applied to XOR games to arrive at a similar conclusion. An interesting class of games which may serve as an intermediate class between XOR and BCS games are “incomplete” XOR games in which there are  $k$  players but queries can involve  $< k$  variables, effectively ignoring some players. Even for  $k = 2$ , Tsirelson’s semidefinite programming characterization of  $\omega^*$  does not apply to incomplete XOR games, although in this case it is still easy to decide whether  $\omega^* = 1$ .

Third, while in this work we have focused on computing the entangled game value  $\omega^*$ , our methods may also be useful from the perspective of Bell inequalities, in which the quantity of interest is the maximal violation achievable by an entangled strategy. While this has

conventionally been measured in terms of the bias ratio  $(\omega^* - 1/2)/(\omega - 1/2)$ , the difference  $2(\omega^* - \omega)$  is an equally natural measure, and we hope that our techniques will render it more amenable to analysis. Indeed, in addition to the construction of Asymptotically Perfect Difference games mentioned above, our results have the following simple consequence: for symmetric games with  $\omega^* = 1$ , our characterization of the optimal strategies (MERP) together with the Grothendieck-type inequality of [3] imply that the bias ratio and difference are both bounded by constants depending only on  $k$ , and that for the difference, this constant is strictly less than one.

Finally, our results are almost entirely concerned with the question of determining whether  $\omega^* = 1$  or  $\omega^* < 1$ . However, we note that the MERP family of strategies includes the optimal strategy for the CHSH game [7] and more generally any multiplayer game with question and answer alphabet size two [31], but not for all XOR games [23]. It is an interesting open question to fully characterize when MERP strategies are optimal. In this setting there are still many classical tools which we do not know how to extend to the quantum case. As an example, consider *overconstrained* games in which there are many more constraints than variables and the signs of those constraints are chosen randomly. In the classical case, second moment methods can show that the value is close to  $1/2$  while in the quantum case we can only conclude that it is  $< 1$ .

## Abstract

We study testing of local properties in one-dimensional and multi-dimensional arrays. A property of  $d$ -dimensional arrays  $f : [n]^d \rightarrow \Sigma$  is  $k$ -local if it can be defined by a family of  $k \times \dots \times k$  forbidden consecutive patterns. This definition captures numerous interesting properties. For example, monotonicity, Lipschitz continuity and submodularity are 2-local; convexity is (usually) 3-local; and many typical problems in computational biology and computer vision involve  $o(n)$ -local properties.

In this work, we present a generic approach to test all local properties of arrays over any finite (and not necessarily bounded size) alphabet. We show that any  $k$ -local property of  $d$ -dimensional arrays is testable by a simple canonical one-sided error non-adaptive  $\epsilon$ -test, whose query complexity is  $O(\epsilon^{-1} k \log \frac{en}{k})$  for  $d = 1$  and  $O(c_d \epsilon^{-1/d} k \cdot n^{d-1})$  for  $d > 1$ . The queries made by the canonical test constitute sphere-like structures of varying sizes, and are completely independent of the property and the alphabet  $\Sigma$ . The query complexity is optimal for a wide range of parameters: For  $d = 1$ , this matches the query complexity of many previously investigated local properties, while for  $d > 1$  we design and analyze new constructions of  $k$ -local properties whose one-sided non-adaptive query complexity matches our upper bounds. For some previously studied properties, our method provides the first known sublinear upper bound on the query complexity.

## 1 Introduction

Property testing [22, 33] is devoted to understanding how much information one needs to extract from an object in order to determine whether it satisfies a given property or is far from satisfying the property. This active research area has seen many developments through the last two decades; see the recent book of Goldreich [21] for a good introduction. The property testing notation we use here is standard, see Subsection 1.7 for the relevant definitions.

In this paper we focus on testing of local properties in structured data. The objects we consider are  $d$ -dimensional arrays, where  $d$  is a positive integer, viewed as a constant. A  $d$ -dimensional array of width  $n$ , or an  $[n]^d$ -array in short, is a function  $A : [n]^d \rightarrow \Sigma$  from the hypergrid  $[n]^d$  to the alphabet  $\Sigma$ , where the alphabet  $\Sigma$  is allowed to be any (arbitrarily large)

finite set; we stress that the size of  $\Sigma$  is usually *not required* to be bounded as a function of the other parameters. For example, a *string* is an  $[n]^1$ -array, and the commonly used RGB representation of images is basically an  $[n]^2$ -array over  $\{0, 1, \dots, 255\}^3$ , where the three values corresponding to each pixel represent the intensity of red, green and blue in it.

## 1.1 Local properties

Korman, Reichman, and the author [7] recently investigated testing of the property of *consecutive pattern freeness*, i.e., not containing a copy of some (predefined) “forbidden” consecutive subarray. Here, a  $[k]^d$ -array  $S$  is a (consecutive) *subarray* of an  $[n]^d$ -array  $A$  in *location*  $(i_1, \dots, i_d) \in [n - k + 1]^d$  if  $A(i_1 + j_1 - 1, \dots, i_d + j_d - 1) = S(j_1, \dots, j_d)$  for any  $j_1, \dots, j_d \in [k]$ .

Naturally, a more general follow-up question raised in [7] was the following: what can be said about testing of properties defined by a *family of forbidden consecutive patterns*? As we shall see soon, many interesting properties of arrays (including a large fraction of the array properties that were previously investigated in the literature) can be characterized this way.

With this in mind, we call a property *local* if it can be characterized by a family of small forbidden consecutive patterns. Formally, a property  $\mathcal{P}$  of  $[n]^d$ -arrays over an alphabet  $\Sigma$  is *k-local* (for  $2 \leq k \leq n$ ) if there exists a family  $\mathcal{F}$  of  $[k]^d$ -arrays over  $\Sigma$  so that the following holds for any  $[n]^d$ -array  $A$  over  $\Sigma$ :

$$A \text{ satisfies } \mathcal{P} \iff \text{None of the (consecutive) subarrays of } A \text{ is in } \mathcal{F}.$$

For  $\mathcal{P}$  as above, we sometimes write  $\mathcal{P} = \mathcal{P}(\mathcal{F})$  to denote that  $\mathcal{P}$  is defined by the forbidden family  $\mathcal{F}$ .

The main contribution of this work is a generic one-sided error non-adaptive framework to test *k-local* properties. In some cases, our method either matches or beats the best known upper bounds on the query complexity (although the running time might be far from optimal in general). We show the optimality of our method by proving a matching lower bound for non-adaptive one-sided tests, as well as a (weaker) lower bound for two-sided tests.

In order to demonstrate the wide range of properties captured by the above definition, we now present various examples of properties that are *k-local* for small *k*, including some of the most widely investigated properties in the property testing literature, as well as properties from areas of computer science that were not systematically studied in the context of property testing. In what follows, the sum of two tuples  $x = (x_1, \dots, x_d), y = (y_1, \dots, y_d)$  is defined as the tuple  $(x_1 + y_1, \dots, x_d + y_d)$ ; additionally,  $e^i$  denotes the *i*-th unit vector in *d* dimensions.

**Monotonicity.** Perhaps the most thoroughly investigated property in the testing literature: see e.g. the entries related to monotonicity testing in the Encyclopedia of Algorithms [14, 32] and the references within. An  $[n]^d$ -array  $A$  over an ordered alphabet  $\Sigma$  is *monotone* (non-decreasing) if  $A(x) \leq A(y)$  for any  $x = (x_1, \dots, x_d)$  and  $y = (y_1, \dots, y_d)$  satisfying  $x_i \leq y_i$  for any *i*. Monotonicity is 2-local: an array  $A$  is monotone if and only if there is no pair  $x, x + e^i \in [n]^d$  so that  $A(x) > A(x + e^i)$ .

**Lipschitz continuity.** Another well-investigated property with connections to differential privacy [3, 10, 15, 24], an  $[n]^d$ -array  $A$  is *c-Lipschitz continuous* if  $|A(x) - A(y)| \leq c \sum_{i=1}^d |y_i - x_i|$  for any  $x, y \in [n]^d$ . This condition holds iff  $|A(x) - A(x + e^i)| \leq c$  for any  $x, x + e^i \in [n]^d$ , and thus Lipschitz continuity is also 2-local.

**Convexity.** Discrete convexity is an important geometric property with connections to optimization and other areas [9, 8, 13, 18, 30, 31]. A one-dimensional array  $A$  is *convex* if  $\lambda A(x) + (1 - \lambda)A(y) \geq A(\lambda x + (1 - \lambda)y)$  for any  $x, y \in [n]$  and  $0 < \lambda < 1$  satisfying

$\lambda x + (1 - \lambda)y \in [n]$ . Convexity is 3-local for the case  $d = 1$ : an array  $A : [n] \rightarrow \Sigma$  is convex if and only if  $A[x] - 2A[x + 1] + A[x + 2] \geq 0$  for any  $x \in [n - 2]$ . In higher dimensions, several different notions of discrete convexity have been used in the literature – see e.g. the introductory sections of the book of Murota on discrete convex analysis [27]. Two of the commonly used definitions,  $M^\#$ -convexity and  $L^\#$ -convexity, are 3-local and 4-local, respectively: see Theorems 4.1 and 4.2 in [26], where it is shown that both notions can be defined locally using slight variants of the Hessian matrix consisting of the partial discrete derivatives. Another common definition that is a natural variant of the continuous case states that convexity is equivalent to the positive semi-definiteness of the Hessian matrix; under this definition, convexity is 3-local. A strictly weaker notion of convexity, called *separate convexity* [13], is defined as follows: an  $[n]^d$ -array  $A$  is separately convex if it is convex along each of the axes. Similarly to one-dimensional convexity, separate convexity is 3-local for any  $d$ .

**Properties of higher order derivatives.** More generally, *any* property of arrays that can be characterized by “forbidden pointwise behavior” of the first  $k$  discrete derivatives [13] is  $(k + 1)$ -local. Monotonicity (for  $k = 1$ ), Lipschitz continuity ( $k = 1$ ) and convexity ( $k = 2$ ) are special cases of such properties.

**Submodularity.** An important property closely related to convexity [10, 11, 30, 34]. Given  $x = (x_1, \dots, x_d), y = (y_1, \dots, y_d) \in [n]^d$ , define  $x \wedge y = (\min(x_1, y_1), \dots, \min(x_d, y_d))$  and  $x \vee y = (\max(x_1, y_1), \dots, \max(x_d, y_d))$ . An  $[n]^d$ -array is *submodular* if  $A[x \wedge y] + A[x \vee y] \leq A[x] + A[y]$  for any  $x, y \in [n]^d$ . Submodularity is 2-local: it is not hard to verify that submodularity is equivalent to the condition that  $A(x) + A(x + e^i + e^j) \leq A(x + e^i) + A(x + e^j)$  for all  $x$ .

**Pattern matching and computer vision.** Tasks involving pattern matching under some limitations – such as noise in the image, obstructed view, or rotation of elements in the image – are at the core of computer vision and its applications. For example, the local property of not containing a good enough  $\ell_1$ -approximation of a given forbidden pattern is of practical importance in computer vision. Sublinear approaches closely related to property testing are known to be effective for problems of this type, see e.g. [25].

**Computational biology.** Many problems in computational biology are closely related to one-dimensional pattern matching. As an example, a defensive mechanism of the human body against RNA-based viruses involves “cutting” a suspicious RNA fragment, if it finds one of a (small) family of short forbidden consecutive patterns in it, indicating that this RNA might belong to a virus. Thus, in order to generate fragments of RNA that are not destroyed by such defensive mechanisms (which is a basic task in computational biology), understanding the process of “repairing” a fragment so that it will not contain any of the forbidden patterns is an interesting problem related to property testing.

## 1.2 Previous results on local properties

### One-dimensional arrays

A seminal result of Ergün et al. [19] shows that for constant  $\epsilon$ , monotonicity is  $\epsilon$ -testable over the line (that is, for one-dimensional arrays) using  $O(\log n)$  queries over general alphabets. The non-adaptive one-sided error test proposed in [19] is based, roughly speaking, on imitating a binary search non-adaptively. It was shown by Fischer [20] that the above is tight even for two-sided error adaptive tests, proving a matching  $\Omega(\log n)$  lower bound. Later on, Parnas, Ron and Rubinfeld [30] and Jha and Raskhodnikova [24] showed that the  $O(\log n)$  upper bound on the non-adaptive one-sided query complexity also holds for convexity and Lipschitz

## 11:4 Testing Local Properties of Arrays

continuity, respectively. For general  $\epsilon$ , the upper bound in [24] is of the type  $O(\epsilon^{-1} \log n)$ ; the same work also presents a matching lower bound of  $\Omega(\log n)$  for the one-sided non-adaptive case, while  $\Omega(\log n)$  lower bounds for two-sided non-adaptive tests of convexity, and more generally, monotonicity of the  $\ell$ -th derivative, are proved by Blais, Raskhodnikova and Yaroslavtsev [13] using a communication complexity based approach [12]. Finally, a recent result of Belovs [4] refines the one-sided non-adaptive query complexity of monotonicity to  $O(\epsilon^{-1} \log \epsilon n)$ .

When the alphabet is binary (of size two), general positive results are known regarding the testability of local properties in one dimension. It follows from the testability of regular languages, established by Alon et al. [2], that any  $k$ -local property is testable in  $O(c(\mathcal{F})\epsilon^{-1}(\log^3(\epsilon^{-1})))$  queries, where  $c(\mathcal{F})$  depends only on the family  $\mathcal{F}$  of forbidden consecutive length- $k$  patterns defining the property. However,  $c(\mathcal{F})$  can be exponential in  $k$  in general.

### Multi-dimensional arrays

Chakrabarty and Seshadhri [16] extended some of the above results to hypergrids, showing that a general class of so-called “bounded derivative” properties (all of which are 2-local), including monotonicity and Lipschitz continuity as special cases, are all testable over  $[n]^d$ -arrays with  $O(\epsilon^{-1} d \log n)$  queries. Another work by the same authors [17] shows a matching lower bound of  $\Omega(\epsilon^{-1} d \log \epsilon n)$  for monotonicity, that holds even for two-sided adaptive tests, while the communication complexity approach of [13] gives a (non-adaptive, two-sided)  $\Omega(d \log n)$  lower bound for convexity, separate convexity and Lipschitz.

Submodularity is testable for  $d = 2$  with  $O(\log^2 n)$  queries [30]; However, no non-trivial upper bound on the query complexity is known for submodularity in the case  $d > 2$  and convexity in the case  $d > 1$  under the Hamming distance and over general alphabets (although [9] proves constant-query testability for 2D convexity over a binary alphabet). Under  $L_1$ -distance and for any  $d$ , it was shown in [10] that convexity in  $[n]^d$ -arrays is testable with number of queries that depends only on  $d$ .

### Pattern freeness

In [7], it was shown that the property of (consecutive) pattern freeness, for a single forbidden pattern, is testable with  $O(c_d/\epsilon)$  queries for any  $d$ . The proof, however, requires multiple sophisticated combinatorial observations and does not seem to translate to the case of a family of forbidden patterns discussed here.

## 1.3 Our results

In this work, we present a generic approach to test *all*  $k$ -local properties of  $[n]^d$ -arrays. Among other consequences, a simple special case of our result in the one-dimensional regime shows that the abundance of properties whose query complexity is  $\Theta(\log n)$  is not a coincidence: in fact, *any*  $O(1)$ -local property of one-dimensional arrays is testable with  $O(\log n)$  queries, using a canonical binary search like querying scheme.

On the other hand, we prove a lower bound for testing local properties in  $d > 1$  dimensions, showing that the query complexity of our test is optimal (for fixed  $d$ ) among non-adaptive one-sided tests, even when restricted to alphabets of size that is polynomial in  $n^d$ . We also prove a lower bound for non-adaptive two-sided tests.

### 1.3.1 Upper bounds

Our first main result is an upper bound on the number of queries required to test any  $k$ -local property of  $[n]^d$ -arrays non-adaptively with one-sided error. The test is *canonical* in a strong sense: The queries it makes depend on  $n, d, k$ , and (relatively weakly) on  $\epsilon$ ; they do not depend on  $\mathcal{P}$  or the alphabet  $\Sigma$ . In other words, it makes the same type of queries for all  $k$ -local properties of  $[n]^d$ -arrays over any finite (and not necessarily bounded-size) alphabet.

► **Theorem 1.** *Let  $2 \leq k \leq n$  and  $d \geq 1$  be integers, and let  $\epsilon > 0$ . Any  $k$ -local property  $\mathcal{P}$  of  $[n]^d$ -arrays over any finite (and not necessarily bounded size) alphabet has a one-sided error non-adaptive  $\epsilon$ -test whose number of queries is*

- $O\left(\frac{k}{\epsilon} \cdot \log \frac{\epsilon n}{k}\right)$  for  $d = 1$ .
- $O\left(c^d \frac{k}{\epsilon^{1/d}} \cdot n^{d-1}\right)$  for  $d > 1$ .

Here,  $c > 0$  is an absolute constant. The test chooses which queries to make based only on the values of  $n, d, k, \epsilon$ , and independently of the property  $\mathcal{P}$  and the alphabet  $\Sigma$ .

Note that we are interested here in the domain where  $n$  is large and  $d$  is considered a constant. Thus, we did not try to optimize the  $c^d$  term in the second bullet, seeing that it is negligible compared to  $n^{d-1}$  anyway.

#### Running time

The main drawback of our approach is the running time of the test, which is high in general. After making all of its queries, our test runs an *inference* step, where it tries to evaluate (by enumerating over all relevant possibilities) whether a violation of the property must occur in view of the queries made, and reject if this is the case.

Without applying any property-specific considerations, the running time of the inference step is of order  $|\Sigma|^{O(n^d)}$ . However, for various specific properties of interest, such as monotonicity and 1D-convexity, it is not hard to make the running time of the inference step of the same order of magnitude as the query complexity. Moreover, in one dimension we can use dynamic programming to achieve running time that is significantly better than the naive one, but still much higher than the query complexity in general:  $O(|\Sigma|^{O(k)}n)$ . This works for any  $k$ -local property in one dimension; see the last part of Subsection 1.4.1 for more details.

#### Proximity oblivious test

Interestingly, the behavior of the test depends quite minimally on  $\epsilon$ , and it can be modified very slightly to create a proximity oblivious test (POT) for any  $k$ -local property. The useful notion of a POT, originally defined by Goldreich and Ron [23], refers to a test that does *not* receive  $\epsilon$  as an input, and whose success probability for an input not satisfying the property is a function of the Hamming distance of the input from the property.

► **Theorem 2.** *Fix  $d > 0$ . Any  $k$ -local property  $\mathcal{P}$  of  $[n]^d$ -arrays over any finite (but not necessarily bounded size) alphabet has a one-sided error non-adaptive proximity oblivious test whose number of queries is  $O(k \log(n/k))$  if  $d = 1$  and  $O(kn^{d-1})$  if  $d > 1$ . For any input  $A$  not satisfying  $\mathcal{P}$ , the rejection probability of  $A$  is linear (for fixed  $d$ ) in the Hamming distance of  $A$  from  $\mathcal{P}$ .*

One can run  $O(c_d/\epsilon)$  iterations of the POT to obtain a standard one-sided error non-adaptive test. The query complexity is  $O(k\epsilon^{-1} \log(n/k))$  for  $d = 1$  and  $O(c_d k \epsilon^{-1} n^{d-1})$  for  $d > 1$ , where  $c_d > 0$  depends only on  $d$ . Thus, the POT-based test is sometimes as good as the test of Theorem 1 (specifically, for  $d = 1$  it matches the above bounds for almost the whole range of  $\epsilon$  and  $k$ ). In any case, the multiplicative overhead of the POT-based test is sublinear in  $1/\epsilon$  across the whole range.

### Type of queries

In one dimension, many of the previously discussed properties, including, for example, monotonicity and Lipschitz continuity, are testable in  $O(\log n)$  queries. Previously known tests for monotonicity and Lipschitz continuity make queries that resemble a binary search: these tests query pairs of entries of distance  $2^i$  for multiple choices of  $0 \leq i \leq \log n$ .

Our test continues the line of works using querying schemes roughly inspired by binary search. The test queries structures that can be viewed, intuitively, as  $L_\infty$ -spheres of different sizes in  $[n]^d$ . For this purpose, an  $L_\infty$ -sphere with radius  $r$  and width  $\ell$  in  $[n]^d$  is a set  $X_1 \times X_2 \times \dots \times X_d \subseteq [n]^d$ , where each  $X_i$  is a union of intervals of the form  $[a_i, a_i + 1, \dots, a_i + \ell - 2, a_i + \ell - 1] \cup [b_i - \ell + 2, b_i - \ell + 3, \dots, b_i - 1, b_i]$ , and  $b_i - a_i \in \{r, r + 1\}$  for any  $i \in [d]$ . More specifically, our test for  $k$ -local properties queries spheres with width  $k - 1$  and radius of order  $2^i$  for different values of  $i$ . In the simple special case where  $d = 1$  and  $k = 2$ , this is very similar to the querying scheme mentioned in the previous paragraph.

### Implications

In one dimension, the query complexity of the test matches the best known upper bounds (and, in some regimes, refines the dependence on  $\epsilon$ ) for several previously investigated properties including monotonicity, Lipschitz continuity and convexity. For monotonicity of  $k$ -th order derivatives, which is  $(k + 1)$ -local, it proves the first sublinear upper bound on the query complexity:  $O(k \log n)$ ; in comparison, the best known lower bound [13] is  $\Omega(\log n)$ .

For pattern matching type properties in 1D arrays (including applications in computational biology and other areas), our approach gives a property- and alphabet-independent upper bound of  $O(k \log n)$  on the query complexity, with essentially optimal dependence on  $\epsilon$  as well. Previously known approaches for testing such properties, like the regular languages testing approach [2], yield tests whose query complexity is dependent on the family of forbidden patterns considered, whose size might be exponential in the locality parameter  $k$ . Our approach, on the other hand, requires an  $O(\log n)$  “overhead”, but its query complexity is independent of the size of the forbidden family discussed. Instead, the dependence in  $k$  is linear.

In multiple dimensions, our approach is far from tight for well-understood properties such as monotonicity and Lipschitz continuity, whose query complexity is known to be  $\Theta(d \log n)$  (in comparison, our approach yields an  $O(n^{d-1})$  type bound). However, for testing of other properties like convexity (for  $d > 1$ ) and submodularity (for  $d > 2$ ) in  $[n]^d$ -arrays, no non-trivial upper bounds on the query complexity are known over general alphabets, so our upper bound of  $O(n^{d-1})$  is the first such bound. While we do not believe this bound is tight in general, this might be a first step towards the development of new tools for efficiently testing such properties.

### Sketching for testing

The fact that the queries made are completely independent of the property suggests the following sketching technique allowing for “testing in retrospect”: Given  $\epsilon$  and  $k$  in advance, we make all queries of the generic  $\epsilon$ -test for  $k$ -local properties in “real time”, and store them for postprocessing. This is suitable, for example, in cases where we have limited access to a large input for a limited amount of time (e.g. when reading the input requires specialized expensive machinery), but the postprocessing time is not an issue. Note that for this approach we do not need to know the property of interest in advance.

### 1.3.2 Lower bounds

Our next main result is a tight lower bound for non-adaptive one-sided error testing of local properties, that applies for any  $d$ , and is tight for any fixed  $d$  satisfying  $d > 1$ .

► **Theorem 3 (One-sided tests).** *Let  $d \geq 1$  and  $n \geq k \geq 2$  be integers, and let  $d/n < \epsilon < 1$ . There exists a  $k$ -local property  $\mathcal{P}$  of  $[n]^d$ -arrays over an alphabet  $\Sigma$  of size  $n^{O(d)}$ , so that any non-adaptive one-sided error  $\epsilon$ -test for  $\mathcal{P}$  requires  $\Omega\left(\min\left\{\frac{k}{d\epsilon^{1/d}} \cdot n^{d-1}, n^d\right\}\right)$  queries.*

Note that the size of the alphabet in Theorem 3 is only polynomial in the input size. We also prove a lower bound for non-adaptive two-sided tests; here the dependence in  $|\Sigma|$  is exponential.

► **Theorem 4 (Two-sided tests).** *Let  $d \geq 1$  and  $n \geq k \geq 2$  be integers, and let  $d/n < \epsilon < 1$ . There exists a  $k$ -local property  $\mathcal{P}$  of  $[n]^d$ -arrays over an alphabet  $\Sigma$  of size  $2^{O(n^d)}$ , so that any non-adaptive two-sided error  $\epsilon$ -test for  $\mathcal{P}$  requires  $\Omega\left(\min\left\{\frac{\sqrt{k}}{d\epsilon^{(d+1)/2d}} \cdot n^{(d-1)/2}, n^d\right\}\right)$  queries.*

For fixed  $d > 1$ , the lower bound for one-sided tests matches the upper bound from Theorem 1 across the whole range of  $\epsilon$  and  $k$ . For  $d = 1$  the bound obtained here is  $\Omega(k/\epsilon)$ , which is tight up to a  $\log n$  factor. Note the threshold behavior occurring at  $k/\epsilon^{1/d} = \Theta(n)$ : When  $k/\epsilon^{1/d} = o(n)$ , the upper bound of Theorem 1 implies that any  $k$ -local property is  $\epsilon$ -testable with a sublinear number of queries, while for  $k/\epsilon^{1/d} = \Omega(n)$ , the property of Theorem 3 requires  $\Omega(n^d)$  non-adaptive one-sided queries to test.

From Theorem 4 we conclude that the improvement in query complexity obtained by two-sided error non-adaptive tests is at most quadratic in the worst case; specifically, there exists a 2-local property requiring  $n^{\Omega(d-1)}$  queries to test by two-sided non-adaptive tests.

## 1.4 Proof ideas and techniques

Here we present the main ideas of our proofs in an informal way, starting with the upper bound. For simplicity, we stick to the one-dimensional case, and assume that  $\epsilon$  is fixed and  $k = o(n)$ .

### 1.4.1 Upper bound for 1D

Suppose that  $\mathcal{P} = \mathcal{P}(\mathcal{F})$  is a  $k$ -local property of  $[n]^1$ -arrays  $A$  over an alphabet  $\Sigma$ , defined by the forbidden family  $\mathcal{F}$ . Let  $S$  be a consecutive subarray of  $A$  of length at least  $2k - 2$ . The *boundary* of  $S$  consists of the first  $k - 1$  elements and the last  $k - 1$  elements of  $S$ , and all other elements of  $S$  are its *interior*. We call  $S$  *unrepairable* if one cannot make the array  $S$  satisfy the property  $\mathcal{P}$  without changing the value of at least one element in its boundary. Otherwise,  $S$  is *repairable*. Observe the following simple facts.

- It suffices to only query the boundary elements of  $S$  in order to determine whether  $S$  is unrepairable.
- If  $S$  is unrepairable, then  $A$  does not satisfy  $\mathcal{P}$ .
- If  $S$  is repairable, then we can delete all forbidden patterns from  $S$  by modifying only entries in its interior, without creating any new copies of forbidden patterns in  $A$ .

We call the process of understanding whether  $S$  is unrepairable using only its boundary elements *inference*. Note that the inference step does not make any additional queries.

### A simple sublinear test

A first attempt at a generic test for local properties is the following: we query  $\Theta(\sqrt{n})$  intervals in  $[n]$ , each containing exactly  $k - 1$  consecutive elements, including the intervals  $\{1, \dots, k - 1\}$  and  $\{n - k + 2, \dots, n\}$ , where the distance between each two neighboring intervals is  $\Theta(\sqrt{n})$ . A *block* is a subarray consisting of all elements in a pair of neighboring intervals and all elements between them. The crucial observation is that at least one of the following must be true, for any array  $A$  that is  $\epsilon$ -far from  $\mathcal{P}$  (recall that  $\epsilon$  is fixed).

- At least one of the blocks is unrepairable.
- At least  $\Omega(\sqrt{n})$  of the blocks do not satisfy  $\mathcal{P}$ .

Indeed, if the first condition does not hold, then one can make  $A$  satisfy  $\mathcal{P}$  by only changing elements in the interiors of blocks that do not satisfy  $\mathcal{P}$ . Seeing that  $A$  is  $\epsilon$ -far from  $\mathcal{P}$  and that we do not need to modify elements in the interiors of blocks that satisfy  $\mathcal{P}$ , this implies that at least  $\Omega(\sqrt{n})$  of the blocks do not satisfy  $\mathcal{P}$ .

Now we are ready to present the test: We query all  $O(k\sqrt{n})$  elements of all intervals, and additionally, all  $O(\sqrt{n})$  elements of  $O(1)$  blocks. Querying all elements of all intervals suffices to determine (with probability 1) whether one of the blocks is unrepairable. If  $A$  is  $\epsilon$ -far from  $\mathcal{P}$  and does not contain unrepairable blocks, querying  $O(1)$  full blocks will catch at least one block not satisfying  $\mathcal{P}$  with constant probability, as desired.

For more details, see Section 3 and the preliminary Section 2 that prepares the required infrastructure.

### The optimal test

Improving the query complexity requires us to construct a system of *grids* – which are merely subsets of  $[n]$  – inspired by the behavior of binary search. In comparison, the approach of the previous test is essentially to work with a single grid.

The first (and coarsest) grid contains only the first  $k - 1$  elements and the last  $k - 1$  elements of  $[n]$ . In other words, it is equal to  $\{1, \dots, k - 1, n - k + 2, \dots, n\}$ . The second grid refines the first grid – that is, it contains all elements of the first grid – and additionally, it contains  $k - 1$  consecutive elements whose center is  $n/2$  (whenever needed, rounding can be done rather arbitrarily). We continue with the construction of grids recursively: To construct grid number  $i + 1$ , we take grid number  $i$  and add  $k - 1$  elements in the middle of each block of grid  $i$  (blocks are defined as before). Note that the length of blocks is roughly halved with each iteration. We stop the recursive construction when the length of all of the blocks becomes no bigger than  $ck$ , where  $c \geq 2$  is an absolute constant.

For each block  $B$  in grid number  $i > 1$ , we define its *parent*, denoted  $\text{Par}(B)$ , as the unique block in interval  $i - 1$  containing it. A block  $B$  in the system of grid is *maximally unrepairable* if it is unrepairable, and all blocks (of all grids in the system) strictly containing it are repairable. It is not hard to see that different maximally unrepairable blocks have disjoint interiors.

The main observation now is that in order to make  $A$  satisfy  $\mathcal{P}$ , it suffices to only modify entries in the interiors of parents of maximally unrepairable blocks. If  $A$  is  $\epsilon$ -far from  $\mathcal{P}$ , then the total length of these parents must therefore be  $\Omega(n)$  (for constant  $\epsilon$ ). However, since the length of  $\text{Par}(B)$  is roughly twice the length of  $B$ , we conclude that the total length of all maximally unrepairable blocks is  $\Omega(n)$ .

With this in hand, it can be verified that the following test has constant success probability. For each grid in the system, we pick one block of the grid uniformly at random, and query all entries of its boundary. Additionally, for the finest grid (whose block length is  $O(k)$ ), we also query all interior elements of the picked block.

For more details, see Section 4 (which builds on the infrastructure of Section 2).

### Running time in 1D

We now show that the running time of the inference step for a block of length  $m$  is  $m|\Sigma|^{O(k)}$ . Summing over all block lengths, this would imply that the total running time of the test is  $n|\Sigma|^{O(k)}$ .

The proof uses dynamic programming. Let  $S$  be an array of length  $m$  over  $\Sigma$ , and assume that  $S(1), S(2), \dots, S(k-1)$  and  $S(m-k+2), \dots, S(m)$  are all known. For each “level” from 1 to  $m-k+1$ , we keep a boolean predicate for each of the  $|\Sigma|^k$  possible patterns of length  $k$  over  $\Sigma$ . These predicates are calculated as follows.

- In the first level, the predicate of  $\sigma = (\sigma_1, \dots, \sigma_k)$  evaluates to TRUE if  $S(1) = \sigma_1, \dots, S(k-1) = \sigma_{k-1}$ , and additionally,  $\sigma \notin \mathcal{F}$ , that is,  $\sigma$  is not a forbidden pattern. Otherwise, the predicate of  $\sigma$  is set to FALSE.
- For  $i = 2$  to  $m-k+1$ , the predicate of  $\sigma = (\sigma_1, \dots, \sigma_k)$  in level  $i$  evaluates to TRUE if and only if
  1.  $\sigma \notin \mathcal{F}$ .
  2. there exists  $\sigma' = (\sigma'_0, \sigma_1, \dots, \sigma_{k-1})$  that evaluates to TRUE in level  $i-1$ .
- Finally, the predicates in level  $m-k+1$  are modified as follows: for all  $\sigma = (\sigma_1, \dots, \sigma_k)$  so that  $\sigma_j \neq S(m-k+j)$  for some  $j \geq 2$ , we set the predicate of  $\sigma$  to FALSE.

It is not hard to see that  $S$  is unrepairable if and only if all predicates at level  $m-k+1$  are FALSE. The running time is  $O(m|\Sigma|^{cd})$  for a suitable constant  $c > 0$ .

### Generalization to higher dimensions

The generalization to higher dimensions is relatively straightforward; the main difference is that the boundary of blocks now is much larger: blocks of size  $m \times \dots \times m$  have boundary of size  $O(kdm^{d-1})$ . Thus, essentially the same proof as above (with suitable adaptations of the definitions) yields a test with query complexity  $O(kdn^{d-1})$  for constant  $\epsilon$ . For the running time, we can no longer use dynamic programming; using the naive approach of enumerating over all possible interior elements of a block, we get that the inference time for a block of size  $m \times \dots \times m$  is  $|\Sigma|^{O(m^d)}$ , making the total running time of the test  $|\Sigma|^{O(n^d)}$ .

#### 1.4.2 Lower bound

The property  $\mathcal{P}$  underlying our lower bound construction consists of  $[n]^d$ -arrays  $A$  over  $\Sigma$  satisfying all of the following properties. Here we provide a construction over alphabet size  $2^{O(n^d)}$ , but in Section 6 of the full version of this paper [5] we show how a simple modification of the property can be conducted in order to decrease the size of the required alphabet to  $n^{O(d)}$  for the proof of Theorem 3 (unfortunately, for the proof of Theorem 4 this modification does not work).

- The alphabet  $\Sigma$  is of the form  $[n]^d \times [n]^d \times 2^{[2n^{d-1}]}$ , where  $2^X$  is the *power set* of a set  $X$ . The value of  $A$  in entry  $x \in [n]^d$  is represented as a tuple  $A_1(x), A_2(x), A_3(x)$ . We view  $A_1(x), A_2(x)$  as *pointers* emanating from  $x$ .
- For every  $x \in [n]^d$  we require  $A_1(x) = x$ . That is,  $A_1$  points to the location of the element itself.
- There exists a special location  $\ell = (\ell_1, \dots, \ell_d) \in [n]^d$  so that all  $x \in [n]^d$  point to  $\ell$  with their second pointer, that is,  $A_2(x) = \ell$ . We call this location the *lower center of gravity*. We define an *upper center of gravity* as  $u = (\ell_1 + 1, \ell_2, \dots, \ell_d)$ .

## 11:10 Testing Local Properties of Arrays

- A *floor* entry  $x = (x_1, \dots, x_d) \in [n]^d$  satisfies  $x_1 = 1$  and a *ceiling* entry satisfies  $x_1 = n$ . For each such floor or ceiling entry  $x$ , we pick  $A_3(x)$  to be a singleton (i.e., a set with one element).
- For each floor element  $x$ , there exists a path  $\Gamma_x$  from  $x$  to the lower center of gravity  $\ell$ . Similarly, for each ceiling element  $y$ , there is a path  $\Gamma_y$  directed towards the upper center of gravity,  $u$ . In both cases, the path is of length  $O(nd)$ . The structure of the path depends only on its start and end points (so depends only on  $x$  and  $\ell$  in the first case, and  $y$  and  $u$  in the second case).
- The  $A_3$ -data “flows” to the center of gravity through paths. Formally, the  $A_3$ -set of each entry  $y$  that is not a floor or ceiling entry is required to be equal to the union  $\bigcup_{x: y \in \Gamma_x} A_3(x)$ . In other words, the data in each location in  $[n]^d$  is an “aggregation” of the data flowing in all paths that intersect it.
- Finally, we require that  $A_3(u) = A_3(\ell)$ .

While  $\mathcal{P}$  was defined above in global terms, we show that it is actually a 2-local property, that is, all conditions specified here can be written in a 2-local way.

To prove the lower bound, we follow Yao’s minimax principle [35], defining a distribution of arrays satisfying  $\mathcal{P}$ , and a distribution of arrays which are  $\Omega(1)$ -far from satisfying  $\mathcal{P}$ , so that a large number of queries is required to distinguish between the distributions.

As positive examples, we take a collection of arrays  $A$  satisfying the property, and require that all the singletons in the floor are pairwise disjoint. For negative examples (that are  $1/4$ -far from  $\mathcal{P}$ ), we consider a collection of arrays satisfying all of the above requirements other than the last. Instead, all singletons in the floor and the ceiling are pairwise disjoint (so in particular,  $A_3(\ell) \cap A_3(u) = \emptyset$ ).

We show that for any given  $x \in [n]^d$ , the expected size of  $A_3(x)$  over each of the distributions is  $O(d)$ . For the one-sided error case, it is shown that one needs to know the values of at least  $\Omega(n^{d-1})$  singletons to be able to distinguish between positive and negative examples with one sided error, implying that  $\Omega(n^{d-1}/d)$  queries are required to reject negative examples with constant probability.

For the two sided error case, the argument is inspired by the birthday paradox. Very loosely speaking, it follows from the fact that, given two unknown unordered sets  $A$  and  $B$  of size  $n$ , one has to make  $\Omega(\sqrt{n})$  queries to distinguish between the case that  $A = B$  and the case that  $A \cap B = \emptyset$ .

Due to space considerations, the full proofs of Theorems 3 and 4 are relegated to the full version of this paper [5]; see Sections 5 and 6 there.

### 1.5 Other related work

This subsection complements Subsection 1.2, presenting other related previous works that were not mentioned above.

#### General results in property testing

This paper adds to the growing list of general characterization results in property testing of strings, images, and multi-dimensional arrays; see [1, 6] and the references within for characterization-type results in these domains, mostly over a fixed size alphabet. In particular, for strings, it was shown by Alon et al. [2] that any local property over a fixed size alphabet is constant-query testable, and this paper shows that an overhead of at most  $O(\log n)$  is required when the alphabet size is unbounded.

## Hyperfiniteness

A graph is hyperfinite if, roughly speaking, it can be decomposed into constant size connected components by deleting only a small constant fraction of the edges. Newman and Sohler [28] investigated the problem of testing in hyperfinite graphs, showing that any property of hyperfinite bounded degree graphs is testable with a constant number of queries. While the graph with which we (implicitly) work – the hypergrid graph, whose vertices are in  $[n]^d$  and two vertices are neighbors if they differ by 1 in one coordinate – is a hyperfinite bounded degree graph (for constant  $d$ ), the results of [28] are incomparable to ours. Indeed, in our case the vertices are inherently ordered, and it does not make sense to allow adding edges between vertices that are not neighbors (as entries of  $[n]^d$ ), unlike the case in [28], where one may add or remove edges arbitrarily between any two vertices. Still, the hyperfiniteness of our graph seems to serve as a major reason that local properties have sublinear tests.

## Block tests for image properties

The works of Berman, Murzabulatov and Raskhodnikova [9] and Korman, Reichman, and the author [7] on testing of image properties (that is, on visual properties of 2D arrays) show that tests based on querying large consecutive blocks are useful for image property testing. In this work, the general queries we make are quite different: we query the *boundaries* of blocks of different sizes, so the queries are *spherical*, in the sense that a block can be seen as a ball in the  $L_\infty$ -metric on vectors in  $[n]^d$ , while its boundary can be seen as the (width- $k$ ) sphere surrounding this ball. This introduces a new type of queries shown to be useful for image property testing.

## 1.6 Discussion

### Small alphabets

The results in this work are alphabet independent, and in particular, they work for alphabets over any size. An intriguing direction of research is to understand whether one can obtain more efficient general testability results for local properties of multi-dimensional arrays over smaller alphabets; this line of research has been conducted for specific properties of interest, like monotonicity and convexity [4, 29]. Note that the one-sided non-adaptive lower bound we prove here can be adapted to yield a  $|\Sigma|^{\Omega(1)}$  lower bound for testing local properties over alphabets  $\Sigma$  of size smaller than  $n^d$ .

The most interesting special case is that of constant-sized (and in particular, binary) alphabets. Here, no lower bounds that depend on  $n$  are known. For the case  $d = 1$ , it is known that all  $O(1)$ -local properties are constant query testable; this follows from a result of Alon et al. [2], who showed that any regular language is constant-query testable. However, it is not known whether an analogous statement holds in higher dimensions. That is, for any  $d > 1$ , the question whether all  $k$ -local properties of  $[n]^d$ -arrays over  $\{0, 1\}$  are  $\epsilon$ -testable with query complexity that depends only on  $d$ ,  $k$ , and  $\epsilon$ , first raised in [7] (see also [1]), remains an intriguing open question. We believe that positive results in this front might also shed light on the question of obtaining more efficient inference for large classes of properties, especially over small alphabets.

### Does adaptivity help?

This work does not provide any lower bounds for adaptive tests, and it will be interesting to do so; previously investigated properties like monotonicity yield an  $\Omega(d \log n)$  lower bound [13, 17], and we believe that “data flow” type properties, somewhat similar to our lower

## 11:12 Testing Local Properties of Arrays

bound constructions, can provide instances of 2-local properties that require at least  $n^c$  queries, for some constant  $c \leq 1$ , for the adaptive two-sided case.

However, it is not clear whether better lower bounds (even bounds of the type  $\Omega(n^{1+c})$ ) exist. It will be very interesting to prove better upper and lower bounds for testing local properties. Our conjecture is that *any* 2-local property is testable in  $n^{1+o(1)}g(d)$  queries (where  $g(d)$  depends only on  $d$ ), but proving a statement of this type might be very difficult.

### Using the unrepairability framework in other contexts

In this work we show that the concept of unrepairability allows to unify and reprove many property testing results on one-dimensional arrays. What about multi-dimensional arrays? for example, can one generalize the currently known proofs for “bounded derivative” properties (including monotonicity and Lipschitz continuity) in  $d$  dimensions to a larger class of local properties?

### Inference

As mentioned in Subsection 1.4.1, our test queries boundaries of block-like structures, and later infers whether each block is *unrepairable* (recall the definition from Subsection 1.4.1). The inference takes place without making any additional queries, and is based only on the property  $\mathcal{P}$ , the alphabet  $\Sigma$ , and the values of  $A$  in the boundary of the block.

The running time of the inference step is very large in general (although, as we have seen, in the 1D case it can be significantly improved using dynamic programming). The naive way to run the inference is by enumerating over all possible ways to fill the interior of the block, and checking whether each such possibility is indeed  $\mathcal{F}$ -free. The running time of this method is of order  $|\Sigma|^{O(n^d)}$  in general for  $d > 1$ , and is exponential in  $n$  even if  $|\Sigma| = 2$ .

However, for many natural properties, inference can be done much more efficiently. For example, in monotonicity testing, the inference amounts to checking that no pair of boundary entries violates the monotonicity. Our lower bound constructions depict other properties where inference is efficient: it is not hard to show that the running time of inference in both cases is  $O(k\epsilon^{-1/d}n^{d-1})$ , which is sublinear in  $n^d$  for a wide range of parameters.

Thus, we believe that understanding inference better – including tasks such as characterizing properties in which inference can be done efficiently, and understanding the inference time of specific properties of interest – would be an interesting direction for future research.

## 1.7 Property testing notation

The property testing notation we use along the paper is standard. Given a property  $\mathcal{P}$  of  $[n]^d$ -arrays over  $\Sigma$ , a proximity parameter  $\epsilon > 0$ , and query access to an unknown  $[n]^d$ -array  $A$ , a *two-sided error  $\epsilon$ -test* must accept  $A$  with probability at least  $2/3$  if  $A$  satisfies  $\mathcal{P}$ , and reject with probability  $2/3$  if  $A$  is  $\epsilon$ -far from  $\mathcal{P}$  (meaning that the relative *Hamming distance* of  $A$  from  $\mathcal{P}$  is at least  $\epsilon$ , that is, we need to modify at least  $\epsilon n^d$  values in  $A$  to make it satisfy  $\mathcal{P}$ ). A *one-sided error test* is defined similarly, but it must accept if  $A$  satisfies  $\mathcal{P}$ . A test is *non-adaptive* if it makes all of its queries in advance (prior to receiving any of the queried values), and *adaptive* otherwise.

### Organization

In Sections 2, 3 and 4 we prove the upper bounds: Section 2 is devoted to the infrastructure needed for the proof, Section 3 presents a simple but non-optimal test, and finally, Section 4 presents the optimal test and proves Theorems 1 and 2.

Due to space considerations, the proofs of the lower bounds are given in Sections 5 and 6 of the full version of this paper [5].

## 2 The grid structure

In this section we present the grid-like structure in  $[n]^d$  that we utilize for our tests.

► **Definition 5 (Interval partition).** A subset  $I \subseteq [n]$  is an *interval* if its elements are consecutive, that is, if  $I = \{x, x+1, \dots, x+y\}$  for some  $x \in [n]$  and  $y \geq 0$ . For any  $\ell \geq 0$ , we denote the set of the smallest  $\ell$  elements of  $I$  by  $I[:\ell]$  and also define  $I[\ell+1:] = I \setminus I[:\ell]$ . In the degenerate case that  $|I| < \ell$ , we define  $I[:\ell]$  to be equal to  $I$ .

For  $1 \leq w \leq n$ , an  $(n, w)$ -interval partition is a partition of  $[n]$  into a collection of disjoint intervals  $\mathcal{I} = (I_1, \dots, I_t)$  where the number of elements in each interval  $I_i$  is either  $w$  or  $w+1$ , and for any  $i < j$ , all elements of  $I_i$  are smaller than those in  $I_j$ .

► **Lemma 6.** For any positive integer  $n$  and  $0 \leq i \leq \log n$ , there exists an  $(n, \lfloor n/2^i \rfloor)$ -interval partition  $\mathcal{I}_i$  containing exactly  $2^i$  intervals, so that the family  $\{\mathcal{I}_i\}_{i=0}^{\lfloor \log n \rfloor}$  satisfies the following. For any  $i > j$  and interval  $I \in \mathcal{I}_i$ , there exists an interval  $I' \in \mathcal{I}_j$  satisfying  $I \subseteq I'$ .

**Proof.** For any  $i$  define  $n_i = \lfloor n/2^i \rfloor$ ; observe that  $n_0 = n$  and  $n_{i+1} = \lfloor n_i/2 \rfloor$  for any  $i$ . We prove the lemma by induction on  $i$ , starting by defining  $\mathcal{I}_0 = ([n])$ . Given  $\mathcal{I}_i = (I_1^i, \dots, I_{2^i}^i)$  in which all intervals are of length  $n_i$  or  $n_i+1$ , we define  $\mathcal{I}_{i+1}$  as follows. Each  $I_j^i \in \mathcal{I}_i$  is decomposed into two intervals  $I_{2j-1}^{i+1}, I_{2j}^{i+1}$  where  $|I_{2j-1}^{i+1}|, |I_{2j}^{i+1}| \in \{n_{i+1}, n_{i+1}+1\}$ , and all elements of  $I_{2j-1}^{i+1}$  are smaller than all elements of  $I_{2j}^{i+1}$ ; observe that such a decomposition is indeed always possible. Now define  $\mathcal{I}_{i+1} = (I_1^{i+1}, \dots, I_{2^{i+1}}^{i+1})$ . Clearly, the intervals of  $\mathcal{I}_{i+1}$  satisfy the last condition of the lemma. ◀

In particular, we conclude that for any positive integer  $w$  and any  $n \geq w$  there exists an integer  $w/2 \leq w' \leq w$  for which an  $(n, w')$ -interval partition exists.

► **Definition 7 ( $(n, d, k, w)$ -grid).** Let  $2 \leq w \leq n$  be integers for which an  $(n, w)$ -interval partition  $\mathcal{I} = (I_1, \dots, I_t)$  exists. For integers  $2 \leq k \leq w$  and  $d \geq 1$ , the  $(d)$ -dimensional  $(n, d, k, w)$ -grid induced by  $\mathcal{I}$  is the set

$$G = \left\{ (x_1, \dots, x_d) \in [n]^d \mid \exists i \in [d] \text{ such that } x_i \in \bigcup_{j=1}^t I_j[:k-1] \right\}.$$

We denote the family of all  $(n, d, k, w)$ -grids by  $\mathcal{G}(n, d, k, w)$ . As we have seen in Lemma 6, the family  $\mathcal{G}(n, d, k, w)$  is non-empty for any  $w = \lfloor n/2^i \rfloor$  satisfying  $w \geq k$ .

► **Definition 8 ( $G$ -block, Boundary, Closure).** Two tuples  $x = (x_1, \dots, x_d)$  and  $y = (y_1, \dots, y_d)$  in  $[n]^d$  are considered *neighbors* if  $\sum_{i=1}^d |x_i - y_i| = 1$ . Given a grid  $G \in \mathcal{G}(n, d, k, w)$ , consider the neighborhood graph of non-grid entries, i.e., the graph whose set of vertices is  $V = [n]^d \setminus G$  and two entries are connected if they are neighbors. A  $G$ -block  $B$  is a connected component of this graph, and the *closure* of  $B$  is

$$\overline{B} = \left\{ (x_1, \dots, x_d) \in [n]^d \mid \exists (y_1, \dots, y_d) \in B \text{ such that } \forall i \in [d] |x_i - y_i| < k \right\}.$$

Note that  $B \subseteq \overline{B}$ . Define the *boundary* of the block  $B$  as  $\partial B = \overline{B} \setminus B$ .

## 11:14 Testing Local Properties of Arrays

The above notions can naturally be defined with Cartesian products. Recall that the Cartesian product of sets  $X_1, \dots, X_d$ , denoted  $\prod_{j=1}^d X_j$  or  $X_1 \times \dots \times X_d$ , is the set of all tuples  $(x_1, \dots, x_d)$  with  $x_j \in X_j$  for any  $j \in [d]$ . Let  $G \in \mathcal{G}(n, d, k, w)$  be the grid induced by the interval partition  $\mathcal{I} = (I_1, \dots, I_t)$ . It is not difficult to verify that any  $G$ -block  $B$  can be defined as a Cartesian product  $B = \prod_{j=1}^d I_{i_j}[k:]$  for some intervals  $I_{i_1}, \dots, I_{i_d} \in \mathcal{I}$  (not necessarily different).

$\overline{B}$  and  $\partial B$  can also be defined accordingly, as we detail next. For  $k$  as above, define  $\overline{I_i} = I_i \cup I_{i+1}[k-1]$  for any  $1 \leq i \leq t$ , where we take  $I_{t+1} = \emptyset$  for consistency. Also define  $\partial I_i = \overline{I_i} \setminus I_i[k:] = I_i[k-1] \cup I_{i+1}[k-1]$ . With these in hand, we have

$$B = \prod_{j=1}^d I_{i_j}[k:]; \quad \overline{B} = \prod_{j=1}^d \overline{I_{i_j}}; \quad \partial B = \bigcup_{j=1}^d \overline{I_{i_1}} \times \dots \times \overline{I_{i_{j-1}}} \times \partial I_{i_j} \times \overline{I_{i_{j+1}}} \times \dots \times \overline{I_{i_d}} \quad (1)$$

Recall that  $|I_{i_j}| \in \{w, w+1\}$  for any  $j$ , implying that  $|I_{i_j}[k:]| \leq w+2-k$  and  $|\overline{I_{i_j}}| \leq w+k$ . Also note that  $|\partial I_{i_j}| \leq 2(k-1)$ . Thus,

$$|B| \leq (w+2-k)^d; \quad |\overline{B}| \leq (w+k)^d; \quad |\partial B| \leq 2d(k-1) \cdot (w+k)^{d-1}, \quad (2)$$

where the inequality on  $|\partial B|$  holds since each set in the union expression in (1) is of size at most  $(2k-2)(w+k)^{d-1}$ .

The following observation is a direct consequence of (1).

► **Observation 9.** *Let  $G \in \mathcal{G}(n, d, k, w)$ . The boundary of any  $G$ -block is contained in  $G$ .*

► **Lemma 10.** *For any  $G \in \mathcal{G}(n, d, k, w)$ , any width- $k$  subarray of an  $[n]^d$ -array intersects exactly one  $G$ -block  $B$ . Moreover, the subarray is contained in  $\overline{B}$ .*

**Proof.** Let  $\mathcal{I} = (I_1, \dots, I_t)$  be the interval partition inducing  $G$ . Suppose that the subarray  $S$  is in location  $(a_1, \dots, a_d)$  where  $a_j \in I_{i_j}$  for some  $i_1, \dots, i_d$  not necessarily distinct. In other words, the set of entries in  $S$  is  $\prod_{j=1}^d S_j$  where  $S_j = \{a_j, a_j+1, \dots, a_j+k-1\}$  for any  $j \in [d]$ . We argue that  $S$  is contained in  $\overline{B}$ , where  $B = I_{i_1}[k:] \times \dots \times I_{i_d}[k:]$ : The fact that  $a_j \in I_{i_j}$  implies that  $a_j+1, \dots, a_j+k-1 \in I_{i_j} \cup I_{i_j+1}[k-1]$ . It follows from (1) that  $S \subseteq \overline{B}$ . From Observation 9 we conclude that  $S$  does not intersect any block other than  $B$ , and it remains to show that  $S$  intersects  $B$ . Indeed, for any  $1 \leq j \leq d$ , the fact that  $a_j \in I_{i_j}$  implies that one of the elements  $a_j, \dots, a_j+k-1$  must be contained in  $I_{i_j}[k:]$ . Denoting this element by  $b_j$ , we conclude that  $(b_1, \dots, b_d) \in S \cap B$ . ◀

### 3 Testing with grid queries

In this section we prove the following upper bound for all  $k$ -local properties; its proof serves as a warm-up towards proving the main upper bound of Theorem 1.

► **Theorem 11.** *Any  $k$ -local property of  $[n]^d$ -arrays over any alphabet is  $\epsilon$ -testable with one-sided error using no more than  $2(d+1)n^{d-\frac{d}{d+1}}k^{\frac{d}{d+1}}\epsilon^{-\frac{1}{d+1}}$  non-adaptive queries.*

The upper bound of Theorem 11 is sublinear in the size of the array as long as  $k/\epsilon^{1/d} = o(n)$ . The rest of the section is dedicated to the proof of the theorem. We may assume that  $k \leq \epsilon^{1/d}n/4$ , as otherwise the expression in the statement of the theorem is larger than  $n^d$  and the proof follows trivially by querying all  $[n]^d$  entries of the given input array. Under this assumption, it holds that  $2k \leq n^{d/(d+1)}k^{1/(d+1)}\epsilon^{1/(d+1)}$ .

► **Definition 12** (Unrepairable block). Let  $A$  be an  $[n]^d$ -array over  $\Sigma$ , and let  $G \in \mathcal{G}(n, d, k, w)$ . A  $G$ -block  $B$  is  $(\mathcal{P}, A)$ -unrepairable (or simply *unrepairable*, if  $\mathcal{P}$  and  $A$  are clear from context) if any  $[n]^d$ -array  $A'$  over  $\Sigma$  that satisfies  $A'(x) = A(x)$  for any  $x \in \partial B$ , including the case  $A' = A$ , contains an  $\mathcal{F}$ -copy in  $\overline{B}$ . Otherwise, the block  $B$  is said to be  $(\mathcal{P}, A)$ -repairable.

Note that the (un)repairability of a block  $B$  is determined solely by the values of  $A$  on  $\partial B$ , and that an unrepairable block always contains an  $\mathcal{F}$ -copy. These two facts inspire the following lemma, which serves as the conceptual core behind the test of Theorem 11.

► **Lemma 13.** *Suppose that  $A$  is an  $[n]^d$ -array that is  $\epsilon$ -far from satisfying a  $k$ -local property  $\mathcal{P}(\mathcal{F})$ , and let  $G \in \mathcal{G}(n, d, k, w)$  where  $w \geq k$ . Then at least one of the following holds.*

- *There exists a  $(\mathcal{P}, A)$ -unrepairable  $G$ -block.*
- *For at least an  $\epsilon$ -fraction of the  $G$ -blocks  $B$ , there is an  $\mathcal{F}$ -copy in  $\overline{B}$ .*

**Proof.** Suppose that the first condition does not hold, that is, all  $G$ -blocks are  $(\mathcal{P}, A)$ -repairable. By Lemma 10, every  $\mathcal{F}$ -copy is contained in the closure of some  $G$ -block.

Let  $\mathcal{C}$  denote the collection of all  $G$ -blocks  $B$  such that  $A$  contains an  $\mathcal{F}$ -copy in  $\overline{B}$ . By the repairability, the values of  $A$  in each block  $B \in \mathcal{C}$  can be modified so that after the modification,  $A$  will not contain an  $\mathcal{F}$ -copy in  $\overline{B}$ . We stress that the modifications for each block  $B$  appear only in  $B$  itself and do not modify entries on the grid, so by Lemma 10, they cannot create new  $\mathcal{F}$ -copies in the closure of other blocks.

After applying all of the above modifications to  $A$ , we get an  $\mathcal{F}$ -free array, i.e., an array that satisfies  $\mathcal{P}$ .  $A$  was initially  $\epsilon$ -far from  $\mathcal{P}$ , and the number of entries in each block is bounded by  $(w + 2 - k)^d \leq w^d$ , implying that at least an  $\epsilon$ -fraction of the blocks belong to  $\mathcal{C}$ . ◀

**Proof of Theorem 11.** We may assume that  $k^d/\epsilon \leq n^d/2$ , otherwise our test may trivially query all  $n^d$  entries of  $A$ . Our (non-adaptive) test  $T$  picks  $W = \lfloor n^{d/(d+1)} k^{1/(d+1)} \epsilon^{1/(d+1)} \rfloor \geq 2k$ , and an integer  $w$  satisfying  $k \leq W/2 \leq w \leq W$ , for which an  $(n, w)$ -interval partition exists.  $T$  now makes the following queries.

1.  $T$  queries all entries of an arbitrarily chosen grid  $G \in \mathcal{G}(n, d, k, w)$ . The number of entries in any grid is at most  $dn^d(k-1)/w \leq 2dn^{d-\frac{d}{d+1}} k^{\frac{d}{d+1}} \epsilon^{-\frac{1}{d+1}}$ .
2.  $T$  chooses a collection  $\mathcal{B}$  of  $2/\epsilon$   $G$ -blocks uniformly at random and queries all entries in these blocks. Since each block contains at most  $(w + 2 - k)^d \leq W^d$  entries, the total number of queries is bounded by  $2W^d/\epsilon \leq 2n^{d-\frac{d}{d+1}} k^{\frac{d}{d+1}} \epsilon^{-\frac{1}{d+1}}$ . Note that the boundaries of all blocks are queried in the first step (since they are contained in the grid). Thus, for any block  $B \in \mathcal{B}$ , the test queries all entries of  $\overline{B}$ .

The total number of queries in the above two steps is  $2(d+1)n^{d-\frac{d}{d+1}} k^{\frac{d}{d+1}} \epsilon^{-\frac{1}{d+1}}$ .

After querying all entries of the grid (and in particular, the whole boundaries of all of the blocks),  $T$  can determine for every  $G$ -block  $B$  whether it is  $(\mathcal{P}, A)$ -unrepairable or not.  $T$  rejects if at least one of the blocks is unrepairable or if it found an  $\mathcal{F}$ -copy in  $\overline{B}$  for some  $B \in \mathcal{B}$ , and accepts otherwise. The test has one-sided error, since an unrepairable block must contain an  $\mathcal{F}$ -copy. In view of Lemma 13,  $T$  rejects arrays  $A$  that are  $\epsilon$ -far from  $\mathcal{P}$  with probability at least  $2/3$ : If  $A$  satisfies the first condition of Lemma 13, then  $T$  always rejects. If the second condition holds, the probability that none of the  $2/\epsilon$  closures  $\overline{B}$  for  $B \in \mathcal{B}$  contains an  $\mathcal{F}$ -copy is bounded by  $(1 - \epsilon)^{2/\epsilon} < e^{-2}$ , so  $T$  rejects with probability at least  $1 - e^{-2} > 2/3$ . ◀

#### 4 Systems of grids and testing with spherical queries

In this section we prove Theorems 1 and 2. We do so by considering a system of grids with varying block sizes, defined as follows.

► **Definition 14.** Let  $d > 0$  and  $2 \leq k \leq w \leq n$  be integers. An  $(n, d, k, w)$ -system of grids is an  $(r + 1)$ -tuple  $(G_0, G_1, \dots, G_r)$  of grids, for  $r(n, w) = \lfloor \log(n/w) \rfloor$ , so that

- $G_i \in \mathcal{G}(n, d, k, \lfloor n/2^{r-i} \rfloor)$  for any  $0 \leq i \leq r$ .
- $G_0 \supseteq G_1 \supseteq \dots \supseteq G_r$  (as subsets of  $[n]^d$ ). In particular, for any  $i < j \leq r$ , any  $G_i$ -block  $B$  is contained in a  $G_j$ -block  $B'$ , and we say that  $B'$  is an *ancestor* of  $B$ . Specifically, the  $G_{i+1}$ -block containing  $B$  is called the *parent* of  $B$  and denoted by  $\text{Par}(B)$ . For the only  $G_r$ -block,  $B_r$ , we define  $\text{Par}(B_r)$  as the whole domain  $[n]^d$ .

$r(n, w)$  was chosen so that  $w \leq n/2^r < 2w$ , making  $G_0$  a  $\mathcal{G}(n, d, k, w')$ -grid for  $w \leq w' < 2w$ . As we shall see, when working with such a system, unrepairability of blocks can be handled in a query-efficient way. The following lemma asserts that such a system of grids exists for any suitable choice of parameters.

► **Lemma 15.** An  $(n, d, k, w)$ -system of grids exists for all  $d > 0$  and  $2 \leq k \leq w \leq n$ .

**Proof.** Consider the family of interval partitions  $\mathcal{I}_0, \dots, \mathcal{I}_{\lfloor \log n \rfloor}$  obtained by Lemma 6. For each  $0 \leq i \leq r(n, w)$  define  $G_i$  as the  $(n, d, k, \lfloor n/2^{r-i} \rfloor)$ -grid induced by  $\mathcal{I}_{r-i}$ . It is not hard to verify that  $(G_0, \dots, G_r)$  satisfies all requirements of an  $(n, d, k, w)$ -system of grids. ◀

For the rest of the section, fix a  $k$ -local property  $\mathcal{P}(\mathcal{F})$  of  $[n]^d$ -arrays over  $\Sigma$ , as well as an  $[n]^d$ -array  $A$  over  $\Sigma$ . Consider an  $(n, d, k, w)$ -system of grids  $(G_0, \dots, G_r)$  constructed as described in the proof of Lemma 15, where  $w$  will be determined later. (For now it suffices to require, as usual, that  $2 \leq k \leq w \leq n$ .)

We say that a  $G_i$ -block  $B$  is a  $(\mathcal{P}, A)$ -witness if one of the following holds.

- $i = 0$  and the array  $A$  contains an  $\mathcal{F}$ -copy in the closure  $\overline{B}$ .
- $i > 0$  and  $B$  is  $(\mathcal{P}, A)$ -unrepairable.

Recall that the closure of unrepairable blocks cannot be  $\mathcal{F}$ -free, so the closure of any witness block contains an  $\mathcal{F}$ -copy. We say that a witness block  $B$  is *maximal* if all of its ancestors are not witnesses, that is, they are repairable.

► **Observation 16.** Any  $(\mathcal{P}, A)$ -witness is contained in a maximal  $(\mathcal{P}, A)$ -witness.

We define the *maximal witness family*  $\mathcal{W}$  as the set of all maximal  $(\mathcal{P}, A)$ -witness blocks. Obviously, the blocks in  $\mathcal{W}$  might come from different  $G_i$ 's

► **Observation 17.**  $B_1 \cap B_2 = \emptyset$  for any two blocks  $B_1, B_2 \in \mathcal{W}$ .

► **Lemma 18.** All  $\mathcal{F}$ -copies in  $A$  are fully contained in  $\bigcup_{B \in \mathcal{W}} \overline{B}$ .

**Proof.** Let  $F$  be an  $\mathcal{F}$ -copy in  $A$ . By Lemma 10,  $F$  is contained in the closure of a unique  $G_0$ -block  $B_F$ ; hence,  $B_F$  is a  $(\mathcal{P}, A)$ -witness. From Observation 16 we have  $B_F \subseteq B'$  for some maximal  $(\mathcal{P}, A)$ -witness  $B'$ . We conclude that  $F \in \overline{B_F} \subseteq \overline{B'}$ . ◀

► **Lemma 19.** One can make  $A$  satisfy  $\mathcal{P}$  by only modifying entries of  $A$  in  $\bigcup_{B \in \mathcal{W}} \text{Par}(B)$ .

**Proof.** Fix  $B \in \mathcal{W}$ .  $B$  is a maximal  $(\mathcal{P}, A)$ -witness, so  $\text{Par}(B)$  is repairable.<sup>1</sup> Thus, One can make  $\overline{\text{Par}(B)}$   $\mathcal{F}$ -free by only modifying entries inside  $\text{Par}(B)$ . By Lemma 10,

<sup>1</sup> Note that when  $B = B_r$  is the maximal witness considered,  $\text{Par}(B)$  is  $[n]^d$ ; the latter is repairable for any non-empty property.

width- $k$  subarrays that are not fully contained in  $\overline{\text{Par}(B)}$  are left unchanged. Therefore, this modification does not create any new  $\mathcal{F}$ -copies in  $A$ . Seeing that all  $\mathcal{F}$ -copies in  $A$  are originally contained in  $\bigcup_{B \in \mathcal{W}} \overline{B} \subseteq \bigcup_{B \in \mathcal{W}} \overline{\text{Par}(B)}$ , applying these modifications for all  $B \in \mathcal{W}$  deletes all  $\mathcal{F}$ -copies in  $A$  without creating new ones, so in the end of the process  $A$  satisfies  $\mathcal{P}$ .  $\blacktriangleleft$

We may assume that  $k \leq \epsilon^{1/d}n/10$ , as otherwise the expression in the theorem is  $\Omega(n^d)$ . We choose  $w = 2k$ , working with an  $(n, d, k, 2k)$ -system of grids from now on. A very useful consequence of this choice of  $w$  is that here the parent of a block  $B$  cannot be much larger than  $B$  itself.

► **Lemma 20.** *Let  $(G_0, G_1, \dots, G_r)$  be an  $(n, d, k, 2k)$ -system of grids. Then for any  $0 \leq i \leq r$  and any  $G_i$ -block  $B$  it holds that  $|\text{Par}(B)|/|B| < 3^d$ .*

**Proof.** For  $i = r$  this is trivial. Now fix  $i < r$  and let  $B$  be a  $G_i$ -block. Recall that, following (1), one can write  $B = \prod_{j=1}^d I_{i_j}[k:]$  where each interval  $I_{i_j}$  (for  $j \in [d]$ ) is of size at least  $2k \geq 4$ . On the other hand, we can also write  $\text{Par}(B) = \prod_{j=1}^d I'_{i'_j}[k:]$  where  $I'_{i'_j} \supseteq I_{i_j}$  for any  $j \in [d]$ . It is not hard to verify that  $|I'_{i'_j}| \leq 2|I_{i_j}| + 1$  most hold, and so

$$\frac{|\text{Par}B|}{|B|} = \prod_{j=1}^d \frac{|I'_{i'_j}| - (k-1)}{|I_{i_j}| - (k-1)} \leq \prod_{j=1}^d \frac{2|I_{i_j}| + 1 - (k-1)}{|I_{i_j}| - (k-1)} \leq \left( \frac{2 \cdot 2k - k + 2}{2k - k + 1} \right)^d < 3^d$$

where the second inequality holds since  $|I_{i_j}| \geq 2k$  for any  $j$ .  $\blacktriangleleft$

The next corollary follows immediately from Lemmas 19 and 20.

► **Corollary 21.** *Suppose that  $A$  is  $\epsilon$ -far from  $\mathcal{P}$ . Then the total number of entries in the blocks of  $\mathcal{W}$  is at least  $\epsilon(n/3)^d$ .*

We are now ready for the proof of the main upper bound of this paper, Theorem 1.

## 4.1 Proof of Theorem 1

As before, we may assume that  $k \leq \epsilon^{1/d}n/10$ . For larger  $k$ , the expression in the theorem dominates  $n^d$  and thus becomes trivial. Consider the  $(n, d, k, 2k)$ -system of grids  $(G_0, G_1, \dots, G_r)$  mentioned above. For any  $0 \leq i \leq r$ , define  $\delta_i = |\mathcal{B}_i \cap \mathcal{W}|/|\mathcal{B}_i|$ , where  $\mathcal{B}_i$  is the set of all  $G_i$ -blocks. In other words,  $\delta_i$  is the fraction of maximal witnesses among the  $G_i$ -blocks. By Corollary 21, if  $A$  is  $\epsilon$ -far from  $\mathcal{P}$  then  $\sum_{i=0}^r \delta_i \geq \epsilon/3^d$ . Define  $r' = \lfloor \log(\epsilon^{1/d}n/k) \rfloor \geq 1$ , noting that  $G_{r'} \in \mathcal{G}(n, d, k, w_{r'})$  with  $w_{r'} \geq 2k \cdot 2^{r'} \geq \epsilon^{1/d}n$ . Thus, the total number of blocks in  $\mathcal{B}_{r'}$  is bounded by  $(n/w_{r'})^d \leq 1/\epsilon$ .

### The test

We iterate the following basic step  $2 \cdot 3^d/\epsilon$  times.

1. Pick  $B \in \mathcal{B}_0$  uniformly at random and query all entries of  $\overline{B}$ .
  2. For any  $1 \leq i \leq r'$ , pick  $B \in \mathcal{B}_i$  uniformly at random and query all entries of  $\bigcup_{B \in \mathcal{Q}_0} \partial B$ .
- Finally, the test rejects if and only if at least one of the blocks  $B$  picked during the process is a  $(\mathcal{P}, A)$ -witness. (Recall that querying all boundary entries of a  $G_i$ -block for  $i > 0$  suffices to determine whether it is unrepairable, and thus a witness.)

The test is clearly non-adaptive, and has one-sided error: It only rejects if it finds a witness. As we have seen earlier, all witnesses contain an  $\mathcal{F}$ -copy.

## 11:18 Testing Local Properties of Arrays

The test is *canonical* in the following sense. The choice of queries in every basic step depends only on  $n, d, k$ , and (weakly) on  $\epsilon$ , and is independent of the property  $\mathcal{P}$  or the alphabet  $\Sigma$ . To determine which entries constitute a block, it suffices to know the parameters of the block, that depend only on  $n, d, k$ ; the dependence in  $\epsilon$  is only taken into account in the choice of  $r'$ . The test only considers  $\mathcal{P}$  in order to determine whether each queried block is a witness.

### Analysis

Suppose that  $A$  is  $\epsilon$ -far from  $\mathcal{P}$ . If  $\delta_i > 0$  for some  $i > r'$  then it must hold that  $\delta_{r'} > 0$  as well (since any unrepairable  $G_i$ -block must contain an unrepairable  $G_{i'}$ -block for any  $i' < i$ ). By the choice of  $r'$ , we must have  $\delta_{r'} \geq 1/|\mathcal{B}_{r'}| \geq \epsilon$  in this case. If the above doesn't hold, then  $\delta_i = 0$  for any  $i \geq r'$ , implying that  $\sum_{i=0}^{r'-1} \delta_i \geq \epsilon/3^d$ . Therefore, in both cases, we have  $\sum_{i=0}^{r'} \delta_i \geq \epsilon/3^d$ .

The probability that a random  $\mathcal{B}_i$ -block is a witness is at least  $\delta_i$ , and therefore the probability that a single basic step leads to a rejection of  $A$  is at least  $\sum_{i=0}^{r'} \delta_i \geq \epsilon/3^d$ . Running  $2 \cdot 3^d/\epsilon$  independent iterations of the basic step ensures that the test will accept  $A$  with probability at most  $(1 - \epsilon/3^d)^{2 \cdot 3^d/\epsilon} \leq e^{-2} < 2/3$ , as desired.

### Query complexity

For  $d = 1$ , the query complexity of each basic step is  $O(kr')$ : The test queries  $\overline{B}$  for a single block  $B \in \mathcal{B}_0$ , and the boundaries of  $r'$  larger blocks. Considering the parameters of our system of grids, we have  $|B| \leq 4k$  and so  $|\overline{B}| < 6k$ . On the other hand, the boundary of each of the larger blocks is of size at most  $2k - 2$ . Therefore, the total query complexity for the 1D test is  $O(kr'/\epsilon) = O\left(\frac{k}{\epsilon} \log(\epsilon n/k)\right)$  as desired.

For  $d > 1$ , consider a single basic step, and for any  $0 \leq i \leq r'$  let  $B_i \in \mathcal{B}_i$  be the  $\mathcal{G}_i$ -block picked in this step. From (2) we have  $|\overline{B}_0| \leq (6k)^d$ , while for any  $i > 0$  we have  $|\partial B_i| \leq 2d(k-1)(4k \cdot 2^i + k)^{d-1} = O(d \cdot (4k)^d \cdot 2^{(d-1)i})$ . Note that the last expression grows exponentially with  $(d-1)i$ , so the total number of queries in a single basic step is  $O((6k)^d + d \cdot (4k)^d 2^{(d-1)r'})$ . Plugging in  $r'$ , we have  $2^{(d-1)r'} = \frac{\epsilon^{(d-1)/d}}{k^{d-1}} n^{d-1}$ . As the test runs  $O(3^d/\epsilon)$  iterations of the basic step, we conclude that the total query complexity is bounded by  $c^d k \epsilon^{-1/d} n^{d-1}$  for an absolute constant  $c > 0$ , completing the proof of Theorem 1.

## 4.2 Proximity oblivious test

The proof of Theorem 2 follows by a very simple modification of the proof of Theorem 1. The desired proximity oblivious test (POT) is the so called “basic step” from the above test, with  $r$  replacing  $r'$  (since  $r'$  depends on  $\epsilon$ ). The POT rejects if it infers that one of the blocks queried is a witness, like the above test. Its query complexity is  $O(kr) = O(k \log n/k)$  for  $d = 1$ . In the case  $d > 1$ , the query complexity is dominated by the size of  $\partial B_r$ , which is bounded by  $O(dkn^{d-1})$ .

Clearly this POT has one-sided error, and its queries do not depend on the property  $\mathcal{P}$  and the alphabet  $\Sigma$  (on the other hand, they do depend on  $n, d, k$ ). Using the notation of the previous subsection and denoting by  $\epsilon_A$  the Hamming distance of a given input  $A$  from  $\mathcal{P}$ , we get (exactly as in the beginning of Subsection 4.1) a rejection probability of at least  $\sum_{i=0}^r \delta_i \geq \epsilon_A/3^d$  for  $A$ , which is linear in  $\epsilon_A$  for fixed  $d$ . This concludes the proof.

## Abstract

This paper studies families of distributions  $\mathcal{T}$  that are amenable to *retentive learning*, meaning that an expert can *retain* users that seek to predict their future, assuming user attributes are sampled from  $\mathcal{T}$  and exposed gradually over time. Limited *attention span* is the main problem experts face in our model. We make two contributions.

First, we formally define the notions of *retentively learnable* distributions and properties. Along the way, we define a *retention complexity* measure of distributions and a natural class of *retentive scoring rules* that model the way users evaluate experts they interact with. These rules are shown to be tightly connected to truth-eliciting “proper scoring rules” studied in Decision Theory since the 1950’s [McCarthy, PNAS 1956].

Second, we take a first step towards relating retention complexity to other measures of significance in computational complexity. In particular, we show that linear properties (over the binary field) are retentively learnable, whereas random Low Density Parity Check (LDPC) codes have, with high probability, maximal retention complexity. Intriguingly, these results resemble known results from the field of property testing and suggest that deeper connections between retentive distributions and locally testable properties may exist.

**2012 ACM Subject Classification** Theory of computation → Models of computation

**Keywords and phrases** retentive learning, retention complexity, information elicitation, proper scoring rules

## 1 Introduction

Certain aspects of life – child development, love, psychological disorders, etc. – seem comprehensible and somewhat predictable *only* when addressed jointly with an expert, via an interactive process that unfolds over time. This work initiates the formal study of phenomena that are amenable to an interactive *collaborative discovery* process between an expert and a layperson. This collaboration unfolds over time, as more aspects of the phenomena become apparent to the layperson. We model this by associating each layperson with a sequence

$x = (x_1, \dots, x_n)$  sampled from some underlying distribution  $\mathcal{T}$ , and assume that attributes of the phenomena (entries of  $x$ ) are gradually exposed over time, in response to active querying by the layperson. The interactive process has the expert predicting the value of  $x_i$  before it is revealed to the layperson. At the time of revelation, the layperson also re-evaluates his assessment of the expert’s utility to him: outcomes that seem “obvious” and predictable to the user are viewed as less helpful than “surprising” and unpredictable ones. At the end of each step, the layperson must decide whether to terminate his relationship with the expert or continue with it.

A major factor in our study is the *limited attention span* that characterizes users; consequently, the expert’s goal is to *retain* the layperson by constantly supplying him with meaningful and surprising insights about the phenomena. The terms *guru* (instead of expert) and *follower* (as opposed to layperson) better capture this dynamic so we use these terms henceforth. The main advantage the guru has over her followers is a greater ability to understand the phenomena, which we model by assuming the guru has a greater *memory span* than her followers. Using these terms, we define a class of distributions to be *retentively learnable* if a fixed *constant* advantage in memory span suffices for a guru to retain her followers throughout the entire collaborative discovery process. Our main complexity result is that the property of *linearity* over the binary field is retentively learnable (Theorem 10), whereas arbitrary linear spaces are maximally non-retentive (Theorem 13). To state these results, we first have to define our model and study its intrinsic properties. These properties turn out to be non-trivial to study, and lead to surprising results that are of independent interest. In particular, our first main result (Theorem 4) is a non-intuitive characterization of retentive scoring rules in terms of *proper scoring rules* studied in Decision Theory.

## Roadmap

Subsection 1.1 further explains, informally, the kind of guru–follower dynamics that we aim to formalize and understand. Subsection 1.2 gives a formal description of the model. In Subsection 1.3, we discuss the concept of *retentive scoring*, which allows us to describe the collaborative discovery process in an incentive-compatible way, taking agent rationality into account. Subsection 1.4 adds the layer of *limited memory span* to characterize the discrepancies between the guru and follower, and between fellow gurus. In Subsection 1.5, we state our main complexity results for linear properties. Subsection 1.6 reviews the latest related work, and finally Subsection 1.7 summarizes the main contributions and questions to be explored in the future.

## 1.1 The Guru’s Problem

In today’s information society, crowd-based automated gurus gather data from users on a voluntary basis in order to produce meaningful insights. The quality of insights greatly depends on the amount and quality of data provided by the users, but those users have limited attention, giving rise to the study of *attention economy* [12, 16]. By asking “*interesting questions*” and making “*meaningful predictions*”, an automated guru can retain users, but only if it “knows” how to ask “interesting” questions and provide “meaningful” feedback.

The phenomenon that motivated this research is that of *early child development*; the gurus are experts in this field and the followers are parents of newborn babies [3]. For the sake of concreteness we shall continue using this particular setting to describe our model but it may be conveniently replaced by the reader with physicians or psychologists playing the gurus as they interact with patients (followers) regarding a complex medical or mental

problem, or with financial advisors as gurus and their follower clientele. In these and similar settings, gurus and followers discuss a complex phenomenon that evolves over time, which the followers wish to understand, and about which the guru claims to have an advantage of “*wisdom*” over them.

## 1.2 The Collaborative Discovery model

The *phenomenon* about which the guru and her followers interact is modeled by a *distribution*  $\mathcal{T}$  over  $\mathcal{X}^\Gamma$ , where  $\Gamma$  is the set of properties manifested by the phenomenon and  $\mathcal{X}$  is an arbitrary input space. The two input spaces mentioned in this paper are the binary space  $\mathcal{X} = \{0, 1\}$  and the finite categorical space  $\mathcal{X} = \{0, \dots, n\}$ . In the context of childhood development,  $\Gamma$  is the set of developmental milestones like “*first smile*”, and each follower (associated, for simplicity, with a parent of a single child) is represented by a sample  $u \in \mathcal{X}^\Gamma$  that describes the ages at which that child achieved each milestone. By time  $t$ , the follower discloses to the guru  $u|_{\Gamma_t}$ , the restriction of her sample  $u$  to a subset  $\Gamma_t \subseteq \Gamma$ . Additional attributes of  $u$  may be revealed later in time, others might be disclosed by the follower if prompted to do so, while certain attributes will remain forever latent.

The follower seeks the guru’s assistance in predicting “meaningful information” that is currently unknown to the follower. The guru and follower *interact* over a number of rounds but the follower will terminate the interaction if the guru is judged to be unhelpful (in a manner formalized below). During each round of interaction, the guru makes a prediction by announcing a distribution  $P_{\gamma_t}$  over  $\mathcal{X}$  that she claims is the true one for a latent attribute  $\gamma_t \notin \Gamma_t$ ; the follower has a distribution  $Q_{\gamma_t}$  that she believes corresponds to  $\gamma_t$ . (Modern gurus and followers are comfortable discussing probabilities rather than predicting a single event as is the case with pre-election polling results.) The way  $\gamma_t$  is selected from  $\Gamma \setminus \Gamma_t$  and its effect on the process is left to future work. The follower now queries  $\gamma_t$  and reports the true value, denoted  $u_{\gamma_t}$ , which is derived from Nature’s “true” distribution. After each round the follower updates the strength of her *retention* by the guru. We assume this strength is given by a *retention parameter*  $r_t$  that starts with a fixed value  $r_0$  and varies with time; once  $r_t$  turns negative the follower will be said to have lost all faith in the guru and therefore terminate the interaction. The main objective of the guru is to maintain  $r_t \geq 0$  for all  $t \geq 0$ ; jumping ahead, a distribution  $\mathcal{T}$  for which there exists a guru that, in expectation, manages to retain followers to eternity (or until  $t = |\Gamma|$  for finite  $\Gamma$ ) will be said to be  *$r_0$ -retainable* and the *retention complexity* of  $\mathcal{T}$  will be the minimal  $r_0$  such that  $\mathcal{T}$  is  $r_0$ -retainable (see Definitions 7, 8).

When the user updates her retention parameter at the end of round  $t$ , she uses a function  $\mathcal{S}(\cdot, \cdot, \cdot)$  that is real-valued and takes three inputs: (i) the guru’s predicted distribution  $P_{\gamma_t}$ ; (ii) the follower’s assessment of that distribution  $Q_{\gamma_t}$ ; and (iii) the value  $u_{\gamma_t}$  that materialized, sampled by Nature. The retention parameter at time  $t$  is given by

$$r_t = r_{t-1} + \mathcal{S}(P_{\gamma_t}, Q_{\gamma_t}, u_{\gamma_t}) \tag{1}$$

► **Remark (Simplifying assumptions).** The formula (1) makes the following assumptions on the follower’s update rule: that it is Markovian, uses  $r_{t-1}$  additively and does not depend on the follower’s identity nor on the identity of the attribute  $\gamma_t$  being predicted. Such assumptions are common when modeling human behavior and we leave the study of more general update functions to future work.

### 1.3 Retentive Scoring Rules

The definition of the function  $\mathcal{S}$  above, and the surprising corollaries of this definition, are what dominates the first part of our study. We assume  $\mathcal{S}$  belongs to a class of functions that *elicit* the true beliefs of both guru and follower regarding the distribution for the attribute  $\gamma_t$ . Truth eliciting rules are ones that incentivize (rational) players to supply the rule with what they believe to be the truth. A famous early example of a truth eliciting rule is that of a one-party *proper scoring rule*, which will be tightly related to our two-party retentive scoring rule  $\mathcal{S}$ , so we start with the simpler, one-party, case.

#### Proper (one-party) Scoring Rules

One-party *proper scoring rules* are used to compensate a single forecaster of Nature in a truth-eliciting manner; these rules are studied extensively in the Decision Theory literature [17, 23, 11] and have interesting connections to the fields of estimation, information theory, and machine learning; see [8] for a recent survey. A scoring rule receives a single forecast, which is a distribution  $P$  over  $\mathcal{X}$  as an input (say, this could be the temperature at noon tomorrow at a fixed location), and scores the forecaster based on the outcome selected by Nature (the actual temperature). A scoring rule is called *proper* if it is maximized by forecasting the true distribution. We recite the definition as it appears in [23, 11]:

► **Definition 1** (Proper Scoring Rule). Let  $\mathcal{P}$  be a convex set of distributions over an arbitrary input space  $\mathcal{X}$ . A (one-party) *scoring rule* is a function  $s : \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$ . The scoring rule  $s$  is *proper* with respect to  $\mathcal{P}$  if, for all  $R \in \mathcal{P}$  (viewed as Nature's true distribution), the expected score  $\mathbb{E}_{x \sim R} [s(P, x)]$  is maximized over  $P \in \mathcal{P}$  at  $P = R$ :

$$\forall P \in \mathcal{P} \quad \mathbb{E}_{x \sim R} [s(P, x)] \leq \mathbb{E}_{x \sim R} [s(R, x)] \quad (2)$$

Intuitively, when the agent forecasts a distribution  $P \in \mathcal{P}$  and event  $x \in \mathcal{X}$  materializes, the reward for the expert is  $s(P, x)$ . To increase clarity when one-party and two-party (retentive) scoring rules are involved, we will use a lowercase  $s$  to denote a proper (one-party) scoring rule, and a calligraphic  $\mathcal{S}$  to denote a retentive (two-party) one.

Many proper scoring rules can be constructed using elementary functions, for example the *logarithmic scoring rule*:

$$s(P, i) = \log p_i \quad (3)$$

and *Brier's scoring rule* [6]:

$$s(P, i) = 2p_i - \sum_j p_j^2 = 2p_i - \|P\|_2^2 \quad (4)$$

#### Retentive (Two-Party) Scoring Rules

In the spirit of proper scoring rules, we define a *retentive* scoring rule which involves two parties: guru and follower. Using an axiomatic approach, we start by defining the desired properties of such a rule:

► **Definition 2** (Retentive Scoring Rule). Let  $\mathcal{P}$  be a convex set of distributions over an arbitrary input space  $\mathcal{X}$ . A function  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  is called a *retentive scoring rule* if it satisfies the following conditions:

1. *Cost of ignorance*: For all distributions  $P \in \mathcal{P}$  and outcomes  $x \in \mathcal{X}$ ,

$$\mathcal{S}(P, P, x) = -1 \tag{5}$$

2. *Proper scorings*: for any distribution  $R \in \mathcal{P}$  dictated by Nature:

- a. *Guru-side*: For any fixed follower belief  $Q \in \mathcal{P}$ , the best guru prediction  $P \in \mathcal{P}$  is Nature's:

$$\mathbb{E}_{x \sim R} [\mathcal{S}(P, Q, x)] \leq \mathbb{E}_{x \sim R} [\mathcal{S}(R, Q, x)] \tag{6}$$

- b. *Follower-side*: For any fixed guru prediction  $P \in \mathcal{P}$ , the best follower belief  $Q \in \mathcal{P}$  is Nature's:

$$\mathbb{E}_{x \sim R} [\mathcal{S}(P, Q, x)] \geq \mathbb{E}_{x \sim R} [\mathcal{S}(P, R, x)] \tag{7}$$

Intuitively, the *cost of ignorance* condition models the “attention economy” cost of interaction, and captures the intuition that the follower will penalize gurus that are no “smarter” than he is. For example, no guru/meteorologist will get followers by predicting “100% chance of sun in the Sahara desert”. The predictions must be surprising to the followers. In the formal definition, the penalty constant is normalized to  $-1$  to simplify analysis.

The output of  $\mathcal{S}$  is a quantity that the guru wishes to maximize, because doing so will mean the follower is retained longer, as seen by Equation (1). Therefore, the *guru-side properness* requirement (Equation (6)) implies that a rational guru will strive to report the correct distribution used by Nature ( $R$ ), if the guru knows that distribution. In other words, we require the scoring rule to elicit *truthful* guru-side inputs.

Similarly, since the follower has a limited attention span, she is incentivized to judge the guru's quality “honestly”, and this is modeled by the *follower-side properness* condition (Equation (7)); it means the follower too will supply the rule  $\mathcal{S}$  with Nature's distribution, if known to her. Notice that the combination of the cost-of-ignorance and two properness results mean that a rational guru will not offer “obvious advice” about which both guru and follower “know the (same) truth”.

### Retentive Rule Construction

One-party scoring rules give rise to two-party retentive scoring rules in a straightforward way: Score the guru and follower *separately* based on Nature's outcome using, perhaps, two different functions, and define the retentive score as the difference between the one-party scores minus a fixed constant (to account for the cost-of-ignorance (5)). A retentive scoring rule of this form is said to be *separable*, and a special case is that of a *symmetric* rule, in which both guru and follower are scored using the same (one-party) scoring rule, formally:

► **Definition 3** (Symmetric Retentive Scoring Rule). A retentive scoring rule  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  is called *symmetric* if there exists a proper one-party scoring rule  $s : \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  such that:

$$\mathcal{S}(P, Q, i) = s(P, i) - s(Q, i) - 1 \tag{8}$$

### Characterization

Restricting the discussion to *categorical distributions*, i.e., to cases where  $\mathcal{X}$  is finite, and assuming the retentive scoring rules are *analytic*, meaning that a uniformly convergent power series expansion exists about any  $P \in \mathcal{P}$ , our first main result is the following statement:

## 12:6 The Complexity of User Retention

► **Theorem 4** (Retentive Scoring Rules are Symmetric). *The function  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  is an analytic retentive scoring rule for categorical distributions if and only if there exists a proper and analytic scoring rule  $s : \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  such that:*

$$\mathcal{S}(P, Q, x) = s(P, x) - s(Q, x) - 1 \quad (9)$$

We find the statement somewhat surprising because it is not intuitively clear that a two-party retentive rule must be separable; symmetry follows rather directly from separability and the cost-of-ignorance assumption. For the proof – given in Section 2 – we use a known result which relates proper scoring rules to convex functions over the probability simplex. We show that each retentive scoring rule corresponds to a solution of a system of partial differential equations (PDEs). Solving the system and characterizing the family of solutions yields the result (see Subsection 2.2).

### 1.4 Memory Span

To model the different prediction capacities of gurus and followers, the forecasting abilities of both types of agents in the Collaborative Discovery model are characterized by a parameter called *memory span*, defined below.

A variety of psychological studies could be summarized by saying that the human short-term memory has a capacity of about “seven, plus-or-minus two” *chunks*, where each chunk can be roughly defined as a collection of elementary information relating to a single concept [18, 24]. What counts as a chunk depends on the knowledge of the person being tested. For instance, a word is a single chunk for a speaker of the language but is many chunks for someone who is totally unfamiliar with the language and sees the word as a collection of phonetic segments.

In the world of child development, young parents (who usually don’t have significant experience or formal child-development education) are likely to predict that their child will start walking around the average time for the entire population. Child development experts, on the other hand, usually have better ability to pick up subtle developmental signals from observed child behavior, and provide a better prediction based on them.

In this spirit, we proceed with the formal definition. In what follows, let  $\Delta(\mathcal{X}^\Gamma)$  denote the simplex of probability distributions over  $\mathcal{X}^\Gamma$  and  $\Delta(\mathcal{X})$  is the simplex of distributions over  $\mathcal{X}$ .

► **Definition 5** (Memory Span). Let  $\mathcal{T} \in \Delta(\mathcal{X}^\Gamma)$  be a distribution. An agent is said to have *memory span*  $m \geq 0$  when its prediction  $P_\gamma \in \Delta(\mathcal{X})$  for coordinate  $\gamma_t \in \Gamma$  of an instance  $u \in \mathcal{X}^\Gamma$  with disclosed parameters  $\Gamma_t \subseteq \Gamma$  (i.e. for which  $u_{\Gamma_t}$  is known) is based on  $m$  disclosed coordinates or less:

$$\forall \gamma \in \Gamma, \exists I_t \subseteq \Gamma_t : |I_t| \leq m, P_\gamma = (\mathcal{T}_\gamma \mid u_{\setminus I_t}) \quad (10)$$

where  $(\mathcal{T}_\gamma \mid u_{\setminus I_t})$  is the marginal distribution of  $\mathcal{T}$  on coordinate  $\gamma$ , conditioned on the event that the coordinates  $I_t$  are set to  $u_{\setminus I_t}$ .

Intuitively, this means that every prediction of an agent is based on its entire knowledge of at most  $m$  coordinates. When  $m = 0$ , a prediction is only based on the marginal distribution of the corresponding parameter in the entire population.

### 1.4.1 Monotonicity

Our second result, stated next, says that if guru  $G$  is “smarter” than guru  $G'$ , meaning her memory span ( $m_g$ ) is greater than his ( $m'_g$ ), the smarter guru  $G$  will also have higher success in retaining followers, in expectation. (Whether this optimistic result holds in the real world is highly debatable.) This result is not implied directly by the definition of the Collaborative Discovery model, and shows that our model exhibits intuitive and desirable properties that substantiate its theoretical appeal:

► **Theorem 6** (Knowledgeable Gurus Retain Better). *Let  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  be an analytic retentive scoring rule, let  $G_1, G_2$  be two gurus with memory spans  $m_g^{(1)} \geq m_g^{(2)}$ . Then for any distribution  $\mathcal{T}$ , any coordinate  $x$ , and follower with memory span  $m_f \leq m_g^{(2)}$ :*

$$\mathbb{E}_{\mathcal{T}}[\mathcal{S}(P_1, Q, x)] \geq \mathbb{E}_{\mathcal{T}}[\mathcal{S}(P_2, Q, x)] \quad (11)$$

where  $P_1, P_2 \in \Delta(\mathcal{X})$  are the distributional forecasts of gurus  $G_1$  and  $G_2$  respectively, and  $Q \in \Delta(\mathcal{X})$  is the belief of the follower.

A technical discussion of the theorem and its proof are provided in Section 3.

### 1.4.2 Retainability as a Function of Memory Span Discrepancy

From here on we assume that the guru has memory span  $m_g$ , and her follower has memory span  $m_f$  and moreover, both parties provide to the retentive scoring rule a distribution that is the correct marginal  $\mathcal{T}_{\gamma_t} \mid u_{\setminus J_t}$ , conditioned on some subset of  $J_t \subset \Gamma_t$  of size  $m_g$  for the guru and  $m_f$  for the follower, respectively. Under this assumption, notice that if  $m_g = m_f$  then both parties supply the same distribution, so the cost-of-ignorance assumption of Definition 2 means the follower will terminate the interaction within  $r_0$  steps; in other words, ignorant gurus will not prevail. Henceforth assume  $m_g > m_f$ . Combining the concepts of limited user attention, retentive scoring, and limited memory span, we can now ask: Is it possible for the guru to retain her follower throughout the process? This leads to the concept of *retainability*:

► **Definition 7** (Retentively Learnable Distribution). *Let  $\mathcal{T} \in \Delta(\mathcal{X}^{\Gamma})$ , and assume  $|\Gamma| = n$ . Given a retentive scoring rule  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$ , guru memory span  $m_g \geq 0$ , follower memory span  $m_f \geq 0$ , and an initial retention parameter  $r_0 > 0$ , we say that  $\mathcal{T}$  is *retentively learnable* with respect to  $(\mathcal{S}, m_g, m_f, r_0)$  if there exists an ordering  $\gamma_1, \dots, \gamma_n$  of  $\Gamma$ , and a sequence of sets  $I_1, \dots, I_n$  such for all  $t \in [n]$ :*

1.  $I_t \subseteq \{\gamma_1, \dots, \gamma_{t-1}\}$
2.  $|I_t| \leq m_g$
3. For every sequence of sets  $J_1, \dots, J_n$  such that  $J_t \subseteq \{\gamma_1, \dots, \gamma_{t-1}\}$ ,  $|J_t| \leq m_f$ :

$$r_t = r_0 + \sum_{t'=1}^t \mathcal{S}((\mathcal{T}_{\gamma_{t'}} \mid u_{\setminus I_{t'}}), (\mathcal{T}_{\gamma_{t'}} \mid u_{\setminus J_{t'}}), \mathcal{T}) \geq 0 \quad (12)$$

Intuitively, a probability distribution is retentively learnable when it is possible to maintain a positive retention parameter throughout the process. From (12) we can see that increasing  $r_0$  does not hurt retainability. In other words, for  $r'_0 > r_0$ , if a distribution is retentively learnable with respect to  $(\mathcal{S}, m_g, m_f, r_0)$ , then it is also retentively learnable for  $(\mathcal{S}, m_g, m_f, r'_0)$ . We know that attention is a very limited resource, so we cannot expect it to be arbitrarily large. This leads to the following question: How large should the “initial retention” be in order for the guru to sustain her follower throughout the collaborative discovery process?

► **Definition 8** (Retention Complexity). The *retention complexity* of a distribution  $\mathcal{T} \in \Delta(\mathcal{X}^\Gamma)$  with respect to  $(\mathcal{S}, m_g, m_f)$  is the minimal value of  $r_0$  such that  $\mathcal{T}$  is retainable:

$$r_{\mathcal{S}, m_g, m_f}(\mathcal{T}) = \min \{r_0 \mid \mathcal{T} \text{ is retainable with respect to } (\mathcal{S}, m_g, m_f, r_0)\} \quad (13)$$

The discussion above leads to the following notion of retentively learnable families of distributions and properties. Recall that a property  $P$  over alphabet  $\mathcal{X}$  is a set of finite strings over  $\mathcal{X}$ . Let  $P_n = P \cap \mathcal{X}^n$  denote the set of strings in  $P$  of length  $n$ . Let  $\mathbb{N}_P = \{n \in \mathbb{N} \mid P_n \neq \emptyset\}$  be the set of lengths of strings that belong to  $P$ . The *family of distributions induced by  $P$*  is the family of uniform distributions over  $P_n$ , defined for  $n \in \mathbb{N}_P$ .

► **Definition 9** (Retentively Learnable Distributions and Properties). Let  $\mathbb{D} = \{\mathcal{T}_i\}_{i \in I}$  be a family of categorical distributions, where each  $\mathcal{T}_i$  is supported on strings of length  $n_i$  over alphabet  $\mathcal{X}$  (the set  $I$  may be infinite). Let  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  be a scoring rule as in Definition 3. We say  $\mathbb{D}$  is *retentively learnable* with respect to  $\mathcal{S}$  if there exist constants  $r_0$  and  $m_g > m_f$  such that each  $\mathcal{T}_i \in \mathbb{D}$  is retainable with respect to  $(\mathcal{S}, m_g, m_f, r_0)$ .

Similarly, a property  $P \subset \mathcal{X}^*$  is said to be *retentively learnable* with respect to  $\mathcal{S}$  if the family of distributions induced by  $P$  is retentively learnable.

Our main complexity result is the following. Recall that the property of linear functions over  $\mathbb{F}_2$  is the set of functions  $f : \mathbb{F}_2^k \rightarrow \mathbb{F}_2$  that satisfy  $f(x+y) = f(x) + f(y)$  for all  $x, y \in \mathbb{F}_2^k$ . For this property we have  $\mathbb{N}_P = \{n = 2^k \mid k \in \mathbb{N}\}$ .

► **Theorem 10** (Linear functions are retentively learnable). *The property of linear functions over the two-element field  $\mathbb{F}_2$  is retentively learnable.*

We elaborate on this result, and related ones, next.

## 1.5 The Retention Complexity of Linear Spaces

To initiate the study of the retentive learning within the context of computational complexity, a natural starting point is that of uniform distributions over linear spaces; linearity is the first object of study in other notable fields of complexity, like property testing [5, 13] and PAC learning [25].

Consider a realization of the model in which each attribute ranges over a binary space, i.e.,  $\mathcal{X}^\Gamma = \{0, 1\}^n$ . The Binary Attributes model describes a universe where each attribute is either present or not for a given user.

We start by redefining the problem using finite-field linear algebra, and then study the retention complexity of several natural families of linear codes, including the Walsh-Hadamard codes and the family of random Low Density Parity Check (LDPC) codes.

In particular, identify  $\{0, 1\}$  with the two-element finite field  $\mathbb{F}_2$  and consider a uniform distribution  $\mathcal{U}$  over a linear space  $U \subseteq \mathbb{F}_2^n$ . Let  $U^\perp$  denote the space dual to  $U$ . Let  $d(U)$  denote the Hamming distance of  $U$  (and  $d(U^\perp)$  is its dual distance), recalling that distance is equal to the minimum Hamming weight of a non-zero word in  $U$  (or  $U^\perp$ , respectively). We assume the guru has infinite memory span and the follower has memory span 0. (The study of the general case of  $0 < m_f < m_g < \infty$  is left for future work.) This means the follower's distribution for each  $i \in [n]$  is the uniform distribution on  $\mathbb{F}_2$  (this assumes  $U$  is not constant on any  $i \in [n]$ ).

We shall use a retentive scoring rule denoted  $\mathcal{S}_{\text{bin}}$ , that has expected value 1 when the guru can predict the next coordinate exactly, i.e., when the value of that coordinate depends linearly on the values of coordinates exposed thus far, and has expected value  $-1$  otherwise, when the distribution on that coordinate is linearly independent of all previously revealed bits.

The following result sets the bounds for our study of retention complexity in this setting, establishing a connection between the retention complexity of  $\mathcal{U}$  and its algebraic properties:

► **Lemma 11** (Retention Complexity Bounds for Linear Spaces). *For a uniform distribution  $\mathcal{U}$  over a linear space  $U \subseteq \mathbb{F}_n^2$  with unbounded guru memory span and zero follower memory span, the retention complexity satisfies:*

$$d(U^\perp) - 1 \leq r_{(\mathcal{S}_{\text{bin}}, \infty, 0)}(\mathcal{U}) \leq \dim(U) \quad (14)$$

Next, we show that the both bounds are tight. We begin by showing that a uniform distribution over codewords of the *Walsh-Hadamard* (WH) code achieves the lower retention complexity bound:

► **Lemma 12** (Walsh-Hadamard Retention Complexity). *For all  $k \in \mathbb{N}$ , a  $k$ -dimensional Walsh-Hadamard code satisfies:*

$$r_{(\mathcal{S}_{\text{bin}}, 2, 0)}(\text{WH}) = 2 \quad (15)$$

As the  $n$ -dimensional Walsh-Hadamard code represents the set of linear functions over  $\mathbb{F}_n^2$ , proving this lemma will also imply Theorem 10.

Finally, we show that a random LDPC code achieves the upper bound (up to multiplicative constants) with high probability, implying that collaborative discovery can be very hard on arbitrary linear spaces:

► **Theorem 13** (LDPC Retention Complexity). *For a proper choice of constants  $c, d > 0$  and sufficiently large  $n$ , the retention complexity of a random  $(c, d)$ -regular LDPC code over  $\mathbb{F}_2^n$  is linear with high probability:*

$$r_{(\mathcal{S}_{\text{bin}}, \infty, 0)}(\text{LDPC}) \stackrel{\text{w.h.p.}}{=} \Omega(\dim(\text{LDPC})) \quad (16)$$

The proofs of these results are provided in Subsection 4.2. The most technically challenging one is the third one and relies on the lower bounds for the testability of random LDPC codes of [4].

## 1.6 Related work

The study of reputation systems is interested in ranking gurus in “meaningful” ways, and is highly investigated empirically and theoretically; cf. [20, 21] and references therein. Closest in rigour to our approach are the papers by (i) Ban and Linial [2] which uses the theory of random processes to identify situations where gurus (called “experts” there) can be robustly ranked, assuming user participation continues indefinitely, and (ii) Chan et al. [7] that classifies interactive crowd-computation games using a small list of modeling parameters.

In the context of machine learning, the task of detecting users who are likely to stop participating in a voluntary system is known as *churn prediction*. For this task, machine learning algorithms are trained to recognize typical usage patterns and predict the likelihood of a termination [26, 9]. Even though general machine learning models provide good “black-box” churn predictors when trained correctly, gaining deep understanding of the underlying phenomena might be challenging.

Comparing our model to prior work, there are two main differences. First, our aim is to model the dynamics of *long-term* interaction between a follower and her guru about a *single complex phenomenon* of interest, asking when do followers abandon their gurus. Second, we

are interested in the *mathematical properties of phenomena* that are prone to collaborative discovery, meaning that for these phenomena a “good” guru will successfully instruct her followers from start to end without losing their attention and faith. This motivation is somewhat similar to that taken in the field of Property Testing [13] which attempts to understand which properties are amenable to “testing”.

## 1.7 Discussion of main contributions and future directions

The properties of retentive scoring rules, the effect of memory span discrepancy on the retention of followers, and the study of retention complexity of specific distributions are the main topics of this work.

We point out a few questions that emerge from the paper:

1. The gurus and followers studied here are assumed to have optimal knowledge of the distribution, up to their memory span limit. In particular, a guru with infinite memory span does not need to *learn* the distribution at all. However, in most realistic settings the distribution is unknown, leading to the question of learning distributions in a way that also maintains good retention properties. For instance, suppose the distribution is an *unknown* linear space  $U$  with retention complexity  $r$ . What is the minimal number of followers with initial retention parameter  $r_0 > r$  (say,  $r_0 = 2 \cdot r$ ) that will be “spent” or “lost” by the guru before she learns enough about  $U$  to fully retain new followers? This particular question is highly relevant to automated gurus that seek to attract users while maintaining high reputation (e.g., high app-store ratings).
2. The gurus and followers used here are computationally unbounded (or, more precisely, bounded only by attention span). Realistically, the computational complexity of computing marginals and evaluating which new attribute  $\gamma_t$  to interact about will be highly non-trivial.
3. Walsh-Hadamard codes are locally testable, correctable and decodable, while random LDPC codes have none of these properties; moreover, the retention complexity for both families of codes is approximately equal to their query complexity (for testability and correctability). This leads to our first question: *Are there tighter connections between retention complexity and query complexity of locally testable/correctable codes?* Do all  $q$ -query locally testable (or correctable) codes have retention complexity  $f(q)$  for some function that depends only on  $q$  and is independent of  $n$  (input size)? Likewise, it seems interesting to ask whether retention complexity is related to basic machine learning measures like VC dimension.

## 2 Retentive Scoring

In this section we study retentive scoring rules, and prove Theorem 4.

### 2.1 Preliminaries and Notations

#### Categorical Probability Distributions

Recall that a *categorical distribution* is a discrete probability distribution that describes the possible results of a random event that can take one of  $K$  possible outcomes. In this section, we assume  $\mathcal{P}$  is a convex set of categorical distributions with  $K = (n + 1)$  possible outcomes, i.e.  $\mathcal{X} = \{0, \dots, n\}$ . We define the number of possible outcomes as  $n + 1$  instead of  $n$  to simplify later calculations.

In addition, recall that the space of categorical distributions with  $(n + 1)$  possible outcomes is equivalent to the  $n$ -dimensional simplex:

$$\mathcal{P} \subseteq \Delta^n = \left\{ (p_0, \dots, p_n) \in \mathbb{R}^{n+1} \mid \sum_i p_i = 1; \forall i : p_i \geq 0 \right\} \quad (17)$$

where  $p_i$  is the probability of categorical event  $i$ .

### Expected Score Notation

Recall Definition 2. Following the conventions of the proper scoring literature, and given probability distributions  $P, Q, R \in \mathcal{P}$ , we denote the *expected retentive score* as:

$$\mathcal{S}(P, Q, R) \equiv \mathbb{E}_{i \sim R} [\mathcal{S}(P, Q, i)] \quad (18)$$

To avoid difficulties in (18), we will assume  $\mathcal{S}(P, Q, R)$  exists and is finite. Similarly, for one-party scoring rules, the common notation of *expected score* is:

$$s(P, R) \equiv \mathbb{E}_{i \sim R} [s(P, i)] \quad (19)$$

The analysis below will use both the single event notation  $\mathcal{S}(P, Q, i)$  and the expected score notation  $\mathcal{S}(P, Q, R)$  (and similarly for one-party scoring rules). To avoid confusion, we will always use upper-case letters to denote random variables and lower-case letters to denote events.

► **Remark (Scoring Rules on Infinite Sample Spaces).** Similar to proper (one-party) scoring rules, it is possible to define retentive scoring rules on infinite sample spaces using measure-theoretic tools. Computers are finite, and therefore many applications can be modeled as finite-dimensional categorical distributions. In this work we consider the finite sample space for concreteness and simplicity, and leave the rigorous measure-theoretic analysis to future work.

### Characterization of Proper Scoring Rules

One of the fundamental results in the research of proper scoring rules is the characterization theorem, first stated by [17], which defines a correspondence between proper scoring rules and convex functions over the probability simplex. We start with some preliminary definitions, and proceed with the characterization theorem itself:

► **Definition 14 (Subgradient).** A function  $\nabla^*G : \mathcal{P} \rightarrow \mathbb{R}^{n+1}$  is a subgradient of  $G$  at the point  $P$  if the following inequality holds for all  $Q \in \mathcal{P}$ :

$$G(Q) \geq G(P) + \langle \nabla^*G(P), (Q - P) \rangle \quad (20)$$

where  $\langle \cdot, \cdot \rangle$  denotes the euclidean inner product over  $\mathbb{R}^{n+1}$ :  $\langle X, Y \rangle = \sum_{i=0}^n x_i y_i$ .

► **Remark (Subgradients of Differentiable Functions).** If  $G$  is differentiable at  $P \in \mathcal{P}$  then  $G$  has a *unique* subgradient at  $P$  and it equals the gradient  $\nabla G = \left( \frac{\partial G}{\partial p_0}, \dots, \frac{\partial G}{\partial p_n} \right)$  at  $P$ .

Recall that a real-valued function  $G : \mathcal{P} \rightarrow \mathbb{R}$  is convex if:  $G((1 - \lambda)P + \lambda Q) \leq (1 - \lambda)G(P) + \lambda G(Q)$  for all  $P, Q \in \mathcal{P}$  and  $\lambda \in [0, 1]$ .

► **Lemma 15** ([15], Theorem 2.1).  $G : \mathcal{P} \rightarrow \mathbb{R}$  is convex if and only if it has a subgradient  $\nabla^*G$  at each point  $P \in \mathcal{P}$ .

► **Theorem 16** (McCarthy's Theorem, [11]). *A scoring rule  $s : \mathcal{P} \times \Omega \rightarrow \mathbb{R}$  is proper relative to  $\mathcal{P}$  if and only if there exists a convex, real-valued function  $G$  on  $\mathcal{P}$  such that:*

$$s(P, i) = G(P) - \langle \nabla^* G(P), P \rangle - (\nabla^* G)_i \quad (21)$$

where  $(\nabla^* G)_i$  is the  $i$ th component of  $(\nabla^* G)$ .

We also define the *Generalized Entropy* as the convex function which is induced by the proper scoring rule:

► **Definition 17** (Generalized Entropy). The convex function  $G(P) = s(P, P)$  induced by a proper scoring rule  $s$  is called the *generalized entropy function* of  $s$ .

Note that a convex general entropy function exists for every proper scoring rule by Theorem 16. For the logarithmic scoring rule defined in (3), the associated general entropy function is the additive inverse of the Shannon entropy:  $G(P) = \sum_{i=0}^n p_i \log p_i$ . Additional information-theoretic quantities can be generalized using proper scoring rules. See [8] for a recent review.

## 2.2 Separability of Retentive Scoring Rules

In this section, we prove that every proper retentive scoring rule can be written as the difference between two proper scoring rules. Recall Theorem 4:

► **Theorem 4** (Retentive Scoring Rules are Symmetric). *The function  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  is an analytic retentive scoring rule for categorical distributions if and only if there exists a proper and analytic scoring rule  $s : \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  such that:*

$$\mathcal{S}(P, Q, x) = s(P, x) - s(Q, x) - 1 \quad (9)$$

The proof has several steps:

1. We verify that symmetric retentive scoring rules are indeed proper (Lemma 18).
2. Conversely, we first define the notion of a *separable scoring rule*, which is a rule which can be written as the difference between two one-party scoring rules. Given a retentive scoring rule, we use the proper scoring characterization theorem (Theorem 16) to construct a system of partial differential equations which describes the constraints that must be satisfied by such a rule (Lemma 20). We then solve the characterizing system of partial differential equations (Lemma 21), and show that every possible solution corresponds to a separable retentive scoring rule (Lemma 22).
3. Finally, we show that every separable retentive scoring rule with constant cost of ignorance is also symmetric, proving the theorem.

We proceed by stating and proving the lemmas, and conclude the section by proving the theorem itself.

### Preliminaries

The proofs of Lemma 18 and Lemma 20 rely on the formalism of proper scoring rules and retentive scoring rules. The proof of Claim 21 relies on basic results from the theory of quasi-linear partial differential equations (refer to [19] for a thorough introduction). For  $D \subseteq \mathbb{R}^n$ , we will refer to a function  $f : D \rightarrow \mathbb{R}$  as *analytic* if its Taylor expansion about  $\mathbf{x} \in D$  converges to  $f(x)$  for all  $\mathbf{x} \in D$ . We use  $e_i \in \mathbb{R}^n$  to denote the  $i$ th vector of the standard basis. The gradient of a differentiable function  $g(\mathbf{x}, \mathbf{y}) : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}$  with respect to  $\mathbf{x} \in \mathbb{R}^n$  is denoted by  $\frac{\partial g}{\partial \mathbf{x}} \equiv \left( \frac{\partial g}{\partial x_1}, \dots, \frac{\partial g}{\partial x_n} \right)^T$ .

### 2.2.1 Symmetric Rules are Retentive

► **Lemma 18.** *Let  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  be a scoring rule. If there is a proper scoring rule  $s : \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  such that:  $\mathcal{S}(P, Q, i) = s(P, i) - s(Q, i) - 1$ , then  $\mathcal{S}(P, Q, i)$  is retentive.*

**Proof.** Let  $P, Q, R \in \mathcal{P}$ . Using (8), the expected score  $\mathcal{S}(P, Q, R)$  is:

$$\mathcal{S}(P, Q, R) = s(P, R) - s(Q, R) - 1 \quad (22)$$

$s$  is proper, and therefore  $s(P, R) \leq s(R, R)$ . Plugging into (22) we obtain:

$$\mathcal{S}(P, Q, R) \leq s_1(R, R) - s_2(Q, R) = \mathcal{S}(R, Q, R) \quad (23)$$

satisfying (6). Similarly,  $s_2$  is also proper, and therefore:

$$\mathcal{S}(P, Q, R) \geq s_1(P, R) - s_2(R, R) = \mathcal{S}(P, R, R) \quad (24)$$

satisfying (6). For  $Q = P$  we get  $\mathcal{S}(P, P, i) = -1$  for all  $i \in \mathcal{X}$ , and therefore  $\mathcal{S}$  is retentive according to Definition 2. ◀

### 2.2.2 Retentive Rules are Separable

We start by formally defining the notion of a separable scoring rule:

► **Definition 19** (Separable Retentive Scoring Rule). A proper retentive scoring rule  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \Omega \rightarrow \mathbb{R}$  is called *separable* if there exists two proper scoring rules  $s_1, s_2 : \mathcal{P} \times \Omega \rightarrow \mathbb{R}$  such that:

$$\mathcal{S}(P, Q, i) = s_1(P, i) - s_2(Q, i) \quad (25)$$

We also say that a two-party scoring rule is *proper* if it satisfies (6), (7). In the following lemma, we say that a bi-variate function  $G : \mathcal{P} \times \mathcal{P} \rightarrow \mathbb{R}$  is convex with respect to its first argument if  $G(P, Q)$  is a convex function of  $P$  for any constant  $Q \in \mathcal{P}$ ; convexity with respect to the second argument is similarly defined by switching the roles of  $P$  and  $Q$ .

► **Lemma 20** (Characterization by subgradients). *A two-party scoring rule  $\mathcal{S}$  is proper with respect to class  $\mathcal{P}$  if and only if there exist two functions  $G, H : \mathcal{P} \times \mathcal{P} \rightarrow \mathbb{R}$  such that:*

1.  $G(P, Q)$  is convex with respect to  $P$ .
2.  $H(P, Q)$  is convex with respect to  $Q$ .
3. For all  $P, Q, R \in \mathcal{P}$ :

$$G + \langle \nabla_P^* G, (R - P) \rangle = -(H + \langle \nabla_Q^* H, (R - Q) \rangle) \quad (26)$$

where  $\nabla_P^* G$  is a subgradient of  $G(P, Q)$  with respect to its first argument, and  $\nabla_Q^* H$  is a subgradient of  $H(P, Q)$  with respect to its second argument.

**Proof.** For the first direction, let  $\mathcal{S}(P, Q, i)$  be a proper retentive scoring rule, and define  $s_Q(P, i) \equiv \mathcal{S}(P, Q, i)$ . Using (6) we obtain that  $s_Q(P, R) \leq s_Q(R, R)$ . Therefore  $s_Q$  is proper, and according to Theorem 16 there exists a convex function  $G_Q : \mathcal{P} \rightarrow \mathbb{R}$  that depends on  $Q$ , such that:

$$s_Q(P, i) = G_Q(P) - \langle \nabla^* G_Q(P), P \rangle + (\nabla^* G_Q(P))_i \quad (27)$$

## 12:14 The Complexity of User Retention

where  $(\nabla^* G_Q(P))_i$  is  $i$ th entry of  $\nabla^* G_Q$  at point  $P$ . Similarly, define  $s_P(Q, i) \equiv \mathcal{S}(P, Q, i)$ . By the same reasoning and using (7) we obtain that  $-s_P$  is proper, and therefore there exists a convex function  $H_P : \mathcal{P} \rightarrow \mathbb{R}$  such that:

$$-s_P(Q, i) = H_P(Q) - \langle \nabla^* H_P(Q), Q \rangle + (\nabla^* H_P(Q))_i \quad (28)$$

Define  $G(P, Q) \equiv G_Q(P)$  and  $H(P, Q) \equiv H_P(Q)$ . Note that  $G$  is convex with respect to  $P$  and  $H$  is convex with respect to  $Q$ , satisfying conditions 1, 2. Let  $R \in \mathcal{P}$ . Using the fact that  $s_P(P, R) = s_Q(Q, R)$ , we can combine (27), (28) to obtain:

$$G + \langle \nabla_P^* G, (R - P) \rangle = -(H + \langle \nabla_Q^* H, (R - Q) \rangle) \quad (29)$$

satisfying condition 3.

Conversely, let  $G, H$  be the functions which satisfy the three conditions above. Define:

$$s_Q(P, i) \equiv G - \langle \nabla_P^* G, P \rangle + (\nabla_P^* G)_i \quad (30)$$

$$s_P(Q, i) \equiv -\left(H - \langle \nabla_Q^* H, H \rangle + (\nabla_Q^* H)_i\right) \quad (31)$$

Note that  $s_Q = -s_P$  by equation (26), and that  $s_P$  and  $-s_Q$  are proper by Theorem 16.

Define  $\mathcal{S}(P, Q, i) = s_Q(P, i) = -s_P(Q, i)$ .  $s_Q$  is proper, and therefore  $\mathcal{S}(P, Q, R) \leq \mathcal{S}(R, Q, R)$ , satisfying the properness condition in (6). Similarly, the properness of  $-s_P$  implies  $\mathcal{S}(P, R, R) \leq \mathcal{S}(P, Q, R)$ , satisfying (7), and therefore  $\mathcal{S}$  is proper. ◀

The following lemma contains a solution of a partial differential equation that will assist us in solving the characterizing equations of proper retentive scoring rules. We obtain the solution using basic tools from the theory of partial differential equations, and the proof is given in Appendix A for completeness:

► **Claim 21.** *Let  $D \subseteq \mathbb{R}^n$  such that  $\mathbf{x}, \mathbf{y} \in D$ . For every analytic function  $u : D \times D \rightarrow \mathbb{R}$  satisfying the equation*

$$u(\mathbf{x}, \mathbf{y}) - \sum_{i=1}^n (y_i - x_i) \frac{\partial u(\mathbf{x}, \mathbf{y})}{\partial x_i} = 0 \quad (32)$$

there exist functions  $\alpha_1, \dots, \alpha_n : D \rightarrow \mathbb{R}$  such that:

$$u(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^n \alpha_i(\mathbf{y})(y_i - x_i) \quad (33)$$

The following lemma is the heart of this part of the proof of Theorem 4 .

► **Lemma 22** (Proper Retentive Rules are Separable). *Let  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  be a retentive scoring rule. If  $\mathcal{S}$  is a proper retentive scoring rule with analytic generalized entropy functions, then there exist two functions  $s_1, s_2 : \mathcal{P} \times \Omega \rightarrow \mathbb{R}$  such that  $\mathcal{S}(P, Q, i) = s_1(P, i) - s_2(Q, i)$ .*

Proof outline:

1. Given a proper retentive scoring rule, Lemma 20 implies the existence of two generalized entropy functions  $G, H : \mathcal{P} \times \mathcal{P} \rightarrow \mathbb{R}$  related by equation (26).
2. We choose a parametrization for points on the simplex  $\Delta^n$ , and use it to define (26) in the convex domain  $D = \{(x_1, \dots, x_n) \in \mathbb{R}_+^n \mid \sum_i x_i \leq 1\}$ .
3. We simplify the resulting equation, and solve it using Claim 21.

4. Applying the correspondence established in Theorem 16 between convex functions on the simplex and proper scoring rules, we show that the generalized entropy functions  $G, H$  induce a separable scoring rule.

Following the conventions of multivariate calculus, in the proof we will use the  $\cdot$  symbol to denote the euclidean inner product over  $\mathbb{R}^n$ :  $\mathbf{x} \cdot \mathbf{y} = \sum_{i=1}^n x_i y_i$ . In addition, the proof employs terms from the theory of multivariate convex analysis: Given a non-empty convex subset  $S \subseteq \mathbb{R}^n$ , its *affine hull*  $\text{Aff}(S)$  is the smallest affine set containing  $S$ . A *relative interior point* is a member of the set  $\{x \in S : \exists \epsilon > 0, N_\epsilon(x) \cap \text{Aff}(S) \subseteq S\}$ , where  $N_\epsilon(x)$  is the  $\epsilon$ -ball around point  $x$ . Refer to [22] for an introduction to convex analysis. In the proof, we also use the *gradient theorem* for line integrals, which is a common generalization of the fundamental theorem of calculus. We recall it here without proof. Refer to Wikipedia entry [14] for discussion and proof:

► **Claim 23** (Gradient Theorem). *Let  $\varphi : U \subseteq \mathbb{R}^n \rightarrow \mathbb{R}$  and  $\gamma$  is any curve from  $\mathbf{p}$  to  $\mathbf{q}$ . Then:*

$$\varphi(\mathbf{q}) - \varphi(\mathbf{p}) = \int_{\gamma[\mathbf{p}, \mathbf{q}]} \nabla \varphi(\mathbf{r}) \cdot d\mathbf{r} \quad (34)$$

**Proof of Lemma 22.** Let  $\mathcal{S}$  be a proper retentive scoring rule. By Lemma 20, there exist two functions  $G, H : \mathcal{P} \times \mathcal{P} \rightarrow \mathbb{R}$  such that  $G(P, Q)$  is convex with respect to its first argument,  $H(P, Q)$  is convex with respect to its second argument, and equation (26) is satisfied.

When  $P, Q$  and  $R$  are categorical random variables with  $n+1$  possible outcomes, equation (26) is defined over the  $n$ -dimensional simplex  $\Delta^n$ . Let  $D = \{(x_1, \dots, x_n) \in \mathbb{R}_+^n \mid \sum_i x_i \leq 1\}$ . Each point  $P$  on the simplex can be represented by a vector  $P = (p_0, \dots, p_n) \in \mathbb{R}_+^{n+1}$  such that  $\sum_{i=0}^n p_i = 1$ . To simplify the constraints, we define a bijection  $f : \Delta^n \rightarrow D$  as follows:

$$f(P) \equiv (p_1, \dots, p_n) \in \mathbb{R}^n \quad (35)$$

$$f^{-1}(\mathbf{x}) \equiv \left(1 - \sum_{i=1}^n x_i, x_1, \dots, x_n\right) \in \Delta^n \quad (36)$$

using this bijection, we represent each point on the simplex using a  $n$ -dimensional vector in the domain. Denote:  $P \equiv f^{-1}(\mathbf{x})$ ,  $Q \equiv f^{-1}(\mathbf{y})$ ,  $R \equiv f^{-1}(\mathbf{z})$ ,  $f(\mathcal{P}) \equiv \{f(P) \mid P \in \mathcal{P}\}$ .

Using this correspondence, we also define  $g(\mathbf{x}, \mathbf{y}) \equiv G(P, Q)$ ,  $h(\mathbf{x}, \mathbf{y}) \equiv H(P, Q)$ . The assumption that  $G, H$  are analytic implies that the gradients of each function coincide with their corresponding subgradients (See Remark 2.1).

We will now write (26) using the new parametrization. Let  $\mathbf{x}, \mathbf{y}, \mathbf{z} \in f(\mathcal{P})$ . For the left-hand side of (26) we obtain:

$$\frac{\partial g}{\partial \mathbf{x}} \cdot (\mathbf{z} - \mathbf{x}) = \sum_{i=1}^n \frac{\partial g}{\partial x_i} (z_i - x_i) \quad (37)$$

[Calculate the derivative of  $g$  using the chain rule]

$$= \sum_{i=1}^n \left( \frac{\partial G}{\partial p_i} - \frac{\partial G}{\partial p_0} \right) (z_i - x_i) \quad (38)$$

[Rearrange the summations]

$$= \frac{\partial G}{\partial p_0} \sum_{i=1}^n (-z_i + x_i) + \sum_{i=1}^n \frac{\partial G}{\partial p_i} \cdot (z_i - x_i) \quad (39)$$

## 12:16 The Complexity of User Retention

$$= \frac{\partial G}{\partial p_0} \left( \left( 1 - \sum_{i=1}^n z_i \right) - \left( 1 - \sum_{i=1}^n x_i \right) \right) + \sum_{i=1}^n \frac{\partial G}{\partial p_i} \cdot (z_i - x_i) \quad (40)$$

[Use the definition of  $\mathbf{x}, \mathbf{z}$ ]

$$= \sum_{i=0}^n \frac{\partial G}{\partial p_i} (r_i - p_i) \quad (41)$$

$$= \nabla G \cdot (R - P) \quad (42)$$

A similar argument on the right-hand side of (26) shows that  $\nabla H \cdot (R - Q) = h + \frac{\partial h}{\partial \mathbf{y}} \cdot (\mathbf{z} - \mathbf{y})$ , and therefore the system defined in (26) is equivalent to:

$$\forall \mathbf{x}, \mathbf{y}, \mathbf{z} \in f(\mathcal{P}) : g + \frac{\partial g}{\partial \mathbf{x}} \cdot (\mathbf{z} - \mathbf{x}) = - \left( h + \frac{\partial h}{\partial \mathbf{y}} \cdot (\mathbf{z} - \mathbf{y}) \right) \quad (43)$$

We will now simplify (43) using its linear properties. Denote the affine hull of  $f(\mathcal{P})$  by  $\text{Aff}(f(\mathcal{P})) \equiv \mathbf{v}_0 + V$ , and assume  $\mathbf{v}_0$  is a relative interior point. Taking  $\mathbf{z} = \mathbf{v}_0$  in equation (43) yields:

$$g + \frac{\partial g}{\partial \mathbf{x}} \cdot (\mathbf{v}_0 - \mathbf{x}) = - \left( h + \frac{\partial h}{\partial \mathbf{y}} \cdot (\mathbf{v}_0 - \mathbf{y}) \right) \quad (44)$$

Similarly, denote the  $i$ th basis vector of  $V$  by  $\bar{\mathbf{v}}_i$ . For any  $i \in [\dim V]$ , taking  $\mathbf{z} = \mathbf{v}_0 + \bar{\mathbf{v}}_i$  in equation (43), with appropriate scaling of  $\bar{\mathbf{v}}_i$  such that  $\mathbf{z} \in f(\mathcal{P})$ , yields:

$$\forall i \in [\dim V] : g + \frac{\partial g}{\partial \mathbf{x}} \cdot (\mathbf{v}_0 + \bar{\mathbf{v}}_i - \mathbf{x}) = - \left( h + \frac{\partial h}{\partial \mathbf{y}} \cdot (\mathbf{v}_0 + \bar{\mathbf{v}}_i - \mathbf{y}) \right) \quad (45)$$

Subtracting (44) from (45) we obtain:

$$\forall i \in [\dim V] : \frac{\partial g(\mathbf{x}, \mathbf{y})}{\partial \mathbf{x}} \cdot \bar{\mathbf{v}}_i = - \frac{\partial h(\mathbf{x}, \mathbf{y})}{\partial \mathbf{y}} \cdot \bar{\mathbf{v}}_i \quad (46)$$

thus  $\frac{\partial g(\mathbf{x}, \mathbf{y})}{\partial \mathbf{x}}$  and  $-\frac{\partial h(\mathbf{x}, \mathbf{y})}{\partial \mathbf{y}}$  are equal component-wise, and therefore  $\frac{\partial g(\mathbf{x}, \mathbf{y})}{\partial \mathbf{x}} + \frac{\partial h(\mathbf{x}, \mathbf{y})}{\partial \mathbf{y}}$  is orthogonal to the affine hull:

$$\forall \mathbf{v} \in V : \left( \frac{\partial g(\mathbf{x}, \mathbf{y})}{\partial \mathbf{x}} + \frac{\partial h(\mathbf{x}, \mathbf{y})}{\partial \mathbf{y}} \right) \cdot \mathbf{v} = 0 \quad (47)$$

Note that  $(\mathbf{z} - \mathbf{x}), (\mathbf{z} - \mathbf{y}), (\mathbf{y} - \mathbf{x}) \in V$ . Substitute (47) back into (43) to obtain:

$$g + \frac{\partial g}{\partial \mathbf{x}} \cdot (\mathbf{y} - \mathbf{x}) = -h \quad (48)$$

Apply  $\frac{\partial}{\partial \mathbf{y}}$  on both sides to get:

$$\frac{\partial g}{\partial \mathbf{y}} + \frac{\partial}{\partial \mathbf{y}} \sum_{i=1}^n \frac{\partial g}{\partial x_i} (y_i - x_i) = - \frac{\partial h}{\partial \mathbf{y}} \quad (49)$$

And using (47) again we obtain:

$$\frac{\partial}{\partial \mathbf{y}} \sum_{i=1}^n \frac{\partial g}{\partial x_i} (y_i - x_i) = 0 \quad (50)$$

Which is equivalent to:

$$\forall k \in [n] : \frac{\partial g}{\partial y_k} + \sum_{i=1}^n (y_i - x_i) \frac{\partial}{\partial x_i} \frac{\partial g}{\partial y_k} = 0 \quad (51)$$

This is a system of  $n$  independent first-order partial differential equations for each element in  $\frac{\partial g}{\partial \mathbf{y}}$ . Using Claim 21, we obtain the general solution for each  $k$ :

$$\forall k \in [n], \exists \alpha_{k,1}, \dots, \alpha_{k,n} : \frac{\partial g}{\partial y_k} = \sum_{i=1}^n \alpha_{k,i}(\mathbf{y})(y_i - x_i) \quad (52)$$

Packing back the equations to vector form, we define a matrix operator  $A : D \rightarrow \mathbb{R}^{n \times n}$  such that  $A_{i,j}[\mathbf{y}] = \alpha_{k,i}(\mathbf{y})$ . The system in (52) in now be compactly represented using matrix multiplication:

$$\frac{\partial g}{\partial \mathbf{y}} = A[\mathbf{y}] (\mathbf{y} - \mathbf{x}) \quad (53)$$

We now use the correspondence established in Theorem 16 to show that the generalized entropy functions  $G, H$  induce a separable scoring rule. Applying the gradient theorem (34) along the curve  $\gamma(t) = \mathbf{0} + t\mathbf{y}$  for  $t \in [0, 1]$  yields:

$$g(\mathbf{x}, \mathbf{y}) - g(\mathbf{x}, \mathbf{0}) = \int_0^1 \left( \mathbf{y}^T \left( \frac{\partial g}{\partial \mathbf{y}} \Big|_{\mathbf{x}, t\mathbf{y}} \right) \right) dt \quad (54)$$

$$= \int_0^1 (\mathbf{y}^T A[t\mathbf{y}] (t\mathbf{y} - \mathbf{x})) dt \quad (55)$$

Denote  $\psi(\mathbf{x}) \equiv g(\mathbf{x}, \mathbf{0})$  and  $\varphi(\mathbf{x}, \mathbf{y}) \equiv \int_0^1 (\mathbf{y}^T A[t\mathbf{y}] (t\mathbf{y} - \mathbf{x})) dt$ . Note that  $\varphi(\mathbf{x}, \mathbf{y})$  is a linear function of  $\mathbf{x}$ . The scoring rule which corresponds to  $g$  is given by Theorem 16:

$$S(\mathbf{x}, \mathbf{y}, \mathbf{z}) = g(\mathbf{x}, \mathbf{y}) + \frac{\partial g(\mathbf{x}, \mathbf{y})}{\partial \mathbf{x}} \cdot (\mathbf{z} - \mathbf{x}) \quad (56)$$

$$= \underbrace{\psi(\mathbf{x}) + \frac{\partial \psi(\mathbf{x})}{\partial \mathbf{x}} \cdot (\mathbf{z} - \mathbf{x})}_{\equiv s_1} + \underbrace{\varphi(\mathbf{x}, \mathbf{y}) + \frac{\partial \varphi(\mathbf{x}, \mathbf{y})}{\partial \mathbf{x}} \cdot (\mathbf{z} - \mathbf{x})}_{\equiv s_2} \quad (57)$$

The terms denoted by  $s_1$  only depend on  $\mathbf{x}$  and  $\mathbf{z}$ , and therefore  $s_1 = s_1(\mathbf{x}, \mathbf{z})$ . In addition,  $\varphi(\mathbf{x}, \mathbf{y})$  is a linear function of  $\mathbf{x}$  and therefore both  $\frac{\partial \varphi(\mathbf{x}, \mathbf{y})}{\partial \mathbf{x}}$  and  $\left( \varphi(\mathbf{x}, \mathbf{y}) - \frac{\partial \varphi(\mathbf{x}, \mathbf{y})}{\partial \mathbf{x}} \cdot \mathbf{x} \right)$  do not depend on  $\mathbf{x}$ , thus  $s_2 = s_2(\mathbf{y}, \mathbf{z})$ . The scoring rule  $S(\mathbf{x}, \mathbf{y}, \mathbf{z})$  can therefore be written in the following form:

$$S(\mathbf{x}, \mathbf{y}, \mathbf{z}) = s_1(\mathbf{x}, \mathbf{z}) - s_2(\mathbf{y}, \mathbf{z}) \quad (58)$$

and applying the reverse transformation from  $\mathbf{x}, \mathbf{y}, \mathbf{z} \in D$  to  $P, Q, R \in \mathcal{P}$  implies the separability of the original scoring rule  $\mathcal{S}$ . ◀

### 2.2.3 Concluding the Proof

We can now conclude the section by proving the characterization theorem for retentive scoring rules. For the final proof, recall Definition 3 of symmetric retentive rules.

## 12:18 The Complexity of User Retention

**Proof of Theorem 4.** Given a proper scoring rule  $s : \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  such that  $\mathcal{S}(P, Q, i) = s(P, i) - s(Q, i) - 1$ , we can apply Lemma 18 to show that  $\mathcal{S}(P, Q, i)$  is retentive. Conversely, given an analytic retentive scoring rule, we can apply Lemma 22 and obtain  $s_1, s_2$  such that  $\mathcal{S}(P, Q, i) = s_1(P, i) - s_2(Q, i)$ . The rule  $\mathcal{S}$  is retentive, and therefore satisfies (5). for all  $P \in \mathcal{P}$  and  $Q = P$  we obtain:

$$\mathcal{S}(P, P, i) = s_1(P, i) - s_2(P, i) = -1 \quad (59)$$

and therefore  $s_1(P, i) = s_2(P, i) - 1$  for all  $P$ , proving that  $\mathcal{S}$  is symmetric. ◀

### 3 Monotonicity

In this section we show that expected retention score in each round grows with the size of memory span, proving Theorem 6:

► **Theorem 6 (Knowledgeable Gurus Retain Better).** *Let  $\mathcal{S} : \mathcal{P} \times \mathcal{P} \times \mathcal{X} \rightarrow \mathbb{R}$  be an analytic retentive scoring rule, let  $G_1, G_2$  be two gurus with memory spans  $m_g^{(1)} \geq m_g^{(2)}$ . Then for any distribution  $\mathcal{T}$ , any coordinate  $x$ , and follower with memory span  $m_f \leq m_g^{(2)}$ :*

$$\mathbb{E}_{\mathcal{T}} [\mathcal{S}(P_1, Q, x)] \geq \mathbb{E}_{\mathcal{T}} [\mathcal{S}(P_2, Q, x)] \quad (11)$$

where  $P_1, P_2 \in \Delta(\mathcal{X})$  are the distributional forecasts of gurus  $G_1$  and  $G_2$  respectively, and  $Q \in \Delta(\mathcal{X})$  is the belief of the follower.

The proof will require a definition and a lemma: We first define the notion of *Localized Expected Gain* (Definition 24), which is a set function that quantifies the expected score for different choices of prior data. We then show that this function is monotone by proving Lemma 25, and use the result to prove the theorem itself.

#### Preliminaries

We denote the jointly distributed vector by  $(X_1, \dots, X_n) \sim \mathcal{T}$ . The marginal distribution of coordinate  $i$  is denoted by  $X_i$ . For  $t \in [n]$  and  $I \subseteq [n]$  such as  $t \notin I$ , the marginal value of coordinate  $t$  conditioned on the event  $X_{\setminus I} = x_{\setminus I}$  is denoted by  $(X_t | x_I)$ . When probability calculations are involved, we will omit the harpoon notation for brevity, and  $x_I$  and  $x_{\setminus I}$  will be used interchangeably.

► **Definition 24 (Localized Expected Gain).** Let  $(X_1, \dots, X_t) \sim D \in \Delta(\mathcal{X}^t)$  be a set of  $t$  jointly-distributed random variables, let  $I \subseteq [t-1]$ , and let  $s : \Delta(\mathcal{X}) \times \mathcal{X} \rightarrow \mathbb{R}$  be a proper (one-party) scoring rule. The *localized expected gain* is a set function  $f : 2^{[t-1]} \rightarrow \mathbb{R}$  defined as follows:

$$\forall I \subseteq [t-1] : f(I) \equiv \mathbb{E}_{(x_1, \dots, x_t) \sim D} [s((X_t | x_I), x_t)] \quad (60)$$

Intuitively, the localized expected gain function  $f(I)$  describes the expected score when  $X_{\setminus I}$  is being used as a prior. For example, for the log scoring rule  $s(P, i) = \log p_i$  defined in (3), the associated expected localized gain function is:

$$f_{\log}(I) = \sum_{x_I} \Pr(x_I) \sum_{x_t} \Pr(x_t | x_I) \log \Pr(x_t | x_I) = -H(X_t | X_I) \quad (61)$$

which is the additive inverse of the conditional entropy of  $X_t$  given  $X_I$ .

We now show that this function is also monotone for general proper scoring rules, which means that expected scores don't decrease when adding prior information, or "more knowledge doesn't hurt" regardless of the proper scoring rule being used:

► **Lemma 25.**  $f$  is a monotone set function:

$$\forall I \subseteq J \subseteq [t-1] : f(I) \leq f(J) \quad (62)$$

**Proof.** We start with the definition of  $f(I)$ :

$$f(I) = \mathbb{E}_{(x_1, \dots, x_t) \sim D} [s((X_t | x_I), x_t)] \quad (63)$$

$$= \sum_{x_{[t-1]}, x_t} \Pr(x_{[t-1]}, x_t) s((X_t | x_I), x_t) \quad (64)$$

[Decompose  $\Pr(x_{[t-1]}, x_t)$  using the law of total probability]

$$= \sum_{x_{[t-1]}, x_t} \Pr(x_J) \Pr(x_t | x_J) \Pr(x_{[t-1] \setminus J} | x_t, x_J) s((X_t | x_I), x_t) \quad (65)$$

[ $s$  does not depend on  $y_{[t] \setminus J}$ . Rearrange the summation]

$$= \sum_{x_J} \Pr(x_J) \sum_{x_t} \Pr(x_t | x_J) s((X_t | x_I), x_t) \sum_{x_{[t-1] \setminus J}} \Pr(x_{[t-1] \setminus J} | x_t, x_J) \quad (66)$$

[The rightmost factor is equal to 1]

$$= \sum_{x_J} \Pr(x_J) \sum_{x_t} \Pr(x_t | x_J) s((X_t | x_I), x_t) \quad (67)$$

Using the definition of expected one-party score defined in (19), we obtain that the rightmost factor in (67) is the expected score of  $P = (X_t | x_I)$  when the reference distribution is  $R = (X_t | x_J)$ :

$$f(I) = \sum_{x_J} \Pr(x_J) s((X_t | x_I), (X_t | x_J)) \quad (68)$$

We can now use the properness of  $s$  (see Definition 1) to obtain:

$$f(I) \leq \sum_{x_J} \Pr(x_J) s((X_t | x_J), (X_t | x_J)) \quad (69)$$

and apply steps (63),..., (67) in reverse order to obtain

$$\sum_{x_J} \Pr(x_J) s((X_t | x_J), (X_t | x_J)) = f(J) \quad (70)$$

proving that  $f(I) \leq f(J)$ . ◀

Using Lemma 25 we can generalize the result to retentive scoring rules, and prove the monotonicity theorem for retentive scoring rules:

**Proof of Theorem 6.** Guru 1 has memory span  $m_g^1$ , and therefore  $P_1 = (\mathcal{T} | u_{\downarrow I_1})$  such that  $|I_1| = m_g^1$ . Similarly, for guru 2 we obtain  $P_2 = (\mathcal{T} | u_{\downarrow I_2})$  such that  $|I_2| = m_g^2$  and for the follower  $Q = (\mathcal{T} | u_{\downarrow J})$  such that  $|J| = m_f$ .

$\mathcal{S}$  is analytic, and therefore symmetric according to Theorem 4. Denote  $\mathcal{S}(P, Q, i) = s(P, i) - s(Q, i) - 1$ . Taking the expectation over  $\mathcal{T}$  we obtain:

$$\mathbb{E}_{\mathcal{T}} [\mathcal{S}(P, Q, i)] = \mathbb{E}_{\mathcal{T}} [s(P, i)] - \mathbb{E}_{\mathcal{T}} [s(Q, i)] - 1 \quad (71)$$

Using Definition 24 we obtain:

$$\mathbb{E}_{\mathcal{T}} [\mathcal{S}(P, Q, i)] = f(I) - f(J) - 1 \quad (72)$$

## 12:20 The Complexity of User Retention

When  $m_g^1 \geq m_g^2$  and under the optimal choice of  $I_1$ , there exists  $I'_1$  such that  $I_2 \subseteq I'_1$  and  $f(I'_1) \leq f(I_1)$ . Applying Lemma 25 we obtain:

$$\mathbb{E}_{\mathcal{T}}[\mathcal{S}(P_1, Q, i)] = f(I_1) - f(J) - 1 \quad (73)$$

$$\geq f(I'_1) - f(J) - 1 \quad (74)$$

$$\geq f(I_2) - f(J) - 1 \quad (75)$$

$$= \mathbb{E}_{\mathcal{T}}[\mathcal{S}(P_2, Q, i)] \quad (76)$$

and therefore  $\mathbb{E}_{\mathcal{T}}[\mathcal{S}(P_1, Q, i)] \geq \mathbb{E}_{\mathcal{T}}[\mathcal{S}(P_2, Q, i)]$ .  $\blacktriangleleft$

### 4 The Binary Attributes Model

Under the Binary Attributes model, the universe of users is modeled using a  $k$ -dimensional linear subspace of  $\mathbb{F}_2^n$ .

$$U = \text{span}\{\bar{u}_1, \dots, \bar{u}_k\} \quad (77)$$

where  $\bar{u}_1, \dots, \bar{u}_k \in \mathbb{F}_2^n$  are a choice of basis vectors for the subspace. Under this realization of the Collaborative Discovery model, each user is represented using an  $n$ -dimensional binary vector, formally  $\mathcal{X}^n = \mathbb{F}_2^n$ .

#### Preliminaries

This section will assume familiarity with basic linear algebra over finite fields. A *view*  $I \subseteq [n]$  of a vector  $u \in \mathbb{F}_2^n$ , denoted by  $u_{\downarrow I}$ , is a linear projection of  $u$  to the subspace  $V_I = \text{span}\{e_i \mid i \in I\}$ . Similar to the previous section, we omit the harpoon notation when complex conditional probability expressions are involved. Given a vector space  $U$ , its *dual space* is defined as the set of linear constraints:  $U^\perp \equiv \{v \in \mathbb{F}_2^n \mid \forall u \in U : \langle u, v \rangle = 0\}$ . The *support* of a vector  $u \in U$  is the set of coordinates that contain non-zero elements:  $\text{support}(u) = \{i \mid u_i \neq 0\}$ . We denote the hamming distance of a vector  $u \in U$  by  $d(u) = |\text{support}(u)|$ . The hamming distance of the space  $U$  is defined as  $d(U) = \min_{u \in U \setminus \{0\}} d(u)$ .

#### 4.1 User Types as a Linear Subspace

We follow with a rigorous definition of the process under the Binary Attributes realization:

##### Initialization

At the start of the Collaborative Discovery process, the type of user  $u$  is picked uniformly from  $U$ , all the coordinates are undisclosed, and the initial retention parameter is  $r_0$ . We will denote the uniform random variable over the linear space by  $\mathcal{U} \sim \text{Uniform}(U)$ .

##### Prediction Rounds

During each round, the expert picks a coordinate  $i$  and provides a prediction distribution  $P \in \Delta(\{0, 1\})$  for its value. The retentive scoring function for this realization of the model is:

$$\mathcal{S}_{\text{bin}}(P, Q, x) = 2 \log_2 p_x - 2 \log_2 q_x - 1 \quad (78)$$

where  $x \in \{0, 1\}$ .  $\mathcal{S}_{\text{bin}}$  can be represented as  $\mathcal{S}_{\text{bin}}(P, Q, x) = s(Q, x) - s(P, x) - 1$ , where  $s(P, x) = 2 \log_2 p_x$  is the logarithmic scoring rule defined in (3), and therefore  $\mathcal{S}_{\text{bin}}$  is symmetric according to Definition 3.

We'll proceed to show that  $\mathcal{S}_{\text{bin}}$  has very intuitive properties. To do that, we start with a few basic claims about the structure of this probability space. The claims can be proved using basic linear algebra and probability. Proofs are included in Appendix B:

► **Claim 26.** *Let  $I \subseteq [n]$ . For every vector  $u_I \in U_I$ :*

$$\Pr(\mathcal{U}_I = u_I) = 2^{-\dim(U_I)} \quad (79)$$

For the following claim, recall that a *singleton distribution* is a probability distribution in which a single outcome has probability 1.

► **Claim 27.** *Let  $I \subseteq [n]$  and  $m \in [n] \setminus I$ , and assume a vector  $u \in \mathbb{F}_2^n$  has been picked uniformly at random from a vector space  $U$ .  $\Pr(u_m \mid u_I)$  is a singleton distribution if and only if  $e_m \in U^\perp_{|[n] \setminus I}$ .*

► **Claim 28.** *Let  $U$  be a linear space over  $\mathbb{F}_2^n$ , and let  $I \subseteq [n]$ ,  $m \in [n] \setminus I$ .  $e_m \in U^\perp_{|[n] \setminus I}$  if and only if  $\dim(U_{|I}) = \dim(U_{|I \cup \{m\}})$ .*

Using this framework, we now have enough tools to characterize the dynamics of scoring rule we defined:

► **Lemma 29** (Binary Attributes Scoring Rule Dynamics). *For a uniform distribution  $\mathcal{U}$  over a linear space  $U$  without constant bits, the retention score for a collaborative discovery process with infinite expert locality and zero layperson locality is given by:*

$$\mathcal{S}_{\text{bin}}((X_m \mid x_I), X_m, \mathcal{U}) = \begin{cases} 1 & e_m \in U^\perp_{|[n] \setminus I} \\ -1 & \text{otherwise} \end{cases} \quad (80)$$

$$= \begin{cases} 1 & \dim(U_{|I \cup \{m\}}) = \dim(U_{|I}) \\ -1 & \dim(U_{|I \cup \{m\}}) = \dim(U_{|I}) + 1 \end{cases} \quad (81)$$

**Proof.** When  $e_m \notin U^\perp_{|[n] \setminus I}$ , we get that  $\dim(U_{|I \cup \{m\}}) = 1$ , allowing us to apply Claim 26 and obtain  $\Pr(u_m = 0 \mid u_I) = \frac{1}{2}$ .

When  $e_m \in U^\perp_{|[n] \setminus I}$  there exists  $v \in U^\perp$ ,  $I' \subseteq I$  such that  $\text{support}(v) = I' \cup \{m\}$ . Claim 27 implies that  $u_m$  is determined given  $u_I$ .

Combining the results, we obtain for all  $I \subseteq [n]$ ,  $m \notin I$ :

$$\Pr(u_m = 0 \mid u_I) \in \begin{cases} \{0, 1\} & e_m \in U^\perp_{|[n] \setminus I} \\ \{\frac{1}{2}\} & \text{otherwise} \end{cases} \quad (82)$$

There are no constant bits in  $U$ , and therefore  $\dim U_{|I \cup \{m\}} = 1$  for all  $m \in [n]$ . By Claim 26 we obtain that the marginal distribution for each coordinate is uniform, and therefore a layperson with zero locality will always predict a uniform distribution.

Plugging (82) into the definition of  $\mathcal{S}_{\text{bin}}$  in equation (78), the score for the first case is  $\log_2 \frac{1}{2 \cdot 0.5^2} = 1$ , and the score for the second case is  $\log_2 \frac{0.5^2}{2 \cdot 0.5^2} = -1$ , leading to equation (80). The transition from (80) to (81) is given by Claim 28. ◀

## 4.2 Retention Complexity of Linear Codes

We will now apply the notion of retention complexity introduced in Definition 8 to the Binary Attributes model. We will first show that there exist non-trivial upper and lower bounds for retention complexity in this realization of the Collaborative Discovery model, and then show that the bounds are tight. Recall Lemma 11:

► **Lemma 30** (Retention Complexity Bounds for Linear Spaces). *For a uniform distribution  $\mathcal{U}$  over a linear space  $U \subseteq \mathbb{F}_n^2$  with unbounded guru memory span and zero follower memory span, the retention complexity satisfies:*

$$d(U^\perp) - 1 \leq r_{(\mathcal{S}_{\text{bin}}, \infty, 0)}(\mathcal{U}) \leq \dim(U) \quad (14)$$

**Proof of Lemma 11.** The retention parameter at the end of each round  $t$  is defined according to equation (1):

$$r_t = r_0 + \sum_{i=1}^t \mathcal{S}_{\text{bin}}((X_{\sigma_i} | x_{I_i}), X_{\sigma_i}, \mathcal{U}) \quad (83)$$

For the lower bound, observe that  $U^\perp_{|[n] \setminus I_t}$  does not contain any singleton element when  $|I_t| \leq d(U^\perp) - 2$ . Since  $|I_t| \leq t - 1$  by definition, we can combine the inequalities and obtain that no punctured-dual-space singleton exists when  $t \leq d(U^\perp) - 1$ . We can now apply Lemma 29 and obtain that  $\mathcal{S}_{\text{bin}}((X_{\sigma_i} | x_{I_i}), X_{\sigma_i}, \mathcal{U}) = -1$  for all  $i \in \{1, \dots, t\}$ . Plugging into the retention parameter at time  $t = d(U^\perp) - 1$ :

$$r_t = r_0 + \sum_{i=1}^{d(U^\perp)-1} (-1) = r_0 - (d(U^\perp) - 1) \quad (84)$$

And the positivity constraint on  $r_t$  implies that  $r_0 \geq (d(U^\perp) - 1)$ .

For the upper bound, assume without loss of generality that the first  $k = \dim(U)$  coordinates of  $U$  are linearly independent, and set  $\sigma_i = i, I_i = \{1, \dots, (i - 1)\}$  for all  $i \in \{1, \dots, k\}$ . Observe that:

$$\dim(U_{|I_i}) = \begin{cases} i - 1 & 1 \leq i \leq k \\ k & k < i \end{cases} \quad (85)$$

Applying Lemma 29 we get:

$$\mathcal{S}_{\text{bin}}((X_{\sigma_i} | x_{I_i}), X_{\sigma_i}, \mathcal{U}) = \begin{cases} -1 & 1 \leq i \leq k \\ 1 & k < i \end{cases} \quad (86)$$

Hence for  $r_0 = k$  we get  $r_t \geq 0$  for all  $t \in \{1, \dots, n\}$ . ◀

In the asymptotic setting it is common to consider  $n, k \rightarrow \infty$ . In this case,  $d(U^\perp)$  can stay constant, forming a large gap between the bounds. We will proceed to show that the upper and lower bounds are indeed tight in the asymptotic setting.

### 4.2.1 Linear Functions are Retentively Learnable

Let  $n = 2^k - 1$ . Given a binary message  $x \in \{0, 1\}^k$ , the *Walsh-Hadamard* code (WH) encodes the message into a codeword  $\text{WH}(x)$  using an encoding function  $\text{WH} : \{0, 1\}^k \rightarrow \{0, 1\}^n$ , such that for every  $y \in (\{0, 1\}^k \setminus \{0^k\})$ , the  $y$ th coordinate of  $\text{WH}(x)$  is equal to  $(x \cdot y)$ .

Walsh-Hadamard is the space of linear functions over  $\mathbb{F}_2^k$ . Note that we slightly deviate from the common definition by omitting the 0th coordinate which is always equal to zero. It is a  $[2^k - 1, k, 2^{k-1}]_2$  locally-correctable code with  $q = 2$  queries. See [1] for a thorough discussion of Walsh-Hadamard codes and its applications in theoretical computer science.

We will show that a uniform distribution over the  $k$ -dimensional WH code achieves the retention complexity lower bound for all  $k \in \mathbb{N}$ . Recall Lemma 12:

► **Lemma 31** (Walsh-Hadamard Retention Complexity). *For all  $k \in \mathbb{N}$ , a  $k$ -dimensional Walsh-Hadamard code satisfies:*

$$r_{(\mathcal{S}_{\text{bin}}, 2, 0)}(\text{WH}) = 2 \quad (15)$$

In order to prove the lemma, we first characterize the constraints of the WH code (Claim 32, Claim 33), and then use the results to construct an explicit formula for the retention score when the  $\mathcal{S}_{\text{bin}}$  retentive score rule is being used (Lemma 34), giving an upper bound for  $r_{(\mathcal{S}_{\text{bin}}, 3, 0)}(\text{WH})$  which is equal to the lower bound we established in Lemma 11. Proofs for the claims can be found in Appendix B.

► **Claim 32.** *Let  $y^{(1)}, \dots, y^{(m)} \in (\{0, 1\}^k \setminus \{0^k\})$ .*

$$\left( \sum_{i=1}^m e_{y^{(i)}} \right) \in \text{WH}^\perp \iff \sum_{i=1}^m y^{(i)} = 0 \quad (87)$$

► **Claim 33.**

$$d(\text{WH}^\perp) = 3 \quad (88)$$

► **Lemma 34.** *Let  $k > 0$ , and let  $u$  be a uniformly-sampled vector from the  $k$ -dimensional WH code. Set a natural ordering over the coordinates ( $\gamma_t = t$  for  $t \in \{1, \dots, 2^k - 1\}$ ), and set a sequence of subsets:*

$$I_t = \begin{cases} \{2^{\lfloor \log_2 t \rfloor}, t - 2^{\lfloor \log_2 t \rfloor}\} & t > 2, \text{ and } t \text{ is not a power of } 2 \\ \emptyset & \text{otherwise} \end{cases}$$

*For collaborative discovery with respect to  $\mathcal{S} = \mathcal{S}_{\text{bin}}$ ,  $m_g = 2$ ,  $m_f = 0$  and  $r_0 = 2$ , the ordering  $\gamma_t$  and sequence of sets  $I_t$  satisfies:*

$$r_t = t - 2^{\lfloor \log_2 t \rfloor} \quad (89)$$

*for all  $1 \leq t < 2^k$ .*

**Proof.** By induction:

For the base case  $t \in \{1, 2\}$ . According to the definition,  $\gamma_1 = 1, \gamma_2 = 2$ , and  $I_1 = I_2 = \emptyset$ . We use Claim 33 and an argument similar to the one in Lemma 11 to show that there's no singleton in the punctured dual-space in the first two rounds. The guess in the first two rounds will therefore be a uniform one, and  $r_1 = 1, r_2 = 0$ . Indeed we can substitute 0, 1 into (89) see that  $1 - 2^{\lfloor \log_2 1 \rfloor} = 1$  and  $1 - 2^{\lfloor \log_2 2 \rfloor} = 1$ .

For  $t > 2$ , assume the retention parameter formula holds for  $t - 1$ , and consider the two following cases:

## 12:24 The Complexity of User Retention

- When  $t$  is not a power of two, it can be represented as the XOR between two preceding coordinates, for example  $t' = 2^{\lfloor \log_2 t \rfloor}$  and  $t'' = t - 2^{\lfloor \log_2 t \rfloor}$ . Note that  $I_t = \{t', t''\}$ , and that  $|I_t| = 2$ , satisfying the  $m_g = 2$  memory span constraint. Using Claim 32 we obtain that  $e_t$  is a singleton in the punctured dual-space, and therefore  $r_t = r_{t-1} + 1$  by Lemma 29. Using the induction hypothesis and the fact that  $\lfloor \log_2 t \rfloor = \lfloor \log_2 (t-1) \rfloor$  when  $t$  is not a power of two, we obtain:

$$\begin{aligned} r_t &= r_{t-1} + 1 \\ &= (t-1) - 2\lfloor \log_2 (t-1) \rfloor + 1 \\ &= t - 2\lfloor \log_2 t \rfloor \end{aligned}$$

- When  $t$  is a power of two, it cannot be represented as the XOR between preceding coordinates, as for all of them the index of the most significant bit is strictly less than  $\log_2 t$ . By Lemma 29 we obtain that  $r_t = r_{t-1} - 1$ , and using the fact that  $\lfloor \log_2 t \rfloor = \lfloor \log_2 (t-1) \rfloor + 1$  when  $t$  is a power of two we indeed get:

$$\begin{aligned} r_t &= r_{t-1} - 1 \\ &= (t-1) - 2\lfloor \log_2 (t-1) \rfloor - 1 \\ &= t - 2\lfloor \log_2 t \rfloor \end{aligned} \quad \blacktriangleleft$$

► **Remark (Non-punctured Walsh-Hadamard).** In the non-punctured Walsh-Hadamard code, the 0th coordinate is not omitted, and always equal to zero. Offsetting the sequences in Lemma 34 can show that the same upper bound also holds for the non-punctured version of the Walsh-Hadamard code.

Combining the results proves Lemma 12:

**Proof of Lemma 12.** Lemma 34 shows an upper bound of 2 for the retention complexity of WH. Lemma 11, together Claim 33, tells us that this is also the lower bound for the retention complexity in this case, and therefore  $r_{(\mathcal{S}_{\text{bin}}, 2, 0)}(\text{WH}) = 2$ .  $\blacktriangleleft$

We can now conclude and prove Theorem 10. Recall the theorem statement:

► **Theorem 10 (Linear functions are retentively learnable).** *The property of linear functions over the two-element field  $\mathbb{F}_2$  is retentively learnable.*

**Proof of Theorem 10.** For linear functions over  $\mathbb{F}_2^n$ , the corresponding family of categorical distributions is  $\mathbb{D} = \{\mathcal{U}_n\}_{n=2^k}$ , where  $\mathcal{U}_i$  is the family of uniform distributions over the non-punctured Walsh-Hadamard code. Lemma 34 shows that each  $\mathcal{U}_i$  is retainable with respect to  $(\mathcal{S}_{\text{bin}}, 2, 0, 2)$ .  $\blacktriangleleft$

### 4.2.2 Random LDPC Codes are Asymptotically Hard to Retain

Let  $G = (L, R, E)$  be a bipartite multigraph with  $|L| = n$ ,  $|R| = m$ . Associate a distinct Boolean variable  $x_i$  with any  $i \in L$ . For each  $j \in R$ , let  $N(j) \subseteq L$  be the set of neighbors of  $j$ . The  $j$ th constraint is  $A_j(x_1, \dots, x_n) = \sum_{i \in N(j)} x_i \pmod 2$ . The code defined by  $G$  is:

$$\mathcal{C}(G) = \{x \in \{0, 1\}^n \mid \forall j \in [m] : A_j(x) = 0\}$$

A random  $(c, d)$ -regular LDPC code of length  $n$  is obtained by taking  $\mathcal{C}(G)$  for a random  $(c, d)$ -regular  $G$  with  $n$  left vertices. Random LDPC codes were first described and analyzed by [10]. We will show that a randomly chosen LDPC code asymptotically achieves the upper bound for retention complexity with high probability. Recall Theorem 13:

► **Theorem 13** (LDPC Retention Complexity). *For a proper choice of constants  $c, d > 0$  and sufficiently large  $n$ , the retention complexity of a random  $(c, d)$ -regular LDPC code over  $\mathbb{F}_2^n$  is linear with high probability:*

$$r_{(\mathcal{S}_{\text{bin}, \infty, 0})}(\text{LDPC}) \stackrel{\text{w.h.p.}}{=} \Omega(\dim(\text{LDPC})) \quad (16)$$

► **Definition 35** ( $(q, \mu)$  code locality, [4]). A linear space  $V$  is  $(q, \mu)$ -local if every  $v \in V$  that is a sum of at least  $\mu m$  basis vectors has  $d(v) \geq q$ .

The following lemma shows that a random LDPC code has  $(q, \mu)$ -locality with high probability for a proper choice of parameters:

► **Lemma 36** ([4], Lemma 3.6). *Fix odd integer  $c \geq 7$  and constants  $\mu, \delta, d > 0$  satisfying:*

$$\mu \leq \frac{c^{-2}}{100}; \quad \delta < \mu^c; \quad d > \frac{2\mu c^2}{(\mu^c - \delta)^2} \quad (90)$$

*Then, for all sufficiently large  $n$ , with high probability for a random  $(c, d)$ -regular graph  $G$  with  $n$  left vertices and  $m = \frac{c}{d}n$  right vertices, the corresponding LDPC code  $\mathcal{C}(G)$  is linearly-independent, and  $(\delta n, \mu)$ -local.*

► **Remark 37** (A Proper Choice of Parameters). For our proof of Theorem 13, the constants in (90) need be chosen such that  $\delta - \frac{2\mu c}{d} \geq 0$ .

Such a choice of random code parameters is indeed possible: For example, by fixing  $c \geq 7$  and taking  $\mu = \frac{c^{-2}}{100}$ ,  $\delta = (\mu^c - \varepsilon_0)$ ,  $d = \frac{8\mu c^2}{(\mu^c - \delta)^2}$  we get:

$$\delta - 2\frac{\mu c}{d} = \mu^c - \varepsilon_0 - 2\frac{\mu c}{\frac{8\mu c^2}{(\mu^c - \delta)^2}} = \mu^c - \varepsilon_0 - \frac{\varepsilon_0^2}{4c}$$

Which is strictly larger than zero for all  $0 < \varepsilon_0 < 2c\left(\sqrt{1 + \frac{\mu^c}{c}} - 1\right)$ .

We now use this to prove Theorem 13:

**Proof of Theorem 13.** Fix odd integer  $c \geq 7$  and constants  $\mu, \varepsilon, \delta, d > 0$  satisfying equation (90) and  $\delta \geq \frac{\mu c}{d}$ . See Remark 37 for a specific choice of such constants. Let  $V$  be a random LDPC code of dimension  $n$  corresponding to this choice of constants. Assume that  $n$  is large enough to satisfy Lemma 36. Assume by contradiction that  $r_0 \leq n\left(\delta - \frac{2\mu c}{d}\right) - 1$ , and the Collaborative Discovery process lasts until round  $n$ . Set  $t = \lfloor \delta n \rfloor - 1$ .

At the end of round  $t$ , the coordinates  $I_t \subseteq [n]$  are disclosed. Denote by  $n_-$  the number of times a uniform distribution was predicted by the expert. Using Lemma 29, the total retention accumulated at the end of round  $t$  is equal to:

$$r_t = r_0 - n_- + (t - n_-) \quad (91)$$

$r_t \geq 0$ , and therefore  $n_- \leq \frac{t+r_0}{2}$ . Using Lemma 29 again, we obtain that  $n_- = \dim(V_{\perp I_t})$ . In addition, the dimensions of a vector space and its dual sum up to  $t$ , hence  $\dim\left((V_{\perp I_t})^\perp\right) = (t - n_-) \geq \frac{t-r_0}{2}$ . This gives us a lower bound for  $\dim\left((V_{\perp I_t})^\perp\right)$ .

$(V_{\perp I_t})^\perp$  consists of vectors  $v \in V^\perp$  such that  $\text{support}(v) \subseteq I_t$ . The conditions of Lemma 36 are satisfied by our choice of constants, and we can apply it to obtain that  $V^\perp$  of the random code we picked is  $(\delta n, \mu)$ -local with high probability, and therefore every  $v \in V^\perp$  that is a

sum of at least  $\frac{c}{d}\mu n$  dual basis vectors has  $d(v) \geq \delta n$ . For  $t < \delta n$ , all the vectors of  $(V_{I_t})^\perp$  are a sum of  $\frac{c}{d}\mu n$  basis vectors at most, hence  $\dim(V_{I_t}^\perp) \leq \frac{c}{d}\mu n$ , implying an upper bound for  $\dim((V_{I_t})^\perp)$ .

Combining the bounds we obtain:

$$\frac{t - r_0}{2} \leq \dim((V_{I_t})^\perp) < \frac{c}{d}\mu n \quad (92)$$

For  $t = \lfloor \delta n \rfloor - 1$  and  $r_0 \leq n(\delta - \frac{2\mu c}{d}) - 1$  we have:

$$\frac{t - r_0}{2} \geq \frac{(\delta n - 1) - (n(\delta - \frac{2\mu c}{d}) - 1)}{2} = \frac{c}{d}\mu n \quad (93)$$

Leading to a contradiction, since the lower bound in equation (92) must be greater than the upper bound. From this we get  $r_0 > n(\delta - \frac{2\mu c}{d})$ , and therefore  $r_0 = \Omega(n) = \Omega(\dim(V))$ . ◀

## A Retentive Scoring Appendices

► **Claim 21.** Let  $D \subseteq \mathbb{R}^n$  such that  $\mathbf{x}, \mathbf{y} \in D$ . For every analytic function  $u : D \times D \rightarrow \mathbb{R}$  satisfying the equation

$$u(\mathbf{x}, \mathbf{y}) - \sum_{i=1}^n (y_i - x_i) \frac{\partial u(\mathbf{x}, \mathbf{y})}{\partial x_i} = 0 \quad (32)$$

there exist functions  $\alpha_1, \dots, \alpha_n : D \rightarrow \mathbb{R}$  such that:

$$u(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^n \alpha_i(\mathbf{y})(y_i - x_i) \quad (33)$$

**Proof of Claim 21.**  $u(\mathbf{x}, \mathbf{y})$  is analytic in  $D$ , and therefore it has a unique representation as a convergent power series about  $(\mathbf{y}, \mathbf{y})$ :

$$u(\mathbf{x}) = \sum_{j_1, \dots, j_{2n}=0}^{\infty} c_{j_1, \dots, j_{2n}} \prod_{k=1}^n (y_k - x_k)^{j_k} \prod_{k'=n+1}^{2n} y_{k'}^{j_{k'}} \quad (94)$$

Note that  $(y - x) \frac{\partial (y-x)^a}{\partial x} = -a(y-x)^a$  for all  $a \in \mathbb{R}$ , and therefore:

$$\sum_{i=1}^n (y_i - x_i) \frac{\partial}{\partial x_i} \prod_{k=1}^n (y_k - x_k)^{j_k} = - \sum_{i=1}^n j_i \prod_{k=1}^n (y_k - x_k)^{j_k} \quad (95)$$

Using the above, we obtain for (32):

$$0 = u + \sum_{i=1}^n (y_i - x_i) \frac{\partial u}{\partial x_i} \quad (96)$$

[Use (94) to represent the rightmost term as a power series]

$$= u + \sum_{i=1}^n (y_i - x_i) \frac{\partial}{\partial x_i} \left( \sum_{j_1, \dots, j_{2n}=0}^{\infty} c_{j_1, \dots, j_{2n}} \prod_{k=1}^n (y_k - x_k)^{j_k} \prod_{k'=n+1}^{2n} y_{k'}^{j_{k'}} \right) \quad (97)$$

[Derivative operator does not affect the factors that don't depend on  $x$ ]

$$= u + \sum_{j_1, \dots, j_{2n}=0}^{\infty} c_{j_1, \dots, j_{2n}} \prod_{k'=n+1}^{2n} y_{k'}^{j_{k'}} \left( \sum_{i=1}^n (y_i - x_i) \frac{\partial}{\partial x_i} \prod_{k=1}^n (y_k - x_k)^{j_k} \right) \quad (98)$$

[Apply the derivative using (95)]

$$= u + \sum_{j_1, \dots, j_{2n}=0}^{\infty} c_{j_1, \dots, j_{2n}} \prod_{k'=n+1}^{2n} y_{k'}^{j_{k'}} \left( - \sum_{i=1}^n j_i \right) \prod_{k=1}^n (y_k - x_k)^{j_k} \quad (99)$$

[Use (94) to represent the leftmost term as a power series]

$$= \sum_{j_1, \dots, j_{2n}=0}^{\infty} c_{j_1, \dots, j_{2n}} \left( 1 - \sum_{i=1}^n j_i \right) \prod_{k'=n+1}^{2n} y_{k'}^{j_{k'}} \prod_{k=1}^n (y_k - x_k)^{j_k} \quad (100)$$

If a convergent power series is equal to zero, then all its coefficients must be equal to zero as well. From (100) we obtain:

$$\forall j_1, \dots, j_n \in \mathbb{N} : c_{j_1, \dots, j_n} \left( 1 - \sum_{i=1}^n j_i \right) = 0 \quad (101)$$

Therefore  $c_{j_1, \dots, j_n} = 0$  when  $\sum_{i=1}^n j_i \neq 1$ , and analytic solutions for (32) can only contain linear coefficients of  $(y_i - x_i)$  in their series expansion. Let  $k \in [n]$ . when  $j_k = 1$  we denote  $c_{j_1, \dots, j_{2n}} \equiv c_{k, j_{n+1}, \dots, j_{2n}}$ . Plug back into the series representation (94) to obtain:

$$u(\mathbf{x}) = \sum_{i=1}^n \left( \sum_{j_{n+1}, \dots, j_{2n}=0}^{\infty} c_{i, j_{n+1}, \dots, j_{2n}} \prod_{k'=n+1}^{2n} y_{k'}^{j_{k'}} \right) (y_i - x_i) \quad (102)$$

Denoting  $\alpha_i(\mathbf{y}) \equiv \left( \sum_{j_{n+1}, \dots, j_{2n}=0}^{\infty} c_{i, j_{n+1}, \dots, j_{2n}} \prod_{k'=n+1}^{2n} y_{k'}^{j_{k'}} \right)$  leads to the linear representation of  $u$  in (33). ◀

## B Binary Attributes Appendices

### B.1 The Binary Attributes Model

► **Claim 26.** Let  $I \subseteq [n]$ . For every vector  $u_I \in U_I$ :

$$\Pr(\mathcal{U}_I = u_I) = 2^{-\dim(U_I)} \quad (79)$$

**Proof of Claim 26.** Without loss of generality assume that  $I = \{1, \dots, |I|\}$ , and choose a basis  $U = \text{span}\{\bar{u}_1, \dots, \bar{u}_k\}$  which is diagonalized. Each vector in  $U$  can be represented as linear combination of basis elements. By definition, only only the first  $\dim(U_I)$  diagonalized

basis vectors have support in  $I$ , and therefore every vector in  $U_I$  can be written as a linear combination of the view of the first  $\dim U_I$  basis vectors of  $U$ :

$$\forall u_I \in U_I, \exists \alpha_1, \dots, \alpha_{\dim(U_I)} : u_I = \sum_{i=1}^{\dim(U_I)} \alpha_i (\bar{u}_i)_{\downarrow I} \quad (103)$$

Picking  $u$  at random is equivalent to choosing each  $\alpha_i$  uniformly, or equivalently, picking  $(\alpha_1, \dots, \alpha_{\dim(U_I)}) \sim \text{Uniform}(\{0, 1\}^{\dim(U_I)})$ . From this correspondence it follows that  $\Pr(u_I) = \Pr(\alpha_1, \dots, \alpha_{\dim(U_I)}) = 2^{-\dim(U_I)}$ . ◀

► **Claim 27.** Let  $I \subseteq [n]$  and  $m \in [n] \setminus I$ , and assume a vector  $u \in \mathbb{F}_2^n$  has been picked uniformly at random from a vector space  $U$ .  $\Pr(u_m \mid u_I)$  is a singleton distribution if and only if  $e_m \in U^\perp_{\downarrow [n] \setminus I}$ .

**Proof of Claim 27.** When  $e_m \in U^\perp_{\downarrow [n] \setminus I}$  there exists a vector  $v \in U^\perp$  and  $I' \subseteq I$  such that  $\text{support}(v) = \{m\} \cup I'$ .  $v$  is a dual-space vector, and therefore  $\sum_{i \in I'} u_i + u_m = 0$ . The value  $u_m \in \{0, 1\}$  is completely determined by the values of  $u_{I'}$ , and therefore  $\Pr(u_m \mid u_I)$  is a singleton distribution.

Conversely, observe that restricting a vector to a subset of coordinates  $I \subseteq [n]$  can be viewed as a linear projection operation  $P_I \equiv \sum_{i \in I} e_i e_i^T$ . Let  $v \in U$  be a vector for which  $v_I = u_I$ . The set of vectors  $u' \in U$  for which  $u'_I = u_I$  is an affine subspace  $U'$  of  $U$ :

$$U' = v + V' = \{v + v' \mid v' \in U, P_I v' = 0\} \quad (104)$$

Note that  $V'$  is a linear subspace of  $U$ , and therefore:

$$(V')^\perp = \text{span}(U^\perp \cup \{e_i \mid i \in I\}) \quad (105)$$

Using the assumption that  $\Pr(u_m \mid u_I)$  is a singleton distribution, we get that the  $m$ -th coordinate is constant in  $U'$ , and therefore  $P_{\{m\}} V' = 0$ , and  $e_m \in (V')^\perp$ . denote  $U^\perp = \text{span}\{\bar{u}_1^\perp, \dots, \bar{u}_{n-k}^\perp\}$ . Using (105) we can write  $e_m$  as a linear combination of spanning set elements:

$$e_m = \sum_{i=1}^{|I|} \alpha_i e_i + \sum_{j=1}^{n-k} \beta_j \bar{u}_j^\perp \quad (106)$$

Restricting the view to coordinates  $[n] \setminus I$ , the terms in the first sum vanish, yielding:

$$e_m = P_{[n] \setminus I} e_m = \sum_{j=1}^{n-k} \beta_j P_{[n] \setminus I} \bar{u}_j^\perp \quad (107)$$

We have shown that it's possible to write  $e_m$  as a linear combination of punctured dual space elements, hence  $e_m \in U^\perp_{\downarrow [n] \setminus I}$ . ◀

► **Claim 28.** Let  $U$  be a linear space over  $\mathbb{F}_n^2$ , and let  $I \subseteq [n]$ ,  $m \in [n] \setminus I$ .  $e_m \in U^\perp_{\downarrow [n] \setminus I}$  if and only if  $\dim(U_{\downarrow I}) = \dim(U_{\downarrow I \cup \{m\}})$ .

**Proof of Claim 28.** Assume a uniform distribution over  $U$ , then  $e_m \in U^\perp_{\downarrow [n] \setminus I}$ , if and only if  $\Pr(u_m \mid u_I)$  is a singleton distribution by Claim 27.

According to the law of total probability,  $\Pr(u_m \mid u_I)$  is a singleton distribution if and only if the following marginal distributions are equal:  $\Pr(u_{I \cup \{m\}}) = \Pr(u_I)$ .

Using Claim 26 we obtain that the two probabilities are equal if and only if  $\dim(U_{\downarrow I}) = \dim(U_{\downarrow I \cup \{m\}})$ . ◀

## B.2 Retention Complexity of the Walsh-Hadamard Code

► **Claim 32.** Let  $y^{(1)}, \dots, y^{(m)} \in (\{0, 1\}^k \setminus \{0^k\})$ .

$$\left( \sum_{i=1}^m e_{y^{(i)}} \right) \in \text{WH}^\perp \iff \sum_{i=1}^m y^{(i)} = 0 \quad (87)$$

**Proof of Claim 32.** By definition,  $(\sum_{i=1}^m e_{y^{(i)}}) \in \text{WH}^\perp$  if and only if  $(\sum_{i=1}^m e_{y^{(i)}}) \cdot u = 0$  for all  $u \in \text{WH}$ . For an arbitrary  $u$ , let  $w \in \{0, 1\}^k$  such that  $u = \text{WH}(w)$ . Plug into the definition of WH and obtain:

$$\begin{aligned} \left( \sum_{i=1}^m e_{y^{(i)}} \right) \cdot u &= \sum_{i=1}^m u_{y^{(i)}} \\ &= \sum_{i=1}^m w \cdot y^{(i)} \\ &= w \cdot \left( \sum_{i=1}^m y^{(i)} \right) \end{aligned}$$

Observe that the inner product is equal to zero for all  $u \in \text{WH}$  if and only if  $w \cdot (\sum_{i=1}^m y^{(i)}) = 0$  for all  $w \in \{0, 1\}^k$ . This happens if and only if  $(\sum_{i=1}^m y^{(i)}) = 0$ , proving our claim. ◀

► **Claim 33.**

$$d(\text{WH}^\perp) = 3 \quad (88)$$

**Proof of Claim 33.** By Claim 32, the vectors corresponding to the support of each constraint in  $\text{WH}^\perp$  must have their XORs equal to zero.

$0^k \notin (\{0, 1\}^k \setminus \{0^k\})$ , and therefore there are no constraints of size 1, and we have  $d(\text{WH}^\perp) > 1$ . Similarly, for all  $x, y \in (\{0, 1\}^k \setminus \{0^k\})$  such that  $x \neq y$  we get  $x + y \neq 0$ , and therefore there are no constraints of size 2, and  $d(\text{WH}^\perp) > 2$ .

Taking  $x \neq y$  and  $z = x + y$  gives 3 coordinates with corresponding vectors that sum up to zero, and therefore  $d(\text{WH}^\perp) \leq 3$  according to Claim 32. Combining the conclusions we obtain  $d(\text{WH}^\perp) = 3$ . ◀

# Torus Polynomials: An Algebraic Approach to ACC Lower Bounds

## Abstract

We propose an algebraic approach to proving circuit lower bounds for  $\text{ACC}^0$  by defining and studying the notion of *torus polynomials*. We show how currently known polynomial-based approximation results for  $\text{AC}^0$  and  $\text{ACC}^0$  can be reformulated in this framework, implying that  $\text{ACC}^0$  can be approximated by low-degree torus polynomials. Furthermore, as a step towards proving  $\text{ACC}^0$  lower bounds for the majority function via our approach, we show that MAJORITY cannot be approximated by low-degree *symmetric* torus polynomials. We also pose several open problems related to our framework.

## 1 Introduction

A major goal of complexity theory is to prove Boolean circuit lower bounds, i.e. find explicit Boolean functions that cannot be computed by small size circuits of a given type. Over the years, three general approaches have been developed to achieve this.

---

<sup>1</sup> Part of this work was done when the author was visiting the University of California, San Diego. Research supported in part by Rutgers AAUP-AFT TA-GA Professional Development Fund.

The first approach is based on random restrictions. It applies to circuit classes in which functions simplify when most inputs are fixed to random values. Classic examples are the proofs by Håstad that  $AC^0$ , i.e. polynomial size circuit families of constant depth consisting of AND, OR, and NOT gates, cannot compute or approximate the PARITY function [6], and the shrinkage of De Morgan formulas (Boolean circuits consisting of AND, OR, and NOT gates whose underlying graph is a tree) under random restrictions [7]. However, random restrictions don't seem to be useful against more powerful circuit classes such as  $AC^0[\oplus]$  – the class of  $AC^0$  circuits equipped with PARITY gates.

The second approach is based on approximation by low-degree polynomials. Razborov [10] and Smolensky [12] used this approach to prove lower bounds for  $AC^0[\oplus] = AC^0[2]$ , and more generally for  $AC^0[p]$  for any prime  $p$  (This is the class of  $AC^0$  circuits that are allowed to have  $MOD_p$  gates<sup>2</sup>). This technique is based on showing that any function in the circuit class can be approximated by a low-degree polynomial over the finite field  $\mathbb{F}_p$ . Then, functions that do not admit such an approximation are provably outside the circuit class. A classic example here is that the MAJORITY function cannot be approximated by a low-degree polynomial over  $\mathbb{F}_p$ , and thus cannot be computed by  $AC^0[p]$ . However, this method also breaks down when considering more powerful circuit classes such as  $AC^0[6]$ , and more generally  $ACC^0$ , i.e.  $AC^0$  circuits with  $MOD_m$  gates where  $m$  is a composite that is not a prime power.

The third method involves designing nontrivial satisfiability algorithms and then using them along with classical tools from structural complexity theory (among other techniques and results) to prove circuit lower bounds against  $ACC^0$  for functions in high complexity classes such as NEXP. Williams [16] used this approach to prove that  $NEXP \not\subseteq ACC^0$ , and very recently, Williams and Murray [8] have extended this to show that  $NQP \not\subseteq ACC^0$ .

The goal of this paper is to focus on the second approach, namely the use of algebraic techniques, and to try and extend these techniques to prove lower bounds against  $ACC^0$ . We show that an extension of finite field polynomials, which we call *torus polynomials*, is a concrete candidate to achieve this. In particular, using a slightly stronger version of a result of Green et al. [5], we show that functions in  $ACC^0$  can be approximated<sup>3</sup> by low-degree torus polynomials. We remark that torus polynomials also generalize the class of *nonclassical polynomials* which arose in number theory and in higher order Fourier analysis [14], and are closely related to them.

This characterization of  $ACC^0$  using torus polynomials raises a host of questions on the approximation of Boolean functions by torus polynomials, the most remarkable being the problem of finding an explicit Boolean function that cannot be approximated by low-degree torus polynomials; an answer to this question would imply  $ACC^0$  lower bounds. In this paper, we take steps towards trying to resolve this question by initiating the study of approximation of Boolean functions by torus polynomials and proving some interesting results along the way. The motivation for our work is two-fold:

1. Given the slew of recent works exploring properties and applications of nonclassical polynomials [13, 14, 2, 3, 4], and the fact that torus polynomials are closely related to nonclassical polynomials, we believe that our characterization of  $ACC^0$  using torus polynomials might pave a way for new  $ACC^0$  lower bounds.
2. While the works of Williams [16] and Williams and Murray [8] are groundbreaking and prove highly nontrivial lower bounds against  $ACC^0$ , their proofs are not purely

<sup>2</sup> a  $MOD_p$  gate outputs 1 if and only if the sum of its inputs is congruent to a non-zero value modulo  $p$ .

<sup>3</sup> The notion of approximation that we use will be made explicit in Section 1.1.

combinatorial/algebraic, and it will be interesting to recover their results using purely algebraic/combinatorial techniques. We hope that our work will renew interest in this line of inquiry.

## 1.1 Torus polynomials

Let  $\mathbb{T} = \mathbb{R}/\mathbb{Z}$  denote the one-dimensional torus. A *torus polynomial* is simply a real polynomial restricted to the domain  $\{0, 1\}^n$  and evaluated modulo one<sup>4</sup>. Namely, a degree- $d$  torus polynomial  $P : \{0, 1\}^n \rightarrow \mathbb{T}$  is

$$P(x) = \sum_{S \subseteq [n], |S| \leq d} P_S \prod_{i \in S} x_i \pmod{1},$$

where  $P_S \in \mathbb{R}$ .

As it shall become evident later, torus polynomials extend finite field polynomials in that they provide a uniform way to capture computation of Boolean functions by polynomials over different finite fields – if a function can be computed by a low-degree polynomial over a finite field then it can be approximated by a low-degree torus polynomial. We will discuss this in detail in Section 2.

For  $z \in \mathbb{T}$ , let  $\iota(z)$  denote the unique representative of  $z$  in  $[-1/2, 1/2)$  (e.g.,  $\iota(0.4) = 0.4$  and  $\iota(0.7) = -0.3$ ). Then we can define its norm, denoted by  $|z \pmod{1}|$ , to be

$$|z \pmod{1}| = |\iota(z)|.$$

For  $F : \{0, 1\}^n \rightarrow \mathbb{T}$ , define

$$\|F \pmod{1}\|_\infty := \max_{x \in \{0, 1\}^n} |F(x) \pmod{1}|.$$

We embed Boolean functions as functions mapping into the torus by enforcing their output to be in  $\{0, 1/2\} \subset \mathbb{T}$  (This can be achieved by scaling the output of the function by  $1/2$ ). The following is the main definition of approximation that we consider:

► **Definition 1.** Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be a Boolean function. For  $\varepsilon > 0$ , a torus polynomial  $P : \{0, 1\}^n \rightarrow \mathbb{T}$  is said to  $\varepsilon$ -approximate  $f$  if

$$\left\| P - \frac{f}{2} \pmod{1} \right\|_\infty \leq \varepsilon.$$

Intuitively, a torus polynomial that approximates  $f$  takes a value “close” to 0 in the torus  $\mathbb{T}$  whenever  $f$  takes the value 0, and takes a value “close” to  $1/2$  in the torus whenever  $f$  takes the value 1.

We now introduce the notion of the *toroidal approximation degree* of a Boolean function.

► **Definition 2 (Toroidal approximation degree of Boolean functions).** Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be a Boolean function. For  $\varepsilon > 0$ , the toroidal  $\varepsilon$ -approximation degree of  $f$  is the minimal  $d \geq 0$ , for which there exists a torus polynomial  $P : \{0, 1\}^n \rightarrow \mathbb{T}$  of degree  $d$ , that satisfies

$$\left\| P - \frac{f}{2} \pmod{1} \right\|_\infty \leq \varepsilon.$$

We denote this by  $\overline{\text{deg}}_\varepsilon(f) = d$ .

<sup>4</sup> For  $x \in \mathbb{R}$ ,  $x$  modulo one, denoted by  $x \pmod{1}$ , is equal to the fractional part of  $x$  given by  $x - \lfloor x \rfloor$ , where  $\lfloor x \rfloor$  is the floor function. For example,  $2.6 \pmod{1}$  is 0.6, and  $-1.3 \pmod{1}$  is 0.7.

We illustrate in Section 2, in increasing generality, the power of torus polynomials. The most general result (Corollary 20) shows that if  $f$  can be computed by an  $\text{ACC}^0$  circuit then

$$\overline{\text{deg}}_\varepsilon(f) \leq \text{polylog}(n/\varepsilon).$$

The proof of this result uses a slightly stronger version of a result of Green et al. [5].

The above characterization paves way for a new approach to proving lower bounds against  $\text{ACC}^0$  for an explicit function, ideally in the class P. Concretely, we pose the following open problem.

► **Problem 3.** *Find an explicit function  $f : \{0,1\}^n \rightarrow \{0,1\}$  in P whose toroidal  $\varepsilon$ -approximation degree is  $\omega(\text{polylog}(n/\varepsilon))$ . By Corollary 20, it cannot be computed by  $\text{ACC}^0$  circuits.*

Williams [16] proved that  $\text{NEXP} \not\subseteq \text{ACC}^0$  via designing nontrivial satisfiability algorithms for  $\text{ACC}^0$ , and Williams and Murray [8] improved the approach to show that  $\text{NQP} \not\subseteq \text{ACC}^0$ . Thus, an intermediate goal towards resolving Problem 3 is to prove toroidal approximation lower bounds for functions  $f \in \text{NEXP}$  or  $f \in \text{NQP}$ .

A long-standing open problem in circuit complexity is to show that MAJORITY cannot be computed in  $\text{ACC}^0$ . Thus the following question is natural.

► **Problem 4.** *What is the toroidal  $\varepsilon$ -approximation degree of MAJORITY?*

How can one go about answering this question? We now turn to the setting of approximation of Boolean functions by real polynomials – which *prima facie* shares some similarities with our setting – for inspiration, highlighting the main differences between the two notions.

## 1.2 Comparison with real polynomials

Given a function  $f : \{0,1\}^n \rightarrow \{0,1\}$ , the real  $\varepsilon$ -approximation degree of  $f$ , denoted by  $\widetilde{\text{deg}}_\varepsilon(f)$ , is the minimal  $d$  such that there is a real polynomial  $P$  of degree  $d$  such that  $\|f - P\|_\infty \leq \varepsilon$  (this is the  $\ell_\infty$ -norm restricted to the domain  $\{0,1\}^n$ ). It is clear that  $\overline{\text{deg}}_\varepsilon(f) \leq \widetilde{\text{deg}}_\varepsilon(f)$ .

A beautiful result of Nisan and Szegedy [9] shows that the real  $\varepsilon$ -approximation degree of MAJORITY is  $\Omega(\sqrt{n})$  for  $\varepsilon < 1/2$ . Their proof proceeds in two stages: (i) showing that if a *symmetric* real polynomial  $\varepsilon$ -approximates MAJORITY then it must have degree  $\Omega(\sqrt{n})$ ; and (ii) that any polynomial that  $\varepsilon$ -approximates MAJORITY can be *symmetrized* and made into a symmetric polynomial with the same degree and approximation guarantee.

Attempting to follow the same strategy in the case of torus polynomials, we show in Corollary 23 in Section 3 that if one restricts attention to *symmetric* torus polynomials (namely, symmetric real polynomials evaluated modulo one), then the toroidal  $(1/20n)$ -approximation degree of MAJORITY is  $\Omega(\sqrt{n/\log n})$ .

Unfortunately, the aforementioned idea of symmetrization cannot be used in the setting of torus polynomials in a straightforward manner and so it's unclear how powerful non-symmetric torus polynomials are compared to their symmetric counterparts. We conjecture that they are not any better at approximating MAJORITY than symmetric torus polynomials:

► **Conjecture 5.** *The toroidal  $(1/20n)$ -approximation degree of MAJORITY is  $\Omega(\sqrt{n/\log n})$ .*

We remark that a positive answer to the above conjecture will give an algebraic proof that MAJORITY is not in  $\text{ACC}^0$ .

Let  $\Delta_w : \{0, 1\}^n \rightarrow \{0, 1\}$  denote the delta function which takes the value 1 on inputs of Hamming weight  $w$  and is 0 elsewhere. En route to proving the aforementioned lower bound for MAJORITY we also prove lower bounds for the delta functions in Theorem 21, showing that one needs symmetric torus polynomials of degree  $\Omega(\sqrt{n/\log n})$  in order to be able to  $(1/20n)$ -approximate the delta functions.

Somewhat surprisingly, for relatively large values of  $\varepsilon$ , the delta functions can be nontrivially  $\varepsilon$ -approximated by low-degree *symmetric* torus polynomials. In particular, we show in Lemma 24 in Section 4 that for every delta function there is a symmetric torus polynomial of degree  $\text{polylog}(n/\varepsilon)/\varepsilon$  that  $\varepsilon$ -approximates it, and thus

$$\overline{\text{deg}}_\varepsilon(\Delta_w) \leq \frac{\text{polylog}(n/\varepsilon)}{\varepsilon}.$$

This kind of dependence of the toroidal approximation degree on  $\varepsilon$  is quite interesting, and is unlike the case of real approximation – the real approximation degree of the delta functions is  $\Omega(\sqrt{n})$  for both small and large values of  $\varepsilon$ . In fact, for constant  $\varepsilon$ , this also shows a super-polynomial separation between real and toroidal approximation degree.

This also highlights other major differences between the real and the toroidal setting. Nisan and Szegedy [9] show that for every Boolean function the real approximation degree is polynomially related to the degree of exact representation by real polynomials. However, in the case of torus polynomials, this is not true: the delta functions require the degree to be  $\Omega(n)^5$  for exact representation whereas their toroidal  $1/3$ -approximation degree is  $O(\text{polylog}(n))$ .

An interesting property of real approximation is its amenability to amplification, namely the fact that, for any Boolean function  $f$  and  $\varepsilon < 1/3$ , given a polynomial  $p$  of degree  $d$  that  $1/3$ -approximates  $f$ , it can be transformed into a polynomial  $p'$  of degree  $d' = O(d \log(1/\varepsilon))$  that  $\varepsilon$ -approximates  $f$ . In other words,  $\overline{\text{deg}}_\varepsilon(f) \leq O(\overline{\text{deg}}_{1/3}(f) \log(1/\varepsilon))$ . It is not clear whether such a transformation is possible in the case of toroidal approximation. In the case of real approximation, the transformation is symmetry preserving, but, given the results for the delta functions discussed in the previous paragraphs, we should not expect this in the toroidal case. This motivates the following problem.

► **Problem 6.** *How is  $\overline{\text{deg}}_\varepsilon(f)$  related to  $\overline{\text{deg}}_{1/3}(f)$ ?*

### 1.3 Comparison with nonclassical polynomials

As mentioned before, torus polynomials generalize the class of nonclassical polynomials (this will be evident from the definition of nonclassical polynomials stated below). We remark that the results of this paper can be similarly phrased in terms of nonclassical polynomials instead of torus polynomials. This is because for the purpose of approximation of Boolean functions – which is the topic of this paper – torus polynomials and nonclassical polynomials are equivalent, as we shall see below. However, torus polynomials are simpler to describe (they are just real polynomials evaluated modulo 1) and more elegant (they are field independent), and hence we believe are a better choice for an algebraic model and for stating our results.

We now give the definition of nonclassical polynomials; here we provide what is known as the global definition of nonclassical polynomials over  $\{0, 1\}^n$ . For simplicity, we restrict our attention to nonclassical polynomials defined over  $\mathbb{F}_2^n$ , but note that the results generalize to nonclassical polynomials defined over  $\mathbb{F}_p^n$  for any constant prime  $p$ .

<sup>5</sup> To see this, note that the delta function  $\Delta_n(x)$  has a unique representation as a torus polynomial given by  $\Delta_n(x) = \frac{x_1 \cdots x_n}{2}$ .

► **Definition 7** (Nonclassical polynomials). A function  $Q : \{0, 1\}^n \rightarrow \mathbb{T}$  is a nonclassical polynomial (over  $\mathbb{F}_2$ ) of degree at most  $d$  if and only if it can be written as

$$Q(x) = \alpha + \sum_{\emptyset \subset S \subseteq [n]; k \geq 0; 0 < |S| + k \leq d} \frac{c_{S,k}}{2^{k+1}} \prod_{i \in S} x_i \pmod{1}$$

where  $c_{S,k} \in \{0, 1\}$  and  $\alpha \in \mathbb{T}$ .

The following simple claim shows that torus polynomials can be approximated by nonclassical polynomials.

► **Claim 8.** Let  $P : \{0, 1\}^n \rightarrow \mathbb{T}$  be a torus polynomial of degree at most  $d$  and let  $\varepsilon \in (0, 1)$ . Then there exists a nonclassical polynomial  $Q$  of degree at most  $O(d \log n + \log(1/\varepsilon))$  such that  $\|P - Q \pmod{1}\|_\infty \leq \varepsilon$ .

**Proof.** Suppose  $P(x) = \alpha + \sum_{\emptyset \subset S \subseteq [n], |S| \leq d} P_S \prod_{i \in S} x_i \pmod{1}$ . We can assume without loss of generality that  $P_S \in [0, 1)$  for all  $S$ . We approximate each  $P_S$  separately using dyadic rationals. Let  $P_S = 0.c_{S,0}c_{S,1}c_{S,2}\dots$ , where  $c_{S,i} \in \{0, 1\}$ , be its binary expansion. Let  $t \geq 1$  be a parameter that we will fix later, and note that

$$\left| P_S - \sum_{0 \leq k \leq t} \frac{c_{S,k}}{2^{k+1}} \right| \leq 2^{-t}.$$

Define the nonclassical polynomial

$$Q(x) = \alpha + \sum_{\emptyset \subset S \subseteq [n]; k \geq 0; 0 < |S| + k \leq t+d} \frac{c'_{S,k}}{2^{k+1}} \prod_{i \in S} x_i \pmod{1},$$

where  $c'_{S,k} = c_{S,k}$  for  $|S| \leq d, k \leq t$ , and is 0 otherwise. Then  $\deg(Q) \leq t + d$ , and

$$|P(x) - Q(x) \pmod{1}| \leq \binom{n}{\leq d} 2^{-t}$$

for all  $x \in \{0, 1\}^n$ . Choosing  $t = O(d \log n + \log(1/\varepsilon))$  completes the proof. ◀

Recall that our goal, motivated by proving ACC<sup>0</sup> lower bounds, is to find a Boolean function which cannot be  $1/\text{poly}(n)$ -approximated by a torus polynomial of degree  $\text{polylog}(n)$ . Given Claim 8, this is equivalent to the problem of finding a Boolean function which cannot be  $1/\text{poly}(n)$ -approximated by a nonclassical polynomial of degree  $\text{polylog}(n)$ . As we mentioned before, owing to the elegance and ease of description of torus polynomials relative to nonclassical polynomials, torus polynomials make for a more convenient choice in our setting.

## 1.4 Comparison with other notions of approximation

It's clear from our discussion in the previous section that torus polynomials are closely related to nonclassical polynomials, and so it's worthwhile to discuss two notions of approximation of Boolean functions by nonclassical polynomials that have been studied in the literature. The first deals with the *exact* computation of a Boolean function by a nonclassical polynomial on a nontrivial fraction of the domain [3]. For example, the work of Bhrushundi et al.[4] shows that any polynomial that computes MAJORITY correctly even on two-thirds of the points must have degree  $\Omega(\sqrt{n})$ . While many of these bounds for nonclassical polynomials should also hold for torus polynomials, we remark that they are not relevant to our setting since our notion of approximation (i.e., point-wise) is incomparable with the above notion.

The second notion is that of correlation with polynomials, which was studied, for example, by Bhowmick and Lovett[3]. Without getting into definitions here, we note that this notion of approximation is *weaker* than that of point-wise approximation<sup>6</sup>, and thus for the purpose of proving lower bounds for  $\text{ACC}^0$  it makes sense to work with only the latter. This also means that the upper bound results proved in the work of Bhowmick and Lovett (i.e., showing how certain Boolean functions can be approximated by low-degree nonclassical polynomials in the correlation sense) don't have any implications for our setting. Even their lower bound results, unfortunately, are not useful for us given that they only work against polynomials of degree  $\ll \log(n)$ , whereas we are dealing with polynomials of degree  $\text{polylog}(n)$ .

## 1.5 Natural proofs

An interesting line of inquiry motivated by the *natural proofs* framework of Razborov and Rudich [11] is whether the property of being inapproximable by low-degree torus polynomials is *natural*. It is not hard to see that it satisfies the *largeness* condition though it's unclear whether it is *constructive*, and so it will be interesting to investigate whether one can efficiently distinguish between Boolean functions which can be approximated by low-degree torus polynomials and a random Boolean function.

► **Problem 9.** *Given the truth table of a function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and  $\varepsilon > 0$ , decide in polynomial time (in  $2^n$  and  $1/\varepsilon$ ) whether  $\text{deg}_\varepsilon(f) \leq \text{polylog}(n/\varepsilon)$ .*

### Paper organization

In Section 2, we prove toroidal approximation results for Boolean functions in bounded circuit classes such as  $\text{AC}^0[p]$  and  $\text{ACC}^0$ . In Section 3, we prove lower bounds against symmetric torus polynomials approximating the MAJORITY function and the delta functions. In Section 4, we show that symmetric torus polynomials have surprising power in approximating the delta functions when the error  $\varepsilon$  is not too small. We introduce definitions and notation along the way, as and when needed.

## 2 Approximation of circuit classes

In this section, we illustrate how the framework of approximation by torus polynomials captures computation of Boolean functions in various models of computation. We begin by showing that functions that are computable by low-degree polynomials over finite fields can be approximated by low-degree torus polynomials.

It might be instructive to keep in mind that, for the scope of the entire paper, whenever we consider polynomials, we restrict ourselves to only *multilinear* polynomials, i.e. polynomials in which the maximum degree of any variable is at most 1. Even if we encounter polynomials that do not adhere to this form during intermediate steps in certain proofs, we can always *multilinearize* the polynomials by making the degrees of all the variables equal to 1 wherever they appear. It suffices to consider multilinear polynomials because we always restrict the variables to the domain  $\{0, 1\}$ .

<sup>6</sup> By this we mean that if a function is point-wise approximated by a low-degree torus polynomial then it is also approximated by that polynomial in the correlation sense.

### 2.1 Polynomials over finite fields

Let  $\mathbb{F}_p$  be a prime finite field. We say a polynomial  $P(x) \in \mathbb{F}_p[x_1, \dots, x_n]$  computes a Boolean function  $f$  if

$$\forall x \in \{0, 1\}^n, f(x) = P(x).$$

Consider a function  $f$  which is computed by a low-degree polynomial over  $\mathbb{F}_p$ . We will now show that it can be approximated by a low-degree torus polynomial. We would require the following theorem on modulus-amplifying polynomials of Beigel and Tarui [1], following previous results of Toda [15] and Yao [17].

► **Lemma 10** (Beigel and Tarui [1]). *For every  $k \geq 1$ , there exists a univariate polynomial  $A_k : \mathbb{Z} \rightarrow \mathbb{Z}$  of degree  $2k - 1$  such that the following holds. For every  $m \geq 2$ ,*

- *If  $x \in \mathbb{Z}$  satisfies  $x \equiv 0 \pmod{m}$  then  $A_k(x) \equiv 0 \pmod{m^k}$ .*
- *If  $x \in \mathbb{Z}$  satisfies  $x \equiv 1 \pmod{m}$  then  $A_k(x) \equiv 1 \pmod{m^k}$ .*

► **Lemma 11.** *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ . Assume that  $f$  can be computed by a polynomial over  $\mathbb{F}_p$  of degree  $d$ . Then for every  $\varepsilon > 0$ ,*

$$\overline{\deg}_\varepsilon(f) \leq O(d \log(1/\varepsilon)).$$

**Proof.** Since  $f$  is computable by degree- $d$  polynomials over  $\mathbb{F}_p$ , there must be an integer polynomial  $F(x)$  (i.e., a polynomial with coefficients in  $\mathbb{Z}$ ) of degree  $d$  such that

$$F(x) \equiv f(x) \pmod{p} \quad \forall x \in \{0, 1\}^n.$$

Let  $k \geq 1$  be large enough so that  $1/p^k \leq \varepsilon$ . Let  $0 \leq q \leq p^k - 1$  be such that

$$\left| \frac{q}{p^k} - \frac{1}{2} \pmod{1} \right| \leq \varepsilon.$$

Define

$$G(x) = \frac{qA_k(F(x))}{p^k} \pmod{1}.$$

We claim that

$$\left| G(x) - \frac{f(x)}{2} \pmod{1} \right| \leq \varepsilon \tag{1}$$

for all  $x$ . To see this, fix  $x$ , and recall that  $F(x) \equiv f(x) \pmod{p}$ , which means that  $A_k(F(x)) \equiv f(x) \pmod{p^k}$ , and hence  $G(x) \equiv \frac{q}{p^k} f(x) \pmod{1}$ . (1) now follows from our choice of  $q$ .

Noting that the degree of  $G$  is  $(2k - 1)d \leq O(d \log(1/\varepsilon))$  completes the proof. ◀

We will later need the following simple variant of Lemma 11. Its proof is identical.

► **Lemma 12.** *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ . Assume that  $f$  can be computed by a polynomial over  $\mathbb{F}_p$  of degree  $d$ . Then for every  $\alpha \in [0, 1]$  and every  $\varepsilon > 0$ , there exists a torus polynomial  $P : \{0, 1\}^n \rightarrow \mathbb{T}$  of degree  $O(d \log(1/\varepsilon))$  such that*

$$\|P - \alpha f \pmod{1}\|_\infty \leq \varepsilon.$$

## 2.2 Circuit class $AC^0[p]$

Recall that, for a fixed prime  $p$ ,  $AC^0[p]$  is the class of functions computable by polynomial size circuits of constant depth, consisting of AND, OR, NOT, and  $MOD_p$  gates. Here a  $MOD_p$  gate is one that outputs 1 if and only if the sum of its inputs is congruent to a non-zero value modulo  $p$ .

Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be a function in  $AC^0[p]$ . We show that it can also be approximated by low-degree torus polynomials. The starting point is the classic result of Razborov [10] and Smolensky [12] which shows that  $AC^0[p]$  circuits can be approximated by random low-degree polynomials over  $\mathbb{F}_p$  in the following sense.

► **Theorem 13** (Razborov-Smolensky[10, 12]). *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be computed by an  $AC^0[p]$  circuit. Then for every  $\varepsilon > 0$ , there exists a distribution  $\nu$  supported on polynomials  $F : \mathbb{F}_p^n \rightarrow \{0, 1\}$  of degree  $d = \text{polylog}(n/\varepsilon)$  such that*

$$\Pr_{P \sim \nu} [P(x) = f(x)] \geq 1 - \varepsilon \quad \forall x \in \{0, 1\}^n.$$

We can assume without loss of generality that all the polynomials in the support of the distribution  $\nu$  have range  $\{0, 1\}$ . This is because given an arbitrary polynomial  $P(x)$  over  $\mathbb{F}_p$  we can convert it into the polynomial  $P'(x) = (P(x))^{p-1}$  which has range  $\{0, 1\}$  by Fermat's little theorem. Note that the degree of  $P'$  is at most  $p$  times the degree of  $P$  which is not really a problem since  $p = O(1)$  for us.

We now show why torus polynomials approximate  $AC^0[p]$  functions.

► **Lemma 14.** *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ . Assume that there exists a distribution  $\nu$  supported on polynomials  $F : \mathbb{F}_p^n \rightarrow \{0, 1\}$  of degree  $d$  such that*

$$\Pr_{P \sim \nu} [P(x) = f(x)] \geq 1 - \varepsilon \quad \forall x \in \{0, 1\}^n.$$

Then

$$\overline{\text{deg}}_{3\varepsilon}(f) \leq O(d \log(n/\varepsilon)).$$

**Proof.** By standard Chernoff bounds, if we sample  $F_1, \dots, F_m \sim \nu$  independently for  $m = O(n/\varepsilon^2)$  then with high probability,

$$|\{i \in [m] : F_i(x) \neq f(x)\}| \leq 2\varepsilon m \quad \forall x \in \{0, 1\}^n.$$

Fix such a sample. Recall that  $F_i : \mathbb{F}_p^n \rightarrow \{0, 1\}$  are computed by degree  $d$  polynomials over  $\mathbb{F}_p$ . Next, apply Lemma 12 with  $\alpha = 1/2m$  and error  $\varepsilon/m$ . This gives us torus polynomials  $P_i : \{0, 1\}^n \rightarrow \mathbb{T}$  of degree  $O(d \log(m/\varepsilon))$  such that

$$\left| P_i(x) - \frac{1}{2m} F_i(x) \pmod{1} \right| \leq \frac{\varepsilon}{m} \quad \forall x \in \{0, 1\}^n.$$

Finally, take

$$P(x) = P_1(x) + \dots + P_m(x) \pmod{1}.$$

We claim that  $P(x)$  is a torus polynomial which  $3\varepsilon$ -approximates  $f(x)$ . To see this, fix  $x \in \{0, 1\}^n$ , and observe that

$$\left| P(x) - \frac{F_1(x) + \dots + F_m(x)}{2m} \pmod{1} \right| \leq \varepsilon$$

## 13:10 Torus Polynomials

and

$$\left| \frac{F_1(x) + \dots + F_m(x)}{2m} - \frac{f(x)}{2} \pmod{1} \right| \leq 2\varepsilon,$$

and so

$$\left| P(x) - \frac{f(x)}{2} \pmod{1} \right| \leq 3\varepsilon.$$

This means that

$$\overline{\deg}_{3\varepsilon}(f) \leq \deg(P) = \max\{\deg(P_i) : i \in [m]\} = O(d \log(m/\varepsilon)) = O(d \log(n/\varepsilon)). \quad \blacktriangleleft$$

► **Corollary 15.** *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be a function in  $AC^0[p]$ . Then for every  $\varepsilon > 0$ ,*

$$\overline{\deg}_\varepsilon(f) \leq \text{polylog}(n/\varepsilon).$$

An interesting question that is motivated by the above results is whether we can have a mini-max type theorem for torus polynomials. Lemma 14 gives such a theorem in a very limited regime. The following is an attempt to generalize this.

► **Problem 16.** *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ . Assume that for any distribution  $\nu$  over  $\{0, 1\}^n$ , there exists a low-degree torus polynomial  $P_\nu : \{0, 1\}^n \rightarrow \mathbb{T}$  such that*

$$\mathbb{E}_{x \sim \nu} \left[ \left| P_\nu(x) - \frac{f(x)}{2} \pmod{1} \right| \right] \leq \varepsilon.$$

*Does that imply that the toroidal approximation degree of  $f$  is small? That is, does there exist a single low-degree torus polynomial which approximates  $f$  on all inputs?*

It might also be useful to assume the stronger assumption that for any distribution  $\nu$  over  $\{0, 1\}^n$  and any  $\alpha \in [0, 1]$  there exists a torus polynomial  $P_{\nu, \alpha} : \{0, 1\}^n \rightarrow \mathbb{T}$  of degree  $d$  such that

$$\mathbb{E}_{x \sim \nu} [|P_{\nu, \alpha}(x) - \alpha f(x) \pmod{1}|] \leq \varepsilon.$$

This is also related to the following problem.

► **Problem 17.** *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ . For any  $\alpha \in [0, 1]$  and  $\varepsilon > 0$  define  $d(\alpha, \varepsilon)$  to be the minimal degree of a torus polynomial  $P : \{0, 1\}^n \rightarrow \mathbb{T}$  such that*

$$\|P - \alpha f \pmod{1}\|_\infty \leq \varepsilon.$$

*What is the behavior of  $d(\alpha, \varepsilon)$  as a function of  $\alpha$  and of  $\varepsilon$ ? Specifically,*

- *Can we bound  $\max_\alpha d(\alpha, \varepsilon)$  in terms of  $d(1/2, \varepsilon)$ ?*
- *Can we bound  $\max_\alpha d(\alpha, \varepsilon)$  in terms of  $\max_\alpha d(\alpha, 0.1)$ ?*

### 2.3 Circuit class $ACC^0$

We now turn our attention to  $ACC^0$  functions and show that they too can be approximated by low-degree torus polynomials. Recall that a function is in  $ACC^0$  if it can be computed by polynomial size circuits of constant depth with AND, OR, NOT, and  $MOD_m$  gates where  $m$  may be composite.

Our starting point is the following result of Green et al. [5] which extends previous results of [17, 1].

► **Theorem 18** (Green et al. [5]). *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be computable by  $\text{ACC}^0$  circuits of depth  $\ell$  and size  $\text{poly}(n)$ . Then for any  $e \geq 1$  there exists an integer polynomial  $F(x)$  of degree  $d = e^{O(\ell)} \log^{O(\ell^2)} n$  which satisfies the following: there is some  $k \geq 1$  such that*

$$\forall x \in \{0, 1\}^n, \quad F(x) = f(x)2^k + E(x) \pmod{2^{k+e}}$$

for some error  $E(x) \leq 2^{k-1}$ .

Note that the above theorem states that the  $k^{\text{th}}$  bit of  $F(x)$  in binary always equals to  $f(x)$  and that it's padded with  $e - 1$  zeros to its left, i.e the  $(k + 1)^{\text{th}}$ ,  $(k + 2)^{\text{th}}$ ,  $\dots$ ,  $(k + e - 1)^{\text{th}}$  bits are all guaranteed to be equal to 0. It turns out that, implicit in their work, is the following slightly stronger version of the above result which lets us pad zeros on both sides of the output bit (i.e., the  $k^{\text{th}}$  bit).

► **Theorem 19** (Implicit in Green et al. [5]). *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be computable by  $\text{ACC}^0$  circuits of depth  $\ell$  and size  $\text{poly}(n)$ . Then for any  $e \geq 1$  there exists an integer polynomial  $F(x)$  of degree  $d = e^{O(\ell)} \log^{O(\ell^2)} n$  which satisfies the following: there is some  $k \geq e$  such that*

$$\forall x \in \{0, 1\}^n, \quad F(x) = f(x)2^k + E(x) \pmod{2^{k+e}}$$

for some error  $E(x) \leq 2^{k-e}$ .

Note the difference between the statements of Theorem 18 and Theorem 19: while the former upper-bounds the error  $E(x)$  by  $2^{k-1}$  the latter bounds it by  $2^{k-e}$ , thus padding the output bit with  $e - 1$  zeros on both the sides.

Since the proof of Theorem 19 is essentially the same as that of Theorem 18 with some very minor tweaks, we choose to omit it here. We now show how to use Theorem 19 to prove that low-degree torus polynomials approximate functions in  $\text{ACC}^0$ .

► **Corollary 20.** *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be a function in  $\text{ACC}^0$ . Then for every  $\varepsilon > 0$ , there is a torus polynomial of degree  $\text{polylog}(n/\varepsilon)$  that  $\varepsilon$ -approximates  $f$ . In other words,*

$$\overline{\text{deg}}_\varepsilon(f) \leq \text{polylog}(n/\varepsilon).$$

**Proof.** Let us assume that  $f$  is computable by  $\text{ACC}^0$  circuits of size  $\text{poly}(n)$  and depth  $\ell$ . Recall that, by definition of  $\text{ACC}^0$ ,  $\ell = O(1)$ . Let  $F(x)$  be the polynomial obtained by applying Theorem 19 to  $f$  with  $e = \log(1/\varepsilon)$  such that for some  $k \geq e$

$$\forall x \in \{0, 1\}^n, \quad F(x) = f(x)2^k + E(x) \pmod{2^{k+e}}.$$

The degree of  $F(x)$  is  $d = e^{O(\ell)} \log^{O(\ell^2)} n = \text{polylog}(n/\varepsilon)$ . Define the following torus polynomial

$$P(x) = \frac{F(x)}{2^{k+1}} \pmod{1}.$$

Clearly  $\text{deg}(P) = d$ . For  $i \geq 0$ , let  $F_i(x)$  denote the  $i^{\text{th}}$  bit of  $F(x)$ . Then, by the definition of  $F$ ,

$$\frac{F(x)}{2^{k+1}} \pmod{1} = \sum_{i=0}^k 2^{i-k-1} F_i(x) \pmod{1} = \frac{f(x)}{2} + \sum_{i=0}^{k-e} 2^{i-k-1} F_i(x) \pmod{1}.$$

As  $F_i(x) \in \{0, 1\}$  for all  $i$ , we can bound

$$\left| P(x) - \frac{f(x)}{2} \pmod{1} \right| \leq 2^{-e} \leq \varepsilon \quad \forall x \in \{0, 1\}^n. \quad \blacktriangleleft$$

### 3 Lower bound for symmetric torus polynomials

In this section we prove a lower bound on the degree of *symmetric* torus polynomials that approximate MAJORITY. It will be instructive to think of symmetric torus polynomials as symmetric real polynomials evaluated modulo one. We start by examining the question for delta functions.

For  $x \in \{0, 1\}^n$ , let  $|x| = \sum x_i$  denote its Hamming weight. The delta function

$$\Delta_w : \{0, 1\}^n \rightarrow \{0, 1\},$$

for  $0 \leq w \leq n$ , is defined as

$$\Delta_w(x) = \begin{cases} 1 & |x| = w \\ 0 & \text{otherwise} \end{cases}.$$

► **Lemma 21.** *Let  $n, d$  be positive integers such that for every  $0 \leq w \leq n$  there exists a symmetric torus polynomial  $Q_w : \{0, 1\}^n \rightarrow \mathbb{T}$  of degree  $d$  that  $\frac{1}{20n}$ -approximates  $\Delta_w(x)$ . Then  $d = \Omega\left(\sqrt{\frac{n}{\log n}}\right)$ .*

**Proof.** Let  $\text{Sym}(n)$  denote the set of symmetric Boolean functions in  $n$  variables and let  $\text{SymPoly}_{d,k}(n)$  denote the set of symmetric torus polynomials in  $n$  variables of degree  $d$  whose coefficients are of the form  $q/2^k$  for  $q \in \{-(2^k - 1), \dots, 0, \dots, 2^k - 1\}$ .

Let  $f$  be an arbitrary function in  $\text{Sym}(n)$ . Abusing notation, we let  $f^{-1}(1)$  denote the set of weights of the layers of the Hamming cube where  $f$  takes value 1. Now define the torus polynomial  $Q_f$  as

$$Q_f(x) = \sum_{i \in f^{-1}(1)} Q_i(x) \pmod{1}.$$

It follows that  $Q_f$  is a symmetric torus polynomial of degree  $d$  that  $\frac{1}{20}$ -approximates  $f$ . Since  $Q_f$  is a symmetric torus polynomial, namely a symmetric real polynomial modulo one, it may be written without loss of generality as

$$Q_f(x) = \sum_{j=0}^d c_j \left(\sum x_i\right)^j \pmod{1},$$

where  $c_j \in [0, 1)$ . Let  $k \geq 0$  be an integer whose value we will fix later. For  $0 \leq j \leq d$ , let  $q_j \in \{-(2^k - 1), \dots, 0, \dots, 2^k - 1\}$  be such that

$$\left| \frac{q_j}{2^k} - c_j \right| \leq \frac{1}{2^k},$$

and define  $Q'_f$  to be the polynomial

$$Q'_f(x) = \sum_{j=0}^d \frac{q_j}{2^k} \cdot \left(\sum x_i\right)^j \pmod{1}.$$

Observe that for every  $x \in \{0, 1\}^n$ ,

$$|Q_f(x) - Q'_f(x) \pmod{1}| \leq \sum_{j=0}^d \left| \frac{q_j}{2^k} - c_j \right| \cdot |x|^j \leq \frac{(d+1) \cdot n^d}{2^k}.$$

If  $k$  is such that  $\frac{(d+1) \cdot n^d}{2^k} \leq \frac{1}{20}$  then

$$\|Q_f - Q'_f \pmod{1}\|_\infty \leq \frac{1}{20},$$

and so

$$\left\| \frac{f}{2} - Q'_f \pmod{1} \right\|_\infty \leq \left\| \frac{f}{2} - Q_f \pmod{1} \right\|_\infty + \|Q_f - Q'_f \pmod{1}\|_\infty \leq \frac{1}{10}.$$

Note that we can choose  $k = O(d \log n)$  while still satisfying the required condition on  $k$ .

So far we have shown that for every  $f \in \text{Sym}(n)$  there is a polynomial  $Q_f \in \text{SymPoly}_{d,k}(n)$  that  $1/10$ -approximates  $f$  where  $k = O(d \log n)$ . In the other direction, one can easily verify that every polynomial in  $\text{SymPoly}_{d,k}(n)$  can  $1/10$ -approximate *at most* one function in  $\text{Sym}(n)$ . This implies that

$$|\text{SymPoly}_{d,k}(n)| \geq |\text{Sym}(n)|.$$

Plugging in  $|\text{SymPoly}_{d,k}(n)| = 2^{(k+1)(d+1)}$  and  $|\text{Sym}(n)| = 2^n$ , and using  $k = O(d \log n)$ , yields the bound  $d = \Omega\left(\sqrt{\frac{n}{\log n}}\right)$ .  $\blacktriangleleft$

Before we proceed, we formally define MAJORITY on  $n$  bits, denoted by  $\text{Maj}_n(x)$ , as

$$\text{Maj}_n(x) = \begin{cases} 1 & |x| \geq \frac{n}{2} \\ 0 & \text{otherwise} \end{cases}.$$

► **Lemma 22.** *If there is a symmetric torus polynomial of degree  $o\left(\sqrt{\frac{n}{\log n}}\right)$  that  $\frac{1}{20n}$ -approximates  $\text{Maj}_n(x)$ , then for every  $0 \leq w \leq n$  there is a symmetric torus polynomial of degree  $o\left(\sqrt{\frac{n}{\log n}}\right)$  that  $\frac{1}{20n}$ -approximates  $\Delta_w(x)$ .*

**Proof.** Fix  $w$ . Let  $\Delta_{\geq w}(x)$  denote the function that takes value 1 iff  $|x| \geq w$ . Then we can write

$$\Delta_{\geq w}(x_1, \dots, x_n) = \text{Maj}_{2n+1}(x_1, \dots, x_n, c_1, \dots, c_{n+1}), \tag{2}$$

where  $c \in \{0, 1\}^{n+1}$  is the string whose first  $n - w + 1$  bits are set to 1 and the rest of the bits are set to 0. Let  $Q(x_1, \dots, x_{2n+1})$  be the symmetric torus polynomial in  $2n + 1$  variables that  $\frac{1}{20(2n+1)}$ -approximates  $\text{Maj}_{2n+1}(x)$ . Let  $Q_{\geq w}(x_1, \dots, x_n)$  be the torus polynomial defined as

$$Q_{\geq w}(x_1, \dots, x_n) = Q(x_1, \dots, x_n, c_1, \dots, c_{n+1}),$$

where  $c \in \{0, 1\}^{n+1}$  is as defined above. It follows from (2) that  $Q_{\geq w}(x_1, \dots, x_n)$   $\frac{1}{40n}$ -approximates  $\Delta_w(x_1, \dots, x_n)$ . Furthermore,

$$\text{deg}(Q_{\geq w}) = o\left(\sqrt{\frac{n}{\log n}}\right).$$

Similarly, we can obtain a symmetric torus polynomial  $Q_{\geq w+1}$  that  $\frac{1}{40n}$ -approximates  $\Delta_{\geq w+1}(x_1, \dots, x_n)$  such that

$$\text{deg}(Q_{\geq w+1}) = o\left(\sqrt{\frac{n}{\log n}}\right).$$

## 13:14 Torus Polynomials

Note that

$$\frac{\Delta_w(x)}{2} \pmod{1} = \left( \frac{\Delta_{\geq w}(x)}{2} - \frac{\Delta_{\geq w+1}(x)}{2} \right) \pmod{1}.$$

Defining  $Q_w(x) = Q_{\geq w}(x) - Q_{\geq w+1}(x) \pmod{1}$ , it follows that

$$\left\| \frac{\Delta_w(x)}{2} - Q_w(x) \pmod{1} \right\|_{\infty} \leq \frac{1}{20n}.$$

This completes the proof. ◀

The main result of this section now follows from Theorem 21 and Lemma 22:

► **Corollary 23.** *Any symmetric torus polynomial of degree  $d$  that  $\frac{1}{20n}$ -approximates  $\text{Maj}_n(x)$  must satisfy  $d = \Omega\left(\sqrt{\frac{n}{\log n}}\right)$ .*

### 4 Upper bound for delta functions

In this section, we prove the somewhat surprising result that if the approximation parameter  $\varepsilon > 0$  is not too small (say,  $\varepsilon$  is a small constant), then the delta function  $\Delta_w$  can be nontrivially approximated by *symmetric* low-degree torus polynomials.

► **Lemma 24.** *For every  $0 \leq w \leq n$  and  $\varepsilon > 0$ , there is a symmetric torus polynomial of degree  $\frac{\text{polylog}(n/\varepsilon)}{\varepsilon}$  that  $\varepsilon$ -approximates  $\Delta_w(x)$ , and thus*

$$\overline{\text{deg}}_{\varepsilon}(\Delta_w) \leq \frac{\text{polylog}(n/\varepsilon)}{\varepsilon}.$$

**Proof.** For any prime  $p \geq 2$ , let  $f_p : \{0, 1\}^n \rightarrow \{0, 1\}$  denote the function

$$f_p(x) = \begin{cases} 1 & |x| \equiv w \pmod{p} \\ 0 & \text{otherwise} \end{cases}.$$

It is computed by the  $\mathbb{F}_p$ -polynomial of degree  $p - 1$

$$f_p(x) = 1 - \left( \sum x_i - w \right)^{p-1} \pmod{p}.$$

Let  $P = \{p_1, \dots, p_t\}$  be the first  $t$  primes, for  $t$  to be chosen later. Applying Lemma 12 with  $\alpha = 1/2t$  and error  $\varepsilon/2t$ , for each  $p \in P$  we obtain a torus polynomial  $Q_p : \{0, 1\} \rightarrow \mathbb{T}$  of degree  $O(p \log(t/\varepsilon))$  such that

$$\left\| Q_p - \frac{1}{2t} f_p \pmod{1} \right\|_{\infty} \leq \frac{\varepsilon}{2t}.$$

Define

$$Q(x) = \sum_{p \in P} Q_p(x) \pmod{1}.$$

We claim that  $Q$  is a symmetric torus polynomial that  $\varepsilon$ -approximates  $\Delta_w$ .

Consider first  $x \in \{0, 1\}^n$  with  $|x| = w$ . In this case, for each  $p \in P$  we have  $f_p(x) = 1$ ,  $|Q_p(x) - \frac{1}{2t} \pmod{1}| \leq \varepsilon/2t$  and hence

$$\left| Q(x) - \frac{1}{2} \pmod{1} \right| \leq \varepsilon/2.$$

Next, assume that  $|x| \neq w$ . Then  $f_p(x) = 1$  only if  $p$  divides  $|x| - w$ . As there are at most  $\log n$  such primes, we have that

$$|Q(x) \pmod{1}| \leq \frac{\varepsilon}{2} + \frac{\log n}{t}.$$

To conclude we choose  $t = O(\log(n)/\varepsilon)$ . The largest prime in  $P$  has size  $O(t \log t)$  which means that

$$\overline{\deg}_\varepsilon(f) \leq \deg(Q) = \max\{\deg(Q_p) : p \in P\} \leq O(t \log t \cdot \log(t/\varepsilon)) = \frac{\text{polylog}(n/\varepsilon)}{\varepsilon}.$$

To see why  $Q$  is symmetric, observe that Lemma 12 preserves symmetry.  $\blacktriangleleft$

## Abstract

We study the existence of allocations of indivisible goods that are envy-free up to one good (EF1), under the additional constraint that each bundle needs to be connected in an underlying item graph  $G$ . When the items are arranged in a path, we show that EF1 allocations are guaranteed to exist for arbitrary monotonic utility functions over bundles, provided that either there are at most four agents, or there are any number of agents but they all have identical utility functions. Our existence proofs are based on classical arguments from the divisible cake-cutting setting, and involve discrete analogues of cut-and-choose, of Stromquist's moving-knife protocol, and of the Su-Simmons argument based on Sperner's lemma. Sperner's lemma can also be used to show that on a path, an EF2 allocation exists for any number of agents. Except for the results using Sperner's lemma, all of our procedures can be implemented by efficient algorithms. Our positive results for paths imply the existence of connected EF1 or EF2 allocations whenever  $G$  is traceable, i.e., contains a Hamiltonian path. For the case of two agents, we completely characterize the class of graphs  $G$  that guarantee the existence of EF1 allocations as the class of graphs whose biconnected components are arranged in a path. This class is strictly larger than the class of traceable graphs; one can check in linear time whether a graph belongs to this class, and if so return an EF1 allocation.

## 1 Introduction

A famous literature considers the problem of *cake-cutting* [10, 25, 24]. There, a divisible heterogeneous resource (a *cake*, usually formalized as the interval  $[0, 1]$ ) needs to be divided among  $n$  agents. Each agent has a valuation function over subsets of the cake, usually formalized as an atomless measure over  $[0, 1]$ . The aim is to partition the cake into  $n$  pieces, and allocate each piece to one agent, in a “fair” way. By fair, we will mean that the allocation is *envy-free*: no agent thinks that another agent’s piece is more valuable than her own.

When there are two agents, the classic procedure of cut-and-choose can produce an envy-free division: a knife is moved from left to right, until an agent shouts to indicate that she thinks the pieces to either side are equally valuable. The other agent then picks one of the pieces, leaving the remainder for the shouter. As is easy to see, the result is an envy-free allocation. For three or more agents, finding an envy-free division has turned out to be much trickier. An early result by Dubins and Spanier [15] used Lyapunov’s Theorem and measure-theoretic techniques to show, non-constructively, that an envy-free allocation always exists. However, as Stromquist [28] memorably writes, “their result depends on a liberal definition of a “piece” of cake, in which the possible pieces form an entire  $\sigma$ -algebra of subsets. A player who only hopes for a modest interval of cake may be presented instead with a countable union of crumbs.” In many applications of resource allocation (such as land division, or the allocation of time slots), agents have little use for a severely disconnected piece of cake.

Stromquist [28] himself offered a solution, and gave a new non-constructive argument (using topology) which proved that there always exists an envy-free division of the cake into *intervals*. Forest Simmons later observed that the proof could be simplified by using Sperner’s lemma, and this technique was subsequently presented in a paper by Su [29]. For the three-agent case, Stromquist [28] also presented an appealing moving-knife procedure that more directly yields a connected envy-free allocation. For  $n \geq 4$  agents, no explicit procedures are known to produce a connected envy-free allocation (i.e., an allocation where the cake is cut in exactly  $n - 1$  places). However, for  $n = 4$ , several moving-knife procedures exist that only need few cuts; for example, the Brams–Taylor–Zwicker [11] procedure requires 11 cuts, and a protocol of Barnabel and Brams [3] requires 5 cuts.

In many applications, the resources to be allocated are not infinitely divisible, and we face the problem of allocating *indivisible goods*. Most of the literature on indivisible goods has not assumed any kind of structure on the item space, in contrast to the rich structure of the interval  $[0, 1]$  in cake-cutting. Thus, there has been little attention on minimizing the number of “cuts” required in an allocation. However, when the items have a spatial or temporal structure, this consideration is important.

In this paper, we study the allocation of items that are arranged on a *path* or other structure, and impose the requirement that only *connected* subsets of items may be allocated to the agents. Formally, we work in the model of [9], who assume that the items form the vertex set of a graph  $G$ ; a bundle is connected if it induces a connected subgraph of  $G$ . In

their paper, it became apparent that techniques from cake-cutting can be usefully ported to achieve good allocations in the indivisible case. For example, moving-knife procedures that achieve proportionality in cake-cutting have analogues that produce allocations that satisfy the *maximin share guarantee* [12].<sup>1</sup>

Do envy-free procedures for cake-cutting also translate to the indivisible case? Of course, in general, it is impossible to achieve envy-freeness with indivisibilities (consider two agents and a single desirable item), but we can look for approximations. A relaxation of envy-freeness that has been very influential recently is envy-freeness *up to one good* (EF1), introduced by Budish [12]. It requires that an agent's envy towards another bundle vanishes if we remove some item from the envied bundle. In the setting without connectivity constraints and with additive valuations, the maximum Nash welfare solution satisfies EF1, as does a simple round-robin procedure [13]. The well-known envy-graph algorithm [21] also guarantees EF1. However, none of these procedures respects connectivity constraints.

When items are arranged on a path, we prove that connected EF1 allocations exist when there are two, three, or four agents. As was necessary in cake-cutting, we use successively more complicated tools to establish these existence results. For two agents, there is a discrete analogue of cut-and-choose that satisfies EF1. In that procedure, a knife moves across the path, and an agent shouts when the knife reaches what we call a *lumpy tie*, that is when the bundles to either side of the knife have equal value *up to one item*. For three agents, we design an algorithm mirroring Stromquist's moving-knife procedure which guarantees EF1. For four agents, we show that Sperner's lemma can be used to prove that an EF1 allocation exists, via a technique inspired by the Simmons–Su approach, and an appropriately triangulated simplex of connected partitions of the path. For five or more agents, we were not able to establish the existence of EF1 allocations on a path, but we can show (again via Sperner's lemma) that EF2 allocations exist, strengthening a prior result of Suksompong [30]. We also show that if all agents have the same valuation function over bundles, then an egalitarian-welfare-optimal allocation, after suitably reallocating some items, is EF1.

These existence results require only that agents' valuations are monotonic (they need not be additive), and in addition ensure that the constructed allocation satisfies the maximin share guarantee (see [5]). Moreover, the fairness guarantee of our algorithms is slightly stronger than the standard notion of EF1: in the returned allocations, envy can be avoided by removing just an *outer* item – one whose removal leaves the envied bundle connected. Computationally speaking, all our existence results are immediately useful, since an example of an EF1 allocation can be found by iterating through all  $O(m^n)$  connected allocation (this stands in contrast to cake-cutting where we cannot iterate through all possibilities). While we know of no faster algorithms to obtain an EF1 allocation in the cases where we appeal to Sperner's lemma, our other procedures can all be implemented efficiently.

In simultaneous and independent work, Oh et al. [23] designed protocols to find EF1 allocations in the setting without connectivity constraints, aiming for low *query complexity*. They found that adapting cake-cutting protocols to the setting of indivisible items arranged on a path is an especially potent way to achieve low query complexity. This led them to also study a discrete version of the cut-and-choose protocol which achieves connected EF1 allocations for two agents, and they found an alternative proof that an EF1 allocation on a path always exists with identical valuations. They also present a discrete analogue of the Selfridge–Conway procedure which, for three agents with additive valuations, produces an

---

<sup>1</sup> Another paper by Suksompong [30] works in the same model, and also found that procedures for proportionality and other concepts can be applied to the indivisible setting.

allocation of a path into bundles that have a constant number of connected components. However, they do not study connected allocations on graphs that are not paths, and they do not consider the case of (non-identical) general valuations with more than two agents.

A recurring theme in our algorithms is the specific way that the moving knives from cake-cutting are rendered in the discrete setting. While one might expect knives to be placed over the edges of the path, and “move” from edge to edge, we find that this movement is too “fast” to ensure EF1 (see also footnote 4). Instead, our knives alternate between hovering over edges and items. When a knife hovers over an item, we imagine the knife’s blade to be “thick”: the knife *covers* the item, and agents then pretend that the covered item does not exist. These intermediate steps are useful, since they can tell us that envy will vanish if we hide an item from a bundle.

What about graphs  $G$  other than paths? Our positive results for paths immediately generalize to traceable graphs (those that contain a Hamiltonian path), since we can run the algorithms pretending that the graph only consists of the Hamiltonian path. For the two-agent case, we completely characterize the class of graphs that guarantee the existence of EF1 allocations: Our discrete cut-and-choose protocol can be shown to work on all graphs  $G$  that admit a *bipolar numbering*, which exists if and only if the biconnected components (blocks) of  $G$  can be arranged in a path. By constructing counterexamples, we prove that no graph failing this condition (for example, a star) guarantees EF1, even for identical, additive, binary valuations. For the case of three or more agents, it is a challenging open problem to characterize the class of graphs guaranteeing EF1 (or even to find an infinite class of non-traceable graphs that guarantees EF1).

## 2 Preliminaries

For each natural number  $s \in \mathbb{N}$ , write  $[s] = \{1, 2, \dots, s\}$ .

Let  $N = [n]$  be a finite set of *agents* and  $G = (V, E)$  be an undirected finite graph. The vertices in  $V$  as *goods* or *items*. A subset  $I$  of  $V$  is *connected* if it induces a connected subgraph of  $G$ . We write  $\mathcal{C}(V)$  for the set of connected subsets of  $V$ . We call a set  $I \in \mathcal{C}(V)$  a (connected) *bundle*. Each agent  $i \in N$  has a *valuation function*  $u_i : \mathcal{C}(V) \rightarrow \mathbb{R}$  over connected bundles, which we will always assume to be *monotonic*, that is,  $X \subseteq Y$  implies  $u_i(X) \leq u_i(Y)$ . We also assume that  $u_i(\emptyset) = 0$  for each  $i \in N$ . Monotonicity implies that items are *goods*; we do not consider *bads* (or *chores*) in this paper. We say that an agent  $i \in N$  *weakly prefers* bundle  $X$  to bundle  $Y$  if  $u_i(X) \geq u_i(Y)$ .<sup>2</sup> A (connected) *allocation*  $A : N \rightarrow \mathcal{C}(V)$  assigns each agent  $i \in N$  a connected bundle  $A(i) \in \mathcal{C}(V)$  such that each item occurs in exactly one bundle, i.e.,  $\bigcup_{i \in N} A(i) = V$  and  $A(i) \cap A(j) = \emptyset$  when  $i \neq j$ .

We say that the agents have *identical valuations* if for all  $i, j \in N$  and every bundle  $I \in \mathcal{C}(V)$ , we have  $u_i(I) = u_j(I)$ . A valuation function  $u_i$  is *additive* if  $u_i(I) = \sum_{v \in I} u_i(\{v\})$  for each bundle  $I \in \mathcal{C}(V)$ . Many examples in this paper will use identical additive valuations, and will take  $G$  to be a path. In this case, we use a shorthand to specify these examples; the meaning of this notation should be clear. For example, we write “2–1–3–1” to denote an instance with four items  $v_1, v_2, v_3, v_4$  arranged on a path, and where  $u_i(\{v_1\}) = 2, \dots, u_i(\{v_4\}) = 1$  for each  $i$ . For such an instance, an allocation will be written as a tuple, e.g., (2, 1–3–1) denoting an allocation allocating bundles  $\{v_1\}$  and  $\{v_2, v_3, v_4\}$ , noting that with identical valuations it does not usually matter which agent receives which bundle.

<sup>2</sup> Our arguments only operate based on agents’ ordinal preferences over bundles, and the (cardinal) valuation functions are only used for notational convenience. One exception, perhaps, is in Algorithm 1 where we calculate a leximin allocation, but the algorithm can be applied after choosing an arbitrary utility function consistent with the ordinal preferences.

An allocation  $A$  is *envy-free* if  $u_i(A(i)) \geq u_i(A(j))$  for every pair  $i, j \in N$  of agents, that is, if every agent thinks that their bundle is a best bundle in the allocation. It is well-known that an envy-free allocation may not exist (consider two agents and one good). The main fairness notion that we study is a version of *envy-freeness up to one good* (EF1), a relaxation of envy-freeness introduced by Budish [12], adapted to the model with connectivity constraints. This property states that an agent  $i$  will not envy another agent  $j$  after we remove some item from  $j$ 's bundle. Since we only allow connected bundles in our set-up, we may only remove an item from  $A(j)$  if removal of this item leaves the bundle connected.

► **Definition 1** (EF1: envy-freeness up to one *outer* good). An allocation  $A$  satisfies *EF1* if for any pair  $i, j \in N$  of agents, either  $A(j) = \emptyset$  or there is a good  $v \in A(j)$  such that  $A(j) \setminus \{v\}$  is connected and  $u_i(A(i)) \geq u_i(A(j) \setminus \{v\})$ .

In the instance 2–1–3–1 for two agents, the allocation (2–1, 3–1) is EF1, since the left agent's envy can be eliminated by removing the item of value 3 from the right-hand bundle. However, the allocation (2, 1–3–1) fails to be EF1 according to our definition, since eliminating either outer good of the right bundle does not prevent envy.<sup>3</sup>

► **Definition 2.** A graph  $G$  *guarantees EF1* (for a specific  $n$ ) if for all possible monotonic valuations for  $n$  agents, there exists some connected allocation that is EF1.

For reasoning about EF1 allocations, let us introduce a few shorthands. Given an allocation  $A$  we will say that  $i \in N$  *does not envy*  $j \in N$  *up to*  $v$  if  $u_i(A(i)) \geq u_i(A(j) \setminus \{v\})$ . The *up-to-one valuation*  $u_i^- : \mathcal{C}(V) \rightarrow \mathbb{R}_{\geq 0}$  of agent  $i \in N$  is defined, for every  $I \in \mathcal{C}(V)$ , as

$$u_i^-(I) := \begin{cases} 0 & \text{if } I = \emptyset, \\ \min \{u_i(I \setminus \{v\}) : v \in I \text{ such that } I \setminus \{v\} \text{ is connected}\} & \text{if } I \neq \emptyset. \end{cases} \quad (1)$$

Thus, an allocation  $A$  satisfies EF1 iff  $u_i(A(i)) \geq u_i^-(A(j))$  for any pair  $i, j \in N$  of agents.

Given an ordered sequence of the vertices  $P = (v_1, v_2, \dots, v_m)$ , and  $j, k \in [m]$  with  $j \leq k$ , we write  $P(v_j, v_k)$  for the subsequence from  $v_j$  to  $v_k$ , so  $P(v_j, v_k) = (v_j, v_{j+1}, \dots, v_{k-1}, v_k)$ . Let  $L(v_j) = P(v_1, v_{j-1})$  be the subsequence of vertices strictly left of  $v_j$  and  $R(v_j) = P(v_{j+1}, v_m)$  be the subsequence of vertices strictly right of  $v_j$ . A *Hamiltonian path* of a graph  $G$  is a path that visits all the vertices of the graph exactly once. A graph is *traceable* if it contains a Hamiltonian path.

### 3 EF1 existence for two agents

In cake-cutting for two agents, the standard way of obtaining an envy-free allocation is the cut-and-choose protocol: Alice divides the cake into two equally-valued pieces, and Bob selects the piece he prefers; the other piece goes to Alice. The same strategy almost works in the indivisible case when items form a path; the problem is that Alice might not be able to divide the items into two exactly-equal pieces. Instead, we ask Alice to divide the items into pieces that are equally valued “up to one good”. The formal version is as follows. For a sequence of vertices  $P = (v_1, v_2, \dots, v_m)$  and an agent  $i$ , we say that  $v_j$  is the *lumpy tie* over  $P$  for agent  $i$  if  $j$  is the smallest index such that

$$u_i(L(v_j) \cup \{v_j\}) \geq u_i(R(v_j)) \quad \text{and} \quad u_i(R(v_j) \cup \{v_j\}) \geq u_i(L(v_j)). \quad (2)$$

<sup>3</sup> This example shows that our definition is strictly stronger than the standard definition of EF1 without connectivity constraints. In the instance 2–1–3–1, considered without connectivity constraints, the allocation (2, 1–3–1) does satisfy EF1 since in the standard setting we are allowed to remove the middle item (with value 3) of the right bundle.

For example, when  $i$  has additive valuations 1–3–2–1–3–1, then the third item (of value 2) is the lumpy tie for  $i$ , since  $1 + 3 + 2 \geq 1 + 3 + 1$  and  $2 + 1 + 3 + 1 \geq 1 + 3$ . The lumpy tie always exists: taking  $j$  to be the smallest index such that  $u_i(L(v_j) \cup \{v_j\}) \geq u_i(R(v_j))$  (which exists as the inequality holds for  $j = m$  by monotonicity), the first part of (2) holds. If  $j = 1$ , the second part of (2) is immediate by monotonicity. If  $j > 1$ , then since  $j$  is minimal, we have  $u_i(L(v_j)) = u_i(L(v_{j-1}) \cup \{v_{j-1}\}) < u_i(R(v_{j-1})) = u_i(R(v_j) \cup \{v_j\})$  as required.

Using lumpy ties, our discrete version of the cut-and-choose protocol is specified as follows.

**Discrete cut-and-choose protocol for  $n = 2$  agents** on a sequence

$P = (v_1, v_2, \dots, v_m)$ :

*Step 1.* Alice selects her lumpy tie  $v_j$  over  $(v_1, v_2, \dots, v_m)$ .

*Step 2.* Bob chooses a weakly preferred bundle among  $L(v_j)$  and  $R(v_j)$ .

*Step 3.* Alice receives the bundle of all the remaining vertices, including  $v_j$ .

Intuitively, the protocol allows Alice to select an item  $v_j$  that she will receive for sure, with the advice that the two pieces to either side of  $v_j$  should have almost equal value to her. Then, Bob is allowed to choose which side of  $v_j$  he wishes to receive. In our example with valuations 1–3–2–1–3–1, Alice selects the lumpy tie of value 2, then Bob chooses the bundle 1–3–1 to the right and receives it, and Alice receives the bundle 1–3–2. The result is EF1. This is true in general, and also if valuations are not identical.

► **Proposition 3.** *When  $G$  is a path and there are  $n = 2$  agents, the discrete cut-and-choose protocol yields an EF1 allocation.*

**Proof.** Clearly, the protocol returns a connected allocation. The returned allocation satisfies EF1: Bob does not envy Alice up to item  $v_j$ , since Bob receives his preferred bundle among  $L(v_j)$  and  $R(v_j)$ . Also, by (2), Alice does not envy Bob, since Alice either receives the bundle  $L(v_j) \cup \{v_j\}$  which she weakly prefers to Bob's bundle  $R(v_j)$ , or she receives the bundle  $R(v_j) \cup \{v_j\}$ , which she weakly prefers to Bob's bundle  $L(v_j)$ . ◀

Proposition 3 implies that an EF1 allocation always exists on a path. Hence, an EF1 allocation exists for every traceable graph  $G$ : simply use the discrete cut-and-choose protocol on a Hamiltonian path of  $G$ . In fact, the discrete cut-and-choose protocol works on a broader class of graphs: We only need to require that the vertices of the graph can be numbered in a way that the allocation resulting from the discrete cut-and-choose protocol is guaranteed to be connected. Since the protocol always partitions the items into an initial and a terminal segment of the sequence, such a numbering needs to satisfy the following property.

► **Definition 4.** A *bipolar numbering* of a graph  $G$  is an ordering  $(v_1, v_2, \dots, v_m)$  of its vertices such that for all  $j \in [n]$ , the sets  $L(v_j) \cup \{v_j\}$  and  $R(v_j) \cup \{v_j\}$  are connected in  $G$ .

An equivalent definition (which is the standard one) says that a numbering is bipolar if for every  $j \in [n]$ , the vertex  $v_j$  has a neighbor that appears earlier in the sequence, and a neighbor that appears later in the sequence. Bipolar numberings are used in algorithms for testing planarity and for graph drawing. A Hamiltonian path induces a bipolar numbering, but there are non-traceable graphs that admit a bipolar numbering, see Figure 1 for examples.

► **Proposition 5.** *When there are  $n = 2$  agents, then the discrete cut-and-choose protocol run on a bipolar numbering of  $G$  yields an EF1 allocation.*

**Proof.** The discrete cut-and-choose protocol returns an allocation whose bundles are either initial or terminal segments of the ordered sequence  $(v_1, v_2, \dots, v_m)$ . By definition of a bipolar numbering, such an allocation is connected, and it is EF1 by Proposition 3. ◀

■ **Figure 1** Non-traceable graphs with bipolar numberings.

It is clear that the discrete cut-and-choose protocol cannot be extended to graphs other than those admitting a bipolar numbering. However, it could be that a different protocol is able to produce EF1 allocations on other graphs. In the remainder of this section, we prove that this is not the case: for  $n = 2$  agents, a connected graph  $G$  guarantees the existence of an EF1 allocation if and only if it admits a bipolar numbering. This completely characterizes the class of graphs that guarantee EF1 existence in the two-agent case.

### 3.1 Characterization of graphs guaranteeing EF1 for two agents

Based on a known characterization of graphs admitting a bipolar numbering, we characterize this class in terms of forbidden substructures. We then show that these forbidden structures are also forbidden for EF1: if a graph contains such a structure, we can exhibit an additive valuation profile for which no EF1 allocation exists.

As a simple example, consider the star with three leaves, which is the smallest connected graph that does not have a bipolar numbering. Take two agents with identical additive valuations that value each item at 1. Any connected allocation must allocate three items to one agent, and a single item to the other agent. Then the latter agent envies the former agent, even up to one good. This star is an example of what we call a *trident*, and forms a forbidden substructure. Informally, the forbidden substructures take one of two forms. We will prove that a graph  $G$  fails to admit a bipolar numbering, and fails to guarantee EF1 for two agents, iff either

- (a) there is a vertex  $s$  whose removal from  $G$  leaves three or more connected components, or
- (b) there are subgraphs  $C, P_1, P_2, P_3$  of  $G$  such that (i)  $G$  is the union of these subgraphs, (ii) the subgraphs  $P_1, P_2, P_3$  are vertex-disjoint, (iii)  $C$  has exactly one vertex in common with  $P_i$ ,  $i = 1, 2, 3$ , and (iv) no edge joins a vertex from one subgraph to a different one.

To reason about these structures, it is useful to consider the *block decomposition* of a graph, which will show that graphs that admit a bipolar numbering have a path-like structure.

► **Definition 6.** A vertex is called a *cut* vertex of a graph  $G$  if removing it increases the number of connected components of  $G$ . A graph  $G$  is *biconnected* if  $G$  does not have a cut vertex. A *block* of  $G$  is a maximal biconnected subgraph of  $G$ .

Equivalently, a block of a graph  $G$  can be defined as a maximal subgraph of  $G$  where each pair of vertices lie on a common cycle [8]. Given a connected graph  $G$ , we define a bipartite graph  $B(G)$  with bipartition  $(\mathcal{B}, \mathcal{S})$ , where  $\mathcal{B}$  is the set of blocks of  $G$  and  $\mathcal{S}$  is the set of cut vertices of a graph  $G$ ; a block  $B$  and a cut vertex  $v$  are adjacent in  $B(G)$  if and only if  $B$  includes  $v$ . Since every cycle of a graph is included in some block, the graph  $B(G)$  is a tree:

- **Lemma 7** (e.g., [8]). *Let  $G$  be a connected graph. Then*
- *any two blocks of  $G$  have at most one cut vertex in common;*
  - *the set of blocks forms a decomposition of  $G$ ; and*
  - *the graph  $B(G)$  is a tree.*

Thus, for a connected graph  $G$ , we call  $B(G)$  the *block tree* of  $G$ . It turns out that  $G$  admits a bipolar numbering if and only if  $B(G)$  is a path. For example, the graphs shown in Figure 1 all have their blocks arranged in a path (so that  $B(G)$  is a path).

- **Lemma 8.** *A graph  $G$  admits a bipolar numbering if its block tree  $B(G)$  is a path.*

**Proof.** Lempel et al. [20] show that  $G$  admits a bipolar numbering if there are  $s, t \in V$  such that adding an edge  $\{s, t\}$  to  $G$  makes it biconnected. If  $B(G)$  is a path, let  $B_1$  and  $B_2$  be the leaf blocks at the ends of the path  $B(G)$ . Take any  $s \in B_1$  and  $t \in B_2$ . If we add the edge  $\{s, t\}$  to  $G$ , the graph becomes biconnected. Hence,  $G$  admits a bipolar numbering. ◀

There is a linear-time algorithm based on depth-first search to construct a bipolar numbering for any biconnected graph [16, 31], and one can also calculate the block tree  $B(G)$  of a given graph in linear time [17]. Thus, in linear time, we can compute a bipolar numbering of a graph or report that none exists. Clearly, given a bipolar numbering, the discrete cut-and-choose protocol can also be run in linear time.

Next, we show that if  $B(G)$  is not a path, then  $G$  cannot guarantee EF1. The proof constructs explicit counter-examples, which have a very simple structure. We say that additive valuations  $u_i$  are *binary* if  $u_i(\{v\}) \in \{0, 1\}$  for every  $v \in V$ .

- **Lemma 9.** *Let  $G$  be a connected graph whose block tree  $B(G)$  is not a path. Then there exist identical, additive, binary valuations over  $G$  for two agents such that no connected allocation is EF1.*

**Proof.** If  $B(G)$  is not a path, then  $B(G)$  has a *trident*, i.e., a vertex with at least three neighbors, and thus either

- (a) there is a cut vertex  $s$  adjacent to three blocks  $B_1$ ,  $B_2$ , and  $B_3$ ; or
- (b) there is a block  $B$  adjacent to three different cut vertices  $s_1$ ,  $s_2$ , and  $s_3$ .

In either case, we construct identical additive valuations that do not admit an EF1 allocation.

In case (a), for each  $i = 1, 2, 3$ , choose a vertex  $v_i$  from  $B_i \setminus \{s\}$ . Note that we can choose such  $v_i \neq s$  due to the maximality of  $B_i$ . The two agents have utility 1 for  $s$ ,  $v_1$ ,  $v_2$ , and  $v_3$ , and 0 for the remaining vertices. Now take any connected allocation  $(I_1, I_2)$ . One of the bundles, say  $I_1$ , includes the cut vertex  $s$ . Then  $I_2$  can contain at most one of the vertices  $v_1$ ,  $v_2$ ,  $v_3$ , since  $I_2$  is connected and does not contain  $s$  yet any path between distinct  $v_i$  and  $v_j$  goes through  $s$ . Hence  $u_i(I_2) \leq 1$ . Now, the bundle  $I_1$  contains  $s$  and at least two of  $v_1$ ,  $v_2$ ,  $v_3$ , so  $u_i(I_1) \geq 3$ . Thus, the allocation is not EF1.

Case (b) is handled similarly; see [5]. ◀

Combining these results, we obtain the promised characterization.

- **Theorem 10.** *The following conditions are equivalent for every connected graph  $G$ :*

1.  $G$  admits a bipolar numbering.
2.  $G$  guarantees EF1 for two agents.
3.  $G$  guarantees EF1 for two agents with identical, additive, binary valuations.
4. The block tree  $B(G)$  is a path.

The equivalence (2)  $\Leftrightarrow$  (3) is noteworthy and perhaps surprising: It is often easier to guarantee fairness when agents' valuations are identical, yet in terms of the graphs that guarantee EF1 for two agents, there is no difference between identical and non-identical valuations. Intriguingly, even for more than two agents, we do not know of a graph which guarantees EF1 for identical valuations, but fails it for non-identical valuations.

#### 4 EF1 existence for three agents: A moving-knife protocol

We will now consider the case of three agents. Stromquist [28] designed a protocol that results in an envy-free contiguous allocation of a divisible cake. In outline, the protocol works as follows. A referee holds a sword over the cake. Each of the three agents holds their own knife over the portion of the cake to the right of the sword, positioning it so that this portion is divided into two pieces they judge to have the same value. Now, initially, the sword is at the left end of the cake. It starts moving at constant speed from left to right, while the agents continuously move their knives to keep dividing the right-hand portion into equally-valued pieces. At some point (when the left-most piece becomes valuable enough), one of the agents shouts “cut”, and the cake will be cut twice: once by the sword, and once by the middle one of the three knives. Agents shout “cut” as soon as the left piece is a highest-valued piece among the three. The agent who shouts receives the left piece. The remaining agents each receive a piece containing their knife. The resulting allocation is envy-free, since the agent receiving the left piece prefers it to the other pieces, and the other agents who are not shouting receive at least half the value of the part of the cake to the right of the sword.

Let  $G$  be a path,  $P = (v_1, v_2, \dots, v_m)$ . There are several difficulties in translating Stromquist’s continuous procedure to the discrete setting for  $G$ . First, agents need to divide the piece to the right of the sword in half, and this might not be possible exactly given indivisibilities; but this can be handled using our concept of lumpy ties from Section 3. Next, when the sword moves one item to the right, the lumpy ties of the agents may need to jump several items to the right, for example because the new member of the left-most bundle is very valuable. To ensure EF1, we will need to smoothen these jumps, so that the middle piece grows one item at a time. Also, it will be helpful to have the sword move in half-steps: it alternates between being placed between items (so it cuts the edge between the items), and being placed over an item, in which case the sword covers the item and agents ignore that item. Finally, while the sword covers an item, we will only terminate if at least *two* agents shout to indicate that they prefer the left-most piece; this will ensure that there is an agent who is flexible about which of the bundles they are assigned. The algorithm moves in steps, and alternates between moving the sword, and updating the lumpy ties.

In our formal description of the algorithm, we do not use swords and knives. Instead, we maintain three bundles  $L$ ,  $M$ , and  $R$  that can be seen as resulting from a certain configuration of these cutting implements. We also need a few definitions. For a subsequence of vertices  $P(v_s, v_r) = (v_s, v_{s+1}, \dots, v_r)$  and an agent  $i$ , recall that  $v_j$  ( $s \leq j \leq r$ ) is the *lumpy tie* over

$P(v_s, v_r)$  for  $i$  if  $j$  is the smallest index such that

$$u_i(L(v_j) \cup \{v_j\}) \geq u_i(R(v_j)) \quad \text{and} \quad u_i(R(v_j) \cup \{v_j\}) \geq u_i(L(v_j)). \quad (3)$$

Here, the definitions of  $L(v_j)$  and  $R(v_j)$  apply to the subsequence  $P(v_s, v_r)$ . The lumpy tie always exists by the discussion after equation (2). Each of the three agents has a lumpy tie over  $P(v_s, v_r)$ ; a key concept for us is the *median lumpy tie* which is the median of the lumpy ties of the three agents, where the median is taken with respect to the ordering of  $P(v_s, v_r)$ . We say that  $i \in N$  is a *left agent* (respectively, a *middle agent* or a *right agent*) over  $P(v_s, v_r)$  if the lumpy tie for  $i$  appears strictly before (respectively, is equal to, or appears strictly after) the median lumpy tie. Note that by definition of median, there is at most one left agent, at most one right agent, and at least one middle agent.

Suppose that the median lumpy tie over the subsequence  $P(v_s, v_r)$  is  $v_j$ , and let  $i$  be an agent. Then using the definitions of lumpy tie and left/right agents, we find that

$$\begin{aligned} u_i(L(v_j)) &\geq u_i(R(v_j) \cup \{v_j\}) && \text{if } i \text{ is a left agent, and} \\ u_i(R(v_j)) &\geq u_i(L(v_j) \cup \{v_j\}) && \text{if } i \text{ is a right agent.} \end{aligned} \quad (4)$$

Given the median lumpy tie  $v_j$  over  $P(v_s, v_r)$ , and a two-agent set  $S = \{i, k\} \subseteq N$ , we define  $\text{Lumpy}(S, v_j, P(v_s, v_r))$  to be the allocation of the items in  $P(v_s, v_r)$  to  $S$  such that

- if  $i$  is a left agent and  $k$  is a right agent, then  $i$  receives  $L(v_j)$  and  $k$  receives  $R(v_j) \cup \{v_j\}$ ;
- if  $i$  is a middle agent, then agent  $k$  receives  $k$ 's preferred bundle among  $L(v_j)$  and  $R(v_j)$ , and agent  $i$  receives the other bundle along with  $v_j$ .

Using (3) and (4), we see that  $\text{Lumpy}(S, v_j, P(v_s, v_r))$  is an EF1 allocation:

► **Lemma 11** (Median Lumpy Ties Lemma). *Let  $S = \{i, k\} \subseteq N$  and let  $v_j$  be the median lumpy tie over  $P(v_s, v_r)$ . Then  $\text{Lumpy}(S, v_j, P(v_s, v_r))$  is an EF1 allocation of the items in  $P(v_s, v_r)$  to  $S$ . Further, each agent in  $S$  weakly prefers their bundle to  $L(v_j)$  and  $R(v_j)$ .*

The algorithm is specified in Figure 2. It alternately moves a left pointer  $\ell$  (in Steps 2 and 3) and a right pointer  $r$  (in Step 4). See [5] for a proof of the following theorem.

► **Theorem 12.** *The moving-knife protocol in Figure 2 finds an EF1 allocation for three agents and runs in  $O(|V|)$  time, when  $G$  is traceable.*

## 5 EF2 existence for any number of agents

For two or three agents, we have seen algorithms that are guaranteed to find an EF1 allocation on a path (and on traceable graphs). Both algorithms were adaptations of procedures that identify envy-free divisions in the cake-cutting problem. For the case of four or more agents, we face a problem: there are no known procedures that find connected envy-free division in cake-cutting if the number of agents is larger than three. However, in the divisible setting, a non-constructive existence result is known: Su [29] proved, using Sperner's lemma, that for any number of agents, a connected envy-free division of a cake always exists. One might try to use this result as a black box to obtain a fair allocation for the indivisible problem on a path: Translate an indivisible instance with additive valuations into a divisible cake (where each item corresponds to a region of the cake), obtain an envy-free division of the cake, and round it to get an allocation of the items. Suksompong [30] followed this approach and showed that the result is an allocation where any agent  $i$ 's envy  $u_i(A(j)) - u_i(A(i))$  is at most  $2u_{\max}$ , where  $u_{\max}$  is the maximum valuation for a single item.

In this section, rather than using Su's [29] result as a black box, we directly apply Sperner's lemma to the indivisible problem. This allows us to obtain a stronger fairness guarantee: We show that on paths (and on traceable graphs), there always exists an EF2

**Discrete moving-knife protocol for  $n = 3$  agents** on a sequence  $P = (v_1, v_2, \dots, v_m)$ :  
 An agent  $i \in N$  is a *shouter* if  $u_i(L) \geq u_i(M)$  and  $u_i(L) \geq u_i(R)$ .

- Step 1.* Initialize  $\ell = 0$  and set  $r$  so that  $v_r$  is the median lumpy tie over the subsequence  $P(v_2, v_m)$ . Initialize  $L = \emptyset$ ,  $M = \{v_2, v_3, \dots, v_{r-1}\}$ , and  $R = \{v_{r+1}, v_{r+2}, \dots, v_m\}$ .
- Step 2.* Add an additional item to  $L$ , i.e., set  $\ell = \ell + 1$  and  $L = \{v_1, v_2, \dots, v_\ell\}$ . If no agent shouts, go to Step 3. If some agent  $s_{\text{left}}$  shouts,  $s_{\text{left}}$  receives the left bundle  $L$ . Allocate the remaining items according to  $\text{Lumpy}(N \setminus \{s_{\text{left}}\}, v_r, P(v_{\ell+1}, v_m))$ .
- Step 3.* Delete the left-most point of the middle bundle, i.e., set  $M = \{v_{\ell+2}, v_{\ell+3}, \dots, v_{r-1}\}$ . If the number of shouters is smaller than two, go to Step 4. If at least two agents shout, we show (next page) that there is a shouter  $s$  who is a middle agent over  $P(v_{\ell+1}, v_m)$ . Then, allocate  $L$  to a shouter  $s_{\text{left}}$  distinct from  $s$ . Let the agent  $c$  distinct from  $s$  and  $s_{\text{left}}$  choose his preferred bundle among  $\{v_{\ell+1}\} \cup M$  and  $\{v_r\} \cup R$ . Agent  $s$  receives the other bundle.
- Step 4.* If  $v_r$  is the median lumpy tie over  $P(v_{\ell+2}, v_m)$ , directly move to the following cases (a)–(d). If  $v_r$  is not the median lumpy tie over  $P(v_{\ell+2}, v_m)$ , set  $r = r + 1$ ,  $M = \{v_{\ell+2}, v_{\ell+3}, \dots, v_{r-1}\}$ , and  $R = \{v_{r+1}, v_{r+2}, \dots, v_m\}$ ; then, go to cases (a)–(d).
- a. If at least two agents shout, find a shouter  $s$  who did not shout at the previous step. If there is a shouter  $s_{\text{left}}$  who shouted at the previous step,  $s_{\text{left}}$  receives  $L$ ; else, give  $L$  to an arbitrary shouter  $s_{\text{left}}$  distinct from  $s$ . The agent  $c$  distinct from  $s$  and  $s_{\text{left}}$  choose his preferred bundle among  $\{v_{\ell+1}\} \cup M$  and  $\{v_r\} \cup R$ , breaking ties in favor of the former option. Agent  $s$  receives the other bundle.
  - b. If  $v_r$  is the median lumpy tie over  $P(v_{\ell+2}, v_m)$  and only one agent  $s_{\text{left}}$  shouts, give  $L \cup \{v_{\ell+1}\}$  to  $s_{\text{left}}$  and allocate the rest according to  $\text{Lumpy}(N \setminus \{s_{\text{left}}\}, v_r, P(v_{\ell+2}, v_m))$ .
  - c. If  $v_r$  is the median lumpy tie over  $P(v_{\ell+2}, v_m)$  but no agent shouts, go to Step 2.
  - d. Otherwise  $v_r$  is not the median lumpy tie over  $P(v_{\ell+2}, v_m)$ : Repeat Step 4.

■ **Figure 2** Algorithm producing EF1 allocations for three agents.

allocation.<sup>4</sup> An allocation is EF2 if any agent's envy can be avoided by removing up to two items from the envied bundle. Again, we only allow removal of items if this operation leaves a connected bundle. For example, on a path, if agent  $i$  envies the bundle of agent  $j$ , then  $i$  does not envy that bundle once we remove its two endpoints.

► **Definition 13** (EF2: envy-freeness up to two outer goods). An allocation  $A$  satisfies EF2 if for any pair  $i, j \in N$  of agents, either  $|A(j)| \leq 1$ , or there are two goods  $u, v \in A(j)$  such that  $A(j) \setminus \{u, v\}$  is connected and  $u_i(A(i)) \geq u_i(A(j) \setminus \{u, v\})$ .

<sup>4</sup> To see that EF2 is a stronger property than bounding envy up to  $2u_{\max}$ , consider a path of four items and two agents with additive valuations 1–10–2–2. The allocation (1, 10–2–2) is not EF2, but the first agent has an envy of  $13 < 20 = 2u_{\max}$ .

Let us first give a high-level illustration with three agents of how Sperner’s lemma can be used to find low-envy allocations. Given a path, say  $P = (a, b, c, d)$ , the family of connected partitions of  $P$  can naturally be arranged as the vertices of a subdivided simplex, as in the figure on the right. For each of these partitions, each agent  $i$  labels the corresponding vertex by the index of a bundle from that partition that  $i$  most-prefers. For example, the top vertex will be labelled as “index 1” by all agents, since they all most-prefer the left-most bundle in  $(abcd, \emptyset, \emptyset)$ . Now, Sperner’s lemma will imply that at least one of the simplices (say the shaded one) is “fully-labeled”, which means that the first agent most-prefers the left-most bundle at one vertex, the second agent most-prefers the middle bundle at another vertex, and the third agent most-prefers the right-most bundle at the last vertex. Notice that the partitions at the corner points of the shaded simplex are all “similar” to each other (they can be obtained from each other by moving only 1 item). Hence, we can “round” the corner-partitions into a common allocation  $A^*$ , say by picking one of the corner partitions arbitrarily and then allocating bundles to agents according to the labels. The resulting allocation has the property that any agents’ envy can be eliminated by moving at most one good.<sup>5</sup>

The argument sketched above does not yield an EF1 nor even an EF2 allocation. Intuitively, the problem is that the connected partitions at the corners of the fully-labeled simplex are “too far apart”, so that no matter how we round the corner partitions into a common allocation  $A^*$ , some agents’ bundles will have changed too much, and so we cannot prevent envy even up to one or two goods. In the following, we present a solution to this problem, by considering a finer subdivision: we introduce  $n - 1$  knives which move in half-steps (rather than full steps), and which might “cover” an item so that it appears in none of the bundles. The result is that the partial partitions in the corners of the fully-labeled simplex are closer together, and can be successfully rounded into an EF2 allocation  $A^*$ .

### 5.1 Sperner’s lemma

We start by formally introducing Sperner’s lemma. Let  $\text{conv}(\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k)$  denote the convex hull of  $k$  vectors  $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k$ . An  $n$ -simplex is an  $n$ -dimensional polytope which is the convex hull of its  $n + 1$  main vertices. A  $k$ -face of the  $n$ -simplex is the  $k$ -simplex formed by the span of any subset of  $k + 1$  main vertices. A triangulation  $T$  of a simplex  $S$  is a

<sup>5</sup> One can generalize this argument to show that on paths, there exists an allocation  $A$  satisfying a weak form of EF1: for any  $i, j \in [n]$ , we have  $u_i(I_i \cup \{g_i\}) \geq u_i(I_j \setminus \{g_j\})$  for some items  $g_i, g_j$  such that  $I_i \cup \{g_i\}$  and  $I_j \setminus \{g_j\}$  are connected. For additive valuations, this implies that envy is bounded by  $u_i(g_i) + u_i(g_j) \leq 2u_{\max}$ , which is Suksompong’s [30] result.

collection of sub- $n$ -simplices whose union is  $S$  with the property that the intersection of any two of them is either the empty set, or a face common to both. Each of the sub-simplices  $S^* \in T$  is called an *elementary* simplex of the triangulation  $T$ . We denote by  $V(T)$  the set of vertices of the triangulation  $T$ , i.e., the union of vertices of the elementary simplices of  $T$ .

Let  $T$  be some fixed triangulation of an  $(n - 1)$ -simplex  $S = \text{conv}(\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n)$ . A *labeling function* is a function  $L : V(T) \rightarrow [n]$  that assigns a number in  $[n]$  (called a *color*) to each vertex of the triangulation  $T$ . A labeling function  $L$  is called *proper* if

- For each main vertex  $\mathbf{v}_i$  of the simplex,  $L$  assigns color  $i$  to  $\mathbf{v}_i$ :  $L(\mathbf{v}_i) = i$ ; and
  - $L(\mathbf{v}) \neq i$  for any vertex  $\mathbf{v} \in V(T)$  belonging to the  $(n - 2)$ -face of  $S$  not containing  $\mathbf{v}_i$ .
- Sperner's lemma states that if  $L$  is a proper labeling function, then there exists an elementary simplex of  $T$  whose vertices all have different labels.

We will consider a generalized version of Sperner's lemma, proved, for example, in [2]. In this version, there are  $n$  labeling functions  $L_1, \dots, L_n$ , and we are looking for an elementary simplex which is *fully-labeled* for some way of assigning labeling functions to vertices, where we must use each labeling function exactly once. The formal definition is as follows.

► **Definition 14** (Fully-labeled simplex). Let  $T$  be a triangulation of an  $(n - 1)$ -simplex, and let  $L_1, \dots, L_n$  be labeling functions. An elementary simplex  $S^*$  of  $T$  is *fully-labeled* if we can write  $S^* = \text{conv}(\mathbf{v}_1^*, \mathbf{v}_2^*, \dots, \mathbf{v}_n^*)$  such that there exists a permutation  $\phi : [n] \rightarrow [n]$  with

$$L_i(\mathbf{v}_i^*) = \phi(i) \quad \text{for each } i \in [n].$$

► **Lemma 15** (Generalized Sperner's Lemma). Let  $T$  be a triangulation of an  $(n - 1)$ -simplex  $S$ , and let  $L_1, \dots, L_n$  be proper labeling functions. Then there is a fully-labeled simplex  $S^*$  of  $T$ .

## 5.2 Existence of EF2 allocations

Suppose that our graph  $G$  is a path  $P = (1, 2, \dots, m)$ , where the items are named by integers. We assume that  $m \geq n$ , so that there are at least as many items as agents (when  $m < n$  it is easy to find EF1 allocations). Our aim is to cut the path  $P$  into  $n$  intervals (bundles)  $I_*^1, I_*^2, \dots, I_*^n$ . Throughout the argument, we use superscripts to denote indices of bundles; index 1 refers to the left-most bundle and index  $n$  refers to the right-most bundle.

**Construction of the triangulation.** Consider the  $(n - 1)$ -simplex

$$S_m = \{ \mathbf{x} \in \mathbb{R}^{n-1} : \frac{1}{2} \leq x^1 \leq x^2 \leq \dots \leq x^{n-1} \leq m + \frac{1}{2} \}. \quad (5)$$

We construct a triangulation  $T_{\text{half}}$  of  $S_m$  whose vertices  $V(T_{\text{half}})$  are the points  $\mathbf{x} \in S_m$  such that each  $x^j$  is either integral or half-integral, namely,

$$V(T_{\text{half}}) = \{ \mathbf{x} \in S_m : x^j \in \{ \frac{1}{2}, 1, \frac{3}{2}, 2, \frac{5}{2}, \dots, m, m + \frac{1}{2} \} \text{ for all } j \in [n] \}.$$

For reasons that will become clear shortly, we call a vector  $\mathbf{x} \in V(T_{\text{half}})$  a *knife position*.

Using Kuhn's triangulation [19, 26, 14], we construct  $T_{\text{half}}$  so we can write each elementary simplex  $S' \in T_{\text{half}}$  as  $S' = \text{conv}(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n)$  and there is a permutation  $\pi : [n] \rightarrow [n]$  with

$$\mathbf{x}_{i+1} = \mathbf{x}_i + \frac{1}{2} \mathbf{e}^{\pi(i)} \quad \text{for each } i \in [n - 1], \quad (6)$$

where  $\mathbf{e}^j = (0, \dots, 1, \dots, 0)$  is the  $j$ -th unit vector. We give an interpretation of (6) shortly.

Each vertex  $\mathbf{x} = (x^1, x^2, \dots, x^{n-1}) \in V(T_{\text{half}})$  of the triangulation  $T_{\text{half}}$  corresponds to a partial partition  $A(\mathbf{x}) = (I^1(\mathbf{x}), I^2(\mathbf{x}), \dots, I^n(\mathbf{x}))$  of  $P$  where  $I^j(\mathbf{x}) := \{y \in \{1, 2, \dots, m\} : x^{j-1} < y < x^j\}$ , writing  $x^0 = \frac{1}{2}$  and  $x^n = m + \frac{1}{2}$  for convenience. Intuitively,  $\mathbf{x}$  specifies the

location of  $n - 1$  knives that cut  $P$  into  $n$  pieces. If  $x^j$  is integral, that is  $x^j \in \{1, \dots, m\}$ , then the  $j$ -th knife “covers” the item  $x^j$ , which is then part of neither  $I^j(\mathbf{x})$  nor  $I^{j+1}(\mathbf{x})$ . This is why  $A(\mathbf{x})$  is a *partial* partition. Since there are only  $n - 1$  knives but  $m \geq n$  items, not all items are covered, so at least one bundle is non-empty.

Property (6) means that, if we visit the knife positions  $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$  at the corners of an elementary simplex in the listed order, then at each step exactly one of the knives moves by half a step, and each knife moves only at one of the steps.

**Construction of the labeling functions.** We now construct, for each agent  $i \in [n]$ , a labeling function  $L_i : V(T_{\text{half}}) \rightarrow [n]$ . The function  $L_i$  takes as input a vertex  $\mathbf{x}$  of the triangulation  $T_{\text{half}}$  (interpreted as the partial partition  $A(\mathbf{x})$ ), and returns a color in  $[n]$ . The color will specify the index of a bundle in  $A(\mathbf{x})$  that agent  $i$  likes most. Formally,

$$L_i(\mathbf{x}) \in \{j \in [n] : u_i(I^j(\mathbf{x})) \geq u_i(I^k(\mathbf{x})) \text{ for all } k \in [n]\}.$$

If there are several most-preferred bundles in  $A(\mathbf{x})$ , ties can be broken arbitrarily. However, we insist that the index  $L_i(\mathbf{x})$  always corresponds to a non-empty bundle (this can be ensured since  $A(\mathbf{x})$  always contains a non-empty bundle, and  $u_i$  is monotonic).

The labeling functions  $L_i$  are proper. For each  $j \in [m]$ , the main vertex  $\mathbf{v}_j$  of the simplex  $S_m$  has the form  $\mathbf{v}_j = (\frac{1}{2}, \dots, \frac{1}{2}, m + \frac{1}{2}, \dots, m + \frac{1}{2})$ , where the first  $j - 1$  entries are  $\frac{1}{2}$  and the rest are  $m + \frac{1}{2}$ . In the partition  $A(\mathbf{v}_j)$ , the bundle  $I^j(\mathbf{v}_j)$  contains all the items, so is most-preferred (since  $u_i$  is monotonic and by our tie-breaking), and so  $L_i(\mathbf{v}_j) = j$ . Further, any vertex  $\mathbf{x}$  belonging to the  $(n - 2)$ -face of  $S_m$  not containing  $\mathbf{v}_j$  satisfies  $x^{j-1} = x^j$ , and thus in partition  $A(\mathbf{x})$ , bundle  $I^j(\mathbf{x})$  is empty, hence is *not* selected, and so  $L_i(\mathbf{x}) \neq j$ .

By the generalized version of Sperner’s lemma (Lemma 15), there exists an elementary simplex  $S^* = \text{conv}(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n)$  of the triangulation  $T_{\text{half}}$  which is fully-labeled, so that, for some permutation  $\phi : [n] \rightarrow [n]$ , we have  $L_i(\mathbf{x}_i) = \phi(i)$  for all  $i \in [n]$ .

**Translation into partial partitions.** The fully-labeled elementary simplex  $S^*$  corresponds to a sequence  $(A_1, A_2, \dots, A_n)$  of partial partitions of  $P$ , which we call the *Sperner sequence*, where  $A_i = (I_i^1, \dots, I_i^n) := A(\mathbf{x}_i)$  for each  $i \in [n]$ . An example of a Sperner sequence is shown in Figure 3. From the labeling, for each agent  $i \in [n]$ , since  $L_i(\mathbf{x}_i) = \phi(i)$ , the bundle with index  $\phi(i)$  in the partition  $A_i$  is a best bundle for  $i$ :

$$u_i(I_i^{\phi(i)}) \geq u_i(I_i^j) \quad \text{for each } j \in [n]. \quad (7)$$

Now, for each  $j \in [n]$ , we define the *basic bundle*  $B^j := I_1^j \cap \dots \cap I_n^j$  to be the bundle of items that appear in the  $j$ -th bundle of every partition in the Sperner sequence. The set of basic bundles is a partial partition. Let us analyze the items between basic bundles. From (6), each of the  $n - 1$  knives moves exactly once, by half a step, while passing through the Sperner sequence  $(A_1, A_2, \dots, A_n)$ . Thus, the numbers  $x_1^j, \dots, x_n^j$  take on two different values, one of which is integral and the other half-integral. We write  $y^j$  for the integral value (so  $y^j = x_i^j$  for some  $i \in [n]$ ), and call  $y^j$  a *boundary item*. The  $j$ -th knife covers the item  $y^j$  in some, but not all, of the partial partitions in the Sperner sequence. Now, there are two cases:

- (a)  $x_1^j = \dots = x_i^j = y^j - \frac{1}{2}$  and  $x_{i+1}^j = \dots = x_n^j = y^j$  for some  $i \in [n]$ , so that  $y^j$  never occurs in the  $j$ -th bundle in the Sperner sequence but sometimes occurs in the  $j + 1$ st bundle, or

■ **Figure 3** Example of the Sperner sequence  $A_1, \dots, A_4$  for  $n = 4$ , as well as the derived partition  $A_*$ . Vertical lines indicate the positions  $x_i^1, x_i^2, x_i^3$  of the knives,  $i = 1, \dots, 4$ . Shaded in gray, for  $i = 1, \dots, 4$ , is the bundle  $I_i^{\phi(i)}$  selected by agent  $i$  as their favorite bundle in  $A_i$ .

(b)  $x_1^j = \dots = x_i^j = y^j$  and  $x_{i+1}^j = \dots = x_n^j = y^j + \frac{1}{2}$  for some  $i \in [n]$ , so that  $y^j$  sometimes occurs in the  $j$ -th bundle in the Sperner sequence but never occurs in the  $j + 1$ st bundle. Since  $y^j$  is sometimes covered by a knife, it is not part of any basic bundle. Note that

$$B^j \subseteq I_i^j \subseteq \{y^{j-1}\} \cup B^j \cup \{y^j\} \quad \text{for every } i, j \in [n]. \quad (8)$$

**Rounding into a complete partition.** We now construct a complete partition of the path  $P$  into the bundles  $(I_*^1, I_*^2, \dots, I_*^n)$  which are defined as follows:

$$I_*^j := I_1^j \cup \dots \cup I_n^j \quad \text{for each } j \in [n].$$

Thus, the bundle  $I_*^j$  contains the basic bundle  $B^j$ , plus all of the boundary items  $y^{j-1}$  or  $y^j$  that occur in the  $j$ -th bundle at some point of the Sperner sequence. Precisely, for each boundary item  $y^j$ ,  $j \in [n - 1]$ , the item  $y^j$  is placed in bundle  $I_*^{j+1}$  in case (a) above, and it is placed in bundle  $I_*^j$  in case (b). Thus, every item is allocated to exactly one bundle.

**An EF2 allocation.** We first show that the partition  $(I_*^1, I_*^2, \dots, I_*^n)$  is such that agents' expectations about the value of the bundles  $I_*^j$  are approximately correct (up to two items):

$$u_i(I_*^j) \geq u_i(I_i^j) \geq u_i(B^j) \quad \text{for every agent } i \in [n] \text{ and every } j \in [n]. \quad (9)$$

This follows by monotonicity of  $u_i$ , since  $I_*^j = I_1^j \cup \dots \cup I_n^j \supseteq I_i^j \supseteq B^j$  by (8).

Now, based on the partition, we define an allocation  $A_*$  by  $A_*(i) = I_*^{\phi(i)}$  for each agent  $i \in [n]$ . Then  $A_*$  satisfies EF2: For any pair  $i, j \in [n]$  of agents, we have

$$u_i(A_*(i)) = u_i(I_*^{\phi(i)}) \stackrel{(9)}{\geq} u_i(I_i^{\phi(i)}) \stackrel{(7)}{\geq} u_i(I_i^{\phi(j)}) \stackrel{(9)}{\geq} u_i(B^{\phi(j)}) \stackrel{(8)}{=} u_i(A_*(j) \setminus \{y^{j-1}, y^j\}).$$

Hence, we have proved the main result of this section:

► **Theorem 16.** *On a path, for any number of agents with monotone valuation functions, a connected EF2 allocation exists.*

## 6 EF1 existence for four agents

We have seen that Sperner's lemma can be used to show EF2 existence for any number of agents. Why does our proof in the previous section only establish EF2, and not EF1? The reason is that agents' expectations about the contents of a bundle might differ by up to *two* goods from what the bundle will actually contain. In the notation of the previous section, an agent  $i$  may be presented with a partial partition  $I_i$  where the  $j$ -th bundle  $I_i^j$  is the basic bundle, i.e.,  $I_i^j = B^j$ . The agent then selects their favorite bundle from  $I_i$ , implicitly assuming that the  $j$ -th bundle in the rounded partition  $I_*$  will also equal  $B^j$ , i.e., that  $I_*^j = B^j$ . However, it may happen that in fact  $I_*^j = \{y^{j-1}\} \cup B^j \cup \{y^j\}$ , and then  $i$  envies the agent who receives bundle  $j$  by a margin of two goods.

For four agents, we can adapt our argument to achieve EF1. To do this, we both change the way we round the Sperner sequence into an allocation, and we define new labeling functions that better anticipate how a partial partition will be rounded into the final allocation. In this way, agents' expectations about bundles will only ever be wrong up to one good. In crude terms, agents will expect that each of the two interior bundles will be assigned at least one of the boundary items, and the rounding method ensures that this will indeed happen.

Let  $n = 4$ . Formally, to define the labeling function, for each agent  $i \in [n]$  we construct a *virtual valuation function*  $\hat{u}_i(\mathbf{x}, j)$  which assigns a value to each bundle  $j \in [n]$  of a partial allocation as specified by a vertex  $\mathbf{x} \in V(T_{\text{half}})$ . The way these virtual valuations are defined differs based on the index  $j$ ; in particular, end bundles ( $j = 1, 4$ ) are treated differently from interior bundles ( $j = 2, 3$ ). The virtual valuations are defined as follows, for each  $\mathbf{x} \in V(T_{\text{half}})$  and each  $i \in [n]$ , where the middle row (11) applies to  $j = 2$  and  $j = 3$ :

$$\hat{u}_i(\mathbf{x}, 1) = \begin{cases} u_i(\{1, \dots, x^1 - 1\}) & \text{if } x^1 \in \mathbb{Z}, \\ u_i(\{1, \dots, x^1 - \frac{3}{2}\}) & \text{if } x^1 \notin \mathbb{Z}. \end{cases} \quad (10)$$

$$\hat{u}_i(\mathbf{x}, j) = \begin{cases} u_i^-(\{x^{j-1}, \dots, x^j\}) & \text{if } x^{j-1} \in \mathbb{Z} \text{ and } x^j \in \mathbb{Z}, \\ u_i(I^j(\mathbf{x})) & \text{otherwise.} \end{cases} \quad (11)$$

$$\hat{u}_i(\mathbf{x}, 4) = \begin{cases} u_i(\{x^3 + 1, \dots, m\}) & \text{if } x^3 \in \mathbb{Z}, \\ u_i(\{x^3 + \frac{3}{2}, \dots, m\}) & \text{if } x^3 \notin \mathbb{Z}. \end{cases} \quad (12)$$

Thus, for an interior bundle  $j = 2, 3$ , if both the items  $x^{j-1}$  and  $x^j$  to either side of the bundle are covered by a knife, an agent expects that one of these items (the less-valuable one) will be put into bundle  $I_*^j$  of the final rounded allocation (recall the definition of  $u_i^-$  in equation (1)). For exterior bundles,  $j = 1$  (resp.  $j = 4$ ), if the item  $x^1$  (resp.  $x^3$ ) is not covered by a knife, the agent does not expect the interior item (next to the knife) to belong to the final bundle  $I_*^j$ , even though it belongs to the observed bundle  $I_i^j$ . Otherwise, the virtual allocations are equal to  $u_i(I^j(\mathbf{x}))$ , so the agent expects that  $I_*^j = I_i^j$ . Later, we show that these expectations are correct up to one item.

Using these virtual valuations, we define labelling functions  $\hat{L}_i : V(T_{\text{half}}) \rightarrow [n]$  so that

$$\hat{L}_i(\mathbf{x}) \in \{j \in [n] : \hat{u}_i(\mathbf{x}, j) \geq \hat{u}_i(\mathbf{x}, k) \text{ for all } k \in [n]\}.$$

One can check that these valuation functions are still proper.

Again, by Sperner's lemma, there exists an elementary simplex  $S^* = \text{conv}(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n)$  of the triangulation  $T_{\text{half}}$  which is fully-labeled according to our new labeling function: there is a permutation  $\phi : [n] \rightarrow [n]$ , with  $\hat{L}_i(\mathbf{x}_i) = \phi(i)$  for all  $i \in [n]$ . Again, this elementary simplex induces a Sperner sequence  $(A_1, \dots, A_n)$  of partial partitions.

To shorten a case distinction, we assume that  $y^2 \in I_1^2 \cup I_2^2 \cup I_3^2 \cup I_4^2$ , i.e., that the boundary item  $y^2$  appears in the second but not in the third bundle in the Sperner sequence. This assumption is without loss of generality, since by the left-right symmetry of the definition of virtual valuations, if necessary we can reverse the path  $P$  and consider the same elementary simplex with vertices ordered in reverse  $(\mathbf{x}_4, \mathbf{x}_3, \mathbf{x}_2, \mathbf{x}_1)$ ; it will still be fully-labeled.

With this assumption made throughout the rest of the argument, we now round the Sperner sequence into a complete partition  $(I_*^1, I_*^2, I_*^3, I_*^4)$  of  $P$  defined as follows:

$$I_*^1 := I_1^1 \cup \dots \cup I_4^1, \quad I_*^2 := I_1^2 \cup \dots \cup I_4^2, \quad I_*^3 := B^3 \cup \{y^3\}, \quad I_*^4 := B^4.$$

Depending on the placement of the boundary item  $y^1$ , we will either have  $I_*^1 = B^1$  or  $I_*^1 = B^1 \cup \{y^1\}$ ; and either  $I_*^2 = \{y^1\} \cup B^2 \cup \{y^2\}$  or  $I_*^2 = B^2 \cup \{y^2\}$ . With these choices, each interior bundle ( $j = 2, 3$ ) receives at least one of the boundary items adjacent to it.

The main part of showing that the partition  $(I_*^1, I_*^2, I_*^3, I_*^4)$  can be made into an EF1 allocation is an analogue of (9), which shows that agents' expectations about their bundle are approximately correct. The following analogous proposition is proved by case analysis.

► **Proposition 17.** *For each  $i \in [n]$  and each  $j \in [n]$ , we have  $u_i(I_*^j) \geq \hat{u}_i(\mathbf{x}_i, j) \geq u_i^-(I_*^j)$ .*

Now again, based on the partition, we can define an allocation  $A_*$  by  $A_*(i) = I_*^{\phi(i)}$  for each agent  $i \in [n]$ . Thus, each agent  $i$  receives the bundle in the complete partition corresponding to  $i$ 's most-preferred index  $\phi(i)$ . We prove that  $A_*$  satisfies EF1: For any pair  $i, j \in [n]$  of agents, we have

$$\begin{aligned} u_i(A_*(i)) = u_i(I_*^{\phi(i)}) &\geq \hat{u}_i(\mathbf{x}_i, \phi(i)) && \text{by Proposition 17} \\ &\geq \hat{u}_i(\mathbf{x}_i, \phi(j)) && \text{since } \hat{L}_i(\mathbf{x}_i) = \phi(i) \\ &\geq u_i^-(I_*^{\phi(j)}) = u_i^-(A_*(j)). && \text{by Proposition 17} \end{aligned}$$

Hence, we have proved the main result of this section:

► **Theorem 18.** *On a path, for four agents with monotone valuation functions, a connected EF1 allocation exists.*

For five or more agents, we were not able to construct labeling functions and a rounding scheme which ensure that agents' expectations are correct up to one item. In the four-agent case, each interior bundle is adjacent to an exterior bundle (which helps in the construction), but for five agents, there is a middle bundle whose neighboring bundles are also interior.

## 7 EF1 existence for identical valuations

A special case of the fair division problem is the case of *identical valuations*, where all agents have the same valuation for the goods: for all agents  $i, j \in N$  and every bundle  $I \in \mathcal{C}(V)$ , we have  $u_i(I) = u_j(I)$ . We then write  $u(I)$  for the common valuation of bundle  $I$ . The case of identical valuations often allows for more positive results and an easier analysis. Indeed, we can prove that, for identical valuations and *any* number of agents, an EF1 allocation connected on a path is guaranteed to exist and can be found in polynomial time.

Now, one might guess that in the restricted case of identical valuations, egalitarian allocations are EF1. However, the leximin-optimal connected allocation may fail EF1: Consider a path with five items and additive valuations 1–3–1–1–1 shared by three agents. The unique leximin allocation is (1, 3, 1–1–1), which induces envy even up to one good. The same allocation also uniquely maximizes Nash welfare, so the Nash optimum also does not guarantee EF1. In contrast, when requiring bundles to satisfy matroid constraints (rather than connectivity constraints), the Nash optimum is EF1 with identical valuations [6].

■ **Figure 4** If  $i$  envies  $j$  even up to one good, Algorithm 1 takes an item out of bundle  $I^j$  and moves it in  $i$ 's direction.

---

**Algorithm 1** Find a connected EF1 allocation of a path  $P$  with identical valuations.

---

- 1: Let  $A = (I^1, \dots, I^n)$  be a leximin allocation of  $P$
  - 2: Fix an agent  $i$  with minimum utility in  $A$ , i.e.,  $u(I^i) \leq u(I^j)$  for all  $j \in [n]$
  - 3: **for**  $j = 1, \dots, i - 1$  **do**
  - 4:     **if**  $i$  envies  $I^j$  even up to one good, i.e.,  $u(I^i) < u^-(I^j)$  **then**
  - 5:         repeatedly delete the right-most item of  $I^j$  and add it to  $I^{j+1}$  until  $u(I^i) \geq u^-(I^j)$
  - 6: **for**  $j = n, \dots, i + 1$  **do**
  - 7:     **if**  $i$  envies  $I^j$  even up to one good, i.e.,  $u(I^i) < u^-(I^j)$  **then**
  - 8:         repeatedly delete the left-most item of  $I^j$  and add it to  $I^{j-1}$  until  $u(I^i) \geq u^-(I^j)$
  - 9: **return**  $A$
- 

Maximizing an egalitarian objective seemed promising because it ensures that no-one is too badly off, and therefore has not much reason to envy others. The problem is that some bundles might be too desirable. To fix this, we could try to reallocate items so that no bundle is too valuable. This is exactly the strategy of our algorithm: It starts with a leximin allocation, and then moves items from high-value bundles to lower-value bundles, until the result is EF1. In more detail, the algorithm identifies one agent  $i$  who is worst-off in the leximin allocation, and then adjusts the allocation so that  $i$  does not envy any other bundle up to one good. The algorithm does this by going through all bundles in the allocation, outside-in, and if  $i$  envies a bundle  $I^j$  even up to one good, it moves one item from  $I^j$  inwards (in  $i$ 's direction), see Figure 4. As we will show, a key invariant preserved by the algorithm is that the value of  $I^i$  never increases, and  $i$  remains worst-off. Thus, since  $i$  does not envy others up to one good, the allocation at the end is EF1.

Formally, a *leximin allocation* is an allocation which maximizes the lowest utility of an agent; subject to that it maximizes the second-lowest utility, and so on. In particular, if the highest achievable minimum utility is  $u_L$ , then the leximin allocation is such that every agent has utility at least  $u_L$ , and the number of agents with utility exactly  $u_L$  is minimum.

► **Theorem 19.** *For identical valuations on a path, Algorithm 1 finds an EF1 allocation.*

**Proof.** For an allocation  $A = (I^1, \dots, I^n)$ , write  $u_L(A) := \min_{j \in [n]} u(I^j)$  for the minimum utility obtained in  $A$ , and write  $L(A) := \{j \in [n] : u(I^j) = u_L(A)\}$  for the set of agents (*losers*) who obtain this utility. For the leximin allocation  $A_{\text{leximin}}$  obtained at the start of the algorithm, write  $u_L^* := u_L(A_{\text{leximin}})$  and  $L^* := L(A_{\text{leximin}})$ . Note that by leximin-optimality, for every allocation  $A$  we must have  $u_L(A) \leq u_L^*$ , and if  $u_L(A) = u_L^*$  then  $|L(A)| \geq |L^*|$ . Let  $i \in L^*$  be the agent fixed at the start of the algorithm.

*Claim 1.* Throughout the algorithm,  $u_L(A) = u_L^*$  and  $L(A) = L^*$ .

The claim is true before we start the for-loops. Suppose the claim holds up until some iteration of the first for-loop, and we now move an item from  $I^j$  to  $I^{j+1}$ , obtaining the new bundles  $I_{\text{new}}^j$  and  $I_{\text{new}}^{j+1}$  in the new allocation  $A_{\text{new}}$ . Then  $u(I_{\text{new}}^j) \geq u^-(I^j) > u(I^i) = u_L^*$ , where the strict inequality holds by the if- and until-clauses. Since no agent other than  $j$  has become worse-off in  $A_{\text{new}}$ , it follows that  $u_L(A_{\text{new}}) \geq u_L(A) = u_L^*$ . As noted, by optimality of  $u_L^*$ , we have  $u_L(A_{\text{new}}) \leq u_L^*$ . Hence  $u_L(A_{\text{new}}) = u_L^*$ . Thus, by optimality of

$L^*$ , we have  $|L(A_{\text{new}})| \geq |L^*|$ . Because agent  $j$  has not become a loser (since  $u(I_{\text{new}}^j) > u_L^*$ , as shown before) and no other agent has become a loser, we have  $L(A_{\text{new}}) \subseteq L(A) = L^*$ . Thus  $L(A_{\text{new}}) = L^*$ , as required. The second for-loop is handled similarly.

*Claim 2.* After both for-loops terminate, agent  $i$  does not envy any agent up to one good.

For any  $j \neq i$ , agent  $i$  does not envy  $j$  up to one good immediately after the relevant loop has handled  $j$ , and at no later stage of the algorithm does  $I^j$  change.

It follows that the allocation  $A$  returned by the algorithm is EF1: By Claim 1, we have  $i \in L(A)$ , so that  $u(I^j) \geq u(I^i)$  for all  $j \in [n]$ . By Claim 2, agent  $i$  does not envy any other agent up to one good, so that  $u(I^i) \geq u^-(I^k)$  for all  $k \in [n]$ . Hence, for all  $j, k \in [n]$ , we have  $u(I^j) \geq u^-(I^k)$ , that is, no agent envies another agent up to one good. ◀

Algorithm 1 can be implemented to run in polynomial time, because with identical valuations, one can use dynamic programming to find a leximin allocation in time  $O(m^2n^2)$ , and the remainder of Algorithm 1 takes time  $O(mn)$ , as each item is moved at most  $n$  times.

The reallocation stage of our algorithm bears some similarity to Suksompong's [30, Thm. 2] proof that a  $u_{\max}$ -equitable allocation exists. In a very recent paper, Oh et al. [23, Lem. C.2] proved independently, using an inductive argument, that EF1 allocations on a path exist for identical valuations, and can be found in polynomial time.

## 8 Conclusion

We have studied the existence of EF1 allocations under connectivity constraints imposed by an undirected graph. We have shown that for two, three, or four agents, an EF1 allocation exists if the graph is traceable. For any number of agents, we also proved that traceable graphs guarantee the existence of an EF2 allocation, and they guarantee the existence of an EF1 allocation with identical valuations.

Several questions are open. We did not settle whether EF1 allocations on a path exist for five or more agents. Our Sperner technique for four agents seems to not extend to five agents. Extensive sampling did not find an example where no EF1 allocation exists.

Many of our procedures admit efficient implementations for finding fair allocations, but for our Sperner results we do not know better algorithms than searching through all connected allocations. For divisible cake-cutting, it is PPAD-complete to find an envy-free allocation [14]. What is the complexity of finding an EF1 or EF2 allocation on a path?

In the setting without connectivity constraints, it is possible to achieve efficiency and fairness simultaneously: the maximum Nash welfare solution yields an allocation that is both EF1 and Pareto-optimal [13, 4]. In our model, this is unfortunately impossible, since on a path there are instances where there is no connected allocation which is EF1 and Pareto-optimal [18], and it is NP-hard to decide whether such an allocation exists [18].

In this paper, we have only considered *goods*, with monotonic valuations. The setting where some or all items are undesirable (so-called *chores*) is also of interest [7, 22, 27, 1]. On a path, a connected *Prop1* allocation always exists [1], but the existence of EF1 or EF2 allocations in this domain is open. For cake-cutting, when agents consider some parts of the cake undesirable, Sperner's lemma does not directly produce a connected envy-free allocation [27], but other methods can prove the existence of such allocations in most cases [27, 22].

### Abstract

---

A critical goal for the field of quantum computation is quantum supremacy – a demonstration of any quantum computation that is prohibitively hard for classical computers. It is both a necessary milestone on the path to useful quantum computers as well as a test of quantum theory in the realm of high complexity. A leading near-term candidate, put forth by the Google/UCSB team, is sampling from the probability distributions of randomly chosen quantum circuits, called Random Circuit Sampling (RCS).

While RCS was defined with experimental realization in mind, we give strong complexity-theoretic evidence for the classical hardness of RCS, placing it on par with the best theoretical proposals for supremacy. Specifically, we show that RCS satisfies an average-case hardness condition – computing output probabilities of typical quantum circuits is as hard as computing them in the worst-case, and therefore  $\#P$ -hard. Our reduction exploits the polynomial structure in the output amplitudes of random quantum circuits, enabled by the Feynman path integral. In addition, it follows from known results that RCS also satisfies an anti-concentration property, namely that errors in estimating output probabilities are small with respect to the probabilities themselves. This makes RCS the first proposal for quantum supremacy with both of these properties. We also give a natural condition under which an existing statistical measure, cross-entropy, verifies RCS, as well as describe a new verification measure which in some formal sense maximizes the information gained from experimental samples.

## Abstract

Property-preserving hashing is a method of compressing a large input  $\mathbf{x}$  into a short hash  $h(\mathbf{x})$  in such a way that given  $h(\mathbf{x})$  and  $h(\mathbf{y})$ , one can compute a property  $P(\mathbf{x}, \mathbf{y})$  of the original inputs. The idea of property-preserving hash functions underlies sketching, compressed sensing and locality-sensitive hashing.

Property-preserving hash functions are usually probabilistic: they use the random choice of a hash function from a family to achieve compression, and as a consequence, err on some inputs. Traditionally, the notion of correctness for these hash functions requires that for every two inputs  $\mathbf{x}$  and  $\mathbf{y}$ , the probability that  $h(\mathbf{x})$  and  $h(\mathbf{y})$  mislead us into a wrong prediction of  $P(\mathbf{x}, \mathbf{y})$  is negligible. As observed in many recent works (incl. Mironov, Naor and Segev, STOC 2008; Hardt and Woodruff, STOC 2013; Naor and Yogev, CRYPTO 2015), such a correctness guarantee assumes that the adversary (who produces the offending inputs) has no information about the hash function, and is too weak in many scenarios.

We initiate the study of *adversarial robustness* for property-preserving hash functions, provide definitions, derive broad lower bounds due to a simple connection with communication complexity, and show the necessity of computational assumptions to construct such functions. Our main positive results are two candidate constructions of property-preserving hash functions (achieving different parameters) for the (promise) gap-Hamming property which checks if  $\mathbf{x}$  and  $\mathbf{y}$  are “too far” or “too close”. Our first construction relies on generic collision-resistant hash functions, and our second on a variant of the syndrome decoding assumption on low-density parity check codes.

## 1 Introduction

The problem of *property-preserving hashing*, namely how to compress a large input in a way that preserves a class of its properties, is an important one in the modern age of massive data. In particular, the idea of property-preserving hashing underlies sketching [23, 22, 1, 8, 6], compressed sensing [7], locality-sensitive hashing [14], and in a broad sense, much of machine learning.

As two concrete examples in theoretical computer science, consider universal hash functions [5] which can be used to test the equality of data points, and locality-sensitive hash functions [14, 13] which can be used to test the  $\ell_p$ -distance between vectors. In both cases, we trade off accuracy in exchange for compression. For example, in the use of universal hash functions to test for equality of data points, one stores the hash  $h(x)$  of a point  $x$  together with the description of the hash function  $h$ . Later, upon obtaining a point  $y$ , one computes  $h(y)$  and checks if  $h(y) = h(x)$ . The pigeonhole principle tells us that mistakes are inevitable; all one can guarantee is that they happen with an acceptably small probability. More precisely, universal hash functions tell us that

$$\forall x \neq y \in D, \Pr[h \leftarrow \mathcal{H} : h(x) \neq h(y)] \geq 1 - \epsilon$$

for some small  $\epsilon$ . A cryptographer's way of looking at such a statement is that it asks the adversary to pick  $x$  and  $y$  first; and evaluates her success w.r.t. a hash function chosen randomly from the family  $\mathcal{H}$ . In particular, the adversary has no information about the hash function when she comes up with the (potentially) offending inputs  $x$  and  $y$ . Locality-sensitive hash functions have a similar flavor of correctness guarantee.

The starting point of this work is that this definition of correctness is too weak in the face of adversaries with access to the hash function (either the description of the function itself or perhaps simply oracle access to its evaluation). Indeed, in the context of equality testing, we have by now developed several notions of robustness against such adversaries, in the form of pseudorandom functions (PRF) [11], universal one-way hash functions (UOWHF) [25] and collision-resistant hash functions (CRHF). Our goal in this work is to expand the reach of these notions beyond testing equality; that is, our aim is *to do unto property-preserving hashing what CRHFs did to universal hashing*.

Several works have observed the deficiency of the universal hash-type definition in adversarial settings, including a wide range of recent attacks within machine learning in adversarial environments (e.g., [20, 17, 28, 26, 16]). Such findings motivate a rigorous approach to combatting adversarial behavior in these settings, a direction in which significantly less progress has been made. Mironov, Naor and Segev [21] showed *interactive protocols* for sketching in such an adversarial environment; in contrast, we focus on non-interactive hash functions. Hardt and Woodruff [12] showed negative results which say that linear functions cannot be robust (even against computationally bounded adversaries) for certain natural  $\ell_p$  distance properties; our work will use non-linearity and computational assumptions to overcome the [12] attack. Finally, Naor and Yagev [24] study adversarial Bloom filters

which compress a set in a way that supports checking set membership; we were able to use their lower bound techniques (in the full version of this paper), proving the necessity for cryptographic assumptions for many predicates.

### Motivating Robustness: Facial Recognition

In the context of facial recognition, authorities  $A$  and  $B$  store the captured images  $x$  of suspects. At various points in time, say authority  $A$  wishes to look up  $B$ 's database for a suspect with face  $x$ .  $A$  can do so by comparing  $h(x)$  with  $h(y)$  for all  $y$  in  $B$ 's database.

This application scenario motivated prior notions of fuzzy extractors and secure sketching. As with secure sketches and fuzzy extractors, a locality-sensitive property-preserving hash guarantees that close inputs (facial images) remain close when hashed [9]; this ensures that small changes in one's appearance do not affect whether or not that person is authenticated. However, neither fuzzy extractors nor secure sketching guarantees that *far* inputs remain far when hashed. Consider an adversarial setting, not where a person wishes to evade detection, but where she wishes to be mistaken for someone else. Her face  $x'$  will undoubtedly be different (far) from her target  $x$ , but there is nothing preventing her from slightly altering her face and passing as a completely different person when using a system with such a one-sided guarantee. This is where our notion of robustness comes in (as well as the need for cryptography): not only will adversarially chosen close  $x$  and  $x'$  map to close  $h(x)$  and  $h(x')$ , but if adversarially chosen  $x$  and  $x'$  are *far*, they will be mapped to far outputs, unless the adversary is able to break a cryptographic assumption.

### Comparison to Secure Sketches and Fuzzy Extractors

It is worth explicitly comparing fuzzy extractors and secure sketching to this primitive [9], as they aim to achieve similar goals. Both of these seek to preserve the privacy of their inputs. Secure sketches generate random-looking sketches that hide information about the original input so that the original input can be reconstructed when given something close to it. Fuzzy extractors generate uniform-looking keys based off of fuzzy (biometric) data also using entropy: as long as the input has enough entropy, so will the output. As stated above, both guarantee that if inputs are close, they will 'sketch' or 'extract' to the same object. Now, the entropy of the sketch or key guarantees that randomly generated far inputs will not collide, but there are no guarantees about adversarially generated far inputs. To use the example above, it could be that once an adversary sees a sketch or representation, she can generate two far inputs that will reconstruct to the correct input.

### Robust Property-Preserving Hash Functions

We put forth several notions of *robustness* for property-preserving hash (PPH) functions which capture adversaries with increasing power and access to the hash function. We then ask which properties admit robust property-preserving hash functions, and show positive and negative results.

- On the negative side, using a connection to communication complexity, we show that most properties and even simple ones such as set disjointness, inner product and greater-than do not admit non-trivial property-preserving hash functions.
- On the positive side, we provide two constructions of robust property-preserving hash functions (satisfying the strongest of our notions). The first is based on the standard cryptographic assumption of collision-resistant hash functions, and the second achieves

more aggressive parameters under a new assumption related to the hardness of syndrome decoding on low density parity-check (LDPC) codes. The first is expanded upon in this version (section 4), while the second is in the full version.

- Finally, in the full version, we show that for essentially any non-trivial predicate (which we call collision-sensitive), achieving even a mild form of robustness requires cryptographic assumptions.

We proceed to describe our contributions in more detail.

## 1.1 Our Results and Techniques

We explore two notions of properties. The first is that of property classes  $\mathcal{P} = \{P : D \rightarrow \{0, 1\}\}$ , sets of single-input predicates. This notion is the most general, and is the one in which we prove lower bounds. The second is that of two-input properties  $P : D \times D \rightarrow \{0, 1\}$ , which compares two inputs. This second notion is more similar to standard notions of universal hashing and collision-resistance, stronger than the first, and where we get our constructions. We note that a two-input predicate has an analogous predicate-class  $\mathcal{P} = \{P_x\}_{x \in D}$ , where  $P_{x_1}(x_2) = P(x_1, x_2)$ .

The notion of a property can be generalized in many ways, allowing for promise properties which output 0, 1 or  $\star$  (a don't care symbol), and allowing for more than 2 inputs. The simplest notion of correctness for property-preserving hash functions requires that, analogously to universal hash functions,

$$\forall x, y \in D, \Pr[h \leftarrow \mathcal{H} : \mathcal{H}.\text{Eval}(h, h(x), h(y)) \neq P(x, y)] = \text{negl}(\lambda)$$

or for single-input predicate-classes

$$\forall x \in D \text{ and } P \in \mathcal{P}, \Pr[h \leftarrow \mathcal{H} : \mathcal{H}.\text{Eval}(h, h(x), P) \neq P(x)] = \text{negl}(\lambda)$$

where  $\lambda$  is a security parameter. Notice in the single-input case, the “second” input can be seen as the predicate chosen from the class.

For the sake of simplicity in our overview, we will focus on two-input predicates.

### Defining Robust Property-Preserving Hashing

We define several notions of *robustness* for PPH, each one stronger than the last. Here, we describe the strongest of all, called *direct-access PPH*.

In a direct-access PPH, the (polynomial-time) adversary is given the hash function and is asked to find a pair of bad inputs, namely  $x, y \in D$  such that  $\mathcal{H}.\text{Eval}(h, h(x), h(y)) \neq P(x, y)$ . That is, we require that

$$\forall \text{ p.p.t. } \mathcal{A}, \Pr[h \leftarrow \mathcal{H}; (x, y) \leftarrow \mathcal{A}(h) : \mathcal{H}.\text{Eval}(h, h(x), h(y)) \neq P(x, y)] = \text{negl}(\lambda),$$

where we use the notation  $\Pr[A_1; \dots; A_m : E]$  to denote the probability that event  $E$  occurs following an experiment defined by executing the sequence  $A_1, \dots, A_m$  in order. The direct-access definition is the analog of collision-resistant hashing for general properties.

Our other definitions vary by how much access the adversary is given to the hash function, and are motivated by different application scenarios. From the strong to weak, these include double-oracle PPH where the adversary is given access to a hash oracle and a hash evaluation oracle, and evaluation-oracle PPH where the adversary is given only a combined oracle. Definitions similar to double-oracle PPH have been proposed in the context of adversarial bloom filters [24], and ones similar to evaluation-oracle PPH have been proposed in the context of showing attacks against property-preserving hash functions [12]. For more details, we refer the reader to Section 2.

## Connections to Communication Complexity and Negative Results

Property-preserving hash functions for a property  $P$ , even without robustness, imply communication-efficient protocols for  $P$  in several models. For example, any PPH for  $P$  implies a protocol for  $P$  in the simultaneous messages model of Babai, Gal, Kimmel and Lokam [3] wherein Alice and Bob share a common random string  $h$ , and hold inputs  $x$  and  $y$  respectively. Their goal is to send a single message to Charlie who should be able to compute  $P(x, y)$  except with small error. Similarly, another formalization of PPH that we present, called PPH for single-input predicate classes (see Section 2) implies efficient protocols in the one-way communication model [31].

We use known lower bounds in these communication models to rule out PPHs for several interesting predicates (even without robustness). There are two major differences between the PPH setting and the communication setting, however: (a) in the PPH setting, we demand an error that is negligible (in a security parameter); and (b) we are happy with protocols that communicate  $n - 1$  bits (or the equivalent bound in the case of promise properties) whereas the communication lower bounds typically come in the form of  $\Omega(n)$  bits. In other words, the communication lower bounds *as-is* do not rule out PPH.

At first thought, one might be tempted to think that the negligible-error setting is the same as the deterministic setting where there are typically lower bounds of  $n$  (and not just  $\Omega(n)$ ); however, this is not the case. For example, the equality function which has a negligible error public-coin simultaneous messages protocol (simply using universal hashing) with communication complexity  $CC = O(\lambda)$  and deterministic protocols require  $CC \geq n$ . Thus, deterministic lower bounds do not (indeed, cannot) do the job, and we must better analyze the randomized lower bounds. Our refined analysis shows the following lower bounds:

- PPH for the Gap-Hamming (promise) predicate with a gap of  $\sqrt{n}/2$  is impossible by refining the analysis of a proof by Jayram, Kumar and Sivakumar [15]. The Gap-Hamming predicate takes two vectors in  $\{0, 1\}^n$  as input, outputs 1 if the vectors are very far, 0 if they are very close, and we do not care what it outputs for inputs in the middle.
- We provide a framework for proving PPHs are impossible for some total predicates, characterizing these classes as *reconstructing*. A predicate-class is *reconstructing* if, when only given oracle access to the predicates of a certain value  $x$ , we can efficiently determine  $x$  with all but negligible probability.<sup>4</sup> With this framework, we show that PPH for the Greater-Than (GT) function is impossible. It was known that GT required  $\Omega(n)$  bits (for constant error) [27], but we show a lower bound of exactly  $n$  if we want negligible error. Index and Exact-Hamming are also reconstructing predicates.
- We also obtain a lower bound for a variant of GT: the (promise) Gap- $k$  GT predicate which on inputs  $x, y \in [N = 2^n]$ , outputs 1 if  $x - y > k$ , 0 if  $y - x > k$ , and we do not care what it outputs for inputs in between. Here, exactly  $n - \log(k) - 1$  bits are required for a perfect PPH. This is tight: we show that with fewer bits, one cannot even have a non-robust PPH, whereas there is a perfect robust PPH that compresses to  $n - \log(k) - 1$  bits.

## New Constructions

Our positive results are two constructions of a direct-access PPH for gap-Hamming for  $n$ -length vectors for large gaps of the form  $\sim O(n/\log n)$  (as opposed to an  $O(\sqrt{n})$ -gap for which we have a lower bound). Let us recall the setting: the gap Hamming predicate  $P_{\text{ham}}$ ,

<sup>4</sup> In the single-predicate language of above, the predicate class corresponds to  $\mathcal{P} = \{P(x, \cdot)\}$ .

parameterized by  $n, d$  and  $\epsilon$ , takes as input two  $n$ -bit vectors  $x$  and  $y$ , and outputs 1 if the Hamming distance between  $x$  and  $y$  is greater than  $d(1 + \epsilon)$ , 0 if it is smaller than  $d(1 - \epsilon)$  and a don't care symbol  $\star$  otherwise. To construct a direct-access PPH for this (promise) predicate, one has to construct a compressing family of functions  $\mathcal{H}$  such that

$$\begin{aligned} \forall \text{ p.p.t. } \mathcal{A}, \Pr[h \leftarrow \mathcal{H}; (x, y) \leftarrow \mathcal{A}(h) : P_{\text{ham}}(x, y) \neq \star \\ \wedge \mathcal{H}.\text{Eval}(h, h(x), h(y)) \neq P_{\text{ham}}(x, y)] = \text{negl}(\lambda). \end{aligned} \quad (1)$$

Our two constructions offer different benefits. The first provides a clean general approach, and relies on the standard cryptographic assumption of collision-resistant hash functions. The second builds atop an existing one-way communication protocol, supports a smaller gap and better efficiency, and ultimately relies on a (new) variant of the syndrome decoding assumption on low-density parity check codes.

**Construction 1.** The core idea of the first construction is to reduce the goal of robust Hamming PPH to the simpler one of robust equality testing; or, in a word, “subsampling.” The intuition is to notice that if  $\mathbf{x}_1 \in \{0, 1\}^n$  and  $\mathbf{x}_2 \in \{0, 1\}^n$  are *close*, then *most small enough subsets* of indices of  $\mathbf{x}_1$  and  $\mathbf{x}_2$  will match identically. On the other hand, if  $\mathbf{x}_1$  and  $\mathbf{x}_2$  are *far*, then *most large enough subsets* of indices will differ.

The hash function construction will thus fix a collection of sets  $\mathcal{S} = \{S_1, \dots, S_k\}$ , where each  $S_i \subseteq [n]$  is a subset of appropriately chosen size  $s$ . The desired structure can be achieved by defining the subsets  $S_i$  as the neighbor sets of a bipartite expander. On input  $\mathbf{x} \in \{0, 1\}^n$ , the hash function will consider the vector  $\mathbf{y} = (\mathbf{x}|_{S_1}, \dots, \mathbf{x}|_{S_k})$  where  $\mathbf{x}|_S$  denotes the substring of  $\mathbf{x}$  indexed by the set  $S$ . The observation above tells us that if  $\mathbf{x}_1$  and  $\mathbf{x}_2$  are close (resp. far), then so are  $\mathbf{y}_1$  and  $\mathbf{y}_2$ .

Up to now, it is not clear that progress has been made: indeed, the vector  $\mathbf{y}$  is not compressing (in which case, why not stick with  $\mathbf{x}_1, \mathbf{x}_2$  themselves?). However,  $\mathbf{y}_1, \mathbf{y}_2$  satisfy the desired Hamming distance properties with fewer symbols over a *large alphabet*,  $\{0, 1\}^s$ . As a final step, we can then leverage (standard) collision-resistant hash functions (CRHF) to compress these symbols. Namely, the final output of our hash function  $h(\mathbf{x})$  will be the vector  $(g(\mathbf{x}|_{S_1}), \dots, g(\mathbf{x}|_{S_k}))$ , where each substring of  $\mathbf{x}$  is individually compressed by a CRHF  $g$ .

The analysis of the combined hash construction then follows cleanly via two steps. The (computational) collision-resistance property of  $g$  guarantees that any efficiently found pair of inputs  $\mathbf{x}_1, \mathbf{x}_2$  will satisfy that their hash outputs

$$h(\mathbf{x}_1) = (g(\mathbf{x}_1|_{S_1}), \dots, g(\mathbf{x}_1|_{S_k})) \quad \text{and} \quad h(\mathbf{x}_2) = (g(\mathbf{x}_2|_{S_1}), \dots, g(\mathbf{x}_2|_{S_k}))$$

are close if and only if it holds that

$$(\mathbf{x}_1|_{S_1}, \dots, \mathbf{x}_1|_{S_k}) \quad \text{and} \quad (\mathbf{x}_2|_{S_1}, \dots, \mathbf{x}_2|_{S_k})$$

are close as well; that is,  $\mathbf{x}_1|_{S_i} = \mathbf{x}_2|_{S_i}$  for most  $S_i$ . (Anything to the contrary would imply finding a collision in  $g$ .) Then, the combinatorial properties of the chosen index subsets  $S_i$  ensures (unconditionally) that any such inputs  $\mathbf{x}_1, \mathbf{x}_2$  must themselves be close. The remainder of the work is to specify appropriate parameter regimes for which the CRHF can be used and the necessary bipartite expander graphs exist. Informally, we get the following theorem statement:

► **Theorem 1** (Collision-resistance-PPH informal). *Let  $\lambda$  be a security parameter. Assuming that CRHFs exist, for any polynomial  $n = n(\lambda)$ , and any constants  $\epsilon, \eta, c > 0$ , there is an  $\eta$ -compressing robust property preserving hash family for  $\text{GAPHAMMING}(n, d, \epsilon)$  where  $d = o(n/\lambda^c)$ .*

**Construction 2.** The starting point for our second construction is a simple non-robust hash function derived from a one-way communication protocol for gap-Hamming due to Kushilevitz, Ostrovsky, and Rabani [19]. In a nutshell, the hash function is parameterized by a random sparse  $m \times n$  matrix  $A$  with 1's in  $1/d$  of its entries and 0's elsewhere; multiplying this matrix by a vector  $\mathbf{z}$  “captures” information about the Hamming weight of  $\mathbf{z}$ . However, this can be seen to be trivially *not robust* when the hash function is given to the adversary. The adversary simply performs Gaussian elimination, discovering a “random collision”  $(x, y)$  in the function, where, with high probability  $x \oplus y$  will have large Hamming weight. This already breaks equation (1).

The situation is somewhat worse. Even in a very weak, oracle sense, corresponding to our evaluation-oracle-robustness definition, a result of Hardt and Woodruff [12] shows that there are no *linear functions*  $h$  that are robust for the gap- $\ell_2$  predicate. While their result does not carry over *as-is* to the setting of  $\ell_0$  (Hamming), we conjecture it does, leaving us with two options: (a) make the domain sparse: both the Gaussian elimination attack and the Hardt-Woodruff attack use the fact that Gaussian elimination is easy on the domain of the hash function; however making the domain sparse (say, the set of all strings of weight at most  $\beta n$  for some constant  $\beta < 1$ ) already rules it out; and (b) make the hash function non-linear: again, both attacks crucially exploit linearity. We will pursue both options, and as we will see, they are related.

But before we get there, let us ask whether we even need computational assumptions to get such a PPH. Can there be information-theoretic constructions? The first observation is that by a packing argument, if the output domain of the hash function has size less than  $2^{n - n \cdot H(\frac{d(1+\epsilon)}{n})} \approx 2^{n - d \log n(1+\epsilon)}$  (for small  $d$ ), there are bound to be “collisions”, namely, two far points (at distance more than  $d(1 + \epsilon)$ ) that hash to the same point. So, you really cannot compress much information-theoretically, especially as  $d$  becomes smaller. A similar bound holds when restricting the domain to strings of Hamming weight at most  $\beta n$  for constant  $\beta < 1$ .

With that bit of information, let us proceed to describe in a very high level our construction and the computational assumption. Our construction follows the line of thinking of Applebaum, Haramaty, Ishai, Kushilevitz and Vaikuntanathan [2] where they used the hardness of syndrome decoding problems to construct collision-resistant hash functions. Indeed, in a single sentence, our observation is that their collision-resistant hash functions are *locality-sensitive* by virtue of being *input-local*, and thus give us a robust gap-Hamming PPH (albeit under a different assumption).

In slightly more detail, our first step is to simply take the construction of Kushilevitz, Ostrovsky, and Rabani [19], and restrict the domain of the function. We show that finding two close points that get mapped to far points under the hash function is simply impossible (for our setting of parameters). On the other hand, there exist two far points that get mapped to close points under the hash functions (in fact, they even collide). Thus, showing that it is hard to find such points requires a computational assumption.

In a nutshell, our assumption says that given a random matrix  $\mathbf{A}$  where each entry is chosen from the Bernoulli distribution with  $\text{Ber}(1/d)$  with parameter  $1/d$ , it is hard to find a large Hamming weight vector  $\mathbf{x}$  where  $\mathbf{Ax} \pmod{2}$  has small Hamming weight. Of course, “large” and “small” here have to be parameterized correctly (see the full version for more details), however we observe that this is a generalization of the syndrome decoding assumption for low-density parity check (LDPC) codes, made by [2].

In our second step, we remove the sparsity requirement on the input domain of the predicate. We show a sparsification transformation which takes arbitrary  $n$ -bit vectors and outputs  $n' > n$ -bit *sparse* vectors such that (a) the transformation is injective, and (b) the

expansion introduced here does not cancel out the effect of compression achieved by the linear transformation  $\mathbf{x} \rightarrow \mathbf{A}\mathbf{x}$ . This requires careful tuning of parameters for which we refer the reader to the full version of this paper. Informally, our theorem statement is

► **Theorem 2** (Shortest-Vector PPH informal). *Let  $\lambda$  be a security parameter. Assuming the shortest-vector assumption (discussed above) with reasonable parameter settings, for any polynomial  $n = n(\lambda)$ , and any constants  $\epsilon, \eta > 0$ , there is an  $\eta$ -compressing robust property preserving hash family for GAPHAMMING( $n, d, \epsilon$ ) where  $d \leq \frac{n}{2 \log n}((1 - \epsilon) + (1 + \epsilon))$ .*

Notice that we get a better parameter  $d$  than from our first construction. This is, of course, because we make a stronger assumption. For more details, we refer the reader to the full version of this paper.

### The Necessity of Cryptographic Assumptions

The goal of robust PPH is to compress beyond the information theoretic limits, to a regime where incorrect hash outputs exist but are hard to find. If robustness is required even when the hash function is given, this inherently necessitates cryptographic hardness assumptions. A natural question is whether weaker forms of robustness (where the adversary sees only oracle access to the hash function) similarly require cryptographic assumptions, and what types of assumptions are required to build non-trivial PPHs of various kinds.

As a final contribution, we identify necessary assumptions for PPH for a kind of predicate we call *collision sensitive*. In particular, PPH for any such predicate in the double-oracle model implies the existence of one-way functions, and in the direct-access model implies existence of collision-resistant hash functions. In a nutshell, collision-sensitive means that finding a collision in the predicate breaks the property-preserving nature of any hash. The proof uses and expands on techniques from the work of Naor and Yaguev on adversarially robust Bloom Filters [24]. The basic idea is the same: without OWFs, we can invert arbitrary polynomially-computable functions with high probability in polynomial time, and using this we get a representation of the hash function/set, which can be used to find offending inputs.

## 2 Defining Property-Preserving Hash Functions

Our definition of property-preserving hash functions (PPHs) comes in several flavors, depending on whether we support total or partial predicates; whether the predicates take a single input or multiple inputs; and depending on the information available to the adversary. We discuss each of these choices in turn.

### Total vs. Partial Predicates

We consider *total predicates* that assign a 0 or 1 output to each element in the domain, and *promise (or partial) predicates* that assign a 0 or 1 to a subset of the domain and a wildcard (don't-care) symbol  $\star$  to the rest. More formally, a *total predicate*  $P$  on a domain  $X$  is a function  $P : X \rightarrow \{0, 1\}$ , well-defined as 0 or 1 for every input  $x \in X$ . A *promise predicate*  $P$  on a domain  $X$  is a function  $P : X \rightarrow \{0, 1, \star\}$ . Promise predicates can be used to describe scenarios (such as gap problems) where we only care about providing an exact answer on a subset of the domain.

Our definitions below will deal with the more general case of promise predicates, but we will discuss the distinction between the two notions when warranted.

### Single-Input vs Multi-Input Predicates

In the case of single-input predicates, we consider a class of properties  $\mathcal{P}$  and hash a single input  $x$  into  $h(x)$  in a way that given  $h(x)$ , one can compute  $P(x)$  for any  $P \in \mathcal{P}$ . Here,  $h$  is a compressing function. In the multi-input setting, we think of a single fixed property  $P$  that acts on a tuple of inputs, and require that given  $h(x_1), h(x_2), \dots, h(x_k)$ , one can compute  $P(x_1, x_2, \dots, x_k)$ . The second syntax is more expressive than the first, and so we use the multi-input syntax for constructions and the single-input syntax for lower bounds<sup>5</sup>.

Before we proceed to discuss robustness, we provide a working definition for a property-preserving hash function for the single-input syntax. For the multi-input predicate definition and further discussion, see the full version.

► **Definition 3.** A (non-robust)  $\eta$ -compressing Property Preserving Hash ( $\eta$ -PPH) family  $\mathcal{H} = \{h : X \rightarrow Y\}$  for a function  $\eta$  and a class of predicates  $\mathcal{P}$  requires the following two efficiently computable algorithms:

- $\mathcal{H}.\text{Samp}(1^\lambda) \rightarrow h$  is a randomized p.p.t. algorithm that samples a random hash function from  $\mathcal{H}$  with security parameter  $\lambda$ .
- $\mathcal{H}.\text{Eval}(h, P, y)$  is a deterministic polynomial-time algorithm that on input the hash function  $h$ , a predicate  $P \in \mathcal{P}$  and  $y \in Y$  (presumably  $h(x)$  for some  $x \in X$ ), outputs a single bit.

Additionally,  $\mathcal{H}$  must satisfy the following two properties:

- *$\eta$ -compressing*, namely,  $\log |Y| \leq \eta(\log |X|)$ , and
- *robust*, according to one of four definitions that we describe below, leading to four notions of PPH: definition 4 (non-robust PPH), 5 (evaluation-oracle-robust PPH or EO-PPH), 7 (double-oracle-robust PPH or DO-PPH), or 9 (direct-access robust PPH or DA-PPH). We will refer to the strongest form, namely direct-access robust PPH as simply robust PPH when the intent is clear from the context. See also Table 1 for a direct comparison between these.

### The Many Types of Robustness

We will next describe four definitions of robustness for PPHs, starting from the weakest to the strongest. Each of these definitions, when plugged into the last bullet of Definition 3, gives rise to a different type of property-preserving hash function. In each of these definitions, we will describe an adversary whose goal is to produce an input and a predicate such that the hashed predicate evaluation disagrees with the truth. The difference between the definitions is in what an adversary has access to, summarized in Table 1.

#### 2.1 Non-Robust PPH

We will start by defining the weakest notion of robustness which we call non-robust PPH. Here, the adversary has no information at all on the hash function  $h$ , and is required to produce a predicate  $P$  and a valid input  $x$ , namely where  $P(x) \neq \star$ , such that  $\mathcal{H}.\text{Eval}(h, P, x) \neq P(x)$  with non-negligible probability. When  $\mathcal{P}$  is the family of point functions (or equality functions), this coincides with the notion of 2-universal hash families [5]<sup>6</sup>.

<sup>5</sup> There is yet a third possibility, namely where there is a *fixed* predicate  $P$  that acts on a single input  $x$ , and we require that given  $h(x)$ , one can compute  $P(x)$ . This makes sense when the computational complexity of  $h$  is considerably less than that of  $P$ , say when  $P$  is the parity function and  $h$  is an  $AC^0$  circuit, as in the work of Dubrov and Ishai [10]. We do not explore this third syntax further in this work.

<sup>6</sup> While 2-universal hashing corresponds with a two-input predicate testing equality, the single-input version ( $\{P_{x_1}\}$  where  $P_{x_1}(x_2) = (x_1 == x_2)$ ) is more general, and so it is what we focus on.

## 16:10 Adversarially Robust Property-Preserving Hash Functions

■ **Table 1** A table comparing the adversary’s access to the hash function within different robustness levels of PPHs.

For security parameter  $\lambda$ , fixed predicate class  $\mathcal{P}$ , and  $h$  sampled from  $\mathcal{H}.\text{Samp}$

Non-Robust PPH	Adversary has no access to hash function or evaluation.
Evaluation-Oracle PPH	Access to the evaluation oracle $\mathcal{O}_h^{\text{Eval}}(x, P) = \mathcal{H}.\text{Eval}(h, P, h(x))$ .
Double-Oracle PPH	Access to both $\mathcal{O}_h^{\text{Eval}}$ (as above) and hash oracle $\mathcal{O}_h^{\text{Hash}}(x) = h(x)$ .
Robust PPH “Direct Access”	Direct access to the hash function, description of $h$ .

Here and in the following, we use the notation  $\Pr[A_1; \dots; A_m : E]$  to denote the probability that event  $E$  occurs following an experiment defined by executing the sequence  $A_1, \dots, A_m$  in order.

► **Definition 4.** A family of PPH functions  $\mathcal{H} = \{h : X \rightarrow Y\}$  for a class of predicates  $\mathcal{P}$  is a family of *non-robust* PPH functions if for any  $P \in \mathcal{P}$  and  $x \in X$  such that for  $P(x) \neq \star$ ,

$$\Pr[h \leftarrow \mathcal{H}.\text{Samp}(1^\lambda) : \mathcal{H}.\text{Eval}(h, P, h(x)) \neq P(x)] \leq \text{negl}(\lambda).$$

### 2.2 Evaluation-Oracle Robust PPH

In this model, the adversary has slightly more power than in the non-robust setting. Namely, she can adaptively query an oracle that has  $h \leftarrow \mathcal{H}.\text{Samp}(1^\lambda)$  in its head, on inputs  $P \in \mathcal{P}$  and  $x \in X$ , and obtain as output the hashed evaluation result  $\mathcal{H}.\text{Eval}(h, P, h(x))$ . Let  $\mathcal{O}_h(x, P) = \mathcal{H}.\text{Eval}(h, P, h(x))$ .

► **Definition 5.** A family of PPH functions  $\mathcal{H} = \{h : X \rightarrow Y\}$  for a class of predicates  $\mathcal{P}$  is a family of *evaluation-oracle robust (EO-robust)* PPH functions if, for any PPT adversary  $\mathcal{A}$ ,

$$\Pr[h \leftarrow \mathcal{H}.\text{Samp}(1^\lambda); (x, P) \leftarrow \mathcal{A}^{\mathcal{O}_h}(1^\lambda) : P(x) \neq \star \wedge \mathcal{H}.\text{Eval}(h, P, h(x)) \neq P(x)] \leq \text{negl}(\lambda).$$

The reader might wonder if this definition is very weak, and may ask if it follows just from the definition of a non-robust PPH family. In fact, for *total predicates*, we show that the two definitions are the same. At a high level, simply querying the evaluation oracle on (even adaptively chosen) inputs cannot reveal information about the hash function since with all but negligible probability, the answer from the oracle will be correct and thus simulatable without oracle access. The proof of the following lemma is in the full version.

► **Lemma 6.** *Let  $\mathcal{P}$  be a class of total predicates on  $X$ . A non-robust PPH  $\mathcal{H}$  for  $\mathcal{P}$  is also an Evaluation-Oracle robust PPH for  $\mathcal{P}$  for the same domain  $X$  and same codomain  $Y$ .*

However, when dealing with *promise* predicates, an EO-robustness adversary has the ability to make queries that do not satisfy the promise, and could get information about the hash function, perhaps even reverse-engineering the entire hash function itself. Indeed, Hardt and Woodruff [12] show that there are no EO-robust *linear* hash functions for a certain promise- $\ell_p$  distance property; whereas, non-robust linear hash functions for these properties follow from the work of Indyk [14, 13].

## 2.3 Double-Oracle PPH

We continue our line of thought, giving the adversary more power. Namely, she has access to two oracles, both have a hash function  $h \leftarrow \mathcal{H}.\text{Samp}(1^\lambda)$  in their head. The hash oracle  $\mathcal{O}_h^{\text{Hash}}$ , parameterized by  $h \in \mathcal{H}$ , outputs  $h(x)$  on input  $x \in X$ . The predicate evaluation oracle  $\mathcal{O}_h^{\text{Eval}}$ , also parameterized by  $h \in \mathcal{H}$ , takes as input  $P \in \mathcal{P}$  and  $y \in Y$  and outputs  $\mathcal{H}.\text{Eval}(h, P, y)$ . When  $\mathcal{P}$  is the family of point functions (or equality functions), this coincides with the notion of pseudo-random functions.

► **Definition 7.** A family of PPH functions  $\mathcal{H} = \{h : X \rightarrow Y\}$  for a class of predicates  $\mathcal{P}$  is a family of *double-oracle-robust PPH (DO-PPH)* functions if, for any PPT adversary  $\mathcal{A}$ ,

$$\Pr[h \leftarrow \mathcal{H}.\text{Samp}(1^\lambda); (x, P) \leftarrow \mathcal{A}^{\mathcal{O}_h^{\text{Hash}}, \mathcal{O}_h^{\text{Eval}}}(1^\lambda) : P(x) \neq \star \wedge \mathcal{H}.\text{Eval}(h, P, h(x)) \neq P(x)] \leq \text{negl}(\lambda).$$

We show that any evaluation-oracle-robust PPH can be converted into a double-oracle-robust PPH at the cost of a computational assumption, namely, one-way functions. In a nutshell, the observation is that the output of the hash function can be encrypted using a symmetric key that is stored as part of the hash description, and the evaluation proceeds by first decrypting. The proof of the following lemma is in the full version.

► **Lemma 8.** *Let  $\mathcal{P}$  be a class of (total or partial) predicates on  $X$ . Assume that one-way functions exist. Then, any EO-robust PPH for  $\mathcal{P}$  can be converted into a DO-robust PPH for  $\mathcal{P}$ .*

## 2.4 Direct-Access Robust PPH

Finally, we define the strongest notion of robustness where the adversary is given the description of the hash function itself. When  $\mathcal{P}$  is the family of point functions (or equality functions), this coincides with the notion of collision-resistant hash families.

► **Definition 9.** A family of PPH functions  $\mathcal{H} = \{h : X \rightarrow Y\}$  for a class of predicates  $\mathcal{P}$  is a family of *direct-access robust PPH* functions if, for any PPT adversary  $\mathcal{A}$ ,

$$\Pr[h \leftarrow \mathcal{H}.\text{Samp}(1^\lambda); (x, P) \leftarrow \mathcal{A}(h) : P(x) \neq \star \wedge \mathcal{H}.\text{Eval}(h, P, h(x)) \neq P(x)] \leq \text{negl}(\lambda).$$

We will henceforth focus on *direct-access-robust* property-preserving hash functions and refer to them simply as robust PPHs.

## 3 Property-Preserving Hashing and Communication Complexity

In this section, we identify and examine a relationship between property-preserving hash families (in the single-input syntax) and protocols in the one-way communication (OWC) model. A OWC protocol is a protocol between two players, Alice and Bob, with the goal of evaluating a certain predicate on their inputs and with the restriction that only Alice can send messages to Bob.

Our first observation is that non-robust property-preserving hash functions and OWC protocols [31] are equivalent except for two changes. First, PPHs require the parties to be computationally efficient, and second, PPHs also require protocols that incur error negligible in a security parameter. It is also worth noting that while we can reference lower-bounds in

the OWC setting, these lower bounds are typically of the form  $\Omega(n)$  and are not exact. On the other hand, in the PPH setting, we are happy with getting a single bit of compression, and so an  $\Omega(n)$  lower bound still does not tell us whether or not a PPH is possible. So, while we can use previously known lower bounds for some well-studied OWC predicates, we need to refine them to be exactly  $n$  in the presence of negligible error. We also propose a framework (for total predicates) that yields exactly  $n$  lower bounds for `INDEXn`, `GREATERTHAN`, and `EXACTHAMMING`.

### 3.1 PPH Lower Bounds from One-Way Communication Lower Bounds

In this section, we will review the definition of OWC, and show how OWC lower bounds imply PPH impossibility results.

► **Definition 10.** [31, 18] A  $\delta$ -error public-coin OWC protocol  $\Pi$  for a two-input predicate  $P : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  consists of a space  $R$  of randomness, and two functions  $g_a : X_1 \times R \rightarrow Y$  and  $g_b : Y \times X_2 \times R \rightarrow \{0, 1\}$  so that for all  $x_1 \in X_1$  and  $x_2 \in X_2$ ,

$$\Pr[r \leftarrow R; y = g_a(x_1; r) : g_b(y, x_2; r) \neq P(x_1, x_2)] \leq \delta.$$

A  $\delta$ -error public-coin OWC protocol  $\Pi$  for a *class of predicates*  $\mathcal{P} = \{P : \{0, 1\}^n \rightarrow \{0, 1\}\}$ , is defined much the same as above, with a function  $g_a : X \times R \rightarrow Y$ , and another function  $g_b : Y \times \mathcal{P} \times R \rightarrow \{0, 1\}$ , which instead of taking a second input, takes a predicate from the predicate class. We say  $\Pi$  has  $\delta$ -error if

$$\Pr[r \leftarrow R; y = g_a(x; r) : g_b(y, P; r) \neq P(x)] \leq \delta$$

Let  $\text{Protocols}_\delta(P)$  denote the set of OWC protocols with error at most  $\delta$  for a predicate  $P$ , and for every  $\Pi \in \text{Protocols}_\delta(P)$ , let  $Y_\Pi$  be the range of messages Alice sends to Bob (the range of  $g_a$ ) for protocol  $\Pi$ .

► **Definition 11.** The randomized, public-coin *OWC complexity* of a predicate  $P$  with error  $\delta$ , denoted  $R_\delta^{A \rightarrow B}(P)$ , is the minimum over all  $\Pi \in \text{Protocols}_\delta(P)$  of  $\lceil \log |Y_\Pi| \rceil$ .

For a predicate class  $\mathcal{P}$ , we define the randomized, public-coin OWC complexity with error  $\delta$ , denoted  $R_\delta^{A \rightarrow B}(\mathcal{P})$ , is the minimum over all  $\Pi \in \text{Protocols}_\delta(\mathcal{P})$  of  $\lceil \log |Y_\Pi| \rceil$ .

A PPH scheme for a two-input predicate<sup>7</sup>  $P$  yields a OWC protocol for  $P$  with communication comparable to a single hash output size.

► **Theorem 12.** *Let  $P$  be any two-input predicate  $P$  and  $\mathcal{P} = \{P_x\}_{x \in \{0, 1\}^n}$  be the corresponding predicate class where  $P_{x_2}(x_1) = P(x_1, x_2)$ . Now, let  $\mathcal{H}$  be a PPH in any model for  $\mathcal{P}$  that compresses  $n$  bits to  $m = \eta n$ . Then, there exists a OWC protocol  $\Pi$  such that the communication of  $\Pi$  is  $m$  and with negligible error.*

*Conversely, the amount of possible compression of any (robust or not) PPH family  $\mathcal{H} : \{h : X \rightarrow Y\}$  is lower bounded by  $R_{\text{negl}(\lambda)}^{A \rightarrow B}(P)$ . Namely,  $\log |Y| \geq R_{\text{negl}(\lambda)}^{A \rightarrow B}(\mathcal{P})$ .*

Essentially, the OWC protocol is obtained by using the public common randomness  $r$  to sample a hash function  $h = \mathcal{H}.\text{Samp}(1^\lambda; r)$ , and then Alice simply sends the hash  $h(x_1)$  of her input to Bob. (Proof in full version.)

<sup>7</sup> Or rather, for the induced class of single-input predicates  $\mathcal{P} = \{P_{x_2}\}_{x_2 \in \{0, 1\}^n}$ , where  $P_{x_2}(x_1) = P(x_1, x_2)$ ; we will use these terminologies interchangeably.

### 3.2 OWC and PPH lower bounds for Reconstructing Predicates

We next leverage this connection together with OWC lower bounds to obtain impossibility results for PPHs. First, we will discuss the total predicate case; we consider some partial predicates in section 3.3.

As discussed, to demonstrate the impossibility of a PPH, one must give an explicit  $n$ -bit communication complexity lower bound (not just  $\Omega(n)$ ) for negligible error. We give such lower bounds for an assortment of predicate classes by a general approach framework we refer to as *reconstructing*. Intuitively, a predicate class is reconstructing if, when given only access to predicates evaluated on an input  $x$ , one can, in polynomial time, determine the exact value of  $x$  with all but negligible probability.

► **Definition 13.** A class  $\mathcal{P}$  of total predicates  $P : \{0, 1\}^n \rightarrow \{0, 1\}$ , is *reconstructing* if there exists a PPT algorithm  $L$  (a ‘learner’) such that for all  $x \in \{0, 1\}^n$ , given randomness  $r$  and oracle access to predicates  $\mathcal{P}$  on  $x$ , denoted  $\mathcal{O}_x(P) = P(x)$ ,

$$\Pr_r[L^{\mathcal{O}_x}(r) \rightarrow x] \geq 1 - \text{negl}(n).$$

► **Theorem 14.** If  $\mathcal{P}$  is a reconstructing class of predicates on input space  $\{0, 1\}^n$ , then a PPH does not exist for  $\mathcal{P}$ .

The full proof appears in the full version. The main idea is to simulate the learner  $L$  on two different inputs  $x_1$  and  $x_2$ : at some query,  $L$  must get a different answer from the oracle, differentiating  $x_1$  from  $x_2$ . Since  $h$  is compressing, there are many  $x_1$  and  $x_2$  that collide on the same output. We show that we can guess such an  $x_1$  that is paired with an  $x_2$ , and the query that they differ on with  $1/\text{poly}(n)$  probability. Once we do that, the oracle must answer incorrectly for one of  $x_1$  or  $x_2$ , and there is a half chance that we chose the  $x_i$  that evaluated incorrectly.

#### Reconstructing using $\text{Index}_n$ , $\text{GreaterThan}$ , or $\text{ExactHamming}$

We turn to specific examples of predicate classes and sketch why they are reconstructing. For formal proofs, we refer the reader to the full version of this paper.

- The  $\text{INDEX}_n$  class of predicates  $\{P_1, \dots, P_n\}$  is defined over  $x \in \{0, 1\}^n$  where  $P_i(x) = x_i$ , the  $i$ ’th bit of  $x$ .  $\text{INDEX}_n$  is reconstructing simply because the learner  $L$  can just query the each of the  $n$  indices of the input and exactly reconstruct:  $x_i = P_i(x)$ .
- The  $\text{GREATERTHAN}$  class of predicates  $\{P_x\}_{x \in [2^n]}$  is defined over  $x \in [2^n] = \{0, 1\}^n$  where  $P_{x_2}(x_1) = 1$  if  $x_1 > x_2$  and 0 otherwise.  $\text{GREATERTHAN}$  is reconstructing because we can run a binary search on the input space, determining the exact value of  $x$  in  $n$  queries.  $\text{GREATERTHAN}$  is an excellent example for how an adaptive learner  $L$  can reconstruct.
- The  $\text{EXACTHAMMING}(\alpha)$  class of predicates  $\{P_x\}_{x \in \{0, 1\}^n}$  is defined over  $x \in \{0, 1\}^n$  where  $P_{x_2}(x_1) = 1$  if  $\|x_1 - x_2\|_0 > \alpha$  and 0 otherwise. To show that  $\text{EXACTHAMMING}(n/2)$  is reconstructing requires a little more work. The learner  $L$  resolves each index of  $x$  independently. For each index,  $L$  makes polynomially many random-string queries  $\mathbf{r}$  to  $\mathcal{O}_x$ ; if the  $i$ ’th bit of  $\mathbf{r}$  equals  $x_i$ , then  $\mathbf{r}$  is more likely to be within  $n/2$  hamming distance of  $\mathbf{x}$ , and if the bits are different,  $\mathbf{r}$  is more likely to not be within  $n/2$  hamming distance of  $\mathbf{x}$ . The proof uses techniques from [15], and is an example where the learner uses randomness to reconstruct.

We note that it was already known that  $\text{INDEX}_n$  and  $\text{EXACTHAMMING}(n/2)$  had OWC complexity of  $n$ -bits for any negligible error [18], though no precise lower bound for randomized OWC protocols was known for  $\text{GREATERTHAN}$ . What is new here is our unified framework.

### 3.3 Lower bounds for some partial predicates

In the previous section, we showed how the ability to reconstruct an input using a class of total predicates implied that PPHs for the class cannot exist. This general framework, unfortunately, does not directly extend to the partial-predicate setting, since it is unclear how to define the behavior of an oracle for the predicate. Nevertheless, we can still take existing OWC lower bounds and their techniques to prove impossibility results in this case. We will show that  $\text{GAPHAMMING}(n, n/2, 1/\sqrt{n})$  (the promise version of  $\text{EXACTHAMMING}$ ) cannot admit a PPH, and that while  $\text{Gap-}k$   $\text{GREATERTHAN}$  has a perfectly correct PPH compressing to  $n - \log(k) - 1$  bits, compressing any further results in polynomial error (and thus no PPH with more compression).

First, we define these partial predicates.

- **Definition 15.** The definitions for  $\text{GAPHAMMING}(n, d, \epsilon)$  and  $\text{Gap-}k$   $\text{GREATERTHAN}$  are:
  - The  $\text{GAPHAMMING}(n, d, \epsilon)$  class of predicates  $\{P_x\}_{x \in \{0,1\}^n}$  has  $P_{x_2}(x_1) = 1$  if  $\|x_1 - x_2\|_0 \geq d(1 + \epsilon)$ , 0 if  $\|x_1 - x_2\|_0 \leq d(1 - \epsilon)$ , and  $\star$  otherwise.
  - The  $\text{Gap-}k$   $\text{GREATERTHAN}$  class of predicates  $\{P_x\}_{x \in [2^n]}$  has  $P_{x_2}(x_1) = 1$  if  $x_1 > x_2 + k$ , 0 if  $x_1 < x_2 - k$ , and  $\star$  otherwise.

Now, we provide some intuition for why these lower bounds (and the upper bound) exist.

#### Gap-Hamming

Our lower bound will correspond to a refined OWC lower bound for the Gap-Hamming problem in the relevant parameter regime. Because we want to prove that we cannot even compress by a single bit, we need to be careful with our reduction: we want the specific parameters for which we have a lower bound, and must keep close track of how the error changes within our reduction.

- **Theorem 16.** *There does not exist a PPH for  $\text{GAPHAMMING}(n, n/2, 1/\sqrt{n})$ .*

To prove, we show the OWC complexity  $R_{\text{negl}(n)}^{A \rightarrow B}(\text{GAPHAMMING}(n, n/2, 1/\sqrt{n})) = n$ . A  $\Omega(n)$  OWC lower bound for Gap-Hamming in this regime has been proved in a few different ways [29, 30, 15]. Our proof will be a refinement of [15] and is detailed in the full version.

The high-level structure of the proof is to reduce  $\text{INDEX}_n$  to  $\text{GAPHAMMING}$  with the correct parameters. Very roughly, the  $i$ th coordinate of an input  $x \in \{0, 1\}^n$  can be inferred from the bias it induces on the Hamming distance between  $x$  and random public vectors. The reduction adds negligible error, but since we require  $n$  bits for negligible-error  $\text{INDEX}_n$ , we also require  $n$  bits for a OWC protocol for  $\text{GAPHAMMING}$ .

Notice that this style of proof looks morally as though we are “reconstructing” the input  $x$  using  $\text{INDEX}_n$ . However, the notion of getting a reduction from  $\text{INDEX}_n$  to another predicate-class in the OWC model is not the same as being able to query an oracle about the predicate and reconstruct based off of oracle queries. Being able to make a similar reconstructing characterization of partial-predicates as we have for total predicates would be useful and interesting in proving further lower bounds.

### Gap- $k$ GreaterThan

This predicate is a natural extension of GREATER THAN: we only care about learning that  $x_1 < x_2$  if  $|x_1 - x_2|$  is larger than  $k$  (the gap). Intuitively, a hash function can maintain this information by simply removing the  $\log(k)$  least significant bits from inputs and directly comparing: if  $h(x_1) = h(x_2)$ , they can be at most  $k$  apart. We can further remove one additional bit using the fact that we know  $x_2$  when given  $h(x_1)$  (considering Gap- $k$  GreaterThan as the corresponding predicate class parameterized by  $x_2$ ).

For the lower bound, we prove a OWC lower bound, showing  $R_{\text{negl}(n)}^{A \rightarrow B}(\mathcal{P}) = n - \log(k) - 1$ . This will be a proof by contradiction: if we compress to  $n - \log(k) - 2$  bits, we obtain many collisions that are more than  $3.5k$  apart. These far collisions imply the existence of inputs that the OWC protocol must fail on, even given the gap. We are able to find these inputs the OWC must fail on with polynomial probability, and this breaks the all-but-negligible correctness of the protocol. Our formal theorem statement is below.

► **Theorem 17.** *There exists a PPH with perfect correctness for Gap- $k$  GREATER THAN compressing from  $n$  bits to  $n - \log(k) - 1$ . This is tight: no PPH for Gap- $k$  GREATER THAN can compress to fewer than  $n - \log(k) - 1$  bits.*

For the proof, see the full version. To understand the construction of the PPH, first consider a hash function that just chops off the least-significant  $\log(k)$  bits from the inputs. Clearly, comparing two hashed values for which is greater than the other gives the gap- $k$ -GREATER THAN result correctly. In order to get the last bit off, we chop off the least-significant  $\log(k)$  bits and then round up or down depending on the  $\log(k) + 1$ 'th significant bit before removing it. Evaluation is almost essentially comparing hashes, but we exploit the fact that we know the entire second input ( $x_2$ ), which is why we are able to remove one extra bit. Proving the lower bound is a bit trickier, but essentially involves simulating a binary search.

## 4 A Gap-Hamming PPH from Collision Resistance

In this section, we present one of our constructions for a PPH for the GAPHAMMING problem. Recall from section 3.3 that the gap-Hamming property  $P = \text{GAPHAMMING}(n, d, \epsilon)$  is parameterized by the input domain  $\{0, 1\}^n$ , an integer  $d \in [n]$  and a parameter  $\epsilon \in \mathbb{R}^{\geq 0}$ , so that  $P(\mathbf{x}_1, \mathbf{x}_2) = 1$  if  $\|\mathbf{x}_1 \oplus \mathbf{x}_2\|_0 \geq d(1 + \epsilon)$  and 0 if  $\|\mathbf{x}_1 \oplus \mathbf{x}_2\|_0 \leq d(1 - \epsilon)$ . Both of our constructions will distinguish between  $d(1 - \epsilon)$ -close and  $d(1 + \epsilon)$ -far vectors for  $d \approx O(n/\log n)$ . This means that the gap is quite large, approximately  $O(n/\log n)$ .

This construction is a robust  $m/n$ -compressing  $\text{GAPHAMMING}(n, d, \epsilon)$  PPH for any  $m = n^{\Omega(1)}$ ,  $d = o(n/\log \lambda)$  and any constant  $\epsilon > 0$ . Security of the construction holds under the (standard) assumption that collision-resistant hash function families (CRHFs) exist.

We now informally describe the idea of the construction which, in one word, is “sub-sampling”. In slightly more detail, the intuition is to notice that if  $\mathbf{x}_1 \in \{0, 1\}^n$  and  $\mathbf{x}_2 \in \{0, 1\}^n$  are *close*, then *most small enough subsets* of indices of  $\mathbf{x}_1$  and  $\mathbf{x}_2$  will match identically. On the other hand, if  $\mathbf{x}_1$  and  $\mathbf{x}_2$  are *far*, then most *large enough subsets* of indices will differ. This leads us to the first idea for the construction, namely, fix a collection of sets  $\mathcal{S} = \{S_1, \dots, S_k\}$  where each  $S_i \subseteq [n]$  is a subset of appropriately chosen size  $s$ . On input  $\mathbf{x} \in \{0, 1\}^n$ , output  $\mathbf{y} = (\mathbf{x}|_{S_1}, \dots, \mathbf{x}|_{S_k})$  where  $\mathbf{x}|_S$  denotes the substring of  $\mathbf{x}$  indexed by the set  $S$ . The observation above tells us that if  $\mathbf{x}_1$  and  $\mathbf{x}_2$  are close (resp. far), so are  $\mathbf{y}_1$  and  $\mathbf{y}_2$ .

However, this does not compress the vector  $\mathbf{x}$ . Since the union of all the sets  $\bigcup_{i \in [k]} S_i$  has to be the universe  $[n]$  (or else, finding a collision is easy), it turns out that we are just comparing the vectors index-by-index. Fortunately, it is not necessary to output  $\mathbf{x}|_{S_i}$  by

themselves; rather we can simply output the collision-resistant hashes. That is, we will let the PPH hash of  $\mathbf{x}$ , denoted  $\mathbf{y}$ , be  $(g(\mathbf{x}|_{S_1}), \dots, g(\mathbf{x}|_{S_k}))$  where  $g$  is a collision resistant hash function randomly drawn from a CRHF family.

This simple construction works as long as  $s$ , the size of the sets  $S_i$ , is  $\Theta(n/d)$ , and the collection  $\mathcal{S}$  satisfies that any subset of disagreeing input indices  $T \subseteq [n]$  has nonempty intersection with roughly the corresponding fraction of subsets  $S_i$ . The latter can be achieved by selecting the  $S_i$  of size  $\Theta(n/d)$  at random, or alternatively as defined by the neighbor sets of a bipartite expander. We are additionally constrained by the fact that the CRHF must be secure against adversaries running in time  $\text{poly}(\lambda)$ . So, let  $t = t(\lambda)$  be the smallest output size of the CRHF such that it is secure against  $\text{poly}(\lambda)$ -time adversaries. Since the input size  $s$  to the CRHF must be  $\omega(t)$  so that  $g$  actually compresses, this forces  $n/d = \omega(t)$ , and thus  $d = o(n/t)$ .

Before presenting our construction more formally, we define our tools.

- We will use a family of CRHFs that take inputs of variable size and produce outputs of  $t$  bits and denote it by  $\mathcal{H}_t = \{h : \{0, 1\}^* \rightarrow \{0, 1\}^t\}$ . We implicitly assume a procedure for sampling a seed for the CRHF given a security parameter  $1^\lambda$ . One could set  $t = \omega(\log \lambda)$  and assume the exponential hardness of the CRHF, or set  $t = \lambda^{O(1)}$  and assume polynomial hardness. These choices will result in different parameters of the PPH hash function.
- We will use an  $(n, k, D, \gamma, \alpha)$ -bipartite expander  $G = (L \cup R, E)$  which is a  $D$ -left-regular bipartite graph, with  $|L| = n$  and  $|R| = k$  such that for every  $S \subset L$  for which  $|S| \leq \gamma n$ , we have  $|N(S)| \geq \alpha|S|$ , where  $N(S)$  is the set of neighbors of  $S$ . For technical reasons, we will need the expander to be  $\delta$ -balanced on the right, meaning that for every  $v \in R$ ,  $|N(v)| \geq (1 - \delta)nD/k$ .

A simple probabilistic construction shows that for every  $n \in \mathbb{N}$ ,  $k = o(n)$  and constant  $a \in (0, 1)$ , and any  $\gamma = o(\frac{k}{n \log(n/k)})$  and  $D = \Theta(\log(1/\gamma))$  so that for every  $\delta > 0$ ,  $\delta$ -balanced  $(n, k, D, \gamma, \alpha)$ -bipartite expanders exist. In fact, there are even explicit efficient constructions that match these parameters [4].

The construction is in Table 2. We first discuss explicit parameter settings.

### Setting the Parameters

The parameters required for this construction to be secure and constructible are as follows.

- Let  $n \in \mathbb{N}$  and constant  $\epsilon > 0$ .
- We require two building blocks: a CRHF and an expander. So, let  $\mathcal{H}_t = \{g : \{0, 1\}^* \rightarrow \{0, 1\}^t\}$  be a family of CRHFs secure against  $\text{poly}(\lambda)$ -time adversaries. Let  $G$  be a  $\delta$ -balanced  $(n, k, D, \gamma, \alpha)$ -expander for a constant  $\delta$  bounding the degree of the right-nodes, where  $n$  is the size of the left side of the graph,  $k$  is the size of the right,  $D$  is the left-degree,  $\gamma n$  is the upper bound for an expanding set on the right that expands to a set of size  $\alpha$  times the original size.
- These building blocks yield the following parameters for the construction: compression is  $\eta = kt/n$  and our center for the Gap-Hamming problem is bounded by  $\frac{\gamma n}{(1+\epsilon)} \leq d < \frac{k}{D(1-\epsilon)}$ .

If we consider what parameter settings yield secure CRHFs with output size  $t$  and for what parameters we have expanders, we have a PPH construction where given any  $n$  and  $\epsilon$ , there exists a  $d = o(n)$  and  $\eta = O(1)$  such that Construction 2 is a robust PPH for gap-Hamming. We will see that the smaller  $t$  is, the stronger the CRHF security assumption, but the better our compression.

Now, given these settings of parameters, we have the following theorem that Construction 2 is a robust Gap-Hamming PPH.

■ **Table 2** Construction 2 of a robust  $\text{GAPHAMMING}(n, d, \epsilon)$  PPH family from CRHFs. Resulting parameters  $(n, m, d, \epsilon)$  discussed in text.

<u>Robust <math>\text{GAPHAMMING}(n, d, \epsilon)</math> PPH family <math>\mathcal{H}</math> from any CRHF</u>	
Our $(n, m, d, \epsilon)$ -robust PPH family $\mathcal{H} = (\mathcal{H}.\text{Samp}, \mathcal{H}.\text{Eval})$ is defined as follows.	
■ $\mathcal{H}.\text{Samp}(1^\lambda, n)$ . Fix a $\delta$ -balanced $(n, k, D, \gamma, \alpha)$ -bipartite expander $G = (L \cup R, E)$ (either deterministically or probabilistically). Sample a CRHF $g \leftarrow \mathcal{H}_t$ . Output $h = (G, g)$ .	
■ $\mathcal{H}.\text{Hash}(h = (G, g), \mathbf{x})$ . For every $i \in [k]$ , compute the (ordered) set of neighbors of the $i$ -th right vertex in $G$ , denoted $N(i)$ . Let $\hat{\mathbf{x}}^{(i)} := \mathbf{x} _{N(i)}$ be $\mathbf{x}$ restricted to the set $N(i)$ . Output	
$h(\mathbf{x}) := (g(\hat{\mathbf{x}}^{(1)}), \dots, g(\hat{\mathbf{x}}^{(k)}))$	
as the hash of $\mathbf{x}$ .	
■ $\mathcal{H}.\text{Eval}(h = (G, g), \mathbf{y}_1, \mathbf{y}_2)$ . Compute the threshold $\tau = D \cdot d \cdot (1 - \epsilon)$ . Parse $\mathbf{y}_1 = (\hat{\mathbf{y}}_1^{(1)}, \dots, \hat{\mathbf{y}}_1^{(k)})$ and $\mathbf{y}_2 = (\hat{\mathbf{y}}_2^{(1)}, \dots, \hat{\mathbf{y}}_2^{(k)})$ . Compute	
$\Delta' = \sum_{i=1}^k \text{Ind}(\hat{\mathbf{y}}_1^{(i)} \neq \hat{\mathbf{y}}_2^{(i)}),$	
where $\text{Ind}$ denotes the indicator predicate. If $\Delta' \leq \tau$ , output <b>CLOSE</b> . Otherwise, output <b>FAR</b> .	

► **Theorem 18.** *Let  $\lambda$  be a security parameter. Assuming that exponentially secure CRHFs exist, then for any polynomial  $n = n(\lambda)$ , and any constants  $\epsilon, \eta > 0$ , Construction 2 is an  $\eta$ -compressing robust property preserving hash family for  $\text{GAPHAMMING}(n, d, \epsilon)$  where  $d = o(n/\log \lambda \log \log \lambda)$ . Assuming only that polynomially secure CRHFs exist, for any constant  $c > 0$ , we achieve  $d = o(n/\lambda^c)$ .*

**Proof.** Before getting into the proof, we more explicitly define the parameters, including parameters associated with the expander in our construction:

1. Let  $n \in \mathbb{N}$  be the input size and let  $\epsilon > 0$  be any constant.
2. Our CRHF is  $\mathcal{H}_t = \{g : \{0, 1\}^* \rightarrow \{0, 1\}^t\}$ .
3. Our expander will be a  $\delta$ -balanced  $(n, k, D, \gamma, \alpha)$ -expander, where  $k < n/t$ ,  $\gamma = o(\frac{k}{n \log(n/k)})$ ,  $D = \Theta(\log(1/\gamma))$ , and  $\alpha > D \cdot \frac{d(1-\epsilon)}{\gamma n}$ .
4. Our center for the gap-hamming problem is  $d$ , and is constrained by  $\frac{\gamma n}{1+\epsilon} \leq d < \frac{k}{D(1-\epsilon)}$ .
5. Constraint 4 implies that  $k = n^{\Omega(1)}$ , since  $\frac{\gamma n \cdot D(1-\epsilon)}{1+\epsilon} < k$ .

Now, we prove our construction is well-defined and efficient. Fix any  $\delta, a \in (0, 1)$ . In the full version, we explicitly prove that  $\delta$ -balanced  $(n, k, D, \gamma, \alpha = an)$ -bipartite expanders exist and can be efficiently sampled for  $k = o(n/\log n)$ ,  $D = \Theta(\log \log n)$ , and  $\gamma = \tilde{\Theta}(1/\log n)$ . Thus, sampling the graph  $G$  before running the construction is efficient. Once we have a  $G$ , sampling and running a CRHF  $k = O(n)$  times is efficient. Comparing  $k$  outputs of the hash function is also efficient. Therefore, each of  $\mathcal{H}.\text{Samp}$ ,  $\mathcal{H}.\text{hash}$ , and  $\mathcal{H}.\text{Eval}$  is efficient in  $\lambda = \text{poly}(n)$ .

Now, we prove that Construction 2 is compressing. Points 2 and 3 mean that  $m = k \cdot t < n/t \cdot t = n$ , as required.

Lastly, we will prove our construction is robust. Let  $\mathcal{A}$  be a PPT adversary. We will show that  $\mathcal{A}$  (in fact, even an unbounded adversary) cannot find  $\mathbf{x}_1$  and  $\mathbf{x}_2$  such that  $\|\mathbf{x}_1 - \mathbf{x}_2\| \leq d(1 - \epsilon)$  but  $\mathcal{H}.\text{Eval}(h, h(\mathbf{x}_1), h(\mathbf{x}_2))$  evaluates to **FAR**, and that  $\mathcal{A}$  must break the collision-resistance of  $\mathcal{H}_t$  in order to find  $\mathbf{x}_1$  and  $\mathbf{x}_2$  where  $\|\mathbf{x}_1 - \mathbf{x}_2\| \geq d(1 + \epsilon)$  but  $\mathcal{H}.\text{Eval}(h, h(\mathbf{x}_1), h(\mathbf{x}_2))$  evaluates to **CLOSE**.

- First, consider any  $\mathbf{x}_1, \mathbf{x}_2 \in \{0, 1\}^n$  where  $\|\mathbf{x}_1 - \mathbf{x}_2\|_0 \leq d(1 - \epsilon)$ . Let  $\Delta = \|\mathbf{x}_1 - \mathbf{x}_2\|_0$ . So, consider the set  $S \subset L$  corresponding to the indices that are different between  $\mathbf{x}_1$  and  $\mathbf{x}_2$ , and  $T = N(S) \subset R$ . The maximum size of  $T$  is  $|S| \cdot D$ , the degree of the graph. For every  $i \in T$ , we get that the intermediate computation has  $\hat{\mathbf{x}}_1^{(i)} \neq \hat{\mathbf{x}}_2^{(i)}$ , but for every  $j \notin T$ , we have  $\hat{\mathbf{x}}_1^{(j)} = \hat{\mathbf{x}}_2^{(j)}$  which implies  $\hat{\mathbf{y}}_1^{(j)} = \hat{\mathbf{y}}_2^{(j)}$  after applying  $g$ . Therefore  $\sum_{i=1}^k \text{Ind}(\hat{\mathbf{y}}_1^{(i)} \neq \hat{\mathbf{y}}_2^{(i)}) \leq \sum_{i \in S} \text{Ind}(\hat{\mathbf{y}}_1^{(i)} \neq \hat{\mathbf{y}}_2^{(i)}) + \sum_{j \notin S} \text{Ind}(\hat{\mathbf{y}}_1^{(j)} \neq \hat{\mathbf{y}}_2^{(j)}) \leq \Delta \cdot D$ . We set the threshold  $\tau = D \cdot d \cdot (1 - \epsilon)$  in the evaluation. Point 4 guarantees that  $\tau < k$  (and implicitly implies  $k > D(1 - \epsilon)$ ), so because  $D \cdot \Delta \leq D \cdot d(1 - \epsilon) = \tau < k$ ,  $\mathcal{H}.\text{Eval}$  will evaluate  $\Delta' \leq \tau$ . Thus,  $\mathcal{H}.\text{Eval}$  will always evaluate to **CLOSE** in this case, regardless of the choice of CRHF.

- Now consider  $\|\mathbf{x}_1 - \mathbf{x}_2\|_0 \geq d(1 + \epsilon)$ , and again, let  $\Delta = \|\mathbf{x}_1 - \mathbf{x}_2\|_0$  and define  $S \subset L$  and  $T \subset R$  as before.

By point 4 again ( $\gamma n \leq d(1 + \epsilon)$ ), we can restrict  $S$  to  $S'$  where  $|S'| = \gamma n$ , and by the properties of expanders  $|N(S')| \geq \gamma n \cdot \alpha$ . Now, point 3 guarantees that  $\tau = D \cdot d \cdot (1 - \epsilon) < \alpha \cdot \gamma n$ . So, for every  $i \in T'$ ,  $\hat{\mathbf{x}}_1^{(i)} \neq \hat{\mathbf{x}}_2^{(i)}$ , and  $|T'| \geq \alpha \cdot \gamma n > \tau$ . Now we want to argue that with all but negligible probability over our choice of  $g$ ,  $g$  will preserve this equality relation, and so  $\Delta' = |T'|$ . Given that our expander is  $\delta$ -balanced for some constant  $\delta > 0$ , we have that  $|\hat{\mathbf{x}}_1^{(i)}| = |\hat{\mathbf{x}}_2^{(i)}| = |N(r_i)| \geq (1 - \delta)nD/k$ . Now, point 3 states that the constraints have  $k < n/t$ , implying  $n/k > t$ . So,  $(1 - \delta)D \cdot n/k > (1 - \delta)D \cdot t$ .

This means that every input to  $g$  will be larger than the output ( $(1 - \delta)$  is a constant and  $D = \omega(1)$ ), and so if  $g(\hat{\mathbf{x}}_1^{(i)}) = g(\hat{\mathbf{x}}_2^{(i)})$  but  $\hat{\mathbf{x}}_1^{(i)} \neq \hat{\mathbf{x}}_2^{(i)}$  for any  $i$ , then our adversary has found a collision, which happens with all but negligible probability for adversaries running in time  $\text{poly}(\lambda)$ .

Therefore, with all but negligible probability over the choice of  $g$  and adversarially chosen  $\mathbf{x}_1$  and  $\mathbf{x}_2$  in this case,  $\Delta' = \sum_{i=1}^{m'} \text{Ind}(\hat{\mathbf{y}}_1^{(i)} \neq \hat{\mathbf{y}}_2^{(i)}) \geq \alpha \cdot \gamma n = \tau$ , and  $\mathcal{H}.\text{Eval}$  outputs **FAR**. ◀

## Abstract

Given a set of  $n$  points in  $\mathbb{R}^d$ , the (monochromatic) *Closest Pair* problem asks to find a pair of distinct points in the set that are closest in the  $\ell_p$ -metric. Closest Pair is a fundamental problem in Computational Geometry and understanding its fine-grained complexity in the Euclidean metric when  $d = \omega(\log n)$  was raised as an open question in recent works (Abboud-Rubinfeld-Williams [FOCS'17], Williams [SODA'18], David-Karthik-Laekhanukit [SoCG'18]).

In this paper, we show that for every  $p \in \mathbb{R}_{\geq 1} \cup \{0\}$ , under the Strong Exponential Time Hypothesis (SETH), for every  $\varepsilon > 0$ , the following holds:

- No algorithm running in time  $O(n^{2-\varepsilon})$  can solve the Closest Pair problem in  $d = (\log n)^{\Omega_\varepsilon(1)}$  dimensions in the  $\ell_p$ -metric.
- There exists  $\delta = \delta(\varepsilon) > 0$  and  $c = c(\varepsilon) \geq 1$  such that no algorithm running in time  $O(n^{1.5-\varepsilon})$  can approximate Closest Pair problem to a factor of  $(1 + \delta)$  in  $d \geq c \log n$  dimensions in the  $\ell_p$ -metric.

In particular, our first result is shown by establishing the computational equivalence of the *bichromatic* Closest Pair problem and the (monochromatic) Closest Pair problem (up to  $n^\varepsilon$  factor in the running time) for  $d = (\log n)^{\Omega_\varepsilon(1)}$  dimensions.

Additionally, under SETH, we rule out nearly-polynomial factor approximation algorithms running in subquadratic time for the (monochromatic) *Maximum Inner Product* problem where we are given a set of  $n$  points in  $n^{o(1)}$ -dimensional Euclidean space and are required to find a pair of distinct points in the set that maximize the inner product.

At the heart of all our proofs is the construction of a dense bipartite graph with low *contact dimension*, i.e., we construct a balanced bipartite graph on  $n$  vertices with  $n^{2-\varepsilon}$  edges whose vertices can be realized as points in a  $(\log n)^{\Omega_\varepsilon(1)}$ -dimensional Euclidean space such that every pair of vertices which have an edge in the graph are at distance exactly 1 and every other pair of vertices are at distance greater than 1. This graph construction is inspired by the construction of locally dense codes introduced by Dumer-Miccancio-Sudan [IEEE Trans. Inf. Theory'03].

## 1 Introduction

The Closest Pair of Points problem or *Closest Pair* problem (CP) is a fundamental problem in computational geometry: given  $n$  points in a  $d$ -dimensional metric space, find a pair of distinct points with the smallest distance between them. The Closest Pair problem for points in the Euclidean plane [51, 11] stands at the origins of the systematic study of the computational complexity of geometric problems [45, 40, 36, 20]. Since then, this problem has found abundant applications in geographic information systems [28], clustering [58, 7], and numerous matching problems (such as stable marriage [56]).

The trivial algorithm for CP examines every pair of points in the point-set and runs in time  $O(n^2d)$ . Over the decades, there have been a series of developments on CP in low dimensional space for the Euclidean metric [10, 29, 35, 51, 11], leading to a deterministic  $O(2^{O(d)}n \log n)$ -time algorithm [11] and a randomized  $O(2^{O(d)}n)$ -time algorithm [46, 35]. For low (i.e., constant) dimensions, these algorithms are tight as a matching lower bound of  $\Omega(n \log n)$  was shown by Ben-Or [9] and Yao [57] in the *algebraic decision tree* model, thus settling the complexity of CP in low dimensions. On other hand, for very high dimensions (i.e.,  $d = \Omega(n)$ ) there are subcubic algorithms [27, 31] in the  $\ell_1, \ell_2$ , and  $\ell_\infty$ -metrics using fast matrix multiplication algorithms [25]. However, CP in medium dimensions, i.e.,  $d = \text{polylog}(n)$ , and in various  $\ell_p$ -metrics, have been a focus of study in machine learning and analysis of Big Data [37], and it is surprising that, even with the tools and techniques that have been developed over many decades, when  $d = \omega(\log n)$ , there is no known subquadratic-time (i.e.,  $O(2^{o(d)}n^{2-\varepsilon})$ -time) algorithm, for CP in any standard distance measure [30, 4, 31]. The absence of such algorithms was explicitly observed as early as the late nineties by Cohen and Lewis [19] but there was not any explanation until recently.

David, Karthik, and Laekhanukit [21] showed that for all  $p > 2$ , assuming the *Strong Exponential Time Hypothesis* (SETH), for every  $\varepsilon > 0$ , no algorithm running in  $n^{2-\varepsilon}$  time can solve CP in the  $\ell_p$ -metric, even when  $d = \omega(\log n)$ . Their conditional lower bound was based on the conditional lower bound (again assuming SETH) of Alman and Williams [6] for the *Bichromatic Closest Pair* problem<sup>3</sup> (BCP) where we are given two sets of  $n$  points in a  $d$ -dimensional metric space, and the goal is to find a pair of points, one from each set, with the smallest distance between them. Alman and Williams showed that for all  $p \in \mathbb{R}_{\geq 1} \cup \{0\}$ , assuming SETH, for every  $\varepsilon > 0$ , no algorithm running in  $n^{2-\varepsilon}$  time can solve BCP in the  $\omega(\log n)$ -dimensional  $\ell_p$ -metric space. Given that [6] show their lower bound on BCP for all  $\ell_p$ -metrics, the lower bound on CP of [21] feels unsatisfactory, since the  $\ell_2$ -metric is arguably the most interesting metric to study CP on. On the other hand, the answer to

<sup>3</sup> We remark that BCP is of independent interest as it's equivalent to finding the *Minimum Spanning Tree* in  $\ell_p$ -metric [3, 38]. Moreover, understanding the fine-grained complexity of BCP has lead to better understanding of the query time needed for *Approximate Nearest Neighbor* search problem (see Razenshteyn's thesis [47] for a survey about the problem) with polynomial preprocessing time [50].

the complexity of CP in the Euclidean metric might be on the positive side, i.e., there might exist an algorithm that performs well in the  $\ell_2$ -metric because there are more tools available, e.g., Johnson-Lindenstrauss' dimension reduction [33]. Thus we have the following question:

► **Open Question 1** (Abboud-Rubinfeld-Williams<sup>4</sup> [2], Williams [55], David -Karthik-Laekhanukit [21]). *Is there an algorithm running in time  $n^{2-\varepsilon}$  for some  $\varepsilon > 0$  which can solve CP in the Euclidean metric when the points are in  $\omega(\log n)$  dimensions?*

Even if the answer to the above question is negative, this does not rule out strong approximation algorithms for CP in the Euclidean metric, which might suffice for all applications. Indeed, we do know of subquadratic approximation algorithms for CP. For example, LSH based techniques can solve  $(1 + \delta)$ -CP (i.e.,  $(1 + \delta)$  factor approximate CP) in  $n^{2-\Theta(\delta)}$  time [32], but cannot do much better [42, 43]. In a recent breakthrough, Valiant [52] obtained an approximation algorithm for  $(1 + \delta)$ -CP with runtime of  $n^{2-\Theta(\sqrt{\delta})}$ . The state of the art is an  $n^{2-\tilde{\Theta}(\delta^{1/3})}$ -time algorithm by Alman, Chan, and Williams [5]. Can the dependence on  $\delta$  be improved indefinitely? For the case of  $(1 + \delta)$ -BCP, assuming SETH, Rubinfeld [50] answered the question in the negative. Does  $(1 + \delta)$ -CP also admit the same negative answer?

► **Open Question 2.** *Is there an algorithm running in time  $n^{2-\varepsilon}$  for some  $\varepsilon > 0$  which can solve  $(1 + \delta)$ -CP in the Euclidean metric when the points are in  $\omega(\log n)$  dimensions for every  $\delta > 0$ ?*

Another important geometric problem is the *Maximum Inner Product* problem (MIP): given  $n$  points in the  $d$ -dimensional Euclidean space, find a pair of distinct points with the largest inner product. This problem along with its bichromatic variant (*Bichromatic Maximum Inner Product* problem, denoted BMIP) is extensively studied in literature (see [2] and references therein). Abboud, Rubinfeld, and Williams [2] showed that assuming SETH, for every  $\varepsilon > 0$ , no  $2^{(\log n)^{1-o(1)}}$ -approximation algorithm running in  $n^{2-\varepsilon}$  time can solve BMIP when  $d = n^{o(1)}$ . It is a natural question to ask if their inapproximability result can be extended to MIP:

► **Open Question 3.** *Is there an algorithm running in time  $n^{2-\varepsilon}$  for some  $\varepsilon > 0$  which can solve  $\gamma$ -MIP in  $n^{o(1)}$  dimensions for even  $\gamma = 2^{(\log n)^{1-o(1)}}$ ?*

## 1.1 Our Results

In this paper we address all three previously mentioned open questions. First, we almost completely resolve Open Question 1. In particular, we show the following.

► **Theorem 4** (Subquadratic Hardness of CP). *Let  $p \in \mathbb{R}_{\geq 1} \cup \{0\}$ . Assuming SETH, for every  $\varepsilon > 0$ , no algorithm running in  $n^{2-\varepsilon}$  time can solve CP in the  $\ell_p$ -metric, even when  $d = (\log n)^{\Omega_\varepsilon(1)}$ .*

In particular we would like to emphasize that the dimension for which we show the lower bound on CP depends on  $\varepsilon$ . We would also like to remark that our lower bound holds even when the input point-set of CP is a subset of  $\{0, 1\}^d$ . Finally, we note that the centerpiece of the proof of the above theorem (and also the proofs of the other results that will be subsequently mentioned) is the construction of a dense bipartite graph with low *contact dimension*, i.e., we construct a balanced bipartite graph on  $n$  vertices with  $n^{2-\varepsilon}$  edges whose

<sup>4</sup> Please see the erratum in [1].

vertices can be realized as points in a  $(\log n)^{\Omega_\varepsilon(1)}$ -dimensional  $\ell_p$ -metric space such that every pair of vertices which have an edge in the graph are at distance exactly 1 and every other pair of vertices are at distance greater than 1. This graph construction is inspired by the construction of locally dense codes introduced by Dumer, Miccancio, and Sudan [23] and uses special density properties of Reed Solomon codes. A detailed proof overview is given in Section 2.1.

Next, we improve our result in Theorem 4 in some aspects by showing  $1 + o(1)$  factor inapproximability of CP even in  $O_\varepsilon(\log n)$  dimensions, but can only rule out algorithms running in  $n^{1.5-\varepsilon}$  time (as opposed to Theorem 4 which rules out exact algorithms for CP running in  $n^{2-\varepsilon}$  time). More precisely, we show the following.

► **Theorem 5** (Subquadratic Hardness of gap-CP). *Let  $p \in \mathbb{R}_{\geq 1} \cup \{0\}$ . Assuming SETH, for every  $\varepsilon > 0$ , there exists  $\delta(\varepsilon) > 0$  and  $c(\varepsilon) > 1$  such that no algorithm running in  $n^{1.5-\varepsilon}$  time that can solve  $(1 + \delta)$ -CP in the  $\ell_p$ -metric, even when  $d = c \log n$ .*

We remark that the  $n^{1.5-\varepsilon}$  lower bound on approximate CP is an artifact of our proof strategy and that a different approach or an improvement in the state-of-the-art bound on the number of minimum weight codewords in algebraic geometric codes (which are used in our proof), will lead to the complete resolution of Open Question 2.

It should also be noted that the approximate version of CP and the dimension are closely related. Namely, using standard dimensionality reduction techniques [33]<sup>5</sup> for  $(1 + \delta)$ -CP, one can always assume that  $d = O_\delta(\log n)$ . In other words, hardness of  $(1 + \delta)$ -CP immediately yields logarithmic dimensionality bound as a byproduct.

Finally, we completely answer Open Question 3 by showing the following inapproximability result for MIP, matching the hardness for BMIP from [2].

► **Theorem 6** (Subquadratic Hardness of gap-MIP). *Assuming SETH, for every  $\varepsilon > 0$ , no algorithm running in  $n^{2-\varepsilon}$  time can solve  $\gamma$ -MIP for any  $\gamma \leq 2^{(\log n)^{1-o(1)}}$ , even when  $d = n^{o(1)}$ .*

Recently, there have been a lot of results connecting BCP or  $(1 + o(1))$ -BCP to other problems (see [50, 15, 16, 17]). Now such connections can be extended to CP as well. For example, the following conditional lower bound follows from [50] for gap-CP in the edit distance metric.

► **Theorem 7** (Subquadratic Hardness of gap-CP in edit distance metric). *Assuming SETH, for every  $\varepsilon > 0$ , there exists  $\delta(\varepsilon) > 0$  and  $c(\varepsilon) > 1$  such that no algorithm running in  $n^{1.5-\varepsilon}$  time can solve  $(1 + \delta)$ -CP in the edit distance metric, even when  $d = c \log n \log \log n$ .*

## 2 Proof Overview

In this section, we provide an overview of our proofs and the formal proofs may be found in the full version of the paper. For ease of presentation, we will sometimes be informal here; all notions and proofs are formalized in subsequent sections. Our overview is organized as follows. First, in Subsection 2.1, we outline our proof of running time lower bounds for exact CP (Theorem 4). Then, in Subsection 2.2, we abstract part of our reduction using error-correcting codes, and relate them back to the works on locally dense codes [23, 18, 41] that inspire our constructions. Finally, in Subsection 2.3, we briefly discuss how to modify the base construction (i.e. code properties) to give conditional lower bounds for approximate CP and MIP (Theorems 5 and 6).

<sup>5</sup> In fact, since our results applies to  $\{0, 1\}$ -vectors, simply subsampling coordinates would also work.

## 2.1 Conditional Lower Bound on Exact Closest Pair

In this subsection, we provide a proof overview of a slightly weaker version of Theorem 4, i.e., we show that assuming SETH, for every  $p \in \mathbb{R}_{\geq 1} \cup \{0\}$ , no subquadratic time algorithm can solve CP in the  $\ell_p$ -metric when  $d = (\log n)^{\omega(1)}$ . We prove such a result by reducing BCP in dimension  $d$  to CP in dimension  $d + (\log n)^{\omega(1)}$ , and the subquadratic hardness for CP follows from the subquadratic hardness of BCP established by [6]. Note that the results in this paper remain interesting even if SETH is false, as our reduction shows that BCP and CP are computationally equivalent<sup>6</sup> (up to  $n^{\omega(1)}$  factor in the running time) when  $d = (\log n)^{\omega(1)}$ . The conditional lower bound on CP is merely a consequence of this computational equivalence. Finally, we note that a similar equivalence also holds between MIP and BMIP.

**Understanding an obstacle of [21].** Our proof builds on the ideas of [21] who showed that assuming SETH, for every  $p > 2$ , no subquadratic time algorithm can solve CP in the  $\ell_p$ -metric when  $d = \omega(\log n)$ . They did so by connecting the complexity of CP and BCP via the *contact dimension* of the balanced complete bipartite graph (biclique), denoted by  $K_{n,n}$ . We elaborate on this below.

To motivate the idea behind [21], let us first consider the trivial reduction from BCP to CP: given an instance  $A, B$  of BCP, we simply output  $A \cup B$  as an instance of CP. This reduction fails because there is no guarantee on the distances of a pair of points both in  $A$  (or both in  $B$ ). That is, there could be two points  $\mathbf{a}, \mathbf{a}' \in A$  such that  $\|\mathbf{a} - \mathbf{a}'\|_p$  is much smaller than the optimum of BCP on  $A, B$ . If we simply solve CP on  $A \cup B$ , we might find such  $\mathbf{a}, \mathbf{a}'$  as the optimal pair but this does not give the answer to the original BCP problem. In order to circumvent this issue, one needs a gadget that “stretch” pairs of points both in  $A$  or both in  $B$  further apart while keeping the pairs of points across  $A$  and  $B$  close (and preserving the optimum of BCP on  $A, B$ ). It turns out that this notion corresponds exactly to the contact dimension of the biclique, which we define below.

► **Definition 8** (Contact Dimension [44]). For any graph  $G = (V, E)$ , a mapping  $\tau : V \rightarrow \mathbb{R}^d$  is said to *realize*  $G$  (in the  $\ell_p$ -metric) if for some  $\beta > 0$ , the following holds for every distinct vertices  $u, v$ :

$$\|\tau(u) - \tau(v)\|_p = \beta \text{ if } \{u, v\} \in E, \text{ and,} \tag{1}$$

$$\|\tau(u) - \tau(v)\|_p > \beta \text{ otherwise.} \tag{2}$$

The *contact dimension* (in the  $\ell_p$ -metric) of  $G$ , denoted by  $\text{cd}_p(G)$ , is the minimum  $d \in \mathbb{N}$  such that there exists  $\tau : V \rightarrow \mathbb{R}^d$  realizing  $G$  in the  $\ell_p$ -metric.

In this paper, we will be mainly interested in the contact dimension of bipartite graphs. Specifically, [21] only consider the contact dimension of the biclique  $K_{n,n}$ . Notice that a realization of biclique ensures that vertices on the same side are far from each other while vertices on different sides are close to each other preserving the optimum of BCP; these are exactly the desired properties of a gadget outlined above. Using this, [21] give a reduction from BCP to CP which shows that the two are computationally equivalent whenever  $d = \Omega(\text{cd}_p(K_{n,n}))$ , as follows.

<sup>6</sup> We can reduce an instance of CP to an instance of BCP by randomly partitioning the input set of CP instance into two, and the optimal closest pair of points will be in different sets with probability  $1/2$  (and this reduction can be made deterministic).

## 17:6 On Closest Pair in Euclidean Metric

Let  $A, B \subseteq \mathbb{R}^d$  each of cardinality  $n$  be an instance of BCP and let  $\tau : A \dot{\cup} B \rightarrow \mathbb{R}^{\text{cd}_p(K_{n,n})}$  be a map realizing the biclique  $(A \dot{\cup} B, A \times B)$  in the  $\ell_p$ -metric; we may assume w.l.o.g. that  $\beta = 1$ . Let  $\delta$  be the distance between any point in  $A$  and any point in  $B$  (i.e.,  $\delta$  is an upper bound on the optimum of BCP). Let  $\rho > 0$  be such that  $\|\tau(\mathbf{a}) - \tau(\mathbf{b})\|_p > 1 + \rho$  for all  $\mathbf{a} \in A, \mathbf{b} \in B$  (and this is guaranteed to exist by (2)). Moreover, let  $k > \delta/\rho$  be any sufficiently large number. Consider the point-sets  $\tilde{A}, \tilde{B} \subseteq \mathbb{R}^{d+\text{cd}_p(K_{n,n})}$  of cardinality  $n$  each defined as

$$\tilde{A} = \{\mathbf{a} \circ (k \cdot \tau(\mathbf{a})) \mid \mathbf{a} \in A\}, \quad \tilde{B} = \{\mathbf{b} \circ (k \cdot \tau(\mathbf{b})) \mid \mathbf{b} \in B\},$$

where  $\circ$  denotes the concatenation between two vectors and  $k \cdot \mathbf{x}$  denotes the usual scalar-vector multiplication (i.e. scaling  $\mathbf{x}$  up by a factor of  $k$ ). For brevity, we write  $\tilde{\mathbf{a}}$  and  $\tilde{\mathbf{b}}$  to denote  $\mathbf{a} \circ (k \cdot \tau(\mathbf{a}))$  and  $\mathbf{b} \circ (k \cdot \tau(\mathbf{b}))$  respectively.

We now argue that, if we can find the closest pair of points in  $\tilde{A} \cup \tilde{B}$ , then we also immediately solve BCP for  $(A, B)$ . More precisely, we claim that  $(\mathbf{a}^*, \mathbf{b}^*) \in A \times B$  is a bichromatic closest pair of  $(A, B)$  if and only if  $(\tilde{\mathbf{a}}^*, \tilde{\mathbf{b}}^*)$  is a closest pair of  $\tilde{A} \cup \tilde{B}$ .

To see that this is the case, observe that, for cross pairs  $(\tilde{\mathbf{a}}, \tilde{\mathbf{b}}) \in \tilde{A} \times \tilde{B}$ , (1) implies that the distance  $\|\tilde{\mathbf{a}} - \tilde{\mathbf{b}}\|_p$  is exactly  $(k^p + \|\mathbf{a} - \mathbf{b}\|_p^p)^{1/p}$ ; hence, among these pairs,  $(\tilde{\mathbf{a}}^*, \tilde{\mathbf{b}}^*)$  is a closest pair iff  $(\mathbf{a}^*, \mathbf{b}^*)$  is a bichromatic closest pair in  $A, B$ . Notice also that, since the bichromatic closest pair in  $A, B$  is of distance at most  $\delta$ , the closest pair in  $\tilde{A} \cup \tilde{B}$  is of distance at most  $(k^p + \delta^p)^{1/p} \leq k + \delta$ .

On the other hand, for pairs both from  $\tilde{A}$  or both from  $\tilde{B}$ , the distance must be at least  $k(1 + \rho)$ , which is more than  $k + \delta$  from our choice of  $k$ . As a result, these pairs cannot be a closest pair in  $\tilde{A} \cup \tilde{B}$ , and this concludes the sketch of the proof.

There are a couple of details that we have glossed over here: one is that the gap  $\rho$  cannot be too small (e.g.,  $\rho$  cannot be as small as  $1/2^n$ ) and the other is that we should be able to construct  $\tau$  efficiently. Nevertheless, these are typically not an issue.

[21] show that  $\text{cd}_p(K_{n,n}) = \Theta(\log n)$  when  $p > 2$  and that the realization can be constructed efficiently and with sufficiently large  $\rho$ . This implies the subquadratic hardness of CP (by reduction from BCP) in the  $\ell_p$ -metric for all  $p > 2$  and  $d = \omega(\log n)$ . However, it was known that  $\text{cd}_2(K_{n,n}) = \Theta(n)$  [24]. Thus, they could *not* extend their conditional lower bound to CP in the Euclidean metric<sup>7</sup> even when  $d = o(n)$ . In fact, this is a serious obstacle as it rules out many natural approaches to reduce BCP to CP in a black-box manner. Elaborating, the lower bound on  $\text{cd}_2(K_{n,n})$  rules out local gadget reductions which would replace each point with a composition of that point and a gadget with a small increase in the number of dimensions, as such gadgets can be used to construct a realization of  $K_{n,n}$  in the Euclidean metric in a low dimensional space, contradicting the lower bound on  $\text{cd}_2(K_{n,n})$ .

**Overcoming the Obstacle: Beyond Biclique.** We overcome the above obstacle by considering dense bipartite graphs, instead of the biclique. More precisely, we show that there exists a balanced bipartite graph  $G^* = (A^* \dot{\cup} B^*, E^*)$  on  $2n$  vertices such that  $|E^*| \geq n^{2-o(1)}$  and  $\text{cd}_p(G^*)$  is small (i.e.  $\text{cd}_p(G^*) \leq (\log n)^{\omega(1)}$ ). We give a construction of such a graph below but before we do so, let us briefly argue why this suffices to show that BCP and CP are computationally equivalent (up to  $n^{o(1)}$  multiplicative overhead in the running time) for dimension  $d = \Omega(\text{cd}_p(G^*))$ .

<sup>7</sup> Note that plugging in the bound on  $\text{cd}_2(K_{n,n})$  in the result of [21] yields that assuming SETH, no subquadratic in  $n$  running time algorithm can solve CP when  $d = \Omega(n)$ . This is not a meaningful lower bound as just the input size of CP when  $d = \Omega(n)$  is  $\Omega(n^2)$ .

Let us consider the same reduction which produces  $\tilde{A}, \tilde{B}$  as before, but instead of using a realization of the biclique, we use a realization  $\tau$  of  $G^*$ . This reduction is of course incorrect: if  $(\mathbf{a}^*, \mathbf{b}^*)$  is not an edge in  $G^*$ , then  $\|\tau(\mathbf{a}^*) - \tau(\mathbf{b}^*)\|_p$  could be large and, thus the corresponding pair of points  $(\tilde{\mathbf{a}}^*, \tilde{\mathbf{b}}^*) \in \tilde{A} \times \tilde{B}$ , may not be the closest pair. Nevertheless, we are not totally hopeless: if  $(\mathbf{a}^*, \mathbf{b}^*)$  is an edge, then we are in good shape and the reduction is correct.

With the above observation in mind, consider picking a random permutation  $\pi$  of  $A \cup B$  such that  $\pi(A) = A$  and  $\pi(B) = B$  and then initiate the above reduction with the map  $(\tau \circ \pi)$  instead of  $\tau$ . Note that  $\tau \circ \pi$  is simply a realization of an appropriate permutation  $G'$  of  $G^*$  (i.e.,  $G'$  is isomorphic to  $G^*$ ). Due to this, the probability that we are “lucky” and  $(\mathbf{a}^*, \mathbf{b}^*)$  is an edge in  $G'$  is  $p := |E|/n^2$ ; when this is the case, solving CP on the resulting instance would give the correct answer for the original BCP instance. If we repeat this  $\log n/p = n^{o(1)}$  times, we would find the optimum of the original BCP instance with high probability.

To recap, even when  $G^*$  is not a biclique, we can still use it to give a reduction from BCP to CP, except that the reduction produces multiple (i.e.  $\tilde{O}(n^2/|E^*|)$ ) instances of CP. We remark here that the reduction can be derandomized: we can deterministically (and efficiently) pick the permutations so that the permuted graphs covers  $K_{n,n}$ . As a minor digression, we would like to draw a parallel here with a recent work of Abboud, Rubinfeld, and Williams [2]. The obstacle raised in [21] is about the impossibility of certain kinds of many-one gadget reductions. We overcame it by designing a reduction from BCP to CP which not only increased the number of dimensions but also the number of points (by creating multiple instances of CP). This technique is also utilized in [2] where they showed the impossibility of Deterministic Distributed PCPs (Theorem I.2 in [2]) but then overcame that obstacle by using an advice (which is then enumerated over resulting in multiple instances) to build Non-deterministic Distributed PCPs.

**Constructing a dense bipartite graph with low contact dimension.** We now proceed to construct the desired graph  $G^* = (A^* \cup B^*, E^*)$ . Note that any construction of a dense bipartite graph with contact dimension  $n^{o(1)}$  is non-trivial. This is because it is known that a random graph has contact dimension  $\Omega(n)$  in the Euclidean metric with high probability [49, 13], and therefore our graph construction must be significantly better than a random graph.

Our realization  $\tau^*$  of  $G^*$  will map into a subset of  $\{0, 1\}^{(\log n)^{\omega(1)}}$ . As a result, we can fix  $p = 0$ , since a realization of a graph with entries in  $\{0, 1\}$  in the Hamming-metric also realizes the same graph in every  $\ell_p$ -metric for any  $p \neq \infty$ .

Fix  $g = \omega(1)$ . We associate  $[n]$  with  $\mathbb{F}_q^h$  where  $q = \Theta((\log n)^g)$  is a prime and  $h = \Theta\left(\frac{\log n}{g \cdot \log \log n}\right)$ . Let  $\mathcal{P}$  be the set of all univariate polynomials (in  $x$ ) over  $\mathbb{F}_q$  of degree at most  $h - 1$ . We have that  $|\mathcal{P}| = q^h = n$  and associate  $\mathcal{P}$  with  $A^*$ . Let  $\mathcal{Q}$  be the set of all univariate monic polynomials (in  $x$ ) over  $\mathbb{F}_q$  of degree  $h$ , i.e.,

$$\mathcal{Q} = \{x^h + p(x) \mid p(x) \in \mathcal{P}\}.$$

We associate the polynomials in  $\mathcal{Q}$  with the vertices in  $B^*$  (note that  $|\mathcal{Q}| = n$ ). In fact, we view the vertices in  $A^*$  and  $B^*$  as being uniquely labeled by polynomials in  $\mathcal{P}$  and  $\mathcal{Q}$  respectively. For notational clarity, we write  $p_a$  (resp.  $p_b$ ) to denote the polynomial in  $\mathcal{P}$  (resp.  $\mathcal{Q}$ ) that is associated to  $a \in A^*$  (resp.  $b \in B^*$ ).

For every  $a \in A^*$  and  $b \in B^*$ , we include  $(a, b)$  as an edge in  $E^*$  if and only if the polynomial  $p_b - p_a$  (which is of degree  $h$ ) has  $h$  distinct roots. This completes the construction of  $G^*$ . We have to now show the following two claims about  $G^*$ : (i)  $|E^*| = n^{2-O(1/g)} = n^{2-o(1)}$  and (ii) there is  $\tau : A^* \dot{\cup} B^* \rightarrow \{0, 1\}^{(\log n)^{O(g)}} = \{0, 1\}^{(\log n)^{\omega(1)}}$  that realizes  $G^*$ .

To show (i), let  $\mathcal{R}$  be the set of all monic polynomials of degree  $h$  with  $h$  distinct roots. We have that  $|\mathcal{R}| = \binom{q}{h}$ . Fix a vertex  $a \in A^*$ . Its degree in  $G^*$  is exactly  $|\mathcal{R}| = \binom{q}{h}$ . This is because, for every polynomial  $r \in \mathcal{R}$ ,  $r + a$  belongs to  $\mathcal{Q}$ , and therefore  $(a, r + a) \in E^*$ . This implies the following bound on  $|E^*|$ :

$$|E^*| = q^h \cdot \binom{q}{h} \geq q^h \cdot \frac{q^h}{h^h} > \frac{n^2}{(\log n)^{\Theta((\log n)/(g \cdot \log \log n))}} = n^{2-O(1/g)}.$$

Next, to show (ii), we construct a realization  $\tau^* : A^* \dot{\cup} B^* \rightarrow \mathbb{F}_q^q$  of  $G^*$ . We note that, it is simple to translate the entries to  $\{0, 1\}$  instead of  $\mathbb{F}_q$ , by replacing  $i \in \mathbb{F}_q$  with the  $i$ -th standard basis  $\mathbf{e}_i \in \{0, 1\}^q$ . This would result in a realization  $\tau^* : A^* \dot{\cup} B^* \rightarrow \{0, 1\}^{q^2}$  of  $G^*$ ; notice that the dimension of  $\tau^*$  is  $q^2 = \Theta((\log n)^{2g})$  as claimed.

We define  $\tau^*$  as follows.

- For every  $a \in A^*$ ,  $\tau^*(a)$  is simply the vector of evaluation of  $p_a$  on every element in  $\mathbb{F}_q$ . More precisely, for every  $j \in [q]$ , the  $j$ -th coordinate of  $\tau^*(a)$  is  $p_a(j - 1)$ .
- Similarly, for every  $b \in B^*$  and  $j \in [q]$ , the  $j$ -th coordinate of  $\tau^*(b)$  is  $p_b(j - 1)$ .

We now show that  $\tau^*$  is indeed a realization of  $G^*$ ; specifically, we show that  $\tau^*$  satisfies (1) and (2) with  $\beta = q - h$ .

Consider any edge  $(a, b) \in E^*$ . Notice that  $\|\tau^*(a) - \tau^*(b)\|_0$  is the number of  $x \in \mathbb{F}_q$  such that  $p_b(x) - p_a(x) \neq 0$ . By definition of  $E^*$ ,  $p_b - p_a$  is a polynomial with  $h$  distinct roots over  $\mathbb{F}_q$ . Thus,  $\|\tau^*(a) - \tau^*(b)\|_0 = q - h = \beta$  as desired.

Next, consider a non-edge  $(a, b) \in (A^* \times B^*) \setminus E^*$ . Then, we know that  $p_b - p_a$  has at most  $h - 1$  distinct roots over  $\mathbb{F}_q$ . Therefore, the polynomial  $p_b - p_a$  is non-zero on at least  $q - h + 1$  coordinates. This implies that  $\|\tau^*(a) - \tau^*(b)\|_0 \geq q - h + 1 > \beta$ .

Finally, for any distinct  $a, a' \in A^*$ , we have  $\|\tau^*(a) - \tau^*(a')\|_0 \geq q - h + 1$  because  $p_a - p_{a'}$  is a non-zero polynomial of degree at most  $h - 1$  and thus can be zero over  $\mathbb{F}_q$  in at most  $h - 1$  locations. Similarly,  $\|\tau^*(b) - \tau^*(b')\|_0 \geq q - h + 1$  for any distinct  $b, b' \in B^*$ .

This completes the proof sketch for both the claims about  $G^*$  and yields Theorem 4 for  $d = (\log n)^{\omega(1)}$ . Finally we remark that in the actual proof of Theorem 4, we will set the parameters in the above construction more carefully and achieve the bound  $\text{cd}_p(G^*) = (\log n)^{O_\varepsilon(1)}$ .

## 2.2 Abstracting the Construction via Error-Correcting Codes

Before we move on to discuss the proofs of Theorems 6 and 5, let us give an abstraction of the construction in the previous subsection. This will allow us to easily generalize the construction for the aforementioned theorems, and also to explain where our motivation behind the construction comes from in the first place.

**Dense Bipartite Graph with Low Contact Dimension from Codes.** In order to construct a balanced bipartite graph  $G^*$  on  $2n$  vertices with  $n^{2-o(1)}$  edges such that  $\text{cd}_p(G^*) \leq d^*$ , it suffices to have a code  $C^*$  with the following properties:

- $C^* \subseteq \mathbb{F}_q^\ell$  of cardinality  $n$  is a linear code with block length  $\ell$  over alphabet  $\mathbb{F}_q$ , and minimum distance  $\Delta$ .
- There exists a *center*  $s^* \in \mathbb{F}_q^\ell$  and  $r^* < \Delta$  such that  $|C^*|^{1-o(1)}$  codewords are at Hamming distance exactly  $r^*$  from  $s^*$  and no codeword is at distance less than  $r^*$  from  $s^*$ .
- $q \cdot \ell = d^*$ .

We also require that  $C^*$  and  $s^*$  can be constructed in  $\text{poly}(n)$  time but we shall ignore this requirement for the ease of exposition.

We describe below how to construct  $G^*$  from  $C^*$ , but first note that the construction of  $G^*$  we saw in the previous subsection was just showing that Reed Solomon codes [48] of block length  $q = \Theta((\log n)^g)$  and message length  $h = \Theta\left(\frac{\log n}{g \cdot \log \log n}\right)$  over alphabet  $\mathbb{F}_q$  with minimum distance  $q - h + 1$  has the above properties. The center  $s^*$  in that construction was the evaluation of the polynomial  $x^h$  over  $\mathbb{F}_q$ , and  $r^*$  was  $q - h$ .

In general, to construct  $G^*$  from  $C^*$ , we first define a subset  $S^* \subseteq \mathbb{F}_q^\ell$  of cardinality  $n$  as follows:

$$S^* = \{s^* + \mathbf{c} \mid \mathbf{c} \in C^*\}.$$

We associate the vertices in  $A^*$  with the codewords of  $C^*$  and vertices in  $B^*$  with the strings in  $S^*$ . For any  $(\mathbf{a}, \mathbf{b}) \in A^* \times B^*$ , let  $(\mathbf{a}, \mathbf{b}) \in E^*$  if and only if  $\|\mathbf{b} - \mathbf{a}\|_0 = r^*$ . This completes the construction of  $G^*$ . We have to now show the following claims about  $G^*$ : (i)  $|E^*| = n^{2-o(1)}$  and (ii) there is  $\tau : A^* \dot{\cup} B^* \rightarrow \{0, 1\}^{q \cdot \ell}$  that realizes  $G^*$ .

Item (i) follows rather easily from the properties of  $C^*$  and  $s^*$ . Let  $T^*$  be the subset of  $C^*$  of all codewords which are at distance exactly equal to  $r^*$  from  $s^*$ . From the definition of  $s^*$ , we have  $|T^*| = |C^*|^{1-o(1)}$ . Fix  $\mathbf{a} \in A^*$ . Its degree in  $G^*$  is  $|T^*| = |C^*|^{1-o(1)}$ . This is because for every codeword  $\mathbf{t} \in T^*$  we have that  $\mathbf{t} - \mathbf{a}$  is a codeword in  $C^*$  (from the linearity of  $C^*$ ) and thus  $s^* - \mathbf{t} + \mathbf{a}$  is in  $S^*$ , and therefore  $(\mathbf{a}, s^* - \mathbf{t} + \mathbf{a}) \in E^*$ .

For item (ii), consider the identity mapping  $\tau^* : A^* \dot{\cup} B^* \rightarrow \mathbb{F}_q^\ell$  that maps each string to itself. It is simple to check that  $\tau^*$  realizes  $G^*$  in the Hamming metric (with  $\beta = r^*$ ).

Recall from the previous subsection that given  $\tau^* : A^* \dot{\cup} B^* \rightarrow \mathbb{F}_q^\ell$  that realizes  $G^*$  in the Hamming metric, it is easy to construct  $\tau : A^* \dot{\cup} B^* \rightarrow \{0, 1\}^{q \cdot \ell}$  that realizes  $G^*$  in the Hamming metric with a  $q$  multiplicative factor blow-up in the dimension. This completes the proof of both the claims about  $G^*$  and gives a general way to prove Theorem 4 given the construction of  $C^*$  and  $s^*$ .

**Finding Center from Another Code.** One thing that might not be clear so far is: where does the center  $s^*$  come from? Here we provide a systematic way to produce such an  $s^*$ , by looking at another code that contains  $C^*$ . More precisely, let  $C^* \subseteq \tilde{C}^* \subseteq \mathbb{F}_q^\ell$  be two linear codes with the same block length and alphabet. Suppose that the distance of  $C^*$  is  $\Delta$ , the distance of  $\tilde{C}^*$  is  $r^*$  and that  $r^* < \Delta$ . It is easy to see that, by taking  $s^*$  to be any element of  $\tilde{C}^* \setminus C^*$ , it holds that every codeword in  $C^*$  is at distance at least  $r^*$  from  $s^*$ , simply because both  $s^*$  and the codewords of  $C^*$  are codewords of  $\tilde{C}^*$ .

Hence, we are only left to argue that there are many codewords of  $C^*$  that is of distance exactly  $r^*$  from  $s^*$ . While this is not true in general, we can show by an averaging argument that this is true (for some  $s^* \in \tilde{C}^*$ ) if a large fraction (e.g.  $|C^*|^{-o(1)}$  fraction) of codewords of  $\tilde{C}^*$  has Hamming weight exactly  $r^*$ .

Indeed, viewing in this light, our previous choice of center for Reed-Solomon code (i.e. evaluation of  $x^h$ ) is not coincidental: we simply take  $\tilde{C}^*$  to be another Reed-Solomon code with message length  $h + 1$  (whereas the base code  $C^*$  is of message length  $h$ ).

**Comparison to Locally Dense Codes.** We end this subsection by remarking that the codes that we seek are very similar to locally dense codes [23, 18, 41], which is indeed our inspiration. A *locally dense code* is a linear code of block length  $\ell$  and large minimum distance

$\Delta$ , admitting a ball centered at  $s$  of radius<sup>8</sup>  $r < \Delta$  and containing a large (i.e.  $\exp(\text{poly}(\ell))$ ) number of codewords<sup>9</sup>. Such codes are non-trivial to construct and in particular all known constructions of locally dense codes are using codes that beat the Gilbert-Varshamov (GV) bound [26, 53]; in other words we need to do better than random codes to construct them. This is because (as noted in [23]), for a random code  $C \subseteq \mathbb{F}_q^\ell$  (or any code that does not beat the GV bound), a random point in  $\mathbb{F}_q^\ell$  acting as the center contains in expectation less than one codeword in a ball of radius  $\Delta$ . Of course, this is simply an intuition and not a formal proof that a locally dense code needs to beat the GV bound, since there may be more sophisticated ways to pick a center.

Although the codes we require are similar to locally dense codes, there are differences between the two. Below we list four such differences: the first two makes it *harder* for us to construct our codes whereas the latter two makes it *easier* for us.

- We seek a center  $s^*$  so that no codewords in  $C^*$  lies at distance less than  $r^*$ , as opposed to locally dense codes which allows codewords to be close to  $s^*$ . This is indeed where our idea of using another code  $\tilde{C}^* \supseteq C^*$  comes in, as picking  $s^*$  from  $\tilde{C}^* \setminus C^*$  ensures us that no codeword of  $C^*$  is too close to  $s^*$ .
- Another difference is that we need the number of codewords at distance  $r^*$  from  $s^*$  to be very large, i.e.,  $|C^*|^{1-o(1)}$ , whereas locally dense codes allow for much smaller number of codewords. Indeed, the deterministic constructions from [18, 41] only yield the bound of  $2^{\mathcal{O}(\sqrt{\log |C^*|})}$ . Hence, these do not directly work for us.
- Locally dense codes requires  $r$  to be at most  $(1 - \varepsilon)\Delta$  for some constant  $\varepsilon > 0$ , whereas we are fine with any  $r^* < \Delta$ . In fact, our Reed-Solomon code based construction above only yields  $r^* = \Delta - 1$  which would not suffice for locally dense codes. Nevertheless, as we will see later for inapproximability of CP, we will also need the ratio  $r^*/\Delta$  to be a constant bounded away from 1 as well and, since we need a code with these extraordinary properties, they are very hard to find. Indeed, in this case we only manage to prove a weaker lower bound on gap-CP.
- Finally, we remark that locally dense codes are required to be efficiently constructed in  $\text{poly}(\log |C^*|)$  time, which is part of why it is hard to find. Specifically, while [23] shows that an averaging argument works for a random center, derandomizing this is a big issue and a few subsequent works are dedicated solely to this issue [18, 41]. (We also note that it remains open whether a center can be deterministically found for a variant of locally dense codes used in hardness of parameterized version of the minimum distance problem. See [12] for more details.) On the other hand, brute force search (over all codewords in  $\tilde{C}^*$ ) suffices to find a center for us, as we are allowed construction time of  $\text{poly}(|C^*|)$ .

### 2.3 Inapproximability of Closest Pair and Maximum Inner Product

In this subsection, we sketch our inapproximability results for MIP and CP. Both these results use the same reduction that we had from BCP to CP, except that we now need stronger properties from the gadget, i.e., the previously used notions of contact dimension does not suffice anymore. Below we sketch the required strengthening of the gadget properties and explain how to achieve them.

<sup>8</sup> Clearly, for the ball to contain more than a single codeword, it must be  $r \geq \Delta/2$ . Here we are interested in balls with radius not much bigger than that, say  $r < \gamma \cdot \Delta$  for some constant  $1/2 < \gamma < 1$ .

<sup>9</sup> Strictly speaking, a locally dense code also requires an auxiliary matrix  $T$  used to index these codewords. However, in previous works, finding  $T$  is typically not hard given the center  $s$ . Hence, we ignore  $T$  in our discussion here for the ease of exposition.

### 2.3.1 Approximate Maximum Inner Product

Observe that the gadget we construct for CP in Subsection 2.2 can also be written in terms of inner product as follows: there exists a dense balanced bipartite graph  $G^* = (A^* \dot{\cup} B^*, E^*)$ , a mapping  $\tau : A^* \dot{\cup} B^* \rightarrow \{0, 1\}^{q \cdot \ell}$  such that the following holds.

- (i) For all edges  $(a, b) \in E^*$ ,  $\langle \tau(a), \tau(b) \rangle = \ell - r^*$ .
- (ii) For all edges  $(a, b) \in (A^* \times B^*) \setminus E^*$ ,  $\langle \tau(a), \tau(b) \rangle < \ell - r^*$ .
- (iii) For all distinct  $a, b$  both from  $A^*$  or both from  $B^*$ ,  $\langle \tau(a), \tau(b) \rangle \leq \ell - \Delta$ .

Notice that we wrote the conditions above in a slightly different way than in previous subsections; previously in the contact dimension notation, (ii) and (iii) would be simply written together as: for all non-edge  $(a, b)$ ,  $\langle \tau(a), \tau(b) \rangle < \ell - r^*$ . This change is intentional, since, to get gap in our reductions, we only need a gap between the bounds in (i) and (iii) (but not in (ii)). In particular, to get hardness of approximating MIP, we require  $\frac{\ell - r^*}{\ell - \Delta}$  to be at least  $(1 + \varepsilon)$  for some  $\varepsilon > 0$ .

From our Reed-Solomon construction above,  $\ell - \Delta$  and  $\ell - r^*$  are exactly the message length of  $C^*$  minus one and the message length of  $\tilde{C}^*$  minus one respectively. Previously, we selected these two to be  $h$  and  $h + 1$ . Now to obtain the desired gap, we simply take the larger code  $\tilde{C}^*$  to be a Reed-Solomon code with larger (i.e.  $(1 + \varepsilon)h$ ) message length<sup>10</sup>.

Finally, we note that even with the above gadget, the reduction only gives a small (i.e.  $1 + o(1)$ ) factor hardness of approximating MIP. To boost the gap to near polynomial, we simply tensor the vectors with themselves.

### 2.3.2 Approximate Closest Pair

Once again, recall that we have the following gadget from Subsection 2.2: there exists a dense balanced bipartite graph  $G^* = (A^* \dot{\cup} B^*, E^*)$ , a mapping  $\tau : A^* \dot{\cup} B^* \rightarrow \{0, 1\}^{q \cdot \ell}$  such that the following holds.

- (i) For all edges  $(a, b) \in E^*$ ,  $\|\tau(a) - \tau(b)\|_0 = r^*$ .
- (ii) For all edges  $(a, b) \in (A^* \times B^*) \setminus E^*$ ,  $\|\tau(a) - \tau(b)\|_0 > r^*$ .
- (iii) For all distinct  $a, b$  both from  $A^*$  or both from  $B^*$ ,  $\|\tau(a) - \tau(b)\|_0 \geq \Delta$ .

Once again, we need an  $(1 + \varepsilon)$  gap between the bounds in (iii) and (i), i.e.,  $\frac{\Delta}{r^*}$ . Unfortunately, we cannot construct such codes using any of the Reed-Solomon code families. We turn to another type of codes that beat the Gilbert-Varshamov bound: Algebraic-Geometric (AG) codes. Similar to the Reed-Solomon code based construction, we take  $C^*$  as an AG code and  $\tilde{C}^*$  to be a “higher degree” AG code; getting the desired gap simply means that the distance of  $C^*$  must be at least  $(1 + \varepsilon)$  times the distance of  $\tilde{C}^*$ .

Recall from Subsection 2.2 also that, to bound the density of  $G^*$ , we need a lower bound on the number of minimum weight codewords of  $\tilde{C}^*$ . Such bounds for AG codes are non-trivial and we turn to the bounds from [8, 54]. Unfortunately, this only gives  $G^*$  with density  $|C^*|^{-1/2 - o(1)}$ , instead of  $|C^*|^{-o(1)}$  as before. This is indeed the reason that our running time lower bound for approximate CP is only  $n^{1.5 - \varepsilon}$ .

We are not aware of any result on the (asymptotic) tightness of the bounds from [8, 54] that we use. However, improving upon such bounds would have other consequences, such as a better bound on the kissing numbers of lattices constructed in [54]. As a result, it seems likely that more understanding of AG codes (and perhaps even new constructions) are needed in order to improve these bounds.

<sup>10</sup>This approach can in fact give not just  $(1 + \varepsilon)$  but arbitrarily large constant gap between the two cases. In the actual reduction, we take this gap to be 3, which makes some computations simpler.

### 3 Discussion and Open Questions

It remains open to completely resolve Open Questions 1 and 2. It is still possible that our framework can be used to resolve these problems: we just need to construct gadgets with better parameters! In particular, to resolve Question 2, it suffices to obtain codes which have a much larger fraction of minimum weight codewords than the state-of-the-art algebraic geometric codes while having the desirable properties of algebraic geometric codes (formalized below). This motivates us to ask the following purely coding theoretic question:

► **Open Question 9.** *For every  $0 < \delta < 1$ , are there linear codes  $\mathcal{C}_1 \subseteq \mathcal{C}_2 \subseteq \mathbb{F}_q^N$  both of block length  $N$  over alphabet  $\mathbb{F}_q$  such that the following holds:*

- $\Delta(\mathcal{C}_1) \geq (1 + f(\delta)) \cdot \Delta(\mathcal{C}_2)$ , for some  $f : (0, 1) \rightarrow (0, 1)$ .
- $|A_{\Delta(\mathcal{C}_2)}(\mathcal{C}_2)|/|\mathcal{C}_2| \geq |\mathcal{C}_1|^{-\delta}$ .

Apart from the aforementioned questions, Rubinfeld [50] pointed out an interesting obstacle, aptly dubbed the “triangle inequality barrier”, to obtain fine-grained lower bounds against 3-approximation algorithms for BCP (see Open Question 3 in [50]). In the case of CP, this barrier turns out to be against 2-approximation algorithms as noted in [21]. We reiterate this below as an open problem to be resolved:

► **Open Question 10.** *Can we show that assuming SETH, for some constant  $\varepsilon > 0$ , no algorithm running in time  $n^{1+\varepsilon}$  can solve 2-CP in any metric when the points are in  $\omega(\log n)$  dimensions?*

Another interesting direction is to extend the hardness of MIP to the  $k$ -vector generalization of the problem, called  $k$ -MIP. In  $k$ -MIP, we are given a set of  $n$  points  $P \subseteq \mathbb{R}^d$  and we would like to select  $k$  distinct points  $\mathbf{a}_1, \dots, \mathbf{a}_k \in P$  that maximizes

$$\langle \mathbf{a}_1, \dots, \mathbf{a}_k \rangle := \sum_{j \in [d]} (\mathbf{a}_1)_j \cdots (\mathbf{a}_k)_j.$$

It is known that the  $k$ -chromatic variant of  $k$ -MIP is hard to approximate (see Appendix B of [34]) but this is not known to be true for  $k$ -MIP itself. Our approach seems quite compatible to tackling this problem as well; in particular, if we can construct a certain (natural) generalization of our gadget for MIP, then we would immediately arrive at the inapproximability of  $k$ -MIP even for  $\{0, 1\}$ -entries vectors. The issue in constructing this gadget is that we are now concerned about agreements of more than two vectors, which does not correspond to error-correcting codes anymore and some additional tools are needed to argue for this more general case.

It should be noted that the hardness of approximating  $k$ -MIP for  $\{0, 1\}$ -entry vectors is equivalent to the *one-sided  $k$ -biclique* problem [39], in which a bipartite graph is given and the goal is to select  $k$  vertices on the right that maximize the number of their common neighbors. The equivalence can be easily seen by viewing the coordinates as the left-hand-side vertices and the vectors as the right-hand-side vertices. The one-sided  $k$ -biclique is shown to be  $W[1]$ -hard to approximate by Lin [39] who also showed a lower bound of  $n^{\Omega(\sqrt{k})}$  for the problem assuming ETH. If the generalization of our gadget for  $k$ -MIP works as intended, then this lower bound can be improved to  $n^{\Omega(k)}$  under ETH and even  $n^{k-o(1)}$  under SETH.

The one-sided  $k$ -biclique is closely related to the (two-sided)  $k$ -biclique problem, where we are given a bipartite graph and we wish to decide whether it contains  $K_{k,k}$  as a subgraph. The  $k$ -biclique problem was considered a major open problem in parameterized complexity (see e.g., [22]) until it was shown by Lin to be  $W[1]$ -hard [39]. Nevertheless, the running time

lower bound known is still not tight: currently, the best lower bound known for this problem is  $n^{\Omega(\sqrt{k})}$  both for the exact version (under ETH) [39] and its approximate variant (under Gap-ETH) [14]. It remains an interesting open question to close the gap between the above lower bounds and the trivial upper bound of  $n^{O(k)}$ . Progresses on the one-sided  $k$ -biclique problem could lead to improved lower bounds for  $k$ -biclique problem too, although several additional steps have to be taken care of.

## Abstract

We introduce new forms of attack on *expander-based cryptography*, and in particular on Goldreich’s pseudorandom generator and one-way function. Our attacks exploit *low circuit complexity* of the underlying expander’s neighbor function and/or of the local predicate. Our two key conceptual contributions are:

1. We put forward the possibility that the *choice of expander* matters in expander-based cryptography. In particular, using expanders whose neighbour function has low circuit complexity might compromise the security of Goldreich’s PRG and OWF in certain settings.
2. We show that the security of Goldreich’s PRG and OWF is closely related to two other long-standing problems: Specifically, to the existence of *unbalanced lossless expanders* with low-complexity neighbor function, and to *limitations on circuit lower bounds* (i.e., natural proofs). In particular, our results further motivate the investigation of affine/local unbalanced lossless expanders and of average-case lower bounds against DNF-XOR circuits.

We prove two types of technical results that support the above conceptual messages. First, we *unconditionally break Goldreich’s PRG* when instantiated with a specific expander (whose existence we prove), for a class of predicates that match the parameters of the currently-best “hard” candidates, in the regime of quasi-polynomial stretch. Secondly, conditioned on the existence of expanders whose neighbor functions have extremely low circuit complexity, we present attacks on Goldreich’s generator in the *regime of polynomial stretch*. As one corollary, conditioned on the existence of the foregoing expanders, we show that either the parameters of natural properties for several constant-depth circuit classes *cannot be improved, even mildly*; or Goldreich’s generator is insecure in the regime of a large polynomial stretch, *regardless of the predicate used*.

## 1 Introduction

Theoretical results provide strong evidence that if secure cryptography is possible, then many fundamental primitives such as one-way functions (OWF) and pseudorandom generators (PRG) can be implemented with a dramatic level of efficiency and parallelism. Specifically, security against efficient adversaries can be achieved by functions where each output bit only depends on a constant number of input bits (see, e.g., [6], and also [2] for a survey of recent results).

A concrete type of such construction is a conjectured form of OWF that is based on any *expander graph* and on a *local predicate*. Specifically, about two decades ago, Goldreich [16, 17] suggested the following candidate  $\text{owf} : \{0, 1\}^n \rightarrow \{0, 1\}^n$ . Fix any bipartite graph  $[n] \times [n]$  of right-degree  $\ell \leq O(\log(n))$  in which every set  $S \subseteq [n]$  of size up to  $k$  on the right-hand side has at least (say)  $1.01 \cdot |S|$  neighbors, and also fix a predicate  $P : \{0, 1\}^\ell \rightarrow \{0, 1\}$ . Then, given input  $x \in \{0, 1\}^n$ , each output bit  $\text{owf}(x)_i$  is computed by applying  $P$  to the bits of  $x$  at the  $\ell$  neighbors of  $i \in [n]$ . The expected running-time of a naive algorithm for inverting  $\text{owf}$  is at least  $\exp(k)$  (see, e.g., [17, Sec. 3.2] and [2, Sec. 3.1]), and Goldreich conjectured that for an appropriate predicate  $P$ , no algorithm can perform significantly better.

In an extensive subsequent line of research (see, e.g., [1, 23, 4, 9, 5, 10, 14, 25, 15, 7, 8], and also see [3] for a related survey), Goldreich’s construction was conjectured to yield not only a one-way function, but also a pseudorandom generator  $\text{prg} : \{0, 1\}^n \rightarrow \{0, 1\}^m$ . In fact, in some settings the two conjectures are essentially equivalent (see [8, Sec. 3]).

The question of whether Goldreich’s constructions are secure is a long-standing open problem. Much research has focused on necessary requirements from the *predicate* and from the *parameters* in order for the construction to be secure. Let us, for simplicity of presentation, focus on the PRG. In this case, the locality  $\ell$  cannot be too small: If we want a PRG with super-linear stretch, then we must use  $\ell \geq 5$  [23];<sup>1</sup> and if we want stretch  $m = n^k$  then  $\ell$  must be at least (roughly)  $3k$  (see [25, Thm. II.11]). Also, as shown in [7], the predicate must have *high resilience* (i.e., all of the predicate’s Fourier coefficients corresponding to sets of size at most  $\Omega(\ell)$  are zero; see [26, Def. 3.4]) and high *rational degree* (this is a generalization of the requirement that the degree of the predicate as a polynomial  $\mathbb{F}_2^\ell \rightarrow \mathbb{F}_2$  is  $\Omega(\ell)$ ; see [26, Def. 3.7]).

The foregoing properties capture most existing attacks in the PRG setting. Indeed, as mentioned above, all these attacks exploit vulnerabilities of the *predicate* and of the *parameters*, but not of the underlying expander. In fact, prior to our work, the PRG was conjectured to be secure for *any underlying expander* with sufficiently good expansion properties. For reference, let us state such a strong form of conjectured security of the OWF, from a recent work by Applebaum and Raykov [8]. We say that a bipartite graph

<sup>1</sup> This impossibility result holds for *any* construction of a pseudorandom generator in  $\mathcal{NC}^0$ .

$G = ([n], [m], E)$  with right-degree  $\ell$  is a  $(k, 0.99)$ -expander if for every set  $S \subseteq [m]$  on the right-hand side of size at most  $k$ , the number of neighbors of  $S$  in  $G$  is at least  $0.99 \cdot \ell \cdot |S|$ .<sup>2</sup> Then, the conjecture is the following:

► **Assumption 1** (the strong EOWF assumption). *For a family  $\mathcal{P} = \{P_\ell : \{0, 1\}^\ell \rightarrow \{0, 1\}\}_{\ell \in \mathbb{N}}$  of predicates, the strong EOWF( $\mathcal{P}$ ) assumption is the following. For any  $(n^{.99}, .99)$ -expander  $G = ([n], [m], E)$  of right-degree  $\ell \leq n^{o(1)}$  such that  $n \leq m \leq n^{\alpha \cdot \ell}$ , where  $\alpha > 0$  is a sufficiently small universal constant, Goldreich’s function instantiated with  $G$  and  $P_\ell$  cannot be inverted by circuits of size  $t \leq \exp(\alpha \cdot n^{.99})$  with success probability  $1/t$ .*

Applebaum and Raykov [8] suggested a suitable candidate predicate, which is the predicate  $\text{XOR-MAJ}(x) = (\oplus_{i=1, \dots, \lfloor \ell/2 \rfloor} x_i) \oplus (\text{MAJ}(x_{\lfloor \ell/2 \rfloor + 1}, \dots, x_\ell))$ ; this predicate indeed has both high resiliency and high rational degree.

## 1.1 A high-level digest of our contributions

Our main contribution is a *new form of attack* on Goldreich’s pseudorandom generator, which exploits *computational complexity* properties (and, in particular, circuit complexity properties) of the expander and/or of the predicate on which the generator is based. In particular, our distinguishers are algorithms associated with *natural properties*, in the sense of Razborov and Rudich [28]. (Recall that a natural property against a circuit class  $\mathcal{C}$  is an efficient algorithm that distinguishes a random string, interpreted as a truth table, from truth tables of  $\mathcal{C}$ -circuits.)<sup>3</sup>

We use our new form of attack to break the generator when it is instantiated with predicates that are sufficiently “strong” to withstand known attacks, but with expanders whose neighbor function has “low” circuit complexity. In high-level, the main conceptual implications of these results are the following:

1. The conjecture that the PRG and OWF are secure with *any expander*, given an appropriate predicate, *might be too naive*. In particular, the security of the constructions might crucially hinge on a choice of expander whose neighbor function has sufficiently high circuit complexity. Alternatively, if the latter is not true (i.e., if the PRG and OWF can be secure given any expander), then the predicate must have sufficiently high circuit complexity for the constructions to be secure in some settings (i.e., when the stretch is quasi-polynomial).

Note that a random graph will (with high probability) not only be an expander, but also have a neighbor function with high circuit complexity. Therefore, our results do not put into question the security of the PRG and OWF when instantiated with a random graph.

2. There are significant interdependencies between *the security of Goldreich’s PRG and OWF*, the existence of *unbalanced lossless expanders* with low-complexity neighbor function, and *limitations on circuit lower bounds* (i.e., natural proofs). Moreover (as further explained below), the questions motivated by our results are closely related both to existing results and to long-standing open problems in each area.

<sup>2</sup> We stress that lossless expansion (i.e., expansion to  $\alpha \cdot \ell \cdot |S|$  vertices for  $\alpha > 1/2$ ) is crucial in the PRG setting. To see this, note that one can duplicate a right-vertex in a  $(k, 0.99)$ -expander: This will produce a graph that, on the one hand, has good (but not lossless!) expansion properties, and on the other hand yields a corresponding PRG that is clearly insecure, regardless of the predicate.

<sup>3</sup> Natural properties are typically used to break *pseudorandom functions*, but the idea of using natural properties to break pseudorandom generators goes back to [28, Thm. 4.2]. Nevertheless, implementing this idea in our setting presents specific new challenges; for further discussion see Section 2.4.

Being more specific, we unconditionally break Goldreich’s generator in the setting of quasi-polynomial stretch when it is instantiated with predicates with *high resilience and rational degree*, but with an expander whose neighbor function can be computed by  $\mathcal{AC}^0[\oplus]$  circuits of (small) subexponential size. In fact, our predicates are variations on the specific XOR-MAJ predicate mentioned above. Using a known reduction of PRGs to OWFs (by [8]), it follows that Assumption 1 *does not* hold for some predicates with high resilience and rational degree. To prove this result we actually prove the *existence* of expanders with neighbor function as above; the latter proof, which uses certain *unconditional* PRGs that can be computed in a *strongly explicit* fashion, might be of independent interest. (See Section 1.2.)

In the regime of polynomial stretch, we put forward two assumptions about plausible extensions of known expander constructions in which the neighbor functions have even lower circuit complexity (compared to the expander mentioned above). Conditioned on *any* of the two assumptions, we show that exactly one of two options holds: Either the parameters of natural properties for certain restricted constant-depth circuit classes *cannot be improved, even mildly*; or Goldreich’s generator is insecure in the regime of a large polynomial stretch, *regardless of the predicate used*. (See Section 1.3.)

Some important cryptographic applications crucially rely on the security of expander-based PRGs with polynomial, or even linear, stretch (see, e.g., [3, Sec. 4, “The Stretch”] and the references therein). We stress that our results for the setting of polynomial stretch are conditional on the existence of suitable expanders, and only break the PRG and OWF if there are natural properties for constant-depth circuit classes beyond what is currently known. Thus, further investigation is needed to determine whether our results have implications on the security of the aforementioned applications.

## 1.2 Unconditional results for quasi-polynomial stretch

Our main result for the setting of quasi-polynomial stretch is an attack that *unconditionally breaks* Goldreich’s PRG when it is instantiated with a *specific expander that has optimal expansion properties*, and with a class of predicates that have both high resilience and high rational degree. Specifically:

► **Theorem 2** (unconditional attack on Goldreich’s PRG with quasi-polynomial stretch; informal). *For every  $d \in \mathbb{N}$  and sufficiently large  $k, c \in \mathbb{N}$  there exists a deterministic polynomial-time algorithm  $A$  that satisfies the following. Let  $n \in \mathbb{N}$  be sufficiently large, let  $m = n^{\log^k(n)}$ , and let  $\ell = c \cdot \log^k(n)$ . Then, there exists an  $(n^{0.99}, 0.99)$ -expander  $G = ([n], [m], E)$  of right-degree  $\ell$  such that for any predicate  $P : \{0, 1\}^\ell \rightarrow \{0, 1\}$  that can be computed by an  $\mathcal{AC}^0[\oplus]$  circuit of depth  $d$  and sufficiently small sub-exponential size, when Goldreich’s generator is instantiated with the expander  $G$  and the predicate  $P$ , the algorithm  $A$  distinguishes the  $m$ -bit output of the generator from a uniform  $m$ -bit string (with gap  $> 1/2$ ).*

In fact, we actually prove a more general theorem, which exhibits a trade-off between the locality  $\ell$  and the size of the  $\mathcal{AC}^0[\oplus]$  circuit for the predicate  $P$  (for a precise statement see [26, Thm. 4.6]). That is, we are able to break the generator even with much larger locality (e.g.,  $\ell = n^{0.01}$ ), at the expense of using a more restricted predicate family, namely that of  $\mathcal{AC}^0[\oplus]$  circuits of smaller size (e.g., polynomial size). We stress that even the latter predicate family is rich enough to contain predicates that have both high resilience and high rational degree (see below).

Recall that the property of the expander  $[n] \times [m]$  that we exploit in our attack is that its *neighbor functions* (i.e., the functions  $\Gamma_i : [m] \rightarrow [n]$  for  $i \in [\ell]$ ) have *low circuit complexity*. The expander in Theorem 2 in particular has neighbor functions that can be computed by  $\mathcal{AC}^0[\oplus]$  circuits of small sub-exponential size, and we prove its existence in [26, Sec. 4.1] (see Section 2.2 for a high-level description).

Combining Theorem 2 with Applebaum and Raykov’s reduction of expander-based PRGs to expander-based OWFs [8, Thm. 3.1] (i.e., they prove that if an arbitrary instance of Goldreich’s OWF is secure, then a closely-related instance of Goldreich’s PRG is also secure), our attack also breaks Goldreich’s OWF. Specifically, we say that a predicate  $P : \{0, 1\}^\ell \rightarrow \{0, 1\}$  is *sensitive* if it is “fully sensitive” to one of its coordinates (i.e., if for all  $x \in \{0, 1\}^\ell$  it holds that  $P(x) = x_i \oplus P'(x)$ , for some  $i \in [\ell]$  and  $P'$  that does not depend on  $x_i$ ). Then:

► **Corollary 3** (unconditional attack on Goldreich’s OWF with quasi-polynomial stretch; informal). *There exists a probabilistic polynomial-time algorithm  $A'$  that satisfies the following. Let  $n \in \mathbb{N}$  be sufficiently large, let  $m' = n^{k' = \text{poly} \log(n)}$ , and let  $\ell = O(k')$ . Then, there exists an  $(n^{0.99}, 0.99)$ -expander  $G = ([n], [m'], E)$  of right-degree  $\ell$  such that for any sensitive predicate  $P : \{0, 1\}^\ell \rightarrow \{0, 1\}$  that can be computed by an  $\mathcal{AC}^0[\oplus]$  circuit of sufficiently small sub-exponential size, when Goldreich’s one-way function is instantiated with the expander  $G$  and the predicate  $P$ , the algorithm  $A$  inverts the function with success probability  $\Omega(1/m'n)$ .*

As immediate corollaries of Theorem 2 and of Corollary 3, we deduce that Assumption 1 does not hold for any sensitive predicate family that can be computed by  $\mathcal{AC}^0[\oplus]$  circuits of sufficiently small sub-exponential size; and similarly, that the “PRG analogue” of Assumption 1, denoted  $EPRG(\mathcal{P})$  in [8], does not hold for any predicate family that can be computed by  $\mathcal{AC}^0[\oplus]$  circuits of sufficiently small sub-exponential size.

Recall that Applebaum and Raykov suggested the candidate predicate XOR-MAJ; we prove that when replacing majority by *approximate majority* (see [26, Def. 4.9]), the resulting predicate XOR-APPROX-MAJ still has both high resilience and high rational degree, and can also be computed by a polynomial-sized  $\mathcal{AC}^0[\oplus]$  circuit (see [26, Sec. 4.3.2]). Thus, the predicate families in Theorem 2 and Corollary 3 contain predicates with high resilience and high rational degree, and even predicates that are variations on the “hard” candidate XOR-MAJ.<sup>4</sup>

Moreover, the predicate XOR-APPROX-MAJ does not even use the “full power” of the predicate family for which Theorem 2 allows us to break Goldreich’s generator – the predicate XOR-APPROX-MAJ is computable by a circuit of polynomial size, whereas we can break the generator when the predicate can be computed by a circuit of sub-exponential size. We use this to our advantage by relying on the more general version of Theorem 2 (i.e., [26, Thm. 4.6]), which exhibits a trade-off between locality and the predicate class. Specifically, we obtain the following theorem, which breaks the generator even when the locality  $\ell$  is large (e.g.,  $\ell = n^{\Omega(1)}$ ) and the predicate has high resilience and rational degree:

► **Theorem 4** (breaking Goldreich’s generator with XOR-APPROX-MAJ and high locality). *There exists  $s > 1$  such that the following holds. Let  $n \in \mathbb{N}$ , let  $m = n^{k = (\log(n))^s}$ , and let  $c \cdot k \leq \ell \leq n^{1/c}$ , where  $c$  is a sufficiently large constant. Then, there exists an  $(n^{0.99}, 0.99)$ -expander  $G = ([n], [m], E)$  of right-degree  $\ell$  and a predicate  $P : \{0, 1\}^\ell \rightarrow \{0, 1\}$  with resilience  $\Omega(\ell)$  and rational degree  $\Omega(\ell)$  (i.e., the predicate XOR-APPROX-MAJ) such that the following holds: When Goldreich’s generator is instantiated with the expander  $G$  and the predicate  $P$ , the output of the generator can be distinguished from a uniform string (with gap  $> 1/2$ ) by a deterministic  $\text{poly}(m)$ -time algorithm.*

<sup>4</sup> Indeed, the main difference between XOR-MAJ and XOR-APPROX-MAJ seems to be in their *circuit complexity*, which corresponds to our main point that circuit complexity considerations are crucial for the security of Goldreich’s PRG and OWF.

### 1.3 Conditional results for large polynomial stretch

Recall that the conjectured “hardness” of Goldreich’s PRG (i.e., Assumption 1) refers both to the regime of polynomial stretch and to the regime of quasi-polynomial stretch (as long as the locality is sufficiently large to support the corresponding stretch). Could it be that complexity-based attacks separate these two parameter regimes? That is, could the reason that our attacks from Section 1.2 work be that the stretch of the generator is super-polynomial?

As mentioned in Section 1.1 (and will be explained in Section 2), the underlying technical components in our complexity-based attacks are *unbalanced lossless expanders*  $[n] \times [m]$  whose neighbor functions have low circuit complexity, and *natural properties* against weak circuit classes. Our main results for the polynomial-stretch regime are of the following form: If lossless expanders  $[n] \times [n^{O(1)}]$  with constant degree and (specific) “very simple” neighbor functions exist, then exactly one of two cases holds:

1. Either the parameters of natural properties for certain well-studied weak circuit classes *cannot be improved*, even mildly; or
2. For a sufficiently large polynomial stretch, Goldreich’s generator is insecure when instantiated with a specific expander, *regardless of the predicate used*.

We now present two plausible assumptions on existence of suitable expanders, which are essentially improvements or extensions of existing explicit constructions. Conditioned on each assumption, we will contrast the security of Goldreich’s PRG with the possibility of extending natural proofs for some well-studied circuit class.

#### 1.3.1 Affine expanders and DNF-XOR circuits

As motivation for our first assumption, let us recall two well-known *explicit* constructions of unbalanced lossless expanders, which were given by Ta-Shma, Umans, and Zuckerman [30], and later on by Guruswami, Umans, and Vadhan [19]. We note that these two constructions are inherently different (the relevant construction from [30] is combinatorial, whereas the construction of [19] is algebraic), and yet in both constructions the neighbor function of the expander can be computed by *single layer of parity gates* (see [26, Sec. 5.1] for further details); we will call expanders with such a neighbor function *affine expanders*.

In the two foregoing affine expanders, the right-degree  $\ell$  is polylogarithmic, and it is an open problem to improve the degree to be constant, which matches the degree of a random construction. However, a random construction is not necessarily affine. Our first assumption is that there indeed exists an *affine expander* with *constant degree*:

► **Assumption 5** (expanders with an affine neighbor function; informal, see [26, Ass. 5.4]). *There exists  $\beta > 3$  such that for every constant  $k \in \mathbb{N}$  and sufficiently large  $n \in \mathbb{N}$ , there exists an  $(n^{.99}, 0.99)$ -expander  $G = ([n], [m = n^k], E)$  with right-degree  $\ell = \beta \cdot k$  whose neighbor function  $\Gamma_G : [m] \rightarrow ([n])^\ell$  can be computed by a single layer of parity gates.*

An unconditional proof of Assumption 5 will contrast the security of Goldreich’s PRG with the possibility of extending the known natural properties for DNF-XOR *circuits of exponential size*.<sup>5</sup> Specifically, known lower bounds for DNF-XOR circuits yield natural

---

<sup>5</sup> Recall that DNF-XOR circuits are depth-3 circuits that consist of a top OR gate, a middle layer of AND gates, and a bottom layer of parities above the inputs.

properties useful against such circuits of size up to  $2^{(1-o(1))\cdot n}$  (see [26, Sec. 5.1.2]).<sup>6</sup> Can these natural properties be extended to functions that are *approximated*, in the average-case sense, by DNF-XOR circuits of size  $2^{\epsilon n}$ , for some  $\epsilon > 0$ ? This is the natural property that we contrast with the security of Goldreich’s PRG:

► **Theorem 6** (is Goldreich’s generator insecure, or are natural properties for DNF-XOR circuits “non-extendable”?; informal statement). *Suppose that Assumption 5 holds. Then, exactly one of the following two options holds:*

1. *For all  $\epsilon > 0$ , there does not exist a natural property for the class of functions that can be approximated with success  $1/2 + o(1)$  by DNF-XOR circuits of size  $2^{\epsilon n}$ .*
2. *For a sufficiently large  $k \in \mathbb{N}$ , Goldreich’s generator is insecure with stretch  $m = n^k$  and locality  $\ell = \beta \cdot k$ , for some expander and regardless of the local predicate used.*

We stress that for any value of  $\beta > 3$  such that Assumption 5 holds, Theorem 6 follows with that value of  $\beta$ . Also note that Cohen and Shinkar [13] specifically conjectured that strong average-case lower bounds for DNF-XOR circuits of size  $2^{\Omega(n)}$  hold, and proved a similar statement for the related-yet-weaker model of parity decision trees. (Their proof for parity decision trees indeed yields a natural property; see [26, Prop. 5.13].)

### 1.3.2 $\mathcal{NC}^0$ expanders and weak $\mathcal{AC}_4^0$ circuits

To motivate our next assumption, recall the recent explicit construction of lossless expanders by Viola and Wigderson [33, Thm. 4] (which builds on the well-known construction of Capalbo *et al.* [11]). In this construction the neighbor function can be computed by an  $\mathcal{NC}^0$  circuit, but this construction is only for *balanced* expanders, rather than unbalanced ones. The following assumption is that such a construction is possible also for unbalanced expanders:

► **Assumption 7** (expanders with  $\mathcal{NC}^0$  neighbor functions; informal, see [26, Ass. 5.19]). *There exists  $\beta > 3$  such that for every constant  $k \in \mathbb{N}$  and sufficiently large  $n \in \mathbb{N}$ , there exists an  $(n^{.99}, 0.99)$ -expander  $G = ([n], [m = n^k], E)$  with right-degree  $\ell = \beta \cdot k$  such that the neighbor function  $\Gamma_G : [m] \rightarrow ([n])^\ell$  can be computed by an  $\mathcal{NC}^0$  circuit.*

An unconditional proof of Assumption 7 will immediately break Goldreich’s PRG in the polynomial-stretch regime by a complexity-based attack, when instantiated with a weak (but non-trivial) predicate class; see [26, Prop. 5.25]. But more importantly, such a proof will contrast the security of Goldreich’s PRG with the possibility of extending the known natural properties for the class of exponential-sized  $\mathcal{AC}^0$  circuits of depth four with constant bottom fan-in and top fan-in.

Since the precise trade-off between the parameters is a bit subtle, let us present the theorem in a simplified form (for a discussion of the more general setting, see [26, Sec. 5.2], and in particular [26, Sec. 5.2.3]). To do so, consider the (optimistic) possibility that in Assumption 7, there exists a single  $t$  such for any  $k \in \mathbb{N}$  the arity of the  $\mathcal{NC}^0$  circuit is  $t$  (i.e., each output bit of the circuit is a function of at most  $t$  input bits, where  $t$  does not depend on  $k$ ); as far as we are aware of, such a hypothesis is possible even with  $t = 1$ . Relying on Håstad’s switching lemma [21], for any  $c = O(1)$  there exists a natural property against depth-four circuits with top fan-in  $c$ , bottom fan-in  $t$ , and size  $2^{\epsilon \cdot (n/\log(c))}$  for a tiny universal

<sup>6</sup> Some of these natural properties actually run in slightly super-polynomial time, rather than in strictly polynomial time, but this issue is not crucial for our purpose of breaking Goldreich’s PRG.

$\epsilon > 0$  (see [26, Cor. 5.24]). In the following theorem, the security of Goldreich’s PRG is contrasted with the possibility of extending these natural properties to work against such circuits of size  $2^{\beta \cdot (n/\log(c))}$  where  $\beta > 3$ .

► **Theorem 8** (is Goldreich’s generator insecure, or are natural properties for very restricted  $\mathcal{AC}^0$  circuits “non-extendable”?; informal statement). *Suppose that Assumption 7 holds and that for any  $k \in \mathbb{N}$ , the arity of the  $\mathcal{NC}^0$  circuit equals  $t = O(1)$ . Then, exactly one of the following two options holds:*

1. *For any  $c \in \mathbb{N}$ , there does not exist a natural property for depth-four  $\mathcal{AC}^0$  circuits with top fan-in  $c$  and bottom fan-in  $t$  and size  $O(2^{\beta \cdot (n/\log(c))})$ .*
2. *For a sufficiently large  $k \in \mathbb{N}$ , Goldreich’s generator is insecure with stretch  $m = n^k$  and predicate locality  $\ell = \beta \cdot k$ , for some expander and regardless of the predicate used.*

Recall that Assumption 7 is parametrized by  $\beta$  and by the arity of the  $\mathcal{NC}^0$  circuit; we stress that for *any* values of  $\beta$  and  $t$  such that Assumption 7 holds, we get a corresponding “win-win” theorem such as Theorem 8 (for further details see [26, Sec. 5.2]). We also stress that both the natural properties that we can unconditionally prove and the natural properties referred to in Theorem 8 are for circuits of exponential size  $2^{\Theta(n/\log(c))}$ , and the difference is in the universal constant hidden in the  $\Theta$ -notation.

As mentioned in Section 1.1, the *explicit* construction of highly unbalanced lossless expanders is a long-standing open problem, regardless of the circuit complexity of their neighbor function (see, e.g., [11], [32, Prob. 5.36 & 6.35], and [34, Chap. 8.7]). Assumptions 5 and 7, however, *do not concern explicit constructions* of expanders, but only assume their *existence*; in particular, the circuit family for the neighbor function of the graph may be *non-uniform*. (This is indeed the case for our construction of expanders in the quasi-polynomial stretch regime.)

## 2 Overviews of the proofs

### 2.1 The general form of attack

A natural property for a class  $\mathcal{F}$  of functions is a deterministic polynomial-time algorithm that rejects all truth-tables of functions from  $\mathcal{F}$ , but accepts the truth-tables of almost all functions.<sup>7</sup> Indeed, a natural property for  $\mathcal{F}$  exists only if almost all functions are *not* in  $\mathcal{F}$ . We will show how to use natural properties to break Goldreich’s pseudorandom generator.

The key step in our proofs is to show, for every fixed  $x \in \{0, 1\}^n$ , that  $\text{prg}(x)$  is the truth-table of a function from some class  $\mathcal{F}$  of “simple” functions (e.g.,  $\text{prg}(x)$  is the truth-table of a small constant-depth circuit). When we are able to show this, it follows that a **natural property** for  $\mathcal{F}$  can distinguish the outputs of the PRG from uniformly-chosen random strings: This is because the natural property rejects any string in the output-set of the PRG (which is the truth-table of a function in  $\mathcal{F}$ ), but accepts a random string, with high probability. (The general idea of using natural properties to break PRGs in this manner goes back to the original work of [28].)

Recall that Goldreich’s PRG (i.e., the function  $\text{prg}$ ) is *always* a very “simple” function, since each output bit depends on a few (i.e.,  $\ell \ll n$ ) input bits. However, in order for our idea to work, we need that a *different* function (i.e., not the function  $\text{prg}$ ) will be simple:

<sup>7</sup> Throughout the paper, we identify a natural property with the “constructive” algorithm that recognizes the property (see [26, Def. 3.8]).

Specifically, for every *fixed* input  $x$ , we want that the function  $g_x : \{0, 1\}^{\log(m)} \rightarrow \{0, 1\}$  such that  $g_x(i) = \text{prg}(x)_i$  will be “simple”. That is, for a *fixed* “seed”  $x$  for the PRG, the function  $g_x$  gets as input an index  $i$  of an output bit, and computes the  $i^{\text{th}}$  output bit of  $\text{prg}(x)$  as a function of  $i$ . Intuitively, given  $i \in [m]$ , the function  $g_x$  needs to compute three different objects, successively:

- The neighbors  $\Gamma_G(i)$  of the vertex  $i \in [m]$  in  $G$ .
- The projections of the (fixed) string  $x$  on locations  $\Gamma_G(i)$ .
- The output of the predicate  $P$  on  $x|_{\Gamma_G(i)}$ .

The proofs of our main theorems consist of showing instantiations of Goldreich’s generator (i.e., choices for an expander and a predicate) such that  $g_x$  is a function from a class against which we can construct natural properties.

An alternative view of the construction of  $g_x$  above is as giving rise to a collection of *pseudorandom functions* (PRFs)  $\{g_x : \{0, 1\}^{\log(m)} \rightarrow \{0, 1\}\}_{x \in \{0, 1\}^n}$  that are based on (an instantiation of) Goldreich’s PRG. In fact, the construction of  $g_x$  is technically reminiscent of constructions of PRFs that are based on Goldreich’s PRG by Applebaum and Raykov [8]. However, the crucial point is that our transformation of Goldreich’s PRG to a PRF incurs very little complexity overhead; in particular, the circuit complexity of  $g_x$  is essentially determined by the circuit complexity of the expander’s neighbor function and of the predicate. For further discussion see Section 2.4.

## 2.2 The setting of quasi-polynomial stretch

The proof of Theorem 2 consists of showing that for a suitable expander  $G$ , and for any predicate  $P$  computable by an  $\mathcal{AC}^0[\oplus]$  circuit of sufficiently small sub-exponential size, the function  $g_x$  can be computed by an  $\mathcal{AC}^0[\oplus]$  circuit of sufficiently small sub-exponential size. Natural properties for such circuits, based on the lower bounds by Razborov and Smolensky [27, 29], are well-known (see, e.g., [28, 12]).

To describe the instantiations and the construction of an  $\mathcal{AC}^0[\oplus]$  circuit for  $g_x$ , let  $n \in \mathbb{N}$ , and let  $m = 2^{(\log(n))^k}$ , for a sufficiently large  $k$ . The first technical component that we need is an expander graph  $G$  such that the function  $i \mapsto \Gamma_G(i)$  can be computed by a sub-exponential sized  $\mathcal{AC}^0[\oplus]$  circuit. We show that there exists such a graph, with essentially optimal parameters:

► **Theorem 9** (strongly-explicit lossless expander in  $\mathcal{AC}^0[p]$ ; see [26], Thm. 4.5). *There exists a universal constant  $d_G \in \mathbb{N}$  such that the following holds. For any  $k \in \mathbb{N}$  and sufficiently large  $n$  and  $m = 2^{(\log(n))^k}$ , there exists a  $(n^{0.99}, 0.99)$ -expander  $G = ([n], [m], E)$  of right-degree  $\ell = O(\log(m)/\log(n))$ , and an  $\mathcal{AC}^0[\oplus]$  circuit  $C_G : \{0, 1\}^{\log(m)} \rightarrow \{0, 1\}^{\ell \cdot \log(n)}$  of depth  $d_G$  and size  $\text{poly}(n)$  such that for every  $i \in [m]$  it holds that  $C_G(i)$  outputs the list of  $\ell$  neighbors of  $i$  in  $G$ .*

We stress that the depth  $d_G$  of the circuit in Theorem 9 does not depend on the relation between  $m$  and  $n$ , which is what will allow us to have a natural property for the circuit  $C_G$ . Specifically, recall that we have natural properties against  $\mathcal{AC}^0[\oplus]$  circuits of depth  $d_G$  over  $\ell_m = \log(m)$  input bits of sub-exponential size  $2^{\Omega(\ell_m^{1/2d_G})}$ . The size of  $C_G$  is  $\text{poly}(n)$ , and thus if we take  $m = 2^{(\log(n))^k}$ , for a sufficiently large  $k$ , then the size of  $C_G$  is a sufficiently small sub-exponent in its input length  $\log(m)$ .

In high-level, our construction of the expander in Theorem 9 is as follows. Our starting point is the well-known fact that a random graph is, with high probability, a good lossless bipartite expander (see, e.g., [26, Thm. 3.2]). The first step is to construct an *efficient*

*test* that gets as input a string  $G \in \{0, 1\}^{m'}$ , where  $m' = m \cdot \ell \cdot \log(n)$ , considers  $G$  as the incidence-list of a graph, and decides whether or not  $G$  is an  $(n^{.99}, .99)$ -expander. We show that such a test can be implemented by a CNF of size  $2^n$  (see [26, Clm. 4.2]). Hence, a pseudorandom generator for CNFs of size  $2^n$  outputs, with high probability, a good expander. Specifically, we will use the pseudorandom generator of Nisan [24], which has seed length  $\text{poly}(n)$ . Thus, for some fixed “good” seed  $s$ , the output  $NW(s) \in \{0, 1\}^{m'}$  of the generator on  $s$  is an  $(n^{.99}, .99)$ -expander.

Our next step is to show that the expander represented by  $NW(s)$  has neighbor functions that can be computed by an  $\mathcal{AC}^0[\oplus]$  circuit. In fact, we will show that there exists a circuit that gets as input the index  $i \in \{0, 1\}^{\log(m')}$  of a bit in  $NW(s)$  and outputs  $NW(s)_i$ . To do so we can rely, for instance, on the recent work of Carmosino *et al.* [12], who showed that Nisan’s generator can be made “strongly-explicit”: That is, there exists an  $\mathcal{AC}^0[\oplus]$  circuit of polynomial size that gets as input a seed  $z$  and an index  $i$  of an output bit, and computes the  $i^{\text{th}}$  output bit of the generator on seed  $z$ .<sup>8</sup> By “hard-wiring” a “good” seed  $s$  into the latter circuit, we obtain an  $\mathcal{AC}^0[\oplus]$  circuit of size  $\text{poly}(n)$  that computes the output bits of the expander  $NW(s)$ . Indeed, a crucial point is that we did not algorithmically look for a good seed  $s$ , but rather non-uniformly fixed a “good” seed and “hard-wired” it into the circuit.

Given this expander construction,  $g_x$  can compute  $i \mapsto \Gamma_G(i)$  in sub-exponential size, and we now need  $g_x$  to compute the projections of  $x$  on locations  $\Gamma_G(i)$ . To do so we simply “hard-wire” the entire string  $x$  into  $g_x$ . Specifically, after computing the function  $i \mapsto \Gamma_G(i)$ , the circuit now has the  $\ell \cdot \log(n)$  bits of  $\Gamma_G(i)$ ; it then uses  $\ell$  depth-two formulas, each over  $\log(n)$  bits and of size  $n$ , to compute the mapping  $\Gamma_G(i) \mapsto x|_{\Gamma_G(i)}$  by brute-force. This increases the size of the circuit for  $g_x$  by  $\ell \cdot n < n^2$  gates, which is minor compared to the size  $\text{poly}(n)$  of  $C_G$  from Theorem 9.

Finally, the circuit  $g_x$  has now computed the  $\ell$  bits corresponding to  $x|_{\Gamma_G(i)}$ , and needs to compute the predicate  $P : \{0, 1\}^\ell \rightarrow \{0, 1\}$  on these bits. To get the circuit to be of sufficiently small sub-exponential size, we require that the predicate can be computed by a sufficiently small sub-exponential sized  $\mathcal{AC}^0[\oplus]$  circuit. Specifically, we want that for some  $d_P$ , the predicate  $P$  can be computed by an  $\mathcal{AC}^0[\oplus]$  circuit of depth  $d_P$  and size  $2^{\ell^\epsilon}$ , for a sufficiently small  $\epsilon < 1/2(d_G + d_P + 2)$ . We thus obtain a circuit for  $g_x$  of depth  $d = d_G + d_P + 2$  and of size  $O(2^{\ell^\epsilon}) < 2^{\log(m)^{1/2d}}$ ,<sup>9</sup> which is sufficiently small such that we have natural properties against it (for a formal statement of the parameters of this well-known natural property, proved by [28, 12], see e.g. [26, Thm. 3.9]).

### 2.3 The setting of large polynomial stretch

Why are the results in Section 2.2 applicable only to the setting of quasi-polynomial stretch? The main bottleneck is the expander construction in Theorem 9, which is an  $\mathcal{AC}^0[\oplus]$  circuit. Specifically, since we only know of natural properties against  $\mathcal{AC}^0[\oplus]$  circuits of at most sub-exponential size, and since the circuit that we obtain is of size at least  $n$  (because we hard-wire  $x \in \{0, 1\}^n$  to the circuit), we were forced to take  $m = n^{\text{poly} \log(n)}$  such that  $n$  will be a small sub-exponential function of  $\log(m)$ .

In this section we circumvent this obstacle by using the hypothesized existence of expanders whose neighbor functions have “extremely simple” circuits. For simplicity, in the current high-level overview we present the attacks that are based on the existence of an expander

<sup>8</sup> A similar observation has appeared in other works, such as in [28, Thm. 4.2].

<sup>9</sup> For this calculation we assumed that  $2^{\ell^\epsilon}$  dominates the size of the circuit (since the size of  $C_G$  is already sufficiently small); and we used the fact that  $\ell = O(\log(m)/\log(n)) < \log(m)$ , and that  $\epsilon < 1/2d$  is sufficiently small).

as in Assumption 5; that is, a lossless expander  $G = ([n], [m = n^k], E)$  of right-degree  $\ell = O(k)$  whose neighbor function is an *affine function* (i.e., each output bit is a parity of input bits). The ideas that underlie the attacks that are based on expanders whose neighbor function is an  $\mathcal{NC}^0$  circuit (as in Assumption 7) are similar, yet require a slightly more subtle parametrization (see [26, Sec. 5.2]).

Consider an instantiation of Goldreich’s predicate with expander  $G$  as above and with a predicate  $P : \{0, 1\}^\ell \rightarrow \{0, 1\}$  that can be computed by a CNF of size  $2^{\delta \cdot \ell}$ , where  $\delta$  can be an arbitrarily large constant compared to  $k$  (or even  $\delta = 1$ , which allows for *any* predicate). In this case, for any  $x \in \{0, 1\}^n$ , the output  $\text{prg}(x)$  of the generator on  $x$  is a truth-table of a function  $g_x$  over an input  $i \in \{0, 1\}^{\log(m)}$  that can be computed as follows. One layer of *parity gates* maps  $i \in [m]$  to  $\Gamma_G(i) \in \{0, 1\}^{\ell \cdot \log(n)}$  (this uses our assumption about the expander). Then,  $\ell$  copies of a DNF over  $\log(n)$  bits and of size  $n$  map the names of the  $\ell$  vertices to  $x|_{\Gamma_G(i)} \in \{0, 1\}^\ell$ , i.e., we project the bits of  $x$  that feed the predicate  $P$  (this DNF is essentially a “hard-wiring” of  $x$  into  $g_x$ ). Finally, the CNF that computes  $P$  of size  $2^{\delta \cdot \ell}$  maps  $x|_{\Gamma_G(i)}$  to the value  $P(x|_{\Gamma_G(i)})$ . After collapsing a layer that connects the top CNF and the DNFs, we obtain an AND-OR-AND-XOR circuit  $g_x$  over  $\ell_m = \log(m)$  input bits of size  $O(\ell \cdot \log(n) + \ell \cdot n + 2^{\ell \cdot \delta}) = O(2^{\ell_m/k})$  with top fan-in  $2^{\delta \cdot \ell} = 2^{O(\delta \cdot k)}$ .

When  $\delta > 0$  is sufficiently small, we are able to unconditionally construct a natural property against circuits as above. However, the main point (i.e., Theorem 6) comes when considering the case  $\delta = 1$ ; that is, *any* predicate  $P : \{0, 1\}^\ell \rightarrow \{0, 1\}$ . In this case, we first use the discriminator lemma of [20] to deduce that  $g_x$  can be  $(1/2 + 1/2^{O(k)})$ -approximated by a DNF-XOR circuit of size  $O(2^{\ell_m/k})$ . Now (still under Assumption 5), exactly one of two options holds. The first option is that there exists a natural property for functions on  $\ell_m$  input bits that can be  $(1/2 + o(1))$ -approximated by DNF-XOR circuits of size  $2^{\Omega(\ell_m)}$ ; in this case, by taking  $k$  sufficiently large so that  $2^{\ell_m/k}$  is sufficiently small, the natural property breaks the generator. The other option is that no such natural property exists, despite the fact that natural properties exist both for functions computed (in the worst-case) by DNF-XOR circuits of size  $2^{(1-o(1)) \cdot \ell_m}$ , and for functions approximated (even weakly) by parity decision trees of such size. This completes the sketch of the proof of Theorem 6.

## 2.4 The connection to expander-based pseudorandom functions

As mentioned in Section 2.1, our construction of the function  $g_x : \{0, 1\}^{\log(m)} \rightarrow \{0, 1\}$  (i.e.,  $g_x(i) = P(x|_{\Gamma_G(i)})$ ) can be viewed as a construction of a collection of *pseudorandom functions* (PRFs)  $\{g_x : \{0, 1\}^{\log(m)} \rightarrow \{0, 1\}\}_{x \in \{0, 1\}^n}$  based on (an instantiation of) Goldreich’s PRG. The crucial point in our transformation of Goldreich’s PRG to a PRF is that the resulting PRF can have very low circuit complexity, depending essentially only on the complexity of the expander’s neighbor function and of the predicate. In contrast, previously-known transformations of Goldreich’s PRG to a PRF incur a significant overhead. Specifically, the transformation of Goldreich, Goldwasser, and Micali [18] yields a circuit with super-constant depth; whereas the constructions of Applebaum and Raykov [8] either yield only a *weak* PRF (which is not broken by natural properties, in general) or require complicated computations, which they implement using majority gates (i.e., the resulting function is in the class  $\mathcal{TC}^0$ , for which natural properties are neither known nor conjectured to exist).

Nevertheless, as pointed out by Applebaum,<sup>10</sup> a transformation of Goldreich’s PRG to a *weak* PRF from [8] can be used to break the PRG when it is instantiated with a *random graph* and with a predicate with sufficiently low circuit complexity; this attack uses algorithms for

<sup>10</sup>Personal communication.

learning from random examples (instead of natural properties). Specifically, assume that Goldreich’s PRG is secure when instantiated with a random graph  $[n] \times [m]$  of right-degree  $\ell$  and a predicate  $P : \{0, 1\}^\ell \rightarrow \{0, 1\}$ . Using the argument that appears in [8, Sec. 1.2.1] it follows that the function  $g_x : \{0, 1\}^{\ell \cdot \log(n)} \rightarrow \{0, 1\}$  that considers its input as a set  $S$  of  $\ell$  vertices in  $[n]$ , and outputs  $g_x(S) = P(x|_S)$ , is a weak PRF against adversaries that make  $m$  (uniformly-chosen) queries. The complexity of  $g_x$  is essentially determined by the complexity of the predicate  $P$ .<sup>11</sup> Thus, if the latter is sufficiently small such that there exists an algorithm for learning  $g_x$  from  $m - 1$  random examples, then  $g_x$  cannot be a weak PRF for adversaries that make  $m$  queries (since such an adversary can use the learning algorithm to predict the  $m^{\text{th}}$  evaluation of the function at a random point, using the first  $m - 1$  evaluations at random points). This contradicts the hypothesis that Goldreich’s PRG is secure when instantiated with the predicate  $P$  and a random graph  $[n] \times [m]$ .

Loosely speaking, the argument above implies that Goldreich’s PRG is not secure when the stretch is quasipolynomial (and the locality is polylogarithmic and sufficiently large), the graph is random, and the predicate is computable by an  $\mathcal{AC}^0$  circuit of sufficiently small sub-exponential size; this relies on the learning algorithm of Linial, Mansour, and Nisan [22].<sup>12</sup> However, the latter class of predicates is much weaker than the class of predicates to which our main unconditional result applies (i.e., than the class of  $\mathcal{AC}^0[\oplus]$  circuits of sufficiently small sub-exponential size, from Theorem 2). For example, such predicates have “low” resilience  $o(\ell)$ , because the Fourier weight of depth- $d$   $\mathcal{AC}^0$  circuits over  $\ell$  bits of size  $2^{\ell^\epsilon}$  is .01-concentrated on sets of size at most  $O(\ell^{\epsilon \cdot (d-1)}) = o(\ell)$  (see [22, 31]); therefore, such predicates do not withstand the attacks from [7]. Finally, recall that it is currently an open problem to understand the learnability of  $\mathcal{AC}^0[\oplus]$  circuits from random examples.

<sup>11</sup> More specifically, the circuit  $g_x$  can be implemented by  $2 \cdot \ell$  depth-two formulas of size  $O(n)$  to compute the mapping  $S \mapsto x|_S$ , and then a circuit for  $P$  to compute  $P(x|_S)$ .

<sup>12</sup> Specifically, let  $n \in \mathbb{N}$ , and let  $\ell = \log^k(n)$  for some  $k \in \mathbb{N}$ . Assume that the predicate  $P : \{0, 1\}^\ell \rightarrow \{0, 1\}$  is computable by an  $\mathcal{AC}^0$  circuit of depth  $d \in \mathbb{N}$  and size  $s = 2^{\ell^\epsilon}$ , where  $\epsilon \leq 1/(d+1)$ . Then,  $g_x$  can be implemented by a circuit of size  $s' = O(\ell \cdot n + s)$  and depth  $d+1$ . The algorithm of [22] learns  $g_x$  with error  $1/s'$  from  $m = n^{O(\log(s'))^d} = o(n^\ell)$  random examples in time  $\text{poly}(m)$ , where the last bound on  $m$  is since  $\epsilon \leq 1/(d+1)$ . Therefore, Goldreich’s PRG is not secure when the locality is  $\ell = \log^k(n)$ , the stretch is  $m = o(n^\ell)$ , and the  $\ell$ -bit predicate is an  $\mathcal{AC}^0$  circuit of depth  $d$  and size  $2^{\ell^\epsilon}$ .

# A Note on the Quantum Query Complexity of Permutation Symmetric Functions

André Chailloux

Inria de Paris, EPI SECRET, Paris, France

andre.chailloux@inria.fr

---

## Abstract

It is known since the work of [1] that for any permutation symmetric function  $f$ , the quantum query complexity is at most polynomially smaller than the classical randomized query complexity, more precisely that  $R(f) = \tilde{O}(Q^7(f))$ . In this paper, we improve this result and show that  $R(f) = O(Q^3(f))$  for a more general class of symmetric functions. Our proof is constructive and relies largely on the quantum hardness of distinguishing a random permutation from a random function with small range from Zhandry [11].

## 1 Introduction

The black box model has been a very fruitful model for understanding the possibilities and limitations of quantum algorithms. In this model, we can prove some exponential speedups for quantum algorithms, which is notoriously hard to do in standard complexity theory. Famous examples are the Deutsch-Josza problem [7] and Simon's problem [10]. There has been a great line of work to understand quantum query complexity, which developed some of the most advanced algorithms techniques. Even Shor's algorithm [9] for factoring fundamentally relies on a black box algorithm for period finding.

We describe here the query complexity model in a nutshell. The idea is that we have to compute  $f(x_1, \dots, x_n)$  where each  $x_i \in [M]$  can be accessed via a query. We consider decision problems meaning that  $f : S \rightarrow \{0, 1\}$  with  $S \subseteq [M]^n$ . In this paper, we will consider inputs  $x \in [M]^n$  equivalently as functions from  $[n] \rightarrow [M]$ . We are not interested in the running time of our algorithm but only want to minimize the number of queries to  $x$ , which in the quantum setting consists of applying the unitary  $\mathcal{O}_x : |i\rangle|j\rangle \rightarrow |i\rangle|j + x_i\rangle$ .  $D(f)$ ,  $R(f)$  and  $Q(f)$  represent the minimal amount of queries to compute  $f$  with probability greater than  $2/3$  (or  $= 1$  for the case of  $D(f)$ ) using respectively a deterministic algorithm with classical queries, a randomized algorithm with classical queries and a quantum algorithm with quantum queries.

As we said before, the query complexity is great for designing new quantum algorithms. It is also very useful for providing black box limitations for quantum algorithms. There are some cases in particular where we can prove that the quantum query complexity of  $f$  is at most polynomially smaller than classical (deterministic or randomized) query complexity. For example:

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

- for specific functions such as search [6] or element distinctness (ED) [2, 8, 4], we have respectively  $Q(\text{Search}) = \Theta(n^{1/2})$ ,  $D(\text{Search}) = \Theta(n)$  and  $Q(\text{ED}) = \Theta(n^{2/3})$ ,  $D(\text{ED}) = \Theta(n)$ .
- For any total function  $f$  i.e. when its domain  $S = [M]^n$ , Beals *et al.* [5] proved using the polynomial method that  $D(f) \leq O(Q^6(f))$ .

Another case of interest where we can lower bound the quantum query complexity is the case of permutation symmetric functions. There are several ways of defining such functions and we will be interested in the following definitions for a function  $f : S \rightarrow \{0, 1\}$  with  $S \subseteq [M]^n$ .

► **Definition 1.**

- $f$  permutation symmetric of the first type iff.  $\forall \pi \in S_n, f(x) = f(x \circ \pi)$ .
- $f$  is permutation symmetric of the second type iff.  $\forall \pi \in S_n, \forall \sigma \in S_M, f(x) = f(\sigma \circ x \circ \pi)$ .

where  $S_n$  (resp.  $S_M$ ) represents the set of permutations on  $[n]$  (resp.  $[M]$ ) and  $\circ$  is the usual function composition.

Here, recall that we consider strings  $x \in [M]^n$  as functions from  $[n] \rightarrow [M]$ . Notice also that this definition implies that  $S$  is stable by permutation, meaning that  $x \in S \Leftrightarrow \forall \pi \in S_n, x \circ \pi \in S$ . We already know from the work of Aaronson and Ambainis the following result:

► **Theorem 2** ([1]). *For any permutation symmetric function  $f$  of the second type (Definition 1),  $R(f) \leq \tilde{O}(Q^7(f))$ .*

In a recent survey on quantum query complexity and quantum algorithms [3], Ambainis writes:

“It has been conjectured since about 2000 that a similar result also holds for  $f$  with a symmetry of the first type.”

**Contribution**

The contribution of this paper is to prove the above conjecture. We show the following:

► **Theorem 3.** *For any permutation symmetric function  $f$  of the first type,  $R(f) \leq O(Q^3(f))$ .*

This result not only generalizes the result for a more general class of permutation symmetric function, but also improves the exponent from 7 to 3. In the case where  $M = 2$ , this result was already known [1] with an exponent of 2, which is tight from Grover’s algorithm.

The proof technique is arguably simple, constructive and relies primarily on the quantum hardness of distinguishing a random permutation from a random function with small range from Zhandry [11]. We start from a permutation symmetric function  $f$ . At high level, the proof goes as follows:

- We start from an algorithm  $\mathcal{A}$  that outputs  $f(x)$  for all  $x$  with high (constant) probability. Let  $q$  the number of quantum queries to  $\mathcal{O}_x$  performed by  $\mathcal{A}$ .
- Instead of running  $\mathcal{A}$  on input  $x$ , we choose a random function  $C : [n] \rightarrow [n]$  with a range of small size  $r$  (from a distribution specified later in the paper) and apply the algorithm  $\mathcal{A}$  where we replace calls to  $\mathcal{O}_x$  with calls to  $\mathcal{O}_{x \circ C}$ . We note that there is a simple procedure to compute  $\mathcal{O}_{x \circ C}$  from  $\mathcal{O}_x$  and  $\mathcal{O}_C$ .

- If we take  $r = \Theta(q^3)$ , we can use Zhandry's lower bound, we show that for each  $x$ , the output will be close to the output of the algorithm  $\mathcal{A}$  where we replace calls to  $\mathcal{O}_{x \circ C}$  with calls to  $\mathcal{O}_{x \circ \pi}$  for a random permutation  $\pi$ . Using the fact that  $f$  is permutation symmetric, the latter algorithm will output with high probability  $f(x \circ \pi) = f(x)$ . In other words, if the algorithm  $\mathcal{A}$  that calls  $\mathcal{O}_{x \circ C}$  wouldn't output  $f(x)$  for a random  $C$  and a fixed  $x$  then we would find a distinguisher between a random  $C$  and a random permutation  $\pi$ , which is hard from Zhandry's lower bound.
- The above tells us that applying  $\mathcal{A}$  where we replace calls to  $\mathcal{O}_x$  with calls to  $\mathcal{O}_{x \circ C}$  gives us output  $f(x)$  with high probability. Knowing  $C$ , we can construct the whole string  $x \circ C$  by querying  $x$  on inputs  $i \in \text{Im}(C)$  which can be done with  $|\text{Im}(C)| \leq r$  classical queries which allows us to construct the unitary  $\mathcal{O}_{x \circ C}$ . This means we can emulate  $\mathcal{A}$  on input  $x \circ C$  with  $r$  classical queries to  $x$  and this gives us  $f(x)$  with high probability.

After presenting a few notations, we dive directly into the proof of our theorem.

## 2 Preliminaries

### 2.1 Notations

For any function  $f$ , let  $\text{Im}(f)$  be its range (or image).

#### Query algorithms

A query algorithm  $\mathcal{A}^\mathcal{O}$  is described by an algorithm that calls another function  $\mathcal{O}$  in a black box fashion. We will never be interested in the running time or the size of  $\mathcal{A}$  but only in the number of calls, or queries, to  $\mathcal{O}$ . We will consider both the cases where the algorithm  $\mathcal{A}^\mathcal{O}$  is classical and quantum. In the latter  $\mathcal{O}$  will be a quantum unitary. In both cases, we only consider algorithms that output a single bit.

#### Oracles

We use oracles to perform black box queries to a function. For any function  $g$ ,  $\mathcal{O}_g^{\text{Classical}}$  is a black box that on input  $i$  outputs  $g(i)$  while  $\mathcal{O}_g$  (without any superscript) is the quantum unitary satisfying

$$\mathcal{O}_g : |i\rangle|j\rangle \rightarrow |i\rangle|j + g(i)\rangle.$$

#### Query complexity

Fix a function  $f : S \rightarrow \{0, 1\}$  where  $S \subseteq [M]^n$ .

► **Definition 4.** The randomized query complexity  $R(f)$  of  $f$  is the smallest integer  $q$  such that there exists a classical randomized algorithm  $\mathcal{A}^\mathcal{O}$  performing  $q$  queries to  $\mathcal{O}$  satisfying:

$$\forall x \in S, \Pr[\mathcal{A}_x^{\mathcal{O}^{\text{Classical}}} \text{ outputs } f(x)] \geq 2/3.$$

► **Definition 5.** The quantum query complexity  $Q(f)$  of  $f$  is the smallest integer  $q$  such that there exists a quantum algorithm  $\mathcal{A}^\mathcal{O}$  performing  $q$  queries to  $\mathcal{O}$  satisfying:

$$\forall x \in S, \Pr[\mathcal{A}_x^{\mathcal{O}} \text{ outputs } f(x)] \geq 2/3.$$

## 2.2 Hardness of distinguishing a random permutation from a random function with small range

Our proof will use a quantum lower bound on distinguishing a random permutation from a random function with small range proven in [11]. Following this paper, we define, for any  $r \in [n]$ , the following distribution  $D_r$  on functions from  $[n]$  to  $[n]$  from which can be sampled as follows.

- Draw a random function  $g$  from  $[n] \rightarrow [r]$ .
- Draw a random injective function  $h$  from  $[r] \rightarrow [n]$ .
- Output the composition  $h \circ g$ .

Notice that any function  $f$  drawn from  $D_r$  is of small range and satisfies  $|Im(f)| \leq r$ . Let also  $D_{\text{perm}}$  be the uniform distribution on permutations on  $[n]$ . Zhandry's lower bound can be stated as follows:

► **Proposition 6** ([11]). *There exists an absolute constant  $\Lambda$  such that for any  $r \in [n]$  and any quantum query algorithm  $\mathcal{B}^\circ$  performing at most  $\lceil \Lambda r^{1/3} \rceil$  queries to  $\mathcal{O}$ :*

$$\forall b \in \{0, 1\}, \left| \mathbb{E}_{\pi \leftarrow D_{\text{perm}}} \Pr[\mathcal{B}^{\circ\pi} \text{ outputs } b] - \mathbb{E}_{C \leftarrow D_r} \Pr[\mathcal{B}^{\circ C} \text{ outputs } b] \right| \leq \frac{2}{27}.$$

This is obtained immediately by combining Theorem 8 and Lemma 1 of [11]<sup>1</sup>.

### 3 Proving our main theorem

The goal of this section is to prove Theorem 3. Fix a function  $f : S \rightarrow \{0, 1\}$  where  $S \subseteq [M]^n$  with  $Q(f) = q$ . This means there exists a quantum query algorithm  $\mathcal{A}^\circ$  performing  $q$  queries to  $\mathcal{O}$  such that

$$\forall x \in S, \Pr[\mathcal{A}^{\circ x} \text{ outputs } f(x)] \geq 2/3.$$

We first amplify the success probability to  $20/27$ .

► **Lemma 7.** *There exists a quantum query algorithm  $\mathcal{A}_3^\circ$  that performs  $3q$  queries to  $\mathcal{O}$  such that*

$$\forall x \in S, \Pr[\mathcal{A}_3^{\circ x} \text{ outputs } f(x)] \geq \frac{20}{27}.$$

**Proof.**  $\mathcal{A}_3^\circ$  will consist of the following: run  $\mathcal{A}^\circ$  independently 3 times and take the output that occurs the most. For each  $x$ , each run of  $\mathcal{A}^{\circ x}$  outputs  $f(x)$  with probability greater than  $2/3$ . The probability that the correct  $f(x)$  appears at least twice out of the 3 results is therefore greater than  $\frac{8}{27} + 3 \cdot \frac{4}{27} = \frac{20}{27}$ . ◀

Using the fact that  $f$  is permutation symmetric, we get the following corollary:

► **Corollary 8.**

$$\forall x \in S, \forall \pi \in S_n, \Pr[\mathcal{A}_3^{\circ x \circ \pi} \text{ outputs } f(x)] = \Pr[\mathcal{A}_3^{\circ x \circ \pi} \text{ outputs } f(x \circ \pi)] \geq \frac{20}{27}.$$

<sup>1</sup> Equivalently, this is obtained immediately by combining Lemma 3.2 and Lemma 3.4 from the arXiv version [quant-ph:1312.1027](https://arxiv.org/abs/1312.1027).

### 3.1 Looking at a small number of indices of $x$

The main idea of the proof is to show that  $\mathcal{A}_3$  will output  $f(x)$  with high probability when replacing queries to  $\mathcal{O}_x$  with queries to  $\mathcal{O}_{x \circ C}$  for  $C$  chosen uniformly from  $D_r$  for some  $r = \Theta(Q^3(f))$ . First notice that for any  $x : [n] \rightarrow [M]$  and any  $g : [n] \rightarrow [n]$ , it is possible to apply  $\mathcal{O}_{x \circ g}$  with 2 calls to  $\mathcal{O}_g$  and 1 call to  $\mathcal{O}_x$  with the following procedure:

$$|i\rangle|j\rangle|0\rangle \rightarrow |i\rangle|j\rangle|g(i)\rangle \rightarrow |i\rangle|j + (x \circ g)(i)\rangle|g(i)\rangle \rightarrow |i\rangle|j + (x \circ g)(i)\rangle|0\rangle$$

where we respectively apply  $\mathcal{O}_g$  on registers (1, 3);  $\mathcal{O}_x$  on registers (3, 2) and  $\mathcal{O}_g^\dagger$  on registers (1, 3).

Therefore, for any fixed (and known)  $x$ , for any function  $g : [n] \rightarrow [n]$ , we can look at  $\mathcal{A}_3^{\mathcal{O}_{x \circ g}}$  as a quantum query algorithm that queries  $\mathcal{O}_g$ . In other words, for each  $x \in S$ , there is a quantum query algorithm  $\mathcal{B}_x^{\mathcal{O}_g}$  such that  $\mathcal{B}_x^{\mathcal{O}_g} = \mathcal{A}^{\mathcal{O}_{x \circ g}}$  for any function  $g : [n] \rightarrow [n]$ . Notice also that since a query to  $\mathcal{O}_{x \circ g}$  is done by doing 2 queries to  $\mathcal{O}_g$ , we have that  $\mathcal{B}^{\mathcal{O}}$  uses twice as many queries than  $\mathcal{A}_3^{\mathcal{O}}$ .

We can now prove our main proposition that shows that we can compute  $f(x)$  by looking only at  $x \circ C$  for a random  $C$  with  $|Im(C)| \leq r$ .

► **Proposition 9.** *Let  $f : [M]^n \rightarrow \{0, 1\}$  with  $Q(f) = q$  and  $r = \lceil 216q^3\Lambda^{-3} \rceil$  where  $\Lambda$  is the absolute constant from Proposition 6.*

$$\forall x \in S, \mathbb{E}_{C \leftarrow D_r} \Pr[\mathcal{A}_3^{\mathcal{O}_{x \circ C}} \text{ outputs } f(x)] \geq 2/3.$$

**Proof.** For each  $x \in S$ , we consider the algorithm  $\mathcal{B}_x^{\mathcal{O}}$  described above. Recall that for all  $g : [n] \rightarrow [n]$ ,  $\mathcal{B}_x^{\mathcal{O}_g} = \mathcal{A}_3^{\mathcal{O}_{x \circ g}}$ . Since  $\mathcal{A}_3^{\mathcal{O}}$  uses  $3q$  queries,  $\mathcal{B}_x^{\mathcal{O}}$  uses  $6q$  queries. We first consider the case where  $g$  is a random permutation. Using Corollary 8:

$$\forall x \in S, \mathbb{E}_{\pi \leftarrow D_{\text{perm}}} \Pr[\mathcal{B}_x^{\mathcal{O}_\pi} \text{ outputs } f(x)] = \mathbb{E}_{\pi \leftarrow D_{\text{perm}}} \Pr[\mathcal{A}_3^{\mathcal{O}_{x \circ \pi}} \text{ outputs } f(x)] \geq \frac{20}{27}$$

Using the lower bound of Proposition 6 noticing that  $6q \leq \Lambda r^{1/3}$ , we have

$$\forall x \in S, \left| \mathbb{E}_{\pi \leftarrow D_{\text{perm}}} \Pr[\mathcal{B}_x^{\mathcal{O}_\pi} \text{ outputs } f(x)] - \mathbb{E}_{C \leftarrow D_r} \Pr[\mathcal{B}_x^{\mathcal{O}_C} \text{ outputs } f(x)] \right| \leq \frac{2}{27}.$$

which gives us

$$\forall x \in S, \mathbb{E}_{C \leftarrow D_r} \Pr[\mathcal{B}_x^{\mathcal{O}_C} \text{ outputs } f(x)] \geq \frac{20}{27} - \frac{2}{27} = 2/3.$$

Since for each  $x \in S$ ,  $\mathcal{B}_x^{\mathcal{O}_C} = \mathcal{A}_3^{\mathcal{O}_{x \circ C}}$ , we can therefore conclude

$$\forall x \in S, \mathbb{E}_{C \leftarrow D_r} \Pr[\mathcal{A}_3^{\mathcal{O}_{x \circ C}} \text{ outputs } f(x)] \geq 2/3. \quad \blacktriangleleft$$

### 3.2 Constructing a classical query algorithm for $f$

We can now use the above proposition to prove our main theorem.

► **Theorem 2 (Restated).** *For any permutation symmetric function  $f$  of the first type,  $R(f) \leq O(Q^3(f))$ .*

**Proof.** Fix a function  $f : S \rightarrow \{0, 1\}$  where  $S \subseteq [M]^n$  with  $Q(f) = q$ . This means there exists a quantum query algorithm  $\mathcal{A}^{\mathcal{O}}$  performing  $q$  queries to  $\mathcal{O}$  such that

$$\forall x \in S, \Pr[\mathcal{A}^{\mathcal{O}_x} \text{ outputs } f(x)] \geq 2/3.$$

We construct a randomized algorithm that performs  $r = \lceil 216q^3\Lambda^{-3} \rceil$  classical queries to  $\mathcal{O}_x^{\text{Classical}}$  as follows:

1. Choose a random  $C$  according to distribution  $D_r$ .
2. Query  $\mathcal{O}_x^{\text{Classical}}$  to get all values  $x_i$  for  $i \in \text{Im}(C)$ . This requires  $|\text{Im}(C)| \leq r$  queries to  $\mathcal{O}_x^{\text{Classical}}$ . These queries fully characterize the function  $x \circ C$ , hence the quantum unitary  $\mathcal{O}_{x \circ C}$ .
3. From  $\mathcal{A}^\circ$ , construct the quantum algorithm  $\mathcal{A}_3^\circ$  as in Lemma 7. Recall that  $\mathcal{A}_3^\circ$  just consists of applying  $\mathcal{A}^\circ$  independently 3 times and output the majority outcome.
4. We consider  $\mathcal{A}_3^{\circ_{x \circ C}}$  as a quantum unitary circuit acting on  $t$  qubits. At each step of the algorithm, we store the  $2^t$  amplitudes. When  $\mathcal{O}_{x \circ C}$  is called, we use its representation from step 2 to calculate its action on the  $2^t$  amplitudes. Other parts of  $\mathcal{A}_3^{\circ_{x \circ C}}$  are treated the same way. While this uses a lot of computing power, it does not require any queries to  $\mathcal{O}_x^{\text{Classical}}$  or  $\mathcal{O}_x$  other than those used at step 2.

Step 4 outputs the same output distribution than the quantum algorithm  $\mathcal{A}_3^{\circ_{x \circ C}}$ . Using Proposition 9, for all  $x \in S$ , this algorithm outputs  $f(x)$  with probability at least  $2/3$ , which implies

$$R(f) \leq r = \lceil 216Q^3(f)\Lambda^{-3} \rceil. \quad \blacktriangleleft$$

Notice that after step 2, it is not possible to just compute  $f(x \circ C)$ , and try to show that it is equal to  $f(x)$  since we don't even always have  $x \circ C \in S$ . This is yet another example in query complexity where we use the behavior of a query algorithm on inputs not necessarily in the domain of  $f$ .

## 4 Conclusion

This result extends the class of functions for which we can show a polynomial relationship between the quantum and the randomized query complexity and improves the polynomial in general for permutation symmetric functions.

The first obvious open question is to close the gap between the best known speed-up for permutation symmetric function - which is quadratic - and the cubic lower bound obtained in this paper. Another open question is to see if such techniques can be extended to the case where the domain  $S$  is permutation symmetric, which implies the case of total functions. While the techniques seem specific to permutation symmetric functions, using a more powerful lower bound or considering inputs  $x$  in superposition (as in [12]) could give interesting results.

Also, we are currently extending those techniques to study the behavior of uniformly random inputs  $x$  in particular in the context of the quantum random oracle model. Here, we are interested in the power of quantum attacks on a cryptographic scheme while performing quantum queries to a uniformly random function. This technique seems promising to show that for many attacks, these quantum queries can be replaced with classical queries in the same way as in our steps 2-4.

## Abstract

Testing monotonicity of a Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is an important problem in the field of property testing. It has led to connections with many interesting combinatorial questions on the directed hypercube: routing, random walks, and new isoperimetric theorems. Denoting the proximity parameter by  $\varepsilon$ , the best tester is the non-adaptive  $\tilde{O}(\varepsilon^{-2}\sqrt{n})$  tester of Khot-Minzer-Safra (FOCS 2015). A series of recent results by Belovs-Blais (STOC 2016) and Chen-Waingarten-Xie (STOC 2017) have led to  $\tilde{\Omega}(n^{1/3})$  lower bounds for *adaptive* testers. Reducing this gap is a significant question, that touches on the role of adaptivity in monotonicity testing of Boolean functions.

We approach this question from the perspective of *parametrized property testing*, a concept recently introduced by Pallavoor-Raskhodnikova-Varma (ACM TOCT 2017), where one seeks to understand performance of testers with respect to parameters other than just the size. Our result is an adaptive monotonicity tester with one-sided error whose query complexity is  $O(\varepsilon^{-2}\mathbf{I}(f)\log^5 n)$ , where  $\mathbf{I}(f)$  is the total influence of the function. Therefore, adaptivity provably helps monotonicity testing for low influence functions.

## 1 Introduction

Monotonicity testing of Boolean functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is a classic problem in property testing that has been extensively studied over the last two decades [11, 8, 6, 2, 4, 3, 9, 1, 5]. Consider the coordinate-wise partial order over  $\{0, 1\}^n$ , denoted by  $\prec$ . A function  $f$  is monotone if  $\forall x, y \in \{0, 1\}^n$  where  $x \prec y$ ,  $f(x) \leq f(y)$ . The distance between two functions  $f, g$  is  $\Pr_x[f(x) \neq g(x)]$ , where  $x$  is u.a.r in  $\{0, 1\}^n$ . The distance of  $f$  to monotonicity is the minimum distance of  $f$  to a monotone  $g$ . Typically, we say that  $f$  is  $\varepsilon$ -far if the distance to monotonicity is at least  $\varepsilon$ .

The goal of monotonicity testing is to design efficient ( $\text{poly}(n)$ ) randomized procedures that distinguish monotone functions from those that are far from monotone. Formally, given query access to  $f$  and a proximity parameter  $\varepsilon > 0$ , a monotonicity tester is a (randomized) procedure that accepts if  $f$  is monotone, and rejects if  $f$  is  $\varepsilon$ -far from being monotone. Both

<sup>2</sup> Supported by NSF TRIPODS CCF-1740850 and NSF CCF-1813165.

the above guarantees should hold with probability at least  $2/3$ . A tester has one-sided error if it always accepts a monotone function, or equivalently, always provides a certificate of rejection. A tester is called *non-adaptive* if all the queries can be made without seeing any of the answers. On the other hand, if the tester’s queries depend on previous answers, the tester is adaptive. As we explain below, the power of adaptivity is the central open question in Boolean monotonicity testing.

Raskhodnikova [11], Goldreich et al. [8], and Dodis et al. [6] initiated the study of monotonicity testing by describing a  $O(n/\varepsilon)$ -query non-adaptive, one-sided tester. Their “edge tester” repeats this simple procedure  $O(n/\varepsilon)$  times: sample a random edge of the hypercube and test for a monotonicity violation among its endpoints. Chakrabarty and Seshadhri [2] described the first  $o(n)$ -query tester, by proving connections between monotonicity testing and directed isoperimetry theorems. Their “path tester” performs random walks on the directed hypercube. Chen-Servedio-Tan [4] gave a tighter analysis to get an  $\tilde{O}(n^{5/6}\varepsilon^{-4})$  bound. In a remarkable result, Khot, Minzer, and Safra [9] (henceforth KMS) prove that the path tester works in  $\tilde{O}(\sqrt{n}/\varepsilon^2)$  queries. This was achieved by a deep isoperimetric result, a directed analog of Talagrand’s isoperimetry theorem [12].

Fischer et al. [7] had proven an  $\Omega(\sqrt{n})$  lower bound for non-adaptive, one-sided testers. Using sophisticated techniques, Chen-De-Servedio-Tan [3] proved an  $\Omega(n^{1/2-\delta})$  (for any fixed  $\delta > 0$ ) lower bound for non-adaptive, two-sided testers. All in all, this nearly resolves the non-adaptive complexity of monotonicity testing.

In a major recent advance, Belovs-Blais [1] proved the first polynomial lower bound of  $\tilde{\Omega}(n^{1/4})$  for any *adaptive* tester. This was further improved by Chen-Waingarten-Xie [5] to  $\tilde{\Omega}(n^{1/3})$ . These are highly non-trivial results. Belovs-Blais also gave a  $O(\log n)$  query adaptive monotonicity tester for the class of regular linear threshold functions (LTFs), the hard functions of Chen et al. [3]. This underscores the challenge of proving adaptive lower bounds and leaves a tantalizing open question. *Can adaptivity always help in Boolean monotonicity testing over the hypercube?*

We approach this question from the perspective of *parametrized property testing*, a concept recently introduced by Pallavoor-Raskhodnikova-Varma [10]. One seeks to understand the performance of testers with respect to parameters other than just the size of the domain. If one can beat existing lower bounds (for some settings of the parameters), this gives insight into the hardest functions for monotonicity testing.

Our main result is the existence of adaptive monotonicity testers parametrized by the total influence,  $\mathbf{I}(f)$ . Letting  $\mathcal{D}$  be the uniform distribution over all pairs  $(x, y)$  at Hamming distance 1,  $\mathbf{I}(f) := n \cdot \Pr_{(x,y) \sim \mathcal{D}}[f(x) \neq f(y)]$ .

► **Theorem 1.** *Consider the class of functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  with total influence at most  $I$ . There exists a one-sided, adaptive monotonicity tester for this class with query complexity  $O(I\varepsilon^{-2} \log^5 n)$ .*

A claim of KMS (Theorem 9.1 in [9]) implies that if  $\mathbf{I}(f) > 6\sqrt{n}$ , then the edge tester is itself a  $O(n/\mathbf{I}(f))$  tester. Combined with Theorem 1, one gets an adaptive  $\tilde{O}(\min(\mathbf{I}(f), n/\mathbf{I}(f))\varepsilon^{-2})$ -query tester. The trade-off point is basically  $\sqrt{n}$ , the maximum possible influence of a monotone function.

## 1.1 Perspective on Theorem 1

- When  $\mathbf{I}(f) \ll \sqrt{n}$ , Theorem 1 beats the lower bounds of [7, 3]. Indeed, the lower bound of Fischer et al. [7] holds for *constant* influence functions, and so adaptivity is crucial for a result like Theorem 1. As mentioned earlier, it was known that adaptivity helps for the structured class of regular LTFs [1]. What is intriguing about Theorem 1 is that no strong structural assumption is required to get  $o(\sqrt{n})$  query testers.

- All adaptive lower bound constructions have functions with influence  $\Theta(\sqrt{n})$  [1, 5]. In light of Theorem 1, this is perhaps no accident. Theorem 1 shows that this is the hard regime for monotonicity testing.
- The  $o(n)$  non-adaptive testers are obtained by directed random walks in the hypercube. One starts at a random  $x$  and walks “up” (consistent with the partial order) the hypercube to reach some  $y$ . Then, the tester compares  $f(x), f(y)$  to detect non-monotonicity. (The intermediate vertices in the random walk are not queried, and this is crucial for getting the  $o(n)$  bound.) The algorithm of Theorem 1 is fundamentally different; it performs standard, *undirected* random walks on the hypercube. The endpoints might not even be comparable, so only querying these is of no use. This is exactly where adaptivity helps, since we can perform binary search to find violations in this path. This leads to a better monotonicity tester for functions with influence  $o(\sqrt{n})$ .

## 1.2 Proof Idea

The  $o(n)$  testers of [2, 4, 9] perform random walks on the directed hypercube with orientation corresponding to the partial order, and query the function at the endpoints of this walk. Their analysis shows that if the function is  $\varepsilon$ -far from being monotone, then there is a significant probability of encountering a violation. At a high level, one of the main observations of [2, 4, 9] is that “longer” walks lead to higher chances of catching a violation. However, the vast majority of vertices in the hypercube have Hamming weight  $n/2 \pm \Theta(\sqrt{n})$ . For the purposes of monotonicity testing, one can assume that vertices outside these middle layers do not participate in any violations to monotonicity. Each step of a directed walk increments the Hamming weight, and thus the walk length can be at most  $\Theta(\sqrt{n})$ . This  $\sqrt{n}$  is precisely what shows up in the final bound of KMS.

Our insight is that one can perform an analogous analysis as above for random walks on the undirected hypercube  $H_n$ . These walks can have length  $\omega(\sqrt{n})$ . Suppose we perform an  $\ell$ -step random walk (on  $H_n$ ) from  $x$  that ends at  $y$ . Note that with high probability,  $x$  and  $y$  will not be comparable. Nonetheless, if  $f(x) \neq f(y)$ , then the walk has passed through an influential edge. The power of adaptivity is that we can find such an influential edge through binary search. This idea of using binary search is indeed also present in a  $O(\log n)$ -query algorithm of Belovs and Blais [1] for adaptive monotonicity testers for regular linear threshold functions.

However, we are not interested in finding an influential edge but rather a *violated* edge. Fix a violated edge  $(u, v)$ . Our insight is to lower bound the probability that  $(u, v)$  is the *unique* influential edge in the undirected random walk. In this scenario, binary search is guaranteed to find a violation. There are two opposing forces here. First, the probability that  $(u, v)$  at all appears in the random walk grows as  $\ell/n$ . On the other hand, the probability that this is the unique influential edge decreases with  $\ell$ ; indeed, this probability depends on the influence of  $f$ . A fairly simple calculation shows that for all but an  $\ell \mathbf{I}(f)/n$  fraction of “bad” vertices, an  $\ell$ -length from a vertex encounters no influential edge with constant probability. Putting these together, we see that setting  $\ell \sim n/\mathbf{I}(f)$  would lead to a good probability of catching a violation; note that if  $\mathbf{I}(f) \ll \sqrt{n}$ , the desired length of the walk would indeed be  $\gg \sqrt{n}$ .

The only fly in the above ointment is if all the violated edges were concentrated on the bad vertices. This is where we invoke the connection between distance to monotonicity and isoperimetry; the directed Talagrand inequality of KMS essentially precludes this scenario by showing that violated edges need to be “spread apart”. The actual math is more subtle. KMS gives a trade-off between the concentration of the violated edges and the number of

violated edges. If all violated edges are incident only on a few vertices, then there must be a lot of violated edges. The latter is where the edge-tester, which is nothing but a length 1 random walk, works. This analysis is similar to what is done in KMS.

### 1.3 Preliminaries

We use  $H_n$  to denote the standard (undirected) hypercube graph on  $\{0, 1\}^n$ , where all pairs at Hamming distance 1 are connected. An edge  $(x, y)$  of  $H_n$  is influential, if  $f(x) \neq f(y)$ . The number of influential edges is precisely  $\mathbf{I}(f) \cdot 2^{n-1}$ . An influential edge  $(x, y)$  is a violating edge if  $x \prec y$ ,  $f(x) = 1$ , and  $f(y) = 0$ . Our tester will perform random walks of  $H_n$ . Note that  $H_n$  is regular, so this is a symmetric Markov Chain.

We crucially use the central result of KMS, which is obtained as a consequence of the directed analogue of Talagrand's isoperimetric theorem.

► **Lemma 2** (Lemma 7.1 in [9], paraphrased). *Given any Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  that is  $\varepsilon$ -far from being monotone, there exists a subgraph  $G = (A, B, E)$  of the hypercube and parameters  $\sigma \in (0, 1)$ ,  $d \in \mathbb{N}$  such that*

- *Each edge  $(a, b) \in E$  with  $a \in A$  and  $b \in B$  is a violating edge.*
- *The degree of each vertex in  $B$  is exactly  $d$  and the degree of each vertex in  $A$  is at most  $2d$ .*
- *$|B| = \sigma \cdot 2^n$ .*
- *$\sigma^2 d = \Omega(\varepsilon^2 / \log^4 n)$ .*

## 2 Tester and Analysis

Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be a Boolean function over the hypercube with total influence  $\mathbf{I}(f)$ .

---

**Algorithm 1** Adaptive Monotonicity Tester for Boolean Functions.

---

**Input:** A Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and a parameter  $\varepsilon \in (0, 1)$

1. Choose  $k \in_R \{0, 1, 2, \dots, \lceil \log n \rceil\}$  uniformly at random. Set  $\ell := 2^k$ .
  2. Choose  $x \in \{0, 1\}^n$  uniformly at random.
  3. Perform an  $\ell$ -length random walk  $p$  on  $H_n$  starting from  $x$  to reach  $y \in \{0, 1\}^n$ .
  4. If  $f(x) \neq f(y)$ :
    - a. Perform binary search on  $p$  to find an influential edge  $(u, v) \in p$ .
    - b. REJECT if  $(u, v)$  is a monotonicity violation.
  5. ACCEPT.
- 

Theorem 1 follows directly from the following theorem by repeating the above subroutine the appropriate number of times. Note that the subroutine above does not need to know  $\mathbf{I}(f)$ .

► **Theorem 3.** *If  $f$  is  $\varepsilon$ -far from being monotone, then the algorithm described in Algorithm 1 rejects with probability  $\Omega\left(\frac{\varepsilon^2}{\mathbf{I}(f) \log^5 n}\right)$ .*

► **Definition 4.** Given a positive integer  $\ell$ , a vertex  $x \in \{0, 1\}^n$  is denoted  $\ell$ -sticky if an  $\ell$ -length random walk from  $x$  on  $H_n$  contains no influential edges with probability  $\geq 1/2$ . A vertex is called non- $\ell$ -sticky otherwise. An edge is  $\ell$ -sticky if both endpoints are  $\ell$ -sticky.

► **Observation 5.** *If a vertex  $x$  is  $\ell$ -sticky and  $\ell' < \ell$ , then  $x$  is  $\ell'$ -sticky as well.*

► **Lemma 6.** *The fraction of non- $\ell$ -sticky vertices of a hypercube is at most  $\frac{2\ell \cdot \mathbf{I}(f)}{n}$ .*

**Proof.** Given  $x \in \{0, 1\}^n$  and a positive integer  $\ell > 0$ , define the random variable  $Z_{x,\ell}$  that is the number of influential edges in a random walk of length  $\ell$  starting from  $x$ . Therefore,  $x$  is non- $\ell$ -sticky iff  $\Pr[Z_{x,\ell} > 0] > 1/2$ . Let  $N$  denote the set of non- $\ell$ -sticky vertices.

Since  $Z_{x,\ell}$  is non-negative and integer valued we get  $\Pr[Z_{x,\ell} > 0] \leq \mathbf{E}[Z_{x,\ell}]$ .

$$|N|/2^n < \frac{2}{2^n} \sum_{x \in N} \Pr[Z_{x,\ell} > 0] < \frac{2}{2^n} \sum_{x \in \{0,1\}^n} \Pr[Z_{x,\ell} > 0] \leq \frac{2}{2^n} \sum_{x \in \{0,1\}^n} \mathbf{E}[Z_{x,\ell}] \quad (1)$$

The RHS above is precisely twice the expected number of influential edges encountered in an  $\ell$ -length random walk starting from the uniform distribution on  $H_n$ . Let  $\mathcal{P}_\ell$  denote the uniform distribution on  $\ell$ -length paths in  $H_n$ . For  $p \sim \mathcal{P}_\ell$ ,  $p_t$  denotes the  $t$ th edge in  $p$ , and let  $\chi(e)$  be the indicator for edge  $e$  being influential. The RHS of (1) is equal to  $2\mathbf{E}_{p \sim \mathcal{P}_\ell}[\sum_{t \leq \ell} \chi(p_t)] = 2 \sum_{t \leq \ell} \mathbf{E}_{p \sim \mathcal{P}_\ell}[\chi(p_t)]$ . Since the uniform distribution is stationary for random walks on  $H_n$ , the distribution induced on  $p_t$  is the uniform distribution on edges in  $H_n$ . Thus,  $\mathbf{E}_{p \sim \mathcal{P}_\ell}[\chi(p_t)] = \mathbf{I}(f)/n$  and the RHS of (1) is  $2\ell \cdot \mathbf{I}(f)/n$ . ◀

For any integer  $\ell > 0$ , let  $F_\ell$  be the set of  $\ell$ -sticky violating edges. That is,

$$F_\ell := \{(x, y) \in H_n : (x, y) \text{ is violating and, } x, y \text{ are } \ell\text{-sticky}\}$$

► **Lemma 7.** *If  $\ell$  is the length of the random walk chosen in Step 1, then Algorithm 1 rejects with probability  $\Omega\left(\frac{\ell}{n} \cdot \frac{|F_\ell|}{2^n}\right)$ .*

**Proof.** Fix an edge  $(u, v) \in F_\ell$ . Let  $p = (e_1, \dots, e_\ell)$  be the edges of a random walk  $p$ . Each edge  $e_t$  for  $1 \leq t \leq \ell$  is a uniformly sampled random edge of  $H_n$ . Therefore, for any fixed edge  $(u, v)$ ,  $\Pr[e_t = (u, v)] = \frac{1}{n \cdot 2^{n-1}}$ .

Now, given  $1 \leq t \leq \ell$ , define  $\mathcal{E}_{u,v}^t$  to be the event that the  $t$ th edge of  $p$  is  $(u, v)$  and no other edge of  $p$  is influential. Define  $\mathcal{E}_{u,v}$  to be the disjoint union  $\bigvee_{t=1}^\ell \mathcal{E}_{u,v}^t$ . Observe that for two distinct edges  $(u, v)$  and  $(u', v')$  in  $F_\ell$ , the events  $\mathcal{E}_{u,v}$  and  $\mathcal{E}_{u',v'}$  are disjoint. Therefore,

$$\Pr[\text{Algorithm 1 rejects for length } \ell] \geq \Pr\left[\bigvee_{(u,v) \in F_\ell} \mathcal{E}_{u,v}\right] = \sum_{(u,v) \in F_\ell} \Pr[\mathcal{E}_{u,v}] \quad (2)$$

The inequality follows since if  $\mathcal{E}_{u,v}$  occurs then the end points of  $p$  must have differing values and binary search on  $p$  will return the violation  $(u, v)$ . The equality follows since the events are mutually exclusive.

Consider the event  $\mathcal{E}_{u,v}^t$ . For this event to occur,  $e_t$  must be  $(u, v)$ . Consider the conditional probability  $\Pr[\mathcal{E}_{u,v}^t \mid e_t = (u, v)]$ . Let  $\mathcal{F}_u$  be the event that a  $(t-1)$ -length random walk from  $u$  contains no influential edges, and let  $\mathcal{F}_v$  be the event that an *independent*  $(\ell-t)$ -length random walk from  $v$  contains no influential edges.

► **Claim 8.**  $\Pr[\mathcal{E}_{u,v}^t \mid e_t = (u, v)] = \Pr[\mathcal{F}_u \wedge \mathcal{F}_v] = \Pr[\mathcal{F}_u] \cdot \Pr[\mathcal{F}_v]$

**Proof.** Conditioned on  $e_t = (u, v)$ , the distribution of the first  $(t-1)$  steps of the random walk is the uniform distribution of  $(t-1)$ -length paths that end at  $u$ . This is the same distribution of the  $(t-1)$ -length random walk starting from  $u$ . The distribution of the last  $(\ell-t)$  steps, conditioned on  $e_t = (u, v)$ , is the  $(\ell-t)$ -length random walk starting from  $v$ . ◀

Since  $(u, v)$  is an  $\ell$ -sticky edge, by Obs 5 and Definition 4,  $\Pr[\mathcal{F}_u] \geq 1/2$  and  $\Pr[\mathcal{F}_v] \geq 1/2$ . The proof is completed by plugging the following bound into (2).

$$\begin{aligned} \Pr[\mathcal{E}_{u,v}] &= \sum_{t=1}^{\ell} \Pr[\mathcal{E}_{u,v}^t] = \sum_{t=1}^{\ell} \Pr[e_t = (u, v)] \cdot \Pr[\mathcal{E}_{u,v}^t \mid e_t = (u, v)] \\ &= \frac{2}{n \cdot 2^n} \sum_{t=1}^{\ell} \Pr[\mathcal{E}_{u,v}^t \mid e_t = (u, v)] \geq \frac{\ell}{4n \cdot 2^n} \quad \blacktriangleleft \end{aligned}$$

We complete the proof of Theorem 3.

**Proof of Theorem 3.** Let  $G = (A, B, E)$ ,  $\sigma, d$  be as in Lemma 2.

**Case 1:**  $\frac{n\sigma}{16\mathbf{I}(f)} \leq 1$ .

In this case, we argue that the edge tester succeeds. More precisely, consider the setting of the algorithm described in Algorithm 1 that sets  $\ell = 1$ , that is, the tester checks whether a random edge of  $H_n$  is a violation. This setting occurs with probability  $\Omega(1/\log n)$ . The number of violated edges is at least  $\sigma d 2^n$ , the number of edges in  $G = (A, B, E)$  (as defined in Lemma 2). Since  $\sigma^2 d = \Omega(\varepsilon^2 / \log^4 n)$ ,  $|E| = \Omega(\frac{\varepsilon^2}{\log^4 n} \cdot \frac{2^n}{\sigma})$ . Since the number of edges of the hypercube is  $\Theta(n 2^n)$ , we get that the probability Algorithm 1 obtains a violation is  $\Omega(\frac{\varepsilon^2}{\log^5 n} \cdot \frac{1}{n\sigma})$ . By assumption,  $\frac{n\sigma}{16\mathbf{I}(f)} \leq 1$ , so this probability is  $\Omega(\frac{\varepsilon^2}{\mathbf{I}(f) \log^5 n})$ .

**Case 2:**  $\frac{n\sigma}{16\mathbf{I}(f)} > 1$ .

In this case, there exists a non-negative power of 2 (call it  $\ell^*$ ) such that  $\frac{\sigma}{16} < \frac{\ell^* \mathbf{I}(f)}{n} \leq \frac{\sigma}{8}$ . Let  $A'$  and  $B'$  be the subset of  $A$  and  $B$  that are  $\ell^*$ -sticky. Let  $E' \subseteq E$  be the edges with end points in  $A'$  and  $B'$ . Note that any edge of  $E' \subseteq F_{\ell^*}$ . By Lemma 6, we get that the fraction of non- $\ell^*$ -sticky vertices is at most  $2^{\ell^*} \cdot \mathbf{I}(f)/n \leq \sigma/4$ . Since the degree of any vertex in  $G$  in Lemma 2 is  $\leq 2d$ ,

$$|F_{\ell^*}| \geq |E'| \geq |E| - (2d) \cdot \frac{\sigma \cdot 2^n}{4} = \frac{\sigma d 2^n}{2}.$$

The probability the algorithm chooses  $\ell = \ell^*$  is  $1/\log n$ . Lemma 7 gives us

$$\begin{aligned} \Pr[\text{Algorithm rejects}] &\geq \frac{1}{\log n} \cdot \Pr[\text{Algorithm rejects} \mid \ell = \ell^*] \\ &\geq \frac{1}{\log n} \cdot \left( \frac{\ell^*}{n} \cdot \frac{|F_{\ell^*}|}{2^n} \right) \quad (\text{by Lemma 7}) \\ &\geq \frac{1}{\log n} \cdot \frac{\ell^*}{n} \cdot \frac{\sigma d}{2} \\ &\geq \frac{1}{\mathbf{I}(f)} \cdot \left( \frac{\sigma^2 d}{32 \log n} \right) \quad (\text{plugging } \ell^* \geq \sigma n / (16 \cdot \mathbf{I}(f))) \\ &= \Omega\left( \frac{\varepsilon^2}{\mathbf{I}(f) \log^5 n} \right) \quad (\text{by Lemma 2}) \quad \blacktriangleleft \end{aligned}$$

## Abstract

For any constant  $d$  and parameter  $\varepsilon > 0$ , we show the existence of (roughly)  $1/\varepsilon^d$  orderings on the unit cube  $[0, 1]^d$ , such that any two points  $p, q \in [0, 1]^d$  that are close together under the Euclidean metric are “close together” in one of these linear orderings in the following sense: the only points that could lie between  $p$  and  $q$  in the ordering are points with Euclidean distance at most  $\varepsilon\|p - q\|$  from  $p$  or  $q$ . These orderings are extensions of the  $\mathcal{Z}$ -order, and they can be efficiently computed.

Functionally, the orderings can be thought of as a replacement to quadtrees and related structures (like well-separated pair decompositions). We use such orderings to obtain surprisingly simple algorithms for a number of basic problems in low-dimensional computational geometry, including (i) dynamic approximate bichromatic closest pair, (ii) dynamic spanners, (iii) dynamic approximate minimum spanning trees, (iv) static and dynamic fault-tolerant spanners, and (v) approximate nearest neighbor search.

## 1 Introduction

In this paper, we describe a technique that leads to new simple algorithms for a number of fundamental proximity problems in low-dimensional Euclidean spaces.

### Notation

The  $O$  notation hides constants that depends (usually exponentially) on  $d$ . Throughout, we assume (without loss of generality) that  $\varepsilon$  is a power of 2; that is  $\varepsilon = 2^{-E}$  for some positive integer  $E$ .

**Z-order**

Consider a point set  $P \subseteq [0, 1)^2$ , its quadtree, and a DFS traversal of this quadtree. One can order the points of  $P$  according to this traversal, resulting in an ordering  $\prec$  of the underlying set  $[0, 1)^2$ . The relation  $\prec$  is the ordering along a space filling mapping, known as the **Z-order**. Specifically, there is a bijection  $z$  from the unit interval  $[0, 1)$  to the unit square  $[0, 1)^2$  such that the ordering along the resulting “curve” is the Z-order. The Z-order mapping  $z$  is not continuous. Nevertheless, the Z-order mapping has the advantage of being easy to define. Indeed, given a real number  $\alpha \in [0, 1)$ , with the binary expansion  $\alpha = 0.x_1x_2x_3\dots$  (i.e.,  $\alpha = \sum_{i=1}^{\infty} x_i2^{-i}$ ), the Z-order mapping of  $\alpha$  is the point  $z(\alpha) = (0.x_2x_4x_6\dots, 0.x_1x_3x_5\dots)$ . Computing the Z-order or its inverse is quite easy, if one is allowed bitwise-logical operations – in particular, the ability to compute compressed quadtrees efficiently is possible only if such operations are available [19]. The approach extends to higher constant dimensions. The idea of using the Z-order can be traced back to the work of Gargantini [16], and it is widely used in databases and seems to improve performance in practice [24]. Once comparison by Z-order is available, building a compressed quadtree is no more than storing the points according to the Z-order, and this yields simple data structures for various problems. For example, Laio *et al.* [27] and Chan [7, 8, 9] applied the Z-order to obtain simple efficient algorithms for approximate nearest neighbor search and related problems.

**Shifting**

The Z-order (and quadtrees) does not preserve distance. That is, two points that are far away might be mapped to two close-together points, and vice versa. This problem is even apparent when using a grid, where points that are close together get separated into different grid cells. One way to get around this problem is to shift the grid (deterministically or randomly) [21]. The same approach works for quadtrees – one can shift the quadtree constructed for a point set several times such that for any pair of points in the quadtree, there will be a shift where the two points are in a cell of diameter that is  $O(1)$  times their distance. Improving an earlier work by Bern [3], Chan [6] showed that  $2\lceil d/2 \rceil + 1$  deterministic shifts are enough in  $d$  dimensions (a proof is reproduced in Appendix A.2). A somewhat similar shifting scheme was also suggested by Feige and Krauthgamer [14]. Random shifting of quadtrees underlines, for example, the approximation algorithm by Arora for Euclidean TSP [2].

By combining Z-order with shifting, both Chan [7] and Laio *et al.* [27] observed an extremely simple data structure for  $O(1)$ -approximate nearest neighbor search in constant dimensions: just store the points in Z-order for each of the  $2\lceil d/2 \rceil + 1$  shifts; given a query point  $q$ , find the successor and predecessor of  $q$  in the Z-order by binary search for each of the shifts, and return the closest point found. The data structure can be easily made dynamic to support insertions and deletions of points, and can also be adapted to find  $O(1)$ -approximate bichromatic closest pairs.

For approximate nearest neighbor (ANN) search, the  $O(1)$  approximation factor can be reduced to  $1 + \varepsilon$  for any fixed  $\varepsilon > 0$ , though the query algorithm becomes more involved [7] and unfortunately cannot be adapted to compute  $(1 + \varepsilon)$ -approximate bichromatic closest pairs. (In the monochromatic case, however, the approach can be adapted to find *exact* closest pairs, by considering  $O(1)$  successors and predecessors of each point [7].)

For other proximity-related problems such as spanners and approximate minimum spanning trees (MST), this approach does not seem to work as well: for example, the static algorithms in [9], which use the  $\mathcal{Z}$ -order, still require explicit constructions of compressed quadtrees and are not easily dynamizable.

### Main new technique: Locality Sensitive Orderings

For any given  $\varepsilon > 0$ , we show that there is a family of  $O((1/\varepsilon^d) \log(1/\varepsilon))$  orderings of  $[0, 1]^d$  with the following property: For any  $p, q \in [0, 1]^d$ , there is an ordering in the family such that all points lying between  $p$  and  $q$  in this ordering are within distance at most  $\varepsilon \|p - q\|$  from  $p$  or  $q$ . The order between two points can be determined efficiently using some bitwise-logical operations. See Theorem 10. We refer to these as **locality-sensitive orderings**. They generalize the previous construction of  $2\lceil d/2 \rceil + 1$  shifted copies of the  $\mathcal{Z}$ -order, which guarantees the stated property only for a large specific constant  $\varepsilon$  (dependent on  $d$ ). The property ensures, for example, that a  $(1 + \varepsilon)$ -approximate nearest neighbor of a point  $q$  can be found among the immediate predecessors and successors of  $q$  in these orderings.

### Applications

Locality-sensitive orderings immediately lead to simple algorithms for a number of problems, as listed below. Many of these results are significant simplification of previous work; some of the results are new.

- (a) **Approximate bichromatic closest pair.** Theorem 12 presents a data structure that maintains a  $(1 + \varepsilon)$ -approximate closest bichromatic pair for two sets of points in  $\mathbb{R}^d$ , with an update time of  $O(\log n)$ , for any fixed  $\varepsilon > 0$ , ignoring factors that depend on  $\varepsilon$  (roughly  $1/\varepsilon^d$ ). Previously, a general technique of Eppstein [12] can be applied in conjunction with a dynamic data structure for ANN, but the amortized update time increases by two  $\log n$  factors.
- (b) **Dynamic spanners.** For a parameter  $t \geq 1$  and a set of points  $P$  in  $\mathbb{R}^d$ , a graph  $G = (P, E)$  is a  $t$ -spanner for  $P$  if for all  $p, q \in P$ , there is a  $p$ - $q$  path in  $G$  of length at most  $t \|p - q\|$ . Static algorithms for spanners have been extensively studied in computational geometry. The dynamic problem appears tougher, and has also received much attention (see Table 1.1). We obtain a very simple data structure for maintaining a dynamic  $(1 + \varepsilon)$ -spanners in Euclidean space with an update (insertion and deletion) time of  $O(\log n)$  and having  $O(n)$  edges in total, for any fixed  $\varepsilon > 0$ , ignoring factors that depend on  $\varepsilon$  (roughly  $1/\varepsilon^d$ ). See Theorem 14. Although Gottlieb and Roditty [17] have previously obtained the same update time  $(1/\varepsilon^{O(d)}) \log n$ , their method requires much more intricate details. (Note that Gottlieb and Roditty's method more generally applies to spaces with bounded doubling dimension, but no simpler methods have been reported in the Euclidean setting.)

## 21:4 On Locality-Sensitive Orderings and Their Applications

■ **Table 1.1** Previous work on dynamic  $(1 + \varepsilon)$ -spanners in  $\mathbb{R}^d$ . Dependencies on  $\varepsilon$  (of the form  $1/\varepsilon^{O(d)}$ ) are omitted in the  $O$  bounds.

Kapoor and Li [25]/Solomon [31]	$O(kn)$	$O(k)$	$O(n \log n + kn)$

- (c) **Dynamic approximate minimum spanning trees.** As is well-known [4, 19], a  $(1 + \varepsilon)$ -approximate Euclidean MST of a point set  $P$  can be computed from the MST of a  $(1 + \varepsilon)$ -spanner of  $P$ . In our dynamic spanner (and also Gottlieb and Roditty’s method [17]), each insertion/deletion of a point causes  $O(1)$  edge updates to the graph. Immediately, we thus obtain a dynamic data structure for maintaining a  $(1 + \varepsilon)$ -approximate Euclidean MST, with update time (ignoring dependencies on  $\varepsilon$ ) equal to that for the dynamic graph MST problem, which is currently  $O(\log^4 n / \log \log n)$  with amortization [22].
- (d) **Static and dynamic vertex-fault-tolerant spanners.** For parameters  $k, t \geq 1$  and a set of points  $P$  in  $\mathbb{R}^d$ , a  $k$ -vertex-fault-tolerant  $t$ -spanner is a graph  $G$  which is a  $t$ -spanner and for any  $P' \subseteq P$  of size at most  $k$ , the graph  $G \setminus P'$  remains a  $t$ -spanner for  $P \setminus P'$ . Fault-tolerant spanners have been extensively studied (see Table 1.2). Locality-sensitive orderings lead to a very simple construction for  $k$ -vertex-fault-tolerant  $(1 + \varepsilon)$ -spanners, with  $O(kn)$  edges, maximum degree  $O(k)$ , and  $O(n \log n + kn)$  running time (ignoring dependencies on  $\varepsilon$ ). See Theorem 16. Although this result was known before, all previous constructions (including suboptimal ones), from Levcopoulos *et al.* [26] to Solomon’s work [31], as listed in Table 1.2, require intricate details. It is remarkable how effortlessly we achieve optimal  $O(k)$  degree, compared to the previous methods. (Note, however, that some of the more recent previous constructions more generally apply to spaces with bounded doubling dimension, and some also achieve good bounds on other parameters such as the total weight and the hop-diameter.) Our algorithm can be easily made dynamic, with  $O(\log n + k)$  update time. No previous results on dynamic fault-tolerant spanners were known.
- (e) **Approximate nearest neighbors.** Locality-sensitive orderings lead to a simple dynamic data structure for  $(1 + \varepsilon)$ -approximate nearest neighbor search with  $O(\log n)$  time per update/query (ignoring dependencies on  $\varepsilon$ ). While this result is not new [7], we emphasize that the query algorithm is the simplest so far – it is just a binary search in the orderings maintained.

## Computational models

The model of computation we have assumed is a unit-cost real RAM, supporting standard arithmetic operations and comparisons (but no floor function), augmented with bitwise-logical operations (bitwise-exclusive-or and bitwise-and), which are commonly available in programming languages (and in reality are cheaper than some arithmetic operations like multiplication).

If we assume that input coordinates are integers bounded by  $U$  and instead work in the word RAM model with  $(\log U)$ -bit words ( $U \geq n$ ), then our approach can actually yield *sublogarithmic* query/update time. For example, we can achieve  $O(\log \log U)$  expected time for dynamic approximate bichromatic closest pair, dynamic spanners, and dynamic ANN, by replacing binary search with van Emde Boas trees [32]. Sublogarithmic algorithms were known before for dynamic ANN [7], but ours is the first sublogarithmic result for dynamic  $(1 + \varepsilon)$ -spanners. Our results also answer the open problem of dynamic  $(1 + \varepsilon)$ -approximate bichromatic closest pair in sublogarithmic time, originally posed by Chan and Skrepetos [10].

## 2 Locality-sensitive orderings

### 2.1 Grids and orderings

► **Definition.** For a set  $X$ , consider a total order (or ordering)  $\prec$  on the elements of  $X$ . Two elements  $x, y \in X$  are **adjacent** if there is no element  $z \in X$ , such that  $x \prec z \prec y$  or  $y \prec z \prec x$ .

Given two elements  $x, y \in X$ , such that  $x \prec y$ , the **interval**  $[x, y)$  is the set  $[x, y) = \{x\} \cup \{z \in X \mid x \prec z \prec y\}$ .

The following is well known, and goes back to a work by Walecki in the 19th century [1]. We include a proof in Appendix A.1 for the sake of completeness.

► **Lemma 1.** *For  $n$  elements  $\{0, \dots, n-1\}$ , there is a set  $\mathfrak{D}$  of  $\lceil n/2 \rceil$  orderings of the elements, such that, for all  $i, j \in \{0, \dots, n-1\}$ , there exist an ordering  $\sigma \in \mathfrak{D}$  in which  $i$  and  $j$  are adjacent.*

► **Definition 2.** Consider an axis-parallel cube  $\mathcal{C} \subseteq \mathbb{R}^d$  with side length  $\ell$ . Partitioning it uniformly into a  $t \times t \times \dots \times t$  grid  $\mathbf{G}$  creates the  **$t$ -grid** of  $\mathcal{C}$ . The grid  $\mathbf{G}$  is a set of  $t^d$  identically sized cubes with side length  $\ell/t$ .

For a cube  $\square \subseteq \mathbb{R}^d$ , its **diameter** is  $\text{diam}(\square) = \text{sidelength}(\square)\sqrt{d}$ .

By Lemma 1 we obtain the following result.

► **Corollary 3.** *For a  $t$ -grid  $\mathbf{G}$  of an axis-parallel cube  $\mathcal{C} \subseteq \mathbb{R}^d$ , there is a set  $\mathfrak{D}(t, d)$  of  $O(t^d)$  orderings, such that for any  $\square_1, \square_2 \in \mathbf{G}$ , there exists an order  $\sigma \in \mathfrak{D}(t, d)$  where  $\square_1$  and  $\square_2$  are adjacent in  $\sigma$ .*

### 2.2 $\varepsilon$ -Quadtrees

► **Definition 4.** An  **$\varepsilon$ -quadtrees**  $\mathcal{T}_\varepsilon$  is a quadtree-like structure, built on a cube with side length  $\ell$ , where each cell is being partitioned into a  $(1/\varepsilon)$ -grid. The construction then continues recursively into each grid cell of interest. As such, a node in this tree has up to  $1/\varepsilon^d$  children, and a node at level  $i \geq 0$  has an associated cube of side length  $\ell\varepsilon^i$ . We call a  $1/2$ -quadtrees a regular quadtree.

■ **Figure 2.1** One ordering of a set of cells.

► **Lemma 5.** Let  $E > 0$  be an integer number,  $\varepsilon = 2^{-E}$ , and  $\mathcal{T}$  be a regular quadtree over  $[0, 2)^d$ . Then there are  $\varepsilon$ -quadtrees  $\mathcal{T}_\varepsilon^1, \dots, \mathcal{T}_\varepsilon^E$ , such that the collection of cells at each level in  $\mathcal{T}$  is contained in exactly one of these  $\varepsilon$ -quadtrees.

**Proof.** For  $i = 0, \dots, E - 1$ , construct the  $\varepsilon$ -quadtree  $\mathcal{T}_\varepsilon^i$  using the cube  $[0, 2^{E-i})^d \supseteq [0, 2)^d$  as the root. Now for  $j \in \{0, \dots, E - 1\}$ , observe that the collection of cells at levels  $j, j + E, j + 2E, \dots$ , of  $\mathcal{T}$  will also be in the quadtree  $\mathcal{T}_\varepsilon^j$ . Indeed, any node at level  $j + \ell E$  in  $\mathcal{T}$  corresponds to a cell of side length  $2^{-(j+\ell E)}$ . Now in the  $(\ell + 1)$ th level of quadtree  $\mathcal{T}_\varepsilon^j$ , this same node will have side length  $\varepsilon^{\ell+1} 2^{E-j} = 2^{-(j+\ell E)}$ . ◀

Consider an  $\varepsilon$ -quadtree  $\mathcal{T}_\varepsilon$ . Every node has up to  $1/\varepsilon^d$  children. Consider any ordering  $\sigma$  of  $\{1, \dots, 1/\varepsilon^d\}$ , and consider a DFS of  $\mathcal{T}_\varepsilon$  that always visits the children of a node in the order specified by  $\sigma$ . This induces an ordering on the points in the cube which is the root of  $\mathcal{T}_\varepsilon$ . Indeed, for any two points, imagine storing them in an  $\varepsilon$ -quadtree – this implies that the two points are each stored in their own leaf node, which contains no other point of interest. Now, independently of what other points are stored in the quadtree, this DFS traversal would visit these two points in the same order. This can be viewed as a space filling curve (which is not continuous) which maps a cube to an interval. This is a generalization of the  $\mathcal{Z}$ -order. In particular, given a point set stored in  $\mathcal{T}_\varepsilon$ , and  $\sigma$ , one can order the points according to this DFS traversal, resulting in 1-dimensional ordering of the points. We denote the resulting ordering by  $(\mathcal{T}_\varepsilon, \sigma)$ .

► **Definition 6.** Let  $\Pi$  be the set of all orderings of  $[0, 2)^d$ , induced by picking one of the  $\lg(1/\varepsilon)$  trees of Lemma 5, together with an ordering  $\sigma \in \mathcal{D}(1/\varepsilon, d)$ , as defined by Lemma 1. Each ordering in  $\Pi$  is called an  **$\varepsilon$ -ordering**.

Any two points that are lucky enough to lie in a cell of the quadtree that has diameter close to their distance, are going to be adjacent in one of the  $\varepsilon$ -orderings. Indeed, consider two points  $p, q \in [0, 1)^d$ , a parameter  $\varepsilon > 0$ , such that  $p, q$  are both contained in a cell  $\square$  of the regular quadtree  $\mathcal{T}$  with  $\|p - q\| > \varepsilon \text{diam}(\square)$ . Then, there is an  $\varepsilon$ -quadtree  $\mathcal{T}_\varepsilon$  that has  $\square$  as a node, and let  $\square_p$  and  $\square_q$  be the two children of  $\square$  in  $\mathcal{T}_\varepsilon$ , containing  $p$  and  $q$  respectively. Furthermore, there is an ordering  $\sigma \in \mathcal{D}(1/\varepsilon, d)$ , such that  $\square_p$  and  $\square_q$  are adjacent. As such, the cube  $\square_p$  (resp.,  $\square_q$ ) corresponds to an interval  $[x, x')$  (resp.,  $[x', x'')$ ) in the ordering  $(\mathcal{T}_\varepsilon, \sigma)$ , and these two intervals are adjacent.

Now consider the case when there are two points close together, but no appropriately sized quadtree cell contains both  $p$  and  $q$ . In other words, two points that are close together might get separated by nodes that are much bigger in the quadtree. This can be resolved using shifting. We need the following result of Chan [6, Lemma 3.3] – a proof is provided in Appendix A.2.

► **Lemma 7.** Consider any two points  $p, q \in [0, 1]^d$ , and let  $\mathcal{T}$  be the infinite quadtree of  $[0, 2]^d$ . For  $D = 2 \lceil d/2 \rceil$  and  $i = 0, \dots, D$ , let  $v_i = (i/(D+1), \dots, i/(D+1))$ . Then there exists an  $i \in \{0, \dots, D\}$ , such that  $p + v_i$  and  $q + v_i$  are contained in a cell of  $\mathcal{T}$  with side length  $\leq 2(D+1) \|p - q\|$ .

### 2.3 Comparing two points according to an $\varepsilon$ -ordering

We now show how to efficiently compare two points in  $P$  according to a given  $\varepsilon$ -ordering  $\sigma$  with a shift  $v_i$ . The shift can be added to the two points directly, and as such only need to worry about how to compare two points according to  $\sigma$ .

► **Observation 8.** Let  $\oplus$  denote the bitwise-exclusive-or operator. Define  $\text{msb}(a) := -\lfloor \lg a \rfloor$  to be the index of the most significant bit in the binary expansion of  $a \in (0, 2]$ . Given  $a, b \in [0, 2)$ , one can compare the  $\text{msb}$  of two numbers using the following:

(a)  $\text{msb}(a) > \text{msb}(b)$  if and only if  $a < b$  and  $a < a \oplus b$ .

(b) If  $a \oplus b \leq a \wedge b$  then  $\text{msb}(a) = \text{msb}(b)$ , where  $\wedge$  is the bitwise-and operator.

► **Lemma 9.** Let  $p = (p_1, \dots, p_d)$  and  $q = (q_1, \dots, q_d)$  be two distinct points in  $P \subseteq [0, 2]^d$  and  $\sigma \in \Pi$  be an  $\varepsilon$ -ordering over the cells of some  $\varepsilon$ -quadtree  $\mathcal{T}_\varepsilon$  storing  $P$ . Then one can determine if  $p \prec_\sigma q$  using  $O(d \log(1/\varepsilon))$  bitwise-logical operations.

**Proof.** Recall  $\varepsilon$  is a power of two and  $E = \lg(1/\varepsilon)$ . In order to compare  $p$  and  $q$ , for  $i = 1, \dots, d$ , compute  $a_i = p_i \oplus q_i$ . Find the index  $i'$  such that  $\text{msb}(a_{i'}) \leq \text{msb}(a_i)$  for all  $i$ , using  $O(d)$  comparisons. Given  $p_{i'}$  and  $q_{i'}$ , our first goal is to determine the place in which  $p_{i'}$  and  $q_{i'}$  first differ in their binary representation. Note that because  $\varepsilon$  is a power of two, each bit in the base  $1/\varepsilon$  expansion of  $p_{i'}$  corresponds to a block of  $E$  bits in the binary expansion of  $p_{i'}$ .

First we find the position within the block of size  $E$  where  $p_{i'}$  and  $q_{i'}$  differ in their binary expansion. For  $j = 1, \dots, E$ , let  $b_j = 2^{E-j}/(2^E - 1) \in (0, 1)$  be the number whose binary expansion has a 1 in positions  $j, j + E, j + 2E, \dots$ , and 0 everywhere else. For  $j = 1, \dots, E$ , compute  $b_j \wedge a_{i'}$  and check if  $\text{msb}(b_j) = \text{msb}(b_j \wedge a_{i'})$ . Once we find a  $j$  such that  $\text{msb}(b_j) = \text{msb}(b_j \wedge a_{i'})$ , stop. We know that that  $p_{i'}$  and  $q_{i'}$  first differ in the  $j$ th position inside some block.

It remains to extract the  $E$  bits from each block in  $p_1, \dots, p_d$ . For  $i = 1, \dots, d$ , let  $B_i \in \{0, 1\}^E$  be the bits inside the block associated with  $p_i$ . For  $k = 1, \dots, E$ , set  $B_{i,k} = \mathbb{1}[\text{msb}(2^{j-k} a_{i'}) = \text{msb}((2^{j-k} a_{i'}) \wedge p_i)]$  (where  $\mathbb{1}[\cdot]$  is the indicator function). By repeating a similar process for all  $q_1, \dots, q_d$ , we obtain the coordinates of the cells in which  $p$  and  $q$  differ. We can then consult  $\sigma$  to determine whether or not  $p \prec_\sigma q$ .

This implies that  $p$  and  $q$  can be compared using  $O(d \log(1/\varepsilon))$  operations by Observation 8. ◀

#### Remark

In the word RAM model for integer input, the extra  $\log(1/\varepsilon)$  factor in the above time bound can be eliminated:  $\text{msb}$  can be explicitly computed in  $O(1)$  time by a complicated algorithm of Fredman and Willard [15]; this allows us to directly jump to the right block of each coordinate and extract the relevant bits.

## 2.4 The result

► **Theorem 10.** *For a parameter  $\varepsilon \in (0, 1)$ , there is a set  $\Pi^+$  of  $O((1/\varepsilon^d) \log(1/\varepsilon))$  orderings of  $[0, 1]^d$ , such that for any two points  $p, q \in [0, 1]^d$  there is an ordering  $\sigma \in \Pi^+$  defined over  $[0, 1]^d$ , such that for any point  $u$  with  $p \prec_\sigma u \prec_\sigma q$  it holds that either  $\|p - u\| \leq \varepsilon \|p - q\|$  or  $\|q - u\| \leq \varepsilon \|p - q\|$ .*

*Furthermore, given such a ordering  $\sigma$ , and two points  $p, q$ , one can compute their ordering, according to  $\sigma$ , using  $O(d \log(1/\varepsilon))$  arithmetic and bitwise-logical operations.*

**Proof.** Let  $\Pi^+$  be the set of all ordering defined by picking an ordering from  $\Pi$ , as defined by Definition 6 using the parameter  $\varepsilon$ , together with a shift from Lemma 7.

Consider any two points  $p, q \in [0, 1]^d$ . By Lemma 7 there is a shift for which the two points fall into a quadtree cell  $\square$  with side length at most  $2(D + 1) \|p - q\|$ . Next, there is an  $\varepsilon$ -quadtree  $\mathcal{T}_\varepsilon$  that contains  $\square$ , and the two children that correspond to two cells  $\square_p$  and  $\square_q$  with side length at most  $2(D + 1)\varepsilon \|p - q\|$ , which readily implies that the diameter of these cells is at most  $2(D + 1)\sqrt{d}\varepsilon \|p - q\|$ . Furthermore, there is an  $\varepsilon$ -ordering in  $\Pi$  such that all the points of  $\square_p$  are adjacent to all the points  $\square_q$  in this ordering. This implies the desired claim, after adjusting  $\varepsilon$  by a factor of  $2(D + 1)\sqrt{d}$  (and rounding to a power of 2). ◀

From now on, we refer to the set of orderings  $\Pi^+$  in the above Theorem as locality-sensitive orderings. We remark that by the readjustment of  $\varepsilon$  in the final step of the proof, the number of locality-sensitive orderings when including the factors involving  $d$  is  $O(d^{3d/2}(1/\varepsilon^d) \log(1/\varepsilon))$ .

### 2.4.1 Discussion

#### Connection to locality-sensitive hashing

Let  $P$  be a set of  $n$  points in  $\{0, 1\}^d$ . Consider the decision version of the  $(1 + \varepsilon)$ -approximate nearest neighbor problem. Specifically, for a pre-specified radius  $r$  and any given query point  $q$ , we would like to efficiently decide whether or not there exists a point  $p \in P$  such that  $\|q - p\|_1 \leq (1 + \varepsilon)r$  or conclude that all points in  $P$  are at least distance  $r$  from  $q$ . The locality-sensitive hashing (LSH) technique [23] can be used to create a data structure supporting these types of decision queries in time  $O(dn^{1/(1+\varepsilon)} \log n)$  time (which is correct with high probability) and using total space  $O(dn^{1+1/(1+\varepsilon)} \log n)$ . Similar results also hold in Euclidean space.

At a high level, LSH works as follows. Start by choosing  $k := k(\varepsilon, r, n)$  indices in  $[d]$  at random (with replacement). Let  $R$  denote the resulting multiset of coordinates. For each point  $p \in P$ , let  $p_R$  be the projection  $p$  onto these coordinates of  $R$ . We can group the points of  $P$  into buckets, where each bucket contains points with the same projection. Given a query point  $q$ , we check if any of the points in the same bucket as  $q_R$  is at distance at most  $(1 + \varepsilon)r$  from  $q$ . This construction can also be repeated a sufficient number of times in order to guarantee success with high probability.

The idea of bucketing can also be viewed as an implicit ordering on the randomly projected point set by ordering points lexicographically according to the  $k$  coordinates. In this sense, the query algorithm can be viewed as locating  $q$  within each of the orderings, and comparing  $q$  to similar points nearby in each ordering. From this perspective, every locality-sensitive ordering can be viewed as a LSH scheme. Indeed, for a given query point  $q$ , the approximate nearest neighbor to  $q$  can be found by inspecting the elements adjacent to  $q$  in each of the locality-sensitive orderings and returning the closest point to  $q$  found (see Theorem 17).

Of course, the main difference between the two schemes is that for every fixed  $\varepsilon$ , the number of “orderings” in a LSH scheme is polynomial in both  $d$  and  $n$ . While for locality-sensitive orderings, the number of orderings remain exponential in  $d$ . This trade-off is required, as locality-sensitive orderings guarantee a much stronger property than that of a LSH scheme.

### Extension of locality-sensitive orderings to other norms in Euclidean space

The result of Theorem 10 also holds for any  $L_p$  norm. The key change that is needed is in the proof of Lemma 7: For any two points  $s, t \in [0, 1]^d$ , there exists a shift  $v$  such that  $s + v$  and  $t + v$  are contained in a quadtree cell of side length at most  $2(D + 1) \|s - t\|_p$ . This extension follows easily from the proof of the Lemma, see Appendix A.2. Theorem 10 then follows by adjusting  $\varepsilon$  by a factor of  $2(D + 1)d^{1/p}$  in the last step, implying that the number of orderings will be  $O(d^{d(1+1/p)}(1/\varepsilon^d) \log(1/\varepsilon))$ .

### Extension of locality-sensitive orderings for doubling metrics

An abstraction of low-dimensional Euclidean space, is a metric space with (low) doubling dimension. Formally, a metric space  $(\mathcal{M}, d)$  has *doubling dimension*  $\lambda$  if any ball of  $\mathcal{M}$  of radius  $r$  can be covered by at most  $2^\lambda$  balls of half the radius (i.e.,  $r/2$ ). It is known that  $\mathbb{R}^d$  has doubling dimension  $O(d)$  [33]. We point out that locality-sensitive orderings still exist in this case, but they are less constructive in nature, since one needs to be provided with all the points of interest in advance.

For a point set  $P \subseteq \mathcal{M}$ , the analogue of a quadtree for a metric space is a net tree [20]. Being somewhat imprecise, a net tree can be constructed as follows: The root node corresponds to the point set  $P \subseteq \mathcal{M}$ . Compute a randomized partition of  $P$  of diameter  $1/2$  (assume  $P$  has diameter one), and for each cluster in the partition, create an associated node and hang it on the root. The tree is computed recursively in this manner, at each level  $i$  computing a random partition of diameter  $2^{-i}$ . The leaves of the tree are points of  $P$ .

As with quadtrees, it is possible during this randomized construction for two nearby points to be placed in different clusters and be separated further down the tree. If  $\ell = d(p, q)$  for two points  $p, q \in P$ , then the probability that  $p$  and  $q$  lie in different clusters of diameter  $r = 2^{-i}$  in the randomized partition is at most  $O((\ell/r) \log n)$  [13]. In particular, for  $r \approx 1/(\ell \log n)$ , the probability  $p$  and  $q$  are separated is at most a constant. If we want even this property to hold with high probability for all pairs of points, one needs to construct  $O(\log n)$  (randomly constructed) net trees of  $P$ . (This corresponds to randomly shifting a quadtree  $O(\log n)$  times in the Euclidean setting.)

Given such a net tree  $T$ , each node has  $I = 2^{O(\lambda)}$  children. We can arbitrarily and explicitly number the children of each node by a distinct label from  $[I]$ . One can define an ordering of such a tree as we did in the Euclidean case, except that the gap (in diameter) between a node and its children is  $O(\varepsilon/\log n)$  instead of  $\varepsilon$ . Repeating our scheme in the Euclidean case, this implies that one would expect to require  $(\varepsilon^{-1} \log n)^{O(\lambda)}$  orderings of  $P$ .

This requires having all the points of  $P$  in advance, which is a strong assumption for a dynamic data structure (like the applications we show next). For example, Gottlieb and Roditty [17] show how to maintain dynamic spanners in a doubling metric, but only assuming that after a point has been deleted from  $P$ , the distance between the deleted point and a point currently in  $P$  can still be computed in constant time.

### 3 Applications

#### 3.1 Bichromatic closest pair

Given an ordering  $\sigma \in \Pi^+$ , and two finite sets of points  $R, B$  in  $\mathbb{R}^d$ , let  $\mathcal{Z} = \mathcal{Z}(\sigma, R, B)$  be the set of all pairs of points in  $R \times B$  that are adjacent in the ordering of  $R \cup B$  according to  $\sigma$ . Observe that inserting or deleting a single point from these two sets changes the content of  $\mathcal{Z}$  by a constant number of pairs. Furthermore, a point participates in at most two pairs.

► **Lemma 11.** *Let  $R$  and  $B$  be two sets of points in  $[0, 1]^d$ , and let  $\varepsilon \in (0, 1)$  be a parameter. Let  $\sigma \in \Pi^+$  be a locality-sensitive ordering (see Theorem 10). Then, one can maintain the set  $\mathcal{Z} = \mathcal{Z}(\sigma, R, B)$  under insertions and deletions to  $R$  and  $B$ . In addition, one can maintain the closest pair in  $\mathcal{Z}$  (under the Euclidean metric). Each update takes  $O(d \log(n) \log(1/\varepsilon))$  time, where  $n$  is the total size of  $R$  and  $B$  during the update operation.*

**Proof.** Maintain two balanced binary search trees  $T_R$  and  $T_B$  storing the points in  $R$  and  $B$ , respectively, according to the order  $\sigma$ . Insertion, deletion, predecessor query and successor query can be implemented in  $O(d \log(1/\varepsilon) \log n)$  time (since any query requires  $O(\log n)$  comparisons costing each  $O(d \log(1/\varepsilon))$  time by Lemma 9). We also maintain a min-heap of the pairs in  $\mathcal{Z}$  sorted according to the Euclidean distance. The minimum is the desired closest pair. Notice that a single point can participate in at most two pairs in  $\mathcal{Z}$ .

We now explain how to handle updates. Given a newly inserted point  $r$  (say a red point that belongs to  $R$ ), we compute its (potential) pairs it participates in, by computing its successor  $r'$  in  $R$ , and its successor  $b'$  in  $B$ . If  $r \prec_\sigma b' \prec_\sigma r'$  then the new pair  $rb'$  should be added to  $\mathcal{Z}$ . The pair before  $r$  in the ordering that might use  $r$  is computed in a similar fashion. In addition, we recompute the predecessor and successor of  $r$  in  $R$ , and we recompute the pairs they might participate in (deleting potentially old pairs that are no longer valid).

Deletion is handled in a similar fashion – all points included in pairs with the deleted point recompute their pairs. In addition, the successor and predecessor (of the same color) need to recompute their pairs. This all requires a constant number of queries in the two trees, and thus takes the running time as stated. ◀

► **Theorem 12.** *Let  $R$  and  $B$  be two sets of points in  $[0, 1]^d$ , and let  $\varepsilon \in (0, 1)$  be a parameter. Then one can maintain a  $(1 + \varepsilon)$ -approximation to the bichromatic closest pair in  $R \times B$  under updates (i.e., insertions and deletions) in  $O(\log(n) \log^2(1/\varepsilon)/\varepsilon^d)$  time per operation, where  $n$  is the total number of points in the two sets. The data structure uses  $O(n \log(1/\varepsilon)/\varepsilon^d)$  space, and at all times maintains a pair of points  $r \in R$ ,  $b \in B$ , such that  $\|r - b\| \leq (1 + \varepsilon)d(R, B)$ , where  $d(R, B) = \min_{r \in R, b \in B} \|r - b\|$ .*

**Proof.** We maintain the data structure of Lemma 11 for all the locality-sensitive orderings of Theorem 10. We might as well maintain all the good pairs for these data structures together in one global min-heap. We claim that the minimum length pair in this heap is the desired approximation.

To see that, consider the bichromatic closest pair  $r \in R$  and  $b \in B$ . By Theorem 10 there is a locality-sensitive ordering  $\sigma$ , such that the interval  $I$  in the ordering between  $r$  and  $b$  contains points that are in distance at most  $\ell = \varepsilon \|r - b\|$  from either  $r$  or  $b$ . In particular, let  $P_r$  (resp.,  $P_b$ ) be all the points in  $I$  in distance at most  $\ell$  from  $r$  (resp.,  $b$ ). Observe that  $P_r \subseteq R$ , as otherwise, there would be a bichromatic pair in  $P_r$ , and since the diameter of this set is at most  $\ell$ , this would imply that  $(r, b)$  is not the closest bichromatic pair – a contradiction. Similarly,  $P_b \subseteq B$ . As such, there must be two points  $b' \in B$  and  $r' \in R$ , that are consecutive in  $\sigma$ , and this is one of the pairs considered by the algorithm (as it is stored

in the min-heap). In particular, by the triangle inequality, we have

$$\|r' - b'\| \leq \|r' - r\| + \|r - b\| + \|b - b'\| \leq 2\ell + \|r - b\| \leq (1 + 2\varepsilon) \|r - b\|.$$

The theorem follows after adjusting  $\varepsilon$  by a factor of 2.  $\blacktriangleleft$

### Remark

In the word RAM model, for integer input in  $\{1, \dots, U\}^d$ , the update time can be improved to  $O((\log \log U) \log^2(1/\varepsilon)/\varepsilon^d)$  expected, by using van Emde Boas trees [32] in place of the binary search trees (and the min-heaps as well). With standard word operations, we may not be able to explicitly map each point to an integer in one dimension following each locality-sensitive ordering, but we can still simulate van Emde Boas trees on the input as if the mapping has been applied. Each recursive call in the van Emde Boas recursion focuses on a specific block of bits of each input coordinate value (after shifting); we can extract these blocks, and perform the needed hashing operations on the concatenation of these blocks over the  $d$  coordinates of each point.

## 3.2 Dynamic spanners

► **Definition 13.** For a set of  $n$  points  $P$  in  $\mathbb{R}^d$  and a parameter  $t \geq 1$ , a  $t$ -**spanner** of  $P$  is an undirected graph  $G = (P, E)$  such that for all  $p, q \in P$ ,

$$\|p - q\| \leq d_G(p, q) \leq t\|p - q\|,$$

where  $d_G(p, q)$  is the length of the shortest path from  $p$  to  $q$  in  $G$  using the edge set  $E$ .

Using a small modification of the results in the previous section, we easily obtain a dynamic  $(1 + \varepsilon)$ -spanner. Note that there is nothing special about how the data structure in Theorem 12 deals with the bichromatic point set. If the point set is monochromatic, modifying the data structure in Lemma 11 to account for the closest monochromatic pair of points leads to a data structure with the same bounds and maintains the  $(1 + \varepsilon)$ -approximate closest pair.

The construction of the spanner is very simple: Given  $P$  and  $\varepsilon \in (0, 1)$ , maintain orderings of the points specified by  $\Pi^+$  (see Theorem 10). For each  $\sigma \in \Pi^+$ , let  $E_\sigma$  be the edge set consisting of edges connecting two consecutive points according to  $\sigma$ , with weight equal to their Euclidean distance. Thus  $|E_\sigma| = n - 1$ . Our spanner  $G = (P, E)$  then consists of the edge set  $E = \bigcup_{\sigma \in \Pi^+} E_\sigma$ .

► **Theorem 14.** *Let  $P$  be a set of  $n$  points in  $[0, 1]^d$  and  $\varepsilon \in (0, 1)$ . One can compute a  $(1 + \varepsilon)$ -spanner  $G$  of  $P$  with  $O(n \log(1/\varepsilon)/\varepsilon^d)$  edges, where every vertex has degree  $O(\log(1/\varepsilon)/\varepsilon^d)$ . Furthermore, insertions and deletions can be performed in  $O(\log(n) \log^2(1/\varepsilon)/\varepsilon^d)$  time, with at most  $O(\log(1/\varepsilon)/\varepsilon^d)$  edges being deleted or inserted into the spanner.*

**Proof.** The construction is described above. The same analysis as in the proof of Theorem 12 implies the number of edges in  $G$  and the update time.

It remains to prove that  $G$  is a spanner. By Theorem 10, for any pair of points  $s, t \in P$ , there is a locality-sensitive ordering  $\sigma \in \Pi^+$ , such that the  $\sigma$ -interval  $[s, t)$  contains only points that are in distance at most  $\varepsilon \|s - t\|$  from either  $s$  or  $t$ . In particular, there must be two points in  $s', t' \in P$  that are adjacent in  $\sigma$ , such that one of them, say  $s'$  (resp.,  $t'$ ) is in distance at most  $\varepsilon \|s - t\|$  from  $s$  (resp.,  $t$ ). As such, the edge  $s't'$  exists in the graph being maintained.

This property is already enough to imply that this graph is a  $(1 + c\varepsilon)$ -spanner for a sufficiently large constant  $c$  – this follows by an induction on the distances between the points (specifically, in the above, we apply the induction hypothesis on the pairs  $s, s'$  and  $t, t'$ ). We omit the easy but somewhat tedious argument – see [4] or [19, Theorem 3.12] for details. The theorem follows after adjusting  $\varepsilon$  by a factor of  $c$ . ◀

### 3.2.1 Static and dynamic vertex-fault-tolerant spanners

► **Definition 15.** For a set of  $n$  points  $P$  in  $\mathbb{R}^d$  and a parameter  $t \geq 1$ , a  $k$ -**vertex-fault-tolerant  $t$ -spanner** of  $P$ , denoted by  $(k, t)$ -VF $T$ S, is a graph  $G = (P, E)$  such that

- (i)  $G$  is a  $t$ -spanner (see Definition 13), and
- (ii) For any  $P' \subseteq P$  of size at most  $k$ , the graph  $G \setminus P'$  is a  $t$ -spanner for  $P \setminus P'$ .

A  $(k, 1 + \varepsilon)$ -VF $T$ S can be obtained by modifying the construction of the  $(1 + \varepsilon)$ -spanner in Section 3.2. Construct a set of locality-sensitive orderings  $\Pi^+$ . For each  $\sigma \in \Pi^+$  and each  $p \in P$ , connect  $p$  to its  $k + 1$  successors and  $k + 1$  predecessors according to  $\sigma$  with edge weights equal to the Euclidean distances. Thus each ordering maintains  $O(nk)$  edges and there are  $O(|\Pi^+|kn) = O(kn \log(1/\varepsilon)/\varepsilon^d)$  edges overall. We now prove that this graph  $G$  is in fact a  $(k, 1 + \varepsilon)$ -VF $T$ S.

► **Theorem 16.** *Let  $P$  be a set of  $n$  points in  $[0, 1]^d$  and  $\varepsilon \in (0, 1)$ . One can compute a  $k$ -vertex-fault-tolerant  $(1 + \varepsilon)$ -spanner  $G$  for  $P$  in time  $O((n \log n \log(1/\varepsilon) + kn) \log(1/\varepsilon)/\varepsilon^d)$ . The number of edges is  $O(kn \log(1/\varepsilon)/\varepsilon^d)$  and the maximum degree is bounded by  $O(k \log(1/\varepsilon)/\varepsilon^d)$ .*

*Furthermore, one can maintain the  $k$ -vertex-fault-tolerant  $(1 + \varepsilon)$ -spanner  $G$  under insertions and deletions in  $O((\log n \log(1/\varepsilon) + k) \log(1/\varepsilon)/\varepsilon^d)$  time per operation.*

**Proof.** The construction algorithm, number of edges, and maximum degree follows from the discussion above. So, consider deleting a set  $P' \subseteq P$  of size at most  $k$  from  $G$ . Consider an ordering  $\sigma \in \Pi^+$  with the points  $P'$  removed. By the construction of  $G$ , all the pairs of points of  $P \setminus P'$  that are (now) adjacent in  $\sigma$  remain connected by an edge in  $G \setminus P'$ . The argument of Theorem 14 implies that the remaining graph is spanner. We conclude that that  $G \setminus P'$  is a  $(1 + \varepsilon)$ -spanner for  $P \setminus P'$ .

As for the time taken to handle insertions and deletions, one simply maintains the orderings of the points using balanced search trees. After an insertion to one of the orderings in  $O(\log n \log(1/\varepsilon))$  time,  $O(k)$  edges have to be added and deleted. Therefore insertions take  $O((\log n \log(1/\varepsilon) + k) |\Pi^+|) = O((\log n \log(1/\varepsilon) + k) \log(1/\varepsilon)/\varepsilon^d)$  time total. Deletions are handled similarly.

The total construction time follows by inserting each of the points into the dynamic data structure. ◀

### 3.3 Dynamic approximate nearest neighbors

Another application of the same data structure in Theorem 12 is supporting  $(1 + \varepsilon)$ -approximate nearest neighbor queries. In this scenario, the data structure must support insertions and deletions of points and the following queries: given a point  $q$ , return a point  $t \in P$  such that  $\|q - t\| \leq (1 + \varepsilon) \min_{p \in P} \|q - p\|$ .

► **Theorem 17.** *Let  $P$  be a set of  $n$  points in  $[0, 1]^d$ . For a given  $\varepsilon > 0$ , one can build a data structure using  $O(n \log(1/\varepsilon)/\varepsilon^d)$  space, that supports insertion and deletion in time  $O(\log(n) \log^2(1/\varepsilon)/\varepsilon^d)$ . Furthermore, given a query point  $q \in [0, 1]^d$ , the data structure returns a  $(1 + \varepsilon)$ -approximate nearest neighbor in  $P$  in  $O(\varepsilon^{-d} \log^2(1/\varepsilon) \log(n))$  time.*

**Proof.** Maintain the data structure of Lemma 11 for all locality-sensitive orderings of Theorem 10, with one difference: Since the input is monochromatic, the data structures for each ordering store distances between all consecutive pairs. The space and update time bounds easily follow by the same analysis.

Given a query point  $q \in [0, 1]^d$ , for each of the orderings the algorithm inspects the predecessor and successor to  $q$ . The algorithm returns the closest point to  $q$  encountered. We claim that the returned point  $p$  is the desired approximate nearest neighbor.

Let  $p^* \in P$  be the nearest neighbor to  $q$  and  $\ell = \|q - p^*\|$ . By Theorem 10, there is a locality-sensitive ordering  $\sigma \in \Pi^+$  such that the  $\sigma$ -interval  $I = [p^*, q)$  contains points that are of distance at most  $\varepsilon\ell$  from  $p^*$  or  $q$  (and this interval contains at least one point of  $P$ , namely,  $p^*$ ). Note that no point of  $P$  can be at distance less than  $\varepsilon\ell$  to  $q$ . Thus, the point  $p \in P$  adjacent to  $q$  in  $I$  is of distance at most  $\varepsilon\ell$  from  $p^*$ . Therefore, for such a point  $p$ , we have  $\|p - q\| \leq \|p - p^*\| + \|p^* - q\| \leq (1 + \varepsilon)\ell$ .

The final query time follows from the time taken for these predecessor and successor queries, as in the proof of Lemma 11. ◀

## A Proofs

■ **Figure A.1** For  $n$  even, a decomposition of  $K_n$  into  $n/2$  Hamiltonian paths.

### A.1 Proof of Lemma 1

► **Lemma 1 (Restated).** For  $n$  elements  $\{0, \dots, n-1\}$ , there is a set  $\mathfrak{D}$  of  $\lceil n/2 \rceil$  orderings of the elements, such that, for all  $i, j \in \{0, \dots, n-1\}$ , there exist an ordering  $\sigma \in \mathfrak{D}$  in which  $i$  and  $j$  are adjacent.

**Proof.** As mentioned earlier this is well known, see [1]. Assume  $n$  is even, and consider the clique  $K_n$ , with its vertices  $v_0, \dots, v_{n-1}$ . The edges of this clique can be covered by  $n/2$  Hamiltonian paths that are edge disjoint. Tracing one of these path gives rise to one ordering, and doing this for all paths results with orderings with the desired property, since edge  $v_i v_j$  is adjacent in one of these paths.

To get this cover, draw  $K_n$  by using the vertices of an  $n$ -regular polygon, and draw all the edges of  $K_n$  as straight segments. For every edge  $v_i v_{i+1}$  of  $K_n$  there are exactly  $n/2$  parallel edges with this slope (which form a matching). Let  $M_i$  denote this matching. Similarly, for the vertex  $v_i$ , consider the segment  $v_i v_{i+n/2}$  (indices are here modulo  $n$ ), and the family of segments (i.e., edges) of  $K_n$  that are orthogonal to this segment. This family is also a matching  $M'_i$  of size  $n/2 - 1$ . Observe that  $\sigma_i = M_i \cup M'_i$  form a Hamiltonian path, as shown in Figure A.1. Since the slopes of the segments in  $M_i$  and  $M'_i$  are unique, for  $i = 0, \dots, n/2 - 1$ , it follows that  $\sigma_0, \dots, \sigma_{n/2-1}$  are an edge disjoint cover of all the edges of  $K_n$  by  $n/2$  Hamiltonian paths.

If  $n$  is odd, use the above construction for  $n + 1$ , and delete the redundant symbol from the computed orderings. ◀

## A.2 Proof of 7 (shifting)

For two positive real numbers  $x$  and  $y$ , let

$$x \% y = x - y \lfloor x/y \rfloor.$$

The basic idea behind shifting is that one can pick a set of values that look the “same” in all resolutions.

► **Lemma 18.** *Let  $n > 1$  be a positive odd integer, and consider the set  $X = \{i/n \mid i = 0, \dots, n-1\}$ . Then, for any  $\alpha = 2^{-\ell}$ , where  $\ell \geq 0$  is integer, we have that  $X \% \alpha = \{i/n \% \alpha \mid i = 0, \dots, n-1\}$  is equal to the set  $\alpha X = \{\alpha i/n \mid i = 0, \dots, n-1\}$ .*

**Proof.** The proof is by induction. For  $\ell = 0$  the claim clearly holds. Next, assume the claim holds for some  $i \geq 0$ , and consider  $\ell = i + 1$ . Setting  $m = (n-1)/2$  and  $\Delta = 2^{-i}/n$ , we have by induction (and rearrangement) that

$$\begin{aligned} X \% 2^{-i} &= 2^{-i} X = \{0, \Delta, \dots, 2m\Delta\} \\ &= \{0, (m+1)\Delta, \Delta, (m+2)\Delta, 2\Delta, \dots, (m+m)\Delta, m\Delta\}. \end{aligned}$$

Settings  $\delta = \Delta/2 = 2^{-i-1}/n$ , and observing that  $(2m+1)\delta = n\delta = 2^{-i-1}$ , we have

$$\begin{aligned} X \% 2^{-i-1} &= (X \% 2^{-i}) \% 2^{-i-1} \\ &= \{0, (m+1)\Delta, \Delta, (m+2)\Delta, 2\Delta, \dots, (m+j)\Delta, j\Delta, \dots, (m+m)\Delta, m\Delta\} \% 2^{-i-1} \\ &= \{0, 2(m+1)\delta, 2\delta, 2(m+2)\delta, 4\delta, \dots, 2(m+j)\delta, 2j\delta, \dots, 2(m+m)\delta, 2m\delta\} \% 2^{-i-1} \\ &= \{0, \delta, 2\delta, 3\delta, 4\delta, \dots, (2j-1)\delta, 2j\delta, \dots, (2m-1)\delta, 2m\delta\}, \end{aligned}$$

since  $2(m+j)\delta \% 2^{-i-1} = (2m+1+2j-1)\delta \% 2^{-i-1} = (2j-1)\delta$ , for  $j = 1, \dots, m$ . ◀

► **Lemma 7 (Restated).** *Consider any two points  $p, q \in [0, 1]^d$ , and let  $\mathcal{T}$  be the infinite quadtree of  $[0, 2]^d$ . For  $D = 2 \lceil d/2 \rceil$  and  $i = 0, \dots, D$ , let  $v_i = (i/(D+1), \dots, i/(D+1))$ . Then there exists an  $i \in \{0, \dots, D\}$ , such that  $p + v_i$  and  $q + v_i$  are contained in a cell of  $\mathcal{T}$  with side length  $\leq 2(D+1) \|p - q\|$ .*

**Proof.** Without loss of generality, suppose  $d$  is even (as such  $D = d$ ). Let  $\ell \in \mathbb{N}$ , such that for  $\alpha = 2^{-\ell}$ , we have

$$(d+1) \|p - q\| < \alpha \leq 2(d+1) \|p - q\|.$$

For  $\tau \in [0, 1]$ , let  $\mathbf{G} + \tau$  denote the (infinite) grid with sidelength  $\alpha$  shifted by the point  $(\tau, \dots, \tau)$ .

Let  $X = \{i/(d+1) \mid i = 0, \dots, d\}$  be the set of shifts considered. Since we are shifting a grid with sidelength  $\alpha$ , the shifting is periodical with value  $\alpha$ . It is thus sufficient to consider the shifts modulo  $\alpha$ .

Let  $p = (p_1, \dots, p_d)$  and  $q = (q_1, \dots, q_d)$ . Assume that  $p_1 \leq q_1$ . A shift  $\tau$  is bad, for the first coordinate, if there is an integer  $i$ , such that  $p_1 \leq \tau + i\alpha \leq q_1$ . The set of bad shifts in the interval  $[0, \alpha]$  is

$$B_1 = \{(p_1, q_1) + i\alpha \mid i \in \mathbb{Z}\} \cap [0, \alpha].$$

The set  $B_1$  is either an interval of length  $|p_1 - q_1| \leq \|p - q\| < \alpha/(d+1)$ , or two intervals (of the same total length) adjacent to 0 and  $\alpha$ . In either case,  $B_1$  can contain at most one point of  $\alpha X = X \% \alpha$ , since the distance between any two values of  $\alpha X$  is at least  $\alpha/(d+1)$ , by Lemma 18.

Namely, the first coordinate rules out at most one candidate shift in  $X \times \alpha$ . Repeating the above argument for all  $d$  coordinates, we conclude that there is at least one shift in  $\alpha X$  that is good for all coordinates. Let  $\beta = \alpha i / (d + 1) \in \alpha X$  this be good shift. Namely,  $p$  and  $q$  belongs the same cell of  $G + \beta$ . The final step is to observe that shifting the points by  $-\beta$ , instead of the grid by distance  $\beta$  has the same effect (and  $-\beta \times \alpha \in \alpha X$ ), and as such, the canonical cell containing both  $p$  and  $q$  is in the quadtree  $\mathcal{T}$  as desired, and the sidelength of this cell is  $\alpha$ . ◀

## Abstract

---

A recent work of Chattopadhyay et al. (CCC 2018) introduced a new framework for the design of pseudorandom generators for Boolean functions. It works under the assumption that the Fourier tails of the Boolean functions are uniformly bounded for all levels by an exponential function. In this work, we design an alternative pseudorandom generator that only requires bounds on the second level of the Fourier tails. It is based on a derandomization of the work of Raz and Tal (ECCC 2018) who used the above framework to obtain an oracle separation between BQP and PH.

As an application, we give a concrete conjecture for bounds on the second level of the Fourier tails for low degree polynomials over the finite field  $\mathbb{F}_2$ . If true, it would imply an efficient pseudorandom generator for  $AC^0[\oplus]$ , a well-known open problem in complexity theory. As a stepping stone towards resolving this conjecture, we prove such bounds for the first level of the Fourier tails.

## 1 Introduction

Pseudorandom generators are widely studied in computational complexity theory. The main focus of this paper is a new framework for the design of pseudorandom generators (abbrv. PRGs) based on Fourier tails, introduced recently by Chattopadhyay et al. [2]. We refer to the survey of Vadhan [14] for an introduction to pseudorandomness in complexity theory, and assume basic knowledge with common concepts.

Let  $\mathcal{F}$  be a family of  $n$ -variate Boolean functions, which is closed under restrictions. Namely, for any  $f \in \mathcal{F}$ , if we restrict some of the inputs of  $f$  to Boolean values, then the restricted function is also in  $\mathcal{F}$ . Nearly all classes of Boolean functions studied in the literature satisfy this property.

Given an  $n$ -variate Boolean function  $f$ , its level- $k$  Fourier tails for  $k = 1, \dots, n$  are defined as

$$\mathcal{L}_{1,k}(f) = \sum_{S \subseteq [n]: |S|=k} |\widehat{f}(S)|.$$

For a function class  $\mathcal{F}$  of  $n$ -variate Boolean functions define

$$\mathcal{L}_{1,k}(\mathcal{F}) = \max_{f \in \mathcal{F}} \mathcal{L}_{1,k}(f).$$

Chattopadhyay et al. [2] proved a general theorem, which constructs an explicit PRG for functions in  $\mathcal{F}$ , assuming that  $\mathcal{F}$  has bounded  $k$ -level Fourier tails for all  $k$ . This property is known to hold for many classes of interest (read-once branching programs of bounded width, low-depth circuits, low sensitivity functions, and more; see [2] for details).

► **Theorem 1** ([2]). *Let  $\mathcal{F}$  be a family of  $n$ -variate Boolean functions that is closed under restrictions. Assume that for some  $a, b \geq 1$  it holds that*

$$\mathcal{L}_{1,k}(\mathcal{F}) \leq a \cdot b^k \quad \forall k = 1, \dots, n.$$

*Then for any  $\varepsilon > 0$ , there exists an explicit PRG for  $\mathcal{F}$  with error  $\varepsilon$  and seed length  $s = b^2 \cdot \text{polylog}(an/\varepsilon)$ .*

Note that for any  $n$ -variate Boolean function one can take  $a = 1, b = \sqrt{n}$ , and hence the quadratic dependence on  $b$  in the seed length is optimal.

The main objective of this current work is to investigate whether PRGs can also be obtained from weaker assumptions on the Fourier tail. Specifically, whether it suffices that  $\mathcal{L}_{1,k}(\mathcal{F})$  is bounded for a few values of  $k$ , instead of for the full regime of  $k = 1, \dots, n$  as was required by [2]. Our main result is that this is indeed the case: it suffices to obtain bounds for the second level of the Fourier tail.

► **Theorem 2** (Main result, informal version). *Let  $\mathcal{F}$  be a family of  $n$ -variate Boolean functions closed under restrictions. Assume that for some  $t \geq 1$  it holds that*

$$\mathcal{L}_{1,2}(\mathcal{F}) \leq t.$$

*Then for any  $\varepsilon > 0$ , there exists an explicit PRG for  $\mathcal{F}$  with error  $\varepsilon$  and seed length  $\text{poly}(t, \log n, 1/\varepsilon)$ .*

For a more precise formula for the seed length see Theorem 6. We note that the dependence on the error parameter  $\varepsilon$  in Theorem 2 is much worse compared to Theorem 1 – polynomial instead of polylogarithmic. We discuss this in Section 4.

## 1.1 A potential PRG for $\mathbb{F}_2$ -polynomials and $\text{AC}^0[\oplus]$

There are known deep relationships between the ability to construct explicit pseudorandom generators, and the ability to prove correlation bounds, for many classes of Boolean functions. One of the few classes where the latter is known but the former is not is  $\text{AC}^0[\oplus]$ , which is the classes of constant-depth polynomial-size Boolean circuits with AND, OR, NOT and PARITY gates. Classical works of Razborov [10] and Smolensky [11] prove that this class cannot approximate the MAJORITY function. On the other hand, the problem of constructing explicit PRGs for  $\text{AC}^0[\oplus]$  is a well-known open problem in complexity theory. We refer to the survey of Viola [15] for further discussion on this challenge.

We give a concrete (and plausible in our minds) conjecture which, combined with Theorem 2, would imply such a PRG. Let  $\text{Poly}_{n,d}$  denote the class of  $n$ -variate Boolean functions which are computed by  $\mathbb{F}_2$ -polynomials of degree at most  $d$ . This class is clearly closed under restrictions.

► **Conjecture 3.**  $\mathcal{L}_{1,2}(\text{Poly}_{n,d}) = O(d^2)$ . That is, if  $p : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$  is a polynomial of degree  $d$ , and  $f(x) = (-1)^{p(x)}$ , then

$$\sum_{i,j \in [n], i < j} |\widehat{f}(\{i,j\})| = O(d^2).$$

A corollary of Conjecture 3, when combined with Theorem 2, is the construction of explicit PRGs for degree- $d$  polynomials over  $\mathbb{F}_2$  with seed length  $\text{poly}(\log n, d, 1/\varepsilon)$ . This would be a major breakthrough in complexity theory, as currently no PRGs are known for polynomials of degree  $d = \Omega(\log n)$ . We note that a similar seed length would follow from a weaker version of Conjecture 3 with the bound  $\mathcal{L}_{1,2}(\text{Poly}_{n,d}) \leq \text{poly}(\log n, d)$ . However, we conjecture that  $O(d^2)$  is the correct bound.

We further note that such PRGs would directly imply PRGs for  $\text{AC}^0[\oplus]$ .

► **Claim 4.** Assume that Conjecture 3 holds. Then, for any  $\varepsilon > 0$  there exists an explicit PRG for the class of  $\text{AC}^0[\oplus]$ -circuits of size  $s$  and depth  $e$  on  $n$  inputs, with error  $\varepsilon$  and seed length  $\text{poly}((\log(s/\varepsilon))^e, \log n, 1/\varepsilon)$ .

In particular, assuming the conjecture, for any constants  $e$  and  $c$ ,  $\text{AC}^0[\oplus]$ -circuits of size at most  $n^c$  and depth at most  $e$  have a PRG with seed length  $\text{poly}(\log n, 1/\varepsilon)$  and error  $\varepsilon$ .

**Proof sketch.** Let  $f : \{0,1\}^n \rightarrow \{0,1\}$  be computed by an  $\text{AC}^0[\oplus]$  circuit of size  $s$  and depth  $e$ . Razborov [10] and Smolensky [12] proved that there exists a distribution over polynomials  $p : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$  of degree  $d = O(\log(s/\varepsilon))^e$  such that for each  $x \in \{0,1\}^n$ ,  $\Pr_p[p(x) \neq f(x)] \leq \varepsilon/3$ . Theorem 2 gives a PRG for polynomials of degree  $d$  with error  $\varepsilon/3$  and seed length  $\text{poly}(\log n, d, 1/\varepsilon)$ . By the Razborov-Smolensky result, this PRG is also a PRG for  $f$  with error  $\varepsilon$ . ◀

### Evidence Supporting The Conjecture

We present three results that supports the validity of Conjecture 3:

1. As a stepping stone towards resolving Conjecture 3, we prove a bound on the first level of the Fourier tail of low degree polynomials over  $\mathbb{F}_2$ .

► **Theorem 5.**  $\mathcal{L}_{1,1}(\text{Poly}_{n,d}) \leq 4d$ .

2. We note that as a special case of the main result in [3], any read-once  $\mathbb{F}_2$ -polynomial  $f$  (i.e., a sum of monomials on disjoint sets of variables) has

$$\mathcal{L}_{1,2}(f) \leq O(\log n)^8.$$

Getting a similar poly  $\log(m)$  bound for **general** polynomials with  $m$  monomials, would be sufficient for the application in Claim 4.

3. In [2] the following exponential bound was proved on the  $\mathcal{L}_{1,2}(\text{Poly}_{n,d})$ :

$$\mathcal{L}_{1,2}(\text{Poly}_{n,d}) \leq 4 \cdot 2^{6d}.$$

(as a special case of a bound on  $\mathcal{L}_{1,k}$  more generally.) We remark that this bound depends only on  $d$  and not on  $n$ . Thus, if our conjecture is false, any counter-example to it must have degree  $d = \omega(1)$ .

### Organization

We prove Theorem 2 in Section 2. We prove Theorem 5 in Section 3. We discuss further research in Section 4.

## 2 PRG from level two Fourier bounds

The main result of this section is an explicit pseudorandom generator for Boolean functions that have bounded Fourier tails on the second level.

► **Theorem 6.** *Let  $\mathcal{F}$  be a family of  $n$ -variate Boolean functions closed under restrictions. Assume that for some  $t \geq 1$  it holds that*

$$\mathcal{L}_{1,2}(\mathcal{F}) \leq t.$$

*Then for any  $\varepsilon > 0$ , there exists an explicit PRG for  $\mathcal{F}$  with error  $\varepsilon$  and seed length  $O((t/\varepsilon)^{2+o(1)} \cdot \text{polylog}(n))$ .*

The framework to construct the PRG is similar to the one used in [2]. The first step is to construct a fractional PRG for  $\mathcal{F}$  that is  $p$ -noticeable. Now using the *polarizing* random walk technique used in [2], we convert this fractional PRG into the required standard PRG. Our fractional PRG is based on ideas developed in [9]. We first recall the basic framework of [2].

### Pseudorandom generators

Let  $f : \{-1, 1\}^n \rightarrow \{-1, 1\}$  be a Boolean function. A PRG for  $f$  with error  $\varepsilon$  is a random variable  $X \in \{-1, 1\}^n$  such that

$$|\mathbf{E}[f(X)] - \mathbf{E}[f(U_n)]| \leq \varepsilon,$$

where  $U_n$  is the uniform distribution in  $\{-1, 1\}^n$ . It has seed length  $s$  if  $X$  can be sampled as

$$X = G(U_s)$$

where  $G : \{-1, 1\}^s \rightarrow \{-1, 1\}^n$  is an explicit function<sup>4</sup>.

$X$  is a PRG for a class of functions  $\mathcal{F}$  if it is a PRG for each function  $f \in \mathcal{F}$ .

---

<sup>4</sup> There are various notions of explicitness used in the complexity literature. For our purposes any notion would do.

### Fractional pseudorandom generators

Let  $f : \{-1, 1\}^n \rightarrow \{-1, 1\}$  be a Boolean function. It has a unique multi-linear extension as  $f : [-1, 1]^n \rightarrow [-1, 1]$ . A fractional PRG for  $f$  with error  $\varepsilon$  is a random variable  $X \in [-1, 1]^n$  such that

$$|\mathbf{E}[f(X)] - f(\vec{0})| \leq \varepsilon.$$

Note that  $f(\vec{0}) = \mathbf{E}[f(U_n)]$ . It has seed length  $s$  if  $X$  can be sampled as

$$X = G(U_s)$$

where  $G : \{-1, 1\}^s \rightarrow [-1, 1]^n$  is an explicit function. The fractional PRG  $X$  is  $p$ -noticeable if

$$\mathbf{E}[X_i^2] \geq p \quad \forall i = 1, \dots, n.$$

### From fractional PRGs to PRGs

The following is the main result of [2], which converts a fractional PRG into a standard PRG.

► **Theorem 7** ([2]). *Let  $\mathcal{F}$  be a family of  $n$ -variate Boolean functions that is closed under restrictions. Let  $X$  be a  $p$ -noticeable fractional pseudorandom generator for  $\mathcal{F}$  with seed length  $s$  and error  $\varepsilon$ . Then, there exists a pseudorandom generator for  $\mathcal{F}$  with seed length  $O(s \cdot \log(n/\varepsilon)/p)$  and error  $O(\varepsilon \cdot \log(n/\varepsilon)/p)$ .*

Given, the above theorem, the missing piece to get the desired PRG in Theorem 6 is to construct an appropriate fractional PRG. The following lemma achieves exactly this.

► **Lemma 8.** *Let  $\mathcal{F}$  be a family of  $n$ -variate Boolean functions closed under restrictions. Assume that for some  $t \geq 1$  it holds that*

$$\mathcal{L}_{1,2}(\mathcal{F}) \leq t.$$

*Then for any  $\varepsilon > 0$ , there exists an explicit  $p$ -noticeable fractional PRG for  $\mathcal{F}$  with error  $\varepsilon$  and seed length  $s$  where:*

$$\begin{aligned} 1/p &= O(\log(n/\varepsilon)) \\ s &= O((t/\varepsilon)^{2+o(1)} \cdot \log(n) \cdot \log(n/\varepsilon)). \end{aligned}$$

It is direct to obtain Theorem 6 from Theorem 7 and Lemma 8. We prove Lemma 8 in the remainder of this section.

As mentioned before, the fractional PRG is constructed based on ideas developed in [9]. In particular, our fractional PRG can be seen as a derandomization of the main distribution used in [9].

We first abstract and restate one of the main arguments in [9]. This abstraction appeared in a blog post of Boaz Barak and Jarosław Błasiok [1]. Below, we abbreviate a Multi-Variate Gaussian as MVG. Given a random variable  $Z \in \mathbb{R}^n$ , we denote by  $\text{trnc}(Z)$  its truncation to  $[-1, 1]^n$ . That is,  $\text{trnc}(Z)_i = \min(1, \max(-1, Z_i))$  for  $i \in [n]$ .

► **Theorem 9** ([9], restated). *Let  $n, t \geq 1, \delta \in (0, 1)$ . Let  $Z \in \mathbb{R}^n$  be a zero-mean MVG random variable with the following two properties:*

- (i) *For  $i \in [n]$ :  $\mathbf{Var}[Z_i] \leq \frac{1}{8 \ln(n/\delta)}$ .*
- (ii) *For  $i, j \in [n], i \neq j$ :  $|\mathbf{Cov}[Z_i, Z_j]| \leq \delta$ .*

*Let  $\mathcal{F}$  be a class of  $n$ -variate Boolean functions which is closed under restrictions. Assume that  $\mathcal{L}_{1,2}(\mathcal{F}) \leq t$ . Then for any  $f \in \mathcal{F}$  it holds that  $|\mathbf{E}[f(\text{trnc}(Z))] - f(\vec{0})| \leq O(\delta \cdot t)$ .*

## 22:6 Pseudorandom Generators from Second Level Fourier Bounds

For completeness, we prove Theorem 9 in the appendix – the proof basically repeats the argument in [9] but for a general multivariate Gaussian distribution, instead of the Forrelation distribution considered there. We now show how to use Theorem 9 to construct a  $p$ -noticeable fractional PRG for  $\mathcal{F}$  with error  $\varepsilon$  and seed length  $s$ , where  $1/p = O(\log(n/\varepsilon))$  and  $s = \text{poly}(t, \log(n), 1/\varepsilon)$ .

- I. We show that a MVG distribution with the parameters needed in Theorem 9 can be of rank  $\ell = \text{poly}(\log(n), t, 1/\varepsilon)$ . That is, we sample  $\ell$  independent  $\mathcal{N}(0, 1)$  random variables and apply an explicit linear transformation  $T : \mathbb{R}^\ell \rightarrow \mathbb{R}^n$  to get a random variable in  $\mathbb{R}^n$  that satisfies the two conditions of Theorem 9.
- II. We discretized the above process.

### Step I: Dimension Reduction

Let  $\delta = \varepsilon/t$  and let  $\ell$  be a parameter to be determined soon. Let  $\mathcal{C}$  be a code on  $\{0, 1\}^\ell$  with at least  $n$  codewords, such that  $\mathcal{C}$  is  $\delta$ -balanced. Namely, every codeword in  $\mathcal{C}$  has Hamming weight between  $(\frac{1}{2} - \delta)\ell$  and  $(\frac{1}{2} + \delta)\ell$ . Such a code can be obtained from explicit constructions of small-biased spaces over  $\{0, 1\}^\ell$ . The best known construction is by Ta-Shma [13] which achieves  $\ell = (\log n)/\delta^{2+o(1)}$ .

Set  $p = 1/(8 \ln(n/\delta))$ . Let  $c^1, \dots, c^n \in \mathcal{C}$  be distinct codewords. Define an  $n \times \ell$  matrix  $A$  given by

$$A_{i,j} = \sqrt{\frac{p}{\ell}} \cdot (-1)^{c_j^i},$$

where  $c^i = (c_1^i, \dots, c_\ell^i)$ . Let  $Y$  be a random vector in  $\mathbb{R}^\ell$  where each  $Y_i$  is an independent  $\mathcal{N}(0, 1)$  Gaussian. Define

$$Z = AY.$$

It is straightforward to verify from the construction that  $Z$  is a multivariate Gaussian distribution over  $\mathbb{R}^n$  with mean zero which satisfies that  $\mathbf{Var}[Z_i] = p$  for all  $i \in [n]$ , and  $|\mathbf{Cov}[Z_i, Z_j]| \leq \delta$  for all distinct  $i, j \in [n]$ .

### Step II: Discretizing the Randomness

We prove the following lemma, which allows to approximately sample a standard MVG  $Y \in \mathbb{R}^\ell$  as needed above using a few random bits.

► **Lemma 10.** *For any  $\ell, \eta > 0$  there exists  $s = O(\ell \cdot \log(\ell/\eta))$  and an explicit generator  $G : \{0, 1\}^s \rightarrow \mathbb{R}^\ell$  such that the following holds.*

*Let  $f : [-1, 1]^n \rightarrow [-1, 1]$  be a multi-linear function,  $A \in [-1, 1]^{n \times \ell}$  and  $Y$  be a random variable over  $\mathbb{R}^\ell$  where each  $Y_i$  is an independent  $\mathcal{N}(0, 1)$  Gaussian. Then*

$$|\mathbf{E}[f(\text{trnc}(AY))] - \mathbf{E}[f(\text{trnc}(AG(U_s)))]| \leq \eta(n + 2).$$

We say that a random variable  $W \in \mathbb{R}$  is a  $\lambda$ -approximate Gaussian if there is a correlated standard Gaussian  $W' \sim \mathcal{N}(0, 1)$  such that  $\mathbf{Pr}[|W - W'| > \lambda] < \lambda$ . We will use the following lemma of Kane [6] which shows how to approximate a Gaussian in a randomness efficient way.

► **Lemma 11 ([6]).** *There is an explicit construction of a  $\lambda$ -approximate Gaussian random variable using  $O(\log(1/\lambda))$  bits of randomness.*

The generator  $G$  would simply be  $\ell$  independent copies of a  $\lambda$ -approximate Gaussian given by the above lemma, with  $\lambda = \frac{\eta}{\ell}$ . We denote by  $Y' = G(U_s)$  and by  $Y$  the coupled standard MVG in  $\mathbb{R}^\ell$ .

Let  $\mathcal{E}$  denote the event that  $\|Y - Y'\|_\infty \leq \lambda$ . By a union bound,  $\Pr(\mathcal{E}) \geq 1 - \eta$ . Conditioned on  $\mathcal{E}$  it is easy to check that  $\|\text{trnc}(AY) - \text{trnc}(AY')\|_\infty \leq \eta$ . Finally, we use the multi-linearity and boundedness of  $f$  in the following lemma to finish the proof.

► **Lemma 12.** *Let  $f : [-1, 1]^n \rightarrow [-1, 1]$  be a multi-linear function. Then for every  $x, y \in [-1, 1]^n$  we have  $|f(x) - f(y)| \leq n \cdot \|x - y\|_\infty$ .*

**Proof.** For every  $i \in \{0, 1, \dots, n\}$  define  $z^{(i)} := (x_1, \dots, x_i, y_{i+1}, \dots, y_n)$ , note that  $z^{(n)} = x$  and  $z^{(0)} = y$ . We have

$$f(x) - f(y) = \sum_{i=1}^n f(z^{(i)}) - f(z^{(i-1)}).$$

Now note that since  $f$  is a multilinear function, for every  $i$ ,

$$|f(z^{(i)}) - f(z^{(i-1)})| = |h_i(x_i) - h_i(y_i)| \leq |x_i - y_i|,$$

where  $h_i(z) = f(x_1, \dots, x_{i-1}, z, y_{i+1}, \dots, y_n)$ . The above inequality holds as  $h_i$  is an affine function mapping  $[-1, 1]$  to  $[-1, 1]$ . We thus obtain that

$$|f(x) - f(y)| \leq \sum_{i=1}^n |x_i - y_i| \leq n \cdot \|x - y\|_\infty. \quad \blacktriangleleft$$

Using Lemma 12 and condition on the event  $\mathcal{E}$  we have

$$|f(\text{trnc}(AY)) - f(\text{trnc}(AY'))| \leq \eta n.$$

As  $f$  is bounded in  $[-1, 1]$  we obtain the bound

$$|\mathbf{E}[f(\text{trnc}(AY))] - \mathbf{E}[f(\text{trnc}(AY'))]| \leq \eta n + 2 \Pr[-\mathcal{E}] \leq \eta(n + 2).$$

### Completing the proof

We put things together to finish the proof of Lemma 8. Recall that  $\delta = \varepsilon/t$  and  $\ell = (\log n)/\delta^{2+o(1)} = (t/\varepsilon)^{2+o(1)} \cdot \log(n)$  from Step I. Set  $p = 1/(8 \ln(n/\delta)) = 1/(8 \ln(nt/\varepsilon))$ . Let  $A \in [-1, 1]^{n \times \ell}$  be the matrix constructed in step I. Set  $\eta = \varepsilon/(n + 2)$  and let  $G : \{0, 1\}^s \rightarrow \mathbb{R}^\ell$  be the generator constructed in step II. We take

$$X = AG(U_s).$$

The arguments above show that  $X$  is a fractional PRG for  $\mathcal{F}$  with error  $O(\varepsilon)$ . In addition,  $X$  is  $p$ -noticeable. To conclude we compute the seed length  $s$ :

$$s = O(\ell \cdot \log(\ell/\eta)) = O\left(\left(\frac{t}{\varepsilon}\right)^{2+o(1)} \cdot \log n \cdot \log(n/\varepsilon)\right).$$

### 3 Level one Fourier bounds for polynomials

In this section we bound the level one Fourier tail of low degree polynomials over  $\mathbb{F}_2$ .

► **Theorem 13.** *Let  $p : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$  be a polynomial of degree  $d$ , and let  $f(x) = (-1)^{p(x)}$ . Then*

$$\mathcal{L}_{1,1}(f) = \sum_{i=1}^n |\widehat{f}(i)| \leq 4d.$$

**Proof.** We assume for simplicity that  $n$  is even; the proof is analogous for odd  $n$ . We have

$$\sum_{i=1}^n |\widehat{f}(i)| = \sum_{i=1}^n s_i \cdot \mathbf{E}_x [f(x)(-1)^{x_i}],$$

where  $s_i = \text{sign}(\widehat{f}(i))$ . We may assume without loss of generality that  $s_i = 1$  for all  $i$ , by replacing  $x_i$  with  $1 - x_i$  whenever  $s_i = -1$ . Thus, it suffices to upper bound

$$E := \mathbf{E}_x \left[ f(x) \sum_{i=1}^n (-1)^{x_i} \right].$$

For  $t = 1, \dots, n/2$  define the functions  $T_t : \{0, 1\}^n \rightarrow \{-1, 0, 1\}$  as follows:

$$T_t(x) := \begin{cases} -1 & \text{if } \sum x_i \geq n/2 + t \\ 1 & \text{if } \sum x_i \leq n/2 - t \\ 0 & \text{otherwise} \end{cases}.$$

Then

$$E = 2 \sum_{t=1}^{n/2} \mathbf{E}_x [f(x)T_t(x)].$$

We need a few more definitions. Let  $U_t := \{x \in \{0, 1\}^n : |\sum x_i - n/2| \geq t\}$ . Define  $M_t : U_t \rightarrow \mathbb{F}_2$  as  $M_t(x) = 0$  if  $\sum x_i \geq n/2 + t$ , and  $M_t(x) = 1$  if  $\sum x_i \leq n/2 - t$ . Note that  $T_t(x) = (-1)^{M_t(x)}$  for  $x \in U_t$ , and  $T_t(x) = 0$  for  $x \notin U_t$ . Let  $A_t := \{x \in U_t : p(x) = M_t(x)\}$ . Then

$$e_t := \mathbf{E}_x [f(x)T_t(x)] = \frac{2|A_t| - |U_t|}{2^n}.$$

We next apply a dimension argument similar to that used by Razborov [10] and Smolensky [11] (we adopt a Kopparty's presentation of the argument [7, Lemma 6]). Consider the space of functions  $g : A_t \rightarrow \mathbb{F}_2$ . On the one hand, its dimension is  $|A_t|$ . On the other hand, any function  $g : U_t \rightarrow \mathbb{F}_2$  can be decomposed as

$$g(x) = g_1(x)M_t(x) + g_2(x),$$

where  $g_1, g_2$  are polynomials over  $\mathbb{F}_2$  of degree  $\leq n/2 - t$ . Thus, any function  $g : A_t \rightarrow \mathbb{F}_2$  can be expressed as a polynomial  $g(x) = g_1(x)p(x) + g_2(x)$  which is of degree  $\leq n/2 - t + d$ . Thus, we can bound  $|A_t|$  by the dimension of this linear space of polynomials,

$$|A_t| \leq \sum_{i=0}^{n/2-t+d} \binom{n}{i}.$$

Using the fact that  $|U_t| = 2 \sum_{i=0}^{n/2-t} \binom{n}{i}$  we can upper bound  $e_t$  by

$$e_t \leq \frac{2 \sum_{i=1}^d \binom{n}{n/2-t+i}}{2^n}.$$

We thus can bound  $E$  by

$$E = 2 \sum_{t=1}^{n/2} e_t \leq 4 \sum_{t=1}^{n/2} \sum_{i=1}^d \frac{\binom{n}{n/2-t+i}}{2^n} = 4 \sum_{i=1}^d \sum_{j=0}^{n/2-1} \frac{\binom{n}{j+i}}{2^n} \leq 4d. \quad \blacktriangleleft$$

### 3.1 Level two Fourier bounds from level one bounds

We present a simple argument showing that for any family  $\mathcal{F}$  of  $n$ -variate Boolean functions that is closed under restrictions, a bound of  $\mathcal{L}_{1,1}(\mathcal{F}) \leq t$  implies  $\mathcal{L}_{1,2}(\mathcal{F}) \leq O(t \cdot \sqrt{n \log n})$ . Using this connection, we get that polynomials of degree  $\text{polylog}(n)$  have  $\mathcal{L}_{1,2}(\cdot)$  at most  $\sqrt{n} \cdot \text{polylog}(n)$ . Recall that we conjecture that the right bound should be  $\text{polylog}(n)$  (i.e., exponentially smaller). Nevertheless, even improving this bound slightly to  $n^{1/2-o(1)}$  would imply a non-trivial PRG fooling  $\text{polylog}(n)$ -degree  $\mathbb{F}_2$ -polynomials and  $\text{AC}^0[\oplus]$  circuits with seed-length  $n^{1-o(1)}$ . In comparison, the current state of the art PRG for  $\text{AC}^0[\oplus]$  circuits has seed-length  $n - n/\text{polylog}(n)$  [4].

► **Claim 14.** *Let  $\mathcal{F}$  be a class of  $n$ -variate Boolean functions that is closed under restrictions. Let  $t \geq 1$ . Assume that  $\mathcal{L}_{1,1}(\mathcal{F}) \leq t$ . Then,  $\mathcal{L}_{1,2}(\mathcal{F}) \leq t \cdot O(\sqrt{n \log n})$ .*

**Proof.** Let  $f : \{-1, 1\}^n \rightarrow \{-1, 1\}$  be some Boolean function in  $\mathcal{F}$ . We bound  $\mathcal{L}_{1,2}(f) = \sum_{i < j} |\hat{f}(i, j)|$ . We begin by partitioning the set of coordinates of  $f$  into two disjoint parts  $[n] = X \cup Y$  and summing only the cross-terms  $L_1(X, Y) = \sum_{i \in X} \sum_{j \in Y} |\hat{f}(i, j)|$ . We note that there exists a partition  $[n] = X \cup Y$  such that  $L_1(X, Y) \geq \mathcal{L}_{1,2}(f)/2$ . This holds since a random partition has on expectation

$$\mathbf{E}_{X, Y} [L_1(X, Y)] = \sum_{i < j} |\hat{f}(i, j)| \cdot (\Pr[i \in X, j \in Y] + \Pr[i \in Y, j \in X]) = \mathcal{L}_{1,2}(f) \cdot \frac{1}{2}.$$

Fix a partition  $(X, Y)$  for which  $L_1(X, Y) \geq \mathcal{L}_{1,2}(f) \cdot \frac{1}{2}$ . In the remainder, we bound

$$L_1(X, Y) = \sum_{i \in X, j \in Y} |\hat{f}(\{i, j\})| = \sum_{i \in X, j \in Y} s_{i, j} \cdot \hat{f}(\{i, j\})$$

for some sign matrix  $s \in \{-1, 1\}^{X \times Y}$ . For any fixed  $x \in \{-1, 1\}^X$  we denote by  $f_x : \{-1, 1\}^Y \rightarrow \{-1, 1\}$  the function defined by  $f_x(y) = f(x, y)$ . Note that  $f_x$  is a restriction of  $f$  thus by our assumption, its  $\mathcal{L}_{1,1}$  is at most  $t$ . We get

$$\begin{aligned} L_1(X, Y) &= \mathbf{E}_{\substack{x \in \{-1, 1\}^X, \\ y \in \{-1, 1\}^Y}} \left[ \sum_{i \in X, j \in Y} s_{i, j} \cdot f(x, y) \cdot x_i \cdot y_j \right] \\ &= \mathbf{E}_{x \in \{-1, 1\}^X} \left[ \sum_{i \in X, j \in Y} s_{i, j} \cdot x_i \cdot \mathbf{E}_{y \in \{-1, 1\}^Y} [f(x, y) \cdot y_j] \right] \\ &= \mathbf{E}_{x \in \{-1, 1\}^X} \left[ \sum_{i \in X, j \in Y} s_{i, j} \cdot x_i \cdot \hat{f}_x(\{j\}) \right] = \mathbf{E}_{x \in \{-1, 1\}^X} \left[ \sum_{j \in Y} \left( \hat{f}_x(\{j\}) \cdot \sum_{i \in X} s_{i, j} \cdot x_i \right) \right] \\ &\leq \mathbf{E}_{x \in \{-1, 1\}^X} \left[ \sum_{j \in Y} |\hat{f}_x(\{j\})| \cdot \left| \sum_{i \in X} s_{i, j} \cdot x_i \right| \right] \leq \mathbf{E}_{x \in \{-1, 1\}^X} \left[ t \cdot \max_{j \in Y} \left| \sum_{i \in X} s_{i, j} \cdot x_i \right| \right] \end{aligned}$$

By Chernoff's bounds, the expectation of  $\max_{j \in Y} |\sum_{i \in X} s_{i,j} \cdot x_i|$  is at most  $O(\sqrt{n \log n})$ . Thus overall  $\mathcal{L}_{1,2}(f) \leq 2 \cdot L_1(X, Y) \leq 2t \cdot O(\sqrt{n \cdot \log n})$ . ◀

#### 4 Further research

A clear advantage of Theorem 2 over Theorem 1 is that only bounds on the second level of the Fourier tails are needed, instead of bounds for all levels. However, we pay a price, as the dependence on the error parameter  $\varepsilon$  is polynomial instead of poly-logarithmic. This raises a natural problem: can a better dependency on  $\varepsilon$  be obtained if the Fourier tails are assumed to be bounded for several levels  $k$ ? In particular, information on how many levels is needed in order to obtain poly-logarithmic dependency on the error  $\varepsilon$ ? We leave these questions to future work.

## A Proof of Theorem 9

Throughout this section we take  $G$  to be a multivariate Gaussian distribution with zero mean, covariances at most  $\delta$  and variances at most 1. That is, if  $G = (G_1, \dots, G_n)$  then  $\mathbf{E}[G_i] = 0$ ,  $\mathbf{E}[G_i^2] \leq 1$  and  $|\mathbf{E}[G_i G_j]| \leq \delta$  for  $i \neq j$ .

### A.1 Preliminaries

Let  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  be a multi-linear function, defined by

$$f(z) = \sum_{S \subseteq [n]} \widehat{f}(S) \cdot \prod_{i \in S} z_i, \quad (1)$$

where  $\widehat{f}(S) \in \mathbb{R}$ . We bound the difference between  $\mathbf{E}_{z \sim G}[f(\text{trnc}(pz))]$  and  $\mathbf{E}_{z \sim G}[f(pz)]$  for a small  $p \in (0, 1)$ . Note that whenever  $z' \in [-1, 1]^n$ , there is no difference between  $f(z')$  and  $f(\text{trnc}(z'))$ , and we only need to bound the difference when  $z'$  is outside  $[-1, 1]^n$ . The next claim bounds the value of  $|f(z')|$  when  $z'$  is outside  $[-1, 1]^n$ .

► **Claim 15** ([9, Claim 5.1]). *Let  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  be a multi-linear function that maps  $\{-1, 1\}^n$  to  $[-1, 1]$ . Let  $z' \in \mathbb{R}^n$ . Then,  $|f(z')| \leq \prod_{i=1}^n \max(1, |z'_i|)$ .*

For  $\alpha \in (0, 1)$ ,  $z \in \mathbb{R}^n$ , we get that the value of  $|f(\alpha z)|$  is bounded by  $\prod_i \max(1, |\alpha z_i|)$ . The following claim bounds the latter times the indicator that  $\alpha z \neq \text{trnc}(\alpha z)$ .

► **Claim 16.** *Let  $\alpha \in (0, 1/\sqrt{4n}]$ . Then,*

$$\mathbf{E}_{z \sim G} \left[ \prod_{i=1}^n \max(1, |\alpha z_i|) \cdot \mathbb{1}_{\alpha z \neq \text{trnc}(\alpha z)} \right] \leq \sum_{k=1}^{\infty} e^{-k/(4\alpha^2 n)} \cdot n^k.$$

**Proof.** For  $i \in [n]$  and  $a_i \in \mathbb{N}$ , we consider the event

$$a_i \leq |\alpha \cdot z_i| < a_i + 1,$$

denoted by  $\mathcal{E}_{i, a_i}$ . Since each  $z_i$  is a Gaussian with mean 0 and variance at most 1, we have  $\Pr[\mathcal{E}_{i, a_i}] \leq e^{-a_i^2/(2\alpha^2)}$ . Using Claim 15 we have

$$\begin{aligned} (*) &= \mathbf{E}_{z \sim G} \left[ \prod_{i=1}^n \max(1, |\alpha z_i|) \cdot \mathbb{1}_{\alpha z \neq \text{trnc}(\alpha z)} \right] \\ &\leq \sum_{\vec{a} \in \mathbb{N}^n, \vec{a} \neq 0^n} \Pr[\wedge_{i=1}^n \mathcal{E}_{i, a_i}] \cdot \prod_{i=1}^n (1 + a_i) \\ &\leq \sum_{\vec{a} \in \mathbb{N}^n, \vec{a} \neq 0^n} \min_{i \in [n]} \{\Pr[\mathcal{E}_{i, a_i}]\} \cdot \prod_{i=1}^n (1 + a_i) \\ &\leq \sum_{\vec{a} \in \mathbb{N}^n, \vec{a} \neq 0^n} \prod_{i=1}^n \Pr[\mathcal{E}_{i, a_i}]^{1/n} \cdot \prod_{i=1}^n (1 + a_i) \end{aligned} \quad (2)$$

We bound

$$\Pr[\mathcal{E}_{i, a_i}]^{1/n} \cdot (1 + a_i) \leq e^{-a_i^2/(2\alpha^2 n)} \cdot (1 + a_i) \leq e^{-a_i^2/(4\alpha^2 n)}$$

22:12 Pseudorandom Generators from Second Level Fourier Bounds

since  $1 + a_i \leq e^{a_i} \leq e^{a_i^2/(4\alpha^2 n)}$  for  $\alpha^2 \leq 1/4n$ . We plug this estimate in Equation (2):

$$\begin{aligned}
 (*) &\leq \sum_{\vec{a} \in \mathbb{N}^n, \vec{a} \neq 0^n} e^{-\sum_i a_i^2/(4\alpha^2 n)} \\
 &\leq \sum_{k=1}^{\infty} e^{-k/(4\alpha^2 n)} \cdot \left| \left\{ \vec{a} \in \mathbb{N}^n : \sum_i a_i = k \right\} \right| \\
 &= \sum_{k=1}^{\infty} e^{-k/(4\alpha^2 n)} \cdot \binom{n+k-1}{k} \leq \sum_{k=1}^{\infty} e^{-k/(4\alpha^2 n)} \cdot n^k. \quad \blacktriangleleft
 \end{aligned}$$

► **Claim 17.** Let  $p \leq 1/4\sqrt{n}$ . Let  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  be a multi-linear function that maps  $\{-1, 1\}^n$  to  $[-1, 1]$ . Let  $v \in [-1/2, 1/2]^n$ . Then,

$$\mathbf{E}_{z \sim G} [|f(\text{trnc}(v + p \cdot z)) - f(v + p \cdot z)|] \leq 2 \cdot \sum_{k=1}^{\infty} e^{-k/(16p^2 n)} \cdot n^k.$$

**Proof.** Let  $\mathcal{E}$  be the event that  $\text{trnc}(v + p \cdot z) \neq v + p \cdot z$ . Note that  $\mathcal{E}$  implies the event  $2pz \neq \text{trnc}(2pz)$  since  $v \in [-1/2, 1/2]^n$ . Using Claim 15, we get

$$\begin{aligned}
 \mathbf{E}_{z \sim G} [|f(\text{trnc}(v + p \cdot z)) - f(v + p \cdot z)|] &\leq \mathbf{E}_{z \sim G} [(1 + |f(v + p \cdot z)|) \cdot \mathbb{1}_{\mathcal{E}}] \\
 &\leq \mathbf{E}_{z \sim G} [(1 + |f(v + p \cdot z)|) \cdot \mathbb{1}_{2pz \neq \text{trnc}(2pz)}] \\
 &\leq \mathbf{E}_{z \sim G} \left[ \left( 1 + \prod_{i=1}^n \max(1, |v_i + p \cdot z_i|) \right) \cdot \mathbb{1}_{2pz \neq \text{trnc}(2pz)} \right] \\
 &\leq \mathbf{E}_{z \sim G} \left[ 2 \cdot \prod_{i=1}^n \max(1, |v_i + p \cdot z_i|) \cdot \mathbb{1}_{2pz \neq \text{trnc}(2pz)} \right].
 \end{aligned}$$

However,  $\prod_{i=1}^n \max(1, |v_i + p \cdot z_i|) \leq \prod_{i=1}^n \max(1, 1/2 + p|z_i|) \leq \prod_{i=1}^n \max(1, 2p|z_i|)$ . Using Claim 16 with  $\alpha = 2p$ , we get

$$\begin{aligned}
 \mathbf{E}_{z \sim G} [|f(\text{trnc}(v + p \cdot z)) - f(v + p \cdot z)|] &\leq \mathbf{E}_{z \sim G} \left[ 2 \cdot \prod_{i=1}^n \max(1, 2p|z_i|) \cdot \mathbb{1}_{2pz \neq \text{trnc}(2pz)} \right] \\
 &\leq 2 \cdot \mathbf{E}_{z \sim G} \left[ \prod_{i=1}^n \max(1, \alpha|z_i|) \cdot \mathbb{1}_{\alpha z \neq \text{trnc}(\alpha z)} \right] \\
 &\leq 2 \cdot \sum_{k=1}^{\infty} e^{-k/(4\alpha^2 n)} \cdot n^k. \quad \blacktriangleleft
 \end{aligned}$$

► **Claim 18 (Application of Isserlis' Theorem).** Let  $G$  be a MVG distribution over  $\mathbb{R}^n$  with zero-mean and covariances at most  $\delta$ . For  $S \subseteq [n]$ , let  $\widehat{G}(S) = \mathbf{E}_{Z \sim G} [\prod_{i \in S} Z_i]$ . Then,

1.  $\widehat{G}(S) = 0$  if  $|S|$  is odd.
2.  $|\widehat{G}(S)| \leq (k-1)!! \cdot \delta^{k/2}$  if  $|S| = k$  is even.

**Proof.** Both items rely on Isserlis' Theorem [5] (See also [http://en.wikipedia.org/wiki/Isserlis'\\_theorem](http://en.wikipedia.org/wiki/Isserlis'_theorem)) that gives a formula for the moments of any zero-mean multi Gaussian distribution. Isserlis' Theorem [5] states that in a zero-mean multivariate Gaussian distribution  $Z_1, \dots, Z_n$ , for a sequence of indices  $(i_1, \dots, i_k) \in [n]$ , we have  $\mathbf{E}[Z_{i_1} \cdots Z_{i_k}] = 0$  if  $k$  is odd and  $\mathbf{E}[Z_{i_1} \cdots Z_{i_k}] = \sum \prod \mathbf{E}[Z_{i_r} Z_{i_\ell}]$ , where the notation  $\sum \prod$  means summing over all distinct ways of partitioning  $Z_{i_1}, \dots, Z_{i_k}$  into pairs and each summand is the product of the  $k/2$  pairs. If  $|S| = k$  is even, since the covariance of each pair in  $G$  is at most  $\delta$  in absolute value and there are at most  $(k-1)!!$  partitions to pairs, we get  $|\widehat{G}(S)| \leq (k-1)!! \cdot \delta^{k/2}$ . ◀

The next claim expresses the difference of a multi-linear function  $f$  on two vectors,  $v$  and  $v + z$ , as the expected difference of random restrictions of  $f$  on  $0$  and  $2z$ , provided that  $v \in [-1/2, 1/2]^n$ . Applying this lemma when the entries of  $z$  are infinitesimally small means that bounded variation of random restrictions of  $f$  around  $0$  implies bounded variation of  $f$  around any  $v \in [-1/2, 1/2]^n$ .

► **Claim 19** ([2, Claim 3.3], restated in [1]). *Let  $f$  be a multi-linear function on  $\mathbb{R}^n$  and  $v \in [-1/2, 1/2]^n$ . There exists a distribution over random restrictions  $\rho$  such that for any  $z \in \mathbb{R}^n$ ,*

$$f(v + z) - f(v) = \mathbf{E}_{\rho} [f_{\rho}(2 \cdot z) - f_{\rho}(\vec{0})].$$

**Proof.** Given  $v \in [-1/2, 1/2]^n$ , we define a distribution  $\mathcal{R}_v$  over restrictions  $\rho \in \{-1, 1, *\}^n$ , as follows. For each entry  $i \in [n]$  independently, we set  $\rho_i = 1$  with probability  $1/4 + v_i/2$ ,  $\rho_i = -1$  with probability  $1/4 - v_i/2$ , and  $\rho_i = *$  with probability  $1/2$ . Note that since  $v \in [-1/2, 1/2]^n$  all these probabilities are indeed non-negative.

Let  $\rho \sim \mathcal{R}_v$ . For any vector  $z \in \mathbb{R}^n$ , we define a vector  $\tilde{z} = \tilde{z}(z, \rho) \in \mathbb{R}^n$ , as follows:

$$\tilde{z}_i = \begin{cases} \rho_i & \text{if } \rho_i \in \{-1, 1\} \\ 2 \cdot z_i & \text{otherwise} \end{cases}$$

Thus, for a fixed  $z \in \mathbb{R}^n$ , the vector  $\tilde{z}$  is a random variable that depends on  $\rho$ . We show that for any fixed  $z \in \mathbb{R}^n$ , the distribution of the random variable  $\tilde{z}$  is a product distribution (over inputs in  $\mathbb{R}^n$ ), and the expectation of  $\tilde{z}$  is the vector  $v + z$ . Indeed, each coordinate  $\tilde{z}_i$  is independent of the other coordinates, and its expected value is

$$\mathbf{E}_{\rho \sim \mathcal{R}_v} [\tilde{z}_i] = v_i + z_i.$$

Hence, since  $f$  is multi-linear and  $\tilde{z}$  has a product distribution, by Equation (1),  $\mathbf{E}_{\rho \sim \mathcal{R}_v} [f(\tilde{z})] = f(v + z)$ . We get

$$f(v + z) - f(v) = \mathbf{E}_{\rho \sim \mathcal{R}_v} [f(\tilde{z}(z, \rho))] - \mathbf{E}_{\rho \sim \mathcal{R}_v} [f(\tilde{z}(\vec{0}, \rho))] = \mathbf{E}_{\rho \sim \mathcal{R}_v} [f(\tilde{z}(z, \rho)) - f(\tilde{z}(\vec{0}, \rho))]$$

However, for any fixed  $\rho$ , we have  $f(\tilde{z}(z, \rho)) = f_{\rho}(2z)$ , where  $f_{\rho}$  is attained from  $f$  by fixing the coordinates that were fixed in  $\rho$ , according to  $\rho$ . Thus,

$$f(v + z) - f(v) = \mathbf{E}_{\rho \sim \mathcal{R}_v} [f_{\rho}(2 \cdot z) - f_{\rho}(\vec{0})]. \quad \blacktriangleleft$$

## A.2 The Proof

► **Claim 20.** *Let  $f : \{-1, 1\}^n \rightarrow \{-1, 1\}$  be a Boolean function with  $\mathcal{L}_{1,2}(f) \leq t$ . Let  $p \leq 1/2n$ . Then,*

$$\left| \mathbf{E}_{Z \sim G} [f(pZ)] - f(\vec{0}) \right| \leq p^2 \cdot t \cdot \delta + O(p^4 \cdot n^4 \cdot \delta^2).$$

**Proof.** By Equation (1) and since  $f(\vec{0}) = \hat{f}(\emptyset)$ ,

$$\begin{aligned} \left| \mathbf{E}_{Z \sim G} [f(pZ)] - f(\vec{0}) \right| &= \left| \mathbf{E}_{Z \sim G} \left[ \sum_{\emptyset \neq S \subseteq [n]} \hat{f}(S) \cdot \prod_{i \in S} (p \cdot Z_i) \right] \right| \\ &= \left| \sum_{\emptyset \neq S \subseteq [n]} \hat{f}(S) \cdot p^{|S|} \cdot \mathbf{E}_{Z \sim G} \left[ \prod_{i \in S} Z_i \right] \right| \\ &\leq \sum_{k=1}^n p^k \cdot \left( \max_{S: |S|=k} |\hat{G}(S)| \right) \cdot \sum_{S \subseteq [n], |S|=k} |\hat{f}(S)| \end{aligned}$$

22:14 Pseudorandom Generators from Second Level Fourier Bounds

For odd  $k$ , Claim 18 gives  $\max_{S:|S|=k} |\widehat{G}(S)| = 0$ . For even  $k$ , we have  $\max_{S:|S|=k} |\widehat{G}(S)| \leq (k-1)!! \cdot \delta^{k/2}$  by Claim 18. Plugging these bounds in the above expression gives

$$\begin{aligned} \left| \mathbf{E}_{Z \sim G}[f(pZ)] - f(\vec{0}) \right| &\leq p^2 \cdot \delta \cdot \sum_{S:|S|=2} |\widehat{f}(S)| + \sum_{k \geq 4, k \text{ even}} p^k \cdot \delta^{k/2} \cdot (k-1)!! \cdot \sum_{S:|S|=k} |\widehat{f}(S)| \\ &\leq p^2 \cdot \delta \cdot t + \sum_{k \geq 4, k \text{ even}} p^k \cdot \delta^{k/2} \cdot (k-1)!! \cdot \binom{n}{k} \\ &\hspace{15em} (\mathcal{L}_{1,2}(f) \leq t \text{ and } \forall S: |\widehat{f}(S)| \leq 1) \\ &\leq p^2 \cdot \delta \cdot t + \sum_{k \geq 4, k \text{ even}} p^k \cdot \delta^{k/2} \cdot n^k \\ &\leq p^2 \cdot \delta \cdot t + O(p^4 \cdot n^4 \cdot \delta^2) \hspace{10em} (p \leq 1/2n) \end{aligned}$$

◀

► **Theorem 21** (Theorem 9, restated). *Let  $n \in \mathbb{N}$ ,  $\delta, \sigma \in (0, 1)$ . Let  $G$  be a zero-mean multivariate Gaussian distribution over  $\mathbb{R}^n$  where  $Z \sim G$  has the following two properties:*

1. For  $i \in [n]$ :  $\mathbf{Var}[Z_i] \leq \sigma^2$
2. For  $i, j \in [n], i \neq j$ :  $|\mathbf{Cov}[Z_i, Z_j]| \leq \delta$ .

*Let  $\mathcal{F}$  be a class of  $n$ -variate Boolean functions which is closed under restrictions. Assume that  $\mathcal{L}_{1,2}(\mathcal{F}) \leq t$ . Then for any  $f \in \mathcal{F}$  it holds that  $|\mathbf{E}[f(\text{trnc}(Z))] - f(\vec{0})| \leq 4\delta \cdot t + 4n \cdot e^{-1/8\sigma^2}$ .*

**Proof.** Let  $m \in \mathbb{N}$  be sufficiently large (in particular  $m \geq (4n)^4$ ) and  $p = 1/\sqrt{m}$ . Let  $Z^{(1)}, \dots, Z^{(m)} \sim G$ . We define  $m+1$  hybrids  $H_0, \dots, H_m$ . Let  $H_0 = \vec{0}$ . For  $i = 1, \dots, m$ , let  $H_i = p \cdot (Z^{(1)} + \dots + Z^{(i)})$ . We observe that  $H_m \sim G$ . This is true since  $H_m$  is a multivariate Gaussian with the same expectation and the same covariance matrix as  $Z \sim G$ . We can think of  $H_0, H_1, \dots, H_m$  as a  $n$ -dimensional random walk. We bound

$$|\mathbf{E}[f(\text{trnc}(H_m))] - f(\vec{0})|$$

by considering two cases depending on whether or not at some point in the random walk we stepped outside of  $[-1/2, 1/2]^n$ .

For  $i \in \{0, \dots, m\}$ , let  $\mathcal{E}_i$  be the event that  $H_i \in [-1/2, 1/2]^n$ . We show that  $\mathcal{E}_i$  happens with high probability. In fact, we show that  $\mathcal{E} = \mathcal{E}_1 \wedge \mathcal{E}_2 \wedge \dots \wedge \mathcal{E}_m$  happens with high probability, with no dependency on the number of steps  $m$ . The claim follows from known properties of Brownian motions. For  $j \in [n]$ , let  $\mathcal{D}^{(j)}$  be the event that there exists an  $i \in [m]$  with  $|(H_i)_j| > 1/2$ . Clearly  $\neg \mathcal{E} \equiv \mathcal{D}^{(1)} \vee \mathcal{D}^{(2)} \vee \dots \vee \mathcal{D}^{(n)}$ .

We show that for each  $j \in [n]$ ,  $\mathbf{Pr}[\mathcal{D}^{(j)}] \leq 4 \cdot e^{-8/\sigma^2}$  and then apply a union bound. Each  $\{(H_i)_j\}_{i=0}^m$  is a random walk with  $m$  steps, which can be viewed as a discretization of a one-dimensional Brownian motion. A standard one-dimensional Brownian motion (or Wiener process) is a random process  $\{B(t)\}_{t \geq 0}$  with the properties: (1)  $B(0) = 0$ , (2) for all  $t, s \geq 0$ ,  $B(t+s) - B(t)$  is independent of the past  $\{B(t')\}_{t' \leq t}$  (3) for all  $t, s \geq 0$ ,  $B(t+s) - B(t) \sim \mathcal{N}(0, s)$ . Let  $\sigma_j^2 := \mathbf{Var}[z_j]$ . We observe that if  $B$  is a standard one-dimensional Brownian motion, then  $\{B(\sigma_j^2 \cdot i/m)\}_{i=0}^m$  is distributed exactly as  $\{(H_i)_j\}_{i=0}^m$ . Let  $M(t) = \sup_{0 \leq s \leq t} B(s)$  and  $M'(t) = \inf_{0 \leq s \leq t} B(s)$ . It suffices to show that  $M(\sigma_j^2) \leq 1/2$  and  $M'(\sigma_j^2) \geq -1/2$  with high probability. Known results on Brownian motions state that  $\mathbf{Pr}[M'(t) < -1/2] = \mathbf{Pr}[M(t) > 1/2] = \mathbf{Pr}[|B(t)| > 1/2]$  (cf. [8, Theorem 2.21]). The latter is at most  $e^{-1/8t}$  since  $B(t) \sim \mathcal{N}(0, t)$ . Overall, we get

$$\mathbf{Pr}[\neg \mathcal{E}] \leq \sum_{j=1}^n \mathbf{Pr}[\mathcal{D}^{(j)}] \leq \sum_{j=1}^n \left( \mathbf{Pr}[M'(\sigma_j^2) < -1/2] + \mathbf{Pr}[M(\sigma_j^2) > 1/2] \right) \leq 2n \cdot e^{-1/8\sigma^2}$$

Next, we bound  $|\mathbf{E}_{Z^{(i+1)}}[f(\text{trnc}(H_i + p \cdot Z^{(i+1)})) - f(\text{trnc}(H_i))]|$  conditioned on the event  $\mathcal{E}_i$ , for  $i = 0, 1, \dots, m-1$ . Let  $v = H_i$ . Condition on the event  $\mathcal{E}_i$ , and in fact condition on the entire history in the first  $i$  steps, which in particular fixes  $v$ . By Claim 19, we have

$$\begin{aligned} \left| \mathbf{E}_{Z^{(i+1)}} [f(v + p \cdot Z^{(i+1)}) - f(v)] \right| &= \left| \mathbf{E}_{Z^{(i+1)}} \mathbf{E}_{\rho} [f_{\rho}(2p \cdot Z^{(i+1)}) - f_{\rho}(\vec{0})] \right| \\ &\leq \mathbf{E}_{\rho} \left| \mathbf{E}_{Z^{(i+1)}} [f_{\rho}(2p \cdot Z^{(i+1)}) - f_{\rho}(\vec{0})] \right|. \end{aligned}$$

By Claim 20 we have that the latter is at most  $(2p)^2 t \delta + O(p^4 n^4 \delta^2)$  as long as  $2p \leq 1/2n$ . We wish to show a similar bound on the truncated version of  $H_i + p \cdot Z^{(i+1)}$ . Note that conditioned on  $\mathcal{E}_i$ , we have  $H_i = \text{trnc}(H_i)$ , but this is not necessarily the case for  $H_i + p \cdot Z^{(i+1)}$ . Using Claim 17 we get  $|\mathbf{E}_{Z^{(i+1)}}[f(p \cdot Z^{(i+1)} + v) - f(\text{trnc}(p \cdot Z^{(i+1)} + v))]| \leq 2 \cdot \sum_{k=1}^{\infty} e^{-k/(16p^2 n)} \cdot n^k$ . By the triangle inequality we get

$$\begin{aligned} &\left| \mathbf{E}_{Z^{(i+1)}} [f(\text{trnc}(v + p \cdot Z^{(i+1)})) - f(\text{trnc}(v))] \right| \\ &\leq \left| \mathbf{E}_{Z^{(i+1)}} [f(\text{trnc}(v + p \cdot Z^{(i+1)})) - f(v + p \cdot Z^{(i+1)})] \right| \\ &\quad + \left| \mathbf{E}_{Z^{(i+1)}} [f(v + p \cdot Z^{(i+1)}) - f(\text{trnc}(v))] \right| \\ &\leq \left( 2 \cdot \sum_{k=1}^{\infty} e^{-k/(16p^2 n)} \cdot n^k \right) + \left( 4p^2 \cdot \delta \cdot t + O(p^4 n^4 \delta^2) \right). \end{aligned} \quad (3)$$

To finish the proof, using triangle inequality we have

$$|\mathbf{E}[f(\text{trnc}(H_m)) - f(\vec{0})]| \leq |\mathbf{E}[f(\text{trnc}(H_m)) \cdot \mathbb{1}_{\mathcal{E}} - f(\vec{0})]| + |\mathbf{E}[f(\text{trnc}(H_m)) \cdot \mathbb{1}_{\neg \mathcal{E}}]|$$

We bound the second summand by  $\mathbf{Pr}[\neg \mathcal{E}]$  since  $f$  is bounded in  $[-1, 1]$  on truncated vectors, whereas the first summand is bounded using a telescopic sum of the  $m+1$  hybrids:

$$\begin{aligned} &|\mathbf{E}[f(\text{trnc}(H_m)) \cdot \mathbb{1}_{\mathcal{E}} - f(\vec{0})]| \\ &\leq \sum_{i=0}^{m-1} |\mathbf{E}[f(\text{trnc}(H_{i+1})) \cdot \mathbb{1}_{\mathcal{E}_1 \wedge \dots \wedge \mathcal{E}_{i+1}} - f(\text{trnc}(H_i)) \cdot \mathbb{1}_{\mathcal{E}_1 \wedge \dots \wedge \mathcal{E}_i}]| \\ &\leq \sum_{i=0}^{m-1} |\mathbf{E}[f(\text{trnc}(H_{i+1})) \cdot \mathbb{1}_{\mathcal{E}_1 \wedge \dots \wedge \mathcal{E}_i} - f(\text{trnc}(H_i)) \cdot \mathbb{1}_{\mathcal{E}_1 \wedge \dots \wedge \mathcal{E}_i}]| \\ &\quad + |\mathbf{E}[f(\text{trnc}(H_{i+1})) \cdot (\mathbb{1}_{\mathcal{E}_1 \wedge \dots \wedge \mathcal{E}_{i+1}} - \mathbb{1}_{\mathcal{E}_1 \wedge \dots \wedge \mathcal{E}_i})]| \\ &\leq \sum_{i=0}^{m-1} \left( 2 \cdot \sum_{k=1}^{\infty} e^{-k/(16p^2 n)} \cdot n^k \right) + \left( 4p^2 \cdot \delta \cdot t + O(p^4 n^4 \delta^2) \right) + \mathbf{E}[\mathbb{1}_{\mathcal{E}_1 \wedge \dots \wedge \mathcal{E}_{i+1}} - \mathbb{1}_{\mathcal{E}_1 \wedge \dots \wedge \mathcal{E}_i}] \\ &\hspace{15em} (\text{Eq. (3), } f \text{ is bounded}) \\ &\leq m \cdot \left( 2 \cdot \sum_{k=1}^{\infty} e^{-k/(16p^2 n)} \cdot n^k \right) + 4p^2 \cdot \delta \cdot t + O(p^4 n^4 \delta^2) + \mathbf{Pr}[\neg \mathcal{E}]. \end{aligned}$$

Overall,

$$\begin{aligned} |\mathbf{E}[f(\text{trnc}(H_m)) - f(\vec{0})]| &\leq m \cdot \left( 2 \cdot \sum_{k=1}^{\infty} e^{-k/(16p^2 n)} \cdot n^k \right) + 4p^2 \cdot \delta \cdot t + O(p^4 n^4 \delta^2) + 2 \mathbf{Pr}[\neg \mathcal{E}] \\ &= m \cdot \left( 2 \cdot \sum_{k=1}^{\infty} e^{-km/(16n)} \cdot n^k \right) + 4m^{-1} \cdot \delta \cdot t + O(m^{-2} n^4 \delta^2) + 2 \mathbf{Pr}[\neg \mathcal{E}] \end{aligned}$$

Taking  $m \rightarrow \infty$  gives the upper bound  $4\delta \cdot t + 2 \mathbf{Pr}[\neg \mathcal{E}] \leq 4\delta \cdot t + 4n \cdot e^{-1/8\sigma^2}$  as promised.  $\blacktriangleleft$

# Classical Algorithms from Quantum and Arthur-Merlin Communication Protocols

## Abstract

In recent years, the polynomial method from circuit complexity has been applied to several fundamental problems and obtains the state-of-the-art running times (e.g., R. Williams's  $n^3/2^{\Omega(\sqrt{\log n})}$  time algorithm for APSP). As observed in [Alman and Williams, STOC 2017], almost all applications of the polynomial method in algorithm design ultimately rely on certain (probabilistic) low-rank decompositions of the computation matrices corresponding to key subroutines. They suggest that making use of low-rank decompositions directly could lead to more powerful algorithms, as the polynomial method is just one way to derive such a decomposition.

Inspired by their observation, in this paper, we study another way of *systematically constructing low-rank decompositions of matrices* which could be used by algorithms – *communication protocols*. Since their introduction, it is known that various types of communication protocols lead to certain low-rank decompositions (e.g., P protocols/rank, BQP protocols/approximate rank). These are usually interpreted as approaches for proving communication lower bounds, while in this work we explore the other direction.

We have the following two generic algorithmic applications of communication protocols:

- **Quantum Communication Protocols and Deterministic Approximate Counting.** Our first connection is that a fast BQP communication protocol for a function  $f$  implies a fast deterministic additive approximate counting algorithm for a related pair counting problem. Applying known BQP communication protocols, we get fast deterministic additive approximate counting algorithms for Count-OV (#OV), Sparse Count-OV and Formula of SYM circuits. In particular, our approximate counting algorithm for #OV runs in near-linear time for all dimensions  $d = o(\log^2 n)$ . Previously, even no truly-subquadratic time algorithm was known for  $d = \omega(\log n)$ .
- **Arthur-Merlin Communication Protocols and Faster Satisfying-Pair Algorithms.** Our second connection is that a fast  $\text{AM}^{\text{cc}}$  protocol for a function  $f$  implies a faster-than-bruteforce algorithm for  $f$ -Satisfying-Pair. Using the classical Goldwasser-Sispe AM protocols for approximating set size, we obtain a new algorithm for approximate Max-IP $_{n,c \log n}$  in time  $n^{2-1/O(\log c)}$ , matching the state-of-the-art algorithms in [Chen, CCC 2018].

We also apply our second connection to shed some light on long-standing open problems in communication complexity. We show that if the Longest Common Subsequence (LCS) problem admits a fast (computationally efficient)  $\text{AM}^{\text{cc}}$  protocol (polylog( $n$ ) complexity), then polynomial-size Formula-SAT admits a  $2^{n-n^{1-\delta}}$  time algorithm for any constant  $\delta > 0$ , which is conjectured to be unlikely by a recent work [Abboud and Bringmann, ICALP 2018]. The same holds even for a fast (computationally efficient)  $\text{PH}^{\text{cc}}$  protocol.

In particular, we thank one anonymous reviewer for pointing out that Theorem 5 can be improved using the polynomial method.

## 1 Introduction

Recent works have shown that the polynomial method, a classical technique for proving circuit lower bounds [41, 45], can be useful in designing efficient algorithms [48, 50, 6, 10, 8, 36, 7].

At a very high level, these algorithms proceed as follows: (1) identify a key subroutine of the core algorithm which has a certain low-degree polynomial representation; (2) replace that subroutine by the corresponding polynomials, and reduce the whole problem to a certain *batched evaluation problem of sparse polynomials*; (3) embed that polynomial evaluation problem to *multiplication of two low-rank (rectangular) matrices*, and apply the fast rectangular matrix multiplication algorithm [26].

As [9] point out. In term of step (3), these algorithms are ultimately making use of the fact that the corresponding matrices of some circuits or subroutines have low *probabilistic rank*. [9] suggest that the *probabilistic rank*, or various low-rank decompositions of matrices in general<sup>1</sup>, could be more powerful than the polynomial method, and lead to more efficient algorithms, as the polynomial method is just one way to construct them.

It has been noted for a long time that communication protocols are closely related to various notions of rank of matrices. To list a few: deterministic communication complexity is lower bounded by the logarithm of the *rank* of the matrix [37]; quantum communication complexity is lower bounded by the logarithm of the *approximate rank* of the matrix [16, 19]; UPP communication complexity is equivalent to the logarithm of the *sign-rank* of the matrix [40].

These connections are introduced (and usually interpreted) as methods for proving communication complexity lower bounds (see, e.g. the survey by Lee and Shraibman [35]), but they can also be interpreted in the other direction, as a way to *systematically construct low-rank decompositions of matrices*.

In this paper, we explore the connection between different types of communication protocols and low-rank decompositions of matrices and establish several applications in algorithm design. For all these connections, we start with an efficient communication protocol for a problem  $F$ , which implies an efficiently constructible low-rank decomposition of the corresponding communication matrix of  $F$ , from which we can obtain fast algorithms.

In fact, in our applications of quantum communication protocols, we also consider  $k$ -party protocols, and our algorithms rely on the approximate low-rank decomposition of the tensor of the corresponding communication problem. To the best of our knowledge, this is the first time that *approximate tensor rank* is used in algorithm design (approximate rank has been used before, see e.g. [11, 18, 13, 12] and the corresponding related works section).<sup>2</sup>

<sup>1</sup> A low probabilistic rank implies a probabilistic low-rank decomposition of the matrix.

<sup>2</sup> We remark that a concurrent work [52] makes algorithmic use of *non-negative tensor approximate rank* to construct an optimal data structure for the succinct rank problem.

## 1.1 Quantum Communication Protocols and Deterministic Approximate Counting

Our first result is a generic connection between quantum communication protocols and deterministic approximate counting algorithms.

► **Theorem 1.** (Informal) Let  $\mathcal{X}, \mathcal{Y}$  be finite sets and  $f : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$  be a Boolean function. Suppose  $f$  has a quantum communication protocol  $\mathcal{P}^3$  with complexity  $C(\mathcal{P})$  and error  $\varepsilon$ . Then there is a classical deterministic algorithm  $\mathcal{C}$  that receives  $A \subseteq \mathcal{X}, B \subseteq \mathcal{Y}$  as input, and outputs a number  $E$  such that

$$\left| \sum_{(x,y) \in A \times B} f(x,y) - E \right| \leq \varepsilon \cdot |A| \cdot |B|.$$

Furthermore,  $\mathcal{C}$  runs in  $(|A| + |B|) \cdot 2^{O(C(\mathcal{P}))}$  time.

We remark here that there is a simple randomized algorithm running in sub-linear time via random-sampling. Thus the above algorithm is indeed a derandomization of that randomized algorithm.

The above theorem can also be easily generalized to the (number-in-hand)  $k$ -party case. See Section 2.5 for the definition of the multiparty quantum communication model.

► **Theorem 2.** (Informal) Let  $\mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k$  be finite sets and  $f : \mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k \rightarrow \{0, 1\}$  be a Boolean function. Suppose  $f$  has a  $k$ -party quantum communication protocol  $\mathcal{P}$  with complexity  $C(\mathcal{P})$  and error  $\varepsilon$ . Then there is a classical deterministic algorithm  $\mathcal{C}$  that receives  $X_1 \subseteq \mathcal{X}_1, X_2 \subseteq \mathcal{X}_2, \dots, X_k \subseteq \mathcal{X}_k$  as input, and outputs a number  $E$  such that

$$\left| \sum_{x_1 \in X_1, x_2 \in X_2, \dots, x_k \in X_k} f(x_1, x_2, \dots, x_k) - E \right| \leq \varepsilon \cdot \prod_{i=1}^k |X_i|.$$

Furthermore,  $\mathcal{C}$  runs in  $(|X_1| + |X_2| + \dots + |X_k|) \cdot 2^{O(C(\mathcal{P}))}$  time.

### Sketching Algorithms

In fact, Theorem 2 implies a stronger *sketching algorithm*. Given subsets  $X_1, X_2, \dots, X_k$ , the algorithm first computes a  $w = 2^{O(C(\mathcal{P}))}$  size sketch  $\text{sk}_i$  from each  $X_i$  in  $O(|X_i| \cdot w)$  time deterministically, and the number  $E$  can be computed from these  $\text{sk}_i$ 's in  $O(k \cdot w)$  time.

The sketch computed by the algorithm is in fact a vector in  $\mathbb{R}^w$ , and it satisfies a nice additive property. That is, the sketch of  $X_1 \sqcup X_2$  (union as a multi-set) is simply  $\text{sk}(X_1) + \text{sk}(X_2)$ .

Applying existing quantum communication protocols, we obtain several applications of Theorem 1 and Theorem 2.

#### 1.1.1 Set-Disjointness and Approximate #OV and # $k$ -OV

We first consider the famous SET-DISJOINTNESS problem (Alice and Bob get two vectors  $u$  and  $v$  in  $\{0, 1\}^d$  correspondingly, and want to determine whether  $\langle u, v \rangle = 0$ ), which has an efficient quantum communication protocol [1] with communication complexity  $O(\sqrt{d})$ .

<sup>3</sup> We need some technical condition on  $\mathcal{P}$ , see Corollary 29 for details.

The corresponding count problem for SET-DISJOINTNESS is the counting version of the Orthogonal Vectors problem (OV), denoted as  $\#OV_{n,d}$ . In this problem, we are given two sets of  $n$  vectors  $S, T \subseteq \{0, 1\}^d$ , and the goal is to count the number of pairs  $u \in S, v \in T$  such that  $\langle u, v \rangle = 0$ .

Applying the quantum communication protocol for SET-DISJOINTNESS and Theorem 2, we immediately get an algorithm for the approximate version of  $\#OV$ .

► **Theorem 3.** *For any  $d$  and any constant  $\varepsilon > 0$ ,  $\#OV_{n,d}$  can be approximated deterministically with additive error  $\varepsilon \cdot n^2$  in  $n \cdot 2^{O(\sqrt{d})}$  time. In particular, it runs in  $n^{1+o(1)}$  time when  $d = o(\log^2 n)$ .*

### Comparison with [22]

[22] gives a *deterministic exact counting* algorithm for  $\#OV_{n,c \log n}$ , which runs in  $n^{2-O(1/\log c)}$  time. Note that their running time is  $n^{2-o(1)}$  when  $d = \omega(\log n)$ , while our algorithm only achieves an additive approximation, but runs in *near-linear* time for all  $d = o(\log^2 n)$ .

Another closely related problem, COUNTING PARTIAL MATCH, is the problem that given  $n$  query strings from  $\{0, 1, \star\}^d$  ( $\star$  is a “don’t care”) and  $n$  strings from  $\{0, 1\}^d$ , and the goal is to count the number of matching string and query pairs.

Using known reductions between PARTIAL MATCH and OV (see, e.g., Section 2 in [6]), together with the approximate counting algorithm for  $\#OV$ , we can also solve COUNTING PARTIAL MATCH approximately in the same running time.

The approximate counting algorithm for  $\#OV$  can be easily generalized to solve  $\#k$ -OV, which is the problem that given  $k$  sets of  $n$  vectors  $X_1, X_2, \dots, X_k \subseteq \{0, 1\}^d$ , and count the number of  $k$ -tuples  $u_1 \in X_1, u_2 \in X_2, \dots, u_k \in X_k$  such that  $\langle u_1, u_2, \dots, u_k \rangle = 0$ .<sup>4</sup>

Applying Theorem 2 and observe that the 2-party SET-DISJOINTNESS protocol in [1] can be easily generalized to solve the  $k$ -party case (in  $k$ -party SET-DISJOINTNESS, there are  $k$  players getting  $u_1, u_2, \dots, u_k$  respectively, and they want to determine whether  $\langle u_1, u_2, \dots, u_k \rangle = 0$ ), we obtain the following approximate counting algorithm for  $\#k$ -OV.

► **Theorem 4.** *For any integers  $k, d$  and any constant  $\varepsilon > 0$ ,  $\#k$ -OV $_{n,d}$  can be approximated deterministically with additive error  $\varepsilon \cdot n^k$  in  $n \cdot 2^{O(k\sqrt{d})}$  time. In particular, it runs in  $n^{1+o(1)}$  time when  $k$  is a constant and  $d = o(\log^2 n)$ .*

► **Remark.** We remark that similar algorithms with slightly worse running time ( $n \cdot d^{O(\sqrt{d})}$  time for additive approximation to  $\#OV_{n,d}$ ) can also be derived using the polynomial method. However, we think our new algorithms via quantum communication protocols have the following extra benefits: (1) our algorithm is slightly faster, with a running time of  $n \cdot 2^{O(\sqrt{d})}$ ; (2) our algorithm is derived via a general connection. Once the connection is set up, the algorithm follows in an elegant and black-box way. We hope this general connection could stimulate more applications of quantum communication protocols.

### 1.1.2 Sparse Set-Disjointness and Approximate Sparse $\#OV$

Next we consider a sparse version of SET-DISJOINTNESS, in which Alice and Bob get two sparse vectors  $u, v \in \{0, 1\}_{\leq d}^m$ <sup>5</sup>, and want to decide whether  $\langle u, v \rangle = 0$ .

<sup>4</sup> the generalized inner product of  $k$  vectors, is defined as  $\langle u_1, u_2, \dots, u_k \rangle = \sum_{i=1}^d \prod_{j=1}^k (u_j)_i$ .

<sup>5</sup> We use  $\{0, 1\}_{\leq d}^m$  to denote all Boolean vectors of length  $m$  with at most  $d$  ones.

Using the famous quantum-walk algorithm for ELEMENT DISTINCTNESS [14], there is an  $O(d^{2/3} \log m)$  communication protocol for sparse SET-DISJOINTNESS, which is much better than the  $O(\sqrt{m})$  protocol for SET-DISJOINTNESS when  $m \gg d$ .

Applying this protocol and Theorem 1, we can give an algorithm for a sparse version of #OV, denoted as #Sparse-OV $_{n,m,d}$ , in which we are given sets  $A, B \subseteq \{0, 1\}_{\leq d}^m$  of  $n$  vectors, and the goal is to count the number of distinct  $(a, b) \in A \times B$  such that  $\langle a, b \rangle = 0$ . Formally, we have:

► **Theorem 5.** *For integers  $n, m, d$  and any constant  $\varepsilon > 0$ , #Sparse-OV $_{n,m,d}$  can be approximated deterministically with additive error  $\varepsilon \cdot n^2$  in*

$$n \cdot 2^{O(d^{2/3} \log(m))}$$

*time. In particular, when  $m = \text{poly}(d)$  and  $d = o\left(\left(\frac{\log n}{\log \log n}\right)^{1.5}\right)$ , it runs in  $n^{1+o(1)}$  time.*

We remark that it is possible to improve Theorem 5 via the polynomial method. Again, we emphasize that our focus here is to provide direct applications of our general framework, with the hope that it could stimulate more applications of quantum communication protocols in the classical settings.

### 1.1.3 Approximate Counting for Formula $\circ$ SYM Circuits

Finally, we apply our algorithm to approximately count solutions (i.e., satisfying assignments) to a class of circuits, for which no non-trivial algorithms were previously known.

A Formula  $\circ$  SYM circuit of size  $m$  is a formula with {AND, OR, NOT} basis on  $m$  SYM gates<sup>6</sup> at the bottom. Using the quantum query algorithm for FORMULA EVALUATION [15] and the split-and-list technique, we obtain the following deterministic approximate counting algorithm for Formula  $\circ$  SYM circuits:

► **Theorem 6.** *For any constant  $\varepsilon > 0$ , the number of solutions to a Formula  $\circ$  SYM circuit of size  $m$  can be approximated deterministically within  $\varepsilon \cdot 2^n$  additive error in  $2^{O(n^{1/2} m^{1/4+o(1)} \sqrt{\log n + \log m})}$  time. In particular, when  $m = n^{2-\delta}$  for some  $\delta > 0$ , the running time is  $2^{o(n)}$ .*

Previously, even no non-trivial deterministic approximate counting algorithms for AND  $\circ$  SYM circuits were known. A recent line of works [31, 32, 44], culminating in [39], construct a PRG for AND $_m$   $\circ$  THR circuits with seed length  $\text{poly}(\log m, \delta^{-1}) \cdot \log n$ , using which one can obtain a quasi-polynomial time deterministic approximate counting algorithm for polynomial size AND  $\circ$  THR circuits. However, their PRG constructions rely on the fact that the solution set of an AND $_m$   $\circ$  THR circuit is a *polytope*, while the solution set of an AND  $\circ$  SYM circuit may not have such a nice geometric structure.

In fact, the only property we need for SYM gates is that they admit an efficient *classical*  $k$ -party communication protocol when the inputs are divided to  $k$  players (each player sends the contribution of her part). Our algorithm actually works for the following more general problem.

► **Problem 1.** *Given  $k$  sets of  $n$  vectors  $X_1, X_2, \dots, X_k \subseteq \{0, \dots, r\}^d$  and  $d$  functions  $f_1, f_2, \dots, f_d$  where each  $f_i$  is from  $[r]^k$  to  $\{0, 1\}$ , and a Boolean formula  $\mathcal{F} : \{0, 1\}^d \rightarrow \{0, 1\}$  of  $O(1)$  fan-in. Count the number of  $k$ -tuples  $u_1 \in X_1, u_2 \in X_2, \dots, u_k \in X_k$  such that*

$$\mathcal{F}(f_1(u_{1,1}, u_{2,1}, \dots, u_{k,1}), f_2(u_{1,2}, u_{2,2}, \dots, u_{k,2}), \dots, f_d(u_{1,d}, u_{2,d}, \dots, u_{k,d})) = 1.$$

<sup>6</sup> A SYM gate is a gate whose output only depends on the number of ones in the input.

► **Theorem 7.** *For any constant  $\varepsilon > 0$ , the above problem can be solved deterministically in  $n \cdot 2^{O(d^{1/2+o(1)} \cdot k(\log d + \log r))}$  time, within  $\varepsilon \cdot n^k$  additive error.*

## 1.2 Arthur-Merlin Communication Protocols and a New Approximate Max-IP Algorithm

Our second connection is an algorithmic application of  $\text{AM}^{\text{cc}}$  protocols. We first define  $\text{AM}^{\text{cc}}$  protocols formally.

► **Definition 8.** An Arthur-Merlin communication protocol ( $\text{AM}^{\text{cc}}$ )  $\Pi$  for a partial function  $F : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1, \perp\}$ <sup>7</sup> proceeds as follows:

- Alice holds input  $x \in \mathcal{X}$  and Bob holds input  $y \in \mathcal{Y}$ .
- Alice and Bob toss some public coins jointly and send the random string  $r \in \{0, 1\}^*$  to Merlin ( $r$  is called the random challenge).
- Based on  $x$ ,  $y$  and the random challenge  $r$ , Merlin sends Alice and Bob a proof  $\psi$ , and Alice and Bob decide to accept or not independently and deterministically. We require the following conditions:
  - If  $F(x, y) = 1$ , with probability  $1 - \varepsilon$  over the random challenge  $r$ , there is a proof  $\psi$  from Merlin such that Alice and Bob both accept.
  - If  $F(x, y) = 0$ , with probability  $1 - \varepsilon$  over the random challenge  $r$ , there is no proof  $\psi$  from Merlin such that Alice and Bob both accept.

We call the parameter  $\varepsilon$  the error of the protocol  $\Pi$ . Moreover, we say the protocol is *computationally efficient* if Alice and Bob's behavior can be computed in polynomial-time w.r.t. their input lengths.

We show that for any function  $F$ , a low-complexity and computationally efficient  $\text{AM}^{\text{cc}}$  protocol implies a faster algorithm for the corresponding  $F$ -Satisfying-Pair problem (defined below).

For a partial function  $F : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1, \perp\}$ , where  $\mathcal{X}$  and  $\mathcal{Y}$  are two sets, we define  $F$ -Satisfying-Pair <sub>$n$</sub>  as the problem that given two sets  $A \subseteq \mathcal{X}$  and  $B \subseteq \mathcal{Y}$  of size  $n$ , distinguish between the following two cases: (1) There is an  $(x, y) \in A \times B$  such that  $F(x, y) = 1$ . (2) For all  $(x, y) \in A \times B$ ,  $F(x, y) = 0$ .

► **Theorem 9 (Algorithms from  $\text{AM}^{\text{cc}}$  protocols).** *Let  $F : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1, \perp\}$  be a partial function. Suppose there is a computationally efficient  $\text{AM}^{\text{cc}}$  protocol for  $F$  with communication complexity  $T$  and error  $\varepsilon$ . Then for  $n$  such that  $2^T \leq (\sqrt{\varepsilon}n)^{0.1}$ , there is an  $O(\varepsilon n^2 \cdot \text{polylog}(n) + n \cdot 2^T)$  time randomized algorithm for  $F$ -Satisfying-Pair <sub>$n$</sub> .*

### 1.2.1 A New Algorithm for Approximate Max-IP

The first application of Theorem 9 is a new algorithm for approximate Maximum Inner Product. We use  $\text{Max-IP}_{n,d}$  to denote the problem that given sets  $A, B \subseteq \{0, 1\}^d$  with size  $n$ , compute  $\text{Max}(A, B) := \max_{(a,b) \in A \times B} \langle a \cdot b \rangle$ .

To phrase this as an  $F$ -Satisfying-Pair problem, we first define the following gap inner product problem.

<sup>7</sup>  $F(x, y) = \perp$  means  $F(x, y)$  is undefined.

► **Definition 10** (Multiplicative-Gap Inner Product). Consider the following problem, denoted as  $\text{Gap-Inner-Product}_d$ , Alice and Bob hold strings  $x, y \in \{0, 1\}^d$  respectively, and they are given an integer  $\tau$ . They want to distinguish between the following two cases: (Yes)  $x \cdot y \geq 2\tau$ ; (No)  $x \cdot y \leq \tau$ .

Adapting the classical Goldwasser-Sisler AM protocol for approximating set size [28], we can derive an efficient  $\text{AM}^{\text{cc}}$  protocol for  $\text{Gap-Inner-Product}_d$ .

► **Lemma 11** ( $\text{AM}^{\text{cc}}$  protocol for  $\text{Gap-Inner-Product}_d$ ). *There is an  $\text{AM}^{\text{cc}}$  protocol which solves  $\text{Gap-Inner-Product}_d$  with error  $\varepsilon$  and communication complexity  $\log \binom{d}{\leq O(\log \varepsilon^{-1})}$ .*<sup>8</sup>

Applying Theorem 9, the following algorithm for approximating Max-IP follows directly, matching the previous best algorithm in [23].

► **Corollary 12.** *There is an algorithm for computing a 2-approximation to  $\text{Max-IP}_{n, c \log n}$ , which runs in  $n^{2-1/O(\log c)}$  time.*

► **Remark.** The constant 2 in Corollary 12 can be replaced by any other constant  $\kappa > 1$ .

We remark here that a direct application of the Goldwasser-Sisler protocol and parallel repetition leads to a communication protocol with communication complexity  $O(\log d \log \varepsilon^{-1})$ , which is slightly worse than Lemma 11. In particular, such a protocol only gives an algorithm with running time  $n^{2-1/O(\log d)}$ , which is worse than  $n^{2-1/O(\log c)}$  when  $c \ll d = c \log n$ . In order to get the improved complexity in Lemma 11, we make use of a clever sampling scheme using Poisson distributions, see Section 4.1 for details.

## 1.2.2 Evidences that Longest Common Subsequence and Edit Distance do not Have Fast $\text{AM}^{\text{cc}}$ Protocols

It has been a long-standing open problem in communication complexity to prove an  $\omega(\log n)$   $\text{AM}^{\text{cc}}$  lower bound for any explicit function [17, 29, 30]—it is consistent with our current knowledge that all known natural communication problems have  $O(\log n)$   $\text{AM}^{\text{cc}}$  protocols.

We consider two natural communication problems here,  $\text{LCS}_d^{\text{cc}}$  and  $\text{Edit-Dist}_d^{\text{cc}}$ , in which Alice and Bob hold strings  $x, y \in \{0, 1\}^d$  respectively, and are given an integer  $\tau$ . Their goal is to decide whether  $\text{LCS}(x, y) \geq \tau$  ( $\text{Edit-Distance}(x, y) \geq \tau$ ).

Our Theorem 9 shows that if  $\text{LCS}^{\text{cc}}$  or  $\text{Edit-Dist}^{\text{cc}}$  admit low-complexity and computationally efficient  $\text{AM}^{\text{cc}}$  protocols, it would imply non-trivial algorithms for the corresponding  $F$ -Satisfying-Pair problem. By a known reduction in [3], that would, in turn, implies non-trivial algorithms for  $\text{Formula-SAT}^9$ —much faster than the current state-of-the-art [47]! Therefore, at least for these two problems, constructing low-complexity  $\text{AM}^{\text{cc}}$  protocol could be hard, which may also be viewed as an evidence that they do not have efficient  $\text{AM}^{\text{cc}}$  protocols.

► **Theorem 13.** *If  $\text{LCS}_d^{\text{cc}}$  admits computationally efficient  $\text{AM}^{\text{cc}}$  protocols with complexity  $\text{polylog}(d)$ , then  $\text{Formula-SAT}$  of polynomial-size formulas admits an  $2^{n-n^{1-\delta}}$  time algorithm for any constant  $\delta > 0$ . The same holds for  $\text{Edit-Dist}^{\text{cc}}$  in place of  $\text{LCS}^{\text{cc}}$ .*

The state-of-the-art algorithm for  $\text{Formula-SAT}$  runs in  $o(2^n)$  time only when the formula size is smaller than  $n^3$  [47]. It is even purposed as a hypothesis that no  $2^n/n^{\omega(1)}$  time algorithm exists for  $n^{3+\Omega(1)}$ -size  $\text{Formula-SAT}$  in [2]. Therefore, our results imply that if  $\text{LCS}^{\text{cc}}$  or  $\text{Edit-Dist}^{\text{cc}}$  admits fast (computationally efficient)  $\text{AM}^{\text{cc}}$  protocols, then that would refute the hypothesis in [2]:

<sup>8</sup>  $\binom{n}{\leq m}$  denotes  $\sum_{i=0}^m \binom{n}{i}$ .

<sup>9</sup>  $\text{Formula-SAT}$  is the problem that deciding whether a given formula is satisfiable.

► **Corollary 14.** *Under the following hypothesis<sup>10</sup>,  $LCS_d^{cc}$  and  $Edit-Dist_d^{cc}$  do not admit computationally efficient  $AM^{cc}$  protocols with complexity  $\text{polylog}(d)$ :*

- *There is a constant  $\delta > 0$  such that Formula-SAT of polynomial-size formulas requires  $2^{n-n^{1-\delta}}$  time.*

In the full version of this paper, we show that the above corollary can be generalized to hold for computationally efficient  $PH^{cc}$  protocols (see the full version for a formal definition). Formally, we have:

► **Theorem 15.** *Under the same hypothesis as in Corollary 14,  $LCS_d^{cc}$  and  $Edit-Dist_d^{cc}$  do not admit computationally efficient  $PH^{cc}$  protocols with complexity  $\text{polylog}(d)$ .*

## 1.3 Related Works

### 1.3.1 Communication Protocols and Fine-Grained Complexity

Recently, since the breakthrough work of [5], communication protocols have been applied to *fine-grained complexity*, and several tight conditional hardness results are proved for many fundamental approximate problems in P [5, 33, 4, 23, 24, 25, 43].

Among these works, the most related one is [23], in which the author also makes use of the  $BQP^{cc}$  protocol for SET-DISJOINTNESS for a different purpose. In [23], the  $BQP^{cc}$  protocol is used to establish a *reduction* from OV to approximate  $\{-1, 1\}$ -Max-IP<sup>11</sup>, thereby showing the SETH-hardness of approximating  $\{-1, 1\}$ -Max-IP. On the other hand, in this work we use  $BQP^{cc}$  protocols directly for algorithmic purposes.

### 1.3.2 Other Algorithmic Applications of Approximate Rank

Alon studies the approximate rank of the identity matrix  $I_n$  in [11]. It is shown that it is at least  $\Omega\left(\frac{\log n}{\varepsilon^2 \log(1/\varepsilon)}\right)$  and at most  $O\left(\frac{\log n}{\varepsilon^2}\right)$ . Built upon this result, several applications in geometry, coding theory, extremal finite set theory and the study of sample spaces supporting nearly independent random variables are derived. The lower bound also has applications in combinatorial geometry and in the study of locally correctable codes over real and complex numbers, as shown in [18]. In [13, 12], several bounds on approximate rank are derived, together with applications of approximate rank in approximating Nash Equilibria, approximating densest bipartite subgraph and covering convex bodies.

## 2 Preliminaries

### 2.1 Fast Rectangular Matrix Multiplication

Similar to previous algorithms using the polynomial method (see, e.g., [50, 10, 6]), our algorithms also make use of algorithms for fast rectangular matrix multiplication.

► **Theorem 16** ([26, 27]). *There is an  $N^2 \cdot \text{polylog}(N)$  time algorithm for multiplying two matrices  $A$  and  $B$  with size  $N \times N^\alpha$  and  $N^\alpha \times N$ , where  $\alpha > 0.172$ .*

<sup>10</sup> which is much weaker than the hypothesis in [2]

<sup>11</sup> a variant of Max-IP with vectors in  $\{-1, 1\}^d$  instead of  $\{0, 1\}^d$

## 2.2 Random Variables and Poisson Distributions

Throughout the paper, we use  $X \simeq Y$  to mean that  $X$  and  $Y$  have the same distribution. We use  $X \succeq Y$  to denote stochastic dominance, i.e.,  $X \succeq Y$  iff for any  $t \in \mathbb{R}$ ,  $\Pr[X \geq t] \geq \Pr[Y \geq t]$ .

We use  $\text{Pois}(\lambda)$  to denote a Poisson distribution with parameter  $\lambda$ . We will need the following two facts about Poisson distributions. The proof can be found in the full version.

► **Lemma 17.** *Suppose  $\{X_i\}_{i=1}^n$  is a set of independent random variables with  $X_i \sim \text{Pois}(\lambda_i)$ , then  $\sum_{i=1}^n X_i \sim \text{Pois}(\sum_{i=1}^n \lambda_i)$ .*

► **Lemma 18.**  $\Pr[\text{Pois}(\lambda) \geq 1.2\lambda] \leq e^{-0.01\lambda}$  and  $\Pr[\text{Pois}(\lambda) \leq 0.8\lambda] \leq e^{-0.01\lambda}$ .

## 2.3 Tensor Ranks

In this paper we are interested in the approximate tensor rank with respect to the  $\ell_\infty$  norm. For more on approximate tensor rank with respect to other norms and their applications, see [46] and the references therein. Now we introduce some relevant definitions.

► **Definition 19.** We say a tensor  $T \in \mathbb{R}^{n_1 \times n_2 \times \dots \times n_k}$  is *simple* if  $T = v_1 \otimes v_2 \otimes \dots \otimes v_k$  where  $v_i \in \mathbb{R}^{n_i}$ .

► **Definition 20.** For a tensor  $T \in \mathbb{R}^{n_1 \times n_2 \times \dots \times n_k}$ , its  $\text{rank}(T)$  is defined to be the smallest integer  $r$  such that  $T = \sum_{i=1}^r A_i$  and  $A_i$  is simple for all  $i \in [r]$ .

► **Definition 21.** For a tensor  $T \in \mathbb{R}^{n_1 \times n_2 \times \dots \times n_k}$ , the approximate rank of  $T$  is defined as follows:  $\text{rank}_\varepsilon(T) = \min\{\text{rank}(S) \mid \|T - S\|_\infty \leq \varepsilon\}$ . Here  $\|\cdot\|_\infty$  is the entry-wise  $\ell_\infty$ -norm of a tensor.

## 2.4 Quantum Query Complexity

In this section we recall some previous results on quantum query complexity. Here we emphasize the number of qubits used by the algorithms, which will be crucial when simulating them using classical algorithms.

► **Definition 22.** In the FORMULA EVALUATION problem, we are given a formula  $\mathcal{F}$  with  $\{\text{AND}, \text{OR}, \text{NOT}\}$  basis and  $O(1)$  fan-in on  $n$  variables  $x_1, x_2, \dots, x_n$ . In each query, the algorithm gets the value of  $x_i$ , where  $i \in [n]$  is determined by the algorithm. The goal is to evaluate the formula.

► **Theorem 23 ([15]).** *The FORMULA EVALUATION problem can be solved in  $O(n^{1/2+o(1)})$  queries using  $O(\text{polylog}(n))$  qubits, with failure probability at most  $1/3$ .*

► **Remark.** There is an optimal  $O(n^{1/2})$  query algorithm for FORMULA EVALUATION [42]. However, that query algorithm doesn't fit in our applications here for two reasons: (1) the algorithm needs  $O(n)$  qubits, which is too much for classical simulation; (2) the algorithm is not *computationally efficient* and it takes too much time to compute the corresponding unitary transformation.

► **Definition 24.** In the ELEMENT DISTINCTNESS problem, we are given  $n$  elements  $X = (x_1, x_2, \dots, x_n) \in [m]^n$ . In each query, the algorithm gets the value of  $x_i$ , where  $i \in [n]$  is determined by the algorithm. The goal is to decide whether there are two distinct indices  $i \neq j$  such that  $x_i = x_j$ .

► **Theorem 25 ([14]).** *The ELEMENT DISTINCTNESS problem can be solved in  $O(n^{2/3})$  queries using  $O(n^{2/3} \log m)$  qubits, with failure probability at most  $1/3$ .*

## 2.5 Multiparty Quantum Communication Protocols

In this section, we give our definition of multiparty quantum communication protocols.

Let  $\mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k$  be finite sets and  $f : \mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k \rightarrow \{0, 1\}$  be a function. In a  $k$ -part quantum communication protocols, there are  $k$  players  $P_1, P_2, \dots, P_k$ , together with a Hilbert space  $H = H_1 \otimes H_2 \otimes \dots \otimes H_k \otimes \overline{H}$ . Here  $H_i$  serves as the inner working space for player  $P_i$ , and  $\overline{H}$  is the communication channel between all the players. Each player  $P_i$  receives an input  $x_i \in \mathcal{X}_i$  and the goal is to determine  $f(x_1, x_2, \dots, x_k)$ .

Now we give the formal definition of a  $k$ -party quantum communication protocol.

► **Definition 26.** A  $k$ -part quantum communication protocol  $\mathcal{P} = \mathcal{P}(x_1, x_2, \dots, x_k)$  is a sequence of  $r$  unitary transforms  $\mathcal{P} = (U_1^{p_1}(x_{p_1}), U_2^{p_2}(x_{p_2}), \dots, U_r^{p_r}(x_{p_r}))$ , such that:

- $U_i^{p_i}(x_{p_i})$  is a unitary transform acting on  $H_{p_i} \otimes \overline{H}_i$  where  $\overline{H}_i$  is a subspace spanned by some qubits of  $\overline{H}^{12}$ . That is, it is the action of  $p_i$ -th player  $P_{p_i}$ , who is in charge of the  $i$ -th turn.
- The sequence  $p_1, p_2, \dots, p_r$ , and  $\overline{H}_1, \overline{H}_2, \dots, \overline{H}_r$  are fixed and do not depend on  $x_1, \dots, x_k$ . In other words,  $\overline{H}_i$  corresponds to the qubits in the channel  $\overline{H}$  that player  $P_{p_i}$  will modify during its action in the  $i$ -th turn, and all players take actions in a fixed, predefined order.
- The communication complexity of  $\mathcal{P}$  is defined to be  $C(\mathcal{P}) = \sum_{i=1}^r \log(\dim(\overline{H}_i))$ . The space complexity of  $P_i$  is defined to be  $S_i(\mathcal{P}) = \log(\dim(H_i \otimes \overline{H}))$ .

For a protocol  $\mathcal{P} = (U_1^{p_1}(x_{p_1}), U_2^{p_2}(x_{p_2}), \dots, U_r^{p_r}(x_{p_r}))$ , we say  $\mathcal{P}$  computes  $f$  with error  $\varepsilon$  if we measure the *first* qubit in  $\overline{H}$  on the state  $U_r^{p_r}(x_{p_r}) \cdot U_{r-1}^{p_{r-1}}(x_{p_{r-1}}) \cdot \dots \cdot U_2^{p_2}(x_{p_2}) \cdot U_1^{p_1}(x_{p_1}) \cdot |0\rangle$ , we get  $f(x_1, x_2, \dots, x_k)$  with probability at least  $1 - \varepsilon$ , for all  $x_1 \in \mathcal{X}_1, x_2 \in \mathcal{X}_2, \dots, x_k \in \mathcal{X}_k$ .

► **Remark.** We remark that our definition here is more complicated than the usual definition of quantum communication protocols in the literature (see, e.g., [34]), but nonetheless, it is equivalent to them. We choose to formulate it in such a way because it is easier to describe the classical simulation of quantum communication protocols for low approximate rank decompositions, and the simulation of quantum query algorithms (see below).

### 2.5.1 Simulating Quantum Query Algorithm in Quantum Communication Protocols

Quantum communication protocols can be built upon quantum query algorithms (see, e.g., [20]). Here we give an example to show how to simulate a quantum query algorithm for FORMULA EVALUATION to construct a quantum communication protocol for the communication problem corresponding to Problem 1, under our definition.

In the corresponding  $k$ -party communication problem, there are  $k$  players, and the  $i$ -th player  $P_i$  is given a vector  $u_i \in [r]^d$ . There are  $d$  functions  $f_1, f_2, \dots, f_d$  where each  $f_i$  is from  $[r]^k$  to  $\{0, 1\}$ , and a Boolean formula  $\mathcal{F} : \{0, 1\}^d \rightarrow \{0, 1\}$  of  $O(1)$  fan-in. Set  $v(i) = f_i(u_{1,i}, u_{2,i}, \dots, u_{k,i})$ . Their goal is to compute  $\mathcal{F}(v(1), v(2), \dots, v(d))$ .

Now we show how to construct a quantum communication protocol for the above problem.

► **Example 27.** Assume that the first player runs a quantum query algorithm for the FORMULA EVALUATION problem. For the simulation, we only need to implement the following query gate  $O_v: |i\rangle |b\rangle \rightarrow |i\rangle |b \oplus v(i)\rangle$ , where  $i$  is the index of a variable written in binary form and  $v(i)$  is the corresponding input bit to  $\mathcal{F}$ .

<sup>12</sup> i.e.,  $U_i^{p_i}(x_{p_i})$  does not alter qubits other than those in  $H_{p_i} \otimes \overline{H}_i$ .

We first specify the channel,  $\overline{H}$  is defined as  $\overline{H}_{\text{index}} \otimes \overline{H}_{\text{output}} \otimes \overline{H}_1 \otimes \cdots \otimes \overline{H}_k$ .  $\overline{H}_{\text{index}}$  and  $\overline{H}_{\text{output}}$  together simulate the query gate, and  $\overline{H}_i$  is the place for player  $P_i$  to write her number.

In the beginning, all qubits in  $\overline{H}$  are  $|0\rangle$ . When the first player wants to apply  $O_v$  on some qubits in  $H_1$ , it first swaps the qubits containing  $i$  and  $b$  in  $H_1$  with  $\overline{H}_{\text{index}}$  and  $\overline{H}_{\text{output}}$  in  $\overline{H}$ .

Each player  $P_j$  in turn reads  $i$  in  $\overline{H}_{\text{index}}$  and writes the value of  $u_{j,i}$  to qubits in  $\overline{H}_j$ . Note that each player can write the value of  $u_{j,i}$  to qubits in  $\overline{H}_j$  using a unitary transformation since all qubits in  $\overline{H}_j$  are  $|0\rangle$  at the beginning, by assumption.

Now, given the value of  $i$  and  $u_{1,i}, u_{2,i}, \dots, u_{k,i}$ , the first player maps  $|i\rangle|b\rangle$  to  $|i\rangle|b \oplus v(i)\rangle$  via a unitary transformation. Now the gate  $O_v$  is implemented, but we still have to clean up the garbages in  $\overline{H}_j$ 's, and set them back to  $|0\rangle$ 's. This can be done by applying reverse transforms of all applied unitary transformation, in the reverse order.

The communication complexity of this protocol is  $O(Q \cdot k(\log d + \log r))$ , where  $Q$  is the query complexity of the quantum query algorithm. Also, using the algorithm in Theorem 23, the communication complexity of this protocol is  $O(n^{1/2+o(1)} \cdot k(\log d + \log r))$ .

### 3 Approximate Counting Algorithms from Quantum Communication Protocols

Let  $\mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k$  be finite sets and  $f : \mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k \rightarrow \{0, 1\}$  be a function. Let  $M_f \in \{0, 1\}^{|\mathcal{X}_1| \times |\mathcal{X}_2| \times \dots \times |\mathcal{X}_k|}$  denote the Boolean tensor whose  $(x_1, x_2, \dots, x_k)$  entry is  $f(x_1, x_2, \dots, x_k)$ . The following connection between 2-party quantum communication complexity and approximate rank is first observed in [21]. This result can be generalized to the  $k$ -party case to get the following theorem. Full details can be found in the full version of this paper.

► **Theorem 28.** *Let  $\mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k$  be finite sets and  $f : \mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k \rightarrow \{0, 1\}$  be a Boolean function. Suppose there exists a  $k$ -party efficient quantum communication protocol  $\mathcal{P}$ , such that  $\mathcal{P}$  gives the correct answer with probability at least  $1 - \varepsilon$  on every input, then  $\text{rank}_\varepsilon(M_f) \leq 2^{O(C(\mathcal{P}))}$ , or equivalently, there exist simple tensors  $A_1, A_2, \dots, A_{2^{O(C(\mathcal{P}))}}$  such that*

$$\left\| M_f - \sum_{i=1}^{2^{O(C(\mathcal{P}))}} A_i \right\|_\infty \leq \varepsilon.$$

In the full version of this paper, we further show how to use classical deterministic algorithms to simulate quantum communication protocols. Notice that here the time complexity depends on the space complexity of the quantum communication protocol to use.

► **Corollary 29.** *Let  $\mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k$  be finite sets and  $f : \mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k \rightarrow \{0, 1\}$  be a Boolean function. Suppose there exists a  $k$ -party efficient quantum communication protocol  $\mathcal{P}$ , such that  $\mathcal{P}$  gives the correct answer with probability at least  $1 - \varepsilon$  on every input, and all the unitary transformation used in the  $\mathcal{P}$  can be constructed in polynomial time (with respect to their sizes) by a deterministic classical algorithm. Then there exists  $k$  deterministic classical algorithms  $\mathcal{A}_{\mathcal{X}_1}, \mathcal{A}_{\mathcal{X}_2}, \dots, \mathcal{A}_{\mathcal{X}_k}$  such that  $\mathcal{A}_{\mathcal{X}_i}$  runs in  $2^{O(C(\mathcal{P})+S_i(\mathcal{P}))}$  time, receives  $x_i \in \mathcal{X}_i$  as input and outputs a vector  $\mathcal{A}_{\mathcal{X}_i}(x_i) \in \mathbb{R}^{2^{O(C(\mathcal{P}))}}$ , and for any  $x_1 \in \mathcal{X}_1, x_2 \in \mathcal{X}_2, \dots, x_k \in \mathcal{X}_k$ ,*

$$-\varepsilon \leq \langle \mathcal{A}_{\mathcal{X}_1}(x_1), \mathcal{A}_{\mathcal{X}_2}(x_2), \dots, \mathcal{A}_{\mathcal{X}_k}(x_k) \rangle - f(x_1, x_2, \dots, x_k) \leq \varepsilon.$$

Based on Corollary 29, for any Boolean function  $f : \mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k \rightarrow \{0, 1\}$  with an efficient quantum communication protocol, there also exists an efficient approximate counting algorithm for  $f$ .

► **Theorem 30.** *Let  $\mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k$  be finite sets and  $f : \mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k \rightarrow \{0, 1\}$  be a Boolean function. Suppose there exists a  $k$ -party efficient quantum communication protocol  $\mathcal{P}$ , such that  $\mathcal{P}$  gives the correct answer with probability at least  $1 - \varepsilon$  on every input, and all the unitary transformation used in the  $\mathcal{P}$  can be constructed in polynomial time (with respect to their sizes) by a deterministic classical algorithm. Then there exists a classical deterministic algorithm  $\mathcal{C}$  that receives  $X_1 \subseteq \mathcal{X}_1, X_2 \subseteq \mathcal{X}_2, \dots, X_k \subseteq \mathcal{X}_k$  as input, and outputs a number  $E$  such that*

$$\left| \sum_{x_1 \in X_1, x_2 \in X_2, \dots, x_k \in X_k} f(x_1, x_2, \dots, x_k) - E \right| \leq \varepsilon \cdot \prod_{i=1}^k |X_i|.$$

Furthermore,  $\mathcal{C}$  runs in  $\sum_{i=1}^k |X_i| \cdot 2^{C(\mathcal{P})+S_i(\mathcal{P})}$  time.

**Proof.** For all  $x_i \in \mathcal{X}_i$  we first use  $\mathcal{A}_{\mathcal{X}_i}$  in Corollary 29 to calculate  $\mathcal{A}_{\mathcal{X}_i}(x_i) \in \mathbb{R}^{2^{O(C(\mathcal{P}))}}$ , in  $\sum_{i=1}^k |X_i| \cdot 2^{C(\mathcal{P})+S_i(\mathcal{P})}$  time. Then we directly output

$$\left\langle \sum_{x_1 \in X_1} \mathcal{A}_{\mathcal{X}_1}(x_1), \sum_{x_2 \in X_2} \mathcal{A}_{\mathcal{X}_2}(x_2), \dots, \sum_{x_k \in X_k} \mathcal{A}_{\mathcal{X}_k}(x_k) \right\rangle.$$

The correctness simply follows from the fact that for all  $(x_1, x_2, \dots, x_k) \in \prod_i \mathcal{X}_i$ ,

$$-\varepsilon \leq \langle \mathcal{A}_{\mathcal{X}_1}(x_1), \mathcal{A}_{\mathcal{X}_2}(x_2), \dots, \mathcal{A}_{\mathcal{X}_k}(x_k) \rangle - f(x_1, x_2, \dots, x_k) \leq \varepsilon. \quad \blacktriangleleft$$

► **Remark.** The algorithm described above is actually a sketching algorithm. We may define the sketch for  $X_i$  as  $\text{sk}_i(X_i) = \sum_{x_i \in X_i} \mathcal{A}_{\mathcal{X}_i}(x_i) \in \mathbb{R}^{2^{O(C(\mathcal{P}))}}$  and the number  $E$  can be computed from these  $\text{sk}_i$ 's. This sketching algorithm satisfies a nice additive property, i.e., the sketch of  $A \sqcup B$  (union as a multi-set) is simply  $\text{sk}_i(A) + \text{sk}_i(B)$ .

Now we give approximate counting algorithms for concrete problems, using Theorem 30.

### 3.1 Counting the $k$ -Tuples of Orthogonal Vectors

The goal of this section is to prove the following theorem.

**Reminder of Theorem 4.** *For any integers  $k, d$  and any constant  $\varepsilon > 0$ ,  $\#k\text{-OV}_{n,d}$  can be approximated deterministically with additive error  $\varepsilon \cdot n^k$  in  $n \cdot 2^{O(k\sqrt{d})}$  time. In particular, it runs in  $n^{1+o(1)}$  time  $k$  is a constant and  $d = o(\log^2 n)$ .*

We first consider quantum communication protocols for the following function  $f$ .

► **Definition 31.** Let  $\mathcal{X}_1 = \mathcal{X}_2 = \dots = \mathcal{X}_k = \{0, 1\}^d$  and

$$f(x_1, x_2, \dots, x_k) = \begin{cases} 1 & \text{if } \langle x_1, x_2, \dots, x_k \rangle = 0 \\ 0 & \text{otherwise} \end{cases}.$$

The corresponding communication problem can be solved using the quantum communication protocol in [1] with communication complexity  $O(k\sqrt{d})$  and space complexity  $O(\text{polylog}(d))$ , with constant failure probability. If we use the algorithm in Theorem 30, together with the efficient quantum communication protocol mentioned above, we can then deterministically count the number of  $k$ -tuples of orthogonal vectors, in time  $n \cdot 2^{O(k\sqrt{d})}$  time, with an additive  $\varepsilon \cdot n^k$  error.

### 3.2 Counting the Pairs of Orthogonal Sparse Vectors

The goal of this section is to prove the following theorem.

**Reminder of Theorem 5.** For integers  $n, m, d$  and any constant  $\varepsilon > 0$ ,  $\#\text{Sparse-OV}_{n,m,d}$  can be approximated deterministically with additive error  $\varepsilon \cdot n^2$  in

$$n \cdot 2^{O(d^{2/3} \log(m))}$$

time. In particular, when  $m = \text{poly}(d)$  and  $d = o\left(\left(\frac{\log n}{\log \log n}\right)^{1.5}\right)$ , it runs in  $n^{1+o(1)}$  time.

Again we consider quantum communication protocols for the following function  $f$ .

► **Definition 32.** Let  $\mathcal{X} = \mathcal{Y} = \{0, 1\}_{\leq d}^m$  and

$$f(x, y) = \begin{cases} 1 & \text{if } \langle x, y \rangle = 0 \\ 0 & \text{otherwise} \end{cases}.$$

The corresponding communication problem can be solved with communication complexity  $O(d^{2/3} \log m)$ , by simulating the quantum query algorithm in Theorem 25 for ELEMENT DISTINCTNESS. To see the connection, let  $S = \{i \mid x_i = 1\}$  and  $T = \{i \mid y_i = 1\}$ . We will have  $f(x, y) = 1$  if and only if all elements in  $S \sqcup T$  (union as a multi-set) are distinct. Now, using the algorithm in Theorem 30, together with the efficient quantum communication protocol mentioned above, we can deterministically count the number of orthogonal pairs in  $S$  and  $T$ , in  $n \cdot 2^{O(d^{2/3} \log(m))}$  time, with an additive  $\varepsilon \cdot n^k$  error.

### 3.3 Counting Solutions to Formula $\circ$ SYM Circuits

The goal of this section is to solve the following problem.

**Reminder of Problem 1.** Given  $k$  sets of  $n$  vectors  $S_1, S_2, \dots, S_k \subseteq \{0, \dots, r\}^d$  and  $d$  functions  $f_1, f_2, \dots, f_d$  where each  $f_i$  is from  $\{0, \dots, r\}^k$  to  $\{0, 1\}$ , and a Boolean formula  $\mathcal{F} : \{0, 1\}^d \rightarrow \{0, 1\}$  of  $O(1)$  fan-in. Count the number of  $k$ -tuples  $u_1 \in S_1, u_2 \in S_2, \dots, u_k \in S_k$  such that

$$\mathcal{F}(f_1(u_{1,1}, u_{2,1}, \dots, u_{k,1}), f_2(u_{1,2}, u_{2,2}, \dots, u_{k,2}), \dots, f_d(u_{1,d}, u_{2,d}, \dots, u_{k,d})) = 1.$$

**Reminder of Theorem 7.** For any constant  $\varepsilon > 0$ , the above problem can be solved deterministically in  $n \cdot 2^{O(d^{1/2+o(1)} \cdot k(\log d + \log r))}$  time, within  $\varepsilon \cdot n^k$  additive error.

The corresponding  $k$ -party communication problem can be solved by a quantum communication protocol with communication complexity  $O(d^{1/2+o(1)} \cdot k(\log d + \log r))$ , by simulating the quantum query algorithm for Formula-Evaluation in Theorem 23. For details see Example 27. By our framework, this implies an approximate counting algorithm to the problem mentioned above in time  $n \cdot 2^{O(d^{1/2+o(1)} \cdot k(\log d + \log r))}$ , with an additive  $\varepsilon \cdot n^k$  error.

Here we mention one application to the approximate counting algorithm above.

**Reminder of Theorem 6.** For any constant  $\varepsilon > 0$ , the number of solutions to a Formula  $\circ$  SYM circuit of size  $m$  can be approximated deterministically within  $\varepsilon \cdot 2^n$  additive error in  $2^{O(n^{1/2} m^{1/4+o(1)} \sqrt{\log n + \log m})}$  time. In particular, when  $m = n^{2-\delta}$  for some  $\delta > 0$ , the running time is  $2^{o(n)}$ .

**Proof of Theorem 6.** Consider a Formula  $\circ$  SYM circuit  $\mathcal{C} : \{0, 1\}^n \rightarrow \{0, 1\}$  with  $m$  symmetric gates  $X_1, X_2, \dots, X_m$  and a Boolean formula  $\mathcal{F}$  of  $O(1)$  fan-in. Here we slightly abuse of notation by regarding  $X_i$  as a function that maps the number of inputs bits with value one to an output in  $\{0, 1\}$ . We can approximately count the number of solutions to  $\mathcal{C}$  as follows.

We split the  $n$  inputs bits into  $s$  groups, each with  $n/s$  input bits. Then for each group, we enumerate all the  $2^{n/s}$  possible assignments to the  $n/s$  input bits. We create a vector in  $\{0, \dots, n/s\}^m$  for each possible assignment, where the  $i$ -th entry is simply the number of ones in the assignment which is an input bit to the  $i$ -th symmetric gate  $X_i$ . Now, the number of solutions to the circuit  $\mathcal{C}$ , is simply the same as Problem 1, by setting

$$f_i(u_{1,i}, u_{2,i}, \dots, u_{k,i}) = X_i(u_{1,i} + u_{2,i} + \dots + u_{k,i}).$$

The total time complexity would be  $2^{n/s} \cdot 2^{O(m^{1/2+o(1)} \cdot s(\log m + \log(n/s)))}$ , with an additive  $\varepsilon \cdot 2^n$  error. Setting  $s = \frac{n^{1/2}}{m^{1/4+o(1)} \sqrt{\log n + \log m}}$ , the final time complexity would be

$$2^{O(n^{1/2} m^{1/4+o(1)} \sqrt{\log n + \log m})}. \quad \blacktriangleleft$$

## 4 Algorithms from Arthur-Merlin Communication Protocols

In this section, we prove our algorithmic applications of  $\text{AM}^{\text{cc}}$  protocols. We first show faster  $\text{AM}^{\text{cc}}$  protocols for  $F$  imply faster  $F$ -Satisfying-Pair algorithms.

**Reminder of Theorem 9.** *Let  $F : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1, \perp\}$  be a partial function. Suppose there is a computationally efficient  $\text{AM}^{\text{cc}}$  protocol for  $F$  with communication complexity  $T$  and error  $\varepsilon$ . Then for  $n$  such that  $2^T \leq (\sqrt{\varepsilon}n)^{0.1}$ , there is an  $O(\varepsilon n^2 \cdot \text{polylog}(n) + n \cdot 2^T)$  time randomized algorithm for  $F$ -Satisfying-Pair $_n$ .*

**Proof.** We first assume  $n < \frac{1}{10\sqrt{\varepsilon}}$ . After drawing a random challenge, for each element  $x \in \mathcal{X}$  and  $y \in \mathcal{Y}$  we construct a Boolean vector  $\mathcal{A}_x(x)$  and  $\mathcal{A}_y(y)$  of length  $2^T$ , where each the  $i$ -th entry indicates whether Alice (Bob) accepts when receiving the proof  $i$  from Merlin. Here we regard  $i$  as a Boolean string of length  $T$  via a natural bijection between  $[2^T]$  and  $\{0, 1\}^T$ .

According to the guarantee of an  $\text{AM}^{\text{cc}}$  protocol, for each  $x \in \mathcal{X}$  and  $y \in \mathcal{Y}$ , when  $F(x, y) = 1$ , with probability at least  $1 - \varepsilon$  over the random challenge, we have  $\langle \mathcal{A}_x(x), \mathcal{A}_y(y) \rangle > 0$ , and when  $F(a, b) = 0$  we have  $\langle \mathcal{A}_x(x), \mathcal{A}_y(y) \rangle > 0$  with probability at most  $\varepsilon$  over the random challenge.

By a union bound on all pairs of elements in  $A$  and  $B$ , we have with probability at least 0.99, for all  $a \in A$  and  $b \in B$ ,  $\langle \mathcal{A}_A(a), \mathcal{A}_B(b) \rangle > 0$  if and only if  $F(a, b) = 1$ . Consequently, with probability at least 0.99,

$$\left\langle \sum_{a \in A} \mathcal{A}_A(a), \sum_{b \in B} \mathcal{A}_B(b) \right\rangle > 0$$

if and only if there exist  $a \in A$  and  $b \in B$  such that  $F(a, b) = 1$ .

For general  $n = |A| = |B|$ , we first split  $A$  and  $B$  into  $O(\sqrt{\varepsilon}n)$  groups, each with at most  $\frac{1}{10\sqrt{\varepsilon}}$  elements. I.e., we assume  $A = \bigcup_{i=1}^g A_i$  and  $B = \bigcup_{i=1}^g B_i$  such that  $g = O(\sqrt{\varepsilon}n)$  and  $|A_i|, |B_i| \leq \frac{1}{10\sqrt{\varepsilon}}$ . For each  $i, j \in [g]$ , we use the algorithm mentioned above to calculate two vectors  $\sum_{a \in A_i} \mathcal{A}_A(a)$  and  $\sum_{b \in B_j} \mathcal{A}_B(b)$ . We write  $\mathcal{M}_A \in \mathbb{R}^{2^T \times g}$  to denote the matrix

$$\left[ \sum_{a \in A_1} \mathcal{A}_A(a), \sum_{a \in A_2} \mathcal{A}_A(a), \dots, \sum_{a \in A_g} \mathcal{A}_A(a) \right]$$

and  $\mathcal{M}_B \in \mathbb{R}^{2^T \times g}$  to denote the matrix

$$\left[ \sum_{b \in B_1} \mathcal{A}_B(b), \sum_{b \in B_2} \mathcal{A}_B(b), \dots, \sum_{b \in B_g} \mathcal{A}_B(b) \right].$$

Since  $2^T \leq (\sqrt{\varepsilon}n)^{0.1} \leq O(g^{0.1})$ , we can use the rectangular matrix multiplication algorithm in Theorem 16 to calculate  $\mathcal{M}_A^T \mathcal{M}_B$  in  $O(g^2 \cdot \text{polylog}(g)) = O(\varepsilon n^2 \text{polylog}(n))$  time. We repeat this procedure for  $O(\log n)$  times. For any  $i, j \in [g]$ , by standard concentration bounds, with probability at least  $1 - \text{poly}(n)$ , there exist  $a \in A_i$  and  $b \in B_j$  such that  $F(a, b) = 1$  if and only if the majority of the  $O(\log n)$  repetitions satisfies  $(\mathcal{M}_A^T \mathcal{M}_B)_{i,j} > 0$ . Applying union bound again over all  $i, j \in [g]$ , we can now solve  $F$ -Satisfying-Pair $_n$  by checking whether there exist  $i$  and  $j$  such that the majority of the  $O(\log n)$  repetitions satisfies  $(\mathcal{M}_A^T \mathcal{M}_B)_{i,j} > 0$ . The overall algorithm runs in  $O(\varepsilon n^2 \cdot \text{polylog}(n))$  time and succeeds with high probability, as stated.  $\blacktriangleleft$

#### 4.1 A New Algorithm for Approximate Max-IP

The first application of Theorem 9 is to use the Goldwasser-Sispe AM protocol [28] for approximating set size to obtain a new algorithm for approximating Max-IP.

We first need the following adaption of [28], which has a better dependence on  $\varepsilon$ .

**Reminder of Lemma 11.** *There is an  $\text{AM}^{\text{cc}}$  protocol for  $\text{Gap-Inner-Product}_d$  with error  $\varepsilon$  and communication complexity  $\log \binom{d}{\leq O(\log \varepsilon^{-1})}$ .*

**Proof.** Recall that  $x, y \in \{0, 1\}^d$  are the inputs hold by Alice and Bob respectively.

Let  $X = \{i \mid x_i = 1\}$  and  $Y = \{i \mid y_i = 1\}$ . The problem is equivalent to determine whether  $|X \cap Y| \geq 2\tau$  or  $|X \cap Y| \leq \tau$ . Here we give an  $\text{AM}^{\text{cc}}$  communication protocol with error  $\varepsilon$  and communication complexity  $\log \binom{d}{\leq O(\log \varepsilon^{-1})}$ .

In the communication protocol, Alice and Bob first generate i.i.d. random variables  $p_i \sim \text{Pois}(k/\tau)$  for each  $i \in [d]$ , for a parameter  $k = \Theta(\log(1/\varepsilon))$  to be determined later. When  $|X \cap Y| \geq 2\tau$ , Merlin finds an arbitrary set  $S \subseteq X \cap Y$  of size  $O(k)$  such that  $\sum_{i \in S} p_i \geq 1.6k$ , and then sends it to Alice and Bob. Upon receiving  $S$ , Alice (Bob) decides to accept or reject by checking whether  $S \subseteq X$  ( $S \subseteq Y$ ) and  $\sum_{i \in S} p_i \geq 1.6k$ . The communication complexity of this protocol is upper bounded by  $\log \binom{d}{\leq O(\log \varepsilon^{-1})}$  since  $|S| \leq 1.6k = O(\log(1/\varepsilon))$ .

Now we prove the correctness by considering the following two cases.

**Case 1:**  $|X \cap Y| \geq 2\tau$ . For this case, we have  $\sum_{i \in X \cap Y} p_i \sim \text{Pois}(|X \cap Y| \cdot k/\tau) \succeq \text{Pois}(2k)$ .

Thus by Lemma 18, with probability at least  $1 - e^{-\Omega(k)}$ ,  $\sum_{i \in X \cap Y} p_i \geq 1.6k$ . Since for each  $p_i > 0$  we must have  $p_i \geq 1$ , with probability at least  $1 - e^{-\Omega(k)}$ , there exists a set  $S \subseteq X \cap Y$  of size  $O(k)$  such that  $\sum_{i \in S} p_i \geq 1.6k$ .

**Case 2:**  $|X \cap Y| \leq \tau$ . For this case, we have  $\sum_{i \in X \cap Y} p_i \sim \text{Pois}(|X \cap Y| \cdot k/\tau) \preceq \text{Pois}(k)$ .

Thus by Lemma 18, with probability at least  $1 - e^{-\Omega(k)}$ ,  $\sum_{i \in X \cap Y} p_i \leq 1.2k$ . When both Alice and Bob accept, it must be the case that  $S \subseteq X \cap Y$  and  $\sum_{i \in S} p_i \geq 1.6k$ . However when  $|X \cap Y| \leq \tau$ , with probability at least  $1 - e^{-\Omega(k)}$ ,  $\sum_{i \in X \cap Y} p_i \leq 1.2k$ . Thus there is no  $S$  such that both Alice and Bob accept, with probability at least  $1 - e^{-\Omega(k)}$ .

The lemma follows by setting  $k$  to be a large enough multiple of  $\log(1/\varepsilon)$ .  $\blacktriangleleft$

By Theorem 9 and the above lemma, Corollary 12 follows from a binary search over  $\tau$ .

**Reminder of Corollary 12.** *There is an algorithm for computing a 2-approximation to  $\text{Max-IP}_{n,c \log n}$ , which runs in  $n^{2-1/O(\log c)}$  time.*

## 4.2 Consequence of Fast $\text{AM}^{\text{cc}}$ Protocols for LCS and Edit-Distance

Next we discuss the consequences of LCS and Edit-Distance having efficient  $\text{AM}^{\text{cc}}$  protocols. We first introduce some classical notations about the communication complexity classes (see [17, 30]). We say a function family  $F = \{F_d : \{0, 1\}^d \times \{0, 1\}^d \rightarrow \{0, 1, \perp\}\}_{d \in \mathbb{N}}$  is in  $\text{AM}^{\text{cc}}$  if  $\text{AM}^{\text{cc}}(F_d) = \text{polylog}(d)$  (we use  $\text{AM}^{\text{cc}}(F_d)$  to denote the  $\text{AM}^{\text{cc}}$  communication complexity for  $F_d$  with error  $1/3$ ).

We also say  $F$  is  $\text{AM}_{\text{eff}}^{\text{cc}}$  if for all  $d \in \mathbb{N}$ ,  $F_d$  admits a computationally efficient  $\text{AM}^{\text{cc}}$  protocol with error  $1/3$  and complexity  $\text{polylog}(d)$ .

Now we prove the consequence of a function family  $F \in \text{AM}_{\text{eff}}^{\text{cc}}$ .

► **Corollary 33** (Consequence of  $F \in \text{AM}_{\text{eff}}^{\text{cc}}$ ). *Let  $F = \{F_d : \{0, 1\}^d \times \{0, 1\}^d \rightarrow \{0, 1, \perp\}\}_{d \in \mathbb{N}}$  be a partial function family. If  $F \in \text{AM}_{\text{eff}}^{\text{cc}}$ , then there is an  $n^2/2^{\log^{1-\delta} n}$  time algorithm for  $F_{\text{polylog}(n)}$ -Satisfying-Pair $_n$ , for any constant  $\delta > 0$ .*

**Proof.** By standard repetition arguments, there exists an  $\text{AM}^{\text{cc}}$  communication protocol with communication complexity  $\text{polylog}(d) \log(1/\varepsilon)$  and failure probability  $1 - \varepsilon$ . In order to invoke Theorem 9 we need to make sure

$$2^{\text{polylog}(d) \log(1/\varepsilon)} = 2^{\text{polyloglog}(n) \log(1/\varepsilon)} < n^{0.1},$$

and thus we can set  $\varepsilon = 2^{-\log^{1-\delta/2} n}$ . For this choice of  $\varepsilon$  we will then get an  $n^2/2^{\log^{1-\delta/2} n}$  time algorithm for  $F_{\text{polylog}(n)}$ -Satisfying-Pair $_n$ , which completes the proof. ◀

Recall that in  $\text{LCS}_d^{\text{cc}}$  ( $\text{Edit-Dist}_d^{\text{cc}}$ ), Alice and Bob hold strings  $x, y \in \{0, 1\}^d$  respectively, and are given an integer  $\tau$ . Their goal is to decide whether  $\text{LCS}(x, y)$  is at least  $\tau$  ( $\text{Edit-Distance}(x, y)$  is at least  $\tau$ ). Now we are ready to prove Theorem 13.

**Reminder of Theorem 13.** *If  $\text{LCS}_d^{\text{cc}}$  admits computationally efficient  $\text{AM}^{\text{cc}}$  protocols with complexity  $\text{polylog}(d)$ , then Formula-SAT of polynomial-size formulas admits an  $2^{n-n^{1-\delta}}$  time algorithm for any constant  $\delta > 0$ . The same holds for  $\text{Edit-Dist}^{\text{cc}}$  in place of  $\text{LCS}^{\text{cc}}$ .*

We will only discuss  $\text{LCS}^{\text{cc}}$  here, the proof for  $\text{Edit-Dist}^{\text{cc}}$  follows exactly the same. We first introduce the reduction from [3] (see also [2]).

► **Theorem 34** (Implicit in [3]). *For a given formula  $\mathcal{F}$  with  $n$  input variables and size  $s$ , let  $a \in \{0, 1\}^{n/2}$  be an assignment to first  $n/2$  variables in  $\mathcal{F}$  and  $b \in \{0, 1\}^{n/2}$  be an assignment to last  $n/2$  variables in  $\mathcal{F}$ . There exists an algorithm  $\mathcal{A}$  which outputs  $G(a) \in \{0, 1\}^{\text{poly}(s)}$  and  $\overline{G}(b) \in \{0, 1\}^{\text{poly}(s)}$  such that for a fixed integer  $Y$  ( $Y$  depends on  $\mathcal{F}$ ),*

- $\text{LCS}(G(a), \overline{G}(b)) = Y$  if  $a \odot b$  is a satisfying assignment to  $\mathcal{F}$ ;
- $\text{LCS}(G(a), \overline{G}(b)) \leq Y - 1$  if  $a \odot b$  is not a satisfying assignment to  $\mathcal{F}$ .

**Proof of Theorem 13.** For a given formula  $\mathcal{F}$  of size  $s = \text{poly}(n)$ , we first enumerate all  $2^{n/2}$  possible assignments to first  $n/2$  variables in  $\mathcal{F}$  and all possible assignments to last  $n/2$  variables in  $\mathcal{F}$ . For each  $a \in \{0, 1\}^{n/2}$  corresponding to an assignment to first  $n/2$  variables in  $\mathcal{F}$  and  $b \in \{0, 1\}^{n/2}$  corresponding to an assignment to last  $n/2$  variables in  $\mathcal{F}$ , we calculate  $G(a)$  and  $\overline{G}(b)$  using Theorem 34. Note that all  $G(a)$ 's and  $\overline{G}(b)$ 's have length  $\text{poly}(s) = \text{poly}(n)$ .

Now suppose  $\text{LCS}^{\text{cc}} \in \text{AM}_{\text{eff}}^{\text{cc}}$  for  $\tau = Y$ . Applying Corollary 33 with all possible  $G(a)$ 's and  $\overline{G}(b)$ 's, we can solve Formula-SAT in  $2^{n-n^{1-\delta}}$  time for any constant  $\delta > 0$ . ◀

## Open Problems and Future Directions

Here we list a few interesting open problems stemming from this work.

- In this work, we applied  $\text{BQP}^{\text{cc}}$  and  $\text{AM}^{\text{cc}}$  protocols for the algorithmic purpose. Can we find algorithmic applications of other communication protocols?
- Or less ambitiously, can we find more interesting algorithmic applications with other known  $\text{BQP}^{\text{cc}}$  or  $\text{AM}^{\text{cc}}$  protocols? (this could even be a motivation to find *new*  $\text{BQP}^{\text{cc}}$  or  $\text{AM}^{\text{cc}}$  protocols!)
- Our additive approximation algorithm for  $\#\text{OV}$  runs in near-linear time when  $d = o(\log^2 n)$ . Is it possible to design a near-linear time algorithm for  $d = n^{o(1)}$  dimensions? Note that by a simple Chernoff bound, there is a deterministic  $n^{1+o(1)}$  time algorithm with  $n^{1+o(1)}$  advice for additive approximations to  $\#\text{OV}$ . So there is a hope to construct such an algorithm.
- Our results show that under the hypothesis of [2],  $\text{LCS}^{\text{cc}}$  and  $\text{Edit-Dist}^{\text{cc}}$  do not admit computationally efficient  $\text{AM}^{\text{cc}}$  or  $\text{PH}^{\text{cc}}$  protocols. Can one prove that *unconditionally*?
- Is it possible to connect these algorithms from  $\text{AM}^{\text{cc}}$  or  $\text{PH}^{\text{cc}}$  protocols to R. Williams' algorithmic approach to circuit lower bounds [49, 51, 38]? In particular, can one show *unconditionally* that, there is a function  $f$  in  $\text{NEXP}$  (or even  $\text{NTIME}[2^{\text{polylog}(n)}]$ ), which doesn't admit  $\text{polylog}(n)$  complexity  $\text{AM}^{\text{cc}}$  or  $\text{PH}^{\text{cc}}$  protocols?

## Abstract

---

We introduce two new “degree of complementarity” measures: *supermodular width* and *superadditive width*. Both are formulated based on natural witnesses of complementarity. We show that both measures are robust by proving that they, respectively, characterize the gap of monotone set functions from being submodular and subadditive. Thus, they define two new hierarchies over monotone set functions, which we will refer to as Supermodular Width (SMW) hierarchy and Superadditive Width (SAW) hierarchy, with foundations – i.e. level 0 of the hierarchies – resting exactly on submodular and subadditive functions, respectively.

We present a comprehensive comparative analysis of the SMW hierarchy and the Supermodular Degree (SD) hierarchy, defined by Feige and Izsak. We prove that the SMW hierarchy is strictly more expressive than the SD hierarchy: Every monotone set function of supermodular degree  $d$  has supermodular width at most  $d$ , and there exists a supermodular-width-1 function over a ground set of  $m$  elements whose supermodular degree is  $m - 1$ . We show that previous results regarding approximation guarantees for welfare and constrained maximization as well as regarding the Price of Anarchy (PoA) of simple auctions can be extended without any loss from the supermodular degree to the supermodular width. We also establish almost matching information-theoretical lower bounds for these two well-studied fundamental maximization problems over set functions. The combination of these approximation and hardness results illustrate that the SMW hierarchy provides not only a natural notion of complementarity, but also an accurate characterization of “near submodularity” needed for maximization approximation. While SD and SMW hierarchies support nontrivial bounds on the PoA of simple auctions, we show that our SAW hierarchy seems to capture more intrinsic properties needed to realize the efficiency of simple auctions. So far, the SAW hierarchy provides the best dependency for the PoA of Single-bid Auction, and is nearly as competitive as the Maximum over Positive Hypergraphs (MPH) hierarchy for Simultaneous Item First Price Auction (SIA). We also provide almost tight lower bounds for the PoA of both auctions with respect to the SAW hierarchy.

**2012 ACM Subject Classification** Theory of computation → Approximation algorithms analysis, Theory of computation → Algorithmic game theory and mechanism design

**Keywords and phrases** set functions, measure of complementarity, submodularity, subadditivity, cardinality constrained maximization, welfare maximization, simple auctions, price of anarchy

## 1 Introduction

For a ground set  $X = [m] = \{1, 2, \dots, m\}$ , a *set function*  $f : 2^X \rightarrow \mathbb{R}$  assigns each subset  $S \subseteq X$  a real value.<sup>4</sup> Function  $f$  is *monotone* if  $f(T) \geq f(S), \forall S \subseteq T \subseteq X$ , and *normalized* if  $f(\emptyset) = 0$ . In this paper, we will focus on normalized monotone set functions, which by definition are non-negative.

Like graphs to network analysis, set functions provide the mathematical language for many applications, ranging from combinatorial auctions (economics) to coalition formation (cooperative game theory; political science) [25, 26] to influence maximization (viral marketing) [24, 17]. Because of its exponential dimensionality, set functions – which are as rich as weighted hypergraphs – are far more expressive mathematically and challenging algorithmically than graphs [28]. However, when monotone set functions are *submodular* [22, 29], or – more generally – *complement-free* [8], algorithms with remarkable performance guarantees have been developed for various optimization, social influence, economic, and learning tasks [2, 17, 20, 3, 23].

In this paper, we study two new *degree-of-complementarity* measures of monotone set functions, and demonstrate their usefulness for several optimization and economic tasks. We prove that our complementarity measures – which are based on natural *witnesses* of complementarity – introduce hierarchies (over monotone set functions) that smoothly move beyond submodularity and subadditivity.

### 1.1 Witnesses to Complementarity: Supermodular Sets and Superadditive Sets

For any sets  $S, T \subseteq X$ , let  $f(S|T) := f(S \cup T) - f(T)$  be the *margin* of  $S$  given  $T$ . Recall that  $f$  is *subadditive* if  $f(S \cup T) \leq f(S) + f(T), \forall S, T \subseteq X$ , and *submodular* if for all  $S, T$  and  $v \in X \setminus T$ ,  $f(v|S \cup T) \leq f(v|S)$ . It is well known that every submodular set function is also subadditive. If there are sets  $S, T \subseteq V$  such that  $f(S \cup T) > f(S) + f(T)$ , then one may say that  $(S, T)$  is a witness to *complementarity* in  $f$ . Motivated by a line of recent work [1, 14, 10, 9, 11, 6], we consider the following fundamental question about set functions:

*Are there other natural, and preferably more general, forms of witnesses to complementarity that have algorithmic consequences?*

The supermodular degree of Feige and Izsak [10] is among the first measures of complementarity that are connected with algorithmic solutions to monotone-set-function maximization and combinatorial auctions. The supermodular degree is defined based on a notion of positive dependency between elements:  $u \in X$  positively depends on  $v \in X \setminus \{u\}$  (denoted by  $u \rightarrow^+ v$ ), if there exists  $S \subseteq X$  such that  $f(u|S) > f(u|S \setminus \{v\})$ .

<sup>4</sup> Throughout the paper we use  $m$  to denote the number of elements in the ground set.

► **Definition 1.1** (Supermodular Degree). The supermodular degree of a set function  $f : 2^X \rightarrow \mathbb{R}^+$ ,  $SD(f)$ , is defined to be  $SD(f) = \max_{u \in X} |\text{Dep}_f^+(u)|$ , where  $\text{Dep}_f^+(u) = \{v | u \rightarrow^+ v\}$ .

Although supermodular degree has been shown useful in a number of settings, it is not clear whether it provides the tightest possible characterization of supermodularity. For example, consider a customer who wants any two or more items out of  $m$  items, but not zero or one item. That is, the customer has a valuation function, where any subset of  $[m]$  of size at least 2 provides utility 1, and any subset of size at most 1 provides utility 0. For this function, according to Feige and Izsak’s definition, any two items depend positively on each other. In particular, any item depends positively on all other items, so the supermodular degree of this valuation function is  $m - 1$  – the largest degree possible. This seems to contradict the intuition that there is only very limited complementarity.

Below, we will provide two perspectives, with the first highlighting *supermodularity* and the second highlighting *superadditivity*. We will then study how these two complementarity measures can be used to capture the performance of basic computational solutions in optimization and auction settings where the utilities are modeled by monotone set functions. In particular, our measure of supermodularity refines supermodular degree, and avoids the kind of overestimation discussed above. Our first definition focuses on modularity:

► **Definition 1.2** (Supermodular Set). Given a normalized monotone set function  $f$  over a ground set  $X$ , a set  $T \subseteq X$  is *supermodular* w.r.t.  $f$  if:

$$\exists S \subseteq X \text{ and } v \in X \setminus T, \text{ such that: } f(v|S \cup T) > \max_{T' \subsetneq T} f(v|S \cup T'). \quad (1)$$

Note that if  $f$  is submodular, then  $f(v|S \cup T) \leq f(v|S \cup T'), \forall T' \subsetneq T$ , implying  $f$  has no supermodular set. Thus, if a set function  $f$  has a supermodular set, then it is not submodular. We say that such a set  $T$  (in Definition 1.2) *complements* item  $v$  given  $S$ , where  $S$  provides the setting that demonstrates the complementarity between  $v$  and  $T$ . In the “customer example” given after Definition 1.1, we can check that any singleton is a supermodular set, but any set with size at least two is not a supermodular set, because any single item in the set already provides all the complementarity for any other single item. A supermodular set behaves similarly to the typical example of complements, namely *complementary bundles*,<sup>5</sup> in the sense that the set as a whole provides more complement to a single item than any of its strict subsets. However, supermodular sets have richer structures while preserving the strong complementarity of such bundles, making them potentially more challenging to deal with mathematically/algorithmically than complementary bundles of a similar size.

Our next definition focuses on additivity:

► **Definition 1.3** (Superadditive Set). Given a normalized monotone set function  $f$  over a ground set  $X$ , a set  $T \subseteq X$  is *superadditive* w.r.t.  $f$  if:

$$\exists S \subseteq X \setminus T \text{ such that: } f(S|T) > \max_{T' \subsetneq T} f(S|T'). \quad (2)$$

In Definition 1.3, we say such a set  $T$  *complements* set  $S$ . Note that if  $f$  is subadditive, then for  $T' = \emptyset$ ,  $f(S|T) = f(S \cup T) - f(T) \leq (f(S) + f(T)) - f(T) = f(S) = f(S) - f(T') = f(S|T')$ , implying  $f$  does not have a superadditive set. In other words, if  $f$  has any superadditive set, then it is not subadditive.

Supermodular/superadditive sets correspond to witnesses that exhibit different kinds of complementarity. Supermodular sets are sensitive to the presence of an environment, and superadditive sets model complements to sets instead of items. The cardinality of the largest

<sup>5</sup>  $S$  is a *complementary bundle* if  $f(S) > 0$  and  $\max_{S' \subsetneq S} f(S') = 0$ .

supermodular sets or superadditive sets provides a measure of the “level of complementarity”, similar to the supermodular degree ([10]), the size of the largest bundle, and the hyperedge size ([9]) (also see Definition 1.16) in previous work.

► **Definition 1.4** (Supermodular Width). The *supermodular width* of a set function  $f$  is:

$$\text{SMW}(f) := \max\{|T| \mid T \text{ is a supermodular set w.r.t. } f\}. \quad (3)$$

► **Definition 1.5** (Superadditive Width). The *superadditive width* of a set function  $f$  is:

$$\text{SAW}(f) := \max\{|T| \mid T \text{ is a superadditive set w.r.t. } f\}. \quad (4)$$

Each measure classifies monotone set functions into a hierarchy of  $m$  levels:

► **Definition 1.6** (Supermodular Width Hierarchy (SMW- $d$ )). For any integer  $d \in \{0, \dots, m-1\}$ , a set function  $f : 2^{[m]} \rightarrow \mathbb{R}$  belongs to the first  $d$ -levels of the *supermodular width hierarchy*, denoted by  $f \in \text{SMW-}d$ , if and only if  $\text{SMW}(f) \leq d$ .

► **Definition 1.7** (Superadditive Width Hierarchy (SAW- $d$ )). For any integer  $d \in \{0, \dots, m-1\}$ , a set function  $f : 2^{[m]} \rightarrow \mathbb{R}$  belongs to the first  $d$  levels of the *superadditive width hierarchy*, denoted by  $f \in \text{SAW-}d$ , if and only if  $\text{SAW}(f) \leq d$ .

We will show that functions at level 0 of the above two hierarchies, respectively, are precisely the families of submodular and subadditive functions. In both hierarchies,  $\text{SMW-}(m-1)$  and  $\text{SAW-}(m-1)$  contains all monotone set functions over  $m$  elements. Coming back again to the customer example, we see that the utility of the customer has supermodular width of 1. Comparing to its supermodular degree of  $m-1$ , our hierarchy characterizes this utility function at a much lower level, which matches our intuition that the complementarity of this customer’s utility function should be limited. We will further show below that this difference also has significant algorithmic implications.

## 1.2 Our Results and Related Work

We now summarize the technical results of this paper. Structurally, we provide strong evidence that our definitions of supermodular/superadditive sets are natural and robust. We show that they – respectively – capture a set-theoretical gap of monotone set functions to submodularity and subadditivity. Algorithmically, we prove that our characterization based on supermodular width is *strictly stronger* than that of Feige-Izsak’s based on supermodular degree, by establishing the following:

1. For every set function  $f : 2^{[m]} \rightarrow \mathbb{R}$ ,  $\text{SD}(f) \leq \text{SMW}(f)$ , and there exists a function whose supermodular degree is much larger than its supermodular width.
2. The SMW hierarchy offers the same level of algorithmic guarantees in the maximization and auction settings as the SD hierarchy.

We will also compare both hierarchies with the MPH hierarchy of [9].

### 1.2.1 Robustness: Capturing the Set-Theoretical Gap to Submodularity/Subadditivity

We interpret the level of complementarity in our formulation of supermodular and superadditive sets from a dual perspective: We prove that they characterize the gaps from a monotone set function to submodularity and subadditivity, respectively. Our characterization uses the following definition.

► **Definition 1.8** (*d*-Scopic Submodularity). For integer  $d \geq 0$ , a normalized monotone set function  $f$  is *d*-scopic submodular if and only if:

$$f(v|T) \leq \max_{T': T' \subseteq T, |T'| \leq d} f(v|S \cup T'), \quad \forall S, T \subseteq X, v \in X \text{ satisfying } S \subseteq T, v \notin T \quad (5)$$

In Condition (5),  $\{S \cup T' | T' \subseteq T, |T'| \leq d\}$  defines a set-theoretical *neighborhood* around  $S$ . The *d*-scopic submodularity means that even if the submodular condition  $f(v|T) \leq f(v|S)$  may not hold for some  $S \subseteq T$ , it holds for some set in  $S$ 's *d*-neighborhood inside  $T$ . Thus, the parameter  $d$  provides a set-theoretical scope for examining submodularity. Similarly:

► **Definition 1.9** (*d*-scopic Subadditivity). For integer  $d \geq 0$ , a set function  $f$  is *d*-scopic subadditive if and only if:

$$f(S|T) \leq \max_{T': T' \subseteq T, |T'| \leq d} f(S|T'), \quad \forall S, T \subseteq X \text{ satisfying } S \cap T = \emptyset. \quad (6)$$

In Section 2, we prove the following two theorems.

► **Theorem 1.10** (Set-Theoretical Characterization of the SMW Hierarchy). *For any integer  $d \geq 0$  and set function  $f : 2^X \rightarrow \mathbb{R}$ ,  $f$  is  $d$ -scopic submodular if and only if  $\text{SMW}(f) \leq d$ .*

► **Theorem 1.11** (Set-Theoretical Characterization of the SAW Hierarchy). *For any integer  $d \geq 0$  and set function  $f : 2^X \rightarrow \mathbb{R}$ ,  $f$  is  $d$ -scopic subadditive if and only if  $\text{SAW}(f) \leq d$ .*

With matching supermodularity/submodularity and superadditivity/subadditivity characterization, Theorems 1.10 and 1.11 illustrate that our definitions of supermodular/superadditive sets are both natural and robust. While monotone submodular functions are all subadditive, some *d*-scopic submodular functions are not *d*-scopic subadditive. In fact, these two hierarchies are not comparable (Propositions 2.6 and 2.7): They model different aspects of complementarity that can be utilized in diverse algorithmic and economic settings.

## 1.2.2 Expressiveness: Strengthening Supermodular Degree

Supermodular sets extend positive dependency (as used in supermodular degree), which – in essence – can be viewed as a graphical approximation of supermodular sets. Thus, our characterization based on supermodular width strengthens Feige-Izsak's the characterization based on supermodular degree [10].

► **Theorem 1.12.** *Every monotone set function  $f$  with supermodular degree  $d$  has supermodular width at most  $d$  (i.e., it is  $d$ -scopic submodular). Moreover, there exists a monotone set function  $f : 2^{[m]} \rightarrow \mathbb{R}^+$  with  $\text{SMW}(f) = 1$  and  $\text{SD}(f) = m - 1$ .*

In other words, the SMW hierarchy strictly *dominates* the SD hierarchy.<sup>6</sup>

## 1.2.3 Usefulness: Algorithmic and Economic Applications

We then show, algorithmically, the SMW hierarchy – while being more expressive than the SD hierarchy – provides a complexity classification as effective as the latter (Theorems 3.2, 3.5 and 4.15). We will illustrate the usefulness of our hierarchies in algorithm and auction design with two archetypal classes of problems, *set function maximization* and

<sup>6</sup> Formally, when comparing two set-function hierarchies, say with name  $\{Y_d\}_{d \in [0, m-1]}$  and  $\{Z_d\}_{d \in [0, m-1]}$ , we say  $Y$  *dominates*  $Z$ , if for all  $d \in [0, m-1]$  and  $f$ ,  $f \in Z_d$  implies  $f \in Y_d$ .

*combinatorial auctions*, which traditionally involve measures of complementarity. Motivated by previous work [10, 14, 11, 9], we will characterize the *approximation guarantee* of polynomial-time set-function maximization algorithms and *efficiency* of simple auction protocols in terms of the complementarity level in our hierarchies. In these settings, we will compare our hierarchies with two most commonly cited complementarity hierarchies: the supermodular degree (SD) hierarchy and the Maximum over Positive Hypergraphs (MPH) hierarchy.

- *Set-Function Maximization*: We will consider both constrained and welfare maximization. The former aims to find a set of a given cardinality with maximum function value. The latter aims to allocate a set of items to  $n$  agents,<sup>7</sup> with potentially different valuations, such that the total value of all agents is maximized. As a set function has exponential dimensions in  $m$ , in both maximization problems, we assume that the input set functions are given by their value oracles.
- *Combinatorial Auctions and Simple Auction Protocols*: We will consider two well-studied simple combinatorial auction protocols: Single-bid Auction and Simultaneous Item First Price Auction (SIA). In both settings, there are multiple agents, each of which has a (potentially different) valuation function over subsets of items. The former auction protocol proceeds by asking each bidder to bid a single price, and letting bidders, in descending order of their bids, buy any available set of items paying their bid for each item. The latter simply runs first-price auctions simultaneously for all items.

#### 1.2.4 Approximation Guarantees According to Supermodular Widths

We will prove that the elegant approximability results for constrained maximization by [14] and for welfare maximization by [10] can be extended from supermodular degree to supermodular width. We obtain the same dependency (see Theorems 3.2 and 3.5) – that is,  $1 - e^{-1/(d+1)}$  and  $\frac{1}{d+2}$  respectively – on the supermodular width  $d$  as what the supermodular degree previously provides for these problems.

Because our SMW hierarchy is strictly more expressive, our upper bounds for SMW- $d$  cover strictly more monotone set functions than previous results for SD- $d$ . We will also complement our algorithmic results with nearly matching information theoretical lower bounds (see Theorems 3.3 and 3.6), for these two well-studied fundamental maximization problems. Our approximation and hardness results illustrate that the SMW hierarchy not only captures a natural notion of complementarity, but also provides an accurate characterization of the “nearly submodular property” needed by approximate maximization problems.

#### 1.2.5 Efficiency of Simple Auctions According to Superadditive/Supermodular Width

Next, we will analyze the efficiency of two well-known simple auction protocols in terms of superadditive width. To state our results and compare them with previous work, we first recall a notation from [9]:

---

<sup>7</sup> Throughout the paper we use  $n$  to denote the number of agents (whenever applicable) unless otherwise specified.

► **Definition 1.13** (Closure under Maximization). For any family of set functions  $\mathcal{F}$  over  $X$ , the closure of  $\mathcal{F}$  under maximization, denoted by  $\max(\mathcal{F})$ , is the following family of set functions:  $f \in \max(\mathcal{F})$  if and only if:

$$\exists k \in \mathbb{N}, f_1, \dots, f_k \in \mathcal{F}, \text{ s.t. } f(S) = \max_{i \in [k]} f_i(S), \forall S \subseteq X. \quad (7)$$

We will prove the following nearly tight upper and lower bounds:

► **Theorem 1.14.** *Single-bid Auction and SIA are approximately efficient for valuation functions in  $\max(\text{SAW}(d))$ , with Price of Anarchy (PoA)  $O(d \log m)$ . In addition, for any  $d > 0$ , there is an instance with SAW- $d$  valuations, where the Price of Stability (PoS) of Single-bid Auction is at least  $d + 1 - \varepsilon$  for any  $\varepsilon > 0$ , and the PoA of SIA is at least  $d$ .*

Although supermodular width strictly strengthens supermodular degree, superadditive width is not comparable with supermodular degree. Nevertheless, our PoA bound of  $O(d \log m)$  is a factor of  $d$  tighter than the  $O(d^2 \log m)$  supermodular-degree based bound of [11] for Single-bid Auction. This improvement of dependency on  $d$ , together with the nearly matching lower bound, suggests that the SAW hierarchy might be more capable in capturing the smooth transition of efficiency of simple auctions. Furthermore, as a byproduct of our efficiency results for the SAW hierarchy, we also obtain similar results, but with a worse dependency on  $d$ , for the SMW hierarchy.

► **Theorem 1.15.** *Single-bid auction and SIA are approximately efficient for valuations in  $\max(\text{SMW-}d \cap \text{SUPADD})$  – with PoA  $O(d^2 \log m)$  – where SUPADD denotes the class of monotone superadditive set functions.*

For Single-bid Auction, this result strengthens the central efficiency result of [11] by replacing the supermodular degree with the more inclusive supermodular width. For the PoA analysis of SIA, the the Maximum over Positive Hypergraphs (MPH) hierarchy of [9] remains the gold standard, by providing asymptotically matching upper and lower bounds. MPH is defined based on the following hypergraph characterization of set functions: Every normalized monotone set function over ground set  $X$  can be uniquely expressed by another set function  $h$  such that  $f(S) = \sum_{T \subseteq S} h(T)$ ,  $\forall S \subseteq X$ , where  $h(T)$  for each  $T$  is called the weight of hyperedge  $T$ .

► **Definition 1.16** (Maximum over Positive Hypergraphs [9]). Let PH- $d$  be the class of set functions whose hypergraph representation  $h$  satisfies: (1)  $h(S) \geq 0$  for all  $S$ , and (2)  $h(S) > 0$  only if  $|S| \leq d$ . The  $d$ -th level of the MPH hierarchy is:  $\text{MPH-}d = \max(\text{PH-}d)$ .

MPH provides the best characterization to the efficiency of SIA as well as ties with SD and SMW regarding the approximation ratio of welfare maximization (although it requires access to the much stronger demand oracles). However, it remains open whether it can be used to analyze constrained set function maximization and Single-bid Auction. See Table 1 for a comparison. We will prove the following theorem which states that, in general, the SAW hierarchy is not comparable with MPH.

► **Theorem 1.17.** *There is a subadditive function that lives in an upper (i.e.  $\geq m/2$ ) MPH level. On the other direction, there is a function on level 2 of MPH, whose superadditive and supermodular widths are both  $m - 1$ .*

It remains open whether  $\text{MPH-}(d + 1)$  – which subsumes  $\text{SD-}d$  as a subset – contains  $\text{SMW-}d$ . In particular, the proof that  $\text{SD-}d \subseteq \text{MPH-}(d + 1)$  in [9] does not appear easily applicable to  $\text{SMW-}d$ .

■ **Table 1** Comparison of hierarchies of complementarity. Note that the  $O(d)$  bound for PoA of SIA with SD- $d$  valuations follows from the fact that SD- $d \subseteq$  MPH- $(d+1)$ , which is not clearly comparable with the PoA bound of SIA with SMW- $d$  valuations. See corresponding references and theorems for more accurate statements.

	SD- $d$	MPH- $(d+1)$	SMW- $d$	SAW- $d$
constrained maximization	$1 - e^{1/(d+1)}$ [14]	?	$1 - e^{1/(d+1)}$ (Thm 3.2)	?
welfare maximization	$1/(d+2)$ [10]	$1/(d+2)$ [9]	$1/(d+2)$ (Thm 3.5)	?
PoA of Single-bid Auction	$O(d^2 \log m)$ [11]	?	$O(d^2 \log m)$ (Thm 4.14)	$O(d \log m)$ (Thm 4.9)
PoA of SIA	$O(d)$ [9]	$O(d)$ [9]	$O(d^2 \log m)$ (Thm 4.15)	$O(d \log m)$ (Thm 4.10)

### 1.2.6 Other Related Work

**Set Function Maximization.** There is a rich body of research focusing on set function maximization with complement-free functions, e.g. [22, 29, 8]. Various information/complexity theoretical lower bounds have been established for both problems, e.g. [21, 7, 20, 18].

**Efficiency of Simple Auctions.** Single-bid Auction with subadditive valuations has a PoA of  $O(\log m)$  [5]. SIA with subadditive valuations has a constant PoA [12]. Posted price auctions with XOS valuations give a constant factor approximate welfare guarantee [13].

**Other Measures of Complementarity.** Some other useful measures include Positive Hypergraph (PH) [1] and Positive Lower Envelop (PLE) [9]. Eden *et al.* recently introduce an extensive measure which ranges from 1 to  $2^m$  to capture the smooth transition of revenue approximation guarantee [6].

## 2 Expressiveness of the New Hierarchies

### 2.1 Characterization of Supermodular/Superadditive Widths

We first prove Theorems 1.10 and 1.11, which characterize supermodular/superadditive widths with  $d$ -scopic submodular/subadditive functions.

**Proof of Theorem 1.10.** We now show  $\text{SMW}(f) \leq d$  iff  $f$  is  $d$ -scopic submodular. First, suppose  $\text{SMW}(f) \leq d$ . Consider any triple  $(T, S, v)$  such that  $S \subseteq T \subseteq X$  and  $v \notin T$ . To show  $f$  is  $d$ -scopic submodular, we prove by induction on the size of  $T$ , that

$$f(v|T) \leq \max_{T': T' \subseteq T, |T'| \leq d} f(v|S \cup T'). \quad (8)$$

As the base case, when  $|T| \leq d$ , the inequality of (8) trivially holds because if  $T' = T \setminus S$ , then  $|T'| \leq d$  and  $f(v|S \cup T') = f(v|T)$ . Inductively, assume that the statement is true for all  $\{V \subseteq X : |V| \leq k\}$  for some  $k \geq d$ . Now consider any set  $T$  with  $|T| = k+1 > d$ . Because  $T$  is not supermodular, there is  $T'' \subsetneq T$ , such that  $f(v|T) \leq f(v|T'')$ . Applying the inductive hypothesis on  $(T'', S, v)$ , we have:

$$f(v|T'') \leq \max_{T': T' \subseteq T'', |T'| \leq d} f(v|S \cup T') \leq \max_{T': T' \subseteq T, |T'| \leq d} f(v|S \cup T').$$

Thus,  $f(v|T) \leq f(v|T'') \leq \max_{T': T' \subseteq T, |T'| \leq d} f(v|S \cup T')$ , and we have demonstrated that  $f$  is  $d$ -scopic submodular. For the other direction, we assume  $f$  is  $d$ -scopic submodular. There is no supermodular set of size larger than  $d$ , because for any  $S, T, v \notin T$  where  $|T| > d$ , there is some  $T' \subseteq T$  where  $|T'| \leq d$ , such that  $f(v|S \cup T) \leq f(v|S \cup T')$ , i.e.  $T$  is not supermodular. Therefore  $\text{SMW}(f) \leq d$ . ◀

► **Corollary 2.1.**  $f$  is submodular iff  $\text{SMW}(f) = 0$  (i.e.,  $f$  has no supermodular set).

**Proof of Theorem 1.11.** We prove  $\text{SAW}(f) \leq d$  iff  $f$  is  $d$ -scopic subadditive. Suppose  $\text{SAW}(f) \leq d$ . Consider  $S$  and  $T$  where  $S \cap T = \emptyset$ . We show  $d$ -scopic subadditivity by induction on the size of  $T$ . When  $|T| \leq d$ , the statement trivially holds. Suppose  $d$ -scopic subadditivity holds for  $|T| \leq k$  where  $k \geq d$ . For  $|T| = k+1 > d$ , since  $T$  is not superadditive, there is  $T'' \subsetneq T$ , such that  $f(S|T) \leq f(S|T'')$ . Applying inductive hypothesis on  $S, T''$  gives  $f(S|T) \leq f(S|T'') \leq \max_{T': T' \subseteq T, |T'| \leq d} f(S|T')$ , i.e.  $f$  is  $d$ -scopic subadditive.

Now assume  $d$ -scopic subadditivity. There is no superadditive set with size larger than  $d$ , because for any  $S$  and  $T$  where  $|T| > d$  and  $S \cap T = \emptyset$ , there is some  $T' \subseteq T$  where  $|T'| \leq d$ , such that  $f(S|T) \leq f(S|T')$ , i.e.  $T$  is not superadditive. ◀

► **Corollary 2.2.**  $f$  is subadditive iff  $\text{SAW}(f) = 0$  (i.e.,  $f$  has no superadditive set).

## 2.2 Supermodular Width vs Supermodular Degree

The following two propositions establish Theorem 1.12, showing supermodular width strictly dominates supermodular degree.

► **Proposition 2.3.** For any set function  $f$ ,  $\text{SD}(f) \leq \text{SMW}(f)$ .

**Proof.** Fix  $f$ . Let  $T$  be a supermodular set of size  $\text{SMW}(f)$ , and  $S, v$  be such that  $f(v|T \cup S) > f(v|T' \cup S), \forall T' \subsetneq T$ . Clearly for any  $t \in T$ ,  $f(v|\{t\} \cup (T \setminus \{t\}) \cup S) > f(v|(T \setminus \{t\}) \cup S)$ . In other words,  $v \rightarrow^+ t$  for all  $t \in T$ , so  $\text{SD}(f) \geq \text{deg}^+(v) \geq |T| = \text{SMW}(f)$ . ◀

► **Proposition 2.4.** There is a monotone set function  $f$  with  $\text{SMW}(f) = 1$  and  $\text{SD}(f) = m-1$ .

**Proof.** Consider a symmetric<sup>8</sup>  $f$  over a ground set  $X = [m]$ , where  $f(S) = 0$  if  $|S| \leq 1$ , and  $f(S) = 1$  otherwise. Observe that for any  $u \neq v$ ,  $1 = f(u|\{v\}) > f(u|\emptyset) = f(u) = 0$ , so  $u \rightarrow^+ v$ , and  $\text{SD}(f) = |\text{Dep}_f^+(u)| = m-1$ . On the other hand, consider any  $T$  where  $|T| \geq 2$ . For any  $v, S$ , we have  $|S \cup T| \geq 2$ , so  $0 = f(v|S \cup T) \leq f(v|S)$ . Thus,  $T$  is not supermodular. Since there is no supermodular set with size larger than 1 and  $f$  is not submodular,  $\text{SMW}(f) = 1$ . ◀

While the SAW hierarchy does not subsume the MPH hierarchy (see Proposition 2.8), we show that there is a monotone set function in the lowest layer of the SAW hierarchy (i.e. a subadditive function) and a notably high layer of the MPH hierarchy.

► **Proposition 2.5.** There is a monotone set function  $f$  with  $\text{SAW}(f) = 0$  and  $\text{MPH}(f) = m/2$ .

**Proof.** The proposition is a direct corollary of Proposition L.2 in [9]. ◀

<sup>8</sup>  $f$  is symmetric if  $f(S)$  depends only on  $|S|$ .

### 2.3 Further Comparisons between Hierarchies

► **Proposition 2.6.** *There is a monotone set function  $f$  with  $\text{SMW}(f) = 1$  and  $\text{SAW}(f) = m/2$ .*

**Proof.** Let  $h_T(S) = \mathbb{I}[T \subseteq S]$ . Consider  $f : 2^X \rightarrow \mathbb{R}^+$  where  $X = [2t]$  and  $f(S) = \sum_{i \in [t]} h_{\{i, i+t\}}(S)$ . Because the only complement set to any item  $i \in [t]$  is  $i + t$ ,  $\text{SMW}(f) = 1$ . Note also  $T = \{t + 1, \dots, 2t\}$  is a complement set to  $S = [t]$ , so  $\text{SAW}(f) = t = m/2$ . ◀

► **Proposition 2.7.** *There is a monotone set function  $f$  with  $\text{SAW}(f) = 0$  and  $\text{SMW}(f) = m - 1$ .*

**Proof.** Consider a symmetric  $f : 2^X \rightarrow \mathbb{R}^+$ , where  $f(\emptyset) = 0$ ,  $f(X) = 2$  and  $f(S) = 1$  otherwise.  $f$  is subadditive so  $\text{SAW}(f) = 0$ . On the other hand,  $X \setminus \{u\}$  for any  $u$  is a complement set to  $u$ , so  $\text{SMW}(f) = m - 1$ . ◀

► **Proposition 2.8.** *There exists a monotone set function  $f$  with  $\text{MPH}(f) = 2$  and  $\text{SMW}(f) = \text{SAW}(f) = m - 1$ .*

**Proof.** Let  $h_T(S) = \mathbb{I}[T \subseteq S]$ . Consider function  $f : 2^X \rightarrow \mathbb{R}^+$  where  $f(S) = \sum_{u \neq v} h_{\{u, v\}}(S)$ . Note that  $f$  is in MPH-2 since its hypergraph representation consists of only hyperedges of size 2. Now consider any  $u$  and  $T = X \setminus \{u\}$ . For any  $T' \subsetneq T$ ,  $f(u|T) = |T| > |T'| = f(u|T')$ . Thus,  $T$  is both supermodular and superadditive, and  $\text{SMW}(f) = \text{SAW}(f) = m - 1$ . ◀

## 3 Expanding Approximation Guarantees for Classic Maximization

In this section, we focus on the connection between supermodular width and two classical optimization problems: the constrained and welfare set-function maximization. For submodular functions, greedy algorithms provide tight approximation guarantees for both problems [22, 29]. Here, simple modifications to these greedy algorithms can effectively utilize the mathematical structure underlying the gap to submodularity in any set function  $f$ . These extensions achieve approximation ratios parametrized by the supermodular width with the same dependency as the supermodular degree provides [14, 10]. We complement our approximation results by nearly tight information-theoretical lower bounds.

### 3.1 Constrained Maximization

We first focus on cardinality constrained maximization, a problem at the center of resource allocation and network influence [24, 17, 22, 29]. Formally:

► **Definition 3.1** (Cardinality Constrained Maximization). Given a monotone set function  $f : 2^X \rightarrow \mathbb{R}^+ \cup \{0\}$  and integer  $k > 0$ , compute a set  $S \subseteq X$  with  $|S| \leq k$  that maximizes  $f(S)$ .

We will analyze an algorithm which performs *batched greedy selection*, – see Algorithm 1 below – where the batch size is a function of the supermodular width of  $f$ . In particular, for an input set function, the batched greedy algorithm chooses a set of size not exceeding  $\text{SMW}(f) + 1$  which maximizes marginal gain, till all  $k$  elements are chosen.

Below, we show that this simple greedy algorithm provides strong approximation guarantees in terms of the supermodular width of the input function.

► **Theorem 3.2** (Extending [14]). *For any monotone set function  $f$  over  $[m]$ , Algorithm 1 achieves  $(1 - e^{-1/(\text{SMW}(f)+1)})$ -approximation for constrained maximization problem after making  $O(m^{\text{SMW}(f)+1})$  value queries.*

---

**ALGORITHM 1:** Batched Greedy Selection for Constrained Maximization  $(f, k)$ .
 

---

```

let  $S_0 \leftarrow \emptyset$ ;  $i = 0$ ;
while  $|S_i| < k$  do
  Let  $i = i + 1$ ;  $T_i \leftarrow \operatorname{argmax}_{T' \subseteq [m], |T'| \leq s} f(T' | S_i)$  where  $s = \min\{\operatorname{SMW}(f) + 1, k - |S_{i-1}|\}$ ;
  let  $S_i \leftarrow S_{i-1} \cup T_i$ ; ;
end
return  $S^{\text{BatchedGreedy}} := S_i$ ;

```

---

**Proof.** The proof uses similar ideas to those in [14], which are originally from [22]. Let  $d = \operatorname{SMW}(f)$  and (w.l.o.g.) let  $S^* = [k] = \{1, \dots, k\}$  be an optimal solution.

$$f(S^*) - f(S_i) \leq f(S^* \cup S_i) - f(S_i) \quad (9)$$

$$\leq f(S^* | S_i) = f([k] | S_i) = \sum_{j \in [k]} f(j | [j-1] \cup S_i) \leq k \max_j f(j | [j-1] \cup S_i)$$

$$\leq k \max_j \max_{U_j: U_j \subseteq [j-1], |U_j| \leq d} f(j | U_j \cup S_i) \quad (10)$$

$$\leq k \max_j \max_{U_j: U_j \subseteq [j-1], |U_j| \leq d} f(\{j\} \cup U_j | S_i) \quad (11)$$

$$\leq k f(S_{i+1} | S_i) \quad (12)$$

$$= k(f(S_{i+1}) - f(S_i))$$

where (9) is by the monotonicity of  $f$ , (10) is by the equivalent  $d$ -scopic submodularity of  $f$ , (11) is again by the monotonicity of  $f$ , and (12) is by the greedy property:  $f(S_{i+1} | S_i) = \max_{S: |S| \leq d+1} f(S | S_i)$ .

Now we have

$$\begin{aligned} f(S^*) - f(S_i) &\leq \frac{k-1}{k} (f(S^*) - f(S_{i-1})) \leq \left(\frac{k-1}{k}\right)^i (f(S^*) - f(S_0)) \\ &= \left(\frac{k-1}{k}\right)^i f(S^*) \leq e^{-i/k} f(S^*). \end{aligned}$$

Because  $f$  is monotone, we have  $|T_i| = d + 1$ , for all intermediate steps, i.e.,  $i < \lceil \frac{k}{\operatorname{SMW}(f)+1} \rceil$ . Thus, Algorithm 1 takes exactly  $t := \lceil \frac{k}{\operatorname{SMW}(f)+1} \rceil$  steps to terminate. The function value of its output  $f(S^{\text{BatchedGreedy}}) := f(S_t) \geq (1 - e^{-1/(\operatorname{SMW}(f)+1)}) f(S^*)$ . ◀

While in general, Theorem 3.2 establishes a tighter approximation guarantee for the SMW hierarchy than that for the SD hierarchy, we note that in case of submodular degree, if the positive dependency graph is given, the running times are often of the form  $\operatorname{poly}(n) \cdot 2^{O(\operatorname{SD}(f))}$ , which can be significantly better than  $n^{O(\operatorname{SMW}(f))}$  even if the submodular width  $\operatorname{SMW}(f)$  is much smaller than the submodular degree  $\operatorname{SD}(f)$ .

We now provide a nearly-matching information-theoretical lower bound, suggesting that our approximation guarantee is essentially optimal. In the theorem below, the exponent  $k^{0.99}$  can be replaced by any function of  $k$  in  $o(k)$ .

▶ **Theorem 3.3.** *For any  $d \in \mathbb{N}$ ,  $\varepsilon > 0$ , and a large enough integer  $k$ , there exists a set function  $f : 2^{[m]} \rightarrow \mathbb{R}^+$ , with  $\operatorname{SMW}(f) = d$ , such that any (possibly randomized) algorithm that produces a  $(1/(d+1) + \varepsilon)$ -approximation (with a constant probability if randomized) for the  $k$ -constrained maximization problem makes at least  $\Omega\left((m/2k)^{k^{0.99}}\right)$  value queries.*

## 24:12 Capturing Complementarity in Set Functions

**Proof.** The proof is based on similar high-level ideas to those in [20], but the detailed construction and key properties used are different. Consider a ground set  $X$  of  $m$  elements, which contains a subset  $R$  of  $r$  “special” elements. We will specify  $r$  below. We now construct a “hard-to-distinguish” function  $f_R$  such that for any  $S \subseteq X$ ,  $f_R(S) = g_R(|S|, \mathbb{I}[R \subseteq S])$  for a function  $g_R : \mathbb{N} \times \{0, 1\} \rightarrow \mathbb{R}$ . In other words,  $f_R$  depends on the cardinality of  $S$  and whether or not  $S$  completely contains  $R$ . For discussion below, let  $D = d + 1$ , and let  $c_1$  and  $c_2$  be two integers to be determined later. We set  $|R| = r = c_1 \cdot D + 1$ . We define  $f_R$  as follows:

$$f_R(S) = \begin{cases} \lfloor |S|/D \rfloor, & |S| \leq c_1 D \\ \lfloor (|S| - c_1 D)/D \rfloor + c_1, & c_1 D < |S| \leq (c_1 + c_2)D, R \not\subseteq S \\ |S| - c_1(D - 1), & c_1 D < |S| \leq (c_1 + c_2)D, R \subseteq S \\ |S| - (c_1 + c_2)(D - 1), & (c_1 + c_2)D < |S| \leq (c_1 + c_2)D + c_2(D - 1), R \not\subseteq S \\ c_1 + c_2 D, & (c_1 + c_2)D < |S| \leq (c_1 + c_2)D + c_2(D - 1), R \subseteq S \\ c_1 + c_2 D, & (c_1 + c_2)D + c_2(D - 1) < |S| \leq m \end{cases}.$$

We will use the following three properties of  $f_R$ :

- Whenever  $|S| \bmod D = D - 1$ , for any  $v \notin S$ ,  $f_R(v|S) = 1$ . Consequently,  $\text{SMW}(f_R) \leq d, \forall R \subseteq X$  with  $|R| = r$ . In fact, this property ensures that  $f_R(v|S \cup T') \geq f_R(v|S \cup T)$ , for any  $v \in X$ ,  $S, T \subseteq X$  with  $|T| \geq D = d + 1$ , and any proper subset  $T'$  of  $T$  with  $|S \cup T'| \bmod D = D - 1$ . Note that such a subset  $T'$  always exists.
- $\max \{f_R(S) \mid |S| = (c_1 + c_2)D\} = c_1 + c_2 D$ . The maximum is achieved whenever  $R \subseteq S$ .
- For any  $S \subseteq X$  satisfying  $|S| = c_1 + c_2 D$  and  $R \not\subseteq S$ ,  $f_R(S) = c_1 + c_2$ .

First, consider  $k = (c_1 + c_2)D$ . We have, for any  $S$  with  $|S| = k$ :

$$f_R(S) = \begin{cases} c_1 + c_2 D & \text{if } R \subseteq S \\ c_1 + c_2 & \text{otherwise.} \end{cases}$$

Suppose  $c_1 = o(c_2)$ . To obtain an approximation ratio better than  $(c_1 + c_2)/(c_1 + c_2 D) \rightarrow 1/D$  for  $k$ -constrained maximization of  $f_R$ , any algorithm must find a set with size  $k$  that contains all special elements in  $R$ .

For our lower bound, we will analyze the following slightly relaxed variation of the problem: Let  $K = (c_1 + c_2)D + c_2(D - 1) - 1 > k$ . Find a set of size  $K$  which contains  $R$  as a subset. Note that  $K$  is the largest number where  $f_R(S)$  – for  $|S| = K$  – depends on whether or not  $S$  contains  $R$ . In this case, note that the algorithm has no incentive to make queries of  $f_R(S)$  for  $|S| < K$  or  $|S| > K$ , because the former reveals no more information than querying any of its supersets of size  $K$ , and the latter simply does not give any information.

We first focus on the query complexity of any deterministic optimization algorithm. Assume the algorithm makes  $T$  queries regarding  $S_1, \dots, S_T$ , where  $|S_i| = K, \forall i \in [T]$ , which are deterministically chosen when the algorithm is fixed. We now establish a condition on  $T$  such that there is a subset  $R$  such that  $R \not\subseteq S_i, \forall i \in [T]$ . Consider the distribution where the  $r$  elements are selected uniformly at random. Let  $C_i$  be the event that  $S_i$  contains  $R$ . Then,

$$\begin{aligned} \Pr[C_1 \cup \dots \cup C_T] &\leq \sum_i \Pr[C_i] < \sum_i \left(\frac{|S_i|}{m}\right)^r \\ &= T \left(\frac{(c_1 + c_2)D + (D - 1)c_2 - 1}{m}\right)^{c_1 D + 1} \leq T \left(\frac{2c_2 D}{m}\right)^{c_1 D}. \end{aligned}$$

So, if  $T \leq [m/(2c_2 D)]^{c_1 D}$  then  $\Pr[C_1 \cup \dots \cup C_T] < 1$ . In other words, for any selections  $S_1, \dots, S_T \subseteq X$  with  $|S_i| = K$ , there is a subset  $R$ , such that  $R \not\subseteq S_i, \forall i \in [T]$ , implying the deterministic algorithm with querying set  $S_1, \dots, S_T$  will not find a good approximation

---

**ALGORITHM 2:** Batched Greedy for Welfare Maximization  $(f_1, \dots, f_n)$ .
 

---

```

for  $j \in [n]$  do
  | let  $X_{j,0} \leftarrow \emptyset$ ;
end
Let  $d = \max_j \{\text{SMW}(f_j)\}$ ; let  $i = 0$ ;
while  $\cup_j X_{j,i} \neq X$  do
  | Let  $i = i + 1$ ; let
  |    $(T_i, j_i^*) = \operatorname{argmax}_{(T', j'): |T'| \leq s, j' \in [n]} f_{j'}(T' | X_{j, i-1})$  where  $s = \min \left\{ d + 1, n - \sum_j |X_{j, i-1}| \right\}$ ;
  | Let  $X_{j_i^*, i} \leftarrow X_{j_i^*, i-1} \cup T_i$ ;
  | for  $j \in [n] \setminus \{j_i^*\}$  do
  |   | let  $X_{j, i} \leftarrow X_{j, i-1}$ ;
  |   end
  | return  $X_j^{\text{BatchedGreedy}} := X_{j, i}$  for every agent  $j$ ;
end

```

---

to  $f_R$ . Let  $c_2 = \frac{1}{2}c_1^{1.01}$ , so  $k^{0.99} = ((c_1 + c_2)D)^{0.99} \leq (c_1^{1.01}D)^{0.99} \leq c_1D$ . We have  $(m/2c_2D)^{c_1D} \geq (m/2k)^{k^{0.99}}$ . Thus, we conclude that any  $(1/(d+1) + \varepsilon)$ -approximation deterministic algorithm must make at least  $(m/2k)^{k^{0.99}}$  value queries.

Now consider a randomized optimization algorithm. Conditioned on the random bits of the algorithm, the above argument still works. Taking expectation of the probability of success, we see that the overall probability of success is at most  $T(2k/m)^{k^{0.99}}$ . Thus, a constant probability of success requires  $T = \Omega\left((m/2k)^{k^{0.99}}\right)$ . ◀

## 3.2 Welfare Maximization

We now turn our attention to welfare maximization. Formally:

► **Definition 3.4** (Welfare Maximization). Given  $n$  monotone set functions  $f_1, \dots, f_n$  over  $2^{[m]}$ , compute  $n$  disjoint sets  $X_1, \dots, X_n$  that maximizes  $\sum_{i \in [n]} f_i(X_i)$ .

Because  $f_1, \dots, f_n$  are monotone, the optimal solution to welfare maximization is a partition of  $X = [m]$ . Thus, welfare maximization can also be viewed as a generalized clustering or multiway partitioning problem.

We will analyze the following greedy algorithm – see Algorithm 2 below – which repeatedly assigns groups of elements to agents. At each step, the algorithm picks a set of size not exceeding  $\max_i \text{SMW}(f_i) + 1$  – as opposed to one – that provides the largest possible marginal gain to some agent and assigns the set to that agent.

We now prove the following approximation guarantee in terms of supermodular width.

► **Theorem 3.5** (Extending [10]). *For any collection of monotone set functions  $f_1, \dots, f_n$  over  $X = [m]$ , Algorithm 2 achieves  $\frac{1}{2 + \max_i \{\text{SMW}(f_i)\}}$ -approximation for welfare maximization, after making  $O\left(nm^{\max_i \{\text{SMW}(f_i)\} + 1}\right)$  value queries.*

The proof uses similar ideas to those in [10], which are originally from [16]. Due to space limit, we relegate the proof to the full version of the paper [4].

To show that our algorithm is nearly optimal, we prove the following information-theoretical lower bound: Similar to Theorem 3.3, the exponent  $(m/n)^{0.99}$  in the theorem below, can be replaced by any function of  $m/n$  in  $o(m/n)$ .

► **Theorem 3.6.** *For any  $d \in \mathbb{N}$ ,  $\varepsilon > 0$ , there is a family of function  $f_1, \dots, f_n : 2^{[m]} \rightarrow \mathbb{R}^+$  with  $\text{SMW}(f_i) = d, \forall i \in [n]$ , such that any (possibly randomized) algorithm that produces a  $(1/(d+1) + \varepsilon)$ -approximation (with constant probability if randomized) for the  $n$ -agent welfare maximization problem makes at least  $\Omega\left((n/2D)^{(m/n)^{0.99}}\right)$  value queries.*

The proof follows from a similar argument as the proof for Theorem 3.3. Due to space limit, we relegate the proof to the full version of the paper.

## 4 Efficiency of Simple Auctions

In this section, we study the connection between the SAW hierarchy and efficiency of auctions. We will draw extensively on previous work in this area, particularly on the characterization based on the *CH hierarchy* – see definition below – which is arguably the most simple class of set functions with complementarity.

► **Definition 4.1** ( *$d$ -Constraint Homogeneous Functions [11]*). A set function  $f$  over ground set  $X$  is  $d$ -constraint homogeneous (CH- $d$ ) if there exists a value  $\hat{f}$ , and disjoint sets  $Q_1, \dots, Q_h \subseteq X$  with  $|Q_i| \leq d, \forall i \in [h]$ , such that (1)  $f(Q_i) = \hat{f} \cdot |Q_i|, \forall i \in [h]$ , and (2) the value of every set  $S \subseteq [m]$  is simply the sum of values of contained  $Q_i$ 's, i.e.,  $f(S) = \sum_{Q_i \subseteq S} f(Q_i) = \hat{f} \cdot \sum_{Q_i \subseteq S} |Q_i|$ .

We will show that previous characterization of auction efficiency [11] can be approximately extended from the CH hierarchy to the SAW hierarchy.

### 4.1 Backgrounds: Related Definitions and Results

We first restate a useful definition and a lemma for analyzing the efficiency of auction mechanisms.

► **Definition 4.2** ([27]). An auction mechanism  $\mathcal{M}$  is  $(\lambda, \mu)$ -smooth for a class of valuations  $\mathcal{F} = \times_i \mathcal{F}_i$  if for any valuation profile  $f \in \mathcal{F}$ , there exists a (possibly randomized) action profile  $a_i^*(f)$  such that for every action profile  $a$ :

$$\sum_i \mathbb{E}_{a_i' \sim a_i^*(f)} [u_i(a_i', a_{-i}; f_i)] \geq \lambda \cdot \text{OPT}(f) - \mu \sum_i P_i(a),$$

where  $u_i(a_i'; f_i)$  is the utility of  $i$  given action profile  $(a_i', a_{-i})$ ,  $\text{OPT}(f)$  is the optimum social welfare given valuation profile  $f$ , and  $P_i(a)$  is the payment of  $i$  given action profile  $a$ .

► **Lemma 4.3** ([27]). *If a mechanism is  $(\lambda, \mu)$ -smooth then the price of anarchy w.r.t. coarse correlated equilibria is at most  $\max\{1, \mu\}/\lambda$ .*

For Single-bid Auction and Simultaneous Item First Price Auction (SIA), we will derive our results from the following results for CH- $d$  and MPH- $d$ .

► **Theorem 4.4** (Smoothness of Single-bid Auction with CH- $d$  Valuations [11]). *Single-bid Auction is a  $((1 - e^{-d})/d, 1)$ -smooth mechanism when agents have CH- $d$  valuations. Consequently, Single-bid Auction has a PoA of  $(1 - e^{-d})/d$  with CH- $d$  valuations w.r.t. coarse correlated equilibria.*

► **Theorem 4.5** (Smoothness of SIA with MPH- $d$  Valuations [9]). *For SIA, when bidders have MPH- $d$  valuations, both the correlated price of anarchy and the Bayes-Nash price of anarchy are at most  $2d$ . The bound follows from a smoothness argument.*

A key concept to extend these results to other valuation classes is the following notion of pointwise approximation defined in [5].

► **Definition 4.6** (Pointwise Approximation [5]). A class of set functions  $\mathcal{F}$  over ground set  $X$  is pointwise  $\beta$ -approximated by another class  $\mathcal{F}'$  of set functions over  $X$  if  $\forall f \in \mathcal{F}, S \subseteq X, \exists f'_S \in \mathcal{F}'$  such that (1)  $\beta f'_S(S) \geq f(S)$  and (2)  $\forall T \subseteq X, f'_S(T) \leq f(T)$ .

For example:

► **Proposition 4.7** ([11]). *The class  $\max(\mathcal{F})$  is pointwise 1-approximated by the class  $\mathcal{F}$ .*

We say a function  $f' : 2^X \rightarrow \mathbb{R}$  pointwise  $\beta$ -approximates  $f : 2^X \rightarrow \mathbb{R}$  (at  $X$ ), if (1)  $\beta f'(X) \geq f(X)$ , and (2)  $\forall T \subseteq X, f'(T) \leq f(T)$ .

The following lemma of [5] provides a way to translate PoA bounds between classes via pointwise approximation.

► **Lemma 4.8** (Extension Lemma [5]). *If a mechanism for a combinatorial auction setting is  $(\lambda, \mu)$ -smooth for the class of set functions  $\mathcal{F}'$ , and  $\mathcal{F}$  is pointwise  $\beta$ -approximated by  $\mathcal{F}'$ , then it is  $(\frac{\lambda}{\beta}, \mu)$ -smooth for the class  $\mathcal{F}$ . And as a result, if a mechanism for a combinatorial auction setting has a PoA of  $\alpha$  given by a smoothness argument for the class  $\mathcal{F}'$ , and  $\mathcal{F}$  is pointwise  $\beta$ -approximated by  $\mathcal{F}'$ , then it has a PoA of  $\alpha\beta$  for the class  $\mathcal{F}$ .*

## 4.2 Efficiency of Simple Auctions Parametrized by SAW

Applying Lemma 4.8, we are able to translate Theorems 4.4 and 4.5 to the SAW hierarchy.

► **Theorem 4.9** (Efficiency of Single-bid Auction with SAW- $d$  Valuations). *When agents have valuations  $f_1, \dots, f_n \in \max(\text{SAW-}d)$ , Single-bid Auction has a price of anarchy of at most  $\frac{2d}{1-e^{-2d}} \cdot H_{\frac{m}{2d}}$  w.r.t. coarse correlated equilibria.*

► **Theorem 4.10** (Efficiency of SIA with SAW- $d$  Valuations). *When agents have valuations  $f_1, \dots, f_n \in \max(\text{SAW-}d)$ , SIA has a price of anarchy of at most  $8d \cdot H_{\frac{m}{2d}}$  w.r.t. coarse correlated equilibria.*

Formally, Theorems 4.9 and 4.10 follow from Theorems 4.4 and 4.5 respectively, with the help of Lemma 4.8, Proposition 4.7, and the technical lemma (Lemma 4.11) that we will establish below, showing that for any  $d \in \mathbb{N}$ , functions in SAW- $d$  can be approximated by CH- $2d$  functions. In particular, Lemma 4.11 establishes the approximation of SAW hierarchy by CH hierarchy with a loss of factor  $O(\log m)$ .

► **Lemma 4.11** (Pointwise Approximation of SAW Hierarchy by CH-Hierarchy). *For any  $d \in \mathbb{N}$ , SAW- $d$  is pointwise  $2H_{\frac{m}{2d}}$ -approximated by CH- $2d$ , where  $H_i = \sum_{k \in [i]} \frac{1}{k}$  is the  $i$ -th harmonic number.*

**Proof.** Our proof is inspired by the constructions of [5] and [11].

For any  $f \in \text{SAW-}d$  over  $X = [m]$ , we first apply the following greedy construction to obtain a partition  $\mathcal{Q} = \{Q_i\}_{i \in [q]}$  of  $[m]$  into sets of size not exceeding  $2d$ : At step  $i$ , we select a new set  $Q_i \subseteq [m] \setminus (Q_1 \cup \dots \cup Q_{i-1})$ , with maximum  $f(Q_i)$ , among all sets of size at most  $2d$ .

We first prove by contradiction that there exists a function  $g$  in CH- $2d$  which  $2H_{\frac{m}{2d}}$ -approximates  $f$  at  $[m]$ . That is, (1)  $2H_{\frac{m}{2d}} g([m]) \geq f([m])$  and (2)  $\forall T \subseteq [m], g(T) \leq f(T)$ .

Suppose this statement is not true. Let

$$h_{\mathcal{Q}}(T) = \frac{f([m])}{\beta \cdot |\cup_i Q_i|} \sum_{Q_i \subseteq T} |Q_i|.$$

## 24:16 Capturing Complementarity in Set Functions

Note that  $h_{\mathcal{Q}} \in \text{CH-}2d$  because  $|Q_i| \leq 2d, \forall Q_i \in \mathcal{Q}$ . We now construct a series of functions based on  $h_{\mathcal{Q}}$ , and prove that for any  $\beta > 0$ , if there is no  $g$  among these functions that is a  $\beta$ -approximation of  $f$  at  $[m]$  – that is, there is no  $g$  such that (1)  $\beta g([m]) \geq f([m])$  and (2)  $\forall T \subseteq [m], g(T) \leq f(T)$ , (below we will refer to this condition as Assumption (\*)) – then  $\beta < 2H_{\frac{m}{2d}}$ .

First consider  $h_{\mathcal{Q}}$ . Note that  $\beta h_{\mathcal{Q}}([m]) = \beta \frac{f([m])}{\beta} \geq f([m])$ , because  $\mathcal{Q}$  is a partition of  $[m]$ . Assumption (\*) then implies there is a  $T_1$  such that  $h_{\mathcal{Q}}(T_1) > f(T_1)$ . W.l.o.g. assume  $T_1$  is a union of sets from  $\mathcal{Q}$  (such  $T_1$  exists because  $f$  is monotone).

Let  $S_1 = [m]$ . We now iteratively define  $S_i = S_{i-1} \setminus T_{i-1}$ , and construct its associated  $T_i$ . The construction maintains the following invariant: Both  $S_i$  and  $T_i$  are unions of sets from  $\mathcal{Q}$ . The former follows directly from the iterative property that  $S_{i-1}$  and  $T_{i-1}$  are both unions of sets from  $\mathcal{Q}$ . Our construction below will ensure the latter.

Let  $\mathcal{Q}_{S_i} = \{Q \in \mathcal{Q} \mid Q \subseteq S_i\}$ . Let

$$h_{\mathcal{Q}_{S_i}} = \frac{f([m])}{\beta \cdot |\cup_{j: Q_j \in \mathcal{Q}_{S_i}} Q_j|} \sum_{j: Q_j \in \mathcal{Q}_{S_i}} |Q_j|.$$

Again,  $h_{\mathcal{Q}_{S_i}} \in \text{CH-}2d$ , and  $h_{\mathcal{Q}_{S_i}}([m]) = \frac{f([m])}{\beta}$ . Assumption (\*) then implies there is a  $T_i$  such that  $h_{\mathcal{Q}_{S_i}}(T_i) > f(T_i)$ . Again, w.l.o.g. assume  $T_i$  is a union of sets from  $\mathcal{Q}$  (such  $T_i$  exists because  $f$  is monotone). This iterative process terminates, producing a partition  $\{T_i\}_{i \in [t]}$  of  $[m]$ , which satisfies:

$$\sum_i f(T_i) < \sum_i h_{\mathcal{Q}_{S_i}}(T_i) = \frac{f([m])}{\beta} \sum_i \frac{|T_i|}{|S_i|} \leq \frac{f([m])}{\beta} \sum_{i \in [t]} \frac{1}{i} \leq \frac{f([m])}{\beta} H_{\frac{m}{2d}}.$$

We now show that  $\sum_i f(T_i) \geq \frac{1}{2} f([m])$ . Recall that each member in partition  $\{T_i\}_i$  is a unions of sets from  $\mathcal{Q}$ . We renumber  $\{T_i\}_i$ , in a way that for any  $i < j$ , there is some  $T_i \supseteq Q_k \in \mathcal{Q}$ , such that for any  $T_j \supseteq Q_l \in \mathcal{Q}$ ,  $k < l$ . That is, the smallest index  $k$  where  $Q_k \in T_i$  is smaller than the smallest index  $l$  where  $Q_l \in T_j$ , as long as  $i < j$ .

Since  $(T_1, \dots, T_t)$  is a partition of  $[m]$ , we have:

$$\begin{aligned} f([m]) &= \sum_i f(T_i | T_{i+1} \cup \dots \cup T_t) \\ &\leq \sum_i \max\{f(T_i | U_i) \mid U_i \subseteq T_{i+1} \cup \dots \cup T_t, |U_i| \leq d\} \end{aligned} \quad (13)$$

$$\leq \sum_i \max\{f(T_i \cup U_i) \mid U_i \subseteq T_{i+1} \cup \dots \cup T_t, |U_i| \leq d\} \quad (14)$$

$$= \sum_i \max\{(f(U_i | T_i) + f(T_i)) \mid U_i \subseteq T_{i+1} \cup \dots \cup T_t, |U_i| \leq d\}$$

$$\leq \sum_i \max\{(f(U_i | V_i) + f(T_i)) \mid U_i \subseteq T_{i+1} \cup \dots \cup T_t, |U_i| \leq d, V_i \subseteq T_i, |V_i| \leq d\} \quad (15)$$

$$\leq \sum_i \max\{(f(U_i \cup V_i) + f(T_i)) \mid U_i \subseteq T_{i+1} \cup \dots \cup T_t, |U_i| \leq d, V_i \subseteq T_i, |V_i| \leq d\} \quad (16)$$

$$\leq \sum_i (f(Q_{k_i}) + f(T_i)), \text{ where } k_i = \min\{k \mid T_i \supseteq Q_k \in \mathcal{Q}\} \quad (17)$$

$$\leq \sum_i 2f(T_i), \quad (18)$$

where (13) and (15) follow from  $d$ -scopic subadditivity of  $f$ , (14), (16) and (18) follow from monotonicity of  $f$ , and (17) holds because, according to the construction of  $\{Q_l\}_l$ ,  $Q_{k_i}$

maximizes  $f$  among all sets of size  $2d$  contained in  $Q_{k_i} \cup \dots \cup Q_q \supseteq T_i \cup \dots \cup T_t$ , and in particular  $U_i \cup V_i \subseteq T_i \cup \dots \cup T_t$ .

Consequently, it follows from  $\sum_i f(T_i) \geq \frac{1}{2}f([m])$  that:

$$\frac{H_{\frac{m}{2d}} f([m])}{\beta} > \sum_i f(T_i) \geq \frac{1}{2}f([m]) \Rightarrow \beta < 2H_{\frac{m}{2d}}.$$

Thus, Assumption (\*) with  $\beta \geq 2H_{\frac{m}{2d}}$  leads to a contradiction. Therefore, we have established that there exists a CH- $2d$  function  $g$  such that (1)  $g([m]) \geq 2H_{\frac{m}{2d}}f([m])$  and (2)  $\forall T \subseteq [m]$ ,  $g(T) \leq f(T)$ .

As in [11], the above proof can be simply extended to prove for any  $S \subseteq X$ , there exists a CH- $2d$  function  $g$  such that (1)  $g(S) \geq 2H_{\frac{m}{2d}}f([m])$  and (2)  $\forall T \subseteq [m]$ ,  $g(T) \leq f(T)$ . Essentially, we restrict the function  $f$  to  $2^S$ , apply the argument above, and then span the obtained function back to  $2^X$ .

Therefore, SAW- $d$  is pointwise  $2H_{\frac{m}{2d}}$ -approximated by CH- $2d$ .  $\blacktriangleleft$

We further analyze previously known hard instances to both auctions, and show that they provide almost matching lower bounds to the above two efficiency upper bounds.

► **Theorem 4.12.** *There is an instance with SAW- $d$  valuations for any  $d$ , where the PoS of Single-bid Auction is at least  $d + 1 - \varepsilon/d$  for any  $\varepsilon > 0$ .*

► **Theorem 4.13.** *There is an instance with SAW- $d$  valuations for any  $d$ , where the PoA of SIA is at least  $d + 1/(d + 1)$ .*

We defer the proofs to the full version of the paper.

### 4.3 Efficiency of Simple Auctions Parametrized by SMW

As a byproduct of our efficiency results for the SAW hierarchy, we prove similar, but slightly weaker, results for the SMW hierarchy. We note that these bounds extend a central result in [11], which states that when agents have valuations in  $\max(\text{SD-}d \cap \text{SUPADD})$ , Single-bid Auction has a PoA of  $O(d^2 \log m)$ .

► **Theorem 4.14** (Extending [11]). *When agents have valuations  $f_1, \dots, f_n \in \max(\text{SMW-}d \cap \text{SUPADD})$ , Single-bid Auction has a price of anarchy of at most  $\frac{(d+1)^2}{1-e^{-(d+1)}} \cdot H_{\frac{m}{d+1}}$  w.r.t. coarse correlated equilibria.*

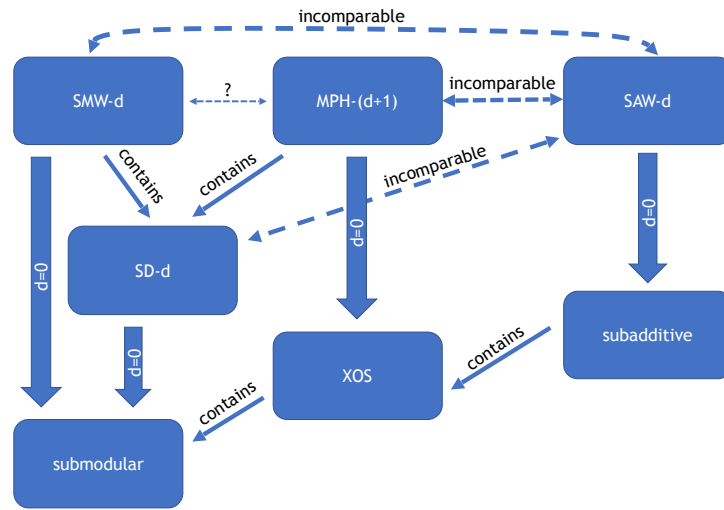

► **Theorem 4.15.** *When agents have valuations  $f_1, \dots, f_n \in \max(\text{SMW-}d \cap \text{SUPADD})$ , SIA has a price of anarchy of at most  $2(d + 1)^2 \cdot H_{\frac{m}{d+1}}$  w.r.t. coarse correlated equilibria.*

Due to space limit, we relegate the proofs to the full version of the paper.

## 5 Remarks

### 5.1 Further Comparative Analysis

As observed by Eden *et al.* [6], the right measure of complementarity often varies from application to application. This seems to be true even with the supermodular vs superadditive widths. We note that while the SD and SMW hierarchies give nontrivial bounds on the PoA of simple auctions, SAW hierarchy seems to capture the intrinsic property needed by efficiency guarantees for simple auctions. It provides tighter characterization of PoA with a gap of

■ **Figure 1** Relationship between hierarchies.

$\log m$  (instead of  $d \log m$ ) between upper and lower bounds. On the other hand, while SMW hierarchy captures the intrinsic property needed by the constrained/welfare maximization, it remains open whether a small superadditive width provides any approximation guarantee for the two optimization problems.

The MPH hierarchy takes a different approach from ours – it relies on a syntactic definition which provides elegant and intuitive structures. In contrast, both SMW and SAW hierarchies – like the SD hierarchy before it – are built on concrete natural concepts of witnesses and semantic intuition of complementarity. In the current definition, the MPH hierarchy is not an extension to submodularity or subadditivity. Rather – as shown in [9] – MPH can be considered as an extension to the fractionally subadditive (or XOS) class proposed in [19]. We therefore consider SMW, MPH and SAW parallel measures of complementarity, just like submodularity, fractional subadditivity and subadditivity in the complement-free case. One key difference is that the three hierarchies seem to diverge at higher levels of complementarity, as opposed to the fact that submodular functions are all fractionally subadditive, and fractionally subadditive functions are all subadditive. This phenomenon provides further evidence that the three hierarchies are likely to capture different aspects of complementarity. See Figure 1 for a comparison.

We also note that all upper bounds supported by our hierarchies are accompanied by almost matching lower bounds, which we consider as a justification of our definitions – they manage to categorize set functions roughly according to their “hardness” in different settings (i.e. optimization for SMW and efficiency for SAW). In contrast, while the less inclusive supermodular degree hierarchy supports a number of upper bounds, to our knowledge, none of those results are proven tight.

## 5.2 Final Remarks and Open Problems

Our SMW and SAW hierarchies may be applied to other problem settings. For example, for the online secretary problem based on supermodular degree [15], we believe that with a slight modification of the algorithms and the analysis, we could replace supermodular degree with supermodular width as well for this problem; also, SMW- $d$  functions are efficiently PAC-learnable under product distributions [30]. It may be possible to look into other venues where SMW and SAW hierarchies are applicable.

There are also a few technical questions to be answered:

- Does MPH- $(d + 1)$  – which subsumes SD- $d$  – include all SMW- $d$  functions?
- Can we improve the SAW-based efficiency characterization of Single-bid Auction and SIA to  $O(d)$ ?
- Can the MPH hierarchy be used to characterize constrained set function maximization?

## Abstract

Non-signaling strategies are a generalization of quantum strategies that have been studied in physics over the past three decades. Recently, they have found applications in theoretical computer science, including to proving inapproximability results for linear programming and to constructing protocols for delegating computation. A central tool for these applications is probabilistically checkable proofs (PCPs) that are *sound against non-signaling strategies*.

In this paper we prove that the exponential-length constant-query PCP construction due to Arora et al. (JACM 1998) is sound against non-signaling strategies.

Our result offers a new length-vs-query tradeoff when compared to the non-signaling PCP of Kalai, Raz, and Rothblum (STOC 2013 and 2014) and, moreover, may serve as an intermediate step to a proof of a non-signaling analogue of the PCP Theorem.

## 1 Introduction

Probabilistically Checkable Proofs (PCPs) [3, 11, 2, 1] are proofs whose validity can be checked by a probabilistic verifier that accesses only a few locations of the proof. PCPs have numerous applications across the theory of computing, including to hardness of approximation [11] and delegation of computation [19, 21].

A seminal result, known as the PCP Theorem [2, 1], states that every language in  $\text{NTIME}(T)$  can be probabilistically checked by a verifier that uses  $O(\log T)$  random bits and makes  $O(1)$  queries to a proof of length  $\text{poly}(T)$ .<sup>1</sup>

In this paper we study PCPs that are sound against *non-signaling strategies* (nsPCPs). These have recently found applications that appear out of the reach of (standard) PCPs, including 1-round delegation of computation from falsifiable assumptions [15, 17] and hardness of approximation for linear programming [16]. The efficiency measures achieved in known nsPCPs appear suboptimal, which affects the quality of the corresponding applications. We thus ask whether a non-signaling analogue of the PCP Theorem holds.

Below we explain the aforementioned notions, and then present our results in this direction.

**Non-signaling strategies.** Non-signaling strategies are a class of “non-local” correlations that strictly generalize quantum strategies, and capture the minimal condition that spatially-isolated parties cannot communicate instantaneously. They have been studied in physics for over three decades [24, 18, 23] in order to better understand quantum entanglement.

There are two definitions, corresponding to whether the strategy is meant to represent a function or isolated parties; the former is the relevant one for nsPCPs [15, 17].<sup>2</sup> Given a locality parameter  $k \in \mathbb{N}$ , a *k-non-signaling function*  $\mathcal{F}$  extends the notion of a function  $f: D \rightarrow \{0, 1\}$  as follows: it is a collection  $\{\mathcal{F}_S\}_{S \subseteq D, |S| \leq k}$  where each  $\mathcal{F}_S$  is a *distribution* over  $\{0, 1\}^S$  and, for every two subsets  $S_1$  and  $S_2$  each of size at most  $k$ , the restrictions of  $\mathcal{F}_{S_1}$  and  $\mathcal{F}_{S_2}$  to  $S_1 \cap S_2$  are equal as distributions.<sup>3</sup> Note that if  $k = |D|$  then  $\mathcal{F}$  is a distribution over functions  $f: D \rightarrow \{0, 1\}$ .

Note that *k-non-signaling functions* are solutions to the linear program arising from the *k-relaxation* in the Sherali–Adams hierarchy [25]. The variables are of the form  $X_{S, \vec{b}}$  (for all  $S \subseteq D$  of size at most  $k$  and  $\vec{b} \in \{0, 1\}^S$ ) and express the probability of  $\vec{b}$  in the distribution  $\mathcal{F}_S$ ; consistency across subsets  $S$  and  $T$  is expressed using the natural linear constraints.<sup>4</sup>

**Non-signaling PCPs.** Recall that a classical PCP verifier is given oracle access to a proof represented as a function  $f: D \rightarrow \{0, 1\}$ . The verifier uses random bits, makes a few queries to  $f$ , and then accepts or rejects. Completeness requires that if the statement being checked is true then there is a function  $f$  that makes the verifier always accept. Soundness requires that if the statement being checked is false then every function  $f$  makes the verifier reject with high probability.

In the non-signaling setting, “proofs” are non-signaling functions rather than (classical) functions. Soundness is correspondingly stronger: given a locality parameter  $k \in \mathbb{N}$ , soundness requires that every *k-non-signaling function*  $\mathcal{F}$  makes the nsPCP verifier reject with high probability.

<sup>1</sup> In particular, for every language in  $\text{NEXP} = \cup_{c \in \mathbb{N}} \text{NTIME}(2^{n^c})$ , the verifier uses  $\text{poly}(n)$  random bits and makes  $O(1)$  queries to a proof of length  $2^{\text{poly}(n)}$ .

<sup>2</sup> The other definition underlies the notion of multi-prover interactive proofs that are sound against non-signaling strategies (nsMIPs). Any nsPCP gives rise to an nsMIP with similar parameters. See [15, 17] for details.

<sup>3</sup> A common relaxation of this condition only requires that the marginals  $\mathcal{F}_{S_1}|_{S_1 \cap S_2}$  and  $\mathcal{F}_{S_2}|_{S_1 \cap S_2}$  are statistically close, rather than equal; a further relaxation only requires these to be computationally close. While we only consider the standard definition (the marginals must equal) we note that [9] shows that this is almost without loss of generality, as every statistically or computationally non-signaling strategy is close to an (exact) non-signaling strategy.

<sup>4</sup> In fact it suffices to only have variables of the form  $X_{S, 1^S}$  since all other probabilities can be computed from these.

Efficiency measures of a nsPCP include familiar notions such as proof length (defined as  $|D|$ ) and the verifier’s randomness and query complexity. In addition, the locality parameter  $k$  controls how hard it is to attain soundness: the smaller  $k$  is, the larger the set of non-signaling functions that the verifier could face. (Note that  $k$ -non-signaling implies  $(k-1)$ -non-signaling.)

There is a qualitative difference between the complexity classes captured by PCPs and by nsPCPs; namely, while PCPs capture *non-deterministic* time languages, nsPCPs capture *deterministic* ones. Indeed, the aforementioned PCP Theorem implies that it is NEXP-hard to approximate the maximum acceptance probability of a PCP verifier (that uses polynomial randomness). In contrast, computing the maximum acceptance probability of an nsPCP verifier that uses  $r$  random bits reduces to a linear program with  $2^{\text{poly}(rk)}$  variables and constraints, a problem solvable in  $\text{EXP} = \cup_{c \in \mathbb{N}} \text{DTIME}(2^{n^c})$ .

If  $k = 2$ , the linear program is solvable in PSPACE [13], which is a tight upper bound [14]. For  $k > 2$  little is known, except for a seminal result of Kalai, Raz, and Rothblum [15, 17], which shows that for  $k = \text{poly}(n)$  it is EXP-hard to approximate a nsPCP verifier’s maximum acceptance probability. In more detail, every language in  $\text{DTIME}(T)$  has a verifier that uses  $\text{poly}(\log T)$  random bits and makes  $\text{poly}(\log T)$  queries to a proof of length  $\text{poly}(T)$ ; soundness holds against  $\text{poly}(\log T)$ -non-signaling functions; the verifier runs in time  $n \cdot \text{poly}(\log T)$  and space  $\text{poly}(\log T)$ .<sup>5</sup>

**The nsPCP Conjecture.** The nsPCP construction behind the above result is a whitebox modification of early PCP constructions [4, 3], and achieves efficiency similar to those. However, modern “PCP technology” goes well beyond these early constructions, via tools such as proof composition [2] and proofs of proximity [10, 6], and enables better efficiency, including the PCP Theorem. Yet, current “nsPCP technology” is limited to the above results, and the question of whether a non-signaling analogue of the PCP Theorem holds remains open.

► **Question 1.** *Is it true that every language in  $\text{DTIME}(T)$  has an nsPCP verifier that uses  $O(\log T)$  random bits, makes  $O(1)$  queries, and is sound against  $O(1)$ -non-signaling functions?*

(As above, we also require that the verifier runs in time  $n \cdot \text{poly}(\log T)$  and space  $\text{poly}(\log T)$ .)

An affirmative answer to the above question would, e.g., improve the hardness result for linear programming in [16], by yielding a reduction that outputs a linear program of polynomial, rather than a quasipolynomial, size. While we do not know if an affirmative answer exists (and we cannot prove that it does not exist), it is clear that the (very few) tools that we have to construct and analyze nsPCPs are far from this goal. In this paper we make headway towards this goal.

## 1.1 Towards a nsPCP Theorem

In [1] a key step towards the PCP Theorem is to prove a weaker result in which the proof has *exponential*, rather than *polynomial*, size (and so the randomness complexity of the verifier is polynomial rather than logarithmic). Namely, one proves that every language in  $\text{NTIME}(T)$  has a PCP verifier that uses  $\text{poly}(T)$  random bits and makes  $O(1)$  queries to a proof of length  $2^{\text{poly}(T)}$ .

<sup>5</sup> Achieving time and space complexities that are  $o(T)$  is important for applications. This is not surprising as every language in  $\text{DTIME}(T)$  has a trivial nsPCP verifier that runs in time  $T$ : the verifier that simply decides the language, without asking any queries. This is unlike the case of PCPs for  $\text{NTIME}(T)$ , where time complexity is less critical.

In this paper we ask whether a non-signaling analogue of this result holds for the class  $\text{DTIME}(T)$ .

► **Question 2.** *Is it true that every language in  $\text{DTIME}(T)$  has an nsPCP verifier that uses  $\text{poly}(T)$  random bits, makes  $O(1)$  queries, and is sound against  $O(1)$ -non-signaling functions?*

We propose this question as a relaxation that, not only is interesting in its own right, but is likely to shed light on Question 1. However, one must be careful with the precise formulation of Question 2. If the verifier can use  $\text{poly}(T)$  random bits then it can simply decide the language by running in time  $T$ , without making any queries. To recover a nontrivial question, we *require* that in order to decide whether an instance  $x$  is in a language  $L \in \text{DTIME}(T)$  the nsPCP verifier first generates queries via a  $\text{poly}(T)$ -time sampler that is *input oblivious* (knows the length of  $x$  but not  $x$  itself), and then rules according to a  $o(T)$ -time decision predicate that knows  $x$ . We stress that all PCP/nsPCP verifiers discussed in this paper are input oblivious.

In this paper we study Question 2 by analyzing a natural candidate construction, and ask:

Is the exponential-length  $O(1)$ -query PCP of [1] sound against  $O(1)$ -non-signaling functions?

Hereafter, we consider the complexity class  $\text{DSIZE}(S)$  (languages decidable by uniform circuits of size  $S(n)$ ) instead of the class  $\text{DTIME}(T)$  (languages decidable by machines in time  $T(n)$ ) because our results, like their classical counterparts, are most easily stated in terms of uniform circuits. This change is only for simplicity, as  $\text{DTIME}(T) \subseteq \text{DSIZE}(\text{poly}(T))$ .

## 1.2 Main theorem

In this paper we prove that the exponential-length constant-query PCP construction of [1] (without modifications) is sound against non-signaling functions. We obtain the following theorem.

► **Theorem 3 (main theorem).** *Every language  $L \in \text{DSIZE}(S)$  has an input-oblivious nsPCP verifier that uses  $O(S^2)$  random bits, makes 11 queries, and is sound against  $O(\log^2 S)$ -non-signaling functions. The query sampler runs in time  $O(S^2)$ , and the decision predicate runs in time  $O(n)$ .*

The theorem is close to answering Question 2, which asks for soundness against  $O(1)$ -non-signaling functions. (See Table 1 for a comparison with the classical result on nondeterministic languages.) At the same time, some may consider Ito’s algorithm [13] as evidence that soundness against  $O(1)$ -non-signaling functions is too much to hope for. Understanding this gap needs further research.

Our result is *incomparable* to the nsPCP of [15, 17], where the nsPCP verifier uses  $\text{poly}(\log S)$  random bits to make  $\text{poly}(\log S)$  queries. The fact that we prove soundness only against  $O(\log^2 S)$ -non-signaling functions (rather than  $O(1)$ -non-signaling functions) is somewhat undesirable, as this implies that the corresponding nsMIP requires  $O(\log^2 S)$  provers. That said, the nsMIP of [15, 17] requires many more provers:  $\text{poly}(\log S)$  with the degree in the polynomial much larger than 2. Another feature of our result is that we have “room” to achieve smaller soundness error *without* using additional provers; for example, by asking more queries to the  $O(\log^2 S)$  provers, we can achieve a sub-constant soundness error of  $2^{-O(\log S)}$ .

Finally, our result is the first to demonstrate that a classical PCP construction is secure against non-signaling functions, *without any modifications*. This should be compared to the construction considered in [15, 17] that, while modeled after the PCP in [4, 3], includes several notable modifications that are needed in the soundness proof.

■ **Table 1** The (linear) ALMSS verifier in different PCP settings.

construction	reference	complexity class	type of PCP	soundness error	proof length	randomness	queries	locality
ALMSS verifier	[1]	NSIZE( $S$ )	PCP	$1 - 1/36$	$2^{O(S^2)}$	$O(S^2)$	11	n/a
+ linearity test	Theorem 3	DSIZE( $S$ )	ns PCP	$1 - 1/10^7$				$O(\log^2 S)$
ALMSS verifier	[1]	NSIZE( $S$ )	LPCP	$3/4$	$O(S^2)$	$O(S)$	4	n/a
	Theorem 4	DSIZE( $S$ )	ns LPCP	$39/40$				$O(\log S)$

### 1.3 Main lemmas

We outline the ideas behind our theorem in Section 2. Concretely, we highlight several statements, which we deem of independent interest, that we prove on the way to the theorem.

Recall that the exponential-length constant-query PCP in [1] is obtained in two steps. First, construct a constant-query verifier where soundness holds as long as the proof string is a *linear function*; this is known as a *linear PCP*. Second, use a linearity test [8] and self-correction to *compile* this linear PCP into a (standard) PCP, where soundness holds against arbitrary proofs.

Our approach follows the same two steps, but adapted to the non-signaling setting. This also departs from the approach in [17], which does not make use of any property testing results.

Note, however, that it is a priori not clear what is the non-signaling analogue of a linear function. A natural attempt would be to say that a non-signaling function  $\mathcal{F}$  is linear iff it passes the BLR linearity test with probability 1 (where the probability is over the test and  $\mathcal{F}$ ). But this attempt is awkward, because the definition depends on a local test, and avoids discussing “global” structure.

A recent work [9] tells us that the right definition is to say that  $\mathcal{F}$  is linear iff it corresponds to a *quasi-distribution* over linear functions. A quasi-distribution is a probability distribution where the weights can be any real number and are not restricted to be in  $[0, 1]$ . Quasi-distributions over functions arise in this context because they are an equivalent description of non-signaling functions.

In light of the above, the notion of a *non-signaling linear PCP* (nsLPCP) is immediate: the definition requires soundness to hold against all *linear* non-signaling functions.

The first step in our proof is showing that the linear PCP verifier of [1] (the “ALMSS verifier”), when used for deterministic computations, is sound against linear non-signaling functions.

► **Theorem 4.** *The (input oblivious) ALMSS verifier, for a given language  $L \in \text{DSIZE}(S)$ , uses  $O(S)$  random bits, makes 4 queries, and is sound against linear  $O(\log S)$ -non-signaling functions.*

See Table 1 for a comparison with the classical result showing soundness against linear functions.

In order to “lift” Theorem 4 to Theorem 3, we need a suitable linearity test.

The linearity test of [8] was recently analyzed in the non-signaling setting by [9], who proved that any  $k$ -non-signaling function  $\mathcal{F}$  that passes the linearity test with probability  $1 - \varepsilon$  can be self-corrected to a  $\lfloor k/2 \rfloor$ -non-signaling function  $\hat{\mathcal{F}}$  that is  $2^{O(k)}\varepsilon$ -close to a linear  $\lfloor k/2 \rfloor$ -non-signaling function  $\mathcal{L}$ . (Self-correction and closeness have precise meanings, discussed later.) However, we cannot directly use [9]’s result, because in our theorem the locality parameter  $k$  is required to be super-constant ( $k = O(\log S)$  in Theorem 4), and thus

the bound on the distance between  $\hat{\mathcal{F}}$  and  $\mathcal{L}$  is too large, even when considering only query sets of small size. Specifically, we need the distance to be a sufficiently small constant on query sets of size 4 (the number of queries in Theorem 4).

We solve this problem by extending the result in [9] in a black-box way and proving that the distance between  $\hat{\mathcal{F}}$  and  $\mathcal{L}$  on a query set  $Q$  is only  $O(|Q| \sqrt{\varepsilon})$ , provided that the error  $\varepsilon$  and  $\mathcal{L}$ 's locality are sufficiently small. Crucially, if  $|Q|$  is constant, so is the distance between  $\hat{\mathcal{F}}$  and  $\mathcal{L}$ . The proof of this statement involves analyzing the *repeated* linearity test, whose behavior in the non-signaling setting is quite subtle when compared to the classical setting (see Section 2.6).

► **Theorem 5.** *Let  $k, \bar{k} \in \mathbb{N}$  and  $\varepsilon \in (0, 1/400]$  be such that  $k = \Omega((\bar{k} + \log \frac{1}{\varepsilon}) \cdot \bar{k})$ . If a  $k$ -non-signaling function  $\mathcal{F}: \{0, 1\}^n \rightarrow \{0, 1\}$  passes the linearity test with probability at least  $1 - \varepsilon$  then there exists a linear  $\bar{k}$ -non-signaling function  $\mathcal{L}: \{0, 1\}^n \rightarrow \{0, 1\}$  such that for all query sets  $Q \subseteq \{0, 1\}^n$  with size  $|Q| \leq \bar{k}$  and for all events  $E \subseteq \{0, 1\}^Q$  it holds that*

$$\left| \Pr[\hat{\mathcal{F}}(Q) \in E] - \Pr[\mathcal{L}(Q) \in E] \right| \leq O(|Q| \sqrt{\varepsilon}) .$$

The above result on linearity testing enables us to transform our nsLPCP, and more generally *any* nsLPCP, into a corresponding nsPCP with minimal changes in parameters (the transformation is exactly the classical compiler). This is the last key statement in the proof of our main theorem.

► **Lemma 6.** *For every  $\varepsilon \in [0, 1]$ , if a language  $L$  has an nsLPCP where the verifier uses  $r$  random bits, makes  $q$  queries, and has soundness error  $1 - \varepsilon$  against linear  $k$ -non-signaling functions  $\mathcal{L}: \{0, 1\}^\ell \rightarrow \{0, 1\}$ , then  $L$  has an nsPCP where the verifier uses  $r + O(q\ell)$  random bits, makes  $O(q)$  queries, and has soundness error  $1 - O_q(\varepsilon^2)$  against  $O_\varepsilon(k^2)$ -non-signaling functions  $\mathcal{F}: \{0, 1\}^\ell \rightarrow \{0, 1\}$ . (Furthermore, if the former is input oblivious, so is the latter.)*

## 1.4 Enriching the toolkit for non-signaling PCPs

Progress in our understanding of PCPs has typically moved hand in hand with progress in our understanding of low-degree testing. In particular, many PCP constructions follow this blueprint:

- (1) a low-degree test that, via only a few queries, ensures that a given proof conforms to a specified algebraic encoding;
- (2) a probabilistic test that, assuming the proof is (essentially) given in this encoding, ensures that the statement being checked is true with high probability.

In contrast, while the nsPCP in [17] is reminiscent of this blueprint, its analysis does not follow it, despite the fact that the construction is modeled after the PCP in [4, 3], for which the two-step analysis *is* possible (in the classical setting). The lack of such general paradigms means that we lack general design principles to construct better nsPCPs.

This state of affairs raises the intriguing question of whether a theory of low-degree testing (and, more generally, property testing) is feasible in the non-signaling setting and, moreover, whether one can build on it to construct nsPCPs in order to make further progress towards Question 1.

An additional contribution of our work is to *enrich* the current “non-signaling toolkit”, by demonstrating an example where the aforementioned blueprint is both possible and useful.

Namely, building on the work of [9] on linearity testing, our results provide a modular paradigm that not only simplifies the overall analysis, thereby enabling us to assert that the construction of [1] *with no modifications* is sound against non-signaling strategies, but also (as discussed later) clarifies the technical barriers that separate us from answering Question 2. All this suggests that our techniques will be helpful for constructing more efficient nsPCPs.

## 1.5 Concurrent work

In a concurrent work, Kiyoshima [20] studies the soundness of ALMSS-type PCPs against non-signaling strategies. Kiyoshima proves that, for a sufficiently large security parameter  $t$  (at least logarithmic in the circuit size), the  $t$ -repetition of a  $O(t)$ -query modification of the ALMSS-verifier has soundness error  $\text{negl}(t)$  against  $O(t^2)$ -non-signaling functions. In comparison, we prove that the *unmodified* 11-query ALMSS PCP has soundness error  $O(1)$  against  $O(\log^2 S)$ -non-signaling strategies (and also that a modification of its  $t$ -repetition has soundness error  $\exp(-t)$  for every  $t = \Omega(\log S)$ ). While both our analysis and Kiyoshima's analysis avoid the use of an augmented circuit (necessarily so as it would have had exponential size), our techniques differ. Kiyoshima conducts a direct analysis of the PCP verifier, while we adopt a modular approach in which we first prove soundness against *linear* non-signaling strategies (a simpler task), and then, building on a recent analysis of the linearity test [9], we deduce soundness against *all* non-signaling strategies. We consider the modular and simple analysis in our work to be of independent interest. Kiyoshima additionally proves that soundness holds against *computational* non-signaling strategies, a relaxation where the marginal distributions on intersections are only required to be computationally close. Our results directly extend to computational non-signaling strategies as every computational non-signaling strategy is close to an exact non-signaling strategy (as proved in [9]).

In another concurrent work, Holmgren and Rothblum [12] study the problem of constructing PCPs/MIPs in which the prover is very efficient in time and space [7], in the non-signaling setting. While they consider a construction that is more closely related to the PCP in [4, 3] (honest proofs are encoded via low-degree polynomials rather than linear functions), their soundness analysis also has the feature that it avoids the use of an augmented circuit.

## 1.6 Open problems

The question of whether the exponential-length constant-query PCP of [1] is sound against  $O(1)$ -non-signaling functions remains open. A concrete approach to affirmatively answer this question is to prove that the *linear* PCP verifier of [1] is sound against  $k$ -non-signaling functions for  $k = O(1)$ , rather than  $k = O(\log S)$  as in Theorem 4. (Our generic compiler from Theorem 6 would then take care of the rest.) Another intriguing possibility is that an affirmative answer to Question 2 could come from a *different* exponential-size constant-query PCP. However, the result due to [13] shows that the class of nsMIPs with 2 provers equals PSPACE, which possibly suggests that soundness against  $O(1)$ -non-signaling functions is too much to hope for.

Moreover, while our results can be interpreted as progress towards a non-signaling analogue of the PCP Theorem (Question 1), it remains unclear whether such an analogue holds, and more investigations in nsPCPs are needed. We believe that our work and our new techniques can inform such investigations.

## 2 Techniques

We outline the techniques used to prove our results. First, in Section 2.1, we explain the transformation from a nsLPCP to a corresponding nsPCP. Next, in Sections 2.2 to 2.5 we discuss the nsLPCP on which we apply this transformation, namely, the ALMSS verifier [1]. Finally, in Section 2.6, we discuss linearity testing with low error, which underlies the transformation.

## 2.1 From nsLPCP to nsPCP

We discuss the transformation from nsLPCP to nsPCP (Theorem 6). We first recall the classical transformation from LPCP to PCP, and then explain how to achieve its non-signaling analogue.

**The classical case.** The classical transformation from LPCP to PCP relies on the following tools.

- *Testing linearity.* Given a boolean function  $f: \{0, 1\}^\ell \rightarrow \{0, 1\}$ , the linearity test draws random  $x, y \in \{0, 1\}^\ell$  and checks that  $f(x) + f(y) = f(x + y)$  [8]. If the test passes with probability  $1 - \varepsilon$ , then  $f$  is  $\varepsilon$ -close to a linear function  $f^*: \{0, 1\}^\ell \rightarrow \{0, 1\}$  [8, 5].
- *Self-correction.* Given  $f$  that is  $\varepsilon$ -close to a linear function  $f^*$ , one can create a probabilistic oracle  $\mathcal{O}$  that, given any  $x \in \{0, 1\}^\ell$ , returns  $f^*(x)$  with probability  $1 - 2\varepsilon$ . Namely,  $\mathcal{O}$  samples a random  $z \in \{0, 1\}^\ell$ , queries  $f$  on  $z + x$  and  $z$ , and answers with  $f(z + x) - f(z)$ .

The above tools imply a transformation from LPCP to PCP: given access to an arbitrary function  $f: \{0, 1\}^\ell \rightarrow \{0, 1\}$ , the PCP verifier runs the linearity test and then runs the LPCP verifier by self-correcting each of its queries. If the LPCP verifier makes  $q$  queries and has soundness error  $\gamma$ , then the resulting PCP verifier makes  $3 + 2q$  queries and has soundness error  $\max\{1 - \varepsilon, \gamma + 2q\varepsilon\}$ , where  $\varepsilon$  is (a bound on) the distance of  $f$  to linear functions. This soundness error is bounded by  $1 - \frac{1-\gamma}{2q+1}$  (the maximum is when the two terms equal), which is bounded away from 1.

If desired, the soundness error can be made arbitrarily close to  $\gamma$  by repeating the linearity test. Given a parameter  $t$ , the repeated linearity test samples  $x_i, y_i \in \{0, 1\}^\ell$  for each  $i \in [t]$  and checks that  $f(x_i) + f(y_i) = f(x_i + y_i)$  for all  $i \in [t]$ . Now, the PCP verifier makes  $3t + 2q$  queries and has soundness error  $\max\{(1 - \varepsilon)^t, \gamma + 2q\varepsilon\}$ , which for suitable  $\varepsilon$  and  $t = O_{\gamma, \varepsilon}(q)$  is arbitrarily close to  $\gamma$ .

**The non-signaling case.** We follow the structure of the classical transformation. However, the non-signaling case not only calls for a different analysis but also raises a problem that we must solve.

The linearity test in the non-signaling setting has the following guarantee [9]: if  $\mathcal{F}$  is a  $k$ -non-signaling function such that  $\Pr_{x, y, \mathcal{F}}[\mathcal{F}(x) + \mathcal{F}(y) = \mathcal{F}(x + y)] \geq 1 - \varepsilon$  then  $\mathcal{F}$  can be self-corrected (in the natural way) to a  $(k/2)$ -non-signaling function  $\hat{\mathcal{F}}$  that is  $2^{O(k)}\varepsilon$ -close to a linear non-signaling function  $\mathcal{L}$ . Note that self-correction is already part of the conclusion.

The above result appears sufficient for compiling a nsLPCP verifier into a corresponding nsPCP verifier. Namely, given a  $k$ -non-signaling function  $\mathcal{F}: \{0, 1\}^\ell \rightarrow \{0, 1\}$ , the nsPCP verifier checks that  $\mathcal{F}(x) + \mathcal{F}(y) = \mathcal{F}(x + y)$  for random  $x, y \in \{0, 1\}^\ell$  and also checks that the nsLPCP verifier accepts  $\hat{\mathcal{F}}$ . Analogously to before, if the nsLPCP verifier makes  $q$  queries and has soundness error  $\gamma$  against linear  $(\frac{k-3}{2})$ -non-signaling functions, then the resulting PCP verifier makes  $3 + 2q$  queries and has soundness error  $\max\{1 - \varepsilon, \gamma + 2^{O(k)}\varepsilon\}$  against arbitrary  $k$ -non-signaling functions.

However, our analysis of the ALMSS verifier (the nsLPCP that we use) will require locality  $k = \Omega(\log N)$ , which means that the additive term  $2^{O(k)}\varepsilon$  grows with  $N$ . This precludes achieving a constant soundness error with constant query complexity.

The foregoing motivates the problem of testing linearity of non-signaling functions *with low error*: how do we ensure that  $\hat{\mathcal{F}}$  is sufficiently close to a linear non-signaling function  $\mathcal{L}$ ? We stress that while in the classical case improving the “quality” of the self-correction has a straightforward solution (repeat the linearity test, and do self-correction), in the non-signaling case this problem is quite involved. Moreover, *we do not wish to modify in any way the classical compiler*, and thus relying on additional queries (even if only a constant number depending on  $q$  and  $\varepsilon$ ) is not an option.

We discuss our solution to this problem later on in Section 2.6, thereby providing the missing ingredient of our compiler from nsLPCP to nsPCP. In the meantime, in Sections 2.2 to 2.5, we discuss how we prove that the ALMSS verifier is secure against linear non-signaling functions.

## 2.2 The linear ALMSS verifier against linear non-signaling functions

Our goal is to establish that the linear PCP verifier of [1] (the “ALMSS verifier”) is sound against linear non-signaling functions, and thus prove that every language  $L \in \text{DSIZE}(S)$  has a constant-query nsLPCP verifier that is sound against linear  $O(\log S)$ -non-signaling functions. Note that we invoke the ALMSS verifier on *deterministic* (DSIZE) computations, rather than on *nondeterministic* (NSIZE) computations as in the classical case. We now recall the ALMSS verifier.

Let  $L \in \text{DSIZE}(S)$  be a language, and let  $\{C_n\}_{n \in \mathbb{N}}$  be a uniform boolean circuit family of size  $N := S(n)$  that decides  $L$  (for all  $x \in \{0, 1\}^n$ ,  $x \in L$  iff  $C_n(x) = 1$ ). Hereafter we omit the subscript in  $C_n$  as it is clear from context. Given an input  $x$ , one can express the condition “ $C(x) = 1$ ” as a system of simple equations over  $C$ ’s wires  $W$ ; the variables are  $\mathbf{w} = (w_1, \dots, w_N)$ , one per wire. We use the convention that the input wires are  $w_1, \dots, w_n$  and the output wire is  $w_N$ . To ensure input consistency we need that  $w_j = x_j$  for every  $j \in \{1, \dots, n\}$ ; to ensure correct gate computations we need that, for every  $j \in \{n+1, \dots, N\}$ ,  $w_j$  is the correct combination of the variables used to compute it (e.g., if  $w_j$  is the output of an AND gate with inputs  $w_{j_1}$  and  $w_{j_2}$  then the equation is  $w_j = w_{j_1} \cdot w_{j_2}$ ); to ensure that the output is 1 we need that  $w_N = 1$ . This can be summarized as a system of  $M := N + 1$  equations  $\{P_j(\mathbf{w}) = c_j\}_{j \in [M]}$ , where  $P_1, \dots, P_M$  are quadratic polynomials (each involving at most three variables in  $\mathbf{w}$ ) and  $c_1, \dots, c_M$  are boolean constants.

The ALMSS verifier is given below. We overload notation and use  $P_j$  to also denote the upper triangular matrix in  $\{0, 1\}^{N^2}$  such that  $P_j(\mathbf{w}) = \langle P_j, \mathbf{w} \otimes \mathbf{w} \rangle$ ; that is, if  $P_j(\mathbf{w}) = \sum_{i=1}^N a_i w_i + \sum_{1 \leq i < i' \leq N} a_{i,i'} w_i w_{i'}$ , then  $P_j$  has  $a_i$  in the diagonal entry  $(i, i)$  and  $a_{i,i'}$  in the entry  $(i, i')$ , for  $1 \leq i < i' \leq N$ . Also, for  $a \in \{0, 1\}^N$ ,  $D_a$  is the diagonal matrix in  $\{0, 1\}^{N^2}$  whose diagonal is  $a$ .

The ALMSS verifier, given input  $x \in \{0, 1\}^n$  and oracle access to a linear non-signaling function  $\mathcal{L}: \{0, 1\}^{N^2} \rightarrow \{0, 1\}$ , works as follows:

1. Use the circuit  $C$  and input  $x$  to construct the matrices  $P_1, \dots, P_M \in \{0, 1\}^{N^2}$  and constants  $c_1, \dots, c_M \in \{0, 1\}$ , which represent the computation of  $C$  on  $x$ .
2. Draw random  $s \in \{0, 1\}^M$ ,  $u, v \in \{0, 1\}^N$ , and query  $\mathcal{L}$  on the set  $\{\sum_{j=1}^M s_j P_j, D_u, D_v, u \otimes v\}$ .
3. Check that  $\mathcal{L}(\sum_{j=1}^M s_j P_j) = \sum_{j=1}^M s_j c_j$  and that  $\mathcal{L}(D_u)\mathcal{L}(D_v) = \mathcal{L}(u \otimes v)$ .

If  $C(x) = 1$ , the honest proof is the linear function  $\pi: \{0, 1\}^{N^2} \rightarrow \{0, 1\}$  where  $\pi(Z) := \langle \mathbf{w} \otimes \mathbf{w}, Z \rangle = \sum_{i,i' \in [N]} w_i w_{i'} \cdot Z_{i,i'}$  where  $w_i$  is now the value of the  $i$ -th wire in the computation of  $C$  on  $x$ .

The challenge is to prove that the ALMSS verifier is sound against *linear non-signaling functions*. Namely, we must show that if there is a linear non-signaling function  $\mathcal{L}$  that is accepted with good probability then  $x \in L$ , or equivalently that  $C(x) = 1$ . We discuss this in the next sub-sections.

### 2.3 A linear local assignment generator suffices

The first step in our soundness analysis shows that, to establish that  $C(x) = 1$ , it suffices to construct a *linear local assignment generator* with sufficiently small error.

A linear  $k$ -local assignment generator for  $(C, x)$  with error  $\varepsilon$  is a linear  $k$ -non-signaling function  $\mathcal{A}: \{0, 1\}^N \rightarrow \{0, 1\}$  that individually satisfies each of the  $M$  constraints with probability  $1 - \varepsilon$  (over the randomness of  $\mathcal{A}$ ). Namely,

- (a) for each  $i \in \{1, \dots, n\}$ ,  $\Pr[\mathcal{A}(e_i) = x_i] \geq 1 - \varepsilon$ ;
- (b) for each  $i \in \{n + 1, \dots, N\}$ , if  $w_i$  is the output of a unary gate  $g$  with input  $w_j$  then  $\Pr[\mathcal{A}(e_i) = g(\mathcal{A}(e_j))] \geq 1 - \varepsilon$ , else if  $w_i$  is the output of a binary gate  $g$  with inputs  $w_{j_1}, w_{j_2}$  then  $\Pr[\mathcal{A}(e_i) = g(\mathcal{A}(e_{j_1}), \mathcal{A}(e_{j_2}))] \geq 1 - \varepsilon$ ;
- (c)  $\Pr[\mathcal{A}(e_N) = 1] \geq 1 - \varepsilon$ .

(Here  $e_i$  is the  $i$ -th vector in the standard basis.)

► **Lemma 7 (informal).** *If there exists a  $k$ -local assignment generator for  $(C, x)$  with error  $\varepsilon$  for  $k = \Omega(\log N)$  and  $\varepsilon = O(\frac{1}{N \log N})$ , then  $C(x) = 1$ .*

We sketch the proof of this lemma. The transcript of the computation of  $C$  on  $x$  is the *unique* correct assignment to all the wires. We say that a wire  $w_i \in W$  of  $C$  is *correct* whenever  $\mathcal{A}(e_i)$  equals the value contained in this transcript; more generally, we say that a vector  $z \in \{0, 1\}^N$  is correct if  $\mathcal{A}(z)$  equals the value of  $z$  in the linear extension of the transcript. Below, we partition  $C$ 's wires  $W$  into layers  $W_1, \dots, W_H$  according to depth. (We assume layered circuits.)

As a warmup, suppose for now that  $k \geq N$ . The probability that all wires in  $W_1$  are correct is at least  $1 - |W_1|\varepsilon$ , and the probability that all the gates are correct is at least  $1 - \sum_{h=2}^H |W_h|\varepsilon$ . Therefore by union bound, the probability that all wires in the circuit are correct is at least  $1 - \sum_{h=1}^H |W_h|\varepsilon$ , because if all the input wires are correct and all the gates are computed correctly, then all the wires in the circuit are correct. In particular, we deduce that the output wire is correct with probability  $1 - \sum_{h=1}^H |W_h|\varepsilon = 1 - |W|\varepsilon = 1 - N\varepsilon$ . Since the output wire is 1 with probability  $1 - \varepsilon$ , and  $\varepsilon = O(\frac{1}{N})$ , we conclude that  $\Pr[C(x) = 1] > 0$ , and thus  $C(x) = 1$ .

The above argument requires that  $k \geq N$ , because we have to simultaneously “view” assignments to all wires in the circuit. While the argument can be easily modified so that we only require  $k$  to be at least twice the width of  $C$ , the latter may still be much larger than  $O(\log N)$ .

Using the linearity of  $\mathcal{A}$ , however, we can modify the argument to merely require  $k = \Omega(\log N)$ . For each layer  $h$ , we define an event  $E_h$  such that if  $E_h$  holds, then any wire in layer  $h$  is correct with high probability. In the warmup above  $E_h$  is the event “all wires in layer  $h - 1$  are correct”; in our proof  $E_h$  is the event “ $t$  random linear combinations of wires in layer  $h$  are correct”. Given a wire  $w_i$  in layer  $h$ , we can bound the event “ $\mathcal{A}(e_i)$  is incorrect and  $E_h$  holds” as follows. If  $\mathcal{A}(e_i)$  is incorrect, then all linear combinations of wires in layer  $h$  can be split into pairs  $z$  and  $z + e_i$ , and exactly one of  $\mathcal{A}(z)$  and  $\mathcal{A}(z + e_i)$  is incorrect. Hence, the probability that a random linear combination of wires in layer  $h$  is correct, given that  $\mathcal{A}(e_i)$  is incorrect, is at most  $1/2$ , and so  $\Pr[E_h \mid \mathcal{A}(e_i) \text{ is incorrect}] \leq 2^{-t}$ , since the  $t$  random linear combinations are independent. Using Bayes’s rule (and an additional assumption that  $\Pr[E_h] \geq 1/2$ ), we deduce that  $\Pr[\mathcal{A}(e_i) \text{ is incorrect} \mid E_h]$  is small. We then proceed inductively on the layers as before.

The argument above requires that  $\varepsilon = O(\frac{1}{N \log N})$ . One may wonder whether a similar result could be proved with, say,  $\varepsilon = O(1)$ . We additionally prove that our analysis is almost tight, in that an error of  $\varepsilon = O(\frac{\log N}{N})$  is necessary, *regardless* of how large the locality  $k$  is.

See the full version of this paper for details.

**Local assignment generators in prior works.** Local assignment generators appear in prior works on nsPCPs [17, 22], but our notion is qualitatively different, as we now explain.

Prior works consider local assignment generators for an *augmented* circuit  $C_{\text{aug}}$  rather than for  $C$  itself. (See Section 1.5 for a discussion of concurrent work that avoids augmented circuits.) Informally,  $C_{\text{aug}}$  not only contains  $C$  as a sub-circuit but also low-degree extensions of  $C$ 's layers as well as subcircuits computing all low-degree tests on these. The wires contained in these additional subcircuits are what enables defining an event  $E_h$  on which to condition for each layer.

The analogue of the augmented circuit  $C_{\text{aug}}$  in our setting, however, has *exponential* size, and thus *we cannot use it*. Namely, we would have to encode each layer of  $C$  via the Hadamard code (all linear combinations of wires in the layer) and then compute all possible linear tests on these.

Instead, our assumption that the local assignment generator is a *linear* non-signaling function implies that we *do not have to construct an augmented circuit*. Namely, the linear combinations that we use to define the event  $E_h$  are implicitly available due this linearity, and so there is no need to augment  $C$  (nor, in particular, to introduce any gates that evaluate linearity tests).

The assumption that the local assignment generator is linear is justified by the fact that a different part of our construction (the linearity test in our generic compiler) ensures the non-signaling function is (close to) linear. Overall, this separation not only avoids the aforementioned issues of using augmented circuits, but also simplifies the analysis of the local assignment generator.

## 2.4 Constructing the linear local assignment generator

Given a  $k$ -non-signaling function  $\mathcal{L}: \{0, 1\}^{N^2} \rightarrow \{0, 1\}$  that is accepted by the ALMSS verifier with probability at least  $1 - \varepsilon$ , we can obtain a linear  $k$ -local assignment generator  $\mathcal{A}: \{0, 1\}^N \rightarrow \{0, 1\}$  with error  $O(\varepsilon)$  by “restricting  $\mathcal{L}$  to its diagonal”. Namely, in order to query  $\mathcal{A}$  at  $v \in \{0, 1\}^N$ , we query  $\mathcal{L}$  at  $D_v \in \{0, 1\}^{N^2}$ , where  $D_v$  is the diagonal matrix that has  $v$  as its diagonal.

We show that, since  $\mathcal{L}$  is accepted with probability at least  $1 - \varepsilon$ ,  $\mathcal{L}$  must satisfy any *individual* constraint  $P_j(\mathbf{w}) = c_j$  with probability at least  $1 - O(\varepsilon)$ , and this directly implies that the linear local assignment generator  $\mathcal{A}$  has error  $O(\varepsilon)$ . (See the full version of this paper for details.)

The discussion so far already gives us a weak bound on the soundness error of the ALMSS verifier, namely  $1 - O(\frac{1}{N \log N})$ . Indeed, for  $k = O(\log N)$  and  $\varepsilon = O(\frac{1}{N \log N})$ , we can apply the lemma above (in Section 2.3) to conclude that  $C(x) = 1$ .

However, our goal is to show that the ALMSS verifier (as is) has *constant* soundness error, and doing so requires more technical work, which we discuss next.

► **Remark.** We stress that proving a soundness error of even  $1 - O(\frac{1}{N \log N})$  is a non-trivial statement. This is in contrast to the classical setting, where if an assignment satisfies an  $1 - \varepsilon$  fraction of the  $M = N + 1$  constraints for  $\varepsilon < 1/M$ , then, trivially, *all* constraints are satisfied.

## 2.5 The ALMSS verifier has constant soundness error

Our goal is to prove that the ALMSS verifier has constant soundness error. In a first step (Section 2.5.1), we use the soundness error proved above (Section 2.4) to show that the  $t$ -repeated ALMSS verifier has soundness error  $\gamma$  when  $t = \Omega(\log N + \log \frac{1}{\gamma})$ . In a second

step (Section 2.5.2), we prove that the basic ALMSS verifier (no repetitions) has constant soundness error. The second step is *generic* and of independent interest: we prove that if a  $t$ -repeated verifier has soundness error  $\exp(-t)$ , then the corresponding basic verifier has soundness error  $O(1)$ .

### 2.5.1 The $t$ -repeated ALMSS verifier has soundness error $\exp(-t)$

While in the classical setting reducing soundness error via simple repetition is straightforward ( $t$ -wise repetition reduces soundness error from  $\delta$  to  $\delta^t$ ), in the non-signaling setting simple repetition *does not work*.<sup>6</sup> Indeed, consider the non-signaling function (in fact, distribution) that, with probability  $1 - \varepsilon$ , answers the verifier's queries in an accepting way, and otherwise answers randomly. This non-signaling function is accepted by the  $t$ -repeated verifier with probability  $\approx 1 - \varepsilon$ , which is about the same as the probability that it is accepted by a single verifier.

However, this example provides intuition for how one circumvents this issue. Informally, we would like to extract the “ $1 - \varepsilon$  good part” that satisfies the verifier, and drop the “ $\varepsilon$  bad part”. We follow a technique used in [17] and, instead of arguing about the probability that  $\mathcal{L}$  passes the  $t$ -repeated verifier, we argue that the non-signaling function  $\mathcal{L}$  *conditioned on passing the  $t$ -repeated verifier* passes the basic verifier with high probability. Indeed, in the aforementioned example, conditioning on at least one test passing removes the “ $\varepsilon$  bad part” injected by the distribution, and intuitively *extracts* the part of  $\mathcal{L}$  that is passing the verifier. An interesting feature of our analysis of the verifier is that our conclusion is about the basic verifier, not the relaxed  $t$ -repeated verifier, which plays a major role in the analysis in [17].<sup>7</sup> This is a qualitative difference in our analysis arising from our use of property testing (not present in [17]), which also simplifies the analysis.

In more detail, let  $\mathcal{L}'$  denote the linear non-signaling function that equals  $\mathcal{L}$  when conditioned on passing the  $t$ -repeated verifier. Namely, if  $E$  is the (random) event that  $\mathcal{L}$  passes the  $t$ -repeated verifier, then for any  $S \subseteq \{0, 1\}^n$  (of some maximal size) and  $\vec{b} \in \{0, 1\}^S$ , we define

$$\Pr[\mathcal{L}'(S) = \vec{b}] := \Pr[\mathcal{L}(S) = \vec{b} \mid E] = \frac{\Pr[\mathcal{L}(S) = \vec{b} \wedge E]}{\Pr[E]}. \quad (1)$$

We then prove that  $\mathcal{L}'$  passes the basic verifier with probability at least  $1 - \frac{1/\Pr[E]}{\exp(t)}$ .

The proof uses a generic lemma stating that, if we run  $t + d$  independent tests, then the probability that at most  $r$  out of the first  $d$  tests pass and all of the last  $t$  tests pass is at most  $(\frac{d}{t+d})^{r+1}$ . A naive application of this lemma (with  $r = 0$  and  $d = 1$ ) shows that  $\mathcal{L}'$  passes the basic verifier with probability at least  $1 - \frac{1/\Pr[E]}{(t+1)}$ . This is not enough, because (using  $\Pr[E] \geq \gamma$ ) we would require  $t = \Omega(N \log N \cdot \frac{1}{\gamma})$  to prove soundness, which is again far too many repetitions.

However, we leverage the linearity of  $\mathcal{L}$  to deduce the stronger guarantee, as we now explain. We want to bound the probability that  $\mathcal{L}'$  does not pass the basic verifier, which means we need to bound the probability that  $\mathcal{L}$  fails exactly the first test of  $t + 1$  independent tests. We do this by arguing this individually for each of the two types of tests made by

<sup>6</sup> Even if simple repetition were to reduce soundness error from  $\delta$  to  $\delta^t$ , then to get  $\delta^t = \gamma$  when  $\delta = 1 - O(\frac{1}{N \log N})$  we would need to repeat  $t = \Omega(N \log N + \log \frac{1}{\gamma})$  times, which requires too large of a locality  $k$  for the analysis.

<sup>7</sup> The relaxed  $t$ -repeated verifier runs  $t$  tests and accepts if a large fraction of them pass.

the ALMSS verifier: the tensor test “ $\mathcal{L}(D_u)\mathcal{L}(D_v) = \mathcal{L}(u \otimes v)$ ” and the satisfiability test “ $\mathcal{L}(\sum_{j=1}^M s_j P_j) = \sum_{j=1}^M s_j c_j$ ”. We will explain our techniques in the case of the satisfiability test; the same techniques work for the tensor test, but the algebra is messier.

In the case of the satisfiability test, we split the “special” test (i.e., the first one) into  $d$  pairs of tests, such that each individual test is random, but each pair is correlated so that if both tests in some pair pass, then the original test passes. Specifically, we draw  $d$  random vectors  $s^{(1)}, \dots, s^{(d)} \in \{0, 1\}^M$ , and then we split the test “ $\mathcal{L}(\sum_{j=1}^M s_j P_j) = \sum_{j=1}^M s_j c_j$ ” into the  $d$  pairs of tests

$$\mathcal{L}\left(\sum_{j=1}^M (s_j + s_j^{(i)}) P_j\right) = \sum_{j=1}^M (s_j + s_j^{(i)}) c_j \quad \text{and} \quad \mathcal{L}\left(\sum_{j=1}^M s_j^{(i)} P_j\right) = \sum_{j=1}^M s_j^{(i)} c_j .$$

This allows us to apply the lemma with  $d = O(t)$ , and  $r = O(t)$ , which shows that  $\mathcal{L}'$  passes the basic verifier with probability at least  $1 - \frac{1/\Pr[E]}{\exp(t)}$ , an exponential decrease in  $t$ .

The above analysis shows soundness error of  $\gamma$  for the  $t$ -repeated verifier, for  $t = O(\log N + \log \frac{1}{\gamma})$ . Indeed, by the above argument, the conditioned function  $\mathcal{L}'$  passes the basic verifier with probability  $1 - \frac{1}{\gamma} \exp(-t) = 1 - O(\frac{1}{N \log N})$ , by choice of  $t$ . The analysis in the previous section (Section 2.4) then implies that  $C(x) = 1$ , proving soundness of the  $t$ -repeated verifier.

Setting  $\gamma = \exp(-t)$ , the discussion so far merely shows that the  $t$ -wise repetition of the ALMSS verifier, which makes  $4t$  queries, has soundness error  $\exp(-t)$  when  $t = \Omega(\log N)$ ; moreover, we get no conclusions for  $t = o(\log N)$ . But we still did not conclude anything about the soundness of a *single* invocation of the 4-query ALMSS verifier. We next discuss how to handle this case.

## 2.5.2 Back to the 4-query ALMSS verifier

We establish that the ALMSS verifier has constant soundness error by proving a generic lemma. The lemma states that, for *any* PCP verifier  $V$ , if the  $t$ -repeated verifier  $V^t$  has soundness error  $\exp(-t)$ , then  $V$  has soundness error  $O(1)$ . Since we have already argued that the  $t$ -repeated ALMSS verifier has soundness error  $\exp(-t)$  for  $t = \Omega(\log N)$ , we can conclude that the basic ALMSS verifier has soundness error  $O(1)$ , against  $O(\log N)$ -non-signaling linear functions.

In the classical case, the proof of this generic fact is trivial: a (classical) function passes a PCP verifier  $V$  with probability  $\delta$  if and only if it passes the  $t$ -repeated verifier  $V^t$  with probability  $\delta^t$ . However, in the non-signaling case, it is not clear what one can say because a non-signaling function can provide correlated answers across repetitions. Nevertheless, we are able to *lower bound* the probability that  $V^t$  accepts by a quantity that is almost  $\delta^t$  (which is, in particular, almost tight).

To our knowledge, we are the first to relate the soundness of  $V$  to the soundness of  $V^t$ . Generic statements in prior works (starting with [15]) have related the soundness of  $V^t$  to the soundness of the  $t$ -repeated relaxed verifier (which accepts if a vast majority of the  $t$  tests pass), but did not provide conclusions about the basic verifier  $V$ .

## 2.6 Testing linearity with low error

Below we discuss linearity testing *with low error* (Theorem 5) in more detail.

**Warmup: distributions.** We have discussed (in Section 2.1) how to test linearity with low error in the classical setting. In order to illustrate some of the difficulties that arise in the non-signaling setting, we first discuss a special case of it: testing linearity against a *distribution* over functions.

First, suppose that  $\mathcal{D}$  is a distribution over functions  $f: \{0,1\}^n \rightarrow \{0,1\}$  that passes the linearity test with probability  $1 - \varepsilon$ . The self-correction  $\hat{\mathcal{D}}$  that on input  $x \in \{0,1\}^n$  samples a random  $z \in \{0,1\}^n$  and outputs  $\hat{\mathcal{D}}(x) = \mathcal{D}(z+x) - \mathcal{D}(z)$  is  $2\varepsilon$ -close to a distribution over *linear* functions  $\mathcal{D}^*$ , namely, for every  $x \in \{0,1\}^n$  it holds that  $|\Pr[\hat{\mathcal{D}}(x) = 1] - \Pr[\mathcal{D}^*(x) = 1]| \leq 2\varepsilon$ . Indeed, consider the distribution  $\mathcal{D}^*$  that samples  $f \leftarrow \mathcal{D}$  and outputs any linear function  $f^*$  closest to  $f$ .<sup>8</sup> Then, for every function  $f$  and  $x \in \{0,1\}^n$ , the probability over a random  $z \in \{0,1\}^n$  that  $f^*(z) = f(z)$  and  $f^*(z+x) = f(z+x)$  is at least  $1 - 2\varepsilon_f$ , where  $\varepsilon_f := 1 - \Pr_{x,y}[f(x) + f(y) = f(x+y)]$ . Denoting by  $d_f$  denotes the probability that  $\mathcal{D}$  samples the function  $f$ , we conclude that  $|\Pr[\mathcal{D}^*(x) = 1] - \Pr[\hat{\mathcal{D}}(x) = 1]| \leq \sum_f 2\varepsilon_f \cdot d_f = 2\varepsilon$ .

Next, suppose that we seek a self-correction of  $\mathcal{D}$  that is  $\delta$ -close to a distribution over linear functions, for  $\delta \ll 2\varepsilon$ . One idea is to follow the same strategy as in the case of a single function: repeat the linearity test and then do self-correction. This idea, however, does not work now.

Consider the distribution  $\mathcal{D} = (1 - \varepsilon) \cdot \mathbf{0} + \varepsilon \cdot \mathbf{1}$ , i.e., the distribution that with probability  $1 - \varepsilon$  answers according to the all-zeros function (a linear function), and with probability  $\varepsilon$  according to the all-ones function (a function maximally far from linear functions). While  $\mathcal{D}$  passes the linearity test with probability  $1 - \varepsilon$ ,  $\mathcal{D}$  also passes the  $t$ -repeated linearity test with probability  $1 - \varepsilon$ . In other words, if  $\mathcal{D}$  passes the  $t$ -repeated linearity test with probability  $1 - \varepsilon$ , we can still only conclude that  $\hat{\mathcal{D}}$  is  $2\varepsilon$ -close to linear, independent of  $t$ .

While repeating the test does not increase the rejection probability, it can still be used to improve the quality of self-correction, by considering a *different* notion of self-correction that penalizes functions in the support of  $\mathcal{D}$  that are far from linear. Concretely, consider the distribution  $\mathcal{D}_t$  that equals  $\mathcal{D}$  when conditioned on the event that the  $t$ -repeated linearity test passes, and then define  $\hat{\mathcal{D}}_t$  to be the self-correction of  $\mathcal{D}_t$ . That is,  $\hat{\mathcal{D}}_t$  samples  $f$  from  $\mathcal{D}_t$  and answers any query  $x \in \{0,1\}^n$  by sampling  $z \in \{0,1\}^n$  and returning  $f(z+x) - f(z)$ . We claim that  $\hat{\mathcal{D}}_t$  is very close to linear.

Indeed, suppose that  $\mathcal{D}$  passes the  $t$ -repeated test with probability  $\gamma > 0$ , and let  $c > 1$  be a parameter. A function  $f$  sampled from  $\mathcal{D}_t$  is  $\frac{\ln c}{t}$ -close to linear with probability at least  $\frac{\gamma - 1/c}{\gamma} = 1 - \frac{1}{\gamma c}$ .<sup>9</sup> Setting  $c := t/\log t$ , the probability that  $\mathcal{D}_t$  outputs a function  $f$  that is  $\frac{\log t - \log \log t}{t}$ -far from linear is at most  $\frac{\log t}{\gamma t}$ . Therefore, by applying the argument from the beginning of this subsection, we conclude that  $\hat{\mathcal{D}}_t$  is  $O_\gamma(\frac{\log t}{t})$ -close to a distribution over linear functions.

We can further reduce the distance to be exponentially small in  $t$  by performing self-correction  $t$  times:  $\hat{\mathcal{D}}_t(x)$  now samples  $z_1, \dots, z_t \in \{0,1\}^n$ , and outputs the majority of  $\{\mathcal{D}(z_i + x) - \mathcal{D}(z_i)\}_{i \in [t]}$  conditioned on the event that the  $t$ -repeated linearity test passes. By setting  $c := 2^{t/10}$  in the discussion above, we conclude that if we sample  $f$  from  $\mathcal{D}_t$ , then  $f$  is 0.1-close to a linear function  $f^*$  with probability  $1 - \frac{1}{\gamma 2^{t/10}}$ . In particular, for every  $x \in \{0,1\}^n$  it holds that  $\Pr_{z_i}[f^*(z_i) = f(z_i) \wedge f^*(z_i + x) = f(z_i + x)] \geq 0.8$ , and so the probability that the majority value of  $\{\mathcal{D}(z_i + x) - \mathcal{D}(z_i)\}_{i \in [t]}$  is not equal to  $f^*(x)$  is  $2^{-O(t)}$ . In sum, the  $t$ -repeated self-correction conditioned on the event that the  $t$ -repeated linearity test passes yields us a distribution that is  $\frac{1}{\gamma} 2^{-O(t)}$ -close to linear.

<sup>8</sup> Recall that if  $f$  is 0.25-close to linear functions then  $f^*$  is unique. We do not rely on uniqueness.

<sup>9</sup> The  $t$ -repeated linearity test accepts a function  $f$  that is  $\frac{\ln c}{t}$ -far from linear with probability at most  $(1 - \frac{\ln c}{t})^t \leq \frac{1}{c}$ .

**The non-signaling case.** The case of non-signaling strategies is similar to the case of distributions in that the analysis of the self-correction involves conditioning over a certain event. Yet, the conclusions and steps of the proof are quite different. Informally, this is because non-signaling functions are quasi-distributions (probabilities can be negative), which prevents us from doing a straightforward analysis such as the one above. We now discuss how we address this.

Suppose that we have a  $k$ -non-signaling function  $\mathcal{F}: \{0, 1\}^n \rightarrow \{0, 1\}$  that passes the linearity test with probability  $1 - \varepsilon$ . The result of [9] proves that the self-correction  $\hat{\mathcal{F}}$  defined as  $\hat{\mathcal{F}}(x) := \mathcal{F}(z+x) - \mathcal{F}(z)$  (where  $z$  is chosen randomly from  $\{0, 1\}^n$ ) is  $2^{O(k)}\varepsilon$ -close to linear. This is too large in our setting as we have  $k = O(\log N)$ , and we would like the distance to be  $O(\varepsilon)$ . Instead, we prove a slightly different guarantee from [9]. Namely, we show that there is a linear non-signaling function  $\mathcal{L}$ , such that on every set  $S$ ,  $\hat{\mathcal{F}}$  is  $O(|S| \sqrt{\varepsilon})$ -close to  $\mathcal{L}$ . Unlike in the result of [9], our distance now decays with  $|S|$ , and is in particular independent of  $k$ . This is sufficient for our purposes, since we set  $|S| = 4$ , the number of queries made by the ALMSS verifier.

In our proof, we consider a *different* self-correction  $\bar{\mathcal{F}}_t$  that, unlike  $\hat{\mathcal{F}}$ , is *only used in the analysis* and is not used by the compiler. First, we show that  $\bar{\mathcal{F}}_t$  passes the linearity test with probability  $1 - \exp(-t)$ , and so the result of [9] implies that  $\bar{\mathcal{F}}_t$  is very close to a linear non-signaling function. Then, we relate  $\bar{\mathcal{F}}_t$  and  $\hat{\mathcal{F}}$  to show that  $\hat{\mathcal{F}}$  is  $O(\sqrt{\varepsilon})$ -close to a linear non-signaling function.

Informally, the self-correction  $\bar{\mathcal{F}}_t$  equals  $\mathcal{F}$  with the standard self-correction procedure repeated  $t$  times, conditioned on  $\mathcal{F}$  passing  $(1 - \sqrt{\varepsilon})t$  of  $t$  repetitions of the linearity test. In more detail, given a subset  $S \subseteq \{0, 1\}^n$ ,  $\bar{\mathcal{F}}_t(S)$  is the following distribution. For each  $x \in S$ , sample uniform and independent  $z_x^{(1)}, \dots, z_x^{(t)} \in \{0, 1\}^n$  conditioned on satisfying the same linear dependencies as in  $S$ ; for instance, if  $S = \{x, y, x+y\}$ , then  $z_x^{(i)} + z_y^{(i)} = z_{x+y}^{(i)}$  holds for all  $i$ . Then  $\bar{\mathcal{F}}_t$  assigns to each  $x \in S$  the value  $\text{MAJ}_{i \in [t]} \{\mathcal{F}(z_x^{(i)} + x) - \mathcal{F}(z_x^{(i)})\}$  *conditioned on the event* that  $\mathcal{F}$  passes at least  $(1 - \sqrt{\varepsilon})t$  of  $t$  repetitions of the basic linearity test. We note that if  $\mathcal{F}$  is linear, then  $\bar{\mathcal{F}}_t \equiv \hat{\mathcal{F}} \equiv \mathcal{F}$ .

The first part of the analysis uses a lemma that informally states that by conditioning on  $\mathcal{F}$  passing most of the  $t$ -repeated linearity tests, we force the conditioned  $\mathcal{F}$  to behave “close” to linear. Specifically, letting  $b_x^{(i)} = \mathcal{F}(z_i + x) - \mathcal{F}(z_i)$ , we get that with probability  $1 - \exp(-t)$  there is a bit  $b_x$  that equals  $b_x^{(i)}$  for at least  $\frac{3t}{4}$  of the  $i$ 's (so the majority is a vast majority), which implies that  $\bar{\mathcal{F}}_t(x) = b_x$ , and analogously for  $y$  and  $x+y$ . Then, via a similar argument, we show that with probability  $1 - \exp(-t)$  for at least  $\frac{3t}{4}$  of the  $i$ 's it holds that  $b_x^{(i)} + b_y^{(i)} = b_{x+y}^{(i)}$ . By union bound, these events hold simultaneously, and so we conclude that  $\bar{\mathcal{F}}_t$  satisfies  $\bar{\mathcal{F}}_t(x) + \bar{\mathcal{F}}_t(y) = \bar{\mathcal{F}}_t(x+y)$  with probability  $1 - \exp(-t)$ . We then invoke the result of [9] and conclude that  $\hat{\mathcal{F}}$  is very close to some linear non-signaling function  $\mathcal{L}$ .

In the second step, we relate  $\hat{\mathcal{F}}$  to  $\bar{\mathcal{F}}_t$  by claiming that if  $\Pr[\mathcal{F}(x) + \mathcal{F}(y) = \mathcal{F}(x+y)] \geq 1 - \varepsilon$ , then  $\hat{\mathcal{F}}$  and  $\bar{\mathcal{F}}_t$  are close in some precise sense. We first observe that if we run the  $t$ -repeated linearity test, i.e., choose  $x^{(1)}, y^{(1)}, \dots, x^{(t)}, y^{(t)}$  and check that  $\mathcal{F}(x^{(i)}) + \mathcal{F}(y^{(i)}) = \mathcal{F}(x^{(i)} + y^{(i)})$  for every  $i$ , then a simple Markov argument shows that with high probability, most of the linearity tests are satisfied. For instance, with probability  $1 - \sqrt{\varepsilon}$  at least  $(1 - \sqrt{\varepsilon})t$  of the  $i$ 's satisfy the linear constraint. This means that the event conditioned on in the definition of  $\bar{\mathcal{F}}_t$  is a large event. We also know from the first part of the analysis that, with high probability, the conditioning causes most of the evaluations of  $\mathcal{F}(z_x^{(i)} + x) - \mathcal{F}(z_x^{(i)})$  to output the same value. Intuitively, this implies that  $\hat{\mathcal{F}}$  is close to  $\bar{\mathcal{F}}_t$ , via the following reasoning. Since  $\bar{\mathcal{F}}_t$  conditions on a large event, it is close to the corresponding self-correction that does not condition at all. Since the majority taken over the evaluations of  $\mathcal{F}(z_x^{(i)} + x) - \mathcal{F}(z_x^{(i)})$

when computing  $\overline{\mathcal{F}}_t$  is a vast majority, with high probability  $\hat{\mathcal{F}}$  (which is a sample from one of the elements the majority is over) will agree with the vast majority. This allows us to conclude that for any set  $S$ ,  $\hat{\mathcal{F}}$  will be  $O(|S|\sqrt{\epsilon})$ -close to  $\overline{\mathcal{F}}_t$ .

See the full version of this paper for details.

## Abstract

*Spiking Neural Networks* (SNN) are mathematical models in neuroscience to describe the dynamics among a set of neurons that interact with each other by firing instantaneous signals, *a.k.a.*, *spikes*. Interestingly, a recent advance in neuroscience [Barrett-Denève-Machens, NIPS 2013] showed that the neurons' *firing rate*, i.e., the average number of spikes fired per unit of time, can be characterized by the optimal solution of a quadratic program defined by the parameters of the dynamics. This indicated that SNN potentially has the computational power to solve non-trivial quadratic programs. However, the results were justified empirically without rigorous analysis.

We put this into the context of *natural algorithms* and aim to investigate the algorithmic power of SNN. Especially, we emphasize on giving rigorous asymptotic analysis on the performance of SNN in solving optimization problems. To enforce a theoretical study, we first identify a simplified SNN model that is tractable for analysis. Next, we confirm the empirical observation in the work of Barrett et al. by giving an upper bound on the convergence rate of SNN in solving the quadratic program. Further, we observe that in the case where there are infinitely many optimal solutions, SNN tends to converge to the one with smaller  $\ell_1$  norm. We give an affirmative answer to our finding by showing that SNN can solve the  $\ell_1$  minimization problem under some regular conditions.

Our main technical insight is a *dual view* of the SNN dynamics, under which SNN can be viewed as a new natural primal-dual algorithm for the  $\ell_1$  minimization problem. We believe that the dual view is of independent interest and may potentially find interesting interpretation in neuroscience.

## 1 Introduction

The theory of *natural algorithms* is a framework that bridges the algorithmic thinking in computer science and the mathematical models in biology. Under this framework, biological systems are viewed as *algorithms* to *efficiently* solve specific *computational problems*. Seminal works such as bird flocking [16, 17], slime systems [51, 65, 10], and evolution [38, 37] successfully provide algorithmic explanations for different natural objects. These works give rigorous theoretical results to confirm empirical observations, shed new light on the biological systems through computational lens, and sometimes lead to new biologically inspired algorithms.

In this work, we investigate *Spiking Neural Networks (SNNs)* as natural algorithms for solving convex optimization problems. SNNs are mathematical models for biological neural networks where a network of neurons transmit information by *firing spikes* through their synaptic connections (i.e., edges between two neurons). Our starting point is a seminal work of Barrett, Denève, and Machens [4], where they showed that the *firing rate* (i.e., the average number of spikes fired by each neuron) of a certain class of *integrate-and-fire* SNNs can be characterized by the optimal solutions of a quadratic program defined by the parameters of SNN. Thus, the SNN can be viewed as a natural algorithm for the corresponding quadratic program. However, no rigorous analysis was given in their work.

We bridge the gap by showing that the firing rate converges to an optimal solution of the corresponding quadratic program with an explicit polynomial bound on the convergent rate. Thus, the SNN indeed gives an *efficient algorithm* for solving the quadratic program. To the best of our knowledge, this is the first result with an explicit bound on the convergent rate. Previous works [58, 59, 63] on related SNN models for optimization problems are either heuristic or only proving convergence results when the time goes to infinity (see Section 1.4 for full discussion on related works).

We take one step further to ask what other optimization problems can SNNs efficiently solve. As our main result, we show that when configured properly, SNNs can solve the  $\ell_1$  *minimization problem*<sup>2</sup> in polynomial time<sup>3</sup>. Our main technical insight is interpreting the dynamics of SNNs in a *dual space*. In this way, SNNs can be viewed as a new primal-dual algorithm for solving the  $\ell_1$  *minimization problem*.

In the rest of the introduction, we will first briefly introduce the background of spiking neural networks (SNNs) and formally define the mathematical model we are working on. Next, our results will be presented and compared with other related works. Finally, we wrap up this section with potential future research directions and perspectives.

### 1.1 Spiking Neural Networks

Spiking neural networks (SNNs) are mathematical models for describing the dynamics of biological neural networks. An SNN consists of neurons, and each of them is associated with an intrinsic electrical charge called *membrane potential*. When the potential of a neuron reaches a certain level, it will fire an instantaneous signal, i.e., *spike*, to other neurons and increase or decrease their potentials.

---

<sup>2</sup> The problem is defined as given  $A \in \mathbb{R}^{m \times n}$ ,  $\mathbf{b} \in \mathbb{R}^m$ , and guaranteed that there is a solution to  $A\mathbf{x} = \mathbf{b}$ . The goal is finding a solution  $\mathbf{x}$  with the smallest  $\ell_1$  norm. See Section 2 for formal definition.

<sup>3</sup> The running time is polynomial in a parameter depending on the inputs. In some cases, this parameter might cause the running to be quasi-polynomial or sub-exponential. See the full version of this paper on arXiv for more details.

Mathematically, the dynamic of neuron's membrane potential in an SNN is typically described by a *differential equation*, and there are many well-studied models such as the *integrate-and-fire model* [35], the *Hodgkin-Huxley model* [27], and their variants [21, 61, 49, 26, 23, 33, 14, 22, 29, 64]. In this work, we focus on the integrate-and-fire model defined as follows. Let  $n$  be the number of neurons and  $\mathbf{u}(t) \in \mathbb{R}^n$  be the vector of membrane potentials where  $\mathbf{u}_i(t)$  is the potential of neuron  $i$  at time  $t$  for any  $i \in [n]$  and  $t \geq 0$ . The dynamics of  $\mathbf{u}(t)$  can be described by the following differential equation: for each  $i \in [n]$  and  $t \geq 0$

$$\frac{d}{dt} \mathbf{u}_i(t) = \sum_{j \in [n]} -C_{ji}(t) \mathbf{s}_j(t) + \mathbf{I}_i(t) \quad (1)$$

where the initial value of the potentials are set to 0, i.e.,  $\mathbf{u}_i(0) = 0$  for each  $i \in [n]$ . There are two terms that determine the dynamics of membrane potentials as shown in (1). The simpler term is the input charging<sup>4</sup>  $\mathbf{I}(t) \in \mathbb{R}^n$ , which can be thought of as an external effect on each neuron. The other term models the instantaneous spike effect among neurons. Specifically, the  $-C_{ji}(t) \mathbf{s}_j(t)$  term models the effect on the potential of neuron  $i$  when neuron  $j$  fires a spike. Here  $C(t) \in \mathbb{R}^{n \times n}$  is the connectivity matrix that encodes the *synapses* between neurons, where  $C_{ji}(t)$  describes the connection strength from neuron  $j$  to neuron  $i$ .  $\mathbf{s}(t) \in \mathbb{R}^n$  is the *spike train* which records the spikes of each neuron, and  $\mathbf{s}_i(t)$  can be thought of as indicating whether neuron  $i$  fires a spike at time  $t$ . To sum up, the  $-C_{ji}(t) \mathbf{s}_j(t)$  term decreases<sup>5</sup> the potential of neuron  $i$  by  $C_{ji}(t^*)$  whenever neuron  $j$  fires a spike at time  $t^*$ .

The spike train  $\mathbf{s}(t)$  is determined by the spike events, which are in turn determined by the spiking rule. A typical spiking rule is the threshold rule. Specifically, let  $\eta > 0$  be the spiking threshold, the threshold rule simply says that neuron  $i$  fires a spike at time  $t$  if and only if  $\mathbf{u}_i(t) > \eta$ . Next, record the timings when neuron  $i$  fires a spike as  $0 \leq t_1^{(i)} < t_2^{(i)} < \dots$  and let  $k_i(t)$  be the number of spikes within time  $[0, t]$ . An important statistics of the dynamics is the *firing rate* defined as  $\mathbf{x}_i(t) := k_i(t)/t$  for neuron  $i \in [n]$  at time  $t$ , namely, the average number of spikes of neuron  $i$  up to time  $t$ . The last thing we need for specifying  $\mathbf{s}(t)$  is the *spike shape*, which can be modeled as a function  $\delta : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}$ . Intuitively, the spike shape describes the effect of a spike, and standard choices of  $\delta$  could be the Dirac delta function or a pulse function with an exponential tail. Now we can define  $\mathbf{s}_i(t) = \sum_{1 \leq s \leq k_i(t)} \delta(t - t_s^{(i)})$  to be the *spike train* of neuron  $i$  at time  $t$ .

We provide the following example to illustrate the SNN dynamics introduced above.

► **Example 1.** Let  $n = 2$ ,  $\eta = 1$ , and  $\delta$  be the Dirac delta function such that for any  $\epsilon > 0$ ,  $\int_0^\epsilon \delta(t) dt = 1$  and  $\delta(t) \geq 0$  for any  $t \geq 0$ . Let both external charging and connectivity matrix be static, i.e.,  $\mathbf{I}(t) = \mathbf{I}$  and  $C(t) = C$  for any  $t \geq 0$ , and consider

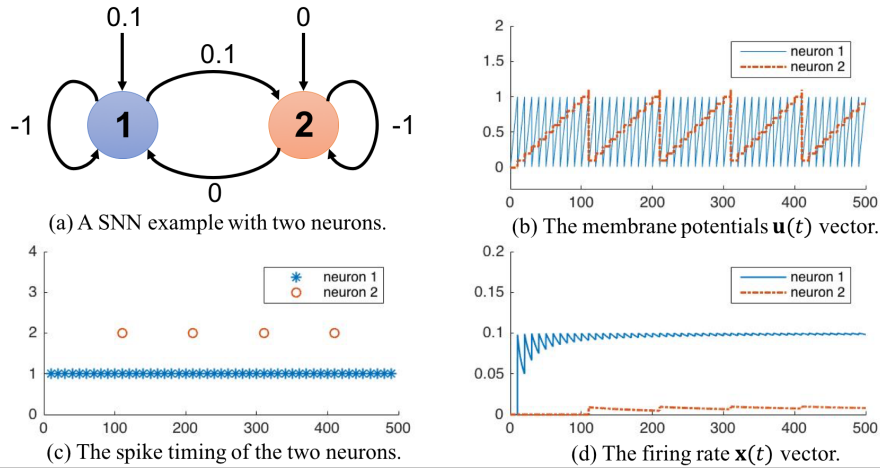

$$C = \begin{pmatrix} 1 & 0 \\ -0.1 & 1 \end{pmatrix}, \quad \mathbf{I} = \begin{pmatrix} 0.1 \\ 0 \end{pmatrix}, \quad \text{and } \mathbf{u}(0) = \begin{pmatrix} 0 \\ 0 \end{pmatrix}.$$

In Figure 1, we simulate this SNN for 500 seconds. We can see that neuron 1 fires a spike every ten seconds while neuron 2 fires a spike every one hundred seconds. As a result, the firing rate of neuron 1 will gradually converge to 0.1 and that of neuron 2 will go to 0.01.

In general, both the input charging vector  $\mathbf{I}(t)$  and the connectivity matrix  $C(t)$  can evolve over time, in which the change of  $\mathbf{I}(t)$  models the variation of the environment and the change of  $C_{ji}(t)$  captures the adaptive *learning* behavior of the neurons to the environmental change.

<sup>4</sup> Also known as *input signal* or *input current*.

<sup>5</sup> If  $C_{ji}(t^*) < 0$ , then the potential of neuron  $i$  actually *increases* by  $|C_{ji}(t^*)|$ .

■ **Figure 1** The example of SNN with two neurons. In (a), we describe the dynamic of this SNN. Note that the effect of spikes is the negation of the synapse encoded in the connectivity matrix  $C$ . In (b), we plot the membrane potential vectors  $\mathbf{u}(t)$ . In (c), we plot the timings when neurons fire a spike. One can see that neuron 1 fires a spike every ten seconds while neuron 2 fires a spike every one hundred seconds. In (d), we plot the firing rate vector  $\mathbf{x}(t)$ . One can see that the firing rate of neuron 1 will gradually converge to 0.1 and that of neuron 2 will go to 0.01.

Understanding how synapses evolve over time (i.e., synapse plasticity) is a very important subject in neuroscience. However, in this work, we follow the choice of Barrett et al. [4] and consider *static* SNN dynamics, where both the input charging  $\mathbf{I}(t)$  and the synapses  $C(t)$  are constants. Although this is a special case compared to the general model in (1), we justify the choice of static SNN by showing that SNN already exhibits non-trivial computational power even in this restricted model.

As in Barrett et al. [4], we focus on static SNN and view it as a natural algorithm for optimization problems. Specifically, given an instance to the optimization problem, the goal is to configure a static SNN (by setting its parameters) so that the firing rate converge to an optimal solution efficiently. In this sense, the result of Barrett et al. [4] can be interpreted as a natural algorithm for certain quadratic programs. In our eyes, the solution being encoded as the firing rate is an interesting and peculiar feature of the SNN dynamics. Also, the dynamics of a static SNN can be viewed as a simple distributed algorithm with a simple communication pattern. Specifically, once the dynamics is set up, each neuron only needs to keep track of its potential and communicate with each other through spikes.

## 1.2 Our Results

Barrett et al. [4] gave a clean characterization of the firing rates by the network connectivity and input signal. Concretely, they consider *static* SNN where both the connectivity matrix  $C \in \mathbb{R}^{n \times n}$  and the external charging  $\mathbf{I} \in \mathbb{R}^n$  do not change with time. They argued that the firing rate would converge to the solution of the following quadratic program.

$$\begin{aligned}
 & \underset{\mathbf{x} \in \mathbb{R}^n}{\text{minimize}} && \|C\mathbf{x} - \mathbf{I}\|_2^2 \\
 & \text{subject to} && \mathbf{x}_i \geq 0, \forall i \in [n].
 \end{aligned} \tag{2}$$

They supported this observation by giving simulations on the so called *tightly balanced networks* and yielded pretty accurate predictions in practice. Also, they heuristically explained the reason how they came up with the quadratic program. However, no rigorous theorem had been proved on the convergence of firing rate to the solution of this quadratic program.

To give a theoretical explanation for the discovery of [4], we start with a simpler SNN model to enable the analysis.

**The simple SNN model.** In the simple SNN model, we make two simplifications on the general model in (1).

First, we pick the shape of spike to be the Dirac delta function. That is, let  $\delta(t) = \mathbf{1}_{t=0}$  and thus  $\mathbf{s}_i(t) = \mathbf{1}_{\mathbf{u}_i(t) > \eta}$ . This simplification saves us from complicated calculation while the Dirac delta function still captures the instantaneous behavior of a spike.

Second, we consider the connectivity matrix  $C$  in the form  $C = \alpha \cdot A^\top A$  where  $\alpha > 0$  is the spiking strength and  $A \in \mathbb{R}^{m \times n}$  is the Cholesky decomposition of  $C$ . The reason for introducing  $\alpha$  is to model the height of the Dirac delta function. Mathematically, it is redundant to have both  $\alpha$  and  $C$  since the model remains the same when combining  $\alpha$  with  $C$ . However, as we will see in the next subsection, separating  $\alpha$  and  $C$  is meaningful as  $C$  corresponds to the *input* of the computational problem and  $\alpha$  is the parameter that one can choose to configure an SNN to solve the problem.

In this work, we focus on the algorithmic power of SNN in the following sense. Given a problem instance, one configures a SNN and sets the firing rate  $\mathbf{x}(t)$  to be the output at time  $t$ . We say this SNN solves the problem if  $\mathbf{x}(t)$  converges to the solution of the problem.

**Simple SNN solves the non-negative least squares.** As mentioned, Barrett et al. [4] identified a connection between the firing rate of SNN with integrate-and-fire neurons and a quadratic programming problem (2). They gave empirical evidence for the correctness of this connection, however, no theoretical guarantee had been provided. Our first result confirms their observation by giving the first theoretical analysis. Specifically, when  $C = A^\top A$  and  $\mathbf{I} = A^\top \mathbf{b}$ , the firing rate will converge to the solution of the following *non-negative least squares problem*.

$$\begin{aligned} & \underset{\mathbf{x} \in \mathbb{R}^n}{\text{minimize}} && \|\mathbf{A}\mathbf{x} - \mathbf{b}\|_2^2 \\ & \text{subject to} && \mathbf{x}_i \geq 0, \forall i \in [n]. \end{aligned} \tag{3}$$

► **Theorem 1 (informal).** *Given  $A \in \mathbb{R}^{m \times n}$ ,  $\mathbf{b} \in \mathbb{R}^m$ , and  $\epsilon > 0$ . Suppose  $A$  satisfies some regular conditions<sup>6</sup>. Let  $\mathbf{x}(t)$  be the firing rate of the simple SNN with  $0 < \alpha \leq \alpha(A)$  where  $\alpha(A)$  is a function depending on  $A$ . When  $t \geq \Omega(\frac{\sqrt{n}}{\epsilon \|\mathbf{b}\|_2})$ ,<sup>7</sup>  $\mathbf{x}(t)$  is an  $\epsilon$ -approximate solution<sup>8</sup> for the non-negative least squares problem of  $(A, \mathbf{b})$ .*

The formal statement and the proof for the theorem are provided in the Section 4 of the full version of this paper. To the best of our knowledge, this is the first<sup>9</sup> theoretical result on the analysis of SNN with an explicit bound on the convergence rate and shows that SNN can be implemented as an efficient algorithm for an optimization problem.

<sup>6</sup> More details about the regular conditions will be discussed in Section 3.3 of the full version.

<sup>7</sup> The  $\Omega(\cdot)$  and the  $O(\cdot)$  later both hide the dependency on some parameters of  $A$ . See Section 3.3 of the full version for more details.

<sup>8</sup> See Definition 3 for the formal definition of  $\epsilon$ -approximate solution.

<sup>9</sup> See Section 1.4 for comparisons with related works.

**Simple SNN solves the  $\ell_1$  minimization problem.** In addition to solving the non-negative least squares problem, as our main result, we also show that the simple SNN is able to solve the  $\ell_1$  *minimization problem*, which is defined as minimizing the  $\ell_1$  norm of the solutions of  $A\mathbf{x} = \mathbf{b}$ .  $\ell_1$  minimization problem is also known as the *basis pursuit* problem proposed by Chen et al. [18]. The problem is widely used for recovering sparse solution in compressed sensing, signal processing, face recognition etc.

Before the discussion on  $\ell_1$  minimization, let us start with a digression on the *two-sided* simple SNN for the convenience of future analysis.

$$\frac{d}{dt}\mathbf{u}(t) = -\alpha \cdot A^\top A\mathbf{s}(t) + A^\top \mathbf{b}$$

where  $\mathbf{s}_i(t) = \mathbf{1}_{\mathbf{u}_i(t) > \eta} - \mathbf{1}_{\mathbf{u}_i(t) < -\eta}$ . Note that the two-sided SNN is a special case of the one-sided SNN in the sense that one can use the one-sided SNN to simulate the two-sided SNN as follows. Given a two-sided SNN described above with connectivity matrix  $C = A^\top A$  and external charging  $\mathbf{I} = A^\top \mathbf{b}$ . Let  $C' = \begin{pmatrix} A^\top A & -A^\top A \\ -A^\top A & A^\top A \end{pmatrix}$  and  $\mathbf{I}' = \begin{pmatrix} A^\top \mathbf{b} \\ -A^\top \mathbf{b} \end{pmatrix}$ . Intuitively, this can be thought of as duplicating each neuron and flip its connectivities with other neurons.

To solve the  $\ell_1$  minimization problem, we simply configure a two-sided SNN as follows. Given an input  $(A, \mathbf{b})$ , let  $C = A^\top A$  and  $\mathbf{I} = A^\top \mathbf{b}$ . Now, we have the following theorem.

► **Theorem 2 (informal).** *Given  $A \in \mathbb{R}^{m \times n}$ ,  $\mathbf{b} \in \mathbb{R}^m$ , and  $\epsilon > 0$ . Suppose  $A$  satisfies some regular conditions. Let  $\mathbf{x}(t)$  be the firing rate of the two-sided simple SNN with  $0 < \alpha \leq \alpha(A)$  where  $\alpha(A)$  is a function depending on  $A$ . When  $t \geq \Omega(\frac{n^3}{\epsilon^2})$ ,  $\mathbf{x}(t)$  is an  $\epsilon$ -approximate solution<sup>10</sup> for the  $\ell_1$  minimization problem of  $(A, \mathbf{b})$ .*

See Theorem 7 for the formal statement of this theorem. As we will discuss in the next subsection, under the dual view of the SNN dynamics, the simple two sided SNN can be interpreted as a new natural primal-dual algorithm for the  $\ell_1$  minimization problem.

### 1.3 A Dual View of the SNN Dynamics

The main techniques in this work is the discovery of a *dual view* of SNN. Recall that the dynamic of a static SNN can be described by the following differential equation.

$$\frac{d}{dt}\mathbf{u}(t) = -\alpha \cdot C\mathbf{s}(t) + \mathbf{I}$$

where  $\mathbf{u}(0) = \mathbf{0}$  the parameters  $C$  and  $\mathbf{I}$  can be represented as  $C = A^\top A$  and  $\mathbf{I} = A^\top \mathbf{b}$  for some  $A \in \mathbb{R}^{m \times n}$  and  $\mathbf{b} \in \mathbb{R}^m$ . For simplicity, we pick the firing threshold  $\eta = 1$  here. Let us call the dynamics of  $\mathbf{u}(t)$  the *primal SNN*. Now, the *dual SNN*, can be defined as follows.

$$\frac{d}{dt}\mathbf{v}(t) = -\alpha \cdot A\mathbf{s}(t) + \mathbf{b}$$

where  $\mathbf{v}(0) = \mathbf{0}$  and  $\mathbf{s}(t)$  defined as the usual way. At first glance, this merely looks like a simple linear transformation, Nevertheless, the dual SNN provides a nice *geometric view* for the SNN dynamics as follows.

At each update in the dynamics, there are two terms affecting the dual SNN  $\mathbf{v}(t)$ : the external charging  $\mathbf{b} \cdot dt$  and the spiking effect  $-\alpha \cdot A\mathbf{s}(t)$ . First, the external charging  $\mathbf{b} \cdot dt$  can be thought of as a constant force that drags that dual SNN in the direction  $\mathbf{b}$ .

<sup>10</sup>See Definition 4 for the formal definition of  $\epsilon$ -approximate solution.

■ **Figure 2** These are examples of the geometric interpretation of the dual SNN. In (a), we have one neuron where  $A_1 = [\frac{1}{2} \ 1]^T$ . In this case, neuron  $i$  would not fire as long as the dual SNN  $\mathbf{v}(t)$  stays in the gray area. In (b), we consider a SNN with 3 neurons where  $A_1 = [1 \ 0]^T$ ,  $A_2 = [0 \ 1]^T$ , and  $A_3 = [\frac{2}{3} \ \frac{2}{3}]^T$ . One can see that the effect of spikes on dual SNN is a jump in the direction of the normal vector of the wall(s).

■ **Table 1** Comparison of the geometric view of primal and dual SNNs.

	Primal SNN $\mathbf{u}(t)$	Dual SNN $\mathbf{v}(t)$
Spiking rule	$\mathbf{u}_i(t) > 1$	$A_i^T \mathbf{v}(t) > 1$
Spiking effect	$-\alpha \cdot A^T A_i$	$-\alpha \cdot A_i$

To explain the effect of spikes in the dual view, let us start with an geometric view for the spiking rule. Recall that neuron  $i$  fires a spike at time  $t$  if and only if  $\mathbf{u}_i(t) > 1$ . In the language of dual SNN, this condition is equivalent to  $A_i^T \mathbf{v}(t) > 1$ . Let  $W_i = \{\mathbf{v} \in \mathbb{R}^m : A_i^T \mathbf{v} = 1\}$  be the *wall* of neuron  $i$ , the above observation is saying that neuron  $i$  will fire a spike once it penetrates the wall  $W_i$  from the half-space  $\{\mathbf{v} \in \mathbb{R}^m : A_i^T \mathbf{v} \leq 1\}$ . See Figure 2 for an example. After neuron  $i$  fires a spike, the spiking effect on the dual SNN  $\mathbf{v}(t)$  would be a  $-\alpha \cdot A_i$  term, which corresponds to a jump in the *normal direction* of  $W_i$ . See Figure 2 for an example.

The geometric interpretation described above is the main advantage of using dual SNN. Specifically, this gives us a clear picture of how spikes affect the SNN dynamics. Namely, neuron  $i$  fires a spike if and only if the dual SNN  $\mathbf{v}(t)$  penetrates the wall  $W_i$  and then  $\mathbf{v}(t)$  jumps back in the normal direction of  $W_i$ . Note that this connection would not hold in the primal SNN. In primal SNN  $\mathbf{u}(t)$ , neuron  $i$  fires a spike if and only if  $\mathbf{u}_i(t) > 1$  while the effect on  $\mathbf{u}(t)$  is moving in the direction  $-A^T A_i$ . See Table 1 for a comparison.

**Dual view of SNN as a primal-dual algorithm for  $\ell_1$  minimization problem.** First, let us write down the  $\ell_1$  minimization problem and its dual.

$$\begin{array}{ll}
 \underset{\mathbf{x} \in \mathbb{R}^n}{\text{minimize}} & \|\mathbf{x}\|_1 \\
 \text{subject to} & \mathbf{A}\mathbf{x} = \mathbf{b}.
 \end{array}
 \qquad
 \begin{array}{ll}
 \underset{\mathbf{v} \in \mathbb{R}^m}{\text{maximize}} & \mathbf{b}^T \mathbf{v} \\
 \text{subject to} & \|A^T \mathbf{v}\|_\infty \leq 1.
 \end{array}$$

Now we observe that the dual dynamics can be viewed as a variant of the projected gradient descent algorithm to solve the dual program. Before the explanation, recall that for the  $\ell_1$  minimization problem, we are considering the two-sided SNN for convenience. Indeed, without the spiking term,  $\mathbf{v}(t)$  simply moves towards the gradient direction  $\mathbf{b}$  of the dual objective function  $\mathbf{b}^\top \mathbf{v}$ . For the spike term  $-\alpha \cdot A\mathbf{s}(t)$ , note that  $\mathbf{s}_i(t) \neq 0$  (i.e., neuron  $i$  fires) if and only if  $|A_i^\top \mathbf{v}(t)| = |\mathbf{u}_i(t)| > 1$ , which means that  $\mathbf{v}(t)$  is outside the feasible polytope  $\{\mathbf{v} : \|A^\top \mathbf{v}\|_\infty \leq 1\}$  of the dual program. Therefore, one can view the role of the spike term as *projecting*  $\mathbf{v}(t)$  back to the feasible polytope. That is, when the dual SNN  $\mathbf{v}(t)$  becomes infeasible, it triggers some spikes, which maintains the dual feasibility and updates the primal solution (the firing rate). To sum up, we can interpret the simple SNN as performing a non-standard projected gradient descent algorithm for the dual program of  $\ell_1$  minimization in the dual view of SNN.

With this primal-dual view in mind, we analyze the SNN algorithm by combining tools from convex geometry and perturbation theory as well as several non-trivial structural lemmas on the geometry of the dual program of  $\ell_1$  minimization. One of the key ingredients here is identifying a *potential function* that (i) upper bounds the error of solving  $\ell_1$  minimization problem and (ii) monotonously converges to 0. More details will be provided in Section 3.

## 1.4 Related Work

We compare this research with other related works in the following four aspects.

**Computational power of SNN.** Recognized as the third generation of neural networks [45], the theoretical foundation for the computability of SNN had been built in the pioneering works of Maass et al. [43, 45, 46, 48] in which SNN was shown to be able to simulate standard computational models such as Turing machines, random access machines (RAM), and threshold circuits.

However, this line of works focused on the universality of the computational power and did not consider the efficiency of SNN in solving specific computational problems. In recent years, a line of exciting research have reported the efficiency of SNN in solving specific computational problems such as sparse coding [68, 62, 63], dictionary learning [36], pattern recognition [19, 32, 6], and quadratic programming [4]. These works indicated the advantage of SNN in handling *sparsity* as well as being *energy efficient* and inspired real-world applications [5]. However, to the best of our knowledge, no theoretical guarantee on the efficiency of SNN had been provided. For instance, Tang et al. [62, 63] only proved the *convergence in the limit* result for SNN solving sparse coding problem instead of giving an explicit convergence rate analysis. The main contribution in this work is giving a rigorous guarantee on the convergence rate of the computational power of SNN.

**The number of spikes versus the timing of spikes.** In this work, we mainly focus on the firing rate of SNN. That is, we only study the computational power with respect to the *number* of spikes. Another important property of SNN is the *timing* of spikes.

The power of the timing of spikes had been reported since the 90s from some experimental evidences indicating that neural systems might use the timing of spikes to encode information [1, 28, 54]. From then on, a bunch of works have been focused on the aspect of time as a basis of information coding both from theoretical [52, 45, 48, 66] and experimental [25, 7, 34] sides. It is generally believed that the timing of spikes is more powerful than the firing rate [67, 56, 53]. Other than the capacity of encoding information, the timing of spikes has also been studied in the context of computational power [67, 44, 45, 24] and learning [12, 3, 60]. See the survey by Paugam et al. [53] for a thorough discussion.

While the timing of spikes is conceived as an important source of the power of SNN, in this work we simply focus on the firing rate and already yield some non-trivial findings in terms of the computational power. We believe that our work is still in the very beginning stage of the study of the computational power of SNN. Investigating how does the timing of spikes play a role is an interesting and important future direction. Immediate open questions here would be how could the timing of spikes fit into our study? What's the dual view of the timing of spikes? Can the timing of spikes solve the optimization problems more efficiently? Can the timing of spikes solve more difficult problems?

**SNN with randomness.** While most of the literature focused on deterministic SNN, there is also an active line of works studying the SNN model with randomness<sup>11</sup> [2, 57, 20, 15, 30, 47, 31, 40, 41, 42, 39].

Buesing et al. [15] used *noisy SNN* to implement MCMC sampling and Jonke et al. [30, 47, 31] further instantiated the idea to attack **NP**-hard problems such as *traveling salesman problem (TSP)* and *constraint satisfaction problem (CSP)*. Concretely, their noisy SNN has a randomized spiking rule and the firing pattern would form a distribution over the solution space whereas the closer a solution is to the optimal solution, the higher the probability it is sampled. They got nice experimental performance in terms of solving empirical instance approximately. They also pointed out that their noisy SNN has the potential to be implemented energy-efficiently in practice.

Lynch, Musco, and Parter [41] studied the *stochastic SNNs* with a focus on the Winner-Take-All (WTA) problem. Their sequence of works [40, 41, 42, 39] gave the first asymptotic analysis for stochastic SNN in solving WTA, similarity testing, and neural coding. They view SNNs as distributed algorithms and derived computational tradeoff in running time and network size.

In this work, we consider the SNN model without randomness and thus is incomparable with the above SNN models with randomness. It is an interesting direction to apply the dual view of deterministic SNN to SNN with randomness.

**Locally competitive algorithms.** Inspired by the dynamics of biological neural networks, Ruzell et al. designed the *locally competitive algorithms (LCA)* [55] for solving the Lasso (least absolute shrinkage and selection operator) optimization problem<sup>12</sup>, which is widely used in statistical modeling. Roughly speaking, LCA is also a dynamics among a set of *artificial neurons* which continuously signal their potential values (or a function of the values) to their neighboring neurons. There are two main differences between SNN and LCA. First, the neuron in SNN fires discrete spikes while the artificial neuron in LCA produces continuous signal. Next, the neurons' potentials in LCA will converge to a fixed value, which is the output of the algorithm. In contrast, in SNN, only the neurons' firing rates may converge instead of their potentials.

Nevertheless, there is a *spikified* version of LCA introduced by Shapero et al. [58, 59] called *spike LCA (S-LCA)* in which the continuous signals are replaced with discrete spikes. S-LCA is almost the same as the SNN we are considering except a shrinkage term<sup>13</sup>. Recently, Tang et al. [63] showed that the firing rate of S-LCA indeed converges to a variant of

<sup>11</sup> SNN model with noise is also known as stochastic SNN or noisy SNN depending on how the randomness involves in the model.

<sup>12</sup> Note that Lasso is equivalent to the Basis Pursuit De-Noising (BPDN) program under certain parameters transformation.

<sup>13</sup> That is, the potential of each neuron will drop with rate proportional to the current potential value.

Lasso problem<sup>14</sup> in the limit. These works also experimentally demonstrated the efficient convergence of S-LCA and its advantage of fast identifying sparse solutions with potentially competitive practical performance to other Lasso algorithms (e.g., FISTA [5]). However, there is no proof of convergence rate, and thus no explicit complexity bound of S-LCA.

## 1.5 Future Works and Perspectives

In this work, we give a theoretical study on the algorithmic power of SNN. Specifically, we focus on the firing rate of SNN and confirm an empirical analysis by Barrett et al. [4] with a convergence theorem (i.e., Theorem 1). Furthermore, we discover a dual view of SNN and show that SNN is able to solve the  $\ell_1$  minimization problem (i.e., Theorem 2). In the following, we give interpretations to our results and point out future research directions.

First, how to interpret the dual dynamics of SNN? In this work, we discover the dual SNN based on mathematical convenience. Is there any biological interpretation?

Second, push further the analysis of simple SNN. We believe the parameters we get in the main theorems are not optimal. Is it possible to further sharpen the upper bound? We think this is both theoretically and practically interesting because both non-negative least squares and  $\ell_1$  minimization are important problems that have been well-studied in the literature. Comparing the running time complexity or parallel time complexity of SNN algorithm with other algorithms could also be of theoretical interest and might inspire new algorithm with better complexity. Also, for practical purpose, having better parameters would give more confidence in implementing SNN as a natural algorithm.

Third, further investigate the potential of SNN dynamics as natural algorithms. The question is two-folded: (i) What algorithms can SNN implement? (ii) What computational problems can SNN solve? It seems that SNN is good at dealing with sparsity. Could it be helpful in related computational tasks such as fast Fourier transform (FFT) or sparse matrix-vector multiplication? It is interesting to identify optimization problems and class of instances where SNN algorithm can outperform other algorithms.

Finally, explore the practical advantage of SNN dynamics as natural algorithms. The potential practical time efficiency, energy efficiency, and simplicity for hardware implementation have been suggested in several works [50, 8, 9]. It would be exciting to see whether SNN has nice performance on practical applications such as compressed sensing, Lasso, and etc.

**Organization.** The rest of the paper is organized as follows. Preliminaries are provided in Section 2. In Section 3, we formally present the dual view of SNN and give a proof sketch for the convergence theorem for  $\ell_1$  minimization problem. The full proofs for Theorem 1 and Theorem 2 are provided in the full version of this paper available on arXiv.

## 2 Preliminaries

In Section 2.1, we build up some notations for the rest of the paper. In Section 2.2, we define two optimization problems and the corresponding convergence guarantees.

### 2.1 Notations

For any  $n \in \mathbb{N}$ , denote  $[n] = \{1, 2, \dots, n\}$  and  $[\pm n] = \{\pm 1, \pm 2, \dots, \pm n\}$ . Let  $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$  be two vectors.  $|\mathbf{x}| \in \mathbb{R}^n$  denotes the entry-wise absolute value of  $\mathbf{x}$ , i.e.,  $|\mathbf{x}|_i = |\mathbf{x}_i|$  for any  $i \in [n]$ .  $\mathbf{x} \preceq \mathbf{y}$  refers to entry-wise comparison, i.e.,  $\mathbf{x}_i \leq \mathbf{y}_i \forall i \in [n]$ .

<sup>14</sup>In this variant, all the entries in matrix  $A$  is non-negative.

Let  $A$  be an  $m \times n$  real matrix. For any  $i \in [n]$ , denote the  $i$ th column of  $A$  as  $A_i$  and its negation to be  $A_{-i}$ , i.e.,  $A_{-i} = -A_i$ . When  $A$  is positive semidefinite, we define the  $A$ -norm of a vector  $\mathbf{x} \in \mathbb{R}^n$  to be  $\|\mathbf{x}\|_A := \sqrt{\mathbf{x}^\top A \mathbf{x}}$ . Let  $A^\dagger$  to be the pseudo-inverse of  $A$ . Define the maximum eigenvalue of  $A$  as  $\lambda_{\max}(A) := \max_{\mathbf{x} \in \mathbb{R}^n: \|\mathbf{x}\|_2=1} \|\mathbf{x}\|_A$ , the minimum non-zero eigenvalue of  $A$  to be  $\lambda_{\min}(A) := 1/(\max_{\mathbf{x} \in \mathbb{R}^n: \|\mathbf{x}\|_2=1} \|\mathbf{x}\|_{A^\dagger})$ , and the condition number of  $A$  to be  $\kappa(A) := \lambda_{\max}(A)/\lambda_{\min}(A)$ . If we do not specify, the following  $\lambda_{\max}$ ,  $\lambda_{\min}$ , and  $\kappa$  are the eigenvalues and condition number of the connectivity matrix  $C = A^\top A$ . For any  $\mathbf{b} \in \mathbb{R}^m$ , we denote  $\mathbf{b}_A$  to be the projection of  $\mathbf{b}$  on the range space of  $A$ .

## 2.2 Optimization problems

In this subsection, we are going to introduce two optimization problems: *non-negative least squares* and  $\ell_1$  *minimization*.

### 2.2.1 Non-negative least squares

► **Problem 1** (non-negative least squares). Let  $m, n \in \mathbb{N}$ . Given  $A \in \mathbb{R}^{m \times n}$  and vector  $\mathbf{b} \in \mathbb{R}^m$ , find  $\mathbf{x} \in \mathbb{R}^n$  that minimizes  $\|\mathbf{b} - A\mathbf{x}\|_2^2/2$  subject to  $\mathbf{x}_i \geq 0$  for all  $i \in [n]$ .

► **Remark.** Recall that the least squares problem is defined as finding  $\mathbf{x}$  that minimize  $\|\mathbf{b} - A\mathbf{x}\|_2$ . That is, the non-negative least squares is a restricted version of the least squares problem. Nevertheless, one can use a non-negative least squares solver to solve the least squares problem by setting  $A' = \begin{pmatrix} A^\top A & -A^\top A \\ -A^\top A & A^\top A \end{pmatrix}$  and  $\mathbf{b}' = \begin{pmatrix} \mathbf{b} \\ -\mathbf{b} \end{pmatrix}$  where  $(A, \mathbf{b})$  is the instance of least squares and  $(A', \mathbf{b}')$  is the instance of non-negative least squares.

The SNN algorithm might not solve the non-negative least squares problem exactly and thus we define the following notion of solving the non-negative least squares problem *approximately*.

► **Definition 3** ( $\epsilon$ -approximate solution to non-negative least squares). Let  $m, n \in \mathbb{N}$  and  $\epsilon > 0$ . Given  $A \in \mathbb{R}^{m \times n}$  and  $\mathbf{b} \in \mathbb{R}^m$ . We say  $\mathbf{x}$  is an  $\epsilon$ -approximate solution to the non-negative least squares problem of  $(A, \mathbf{b})$  if  $\|A\mathbf{x} - A\mathbf{x}^*\|_2 \leq \epsilon \|\mathbf{b}\|_2$  where  $\mathbf{x}^*$  is an optimal solution.

### 2.2.2 $\ell_1$ minimization

► **Problem 2** ( $\ell_1$  minimization). Let  $m, n \in \mathbb{N}$ . Given  $A \in \mathbb{R}^{m \times n}$  and  $\mathbf{b} \in \mathbb{R}^m$  such that there exists a solution to  $A\mathbf{x} = \mathbf{b}$ . The goal of  $\ell_1$  minimization is to solve the following optimization problem.

$$\begin{aligned} & \underset{\mathbf{x} \in \mathbb{R}^n}{\text{minimize}} && \|\mathbf{x}\|_1 \\ & \text{subject to} && A\mathbf{x} = \mathbf{b}. \end{aligned}$$

Similarly, we do not expect SNN algorithm to solve the  $\ell_1$  minimization exactly. Thus, we define the notion of solving the  $\ell_1$  minimization problem *approximately* as follows.

► **Definition 4** ( $\epsilon$ -approximate solution to  $\ell_1$  minimization). Let  $m, n \in \mathbb{N}$  and  $\epsilon > 0$ . Given  $A \in \mathbb{R}^{m \times n}$  and  $\mathbf{b} \in \mathbb{R}^m$ . Let  $\mathbf{OPT}^{\ell_1}$  denote the optimal value of the  $\ell_1$  minimization problem of  $(A, \mathbf{b})$ . We say  $\mathbf{x} \in \mathbb{R}^n$  is an  $\epsilon$ -approximate solution of the  $\ell_1$  minimization problem of  $(A, \mathbf{b})$  if  $\|\mathbf{b} - A\mathbf{x}\|_2 \leq \epsilon \cdot \|\mathbf{b}\|_2$  and  $\|\mathbf{x}\|_1 - \mathbf{OPT}^{\ell_1} \leq \epsilon \cdot \mathbf{OPT}^{\ell_1}$ .

### 2.3 Karush-Kuhn-Tucker conditions

Karush-Kuhn-Tucker (KKT) conditions are necessary and sufficient conditions for the optimality of optimization problems under some regular assumptions. Consider the following optimization program.

$$\begin{aligned} & \underset{\mathbf{x} \in \mathbb{R}^n}{\text{minimize}} && f(\mathbf{x}) \\ & \text{subject to} && g_i(\mathbf{x}) \leq 0, \quad \forall i = 1, 2, \dots, m, \\ & && h_j(\mathbf{x}) = 0, \quad \forall j = 1, 2, \dots, k, \end{aligned} \tag{4}$$

where  $f, g_1, \dots, g_m, h_1, \dots, h_k$  are convex and differentiable. Let  $\mathbf{v} \in \mathbb{R}^m$  and  $\boldsymbol{\mu} \in \mathbb{R}^k$  be the dual variables. KKT conditions give necessary and sufficient conditions for  $(\mathbf{x}, \mathbf{v}, \boldsymbol{\mu})$  be a pair of primal and dual optimal solutions.

► **Theorem 5** (KKT conditions, Chapter 5.5.3 in [13]).  *$(\mathbf{x}, \mathbf{v}, \boldsymbol{\mu})$  are a pair of primal and dual optimal solutions for (4) if and only if the following conditions hold.*

- $\mathbf{x}$  is primal feasible, i.e.,  $g_i(\mathbf{x}) \leq 0$  and  $h_j(\mathbf{x}) = 0$  for all  $i \in [m]$  and  $j \in [k]$ .
- $(\mathbf{v}, \boldsymbol{\mu})$  is dual feasible, i.e.,  $\mathbf{v}_i \geq 0$  for all  $i \in [m]$ .
- The Lagrange multiplier vanishes, i.e.,  $\nabla f(\mathbf{x}) + \sum_{i \in [m]} \mathbf{v}_i \nabla g_i(\mathbf{x}) + \sum_{j \in [k]} \boldsymbol{\mu}_j \nabla h_j(\mathbf{x}) = 0$ .
- $(\mathbf{x}, \mathbf{v}, \boldsymbol{\mu})$  satisfy complementary slackness, i.e.,  $\mathbf{v}_i f_i(\mathbf{x}) \geq 0$  for all  $i \in [m]$ .

### 2.4 Perturbation theory

Perturbation theory, sometimes known as sensitivity analysis, for optimization problems concerns the situation where the optimization program is perturbed and the goal is to give a good estimation for the optimal solution. See a nice survey by Bonnans and Shapiro [11]. In the following we state a special case for convex optimization program with strong duality.

► **Theorem 6** (perturbation, Chapter 5.6 in [13]<sup>15</sup>). *Given the following two optimization programs where the strong duality holds and there exists feasible dual solution.*

$$\begin{aligned} & \underset{\mathbf{x}}{\text{minimize}} && f(\mathbf{x}) & & \underset{\mathbf{x}}{\text{minimize}} && f(\mathbf{x}) \\ & \text{subject to} && g_i(\mathbf{x}) \leq 0, \quad \forall i = 1, 2, \dots, m, & & \text{subject to} && g_i(\mathbf{x}) \leq \mathbf{a}_i, \quad \forall i = 1, 2, \dots, m, \\ & && h_j(\mathbf{x}) = 0, \quad \forall j = 1, 2, \dots, k. & & && h_j(\mathbf{x}) = \mathbf{b}_j, \quad \forall j = 1, 2, \dots, k. \end{aligned} \tag{5} \tag{6}$$

Let  $\text{OPT}^{\text{original}}$  be the optimal value of the original program (5) and  $\text{OPT}^{\text{perturbed}}$  be the optimal value of the perturbed program (6). Let  $(\mathbf{v}^*, \boldsymbol{\mu}^*) \in \mathbb{R}^m \times \mathbb{R}^k$  be the optimal dual solution of the perturbed program (6). We have

$$\text{OPT}^{\text{original}} \geq \text{OPT}^{\text{perturbed}} + \mathbf{a}^\top \mathbf{v}^* + \mathbf{b}^\top \boldsymbol{\mu}^*.$$

<sup>15</sup>Note that we switch the original and perturbed programs in the statement in [13].

### 3 A simple SNN algorithm for $\ell_1$ minimization

In this section, we focus on the discovery of the dual view of simple SNN and how it can be viewed as a *primal-dual algorithm* for solving the  $\ell_1$  minimization problem.

Recall that for the  $\ell_1$  minimization problem, we are working on the *two-sided* simple SNN for the convenience of future analysis. That is,

$$\frac{d}{dt} \mathbf{u}(t) = -\alpha \cdot A^\top A \mathbf{s}(t) + A^\top \mathbf{b},$$

where  $\mathbf{s}_i(t) = \mathbf{1}_{\mathbf{u}_i(t) > \eta} - \mathbf{1}_{\mathbf{u}_i(t) < -\eta}$ . To solve the  $\ell_1$  minimization problem, we configure a two-sided simple SNN as follows. Given an input  $(A, \mathbf{b})$ , let  $C = A^\top A$  and  $\mathbf{I} = A^\top \mathbf{b}$ . However, currently it is unclear how does the above simple SNN dynamics relate to the  $\ell_1$  minimization problem.

$$\begin{aligned} & \underset{\mathbf{x} \in \mathbb{R}^n}{\text{minimize}} && \|\mathbf{x}\|_1 \\ & \text{subject to} && A\mathbf{x} = \mathbf{b}. \end{aligned} \tag{7}$$

Interesting, the connection between simple SNN and the  $\ell_1$  minimization problem happens in the *dual program* of the  $\ell_1$  minimization problem. Before we formally explain this connection, let us write down the dual program of (7).

$$\begin{aligned} & \underset{\mathbf{v} \in \mathbb{R}^m}{\text{maximize}} && \mathbf{b}^\top \mathbf{v} \\ & \text{subject to} && \|A^\top \mathbf{v}\|_\infty \leq 1. \end{aligned} \tag{8}$$

Let us try to make some geometric observations on (8). First, the objective of the dual program is to maximize the inner product with  $\mathbf{b}$ , which is quite related to the external charging of SNN since we take  $\mathbf{I} = A^\top \mathbf{b}$ . Next, the feasible region of the dual program is a polytope (or a polyhedron) defined by the intersection of half-spaces  $\{\mathbf{v} \in \mathbb{R}^m : A_i^\top \mathbf{v} \leq 1\}$  and  $\{\mathbf{v} \in \mathbb{R}^m : -A_i^\top \mathbf{v} \leq 1\}$  for each  $i \in [n]$  where  $A_i$  denotes the  $i^{\text{th}}$  column of  $A$ .

It will be convenient to introduce the following notation before we move on. For  $i \in [n]$ , let  $A_{-i} = -A_i$ . Let  $[\pm n] = \{\pm 1, \pm 2, \dots, \pm n\}$ . Thus, the feasible polytope of the dual program is defined by the intersection of half-spaces defined by  $A_j^\top \mathbf{v} \leq 1$  for all  $j \in [\pm n]$ . We call this polytope the *dual polytope*<sup>16</sup>. Moreover, for each  $j \in [\pm n]$ , we call the hyperplane  $\{\mathbf{v} : A_j^\top \mathbf{v} = 1\}$  the *wall*  $W_j$  of the dual polytope. See Figure 3 for examples.

Now, the key observation is that by a linear transformation, the dynamics of simple SNN has a natural interpretation in the dual space. We call it the *dual SNN* defined as follows.

#### 3.1 Dual SNN

We first recall the simple SNN dynamics which we call the *primal SNN* from now on. For convenience, we set the threshold parameter  $\eta = 1$ . For any  $t \geq 0$ ,

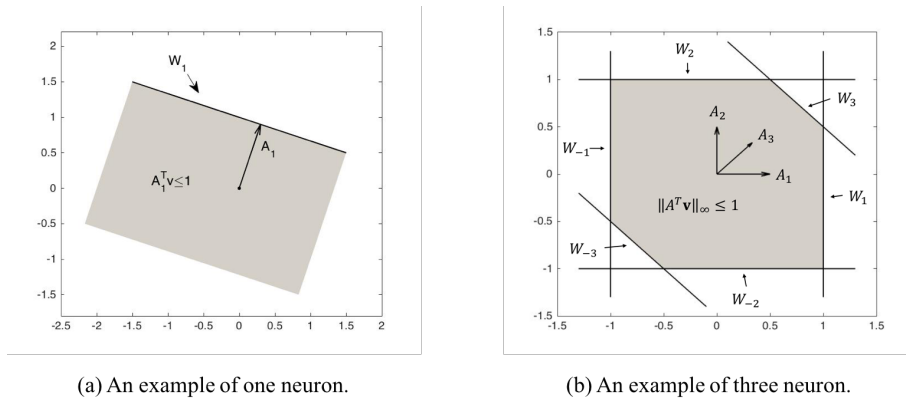

$$\mathbf{u}(t + dt) = \mathbf{u}(t) - \alpha \cdot A^\top A \cdot \mathbf{s}(t) + A^\top \mathbf{b} \cdot dt. \tag{9}$$

Now, we define the dual SNN  $\mathbf{v}(t) \in \mathbb{R}^m$  as follows. Let  $\mathbf{v}(0) = \mathbf{0}$  and for each  $t \geq 0$ , define

$$\mathbf{v}(t + dt) = \mathbf{v}(t) - \alpha \cdot A \mathbf{s}(t) + \mathbf{b} \cdot dt. \tag{10}$$

<sup>16</sup>In the case where the feasible region of the dual program is not bounded, it is a dual *polyhedron*. For the convenience of the presentation, we usually assume the feasible region is bounded.

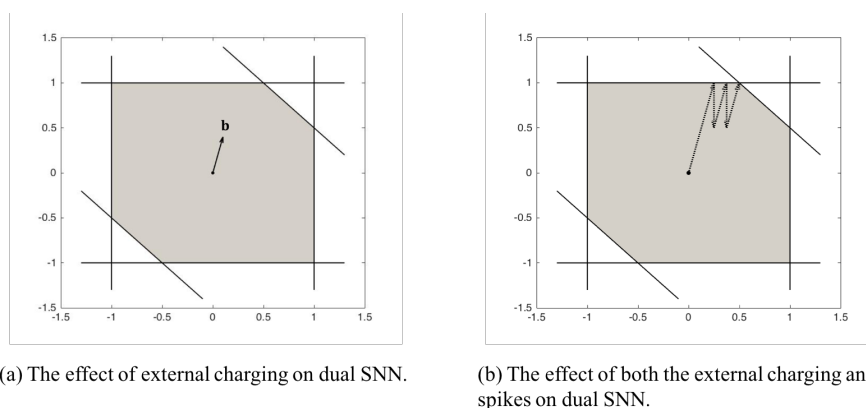

■ **Figure 3** This is examples of the geometric interpretation of the dual program of  $\ell_1$  minimization problem. In (a), we have  $n = 1$  where  $A_1 = [\frac{1}{3} \ 1]^T$ . In this case, the gray area, i.e., the feasible region of the dual program, is unbounded. In (b), we have  $n = 3$  where  $A_1 = [1 \ 0]^T$ ,  $A_2 = [0 \ 1]^T$ , and  $A_3 = [\frac{2}{3} \ \frac{2}{3}]^T$ . In this case, the gray area is bounded and thus called dual polytope.

Let us make some remarks about the connection between the primal and dual SNNs. First, it can be immediately seen that  $\mathbf{u}(t) = A^T \mathbf{v}(t)$  for each  $t \in \mathbb{N}$  from (9) and (10). That is, given  $\mathbf{v}(t)$ , it is easy to get  $\mathbf{u}(t)$  by multiplying  $\mathbf{u}(t)$  with  $A^T$  on the left. It turns out that the other direction also holds. For each  $t \in \mathbb{N}$ , we have  $\mathbf{v}(t) = (A^T)^\dagger \mathbf{u}(t)$ , where  $(A^T)^\dagger$  is the pseudo-inverse of  $A^T$ . The reason is because the primal SNN  $\mathbf{u}(t)$  lies in the column space of  $A$ . Thus, the two dynamics are in fact *isomorphic* to each other.

Now let us understand the dynamics of dual SNN in the dual space  $\mathbb{R}^m$ . At each timestep, there are two terms, i.e., the external charging  $\mathbf{b} \cdot dt$  and the spiking effect  $-\alpha \mathbf{A} \mathbf{s}(t)$ , that affect the dual SNN  $\mathbf{v}(t)$ . The external charging can be thought of as a constant force that drags that dual SNN in the direction  $\mathbf{b}$ . See Figure 4. This coincides with the objective function of the dual program (8) and thus the external charging can then be viewed as taking a *gradient* step towards solving (8).

Nevertheless, to solve (8), one need to make sure the solution  $\mathbf{v}$  is feasible, i.e.,  $\mathbf{v}$  should lie in the dual polytope. Interestingly, this is exactly what the spike is doing! Recall that neuron  $i$  fires a spike if  $|u_i(t)| > 1$  (recall that we set  $\eta = 1$ ), which corresponds to  $|A_i^T \mathbf{v}(t)| > 1$  in the dual space. Thus, the spike term has the following nice geometric interpretation: if  $\mathbf{v}(t)$  “exceeds” the wall  $W_j$  for some  $j \in [\pm n]$ , then neuron  $|j|$  fires a spike and  $\mathbf{v}(t)$  is “bounced back” in the normal direction of the wall  $W_j$  in the sense that  $\mathbf{v}(t)$  is subtracted by  $\alpha \cdot A_j$ . See Figure 4 for example.

Therefore, one can view the dual SNN as performing a variant of projected gradient descent algorithm for the dual program of  $\ell_1$  minimization problem. Specifically, to maintain the feasibility, the vector is not projected back to the feasible region as usual, but is “bounced back” in the normal direction of the wall  $W_j$  corresponding to the violated constraint  $A_j^T \mathbf{v} \leq 1$ . An advantage of this variant is that the “bounced back” operation is simply subtraction of  $\alpha \cdot A_j$ , which is significantly more efficient than the orthogonal projection back to the feasible region. On the other hand, note that the dynamics might not exactly converge to the optimal dual solution  $\mathbf{v}^{\text{OPT}}$ . Intuitively, the best we can hope for is that  $\mathbf{v}(t)$  will converge to a small neighboring region of  $\mathbf{v}^{\text{OPT}}$  (assuming the spiking strength  $\alpha$  is sufficiently small). The above intuition of viewing dual SNN as a projected gradient descent algorithm for the dual program of the  $\ell_1$ -minimization problem will be formally proved in the full version of this paper.

■ **Figure 4** This is examples of the geometric interpretation of the dual We consider the same matrix  $A$  as in Figure 3 and  $\mathbf{b} = [0.1 \ 0.4]^T$ . In (a), one can see that the external charging  $\mathbf{b}$  points the direction that dual SNN is moving. In (b), one can see that the effect of spikes on dual SNN is a jump in the direction of the normal vector of the wall.

**The primal-dual connection.** So far we have informally seen that the dual SNN can be viewed as solving the dual program of the  $\ell_1$ -minimization problem. However, this does not immediately give us a reason why the firing rate would converge to the solution of the primal program. It turns out that there is a beautiful connection between the dual SNN and firing rate through the *Karush-Kuhn-Tucker (KKT) conditions* (see Section 2.3) and perturbation theory (see Section 2.4).

We now discuss some intuitions about how the dual solution translates to the primal solution. To jump into the core idea, let us consider an ideal scenario where the dual SNN  $\mathbf{v}(t)$  is already very close to the optimal dual solution  $\mathbf{v}^{\text{OPT}}$  for the dual program of the  $\ell_1$  minimization problem. Since  $\mathbf{v}^{\text{OPT}}$  is the optimal solution and thus it must lie on the boundary of the dual polytope. Let  $\Gamma \subseteq [\pm n]$  be the set of walls that  $\mathbf{v}^{\text{OPT}}$  touches. That is,  $j \in \Gamma$  if and only if  $A_j^T \mathbf{v}^{\text{OPT}} = 1$ . Now, let  $\mathbf{x}^{\text{OPT}}$  denote the optimal primal solution of the  $\ell_1$  minimization problem. Observe that by the complementary slackness in the KKT conditions, for each  $i \in [n]$ , we have  $\mathbf{x}_i^{\text{OPT}} > 0$  (resp.  $\mathbf{x}_i^{\text{OPT}} < 0$ ) if  $i \in \Gamma$  (resp.  $-i \in \Gamma$ ) and  $\mathbf{x}_i^{\text{OPT}} = 0$  if  $i, -i \notin \Gamma$ . To summary, this is saying that  $\Gamma$  contains the coordinates that are non-zero in the primal optimal solution  $\mathbf{x}^{\text{OPT}}$ . See Figure 5 for an example.

With this observation, once the dual SNN  $\mathbf{v}(t)$  is very close to the optimal dual solution  $\mathbf{v}^{\text{OPT}}$  and stays nearby, only those neurons correspond to  $\Gamma$  would fire spikes. In other words, the firing rate of the non-zero coordinates in the primal optimal solution  $\mathbf{x}^{\text{OPT}}$  will remain non-zero due to the spikes while the other coordinates will gradually go to zero.

At this point, we have seen that (i) the dual SNN can be viewed as a projected gradient descent algorithm for the dual program of  $\ell_1$  minimization problem and (ii) the dual solution (resp. dual SNN) and primal solution (resp. firing rate) have a natural connection through the KKT conditions. Now, let us formally state the main theorem of this section about simple SNN solving  $\ell_1$  minimization problem.

► **Theorem 7.** *Given  $A \in \mathbb{R}^{m \times n}$  and  $\mathbf{b} \in \mathbb{R}^m$  where all the row of  $A$  has unit norm. Let  $\gamma(A)$  be the niceness parameter<sup>17</sup> of  $A$ . Suppose  $\gamma(A) > 0$  and there exists a solution to  $A\mathbf{x} = \mathbf{b}$ . There exists a polynomial  $\alpha(\cdot)$  such that for any  $t \geq 0$ , let  $\mathbf{x}(t)$  be the firing rate*

<sup>17</sup>The niceness parameter is formally defined in Definition 4 of the full version of this paper.

■ **Figure 5** This is an example based on Figure 3 and Figure 4. In this example,  $A_1 = [1 \ 0]^\top$ ,  $A_2 = [0 \ 1]^\top$ ,  $A_3 = [\frac{2}{3} \ \frac{2}{3}]^\top$ , and  $\mathbf{b} = [0.1 \ 0.4]^\top$ . The optimal dual solution is  $\mathbf{v}^{\text{OPT}} = [\frac{1}{2} \ 1]^\top$  as shown in the figure. Thus, by the above definition we have  $\Gamma = \{2, 3\}$ . By the KKT conditions, we then know that only the 2<sup>nd</sup> and 3<sup>rd</sup> coordinate of the optimal primal solution are non-zero. Indeed, the optimal primal solution is  $\mathbf{x}^{\text{OPT}} = [0 \ \frac{3}{10} \ \frac{3}{20}]^\top$ .

of the simple SNN with  $C = A^\top A$ ,  $\mathbf{I} = A^\top \mathbf{b}$ ,  $\eta = 1$ ,  $0 < \alpha \leq \alpha(\frac{\gamma(A)}{n \cdot \lambda_{\max}})$ . Let  $\text{OPT}^{\ell_1}$  be the optimal value of the  $\ell_1$  minimization problem. For any  $\epsilon > 0$ , when  $t \geq \Omega(\frac{m^2 \cdot n \cdot \|\mathbf{b}\|_2^2}{\epsilon^2 \cdot \lambda_{\min} \cdot \text{OPT}^{\ell_1}})$ , then  $\mathbf{x}(t)$  is an  $\epsilon$ -approximate solution to the  $\ell_1$  minimization problem for  $(A, \mathbf{b})$ .

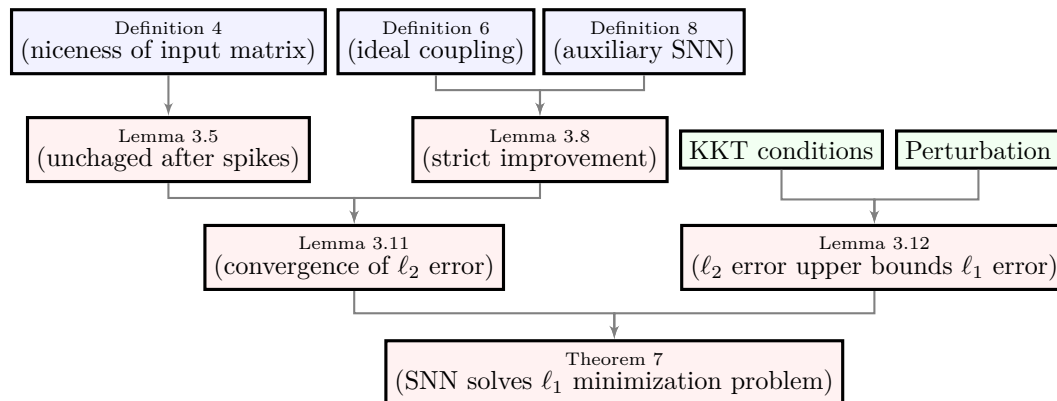

Two remarks on the statement of Theorem 7. First, we consider the *continuous SNN* instead of the discrete SNN, which is of interest for simulation on classical computer. In discrete SNN, the *step size* is some non-negligible  $\Delta t > 0$  instead of  $dt$ . The main reason for considering continuous SNN is that this significantly simplify the proof by avoiding a huge amount of nasty calculations. We suspect that the proof idea would hold for discrete SNN with discretization parameter  $\Delta t \leq \Delta t(\frac{\gamma(A)}{n \cdot \lambda_{\max}})$  for some polynomial  $\Delta t(\cdot)$ . Second, the parameters in Theorem 7 have not been optimized and we believe all the dependencies can be improved. Since the parameters highly affect the efficiency of SNN as an algorithm for  $\ell_1$  minimization problem, we pose it as an interesting open problem to study what are the best dependencies one can get.

### 3.2 Overview of the proof for Theorem 7

The proof for Theorem 7 consists of two main steps as mentioned in the previous subsection. The first step argues that the dual SNN  $\mathbf{v}(t)$  would converge to the neighborhood of the optimal dual solution  $\mathbf{v}^{\text{OPT}}$ . The second step is connecting the dual solution (i.e., the dual SNN) to the primal solution (i.e., the firing rate). In the subsection, we sketch the proof for Theorem 7 while some lemmas and definitions might not appear in this conference version and can found in the full version of this paper.

In the first step, we try to identify a *potential function*<sup>18</sup> that captures how close is  $\mathbf{v}(t)$  to the optimal dual solution  $\mathbf{v}^{\text{OPT}}$ . It turns out that this is not an easy task since the effect of spikes makes the behavior of dual SNN very non-monotone. We conquer the difficulty via a technique that we call *ideal coupling* (see Definition 6 and Figure 7 in the full version).

<sup>18</sup> Potential function is widely used in the analysis of many gradient-descent based algorithm. The difficulty lies in the search of a good potential function for the algorithm.

■ **Figure 6** Overview of the proof for Theorem 7. The missing lemmas and definitions can be found in the full version of this paper.

The idea is associating the dual SNN  $\mathbf{v}(t)$  with an *ideal SNN*  $\mathbf{v}^{\text{ideal}}(t)$  for every  $t \geq 0$  such that the ideal SNN would have *smoother* behavior comparing to the spiking phenomenon in the dual SNN. We will formally define the ideal SNN in Section 3.4 of the full version. There are two advantages of using ideal SNN instead of handling dual SNN directly: (i) Ideal SNN is smoother than dual SNN in the sense that it would not change after spikes (see Lemma 3.5 in the full version). Further, by introducing some auxiliary processes (i.e., the auxiliary SNNs defined in Definition 8 in the full version), we are able to identify a potential function that is strictly improving at any moment and measures how well the dual SNN has been solving the  $\ell_1$  minimization problem (see Lemma 3.8 in the full version). (ii) ideal SNN is naturally associated with an *ideal solution* (defined in Definition 7 in the full version) which is easier to analyze than the firing rate. Using these good properties of ideal SNN, we can prove in Lemma 3.11 (in the full version) that the  $\ell_2$  residual error of the ideal solution will converge to 0.

After we are able to show the convergence of the  $\ell_2$  residual error in Lemma 3.11 (in the full version), we move to the second step where the goal is showing that the  $\ell_1$  norm of the solution is also small. We look at the KKT conditions of the  $\ell_1$  minimization problem and observe that the primal and dual solutions of SNN satisfy the KKT conditions of a *perturbed* program of the  $\ell_1$  minimization problem. Finally, combine tools from perturbation theory, we can upper bound the  $\ell_1$  error of the ideal solution by its  $\ell_2$  residual error in Lemma 3.12 (in the full version).

Theorem 7 then follows from Lemma 3.11 and Lemma 3.12 (in the full version) with some special cares on how to transform everything for ideal solution to the firing rate. See Figure 6 for an overall structure of the proof for Theorem 7.

The full proof for Theorem 7 and other technical details are all provided in the full version of this paper.

## Abstract

Motivated by applications in Game Theory, Optimization, and Generative Adversarial Networks, recent work of Daskalakis et al [Daskalakis et al., ICLR, 2018] and follow-up work of Liang and Stokes [Liang and Stokes, 2018] have established that a variant of the widely used Gradient Descent/Ascent procedure, called “Optimistic Gradient Descent/Ascent (OGDA)”, exhibits last-iterate convergence to saddle points in *unconstrained* convex-concave min-max optimization problems. We show that the same holds true in the more general problem of *constrained* min-max optimization under a variant of the no-regret Multiplicative-Weights-Update method called “Optimistic Multiplicative-Weights Update (OMWU)”. This answers an open question of Syrgkanis et al [Syrgkanis et al., NIPS, 2015].

The proof of our result requires fundamentally different techniques from those that exist in no-regret learning literature and the aforementioned papers. We show that OMWU monotonically improves the Kullback-Leibler divergence of the current iterate to the (appropriately normalized) min-max solution until it enters a neighborhood of the solution. Inside that neighborhood we show that OMWU becomes a contracting map converging to the exact solution. We believe that our techniques will be useful in the analysis of the last iterate of other learning algorithms.

## 1 Introduction

A central problem in Game Theory and Optimization is computing a pair of probability vectors  $(\mathbf{x}, \mathbf{y})$ , solving

$$\min_{\mathbf{y} \in \Delta_m} \max_{\mathbf{x} \in \Delta_n} \mathbf{x}^\top \mathbf{A} \mathbf{y}, \tag{1}$$

## 27:2 Last-Iterate Convergence

where  $\Delta_n \subset \mathbb{R}^n$  and  $\Delta_m \subset \mathbb{R}^m$  are probability simplices, and  $A$  is a  $n \times m$  matrix. Von Neumann's celebrated minimax theorem informs us that

$$\min_{\mathbf{y} \in \Delta_m} \max_{\mathbf{x} \in \Delta_n} \mathbf{x}^\top A \mathbf{y} = \max_{\mathbf{x} \in \Delta_n} \min_{\mathbf{y} \in \Delta_m} \mathbf{x}^\top A \mathbf{y}, \quad (2)$$

and that all solutions to the LHS are solutions to the RHS, and vice versa. This result was a founding stone in the development of Game Theory. Indeed, interpreting  $\mathbf{x}^\top A \mathbf{y}$  as the payment of the “min player” to the “max player” when the former selects a distribution  $\mathbf{y}$  over columns and the latter selects a distribution  $\mathbf{x}$  over rows of matrix  $A$ , a solution to (1) constitutes an equilibrium of the game defined by matrix  $A$ , called a “minimax equilibrium”, a pair of randomized strategies such that neither player can improve their payoff by unilaterally changing their distribution.

Besides their fundamental value for Game Theory, it is known that (1) and (2) are also intimately related to Linear Programming. It was shown by von Neumann that (2) follows from strong linear programming duality. Moreover, it was suggested by Dantzig [7] and recently proven by Adler [1] that any linear program can be solved by solving some min-max problem of the form (1). In particular, min-max problems of form (1) are exactly as expressive as min-max problems of the following form, which capture any linear program (by Lagrangifying the constraints):

$$\min_{\mathbf{y} \geq 0} \max_{\mathbf{x} \geq 0} (\mathbf{x}^\top A \mathbf{y} + b^\top \mathbf{x} + c^\top \mathbf{y}). \quad (3)$$

Soon after the minimax theorem was proven and its connection to linear programming was forged, researchers proposed dynamics for solving min-max optimization problems by having the min and max players of (1) run a simple learning procedure in tandem. An early method, proposed by Brown [4] and analyzed by Robinson [18], was fictitious play. Soon after, Blackwell's approachability theorem [3] propelled the field of online learning, which led to the discovery of several learning algorithms converging to minimax equilibrium at faster rates, while also being robust to adversarial environments, situations where one of the players of the game deviates from the prescribed dynamics; see e.g. [5]. These learning methods, called “no-regret”, include the celebrated multiplicative-weights-update method, follow-the-regularized-leader, and follow-the-perturbed-leader. Compared to centralized linear programming procedures the advantage of these methods is the simplicity of executing their steps, and their robustness to adversarial environments, as we just discussed.

### Last vs Average Iterate Convergence

Despite the extensive literature on no-regret learning, an unsatisfactory feature of known results is that min-max equilibrium is shown to be attained only in an average sense. To be precise, if  $(\mathbf{x}^t, \mathbf{y}^t)$  is the trajectory of a no-regret learning method, it is usually shown that the average  $\frac{1}{t} \sum_{\tau \leq t} \mathbf{x}^\tau \mathbf{y}^\tau$  converges to the optimal value of (1), as  $t \rightarrow \infty$ . Moreover, if the solution to (1) is unique, then  $\frac{1}{t} \sum_{\tau \leq t} (\mathbf{x}^\tau, \mathbf{y}^\tau)$  converges to the optimal solution. Unfortunately that does not mean that the last iterate  $(\mathbf{x}^t, \mathbf{y}^t)$  converges to an optimal solution, and indeed it commonly diverges or enters a limit cycle. Furthermore, in the optimization literature, Nesterov [15] provides a method that can give pointwise convergence (i.e., convergence of the last iterate) to problem (1)<sup>3</sup>, however his algorithm is not a no-regret

<sup>3</sup> Nesterov showed that by optimizing  $f_\mu(\mathbf{x}) := \mu \ln(\frac{1}{m} \sum_{j=1}^m e^{-\frac{1}{\mu}(A\mathbf{x})_j})$ ,  $g_\nu(\mathbf{y}) := \nu \ln(\frac{1}{n} \sum_{j=1}^n e^{\frac{1}{\nu}(A^\top \mathbf{y})_j})$  for  $\mu = \Theta(\frac{\epsilon}{\log m})$ ,  $\nu = \Theta(\frac{\epsilon}{\log n})$  yields an  $O(\epsilon)$  approximation to the problem (1).

learning algorithm. Recent work by Daskalakis et al [8] and Liang and Stokes [11] studies whether last iterate convergence can be established for no-regret learning methods in the simple unconstrained min-max problem of the form:

$$\min_{\mathbf{y} \in \mathbb{R}^m} \max_{\mathbf{x} \in \mathbb{R}^n} (\mathbf{x}^\top A \mathbf{y} + b^\top \mathbf{x} + c^\top \mathbf{y}). \quad (4)$$

For this problem, it is known that Gradient Descent/Ascent (GDA) is a no-regret learning procedure, corresponding to follow-the-regularized leader (FTRL) with  $\ell_2^2$ -regularization. As such, the average trajectory traveled by GDA converges to a min-max solution, in the afore-described sense. On the other hand, it is also known that GDA may diverge from the min-max solution, even in trivial cases such as  $A = I, n = m = 1, b = c = 0$ . Interestingly, [8, 11] show that a variant of GDA, called “Optimistic Gradient Descent/Ascent (OGDA),<sup>4</sup> exhibits last iterate convergence. Inspired by their theoretical result for the performance of OGDA in (4), Daskalakis et al. [8] even propose the use of OGDA for training Generative Adversarial Networks (GANs) [10]. Moreover, Syrgkanis et al. [19] provide numerical experiments which indicate that the trajectories of Optimistic Hedge (variant of Hedge in the same way OGDA is a variant of GDA) stabilize (i.e., converge pointwise) as opposed to (classic) Hedge and they *posed the question whether Optimistic Hedge actually converges pointwise*.

Motivated by the afore-described lines of work, and the importance of last iterate convergence for Game Theory and the modern applications of GDA-style methods in Optimization, our goal in this work is to generalize the results of [8, 11] to the general min-max problem (3), or equivalently (1); indeed, we will focus on the latter, but our algorithms are readily applicable to the former as the two problems are equivalent [1]. With the constraint that  $(\mathbf{x}, \mathbf{y})$  should remain in  $\Delta_n \times \Delta_m$ , GDA and OGDA are not applicable. Indeed, the natural GDA-style method for min-max problems in this case is the celebrated Multiplicative-Weights-Update (MWU) method, which is tantamount to FTRL with entropy-regularization. Unsurprisingly, in the same way that GDA suffers in the unconstrained problem (4), MWU exhibits cycling in the constrained problem (1) (a recent work is [2] and was also shown empirically in [19]). So it is natural for us to study instead its optimistic variant, “Optimistic Multiplicative-Weights-Update (OMWU),” (called Optimistic Hedge in [19]) which corresponds to Optimistic FTRL with entropy-regularization, the equations of which are given in Section 2.2. Our main result is the following (restated as Theorem 5 after Section 2.2) and answers an open question asked in [19] as applicable to two player zero sum games:

► **Theorem 1 (Last-Iterate Convergence of OMWU).** *Whenever (1) has a unique optimal solution  $(\mathbf{x}^*, \mathbf{y}^*)$ , OMWU with a small enough learning rate and initialized at the pair of uniform distributions  $(\frac{1}{n}\mathbf{1}, \frac{1}{m}\mathbf{1})$  exhibits last-iterate convergence to the optimal solution. That is, if  $(\mathbf{x}^t, \mathbf{y}^t)$  are the vectors maintained by OMWU at step  $t$ , then  $\lim_{t \rightarrow \infty} (\mathbf{x}^t, \mathbf{y}^t) = (\mathbf{x}^*, \mathbf{y}^*)$ .*

► **Remark.** We note that the assumption about uniqueness of the optimal solution for problem (1) is generic in the following sense: Within the set of all zero-sum games, the set of zero-sum games with non-unique equilibrium has Lebesgue measure zero [2, 6]. This implies that if  $A$ ’s entries are sampled independently from some continuous distribution, then with probability one the min-max problem (1) will have a unique solution.

Our paper provides *two important messages*:

<sup>4</sup> OGDA is tantamount to Optimistic FTRL with  $\ell_2^2$ -regularization, in the same way that GDA is tantamount to FTRL with  $\ell_2^2$ -regularization; see e.g. [17]. OGDA essentially boils down to GDA with negative momentum.

- It strengthens the intuition that optimism helps the trajectories of learning dynamics stabilize (e.g., Optimistic MWU vs MWU or Optimistic GDA vs GDA; as the papers of Syrgkanis et al [19] and Daskalakis et al [8] also do).
- The techniques we use (typically appear in dynamical systems literature) to prove convergence for the last iterate, are fundamentally different from those commonly used to prove convergence of the time average of a learning algorithm.

**Notation.** Vectors in  $\Delta_n, \Delta_m$  are denoted in boldface  $\mathbf{x}, \mathbf{y}$ . Time indices are denoted by superscripts. Thus, a time indexed vector  $\mathbf{x}$  at time  $t$  is denoted as  $\mathbf{x}^t$ . We use the letter  $J$  to denote the Jacobian of a function (with appropriate subscript),  $\mathbf{I}, \mathbf{0}, \mathbf{1}$  to denote the identity, zero matrix and all ones vector respectively with appropriate subscripts to indicate the size. Moreover,  $(A\mathbf{y})_i$  captures  $\sum_j A_{ij}y_j$ . The support of  $\mathbf{x}$  is denoted by  $\text{Supp}(\mathbf{x})$ . Finally we use  $(\mathbf{x}^*, \mathbf{y}^*)$  to denote the optimal solution for the min-max problem (1) and  $[n]$  to denote  $\{1, \dots, n\}$ .

## 2 Preliminaries

### 2.1 Definitions and facts

#### Dynamical Systems

A recurrence relation of the form  $\mathbf{x}^{t+1} = w(\mathbf{x}^t)$  is a discrete time dynamical system, with update rule  $w : \mathcal{S} \rightarrow \mathcal{S}$  where  $\mathcal{S} = \Delta_n \times \Delta_m \times \Delta_n \times \Delta_m$  for our purposes. The point  $\mathbf{z}$  is called a *fixed point* or *equilibrium* of  $w$  if  $w(\mathbf{z}) = \mathbf{z}$ . We will be interested in the following well known fact that will be used in our proofs.

► **Proposition 2** (e.g. [9]). *If the Jacobian of the update rule  $w^5$  at a fixed point  $\mathbf{z}$  has spectral radius less than one, then there exists a neighborhood  $U$  around  $\mathbf{z}$  such that for all  $\mathbf{x} \in U$ , the dynamics converges to  $\mathbf{z}$ , i.e.,  $\lim_{n \rightarrow \infty} w^n(\mathbf{x}) = \mathbf{z}$ . We call  $w$  a contraction mapping in  $U$ .*

### 2.2 OMWU Method

Our main contribution is that the last iterate of OMWU converges to the optimal solution. The OMWU dynamics is defined as follows ( $t \geq 1$ ):

$$\begin{aligned} x_i^{t+1} &= x_i^t \frac{e^{2\eta(A\mathbf{y}^t)_i - \eta(A\mathbf{y}^{t-1})_i}}{\sum_{j=1}^n x_j^t e^{2\eta(A\mathbf{y}^t)_j - \eta(A\mathbf{y}^{t-1})_j}} \text{ for all } i \in [n], \\ y_i^{t+1} &= y_i^t \frac{e^{-2\eta(A^\top \mathbf{x}^t)_i + \eta(A^\top \mathbf{x}^{t-1})_i}}{\sum_{j=1}^m y_j^t e^{-2\eta(A^\top \mathbf{x}^t)_j + \eta(A^\top \mathbf{x}^{t-1})_j}} \text{ for all } i \in [m]. \end{aligned} \quad (5)$$

Points  $(\mathbf{x}^1, \mathbf{y}^1), (\mathbf{x}^0, \mathbf{y}^0)$  are the initial conditions and are given as input. We call  $0 < \eta < 1$  the *stepsize* of the dynamics. It is more convenient to interpret OMWU dynamics as mapping a quadruple to quadruple  $((\mathbf{x}^t, \mathbf{y}^t, \mathbf{x}^{t-1}, \mathbf{y}^{t-1}) \rightarrow (\mathbf{x}^{t+1}, \mathbf{y}^{t+1}, \mathbf{x}^t, \mathbf{y}^t)$ , see Section 3.2 for the construction of the dynamical system).

► **Remark.** Let  $(\mathbf{x}^*, \mathbf{y}^*)$  be the optimal solution. We see that  $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$  is a fixed point of the mapping. Furthermore,  $\Delta_n \times \Delta_m \times \Delta_n \times \Delta_m$  is invariant under OMWU dynamics. For  $t \geq 1$ , if  $x_i^t = 0$  then  $x_i$  remains zero for all times greater than  $t$ , and if it is positive, it remains positive (both numerator and denominator are positive)<sup>6</sup>. In words, at all times the

<sup>5</sup> We assume  $w$  is a continuously differential function.

<sup>6</sup> Same holds for vector  $\mathbf{y}$ .

OMWU satisfies the non-negativity constraints and the renormalization factor (denominator) makes both  $\mathbf{x}, \mathbf{y}$ 's coordinates sum up to one. A last observation is that every fixed point of OMWU dynamics (mapping a quadruple to quadruple) has the form  $(\mathbf{x}, \mathbf{y}, \mathbf{x}, \mathbf{y})$  (two same copies). Equation (8) shows how to express OMWU dynamics as a dynamical system.

### 2.3 Linear Variant of OMWU

We provide the linear variant of OMWU dynamics (5) because we use it in some intermediate lemmas (appear in appendix).

$$\begin{aligned} x_i^{t+1} &= x_i^t \frac{1+2\eta(\mathbf{A}\mathbf{y}^t)_i - \eta(\mathbf{A}\mathbf{y}^{t-1})_i}{\sum_{j=1}^n x_j^t (1+2\eta(\mathbf{A}\mathbf{y}^t)_j - \eta(\mathbf{A}\mathbf{y}^{t-1})_j)} \text{ for all } i \in [n], \\ y_i^{t+1} &= y_i^t \frac{1-2\eta(\mathbf{A}^\top \mathbf{x}^t)_i + \eta(\mathbf{A}^\top \mathbf{x}^{t-1})_i}{\sum_{j=1}^m y_j^t (1-2\eta(\mathbf{A}^\top \mathbf{x}^t)_j + \eta(\mathbf{A}^\top \mathbf{x}^{t-1})_j)} \text{ for all } i \in [m]. \end{aligned} \quad (6)$$

This dynamics is derived by considering the first order approximation of the exponential function. Step size  $\eta$  in this case should be chosen sufficiently small so that both numerator and denominator are positive.

### 2.4 More definitions and statement of our result

► **Definition 3** ([12]). Assume  $\alpha > 0$ . We call a point  $(\mathbf{x}, \mathbf{y}) \in \Delta_n \times \Delta_m$   $\alpha$ -close if for each  $i$  we have that  $x_i \leq \alpha$  or  $|\mathbf{x}^\top \mathbf{A}\mathbf{y} - (\mathbf{A}\mathbf{y})_i| \leq \alpha$  and for each  $j$  it holds  $y_j \leq \alpha$  or  $|\mathbf{x}^\top \mathbf{A}\mathbf{y} - (\mathbf{A}^\top \mathbf{x})_j| \leq \alpha$ .

► **Remark.** Think of  $\alpha$ -close points as  $\alpha$ -approximate optimal solutions for min-max problems that are induced by *submatrices* of  $A$  ( $\alpha$ -approximate stationary points). Moreover, if  $(\mathbf{x}, \mathbf{y})$  is 0-close point does not necessarily imply  $(\mathbf{x}, \mathbf{y})$  is the optimal solution of problem (1)!

► **Definition 4** (Approximate solution). Assume  $\epsilon > 0$ . We call a point  $(\mathbf{x}, \mathbf{y}) \in \Delta_n \times \Delta_m$   $\epsilon$ -approximate (or  $\epsilon$ -approximate Nash equilibrium) if for all  $\tilde{\mathbf{x}} \in \Delta_n$  we get that  $\tilde{\mathbf{x}}^\top \mathbf{A}\mathbf{y} \leq \mathbf{x}^\top \mathbf{A}\mathbf{y} + \epsilon$  (max player deviates) and for all  $\tilde{\mathbf{y}} \in \Delta_m$  we get that  $\mathbf{x}^\top \mathbf{A}\tilde{\mathbf{y}} \geq \mathbf{x}^\top \mathbf{A}\mathbf{y} - \epsilon$  (min player deviates).

► **Remark.** Think of  $\epsilon$ -approximate points as approximate optimal solutions to the min-max problem (1). Moreover, if  $(\mathbf{x}, \mathbf{y})$  is 0-approximate then  $(\mathbf{x}, \mathbf{y})$  is the optimal solution of problem (1).

#### Statement of our results

We finish the preliminary section by stating formally the main result.

► **Theorem 5** (OMWU converges). *Let  $A$  be a  $n \times m$  matrix and assume that*

$$\min_{\mathbf{y} \in \Delta_m} \max_{\mathbf{x} \in \Delta_n} \mathbf{x}^\top \mathbf{A}\mathbf{y}$$

*has a unique solution  $(\mathbf{x}^*, \mathbf{y}^*)$ . It holds that for  $\eta$  sufficiently small (depends on  $n, m, A$ ), starting from the uniform distribution, i.e.,  $(\mathbf{x}^1, \mathbf{y}^1) = (\mathbf{x}^0, \mathbf{y}^0) = (\frac{1}{n}\mathbf{1}, \frac{1}{m}\mathbf{1})$ , it holds*

$$\lim_{t \rightarrow \infty} (\mathbf{x}^t, \mathbf{y}^t) = (\mathbf{x}^*, \mathbf{y}^*),$$

*under OMWU dynamics. The step size  $\eta$  is constant, i.e., does not scale with time<sup>7</sup>.*

<sup>7</sup> Our proof also works if the starting points  $(\mathbf{x}^1, \mathbf{y}^1), (\mathbf{x}^0, \mathbf{y}^0)$  are both in the interior of  $\Delta_n \times \Delta_m$  and not necessarily uniform, however the choice of  $\eta$  depends on the initial distributions as well and not only on  $n, m, A$ .

We need to note that it is not clear from our theorem how small  $\eta$  is and its dependence on the size of  $A$ . Nevertheless, our convergence result holds for constant stepsizes as opposed to the classic no-regret learning literature where  $\eta$  scales like  $\frac{1}{\sqrt{T}}$  after  $T$  iterations. Another result we know of this flavor is about MWU algorithm on congestion games [16].

### 3 Last iterate convergence of OMWU

In this section we show our main result (Theorem 5), by breaking the proof into three key theorems. The first theorem says that KL divergence from the  $t$ -th iterate  $(\mathbf{x}^t, \mathbf{y}^t)$  to the optimal solution  $(\mathbf{x}^*, \mathbf{y}^*)$ , i.e., (sum of KL divergences to be exact)

$$\sum_i x_i^* \ln(x_i^*/x_i^t) + \sum_i y_i^* \ln(y_i^*/y_i^t),$$

decreases with time  $t \geq 2$  by at least a factor of  $\eta^3$  per iteration, unless the iterate  $(\mathbf{x}^t, \mathbf{y}^t)$  is  $O(\eta^{1/3})$ -close (see Definition 3). Moreover, provided that the stepsize  $\eta$  is small enough, we can show the structural result that  $(\mathbf{x}^t, \mathbf{y}^t)$  lies in a neighborhood of  $(\mathbf{x}^*, \mathbf{y}^*)$  that becomes smaller and smaller as  $\eta \rightarrow 0$ . Finally, as long as OMWU dynamics has reached a small neighborhood around  $(\mathbf{x}^*, \mathbf{y}^*)$ , we show that the update rule of the dynamical system induced by OMWU is contracting, and the last iterate convergence result follows. Formally we show:

► **Theorem 6** (KL decreasing). *Let  $(\mathbf{x}^*, \mathbf{y}^*)$  be the unique optimal solution of problem (1) and  $\eta$  sufficiently small. Then*

$$D_{KL}((\mathbf{x}^*, \mathbf{y}^*) || (\mathbf{x}^t, \mathbf{y}^t))$$

*is decreasing with time  $t$  by (at least)  $\Omega(\eta^3)$  unless  $(\mathbf{x}^t, \mathbf{y}^t)$  is  $O(\eta^{1/3})$ -close.*

► **Theorem 7** ( $\eta^{1/3}$ -close implies close to optimum in  $\ell_1$ ). *Assume that  $(\mathbf{x}^*, \mathbf{y}^*)$  is unique optimal solution of the problem (1). Let  $T$  (depends on  $\eta$ ) be the first time KL divergence does not decrease by  $\Omega(\eta^3)$ . It follows that as  $\eta \rightarrow 0$ , the  $\eta^{1/3}$ -close point  $(\mathbf{x}^T, \mathbf{y}^T)$  has distance from  $(\mathbf{x}^*, \mathbf{y}^*)$  that goes to zero, i.e.,  $\lim_{\eta \rightarrow 0} \|(\mathbf{x}^*, \mathbf{y}^*) - (\mathbf{x}^T, \mathbf{y}^T)\|_1 = 0$ .*

► **Theorem 8** (OMWU is a contraction). *Let  $(\mathbf{x}^*, \mathbf{y}^*)$  be the unique optimal solution to the min-max problem (1). There exists a neighborhood  $U \subset \Delta_n \times \Delta_m \times \Delta_n \times \Delta_m$  of  $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$ <sup>8</sup> so that for all  $(\mathbf{x}^1, \mathbf{y}^1, \mathbf{x}^0, \mathbf{y}^0) \in U$  we have that  $\lim_{t \rightarrow \infty} (\mathbf{x}^t, \mathbf{y}^t, \mathbf{x}^{t-1}, \mathbf{y}^{t-1}) = (\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$  under OMWU dynamics as defined in (5) and (8) (Section 3.2).*

Assuming these three theorems, our main result is straightforward.

**Proof of Theorem 5.** Let  $\eta$  be sufficiently small. If  $(\mathbf{x}^1, \mathbf{y}^1) = (\frac{1}{n}\mathbf{1}, \frac{1}{m}\mathbf{1})$  (starting point is uniform) then an easy upper bound (by removing negative terms) on KL divergence from  $(\mathbf{x}^1, \mathbf{y}^1)$  to  $(\mathbf{x}^*, \mathbf{y}^*)$  is  $-\sum_{i=1}^n x_i^* \log x_i^1 + \sum_{i=1}^m y_i^* \log y_i^1 = \log(nm)$ . Therefore using Theorem 6 we have that after at most  $T$  that is  $O(\frac{\log(nm)}{\eta^3})$  steps, OMWU reaches a  $O(\eta^{1/3})$ -close point ( $T$  is the first time so that KL divergence from current iterate to optimal solution  $(\mathbf{x}^*, \mathbf{y}^*)$  has not decreased by at least a factor of  $\eta^3$ ) or the KL divergence between the optimal solution and  $(\mathbf{x}^T, \mathbf{y}^T)$  is  $O(\eta^3)$  (KL divergence was decreasing by at least a factor of  $\eta^3$  for all iterations until the iterate reached a  $\ell_1$  distance  $O(\eta^3)$ ). In the latter case it

<sup>8</sup> Since  $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$  might be on the boundary of  $\Delta_n \times \Delta_m \times \Delta_n \times \Delta_m$ ,  $U$  is the intersection of an open ball around  $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$  with  $\Delta_n \times \Delta_m \times \Delta_n \times \Delta_m$ .

follows  $\|(\mathbf{x}^*, \mathbf{y}^*) - (\mathbf{x}^T, \mathbf{y}^T)\|_1^2$  is  $O(\eta^3)$  and hence  $(\mathbf{x}^T, \mathbf{y}^T)$  is  $O(\eta^{3/2})$  in  $\ell_1$  distance from the optimal solution, therefore for small  $\eta$ ,  $(\mathbf{x}^{T+1}, \mathbf{y}^{T+1}, \mathbf{x}^T, \mathbf{y}^T)$  is in the neighborhood  $U$  that is needed for contraction (Theorem 8). In the former case, by Theorem 7 (for  $\eta$  sufficiently small) it follows that  $(\mathbf{x}^{T+1}, \mathbf{y}^{T+1}, \mathbf{x}^T, \mathbf{y}^T)$  is also in the neighborhood  $U$  that is needed for contraction (Theorem 8)<sup>9</sup>. The proof follows by Theorem 8.  $\blacktriangleleft$

In the next subsections we will provide the proofs to all three key theorems.

### 3.1 KL decreases and OMWU reaches neighborhood

In this subsection we argue about the proofs of Theorems 6 and 7. The inequality we managed to prove (see in the appendix the proof of Theorem 6) is the following:

$$\begin{aligned} & D_{KL}((\mathbf{x}^*, \mathbf{y}^*) \| (\mathbf{x}^{t+1}, \mathbf{y}^{t+1})) - D_{KL}((\mathbf{x}^*, \mathbf{y}^*) \| (\mathbf{x}^t, \mathbf{y}^t)) \leq \\ & - \sum_{i=1}^n x_i^t \left( \left( \frac{1}{2} - O(\eta) \right) \eta^2 \left( 2(A\mathbf{y}^t)_i - 2\mathbf{x}^{t \top} A\mathbf{y}^t - (A\mathbf{y}^{t-1})_i + \mathbf{x}^{t \top} A\mathbf{y}^{t-1} \right)^2 \right) \\ & - \sum_{i=1}^m y_i^t \left( \left( \frac{1}{2} - O(\eta) \right) \eta^2 \left( 2(A^\top \mathbf{x}^t)_i - 2\mathbf{x}^{t \top} A\mathbf{y}^t - (A^\top \mathbf{x}^{t-1})_i + \mathbf{x}^{t-1 \top} A\mathbf{y}^t \right)^2 \right) + O(\eta^3). \end{aligned} \quad (7)$$

The proof of the inequality is quite long, we choose to provide intuition and skip the details. We refer to the appendix for a proof. The inequality says that OMWU dynamics has a good progress (KL divergence decreases by at least a factor of  $\eta^3$ ) as long as the current and previous iterate  $(\mathbf{x}^t, \mathbf{y}^t)$ ,  $(\mathbf{x}^{t-1}, \mathbf{y}^{t-1})$  are not  $\alpha$ -close for  $\alpha$  chosen to be  $O(\eta^{1/3})$ . This situation appears a lot in gradient methods when the dynamics is close to a stationary point, the gradient of  $f$  is small and the progress is small as opposed to the case where the gradient of  $f$  is big and there is satisfying progress. The RHS of inequality (7) captures the “distance” from stationarity. Thus, as long as we are not close to a stationary point (i.e.,  $O(\eta^{1/3})$ -close) in a time window between  $1, 2, \dots, k$ , KL divergence from current iterate ( $k$ -th) to the optimum has decreased by (at least)  $\Omega(k\eta^3)$  compared to KL divergence from first iterate to the optimum.

Moreover, suppose that at some point of OMWU dynamics, KL divergence from current iterate to the optimum did not decrease by at least a factor of  $\eta^3$  and let  $T$  be the iteration this happened. As we have already argued,  $(\mathbf{x}^T, \mathbf{y}^T)$  is a  $O(\eta^{1/3})$ -close point. We can show that as long as  $\eta$  is sufficiently small, then for all  $i, j$  in the support of  $(\mathbf{x}^*, \mathbf{y}^*)$ ,  $x_i^T, y_j^T$  are (at least)  $\Omega(\eta^{1/3})$  i.e., coordinates in the support of the optimum will have non negligible probability in  $(\mathbf{x}^T, \mathbf{y}^T)$ . Formally:

► **Lemma 9.** *Let  $i \in \text{Supp}(\mathbf{x}^*)$  and  $j \in \text{Supp}(\mathbf{y}^*)$ . It holds that  $x_i^T \geq \frac{1}{2}\eta^{1/3}$  and  $y_j^T \geq \frac{1}{2}\eta^{1/3}$  as long as*

$$\eta^{1/3} \leq \min_{s \in \text{Supp}(\mathbf{x}^*)} \frac{1}{(nm)^{1/x_s^*}}, \min_{s \in \text{Supp}(\mathbf{y}^*)} \frac{1}{(nm)^{1/y_s^*}}.$$

**Proof.** By definition of  $T$ , the KL divergence is decreasing for  $2 \leq t \leq T-1$ , thus

$$D_{KL}((\mathbf{x}^*, \mathbf{y}^*) \| (\mathbf{x}^{T-1}, \mathbf{y}^{T-1})) < D_{KL}((\mathbf{x}^*, \mathbf{y}^*) \| (\mathbf{x}^1, \mathbf{y}^1)).$$

Therefore  $x_i^* \log \frac{1}{x_i^{T-1}} < \sum_i x_i^* \log \frac{1}{x_i^1} + \sum_i y_j^* \log \frac{1}{y_j^1} = \log(mn)$ . It follows that  $x_i^T > 1/(mn)^{\frac{1}{x_i^*}} \geq \eta^{1/3}$  for  $x_i^* > 0$  ( $i \in \text{Supp}(\mathbf{x}^*)$ ). Since  $|x_i^T - x_i^{T-1}|$  is  $O(\eta)$  (Lemma 11) the result follows. Similarly, the argument works for  $y_j^T$ .  $\blacktriangleleft$

<sup>9</sup> In both cases we used that iterate  $(\mathbf{x}^T, \mathbf{y}^T)$  and  $(\mathbf{x}^{T+1}, \mathbf{y}^{T+1})$  have  $\ell_1$  distance  $O(\eta)$ , this is Lemma 11.

Lemma 9 indicates that the stepsize  $\eta$  might have to be exponentially small in the dimension (OMWU dynamics is slow when  $\eta$  is very small). We can now prove Theorem 7.

**Proof of Theorem 7.** From Lemma 9 and definition of  $T$ , we get that  $|(A\mathbf{y}^T)_i - \mathbf{x}^T \top A\mathbf{y}^T|$  is  $O(\eta^{1/3})$  for all  $i$  in the support of  $\mathbf{x}^*$  and  $|(A^\top \mathbf{x}^T)_j - \mathbf{x}^T \top A\mathbf{y}^T|$  is  $O(\eta^{1/3})$  for all  $j$  in the support of  $\mathbf{y}^*$ . We consider  $(\mathbf{w}^T, \mathbf{z}^T)$  to be the projection of the point  $(\mathbf{x}^T, \mathbf{y}^T)$  by removing all the coordinates that have probability mass less than  $\frac{1}{2}\eta^{1/3}$  and rescale so that the coordinates sum up to one.

We restrict ourselves to the corresponding subproblem (submatrix). It is clear that  $(\mathbf{w}^T, \mathbf{z}^T)$  is a  $O(\eta^{1/3})$ -approximate solution<sup>10</sup> for the subproblem. Let  $v = \mathbf{x}^* A \mathbf{y}^*$  be the optimal value. By uniqueness of the optimal solution, we get that  $(A\mathbf{y}^*)_i = v$  for all  $i \in \text{Supp}(\mathbf{x}^*)$  and  $(A\mathbf{y}^*)_i < v$  otherwise (check Lemma C.3 in paper [13] for a proof, where they use Farkas' lemma to show it, we use this fact later in Section 3.2). Similarly  $(A^\top \mathbf{x}^*)_j = v$  for the min player  $\mathbf{y}$  if  $j$  lies in the support of  $\mathbf{y}^*$  and  $(A^\top \mathbf{x}^*)_j > v$  otherwise. We choose  $\eta$  so small that every  $O(\eta^{1/3})$ -approximate solution  $(\mathbf{x}, \mathbf{y})$  has the property that  $(A\mathbf{y})_i \leq v - \eta^{1/4}$ ,  $(A^\top \mathbf{x})_j \geq v + \eta^{1/4}$  for all  $i \notin \text{Supp}(\mathbf{x}^*)$  and  $j \notin \text{Supp}(\mathbf{y}^*)$  respectively (this is possible by continuity of the bilinear function and Claim 10 below). Hence we conclude that if  $\eta$  is small enough, the coordinates in the vector  $(\mathbf{w}^T, \mathbf{z}^T)$  that are not in the support of the optimal solution (since  $\eta^{1/4} \gg \eta^{1/3}$ ), should have probability mass  $O(\eta^{1/3})$  at time  $T$ .

► **Claim 10.** *Let  $(\mathbf{x}^*, \mathbf{y}^*)$  be the unique optimal solution to the problem (1). For every  $\epsilon > 0$ , there exists an  $\delta(\epsilon) > 0$  so that for every  $\delta$ -approximate solution  $(\mathbf{x}, \mathbf{y})$  we get that  $|x_i - x_i^*| < \epsilon$  for all  $i \in [n]$ . Analogously holds for player  $\mathbf{y}$ .*

**Proof.** We will prove this by contradiction. Assume there is an  $\epsilon$  that violates this statement. We choose a sequence  $\delta_k$  so that  $\lim_{k \rightarrow \infty} \delta_k = 0$  and also there is a sequence  $(\mathbf{x}_k, \mathbf{y}_k)$  of  $\delta_k$ -approximate Nash equilibrium with  $|x_{k,i} - x_i^*| \geq \epsilon$  for some strategy  $i$ . Since  $\Delta_n \times \Delta_m$  is compact and the sequence above is bounded, there is a convergent subsequence. The limit of the convergent subsequence is a Nash equilibrium by definition of  $\delta$ -approximate (Definition 4). By uniqueness it follows that the  $i$ -th coordinate of the convergent sequence must converge to  $x_i^*$ , hence we reached a contradiction. ◀

Therefore, if we restrict to the subproblem induced by the strategies in the support of  $(\mathbf{x}^*, \mathbf{y}^*)$ , the projected vector  $(\mathbf{w}^T, \mathbf{z}^T)$  is a  $O(\eta^{1/3})$ -approximate solution of the subgame.

From Claim 10, as  $\eta \rightarrow 0$  it follows that the  $\ell_1$  distance (any distance suffices) between the projected  $(\mathbf{w}^T, \mathbf{z}^T)$  and the optimal solution (Nash equilibrium) of the subgame goes to zero. Since the optimal solution of the subgame is exactly the same as the optimal solution of the original game we get that as  $\eta \rightarrow 0$ ,  $(\mathbf{x}^T, \mathbf{y}^T)$  reaches  $(\mathbf{x}^*, \mathbf{y}^*)$ . In particular, since  $\|(\mathbf{x}^{T+1}, \mathbf{y}^{T+1}) - (\mathbf{x}^T, \mathbf{y}^T)\|_1$  is  $O(\eta)$  (see Lemma 11) there exists a  $\eta$  small so that  $(\mathbf{x}^{T+1}, \mathbf{y}^{T+1}, \mathbf{x}^T, \mathbf{y}^T)$  is inside the necessary neighborhood  $U$  of  $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$  that gives contraction (Theorem 8). ◀

### 3.2 Proving contraction

The purpose of this section is to prove Theorem 8. To show contraction of OMWU dynamics in a neighborhood of the optimal solution  $(\mathbf{x}^*, \mathbf{y}^*)$ , we first construct a dynamical system that captures OMWU. Moreover, we prove that the Jacobian of the update rule of that particular

<sup>10</sup>By  $\epsilon$ -approximate optimal solution we mean the  $\epsilon$ -approximate Nash equilibrium notion (additive), see Definition 4.

dynamical system computed at the optimal solution, has spectral radius less than one. This suffices to prove contraction (see Proposition 2). As a result, as long as OMWU reaches a small neighborhood of  $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$ , it converges pointwise (last iterate convergence) to it<sup>11</sup>. Below we provide the update rule  $g$  of the dynamical system, which consists of 4 components:

$$\begin{aligned} g(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}) &:= (g_1(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}), g_2(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}), g_3(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}), g_4(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w})), \\ g_{1,i}(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}) &:= (g_1(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}))_i := x_i \frac{e^{2\eta(A\mathbf{y})_i - \eta(A\mathbf{w})_i}}{\sum_t x_t e^{2\eta(A\mathbf{y})_t - \eta(A\mathbf{w})_t}} \text{ for all } i \in [n], \\ g_{2,i}(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}) &:= (g_2(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}))_i := y_i \frac{e^{-2\eta(A^\top \mathbf{x})_i + \eta(A^\top \mathbf{z})_i}}{\sum_t y_t e^{-2\eta(A^\top \mathbf{x})_t + \eta(A^\top \mathbf{z})_t}} \text{ for all } i \in [m], \\ g_3(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}) &:= \mathbf{I}_{n \times n} \mathbf{x}, \\ g_4(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}) &:= \mathbf{I}_{m \times m} \mathbf{y}. \end{aligned} \quad (8)$$

It is not hard to check that

$$(\mathbf{x}_{t+1}, \mathbf{y}_{t+1}, \mathbf{x}_t, \mathbf{y}_t) = g(\mathbf{x}_t, \mathbf{y}_t, \mathbf{x}_{t-1}, \mathbf{y}_{t-1}),$$

so  $g$  captures exactly the dynamics of OMWU (5). The equations of the Jacobian of  $g$  can be found in the appendix (see Section A).

### Spectral analysis the Jacobian of OMWU at the optimal solution

The rest of the section constitutes the proof of Theorem 8. Assume  $v = \mathbf{x}^{*\top} A \mathbf{y}^*$ , i.e.,  $v$  is the value of the bilinear function  $\mathbf{x}^\top A \mathbf{y}$  at the optimal solution. We will analyze the Jacobian computed at  $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$ <sup>12</sup>.

Assume  $i \notin \text{Supp}(\mathbf{x}^*)$ , then

$$\frac{\partial g_{1,i}}{\partial x_i} = \frac{e^{\eta(A\mathbf{y}^*)_i}}{\sum_t x_t^* e^{\eta(A\mathbf{y}^*)_t}} = \frac{e^{\eta(A\mathbf{y}^*)_i}}{e^{\eta v}}$$

and all other partial derivatives of  $g_{1,i}$  are zero, thus  $\frac{e^{\eta(A\mathbf{y}^*)_i}}{e^{\eta v}}$  is an eigenvalue of the Jacobian computed at  $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$ . Moreover because of uniqueness of the optimal solution, it holds that  $\frac{e^{\eta(A\mathbf{y}^*)_i}}{e^{\eta v}} < 1$  because  $(A\mathbf{y}^*)_i - v < 0$  (check Lemma C.3 in [13] for a proof, where they use Farkas' Lemma to show it). Similarly, it holds for  $j \notin \text{Supp}(\mathbf{y}^*)$  that  $\frac{\partial g_{2,j}}{\partial y_j} = \frac{e^{-\eta(A^\top \mathbf{x}^*)_j}}{e^{-\eta v}} < 1$  (again by C.3 in [13] it holds that  $(A\mathbf{x}^*)_j - v > 0$ ) and all other partial derivatives of  $g_{2,j}$  are zero, hence  $\frac{e^{-\eta(A^\top \mathbf{x}^*)_j}}{e^{-\eta v}}$  is an eigenvalue of the Jacobian computed at the optimal solution.

Let  $D_x$  be the diagonal matrix of size  $|\text{Supp}(\mathbf{x}^*)| \times |\text{Supp}(\mathbf{x}^*)|$  that has on the diagonal the nonzero entries of  $\mathbf{x}^*$  and similarly we define  $D_y$  of size  $|\text{Supp}(\mathbf{y}^*)| \times |\text{Supp}(\mathbf{y}^*)|$ . We set  $k_1 = |\text{Supp}(\mathbf{x}^*)|$ ,  $k_2 = |\text{Supp}(\mathbf{y}^*)|$  and  $k = k_1 + k_2$ . Let  $\mathbf{x}', \mathbf{y}'$  be the optimal solution to the min-max problem with payoff matrix the corresponding submatrix of payoff matrix  $A$  (denoted by  $B$ ) after removing the rows/columns which correspond to the coordinates that are not in the support of the unique optimal solution  $(\mathbf{x}^*, \mathbf{y}^*)$ <sup>13</sup>. We consider the submatrix  $\tilde{J}$  of the Jacobian matrix that is created by removing rows and columns of the corresponding coordinates that are not in the support of optimum (for the variables  $\mathbf{x}$  and  $\mathbf{y}$ , these are exactly  $n + m - k$ ). It is clear from above, that the Jacobian of OMWU has eigenvalues

<sup>11</sup> Since the dynamical system is from a quadruple to a quadruple, it is a neighborhood of  $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$ .

<sup>12</sup> See also Equations (14) of the Jacobian computed at  $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$ .

<sup>13</sup> Note that  $(\mathbf{x}', \mathbf{y}')$  should be the *unique* optimal solution to the min-max problem with payoff matrix  $B$ .

with absolute value less than one iff  $\tilde{J}$  has as well. After also removing the rows (and the corresponding columns) that have only zero entries (these are exactly  $n + m - k$ , result zero eigenvalues and correspond to variables  $\mathbf{z}$  and  $\mathbf{w}$ ) the resulting submatrix (denote it by  $J$ ) boils down to the following matrix  $J$ :

$$\begin{pmatrix} \mathbf{I}_{k_1 \times k_1} - D_x \mathbf{1}_{k_1} \mathbf{1}_{k_1}^\top & 2\eta D_x (B - v \mathbf{1}_{k_1} \mathbf{1}_{k_2}^\top) & \mathbf{0}_{k_1 \times k_1} & -\eta D_x (B - v \mathbf{1}_{k_1} \mathbf{1}_{k_2}^\top) \\ 2\eta D_y (v \mathbf{1}_{k_2} \mathbf{1}_{k_1}^\top - B^\top) & \mathbf{I}_{k_2 \times k_2} - D_y \mathbf{1}_{k_2} \mathbf{1}_{k_2}^\top & -\eta D_y (v \mathbf{1}_{k_2} \mathbf{1}_{k_1}^\top - B^\top) & \mathbf{0}_{k_2 \times k_2} \\ \mathbf{I}_{k_1 \times k_1} & \mathbf{0}_{k_1 \times k_2} & \mathbf{0}_{k_1 \times k_1} & \mathbf{0}_{k_1 \times k_2} \\ \mathbf{0}_{k_2 \times k_1} & \mathbf{I}_{k_2 \times k_2} & \mathbf{0}_{k_2 \times k_1} & \mathbf{0}_{k_2 \times k_2} \end{pmatrix}. \quad (9)$$

It is clear that  $(\mathbf{1}_{k_1}, \mathbf{0}_{k_2}, \mathbf{0}_{k_1}, \mathbf{0}_{k_2})$ ,  $(\mathbf{0}_{k_1}, \mathbf{1}_{k_2}, \mathbf{0}_{k_1}, \mathbf{0}_{k_2})$  are left eigenvectors with eigenvalues zero and thus any right eigenvector  $(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}, \tilde{\mathbf{z}}, \tilde{\mathbf{w}})$  with nonzero eigenvalue has the property that  $\tilde{\mathbf{x}}^\top \mathbf{1}_{k_1} = 0$  and  $\tilde{\mathbf{y}}^\top \mathbf{1}_{k_2} = 0$ . Hence every nonzero eigenvalue of the matrix above is an eigenvalue of the matrix below:

$$J_{\text{new}} = \begin{pmatrix} \mathbf{I}_{k_1 \times k_1} & 2\eta D_x B & \mathbf{0}_{k_1 \times k_1} & -\eta D_x B \\ -2\eta D_y B^\top & \mathbf{I}_{k_2 \times k_2} & \eta D_y B^\top & \mathbf{0}_{k_2 \times k_2} \\ \mathbf{I}_{k_1 \times k_1} & \mathbf{0}_{k_1 \times k_2} & \mathbf{0}_{k_1 \times k_1} & \mathbf{0}_{k_1 \times k_2} \\ \mathbf{0}_{k_2 \times k_1} & \mathbf{I}_{k_2 \times k_2} & \mathbf{0}_{k_2 \times k_1} & \mathbf{0}_{k_2 \times k_2} \end{pmatrix}. \quad (10)$$

Let  $p(\lambda)$  be the characteristic polynomial of the matrix (10). After row/column operations it boils down to

$$(-1)^k \det \begin{pmatrix} \lambda(1-\lambda)\mathbf{I}_{k_1 \times k_1} & (2\lambda-1)\eta D_x B \\ -\eta(2\lambda-1)D_y B^\top & \lambda(1-\lambda)\mathbf{I}_{k_2 \times k_2} \end{pmatrix} = (1-2\lambda)^k q \left( \frac{\lambda(\lambda-1)}{2\lambda-1} \right), \quad (11)$$

where  $q(\lambda)$  is the characteristic polynomial of

$$J_{\text{small}} = \begin{pmatrix} \mathbf{0}_{k_1 \times k_1} & \eta D_x B \\ -\eta D_y B^\top & \mathbf{0}_{k_2 \times k_2} \end{pmatrix}. \quad (12)$$

Observe that

$$J_{\text{small}} \cdot \begin{pmatrix} D_x & \mathbf{0}_{k_1 \times k_2} \\ \mathbf{0}_{k_2 \times k_1} & D_y \end{pmatrix} \text{ is real skew symmetric,}$$

and hence by Lemma 16,  $J_{\text{small}}$  has eigenvalues of the form<sup>14</sup>  $\pm i\eta\tau$  with  $\tau \in \mathbb{R}$  (i.e., imaginary eigenvalues; we include  $\eta$  in the expression to conclude that  $\sigma := \eta\tau$  can be sufficiently small in absolute value). We conclude that any nonzero eigenvalue  $\lambda$  of the matrix  $J$  should satisfy the equation  $\frac{\lambda(\lambda-1)}{2\lambda-1} = i\sigma$  for some small in absolute value  $\sigma \in \mathbb{R}$ . Finally we get that

$$\lambda = \frac{1 + 2i\sigma \pm \sqrt{1 - 4\sigma^2}}{2}.$$

We compute the square of the magnitude of  $\lambda$  and we get  $|\lambda|^2 = \frac{2-4\sigma^2 \pm 2\sqrt{1-4\sigma^2} + 4\sigma^2}{4} = \frac{1 \pm \sqrt{1-4\sigma^2}}{2} < 1$  unless  $\sigma = 0$  (i.e.,  $\tau = 0$ ). If  $\sigma = 0$ , it means that  $J_{\text{new}}$  has an eigenvalue which is equal to one. Assume that  $(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}, \tilde{\mathbf{z}}, \tilde{\mathbf{w}})$  is the corresponding right eigenvector, it holds that  $B\tilde{\mathbf{y}} = \mathbf{0}$  and  $B^\top \tilde{\mathbf{x}} = \mathbf{0}$ . Assume also that there exists an eigenvalue that is equal to one in the original matrix  $J$ . It follows that  $\mathbf{1}_{k_2}^\top \tilde{\mathbf{y}} = 0$  and  $\mathbf{1}_{k_1}^\top \tilde{\mathbf{x}} = 0$ . It holds that  $\tilde{\mathbf{x}} = \mathbf{0}_{k_1}$  and  $\tilde{\mathbf{y}} = \mathbf{0}_{k_2}$  otherwise  $(\mathbf{x}', \mathbf{y}') + t(\tilde{\mathbf{x}}, \tilde{\mathbf{y}})$  would be another optimal solution (for the min-max problem with payoff matrix  $B$ ; by padding zeros to the vector, we could create another optimal solution for the original min-max problem with payoff matrix  $A$ ) for small enough  $t$ . We reached contradiction because we have assumed uniqueness. Hence all the eigenvalues of  $J$  are less than 1, i.e., the mapping is a contraction mapping and the proof is complete.

<sup>14</sup>We denote  $i = \sqrt{-1}$ .

**Figure 1** In the  $x$  axis we have the number of rows of a square matrix  $A$  and on  $y$  axis the number of iterations of OMWU. This figure captures how the number of iterations depends on the dimensionality of the min-max problem.

## 4 Experiments

The purpose of our experiments is primarily to understand how the speed of convergence of OMWU dynamics (5) scales with the size of matrix  $A$ . Moreover, for  $A$  of fixed size, we are interested in how the speed of convergence scales with the error of the output of OMWU dynamics. By error we mean the  $\ell_1$  distance between the last iterate of OMWU and the optimal solution.

For the former case, we fix the error to be 0.1 and we run OMWU for  $n = 25, 50, \dots, 250$  where the input matrix  $A$  has size  $n \times n$  with entries i.i.d random variables sampled from uniform  $[-1, 1]$ . We output the number of iterations OMWU needs starting from uniform  $(\frac{1}{n}, \dots, \frac{1}{n})$  to reach a solution that is at most 0.1 away from optimal in  $\ell_1$  distance. We note that we computed the optimal solutions using LP-solvers.

For the latter case, we fix  $n = 50$  and we consider the error  $\epsilon$  to be  $\{0.5, 0.25, 0.0625, 0.015625, 0.007812\}$ . Starting from uniform distribution, we count the number of iterations to reach error  $\epsilon$ . The stepsize  $\eta$  is fixed at 0.01 at all times. The results can be found in Figures 1 and 2. If we had to guess, it seems that the relation between dimension and iterations is between linear and quadratic (i.e., OMWU dynamics has roughly cubic-quartic running time in  $n$  if we count the cost of each iteration as quadratic) and the dependence between error  $\epsilon$  and iterations  $t$  seems like  $t$  is inverse polynomial in  $\epsilon$ .

We note the importance of stepsize  $\eta$ .  $\eta$  must be sufficiently small for our proofs to work. If  $\eta$  is chosen to be big, then OMWU might not converge (might cycle, we observed such behavior in experiments). On the other hand, the smaller  $\eta$  is chosen, the smaller the progress of OMWU dynamics (see the inequality claim for KL divergence) and hence the slower the dynamics.

## 5 Conclusion

In this paper we showed that a no-regret algorithm called Optimistic Multiplicative Weights Update (OMWU) converges pointwise to a Nash equilibrium in two player zero sum games (See also a concurrent work to ours [14], in which the authors provide a pointwise result about other dynamics, using different techniques). Our analysis is novel and does not follow the standard approaches of the literature of no-regret learning. We believe that our techniques can be useful in the analysis of other learning algorithms with no provable guarantees of pointwise convergence.

■ **Figure 2** In the  $x$  axis we have the number of iterations of OMWU and on  $y$  axis the  $\ell_1$  distance from the optimal solution. This figure captures how the number of iterations scales with the error.

One interesting open question is to show that OMWU algorithm converges in polynomial time in  $n, m$  (for proper choice of stepsize  $\eta$ ) and find exact rates of convergence. Another possible future direction is to generalize our results about OMWU beyond the bilinear setting.

## A Equations of the Jacobian of OMWU dynamics

### A.1 Equations computed at point $(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w})$

Set  $S_x = \sum_{t=1}^n x_t e^{2\eta(A\mathbf{y})_t - \eta(A\mathbf{w})_t}$ ,  $S_y = \sum_{t=1}^m y_t e^{-2\eta(A^\top \mathbf{x})_t + \eta(A^\top \mathbf{z})_t}$  and let  $i, j$  be arbitrary indexes ( $g_{1,i}$  captures the  $i$ -th coordinate of function  $g_1$  etc),

$$\begin{aligned}
\frac{\partial g_{1,i}}{\partial x_i} &= \frac{e^{2\eta(A\mathbf{y})_i - \eta(A\mathbf{w})_i}}{S_x} - x_i \frac{(e^{2\eta(A\mathbf{y})_i - \eta(A\mathbf{w})_i})^2}{S_x^2} \text{ for all } i \in [n], \\
\frac{\partial g_{1,i}}{\partial x_j} &= -x_i e^{2\eta(A\mathbf{y})_j - \eta(A\mathbf{w})_j} \cdot \frac{e^{2\eta(A\mathbf{y})_i - \eta(A\mathbf{w})_i}}{S_x^2} \text{ for all } i \in [n], j \in [n] \text{ and } j \neq i, \\
\frac{\partial g_{1,i}}{\partial y_j} &= x_i e^{2\eta(A\mathbf{y})_i - \eta(A\mathbf{w})_i} \cdot \frac{2\eta A_{ij} S_x - 2\eta \sum_t A_{tj} x_t e^{2\eta(A\mathbf{y})_t - \eta(A\mathbf{w})_t}}{S_x^2} \text{ for all } i \in [n], j \in [m], \\
\frac{\partial g_{1,i}}{\partial z_j} &= 0 \text{ for all } i, j \in [n], \\
\frac{\partial g_{1,i}}{\partial w_j} &= x_i e^{2\eta(A\mathbf{y})_i - \eta(A\mathbf{w})_i} \cdot \frac{-\eta A_{ij} S_x + \eta \sum_t A_{tj} x_t e^{2\eta(A\mathbf{y})_t - \eta(A\mathbf{w})_t}}{S_x^2} \text{ for all } i \in [n], j \in [m], \\
\frac{\partial g_{2,i}}{\partial y_i} &= \frac{e^{-2\eta(A^\top \mathbf{x})_i + \eta(A^\top \mathbf{z})_i}}{S_y} - y_i \frac{(e^{-2\eta(A^\top \mathbf{x})_i + \eta(A^\top \mathbf{z})_i})^2}{S_y^2} \text{ for all } i \in [m], \\
\frac{\partial g_{2,i}}{\partial y_j} &= -y_i e^{-2\eta(A^\top \mathbf{x})_j + \eta(A^\top \mathbf{z})_j} \cdot \frac{e^{-2\eta(A^\top \mathbf{x})_i + \eta(A^\top \mathbf{z})_i}}{S_y^2} \text{ for all } i \in [m], j \in [m] \text{ and } j \neq i, \\
\frac{\partial g_{2,i}}{\partial x_j} &= y_i e^{-2\eta(A^\top \mathbf{x})_i + \eta(A^\top \mathbf{z})_i} \cdot \frac{-2\eta A_{ij}^\top S_y + 2\eta \sum_t A_{tj}^\top y_t e^{-2\eta(A^\top \mathbf{x})_t + \eta(A^\top \mathbf{z})_t}}{S_y^2} \text{ for all } i \in [m], j \in [n], \\
\frac{\partial g_{2,i}}{\partial z_j} &= y_i e^{-2\eta(A^\top \mathbf{x})_i + \eta(A^\top \mathbf{z})_i} \cdot \frac{\eta A_{ij}^\top S_y - \eta \sum_t A_{tj}^\top x_t e^{-2\eta(A^\top \mathbf{x})_t + \eta(A^\top \mathbf{z})_t}}{S_y^2} \text{ for all } i \in [m], j \in [n], \\
\frac{\partial g_{2,i}}{\partial w_j} &= 0 \text{ for any } i, j \in [m], \\
\frac{\partial g_{3,i}}{\partial x_i} &= 1 \text{ for all } i \in [n] \text{ and zero all the other partial derivatives of } g_{3,i}, \\
\frac{\partial g_{4,i}}{\partial y_i} &= 1 \text{ for all } i \in [m] \text{ and zero all the other partial derivatives of } g_{4,i}.
\end{aligned} \tag{13}$$

### A.2 Equations computed at point $(\mathbf{x}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{y}^*)$

Set  $S_x = \sum_{t=1}^n x_t^* e^{\eta(A\mathbf{y}^*)_t}$ ,  $S_y = \sum_{t=1}^m y_t^* e^{-\eta(A^\top \mathbf{x}^*)_t}$  and let  $i, j$  be arbitrary indexes ( $g_{1,i}$  captures the  $i$ -th coordinate of function  $g_1$  etc). Assume  $\mathbf{v} = \mathbf{x}^{*\top} A \mathbf{y}^*$ , it is not hard to see

## 27:14 Last-Iterate Convergence

that  $(A^\top \mathbf{x}^*)_i = (A\mathbf{y}^*)_j = v$  for all  $i \in \text{Supp}(\mathbf{x}^*), j \in \text{Supp}(\mathbf{y}^*)$  and  $S_x = e^{\eta v}, S_y = e^{-\eta v}$ . We get that:

$$\begin{aligned}
\frac{\partial g_{1,i}}{\partial x_i} &= 1 - x_i^* \text{ for all } i \in \text{Supp}(\mathbf{x}^*), \\
\frac{\partial g_{1,i}}{\partial x_i} &= \frac{e^{\eta(A\mathbf{y}^*)_i}}{e^{\eta v}} \text{ for all } i \notin \text{Supp}(\mathbf{x}^*), \\
\frac{\partial g_{1,i}}{\partial x_j} &= -x_i^* \text{ for all } i, j \in \text{Supp}(\mathbf{x}^*) \text{ and } j \neq i, \\
\frac{\partial g_{1,i}}{\partial x_j} &= 0 \text{ for all } i \notin \text{Supp}(\mathbf{x}^*), j \in [n] \text{ and } j \neq i, \\
\frac{\partial g_{1,i}}{\partial y_j} &= x_i^*(2\eta A_{ij} - 2\eta v) \text{ for all } i \in \text{Supp}(\mathbf{x}^*), j \in \text{Supp}(\mathbf{y}^*), \\
\frac{\partial g_{1,i}}{\partial y_j} &= 0 \text{ for all } i \notin \text{Supp}(\mathbf{x}^*), j \in [m], \\
\frac{\partial g_{1,i}}{\partial z_j} &= 0 \text{ for all } i, j \in [n], \\
\frac{\partial g_{1,i}}{\partial w_j} &= x_i^*(-\eta A_{ij} + \eta v) \text{ for all } i \in \text{Supp}(\mathbf{x}^*), j \in \text{Supp}(\mathbf{y}^*), \\
\frac{\partial g_{1,i}}{\partial w_j} &= 0 \text{ for all } i \notin \text{Supp}(\mathbf{x}^*), j \in [m], \\
\frac{\partial g_{2,i}}{\partial y_i} &= 1 - y_i^* \text{ for all } i \in \text{Supp}(\mathbf{y}^*), \\
\frac{\partial g_{2,i}}{\partial y_i} &= \frac{e^{-\eta(A\mathbf{x}^*)_i}}{e^{-\eta v}} \text{ for all } i \notin \text{Supp}(\mathbf{y}^*), \\
\frac{\partial g_{2,i}}{\partial y_j} &= -y_i^* \text{ for all } i, j \in \text{Supp}(\mathbf{y}^*) \text{ and } j \neq i, \\
\frac{\partial g_{2,i}}{\partial y_j} &= 0 \text{ for all } i \notin \text{Supp}(\mathbf{y}^*), j \in [m] \text{ and } j \neq i, \\
\frac{\partial g_{2,i}}{\partial x_j} &= y_i^*(-2\eta A_{ij}^\top + 2\eta v) \text{ for all } i \in \text{Supp}(\mathbf{y}^*), j \in \text{Supp}(\mathbf{x}^*), \\
\frac{\partial g_{2,i}}{\partial x_j} &= 0 \text{ for all } i \notin \text{Supp}(\mathbf{y}^*), j \in [n], \\
\frac{\partial g_{2,i}}{\partial z_j} &= y_i^*(\eta A_{ij}^\top - \eta v) \text{ for all } i \in \text{Supp}(\mathbf{y}^*), j \in \text{Supp}(\mathbf{x}^*), \\
\frac{\partial g_{2,i}}{\partial z_j} &= 0 \text{ for all } i \notin \text{Supp}(\mathbf{y}^*), j \in [n], \\
\frac{\partial g_{2,i}}{\partial w_j} &= 0 \text{ for any } i, j \in [m], \\
\frac{\partial g_{3,i}}{\partial x_i} &= 1 \text{ for all } i \in [n] \text{ and zero all the other partial derivatives of } g_{3,i}, \\
\frac{\partial g_{4,i}}{\partial y_i} &= 1 \text{ for all } i \in [m] \text{ and zero all the other partial derivatives of } g_{4,i}.
\end{aligned} \tag{14}$$

### B Missing claims and proofs

Lemma 11 shows that the change between next and current iterate in both OMWU algorithms (classic and linear variant) is of order  $O(\eta)$  and that the difference between the next iterate of both algorithms is  $O(\eta^2)$ .

► **Lemma 11.** *Let  $\mathbf{x} \in \Delta_n$  be the vector of the max player,  $\mathbf{w}, \mathbf{z} \in \Delta_m$  and suppose  $\mathbf{x}', \mathbf{x}''$  are the next iterates of OMWU and its linear variant with current vector  $\mathbf{x}$  and vectors  $\mathbf{w}, \mathbf{z}$  of the min player. It holds that*

$$\|\mathbf{x}' - \mathbf{x}''\|_1 \text{ is } O(\eta^2), \text{ and } \|\mathbf{x}' - \mathbf{x}\|_1, \|\mathbf{x}'' - \mathbf{x}\|_1 \text{ are } O(\eta).$$

Analogously, it holds for vector  $\mathbf{y} \in \Delta_m$  of the min player and its next iterates.

**Proof.** Let  $\eta$  be sufficiently small (smaller than maximum in absolute value entry of  $A$ ).

$$\begin{aligned}
|x'_i - x''_i| &= x_i \left| \frac{e^{2\eta(A\mathbf{w})_i - \eta(A\mathbf{z})_i}}{\sum_j x_j e^{2\eta(A\mathbf{w})_j - \eta(A\mathbf{z})_j}} - \frac{1 + 2\eta(A\mathbf{w})_i - \eta(A\mathbf{z})_i}{\sum_j x_j (1 + 2\eta(A\mathbf{w})_j - \eta(A\mathbf{z})_j)} \right| \\
&= x_i \left| \frac{1 + 2\eta(A\mathbf{w})_i - \eta(A\mathbf{z})_i \pm O(\eta^2)}{\sum_j x_j (1 + 2\eta(A\mathbf{w})_j - \eta(A\mathbf{z})_j) \pm O(\eta^2)} - \frac{1 + 2\eta(A\mathbf{w})_i - \eta(A\mathbf{z})_i}{\sum_j x_j (1 + 2\eta(A\mathbf{w})_j - \eta(A\mathbf{z})_j)} \right| \\
&\text{which is } O(\eta^2)x_i
\end{aligned}$$

and hence  $\|\mathbf{x}' - \mathbf{x}''\|_1$  is  $O(\eta^2)$ . Moreover we have that

$$\begin{aligned} |x_i - x_i''| &= x_i \left| 1 - \frac{1 + 2\eta(\mathbf{A}\mathbf{w})_i - \eta(\mathbf{A}\mathbf{z})_i}{\sum_j x_j(1 + 2\eta(\mathbf{A}\mathbf{w})_j - \eta(\mathbf{A}\mathbf{z})_j)} \right| \\ &= x_i \left| \frac{\sum_j x_j(1 + 2\eta(\mathbf{A}\mathbf{w})_j - \eta(\mathbf{A}\mathbf{z})_j) - (1 + 2\eta(\mathbf{A}\mathbf{w})_i - \eta(\mathbf{A}\mathbf{z})_i)}{\sum_j x_j(1 + 2\eta(\mathbf{A}\mathbf{w})_j - \eta(\mathbf{A}\mathbf{z})_j)} \right| \\ &= x_i \left| \frac{\sum_j x_j(2\eta(\mathbf{A}\mathbf{w})_j - \eta(\mathbf{A}\mathbf{z})_j) - 2\eta(\mathbf{A}\mathbf{w})_i + \eta(\mathbf{A}\mathbf{z})_i}{\sum_j x_j(1 + 2\eta(\mathbf{A}\mathbf{w})_j - \eta(\mathbf{A}\mathbf{z})_j)} \right| \text{ which is } O(\eta)x_i. \end{aligned}$$

By triangle inequality and the two above proofs we get the third part of the lemma.  $\blacktriangleleft$

Lemmas 12, 13 and 15 will be used in the proof of Theorem 6.

**► Lemma 12.** *Let  $\mathbf{x} \in \Delta_n$ ,  $\mathbf{w}, \mathbf{z} \in \Delta_m$  and suppose  $\mathbf{x}', \mathbf{x}''$  are the next iterates of OMWU and its linear variant with current vector  $\mathbf{x}$  and inputs  $\mathbf{w}, \mathbf{z}$ , i.e.,  $\mathbf{x}'$  has coordinates  $x'_i = x_i \frac{e^{2\eta(\mathbf{A}\mathbf{w})_i - \eta(\mathbf{A}\mathbf{z})_i}}{\sum_j x_j e^{2\eta(\mathbf{A}\mathbf{w})_j - \eta(\mathbf{A}\mathbf{z})_j}}$  and  $\mathbf{x}''$  has coordinates  $x''_i = x_i \frac{1 + 2\eta(\mathbf{A}\mathbf{w})_i - \eta(\mathbf{A}\mathbf{z})_i}{\sum_j x_j(1 + 2\eta(\mathbf{A}\mathbf{w})_j - \eta(\mathbf{A}\mathbf{z})_j)}$ . It holds that (for  $\eta$  sufficiently small)*

$$\begin{aligned} \eta \mathbf{x}'^\top \mathbf{A}(2\mathbf{w} - \mathbf{z}) - \eta \mathbf{x}^\top \mathbf{A}(2\mathbf{w} - \mathbf{z}) &= \\ &= (\eta \mathbf{x}''^\top \mathbf{A}(2\mathbf{w} - \mathbf{z}) - \eta \mathbf{x}^\top \mathbf{A}(2\mathbf{w} - \mathbf{z})) - O(\eta^3) = \\ &= (1 - O(\eta))\eta^2 \sum_i x_i (2\mathbf{x}^\top \mathbf{A}\mathbf{w} - \mathbf{x}^\top \mathbf{A}\mathbf{z} - 2(\mathbf{A}\mathbf{w})_i + (\mathbf{A}\mathbf{z})_i)^2 - O(\eta^3) \\ &= (1 - O(\eta))\eta^2 \sum_i x'_i (2\mathbf{x}'^\top \mathbf{A}\mathbf{w} - \mathbf{x}'^\top \mathbf{A}\mathbf{z} - 2(\mathbf{A}\mathbf{w})_i + (\mathbf{A}\mathbf{z})_i)^2 - O(\eta^3). \end{aligned}$$

**Proof.** It suffices to prove the second equality. The rest follow from Lemma 11. Set  $B = (\mathbf{1}_n \mathbf{1}_m^\top + \eta A)$ . We have that  $x''_i = x_i \frac{(B(2\mathbf{w} - \mathbf{z}))_i}{\mathbf{x}^\top B(2\mathbf{w} - \mathbf{z})}$  (from definition of linear variant of OMWU dynamics). It follows that

$$\begin{aligned} (\mathbf{x}''^\top B(2\mathbf{w} - \mathbf{z})) \cdot (\mathbf{x}^\top B(2\mathbf{w} - \mathbf{z})) &= \sum_{ij} B_{ij} x''_i (2\mathbf{w} - \mathbf{z})_j \cdot (\mathbf{x}^\top B(2\mathbf{w} - \mathbf{z})) \\ &= \sum_{ij} B_{ij} \left( x_i \frac{(B(2\mathbf{w} - \mathbf{z}))_i}{\mathbf{x}^\top B(2\mathbf{w} - \mathbf{z})} \right) (2\mathbf{w} - \mathbf{z})_j \cdot (\mathbf{x}^\top B(2\mathbf{w} - \mathbf{z})) \\ &= \sum_{ij} B_{ij} (x_i (B(2\mathbf{w} - \mathbf{z}))_i) (2\mathbf{w} - \mathbf{z})_j \\ &= \sum_i x_i (B(2\mathbf{w} - \mathbf{z}))_i^2 \\ &= (\mathbf{x}^\top B(2\mathbf{w} - \mathbf{z}))^2 + \sum_i x_i (\mathbf{x}^\top B(2\mathbf{w} - \mathbf{z}) - (B(2\mathbf{w} - \mathbf{z}))_i)^2. \end{aligned}$$

where the last inequality comes from the fact that for a random variable  $\xi$  we have  $\mathbb{E}[\xi^2] = \mathbb{E}^2[\xi] + \mathbb{V}[\xi]$ . Therefore by dividing LHS and RHS by  $\mathbf{x}^\top B(2\mathbf{w} - \mathbf{z})$  which is  $1 \pm O(\eta)$  we get

$$\begin{aligned} (\mathbf{x}''^\top B(2\mathbf{w} - \mathbf{z})) &= (\mathbf{x}^\top B(2\mathbf{w} - \mathbf{z})) + (1 - O(\eta)) \sum_i x_i (\mathbf{x}^\top B(2\mathbf{w} - \mathbf{z}) - (B(2\mathbf{w} - \mathbf{z}))_i)^2 \\ &= (\mathbf{x}^\top (\mathbf{1}_n \mathbf{1}_m^\top + \eta A)(2\mathbf{w} - \mathbf{z})) + \\ &\quad + (1 - O(\eta))\eta^2 \sum_i x_i (\mathbf{x}^\top \mathbf{A}(2\mathbf{w} - \mathbf{z}) - (\mathbf{A}(2\mathbf{w} - \mathbf{z}))_i)^2. \end{aligned}$$

The proof is complete by Lemma 11.  $\blacktriangleleft$

## 27:16 Last-Iterate Convergence

Using same arguments as in proof of Lemma 12 we have the following lemma:

► **Lemma 13.** Let  $\mathbf{y} \in \Delta_m$ ,  $\mathbf{w}, \mathbf{z} \in \Delta_n$  and suppose  $\mathbf{y}'$  is the next iterate of OMWU with current vector  $\mathbf{y}$  and inputs  $\mathbf{w}, \mathbf{z}$ , i.e.,  $\mathbf{y}'$  has coordinates  $y'_i = y_i \frac{e^{-2\eta(A^\top \mathbf{w})_i + \eta(A^\top \mathbf{z})_i}}{\sum_j y_j e^{-2\eta(A^\top \mathbf{w})_j + \eta(A^\top \mathbf{z})_j}}$ . It holds that (for  $\eta$  sufficiently small)

$$\begin{aligned} & \eta \mathbf{y}'^\top A^\top (\mathbf{z} - 2\mathbf{w}) - \eta \mathbf{y}^\top A^\top (\mathbf{z} - 2\mathbf{w}) \\ &= (1 - O(\eta)) \eta^2 \sum_i y'_i (\mathbf{y}'^\top A^\top \mathbf{z} - 2\mathbf{y}'^\top A^\top \mathbf{w} - (A^\top \mathbf{z})_i + 2(A^\top \mathbf{w})_i)^2 - O(\eta^3). \end{aligned}$$

► **Lemma 14.** Let  $(\mathbf{x}^t, \mathbf{y}^t)$  be the  $t$ -th iterate of OMWU dynamics (5). For each time step  $t \geq 2$  it holds that

$$\begin{aligned} & \eta \mathbf{x}^{t-1 \top} A \mathbf{y}^t - \eta \mathbf{x}^t \top A \mathbf{y}^{t-1} \leq \\ & \leq -(1 - O(\eta)) \eta^2 \sum_i x_i^t (2\mathbf{x}^{t \top} A \mathbf{y}^t - \mathbf{x}^t \top A \mathbf{y}^{t-1} - 2(A \mathbf{y}^t)_i + (A \mathbf{y}^{t-1})_i)^2 - \\ & - (1 - O(\eta)) \eta^2 \sum_i y_i^t (\mathbf{y}^{t \top} A^\top \mathbf{x}^{t-1} - 2\mathbf{y}^{t \top} A^\top \mathbf{x}^t - (A^\top \mathbf{x}^{t-1})_i + 2(A^\top \mathbf{x}^t)_i)^2 + O(\eta^3). \end{aligned}$$

**Proof.**

$$\begin{aligned} & \eta \mathbf{x}^{t-1 \top} A \mathbf{y}^t - \eta \mathbf{x}^t \top A \mathbf{y}^{t-1} = \\ & = \eta \mathbf{x}^{t-1 \top} A \mathbf{y}^t - \frac{1}{2} \eta \mathbf{x}^{t-1 \top} A \mathbf{y}^{t-1} + \frac{1}{2} \eta \mathbf{x}^{t-1 \top} A \mathbf{y}^{t-1} - \eta \mathbf{x}^t \top A \mathbf{y}^{t-1} \\ & = \eta \mathbf{x}^t \top A \mathbf{y}^t - \frac{1}{2} \eta \mathbf{x}^t \top A \mathbf{y}^{t-1} + \frac{1}{2} \eta \mathbf{x}^{t-1 \top} A \mathbf{y}^t - \eta \mathbf{x}^t \top A \mathbf{y}^t - \\ & - \left( \frac{1}{2} - O(\eta) \right) \eta^2 \sum_i x_i^t (2\mathbf{x}^{t \top} A \mathbf{y}^t - \mathbf{x}^t \top A \mathbf{y}^{t-1} - 2(A \mathbf{y}^t)_i + (A \mathbf{y}^{t-1})_i)^2 - \\ & - \left( \frac{1}{2} - O(\eta) \right) \eta^2 \sum_i y_i^t (\mathbf{y}^{t \top} A^\top \mathbf{x}^{t-1} - 2\mathbf{y}^{t \top} A^\top \mathbf{x}^t - (A^\top \mathbf{x}^{t-1})_i + \\ & + 2(A^\top \mathbf{x}^t)_i)^2 + O(\eta^3). \end{aligned}$$

The second equality comes from Lemmas 12 and 13. By canceling out the common terms and bring to the LHS the appropriate remaining terms, the claim follows. ◀

► **Lemma 15.** Let  $(\mathbf{x}^t, \mathbf{y}^t)$  denote the  $t$ -th iterate of OMWU dynamics. It holds for  $t \geq 2$  that

$$\mathbf{x}^* \top A (2\mathbf{y}^t - \mathbf{y}^{t-1}) \geq \mathbf{x}^* \top A \mathbf{y}^* \text{ and } (2\mathbf{x}^t \top - \mathbf{x}^{t-1 \top}) A \mathbf{y}^* \leq \mathbf{x}^* \top A \mathbf{y}^*,$$

where  $(\mathbf{x}^*, \mathbf{y}^*)$  is the optimal solution of the min-max problem.

**Proof.** It is true that  $x_i^t \geq (1 - O(\eta)) x_i^{t-1}$ , hence  $x_i^t \geq \frac{1}{2} x_i^{t-1}$  for  $\eta$  sufficiently small. Therefore  $2\mathbf{x}^t - \mathbf{x}^{t-1}$  lies in the simplex  $\Delta_n$ . Hence since  $(\mathbf{x}^*, \mathbf{y}^*)$  is the optimum (Nash equilibrium) we get that  $(2\mathbf{x}^t \top - \mathbf{x}^{t-1 \top}) A \mathbf{y}^* \leq \mathbf{x}^* \top A \mathbf{y}^*$  ( $\mathbf{x}$  is the max player). Similarly the second inequality can be proved. ◀

**Proof of Theorem 6.** We compute the difference between

$D_{KL}((\mathbf{x}^*, \mathbf{y}^*) || (\mathbf{x}^{t+1}, \mathbf{y}^{t+1}))$  and  $D_{KL}((\mathbf{x}^*, \mathbf{y}^*) || (\mathbf{x}^t, \mathbf{y}^t))$

$$\begin{aligned}
& D_{KL}((\mathbf{x}^*, \mathbf{y}^*) || (\mathbf{x}^{t+1}, \mathbf{y}^{t+1})) - D_{KL}((\mathbf{x}^*, \mathbf{y}^*) || (\mathbf{x}^t, \mathbf{y}^t)) \\
&= - \left( \sum_i \mathbf{x}_i^* \ln \frac{x_i^{t+1}}{x_i^t} + \sum_i y_i^* \ln \frac{y_i^{t+1}}{y_i^t} \right) \\
&= - \left( \sum_i \mathbf{x}_i^* \ln e^{2\eta(\mathbf{A}\mathbf{y}^t)_i - \eta(\mathbf{A}\mathbf{y}^{t-1})_i} + \sum_i y_i^* \ln e^{-2\eta(\mathbf{A}^\top \mathbf{x}^t)_i + \eta(\mathbf{A}^\top \mathbf{x}^{t-1})_i} \right) + \\
&\quad + \ln \left( \sum_i x_i^t e^{2\eta(\mathbf{A}\mathbf{y}^t)_i - \eta(\mathbf{A}\mathbf{y}^{t-1})_i} \right) + \ln \left( \sum_i y_i^t e^{-2\eta(\mathbf{A}^\top \mathbf{x}^t)_i + \eta(\mathbf{A}^\top \mathbf{x}^{t-1})_i} \right) \\
&= -2\eta \mathbf{x}^{* \top} \mathbf{A}\mathbf{y}^t + \eta \mathbf{x}^{* \top} \mathbf{A}\mathbf{y}^{t-1} + 2\eta \mathbf{x}^t \top \mathbf{A}\mathbf{y}^* - \eta \mathbf{x}^{t-1 \top} \mathbf{A}\mathbf{y}^* + \\
&\quad + \ln \left( \sum_i x_i^t e^{2\eta(\mathbf{A}\mathbf{y}^t)_i - \eta(\mathbf{A}\mathbf{y}^{t-1})_i} \right) + \ln \left( \sum_i y_i^t e^{-2\eta(\mathbf{A}^\top \mathbf{x}^t)_i + \eta(\mathbf{A}^\top \mathbf{x}^{t-1})_i} \right).
\end{aligned}$$

We use Lemma 15 and get that  $-2\eta \mathbf{x}^{* \top} \mathbf{A}\mathbf{y}^t + \eta \mathbf{x}^{* \top} \mathbf{A}\mathbf{y}^{t-1} + 2\eta \mathbf{x}^t \top \mathbf{A}\mathbf{y}^* - \eta \mathbf{x}^{t-1 \top} \mathbf{A}\mathbf{y}^* \leq 0$ , therefore the LHS (difference in the KL divergence) is at most

$$\begin{aligned}
& \overbrace{-2\eta \mathbf{x}^t \top \mathbf{A}\mathbf{y}^t + \eta \mathbf{x}^t \top \mathbf{A}\mathbf{y}^{t-1} + 2\eta \mathbf{x}^t \top \mathbf{A}\mathbf{y}^* - \eta \mathbf{x}^{t-1 \top} \mathbf{A}\mathbf{y}^t - \eta \mathbf{x}^t \top \mathbf{A}\mathbf{y}^{t-1} + \eta \mathbf{x}^{t-1 \top} \mathbf{A}\mathbf{y}^t}_{=0} \\
&\quad + \ln \left( \sum_i x_i^t e^{2\eta(\mathbf{A}\mathbf{y}^t)_i - \eta(\mathbf{A}\mathbf{y}^{t-1})_i} \right) + \ln \left( \sum_i y_i^t e^{-2\eta(\mathbf{A}^\top \mathbf{x}^t)_i + \eta(\mathbf{A}^\top \mathbf{x}^{t-1})_i} \right) \\
&= \ln \left( \sum_i x_i^t e^{2\eta((\mathbf{A}\mathbf{y}^t)_i - \mathbf{x}^t \top \mathbf{A}\mathbf{y}^t) - \eta((\mathbf{A}\mathbf{y}^{t-1})_i - \mathbf{x}^t \top \mathbf{A}\mathbf{y}^{t-1})} \right) + \\
&\quad \ln \left( \sum_i y_i^t e^{-2\eta((\mathbf{A}^\top \mathbf{x}^t)_i - \mathbf{x}^t \top \mathbf{A}\mathbf{y}^t) + \eta((\mathbf{A}^\top \mathbf{x}^{t-1})_i - \mathbf{x}^{t-1 \top} \mathbf{A}\mathbf{y}^t)} \right) - \eta \mathbf{x}^t \top \mathbf{A}\mathbf{y}^{t-1} + \eta \mathbf{x}^{t-1 \top} \mathbf{A}\mathbf{y}^t
\end{aligned}$$

We furthermore use second order Taylor approximation ( $\eta$  is sufficiently small) to the function  $e^x$  and we get that previous expression is at most

$$\begin{aligned}
& \leq \ln \left( \sum_i x_i^t (1 + 2\eta((\mathbf{A}\mathbf{y}^t)_i - \mathbf{x}^t \top \mathbf{A}\mathbf{y}^t) - \eta((\mathbf{A}\mathbf{y}^{t-1})_i - \mathbf{x}^t \top \mathbf{A}\mathbf{y}^{t-1})) + \right. \\
&\quad \left. + \sum_i x_i^t \left( \frac{1}{2} + O(\eta) \right) \eta^2 (2(\mathbf{A}\mathbf{y}^t)_i - 2\mathbf{x}^t \top \mathbf{A}\mathbf{y}^t - (\mathbf{A}\mathbf{y}^{t-1})_i + \mathbf{x}^t \top \mathbf{A}\mathbf{y}^{t-1})^2 \right) + \\
&\quad + \ln \left( \sum_i y_i^t (1 - 2\eta((\mathbf{A}^\top \mathbf{x}^t)_i - \mathbf{x}^t \top \mathbf{A}\mathbf{y}^t) + \eta((\mathbf{A}^\top \mathbf{x}^{t-1})_i - \mathbf{x}^{t-1 \top} \mathbf{A}\mathbf{y}^t)) + \right. \\
&\quad \left. + \sum_i y_i^t \left( \frac{1}{2} + O(\eta) \right) \eta^2 (2(\mathbf{A}^\top \mathbf{x}^t)_i - 2\mathbf{x}^t \top \mathbf{A}\mathbf{y}^t - (\mathbf{A}^\top \mathbf{x}^{t-1})_i + \mathbf{x}^{t-1 \top} \mathbf{A}\mathbf{y}^t)^2 \right) - \\
&\quad - \eta \mathbf{x}^t \top \mathbf{A}\mathbf{y}^{t-1} + \eta \mathbf{x}^{t-1 \top} \mathbf{A}\mathbf{y}^t
\end{aligned}$$

Finally, using Taylor approximation on  $\log(1+x)$  and Lemma 14 (last equality) we get

## 27:18 Last-Iterate Convergence

the following system:

$$\begin{aligned}
&\leq \eta \mathbf{x}^{t-1 \top} \mathbf{A} \mathbf{y}^t - \eta \mathbf{x}^t \top \mathbf{A} \mathbf{y}^{t-1} + \\
&+ \sum_i x_i^t \left( \left( \frac{1}{2} + O(\eta) \right) \eta^2 \left( 2(\mathbf{A} \mathbf{y}^t)_i - 2 \mathbf{x}^t \top \mathbf{A} \mathbf{y}^t - (\mathbf{A} \mathbf{y}^{t-1})_i + \mathbf{x}^t \top \mathbf{A} \mathbf{y}^{t-1} \right)^2 \right) + \\
&+ \sum_i y_i^t \left( \left( \frac{1}{2} + O(\eta) \right) \eta^2 \left( 2(\mathbf{A}^\top \mathbf{x}^t)_i - 2 \mathbf{x}^t \top \mathbf{A} \mathbf{y}^t - (\mathbf{A}^\top \mathbf{x}^{t-1})_i + \mathbf{x}^{t-1 \top} \mathbf{A} \mathbf{y}^t \right)^2 \right) \\
&= - \sum_i x_i^t \left( \left( \frac{1}{2} - O(\eta) \right) \eta^2 \left( 2(\mathbf{A} \mathbf{y}^t)_i - 2 \mathbf{x}^t \top \mathbf{A} \mathbf{y}^t - (\mathbf{A} \mathbf{y}^{t-1})_i + \mathbf{x}^t \top \mathbf{A} \mathbf{y}^{t-1} \right)^2 \right) \\
&- \sum_i y_i^t \left( \left( \frac{1}{2} - O(\eta) \right) \eta^2 \left( 2(\mathbf{A}^\top \mathbf{x}^t)_i - 2 \mathbf{x}^t \top \mathbf{A} \mathbf{y}^t - (\mathbf{A}^\top \mathbf{x}^{t-1})_i + \mathbf{x}^{t-1 \top} \mathbf{A} \mathbf{y}^t \right)^2 \right) + O(\eta^3).
\end{aligned}$$

It is clear that as long as  $(\mathbf{x}^t, \mathbf{y}^t)$  (and thus  $(\mathbf{x}^{t-1}, \mathbf{y}^{t-1})$  by Lemma 11) is not  $O(\eta^{1/3})$ -close, from above inequalities/equalities we get

$$D_{KL}((\mathbf{x}^*, \mathbf{y}^*) || (\mathbf{x}^{t+1}, \mathbf{y}^{t+1})) - D_{KL}((\mathbf{x}^*, \mathbf{y}^*) || (\mathbf{x}^t, \mathbf{y}^t)) \leq -\Omega(\eta^3),$$

meaning that KL divergence decreases by at least a factor of  $\eta^3$  and the claim follows. ◀

► **Lemma 16.** *Let  $D$  be a real diagonal matrix with positive diagonal entries and  $S$  be a real skew-symmetric matrix ( $S^\top = -S$ ). It holds that  $SD$  has eigenvalues with real part zero (i.e., it has only imaginary eigenvalues).*

**Proof.** Let  $\mathbf{z}^*$  be the conjugate transpose of  $\mathbf{z}$  and  $\mathbf{z}^*$  be a left eigenvector of  $SD$  with complex eigenvalue  $\lambda$ . It holds that

$$\begin{aligned}
\lambda \mathbf{z}^* D^{-1} \mathbf{z} &= \mathbf{z}^* S D D^{-1} \mathbf{z} \\
&= \mathbf{z}^* S \mathbf{z} \\
&= -(\mathbf{z}^* S \mathbf{z})^* \text{ (since } S \text{ is skew symmetric)} \\
&= -(\lambda \mathbf{z}^* D^{-1} \mathbf{z})^* \text{ (using first and second equalities above)} \\
&= -\bar{\lambda} \mathbf{z}^* D^{-1} \mathbf{z}.
\end{aligned}$$

Since  $D$  has positive diagonal entries, we conclude that  $\mathbf{z}^* D^{-1} \mathbf{z} \neq 0$  (since  $\mathbf{z} \neq \mathbf{0}$ ), thus  $\lambda = -\bar{\lambda}$  and the claim follows. ◀

## Abstract

---

We study density estimation for classes of *shift-invariant* distributions over  $\mathbb{R}^d$ . A multidimensional distribution is “shift-invariant” if, roughly speaking, it is close in total variation distance to a small shift of it in any direction. Shift-invariance relaxes smoothness assumptions commonly used in non-parametric density estimation to allow jump discontinuities. The different classes of distributions that we consider correspond to different rates of tail decay.

For each such class we give an efficient algorithm that learns any distribution in the class from independent samples with respect to total variation distance. As a special case of our general result, we show that  $d$ -dimensional shift-invariant distributions which satisfy an exponential tail bound can be learned to total variation distance error  $\varepsilon$  using  $\tilde{O}_d(1/\varepsilon^{d+2})$  examples and  $\tilde{O}_d(1/\varepsilon^{2d+2})$  time. This implies that, for constant  $d$ , multivariate log-concave distributions can be learned in  $\tilde{O}_d(1/\varepsilon^{2d+2})$  time using  $\tilde{O}_d(1/\varepsilon^{d+2})$  samples, answering a question of [29]. All of our results extend to a model of *noise-tolerant* density estimation using Huber’s contamination model, in which the target distribution to be learned is a  $(1 - \varepsilon, \varepsilon)$  mixture of some unknown distribution in the class with some other arbitrary and unknown distribution, and the learning algorithm must output a hypothesis distribution with total variation distance error  $O(\varepsilon)$  from the target distribution. We show that our general results are close to best possible by proving a simple  $\Omega(1/\varepsilon^d)$  information-theoretic lower bound on sample complexity even for learning bounded distributions that are shift-invariant.

## 1 Introduction

In multidimensional density estimation, an algorithm has access to independent draws from an unknown target probability distribution over  $\mathbb{R}^d$ , which is typically assumed to belong to or be close to some class of “nice” distributions. The goal is to output a hypothesis distribution which with high probability is close to the target distribution. A number of different distance measures can be used to capture the notion of closeness; in this work we use the total variation distance (also known as the “statistical distance” and equivalent to the  $L_1$  distance). This is a well studied framework which has been investigated in detail, see e.g. the books [23, 24].

Multidimensional density estimation is typically attacked in one of two ways. In the first general approach a parameterized hypothesis class is chosen, and a setting of parameters is chosen based on the observed data points. This approach is justified given the belief that the parameterized class contains a good approximation to the distribution generating the data, or even that the parameterized class actually contains the target distribution. See [14, 33, 39] for some well-known multidimensional distribution learning results in this line.

In the second general approach a hypothesis distribution is constructed by “smoothing” the empirical distribution with a kernel function. This approach is justified by the belief that the target distribution satisfies some smoothness assumptions, and is more appropriate when studying distributions that do not have a parametric representation. The current paper falls within this second strand.

The most popular smoothness assumption is that the distribution has a density that belongs to a Sobolev space [42, 6, 30, 24]. The simplest Sobolev space used in this context corresponds to having a bound on the average of the partial first “weak derivatives” of the density; other Sobolev spaces correspond to bounding additional derivatives. A drawback of this approach is that it does not apply to distributions whose densities have jump discontinuities. Such jump discontinuities can arise in various applications, for example, when objects under analysis must satisfy hard constraints.

To address this, some authors have used the weaker assumption that the density belongs to a Besov space [7, 22, 38, 43, 3]. In the simplest case, this allows jump discontinuities as long as the function does not change very fast on average. The precise definition, which is quite technical (see [22]), makes reference to the effect on a distribution of shifting the domain by a small amount.

**The densities we consider.** In this paper we analyze a clean and simple smoothness assumption, which is a continuous analog of the notion of shift-invariance that has recently been used for analyzing the learnability of various types of discrete distributions [5, 16, 21]. The assumption is based on the *shift-invariance of  $f$  in direction  $v$  at scale  $\kappa$* , which, for a density  $f$  over  $\mathbb{R}^d$ , a unit vector  $v \in \mathbb{R}^d$ , and a positive real value  $\kappa$ , we define to be

$$\text{SI}(f, v, \kappa) \stackrel{\text{def}}{=} \frac{1}{\kappa} \cdot \sup_{\kappa' \in [0, \kappa]} \int_{\mathbb{R}^d} |f(x + \kappa'v) - f(x)| dx.$$

We define the quantity  $\text{SI}(f, \kappa)$  to be the worst case of  $\text{SI}(f, v, \kappa)$  over all directions  $v$ , i.e.  $\text{SI}(f, \kappa) \stackrel{\text{def}}{=} \sup_{v: \|v\|_2=1} \text{SI}(f, v, \kappa)$ . For any constant  $c$ , we define the class of densities  $\mathcal{C}_{\text{SI}}(c, d)$  to consist of all  $d$ -dimensional densities  $f$  with the property that  $\text{SI}(f, \kappa) \leq c$  for all  $\kappa > 0$ .

Our notion of shift-invariance provides a quantitative way of capturing the intuition that the density  $f$  changes gradually on average in every direction. Several natural classes fit nicely into this framework; for example, we note that  $d$ -dimensional standard normal distributions are easily shown to belong to  $\mathcal{C}_{\text{SI}}(1, d)$ . As another example, we will show later that any  $d$ -dimensional isotropic log-concave distribution belongs to  $\mathcal{C}_{\text{SI}}(O_d(1), d)$ .

Many distributions arising in practice have light tails, and distributions with light tails can in general be learned more efficiently. To analyze learning shift-invariant distributions in a manner that takes advantage of light tails when they are available, while accommodating heavier tails when necessary, we define classes with different combinations of shift-invariant and tail behavior. Given a nonincreasing function  $g : \mathbb{R}^+ \rightarrow [0, 1]$  which satisfies  $\lim_{t \rightarrow +\infty} g(t) = 0$ , we define the class of densities  $\mathcal{C}_{\text{SI}}(c, d, g)$  to consist of those  $f \in \mathcal{C}_{\text{SI}}(c, d)$  which have the additional property that for all  $t > 0$ , it holds that  $\Pr_{\mathbf{x} \leftarrow f} [\|\mathbf{x} - \mu\| > t] \leq g(t)$ , where  $\mu \in \mathbb{R}^d$  is the mean of the distribution  $f$ .

As motivation for its study, we feel that  $\mathcal{C}_{\text{SI}}(c, d, g)$  is a simple and easily understood class that exhibits an attractive tradeoff between expressiveness and tractability. As we show, it is broad enough to include distributions of central interest such as multidimensional isotropic log-concave distributions, but it is also limited enough to admit efficient density estimation algorithms.

**Our density estimation framework.** We recall the standard notion of density estimation with respect to total variation distance. Given a class  $\mathcal{C}$  of densities over  $\mathbb{R}^d$ , a density estimation algorithm for  $\mathcal{C}$  is given access to i.i.d. draws from  $f$ , where  $f \in \mathcal{C}$  is the unknown *target density* to be learned. For any  $f \in \mathcal{C}$ , given any parameter  $\varepsilon > 0$ , after making some number of draws depending on  $d$  and  $\varepsilon$  the density estimation algorithm must output a description of a hypothesis density  $h$  over  $\mathbb{R}^d$  which, with high probability over the draws from  $f$ , satisfies  $d_{\text{TV}}(f, h) \leq \varepsilon$ . It is of interest both to bound the *sample complexity* of such an algorithm (the number of draws from  $f$  that it makes) and its running time. In the full version of this paper [20], we show that our learning results can be extended to a challenging model of *noise-tolerant* density estimation for a class  $\mathcal{C}$ .

## 1.1 Results

Our main positive result is a general algorithm which efficiently learns any class  $\mathcal{C}_{\text{SI}}(c, d, g)$ . Given a constant  $c$  and a tail bound  $g$ , we show that any distribution in the class  $\mathcal{C}_{\text{SI}}(c, d, g)$  can be learned to any error  $O(\varepsilon)$  with a sample complexity that depends on  $c, g, \varepsilon$  and  $d$ . The running time of our algorithm is roughly quadratic in the sample complexity, and the sample complexity is  $O_{c,d,g}(1) \cdot (\frac{1}{\varepsilon})^{d+2}$  (see Theorem 12 in Section 4 for a precise statement of the exact bound). These bounds on the number of examples and running time do not depend on which member of  $\mathcal{C}_{\text{SI}}(c, d, g)$  is being learned.

**Application: Learning multivariate log-concave densities.** A multivariate density function  $f$  over  $\mathbb{R}^d$  is said to be *log-concave* if there is an upper semi-continuous concave function  $\phi : \mathbb{R}^d \rightarrow [-\infty, \infty)$  such that  $f(x) = e^{\phi(x)}$  for all  $x$ . Log-concave distributions arise in a range of contexts and have been well studied; see [11, 12, 3, 1, 9, 25] for work on density estimation of univariate (discrete and continuous) log-concave distributions. In the multivariate case, [35] gave a sample complexity lower bound (for squared Hellinger distance) which implies that  $\Omega(1/\varepsilon^{(d+1)/2})$  samples are needed to learn  $d$ -dimensional log-concave densities to error  $\varepsilon$ . More recently, [29] established the first finite sample complexity upper bound for multivariate log-concave densities, by giving an algorithm that learns any  $d$ -dimensional log-concave density using  $\tilde{O}_d(1/\varepsilon^{(d+5)/2})$  samples. The algorithm of [29] is not computationally efficient, and indeed, Diakonikolas et al. ask if there is an algorithm with running time polynomial in the sample complexity, referring to this as “a challenging and important open question.” A subsequent (and recent) work of Carpenter et al. [10] showed that the maximum likelihood estimator (MLE) is statistically efficient (i.e., achieves near optimal sample complexity).

We show that multivariate log-concave densities can be learned in polynomial time as a special case of our main algorithmic result. We establish that any  $d$ -dimensional near-isotropic log-concave density is  $O_d(1)$ -shift-invariant. Together with well-known tail bounds on  $d$ -dimensional log-concave densities, this easily yields that any  $d$ -dimensional near-isotropic log-concave density belongs to  $\mathcal{C}_{\text{SI}}(c, d, g)$  where the tail bound function  $g$  is inverse exponential. Theorem 12 then immediately gives a  $\tilde{O}_d(1/\varepsilon^{2d+2})$ -time algorithm for learning near-isotropic log-concave densities. Adding a preprocessing step to reduce to the near-isotropic case yields an algorithm that works for all log-concave densities.

While our sample complexity is quadratically larger than the optimal sample complexity for learning log-concave distributions (from [29]), such *computational-statistical* tradeoffs are in fact quite common (see, for example, the work of [8] which gives a faster algorithm for learning Gaussian mixture models by using more samples).

**A lower bound.** We also prove a simple lower bound, showing that any algorithm that learns shift-invariant  $d$ -dimensional densities with bounded support to error  $\varepsilon$  must use  $\Omega(1/\varepsilon^d)$  examples. These densities may be thought of as satisfying the strongest possible rate of tail decay as they have zero tail mass outside of a bounded region (corresponding to  $g(t) = 0$  for  $t$  larger than some absolute constant). This lower bound shows that a sample complexity of at least  $1/\varepsilon^d$  is necessary even for very structured special cases of our multivariate density estimation problem.

## 1.2 Our approach

For simplicity, and because it is a key component of our general algorithm, we first describe how our algorithm learns an  $\varepsilon$ -error hypothesis when the target distribution belongs to  $\mathcal{C}_{\text{SI}}(c, d)$  and also has *bounded support*: all its mass is on points in the origin-centered ball of radius  $1/2$ .

In this special case, analyzed in Section 3, our algorithm has two conceptual stages. First, we smooth the density that we are to learn through convolution – this is done in a simple way by randomly perturbing each draw. This convolution uses a kernel that damps the contributions to the density coming from high-frequency functions in its Fourier decomposition; intuitively, the shift-invariance of the target density ensures that the convolved density (which is an average over small shifts of the original density) is close to the original density. In the second conceptual stage, the algorithm approximates relatively few Fourier coefficients of the smoothed density. We show that an inverse Fourier transformation using this approximation still provides an accurate approximation to the target density.<sup>3</sup>

Next, in Section 4, we consider the more general case in which the target distribution belongs to the class  $\mathcal{C}_{\text{SI}}(c, d, g)$ . Here the high-level idea of our approach is very straightforward: it is essentially to reduce to the simpler special case (of bounded support and good shift-invariance in every direction) described above. (A crucial aspect of this transformation algorithm is that it uses only a small number of draws from the original shift-invariant distribution; we return to this point below.) We can then use the algorithm for the special case to obtain a high-accuracy hypothesis, and perform the inverse transformation to obtain

---

<sup>3</sup> We note that a simpler version of this approach, which only uses a smoothing kernel and does not employ Fourier analysis, can be shown to give a similar, but quantitatively worse, results, such as a sample complexity of essentially  $1/\varepsilon^{2d}$  when  $g(t)$  is zero outside of a bounded region. However, this is worse than the lower bound of  $\Omega(1/\varepsilon^d)$  by a quadratic factor, whereas our algorithm essentially achieves this optimal sample complexity.

a high-accuracy hypothesis for the original general distribution. We remark that while the conceptual idea is thus very straightforward, there are a number of technical challenges that must be met to implement this approach. One of these is that it is necessary to truncate the tails of the original distribution so that an affine transformation of it will have bounded support, and doing this changes the shift-invariance of the original distribution. Another is that the transformation procedure only succeeds with non-negligible probability, so we must run this overall approach multiple times and perform hypothesis selection to actually end up with a single high-accuracy hypothesis.

In Section 5 we apply the above results to establish efficient learnability of log-concave densities over  $\mathbb{R}^d$ . To apply our results, we need to have (i) bounds on the rate of tail decay, and (ii) shift-invariance bounds. As noted earlier, exponential tail bounds on  $d$ -dimensional log-concave densities are well known, so it remains to establish shift-invariance. Using basic properties of log-concave densities, in Section 5 we show that any  $d$ -dimensional isotropic log-concave density is  $O_d(1)$ -shift-invariant. Armed with this bound, by applying our learning result (Theorem 12) we get that any  $d$ -dimensional isotropic log-concave density can be learned in time  $\tilde{O}_d(1/\varepsilon^{2d+2})$ , using  $\tilde{O}_d(1/\varepsilon^{d+2})$  samples. Log-concave distributions are shift-invariant even if they are only approximately isotropic. We show that general log-concave distributions may be learned by bringing them into approximately isotropic position with a preprocessing step, borrowing techniques from [37].

### 1.3 Related work

The most closely related work that we are aware of was mentioned above: Holmström and Klemelä [30] obtained bounds similar to ours for using kernel methods to learn densities that belong to various Sobolev spaces. As mentioned above, these results do not directly apply for learning densities in  $\mathcal{C}_{\text{SI}}(c, d, g)$  because of the possibility of jump discontinuities. Holmström and Klemelä also proved a lower bound on the sample complexity of algorithms that compute kernel density estimates. In contrast our lower bound holds for any density estimation algorithm, kernel-based or otherwise.

The assumption that the target density belongs to a Besov space (see [36]) makes reference to the effect of shifts on the distribution, as does shift-invariance. We do not see any obvious containments between classes of functions defined through shift-invariance and Besov spaces, but this is a potential topic for further research.

Another difference with prior work is the ability of our approach to succeed in the challenging noise-tolerant learning model. We are not aware of analyses for density estimation of densities belonging to Sobolev or Besov spaces that extend to the noise-tolerant setting in which the target density is only assumed to be close to some density in the relevant class.

As mentioned above, shift-invariance was used in the analysis of algorithms for learning discrete probability distributions in [5, 16]. Likewise, both the discrete and continuous Fourier transforms have been used in the past to learn discrete probability distributions [26, 27, 15].

## 2 Preliminaries

We write  $B(r)$  to denote the radius- $r$  ball in  $\mathbb{R}^d$ , i.e.  $B(r) = \{x \in \mathbb{R}^d : x_1^2 + \dots + x_d^2 \leq r^2\}$ . If  $f$  is a probability density over  $\mathbb{R}^d$  and  $S \subset \mathbb{R}^d$  is a subset of its domain, we write  $f_S$  to denote the density of  $f$  conditioned on  $S$ .

## 2.1 Shift-invariance

Roughly speaking, the shift-invariance of a distribution measures how much it changes (in total variation distance) when it is subjected to a small translation. The notion of shift-invariance has typically been used for discrete distributions (especially in the context of proving discrete limit theorems, see e.g. [13] and many references therein). We give a natural continuous analogue of this notion below.

► **Definition 1.** Given a probability density  $f$  over  $\mathbb{R}^d$ , a unit vector  $v$ , and a positive real value  $\kappa$ , we say that the *shift-invariance of  $f$  in direction  $v$  at scale  $\kappa$* , denoted  $\text{SI}(f, v, \kappa)$ , is

$$\text{SI}(f, v, \kappa) \stackrel{\text{def}}{=} \frac{1}{\kappa} \cdot \sup_{\kappa' \in [0, \kappa]} \int_{\mathbb{R}^d} |f(x + \kappa'v) - f(x)| dx. \quad (1)$$

Intuitively, if  $\text{SI}(f, v, \kappa) = \beta$ , then for any direction (unit vector)  $v$  the variation distance between  $f$  and a shift of  $f$  by  $\kappa'$  in direction  $v$  is at most  $\kappa\beta$  for all  $0 \leq \kappa' \leq \kappa$ . The factor  $\frac{1}{\kappa}$  in the definition means that  $\text{SI}(f, v, \kappa)$  does not necessarily go to zero as  $\kappa$  gets small; the effect of shifting by  $\kappa$  is measured relative to  $\kappa$ .

Let  $\text{SI}(f, \kappa) \stackrel{\text{def}}{=} \sup\{\text{SI}(f, v, \kappa) : v \in \mathbb{R}^d, \|v\|_2 = 1\}$ . For any constant  $c$  we define the class of densities  $\mathcal{C}_{\text{SI}}(c, d)$  to consist of all  $d$ -dimensional densities  $f$  with the property that  $\text{SI}(f, \kappa) \leq c$  for all  $\kappa > 0$ .

We could obtain an equivalent definition if we removed the factor  $\frac{1}{\kappa}$  from the definition of  $\text{SI}(f, v, \kappa)$ , and required that  $\text{SI}(f, v, \kappa) \leq c\kappa$  for all  $\kappa > 0$ . This could of course be generalized to enforce bounds on the modified  $\text{SI}(f, v, \kappa)$  that are not linear in  $\kappa$ . We have chosen to focus on linear bounds in this paper to have cleaner theorems and proofs.

We include “sup” in the definition due to the fact that smaller shifts can sometimes have bigger effects. For example, a sinusoid with period  $\xi$  is unaffected by a shift of size  $\xi$ , but profoundly affected by a shift of size  $\xi/2$ . Because of possibilities like this, to capture the intuitive notion that “small shifts do not lead to large changes”, we seem to need to evaluate the worst case over shifts of at most a certain size.

As described earlier, given a nonincreasing “tail bound” function  $g : \mathbb{R}^+ \rightarrow (0, 1)$  which is absolutely continuous and satisfies  $\lim_{t \rightarrow +\infty} g(t) = 0$ , we further define the class of densities  $\mathcal{C}_{\text{SI}}(c, d, g)$  to consist of those  $f \in \mathcal{C}_{\text{SI}}(c, d)$  which have the additional property that  $f$  has  *$g$ -light tails*, meaning that for all  $t > 0$ , it holds that  $\mathbf{Pr}_{\mathbf{x} \leftarrow f} [\|\mathbf{x} - \mu\| > t] \leq g(t)$ , where  $\mu \in \mathbb{R}^d$  is the mean of  $f$ .

► **Remark.** It will be convenient in our analysis to consider only tail bound functions  $g$  that satisfy  $\min\{r \in \mathbb{R} : g(r) \leq 1/2\} \geq 1/10$  (the constants  $1/2$  and  $1/10$  are arbitrary here and could be replaced by any other absolute positive constants). This is without loss of generality, since any tail bound function  $g$  which does not meet this criterion can simply be replaced by a weaker tail bound function  $g^*$  which does meet this criterion, and clearly if  $f$  has  $g$ -light tails then  $f$  also has  $g^*$ -light tails.

We will (ab)use the notation  $g^{-1}(\varepsilon)$  to mean  $\inf\{t : g(t) \leq \varepsilon\}$ .

The complexity of learning with a tail bound  $g$  will be expressed in part using  $I_g \stackrel{\text{def}}{=} \int_0^\infty g(\sqrt{z}) dz$ . We remark that the quantity  $I_g$  is the “right” quantity in the sense that the integral  $I_g$  is finite as long as the density has “non-trivial decay”. More precisely, note that by Chebyshev’s inequality,  $g(\sqrt{z}) = O(z^{-1})$ . Since the integral  $\int O(z^{-1}) dz$  diverges, this means that if  $I_g$  is finite, then the density  $f$  has a decay sharper than the trivial decay implied by Chebyshev’s inequality.

## 2.2 Fourier transform of high-dimensional distributions

In this subsection we gather some helpful facts from multidimensional Fourier analysis.

While it is possible to do Fourier analysis over  $\mathbb{R}^d$ , in this paper, we will only do Fourier analysis for functions  $f \in L_1([-1, 1]^d)$ .

► **Definition 2.** For any function  $f \in L_1([-1, 1]^d)$ , we define  $\widehat{f} : \mathbb{R}^d \rightarrow \mathbb{C}$  by  $\widehat{f}(\xi) = \int_{x \in \mathbb{R}^d} f(x) \cdot e^{\pi i \cdot \langle \xi, x \rangle} dx$ .

Next, we recall the following standard claims about Fourier transforms of functions, which may be found, for example, in [41].

► **Claim 3.** For  $f, g \in L_1([-1, 1]^d)$  let  $h(x) = \int_{y \in \mathbb{R}^d} f(y) \cdot g(x - y) dy$  denote the convolution  $h = f * g$  of  $f$  and  $g$ . Then for any  $\xi \in \mathbb{R}^d$ , we have  $\widehat{h}(\xi) = \widehat{f}(\xi) \cdot \widehat{g}(\xi)$ .

Next, we recall Parseval's identity on the cube.

► **Claim 4 (Parseval's identity).** For  $f : [-1, 1]^d \rightarrow \mathbb{R}$  such that  $f \in L_2([-1, 1]^d)$ , it holds that  $\int_{[-1, 1]^d} f(x)^2 dx = \frac{1}{2^d} \cdot \sum_{\xi \in \mathbb{Z}^d} |\widehat{f}(\xi)|^2$ .

The next claim says that the Fourier inversion formula can be applied to any sequence in  $\ell_2(\mathbb{Z}^d)$  to obtain a function whose Fourier series is identical to the given sequence.

► **Claim 5 (Fourier inversion formula).** For any  $g : \mathbb{Z}^d \rightarrow \mathbb{C}$  such that  $\sum_{\xi \in \mathbb{Z}^d} |g(\xi)|^2 < \infty$ , the function  $h(x) = \sum_{\xi \in \mathbb{Z}^d} \frac{1}{2^d} \cdot g(\xi) \cdot e^{\pi i \cdot \langle \xi, x \rangle}$ , is well defined and satisfies  $\widehat{h}(\xi) = g(\xi)$  for all  $\xi \in \mathbb{Z}^d$ .

We will also use Young's inequality:

► **Claim 6 (Young's inequality).** Let  $f \in L_p([-1, 1]^d)$ ,  $g \in L_q([-1, 1]^d)$ ,  $1 \leq p, q, r \leq \infty$ , such that  $1 + 1/r = 1/p + 1/q$ . Then  $\|f * g\|_r \leq \|f\|_p \cdot \|g\|_q$ .

## 2.3 A useful mollifier

Our algorithm and its analysis require the existence of a compactly supported distribution with fast decaying Fourier transform. Since the precise rate of decay is not very important, we use the  $C^\infty$  function  $b : [-1, 1] \rightarrow \mathbb{R}^+$  as follows:

$$b(x) = \begin{cases} c_0 \cdot e^{-\frac{x^2}{1-x^2}} & \text{if } |x| < 1 \\ 0 & \text{if } |x| = 1. \end{cases} \quad (2)$$

Here  $c_0 \approx 1.067$  is chosen so that  $b$  is a pdf; by symmetry, its mean is 0. (This function has previously been used as a mollifier [34, 28].) The following fact can be found in [32] (while it is proved only for  $\xi \in \mathbb{Z}$ , it is easy to see that the same proof holds if  $\xi \in \mathbb{R}$ ).

► **Fact 7.** For  $b : [-1, 1] \rightarrow \mathbb{R}^+$  defined in (2) and  $\xi \in \mathbb{Z} \setminus \{0\}$ , we have that  $|\widehat{b}(\xi)| \leq e^{-\sqrt{|\xi|}} \cdot |\xi|^{-3/4}$ .

Let us now define the function  $b_{d,\gamma} : \mathbb{R}^d \rightarrow \mathbb{R}^+$  as  $b_{d,\gamma}(x_1, \dots, x_d) = \frac{1}{\gamma^d} \cdot \prod_{j=1}^d b(x_j/\gamma)$ . Combining this definition and Fact 7, we have the following claim:

► **Claim 8.** For  $\xi \in \mathbb{Z}^d$  with  $\|\xi\|_\infty \geq t$ , we have  $|\widehat{b_{d,\gamma}}(\xi)| \leq e^{-\sqrt{\gamma \cdot t}} \cdot (\gamma \cdot t)^{-3/4}$ .

The next fact is immediate from (2) and the definition of  $b_{d,\gamma}$ :

► **Fact 9.**  $\|b_{d,\gamma}\|_\infty = (c_0/\gamma)^d$  and as a consequence,  $\|b_{d,\gamma}\|_2^2 \leq (c_0/\gamma)^{2d}$ .

### 3 A restricted problem: learning shift-invariant distributions with bounded support

As sketched in Section 1.2, we begin by presenting and analyzing a density estimation algorithm for densities that, in addition to being shift-invariant, have support bounded in  $B(1/2)$ . Our analysis also captures the fact that, to achieve accuracy  $\varepsilon$ , an algorithm often only needs the density to be learned to have shift invariance at a scale slightly finer than  $\varepsilon$ .

► **Lemma 10.** *There is an algorithm learn-bounded with the following property: For all constant  $d$ , for all  $\varepsilon, \delta > 0$ , all  $0 < \kappa < \varepsilon < 1/2$ , and all  $d$ -dimensional densities  $f$  with support in  $B(1/2)$  such that  $\kappa\text{SI}(f, \kappa) \leq \varepsilon/2$ , given access to independent draws from  $f$ , the algorithm runs in  $O_d\left(\frac{1}{\varepsilon^2} \left(\frac{1}{\kappa}\right)^{2d} \log^{4d}\left(\frac{1}{\kappa}\right) \log\left(\frac{1}{\kappa\delta}\right)\right)$  time uses  $O_d\left(\frac{1}{\varepsilon^2} \left(\frac{1}{\kappa}\right)^d \log^{2d}\left(\frac{1}{\kappa}\right) \log\left(\frac{1}{\kappa\delta}\right)\right)$  samples, and with probability  $1 - \delta$ , outputs a hypothesis  $h : [-1, 1]^d \rightarrow \mathbb{R}^+$  such that  $\int_{x \in \mathbb{R}^d} |f(x) - h(x)| \leq \varepsilon$ .*

*Further, given any point  $z \in [-1, 1]^d$ ,  $h(z)$  can be computed in time  $O_d\left(\frac{\log^{2d}(1/\kappa)}{\kappa^d}\right)$  and satisfies  $h(z) \leq O_d\left(\frac{\log^{2d}(1/\kappa)}{\kappa^d}\right)$ .*

**Proof.** Let  $0 < \gamma := \frac{\kappa}{\sqrt{d}}$ , and let us define  $q = f * b_{d,\gamma}$ . (Here  $*$  denotes convolution and  $b_{d,\gamma}$  is the mollifier defined in Section 2.3.) We make a few simple observations about  $q$ :

- (i) Since  $\gamma \leq 1/2$ , we have that  $q$  is a density supported on  $B(1)$ .
- (ii) Since  $d$  is a constant, a draw from  $b_{d,\gamma}$  can be generated in constant time. Thus given a draw from  $f$ , one can generate a draw from  $q$  in constant time, simply by generating a draw from  $b_{d,\gamma}$  and adding it to the draw from  $f$ .
- (iii) By Young's inequality (Claim 6), we have that  $\|q\|_2 \leq \|f\|_1 \cdot \|b_{d,\gamma}\|_2$ . Noting that  $f$  is a density and thus  $\|f\|_1 = 1$  and applying Fact 9, we obtain that  $\|q\|_2$  is finite. As a consequence, the Fourier coefficients of  $q$  are well-defined.

**Preliminary analysis.** We first observe that because  $b_{d,\gamma}$  is supported on  $[-\gamma, \gamma]^d$ , the distribution  $q$  may be viewed as an average of different shifts of  $f$  where each shift is by a distance at most  $\gamma\sqrt{d} \leq \kappa$ . Fix any direction  $v$  and consider a shift of  $f$  in direction  $v$  by some distance at most  $\gamma\sqrt{d} \leq \kappa$ . Since  $\kappa\text{SI}(f, \kappa) \leq \varepsilon/2$ , we have that the variation distance between  $f$  and this shift in direction  $v$  is at most  $\varepsilon/2$ . Averaging over all such shifts, it follows that  $d_{\text{TV}}(q, f) \leq \varepsilon/2$ .

Next, we observe that by Claim 3, for any  $\xi \in \mathbb{Z}^d$ , we have  $\widehat{q}(\xi) = \widehat{f}(\xi) \cdot \widehat{b_{d,\gamma}}(\xi)$ . Since  $f$  is a pdf,  $|\widehat{f}(\xi)| \leq 1$ , and thus we have  $|\widehat{q}(\xi)| \leq |\widehat{b_{d,\gamma}}(\xi)|$ . Also, for any parameter  $k \in \mathbb{Z}^+$ , define  $C_k = \{\xi \in \mathbb{Z}^d : \|\xi\|_\infty = k\}$ . Let us fix another parameter  $T$  (to be determined later). Applying Claim 8, we obtain

$$\begin{aligned} \sum_{\xi: \|\xi\|_\infty > T} |\widehat{q}(\xi)|^2 &\leq \sum_{\xi: \|\xi\|_\infty > T} |\widehat{b_{d,\gamma}}(\xi)|^2 \leq \sum_{k > T} \sum_{\xi: \|\xi\|_\infty = k} |\widehat{b_{d,\gamma}}(\xi)|^2 \\ &\leq \sum_{k > T} |C_k| \cdot e^{-2\sqrt{\gamma \cdot k}} \cdot (\gamma \cdot k)^{-3/2} \leq \sum_{k > T} (2k+1)^d \cdot e^{-2\sqrt{\gamma \cdot k}} \cdot (\gamma \cdot k)^{-3/2}. \end{aligned}$$

An easy calculation shows that if  $T \geq \frac{4d^2}{\gamma} \cdot \ln^2\left(\frac{d}{\gamma}\right)$ , then  $\sum_{\xi: \|\xi\|_\infty > T} |\widehat{q}(\xi)|^2 \leq 2(2T+1)^d \cdot e^{-2\sqrt{\gamma \cdot T}} \cdot (\gamma \cdot T)^{-3/2}$ . If we now set  $T$  to be  $\frac{4d^2}{\gamma} \cdot \ln^2\left(\frac{d}{\gamma}\right) + \frac{1}{\gamma} \cdot \ln^2\left(\frac{8}{\varepsilon}\right)$ , then  $\sum_{\xi: \|\xi\|_\infty > T} |\widehat{q}(\xi)|^2 \leq \frac{\varepsilon^2}{8}$ .

**The algorithm.** We first observe that for any  $\xi \in \mathbb{Z}^d$ , the Fourier coefficient  $\widehat{q}(\xi)$  can be estimated to good accuracy using relatively few draws from  $q$  (and hence from  $f$ , recalling (ii) above). More precisely, as an easy consequence of the definition of the Fourier transform, we have:

► **Observation 11.** *For any  $\xi \in \mathbb{Z}^d$ , the Fourier coefficient  $\widehat{q}(\xi)$  can be estimated to within additive error of magnitude at most  $\eta$  with confidence  $1 - \beta$  using  $O(1/\eta^2 \cdot \log(1/\beta))$  draws from  $q$ .*

Let us define the set **Low** of low-degree Fourier coefficients as  $\text{Low} = \{\xi \in \mathbb{Z}^d : \|\xi\|_\infty \leq T\}$ . Thus,  $|\text{Low}| \leq (2T+1)^d$ . Thus, using  $S = O(\eta^{-2} \cdot \log(T/\delta))$  draws from  $f$ , by Observation 11, with probability  $1 - \delta$ , we can compute a set of values  $\{\widehat{u}(\xi)\}_{\xi \in \text{Low}}$  such that

$$\text{For all } \xi \in \text{Low}, |\widehat{u}(\xi) - \widehat{q}(\xi)| \leq \eta. \quad (3)$$

Recalling (ii), the sequence  $\{\widehat{u}(\xi)\}_{\xi \in \text{Low}}$  can be computed in  $O(|S| \cdot |\text{Low}|)$  time. Define  $\widehat{u}(\xi) = 0$  for  $\xi \in \mathbb{Z}^d \setminus \text{Low}$ . Combining (3) with this, we get

$$\begin{aligned} \sum_{\xi \in \mathbb{Z}^d} |\widehat{u}(\xi) - \widehat{q}(\xi)|^2 &\leq \sum_{\xi \in \text{Low}} |\widehat{u}(\xi) - \widehat{q}(\xi)|^2 + \sum_{\xi \notin \text{Low}} |\widehat{u}(\xi) - \widehat{q}(\xi)|^2 \\ &\leq \sum_{\xi \in \text{Low}} |\widehat{u}(\xi) - \widehat{q}(\xi)|^2 + \frac{\varepsilon^2}{8} |\text{Low}| \cdot \eta^2 + \frac{\varepsilon^2}{8} \leq (2T+1)^d \cdot \eta^2 + \frac{\varepsilon^2}{8}. \end{aligned}$$

Thus, setting  $\eta$  as  $\eta^2 = (2T+1)^{-d} \cdot \frac{\varepsilon^2}{8}$ , we get that  $\sum_{\xi \in \mathbb{Z}^d} |\widehat{u}(\xi) - \widehat{q}(\xi)|^2 \leq \frac{\varepsilon^2}{4}$ . Note that by definition  $\widehat{u} : \mathbb{Z}^d \rightarrow \mathbb{C}$  satisfies  $\sum_{\xi \in \mathbb{Z}^d} |\widehat{u}(\xi)|^2 < \infty$ . Thus, we can apply the Fourier inversion formula (Claim 5) to obtain a function  $u : [-1, 1]^d \rightarrow \mathbb{C}$  such that

$$\int_{[-1, 1]^d} |u(x) - q(x)|^2 dx = \frac{1}{2^d} \cdot \left( \sum_{\xi \in \mathbb{Z}^d} |\widehat{u}(\xi) - \widehat{q}(\xi)|^2 \right) \leq \frac{\varepsilon^2}{4 \cdot 2^d}, \quad (4)$$

where the first equality follows by Parseval's identity (Claim 4). By the Cauchy-Schwarz inequality,  $\int_{[-1, 1]^d} |u(x) - q(x)| dx \leq \sqrt{2^d} \cdot \sqrt{\int_{[-1, 1]^d} |u(x) - q(x)|^2 dx}$ . Plugging in (4), we obtain  $\int_{[-1, 1]^d} |u(x) - q(x)| dx \leq \frac{\varepsilon}{2}$ . Let us finally define  $h$  (our final hypothesis),  $h : [-1, 1]^d \rightarrow \mathbb{R}^+$ , as follows:  $h(x) = \max\{0, \text{Re}(u(x))\}$ . Note that since  $q(x)$  is a non-negative real value for all  $x$ , we have

$$\int_{[-1, 1]^d} |h(x) - q(x)| dx \leq \int_{[-1, 1]^d} |u(x) - q(x)| dx \leq \frac{\varepsilon}{2}. \quad (5)$$

Finally, recalling that we previously proved  $d_{\text{TV}}(f, q) \leq \frac{\varepsilon}{2}$ , it follows that  $\int_{[-1, 1]^d} |h(x) - f(x)| dx \leq \varepsilon$ .

**Complexity analysis.** We now analyze the time and sample complexity of this algorithm as well as the complexity of computing  $h$ . First of all, observe that plugging in the value of  $\gamma$  and recalling that  $d$  is a constant, we get that  $T = \frac{4d^2}{\gamma} \cdot \ln^2\left(\frac{d}{\gamma}\right) + \frac{1}{\gamma} \cdot \ln^2\left(\frac{8}{\varepsilon}\right) = O\left(\frac{\log^2(1/\kappa)}{\kappa}\right)$ . Combining this with the choice of  $\eta$  we get that the algorithm uses

$$\begin{aligned} S &= O\left(\frac{1}{\eta^2} \cdot \log\left(\frac{|\text{Low}|}{\delta}\right)\right) = O\left(\frac{1}{\eta^2} \cdot \log\left(\frac{T}{\delta}\right)\right) = O\left(\frac{(2T+1)^d \cdot \log\left(\frac{T}{\delta}\right)}{\varepsilon^2}\right) \\ &= O_d\left(\frac{1}{\varepsilon^2} \left(\frac{1}{\kappa}\right)^d \log^{2d}\left(\frac{1}{\kappa}\right) \log\left(\frac{1}{\kappa\delta}\right)\right) \end{aligned}$$

draws from  $p$ . Next, as we have noted before, computing the sequence  $\{\widehat{u}(\xi)\}$  takes time

$$\begin{aligned} O(S \cdot |\text{Low}|) &= O_d\left(\frac{1}{\varepsilon^2} \left(\frac{1}{\kappa}\right)^d \log^{2d}\left(\frac{1}{\kappa}\right) \log\left(\frac{1}{\kappa\delta}\right) T^d\right) \\ &= O_d\left(\frac{1}{\varepsilon^2} \left(\frac{1}{\kappa}\right)^{2d} \log^{4d}\left(\frac{1}{\kappa}\right) \log\left(\frac{1}{\kappa\delta}\right)\right). \end{aligned}$$

To compute the function  $u$  (and hence  $h$ ) at any point  $x \in [-1, 1]^d$  takes time  $O(|\text{Low}|) = O_d\left(\frac{\log^{2d}(1/\kappa)}{\kappa^d}\right)$ . This is because the Fourier inversion formula (Claim 5) has at most  $O(|\text{Low}|)$  non-zero terms.

Finally, we prove the upper bound on  $h$ . If the training examples are  $x_1, \dots, x_S$ , then for any  $z \in [-1, 1]^d$ , we have

$$\begin{aligned} h(z) &\leq |u(z)| = \left| \sum_{\xi \in \text{Low}} \frac{1}{2^d} \cdot \widehat{u}(\xi) \cdot e^{\pi i \cdot \langle \xi, z \rangle} \right| = \left| \sum_{\xi \in \text{Low}} \frac{1}{2^d} \cdot \left( \frac{1}{S} \sum_{t=1}^S e^{\pi i \cdot \langle \xi, x_t \rangle} \right) \cdot e^{\pi i \cdot \langle \xi, z \rangle} \right| \\ &\leq \frac{|\text{Low}|}{2^d} = O_d\left(\frac{\log^{2d}(1/\kappa)}{\kappa^d}\right), \end{aligned}$$

completing the proof.  $\blacktriangleleft$

#### 4 Density estimation for densities in $\mathcal{C}_{\text{SI}}(c, d, g)$

Fix any nonincreasing tail bound function  $g : \mathbb{R}^+ \rightarrow [0, 1]$  which satisfies  $\lim_{t \rightarrow +\infty} g(t) = 0$  and  $\min\{r \in \mathbb{R} : g(r) \leq 1/2\} \geq 1/10$  and any constant  $c \geq 1$ . In this section we prove the following theorem which gives a density estimation algorithm for the class of distributions  $\mathcal{C}_{\text{SI}}(c, d, g)$ :

► **Theorem 12.** *For any  $c, g$  as above and any  $d \geq 1$ , there is an algorithm with the following property: Let  $f$  be any target density (unknown to the algorithm) which belongs to  $\mathcal{C}_{\text{SI}}(c, d, g)$ . Given any error parameter  $0 < \varepsilon < 1/2$  and confidence parameter  $\delta > 0$  and access to independent draws from  $f$ , the algorithm with probability  $1 - O(\delta)$  outputs a hypothesis  $h : [-1, 1]^d \rightarrow \mathbb{R}^{\geq 0}$  such that  $\int_{x \in \mathbb{R}^d} |f(x) - h(x)| \leq O(\varepsilon)$ .*

*The algorithm runs in  $O_{c,d}\left(\left((g^{-1}(\varepsilon))^{2d} \left(\frac{1}{\varepsilon}\right)^{2d+2} \log^{4d}\left(\frac{g^{-1}(\varepsilon)}{\varepsilon}\right) \log\left(\frac{g^{-1}(\varepsilon)}{\varepsilon\delta}\right) + I_g\right) \log \frac{1}{\delta}\right)$  time and uses  $O_{c,d}\left(\left((g^{-1}(\varepsilon))^d \left(\frac{1}{\varepsilon}\right)^{d+2} \log^{2d}\left(\frac{g^{-1}(\varepsilon)}{\varepsilon}\right) \log\left(\frac{g^{-1}(\varepsilon)}{\varepsilon\delta}\right) + I_g\right) \log \frac{1}{\delta}\right)$  samples.*

##### 4.1 Outline of the proof

Theorem 12 is proved by a reduction to Lemma 10. The main ingredient in the proof of Theorem 12 is a “transformation algorithm” with the following property: given as input access to i.i.d. draws from any density  $f \in \mathcal{C}_{\text{SI}}(c, d, g)$ , the algorithm constructs parameters which enable draws from the density  $f$  to be transformed into draws from another density, which we denote  $r$ . The density  $r$  is obtained by approximating  $f$  after conditioning on a non-tail sample, and scaling the result so that it lies in a ball of radius  $1/2$ .

Given such a transformation algorithm, the approach to learn  $f$  is clear: we first run the transformation algorithm to get access to draws from the transformed distribution  $r$ . We then use draws from  $r$  to run the algorithm of Lemma 10 to learn  $r$  to high accuracy. (Intuitively, the error relative to  $f$  of the final hypothesis density is  $O(\varepsilon)$  because at most

$O(\varepsilon)$  comes from the conditioning and at most  $O(\varepsilon)$  from the algorithm of Lemma 10.) We note that while this high-level approach is conceptually straightforward, a number of technical complications arise; for example, our transformation algorithm only succeeds with some non-negligible probability, so we must run the above-described combined procedure multiple times and perform hypothesis testing to identify a successful final hypothesis from the resulting pool of candidates.

The rest of this section is organized as follows: In Section 4.2 we give various necessary technical ingredients for our transformation algorithm. We state and prove the key results about the transformation algorithm in Section 4.3, and we use the transformation algorithm to prove Theorem 12 in Section 4.4.

## 4.2 Technical ingredients for the transformation algorithm

As sketched earlier, our approach will work with a density obtained by conditioning  $f \in \text{SI}(c, d)$  on lying in a certain ball that has mass close to 1 under  $f$ . While we know that the original density  $f \in \text{SI}(c, d)$  has good shift-invariance, we will further need the conditioned distribution to also have good shift-invariance in order for the learn-bounded algorithm of Section 3 to work. Thus we require the following simple lemma, which shows that conditioning a density  $f \in \text{SI}(c, d)$  on a region of large probability cannot hurt its shift invariance too much.

► **Lemma 13.** *Let  $f \in \text{SI}(c, d)$  and let  $B$  be a ball such that  $\Pr_{\mathbf{x} \sim f}[\mathbf{x} \in B] \geq 1 - \delta$  where  $\delta < 1/2$ . If  $f_B$  is the density of  $f$  conditioned on  $B$ , then, for all  $\kappa > 0$ ,  $\text{SI}(f_B, \kappa) \leq \frac{4\delta}{\kappa} + 2c$ .*

**Proof.** Let  $v$  be any unit vector in  $\mathbb{R}^d$ . Note that  $f$  can be expressed as  $(1 - \delta)f_B + \delta \cdot f_{err}$  where  $f_{err}$  is some other density. As a consequence, for any  $\kappa > 0$ , using the triangle inequality we have that

$$\int_{\mathbf{x}} |f(\mathbf{x}) - f(\mathbf{x} + \kappa v)| d\mathbf{x} \geq (1 - \delta) \int_{\mathbf{x}} |f_B(\mathbf{x}) - f_B(\mathbf{x} + \kappa v)| d\mathbf{x} - \delta \int_{\mathbf{x}} |f_{err}(\mathbf{x}) - f_{err}(\mathbf{x} + \kappa v)| d\mathbf{x}.$$

Since  $f \in \mathcal{C}_{\text{SI}}(c, d)$  the left hand side is at most  $c\kappa$ , whereas the subtrahend on the right hand side is trivially at most  $2\delta$ . Thus, we get  $\int_{\mathbf{x}} |f_B(\mathbf{x}) - f_B(\mathbf{x} + \kappa v)| d\mathbf{x} \leq \frac{2\delta}{1-\delta} + \frac{c\kappa}{1-\delta}$ , completing the proof. ◀

If  $f$  is an unknown target density then of course its mean is also unknown, and thus we will need to approximate it using draws from  $f$ . To do this, it will be helpful to convert our condition on the tails of  $f$  to bound the variance of  $\|\mathbf{x} - \mu\|$ , where  $\mathbf{x} \sim f$ .

► **Lemma 14.** *For any  $f \in \mathcal{C}_{\text{SI}}(c, d, g)$ , we have  $\mathbf{E}_{\mathbf{x} \sim f}[\|\mathbf{x} - \mu\|^2] \leq I_g$ .*

**Proof.** We have  $\mathbf{E}_{\mathbf{x} \sim f}[\|\mathbf{x} - \mu\|^2] = \int_0^\infty \Pr_{\mathbf{x} \sim f}[\|\mathbf{x} - \mu\|^2 \geq z] dz \leq \int_0^\infty g(\sqrt{z}) dz = I_g$ . ◀

The following easy proposition gives a guarantee on the quality of the empirical mean:

► **Lemma 15.** *For any  $f \in \mathcal{C}_{\text{SI}}(c, d, g)$ , if  $\mu \in \mathbb{R}^d$  is the mean of  $f$  and  $\hat{\mu}$  is its empirical estimate based on  $M$  samples, then for any  $t > 0$  we have  $\Pr[\|\mu - \hat{\mu}\|^2 \geq t] \leq \frac{I_g}{Mt}$ .*

**Proof.** If  $\mathbf{x}_1, \dots, \mathbf{x}_M$  are independent draws from  $f$ , then

$$\mathbf{E}[\|\mu - \hat{\mu}\|^2] = \mathbf{E}\left[\left\|\mu - \frac{\mathbf{x}_1 + \dots + \mathbf{x}_M}{M}\right\|^2\right] = \sum_{i=1}^M \frac{1}{M^2} \mathbf{E}\left[\|\mu - \mathbf{x}_i\|^2\right] = \frac{I_g}{M},$$

where the last inequality is by Lemma 14. Applying Markov's inequality on the left hand side, we get the stated claim. ◀

### 4.3 Transformation algorithm

► **Lemma 16.** *There is an algorithm compute-transformation such that given access to samples from  $f \in \mathcal{C}_{\text{SI}}(c, d, g)$  and an error parameter  $0 < \varepsilon < 1/2$ , the algorithm takes  $O(I_g)$  samples from  $f$  and with probability at least  $9/10$  produces a vector  $\tilde{\mu} \in \mathbb{R}^d$  and a real number  $t$  with the following properties: (1) For  $B_t = \{x : \|x - \tilde{\mu}\| \leq \sqrt{t}\}$ , we have  $\Pr_{\mathbf{x} \sim f}[\mathbf{x} \in B_t] \geq 1 - \varepsilon$ ; (2)  $t = O(g^{-1}(\varepsilon)^2)$ ; (3) For all  $\kappa > 0$ , the density  $f_{B_t}$  satisfies  $\text{SI}(f_{B_t}, \kappa) \leq \frac{4\varepsilon}{\kappa} + 2c$ .*

**Proof.** For  $M = 100I_g$ , the algorithm compute-transformation simply works as follows: set  $\tilde{\mu}$  to be the empirical mean of the  $M$  samples, and  $t = 2((g^{-1}(\varepsilon))^2 + 1/10)$ . (Note that since  $\min\{r \in \mathbb{R} : g(r) \leq 1/2\} \geq 1/10$  we have  $t = \Theta(g^{-1}(\varepsilon)^2)$ .) Let  $\mu$  denote the true mean of  $f$ . First, by Lemma 15, with probability at least  $0.9$ , the empirical mean  $\hat{\mu}$  will satisfy  $\|\mu - \hat{\mu}\|^2 \leq \frac{1}{10}$ . Let us assume for the rest of the proof that this happens; fix any such outcome and denote it  $\tilde{\mu}$ .

We have  $\|x - \tilde{\mu}\|^2 \leq 2(\|x - \mu\|^2 + \|\mu - \tilde{\mu}\|^2) \leq 2(\|x - \mu\|^2 + 1/10)$  and so

$$\Pr_{\mathbf{x} \in f}[\|\mathbf{x} - \tilde{\mu}\|^2 > t] \leq \Pr_{\mathbf{x} \in f}[2(\|\mathbf{x} - \mu\|^2 + 1/10) > t] = \Pr[\|\mathbf{x} - \mu\|^2 \geq g^{-1}(\varepsilon)] \leq \varepsilon.$$

Applying Lemma 13 completes the proof. ◀

The following proposition elaborates on the properties of the output of the transformation algorithm.

► **Lemma 17.** *Let  $f \in \mathcal{C}_{\text{SI}}(c, d, g)$ ,  $\varepsilon > 0$ ,  $\tilde{\mu} \in \mathbb{R}^d$ , and  $t \in \mathbb{R}$  satisfy the properties stated in Lemma 16. Consider the density  $f_{\text{scaled}}$  defined by  $f_{\text{scaled}}(x) \stackrel{\text{def}}{=} 2\sqrt{t} \cdot f(2\sqrt{t} \cdot (x + \tilde{\mu}))$  and  $f_{\text{scaled}}(x) \stackrel{\text{def}}{=} f_{\text{scaled}, B(1/2)}(x)$  where  $f_{\text{scaled}, B(1/2)}$  is the result of conditioning  $f_{\text{scaled}}$  on membership in  $B(1/2)$ . Then the density  $f_{\text{scaled}}$  satisfies the following properties: (1) The density  $f_{\text{scaled}}$  is supported in the ball  $B(1/2)$ ; (2) For all  $\varepsilon < 1/2$  and  $\kappa > 0$ , the density  $f_{\text{scaled}}$  satisfies  $\text{SI}(f_{\text{scaled}}, \kappa) \leq \frac{4\varepsilon}{\kappa} + 4c\sqrt{t}$ .*

**Proof.** First, it is easy to verify that function  $f_{\text{scaled}}$  defined above is indeed a density. Item 1 is enforced by fiat. Now, for any direction  $v$ , we have

$$\begin{aligned} \text{SI}(f_{\text{scaled}}, v, \kappa) &= \frac{1}{\kappa} \cdot \sup_{\kappa' \in [0, \kappa]} \int_{\mathbb{R}^d} |f_{\text{scaled}}(x + \kappa'v) - f_{\text{scaled}}(x)| dx \\ &= \frac{2\sqrt{t}}{\kappa} \cdot \sup_{\kappa' \in [0, \kappa]} \int_{\mathbb{R}^d} |f(2\sqrt{t}(x + \kappa'v)) - f(2\sqrt{t}x)| dx. \end{aligned}$$

Using a change of variables,  $u = 2\sqrt{t}x$ , we get

$$\begin{aligned} \text{SI}(f_{\text{scaled}}, v, \kappa) &= \frac{1}{\kappa} \cdot \sup_{\kappa' \in [0, \kappa]} \int_{\mathbb{R}^d} |f(u + \kappa'2\sqrt{t}v) - f(u)| du \\ &= \frac{1}{\kappa} \cdot \sup_{\kappa' \in [0, 2\sqrt{t}\kappa]} \int_{\mathbb{R}^d} |f(u + \kappa'v) - f(u)| du \\ &= 2\sqrt{t} \cdot \text{SI}(f, v, 2\sqrt{t}\kappa) \leq 2c\sqrt{t}. \end{aligned} \tag{6}$$

The last inequality uses that  $f \in \mathcal{C}_{\text{SI}}(c, d, g)$ . Inequality (6) implies that  $f_{\text{scaled}} \in \mathcal{C}_{\text{SI}}(2c\sqrt{t}, d, g)$ . Now,  $\Pr_{\mathbf{x} \sim f_{\text{scaled}}}(\mathbf{x} \in B(1/2)) = \Pr_{\mathbf{x} \sim f}(\mathbf{x} \in B_t) \geq 1 - \varepsilon$ , so applying Lemma 13 completes the proof. ◀

#### 4.4 Proof of Theorem 12

We are now ready to prove Theorem 12. Consider the following algorithm, which we call **construct-candidates**:

1. Run the transformation algorithm **compute-transformation**  $D := O(\ln(1/\delta))$  many times (with parameter  $\varepsilon$  each time). Let  $(\tilde{\mu}^{(i)}, t)$  be the output that it produces on the  $i$ -th run, where  $t = O(g^{-1}(\varepsilon)^2)$ .
2. For each  $i \in [D]$ , let  $B_t^{(i)} = \{x : \|x - \tilde{\mu}\| \leq \sqrt{t}\}$  and  $f_{\text{scnd}}^{(i)}$  be the density defined from  $(\tilde{\mu}^{(i)}, t)$  as in Lemma 17.

Before describing the third step of the algorithm, we observe that given the pair  $(\tilde{\mu}^{(i)}, t)$  it is easy to check whether any given  $x \in \mathbb{R}^d$  belongs to  $B_t^{(i)}$ . If  $\Pr_{\mathbf{x} \sim f}[\mathbf{x} \in B_t^{(i)}] \geq 1/2$ , then with probability at least  $1/2$  a draw from  $f$  can be used as a draw from  $f_{B_t^{(i)}}$ . In this case, via rejection sampling, it is easy to very efficiently simulate draws from  $f_{\text{scnd}}^{(i)}$  given access to samples from  $f$  (the average slowdown is at most a factor of 2). Note that if  $(\tilde{\mu}^{(i)}, t)$  satisfies the properties of Lemma 16, then  $\Pr_{\mathbf{x} \sim f}[\mathbf{x} \in B_t^{(i)}] \geq 1 - \varepsilon$  and we fall into this case. On the other hand, if  $\Pr_{\mathbf{x} \sim f}[\mathbf{x} \in B_t^{(i)}] < 1/2$ , then it may be inefficient to simulate draws from  $f_{\text{scnd}}^{(i)}$ . But any such  $i$  will not satisfy the properties of Lemma 16, so if rejection sampling is inefficient to simulate draws from  $f_{\text{scnd}}^{(i)}$  then we can ignore such an  $i$  in what follows. With this in mind, the third and fourth steps of the algorithm are as follows:

3. For each  $i \in [D]$ ,<sup>4</sup> run the algorithm **learn-bounded** using  $m$  samples from  $f_{\text{scnd}}^{(i)}$ , where  $m = m(\varepsilon, \delta, d)$  is the sample complexity of **learn-bounded** from Lemma 10. Let  $h_{\text{scnd}}^{(i)}$  be the resulting hypothesis that **learn-bounded** outputs.
4. Finally, for each  $i \in [D]$  output the hypothesis obtained by inverting the mapping of Lemma 17, i.e.

$$h^{(i)}(x) \stackrel{\text{def}}{=} \frac{1}{2\sqrt{t}} \cdot h_{\text{scnd}}^{(i)} \left( \frac{1}{2\sqrt{t}} \cdot (x - \tilde{\mu}^{(i)}) \right). \quad (7)$$

Thus the output of **construct-candidate** is a  $D$ -tuple of hypotheses  $(h^{(1)}, \dots, h^{(D)})$ .

We now analyze the **construct-candidate** algorithm. Given Lemma 16 and Lemma 17, it is not difficult to show that with high probability at least one of the hypotheses that it outputs has error  $O(\varepsilon)$  with respect to  $f$ :

► **Lemma 18.** *With probability at least  $1 - O(\delta)$ , at least one  $h^{(i)}$  has  $\int_x |h^{(i)}(x) - f(x)| dx \leq O(\varepsilon)$ .*

**Proof.** It is immediate from Lemma 16 and the choice of  $D$  that with probability  $1 - \delta$  at least one triple  $(\tilde{\mu}^{(i)}, t)$  satisfies the properties of Lemma 16. Fix  $i'$  to be an  $i$  for which this holds.

Given any  $i \in [D]$ , it is easy to carry out the check for whether rejection sampling is too inefficient in simulating  $f_{\text{scnd}}^{(i)}$  in such a way that algorithm **learn-bounded** will indeed be run to completion (as opposed to being terminated) on  $f_{\text{scnd}}^{(i')}$  with probability at least  $1 - \delta$ , so we henceforth suppose that indeed **learn-bounded** is actually run to completion on  $f_{\text{scnd}}^{(i')}$ . Since  $(\tilde{\mu}^{(i')}, t)$  satisfies the properties of Lemma 16, by Lemma 17, taking

<sup>4</sup> Actually, as described above, this and the fourth step are done only for those  $i$  for which rejection sampling is not too inefficient in simulating draws from  $f_{\text{scnd}}^{(i)}$  given draws from  $f$ ; for the other  $i$ 's, the run of **learn-bounded** is terminated.

$\kappa = \min\{\varepsilon/2, \varepsilon/(4g^{-1}(\varepsilon)c)\}$  the density  $f_{\text{scnd}}^{(i')}$  satisfies the required conditions for Lemma 10 to apply with that choice of  $\kappa$ . The following simple proposition, proved in the long version of this paper [20], implies that  $h^{(i)}$  is likewise  $O(\varepsilon)$ -close to  $f_{B_i}$ :

► **Proposition 19.** *Let  $f$  and  $g$  be two densities in  $\mathbb{R}^d$  and let  $x \mapsto A(x - z)$  be any invertible linear transformation over  $\mathbb{R}^d$ . Let  $f_A(x) = \det(A) \cdot f(A(x - z))$  and  $g_A(x) = \det(A) \cdot g(A(x - z))$  be the densities from  $f$  and  $g$  under this transformation. Then  $d_{\text{TV}}(f, g) = d_{\text{TV}}(f_A, g_A)$ .*

It remains only to observe that by property 1 of Lemma 16 the density  $f_{B_i}$  is  $\varepsilon$ -close to  $f$ , and then by the triangle inequality we have that  $h^{(i)}$  is  $O(\varepsilon)$ -close to  $f$ . This gives Lemma 18. ◀

Tracing through the parameters, it is straightforward to verify that the sample and time complexities of **construct-candidates** are as claimed in the statement of Theorem 12. These sample and time complexities dominate the sample and time complexities of the remaining portion of the algorithm, the hypothesis selection procedure discussed below.

All that is left is to identify a good hypothesis from the pool of  $D$  candidates. This can be carried out rather straightforwardly using well-known tools for hypothesis selection. Many variants of the basic hypothesis selection procedure have appeared in the literature, see e.g. [44, 18, 2, 17, 19]). The following is implicit in the proof of Proposition 6 from [19]:

► **Proposition 20.** *Let  $\mathbf{D}$  be a distribution with support contained in a set  $W$  and let  $\mathcal{D}_\varepsilon = \{\mathbf{D}_j\}_{j=1}^M$  be a collection of  $M$  hypothesis distributions over  $W$  with the property that there exists  $i \in [M]$  such that  $d_{\text{TV}}(\mathbf{D}, \mathbf{D}_i) \leq \varepsilon$ . There is an algorithm  $\text{Select}^{\mathbf{D}}$  which is given  $\varepsilon$  and a confidence parameter  $\delta$ , and is provided with access to (i) a source of i.i.d. draws from  $\mathbf{D}$  and from  $\mathbf{D}_i$ , for all  $i \in [M]$ ; and (ii) a  $(1 + \beta)$  “approximate evaluation oracle”  $\text{eval}_{\mathbf{D}_i}(\beta)$ , for each  $i \in [M]$ , which, on input  $w \in W$ , deterministically outputs  $\tilde{D}_i^\beta(w)$  such that the value  $\frac{\mathbf{D}_i(w)}{1+\beta} \leq \tilde{D}_i^\beta(w) \leq (1 + \beta) \cdot \mathbf{D}_i(w)$ . Further,  $(1 + \beta)^2 \leq (1 + \varepsilon/8)$ . The  $\text{Select}^{\mathbf{D}}$  algorithm has the following behavior: It makes  $m = O((1/\varepsilon^2) \cdot (\log M + \log(1/\delta)))$  draws from  $\mathbf{D}$  and from each  $\mathbf{D}_i$ ,  $i \in [M]$ , and  $O(m)$  calls to each oracle  $\text{eval}_{\mathbf{D}_i}$ ,  $i \in [M]$ . It runs in time  $\text{poly}(m, M)$  (counting each call to an  $\text{eval}_{\mathbf{D}_i}$  oracle and draw from a  $\mathbf{D}_i$  distribution as unit time), and with probability  $1 - \delta$  it outputs an index  $i^* \in [M]$  that satisfies  $d_{\text{TV}}(\mathbf{D}, \mathbf{D}_{i^*}) \leq 6\varepsilon$ .*

As suggested above, the remaining step is to apply Proposition 20 to the list of candidate hypothesis  $h^{(i)}$  which satisfies the guarantee of Lemma 18. However, to bound the sample and time complexity of running the procedure Proposition 20, we need to bound the complexity both of sampling from  $\{h^{(i)}\}_{i \in [D]}$  as well as of constructing approximate evaluation oracles for these measures.<sup>5</sup> In fact, we will first construct densities out of the measures  $\{h^{(i)}\}_{i \in [D]}$  and show how to both efficiently sample from these measures as well as construct approximate evaluation oracles for these densities.

Towards this, let us now define  $H_{\max}$  as follows:  $H_{\max} = \max_{i \in [D]} \max_{z \in [-1, 1]^n} h_{\text{scnd}}^{(i)}(z)$ . From Lemma 10 (recall that Lemma 10 was applied with  $\kappa = \min\{\varepsilon/2, \varepsilon/(4g^{-1}(\varepsilon)c)\}$ ) we get that  $H_{\max} = O_{c,d} \left( \left( \frac{g^{-1}(\varepsilon)}{\varepsilon} \right)^d \log^{2d} \frac{g^{-1}(\varepsilon)}{\varepsilon} \right)$ . We will carry out the rest of our calculations in terms of  $H_{\max}$ .

<sup>5</sup> Note that while  $h^{(i)}$  are forced to be non-negative and thus can be seen as measures, they need not integrate to 1 and thus need not be densities.

► **Observation 21.** For any  $i \in [D]$ ,  $\int_{x \in [-1,1]^d} h_{\text{scnd}}^{(i)}(x) dx$  can be estimated to additive accuracy  $\pm \varepsilon$  and confidence  $1 - \delta$  in time  $O_d \left( \frac{H_{\text{max}}^2}{\varepsilon^2} \cdot \log(1/\delta) \right)$ .

**Proof.** First note that it suffices to estimate the quantity  $\mathbf{E}_{x \in [-1,1]^d} [h_{\text{scnd}}^{(i)}(x)]$  to additive error  $\varepsilon/2^d$ . However, this can be estimated using the trivial random sampling algorithm. In particular, as  $h_{\text{scnd}}^{(i)}(x) \in [0, H_{\text{max}}]$ , the variance of the simple unbiased estimator for  $\mathbf{E}_{x \in [-1,1]^d} [h_{\text{scnd}}^{(i)}(x)]$  is also bounded by  $H_{\text{max}}^2$ . This finishes the proof. ◀

Note that, while the algorithm of Observation 21 does random sampling, this sampling is not from  $f$ , so it adds nothing to the sample complexity of the learning algorithm.

Next, for  $i \in [D]$ , let us define the quantity  $Z_i$  to be  $Z_i = \int_x h^{(i)}(x) dx$ . Since the functions  $h^{(i)}$  and  $h_{\text{scnd}}^{(i)}$  are obtained from each other by linear transformations (recall (7)), we get that  $2\sqrt{t}Z_i = \int_x h_{\text{scnd}}^{(i)} \left( \frac{1}{2\sqrt{t}} \cdot (x - \tilde{\mu}^{(i)}) \right) dx$ . We now define the functions  $H^{(i)}$  and  $H_{\text{scnd}}^{(i)}$  as  $H^{(i)}(x) = \frac{h^{(i)}(x)}{Z_i}$  and  $H_{\text{scnd}}^{(i)}(x) = \frac{h_{\text{scnd}}^{(i)} \left( \frac{1}{2\sqrt{t}} \cdot (x - \tilde{\mu}^{(i)}) \right)}{Z_i} \cdot \frac{1}{2\sqrt{t}}$ . Observe that the functions  $H^{(i)}$  and  $H_{\text{scnd}}^{(i)}$  are densities (i.e. they are non-negative and integrate to 1). First, we will show that it suffices to run the procedure  $\text{Select}^{\mathbf{D}}$  on the densities  $H^{(i)}$ . To see this, note that Lemma 18 says that there exists  $i \in [D]$  such that  $h^{(i)}$  satisfies  $\int_x |h^{(i)}(x) - f(x)| = O(\varepsilon)$ . For such an  $i$ ,  $Z_i \in [1 - O(\varepsilon), 1 + O(\varepsilon)]$ . Thus, we have the following corollary.

► **Corollary 22.** With probability at least  $1 - \delta$ , at least one  $H^{(i)}$  satisfies  $\int_x |H^{(i)}(x) - f(x)| = O(\varepsilon)$ . Further, for such an  $i$ ,  $Z_i \in [1 - O(\varepsilon), 1 + O(\varepsilon)]$ .

Thus, it suffices to run the procedure  $\text{Select}^{\mathbf{D}}$  on the candidate distributions  $\{H^{(i)}\}_{i \in [D]}$ . The next proposition shows that the densities  $\{H^{(i)}\}_{i \in [D]}$  are samplable.

► **Proposition 23.** A draw from the density  $H^{(i)}(x)$  can be sampled in time  $O(H_{\text{max}}/Z_i)$ .

**Proof.** First of all, note that it suffices to sample from  $H_{\text{scnd}}^{(i)}$  since  $H^{(i)}$  and  $H_{\text{scnd}}^{(i)}$  are linear transformations of each other. However, sampling from  $H_{\text{scnd}}^{(i)}$  is easy using rejection sampling. More precisely, the distribution  $H_{\text{scnd}}^{(i)}$  is supported on  $[-1, 1]^d$ . We sample from  $H_{\text{scnd}}^{(i)}$  as follows:

1. Let  $C = [-1, 1]^d \times [0, H_{\text{max}}]$ . Sample a uniformly random point  $z' = (z_1, \dots, z_{d+1})$  from  $C$ .
2. If  $z_{d+1} \leq h_{\text{scnd}}^{(i)}(z_1, \dots, z_d)$ , then return the point  $z = (z_1, \dots, z_d)$ .
3. Else go to Step 1 and repeat.

Now note that conditioned on returning a point in step 2, the point  $z$  is returned with probability proportional to  $h_{\text{scnd}}^{(i)}(z)$ . Thus, the distribution sampled by this procedure is indeed  $H_{\text{scnd}}^{(i)}(z)$ . To bound the probability of success, note that the total volume of  $C$  is  $2^d \times H_{\text{max}}$ . On the other hand, step 2 is successful only if  $z'$  falls in a region of volume  $Z_i$ . This finishes the proof. ◀

The next proposition says that if  $Z_i \geq 1/2$ , then there is an approximate evaluation oracle for the density  $H^{(i)}$ .

► **Proposition 24.** Suppose  $Z_i \geq 1/2$ . Then there is a  $(1 + O(\varepsilon))$ -approximate evaluation oracle for  $H^{(i)}$  which can be computed at any point  $w$  in time  $O \left( \frac{H_{\text{max}}^2}{\varepsilon^2} \right)$ .

**Proof.** Note that we can evaluate  $h^{(i)}$  at any point  $w$  exactly and thus the only issue is to estimate the normalizing factor  $Z_i$ . Note that since  $Z_i \geq 1/2$ , estimating  $Z_i$  to within an additive  $O(\varepsilon)$  gives us a  $(1 + O(\varepsilon))$  multiplicative approximation to  $Z_i$  and hence to  $H^{(i)}(w)$  at any point  $w$ . However, by Observation 21, this takes time  $O\left(\frac{H_{\max}^2}{\varepsilon^2}\right)$ , concluding the proof.  $\blacktriangleleft$

We now apply Proposition 20 as follows.

1. For all  $i \in [D]$ , estimate  $Z_i$  using Observation 21 up to an additive error  $\varepsilon$ . Let the estimates be  $\widehat{Z}_i$ .
2. Let us define  $S_{\text{feas}} = \{i \in [D] : \widehat{Z}_i \geq 1/2\}$ .
3. We run the routine **Select<sup>D</sup>** on the densities  $\{H^{(i)}\}_{i \in S_{\text{feas}}}$ . To sample from a density  $H^{(i)}$ , we use Proposition 23. We also construct a  $\beta = \varepsilon/32$  approximation oracle for each of the densities  $H^{(i)}$  using Proposition 24. Return the output of **Select<sup>D</sup>**.

The correctness of the procedure follows quite easily. Namely, note that Corollary 22 implies that there is one  $i$  such that both  $Z_i \in [1 - O(\varepsilon), 1 + O(\varepsilon)]$  and  $\int_x |H^{(i)}(x) - f(x)| = O(\varepsilon)$ . Thus such an  $i$  will be in  $S_{\text{feas}}$ . Thus, by the guarantee of **Select<sup>D</sup>**, the output hypothesis is  $O(\varepsilon)$  close to  $f$ .

We now bound the sample complexity and time complexity of this hypothesis selection portion of the algorithm. First of all, the number of samples required from  $f$  for running **Select<sup>D</sup>** is  $O((1/\varepsilon^2) \cdot (\log(1/\delta) + d^2 \log d + \log \log(1/\delta))) = O((1/\varepsilon^2) \cdot (\log(1/\delta) + d^2 \log d))$ . This is clearly dominated by the sample complexity of the previous parts. To bound the time complexity, note that the time complexity of invoking the sampling oracle for any  $H^{(i)}$  ( $i \in S_{\text{feas}}$ ) is dominated by the time complexity of the approximate oracle which is  $2^{O(d)} \cdot H_{\max}^2/\varepsilon^2$ . The total number of calls to the sampling as well as evaluation oracle is upper bounded by  $\frac{1}{\varepsilon^2}(D \log D + D \log(1/\delta))$ . Plugging in the value of  $H_{\max}$  as well as  $D$ , we see that the total time complexity is dominated by the bound in the statement of Theorem 12. This finishes the proof.

## 5 Efficiently learning multivariate log-concave densities

In this section we present our main application, which is an efficient algorithm for learning  $d$ -dimensional log-concave densities. We prove the following:

► **Theorem 25.** *There is an algorithm with the following property: Let  $f$  be a unknown log-concave density over  $\mathbb{R}^d$ . Given any error parameter  $\varepsilon > 0$  and confidence parameter  $\delta > 0$  and access to independent draws from  $f$ , the algorithm with probability  $1 - \delta$  outputs a hypothesis density  $h : \mathbb{R}^d \rightarrow \mathbb{R}^{\geq 0}$  such that  $\int_{x \in \mathbb{R}^d} |f(x) - h(x)| \leq O(\varepsilon)$ . The algorithm runs in time  $O_d\left(\left(\frac{1}{\varepsilon}\right)^{2d+2} \log^{7d}\left(\frac{1}{\varepsilon}\right) \log\left(\frac{1}{\varepsilon\delta}\right) \log\left(\frac{1}{\delta}\right)\right)$  and uses  $O_d\left(\left(\frac{1}{\varepsilon}\right)^{d+2} \log^{4d}\left(\frac{1}{\varepsilon}\right) \log\left(\frac{1}{\varepsilon\delta}\right) \log\left(\frac{1}{\delta}\right)\right)$  samples.*

We will establish Theorem 25 in two stages. First, we will show that any log-concave  $f$  that is nearly isotropic in fact belongs to a suitable class  $\mathcal{C}_{\text{SI}}(c, d)$ ; given this, the theorem follows immediately from Theorem 12 and a straightforward tracing through of the resulting time and sample complexity bounds. Then, we will reduce to the near-isotropic case, similarly to what was done in [37, 4].

First, let us state the theorem for the well-conditioned case. For this, the following definitions will be helpful.

► **Definition 26.** Let  $\Sigma$  and  $\tilde{\Sigma}$  be two positive semidefinite matrices. We say that  $\Sigma$  and  $\tilde{\Sigma}$  are  $C$ -approximations of each other (denoted by  $\Sigma \approx_C \tilde{\Sigma}$ ) if for every  $x \in \mathbb{R}^n$  such that  $x^T \tilde{\Sigma} x \neq 0$ , we have  $\frac{1}{C} \leq \frac{x^T \Sigma x}{x^T \tilde{\Sigma} x} \leq C$ .

► **Definition 27.** Say that the probability distribution is  $C$ -nearly-isotropic if its covariance matrix  $C$ -approximates  $I$ , the  $d$ -by- $d$  identity matrix.

► **Theorem 28.** *There is an algorithm with the following property: Let  $f$  be a unknown  $C$ -nearly-isotropic log-concave density over  $\mathbb{R}^d$ , where  $C$  and  $d$  are constants.*

*Given any error parameter  $\varepsilon > 0$  and confidence parameter  $\delta > 0$  and access to independent draws from  $f$ , the algorithm with probability  $1 - \delta$  outputs a hypothesis density  $h : \mathbb{R}^d \rightarrow \mathbb{R}^{\geq 0}$  such that  $\int_{x \in \mathbb{R}^d} |f(x) - h(x)| \leq O(\varepsilon)$ . The algorithm runs in time  $O_{C,d} \left( \left( \frac{1}{\varepsilon} \right)^{2d+2} \log^{7d} \left( \frac{1}{\varepsilon} \right) \log \left( \frac{1}{\varepsilon \delta} \right) \log \frac{1}{\delta} \right)$  and uses  $O_{C,d} \left( \left( \frac{1}{\varepsilon} \right)^{d+2} \log^{4d} \left( \frac{1}{\varepsilon} \right) \log \left( \frac{1}{\varepsilon \delta} \right) \log \frac{1}{\delta} \right)$  samples.*

By Theorem 12, Theorem 28 is an immediate consequence of the following theorem on the shift-invariance of near-isotropic log-concave distributions.

► **Theorem 29.** *Let  $f$  be a  $C$ -nearly-isotropic log-concave density in  $\mathbb{R}^d$ , for constants  $C$  and  $d$ . Then, for  $g(t) = e^{-\Omega(t)}$ , there is a constant  $c_1 = O_{C,d}(1)$  such that  $f \in \mathcal{C}_{\text{SI}}(c_1, d, g)$ .*

**Proof.** The fact that  $f$  has  $e^{-\Omega(t)}$ -light tails directly follows from Lemma 5.17 of [37], so it remains to prove that there is a constant  $c_1$  such that  $f \in \mathcal{C}_{\text{SI}}(c_1, d)$ . Because membership in  $\mathcal{C}_{\text{SI}}(c_1, d)$  requires that a condition be satisfied for all directions  $v$ , rotating a distribution does not affect its membership in  $\mathcal{C}_{\text{SI}}(c_1, d)$ .

Choose a unit vector  $v$  and  $\kappa > 0$ . By rotating the distribution if necessary, we may assume that  $v = e_1$ , and our goal of showing that  $\text{SI}(f, e_1, \kappa) \leq c_1$  is equivalent to showing that  $\int |f(x) - f(x + \kappa' e_1)| dx \leq c_1 \kappa$  for all  $\kappa' \leq \kappa$ .

We bound the integral of the LHS as follows. Fix some value of  $x' \stackrel{\text{def}}{=} (x_2, \dots, x_d)$ . Let us define  $L_{x'} \stackrel{\text{def}}{=} \{(x_1, x_2, \dots, x_d) : x_1 \in \mathbb{R}\}$  to be the line through  $(0, x_2, \dots, x_d)$  and  $(1, x_2, \dots, x_d)$ . Since the restriction of a concave function to a line is concave, the restriction of a log-concave distribution to a line is log-concave. Since

$$\int |f(x) - f(x + \kappa' e_1)| dx = \int_{x'} \int_{x_1} |f(x_1, x_2, \dots, x_d) - f(x_1 + \kappa', x_2, \dots, x_d)| dx_1 dx' \quad (8)$$

we are led to examine the one-dimensional log-concave measure  $f(\cdot, x_2, \dots, x_d)$ . The following will be useful for that.

► **Claim 30.** *Let  $\ell : \mathbb{R} \rightarrow \mathbb{R}$  be a log-concave measure. Then,  $\int |\ell(t) - \ell(t + h)| dt \leq 3h \cdot \max_{t \in \mathbb{R}} \ell(t)$ .*

**Proof.** Log-concave measures are unimodal (see [31]). Let  $z$  be the mode of  $\ell$ , so that  $\ell$  is non-decreasing on the interval  $[-\infty, z]$  and non-increasing in  $[z, \infty]$ . We have

$$\begin{aligned} & \int |\ell(t) - \ell(t + h)| dt \\ &= \int_{-\infty}^{z-h} |\ell(t) - \ell(t + h)| dt + \int_{z-h}^z |\ell(t) - \ell(t + h)| dt + \int_z^{\infty} |\ell(t) - \ell(t + h)| dt \end{aligned}$$

$$\begin{aligned}
 &= \int_{-\infty}^{z-h} \ell(t+h) - \ell(t) dt + \int_{z-h}^z |\ell(t) - \ell(t+h)| dt + \int_z^{\infty} \ell(t) - \ell(t+h) dt \\
 &\hspace{10em} \text{(since } z \text{ is the mode of } \ell) \\
 &= \int_{z-h}^z \ell(t) dt + \int_{z-h}^z |\ell(t) - \ell(t+h)| dt + \int_z^{z+h} \ell(t) dt \leq 3h \max_{t \in \mathbb{R}} \ell(t). \quad \blacktriangleleft
 \end{aligned}$$

Returning to the proof of Theorem 29, applying Claim 30 with (8), we get

$$\int |f(x) - f(x + \kappa' e_1)| dx \leq 3\kappa' \int_{x'} \left( \max_{x_1 \in L_{x'}} f(x_1, x') \right) dx'. \quad (9)$$

Now, since an isotropic log-concave distribution  $g$  satisfies  $g(x) \leq K \exp(-\|x\|)$  for an absolute constant  $K$  (see Theorem 5.1 of [40]), our  $C$ -nearly-isotropic log-concave distribution  $f$  satisfies  $f(x) \leq C^d K \exp(-\|x\|) = O_{C,d}(\exp(-\|x\|))$ . Plugging this into (9), we get

$$\begin{aligned}
 \int |f(x) - f(x + \kappa' e_1)| dx &\leq O_{C,d}(\kappa') \int_{x'} \left( \max_{x_1 \in L_{x'}} \exp(-\|(x_1, x')\|) \right) dx' \\
 &\leq O_{C,d}(\kappa') \int_{x'} \exp(-\|x'\|) dx'.
 \end{aligned}$$

Since the integral converges, this finishes the proof.  $\blacktriangleleft$

To learn log-concave distributions that are not  $C$ -nearly-isotropic, using techniques from [37], we preprocess the data to bring it into isotropic position, and then apply Theorem 29. The details are in the long version of this paper [20].

## 6 Learning shift-invariant densities over $\mathbb{R}^d$ with bounded support requires $\Omega(1/\varepsilon^d)$ samples

The following lower bound is proved in the long version of this paper [20].

**► Theorem 31.** *Given  $d \geq 1$ , there is a constant  $c_d = \Theta(\sqrt{d})$  such that the following holds: For all sufficiently small  $\varepsilon$ , let  $A$  be an algorithm with the following property: given access to  $m$  i.i.d. samples from an arbitrary (and unknown) finitely supported density  $f \in \mathcal{C}_{\text{SI}}(c_d, d)$ , with probability at least 99/100,  $A$  outputs a hypothesis density  $h$  such that  $d_{\text{TV}}(f, h) \leq \varepsilon$ . Then  $m \geq \Omega((1/\varepsilon)^d)$ .*

## Abstract

A local tester for an error-correcting code is a probabilistic procedure that queries a small subset of coordinates, accepts codewords with probability one, and rejects non-codewords with probability proportional to their distance from the code. The local tester is *robust* if for non-codewords it satisfies the stronger property that the average distance of local views from accepting views is proportional to the distance from the code. Robust testing is an important component in constructions of locally testable codes and probabilistically checkable proofs as it allows for composition of local tests.

In this work we show that for certain codes, any (natural) local tester can be converted to a robust tester with roughly the same number of queries. Our result holds for the class of *affine-invariant lifted codes* which is a broad class of codes that includes Reed-Muller codes, as well as recent constructions of high-rate locally testable codes (Guo, Kopparty, and Sudan, ITCS 2013). Instantiating this with known local testing results for lifted codes gives a more direct proof that improves some of the parameters of the main result of Guo, Haramaty, and Sudan (FOCS 2015), showing robustness of lifted codes.

To obtain the above transformation we relate the notions of local testing and robust testing to the notion of *agreement testing* that attempts to find out whether valid partial assignments can be stitched together to a global codeword. We first show that agreement testing implies robust testing, and then show that local testing implies agreement testing. Our proof is combinatorial, and is based on expansion / sampling properties of the collection of local views of local testers. Thus, it immediately applies to local testers of lifted codes that query random affine subspaces in  $\mathbb{F}_q^m$ , and moreover seems amenable to extension to other families of locally testable codes with expanding families of local views.

## 1 Introduction

Our main result shows a transformation from *local testing* to *robust testing* for the class of *affine-invariant lifted codes*. We start by describing the notions of local testing, robust testing, and lifted codes.

### 1.1 Local testing and robust testing

A code is a subset  $C \subseteq \Sigma^n$ . The elements of  $C$  are called *codewords*,  $\Sigma$  is the *alphabet* of the code, and  $n$  is the *block length*. The *rate* of the code is the ratio  $(\log_{|\Sigma|} |C|)/n$ . The code is *linear* if  $\Sigma = \mathbb{F}_q$  where  $\mathbb{F}_q$  is the finite field of  $q$  elements, and  $C$  is an  $\mathbb{F}_q$ -linear subspace of  $\mathbb{F}_q^n$ . It will be convenient to think of codewords in  $C$  as functions  $f : U \rightarrow \Sigma$  where  $U$  is a domain of size  $n$ . For a pair of functions  $f, g : U \rightarrow \Sigma$  we let  $\text{dist}(f, g)$  denote the fraction of inputs  $x \in U$  for which  $f(x) \neq g(x)$ . The *relative distance*  $\text{dist}(C)$  of the code is the minimum of  $\text{dist}(f, g)$  over all codewords  $f, g \in C$ . For a function  $f : U \rightarrow \Sigma$  we let  $\text{dist}(f, C)$  denote the minimum of  $\text{dist}(f, g)$  over all codewords  $g \in C$ .

A *local tester* for the code  $C$  is a probabilistic oracle algorithm that on oracle access to a function  $f : U \rightarrow \Sigma$  makes at most  $Q$  queries to  $f$ , and accepts  $f \in C$  with probability one, while rejecting  $f \notin C$  with probability at least  $\alpha \cdot \text{dist}(f, C)$ . We refer to  $Q$  as the *query complexity* of the tester, and to  $\alpha$  as the *soundness*. In this work we shall restrict our attention to local testers that pick a random subset  $K \subseteq U$  of cardinality  $Q$  according to some distribution, and accept if and only if  $f|_K \in C|_K$ .<sup>3</sup> The requirement then is that  $f|_K \in C|_K$  with probability one whenever  $f \in C$ , and

$$\Pr_K[f|_K \notin C|_K] \geq \alpha \cdot \text{dist}(f, C) \quad (1)$$

otherwise.

In this work we will be interested in the stronger notion of robustness. We say that a local tester as above is *robust* if for non-codewords the average distance of its local views from accepting views is proportional to the distance of the given function from the code. That is, as before we require that  $f|_K \in C|_K$  with probability one whenever  $f \in C$ , but instead of (1) we now require that

$$\mathbb{E}_K[\text{dist}(f|_K, C|_K)] \geq \alpha \cdot \text{dist}(f, C) \quad (2)$$

whenever  $f \notin C$ . Here we refer to  $\alpha$  as the *robustness* of the tester.

The notion of robustness was introduced by Ben-Sasson and Sudan [8] based on analogous notions for probabilistically checkable proofs [5, 15]. Robustness is a natural property of local testers that relates the global distance of a function from the code to its local distance from accepting views on local views. Moreover, robustness is also an important ingredient in constructions of locally testable codes and probabilistically checkable proofs as it allows for composition of local tests. Specifically, it follows by definition that if a code  $C$  is robustly

<sup>3</sup> Local testers may generally apply a more complex predicate on  $f|_K$ . However, natural local testers are typically of the restricted form we consider, and moreover it can be shown that a local tester for a linear code must be of this form [6].

testable with query complexity  $Q$  and soundness  $\alpha$ , and additionally each local restriction  $C|_K$  is locally testable with query complexity  $Q'$  and soundness  $\alpha'$ , then the code  $C$  is locally testable with query complexity  $Q'$  and soundness  $\alpha \cdot \alpha'$ . This property is useful when local restrictions can be tested efficiently which can happen if the code has many symmetries (as is the case with the class of lifted codes considered in this work) or can be achieved, in the case of probabilistically checkable proof, by attaching a short proof of proximity.

One can easily observe that (2) implies (1) since  $f|_K \notin C|_K$  whenever  $\text{dist}(f|_K, C|_K) > 0$ , so robustness is a stronger requirement than local testing. For the other direction, note that a local tester with soundness  $\alpha$  has robustness at least  $\alpha/Q$  since  $\text{dist}(f|_K, C|_K) \geq 1/Q$  whenever  $f|_K \notin C|_K$ . A natural question is whether this loss in robustness is necessary, and whether robustness is strictly stronger notion than local testing. In this work we shall show that this loss is unnecessary for the class of lifted codes, discussed below.

## 1.2 Lifted codes

Lifted codes are specified by a *base code*  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  and a dimension  $m \geq \ell$ . We further assume that the base code  $C$  is linear and *affine-invariant*, that is, for any codeword  $f \in C$ , and for any affine transformation  $A : \mathbb{F}_q^\ell \rightarrow \mathbb{F}_q^\ell$  it holds that  $f \circ A \in C$ . Given these we define the *lifted code*  $C^{\ell \nearrow m}$  to be the code consisting of all functions  $f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$  that satisfy that  $f|_L \in C$  for any  $\ell$ -dimensional affine subspace  $L$ .

Lifted codes were first introduced by Ben-Sasson et al [7], and their local testability properties were further explored in subsequent work [20, 21, 19]. They are a natural generalization of the well-studied family of Reed-Muller codes, and moreover they also give rise to new families of locally testable codes that outperform Reed-Muller codes in certain range of parameters [20]. Specifically, lifted codes lead to one of the two known constructions (the other one being tensor codes [8, 9, 27, 24]) of high-rate locally testable codes (i.e., locally testable codes with rate approaching one and sublinear locality). Generally, lifted codes form a natural subclass of affine-invariant codes satisfying the “single-orbit characterization” property that is known to imply local testability, as well as local decodability [23].

There is a natural local test associated with lifted codes: on oracle access to a function  $f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$ , pick a uniform random  $\ell$ -dimensional affine subspace  $L$  and accept if and only if  $f|_L \in C$ . It follows immediately by definition that this test accepts any valid codeword  $f \in C^{\ell \nearrow m}$  with probability one, but more work is required to show that this test is sound. Specifically, since the test forms a single orbit characterization, it follows from [23] that it has soundness roughly  $q^{-2\ell}$ . The dependence of the soundness on the dimension  $\ell$  was later eliminated in [21] who showed soundness that is only a function of  $q$  (though an extremely quickly decaying one).

As for robustness, the above local testing results, together with the straightforward transformation from local testing to robust testing, immediately give robustness that is dependent on the dimension  $\ell$ . This was eliminated recently in [19] who showed robustness of the form  $\text{poly}(\delta)$  (about  $\delta^{74}$ , where  $\delta$  is the relative distance of the code) for the local test that queries subspaces of slightly larger dimension of  $2\ell$ . Interestingly, [19] did not rely on the aforementioned local testing results, but rather relied on viewing lifted codes as the intersection of “modified tensor codes”. They then proceeded by showing that these modified tensor codes are robustly testable (using the proof method of [27] showing robustness of tensor codes), and that this implies local testability of the lifted code (see Section 2.4 for more details about the proof method of [19]).

### 1.3 Our results

Our main result gives a transformation from local testing to robust testing, that does not suffer the factor of  $Q$  (the query complexity) loss in robustness, for the class of lifted codes. The transformation uses local testability in a “black-box” manner, and shows that if a code in this family is locally testable (using the natural subspace tester) then it is also robustly testable with roughly the same number of queries and robustness.

For  $k \geq \ell$ , let the  $k$ -dimensional (subspace) test denote the local tester that on oracle access to a function  $f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$  queries a uniform random  $k$ -dimensional affine subspace  $K$  and accepts if and only if  $f|_K \in C^{\ell \nearrow k}$ .

► **Theorem 1 (Main).** *Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq k \geq \ell$ . Suppose that  $C^{\ell \nearrow m}$  is locally testable using the  $k$ -dimensional test with query complexity  $q^k$  and soundness  $\alpha$ , and let  $\delta := \min_{k \leq r \leq m} \text{dist}(C^{\ell \nearrow r})$ . Then  $C^{\ell \nearrow m}$  is robustly testable using the  $(2k + \log_q(4/\delta))$ -dimensional test with query complexity  $O(q^{2k}/\delta)$  and robustness  $\Omega(\alpha \cdot \delta^3)$ .*

Note that if the relative distance  $\delta$  is constant, we only incur a constant multiplicative loss in robustness and testing dimension.

To apply the above theorem one can instantiate it with the local testing result of [23] that says that lifted codes are locally testable using the  $\ell$ -dimensional test with soundness  $\approx q^{-2\ell}$  (see Theorem 6 below). However, to obtain constant robustness we need that the soundness of the initial local tester would be constant (independent of  $q$  and  $\ell$ ), and for this we observe (in Proposition 19) that the soundness of [23] can be easily amplified to  $\Omega(1)$  at the cost of increasing the testing dimension to  $\approx 3\ell$ .<sup>4</sup> Using this observation we obtain the following.

► **Corollary 2.** *Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code of relative distance  $\delta$ , and  $m \geq \ell$ . Then  $C^{\ell \nearrow m}$  is robustly testable using the  $(6\ell + \log_q(128/\delta))$ -dimensional test with robustness  $\Omega(\delta^3)$ .*

Compared to the above corollary, [19] use lower dimension of  $2\ell$ , but also obtain lower soundness of  $\Omega(\delta^{74})$ .

As described next, our proof is combinatorial, relying mainly on expansion / sampling properties of the collection of local views. In particular, it uses very little about the algebraic structure of lifted codes or the base code. We thus hope that such techniques would prove useful in the future for showing robustness for other families of locally testable codes with similar expansion properties.

## 2 Proof overview

Our proof is based on a new connection between the notions of local testing, robust testing, and *agreement testing*. Specifically, we show that for the class of lifted codes agreement testing implies robust testing, and local testing implies agreement testing. The combination of these two implications gives our main Theorem 1. Next we elaborate on the notion of agreement testing, followed by an overview of each of the implications.

<sup>4</sup> Such an amplification with similar blow-up in query complexity can be easily obtained by repeating the test and accepting if and only if all invocations accept; we however need that the tester would be a subspace tester which can be obtained using sampling properties of affine subspaces.

## 2.1 Agreement testing

An *agreement test* attempts to find out whether partial assignments to local views can be stitched together to a single global codeword. Let  $C \subseteq \{U \rightarrow \Sigma\}$  be a code, and let  $\mathcal{S}$  be a collection of subsets of  $U$ . An *agreement tester* for  $C, \mathcal{S}$  is a probabilistic oracle algorithm that receives oracle access to a collection of partial assignments  $\{f_S : S \rightarrow \Sigma \mid S \in \mathcal{S}\}$  on sets of  $\mathcal{S}$ , where  $f_S \in C|_S$  for any  $S \in \mathcal{S}$ . The tester queries a few of the  $f_S$ 's, and is required to accept with probability one any collection  $(f_S)_S$  that is consistent with some global codeword  $g \in C$  (that is,  $g|_S = f_S$  for any  $S \in \mathcal{S}$ ), while rejecting any inconsistent collection  $(f_S)_S$  with probability proportional to the minimal fraction of  $f_S$ 's that must be changed in order to be consistent with some global codeword. In this work we focus on the two query agreement tester that picks a pair of sets  $S, S' \in \mathcal{S}$  according to some distribution and accepts if and only if  $f_S$  and  $f_{S'}$  agree on their intersection  $S \cap S'$ .

Agreement testing has first appeared in PCP constructions [3, 2] as so-called “low degree tests”, and is a key component in the proof of almost all PCP theorems. A prime example is the line vs. line low degree test [17, 26] in the proof of the PCP theorem. In the PCP construction, a function on a large vector space is replaced by an ensemble of (supposed) restrictions to all possible affine lines. These restrictions are supplied by a prover and are not a priori guaranteed to agree with any single global function. The “low degree test” is run by the verifier to check that restrictions on intersecting lines agree with each other, i.e. they give the same value to the point of intersection. The main point of the argument is to show that the passing of the test implies agreement with a single global function. In these early low degree tests (including the linearity testing work of [10]) an agreement test component can be discerned but quite implicitly. Indeed, it was only separated in the works [25, 4] that looked at the so-called list-decoding regime<sup>5</sup>, with the goal of proving a large gap for the PCP.

Goldreich and Safra [18] tried to separate the algebraic aspect of the low degree test from the combinatorial, and formulated a more general “consistency test” which is also referred to as an agreement test. They also proved a certain local to global result which was too weak to be useful for PCPs. In hindsight it is clear that since their family of subsets consisted of axis parallel lines, the expansion was not strong enough for a good agreement test. Only recently [13] the role of expansion underlying the family of subsets had begun to be uncovered.

Work on agreement testing then continued the combinatorial direction of [18] mainly in the list-decoding regime for direct product testing [15, 12, 22, 16, 14]. The techniques developed in this line of work turn out to be useful also for agreement testing in the unique-decoding regime (which is the more standard testing regime), and in particular for our work here.

## 2.2 Agreement testing implies robust testing

We begin with an overview of the simpler implication from agreement testing to robust testing. Suppose that we have a two query agreement tester for  $C, \mathcal{S}$  as described above. We would like to show that the local tester that queries a random  $S \in \mathcal{S}$  is robust. Let  $\mathcal{T}$  be the collection of subsets of  $U$  formed by pairwise intersections of sets in  $\mathcal{S}$ . The main properties we need out of  $\mathcal{S}, \mathcal{T}$  are sampling properties, specifically, that  $\mathcal{S}$  samples well the set of points  $U$ , and that for any  $S \in \mathcal{S}$  all sets in  $\mathcal{T}$  contained in  $S$  sample well the set of points in  $S$ . The main property we need out of the code is that its restrictions to sets in  $\mathcal{T}$

<sup>5</sup> In the list decoding regime one would like to reject a function that is  $(1 - \epsilon)$ -far from the code with very high-probability of  $1 - O(\epsilon)$ .

have distance. In the case of lifted codes these properties can be guaranteed by letting  $\mathcal{S}, \mathcal{T}$  be families of affine subspaces of fixed dimension.

To see that the proposed local tester is indeed robust, suppose that we have a function  $f : U \rightarrow \Sigma$  that is close to  $C|_S$  on a typical  $S$ , our goal is to show that  $f$  is close to a codeword  $g \in C$ . We first create an instance  $(f_S)_S$  for the agreement tester by letting  $f_S \in C|_S$  be the closest valid assignment to  $f|_S$ . Next observe that since  $f|_S$  is typically close to  $f_S$ , and by assumption that  $T$ 's sample well inside  $S$ 's, for a typical  $T$  and  $S, S'$  containing  $T$  it holds that  $f_S|_T \approx f|_T \approx f_{S'}|_T$ , and by distance property on  $\mathcal{T}$  this implies in turn that typically  $f_S|_T = f_{S'}|_T$ . Consequently, agreement testability implies the existence of a codeword  $g \in C$  that agrees with most  $f_S$ , and so  $g|_S = f_S \approx f|_S$  for most  $S$ . But since  $\mathcal{S}$  samples well inside  $U$  we conclude that  $f$  must be close to  $g$  as required.

### 2.3 Local testing implies agreement testing

We now turn to the local testing to agreement testing implication which is a bit more involved. Suppose that we have a local testing algorithm for  $C$  that queries a random set  $K \in \mathcal{K}$  and accepts if and only if  $f|_K \in C|_K$ . We would like to obtain an agreement tester for  $C$  with respect to some collection of subsets  $\mathcal{S}$ . As before, let  $\mathcal{T}$  be the collection of subsets of  $U$  formed by pairwise intersections of sets in  $\mathcal{S}$ . Once more the main properties we require out of  $\mathcal{S}, \mathcal{T}, \mathcal{K}$  are sampling properties. Specifically, we need that  $\mathcal{S}$  samples well inside  $U$ , and that for any  $T \in \mathcal{T}$  all sets in  $\mathcal{K}$  contained in  $T$  sample well inside  $T$ . We also require distance properties out of  $C$ , specifically that  $C$  has distance on  $U$  and on restrictions to sets in  $\mathcal{S}$  and  $\mathcal{T}$ . Once more, in the case of lifted codes these properties can be guaranteed by letting  $\mathcal{S}, \mathcal{T}, \mathcal{K}$  be families of affine subspaces of fixed dimension.

To show agreement testability, let  $(f_S)_S$  be a collection of valid assignments to sets in  $\mathcal{S}$  (so  $f_S \in C|_S$  for any  $S$ ), and suppose that  $f_S$  agrees with  $f_{S'}$  on  $S \cap S'$  for most pairs  $S, S'$ . Our goal will be to find a global codeword  $g \in C$  that agrees with most  $f_S$ . We find the function  $g$  in the following three stages.

#### Initial stage

In the first stage we define for any  $K \in \mathcal{K}$  a “most popular function”  $\text{Plur}_K$  by choosing the most common value among  $f_S|_K$  going over all  $S \in \mathcal{S}$  containing  $K$ . We then show, using the assumption that  $f_S$ 's typically agree on their intersections, that this most popular function is obtained with overwhelming probability for a typical  $K$ .

#### Local structure stage

In the second stage we define for each  $K \in \mathcal{K}$  a function  $g_K : U \rightarrow \Sigma$  by letting  $g_K(x)$  be the most common “vote” among all  $f_S$  that contain  $K$  and  $x$  and agree with  $\text{Plur}_K$  on  $K$  (this function is well defined because of the initial stage). We then show that for a typical  $K$ ,  $g_K$  is close to some function  $h_K \in C$ , and moreover  $h_K|_S = f_S$  for most  $S$  containing  $K$ .

To see why the above holds, first note that by assumptions that  $C$  has distance on  $T$ 's, and  $K$ 's sample well inside  $T$ 's, if a pair of  $f_S$ 's agree on  $K$  then they must typically also agree on their whole intersection. Therefore  $g_K(x)$  is also typically defined with overwhelming probability. Consequently, for a typical  $K$ , and most  $K'$ ,  $g_K|_{K'}$  agrees with some  $f_S$ . Recalling that  $f_S$ 's are valid assignments, local testability then implies the existence of  $h_K \in C$  that is close to  $g_K$ . The fact that  $h_K|_S = f_S$  for most  $S$  containing  $K$  follows by assumption that  $\mathcal{S}$  samples well  $U$ , and distance property on  $\mathcal{S}$ .

### Global structure stage

In the final stage we show that there exists  $\hat{K}$  such that  $h_{\hat{K}}$  agrees with  $f_S$  for most  $S$  (not necessarily containing  $\hat{K}$ ). We can then set our “global function”  $g$  to be equal to  $h_{\hat{K}}$ . To this end, we first observe that it suffices to show that most functions  $h_K$  are in fact identical. This now follows since for typical  $S \supseteq K \cup K'$  it holds that  $h_K|_S = f_S = h_{K'}|_S$ , and consequently since  $\mathcal{S}$  samples  $U$  it must typically hold that  $h_K = h_{K'}$ .

## 2.4 The proof method of Guo et al

The proof method of Guo et al [19] for showing robustness of lifted codes is very different from ours. In particular, it relies heavily on the algebraic structure of lifted codes. More specifically, the proof is based on viewing the lifted codes as the intersection of “modified tensor codes”. The *tensor product*  $C^{\otimes m}$  of a code  $C \subseteq \{\mathbb{F}_q \rightarrow \mathbb{F}_q\}$  can be thought of as the ‘axis-parallel lifting’ of  $C$ , that is, it is the code that consists of all functions  $f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$  whose restrictions to any axis-parallel line belong to  $C$ . The “modified tensor code” is a code of the form  $C_b^{\otimes m}$  where  $b$  is a direction in  $\mathbb{F}_q^m$ , and  $C_b^{\otimes m}$  consists of all functions  $f \in C^{\otimes m}$  whose restrictions to lines in direction  $b$  also belong to  $C$ .

The authors first use the proof method of [27], showing robust testing of tensor codes, to show that the modified tensor codes are also robustly testable. They then use the fact that the lifted code is the intersection of all codes of the form  $C_b^{\otimes m}$  for all directions  $b$  (this is true when the dimension of the base code for lifting is  $\ell = 1$ ; when  $\ell > 1$  the proof becomes more complicated) to deduce robust testability for the lifted code. However, since intersection of robustly testable codes is not necessarily robustly testable, a non-trivial work is required to show robust testability, which in particular exploits the degree structure of affine-invariant lifted codes.

The above program can be carried out only when the dimension  $m$  of the lifted code is a small constant multiple of  $\ell$ , and the authors use the “bootstrapping” technique [26, 2, 4, 1] to extend the result to work for arbitrary large  $m$ .

In contrast, we work directly with lifted codes of large dimension which allows us to exploit the sampling / expansion properties of large affine subspaces in  $\mathbb{F}_q^m$ . To the best of our knowledge, even for the special case of low-degree polynomials, this gives the first analysis of robustness that is not based on the two step approach of first analyzing the constant dimensional case and only then moving to the general dimensional case.

As opposed to [19] who reprove local testability on the way, our proof uses local testability in a black-box manner. Thus, it exhibits a separation between the algebraic properties that are used for showing local testability, and the combinatorial properties that are needed in order to turn local testability into robust testability.

### Paper organization

The rest of the paper is organized as follows. In Section 3 we set some notation, provide some definitions, and present the expansion properties of subspaces that we use. The transformation from agreement testing to robust testing is given in Section 4, while the transformation from local testing to agreement testing appears in Section 5. We wrap-up in Section 6 with the full transformation from local testing to robust testing that proves our main Theorem 1 and Corollary 2.

### 3 Preliminaries

For a prime power  $q$ , let  $\mathbb{F}_q$  denote the finite field of  $q$  elements. Let  $\{\mathbb{F}_q^m \rightarrow \mathbb{F}_q\}$  denote the set of functions mapping  $\mathbb{F}_q^m$  to  $\mathbb{F}_q$ . In what follows we focus on codes which are subsets of functions  $C \subseteq \{\mathbb{F}_q^m \rightarrow \mathbb{F}_q\}$ . For a pair of functions  $f, g : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$  we use  $\text{dist}(f, g)$  to denote the fraction of inputs  $x \in \mathbb{F}_q^m$  for which  $f(x) \neq g(x)$ . The *relative distance*  $\text{dist}(C)$  of the code  $C$  is  $\min_{f \neq g \in C} \{\text{dist}(f, g)\}$ . For a function  $f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$  we use  $\text{dist}(f, C)$  to denote  $\min_{g \in C} \{\text{dist}(f, g)\}$ .

The code  $C$  is said to be *linear* if it is an  $\mathbb{F}_q$ -linear subspace, i.e., for every  $\alpha \in \mathbb{F}_q$  and  $f, g \in C$ , we have  $\alpha f + g \in C$ . A function  $A : \mathbb{F}_q^m \rightarrow \mathbb{F}_q^m$  is said to be an *affine transformation* if there exist a matrix  $M \in \mathbb{F}_q^{m \times m}$  and a vector  $b \in \mathbb{F}_q^m$  such that  $A(x) = Mx + b$ . The code  $C$  is said to be *affine-invariant* if for every affine transformation  $A$  and every  $f \in C$  we have  $f \circ A \in C$  (where  $(f \circ A)(x) = f(A(x))$ ).

#### 3.1 Lifted codes

A subset  $L \subseteq \mathbb{F}_q^m$  is said to be an  $\ell$ -dimensional affine subspace if there exist  $\alpha_0 \in \mathbb{F}_q^m$  and linearly independent  $\alpha_1, \dots, \alpha_\ell \in \mathbb{F}_q^m$  such that  $L = \{\alpha_0 + \sum_{i=1}^{\ell} \alpha_i x_i \mid x_1, \dots, x_\ell \in \mathbb{F}_q\}$ . We fix an arbitrary affine map  $\gamma_L : \mathbb{F}_q^\ell \rightarrow L$  (which we can view as a parameterization of  $L$ ). For a function  $f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$ , the restriction  $f|_L$  is viewed as a function in  $\{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  through  $f \circ \gamma_L : \mathbb{F}_q^\ell \rightarrow \mathbb{F}_q$ . In particular, when we ask if  $f|_L \stackrel{?}{\in} C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  what we are really asking is whether  $f \circ \gamma_L \in C$ . Note that if  $C$  is affine-invariant, whether  $f|_L \in C$  does not depend on the choice of the parametrization  $\gamma_L$ .

► **Definition 3** (Lifted codes). Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq \ell$ . The  $m$ -dimensional lift  $C^{\ell \nearrow m}$  of  $C$  is given by

$$C^{\ell \nearrow m} := \{f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q \mid f|_L \in C \text{ for every } \ell\text{-dimensional affine subspace } L \subseteq \mathbb{F}_q^m\}.$$

► **Proposition 4** (Distance of lifted codes, [20], Theorem 5.1, Part (2)). Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq \ell$ . Then  $\text{dist}(C^{\ell \nearrow m}) \geq \text{dist}(C) - q^{-\ell}$ .

#### 3.2 Local testing, robust testing, and agreement testing

We now formally define the notions of local testing, robust testing, and agreement testing, specialized to the class of lifted codes and subspace testers. In the case of local testing and robust testing this simply means that the tester samples a uniform random  $k$ -dimensional affine subspace and its accepting views are codewords in  $C^{\ell \nearrow k}$ .

► **Definition 5** (Local testing of lifted codes). Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq k \geq \ell$ . The  $m$ -dimensional lift  $C^{\ell \nearrow m}$  is  $(k, \alpha)$ -testable if for every  $f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$  it holds that

$$\Pr_K [f|_K \notin C^{\ell \nearrow k}] \geq \alpha \cdot \text{dist}(f, C^{\ell \nearrow m}),$$

where the probability is over a uniform random  $k$ -dimensional affine subspace  $K \subseteq \mathbb{F}_q^m$ .

► **Theorem 6** ([23], Theorem 2.9). Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq \ell$ . Then the  $\ell$ -dimensional test rejects a function  $f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$  with probability at least  $\frac{1}{2} \cdot \min \{q^{-2\ell}, \text{dist}(f, C^{\ell \nearrow m})\}$ . In particular,  $C^{\ell \nearrow m}$  is  $(\ell, \frac{q^{-2\ell}}{2})$ -testable.

► **Definition 7** (Robust testing of lifted codes). Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq k \geq \ell$ . The  $m$ -dimensional lift  $C^{\ell \nearrow m}$  is  $(k, \alpha)$ -robust if for every  $f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$  it holds that

$$\mathbb{E}_K [\text{dist}(f|_K, C^{\ell \nearrow k})] \geq \alpha \cdot \text{dist}(f, C^{\ell \nearrow m}),$$

where the expectation is over a uniform random  $k$ -dimensional affine subspace  $K \subseteq \mathbb{F}_q^m$ .

We note the following easy implications.

► **Proposition 8.** Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq k \geq \ell$ . Then the following hold.

1. If  $C^{\ell \nearrow m}$  is  $(k, \alpha)$ -robust then it is  $(k, \alpha)$ -testable.
2. If  $C^{\ell \nearrow m}$  is  $(k, \alpha)$ -testable then it is  $(k, \alpha \cdot q^{-k})$ -robust.
3. If  $C^{\ell \nearrow m}$  is  $(k, \alpha)$ -testable then it is  $(r, \alpha)$ -testable for any  $k \leq r \leq m$ .
4. If  $C^{\ell \nearrow m}$  is  $(k, \alpha)$ -robust then it is  $(r, \alpha)$ -robust for any  $k \leq r \leq m$ .

**Proof.** Part (1) follows since  $f|_K \notin C^{\ell \nearrow k}$  whenever  $\text{dist}(f|_K, C^{\ell \nearrow k}) > 0$ , while Part (2) follows since  $\text{dist}(f|_K, C^{\ell \nearrow k}) \geq q^{-k}$  whenever  $f|_K \notin C^{\ell \nearrow k}$ .

Part (3) follows by observing that for a uniform random  $r$ -dimensional affine subspace  $R$ ,

$$\begin{aligned} \Pr_R [f|_R \notin C^{\ell \nearrow r}] &= \mathbb{E}_R [\mathbb{1}_{f|_R \notin C^{\ell \nearrow r}}] \\ &\geq \mathbb{E}_R \left[ \Pr_{K \subseteq R} [f|_K \notin C^{\ell \nearrow k}] \right] \\ &= \Pr_K [f|_K \notin C^{\ell \nearrow k}], \end{aligned}$$

where the inequality follows since  $f|_R \in C^{\ell \nearrow r}$  implies that  $f|_K \in C^{\ell \nearrow k}$  for any  $K$ .

Finally, Part (4) follows by letting  $f_R$  be the codeword in  $C^{\ell \nearrow r}$  that is closest to  $f|_R$ , and noting that

$$\begin{aligned} \mathbb{E}_R [\text{dist}(f|_R, C^{\ell \nearrow r})] &= \mathbb{E}_R [\text{dist}(f|_R, f_R)] \\ &= \mathbb{E}_R [\mathbb{E}_{K \subseteq R} [\text{dist}(f|_K, f_R|_K)]] \\ &\geq \mathbb{E}_R [\mathbb{E}_{K \subseteq R} [\text{dist}(f|_K, C^{\ell \nearrow k})]] \\ &= \mathbb{E}_K [\text{dist}(f|_K, C^{\ell \nearrow k})], \end{aligned}$$

where the inequality follows since  $f_R|_K \in C^{\ell \nearrow k}$  for any  $K$ . ◀

We now turn to the definition of agreement testing. The agreement testers we consider are two query testers that for  $t < s$ , sample a uniform random  $t$ -dimensional affine subspace  $T$ , and a pair of uniform random  $s$ -dimensional affine subspaces  $S, S'$  containing  $T$ , and accept if and only if  $f_S, f_{S'}$  agree on  $T$ .

For a code  $C \subseteq \{\mathbb{F}_q^m \rightarrow \mathbb{F}_q\}$  we let  $C(s)$  be the code containing all collections  $(f_S)_S$  of partial assignments to  $s$ -dimensional affine subspaces that are consistent with some global codeword  $g \in C$ , formally,

$$C(s) := \{(f_S)_S \mid \exists g \in C \text{ such that } g|_S = f_S \text{ for any } s\text{-dimensional affine subspace } S\}.$$

For a pair of collections  $(f_S)_S, (g_S)_S$  of partial assignments to  $s$ -dimensional affine subspaces we denote by  $\text{dist}((f_S)_S, (g_S)_S)$  the fraction of  $s$ -dimensional affine subspaces  $S$  for which  $f_S \neq g_S$ , and we define  $\text{dist}((f_S)_S, C(s))$  accordingly.

► **Definition 9** (Agreement testing of lifted codes). Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq s > t \geq \ell$ . The  $m$ -dimensional lift  $C^{\ell \nearrow m}$  is  $(s, t, \alpha)$ -agreement testable if for every collection  $(f_S)_S$  where  $f_S \in C^{\ell \nearrow s}$  for every  $s$ -dimensional affine subspace  $S$  it holds that

$$\Pr_{T, S \supseteq T, S' \supseteq T} [f_S|_T \neq f_{S'}|_T] \geq \alpha \cdot \text{dist}((f_S)_S, C^{\ell \nearrow m}(s)),$$

where the probability is over a uniform random  $t$ -dimensional affine subspace  $T \subseteq \mathbb{F}_q^m$ , and uniform random  $s$ -dimensional affine subspaces  $S, S'$  containing  $T$ .

### 3.3 Subspace expansion

Let  $d_0, d_1, d_2 \in \{0, 1, \dots, m\}$  be integers, and let  $W \subseteq \mathbb{F}_q^m$  be a fixed affine subspace of dimension  $d_0$ . We denote by  $\mathcal{I}_{d_1, d_2}(d_0)$  the bipartite graph whose left side are all  $d_1$ -dimensional affine subspaces of  $\mathbb{F}_q^m$ , whose right side are all  $d_2$ -dimensional affine subspaces of  $\mathbb{F}_q^m$  containing  $W$ , and an edge  $(U, V)$  is present in the graph if and only if  $U \subseteq V$  (note that the structure of the graph is independent of the choice of  $W$ ). Our proof makes use of expansion properties of this graph.

► **Proposition 10.** *The second largest normalized singular value of the adjacency matrix of  $\mathcal{I}_{d_1, d_2}(d_0)$  is at most  $q^{-(d_2 - d_1 - d_0)/2}$ .*

**Proof.** Let  $\text{Gr}(m, d_1)$  be the Grassmann graph whose vertices are  $d_1$ -dimensional spaces and edges connect two  $d_1$ -spaces that intersect on an  $d_1 - 1$  space. We quote [11, Theorem 9.3.3] that gives the un-normalized eigenvalues

$$\theta_j = q^{j+1} \begin{bmatrix} d_1 - j \\ 1 \end{bmatrix} \begin{bmatrix} n - d_1 - j \\ 1 \end{bmatrix} - \begin{bmatrix} j \\ 1 \end{bmatrix}$$

and the degree is

$$k = q \begin{bmatrix} d_1 \\ 1 \end{bmatrix} \begin{bmatrix} n - d_1 \\ 1 \end{bmatrix}$$

Plugging in  $j = 1$  one gets the second largest eigenvalue in absolute value is approximately

$$\lambda(\text{Gr}(m, d_1)) \approx \frac{1}{\sqrt{q}}. \quad (3)$$

It can be shown that  $\lambda(\mathcal{I}_{d_1, d_2}(0)) \approx (\lambda(\text{Gr}(m, d_1)))^{d_2 - d_1}$ . When adding  $W$  we are essentially moving to the graph  $\mathcal{I}_{d_1, d_2 - d_0}(0)$ , i.e.  $\lambda(\mathcal{I}_{d_1, d_2}(d_0)) \approx \lambda(\mathcal{I}_{d_1, d_2 - d_0}(0))$ . ◀

We shall use the following sampling property of  $\mathcal{I}_{d_1, d_2}(d_0)$ .

► **Proposition 11.** *Let  $G = (L \cup R, E)$  be a bipartite graph with second largest normalized singular value  $\lambda$ . Then for any subset  $A \subseteq L$  of density  $\alpha$  it holds that  $|N(A)| \geq (1 - \lambda^2/\alpha) \cdot |R|$  where  $N(A)$  denotes the set of neighbors of  $A$  in  $R$ .*

**Proof.** Let  $B := R \setminus N(A)$  and  $\beta := |B|/|R|$ . Noting that  $\Pr_{(u,v) \in E} [u \in A \wedge v \in B] = 0$ , by expander mixing lemma (see e.g., [13, Lemma 2.8.]) we have that

$$\alpha\beta = \left| \Pr_{(u,v) \in E} [u \in A \wedge v \in B] - \alpha\beta \right| \leq \lambda\sqrt{\alpha\beta},$$

and so  $\beta \leq \lambda^2/\alpha$ . It follows that  $|N(A)| = (1 - \beta)|R| \geq (1 - \lambda^2/\alpha)|R|$ . ◀

## 4 From agreement testing to robust testing

In this section we prove the following lemma showing the agreement testing to robust testing implication.

► **Lemma 12** (Agreement testing implies robust testing). *Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq s > t \geq \ell$ . Suppose that  $C^{\ell \nearrow m}$  is  $(s, t, \alpha)$ -agreement testable, and let  $\delta := \text{dist}(C^{\ell \nearrow t})$ . Then  $C^{\ell \nearrow m}$  is  $(s, \Omega(\alpha\delta))$ -robust.*

**Proof.** For simplicity of notation, in what follows we let  $T, S$  denote the random variables obtained by sampling a uniform random affine subspace of dimension  $t, s$  respectively. Suppose that  $f : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$  has  $\mathbb{E}_S[\text{dist}(f|_S, C^{\ell \nearrow s})] \leq \epsilon$ , our goal is to find a codeword  $g \in C^{\ell \nearrow m}$  such that  $\text{dist}(f, g) \leq O(\epsilon/(\alpha\delta))$ .

The proof proceeds as follows. We would like to apply our assumption on agreement testability, and towards this, we create an instance  $(f_S)_S$  for the agreement tester by letting  $f_S$  be the codeword in  $C^{\ell \nearrow s}$  that is closest to  $f|_S$ . We then use the fact that  $f_S$  is typically close to  $f|_S$ , together with the fact that  $t$ -dimensional affine subspaces sample well inside  $s$ -dimensional affine subspaces, and the assumption that  $C$  has distance on  $t$ -dimensional affine subspaces, to show that  $\Pr_{T, S \supseteq T, S' \supseteq T}[f_S|_T \neq f_{S'}|_T]$  is small. Agreement testability then gives a codeword  $g \in C^{\ell \nearrow m}$  that is consistent with most  $f_S$ , and using the fact that  $s$ -dimensional affine subspaces sample well inside  $\mathbb{F}_q^m$  this implies in turn that  $\text{dist}(f, g)$  is small. Details follow.

We begin by showing that  $\Pr_{T, S \supseteq T, S' \supseteq T}[f_S|_T \neq f_{S'}|_T]$  is small. Recall first that  $\mathbb{E}_S[\text{dist}(f|_S, f_S)] = \mathbb{E}_S[\text{dist}(f|_S, C^{\ell \nearrow s})] \leq \epsilon$ . Next observe that for a fixed  $s$ -dimensional affine subspace  $S$ , any point in a uniform random  $t$ -dimensional affine subspace contained in  $S$  is uniform in  $S$ . Thus we also have that  $\mathbb{E}_{S, T \subseteq S}[\text{dist}(f|_T, f_S|_T)] \leq \epsilon$ , and consequently

$$\begin{aligned} \Pr_{T, S \supseteq T, S' \supseteq T}[\text{dist}(f_S|_T, f_{S'}|_T) \geq \delta] &\leq 2 \cdot \Pr_{T, S \supseteq T}[\text{dist}(f|_T, f_S|_T) \geq \delta/2] \\ &= 2 \cdot \Pr_{S, T \subseteq S}[\text{dist}(f|_T, f_S|_T) \geq \delta/2] \\ &\leq \frac{4\epsilon}{\delta}. \end{aligned}$$

But since  $f_S|_T, f_{S'}|_T$  are both codewords of  $C^{\ell \nearrow t}$ , a code of relative distance  $\delta$ , the above implies in turn that  $\Pr_{T, S \supseteq T, S' \supseteq T}[f_S|_T \neq f_{S'}|_T] \leq \frac{4\epsilon}{\delta}$ .

Our assumption on agreement testability now gives a codeword  $g \in C^{\ell \nearrow m}$  that has  $\Pr_S[g|_S \neq f_S] \leq 4\epsilon/(\alpha\delta)$ . But since any point in a uniform random  $s$ -dimensional affine subspace is uniform in  $\mathbb{F}_q^m$  this gives in turn that

$$\text{dist}(f, g) = \mathbb{E}_S[\text{dist}(f|_S, g|_S)] \leq \mathbb{E}_S[\text{dist}(f|_S, f_S)] + \mathbb{E}_S[\text{dist}(f_S, g|_S)] \leq \epsilon + \frac{4\epsilon}{\alpha\delta} \leq \frac{5\epsilon}{\alpha\delta}. \quad \blacktriangleleft$$

## 5 From local testing to agreement testing

In this section we prove the following lemma that gives the local testing to agreement testing implication.

► **Lemma 13** (Local testing implies agreement testing). *Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq k \geq \ell$ . Suppose that  $C^{\ell \nearrow m}$  is  $(k, \alpha)$ -testable, and let  $\delta := \min_{k \leq r \leq m} \text{dist}(C^{\ell \nearrow r})$ . Then  $C^{\ell \nearrow m}$  is  $(2k + \log_q(4/\delta), k + 1, \Omega(\alpha \cdot \delta^2))$ -agreement testable.*

**Proof outline**

For simplicity of notation, in what follows let  $s := 2k + \log_q(4/\delta)$  and  $t := k + 1$ . We let both  $S, S'$  ( $T, T'$  and  $K, K'$ , resp.) denote random variables obtained by sampling a uniform random affine subspace of dimension  $s$  ( $t, k$ , resp.).

Let  $(f_S)_S$  be a collection of partial assignments such that  $f_S \in C^{\ell, \gamma^s}$  for every  $S$ , and

$$\Pr_{T, S \supseteq T, S' \supseteq T} [f_S|_T \neq f_{S'}|_T] \leq \epsilon. \quad (4)$$

Our goal is to find a global codeword  $g \in C^{\ell, \gamma^m}$  that has

$$\Pr_S [g|_S \neq f_S] \leq O\left(\frac{\epsilon}{\alpha \cdot \delta^2}\right). \quad (5)$$

We find the codeword  $g$  in three stages.

1. In the initial stage (Section 5.1) we define for any  $k$ -dimensional affine subspace  $K$  a “most popular function”  $\text{Plur}_K : \mathbb{F}_q^k \rightarrow \mathbb{F}_q$  by choosing the most common value among  $f_S|_K$  going over all  $S \supseteq K$ . We show that for a typical  $K$ , this function is obtained with an overwhelming plurality of  $1 - O(\epsilon)$ .
2. In the “local structure” stage (Section 5.2) we define for any  $k$ -dimensional affine subspace  $K$  a function  $g_K : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$  by letting  $g_K(x)$  be the most common “vote” among all  $f_S$  that contain both  $K$  and  $x$  and agree with  $\text{Plur}_K$  on  $K$ . We then show that for a typical  $K$ ,  $g_K$  is close to some codeword  $h_K \in C^{\ell, \gamma^m}$ , and moreover  $h_K|_S = f_S$  for most  $S$  containing  $K$ .
3. In the “global structure” stage (Section 5.3) we show that there exists  $\hat{K}$  for which  $h_{\hat{K}}|_S = f_S$  for most  $S$  (not necessarily containing  $\hat{K}$ ). We can then set our “global function”  $g$  to be equal to  $h_{\hat{K}}$ .

## 5.1 Initial stage

For any  $k$ -dimensional affine subspace  $K$  we let  $\text{Plur}_K : \mathbb{F}_q^k \rightarrow \mathbb{F}_q$  denote the most common value among  $f_S|_K$  for  $S$  containing  $K$ , that is,

$$\text{Plur}_K := \text{plurality}_{S \supseteq K} \{f_S|_K\}.$$

Next we use our assumption (4) to show that for a typical  $K$ , the function  $\text{Plur}_K$  is obtained with overwhelming plurality.

► **Lemma 14.**

$$\mathbb{E}_K \left[ \Pr_{S \supseteq K} [f_S|_K \neq \text{Plur}_K] \right] \leq 2\epsilon.$$

**Proof.** Since the collision probability lower bounds the probability of hitting the most common value, it suffices to show that

$$\Pr_{K, S \supseteq K, S' \supseteq K} [f_S|_K \neq f_{S'}|_K] \leq 2\epsilon. \quad (6)$$

Clearly if  $t = k$  we would be done by (4), so the whole point is to show the same for  $t > k$ . We describe a distribution on triples  $(S_1, S', S_2)$  such that  $(S_1, S_2)$  are distributed as in (6) but the pairs  $(S_1, S')$  and  $(S', S_2)$  are distributed as in (4):

1. Choose a uniform random  $k$ -dimensional affine subspace  $K$ .
2. Choose a pair of uniform random  $t$ -dimensional affine subspaces  $T_1, T_2$  containing  $K$ .

3. For  $i = 1, 2$ , choose a uniform random  $s$ -dimensional affine subspace  $S_i$  containing  $T_i$ .
4. Choose a uniform random  $s$ -dimensional affine subspace  $S'$  containing  $T_1 \cup T_2$  (this can be done since  $t = k + 1$  and  $s \geq k + 2$ ).

One can check that indeed  $K, S_1, S_2$  are distributed as in (6) while  $T_i, S_i, S'$  are distributed as in (4). Thus by our assumption (4),

$$\begin{aligned} & \Pr_{K, S_1 \supseteq K, S_2 \supseteq K} [f_{S_1}|_K \neq f_{S_2}|_K] \\ & \leq \Pr_{T_1, S_1 \supseteq T_1, S' \supseteq T_1} [f_{S_1}|_{T_1} \neq f_{S'}|_{T_1}] + \Pr_{T_2, S' \supseteq T_2, S_2 \supseteq T_2} [f_{S'}|_{T_2} \neq f_{S_2}|_{T_2}] \leq 2\epsilon. \quad \blacktriangleleft \end{aligned}$$

## 5.2 Local structure

Next we define for every  $k$ -dimensional affine subspace  $K$  the function  $g_K : \mathbb{F}_q^m \rightarrow \mathbb{F}_q$ . As described above, for every  $x \in \mathbb{F}_q^m$ , we let  $g_K(x)$  be the most common value among  $f_S(x)$  for  $S$  that contain both  $K$  and  $x$  and agree with  $\text{Plur}_K$  on  $K$ , that is,

$$g_K(x) := \text{plurality}_{S \supseteq K \cup \{x\}, f_S|_K = \text{Plur}_K} \{f_S(x)\}.$$

Next we would like to show that for a typical  $K$ ,  $g_K$  is close to some codeword  $h_K \in C^{\ell \nearrow m}$ , and additionally  $h_K|_S = f_S$  for most  $S$  containing  $K$ . We show these in three steps:

1. Boosting step (Lemma 15): In this step we show that for typical  $K, x$ , the plurality in the definition of  $g_K(x)$  is obtained with overwhelming probability.
2. LTC step (Lemma 16): In this step we use the previous step to show that for a typical  $g_K$ , for most  $K'$ ,  $g_K|_{K'}$  agrees with some  $f_S$  on  $K'$ , and therefore is a codeword of  $C^{\ell \nearrow k}$ . By local testability assumption this implies in turn that such  $g_K$  is close to being in the code  $C^{\ell \nearrow m}$ , and we denote by  $h_K \in C^{\ell \nearrow m}$  the closest codeword to  $g_K$ .
3. Agreement step (Lemma 17): In this step we show that a typical  $h_K$  agrees with most  $f_S$  for  $S \supseteq K$ .

We start with the boosting step, showing that for typical  $K, x$ , the plurality in the definition of  $g_K(x)$  is obtained with overwhelming probability. Intuitively, this follows by assumption that the code has distance on  $t$ -dimensional affine subspaces, together with the fact that  $k$ -dimensional affine subspaces sample well inside  $t$ -dimensional affine subspaces, which imply that if a pair of  $f_S$  agree on  $K$  then they must typically also agree on their whole intersection.

► **Lemma 15** (Boosting step).

$$\mathbb{E}_{K, x \notin K} \left[ \Pr_{S \supseteq K \cup \{x\}} [f_S(x) \neq g_K(x) \mid f_S|_K = \text{Plur}_K] \right] \leq O \left( q^{-k} \cdot \frac{\epsilon}{\delta \cdot (1 - 4\epsilon)} \right).$$

**Proof.** Since the collision probability lower bounds the probability of hitting the most common value, it suffices to show that

$$\Pr_{K, x \notin K, S \supseteq K \cup \{x\}, S' \supseteq K \cup \{x\}} [f_S(x) \neq f_{S'}(x) \mid f_S|_K = f_{S'}|_K = \text{Plur}_K] \leq O \left( q^{-k} \cdot \frac{\epsilon}{\delta \cdot (1 - 4\epsilon)} \right).$$

Now we have that

$$\begin{aligned} & \Pr_{K, x \notin K, S \supseteq K \cup \{x\}, S' \supseteq K \cup \{x\}} [f_S(x) \neq f_{S'}(x) \mid f_S|_K = f_{S'}|_K = \text{Plur}_K] \\ & \leq \Pr_{K, T \supseteq K, S \supseteq T, S' \supseteq T} [f_S|_T \neq f_{S'}|_T \mid f_S|_K = f_{S'}|_K = \text{Plur}_K] \\ & = \frac{\Pr_{T, S \supseteq T, S' \supseteq T, K \subseteq T} [f_S|_K = f_{S'}|_K = \text{Plur}_K \mid f_S|_T \neq f_{S'}|_T] \cdot \Pr_{T, S \supseteq T, S' \supseteq T} [f_S|_T \neq f_{S'}|_T]}{\Pr_{K, T \supseteq K, S \supseteq T, S' \supseteq T} [f_S|_K = f_{S'}|_K = \text{Plur}_K]}. \end{aligned}$$

## 29:14 From Local to Robust Testing via Agreement Testing

Next we bound each of the terms above.

By our assumption (4), the right hand term in the numerator is upper bounded by  $\epsilon$ . To bound the denominator note that by Lemma 14,

$$\Pr_{K, T \supseteq K, S \supseteq T, S' \supseteq T} [f_S|_K = f_{S'}|_K = \text{Plur}_K] \geq 1 - 2 \cdot \Pr_{K, S \supseteq K} [f_S|_K \neq \text{Plur}_K] \geq 1 - 4\epsilon. \quad (7)$$

To bound the left hand term in the numerator note first that since  $f_S, f_{S'}$  are both codewords of  $C^{\ell, \lambda^s}$  then  $f_S|_T, f_{S'}|_T$  are distinct codewords in  $C^{\ell, \lambda^t}$ , and so  $\text{dist}(f_S|_T, f_{S'}|_T) \geq \delta$ . We now apply Propositions 10 and 11 on the graph  $\mathcal{I}_{0,k}(0)$ : The ambient space is  $T$ , and the graph connects the points of  $T$  (which are the 0-dimensional affine subspaces contained in  $T$ ) on the left to the  $k$ -dimensional affine subspaces contained in  $T$  on the right. By Proposition 10 the graph  $\mathcal{I}_{0,k}(0)$  has second largest normalized singular value at most  $q^{-k/2}$ , and so taking  $A = \{x \in T \mid f_S(x) \neq f_{S'}(x)\}$  in Proposition 11 we deduce that at most  $q^{-k}/\delta$  fraction of  $K$  can miss  $A$  altogether. Thus,

$$\Pr_{T, S \supseteq T, S' \supseteq T, K \subseteq T} [f_S|_K = f_{S'}|_K \mid f_S|_T \neq f_{S'}|_T] \leq \frac{q^{-k}}{\delta}. \quad (8)$$

The final bound is obtained by combining the bounds in (4), (7), and (8).  $\blacktriangleleft$

Next we use the assumption on local testability to show that for a typical  $K$ ,  $g_K$  is close to being a codeword of  $C^{\ell, \lambda^m}$ .

► **Lemma 16** (LTC step).

$$\mathbb{E}_K [\text{dist}(g_K, C^{\ell, \lambda^m})] \leq O\left(\frac{\epsilon}{\alpha \cdot \delta}\right).$$

**Proof.** To apply our assumption on local testability we first show that  $g_K|_{K'}$  is typically a codeword of  $C^{\ell, \lambda^k}$ . For this, first observe that if  $g_K|_{K'}$  is not a codeword of  $C^{\ell, \lambda^k}$  then  $g_K|_{K'} \neq f_S|_{K'}$  for all  $S$  (since  $f_S \in C^{\ell, \lambda^s}$  and so  $f_S|_{K'} \in C^{\ell, \lambda^k}$ ). Thus we have

$$\begin{aligned} \mathbb{E}_{K, K'} [\mathbb{1}_{g_K|_{K'} \notin C^{\ell, \lambda^k}}] &\leq \mathbb{E}_{K, K'} \left[ \Pr_{S \supseteq K \cup K'} [g_K|_{K'} \neq f_S|_{K'}] \right] \\ &\leq \mathbb{E}_{K, K'} \left[ \Pr_{S \supseteq K \cup K'} [g_K|_{K'} \neq f_S|_{K'} \mid f_S|_K = \text{Plur}_K] \right] + \Pr_{K, S \supseteq K} [f_S|_K \neq \text{Plur}_K] \end{aligned}$$

We claim that the above expression is at most  $O(\epsilon/\delta)$ . To see this note first that by Lemma 14 the right hand term is at most  $2\epsilon$ . To bound the left hand term, note that since each individual point in  $K'$  is uniformly distributed in  $\mathbb{F}_q^m$  this term is upper bounded by

$$q^k \cdot \mathbb{E}_{K, x} \left[ \Pr_{S \supseteq K \cup \{x\}} [g_K(x) \neq f_S(x) \mid f_S|_K = \text{Plur}_K] \right],$$

which is in turn at most  $O(\epsilon/\delta)$  by Lemma 15 (noting that the probability in the above expression is zero whenever  $x \in K$ ).

Finally, for any  $k$ -dimensional affine subspace  $K$  let  $\epsilon_K := \Pr_{K'} [g_K|_{K'} \notin C^{\ell, \lambda^k}]$ . Then on the one hand  $\mathbb{E}_K[\epsilon_K] = \mathbb{E}_{K, K'} [\mathbb{1}_{g_K|_{K'} \notin C^{\ell, \lambda^k}}] \leq O(\epsilon/\delta)$ , and on the other hand  $\text{dist}(g_K, C^{\ell, \lambda^m}) \leq \epsilon_K/\alpha$  for any  $K$  by assumption that  $C^{\ell, \lambda^m}$  is  $(k, \alpha)$ -testable. We conclude that

$$\mathbb{E}_K [\text{dist}(g_K, C^{\ell, \lambda^m})] \leq \mathbb{E}_K \left[ \frac{\epsilon_K}{\alpha} \right] \leq O\left(\frac{\epsilon}{\alpha \cdot \delta}\right). \quad \blacktriangleleft$$

For any  $k$ -dimensional affine subspace  $K$  let  $h_K \in C^{\ell, \lambda^m}$  be the codeword that is closest to  $g_K$ . Then by the above lemma,

$$\mathbb{E}_K [\text{dist}(g_K, h_K)] \leq O\left(\frac{\epsilon}{\alpha \cdot \delta}\right).$$

The following lemma says that for a typical  $K$  we have that  $h_K|_S = f_S$  for most  $S$  containing  $K$ , which follows by the fact that  $s$ -dimensional affine subspaces sample well inside  $\mathbb{F}_q^m$  and by assumption that the code has distance on  $s$ -dimensional affine subspaces.

► **Lemma 17** (Agreement step).

$$\mathbb{E}_K \left[ \Pr_{S \supseteq K} [h_K|_S \neq f_S] \right] \leq O\left(\frac{\epsilon}{\alpha \cdot \delta^2}\right).$$

**Proof.** We show that for typical  $S \supseteq K$ , on the one hand, by Lemma 16 and the fact that  $s$ -dimensional affine subspaces sample well inside  $\mathbb{F}_q^m$ ,  $\text{dist}(h_K|_S, g_K|_S)$  is small, and on the other hand, by Lemma 15,  $\text{dist}(g_K|_S, f_S)$  is small. We then conclude by triangle inequality that  $\text{dist}(h_K|_S, f_S)$  is small, which implies in turn that  $h_K|_S = f_S$  by assumption that the code has distance on  $s$ -dimensional subspaces.

We start by showing that  $\text{dist}(h_K|_S, g_K|_S)$  is typically small. For this note that for a fixed  $k$ -dimensional affine subspace  $K$  and uniform random  $S$  containing  $K$ , each individual point in  $S \setminus K$  is uniformly distributed in  $\mathbb{F}_q^m \setminus K$ . Thus we have

$$\mathbb{E}_{K, S \supseteq K} [\text{dist}(h_K|_S, g_K|_S)] \leq q^{-(s-k)} + \mathbb{E}_K [\text{dist}(h_K, g_K)] \leq \frac{\delta}{4} + O\left(\frac{\epsilon}{\alpha \cdot \delta}\right), \quad (9)$$

where the last inequality follows by choice of  $s \geq k + \log_q(4/\delta)$  and Lemma 16.

Next we show that  $\text{dist}(h_K|_S, f_S)$  is typically small. For this note that

$$\begin{aligned} & \mathbb{E}_{K, S \supseteq K} [\text{dist}(g_K|_S, f_S)] \\ & \leq q^{-(s-k)} + \mathbb{E}_{K, x \notin K} \left[ \Pr_{S \supseteq K \cup \{x\}} [g_K(x) \neq f_S(x)] \right] \\ & \leq q^{-(s-k)} + \mathbb{E}_{K, x \notin K} \left[ \Pr_{S \supseteq K \cup \{x\}} [g_K(x) \neq f_S(x) \mid f_S|_K = \text{Plur}_K] \right] + \Pr_{K, S \supseteq K} [f_S|_K \neq \text{Plur}_K] \\ & \leq \frac{\delta}{4} + O\left(\frac{\epsilon}{\delta}\right), \end{aligned} \quad (10)$$

where the last inequality follows by choice of  $s \geq k + \log_q(4/\delta)$  and Lemmas 15 and 14.

Combining (9) and (10), by triangle inequality we have that

$$\mathbb{E}_{K, S \supseteq K} [\text{dist}(h_K|_S, f_S)] \leq \frac{\delta}{2} + O\left(\frac{\epsilon}{\alpha \cdot \delta}\right),$$

and by Markov's inequality,

$$\Pr_{K, S \supseteq K} [\text{dist}(h_K|_S, f_S) \geq \delta] \leq O\left(\frac{\epsilon}{\alpha \cdot \delta^2}\right).$$

Finally, since both  $h_K|_S$  and  $f_S$  are codewords of  $C^{\ell, \lambda^s}$  and  $\text{dist}(C^{\ell, \lambda^s}) \geq \delta$  we conclude that  $h_K|_S \neq f_S$  with probability at most  $O\left(\frac{\epsilon}{\alpha \cdot \delta^2}\right)$  over the choice of  $K$  and  $S \supseteq K$ . ◀

### 5.3 Global structure

We now complete the proof of Lemma 13 by showing that there exists a codeword  $g \in C^{\ell, \gamma^m}$  that agrees with most  $f_S$ . We start by showing that most functions  $h_K$  are in fact identical, which follows by Lemma 17 and the fact that  $s$ -dimensional affine subspaces sample well inside  $\mathbb{F}_q^m$ .

► **Lemma 18.** *There exists a  $k$ -dimensional affine subspace  $\hat{K}$  such that*

$$\Pr_K [h_K \neq h_{\hat{K}}] \leq O\left(\frac{\epsilon}{\alpha \cdot \delta^2}\right).$$

**Proof.** By Lemma 17,

$$\Pr_{K, K', S \supseteq K \cup K'} [h_K|_S \neq h_{K'}|_S] \leq 2 \cdot \Pr_{K, S \supseteq K} [h_K|_S \neq f_S] \leq O\left(\frac{\epsilon}{\alpha \cdot \delta^2}\right),$$

and so by averaging there exists  $\hat{K}$  such that

$$\Pr_{K, S \supseteq K \cup \hat{K}} [h_K|_S \neq h_{\hat{K}}|_S] \leq O\left(\frac{\epsilon}{\alpha \cdot \delta^2}\right).$$

Markov's inequality then implies that

$$\Pr_{S \supseteq K \cup \hat{K}} [h_K|_S \neq h_{\hat{K}}|_S] \geq \frac{1}{2}$$

with probability at most  $O\left(\frac{\epsilon}{\alpha \cdot \delta^2}\right)$  over the choice of  $K$ .

Next observe that if  $h_K \neq h_{\hat{K}}$  then since  $h_K, h_{\hat{K}}$  are both codewords of  $C^{\ell, \gamma^m}$  and  $\text{dist}(C^{\ell, \gamma^m}) \geq \delta$ , it must hold that  $\text{dist}(h_K, h_{\hat{K}}) \geq \delta$ . We now apply Propositions 10 and 11 on the graph  $\mathcal{I}_{0,s}(2k)$  that connects the points of  $\mathbb{F}_q^m$  on the left to the  $s$ -dimensional affine subspaces containing  $K \cup \hat{K}$  on the right. By Proposition 10 the graph  $\mathcal{I}_{0,s}(2k)$  has second largest normalized singular value at most  $q^{-(s-2k)/2}$ , and so taking  $A = \{x \in \mathbb{F}_q^m \mid h_K(x) \neq h_{\hat{K}}(x)\}$  in Proposition 11 we deduce that

$$\Pr_{S \supseteq K \cup \hat{K}} [h_{\hat{K}}|_S \neq h_K|_S] \geq 1 - \frac{q^{-(s-2k)}}{\delta} \geq 1/2,$$

where the last inequality follows by assumption that  $s \geq 2k + \log_q(2/\delta)$ .

It now follows that  $h_K \neq h_{\hat{K}}$  with probability at most  $O\left(\frac{\epsilon}{\alpha \cdot \delta^2}\right)$  over the choice of  $K$ . ◀

We can now complete the proof of Lemma 13.

**Proof of Lemma 13.** Set  $g \in C^{\ell, \gamma^m}$  to be the function  $h_{\hat{K}}$  guaranteed by Lemma 18. By Lemmas 17 and 18,

$$\Pr_S [g|_S \neq f_S] = \Pr_{K, S \supseteq K} [g|_S \neq f_S] \leq \Pr_K [g \neq h_K] + \Pr_{K, S \supseteq K} [h_K|_S \neq f_S] \leq O\left(\frac{\epsilon}{\alpha \cdot \delta^2}\right).$$

So  $g$  satisfies (5) as required. ◀

## 6 From local testing to robust testing

### 6.1 Proof of Main Theorem 1

We can now combine Lemmas 12 and 13 to prove our main Theorem 1, showing a transformation from local testing to robust testing.

**Proof of Theorem 1.** By Lemma 13 we have that  $C^{\ell, \gamma^m}$  is  $(2k + \log_q(4/\delta), k + 1, \Omega(\alpha \cdot \delta^2))$ -agreement testable, and by Lemma 12 this implies in turn that  $C^{\ell, \gamma^m}$  is  $(2k + \log_q(4/\delta), \Omega(\alpha \cdot \delta^3))$ -robust. ◀

## 6.2 Proof of Corollary 2

We now instantiate our main Theorem 1 with Theorem 6 to show that lifted codes are robustly testable. For this, we first observe that one can amplify the soundness of the tester given by Theorem 6 to a constant (independent of  $q$  and  $\ell$ ) at the cost of increasing the testing dimension to  $\approx 3\ell$ .

► **Proposition 19.** *Let  $C \subseteq \{\mathbb{F}_q^\ell \rightarrow \mathbb{F}_q\}$  be an affine-invariant linear code, and  $m \geq 3\ell + \log_q 4$ . Then  $C^{\ell \nearrow m}$  is  $(3\ell + \log_q 4, \Omega(1))$ -testable.*

**Proof.** If the  $\ell$ -dimensional test rejects with probability at least  $\frac{1}{2} \cdot \text{dist}(f, C^{\ell \nearrow m})$  then by Part (3) of Proposition 8, the  $(3\ell + \log_q 4)$ -dimensional test also rejects with the same probability and we are done. Otherwise, by Theorem 6, the  $\ell$ -dimensional test rejects with probability at least  $\frac{1}{2} \cdot q^{-2\ell}$ .

Consider the graph  $\mathcal{I}_{\ell, 3\ell + \log_q 4}(0)$  with left hand side being all  $\ell$ -dimensional affine subspaces of  $\mathbb{F}_q^m$  and right hand side being all  $(3\ell + \log_q 4)$ -dimensional affine subspaces of  $\mathbb{F}_q^m$ . Next we apply Propositions 10 and 11 on the graph  $\mathcal{I}_{\ell, 3\ell + \log_q 4}(0)$  with  $A$  being the collection of all  $\ell$ -dimensional affine subspaces on which the  $\ell$ -dimensional test rejects. Noting that the  $(3\ell + \log_q 4)$ -dimensional test will reject on any neighbor of  $A$  we conclude that the  $(3\ell + \log_q 4)$ -dimensional test rejects with probability at least  $1 - \frac{q^{-(2\ell + \log_q 4)}}{q^{-2\ell/2}} = \frac{1}{2}$ . ◀

We now turn to the proof of Corollary 2.

**Proof of Corollary 2.** Suppose first that  $\delta < 2q^{-\ell}$ . In this case by Theorem 6,  $C^{\ell \nearrow m}$  is  $(\ell, \Omega(q^{-2\ell}))$ -testable, and so by Part (2) of Proposition 8,  $C^{\ell \nearrow m}$  is also robustly testable using the  $\ell$ -dimensional test with robustness  $\Omega(q^{-3\ell}) \geq \Omega(\delta^3)$ . By Part (4) of Proposition 8 it follows that the  $(6\ell + \log_q(128/\delta))$ -dimensional test also has robustness  $\Omega(\delta^3)$ .

Next assume that  $\delta \geq 2q^{-\ell}$ . In this case Proposition 4 gives that  $\text{dist}(C^{\ell \nearrow r}) \geq \delta/2$  for any  $\ell \leq r \leq m$ , and so we may apply Proposition 19 and Theorem 1 and conclude that  $C^{\ell \nearrow m}$  is  $(6\ell + \log_q(128/\delta), \Omega(\delta^3))$ -robust. ◀

## Abstract

We show that every set in  $\mathcal{P}$  is strongly testable under a suitable encoding. By “strongly testable” we mean having a (proximity oblivious) tester that makes a constant number of queries and rejects with probability that is proportional to the distance of the tested object from the property. By a “suitable encoding” we mean one that is polynomial-time computable and invertible. This result stands in contrast to the known fact that some sets in  $\mathcal{P}$  are extremely hard to test, providing another demonstration of the crucial role of representation in the context of property testing.

The testing result is proved by showing that any set in  $\mathcal{P}$  has a *strong canonical PCP*, where canonical means that (for YES-instances) there exists a single proof that is accepted with probability 1 by the system, whereas all other potential proofs are rejected with probability proportional to their distance from this proof. In fact, we show that  $\mathcal{UP}$  equals the class of sets having strong canonical PCPs (of logarithmic randomness), whereas the class of sets having strong canonical PCPs with polynomial proof length equals “unambiguous- $\mathcal{MA}$ ”. Actually, for the testing result, we use a PCP-of-Proximity version of the foregoing notion and an analogous positive result (i.e., strong canonical PCPPs of logarithmic randomness for any set in  $\mathcal{UP}$ ).

## 1 Introduction

In the last couple of decades, the area of property testing has attracted much attention (see, e.g., a recent textbook [12]). Loosely speaking, property testing typically refers to super-fast probabilistic algorithms for deciding whether a given object has a predetermined property or is far from any object having this property. Such algorithms, called testers, obtain local views of the object by performing queries; that is, the tested object is modeled as a function and the testers get oracle access to this function (and thus may be expected to work in time that is sub-linear in the size of the object).

<sup>2</sup> Supported by the Israel Science Foundation (grants No. 671/13 and 1146/18).

<sup>3</sup> Supported in part by the UC Berkeley Center for Long-Term Cybersecurity.

It is well known that property testing is very sensitive to the representation of the tested objects, far more so than standard studies in complexity theory (cf. [12, Sec. 1.2.5]). For example, while the adjacency matrix and the incident lists representations are equivalent as far as complexity classes such as  $\mathcal{P}$  are concerned, in the case of property testing there is a significant difference between the *adjacency matrix model* (a.k.a. the *dense graph model* [13]) and the *incidence graph model* (a.k.a. the *bounded-degree graph model* [16]).

In this paper we provide another demonstration of the crucial role of representation in the context of property testing. Specifically, in contrast to the known fact that some sets in  $\mathcal{P}$  are extremely hard to test (see, e.g., [15, Theorem 7]),<sup>4</sup> we show that, *under a suitable polynomial-time computable (and invertible) encoding, all sets in  $\mathcal{P}$  are extremely easy to test*, where by “extremely easy to test” we mean having a Proximity Oblivious Tester (POT).

### 1.1 Our main result: a POT for an encoding of any set in $\mathcal{P}$

The standard definition of a property tester refers to randomized oracle machines that are given two parameters as explicit inputs along with oracle access to some string (or function). The two parameters are the *size parameter*, representing the size of the tested object, and a *proximity parameter*, denoted  $\epsilon$ , which determines which objects are considered *far from the property*<sup>5</sup> (according to a fixed metric, typically the relative Hamming distance). Specifically, on input parameters  $n$  and  $\epsilon$ , the test is required to distinguish (with constant probability)  $n$ -bit long strings that have the property from  $n$ -bit long strings that are  $\epsilon$ -far from the property, where  $x \in \{0, 1\}^n$  is  $\epsilon$ -far from  $S$  if for every  $x' \in S \cap \{0, 1\}^n$  it holds that  $\delta(x, x') \stackrel{\text{def}}{=} |\{i \in [n] : x_i \neq x'_i\}|/n$  is greater than  $\epsilon$ . (Otherwise, we say that  $x$  is  $\epsilon$ -close to  $S$ .)

The query complexity of testers is stated as a function of the two explicit parameters,  $n$  and  $\epsilon$ . Two extreme cases are the case of query complexity  $n$ , which can be obtained for any property, and the case that the query complexity depends only on the proximity parameter, which is sometimes considered the yardstick for “easy testability” (see, e.g., [1, 2]). Typically, the query complexity is  $\Omega(1/\epsilon)$ , and so testers of such complexity are extremely efficient. An even more restricted case refers to one in which the tester operates by repeating some constant-query check for  $O(1/\epsilon)$  times, where the celebrated linearity tester of Blum, Luby, and Rubinfeld [7] is an archetypical case. The effect of a single repetition of the constant-query check is captured by the notion of a *proximity oblivious tester* [17].

A Proximity Oblivious Tester (POT) does not obtain a proximity parameter as input, but rather the probability gap with which it distinguishes inputs that have the property from ones that lack the property is allowed to be a function of the distance of the tested input from the property (defined in (1)). Further restricting ourselves to the case of one-sided error testers, we require that the POT always accepts inputs that have the property and rejects objects that lack the property with probability that increases with the distance of the object from the property.<sup>6</sup> For sake of clarity, we recall that the distance of  $x$  from  $S$ , denoted  $\delta_S(x)$ , is defined as follows

$$\delta_S(x) \stackrel{\text{def}}{=} \min_{x' \in \{0,1\}^{|x|} \cap S} \{\delta(x, x')\}, \quad (1)$$

where  $\delta_S(x) = 1$  if  $\{0, 1\}^{|x|} \cap S = \emptyset$ .

<sup>4</sup> This is essentially due to [13, Prop 4.1.1].

<sup>5</sup> As usual in the area, we associate the notion of having a property with the notion of being in the (set of objects that have the) property.

<sup>6</sup> A two-sided error version was also studied (see [18]), but the one-sided error version that we consider here is much better known.

► **Definition 1.1** (Proximity Oblivious Testers).<sup>7</sup> Let  $\varrho: (0, 1] \rightarrow (0, 1]$  be monotonically non-decreasing.<sup>8</sup> A proximity oblivious tester (POT) with detection probability function  $\varrho$  for  $S$  is a probabilistic oracle machine, denoted  $T$ , that makes a constant number of queries and satisfies the following two conditions.

1.  $T$  always accepts inputs in  $S$ : For every  $n \in \mathbb{N}$  and every  $w \in S \cap \{0, 1\}^n$ , it holds that  $\Pr[T^w(n) = 1] = 1$ .
2.  $T$  rejects inputs that are not in  $S$  with probability that increases as a function of their distance from  $S$ : For every  $n \in \mathbb{N}$  and every  $w \in \{0, 1\}^n \setminus S$ , it holds that  $\Pr[T^w(n) = 0] \geq \varrho(\delta_S(w))$ .

The case that  $\varrho$  is linear is of special interest; in this case the rejection probability is proportional to the distance of the input from the set  $S$ .

Our main result asserts the existence of a POT for some encoding of any set in  $\mathcal{P}$ . Starting with some natural representation of a set  $S \subseteq \{0, 1\}^*$ , we consider a representation obtained by applying an invertible encoding  $E: \{0, 1\}^* \rightarrow \{0, 1\}^*$  (i.e., we require that  $E$  is one-to-one). Furthermore, we consider the natural case in which this encoding is polynomial-time computable and invertible. For example, we may consider an encoding such as  $E(x_1 \cdots x_n) = x_1 x_1 \cdots x_n x_n$  or encodings that map graphs in the adjacency matrix representation to the incidence list representation.

► **Theorem 1.2** (a POT for a suitable encoding of any set in  $\mathcal{P}$ ). *For any  $S \in \mathcal{P}$  there exist polynomial-time encoding and decoding algorithms  $E$  and  $D = E^{-1}$  such that the set  $S' \stackrel{\text{def}}{=} \{E(x) : x \in S\}$  has a proximity oblivious tester of linear detection probability. Furthermore,  $|E(x)| = |E(1^{|x|})|$  for every  $x$ , the encoding  $E$  has constant relative distance,<sup>9</sup> and the POT runs in polylogarithmic time and has logarithmic randomness complexity.*

Recall that POTs were defined as having constant query complexity, and note that the added conditions regarding  $E$  (i.e., being “length regular” and having constant relative distance) only make the result potentially more appealing. Theorem 1.2 cannot be significantly extended, since the existence of a polynomial-time tester (of arbitrary query complexity) for  $\{E(x) : x \in S\}$  such that  $E$  is polynomial-time computable implies that  $S \in \mathcal{BPP}$  (and  $S \in \mathcal{P}$  follows if the tester has logarithmic randomness complexity).<sup>10</sup>

## 1.2 The way to our main result: strong canonical PCPPs

Theorem 1.2 is proved by using an encoding that maps the input  $x$  to a pair of the form  $(C(x)^{t(|x|)}, \Pi(x))$ , where  $C$  is an error-correcting code,  $\Pi(x)$  is a PCP proof that  $C(x) \in \{C(z) : z \in S\}$ , and  $t(|x|) \approx |\Pi(x)|/|C(x)|$  (so that the two parts of the pair have approximately the same length). This idea, which can be traced back to [19], works only when the PCP system is of a certain type, as discussed next.

<sup>7</sup> Unlike in [17], which considered POTs of arbitrary query complexity, here we mandate that a POT has constant query complexity. This choice is justified by the fact that our result establishes the existence of such POTs. Ditto regarding our choice to consider one-sided error only.

<sup>8</sup> The postulate that  $\varrho$  is monotonically non-decreasing means that *any input that is  $\epsilon$ -far from  $S$  is rejected with probability at least  $\varrho(\epsilon)$* ; that is, if  $\delta_S(f) \geq \epsilon$  (and not only if  $\delta_S(f) = \epsilon$ ), then  $f$  is rejected with probability at least  $\varrho(\epsilon)$ . This postulate is natural (and it can be enforced in general by redefining  $\varrho(\epsilon) \leftarrow \inf_{\delta \geq \epsilon} \{\varrho(\delta)\}$ ).

<sup>9</sup> That is, for every  $x \neq y$ , the encodings  $E(x)$  and  $E(y)$  differ on a constant fraction of the coordinates.

<sup>10</sup> The decision procedure maps  $x$  to  $E(x)$  and invokes the tester with proximity parameter  $1/2|E(x)|$ . In case  $E$  has relative distance  $\delta$ , invoking the tester with proximity parameter  $\delta/2$  will do.

First, we need a PCP of Proximity (a.k.a. assignment testers), rather than a PCP. The difference is that a PCP of Proximity does not get an explicit (main) input, but rather oracle access to both the main input and the alleged proof. Indeed, PCPs of Proximity can be viewed as a “property testing” variant of PCPs (or “PCP-aided variants” of property testers). Second, valid assertions in these PCPs of Proximity must have *unique* valid proofs, otherwise the mapping  $x \mapsto \Pi(x)$  is not even well-defined. Furthermore, the PCP of Proximity should reject (with constant probability) not only inputs (that encode) strings far from  $S$ , but also proof-parts that are far from the corresponding (unique) valid proof. Last, to get a POT rather than a tester that works only for constant values of the proximity parameter (i.e., constant  $\epsilon > 0$ ), also inputs and alleged proofs that are close to being valid should be rejected with probability that is related to their distance from a valid object. A PCP of Proximity that satisfies all of these conditions is called *strongly canonical*.<sup>11</sup>

The foregoing aspects were dealt with in [19], but only for the special case of  $S = \{0, 1\}^*$ , where the issue was to test that the input-part is a valid codeword (with respect to code  $C$ ). Using a linear code  $C$ , this was reduced to the special case in which the set (for which the PCP of Proximity is designed) is a linear space, but even this case was not handled in full generality in [19]. Subsequent work [21, 14, 20] culminated in providing strongly canonical PCPs of Proximity for any linear space, but left open the problem of providing strongly canonical PCPs of Proximity for any set in  $\mathcal{P}$ , let alone  $\mathcal{UP}$ .

Recall that the class  $\mathcal{UP}$  is defined as the subset of  $\mathcal{NP}$  in which each YES-instance has a unique valid proof. In this paper, we show that *every set in  $\mathcal{UP}$  has a strong canonical PCP of Proximity*. Furthermore, we provide a polynomial-time transformation of NP-witnesses (with respect to the original NP-witness relation of the set) to valid proofs (for the resulting PCP of Proximity).

We seize the opportunity to study the simpler case of strong canonical PCPs. Loosely speaking, a **strong canonical PCP** for a set  $S$  is a PCP system in which each  $x \in S$  has a unique valid proof  $\Pi(x)$  that is accepted with probability 1, whereas each other alleged proof is rejected with probability that is related to its distance from  $\Pi(x)$ . We show that:

1. *Every set in  $\mathcal{UP}$  has a strong canonical PCP of logarithmic randomness, and only sets in  $\mathcal{UP}$  have such a PCP* (see Theorem 3.1).
2. *Similarly, the class of sets having (sufficiently)<sup>12</sup> strong canonical PCPs with polynomial proof length equals “unambiguous-MA”* (see Theorem 3.4).

All our constructions are obtained in two steps. First, we show that sets in the relevant class have PCP systems in which each string in the set has a unique valid proof (that is accepted with probability 1). Specifically, we show that the only proofs that are accepted with probability 1 by these PCP systems are the images of the standard transformation of NP-witnesses to PCP-oracles. Next, we observe that these PCP systems can be made strongly canonical by a suitable padding of the proofs. Specifically, the padding is determined such that the ratio of the length of the original proof over the length of the padded proof equals the lower bound on the rejection probability of invalid proofs (under the original PCP). Indeed, this simple observation reduces the construction of strong canonical PCPs to the construction of PCPs that have unique valid proofs.

<sup>11</sup> See Definition 2.2, which requires that the rejection probability of the oracle pair  $(x, \pi)$  be related to the maximum, over all  $x' \in \{0, 1\}^{|x|} \cap S$ , of  $\delta(x, x')$  and  $\delta(\pi, \Pi(x'))$ .

<sup>12</sup> Here we require that any alleged proof is rejected with probability that is *polynomially related* to its distance from  $\Pi(x)$  (i.e.,  $\varrho(\delta) = \text{poly}(\delta)$ ).

Focusing on the construction of PCPs that have unique valid proofs (for sets in  $\mathcal{UP}$ ), we note that the original PCP construction of Arora et al. [4, 3] will not do. Still, it is possible that this construction can be modified and augmented so that it has unique valid proofs (or even becomes a strong canonical PCP). Such an augmentation was indeed performed by Goldreich and Sudan [19], alas only for the special case of linear spaces, and the route taken there was quite tedious. Hence, we preferred to work with the gap amplification construction of Dinur [8], which is more transparent. Starting with a trivial weak-PCP that has unique valid proofs, we observe that the gap amplification operation is a parsimonious reduction, and so we are done.

### 1.3 Organization

In Section 2 we recall the definitions of strong canonical PCPs and PCPPs, starting with the basic PCP model. In Section 3 we characterize the classes of sets having strong canonical PCPs of certain types (see Theorems 3.1 and 3.4), and obtain analogous PCPP systems (see Theorem 3.5). The latter PCPP systems will be used in Section 4 towards establishing Theorem 1.2. We conclude by spelling out some directions for further research (see Section 5).

## 2 Definitions of strong canonical PCPs and PCPPs

In this section, we recall the definitions of strong canonical PCPs and PCPPs. Essentially, we follow the definitional approach presented in [19, Sec. 5.3] (while correcting an error in one of the actual definitions [19, Def. 5.7]).

### 2.1 Preliminaries: The PCP model

We start by recalling the basic definition of Probabilistically Checkable Proofs (PCPs): These are randomized verification procedures that are given an explicit input and oracle access to an alleged proof  $\pi$ , and are aimed to verify the membership of the (main) input in a predetermined set by making few (random) queries to the proof (see, e.g., [11, Sec. 9.3]). Specifically, for a predetermined set  $S \subseteq \{0, 1\}^*$ , on input  $x$  and oracle access to an alleged proof  $\pi$ , a PCP verifier  $V$  reads  $x$ , makes a constant number of random queries to the proof  $\pi$ , and satisfies the following conditions.

**Completeness:** If  $x \in S$ , then there exists a valid proof  $\pi$  such that  $V$  always accepts  $x$  when given oracle access to  $\pi$ ; that is,  $\Pr[V^\pi(x) = 1] = 1$ .

**Soundness:** If  $x \notin S$ , then for every string  $\pi$ , with probability at least  $1/2$  the verifier  $V$  rejects  $x$  when given oracle access to  $\pi$ ; that is,  $\Pr[V^\pi(x) = 0] \geq 1/2$ .<sup>13</sup>

Indeed, a string  $\pi$  that makes  $V$  always accept  $x$  (i.e., that satisfies  $\Pr[V^\pi(x) = 1] = 1$ ) is called a **valid proof for  $x$** ; the soundness condition implies that valid proofs exist only for members of  $S$ , and the completeness condition asserts that each member of  $S$  has a valid proof. We stress that it is not necessarily the case that the valid proofs are unique; that is, the same  $x \in S$  may have several valid proofs (with respect to a fixed verifier).

<sup>13</sup> Actually, the constant  $1/2$  can be replaced by any other constant in  $(0, 1)$ .

### Weak-PCPs

We shall also refer to the notion of a *weak-PCP*, which is defined as above with the crucial exception that its soundness condition is extremely weak. Specifically, this weak soundness condition only requires that for every  $x \notin S$  and  $\pi$ , with positive probability, the verifier rejects  $x$  when given oracle access to  $\pi$  (i.e.,  $\Pr[V^\pi(x)=0] > 0$ ). Indeed, an oracle machine that on input a 3CNF and oracle access to a truth assignment to its variables checks the values assigned to the variables of a uniformly selected clause constitutes such a trivial weak-PCP. (Recall that Dinur's construction [8], which we shall use, gradually transforms such a weak-PCP into a full fledged PCP.)

## 2.2 Strong canonical PCPs

We focus on the special case of PCP verifiers, for a set  $S$ , with respect to which each  $x \in S$  has a *unique* valid proof, and call such verifiers **canonical**. Furthermore, we are interested in the case that invalid proofs are not merely rejected with positive probability, but are rather rejected with probability that is related to their distance from the (unique) valid proof. We shall call such verifiers **strongly canonical**, and quantify their strength by a function  $\varrho$  that relates their rejection probability to the latter distance. Details follow.

We denote the empty string by  $\lambda$ . For two strings  $w, w' \in \{0, 1\}^m$ , we let  $\delta(w, w')$  denote the relative Hamming distance between  $w$  and  $w'$ ; that is,  $\delta(w, w') = |\{i \in [m] : w_i \neq w'_i\}|/m$ . For sake of convenience, we define  $\delta(w, w') = 1$  if  $w$  and  $w'$  have different lengths (e.g., the distance between a non-empty string and the empty string is 1).

► **Definition 2.1** (strong canonical PCPs). For a set  $S \subseteq \{0, 1\}^*$ , a monotonically non-decreasing function  $\varrho: [0, 1] \rightarrow [0, 1]$  such that  $\varrho(\alpha) = 0$  if and only if  $\alpha = 0$ , and an oracle machine  $V$ , we say that  $V$  is a  $\varrho$ -strong canonical PCP for  $S$  if  $V$  makes a constant number of queries to the oracle and there exist functions  $\ell: \mathbb{N} \rightarrow \mathbb{N}$  and  $\Pi: \{0, 1\}^* \rightarrow \{0, 1\}^*$  such that the following conditions hold.

- **Canonical Completeness:** For every  $x \in S$ , it holds that  $\Pi(x) \in \{0, 1\}^{\ell(|x|)}$ , and the verifier always accepts  $x$  when given oracle access to  $\Pi(x)$ ; that is,  $\Pr[V^{\Pi(x)}(x)=1] = 1$ .
- **Strong Canonical Soundness:** For every  $x \in \{0, 1\}^*$  and  $\pi \in \{0, 1\}^*$ , the verifier rejects  $x$  when given access to the oracle  $\pi$  with probability at least  $\varrho(\delta(\pi, \Pi(x)))$ , where  $\Pi(x) \stackrel{\text{def}}{=} \lambda$  if  $x \notin S$  (and in this case  $\delta(\pi, \Pi(x)) = 1$ ); that is,  $\Pr[V^\pi(x)=0] \geq \varrho(\delta(\pi, \Pi(x)))$ .

The function  $\varrho$  is called  $V$ 's detection probability function, and  $\ell$  is called its **proof complexity**. We say that  $V$  is a **strong canonical PCP** for  $S$  if, for some  $\varrho$  as above,  $V$  is a  $\varrho$ -strong canonical PCP for  $S$ .

Indeed, the foregoing conditions assert that  $\Pi(x)$  is the unique valid proof for  $x \in S$ , and that the verifier is strongly canonical with strength  $\varrho$ . Note that strong canonical soundness implies (standard) soundness by the convention that  $\varrho(\delta(\pi, \Pi(x))) = \varrho(1) = \Omega(1)$  for  $x \notin S$ . More generally, recall that  $\delta(\pi, \Pi(x)) = 1$  if  $|\pi| \neq |\Pi(x)|$ . The case that  $\varrho$  is linear is of special interest; in this case invalid proofs are rejected with probability that is proportional to their distance from the valid proof.

## 2.3 Adaptation to the model of PCP of Proximity

Probabilistically checkable proofs of proximity (PCPs of Proximity, abbreviated PCPPs and a.k.a. assignment testers) are proof systems in which the verifier has oracle access to both its main input and an alleged proof, and is required to decide whether the main input is in

some predetermined set or is far from any string that is in this set (cf. [5, 10]). We call such a PCPP system **strong** if it rejects every NO-instance with probability that is related to the distance of the instance from the predetermined set. For simplicity, when we say a PCPP system, we mean a strong one.

Analogously to the case of PCPs, we consider **strong canonical PCPs of Proximity**<sup>14</sup> (henceforth scPCPs of Proximity), which are PCPs of Proximity in which every statement has a unique valid proof such that a statement–proof pair is rejected with probability that is related to its distance from a true statement and its corresponding unique valid proof. The actual definition builds on Definition 2.1, while adapting it to the proofs of proximity model.

► **Definition 2.2** (strong canonical PCPs of Proximity). For a set  $S$ , a function  $\varrho$  as in Definition 2.1, and an oracle machine  $V$  that accesses two oracles, we say that  $V$  is a  $\varrho$ -strong canonical PCP of Proximity for  $S$  if  $V$  makes a constant number of queries to each of its oracles and there exist functions  $\ell: \mathbb{N} \rightarrow \mathbb{N}$  and  $\Pi: \{0, 1\}^* \rightarrow \{0, 1\}^*$  such that the following conditions hold.

- **Canonical Completeness:** For every  $x \in S$ , it holds that  $\Pi(x) \in \{0, 1\}^{\ell(|x|)}$  and the verifier always accepts the pair of oracles  $(x, \Pi(x))$ ; that is,  $\Pr[V^{x, \Pi(x)}(1^{|x|}) = 1] = 1$ .
- **Strong Canonical Soundness:** For every  $x \in \{0, 1\}^*$  and  $\pi \in \{0, 1\}^*$ , the verifier rejects the pair of oracles  $(x, \pi)$  with probability at least  $\varrho(\delta_\Pi(x, \pi))$ , where<sup>15</sup>

$$\delta_\Pi(x, \pi) \stackrel{\text{def}}{=} \min_{x' \in \{0, 1\}^{|x|}} \{\max(\delta(x, x'), \delta(\pi, \Pi(x')))\}; \quad (2)$$

that is,  $\Pr[V^{x, \pi}(1^{|x|}) = 0] \geq \varrho(\delta_\Pi(x, \pi))$ .

The function  $\varrho$  is called  $V$ 's detection probability function, and  $\ell$  is called its proof complexity. We say that  $V$  is a **strong canonical PCPP** for  $S$  if, for some  $\varrho$  as above,  $V$  is a  $\varrho$ -strong canonical PCPP for  $S$ .

We stress that the rejection probability depends on the distance of the oracle-pair  $(x, \pi)$  from a valid pair consisting of  $x' \in S \cap \{0, 1\}^{|x|}$  and the corresponding valid proof  $\Pi(x')$ , where the distance between pairs is defined as the maximum of the distance between the corresponding elements.<sup>16</sup> This represents the fact that we wish to reject with probability that not only depends on the distance of the input  $x$  to a string  $x' \in S$ , but also depends on the distance of the alleged proof  $\pi$  to the corresponding valid proof  $\Pi(x')$ . Indeed, proximity oblivious testers (POTs) can be viewed as strong canonical PCPs of Proximity with proof complexity zero.

### 3 On the existence of strong canonical PCPs and PCPPs

Our first result is a characterization of the class of sets having strong canonical PCPs of *logarithmic randomness*. It turns out that this class equals  $\mathcal{UP}$ . Recall that the class  $\mathcal{UP}$  is defined as the subset of  $\mathcal{NP}$  in which each YES-instance has a unique valid proof; that is,  $S \in \mathcal{UP}$  if there exists a polynomially-bounded relation  $R$  that is recognizable in polynomial-time such that for every  $x \in S$  there exists a unique  $w \in R(x) = \{y : (x, y) \in R\}$  whereas  $R(x) = \emptyset$  if  $x \notin S$ .

<sup>14</sup> Alternatively, we use the term *strongly canonical*.

<sup>15</sup> Recall that  $\Pi(x') \stackrel{\text{def}}{=} \lambda$  if  $x' \notin S$ , and in this case  $\delta(\pi, \Pi(x')) = 1$ .

<sup>16</sup> That is, we effectively define  $\delta(\langle x, y \rangle, \langle x', y' \rangle)$  as  $\max(\delta(x, x'), \delta(y, y'))$ . Taking the sum of the latter distances (or their average) would have been as good, since  $\frac{\alpha + \beta}{2} \leq \max(\alpha, \beta) \leq \alpha + \beta$ .

► **Theorem 3.1** (*UP and strong canonical PCPs*). *The set  $S$  has a strong canonical PCP of logarithmic randomness if and only if  $S \in \mathcal{UP}$ . Furthermore, the resulting PCP is  $\varrho$ -strong for  $\varrho(\alpha) = \alpha/4$  and there exists a polynomial-time transformation of NP-witnesses for  $S \in \mathcal{UP}$  to valid proofs for the resulting PCP.*

**Proof.** The necessary condition is quite straightforward: Let  $V$  be a strong canonical PCP of logarithmic randomness for  $S$ , and assume for simplicity that its proof complexity is polynomial. Now, define  $R = \{(x, \pi) : \Pr[V^\pi(x) = 1] = 1\}$ , and observe that membership in  $R$  can be decided in polynomial-time by trying all possible random choices of  $V$ . Hence,  $S = \{x : R(x) \neq \emptyset\}$  is in  $\mathcal{NP}$ , and the hypothesis that the valid proofs (with respect to  $V$ ) are unique implies that  $S \in \mathcal{UP}$ . In the general case (i.e., when the proof length may be super-polynomial), one may consider the “effective proofs” (i.e., the values of  $\pi$  at locations that are read by  $V$  on some random choices). That is, in this case, we define  $R = \{(x, (I(x), \pi_{I(x)})) : \Pr[V^\pi(x) = 1] = 1\}$ , where  $I(x)$  is the set of locations that are in the “effective proof” (i.e., locations that  $V(x)$  probes with positive probability).

Note that the foregoing argument holds also for very weak PCP systems, provided that they have logarithmic randomness complexity and unique valid proofs. That is, we only used the hypothesis that for every  $x \in S$ , there exists a unique  $\pi$  such that  $p_x(\pi) \stackrel{\text{def}}{=} \Pr[V^\pi(x) = 1] = 1$ , and capitalized on the fact that it is feasible to compute  $p_x(\pi)$  exactly.

Turning to the opposite direction, we show that each  $S \in \mathcal{UP}$  has a strong canonical PCP of logarithmic randomness by presenting such a PCP for **USAT** and recalling that each set in  $\mathcal{UP}$  is reducible to **USAT** via a parsimonious reduction (see, e.g., [11, Ex 2.29]). Recall that **USAT** is the promise problem in which **YES**-instances are 3CNF formulas with a *unique* satisfying assignment and **NO**-instances are formulas with no satisfying assignments. (Actually, we need to define PCPs for promise problems and state, as well as prove, Proposition 3.2 in this more general setting, but we avoid doing so while commenting that the extension is straightforward.)<sup>17</sup>

The key observation is that it suffices to show a PCP for  $S$  in which each  $x \in S$  has a unique valid proof. This is the case because such PCPs can be transformed into strong canonical ones, as stated next.

► **Proposition 3.2** (*deriving strong canonical PCPs from PCPs with unique valid proofs*). *Let  $V$  be a PCP system of logarithmic randomness complexity for  $S$ , and suppose that for every  $x \in S$  there exists a unique  $\pi$  such that  $\Pr[V^\pi(x) = 1] = 1$ . Then, there exist a strong canonical PCP of logarithmic randomness for  $S$  and a polynomial-time transformation of valid proof with respect to  $V$  to valid proofs for the resulting PCP. Furthermore, the resulting PCP is  $\varrho$ -strong for  $\varrho(\alpha) = \alpha/4$  and its proof complexity is  $2^r \cdot \ell$ , where  $r$  and  $\ell$  are the randomness and proof complexity of  $V$ .*

**Proof.** Again, we may assume, without loss of generality, that  $V$  has polynomial proof complexity, since we can efficiently determine all relevant locations (i.e., those queried under any choice of randomness) without making any queries.

Letting  $\Pi$  be the function mapping instances to their canonical proofs, as in Definition 2.1, we define  $\Pi'(x) = \mathbf{1}_{(2^{r(|x|)} - 1) \cdot \ell(|x|)} \Pi(x) \in \{0, 1\}^{2^{r(|x|)} \cdot \ell(|x|)}$  if  $\Pi(x) \neq \lambda$  and  $\Pi'(x) = \lambda$  otherwise. Note that, for every  $x \in S$  and  $\pi \in \{0, 1\}^{\ell(|x|)}$ , it holds that

$$\delta(\mathbf{1}_{(2^{r(|x|)} - 1) \cdot \ell(|x|)} \pi, \Pi'(x)) \leq 2^{-r(|x|)},$$

<sup>17</sup> Specifically, the canonical soundness condition has to be satisfied only for inputs that satisfy the promise, whereas the canonical completeness condition is stated for the **YES**-instances only.

which means that invalid proofs for  $x \in S$  are extremely close to valid proofs, and so it suffices to reject them with tiny probability. This suggests the following verifier, which on input  $x \in \{0, 1\}^n$  and access to oracle  $\pi' \in \{0, 1\}^{2^{r(n)} \cdot \ell(n)}$ , selects uniformly at random one of the following two tests and performs it.

1. The verifier selects at random  $i \in [(2^{r(n)} - 1) \cdot \ell(n)]$ , and accepts if and only if the  $i^{\text{th}}$  bit of  $\pi'$  equals 1.
2. The verifier invokes  $V$  on input  $x$ , while providing it with oracle access to the  $\ell(n)$ -bit long suffix of  $\pi'$ , and outputs the verdict of  $V$ .

Turning to the analysis, we first note that if  $x \notin S$ , then (by virtue of  $V$ ) the resulting verifier rejects  $x$  with probability at least  $\frac{1}{2} \cdot \frac{1}{2}$ , regardless of the identity of the oracle  $\pi'$ . Hence, from this point on we assume  $x \in S$ , and let  $\Pi(x)$  denote the unique valid proof with respect to  $V$ .

Now, let  $\pi' \equiv (w, \pi) \in \{0, 1\}^{2^{r(n)} \cdot \ell(n)}$  such that  $|\pi| = \ell(n)$ . Observe that, on input  $x$  and access to  $\pi'$ , the new verifier rejects with probability that is lower-bounded by (half) the fraction of 0's in  $w$ , since with probability  $1/2$  this verifier test whether the  $(2^{r(n)} - 1) \cdot \ell(n)$ -bit long prefix equals the all-1 string. Next, recall that, for any  $\pi \in \{0, 1\}^{\ell(n)}$ , it holds that  $\pi'' = 1^{(2^{r(n)} - 1) \cdot \ell(n)} \pi$  is  $2^{-r(|x|)}$ -close to  $\Pi'(x) = 1^{(2^{r(n)} - 1) \cdot \ell(n)} \Pi(x)$ , since  $\delta(\pi, \Pi(x)) \leq 1$ . Hence, rejecting  $\pi''$  with probability at least  $\frac{1}{2} \cdot 2^{-r(n)}$  suffices when  $\pi \neq \Pi(x)$ . It follows that a generic  $\pi' \equiv (w, \pi) \neq \Pi'(x) \neq \lambda$  is rejected with probability

$$\begin{aligned} \frac{1}{2} \cdot \delta(w, 1^{(2^{r(n)} - 1) \cdot \ell(n)}) + \frac{1}{2} \cdot 2^{-r(n)} &\geq \frac{1}{2} \cdot \delta(w, 1^{(2^{r(n)} - 1) \cdot \ell(n)}) + \frac{1}{2} \cdot 2^{-r(n)} \cdot \delta(\pi, \Pi(x)) \\ &\geq \frac{1}{2} \cdot \delta(\pi', \pi'') + \frac{1}{2} \cdot \delta(\pi'', \Pi'(x)), \end{aligned}$$

where the second inequality uses  $\delta(w, 1^{(2^{r(n)} - 1) \cdot \ell(n)}) \geq \delta(w\pi, 1^{(2^{r(n)} - 1) \cdot \ell(n)} \pi) = \delta(\pi', \pi'')$  and

$$\begin{aligned} \delta(\pi, \Pi(x)) &= 2^{r(|x|)} \cdot \delta(1^{(2^{r(n)} - 1) \cdot \ell(n)} \pi, 1^{(2^{r(n)} - 1) \cdot \ell(n)} \Pi(x)) \\ &= 2^{r(|x|)} \cdot \delta(\pi'', \Pi'(x)). \end{aligned}$$

Using  $\delta(\pi', \pi'') + \delta(\pi'', \Pi'(x)) \geq \delta(\pi', \Pi'(x))$ , it follows that, on input  $x$  and access to  $\pi'$ , the new verifier rejects with probability at least  $\delta(\pi', \Pi'(x))/2$ , which means that it constitutes a strong canonical PCP for  $S$ . Indeed, the PCP is  $\varrho$ -strong for  $\varrho(\alpha) = \alpha/4$ .<sup>18</sup> ◀

In light of Proposition 3.2, it suffices to show a PCP of logarithmic randomness and unique valid proofs for USAT. This PCP is constructed by merely following the construction of Dinur [8], while noting that her gap amplification transformation is a parsimonious reduction.

► **Proposition 3.3** (PCPs with unique valid proofs for USAT). *There exists a PCP system of logarithmic randomness for USAT such that for every satisfiable formula there exists a unique valid proof with respect to this system. Furthermore, there exists a polynomial-time transformation of satisfying assignments for the input formula to valid proofs for the resulting PCP.*

**Proof.** Let  $\psi$  be an  $m$ -clause 3CNF formula over  $n$  variables, promised to have at most one satisfying assignment. Let  $V_0$  be the trivial weak-PCP system with soundness  $1/m$ , in which the oracle is allegedly the unique satisfying assignment of  $\psi$ , and the verifier checks that

<sup>18</sup>The factor of  $1/4$  is due to the case that  $x \notin S$ , which is rejected with probability at least  $1/4$ .

this assignment satisfies a random clause of  $\psi$ . By construction,  $V_0$  has unique valid proofs. Applying the gap amplification transformation of Dinur [8] to  $V_0$ , we obtain a PCP system  $V$  of logarithmic randomness for USAT.

As stated above, the crucial point is showing that the aforementioned transformation is a parsimonious reduction. The argument is detailed in our technical report [9, Appendix A]; it consists of showing that gap amplification is a one-to-one transformation, and that the only valid proofs with respect to the resulting proof system are those in the range of the transformation. These facts are demonstrated by closely inspecting each of the four steps in the gap amplification procedure: degree reduction, “expanderization”, powering, and alphabet reduction. We show that each of these steps satisfies the two aforementioned properties, where in the analysis of the alphabet reduction step we assume that it is performed by composition with a PCPP that has unique valid proofs. Such a PCPP is immediately implied by the Hadamard code (alternatively, by the long code); see details in [9, Appendix A.4]. ◀

Combining Proposition 3.2 and 3.3, the theorem follows. ◀

### A detour: A variant of Theorem 3.1

Our next result is a characterization of the class of sets having strong canonical PCPs of *polynomial proof length*. It turns out that this class equals “unambiguous- $\mathcal{MA}$ ” (denoted  $\mathcal{UM\mathcal{A}}$ , and defined next). Recall that the class  $\mathcal{MA}$  consists of all sets having a non-interactive probabilistic proof system; that is,  $S \in \mathcal{MA}$  if there exists a polynomially-bounded relation  $R$  that is recognizable in  $\text{co}\mathcal{RP}$  such that  $S = \{x : \exists w (x, w) \in R\}$ .<sup>19</sup> We define  $\mathcal{UM\mathcal{A}}$  as the subset of  $\mathcal{MA}$  in which the non-interactive proof system has unique valid proofs; that is,  $S \in \mathcal{UM\mathcal{A}}$  if there exists a polynomially-bounded relation  $R$  that is recognizable in  $\text{co}\mathcal{RP}$  such that for every  $x \in S$  there exists a unique  $w \in R(x) = \{y : (x, y) \in R\}$ , whereas  $R(x) = \emptyset$  if  $x \notin S$ . (Note that in this case  $|R(x)| \leq 1$  for every  $x$ .)

► **Theorem 3.4** ( *$\mathcal{UM\mathcal{A}}$  and strong canonical PCPs*). *The set  $S$  has a poly-strong canonical PCP of polynomial proof complexity if and only if  $S \in \mathcal{UM\mathcal{A}}$ .*

Above, recall that by poly-strong we mean  $\varrho$ -strong with respect to  $\rho(\delta) = \delta^c$ . We stress that, unlike in Theorem 3.1, here we do not know whether a  $\varrho$ -strong canonical PCP with arbitrary  $\varrho$  for  $S$  implies that  $S \in \mathcal{UM\mathcal{A}}$ . The point is that invalid proofs of length  $\ell$  are only guaranteed to be rejected with probability at least  $\varrho(1/\ell)$ , which may be negligible. On the other hand, the existence of poly-strong canonical PCP (of polynomial-length) for  $S$ , implies  $S \in \mathcal{UM\mathcal{A}}$ , which in turn is shown to imply that  $S$  has a  $\varrho$ -strong canonical PCP (of polynomial-length) with a linear  $\varrho$  (i.e.,  $\varrho(\alpha) = \Omega(\alpha)$ ).

**Proof.** We follow the outline of the proof of Theorem 3.1, while introducing several relevant modifications. For example, in the proof of the necessary condition we can no longer assume that the PCP has logarithmic randomness; instead we directly use the hypothesis that the PCP has polynomial proof complexity, and derive a verification procedure that places the set in  $\mathcal{UM\mathcal{A}}$  (rather than in  $\mathcal{UP}$ ). Furthermore, using the hypothesis that the PCP is poly-strong, we infer that invalid proofs are rejected with noticeable probability (i.e., probability at least  $\varrho(1/\ell) = \text{poly}(1/\ell)$ ). This fact allows for the rejection of invalid proofs by invoking the PCP

<sup>19</sup>This perfect completeness version of  $\mathcal{MA}$  equals the non-perfect one in which  $R$  is only required to be recognizable in  $\mathcal{BPP}$  (see [11, Ex. 6.12 (2)]).

verifier polynomially many times. Specifically, let  $V$  be a  $\varrho$ -strong canonical PCP of proof complexity  $\ell = \text{poly}$  for  $S$ , and define  $R = \{(x, \pi) : \Pr[V^\pi(x) = 1] = 1\}$ . Then,  $R \in \text{coRP}$ , by letting the decision procedure emulate  $O(1/\varrho(1/\ell(|x|))) = \text{poly}(|x|)$  executions of  $V^\pi(x)$ , and accept if and only if all executions accepted. Hence,  $S = \{x : R(x) \neq \emptyset\}$  is in  $\mathcal{MA}$ , and the hypothesis that the valid proofs (with respect to  $V$ ) are unique implies that  $S \in \mathcal{UMMA}$ .

Turning to the opposite direction, we show that each  $S \in \mathcal{UMMA}$  has a poly-strong canonical PCP of polynomial proof length, by using a randomized reduction of  $S$  to  $\text{USAT}$  (or rather to a promise problem in the corresponding class  $\mathcal{UP}$ ). Let  $R$  be the binary relation guaranteed by the definition of  $\mathcal{UMMA}$ , and suppose, without loss of generality, that  $R \subseteq \cup_{n \in \mathbb{N}} (\{0, 1\}^n \times \{0, 1\}^{p(n)})$  for some polynomial  $p$ . Let  $p'$  be a polynomial that upper bounds the randomness complexity of the decision procedure for  $R$ , and let  $D'$  denote the residual decision predicate of that procedure; that is,  $D'_{r_i}(x, w)$  denotes the verdict on input  $(x, w)$  when using randomness  $r \in \{0, 1\}^{p'(n+p(n))}$ . Recall that for  $(x, w) \notin R$ , it holds that  $\Pr_r[D'_{r_i}(x, w) = 1] \leq 1/2$ , and it follows that, for every  $x$  and  $w \notin R(x) = \{y : (x, y) \in R\}$ ,

$$\Pr_{r_1, \dots, r_m \in \{0, 1\}^{p'(n+p(n))}} [\forall i \in [m] D'_{r_i}(x, w) = 1] \leq 2^{-m}.$$

Note that if we pick  $m = p(n) + 2$ , then an application of a union bound implies that, for every  $x \in \{0, 1\}^n$ , it holds

$$\Pr_{r_1, \dots, r_m \in \{0, 1\}^{p'(n+p(n))}} [\exists w \notin R(x) \forall i \in [m] D'_{r_i}(x, w) = 1] \leq 1/4.$$

Now, consider the randomized mapping of  $x \in \{0, 1\}^n$  to  $(x, r_1, \dots, r_m)$ , denoted  $\Psi$ , where  $m = p(n) + 2$  and the  $r_i$ 's are selected uniformly and independently in  $\{0, 1\}^{p'(n+p(n))}$ . Recall that  $|R(x)| \leq 1$  for any  $x$ . Now, let  $P$  (standing for promise) denote the set of tuples  $(x, r_1, \dots, r_m)$  for which  $\forall i \in [m] D'_{r_i}(x, w) = 1$  holds only for  $w \in R(x)$ , and  $S'$  denote the set of tuples  $(x, r_1, \dots, r_m)$  with  $x \in S$ . Then, it holds that  $\Pr[\Psi(x) \in P] \geq 3/4$  and  $\Pr[\Psi(x) \in S' \Leftrightarrow x \in S] = 1$  for each  $x$ , where  $\Psi(x)$  is as defined above.<sup>20</sup> Letting  $R'(x, r_1, \dots, r_m) = R(x)$ , observe that for every  $(x, r_1, \dots, r_m) \in P$  it holds that  $w \in R'(x, r_1, \dots, r_m)$  if and only if  $\forall i \in [m] D'_{r_i}(x, w) = 1$ . Hence, the promise problem  $(P \cap S', P \setminus S')$  is in the class of promise problems associated with  $\mathcal{UP}$ , and we can apply the PCP of Theorem 3.1 to it. Furthermore, recall that the function  $\Pi'$  (which generates the canonical proof) used to construct the strong canonical PCP system in Theorem 3.1 denoted  $V'$ , assigns to the input  $(x, r_1, \dots, r_m) \in P \cap S'$  the unique proof  $1^t w$  such that  $R(x) = \{w\}$ , where  $t$  is polynomial in  $|(x, r_1, \dots, r_m)|$ . Combining  $\Psi$  with  $V'$  yields a PCP system for  $S$  that, on input  $x$  and oracle access to  $\pi$ , invokes  $V'$  on input  $\Psi(x)$  and provides  $V'$  with oracle access to  $\pi$ . The corresponding verifier, denoted  $V$ , has the following features:

- It (i.e.,  $V$ ) has polynomial proof complexity.  
This feature is inherited from the proof complexity of  $V'$  and the fact that  $|\Psi(x)| = \text{poly}(|x|)$ .
- It satisfies canonical completeness with respect to the function  $\Pi$  such that  $\Pi(x) = 1^t w$  if and only if  $R(x) = \{w\}$ . Indeed,  $\Pi(x) = \Pi'(\Psi(x))$  holds whenever  $\Psi(x) \in P \cap S'$ .  
This is the case because  $\Pr[\Psi(x) \in S'] = 1$  for any  $x \in S$ , and  $1^t w = \Pi'(x, r_1, \dots, r_m)$  and  $R(x) = \{w\}$  hold for any  $(x, r_1, \dots, r_m) \in P \cap S'$ . (We also use the canonical completeness of  $V'$ .)

<sup>20</sup>That is,  $\Psi(x)$  is uniformly distributed over  $\{(x, r_1, \dots, r_{m(|x|)}) : \forall i \in [m(|x|)] r_i \in \{0, 1\}^{p'(|x|+p(|x|))}\}$  and  $m(n) = p(n) + 2$ .

## 30:12 Every Set in $\mathcal{P}$ Is Strongly Testable Under a Suitable Encoding

- It satisfies canonical soundness with respect to the foregoing function  $\Pi$ . Furthermore, invalid proofs are rejected with probability that is proportional to their distance from the valid proof.

This is the case because  $\Pr[\Psi(x) \in P] \geq 3/4$  for any  $x$ , and in that case the strong canonical soundness of  $V'$  beats in. The furthermore clause follows by the fact that  $V'$  is a  $\varrho'$ -strong canonical PCP for  $\varrho'(\alpha) = \alpha/4$ .

Hence,  $V$  is a  $(3\varrho'/4)$ -strong canonical PCP (of polynomial proof complexity) for  $S$ . Note that (typically)  $V$  uses super-logarithmic randomness complexity.<sup>21</sup> ◀

### Strong canonical PCPs of Proximity

Next, we adapt the proof of the positive direction of Theorem 3.1 to the PCPP model.

► **Theorem 3.5** (*UP and strong canonical PCPPs*). *Every set in UP has a strong canonical PCP of Proximity of logarithmic randomness and linear detection probability function. Furthermore, there exists a polynomial-time transformation of NP-witnesses for membership in the set to valid proofs for the resulting PCP.*

Indeed, the positive direction of Theorem 3.1 follows from Theorem 3.5 by applying the latter to the set  $S' = \{C(x) : x \in S\}$ , where  $C$  is a good error correcting code. Note that the claimed PCP system (for  $S$ ) emulates the input-oracle of the PCPP system (for  $S'$ ) by applying  $C$  to its own input  $x$ , and emulating the proof-oracle of the PCPP system by using its own proof-oracle. The canonical soundness of the PCP system (for  $S$ ) follows from the canonical soundness of the PCPP system (for  $S'$ ), since in the case that  $x \notin S$  it holds that the relative distance of  $C(x)$  from the set  $S'$  is a constant.

**Proof.** The construction and its analysis are analogous to those in the proof of Theorem 3.1, except that here we start with a trivial weak-PCPP for the set  $S \in \mathcal{UP}$ , use (parsimonious) gap amplification for PCPPs (see [9, Appendix A.5]), and apply a PCPP version of Proposition 3.2. Details follow.

Starting with the PCPP analogue of Proposition 3.3, we use a similar construction except that we apply it to a fixed 3CNF (which is generated based on the input length only). Recall that the construction consists of two steps: First, we construct a trivial weak-PCPP with unique proofs, and then we apply the gap amplification procedure to it (obtaining a PCPP with unique proofs).

Specifically, in the first step, we reduce the verification of the claim  $x \in S$  to the satisfiability of a fixed 3CNF by an assignment that extends  $x$ , where the formula is derived by the standard Cook–Levin reduction of  $S$  to 3SAT. The fixed formula has main variables  $X$  (which are set by the assignment  $x$ ) and auxiliary variables  $Y$  (which represent the NP-witness for  $x$  as well as intermediate gate-values in the corresponding computation), and the question is whether this formula is satisfiable by an assignment in which  $X = x$ . (Note that when  $x \in S$  there is a unique assignment  $y$  to  $Y$  such that the assignment  $(X, Y) = (x, y)$  satisfies the fixed formula.) The first step is completed by observing that the foregoing formula yields a trivial weak-PCPP (with small but noticeable soundness) that is given oracle access to the input  $x$  (i.e.,  $x$  is the input-oracle) as well as to a proof that corresponds to an assignment to the auxiliary variables. This PCPP has unique valid proofs.

<sup>21</sup> This is inherited from the super-logarithmic length of the proofs employed by the MA system (or, alternatively, from its super-logarithmic randomness complexity). Note that MA systems with logarithmic proof length (resp., logarithmic randomness) exist only for  $\text{co}\mathcal{RP}$  (resp.,  $\mathcal{NP}$ ).

In the second step, we apply the gap amplification procedure, which treats the foregoing PCPP execution as a 2CSP instance such that some variables of the 2CSP are identified with the bits of the input-oracle and the other variables represent various auxiliary values. The set of variables that represents bits of the input-oracle will remain intact throughout the entire process of gap amplification (see [9, Appendix A.5]). Hence, when viewing the resulting 2CSP as a PCPP, the input-oracle of the resulting PCPP equals the input-oracle of the original (trivial) PCPP. Observing (as in the proof of Proposition 3.3) that the gap amplification process maintains the number of valid proofs for each input (see [9, Appendix A.5]), we obtain a PCPP with unique proofs for  $S$ .

Next, we turn to establish a PCPP analogue of Proposition 3.2. This version asserts a transformation of PCPPs with unique proofs to strong canonical PCPPs, and its proof is obtained by a straightforward adaptation of the original (PCP) version.<sup>22</sup> Using the notation of Proposition 3.2, the crux of the analysis is that the pair of oracles  $(x, \pi')$ , where  $x \in \{0, 1\}^n$  (such that  $S \cap \{0, 1\}^n \neq \emptyset$ )<sup>23</sup> and  $\pi' \equiv (w, \pi) \in \{0, 1\}^{(2^{r(n)}-1) \cdot \ell(n) + \ell(n)}$ , is rejected with probability at least

$$\min_{x' \in S \cap \{0, 1\}^n} \{ \max(\Omega(\delta(x, x')), 0.5 \cdot \delta(w, 1^{(2^{r(n)}-1) \cdot \ell(n)}) + 0.5 \cdot 2^{-r(|x|)} \cdot \delta(\pi, \Pi(x'))) \}, \quad (3)$$

where the foregoing lower bound of  $\Omega(\delta(x, x'))$  follows from the soundness of the original PCPP system outlined above. As shown in the proof of Proposition 3.2, it holds that  $\delta(w, 1^{(2^{r(n)}-1) \cdot \ell(n)}) + 2^{-r(|x|)} \cdot \delta(\pi, \Pi(x')) \geq \delta(\pi', \Pi'(x'))$ , which implies that (3) is lower-bounded by  $\Omega(\delta_{\Pi}(x, \pi'))$ .  $\blacktriangleleft$

## 4 The testing result

With strong canonical PCPs of Proximity (as provided by Theorem 3.5) at our disposal, it is quite straightforward to obtain a proximity oblivious tester for a suitable encoding of any set in  $\mathcal{P}$ . Such an encoding incorporates copies of the target object as well as a corresponding PCPP-oracle that attests its membership in the set. To be meaningful, this encoding should be polynomial-time computable and invertible.<sup>24</sup> One may also require that the encoding is “length regular” (i.e., equal length strings have an equal encoding length) and has a constant relative distance, but this seems less essential.

► **Theorem 1.2 (restated).** *For any  $S \in \mathcal{P}$  there exist polynomial-time encoding and decoding algorithms  $E$  and  $D = E^{-1}$  such that the set  $S' \stackrel{\text{def}}{=} \{E(x) : x \in S\}$  has a proximity oblivious tester of linear detection probability. Furthermore,  $|E(x)| = |E(1^{|x|})|$  for every  $x$ , the encoding  $E$  has constant relative distance, and the POT runs in polylogarithmic time and has logarithmic randomness complexity.*

<sup>22</sup> Alternatively, the current version can be derived as a special case of Proposition 5.3.

<sup>23</sup> If  $S \cap \{0, 1\}^n = \emptyset$ , then  $(x, \pi')$  is rejected with probability at least  $\Omega(1)$ , and the claim follows (since in this case  $\delta_{\Pi}(x, \pi') = 1$ ).

<sup>24</sup> The following examples illustrate that restricting the complexity of the encoding is essential for the meaningfulness of Theorem 1.2. Suppose, for example, that for some  $m : \mathbb{N} \rightarrow \mathbb{N}$  it holds that  $|S \cap \{0, 1\}^n| = 2^{m(n)}$ , and consider the length preserving bijection  $E$  that maps the elements of  $S \cap \{0, 1\}^n$  to  $0^{n-m(n)}\{0, 1\}^{m(n)}$ . Then, testing  $\{E(x) : x \in S\}$  amounts to selecting uniformly  $i \in [n - m(n)]$  and checking that the  $i^{\text{th}}$  bit of the  $n$ -bit long input equals 0. More generally, assuming that both  $S$  and  $\bar{S} = \{0, 1\}^* \setminus S$  are infinite, and letting  $\text{idx}_S(w)$  denote the index of  $w \in S$  (e.g., according to the standard lexicographical order), consider the bijection  $E$  such that  $E(x) = y$  if  $x \in S$  (resp.,  $x \in \bar{S}$ ) and  $\text{idx}_S(x) = \text{idx}_T(y)$  (resp.,  $\text{idx}_{\bar{S}}(x) = \text{idx}_{\bar{T}}(y)$ ), where  $T = \cup_{m \in \mathbb{N}} \{0, 1\}^{2m+1}$ . Then, testing  $\{E(x) : x \in S\} = T$  is trivial.

## 30:14 Every Set in $\mathcal{P}$ Is Strongly Testable Under a Suitable Encoding

Recall that proximity oblivious testers (POTs) were defined as having constant query complexity, and that their detection probability function represents a lower bound on their rejection probability as a function of the distance of the tested object from the property.

**Proof.** Let  $C: \{0, 1\}^* \rightarrow \{0, 1\}^*$  be an arbitrary systematic code (i.e.,  $x$  is a prefix of  $C(x)$ ) of relative distance, say,  $1/8$  such that the mapping  $x \mapsto C(x)$  can be computed in polynomial time. Consider a strong canonical PCPP for the set  $C(S) \stackrel{\text{def}}{=} \{C(x) : x \in S\}$ , as guaranteed by Theorem 3.5, and let  $\Pi(C(x))$  denote the (unique) valid proof for  $C(x) \in C(S)$ . The basic idea is to combine the input and proof oracles of the PCPP into a single codeword that will be accessed by the POT as an oracle; in order to maintain the soundness guarantee, it is important that each part of the combined codeword will have approximately the same length. Since the proof-oracle is typically longer, this requires repeating the input-oracle sufficiently many times.

Recalling that  $|\Pi(C(x))| = \ell(|C(x)|)$  for some polynomial  $\ell$ , we proceed to present the claimed algorithms.

**The encoding function  $E$ :** On input  $x \in \{0, 1\}^*$ , we let  $n = |C(x)|$  and  $t = \ell(n)/n$ . Then,  $E(x) = C(x)^t \pi$  such that  $\pi = \Pi(C(x))$  if  $x \in S$ , and  $\pi = 1^{\ell(n)}$  otherwise.

The encoding can be computed in polynomial time, since the canonical proof  $\Pi(C(x))$  can be computed in polynomial time because  $S \in \mathcal{P}$  (and  $C$  is polynomial-time computable). (Formally, the reader may think of  $S$  as being in  $\mathcal{UP}$  by virtue of the witness relation  $R = \{(x, x) : x \in S\}$ , and recall that given an NP-witness one can efficiently obtain the corresponding proof-oracle.)

The code  $C$  and the repetitions are used to create and maintain distance; that is,  $\delta(E(x), E(x')) \geq 0.5 \cdot \delta(C(x), C(x')) \geq 1/16$  for every two distinct  $x, x'$  of equal length.

**The decoding function  $D$ :** On input  $y \in \{0, 1\}^*$ , the algorithm outputs  $x$  if  $|y| = 2\ell(n)$  and  $y = C(x)^{\ell(n)/n} \Pi(C(x))$ , and outputs a special failure symbol otherwise. Specifically, the algorithm first determines  $n = \ell^{-1}(|y|/2)$ , then determines  $k$  such that  $n = |C(1^k)|$ , and finally sets  $x$  as the  $k$ -bit long prefix of  $y$  (and verifies that  $y = C(x)^{\ell(n)/n} \Pi(C(x))$  holds). Note that checking that the suffix of  $y$  is the canonical proof  $\Pi(C(x))$  can be done in polynomial time, since  $x$  is a prefix of  $y$  and  $\Pi \circ C$  is polynomial-time computable.

**The tester  $T$ :** On input  $y \in \{0, 1\}^{2\ell(n)}$ , the tester parses  $y$  into  $(w_1, \dots, w_t, \pi)$  such that  $|w_1| = \dots = |w_t| = n$  and  $|\pi| = \ell(n)$ . It first checks at random that the  $w_i$ 's are all identical to  $w_1$ , by selecting a random  $i \in [t]$  and comparing a random position in  $w_i$  and  $w_1$ . Next, it invokes the (strong canonical) PCPP verifier, providing it with access to the input-oracle  $w_1$  and the proof-oracle  $\pi$ .

We first note that  $D(E(x)) = x$  for every  $x$ . Next, we show that  $T$  is a POT for the set  $S' = \{E(x) : x \in S\}$ . Observe, on the one hand, that for every  $y \in S'$ , it holds that  $y = E(x) = C(x)^t \Pi(C(x))$  for some  $x \in S$ , and the tester  $T$  accepts  $y$  with probability 1 (by virtue of the perfect completeness of the PCPP verifier). On the other hand, turning to the case of  $y \notin S'$  and letting  $y \equiv (w_1, \dots, w_t, \pi) \in \{0, 1\}^{t \cdot n + \ell(n)}$ , we consider three cases (where below, by “far” we mean being at relative distance  $\Omega(\delta_{S'}(y))$ ).

1. If  $(w_1, \dots, w_t)$  is far from  $w_1^t$ , then  $y$  is rejected with proportional probability by the first check of  $T$ .
2. If  $(y$  is close to  $w_1^t$  but)  $w_1$  is far from  $C(S)$ , then  $y$  is rejected with proportional probability by the (strong canonical) PCPP verifier (which is invoked with input-oracle  $w_1$ ).
3. If  $w_1$  is close to  $C(x) \in C(S)$  but  $\pi$  is far from the canonical proof  $\Pi(C(x))$ , then  $y$  is rejected with proportional probability by the (strong canonical) PCPP verifier (which is invoked with input-oracle  $w_1$  and the proof-oracle  $\pi$ ).

(Here we use the fact that if  $w_1$  is close to  $C(x)$ , then it is far from  $C(x')$  for any  $x' \neq x$ . Hence,  $\min_{w'} \{\max(\delta(w_1, w'), \delta(\pi, \Pi(w')))\}$  equals  $\min_{x' \in S} \{\max(\delta(w_1, C(x')), \delta(\pi, \Pi(C(x'))))\}$ , which equals  $\max(1/8, \delta(\pi, \Pi(C(x))))$ .)

Hence,  $T$  is a POT (of linear detection probability) for  $S'$ .  $\blacktriangleleft$

## 5 Directions for further research

The begging question is whether a result like Theorem 1.2 can be proved when using an encoding function of smaller stretch, where the stretch of  $E: \{0, 1\}^* \rightarrow \{0, 1\}^*$  is the function that maps  $n$  to  $|E(1^n)|$ . Specifically, which sets  $S$  satisfy the conclusion of Theorem 1.2 with respect to an encoding of almost linear stretch?

Recalling that our proof of Theorem 1.2 is pivoted at the existence of strong canonical PCPs of Proximity, it is natural to ask which sets have a strong canonical PCP of Proximity of almost-linear proof complexity. We believe that USAT has such a PCP of Proximity, and suggest establishing this conjecture as an open problem.

► **Problem 5.1** (almost-linear length strong canonical PCPPs). *Show that USAT has a strong canonical PCP of Proximity of almost-linear proof complexity. Furthermore, show that valid proofs for this PCPP can be constructed in polynomial-time when given the input formula and a satisfying assignment to it.*

Recall that 3SAT has a PCP of Proximity of almost-linear proof complexity: We refer to the PCPP system of Dinur [8], which builds upon the work of Ben-Sasson and Sudan [6]. A possible route towards resolving Problem 5.1 is to show that this PCPP is a strong canonical PCPP, or can be transformed into such a PCPP at moderate cost (i.e., increasing the proof complexity by a poly-logarithmic factor). We actually believe that such a transformation is needed, since we believe that the PCPP of [8] is almost there (i.e., it satisfies a relaxed form of being strongly canonical (detailed below)), and that the extra step can be made by a generalization (of a PCPP version) of Proposition 3.2.

In order to detail this idea, we need a refinement of Definition 2.2. In this refinement, the rejection probability is not lower-bounded by a function of the maximum of the distances  $\delta(x, x')$  and  $\delta(\pi, \Pi(x))$ , but is rather the maximum of two (potentially) different functions applied to the two distances. Maybe more importantly, we allow these functions to depend also on the input length.

► **Definition 5.2** (Definition 2.2, refined). Let  $\varrho_I, \varrho_P: \mathbb{N} \times [0, 1] \rightarrow [0, 1]$  be monotonically non-decreasing in their second argument such that  $\varrho_I(n, \alpha) = 0$  (resp.,  $\varrho_P(n, \alpha) = 0$ ) if and only if  $\alpha = 0$ . For a set  $S \subseteq \{0, 1\}^*$  and an oracle machine  $V$  that accesses two oracles, we say that  $V$  is a  $(\varrho_I, \varrho_P)$ -strong canonical PCP of Proximity for  $S$  if  $V$  makes a constant number of queries to each of its oracles and there exist functions  $\ell: \mathbb{N} \rightarrow \mathbb{N}$  and  $\Pi: \{0, 1\}^* \rightarrow \{0, 1\}^*$  such that the following conditions hold.

- **Canonical Completeness:** As in Definition 2.2.<sup>25</sup>
- **Strong Canonical Soundness:** For every  $x \in \{0, 1\}^*$  and  $\pi \in \{0, 1\}^{\ell(|x|)}$ , the verifier rejects the pair of oracles  $(x, \pi)$  with probability at least

$$\min_{x' \in \{0, 1\}^{|x|}} \{\max(\varrho_I(|x|, \delta(x, x')), \varrho_P(|x|, \delta(\pi, \Pi(x'))))\}. \quad (4)$$

<sup>25</sup>That is, for every  $x \in S$ , it holds that  $\Pi(x) \in \{0, 1\}^{\ell(|x|)}$  and the verifier always accepts the pair of oracles  $(x, \Pi(x))$ ; i.e.,  $\Pr[V^{x, \Pi(x)}(1^{|x|}) = 1] = 1$ .

### 30:16 Every Set in $\mathcal{P}$ Is Strongly Testable Under a Suitable Encoding

We say that  $V$  is a strong canonical PCP of Proximity for  $S$  if both  $\varrho_{\mathcal{I}}$  and  $\varrho_{\mathcal{P}}$  are oblivious of the length parameter (i.e., if  $\varrho_{\mathcal{I}}(n, \alpha) = \varrho_{\mathcal{I}}'(\alpha)$  for some  $\varrho_{\mathcal{I}}' : [0, 1] \rightarrow [0, 1]$ , and ditto for  $\varrho_{\mathcal{P}}$ ), and say that  $V$  is a semi-strong canonical PCP of Proximity for  $S$  if  $\varrho_{\mathcal{I}}$  is oblivious of the length parameter. As in Definition 2.2,  $\ell$  is called the proof complexity of  $V$ .

Indeed, Definition 2.2 is obtained as a special case by letting  $\varrho_{\mathcal{I}}(n, \alpha) = \varrho_{\mathcal{P}}(n, \alpha) = \varrho(\alpha)$  for  $\varrho : [0, 1] \rightarrow [0, 1]$ . We conjecture that the PCPP system of Dinur [8], which builds on the work of Ben-Sasson and Sudan [6], yields a semi-strong canonical PCP of Proximity of logarithmic randomness and almost linear proof complexity for **USAT**, and that the corresponding function  $\varrho_{\mathcal{P}}$  has the form  $\varrho_{\mathcal{P}}(n, \alpha) = \alpha / \text{poly}(\log n)$ . If this is indeed the case, then using the following transformation, which generalizes Proposition 3.2, yields a strong canonical PCP of Proximity of almost-linear proof complexity for **USAT**, which in turn resolves Problem 5.1.

► **Proposition 5.3** (deriving strong canonical PPCPs from semi-strong ones). *Let  $V$  be a  $(\varrho_{\mathcal{I}}, \varrho_{\mathcal{P}})$ -strong canonical PCPP system of logarithmic randomness complexity and proof complexity  $\ell$  for  $S$ , and suppose that  $\varrho_{\mathcal{I}}(n, \alpha) = \varrho(\alpha) \leq \alpha$  and  $\varrho_{\mathcal{P}}(n, \alpha) = \varrho'_{\mathcal{P}}(n) \cdot \alpha$  for some  $\varrho'_{\mathcal{P}} : \mathbb{N} \rightarrow (0, 1]$ . Then, there exists a  $\varrho$ -strong canonical PCP of logarithmic randomness and proof complexity  $\ell / \varrho'_{\mathcal{P}}$  for  $S$ . Furthermore, there exists a polynomial-time transformation of valid proofs with respect to  $V$  to valid proofs for the resulting PCP.*

Note that the PCPP analogue of Proposition 3.2 follows as a special case by observing that any canonical PCPP system (i.e., one that has unique valid proofs) of randomness complexity  $r$  is an  $(\varrho_{\mathcal{I}}, \varrho_{\mathcal{P}})$ -strong canonical PCPP, where  $\varrho_{\mathcal{I}}$  is oblivious of the length parameter and  $\varrho_{\mathcal{P}}(n, \alpha) = 2^{-r(n)}$ .

**Proof.** We observe that the proof of Proposition 3.2 can be adapted and generalized as follows. Again, we may assume, without loss of generality, that  $V$  has polynomial proof complexity, and let  $t(n) = 1 / \varrho'_{\mathcal{P}}(n)$ . Letting  $\Pi$  be as in Definition 2.2, we define  $\Pi'(x) = 1^{(t(n)-1) \cdot \ell(x)} \Pi(x)$  if  $\Pi(x) \neq \lambda$ , and  $\Pi'(x) = \lambda$  otherwise. Analogously to the proof of Proposition 3.2, we consider the following verifier, which given oracle access to an input  $x \in \{0, 1\}^n$  and an alleged proof  $\pi' \in \{0, 1\}^{t(n) \cdot \ell(n)}$ , selects uniformly at random one of the following two tests and performs it.

1. The verifier selects at random  $i \in [(t(n) - 1) \cdot \ell(n)]$ , and accepts if and only if the  $i^{\text{th}}$  bit of  $\pi'$  equals 1.
2. The verifier invokes  $V$  on input  $x$  and the  $\ell(n)$ -bit long suffix of  $\pi'$ . That is,  $V$ 's queries to the input-oracle are answered by the input-oracle of the new verifier, whereas  $V$ 's queries to the proof-oracle are answered by accessing the suffix of the proof-oracle of the new verifier (i.e., query  $i \in [\ell(n)]$  is answered by querying the location  $(t(n) - 1) \cdot \ell(n) + i$  in  $\pi'$ ).

Turning to the analysis, we first note that if  $S \cap \{0, 1\}^n = \emptyset$ , then  $(x, \pi')$  is rejected with probability at least  $\delta(1) = \Omega(1)$ , and the claim follows. Hence, we may assume that  $S \cap \{0, 1\}^n \neq \emptyset$ . Letting  $\pi' \equiv (w, \pi) \in \{0, 1\}^{(t(n)-1) \cdot \ell(n) + \ell(n)}$ , we infer that the pair of oracles  $(x, \pi') \in \{0, 1\}^n \times \{0, 1\}^{t(n) \cdot \ell(n)}$  is rejected with probability at least

$$\min_{x' \in S \cap \{0, 1\}^n} \{ \max(\varrho(\delta(x, x')), 0.5 \cdot \delta(w, 1^{(t(n)-1) \cdot \ell(n)}) + 0.5 \cdot \varrho'_{\mathcal{P}}(n) \cdot \delta(\pi, \Pi(x'))) \}.$$

Observing that

$$\begin{aligned} & \delta(w, 1^{(t(n)-1) \cdot \ell(n)}) + \varrho'_{\mathcal{P}}(n) \cdot \delta(\pi, \Pi(x')) \\ & \geq \delta(w\pi, 1^{t(n)-1} \cdot \ell(n) \pi) + \varrho'_{\mathcal{P}}(n) \cdot t(n) \cdot \delta(1^{t(n)-1} \cdot \ell(n) \pi, 1^{t(n)-1} \cdot \ell(n) \Pi(x')) \\ & = \delta(\pi', 1^{t(n)-1} \cdot \ell(n) \pi) + \delta(1^{t(n)-1} \cdot \ell(n) \pi, \Pi'(x')) \\ & \geq \delta(\pi', \Pi'(x')), \end{aligned}$$

it follows that  $(x, \pi')$  is rejected with probability at least

$$\min_{x' \in S \cap \{0,1\}^n} \{\max(\varrho(\delta(x, x')), 0.5 \cdot \delta(\pi', \Pi'(x')))\}.$$

Using  $\varrho(\alpha) \leq \alpha$ , it follows that the new verifier is a  $0.5\varrho$ -strong canonical PCPP of proof complexity  $\ell/\varrho'_p$ . ◀

## Abstract

To select a subset of samples or “winners” from a population of candidates, order sampling [20] and the  $k$ -unit Myerson auction [17] share a common scheme: assign a (random) score to each candidate, then select the  $k$  candidates with the highest scores. We study a generalization of both order sampling and Myerson’s allocation rule, called *winner-selecting dice*. The setting for winner-selecting dice is similar to auctions with feasibility constraints: candidates have random types drawn from independent prior distributions, and the winner set must be feasible subject to certain constraints. Dice (distributions over scores) are assigned to each type, and winners are selected to maximize the sum of the dice rolls, subject to the feasibility constraints. We examine the existence of winner-selecting dice that implement prescribed probabilities of winning (i.e., an interim rule) for all types.

Our first result shows that when the feasibility constraint is a matroid, then for any feasible interim rule, there always exist winner-selecting dice that implement it. Unfortunately, our proof does not yield an efficient algorithm for constructing the dice. In the special case of a 1-uniform matroid, i.e., only one winner can be selected, we give an efficient algorithm that constructs winner-selecting dice for any feasible interim rule. Furthermore, when the types of the candidates are drawn in an i.i.d. manner and the interim rule is symmetric across candidates, unsurprisingly, an algorithm can efficiently construct symmetric dice that only depend on the type but not the identity of the candidate.

One may ask whether we can extend our result to “second-order” interim rules, which not only specify the winning probability of a type, but also the winning probability conditioning on each other candidate’s type. We show that our result does not extend, by exhibiting an instance of *Bayesian persuasion* whose optimal scheme is equivalent to a second-order interim rule, but which does not admit any dice-based implementation.

## 1 Introduction

Economic design often features scenarios in which choices must be made based on stochastic inputs. In auction design, bidders drawn from a population interact with an auction mechanism, and the mechanism must then choose winners and losers of the auction. In information structure design, a principal observes information pertinent to the various actions available to one or more decision makers, and must use this information to recommend actions to the decision makers. In such settings, an important framing device is the notion of an *interim rule* (also called a *reduced form*) of an (ex-post) winner selection rule, summarizing the probability for each candidate to be selected.

We focus on the simplest and most natural class of such decision making scenarios, one which includes auctions and Bayesian persuasion [12] as special cases. In a *winner selection* environment, there is a set of *candidates*  $\mathcal{C}$ , each equipped with a random attribute known as its *type*. A *winner selection rule* is a randomized function (or algorithm) which maps each profile of types, one per candidate, to a choice of winning candidates, subject to the requirement that the set of winners must belong to a specified family  $\mathcal{I} \subseteq 2^{\mathcal{C}}$  of feasible sets. The winner selection rule is also referred to as an ex-post rule since it specifies the winning probabilities conditioned on every realized type profile. In auctions, candidates correspond to bidders, and a winner selection rule is an allocation rule of the auction. In Bayesian persuasion, candidates correspond to actions available to a decision maker, and a winner selection rule corresponds to a persuasion scheme used by a principal to recommend one of the actions to the decision maker. We restrict our attention to winner selection scenarios in which the types of different candidates are independently distributed.

We distinguish two classes of interim rules: *first-order* and *second-order*. The former is the traditional notion from auction theory, while the latter is the notion better suited for persuasion. A *first-order interim rule* specifies, for each candidate  $i$  and type  $t$  of candidate  $i$ , the conditional probability of  $i$  winning given that his type is  $t$ . A *second-order interim rule* specifies more information: for each pair of candidates  $i, j$  and type  $t$  of candidate  $j$ , it specifies the conditional probability of  $i$  winning given that  $j$  has type  $t$ . First-order interim rules, when combined with a payment rule, suffice for evaluating the welfare, revenue, and incentive-compatibility of a single-item auction. For Bayesian persuasion, second-order interim rules are needed for evaluating the incentive constraints of a persuasion scheme.

Our motivation for studying winner selection at this level of generality stems from the success of Myerson's [17] famous and elegant characterization of revenue-optimal single-item auctions when bidder type distributions are independent. In that special case, Myerson showed that the optimal *single-item* auction features a particularly structured winner-selection rule: each type is associated with a virtual value, and given a profile of reported types, the rule selects the bidder with the highest (non-negative) virtual value as the winner.

Interestingly, order sampling [20] works in a similar way as Myerson's auction, in the special case when the feasible sets are sets of  $k$  or fewer candidates, and each candidate has only one type. Order sampling assigns each candidate a random score variable (a die). The winners are the candidates with the  $k$  highest score variables. In the language of order sampling, virtual value functions define a single-sided die for each type. Unlike Myerson's auction, there is no notion of "revenue" or "incentive constraints" in order sampling. The task is simply to find dice that will induce a prescribed first-order interim rule.

As a generalization of order sampling and Myerson's virtual-value approach, a *dice-based winner-selection rule* assigns each type a die, and selects the feasible set of winners maximizing the sum of the dice rolls. *We explore the extent to which dice-based rules are applicable beyond*

*single-parameter auctions or single-type environments, to winner selection with independent type distributions under more complex constraints.* In particular, we examine whether dice-based winner-selection rules exist for winner selection subject to matroid constraints and for Bayesian persuasion.

## 1.1 Our Results

As mentioned previously, all of our results are restricted to settings in which the candidates' type distributions are independent. It follows from Myerson's characterization that every first-order interim rule *corresponding to some optimal auction* admits a dice-based implementation.<sup>1</sup> Our main result (in Section 3) is an existential proof showing that *every* feasible first-order interim rule with respect to a matroid constraint admits a dice-based implementation. This illustrates that the structure revealed by Myerson's characterization is more general, and applies to other settings in which only first-order interim information is relevant. For example, single-item auctions with (public or private) budgets are such a setting (see, e.g., [19]). Our result also provides a generalization of order sampling from the  $k$ -winner setting to the general matroid, multi-type setting.

Beyond the existential proof of dice-based implementations, we show (in Section 4) that for single-winner environments, an algorithm can construct the dice-based rule *efficiently*. When the types are identically distributed, we also constructively show (in the full version) that every first-order interim rule which is symmetric across candidates admits a symmetric dice implementation; i.e., different candidates have the same die for the same type. This is consistent with Myerson's symmetric characterization of optimal single-item auctions with i.i.d. bidders, and generalizes it to any other first-order single-winner selection setting in which candidates are identical. Single-item auctions with identically distributed budgeted bidders are such a setting, and a symmetric dice-based implementation of the optimal allocation rule was already known from [19].

For single-winner cases, we also show the converse direction: how to efficiently compute the first-order interim rule of a given dice-based winner selection rule. In effect, these results show that collections of dice are a computationally equivalent description of single-winner first-order interim information. This implies a kind of equivalence between the two dominant approaches for mechanism design: the Myersonian approach based on virtual values (i.e., dice), and the Borderian approach based on optimization over interim rules.

In an attempt to leverage the same kinds of insights for Bayesian persuasion, we examine (in Sections 5 and 6) the dice implementability of second-order interim rules. When the candidate type distributions are non-identical, we show an impossibility result. We construct an instance of Bayesian persuasion with independently distributed non-identical actions, and show that no optimal persuasion scheme for this instance can be implemented by dice. Since second-order interim rules are sufficient for evaluating the objective and constraints of Bayesian persuasion, this implies that there exist second-order interim rules which are not dice-implementable. This rules out the Myersonian approach for characterizing and computing optimal schemes for Bayesian persuasion with independent non-identical actions, complementing the negative result of [8] which rules out the Borderian approach for the same problem.

---

<sup>1</sup> As we show in the full version, there are interim rules which are not optimal for any auction.

Our impossibility result disappears when the actions are i.i.d., since second-order interim rules collapse to first-order interim rules in symmetric settings. In particular, as we show in Section 6, our results for first-order interim rules, combined with those of [8], imply that Bayesian persuasion with i.i.d. actions admits an optimal dice-based scheme, which can be computed efficiently.

## 1.2 Additional Discussion of Related Work

Myerson [17] was the first to characterize revenue-optimal single-item auctions; this characterization extends to single-parameter mechanism design settings more generally (see, e.g., [11]). The (first-order) interim rule of an auction, also known as its reduced form, was first studied by Maskin and Riley [14] and Matthews [15]. The inequalities characterizing the space of feasible interim rules were described by Border [3, 4]. Border’s analytically tractable characterization of feasible interim rules has served as a fruitful framework for mechanism design, since an optimal auction can be viewed as the solution of a linear program over the space of interim rules. Moreover, this characterization has enabled the design of efficient algorithms for recognizing interim rules and optimizing over them, by Cai et al. [5] and Alaei et al. [2]. This line of work has served as a foundation for much of the recent literature on Bayesian algorithmic mechanism design in multi-parameter settings.

It is important to contrast our dice-based rule with the characterization of Cai et al. [5]. In particular, the results of Cai et al. [5] imply that every first-order interim rule can be efficiently implemented as a distribution over virtual value maximizers. In our language, this implies the existence of an efficiently computable dice-based implementation *in which the dice may be arbitrarily correlated*. Our result, in contrast, efficiently computes a family of *independent dice* implementing any given first-order interim rule in single-winner settings, and shows the existence of a dice-based rule in matroid settings. This is consistent with Myerson’s characterization, in which virtual values are drawn independently.

Alaei et al. [2] also studied winner-selection environments, under the different name “service based environments.” For single-winner settings, they proposed a mechanism called stochastic sequential allocation (SSA). The mechanism also implements any feasible first-order interim rule, by creating a token of winning and transferring the token sequentially from one candidate to another, with probabilities defined by an efficiently computed transition table. Dice can be considered as the special case of SSA in which the transition probabilities are independent of the current owner of the token.

As another motivation for our focus on dice-based rules, order sampling studies how to sample  $k$  winners from  $n$  candidates with given inclusion probabilities (i.e., implement an interim rule), by assigning a random score variable (die) to each candidate. Rosén [20] showed that parameterized Pareto distributions can be used to implement a given interim rule asymptotically. Aires et al. [1] proved the existence of an order sampling scheme that exactly implements any feasible interim rule. Our existential proof is a generalization of the proof of [1] to settings with multiple types and matroid constraints.

The Bayesian persuasion model is due to Kamenica and Gentzkow [12], and is the most influential model in the general space of information structure design (see the survey by Dughmi [7] for references). Bayesian persuasion was examined algorithmically by Dughmi and Xu [8], who observed its connection to auction theory and interim rules, and examined the computational complexity of optimal schemes through the lens of optimization over interim rules.

Of particular relevance to our work is the negative result of Dughmi and Xu [8] for Bayesian persuasion with independent non-identical actions: it is  $\#P$ -hard to compute the interim rule (first- or second-order) of the optimal scheme, or more simply even the sender's optimal utility. Most notable about this result is what it *does not* rule out: an algorithm implementing the optimal persuasion scheme “on the fly,” in the sense that it efficiently samples the optimal scheme's (randomized) recommendation when given as input the profile of action types. Stated differently, the negative result of Dughmi and Xu [8] merely rules out the Borderian approach for this problem, leaving other approaches – such as the Myersonian one – viable as a means of obtaining an efficient “on the fly” implementation. This would not be unprecedented: Gopalan et al. [9] exhibit a simple single-parameter auction setting for which the optimal interim rule is  $\#P$  hard to compute, yet Myerson's virtual values can be sampled efficiently and used to efficiently implement the optimal auction. Our negative result in Section 6 rules out such good fortune for Bayesian persuasion with independent non-identical actions: there does not exist a (Myersonian) dice-based implementation of the optimal persuasion scheme in general.

## 2 Preliminaries

### 2.1 Winner Selection

Consider choosing a set of winners from among  $n$  candidates. Each candidate  $i$  has a type  $t_i \in T_i$ , drawn independently from a distribution  $f_i$ . A winner-selection rule  $\mathcal{A}$  maps each type profile  $\mathbf{t} = (t_1, \dots, t_n)$ , possibly randomly, to one of a prescribed family of feasible sets  $\mathcal{I} \subseteq 2^{[n]}$ . When  $i \in \mathcal{A}(\mathbf{t})$ , we refer to  $i$  as a *winning candidate*, and to  $t_i$  as his *winning type*. Writing  $f = f_1 \times \dots \times f_n$  for the (independent) joint type distribution, we also refer to  $(f, \mathcal{I})$  as the *winner-selection environment*. When  $\mathcal{I}$  is the family of singletons, as in the setting of the single item auction, we call  $(f, \mathcal{I})$  a *single-winner environment*.

This general setup captures the allocation rules of general auctions with independent unit-demand buyers, albeit without specifying payment rules or imposing incentive constraints. Moreover, it captures Bayesian persuasion with independent action payoffs, albeit without enforcing persuasiveness (also called *obedience*) constraints.

### 2.2 Matroids

In this paper, we focus on settings in which the feasible sets  $\mathcal{I}$  are the independent sets of a matroid. We use the standard definition of a matroid  $\mathcal{M}$  as a pair  $(E, \mathcal{I})$ , where  $E$  is the *ground set* and  $\mathcal{I} \subseteq 2^E$  is a family of so-called *independent sets*, satisfying the three matroid axioms. We also use the standard definitions of a *circuit* and *rank function*  $r_{\mathcal{M}} : 2^E \rightarrow \mathbb{N}$ . The *restriction*  $\mathcal{M}|_S$  of  $\mathcal{M} = (E, \mathcal{I})$  to some  $S \subseteq E$  is the matroid  $(E, \mathcal{I} \cap 2^S)$ .<sup>2</sup> For details on matroids, we refer the reader to Oxley [18].

A matroid  $\mathcal{M} = (E, \mathcal{I})$  is *separable* if it is a *direct sum* of two matroids  $\mathcal{M}_1 = (E_1, \mathcal{I}_1)$  and  $\mathcal{M}_2 = (E_2, \mathcal{I}_2)$ . Namely,  $E = E_1 \uplus E_2$ ,  $\mathcal{I} = \{A \cup B \mid A \in \mathcal{I}_1, B \in \mathcal{I}_2\}$ . Note that if  $\mathcal{M}$  is non-separable, then  $r_{\mathcal{M}}(E) < |E|$ ; otherwise  $\mathcal{M}$  is the direct sum of singleton matroids. We use the following theorem.

► **Theorem 1** (Whitney [21]). (1) When  $\mathcal{M} = (E, \mathcal{I})$  is a non-separable matroid, for every  $a, b \in E$ , there is a circuit containing both  $a$  and  $b$ . (2) Any separable matroid  $\mathcal{M}$  is a direct sum of two or more non-separable matroids called the components of  $\mathcal{M}$ .

<sup>2</sup> Note that we deviate slightly from the standard definition in that we do not restrict the ground set.

In most of the remainder of the paper, we focus on winner selection environments  $(f, \mathcal{I})$  where  $\mathcal{I}$  is the family of independent sets of a matroid  $\mathcal{M}$ . We therefore also use  $(f, \mathcal{M})$  to denote the environment.

## 2.3 Interim Rules and Border's Theorem

A (first-order) interim rule  $\mathbf{x}$  specifies the winning probability  $x_i(t) \in [0, 1]$  for all  $i \in [n], t \in T_i$  in an environment  $(f, \mathcal{I})$ . More precisely, we say that a winner-selection rule  $\mathcal{A}$  implements the interim rule  $\mathbf{x}$  for a prior  $f$  if it satisfies the following: if the type profile  $\mathbf{t} = (t_1, \dots, t_n)$  is drawn from the prior distribution  $f = f_1 \times \dots \times f_n$ , then  $\Pr[i \in \mathcal{A}(\mathbf{t}) \mid t_i = t] = x_i(t)$ . An interim rule is *feasible* (or *implementable*) within an environment  $(f, \mathcal{I})$  if there is a winner-selection rule implementing it that always outputs an independent set of  $\mathcal{I}$ .

### 2.3.1 Border's theorem and implications for single-winner environments

The following theorem characterizes the space of feasible interim rules for single-winner settings.

► **Theorem 2** (Border [3, 4]). *An interim rule  $\mathbf{x}$  is feasible for a single-winner setting if and only if for all possible type subsets  $S_1 \subseteq T_1, S_2 \subseteq T_2, \dots, S_n \subseteq T_n$ ,*

$$\sum_{i=1}^n \sum_{t \in S_i} f_i(t) x_i(t) \leq 1 - \prod_{i=1}^n \left( 1 - \sum_{t \in S_i} f_i(t) \right). \quad (1)$$

The following result leverages Theorem 2 to show that efficient algorithms exist for checking the feasibility of an interim rule, and for implementing a feasible interim rule.

► **Theorem 3** ([5, 2]). *Given explicitly represented priors  $f_1, \dots, f_n$  and an interim rule  $\mathbf{x}$  in a single-winner setting, the feasibility of  $\mathbf{x}$  can be checked in time polynomial in the number of candidates and types. Moreover, given a feasible interim rule  $\mathbf{x}$ , an algorithm can find a winner-selection rule implementing  $\mathbf{x}$  in time polynomial in the number of candidates and types.*

In our efficient construction for single-winner settings, we utilize a structural result which shows that checking only a subset of Border's constraints suffices [3, 16, 5]. This subset of constraints can be identified efficiently.

► **Theorem 4** (Theorem 4 of [5]). *An interim rule  $\mathbf{x}$  is feasible for a single-winner setting if and only if for all possible  $\alpha \in [0, 1]$ , the sets  $S_i(\alpha) = \{t \in T_i \mid x_i(t) > \alpha\}$  satisfy the following Border's constraint:*

$$\sum_{i=1}^n \sum_{t \in S_i(\alpha)} f_i(t) x_i(t) \leq 1 - \prod_{i=1}^n \left( 1 - \sum_{t \in S_i(\alpha)} f_i(t) \right).$$

When the candidates' type distributions are i.i.d., i.e.,  $T_i$  and  $f_i$  are the same for all candidates  $i$ , it is typically sufficient to restrict attention to *symmetric* interim rules. For such rules,  $x_i(t)$  is equal for all candidates  $i$ . In the i.i.d. setting, we therefore notationally omit the dependence on the candidate and let  $T$  refer to the common type set of all candidates,  $f$  to the candidates' (common) type distribution, and  $x(t)$  to the probability that a particular candidate wins conditioned on having type  $t$ . In the i.i.d. setting, only the symmetric constraints from Theorem 2 suffice to characterize feasibility [3]; namely,

$$n \cdot \sum_{t \in S} f(t) x(t) \leq 1 - \left( 1 - \sum_{t \in S} f(t) \right)^n, \quad (2)$$

for all  $S \subseteq T$ . Theorem 4 then implies that it suffices to check Inequality (2) for sets of the form  $S(\alpha) = \{t \in T : x(t) > \alpha\}$  with  $\alpha \in [0, 1]$ .

### 2.3.2 Border’s Theorem for matroid environments

For general settings with matroid constraints, Alaei et al. [2] established the following generalized “Border’s Theorem.”

► **Theorem 5** (Theorem 7 of [2]). *Let  $\nu$  map each type  $t$  to the (unique) candidate  $i$  with  $t \in T_i$ . An interim rule  $\mathbf{x}$  is feasible within an environment  $(f, \mathcal{M})$  if and only if for all possible type subsets  $S_1 \subseteq T_1, S_2 \subseteq T_2, \dots, S_n \subseteq T_n$ ,  $\sum_{i=1}^n \sum_{t \in S_i} f_i(t)x_i(t) \leq \mathbb{E}_{\mathbf{t} \sim f} [r_{\mathcal{M}}(\nu(\mathbf{t} \cap S))]$ , where  $S = \bigcup_{i=1}^n S_i$ .*

In later sections, we omit the function  $\nu$ , and for any type set  $S$  just write  $r_{\mathcal{M}}(S)$  instead of  $r_{\mathcal{M}}(\nu(S))$ .

## 2.4 Winner-Selecting Dice

We study winner-selection rules based on *dice*, as a generalization of order sampling to multiple types and general constraints. A *dice-based rule* fixes, for each type  $t \in T_i$ , a distribution  $D_{i,t}$  over real numbers, which we call a *die*. Given as input the type profile  $\mathbf{t} = (t_1, \dots, t_n)$ , the rule independently draws a score  $v_i \sim D_{i,t_i}$  for each candidate  $i$  by “rolling his die;” it then selects the feasible set of candidates maximizing the sum of scores as the winner set, breaking ties with a predefined rule. In this paper, we will mainly discuss matroid feasibility constraints, for which a feasible set maximizing the sum of scores can be found by a simple greedy algorithm: candidates are added to the winner set in decreasing order of their scores, breaking ties uniformly at random, as long as the new winner set is still an independent set of the matroid and their scores are positive. When candidates have the same type sets, we call a dice-based rule *symmetric* if  $D_{i,t}$  is the same for all  $i$ .

Myerson’s optimal auction is a dice-based winner-selection rule. In Myerson’s nomenclature,  $\bar{v}_i$  is candidate  $i$ ’s *virtual value*, and  $D_{i,t}$  is a single-sided die with the virtual value.

Let  $T$  be the set of all types of all candidates and  $\mathcal{D} = (D_t)_{t \in T}$  be a vector of dice, one per type. Given an interim rule  $\mathbf{x}$ , and a winner-selection environment  $(f, \mathcal{I})$ , we say that  $\mathcal{D}$  *implements*  $\mathbf{x}$ , or  $\mathcal{D}$  describes *winner-selecting dice* for  $\mathbf{x}$  in  $(f, \mathcal{I})$ , if the dice-based rule given by  $\mathcal{D}$  implements  $\mathbf{x}$  within the environment  $(f, \mathcal{I})$ .

## 2.5 Second-order Interim Rules

A (first-order) interim rule, as defined in Section 2.3, specifies, for each candidate  $i$ , the conditional type distribution of  $i$  in the event that  $i$  is chosen as the winner. We define a *second-order interim rule*<sup>3</sup> which maintains strictly more information, as needed for describing the incentive constraints of Bayesian persuasion. Such a rule specifies, for each pair of candidates  $i$  and  $i'$  (where  $i'$  may or may not be equal to  $i$ ), the conditional type distribution of  $i'$  in the event that  $i$  is chosen as the winner. Formally, a second-order interim

<sup>3</sup> Our notion of second-order interim rules is different from the notion defined in [6]. Because Cai et al. [6] consider correlation in types, their notion of second-order interim rules is aimed at capturing the allocation dependencies arising through such type correlation, rather than solely through the mechanism’s choice.

rule  $\mathbf{X}$  specifies  $x_{i,i',t} \in [0, 1]$  for each pair of candidates  $i, i' \in [n]$ , and type  $t \in T_{i'}$ . We say that a winner-selection rule  $\mathcal{A}$  *implements*  $\mathbf{X}$  for a prior  $f$  if it satisfies the following: if the type profile  $\mathbf{t} = (t_1, \dots, t_n)$  is drawn from the prior distribution  $f = f_1 \times \dots \times f_n$ , then  $\Pr[i \in \mathcal{A}(\mathbf{t}) \mid t_{i'} = t] = x_{i,i',t}$ . A second-order interim rule is *feasible* if there is a winner selection rule implementing it.

### 3 Existence of Dice Implementation for Matroids

In this section, we outline the proof of our first theorem:

► **Theorem 6.** *Let  $(f, \mathcal{M})$  be a matroid winner selection-environment with a total of  $m$  types, and let  $\mathbf{x}$  be an interim rule that is feasible within  $(f, \mathcal{M})$ . There exist winner-selecting dice  $\mathcal{D}$ , each of which has at most  $m + 1$  faces, which implement  $\mathbf{x}$ .*

The proof consists of two parts. First, we generalize the result of [1], which showed the existence of continuous winner-selecting dice for feasible interim rules for a  $k$ -uniform matroid with fixed types, to general matroids and multiple types. Second, we convert the continuous dice to dice with at most  $m + 1$  faces each, while keeping the interim probabilities unchanged.

#### 3.1 Continuous Winner-Selecting Dice

► **Theorem 7.** *Let  $\mathcal{M}$  be a matroid, and  $\mathbf{x}$  a feasible interim rule within the winner-selection environment  $(f, \mathcal{M})$ . There exist winner-selecting dice  $\mathcal{D}$  over  $\mathbb{R}$  that implement  $\mathbf{x}$  in  $(f, \mathcal{M})$ .*

We assume without loss of generality that the candidates' type sets are disjoint, and use  $T = \bigsqcup_{i=1}^n T_i$  to denote the set of all types. We use  $f(t)$  and  $x(t)$  as shorthand for  $f_i(t)$  and  $x_i(t)$ , where  $i = \nu(t)$  is the candidate for whom  $t \in T_i$ . Moreover, given a set of types  $S \subseteq T$ , we write  $S_i = S \cap T_i$ . Recall the Border constraints

$$\sum_{i=1}^n \sum_{t \in S_i} f_i(t)x_i(t) \leq R(S), \quad (3)$$

where  $R(S) = \mathbb{E}_{\mathbf{t} \sim f} [r_{\mathcal{M}}(\mathbf{t} \cap S)]$  is the expected rank of types in  $S$  which show up, a submodular function over the type set  $T$ . The Border constraints can therefore be interpreted as follows: An interim rule  $\mathbf{x} : T \rightarrow [0, 1]$  is feasible for  $f$  and  $\mathcal{M}$  if and only if  $\tilde{\mathbf{x}}$  is in the polymatroid given by  $R(S)$ , where  $\tilde{\mathbf{x}}(t) := f(t)x(t)$ . Equivalently,  $\mathbf{x}$  is feasible if and only if the submodular *slack function*  $\sigma(S) = R(S) - \sum_{t \in S} f(t)x(t)$  is non-negative everywhere.

When  $\mathbf{x}$  is feasible, we call a set  $S \subseteq T$  *tight* for  $(f, \mathbf{x}, \mathcal{M})$  if the Border constraint (3) corresponding to  $S$  is tight at  $\mathbf{x}$ , i.e.,  $\sum_{i=1}^n \sum_{t \in S_i} f_i(t)x_i(t) = R(S)$ . By definition,  $S = \emptyset$  is always tight. The family of tight sets, being the family of minimizers of the submodular slack function, forms a lattice: the intersection and the union of two tight sets is a tight set.

► **Remark.** The tightness of a set  $S$  means that the expected number of winners from  $S$  equals the expected rank of types in  $S$  which show up. In other words,  $S$  is tight if and only if a maximum independent subset of  $\mathbf{t} \cap S$  is always selected as winners.

By the preceding remark, the types in minimal non-empty tight sets need to be treated preferentially, i.e., assigned higher faces on their dice, compared to types outside them. Because they play such an important role, we define them as *barrier sets*. Formally, we define the set of *active* types  $T^+ = \{t \in T : f(t)x(t) > 0\}$  to be the types who win with positive probability. Barrier sets are subsets of  $T^+$ . If there is at least one non-empty tight set of active types, we define the barrier sets as the (inclusion-wise) minimal such sets. Otherwise, we designate the entire set  $T^+$  of active types as the unique barrier set.

To prove Theorem 7, we first assume that the matroid  $\mathcal{M}$  is non-separable. Separable matroids will be handled in the proof of Theorem 7 by combining the dice of their non-separable components. Because barrier sets get precedence, we first show how to construct dice for barrier sets with Lemma 8. Once we have dice for barrier sets, we can repeatedly “peel off” the tight sets and combine their dice, which is captured in Lemma 9. We start with the existence of dice for barrier sets:

► **Lemma 8.** *Let  $\mathcal{M}$  be a non-separable matroid, and  $\mathbf{x} > \mathbf{0}$  a feasible interim rule within the winner-selection environment  $(f, \mathcal{M})$ . Let  $S$  be a barrier set for  $(f, \mathbf{x}, \mathcal{M})$ , and define  $\mathbf{x}_S$  to be  $(x(t))_{t \in S}$ . There exists a vector of distributions  $\mathcal{D} = (D_t)_{t \in S}$  over  $\mathbb{R}$ , such that  $\mathcal{D}$  implements  $\mathbf{x}_S$  in  $(f, \mathcal{M}|S)$ .*

The proof is quite technically involved, and due to space constraints, it is entirely deferred to the full version. The high-level idea is to base the dice upon any full-support continuous distribution for the dice. This distribution is scaled by different parameters  $\theta_i$  for different types  $i$ , and shifted by a constant  $\tau$ . Matching the prescribed interim winning probabilities  $x(i)$  imposes a system of non-linear equations on the  $\theta_i$ . We establish that the winning probabilities of different types satisfy certain key monotonicity properties in the parameters  $\theta_i$ ; these monotonicity properties are proved using the fact that the feasible sets form a matroid. Then, we apply the Intermediate Value Theorem inductively for all types  $i$  to non-constructively prove the existence of the desired  $\theta_i$ .

To generalize Lemma 8 to arbitrary sets of types, we will need a construction that allows us to “scale” the faces of some dice such that they will always be above/below the faces of another set of newly introduced dice; such a construction will allow us to give dice for types in barrier sets higher faces than other dice. For the types of full-support distributions over  $[0, \infty)$  we have been using so far, this would be impossible. There is a simple mapping that guarantees our desired properties: we map faces from  $(0, \infty)$  to the set  $(1, 2)$  by mapping all positive  $s \mapsto 2 - \frac{1}{1+s}$ , and mapping all negative  $s$  to  $-1$ . Notice that the new dice implement the same interim rule as the old ones: in matroid environments, the set maximizing the sum of die rolls is determined by the greedy algorithm, and hence, only the relative order between die faces matters. With the help of this mapping, we prove the following lemma, similar to Lemma 8. The proof is again only given in the full version.

► **Lemma 9.** *Let  $\mathbf{x} > \mathbf{0}$  be a feasible interim rule within a winner-selection environment  $(f, \mathcal{M})$ , where  $\mathcal{M}$  is a non-separable matroid. Fix a tight set  $S$ , and let  $\hat{S}$  be a minimal tight set that includes  $S$  as a proper subset, if such a set exists; otherwise let  $\hat{S} = T$ . Given dice  $\mathcal{D} = (D_t)_{t \in S}$  that implement  $\mathbf{x}_S$  in  $(f, \mathcal{M}|S)$ , there are dice  $\mathcal{D}' = (D'_t)_{t \in \hat{S}}$  which implement  $\mathbf{x}_{\hat{S}}$  in  $(f, \mathcal{M}|\hat{S})$ .*

**Proof of Theorem 7.** First consider the case when  $\mathcal{M}$  is non-separable. Let  $T$  be the type set with  $m$  types. We define the dice system as follows: First, for all types  $t$  with  $x(t) = 1$ , assign them a point distribution (single-sided die) at 2, so they always win. Next, for all types  $t$  with  $x(t) = 0$ , assign them a point distribution at  $-1$ , so they never win. Next, we create dice for barrier sets  $S$  according to Lemma 8. Then, starting from the barrier sets, we repeatedly apply Lemma 9 to construct dice for larger tight sets  $\hat{S} \supsetneq S$  (or all of  $T$ ) implementing  $\mathbf{x}_{\hat{S}}$ .

If  $\mathcal{M}$  is separable, let  $\mathcal{M}_1, \dots, \mathcal{M}_k$  be the components of  $\mathcal{M}$ . Using the construction from the previous paragraph for each  $\mathcal{M}_j$ , let  $\mathcal{D}_j$  be the dice set constructed for  $\mathcal{M}_j$ . Since there is no circuit containing two candidates from different components, the winner set of one component has no effect on the winner set of any other component. Thus, the union  $\bigcup_{j=1}^k \mathcal{D}_j$  of dice implements the desired interim rule. ◀

**ALGORITHM 1:** FIND BARRIER SET( $f, \mathbf{x}$ ).

---

```

1  $T^+ \leftarrow \{t \in T : f(t)x(t) > 0\}$ .
2 Define  $g(S) = f(S) - \sum_{t \in S} f(t)x(t)$  for  $S \subseteq T^+$ .
3 if  $\min \{g(S) : \emptyset \subsetneq S \subseteq T^+\} \neq 0$  then
4   return  $T^+$ .
5 else
6    $T^* \leftarrow T^+$ .
7   while there is a type  $t \in T^*$  such that  $\min \{g(S) : \emptyset \subsetneq S \subseteq T^* \setminus \{t\}\} = 0$  do  $T^* \leftarrow T^* \setminus \{t\}$ .
8   return  $T^*$ .

```

---

We use the same notation  $f(t)$  and  $x(t)$  as in Section 3. In the single-winner setting, the function  $R(S) = \mathbb{E}_{t \sim f} [r_{\mathcal{M}}(\mathbf{t} \cap S)]$  can be treated as a natural extension of  $f$  to subsets of  $T$ : given  $S \subseteq T$ , we let  $R(S) = f(S) = 1 - \prod_{i=1}^n (1 - \sum_{t \in S_i} f(t))$ , which is the probability that at least one type in  $S$  shows up. Border's constraints can then be written as follows:  $\sum_{t \in S} f(t)x(t) \leq f(S)$  for all  $S \subseteq T$ . The slack function becomes  $\sigma_{f, \mathbf{x}}(S) = f(S) - \sum_{t \in S} f(t)x(t)$  and is nonnegative everywhere when  $\mathbf{x}$  is feasible.

Tight sets and barrier sets are defined as the special case of the definition for general matroids in Section 3. The algorithm FIND BARRIER SET, given as Algorithm 1, simply implements the definition of barrier sets as minimal non-empty tight sets, and therefore correctly computes a barrier set.

The following lemma characterizes the key useful structure of barrier sets for the single-winner setting.

► **Lemma 12.** *Let  $f$  and  $\mathbf{x}$  be such that  $\mathbf{x}$  is feasible for  $f$ . If there are multiple barrier sets for  $(f, \mathbf{x})$ , then there is a candidate  $i^*$  such that each barrier set is a singleton  $\{t\}$  with  $t \in T_{i^*}$ .*

**Proof.** Let  $A, B$  be any two barrier sets. Because  $A$  and  $B$  are both tight, the lattice property of tight sets implies that  $A \cap B = \emptyset$ .

We first show that there is a candidate  $i^*$  with  $A \subseteq T_{i^*}$  and  $B \subseteq T_{i^*}$ . Suppose not for contradiction; then, there exist  $i \neq j$  and types  $t_i \in A \cap T_i$  and  $t_j \in B \cap T_j$ . With non-zero probability, the types  $t_i$  and  $t_j$  show up at the same time. However, according to the definition of a tight set, when a type in  $A$  shows up, the winner must be a candidate with type in  $A$ , and the same must hold for  $B$ . Then, the winner's type would have to be in  $A \cap B$  with non-zero probability. This contradicts the disjointness of  $A$  and  $B$ .

It remains to show that all barrier sets are singletons. Since  $A$  is tight and all types in  $A$  belong to the same candidate,  $\sum_{t \in A} f(t)x(t) = f(A) = \sum_{t \in A} f(t)$ . Hence,  $x(t) = 1$  for all  $t \in A$ , and because barrier sets are minimally tight,  $A$  must be a singleton. ◀

## 4.1 Description of the Algorithm

Given a prior  $f$  and a feasible interim rule  $\mathbf{x}$ , the recursive procedure CONSTRUCT DICE, shown in Algorithm 2, returns a family of dice  $\mathcal{D}$  implementing  $\mathbf{x}$  for  $f$ . It operates as follows. There are two simple base cases: when no candidate ever wins, and when a single type of a single candidate always wins. In the recursive case, the algorithm carefully selects a type  $t^*$  and awards its die the highest-valued face  $M^t$ . It assigns this new face a probability as large as possible, subject to still permitting implementation of  $\mathbf{x}$ . We choose  $t^*$  as a member of a barrier set; this is important in order to guarantee that the algorithm makes significant progress.

---

**ALGORITHM 2:** CONSTRUCT DICE ( $f, \mathbf{x}$ ).

---

**Input** : PDFs  $f_1, \dots, f_n$  supported on disjoint type sets  $T_1, \dots, T_n$ .  
**Input** : Interim rule  $\mathbf{x}$  feasible for  $f$ .  
**Output** : Vector of dice  $(D_t)_{t \in \biguplus_{i=1}^n T_i}$ .

- 1 Let  $T = \biguplus_i T_i$ .
- 2 Let  $T_i^+ = \{t \in T_i : f_i(t)x_i(t) > 0\}$ , and let  $T^+ = \biguplus_{i=1}^n T_i^+$ .
- 3 **if**  $T^+ = \emptyset$  **then**
- 4 **for all** types  $t \in T$ , let  $D_t$  be a single-sided die with a  $-1$  face.
- 5 **else if** there is a type  $t^* \in T^+$  with  $f(t^*)x(t^*) = 1$  **then**
- 6 Let  $D_{t^*}$  be a single-sided die with a  $+1$  face.
- 7 **for all** other types  $t \in T \setminus \{t^*\}$ , let  $D_t$  be a single-sided die with a  $-1$  face.
- 8 **else**
- 9 Let  $T^* = \text{FIND BARRIER SET}(f, \mathbf{x})$ .
- 10 Let  $t^* \in T^*$  be a type chosen arbitrarily.
- 11 Let  $(f', \mathbf{x}') = \text{DECREMENT}(f, \mathbf{x}, t^*, q^*)$ , for the largest value of  $q^* \in [0, f(t^*)x(t^*)]$  such that  $\mathbf{x}'$  is feasible for  $f'$ . /\* Note that  $f(t^*)x(t^*) < 1$ . \*/
- 12 Let  $(D'_t)_{t \in T} \leftarrow \text{CONSTRUCT DICE}(f', \mathbf{x}')$ .
- 13 Let  $M$  be the maximum possible face of any die  $D'_t$ , and  $M' := \max(M, 0) + 1$ .
- 14 Let  $D_t = D'_t$  for all types  $t \neq t^*$ .
- 15 Let  $D_{t^*}$  be the die which rolls  $M'$  with probability  $\frac{q^*}{f(t^*)}$ , and  $D'_{t^*}$  with probability  $1 - \frac{q^*}{f(t^*)}$ .
- 16 **return**  $(D_t)_{t \in T}$ .

---

---

**ALGORITHM 3:** DECREMENT( $f, \mathbf{x}, t^*, q$ ).

---

*/\*  $q \geq 0$  is the probability allocated to the highest face. Because it is a contribution to the unconditional winning probability  $f(t^*)x(t^*)$  of type  $t^*$ , and we separated out the case that a single type has unconditional winning probability 1,  $q$  satisfies  $q \leq f(t^*)x(t^*) < 1$ . \*/*

- 1 **if**  $q = f(t^*)$ , **then** let  $f'(t^*) \leftarrow 0$  and  $x'(t^*) \leftarrow 0$
- 2 **else** let  $f'(t^*) \leftarrow \frac{f(t^*)-q}{1-q}$  and  $x'(t^*) \leftarrow \frac{f(t^*)x(t^*)-q}{f(t^*)-q}$ .
- 3 Let  $i^*$  be such that  $t^* \in T_{i^*}$ .
- 4 **for all**  $t \in T_{i^*}, t \neq t^*$ , let  $f'(t) \leftarrow \frac{f(t)}{1-q}$  and  $x'(t) \leftarrow x(t)$ .
- 5 **for all**  $t \in T \setminus T_{i^*}$ , let  $f'(t) \leftarrow f(t)$  and  $x'(t) \leftarrow \frac{x(t)}{1-q}$ .
- 6 **return**  $(f', \mathbf{x}')$ .

---

The subroutine DECREMENT, shown as Algorithm 3, essentially conditions both  $f$  and  $\mathbf{x}$  on the face  $M'$  not winning. Specifically, DECREMENT computes the conditional type distribution  $f'$ , and an interim rule  $\mathbf{x}'$ , such that if there were a dice implementation of  $\mathbf{x}'$  for  $f'$ , then adding  $M'$  to the die of  $t^*$  would yield a set of dice implementing  $\mathbf{x}$  for  $f$ .

We now provide a formal analysis of our algorithm. Theorem 11 follows from Lemmas 13–15.

► **Lemma 13.** *If CONSTRUCT DICE terminates, it outputs dice implementing  $\mathbf{x}$  for  $f$ .*

► **Lemma 14.** *CONSTRUCT DICE terminates after at most  $m^2$  recursive calls. (Recall that  $m = \sum_i |T_i|$ .)*

► **Lemma 15.** *Excluding the recursive call, each invocation of CONSTRUCT DICE can be implemented in time polynomial in  $n$  and  $m$ .*

## 4.2 Proof of Lemma 13 (Correctness)

We prove the lemma by induction over the algorithm's calls. Correctness is obvious for the two base cases: when  $T^+ = \emptyset$  (no type should win), and when there exists a type  $t^*$  with  $f(t^*)x(t^*) = 1$  ( $t^*$  always shows up and should always win). For the inductive step, suppose that the recursive call in step 12 returns dice  $\mathcal{D}' = (D'_t)_{t \in T}$ , correctly implementing  $\mathbf{x}'$  for  $f'$ , and let  $\mathcal{D} = (D_t)_{t \in T}$  be the new dice defined in steps 14 and 15.

We analyze the interim winning probability of each type when using the dice-based winner selection rule given by  $\mathcal{D}$ . For each type  $t$ , let  $\bar{v}_t \sim D_t$  be a roll of the die for type  $t$ , and for each  $i$ , let  $t_i \sim f_i$  be a draw of a type; all  $\bar{v}_t$  and  $t_i$  are mutually independent. In other words, we may assume that the die of *every* type is rolled (including types that do not show up), then the type profile is drawn independently. The winning type is then the type  $t_i$  with largest positive  $\bar{v}_{t_i}$ ; if all  $\bar{v}_{t_i}$  are negative, then no type wins.

Let  $t^* \in T_{i^*}$  be as defined in step 10. Let  $\mathcal{E}$  be the event that  $i^*$  has type  $t^*$  and that  $\bar{v}_{t^*} = M'$ , and let  $\bar{\mathcal{E}}$  be its complement. By independence of the random choices, the probability of  $\mathcal{E}$  is  $f(t^*) \cdot \frac{q^*}{f(t^*)} = q^*$ . Type  $t^*$  always wins under the event  $\mathcal{E}$ . Conditioned on  $\bar{\mathcal{E}}$ , each  $\bar{v}_t$  (including  $\bar{v}_{t^*}$ ) is distributed as a draw from  $D'_t$ , the type vector  $\mathbf{t}$  is distributed as a draw from  $f'_1 \times \dots \times f'_n$ , and the  $\bar{v}_t$ 's and  $\mathbf{t}$  are mutually independent. By the inductive hypothesis, conditioned on  $\bar{\mathcal{E}}$ , each type  $t$  wins with probability  $f'(t)x'(t)$ . Using the definition of  $f'$  and  $\mathbf{x}'$  from the DECREMENT subroutine, the total winning probability for  $t^*$  is  $q^* \cdot 1 + (1 - q^*) \cdot f'(t^*)x'(t^*) = q^* + (1 - q^*) \cdot \frac{f(t^*)x(t^*) - q^*}{1 - q^*} = f(t^*)x(t^*)$ . For  $t \neq t^*$ , the total winning probability is  $q^* \cdot 0 + (1 - q^*)f'(t)x'(t) = (1 - q^*) \cdot \frac{f(t)x(t)}{1 - q^*} = f(t)x(t)$ . Therefore, the interim winning probability for each type  $t$  is  $x(t)$ , and the dice  $\mathcal{D}$  implement  $\mathbf{x}$  for  $f$ .

## 4.3 Proof of Lemma 14 (Number of Recursive Calls)

The following lemma is essential in that it shows that invoking DECREMENT maintains feasibility and tightness of sets.

► **Lemma 16.** *Let  $f, \mathbf{x}, t^*$  and  $q$  be valid inputs for DECREMENT, and  $f', \mathbf{x}'$  the output of the call to DECREMENT( $f, \mathbf{x}, t^*, q$ ). Let  $S$  be any set of types with  $t^* \in S$ . Then,*

1. *The Border constraint for  $S$  is satisfied for  $(f', \mathbf{x}')$  if and only if it is satisfied for  $(f, \mathbf{x})$ .*
2. *The Border constraint for  $S$  is tight for  $(f', \mathbf{x}')$  if and only if it is tight for  $(f, \mathbf{x})$ .*

**Proof.** We will show that the slack for every  $S \ni t^*$  satisfies  $\sigma_{f', \mathbf{x}'}(S) = \frac{\sigma_{f, \mathbf{x}}(S)}{1 - q}$ , which implies both claims. Let  $i^*$  be such that  $t^* \in T_{i^*}$ . Using the definitions of  $f'$  and  $\mathbf{x}'$ ,

$$\begin{aligned} \sigma_{f', \mathbf{x}'}(S) &= f'(S) - \sum_{t \in S} f'(t)x'(t) \\ &= 1 - \left(1 - \frac{f(S_{i^*}) - q}{1 - q}\right) \cdot \prod_{i \neq i^*} (1 - f(S_i)) - \frac{(\sum_{t \in S} f(t)x(t)) - q}{1 - q} \\ &= \frac{1}{1 - q} \cdot \left(1 - (1 - f(S_{i^*})) \cdot \prod_{i \neq i^*} (1 - f(S_i)) - \sum_{t \in S} f(t)x(t)\right) = \frac{\sigma_{f, \mathbf{x}}(S)}{1 - q}. \quad \blacktriangleleft \end{aligned}$$

We are now ready to prove Lemma 14. We will show that with each recursive invocation of CONSTRUCT DICE (step 12), at least one of the following happens: (1) The number of active types  $|T^+|$  decreases; (2) The size of the barrier set  $|T^*|$  decreases.

Notice that the number of active types or the size of a barrier set never *increase*. Because the size of the barrier set can only decrease at most  $m$  times, the number of active types must decrease at least every  $m$  recursive invocations. It, too, can decrease at most  $m$  times, implying the claim of the lemma.

Let  $T^*$ ,  $t^*$ , and  $(q^*, f', \mathbf{x}')$  be as chosen in steps 9, 10, and 11, respectively. Let candidate  $i^*$  be such that  $t^* \in T_{i^*}$ . If  $q^* = f(t^*)x(t^*)$ , then the type  $t^*$  will be inactive in  $(f', \mathbf{x}')$ , and there will be one fewer active type in the subsequent invocation of **CONSTRUCT DICE** (step 12). We distinguish the cases  $|T^*| = 1$  and  $|T^*| > 1$ .

If  $|T^*| = 1$ , then  $T^* = \{t^*\}$ . By definition of a barrier set,  $T^*$  is tight, implying (for a singleton set) that  $x(t^*) = 1$ . We claim that  $q^*$  is set to  $f(t^*) = f(t^*)x(t^*)$  in step 11, implying that the number of active types decreases. To prove that  $q^* = f(t^*)$ , we will show that this choice of  $q^*$  is feasible in the invocation of **DECREMENT** $(f, \mathbf{x}, t^*, f(t^*))$ . Consider the  $\hat{f}, \hat{\mathbf{x}}$  resulting from such an invocation of **DECREMENT**. Lemma 16 implies that the feasibility of each Border constraint corresponding to a set  $S \ni t^*$  is preserved for  $(\hat{f}, \hat{\mathbf{x}})$ . For type sets  $S$  excluding  $t^*$ ,

$$\begin{aligned} \sigma_{\hat{f}, \hat{\mathbf{x}}}(S) &= \hat{f}(S) - \sum_{t \in S} \hat{f}(t) \hat{\mathbf{x}}(t) = 1 - \left(1 - \frac{f(S_{i^*})}{1 - f(t^*)}\right) \cdot \prod_{i \neq i^*} (1 - f(S_i)) - \frac{\sum_{t \in S} f(t)x(t)}{1 - f(t^*)} \\ &= \frac{1}{1 - f(t^*)} \cdot \left(1 - (1 - f(S_{i^*}) + f(t^*)) \cdot \prod_{i \neq i^*} (1 - f(S_i))\right. \\ &\quad \left. - \left(\sum_{t \in S} f(t)x(t) + f(t^*)x(t^*)\right)\right) \\ &= \frac{\sigma_{f, \mathbf{x}}(S \cup \{t^*\})}{1 - f(t^*)}, \end{aligned}$$

which is nonnegative because  $\mathbf{x}$  is feasible for  $f$ . Therefore, step 11 indeed chooses  $q^* = f(t^*)$ .

Next, we consider the case  $|T^*| > 1$ , and assume that  $q^* < f(t^*)x(t^*)$  (since otherwise, we are done). Then, the set of active types  $T^+$  is the same for both  $(f, \mathbf{x})$  and  $(f', \mathbf{x}')$ .

If the instance  $(f', \mathbf{x}')$  for the recursive call has multiple barrier sets, then by Lemma 12, they are all singletons, and indeed the size of the barrier set in the next recursive call (which is 1) is strictly smaller than  $|T^*|$ . So we assume that  $(f', \mathbf{x}')$  has a unique barrier set  $T'$ .

Because  $|T^*| > 1$ , Lemma 12 implies that  $T^*$  is the unique barrier set for  $(f, \mathbf{x})$ . Therefore, by the definition of barrier sets,  $T^*$  (and hence also  $t^*$ ) is contained in every tight set of active types for  $(f, \mathbf{x})$  (if any). Because  $t^*$  is contained in all tight sets, Lemma 16 implies that for every  $q \in [0, f(t^*)x(t^*)]$ , the result of **DECREMENT** $(f, \mathbf{x}, t^*, q)$  does not violate any constraints which are already tight for  $(f, \mathbf{x})$ , and in fact preserves their tightness.

Because all other constraints have slack, the optimal  $q^*$  is strictly positive. By assumption, we also have that  $q^* < f(t^*)x(t^*)$ ; therefore, a non-empty set  $S'$  which was not tight for  $(f, \mathbf{x})$  must have become tight for  $(f', \mathbf{x}') = \text{DECREMENT}(f, \mathbf{x}, t^*, q^*)$ . By Lemma 16, this set  $S'$  does not include  $t^*$ . Because discarding inactive types preserves tightness, we may assume without loss of generality that  $S' \subseteq T^+$ .

We have shown the existence of a non-empty tight set  $S' \subseteq T^+ \setminus \{t^*\}$  for  $(f', \mathbf{x}')$ . By definition, the barrier set  $T'$  is the (unique, in our case) minimal tight set for  $(f', \mathbf{x}')$ , so  $T' \subseteq S'$ . We distinguish two cases, based on the possible definitions of barrier sets:

- If  $T^* = T^+$ , then because  $S' \subsetneq T^+ = T^*$ , the barrier set  $T'$  is strictly smaller than  $T^*$ .
- If  $T^*$  is tight for  $(f, \mathbf{x})$ , then it is also tight for  $(f', \mathbf{x}')$  by Lemma 16; since both  $S'$  and  $T^*$  are tight for  $(f', \mathbf{x}')$ , we get that  $T' \subseteq T^* \cap S' \subseteq T^* \setminus \{t^*\}$  is strictly smaller than  $T^*$ .

#### 4.4 Proof of Lemma 15 (Runtime per Call)

There are only two steps for which polynomial runtime is not immediate: the computation of  $q^*$  in step (11) of **CONSTRUCT DICE**, and finding a non-empty minimizer of a submodular function in steps (3) and (7) of **FIND BARRIER SET**. We prove polynomial-time implementability of both steps in the following lemmas.

► **Lemma 17.** *In step 11 of **CONSTRUCT DICE**,  $q^*$  can be computed in  $\text{poly}(m)$  time.*

**Proof.** Let  $f$ ,  $\mathbf{x}$ , and  $t^*$  be as in step 11, and let the candidate  $i^*$  be such that  $t^* \in T_{i^*}$ . For each  $q \in [0, f(t^*)x(t^*)] \subseteq [0, 1)$ , let  $(f_q, \mathbf{x}_q) = \text{DECREMENT}(f, \mathbf{x}, t^*, q)$  be the result of running **DECREMENT** $(f, \mathbf{x}, t^*, q)$  with parameter  $q$ . Lemma 16 implies that all Border constraints for  $S \ni t^*$  remain feasible for  $(f_q, \mathbf{x}_q)$ . For type sets  $S \not\ni t^*$ , we can write the slack in the corresponding Border constraint as a function of  $q$  as follows:

$$\begin{aligned} \sigma_{f_q, \mathbf{x}_q}(S) &= f_q(S) - \sum_{t \in S} f_q(t)x_q(t) \\ &= 1 - \left(1 - \frac{f(S_{i^*})}{1-q}\right) \cdot \prod_{i \neq i^*} (1 - f(S_i)) - \frac{\sum_{t \in S} f(t)x(t)}{1-q} \\ &= \frac{1}{1-q} \cdot \left(1 - (1 - f(S_{i^*}) - q) \cdot \prod_{i \neq i^*} (1 - f(S_i)) - \sum_{t \in S} f(t)x(t) - q\right) \\ &= \frac{1}{1-q} (\sigma_{f, \mathbf{x}}(S) - qf(S \setminus S_{i^*})). \end{aligned}$$

The preceding expression is nonnegative if and only if  $q \leq h(S) := \frac{\sigma_{f, \mathbf{x}}(S)}{f(S \setminus S_{i^*})}$ . Therefore,  $q^*$  is the minimum of  $f(t^*)x(t^*)$  and  $\min_{S \subseteq T \setminus \{t^*\}} h(S)$ . The function  $h(S)$  does not appear to be submodular, and hence efficient minimization is not immediate. We utilize Theorem 4 to reduce the search space and compute  $q^*$  efficiently.

For an interim rule  $\mathbf{x} : T \rightarrow [0, 1]$ , we call  $S \subseteq T$  a *level set* of  $\mathbf{x}$  if there exists an  $\alpha \in [0, 1]$  such that  $S = \{t \in T : x(t) > \alpha\}$ . If  $q^* = \min_{S \not\ni t^*} h(S)$ , then at least one Border constraint just becomes tight at  $q = q^*$ . Theorem 4 implies that at least one level set of  $\mathbf{x}_{q^*}$  corresponds to one of these newly tightened constraints, and  $h$  is minimized by such a level set. It follows that, in order to compute  $q^*$ , it suffices to minimize  $h$  over all those sets  $S \not\ni t^*$  which could possibly arise as level sets of some  $\mathbf{x}_q$  for  $q \in [0, f(t^*)x(t^*)]$ .

Let  $t_1, \dots, t_K$  be the types in  $T_{i^*} \setminus \{t^*\}$ , ordered by non-increasing  $x(t)$ ; similarly, let  $t'_1, \dots, t'_L$  be the types in  $T \setminus T_{i^*}$ , ordered by non-increasing  $x(t)$ . The relative order of types in  $T_{i^*} \setminus \{t^*\}$  is the same under  $x_q(t)$  as under  $x(t)$ , because  $x_q(t) = x(t)$ ; similarly, the relative order of types in  $T \setminus T_{i^*}$  is the same under  $x_q(t)$  as under  $x(t)$ , because  $x_q(t) = \frac{x(t)}{1-q}$ . Therefore, the family  $\{\{t_1, \dots, t_k, t'_1, \dots, t'_\ell\} : k \leq K, \ell \leq L\}$  includes all level sets of every  $\mathbf{x}_q$  excluding  $t^*$ . There are at most  $m^2$  type sets in this family, and those sets can be enumerated efficiently to minimize  $h$ . ◀

► **Lemma 18.** *There is an algorithm for computing a non-empty minimizer of a submodular function in the value oracle model, with runtime polynomial in the size of the ground set.*

**Proof.** For a submodular function  $g : 2^T \rightarrow \mathbb{R}$ , let  $g_t(S) = g(S \cup \{t\})$ , for  $t \in T$ .  $g_t$  is also submodular, and can be minimized in time polynomial in  $|T|$  [10]. Let  $S_t$  be a minimizer of  $g_t$  and  $t^* \in \arg \min_{t \in T} g_t(S_t)$ .  $S_{t^*} \cup \{t^*\}$  is a non-empty minimizer of  $g$ . ◀

## 5 From Winner-Selecting Dice to Interim Rules for Single-Winner Settings

Having shown how to compute winner-selecting dice implementing a given interim rule, we next show the easier converse direction: how to compute the interim rule given winner-selecting dice  $\{D_{i,t}\}$  in single-winner environments. As before, we denote the type set of candidate  $i$  by  $T_i$ , and assume without loss of generality that the type sets of different candidates are disjoint. For simplicity of exposition, we assume that each die has a given finite support<sup>4</sup>, and we write  $U_i := \bigcup_{t \in T_i} \text{supp}(D_{i,t})$  for the combined support of candidate  $i$ 's dice. We also assume that we can evaluate the probability  $\Pr[D_{i,t} = u]$  of the face labeled with  $u$ , for all candidates  $i$ , types  $t$ , and faces  $u \in U_i$ .

► **Theorem 19.** *Consider a single-winner selection environment with  $n$  candidates and independent priors  $f_1, \dots, f_n$ , where  $f_i$  is supported on  $T_i$ . Given dice  $\{D_{i,t} \mid i \in [n], t \in T_i\}$  represented explicitly, the interim rule of the corresponding dice-based winner selection rule can be computed in time polynomial in  $n$ ,  $m = \sum_i |T_i|$ , and the total support size  $|\bigcup_i U_i|$  of all the dice.*

**Proof.** First, we can compute the probability mass function of each candidate  $i$ 's (random) score  $\bar{v}_i$ . Given  $u \in U_i$ , we have  $\Pr[\bar{v}_i = u] = \sum_{t \in T_i} f_i(t) \cdot \Pr[D_{i,t} = u]$ .

From this probability mass function, we easily compute  $\Pr[\bar{v}_i \leq u]$  for each  $u \in U_i$  by the appropriate summation. When all dice faces are distinct, this is all we need; since  $\Pr[\bar{v}_{i'} < u] = \Pr[\bar{v}_{i'} \leq u]$  for  $i' \neq i$  and  $u \in U_i$ , the interim rule is given by the following simple equation:

$$x_i(t) = \sum_{u \in \text{supp}(D_{i,t})} \Pr[D_{i,t} = u] \cdot \prod_{i' \neq i} \Pr[\bar{v}_{i'} \leq u].$$

When the dice's faces are not distinct, recall that we break ties uniformly at random. To account for the contribution of this tie-breaking rule, we need the distribution of the number of other candidates that tie candidate  $i$ 's score of  $u$ ; this is a Poisson Binomial distribution. More, precisely, we need the Poisson Binomial distribution with the  $n - 1$  parameters  $\left( \frac{\Pr[\bar{v}_{i'} = u]}{\Pr[\bar{v}_{i'} \leq u]} \right)_{i' \neq i}$ ; we denote its probability mass function by  $B_{i,u}$ . It is well known, and easy to verify, that a simple dynamic program computes the probability mass function of a Poisson Binomial distribution in time polynomial in its number of parameters. Therefore, we can compute  $B_{i,u}(k)$  for each  $i \in [n]$ ,  $u \in U_i$  and  $k \in \{1, \dots, n - 1\}$ . The interim rule is then given by the following equation:

$$x_i(t) = \sum_{u \in \text{supp}(D_{i,t})} \Pr[D_{i,t} = u] \cdot \left( \prod_{i' \neq i} \Pr[\bar{v}_{i'} \leq u] \right) \cdot \sum_{k=0}^{n-1} \frac{B_{i,u}(k)}{k+1}.$$

It is easy to verify that all the above computations satisfy the claimed runtime. ◀

<sup>4</sup> Our approach extends easily to the case of continuously supported dice, so long as we can perform integration with respect to the distributions of the various dice.

## 6 Winner-Selecting Dice and Persuasion

In this section, we investigate the existence of winner-selecting dice for instances of Bayesian persuasion. Our main result (Theorem 20) is to exhibit an instance with independent non-identical actions for which there is no optimal signaling scheme that can be implemented using winner-selecting dice. This result is contrasted with Theorem 21, which shows that when the actions' types are not just independent, but identically distributed as well, a dice-based implementation always *does* exist.

► **Theorem 20.** *There is an instance of Bayesian persuasion (given in Table 1) with independent actions which does not admit a dice-based implementation of any optimal signaling scheme. Consequently, there exists a second-order interim rule which does not admit a dice-based implementation.*

► **Theorem 21.** *Every Bayesian persuasion instance with i.i.d. actions admits an optimal dice-based signaling scheme. Moreover, when the prior type distribution is given explicitly, the corresponding dice can be computed in time polynomial in the number of actions and types.*

The negative result of Theorem 20 has interesting implications. Since second-order interim rules summarize all the attributes of a winner selection rule relevant to persuasion, second-order interim rules, unlike their first-order brethren, can in general not be implemented by dice. Most importantly, this result draws a sharp contrast between persuasion and single-item auctions, despite their superficial similarity: it rules out a Myerson-like virtual-value characterization of optimal persuasion schemes, and it joins the #P-hardness result of [8] as evidence of the intractability of optimal persuasion.

### 6.1 Basics of Bayesian Persuasion

In *Bayesian persuasion*, the  $n$  candidates are *actions* which a *receiver* can take. Each action  $i$  has a type  $t_i$ , drawn *independently*<sup>5</sup> from the set  $T_i$ , according to a commonly known distribution  $f_i$ . Each type  $t_i$  has associated payoffs  $s(i, t_i)$  and  $r(i, t_i)$  for the sender and receiver, respectively. The *sender* (or *principal*) also has access to the *actual* draws  $\mathbf{t} = (t_1, \dots, t_n)$  of the types, and would like to use this leverage to persuade the receiver to take an action favorable to him<sup>6</sup>.

Thereto, the sender can commit to a (typically randomized) policy  $\mathcal{A}$ — called a *signaling scheme*— of revealing some of this information to the receiver. It was shown by Kamenica and Gentzkow [12] that the sender can restrict attention, without loss, to *direct schemes*: randomized functions  $\mathcal{A}$  mapping type profiles to recommended actions. Naturally, the function must be *persuasive*: if action  $i$  is recommended, the receiver's posterior expected utility from action  $i$  must be no less than her posterior expected utility from any other action  $i'$ . In this sense, direct schemes can be viewed as winner selection rules in which the actions are the candidates, and persuasiveness constraints must be obeyed.

### 6.2 Proof of Theorems

**Proof of Theorem 20.** The persuasion instance, shown in Table 1, features three actions  $\{A, B, C\}$ , each of which has two types  $\{1, 2\}$ . The types of the different actions are distributed independently. In the instance, the sender's utility from any particular action is a constant, independent of the action's type.

<sup>5</sup> The draws are independent in this paper. In more general Bayesian persuasion models, they can be correlated.

<sup>6</sup> To avoid ambiguities, we always use male pronouns for the sender and female ones for the receiver.

■ **Table 1** A Persuasion instance with no dice-based implementation. The notation  $p \times (s, r)$  denotes that the type  $(s, r)$  (in which the sender and receiver payoffs are  $s$  and  $r$ , respectively) has probability  $p$ .

action \ type	1	2
A	$0.5 \times (100, 2)$	$0.5 \times (100, -\infty)$
B	$0.99 \times (1, 3)$	$0.01 \times (1, -\infty)$
C	$0.5 \times (0, 0)$	$0.5 \times (0, 6)$

One (optimal, as we will show implicitly) signaling scheme is the following. (In writing a type vector, here and below, we use  $*$  to denote that the type of an action is irrelevant.)

- If the type vector is  $(1, *, 1)$ , then recommend action  $A$ .
- If the type vector is  $(1, *, 2)$ , then recommend each of  $A, C$  with equal probability  $\frac{1}{2}$ .
- If the type vector is  $(2, 1, *)$ , then recommend action  $B$ .
- If the type vector is  $(2, 2, *)$ , then recommend action  $C$ .

While this is not the unique optimal scheme, we next prove that none of the optimal persuasion schemes admit a dice-based implementation.

The given signaling scheme recommends action  $A$  with probability  $3/8$  overall, action  $B$  with probability  $\frac{99}{200}$  overall, and action  $C$  with the remaining probability. No persuasive signaling scheme can recommend  $A$  with probability strictly more than  $3/8$ , because conditioned on receiving the recommendation  $A$ , action  $C$  must be at least twice as likely to be of type 1 as of type 2, in addition to action  $A$  being of type 1 with probability 1. Similarly, no persuasive scheme can recommend  $B$  with probability strictly more than  $\frac{99}{200}$ , because action  $C$  must be at least as likely to be of type 1 as of type 2 when  $C$  is recommended, in addition to action  $B$  being of type 1 with probability 1. Hence, any optimal signaling scheme must recommend  $A$  with probability  $3/8$  and  $B$  with probability  $\frac{99}{200}$ , and the given scheme is in fact optimal.

Suppose for a contradiction that there exist dice  $(D_{i,j})_{i \in \{A,B,C\}, j \in \{1,2\}}$  implementing an optimal signaling scheme. We gradually derive properties of these optimal signaling schemes, eventually leading to a contradiction.

1. Since action  $A$  can never be recommended when it has type 2 (the receiver would never follow the recommendation), it must be recommended with probability  $\frac{3}{4}$  conditioned on having type 1.
2. In particular, whenever the type profile is  $(1, *, 1)$ , action  $A$  must be recommended, regardless of the type of action  $B$ . This is because action  $C$  must be at least twice as likely of type 1 as of type 2 for a recommendation of  $A$  to be persuasive.
3. Therefore, all faces on  $D_{A,1}$  must be larger than all faces on  $D_{B,1}$  and on  $D_{C,1}$ .
4. Because of this, action  $B$  can never be recommended when the type profile is  $(1, *, 2)$ .
5. Thus, when the type profile is  $(1, *, 2)$ , the signaling scheme has to recommend each of  $A$  and  $C$  with probability  $\frac{1}{2}$ . (The recommendation could of course follow different distributions based on the type of  $B$ ; such a correlation is immaterial for our argument.)
6. Given that action  $B$  cannot be recommended when action  $A$  has type 1, or when action  $B$  has type 2, it must *always* be recommended for type vectors  $(2, 1, *)$ .
7. This implies that all faces of  $D_{B,1}$  must be larger than all faces on  $D_{C,1}$  and on  $D_{C,2}$ .
8. This is a contradiction to Step 5, which states that with positive probability,  $D_{C,2}$  beats  $D_{B,1}$ .

Thus, we have proved that there is no dice-based implementation of any optimal signaling scheme for the given instance. ◀

**Proof of Theorem 21.** When the actions' (or more generally: candidates') type distributions are i.i.d., i.e.,  $T_i$  and  $f_i$  are the same for all candidates  $i$ , Dughmi and Xu [8] have shown that there is an optimal *symmetric* signaling scheme, or more generally a symmetric second-order interim rule  $\mathbf{X}$ . We show that any symmetric second-order interim rule  $\mathbf{X}$  is uniquely determined by its first-order component, a fact implicit in [8].

For symmetric rules,  $x_{i,i',t}$  depends only on whether  $i = i'$  or  $i \neq i'$ , but not on the identities of the candidates  $i$  and  $i'$ . Therefore,  $\mathbf{X}$  can be equivalently described by two type-indexed vectors  $\mathbf{y}$  and  $\mathbf{z}$ , where  $y_t = x_{i,i,t}$  for all candidates  $i$ , and  $z_t = x_{i,i',t}$  for all candidates  $i$  and  $i'$  with  $i \neq i'$ . The vector  $\mathbf{y}$  is a first-order interim rule, and we refer to it as the *first-order component* of  $\mathbf{X}$ . If  $\mathbf{X}$  is feasible and implemented by  $\mathcal{A}$ , then  $y_t = x_{i,i,t} = \Pr[\mathcal{A}(t) = i \mid t_i = t]$  for all candidates  $i$ , so  $\mathbf{y}$  is the first-order interim rule implemented by  $\mathcal{A}$ . For every candidate  $i$  and type  $t$ , we have

$$1 = \sum_{i'=1}^n \Pr[\mathcal{A}(t) = i' \mid t_i = t] = (n-1)z_t + y_t.$$

Therefore,  $\mathbf{z} = \frac{1-\mathbf{y}}{n-1}$ , and the first-order component of a symmetric second-order interim rule suffices to fully describe it. The second-order rule is also, by the preceding argument, efficiently computable from its first-order component, and is feasible if and only if its first-order component is a feasible symmetric interim rule. Moreover, by [5], feasibility of symmetric second-order interim rules can be checked in time polynomial in the number of types and candidates, and given a feasible symmetric second-order interim rule  $\mathbf{X}$ , a winner selection rule implementing  $\mathbf{X}$  can be evaluated in polynomial time. ◀

## 7 Directions for Future Work

We have begun an investigation of dice-based winner selection rules, in which each of several candidates independently draws a “score” from a distribution (rolling a “die”), and a candidate set is selected to maximize the sum of scores, subject to a feasibility constraint. We have shown that dice-based winner selection rules can implement all first-order interim rules with matroid constraints, but not all second-order interim rules; in particular, there are instances of Bayesian persuasion in which no optimal signaling scheme can be implemented using dice.

A natural direction for future work is to understand the limits of dice-based winner selection rules. While our existence proof uses matroid properties, matroid constraints are not the limit of implementability by dice: in the full version, we show an example in which the feasible sets do not form a matroid, yet every feasible interim rule within the environment is implementable with dice. This rules out a characterization of the form “a feasibility constraint  $\mathcal{I}$  has all feasible  $(\mathbf{x}, f)$  implementable by dice if and only if  $\mathcal{I}$  is a matroid.” In fact, we do not know of any feasibility constraint and corresponding first-order feasible interim rule for which a dice-based implementation can be ruled out, though we strongly suspect that such examples exist. A difficulty in verifying our conjecture is that we are not aware of a useful general technique for proving the *non-existence* of a dice-based implementation for a given interim rule.

Another direction is to find an efficient algorithm for matroid environments. To derive an efficient algorithm from our existential proof, the functions  $g_t$  and  $h_t$  would have to be evaluated efficiently. Furthermore, even if a set of continuous dice is given, it is still unclear how to convert them to dice with finitely many faces in polynomial time.

## Abstract

---

We introduce a simple logical inference structure we call a *spanoid* (generalizing the notion of a matroid), which captures well-studied problems in several areas. These include combinatorial geometry (point-line incidences), algebra (arrangements of hypersurfaces and ideals), statistical physics (bootstrap percolation), network theory (gossip / infection processes) and coding theory. We initiate a thorough investigation of spanoids, from computational and structural viewpoints, focusing on parameters relevant to the applications areas above and, in particular, to questions regarding Locally Correctable Codes (LCCs).

One central parameter we study is the *rank* of a spanoid, extending the rank of a matroid and related to the dimension of codes. This leads to one main application of our work, establishing the first known barrier to improving the nearly 20-year old bound of Katz-Trevisan (KT) on the dimension of LCCs. On the one hand, we prove that the KT bound (and its more recent refinements) holds for the much more general setting of spanoid rank. On the other hand we show that there exist (random) spanoids whose rank matches these bounds. Thus, to significantly improve the known bounds one must step out of the spanoid framework.

Another parameter we explore is the *functional rank* of a spanoid, which captures the possibility of turning a given spanoid into an actual code. The question of the relationship between rank and functional rank is one of the main questions we raise as it may reveal new avenues for constructing new LCCs (perhaps even matching the KT bound). As a first step, we develop an entropy relaxation of functional rank to create a small constant gap and amplify it by tensoring to construct a spanoid whose functional rank is smaller than rank by a polynomial factor. This is evidence that the entropy method we develop can prove polynomially better bounds than KT-type methods on the dimension of LCCs.

To facilitate the above results we also develop some basic structural results on spanoids including an equivalent formulation of spanoids as set systems and properties of spanoid products. We feel that given these initial findings and their motivations, the abstract study of spanoids merits further investigation. We leave plenty of concrete open problems and directions.

## 1 Introduction

This (somewhat long) introduction will be organized as follows. We begin by discussing Locally Correctable Codes (LCCs) and the main challenges they present as this was the primary motivation for this work. We proceed to define spanoids as an abstraction of LCCs, and state some results about their rank which hopefully illuminate the difficulties with LCCs in a new light. We continue by describing other natural settings in which the spanoid structure arises in the hope of motivating the questions raised in the context of LCCs and demonstrating their potential to contribute to research in other areas. We then turn to the investigation of functional rank of spanoids, which aims to convert them to actual LCCs. We conclude with describing some of the structural results about spanoids obtained here.

### 1.1 Locally Correctable Codes

The introduction of *locality* to coding theory has created a large body of research with wide-ranging applications and connections, from probabilistically checkable proofs, private information retrieval, program testing, fault-tolerant storage systems, and many others in computer science and mathematics. We will not survey these, and the reader may consult the surveys [27, 10]. Despite much progress, many basic questions regarding local testing, decoding and correcting of codes remain open. Here we focus on the efficiency of locally *correctable* codes, that we now define. Note that the related, locally *decodable* codes (LDCs), will not be discussed in this paper, as our framework is not relevant to them (LCCs can be converted to LDCs with a small loss in parameters).

► **Definition 1** (*q*-LCCs). A code  $C \subseteq \Sigma^n$  is called a *q*-query locally correctable code with error-tolerance  $\delta > 0$ , if for every  $i \in [n]$  there is a family (called a *q*-*matching*)  $M_i$ , of at least  $\delta n$  disjoint *q*-subsets of  $[n]$ , with the following *decodability* property. For every codeword  $c \in C$ , and for every  $i \in [n]$ , the value of  $c_i$  is *determined*<sup>5</sup> by the values of  $c$  in coordinates  $S$ , for every *q*-subset  $S$  in  $M_i$ .<sup>6</sup>

<sup>5</sup> Through some function that does not depend on the codeword  $c$ .

<sup>6</sup> Our definition is a ‘zero-error’ version of the standard definition. By ‘zero-error’ we mean that for any codeword  $c$ , the value of  $c_i$  can be determined correctly (without error) from the coordinates of  $c$  at any *q*-subset  $S$  in the matching  $M_i$ . A more general definition would say that  $c_i$  can be computed from  $c|_S$  with high probability, or even just slightly better than a random guess. Our definition is equivalent to the more general definition for linear codes, which comprise all of the interesting examples. We still allow ‘global’ error in the sense that a large (constant) fraction of the coordinates can be corrupted (this global error tolerance is captured by the parameter  $\delta$ ).

Intuitively, given a vector  $c' \in \Sigma^n$  which results from corrupting less than (say)  $\epsilon \delta n$  coordinates of a codeword  $c \in C$ , recovering  $c_i$  for any given  $i \in [n]$  is simple. Picking a random  $q$ -subset from  $M_i$  and decoding  $c_i$  according to it will succeed with probability at least  $1 - \epsilon$ , as only an  $\epsilon$ -fraction of these  $q$ -subsets can be corrupted.

We focus in this paper on the most well-studied and well-motivated regime where both the “query-complexity”  $q$  and the error-tolerance  $\delta$  are constants. It is not hard to see that there are no LCCs with  $q = 1$  (unless the dimension is constant) and so we will start with the first interesting case of  $q = 2$ . A canonical example of a 2-query LCC, which will serve us several times below, is the Hadamard code. Here  $\Sigma = \mathbb{F}_2$ . Let  $k$  be any integer and set  $n = 2^k - 1$ . Let  $A$  be the  $k \times n$  matrix whose columns are all non-zero  $k$ -bit vectors. The Hadamard code  $C_H \in \mathbb{F}_2^n$  is generated by  $A$ , namely  $H$  consists of all linear combinations of rows of  $A$ . Since every column of  $A$  can be written as a sum of (namely, spanned by) pairs of other columns in  $(n - 1)/2$  different ways, the matching  $M_i$  suggest themselves, and so is the *linear* correcting procedure: add the values in coordinates of the random pair  $S$  from  $M_i$  to determine the  $i$ th coordinate.

A central parameter of codes is their *rate*, capturing the redundancy between the *dimension*, namely the number of information bits encoded (here  $k$ ), and the length of the codeword (here  $n$ ). As in this paper this  $k$  will be a tiny function of  $n$ , we will focus on the *dimension* itself. Note that in the example above, as in every *linear* code, this dimension is also the *rank* of the generating matrix. In general codes, dimension may be fractional, and is defined as follows. All logarithms are in base 2 unless otherwise noted.

► **Definition 2** (Dimension and rate of a code). For a general, possibly non-linear code  $C \subseteq \Sigma^n$ , we define the dimension of  $C$  to be  $\dim(C) = \log |C| / \log |\Sigma|$ . Note that this coincides with the linear algebraic definition of dimension when  $C$  is a subspace. We refer to the ratio  $\dim(C)/n$  as the ‘rate’ of the code.

Note that while the Hadamard code ( $C_H$ ) has fantastic local correction (only 2 queries), its dimension is only  $k \sim \log n$ , which is pathetic from a coding theory perspective. However, no better 2-query LCC can exist, regardless of the alphabet.

► **Theorem 3** (2-LCCs). For all large enough  $n$  and over any alphabet:

- There exists a 2-query LCC of dimension  $\Omega(\log n)$  and constant  $\delta$  (Folklore: Hadamard code).
- Every 2-query LCC must have dimension at most  $O(\log n)$  (for any constant  $\delta$ ) [6].

While we know precisely the optimal dimension for 2 queries, for  $q \geq 3$  the gap between known upper and lower bounds is huge. The best lower bounds (constructions) are polylogarithmic: they come from Reed-Muller codes (using polynomials over finite fields), and yield dimension  $\Omega((\log n)^{q-1})$ .

The best LCC upper bounds are only slightly sub-linear, giving  $\dim(C) \leq \tilde{O}(n^{1-\frac{1}{q-1}})$  (up to logarithmic factors). This bound, which we will refer to as the Katz-Trevisan (KT) bound, is actually a slight refinement/improvement over the bound originally appearing in [19] (which gave  $n^{1-1/q}$ ). This improvement was implicit in several works (e.g. [9, 25]) and is explicitly stated in [18]. We should also note that, over constant-size alphabets, Kerenidis and De-Wolf proved an even stronger bound using quantum information theory [21]. This exponential gap between the upper and lower bounds, which we formally state below, has not been narrowed in over two decades.<sup>7</sup> Explaining this gap (in the hope of finding ways to close it) is one major motivation of this work.

<sup>7</sup> For LDCs better constructions than Reed-Muller codes are known, through the seminal works of [26, 12], but as mentioned we will not discuss them here. Still, the upper bounds for LDCs are the same as for

- **Theorem 4** ( $q$ -LCCs,  $q \geq 3$ ). For every fixed  $q \geq 3$  and all large enough  $n$ :
  - There exists a  $q$ -query LCC of dimension  $\Omega((\log n)^{q-1})$  (with constant  $\delta$  and alphabet of size  $q + 1$ ) (Reed-Muller codes, see e.g. the survey [27]).
  - Every  $q$ -query LCC must have dimension at most  $\tilde{O}(n^{1-\frac{1}{q-1}})$  (for any constant  $\delta$  and any alphabet) [18].

## 1.2 Spanoids

We shall now abstract the notion of inference used in LCCs. There, for a collection of pairs  $(S, i)$  with  $S \subseteq [n]$  and  $i \in [n]$ , the values of codewords in coordinate positions  $S$ , determine the value of some other coordinate  $i$ . We shall forget (for now) the underlying code altogether, and abstract this relation by the formal “inference” symbol  $S \rightarrow i$ , to be read “ $S$  spans  $i$ ”.

► **Definition 5** (Spanoid). A *spanoid*  $\mathcal{S}$  over  $[n]$  is a family of pairs  $(S, i)$  with  $S \subseteq [n]$  and  $i \in [n]$ . The pair  $(S, i)$  will sometimes be written as  $S \rightarrow i$  and read as  $S$  spans  $i$  in the spanoid  $\mathcal{S}$ .

One natural way to view a spanoid is as a logical inference system, with the pairs indicating all inference rules. The elements of  $[n]$  indicate some  $n$  formal statements, and an inference  $S \rightarrow i$  of the spanoid means that if we know the truth of the statements in  $S$ , we can infer the truth of the  $i$ th statement. With this intuition, we shall adopt the convention that the inferences  $i \rightarrow i$  are implicit in any spanoid, and that *monotonicity* holds: if  $S \rightarrow i$  then also  $S' \rightarrow i$  for every  $S' \supseteq S$ . These conventions will be formally stated below when we define general derivations, which sequentially combine these implicit rules and the stated rules (pairs) of the spanoid.

A key concept of spanoids is, naturally, the *span*. Given a subset  $T \subseteq [n]$  (which we can think of as “axioms”), we can explore everything they can span by a sequence of applications of the inference rules of the spanoid  $\mathcal{S}$ .

► **Definition 6** (Derivation, Span). A *derivation* in  $\mathcal{S}$  of  $i \in [n]$  from  $T \subseteq [n]$ , written  $T \models_{\mathcal{S}} i$ , is a sequence of sets  $T = T_0, T_1, \dots, T_r$  with  $i \in T_r$  such that for each  $j \in [r]$ ,  $T_j = T_{j-1} \cup i_j$  for some  $i_j \in [n]$  and there exists  $S \subset T_{j-1}$  such that  $(S, i_j) \in \mathcal{S}$  is one of the spanoid rules.

The *span* (or *closure*) of  $T$ , denoted  $\text{span}_{\mathcal{S}}(T)$ , is the set of all  $i$  for which  $T \models_{\mathcal{S}} i$ . We shall remove the subscript  $\mathcal{S}$  from these notations when no confusion about the underlying spanoid can arise, and write  $T \models i$  and  $\text{span}(T)$  for short.

Despite being highly abstract, we will see that spanoids can lead to a rich family of questions and definitions. The first, and perhaps one of the most central definitions is that of the *rank* of a spanoid. We shall see other notions of spanoid rank later on (and will discuss the relation between them).

► **Definition 7** (Rank). The *rank* of a spanoid  $\mathcal{S}$ , denoted  $\text{rank}(\mathcal{S})$ , is the size of the *smallest* subset  $T \subseteq [n]$  such that  $\text{span}(T) = [n]$ . Note that by the definition of span we always have  $\text{rank}(\mathcal{S}) \leq n$ .

We note that the “rank” of a logical inference system does appear (under different names) in *proof complexity*. It is the starting point for *expansion-based* lower bounds on a variety of proof systems, as introduced for Resolution proofs in [5], and used for many others e.g. in [1] and [2]). We shall return to this connection presently.

---

LCCs, and obtained by the same KT-type argument, so the results in this paper may serve to better understand the (smaller, but still quite large) gap between upper and lower bounds in LDCs as well.

We can now define the spanoid analog of  $q$ -LCCs as spanoids which only specify the correction structure (the matchings  $M_i$ ) without requiring any codewords or alphabet.

► **Definition 8** ( $q$ -LCS, Locally correctable spanoid). A spanoid  $\mathcal{S}$  over  $[n]$  is a  $q$ -LCS with error-tolerance  $\delta$  if for every  $i \in [n]$  there exists a family  $M_i$  of at least  $\delta n$  disjoint  $q$ -subsets of  $[n]$  such that for each  $S \in M_i$  we have  $(S, i) \in \mathcal{S}$ . Namely, each  $i \in [n]$  is spanned (in  $\mathcal{S}$ ) by at least  $\delta n$  disjoint subsets of  $q$ -elements.

One can now ask about the highest possible rank of a  $q$ -LCS. It is not hard to see that the existence of a  $q$ -LCC (over any alphabet)  $C \subset \Sigma^n$  with dimension  $\dim(C) = d$  automatically implies that there exists a  $q$ -LCS (namely, the one given by the same matchings used in  $C$ ) with rank at least  $\lceil d \rceil$ . Indeed, otherwise there would be  $r < d$  coordinates in  $[n]$  that determine any codeword  $c \in C$  and this would limit the number of codewords to  $\Sigma^r$ .

One of our main observations is that, remarkably, in locally correctable spanoids there is *no* gap between the upper and lower bounds: we know the precise answer up to logarithmic factors, and it matches the *upper bounds* for LCCs! Observe the analogies to the theorems in the previous subsection, for  $q = 2$  and  $q \geq 3$ .

► **Theorem 9** (2-LCSs). *For all large enough  $n$ :*

- *There exists a 2-LCS over  $[n]$  with error-tolerance  $\delta$  of rank  $\Omega(\frac{1}{8} \log(\delta n))$ .*
- *Every 2-LCS over  $[n]$  with error-tolerance  $\delta$  must have rank at most  $O(\frac{1}{8} \log(n))$ .*<sup>8</sup>

Here, of course, the inference structure of the Hadamard code proves the first item. To get the required dependence on  $\delta$ , one can take  $\frac{1}{8}$  disjoint copies of such spanoids. The second item requires a new proof we discuss below, which generalizes (and implies) the one in Theorem 3. It is quite surprising that, even in this abstract setting, with no need for codewords or alphabet, one cannot do better than the Hadamard code!

We now state our results for  $q \geq 3$ .

► **Theorem 10** ( $q$ -LCSs with  $q \geq 3$ ). *For every fixed  $q \geq 3$  and all large enough  $n$ :*

- *There exist a  $q$ -LCS of rank  $\tilde{\Omega}(n^{1-\frac{1}{q-1}})$  (with constant  $\delta$ ).*
- *Every  $q$ -LCS over  $[n]$  has rank at most  $\tilde{O}(n^{1-\frac{1}{q-1}})$  (for any constant  $\delta$ ).*

Both parts of this theorem demand discussion. The possibly surprising (and tight) lower bound follows from a simple probabilistic argument (indeed, one which is repeatedly used to prove expansion in the proof complexity references cited above), where the matchings  $M_i$  are simply chosen uniformly at random. It seems to reveal how significant a relaxation spanoids are of LCCs (where probabilistic arguments fail completely). However, the best known LCC upper bound (Theorem 4) does not rule out the possibility that, at least for large alphabets, the two (LCC's dimension and LCS's rank) have the same behavior! From a more pessimistic (and perhaps more realistic) perspective, our lower bound shows the limitations of any (upper bound) proof technique which, in effect, applies also for spanoids. These are proofs in which the LCC structure is used to show that a small subset spans all the others. We note that there are several LCC upper bounds which 'beat' the  $n^{1-\frac{1}{q-1}}$  bound for certain very special cases by using additional structure not present in the corresponding abstract spanoid. One example is the bound of [21], which uses arguments from quantum information theory to roughly *halve* the number of queries, over binary (or small) alphabets. Another example is

<sup>8</sup> The results of [6] can be interpreted as an upper bound of  $O(\text{poly}(1/\delta) \log(n))$  on the rank of 2-LCS with error-tolerance  $\delta$ .

■ **Figure 1** The pentagon spanoid  $\Pi_5$  where each coordinate is spanned by the coordinates of the opposite edge.

the paper [11], which gives an improved upper bound on the dimension for linear 3-LCCs defined over the real numbers, using specific properties of the Reals such as distance and volume arguments.

Our proof of the upper bound, is again more general than for LCCs, and interesting in its own right. We use a simple technique which performs random restrictions and contractions of graphs and hypergraphs (and originates in [11]). It will be described in Section 3, after we have formulated an equivalent, set-theoretic formulation of spanoids in Section 2.2.

### 1.2.1 Functional rank: bridging the gap between LCCs and LCSs

We conclude this section of the introduction with an attempt to understand (and possibly bridge) the gap between LCCs and their spanoid abstraction. The idea is to start with an LCS of high rank (which we know is possible), and convert it to an LCC without losing too much in the parameters. More generally, for a given spanoid  $\mathcal{S}$ , we would like to investigate the code  $C$  with largest dimension (over any alphabet  $\Sigma$ ) which would be consistent with the inferences of  $\mathcal{S}$ . This is captured in the notion of *functional rank* which we now define.

► **Definition 11** (Functional rank). Let  $\mathcal{S}$  be a spanoid over  $[n]$ . A code  $C \subset \Sigma^n$  is *consistent* with  $\mathcal{S}$  if for every inference  $(S, i)$  in  $\mathcal{S}$ , and for every codeword  $c \in C$ , its values of coordinates  $S$  determine its value in coordinate  $i$  (by some fixed function,  $f_{S,i}$  not depending on  $c$ ).<sup>9</sup>

Define the *functional rank* of  $\mathcal{S}$ , denoted  $\text{f-rank}(\mathcal{S})$ , to be equal to the supremum of the dimension  $\dim(C)$ , over all possible finite alphabets  $\Sigma$  and codes  $C \subset \Sigma^n$  which are consistent with  $\mathcal{S}$ .

Of course, the strategy of constructing LCCs in two stages as above can only work if we can bound the gap between  $\text{rank}(\mathcal{S})$  and  $\text{f-rank}(\mathcal{S})$ . This question, of bounding this gap or proving it can be large, is perhaps the most interesting one we raise (and leave mostly open for now). For now, we are able to show an example in which the two are different. The example providing a gap is depicted in Figure 1, arranging the coordinates as the vertices of a pentagon, the pair of vertices of each edge span the vertex opposite to it. That is,  $\{x_1, x_2\} \rightarrow x_4, \{x_2, x_3\} \rightarrow x_5$  etc.

► **Theorem 12** (Constant gap between rank and functional rank). *The pentagon spanoid  $\Pi_5$  depicted in Figure 1 has  $\text{rank}(\Pi_5) = 3$  but  $\text{f-rank}(\Pi_5) = 2.5$ .*

<sup>9</sup> One can think of a code consistent with  $\mathcal{S}$  also as a ‘representation’ of  $\mathcal{S}$  in the spirit of matroid theory.

Seeing that  $\text{rank}(\Pi_5) = 3$  is easy by inspection. The lower bound of 2.5 on functional rank comes from a set-theoretic construction of consistent codes. This comes from a simple linear programming (LP) relaxation we develop for  $\text{rank}(\mathcal{S})$  called  $\text{LP}^{\text{cover}}(\mathcal{S})$ , but surprisingly this LP captures the best set-theoretic construction of consistent codes. But even in this small example, the upper bound on functional rank is nontrivial to determine, as we allow all possible alphabets and consistent codes. Not surprisingly, Shannon entropy is the key to proving such a bound. We develop a linear programming relaxation, based on entropy whose optimum  $\text{LP}^{\text{entropy}}(\mathcal{S})$  upper bounds  $\text{f-rank}(\mathcal{S})$ . In this example, it proves 2.5 to be the optimum. For the definitions of  $\text{LP}^{\text{entropy}}(\mathcal{S})$ ,  $\text{LP}^{\text{cover}}(\mathcal{S})$  and the proof of Theorem 12 see the full version. One natural way of amplifying gaps as in the example above, which may also be useful in creating codes of high functional rank, is the idea of *tensoring*. We develop different notions of tensoring *spanoids* inspired by tensoring of codes. In particular, we define a product of spanoids called the *semi-direct product* under which  $\text{rank}$  is multiplicative and  $\text{f-rank}$  is sub-multiplicative. By repeatedly applying this product to  $\Pi_5$ , we get a spanoid with polynomial gap between  $\text{f-rank}$  and  $\text{rank}$ . See the full version for details.

► **Theorem 13** (Polynomial gap between rank and function rank). *There exists a spanoid  $\mathcal{S}$  on  $n$  elements with  $\text{rank}(\mathcal{S}) \geq n^c \text{f-rank}(\mathcal{S})$  where  $c = \log_5 3 - \log_5 2.5 \geq 0.113$ .*

Summarizing, we have the following obvious inequalities between the measures we described so far for every spanoid  $\mathcal{S}$ . We feel that understanding the exact relationships better is worthy of further study

$$\text{LP}^{\text{cover}}(\mathcal{S}) \leq \text{f-rank}(\mathcal{S}) \leq \text{LP}^{\text{entropy}}(\mathcal{S}) \leq \text{rank}(\mathcal{S}). \quad (1)$$

### 1.3 Other motivations and incarnations of spanoids

We return to discuss other structures, combinatorial, geometric and algebraic, in which the same notions of span and inference naturally occur, leading to a set-theoretic one that elegantly captures spanoids precisely. These raise further issues, some of which we study in this paper and some are left for future work. These serves to illustrate the breadth of the spanoid framework.

#### 1.3.1 Bootstrap percolation and gossip processes

The following general set-up occurs in statistical physics, network theory and probability theory. Fix an undirected graph  $G([n], E)$ . In a gossip or infection process, or equivalently bootstrap percolation, we are given a set of “rules” specifying, for every vertex  $v \in [n]$ , a family of subsets of its neighbors. The intended meaning of such a rule is that if *every* member of one such subset is “infected” at a certain time step, then the vertex  $v$  becomes infected in the next time step. Given a set of initial infected vertices, this defines a process in which infection spreads, and eventually stabilizes. A well studied special case is the (uniform) *r-bond percolation* [7], where the family for each vertex is all  $r$ -subsets of its neighbors. Many variants exist, e.g. one can have a similar process on the edges, rather than vertices of the graph. An important parameter of such a process is the following: what is the size of the smallest set of vertices which, if infected, will eventually infect all other vertices<sup>10</sup>.

<sup>10</sup>This turns out to be crucial for understanding, at least for certain structured graphs like lattices studied by physicists, the threshold probability for percolation when initial infections are random.

A moment’s thought will convince the reader that this structure is precisely a spanoid (where inferring sets are restricted by the graph structure). The infection process is precisely the inference process defining span in spanoids. Furthermore, the smallest size of an infecting set is *precisely* the rank of that spanoid! Much work has been invested to determine that rank even in very special cases, e.g. for the  $r$ -bond percolation above, in e.g. Boolean hypercubes, where it is known precisely. Interestingly, the paper [16] uses the so-called “polynomial method” to reprove that bound, which fits even deeper with our framework. In our language, their method determines the *functional rank* of this spanoid, and one direction is through constructing an explicit code that is consistent with the spanoid! The reader is encouraged to work out the details.

### 1.3.2 Independence systems and Matroids

An *independence system* over  $[n]$  is a family  $\mathcal{F}$  of subsets of  $[n]$  which is downwards-closed (if a set is in  $\mathcal{F}$ , so are all its subsets). The members of  $\mathcal{F}$  are called *independent*. While much of what we say below generalizes to all independence systems, we specify them for the important special systems called *matroids*.

A *matroid* is an independence system in which the independent sets satisfy the so-called “exchange axiom” (which we will not define here). Matroids abstract *linear* independence in subsets of a vector space over a field<sup>11</sup>, and capture algorithmic problems in which optimization is possible through the greedy algorithm. Matroids thus come with natural notions of span and rank, extending the ones in the linear algebraic setting. The rank of a set is the size of the largest independent set it contains. The span of a set is the maximal superset of it of the same rank. A matroid can thus be naturally viewed as a spanoid, with the inference rules  $F \rightarrow i$  for every independent  $F \in \mathcal{F}$  and every  $i$  for which  $F \cup \{i\}$  is *not* independent (such minimal dependent sets as  $F \cup \{i\}$  are called *cycles*). It is easy to verify that the notions of span and rank of the matroid and the spanoid it defines coincide. This also raises the natural question of bounding the gap between **f-rank** and **rank** for the special case of spanoids arising from matroids.

Note that a spanoid resulting from a matroid this way is *symmetric*: by the exchange property of matroids, if  $E \subset [n]$  is a cycle of  $\mathcal{F}$ , then for *every*  $i \in E$  it contains the inference  $E \setminus \{i\} \rightarrow i$ . Symmetric spanoids are interesting, and we note that the pentagon example witnessing the gap between rank and functional rank is *not* symmetric, and we do not know such a gap for symmetric spanoids. We also don’t know if symmetric spanoids can achieve the lower bound in Theorem 10.

### 1.3.3 Point-line incidences

Sylvester-Gallai theorem is a celebrated result in combinatorial geometry conjectured by Sylvester and proved independently by Melchior and Gallai. It states that for any set of  $n$  points in Euclidean space  $\mathbb{R}^d$ , if the line through any two points passes through a third point, then they must all be collinear (namely, they span a 1-dimensional affine space). Over the complex numbers, one can prove a similar theorem but with the conclusion that the points span a 2-dimensional affine space (and there are in fact two dimensional examples known) [20]. Over finite fields the conclusion is even weaker, saying that the span has dimension at most  $O(\log(n))$  and this is tight as the example of all points in  $\mathbb{F}_p^k$  with  $n = p^k$  shows. It

<sup>11</sup> Matroids are in fact more general than linear independent sets of vectors over a field, for example the Vámos matroid on eight elements is not representable over any field.

is not a coincidence that this example reminds one of the Hadamard code described before as an example of a 2-query LCC. It is in fact true that there is a tight connection between configurations of points with many collinear triples and linear 2-query LCCs. This was first noticed in [4, 3] and was used to prove that 2-LCCs do not exist over the characteristic zero fields (for  $q \geq 3$  these questions are wide open with even larger gaps than in the finite field case). LCCs with more than 2 queries naturally correspond to point configurations with many  $(q - 2)$ -dimensional affine spaces containing at least  $q$  points.

Given the connections between Sylvester-Gallai type incidence structures and LCCs, and the insights offered by spanoids for studying LCCs, it is natural that the study of the spanoid structures can help us get new insights on incidence geometry problems. A *dual* way to view these incidences, which we shall presently generalize, is to consider each point  $p_i : i \in [n]$  as representing a hyperplane  $F_i$  through the origin (in the appropriate vector space) vanishing on the linear function defined by  $p_i$ . A point  $p_i$  is spanned by a collection of points  $\{p_j : j \in S\}$  iff  $F_i \supset \bigcap_{j \in S} F_j$ . Therefore the spanning structure of the points  $p_1, p_2, \dots, p_n$  is captured by the spanoid where we would add the inference  $S \rightarrow i$  iff  $F_i$  contains the common intersection of all  $F_j : j \in S$ .

### 1.3.4 Systems of polynomial equations

Given the above example, there is no reason to stop at the linear setting. Instead of lines we can consider  $n$  (multivariate) polynomials  $f_i$  over a field, and again consider  $F_i$  to be the zero set of  $f_i$ . The spanoid above, having an inference  $S \rightarrow i$  whenever the set  $F_i$  contains the common intersection of all  $F_j : j \in S$ , is capturing another natural algebraic notion. Namely, it says that the polynomial  $f_i$  vanishes on all the common roots of the polynomials  $\{f_j : j \in S\}$ . By the celebrated Hilbert's Nullstellensatz theorem, over algebraically closed fields, this implies that  $f_i$  belongs to the radical of the ideal generated by the  $f_j$ 's. Here the rank function is far from being that of a matroid; the complex spanoid which arises (and in general is far from understood) plays a role in arithmetic complexity (a beautiful example is the recent [23] dealing with degree-2 polynomials).

### 1.3.5 Intersecting set systems

Let us remove all restrictions from the origin or nature of the  $n$  sets  $F_i$  discussed in the previous discussion. Assume we are given any such family  $\mathcal{F}$  of sets (from an arbitrary universe, say  $U$ ). As above, a natural spanoid  $\mathcal{S}_{\mathcal{F}}$  will have the inference  $S \rightarrow i$  whenever the set  $F_i$  contains the common intersection of all  $F_j : j \in S$ . Such situations (and hence, spanoids) arise in many questions of extremal set theory, for example the study of (weak) sunflowers, or families with certain forbidden intersection (or union) patterns, e.g. [14, 13, 15].

What is interesting in this more general framework, where the initial family of sets  $\mathcal{F}$  is arbitrary, is that it becomes *equivalent* to spanoids! In other words, every spanoid  $\mathcal{S}$  arises as  $\mathcal{S}_{\mathcal{F}}$  of *some* family of sets  $\mathcal{F}$ . This possibly surprising fact is not much more than an observation, but it turns out to be an extremely useful formulation for proving some of the results in this paper. Let us state it formally (it will be proved in Section 2.2).

► **Theorem 14** (Spanoids and intersecting sets). *Let  $\mathcal{S}$  be any spanoid on  $[n]$ . Then, there exists a universe  $U$  and a family  $\mathcal{F}$  of  $n$  sets of  $U$ ,  $\mathcal{F} = \{F_1, F_2, \dots, F_n\}$ , such that  $\mathcal{S} = \mathcal{S}_{\mathcal{F}}$ .*

It is convenient to assume that the sets in  $\mathcal{F}$  have no element in common to all<sup>12</sup>.

The notions of rank and span are extremely simple in this set-theoretic setting, and do not require the sequential “derivation” and the implicit ordering which we require to define these in spanoids. For a family  $\mathcal{F}$  of  $n$  sets and a subset  $S \subset [n]$ , let us denote by  $\cap S$  the subset of  $U$  which is the intersection of all  $\{F_j : j \in S\}$ . Then the rank of  $S$  is the size of the smallest subset  $S' \subseteq S$  for which  $\cap S' = \cap S$ . Similarly, the span of  $S$  is the largest superset  $S'' \supseteq S$  for which  $\cap S'' = \cap S$ .

These static definitions of rank and span make many things transparent. For example, the expected fact that testing if the rank of a spanoid (namely the rank of the set  $[n]$ ) is at most some given integer  $k$  is *NP-complete* (Claim 22). Complementing the sets  $F_i$  in  $\mathcal{F}$ , and replacing intersection with union, this is precisely the Set Cover problem. This connection also underlies the cover-based linear program discussed earlier, as well as proofs of the main quantitative results Theorem 9 and Theorem 10.

### 1.3.6 Union-closed families

Spanoids over  $[n]$  are equivalent to union-closed families of subsets of  $[n]$  i.e. a family of subsets of  $[n]$  such that the union of any two members is again in the family. A closed set of a spanoid  $\mathcal{S}$  is a subset  $A \subset [n]$  such that  $\text{span}(A) = A$ . The family of all closed sets of a spanoid  $\mathcal{S}$  is denoted by  $\mathcal{C}_{\mathcal{S}}$  which is an intersection-closed family. Thus the family of all open sets which are complements of closed sets is a union-closed family and is denoted by  $\mathcal{O}_{\mathcal{S}}$ . One can construct all the derivations of the spanoid given its family of open or closed sets. Conversely, given any union-closed family of subsets of  $[n]$ , one can define a spanoid whose open sets are precisely the given family. Thus spanoids on  $[n]$  are equivalent to union-closed families of subsets of  $[n]$ . The rank of a spanoid has a very simple interpretation in terms of its open sets,  $\text{rank}(\mathcal{S})$  is equal to the size of the smallest hitting set for its family of open sets  $\mathcal{O}_{\mathcal{S}}$ . Moreover,  $\text{rank}(\mathcal{S})$  is at most  $\log |\mathcal{O}_{\mathcal{S}}|$ . These connections are discussed in Section 2.1.

Union-closed families are interesting combinatorial objects with a rich structure. The widely open Frankl’s union-closed conjecture states that in every union-closed family of  $N$  sets, there exists an element which is contained in at least  $N/2$  sets. Though this was proved for various special classes (see survey [8]), the best general bound is  $\Omega(N/\log N)$  due to [22, 24]. When seen in the framework of spanoids, this follows immediately from Claim 19 which says that there is a  $\log N$  sized hitting set for every union-closed family of  $N$  sets. Thus there is an element which should hit at least  $N/\log_2(N)$  sets. We hope that viewing union-closed families as spanoids could be of use in understanding them.

## 1.4 Organization

In Section 2, we will present two alternative ways to represent spanoids that will be very useful. In Section 3, we show upper bounds on the rank of  $q$ -LCSs for  $q \geq 2$  thus proving the upper bounds in Theorems 27 and 29. In Section 4, we construct  $q$ -LCSs thus proving the lower bound in Theorem 29.

---

<sup>12</sup>Indeed, otherwise we can remove the common intersection (if non-empty) of *all* members of  $\mathcal{F}$  from each of them, as it does not change the underlying spanoid.

## 2 Preliminaries on spanoids

We will now describe two equivalent ways to define spanoids which will turn out to be very useful.

### 2.1 Spanoids as union-closed or intersection-closed families

In this subsection, we will define an equivalent and more canonical way of describing spanoids in terms of intersection closed or union closed families. We have defined spanoids in Definition 5 by specifying the initial set of derivation rules such as  $A \rightarrow i$ . But two different initial set of rules can lead to the same set of derivations and we should consider two spanoids to be equivalent if they lead to the same set of derivations. We will present an alternative way to describe spanoids which makes them equivalent to union-closed families of sets or alternatively intersection-closed families of sets. Moreover this new representation is a more canonical way to represent spanoids since it will be based only on the set of derivations. For this, the main new notions we need to define are that of a ‘closed set’ and an ‘open set’.

► **Definition 15.** (Closed and open sets) Let  $\mathcal{S}$  be a spanoid on  $[n]$ . A *closed set*<sup>13</sup> is a subset  $B \subset [n]$  for which  $\text{span}(B) = B$ . A subset  $B \subset [n]$  is called an *open set* if its complement is a closed set. The family of all closed sets of  $\mathcal{S}$  is denoted by  $\mathcal{C}_{\mathcal{S}}$  and the family of all open sets of  $\mathcal{S}$  by  $\mathcal{O}_{\mathcal{S}}$  (when it is clear from the context, we will drop the subscript  $\mathcal{S}$ ).

► **Claim 16.** In any spanoid  $\mathcal{S}$  on  $[n]$ ,

1. the intersection of any number of closed sets is a closed set i.e.  $\mathcal{C}_{\mathcal{S}}$  is an intersection-closed family,
2. the union of any number of open sets is an open set i.e.  $\mathcal{O}_{\mathcal{S}}$  is a union-closed family and
3. for any set  $A \subset [n]$ ,  $\text{span}(A)$  is equal to the intersection of all closed sets containing  $A$  i.e.  $\text{span}(A) = \bigcap_{B \supset A, B \in \mathcal{C}_{\mathcal{S}}} B$ .

**Proof.**

- (1) Let  $F = F_1 \cap F_2$  be the intersection of two closed sets. Suppose in contradiction that  $F$  spans some element  $x \in [n] \setminus F$  then, by monotonicity, both  $F_1$  and  $F_2$  have to span  $x$ . Hence,  $x \in \text{span}(F_1) \cap \text{span}(F_2) = F_1 \cap F_2 = F$  in contradiction.
- (2) This just follows from (1) by taking complements.
- (3) Let  $F(A)$  be the intersection of all closed sets containing  $A$ . Since  $\text{span}(A)$  is a closed set we clearly have  $F(A) \subset \text{span}(A)$ . To see the other direction, suppose  $x \in \text{span}(A)$  and let  $F$  be any closed set containing  $A$ . Then, by monotonicity,  $F$  must also span  $x$  and so we must have  $x \in F$ . ◀

► **Claim 17.** A spanoid is uniquely determined by the set of all its closed (open) sets which is an intersection-closed (union-closed) family of subsets of  $[n]$ . Conversely, every intersection-closed (union-closed) family of subsets of  $[n]$  defines a spanoid whose closed (open) sets are the given family.

**Proof.** Given a spanoid  $\mathcal{S}$  on  $[n]$ , by Claim 16, we can define  $\text{span}(A)$  in  $\mathcal{S}$  using just the closed sets as:

$$\text{span}(A) = \bigcap_{B \supset A, B \in \mathcal{C}_{\mathcal{S}}} B.$$

<sup>13</sup>Closed sets are analogous to ‘flats’ or ‘subspaces’ in matroids.

And  $A \models i$  in  $\mathcal{S}$  iff  $i \in \text{span}(A)$ . Thus given the set of all closed sets, we can reconstruct all the derivations of the spanoid.

For the converse, suppose we are given an intersection-closed family of subsets of  $[n]$ , say  $\mathcal{C}$ . We can define  $\text{span}_{\mathcal{C}}(A) = \bigcap_{B \supset A, B \in \mathcal{C}} B$  and define a spanoid  $\mathcal{S}_{\mathcal{C}}$  where  $A \models i$  iff  $i \in \text{span}_{\mathcal{C}}(A)$ . It is easy to see that the closed sets of this spanoid  $\mathcal{S}_{\mathcal{C}}$  is exactly  $\mathcal{C}$ . ◀

Thus an equivalent way to define a spanoid is to define all its closed (open) sets which is some intersection (union) closed family. The following claim shows that the rank of a spanoid has a very natural interpretation in terms of the open sets.

► **Claim 18.** *The rank of a spanoid  $\mathcal{S}$  is the size of the smallest hitting set for the collection  $\mathcal{O}_{\mathcal{S}}$  i.e. a set which intersects every open set in  $\mathcal{O}_{\mathcal{S}}$  non-trivially.*

**Proof.** Observe that a subset  $A \subset [n]$  spans  $[n]$  iff it is a hitting set for all the open sets in  $\mathcal{O}_{\mathcal{S}}$ . This is because if  $A$  doesn't hit some open set  $B$ , then  $A$  lies in the complement of  $B$  i.e.  $A \subset \bar{B}$ . Since  $\bar{B}$  is closed,  $\text{span}(A) \subset \bar{B} \neq [n]$ . Therefore  $\text{rank}(\mathcal{S})$  is the size of the smallest hitting set for  $\mathcal{O}_{\mathcal{S}}$ . ◀

This interpretation of the rank is used to give a linear programming relaxation  $\text{LP}^{\text{cover}}$  which lower bounds the rank. We can also upper bound the rank of a spanoid in terms of the number of closed or open sets as the following claim shows.

► **Claim 19.** *Let  $\mathcal{S}$  be a spanoid, then  $\text{rank}(\mathcal{S}) \leq \log_2(|\mathcal{C}_{\mathcal{S}}|) = \log_2(|\mathcal{O}_{\mathcal{S}}|)$ .*

**Proof.** Let  $r = \text{rank}(\mathcal{S})$  and  $R \subset [n]$  be a set of size  $|R| = r$  spanning  $[n]$ . Since the rank of  $\mathcal{S}$  is  $r$  we know that  $R$  is independent (not spanned by any proper subset). For each of the  $2^r$  subsets  $S \in 2^R$  we consider the closed set  $F_S = \text{span}(S)$ . We claim that all of these are distinct. Suppose in contradiction that there were two distinct sets  $S \neq T \in 2^R$  with  $\text{span}(S) = \text{span}(T)$ . W.l.o.g suppose there is an element  $x \in T \setminus S$ . Then  $x \in \text{span}(S)$  and so we get that  $R \setminus \{x\}$  spans  $R$  (by monotonicity) and so spans the entire spanoid in contradiction. Thus  $|\mathcal{C}_{\mathcal{S}}| \geq 2^r$ . ◀

## 2.2 Spanoids as set systems

In this subsection, we will show yet another way of representing spanoids by families of sets. This representation (which is equivalent to spanoids) will be easier to work with and, in fact, we will later work almost exclusively with it instead of with the definition given in the introduction. Recall the notation introduced at the end of the introduction that, for sets  $S_1, \dots, S_n$  and for a subset  $A \subset [n]$  we let  $\cap A = \bigcap_{i \in A} S_i$ .

► **Definition 20** (Intersection Dimension of a set system). The *intersection-dimension* of a family of sets  $S_1, \dots, S_n$ , denoted  $\text{idim}(S_1, \dots, S_n)$  is the smallest integer  $d$  such that there exist a set  $A \subset [n]$  of size  $d$  such that  $\cap A = \cap [n]$ .

► **Lemma 21** (Set-Representation of spanoids). *Let  $\mathcal{S}$  be a spanoid on  $[n]$  with  $\text{rank}(\mathcal{S}) = r$ . Then there exists a family of sets  $S_1, \dots, S_n$  such that  $A \models i$  in  $\mathcal{S}$  iff  $\cap A \subset S_i$ . In this case we say that the set family  $(S_1, S_2, \dots, S_n)$  is a set-representation of  $\mathcal{S}$  and this implies in particular that  $\text{idim}(S_1, \dots, S_n) = \text{rank}(\mathcal{S})$ .*

**Proof.** For  $i \in [n]$  we define  $S_i \subset \mathcal{C}_{\mathcal{S}}$  to be the subfamily of closed sets of  $\mathcal{S}$  containing the element  $i \in [n]$ . For the first direction of the proof suppose that  $A$  spans  $x$  in the spanoid  $\mathcal{S}$ . Then, by Claim 16,  $x$  belongs to any closed set containing  $A$  and so  $\bigcap_{i \in A} S_i \subset S_x$ . For the other direction, suppose  $\bigcap_{i \in A} S_i \subset S_x$  or that any closed set containing  $A$  must also contain  $x$ . Hence,  $x$  is in the intersection of all closed sets containing  $A$  and, by Claim 16 we have that  $x \in \text{span}(A)$ . ◀

An alternative way to represent spanoids is by unions.  $(T_1, T_2, \dots, T_n)$  is called a *union set-representation* of the spanoid  $\mathcal{S}$  when,  $A \models i$  in  $\mathcal{S}$  iff  $T_i \subset \cup_{j \in A} T_j$ . Note that if  $(S_1, S_2, \dots, S_n)$  is an (intersection) set-representation for  $\mathcal{S}$  as in Lemma 21, then by taking complements,  $(\bar{S}_1, \bar{S}_2, \dots, \bar{S}_n)$  is a union set-representation for  $\mathcal{S}$  and vice versa. Thus these two notions of representing a spanoid by sets is equivalent.

► **Claim 22.** *Given a spanoid  $\mathcal{S}$  and some positive integer  $k$ , deciding if the rank of the spanoid is at most  $k$  is NP-complete.*

**Proof.** Given the description of a spanoid and a subset of its elements, we can check in polynomial time whether the subset has size at most  $k$  and spans all the elements. So the problem is in NP. To prove that it is NP-complete, we reduce Set Cover problem to this.

Given a collection of sets  $S_1, S_2, \dots, S_n \subset U$  such that  $\cup_i S_i = U$  and some positive integer  $k$ , the Set Cover problem asks if there are at most  $k$  sets in the collection whose union is  $U$ . To reduce it to the spanoid rank problem, we can create a spanoid over  $[n]$  elements where the inference rules are given by  $A \models i$  iff  $\cup_{j \in A} S_j \supset S_i$ . The rank of this spanoid is at most  $k$  iff there exists  $k$  sets in the collection which cover all of  $U$ . ◀

### 3 Upper bounds on the rank of $q$ -LCSs

In this section we prove the upper bounds on the rank of  $q$ -LCSs stated in Theorems 9 and 10. The proofs will rely on the set representation described in Section 2.2 and on random restriction and contraction arguments given below.

#### 3.1 Graph theoretic lemmas

In this subsection, we will prove a key technical lemma about a random graph process that will be useful for proving upper bounds on the rank of  $q$ -LCSs. We denote by  $\mathcal{D}(n)$  the set of simple directed graphs on  $n$  vertices. We always assume w.l.o.g that the set of vertices are the integers between 1 and  $n$ .

► **Definition 23** ( $(\alpha, \beta)$ -spread distribution). Let  $\mu$  be a distribution on  $\mathcal{D}(n)$ . We say that  $\mu$  is  $(\alpha, \beta)$ -spread if the following conditions are true for a graph  $G$  sampled from  $\mu$ :

1. Each vertex  $i \in [n]$  has an incoming edge with probability at least  $\alpha$  i.e.

$$\forall i \Pr_{G \sim \mu} [\exists j : (j, i) \in E(G)] \geq \alpha.$$

2. For every  $i, j \in [n]$ , the probability that  $(j, i)$  is an edge is at most  $\beta/n$  i.e.

$$\forall i, j \Pr_{G \sim \mu} [(j, i) \in E(G)] \leq \frac{\beta}{n}.$$

For example, one can generate an  $(k/n, 1)$ -spread distribution  $\mu$  on  $\mathcal{D}(n)$  in the following way: Fix arbitrary sets  $S_1, \dots, S_n \subset [n]$  of size  $k$  each. To sample a graph  $G$  from  $\mu$ , pick a uniformly random element  $j \in [n]$  and let  $G$  be the directed graph containing the edges  $(j, i)$  for each  $i$  such that  $j \in S_i$ . This satisfies the definition since for any fixed  $i \in [n]$ ,  $i$  has an incoming edge if  $j \in S_i$  which happens with probability  $|S_i|/n = k/n$ . And for any fixed  $i', j' \in [n]$ , the probability that  $(j', i')$  is an edge is at most  $1/n$  since this happens only when  $j' = j$  and  $j$  is chosen uniformly at random from  $[n]$ . Note that the sampled edges overall are highly correlated (they all have  $j$  as an endpoint).

We will need following simple observation about  $(\alpha, \beta)$ -spread distributions.

► **Lemma 24.** *Let  $\mu$  be an  $(\alpha, \beta)$ -spread distribution on  $\mathcal{D}(n)$ . For every vertex  $i$  and every subset  $S \subset [n]$  of size at most  $\frac{\alpha n}{2\beta}$ ,*

$$\Pr_{G \sim \mu}[\exists j \notin S : (j, i) \in E(G)] \geq \frac{\alpha}{2}.$$

**Proof.** This follows from union bound and properties of  $(\alpha, \beta)$ -spread distributions.

$$\begin{aligned} \alpha &\leq \Pr_{G \sim \mu}[\exists j : (j, i) \in E(G)] \\ &\leq \Pr[\exists j \in S : (j, i) \in E(G)] + \Pr[\exists j \notin S : (j, i) \in E(G)] \\ &\leq \sum_{j \in S} \Pr[(j, i) \in E(G)] + \Pr[\exists j \notin S : (j, i) \in E(G)] \\ &\leq \frac{\alpha n}{2\beta} \cdot \frac{\beta}{n} + \Pr[\exists j \notin S : (j, i) \in E(G)] \\ &= \frac{\alpha}{2} + \Pr[\exists j \notin S : (j, i) \in E(G)] \quad \blacktriangleleft \end{aligned}$$

Given a distribution  $\mu$  on graphs we would like to study the random process in which we, at each iteration, sample from  $\mu$  and ‘add’ the edges we got to the graph obtained so far. For two graphs  $G$  and  $H$  on the same set of vertices, we denote by  $G \cup H$  their set theoretic union (as a union of edges).

► **Definition 25** (Graph process associated with  $\mu$ ). Let  $\mu$  be a distribution on  $\mathcal{D}(n)$ . We define a sequence of random variables  $G_t^\mu$ ,  $t = 0, 1, 2, \dots$  as follows.  $G_0^\mu$  is the empty graph on  $[n]$  vertices. At each step  $t \geq 1$  we sample a graph  $G$  according to  $\mu$  (independently from all previous samples) and set  $G_t = G_{t-1} \cup G$ .

For a graph  $G \in \mathcal{D}(n)$  and a vertex  $i \in [n]$  we denote by  $\text{Rea}(i)$  the set of vertices that are reachable from  $i$  (via walking on directed edges). By convention, a vertex is always reachable from itself. Similarly, for a set of vertices  $S \subset [n]$  we denote by  $\text{Rea}(S) = \cup_{i \in S} \text{Rea}(i)$  the set of vertices reachable from some vertex in  $S$ . We denote the set of strongly connected components of  $G$  by  $\Gamma(G)$ . We denote by  $C(i) \in \Gamma(G)$  the strongly connected component of  $G$  containing  $i$ . We say that  $C \in \Gamma(G)$  is a *source* if  $C$  has no incoming edges from any vertex not in  $C$ .

► **Lemma 26.** *Let  $\mu$  be an  $(\alpha, \beta)$ -spread distribution on  $\mathcal{D}(n)$  and let  $G_t^\mu$  be its associated graph process. Then, for all  $t \geq 0$ , there is positive probability that the graph  $\Gamma(G_t^\mu)$  has at most*

$$n \cdot (1 - \alpha/4)^t + \frac{2\beta}{\alpha}$$

*sources.*

**Proof.** If  $C \in \Gamma(G)$  is a source, we define the *weight* of  $C$  to be the number of vertices reachable from  $C$  (including vertices of  $C$ ) that are not reachable from any other source of  $G$ . More formally, let

$$\text{Rea}'(C) = \{j \in \text{Rea}(C) \mid j \notin \text{Rea}(C'), \text{ for all sources } C' \in \Gamma(G), C' \neq C\}.$$

Then the weight of a source  $C \in \Gamma(G)$  is denoted by  $w(C) = |\text{Rea}'(C)|$  (we do not define weight for components that are not sources). Let us call a source  $C \in \Gamma(G_t)$  ‘light’ if its weight  $w(C)$  is at most  $k = \frac{\alpha n}{2\beta}$  and ‘heavy’ otherwise. By the definition of weight, there could be at most  $n/k = 2\beta/\alpha$  heavy sources.

We will argue that, in each step, as we move from  $G_t$  to  $G_{t+1}$ , the number of light sources must decrease by a factor of  $(1 - \alpha/4)$  with positive probability. For that purpose, suppose there are  $m_t$  sources in  $G_t$  and among them  $m'_t$  are light. Fix some light source and pick a representative vertex  $i$  from it. Since  $i$  is contained in a light source,  $|\text{Rea}'(C(i))| \leq \frac{\alpha n}{2\beta}$ . When going to  $G_{t+1} = G_t \cup G$ ,  $i$  gets an incoming edge from outside the set  $\text{Rea}'(C(i))$  with probability at least  $\alpha/2$  by Lemma 24. If this happens then in  $G_{t+1}$ , this source will either stop being a source or merge with another source.

Picking a representative for each light source in  $G_t$ , we see that the expected number of representatives  $i$  which get a new incoming edge from outside  $\text{Rea}'(C(i))$  is at least  $(\alpha/2)m'_t$ . Hence, this quantity is obtained with positive probability. Now, if at least  $(\alpha/2)m'_t$  light sources ‘merge’ with another source or stop being a source in  $G_{t+1}$  then the total number of light sources must decrease by at least  $(\alpha/4)m'_t$  (the worst case being that  $(\alpha/4)m'_t$  disjoint pairs of light sources merge with each other). Hence, with positive probability we get that  $m'_{t+1} \leq m'_t \cdot (1 - \alpha/4)$ . Therefore, since the samples in each step  $t$  are independent, there is also a positive probability that  $m'_t \leq n \cdot (1 - \alpha/4)^t$  and  $m_t \leq m'_t + 2\beta/\alpha$ . This completes the proof.  $\blacktriangleleft$

### 3.2 Proof of upper bound from Theorem 9

► **Theorem 27** (Rank of 2-LCSs). *Let  $\mathcal{S}$  be a 2-LCS on  $[n]$  with error-tolerance  $\delta$ . Then  $\text{rank}(\mathcal{S}) \leq O(\frac{1}{\delta} \log_2 n)$ .*

**Proof.** We will work with the (equivalent) set formulation: let  $\mathcal{F} = \{S_1, \dots, S_n\}$  be a set system representing the spanoid  $\mathcal{S}$  as in Lemma 21.

We start by defining an  $(\alpha, \beta)$ -spread distribution  $\mu$  on  $\mathcal{D}(n)$  as follows: To sample a graph  $G$  from  $\mu$  we first pick  $\ell \in [n]$  uniformly at random. Then we add a directed edge from  $j$  to  $i$  for every  $i, j$  such that  $\{j, \ell\} \in M_i$ . In this case we have  $S_j \cap S_\ell \subseteq S_i$  and so, after restricting to  $S_\ell$  we have  $S_j \cap S_\ell \subseteq S_i \cap S_\ell$ .

► **Claim 28.**  *$\mu$  is a  $(2\delta, 1)$ -spread distribution.*

**Proof.** For any fixed  $i \in [n]$ ,  $i$  will get an incoming edge if  $\ell$ , which is randomly chosen from  $[n]$ , belongs to  $M_i$ . Since  $M_i$  has at least  $\delta n$  edges, this will happen with probability at least  $2\delta$ . Now fix any  $i, j \in [n]$ ,  $(j, i)$  will be an edge iff  $\ell$  is equal to the vertex that matches  $j$  in the matching  $M_i$ , this happens with probability at most  $1/n$ . If  $j$  is not matched in  $M_i$ , the probability is zero.  $\blacktriangleleft$

Consider the graph process  $G_t^\mu$  and let  $S_{\ell_1}, \dots, S_{\ell_t}$  be the sets chosen in the  $t$  iterations of sampling from  $\mu$ . If  $i \in \text{Rea}(j)$  in the graph  $G_t^\mu$ , this means that, after restricting to the intersection  $S = S_{\ell_1} \cap \dots \cap S_{\ell_t}$ , the set  $S_j$  is contained in  $S_i$  (i.e.,  $S_j \cap S \subseteq S_i \cap S$ ). By Lemma 26, after  $t = O(\frac{1}{\delta} \log_2 n)$  steps, the graph process  $G_t^\mu$  will contain  $r = O(1/\delta)$  sources. Pick a representative  $S_{a_1}, \dots, S_{a_r}$  from each of these sources. Then, the intersection of the  $t + r = O(\frac{1}{\delta} \log_2 n)$  sets  $S_{\ell_1}, \dots, S_{\ell_t}$  and  $S_{a_1}, \dots, S_{a_r}$  is contained in all  $n$  sets  $S_1, \dots, S_n$ . That is because, when restricted to the intersection of  $S_{\ell_1}, \dots, S_{\ell_t}$ , each set  $S_i$  contains one of the sets  $S_{a_j}, j \in [r]$ .  $\blacktriangleleft$

### 3.3 Proof of upper bound from Theorem 10

► **Theorem 29** (Rank of  $q$ -query LCSs). *Let  $\mathcal{S}$  be a  $q$ -LCS with error-tolerance  $\delta$  and  $q \geq 3$ . Then*

$$\text{rank}(\mathcal{S}) \leq O\left(\delta^{-\frac{1}{q-1}} \cdot n^{\frac{q-2}{q-1}} \log_2 n\right).$$

**Proof.** Like the 2-query case, we work with the set representation  $\mathcal{F} = \{S_1, \dots, S_n\}$  of  $\mathcal{S}$  as in Lemma 21. We follow the same strategy as in the proof of the 2-query case. The difference is that, in this case, we will need to pick many sets to restrict to in each step instead of just one. The first observation is that, if  $\{j_1, \dots, j_q\} \in M_i$  then, restricted to the intersection  $S = S_{j_1} \cap \dots \cap S_{j_{q-1}}$  we have  $S_{j_q} \subset S_i$ . The second observation is that, if we choose a subset  $J \subset [n]$  of size roughly  $n^{\frac{q-2}{q-1}}$  then, in expectation,  $J$  will contain  $q-1$  elements in one of the  $q$ -subsets of  $M_i$  for a constant fraction of the  $i$ 's. Repeating this a logarithmic number of times and using Lemma 26, as in the proof of Theorem 27 will then complete the proof.

We start by defining an  $(\alpha, \beta)$ -spread distribution  $\mu$  on  $\mathcal{D}(n)$ . To sample a graph  $G$  from  $\mu$  we first pick a random set  $J \subset [n]$  such that each  $j \in [n]$  is chosen to be in  $J$  independently with probability  $(\delta n)^{-1/(q-1)}$ . By Markov's inequality we have that

$$\Pr \left[ |J| \geq 4 \cdot \delta^{-\frac{1}{q-1}} n^{\frac{q-2}{q-1}} \right] \leq 1/4. \quad (2)$$

For each  $i \in [n]$  and each  $q$ -subset  $T \in M_i$  we select  $q-1$  elements of  $T$  arbitrarily and refer to them as the *distinguished*  $(q-1)$ -subset of  $T$ . We now argue that, for each  $i \in [n]$ , there is relatively high probability that  $J$  will contain the distinguished  $(q-1)$ -subset of at least one  $q$ -subset in  $M_i$ .

► **Claim 30.** *Let  $E_i$  denote the event that  $J$  contains the distinguished  $(q-1)$ -subset from at least one  $q$ -subset in  $M_i$ . Then, for each  $i \in [n]$  we have that  $\Pr[E_i] \geq 1/2$ .*

**Proof.**  $J$  will contain the distinguished  $q-1$  elements in a specific  $q$ -subset with probability  $(\delta n)^{-1}$ . Since the  $\delta n$   $q$ -subsets in  $M_i$  are disjoint, the probability that  $J$  will not contain any of the distinguished  $(q-1)$ -subsets is at most  $(1 - (1/\delta n))^{\delta n} \leq 1/2$ . ◀
